PREFACE

Previous editions of *Comprehensive Medicinal Chemistry*, published in 1990 and 2006, provided an integrated reference source that encompassed all major aspects of drug discovery research. The third edition follows this tradition and considerably expands its scope and content.

The trailblazing scientific discoveries of the 21st century have brought new opportunities for drug discovery research. The discipline of medicinal chemistry continues to evolve as it adapts to these new opportunities and strives to solve new challenges. Covered in the new edition are not only the breakthrough therapies of the past decade in cancer, hepatitis C, heart failure, dyslipidemia, cystic fibrosis, multiple sclerosis, HIV, etc., but also extensive discussion of new business models in drug discovery research, shifting industry demographics, emerging technologies, *in silico* drug discovery tools, experimental ADME and toxicology, and biologics medicine. The tone of this edition is prospective in which contributors identify outstanding issues and paths forward in their area of expertise. The aim is to provide drug discovery scientists in industry, government, academia, and research organizations with a contemporary global perspective on the field that includes a look ahead in selected areas.

The eight individual volumes fulfill these objectives and include extensive discussion of biomolecular therapeutics, drug targeting and delivery, development of chemical biology tools, data collection and analysis, *in silico* models as predictors for biological properties, identification/validation of new targets, approaches to quantify target engagement, new methods for synthesis of drug candidates such as green chemistry, development of novel scaffolds for drug discovery, and the role of regulatory agencies in drug discovery.

The individual volume editors have done an outstanding job to identify topics and contributors to meet these goals and we thank them for their hardwork and diligence. In volume 1, Ana Martinez and Carmen Gil recruited an international group of contributors who provide chapters on the emerging role of organizations other than traditional pharmaceutical companies in drug discovery, the evolving science of chemical biology, and new organic chemistry contributions to the discipline. In volume 2, Helmut Buschmann, Norbert Handler, and Andrea Wolkerstorfer have accomplished a seemingly impossible task and attracted world-leading experts across the wide field of drug discovery enabling technologies, covering contemporary thinking in a wide range of key disciplines that enable modern medicinal chemistry and drug discovery and development. The computational enabling technologies are the focus of volume 3, in which Andy Davis and Colin Edge have assembled chapters covering both ligand-based and protein structure–based advances as well as exciting new methodologies and case studies exploiting these. Alan Wilson identified experts in the fields of pharmacokinetics and toxicology who describe a wide range of contemporary advances in prediction and analysis of pharmaceutical properties and drug safety in volume 4. In volume 5, Ian Collins, Louis Lombardo, and Will Watkins have assembled leading experts to discuss high impact drug discovery accomplishments over the past decade in cancer chemotherapeutics, immunology and inflammation, and infectious diseases therapeutic areas. Ved Srivastava edited volume 6 on biologic medicines, a significant and rapidly evolving area where medicinal chemistry plays an important role. The chapters in this volume provide timely information on not only protein-based drugs, such as monoclonal antibodies and therapeutic proteins, but also peptides and nucleic acid–based therapeutics. Volume 7, edited by Adrian Hall, Santhosh Neelamkavil, and Rob Jones, presents a detailed account of the major advances in CNS, metabolic, and cardiovascular fields over the past decade and the promising new opportunities. Joerg Holenz edited volume 8 that presents case histories of successful drug discovery and strategic differentiation that have resulted in commercialized drugs and candidates in advanced clinical trials.

We are truly grateful to the publishing team at Elsevier that includes Gemma Tomalin, Rachel Gerlis, Marise Willis, and Sean Simms for their assistance and support throughout the process. With their expertise, this project became what we believe is a noteworthy and valuable resource for the discipline of medicinal chemistry. We look forward to the response and feedback of our colleagues who will use this information in their own work.

Samuel Chackalamannil, David P. Rotella, and Simon E. Ward

EDITORS-IN-CHIEF: BIOGRAPHIES

Dr. Samuel Chackalamannil

Dr. Chackalamannil obtained his PhD in chemistry from Yale University in 1984 and subsequently worked in drug discovery research at Schering-Plough Corporation and Merck Research Laboratories, where he was a distinguished fellow when he left in 2011. Since then, he has been teaching at Ernest Mario School of Pharmacy, Rutgers University, New Jersey.

Dr. Chackalamannil has significant accomplishments in the discovery of new medicines. He led the discovery of vorapaxar (Zontivity®), an FDA-approved antiplatelet drug for the prevention of heart attack and stroke. His group also discovered a PDE-5 inhibitor clinical candidate dasantafil and an adenosine A2a antagonist clinical candidate for the treatment of Parkinson's disease. Altogether, he was responsible for the discovery of nine development candidates in cardiovascular, central nervous system, and metabolic disease areas.

Dr. Chackalamannil is a coinventor of 62 allowed US patents and numerous patent applications worldwide. He has published 81 peer-reviewed articles and has coauthored a book. He has also given numerous lectures at international meetings and academic institutions.

Dr. Chackalamannil is a two-time recipient of the Thomas Alva Edison Award for Emerging Technology Patent and a two-time recipient of the Presidential Award for Discovery at Schering-Plough Research Institute. He has chaired several sessions at American Chemical Society national meetings and Gordon Research Conference on Medicinal Chemistry and was an organizer for Chemistry as a Life Science Symposium.

Dr. David Rotella

Dr. Rotella earned a PhD in medicinal chemistry from The Ohio State University and carried out postdoctoral research in organic chemistry at Penn State University. He joined the faculty at Montclair State University in July 2011 as the Margaret and Herman Sokol Professor of medicinal chemistry after a successful career in the pharmaceutical industry. He is an expert in the discovery and optimization of small molecule drug candidates for use in metabolic, cardiovascular, cancer, and central nervous system diseases. His current research is focused on discovering new lead compounds for use in parasitic and central nervous system diseases. He has coedited the seventh edition of *Burger's Medicinal Chemistry* and is a senior editor for the Royal Society of Chemistry's Drug Discovery book series. He has authored over 40 peer-reviewed articles, is an inventor on 8 issued US patents, and has contributed 10 book chapters.

Simon E. Ward

Simon Ward has an MA in natural sciences and PhD in synthetic organic chemistry from Cambridge University, UK. He has a wide-ranging experience of drug discovery in both large and small companies (GlaxoSmithKline, Knoll Pharmaceuticals, Vernalis, Chiroscience, BioCrea) and specialist experience of discovering and developing drugs for central nervous system indications. He has led multidisciplinary project teams and medicinal chemistry groups from target identification through to early clinical studies, delivering multiple clinical development candidates across indications. He is a fellow of the Royal Society of Chemistry. He is currently a professor of medicinal chemistry at the University of Sussex, UK, and the director of the Sussex Drug Discovery Centre, which he established within the University of Sussex in 2010.

General Perspective—The Future of Medicinal Chemistry *xxv*

VOLUME 1: GENERAL PERSPECTIVE - THE FUTURE OF DRUG DISCOVERY

1.01 Academic Drug Discovery Centers: Key Players in the Future of the Pharmaceutical Industry 1
M Abou-Gharbia, B E Blass, and W E Childers

1.02 Drug Repurposing Review 11
D Cavalla, E Oerton, and A Bender

1.03 Human iPSC Models in Drug Discovery: Opportunities and Challenges 48
M C Silva, A Cross, N J Brandon, and S.J. Haggarty

1.04 From Imaging Agents to Theranostic Drugs in Alzheimer's Disease 74
M L Bolognesi

1.05 Nutraceuticals 107
A Rajasekaran

1.06 Continuous Flow Processing as a Tool for Medicinal Chemical Synthesis 135
D L Browne, J L Howard, and C Schotten

1.07 Beyond Bioisosterism: New Concepts in Drug Discovery 186
L M Lima and E J Barreiro

1.08 Spirocyclic Scaffolds in Drug Discovery 211
C M Tice, Y Zheng, and S B Singh

1.09 Nanotechnology in Drug Discovery and Development 264
L Gutiérrez, G Stepien, L Gutiérrez, M Pérez-Hernández, J Pardo, J Pardo, V Grazú, and J M de la Fuente

1.10 Click Chemistry in Medicinal Chemistry for Comprehensive Medicinal Chemistry III 296
P Thirumurugan and K Jozwiak

1.11 Future of Medicinal Chemistry: Next-Generation Therapeutics 326
N Tsomaia, M Ufret, A Bhat, and J Nakhle

1.12 Anti-Aging Drugs 349
A M Vaiserman

1.13 Regenerative Medicine 379
S G Davies, P D Kennewell, A J Russell, L Silpa, R Westwood, and G M Wynne

1.14 Data Integration and Sharing Supporting Drug R&D 436
F Sanz

1.15 Structural Chemogenomics Databases to Navigate Protein–Ligand Interaction Space 444
G K Kanev, A J Kooistra, I J P de Esch, and C de Graaf

1.16 Nontest Methods for REACH Legislation 472
A Gissi, G F Mangiatordi, T Sobański, T Netzeva, and O Nicolotti

1.17 New Models of Drug Discovery and Development for Neglected Disease Populations 491
T N C Wells, R Hooft van Huijsduijnen, and J N Burrows

1.18 European Lead Factory 505
F Giordanetto, P Jones, A Nelson, J Benningshof, G Müller, A Pannifer, S van Boeckel, and D Tzalis

1.19 Closing Distances Between Academia and Market 520
F Cesaroni, D Baglieri, and A Crupi

1.20 Present and Future Challenges and Opportunities for Intellectual Property in an Open Landscape: Open Labs and the Internet 529
H Céster Schlaak

1.21 Ethics in Drug Discovery 540
M Snape

1.22 The Rise of Rare Disease Foundations: How Patient Associations Can Drive the Drug Discovery Process 549
M R Tranfaglia

1.23 Contemporary Considerations for Discovering a Successful Medicine 560
M M Hann, M K Bayliss, and A R Leach

1.24 Perspectives of Carbohydrates in Drug Discovery 577
J Rojo, A Sousa-Herves, and A Mascaraque

VOLUME 2: DRUG DISCOVERY TECHNOLOGIES

2.01 Drug Discovery Technologies: Current and Future Trends 1
M C Noe and M-C Peakman

2.02 Hit and Lead Generation Strategies 33
P Ettmayer, R Schnitzer, A Bergner, and H Nar

2.03 Multiobjective Optimization of Biological and Physical Properties in Drug Discovery 64
M P Gleeson and D Montanari

2.04 Predictive Toxicology: Latest Scientific Developments and Their Application in Safety Assessment 94
D Armstrong, S Li, W Frieauff, H-J Martus, J Reilly, D Mikhailov, S Whitebread, and L Urban

2.05 Privileged Structures and Motifs (Synthetic and Natural Scaffolds) 116
A M Jones

2.06 High-Throughput Crystallography and Its Applications in Drug Discovery 153
H Nar, D Fiegen, S Hörer, A Pautsch, and D Reinert

2.07 Kinetics, Thermodynamics, and Ligand Efficiency Metrics in Drug Discovery 180
G A Holdgate

2.08 Fragment-Based Drug Design: Strategic Advances and Lessons Learned 212
H Chen, X Zhou, Y Gao, H Chen, and J Zhou

2.09 Computational Models to Predict Toxicological Endpoints in Drug Discovery and Strategies for Data Integration 233
A Brigo and W Muster

2.10 Overview of Drug Polypharmacology and Multitargeted Molecular Design 259
R Chaudhari, Z Tan, and S Zhang

2.11 Allosteric Modulators 276
S Lu and J Zhang

2.12 Novel Therapeutics Targeting Epigenetics 297
P M Woster

2.13 Small-Molecule Inhibitors of Protein−Protein Interactions 329
Z Liu, H Chen, E A Wold, and J Zhou

2.14 Next Generation Sequencing Technologies 354
R Rajesh Singh

2.15 Cellular Imaging in Drug Discovery: Imaging and Informatics for Complex Cell Biology 362
Z Li, M E Cvijic, and L Zhang

2.16 3D High-Content Screening of Organoids for Drug Discovery 388
L Li and D V LaBarbera

2.17 Label-Free Screening Technologies 416
Y Fang

2.18 Systems Biology: Methods and Applications 434
B Titz, A Knorr, A Sewer, F Martin, N V Ivanov, M Talikka, I Gonzalez Suarez, M C Peitsch, and J Hoeng

2.19 Systems Chemical Biology: Integrating Medicinal Chemistry and Systems Biology for Drug Discovery 481
R-S Wang and J Loscalzo

2.20 Translational Aspects in Drug Discovery 495
L Detalle, K Vanheusden, M L Sargentini-Maier, and T Stöhr

2.21 Companion Diagnostics: From Biomarkers to Diagnostics 530
J T Jørgensen and K B Nielsen

VOLUME 3: IN SILICO DRUG DISCOVERY TOOLS

3.01 Perspective on Calculations of Binding Free Energies 1
H Yoon and A Warshel

3.02 Advances in Molecular Simulation 14
M Aldeghi and P C Biggin

3.03 Recent Progress in Free Energy Methods 34
G Saladino, C Estarellas, and F L Gervasio

3.04 Molecular Dynamics, Quantum Mechanics, and Combined Quantum Mechanics/Molecular Mechanics Methods for Drug Discovery and Development 51
E J M Lang and A J Mulholland

3.05 Progress in the Understanding of Traditional and Nontraditional Molecular Interactions 67
Robin Taylor

3.06 Using 3D Structural Information in Computational Design 101
A M Davis and C M Edge

3.07 Protein Structure Prediction and Homology Modeling 120
A R Leach and P J Thomas

3.08 Modeling and Design for Membrane Protein Targets 145
M Congreve, A Bortolato, G Brown, and R M Cooke

3.09 2/3D Pharmacophore Definitions and Their Application 189
R A Lewis and F Sirockin

3.10 Matched Molecular Pair Analysis 221
A G Leach, I Lukac, J M Zarnecka, A G Dossetter, and E J Griffen

3.11 Lessons and Successes in the Use of Molecular Fields 253
P Tosco and M Mackey

3.12 Molecular Docking—A Solved Problem? 297
J Cole, E Davis, G Jones, and C R Sage

3.13 Modeling Protein Flexibility in Molecular Docking 319
C Yan and X Zou

3.14 Chemical Data Formats, Fingerprints, and Other Molecular Descriptions for Database Analysis and Searching 329
D Bajusz, A Rácz, and K Héberger

3.15 Quantitative Structure–Activity Relationships 379
A M Davis

3.16 Empirical and Physics-Based Calculations of Physical–Chemical Properties 393
E L Ratkova, Y A Abramov, I I Baskin, D J Livingstone, M V Fedorov, M Withnall, and I V Tetko

3.17 Predicting Target and Chemical Druggability 429
T I Oprea and C Hasselgren

3.18 Data Analysis and Visualization Tools 440
C J Swain

3.19 Examples of SAR-Centric Patent Mining Using Open Resources 464
C Southan

3.20 An Introduction to Systems Biology and Quantitative Systems Pharmacology 488
B C Gomes

VOLUME 4: EXPERIMENTAL ADME AND TOXICOLOGY

4.01 Role of ADME/PK in Drug Discovery, Safety Assessment, and Clinical Development 1
R E White

4.02 ADME Optimization in Drug Discovery 34
D F McGinnity and K Grime

4.03 Drug-Metabolizing Enzyme Systems I 45
H Yamazaki

4.04 Human PK Prediction and Modeling 51
T H Grasela, V Lukacova, D N Morris, R D Clark, K A Andrews, and M B Bolger

4.05 PBPK Modeling to Estimate Metabolite Formation From First-Pass Organs: Intestine and Liver 83
Qi Joy Yang and K Sandy Pang

4.06 Drug Classification and Drug Disposition Prediction 102
C M Hosey and L Z Benet

4.07 Genetically Humanized Animal Models 130
K Samuelsson, N Scheer, I Wilson, C R Wolf, and C J Henderson

4.08 A Comprehensive Overview of the Current Status and Application of Predictive ADMET: Introduction and Overview 150
T Hartung

4.09 *In Silico* Tools and their Application 156
G J Myatt, L D Beilke, and K P Cross

4.10 Use of Stem Cells in Toxicology 177
P Matz, L-S Spitzhorn, J Otte, M-A Kawala, J Woestmann, H Yigit, W Wruck, and J Adjaye

4.11 Genetic Toxicology 195
Sudheer Beedanagari

4.12 Drug-Induced Liver Disease 204
A K Daly

4.13 Drug-Induced Liver Injury: Mechanism-Informed Prediction in Drug Development 217
C Goldring, R Weaver, B Kramer, U Klingmueller, A Oppelt, B Van der Water, J Commandeur, A Guillouzo, D Naisbitt, N French, N Kitteringham, C Pridgeon, P Knolle, J Sidaway, R Sison-Young, L Kamalian, A Mercer, L Faulkner, R Pieters, M Ingelman-Sundberg, and B Kevin Park

4.14 The Future of Carcinogenicity Testing 239
A Pandiri, R Kovi, C Alden, and R Sills

4.15 Emerging Translatable Safety Biomarkers 255
J Tarrant

4.16 Toxicity Prediction—Regulatory Perspective 285
J P Hanig and W Slikker

VOLUME 5: CANCER, IMMUNOLOGY AND INFLAMMATION, AND INFECTIOUS DISEASE

5.01 Cancer Biology and the Principles of Targeted Cancer Drug Discovery 1
P Hillmann, D Schmitz, J Mestan, S D′ Alonzo, and D Fabbro

5.02 Selective Kinase Inhibitors in Cancer 39
A A Mortlock, D M Wilson, J G Kettle, F W Goldberg, and K M Foote

5.03 Covalent Kinase Inhibitors for Cancer 76
Timothy D Owens and Yan Lou

5.04 Targeting DNA Damage Response Pathways in Cancer 104
Ganiy Opeyemi Abdulrahman, and N J Curtin

5.05 Targeting the Androgen Receptor Signaling Axis 134
H Li, P Rennie, and A Cherkasov

5.06 Protein–Protein Interaction Inhibitors in Cancer 154
I R Hardcastle

5.07 Targeting Protein Synthesis, Folding, and Degradation Pathways in Cancer 202
A Elisa Pasqua, B Wilding, M D Cheeseman, and K Jones

5.08 Inhibitors of Epigenetic Regulation in Cancer 281
D Harvey and M Foley

5.09 Targeting Promoter Quadruplex Nucleic Acids for Cancer Therapy 308
A Paulo, C C Castillo, and S Neidle

5.10 Targeting Pre-mRNA Processing in Cancer 341
T R Webb and S Stamm

5.11 Cancer Immunotherapy—An Emerging Field That Bridges Oncology and Immunology Research 357
J L Adams, K J Duffy, M L Moore, and J Yang

5.12 Evolution of Small-Molecule Immunology Research—Changes Since CMC II 395
T G Murali Dhar and A J Dyckman

5.13 Small Molecule Immunosuppressants in Inflammatory Disease 420
R Fleischmann

5.14 Therapeutic Approaches to MS and Other Neurodegenerative Diseases 439
L P Kotra and J Park

5.15 Lupus and Lupus Overlap Diseases: Emerging Therapies 474
V C Kyttaris

5.16 Small-Molecule Drugs for the Treatment of Inflammatory Bowel Disease 495
L R Fitzpatrick and T Woldemariam

5.17 Recent Epidemiological Changes in Infectious Diseases 511
M J Pucci, C Callebaut, A Cathcart, and K Bush

5.18 Direct-Acting Antiviral Agents for the Treatment of Hepatitis C Virus Infection 553
N A Meanwell

5.19 New Antiretrovirals for HIV and Antivirals for HBV 628
S E Lazerwith, D Siegel, R M McFadden, M R Mish, and W C Tse

5.20 Antiviral Drugs for Acute Infections 665
K L Powell, E Thomas, and G S Cockerill

5.21 New Drugs and Emerging Leads in Antibacterial Drug Discovery 682
D G Brown

5.22 Antifungal Chemistry Review 703
M Birch and G Sibley

5.23 Antiparasitic Agents 717
R T Jacobs

VOLUME 6: BIOLOGICS MEDICINE

6.01 Peptide-Based Cancer Vaccines and Therapeutics for Solid Tumors Overexpressing HER-1, HER-2, HER-3, VEGF and IGF-1R 1
P T P Kaumaya and T Bekaii-Saab

6.02 Cancer Immunotherapy 32
R Ajina, D AlDeghaither, S Jablonski, and L M Weiner

6.03 Strategy and Tactics for Designing Analogs: Biochemical Characterization of the Large Molecules 66
J-M Ahn, K Kassees, T-K Lee, B Manandhar, and A M Yousif

6.04 Chimeric Somatostatin—Dopamine Compounds (Dopastatins) for the Treatment of Neuroendocrine Disease 116
J Hill, S Kim, N Tsomaia, J Z Dong, and M Culler

6.05 Basic Principles of Formulation for Biotherapeutics: Approaches to Alternative Drug Delivery 131
L Otvos, Jr.

6.06 Orally Delivered Peptides for Treatment of Inflammatory Bowel Disease 157
M L Smythe

6.07 Evolution of mAb Downstream Process Platforms 171
A A Shukla, L Wolfe, and C Norman

6.08 Emerging Bioanalytical Methods for the Bioanalysis of Biotherapeutics 180
B Gorovits and R Pillutla

6.09 Analytical and Formulation Development Road Map for Protein Therapeutics 198
M P Ramprasad

6.10 Recent Advances in Medicinal Chemistry of Antisense Oligonucleotides 216
K R Ito and S Obika

6.11 Manufacturing of Oligonucleotides 233
E Paredes, V Aduda, K L Ackley, and H Cramer

6.12 Current Progress and Future Prospects in Nucleic Acid Based Therapeutics 280
M Takahashi, S-p Han, L J Scherer, S Yoon, and J J Rossi

VOLUME 7: CNS, PAIN, METABOLIC SYNDROME, CARDIOVASCULAR, TISSUE FIBROSIS AND URINARY INCONTINENCE

7.01 Recent Advances and Future Directions in the Treatment of Epilepsy 1
T Kurokawa, Y Kazuta, and T Watanabe

7.02 Progress and Challenges in the Development of PET Ligands to Aid CNS Drug Discovery 20
J Mercier, L Provins, and J Hannestad

7.03 Progress in the Discovery of Ca Channel Blockers for the Treatment of Pain 65
P Beswick

7.04 Sodium Channel Blockers for the Treatment of Pain 131

GENERAL PERSPECTIVE—THE FUTURE OF MEDICINAL CHEMISTRY

Introduction

This first volume of the third edition of *Comprehensive Medicinal Chemistry* is entitled "The Future of Medicinal Chemistry" with the aim to describe not only a full perspective of our field in these first years of the 21st century but also the most relevant changes that will impact it without any doubt in the next future. The volume contains 24 chapters addressing our changing landscape and practice of drug discovery, the important role of academic laboratories and small companies in this task, the new methodologies for drug discovery and drug synthesis, the role of public–private collaboration sectors, the importance of intellectual property coverage and the interaction with patients associations, and how to effectively measure the value of new drugs, among others. Written by a combination of notable academic and industry experts working in the field, this volume tries to show how the dynamic environment of the 21st century has brought and will bring new challenges and opportunities for the drug discovery and development process. Hopefully, researchers working together will be able to offer patients and society better and safer drugs that enhance the quality of life.

This general perspective of the future of medicinal chemistry intends to be an essential and professional reference to this important field for students and researchers in chemistry, biochemistry, pharmaceutical sciences, and drug discovery. Also the book will be essential reading for scientists at all levels who wish to improve their scientific horizon.

We would like to sincerely thank all the contributors for their time, professional work, and enthusiasm while preparing this book. We also hope that all researchers working in the exciting world of drug discovery enjoy and create new ideas while reading this volume.

There can be no question that the pharmaceutical industry has played a major role in improving the lives of patients across the globe through the development of novel therapeutics. People suffering with cardiovascular diseases, cancer, and even HIV/AIDS have dramatically improved prospects thanks in large part to the pharmaceutical industry. The identification and commercialization of multi-billion dollar drugs such as Lipitor (Atorvastatin),[1] Gleevac (Imatinib),[2] Plavix (Clopidogrel),[3] and Singulair (Monteluclast),[4] (**Fig. 1**) provided the pharmaceutical industry with unprecedented levels of cash flow to support on-going operations, as well as the search for cures to additional, unmet medical conditions. By 2010, these four drugs alone had combined annual sales of nearly $31 billion.[5] The industry that started with Paul Ehrlich[6] at the beginning of the 20th century reached a high point by the 1990s. In 1996, 53 new molecular entities were approved by the FDA,[7] and new technologies such as high through-put screening,[8] chemical library synthesis,[9] genome sequencing,[10] and biotechnology[11] appeared to provide a runway for even greater success.

1.01.1 Pharmaceutical Industry Challenges: Productivity, Cost, Politics, and Patent Expirations

Over the past 30 years, however, the pharmaceutical industry has struggled to realize the lofty visions that were set for it in the 1980s and 1990s. The high water mark of the 1996 class of FDA approved drugs was followed by nearly 20 years of lower than expected productivity as measured by new drug approvals, a dramatic rise in the cost of research (Fig. 2),[7] increased competition from generic drug companies, and greater focus on the overall cost of health care. Between 1997 and 2011, the number of new molecule achieving FDA approval hovered at 26, while the cost of research sky rocketed. In 1996, research and development expenditures were approximately $17 billion, but by 2012 these costs were just under $50 billion. Similarly, the cost of a single FDA approval increased at an alarming rate. In 1987, a Tufts Center for the Study of Drug Development analysis concluded these costs at $231 million, but by 2010 the cost estimate had reached $1.75 billion, over 7.5 times the cost in 1987.[12] Generic drug companies have also added to the strain on the pharmaceutical industry, as the number of Abbreviated New Drug Application (ANDA) challenges to branded companies' patents has increased by over 450%.[13] Many brand companies sought to mitigate the potential impact of generic drugs by increasing their efforts in biologics (e.g., antibodies, protein therapeutics, etc.), as the pathway to generic biologic (biosimilars) represented uncharted territory. This changed, however, with passage of the Biologics Price Competition and Innovation (BPCI) Act in 2009 and the Patient Protection and Affordable Care Act in 2010.[14] This legislation codified a regulatory pathway for biosimilars, and the first biosimilar, Zarxio, a biosimilar version of Amgen's Neuogen), was approved by the FDA in Mar. 2015.[15]

The twin forces of politics and patent expirations have also increased over the last 30 years. Politicians and public figures routinely site the pharmaceutical industry as a leading cause of increased health care cost without recognizing the enormous benefits of the "wonder drugs" provided by the industry. This has led to wide spread questioning of pricing practices and the "profit before patient" view of the pharmaceutical industry. The atmosphere is mistrust of the pharmaceutical industry lead numerous insurance companies to refuse to pay for new, important medications. Payment for Advair (fluticasone propionate/salmeterol), an important new drug for asthma and chronic obstructive pulmonary disease (COPD) met stiff resistance in 2014.[16] In a similar manner, the high price of Harvoni (ledipasvir/sofobovir), a single pill fixed dose combination medicine capable of eradicating hepatitis C, has lead numerous health insurance companies to deny coverage.[17] The overall cost benefit of curing hepatitis C in 12 weeks and preventing liver damage that could ultimately result in liver transplant was lost in the chorus of calls for decreased drug prices. At the same time, the expected jump in innovation as a result of technological advances failed to materialize, creating a significant patent cliff for the pharmaceutical industry. Nearly $70 billion in branded pharmaceuticals lost patent protection in 2010–12,[18] and an estimated $290 billion of branded product sales are at risk between 2012 and 2018 as a result of patent expiration.[5]

All of these factors forced the pharmaceutical industry to undertake significant structural changes. Mergers and acquisitions, layoffs, and out-sourcing of research became common place in an industry that had previously been nearly immune to these activities. During the 2000–09 time period, over 1345 merger and acquisition deals valued at over $690 billion were consummated.[19] Over 300,000 pharmaceutical jobs were eliminated as a result of these activities,[20] and this substantial decrease in internal resources forced the pharmaceutical industry to abandon its staunchly held position that all R&D efforts should be done internally. Pharmaceutical companies began to increase their emphasis on "externally driven" research programs. Contract research organizations (CROs) and contract manufacturing organizations (CMOs) became an integral part of the pharmaceutical industry and flourished, but at the same time, a new player entered the drug discovery and development landscape, the academic drug discovery center.

1.01.2 The Bayh–Dole Act of 1980: A Catalyst for Academic Drug Discovery

There is no doubt that academic institutions have played, and will continue to play, a major role in the study of disease pathology and the identification of potential therapeutic targets. Prior to 1980, however, academic institutions rarely took part in the

commercially focused drug discovery arena. The vast majority of academic research was, and continues to be funded by federal research grants, and prior to 1980, patents developed using federal funds could only be licensed to commercial entities on a nonexclusive basis. Success in the pharmaceutical industry is predicated upon product exclusivity, and as a result, the industry had little interest in cooperating with academic institutions. This changed dramatically with the passage of the Bayh–Dole act of 1980, also referred to as the Patent and Trademark Law Amendment Act. Under this new law, universities and colleges were free to provide exclusive licenses to patents that were developed using federal funding.[21] In effect, the provisions of this law open the door to increased collaboration between the pharmaceutical industry and the academic world.

Over the next 35 years, as the pharmaceutical industry was contracting its scientific workforce, academic institution began building expertise in drug discovery. Not surprisingly, initial efforts took place in isolated academic laboratories, and some in the academic community were leery of partnering with commercial organizations. Lack of industrial experience also hampered early efforts, but as industrial scientists were laid off from commercial organizations, some took positions in academic institutions, providing real world experience to academic research. By 2001, 12 academic drug discovery centers had been established in the United States, and by 2013 there were over 100 centers in the United States and numerous academic drug discovery centers across the globe (**Table 1**).[22] These centers act as a source of novel science that bolsters the pharmaceutical industry's efforts to identify novel therapies for patients in need, while also providing academic scientists with the opportunity to move their research into the commercial realm, where it could provide real world benefits. This chapter provides an overview of the role academic drug discovery centers play in the modern pharmaceutical industry landscape, the resources and commitment required for a successful academic center, and representative success stories.

1.01.2.1 The Role of Academic Drug Discovery Centers

In general, academic drug discovery centers align their resources and programs to fulfill two important missions. First, these centers act as training grounds for the next generation of drug discovery scientists. While it is possible for young scientists interested in careers in the pharmaceutical industry to gain employment through a traditional single discipline educational path, this route does not provide the breadth of experience necessary for success in the pharmaceutical industry. Academic drug discovery centers, on the other hand, offer students the opportunity to engage in multidisciplinary programs focused on the identification of novel therapeutics. Students become experts in their chosen field of study, while also engaging in team based programs similar to those that occur in the pharmaceutical industry. This is especially true in fully integrated academic drug discovery centers (see below).

The second and equally important mission of the academic drug discovery center is to move academic science beyond the laboratory and into the commercial world. As noted earlier, the pharmaceutical industry's ability to innovate has decreased over the last 35 years as a result of mergers, layoffs, and numerous other factors. Over that same time period, the academic community has continued to be a source of innovation. In fact, one could argue that the innovative capacity of the academic community has increased as many highly qualified scientists made the transition from the industrial community into the academic arena.

The pharmaceutical industry has recognized the potential of the combination of cutting edge academic research and entrepreneurially minded academic scientists (especially those with previous industrial careers) and has expanded its effort to engage academic drug discovery centers. In some cases, these interactions are in the form of traditional sponsored research programs, but other forms of collaborations have been established. The California Institute for Biomedical Research (Calibr), for example, was established by Merck in 2012 as an independent, nonprofit academic institute dedicated to advancing the discoveries of academic scientists from around the world.[23] Pfizer established similar institutions in multiple locations. The "Centers for Therapeutic Innovation" (CTIs) in Boston, New York, San Diego, and San Francisco were opened by Pfizer with the expressed intent of collaborating with academic scientists.[24] Eli Lilly and GlaxoSmithKline have taken a more hands-off approach by establishing programs designed to provide academic scientist with access to their resources. The "Open Innovation Drug Discovery Program" at Eli Lilly provides academic scientists with access to a suite of established *in vitro* screening assays of interest to the company. Data is provided free of charge and academic scientists have the opportunity to engage the company to explore opportunities to move the program forward together or they can move forward on their own.[25] GlaxoSmithKline's "Discovery Fast Track Challenge"[26] and "Discovery Partnerships with Academia (DPAc),"[27] on the other hand, are more akin to the traditional grant submission process. Academic scientists submit proposals that are examined by a GlaxoSmithKline's review board to determine if the proposal is in line with the company's interests and meets their scientific standards. Irrespective of the form of the interaction, it is clear that the pharmaceutical industry has recognized the growing importance of academic drug discovery centers, and it is highly likely that these new organizations will continue to play an important role in the identification of novel therapeutics.

1.01.2.2 Academic Drug Discovery Center Structure and Function

The concept of structure dictating function that has long been recognized in biology also applies to the world of academic drug discovery centers. The capabilities and capacities of individual academic drug discovery centers are dictated by the overall organizational structure and support systems. While these features are certainly subject to change over time as centers evolve, there are essentially three types of centers that have appeared over the last 35 years: (1) those that are based on the founders expertise and research focus, (2) those that focus on coordinating the research efforts of outside groups, and (3) integrated centers whose operations are akin to a small biotech company. Each of these scenarios has benefits and weaknesses that merit further exploration.

1.01.2.3 Founder Focused Academic Drug Discovery Centers

In many cases, academic drug discovery centers are heavily focused on a particular area of biology or specific disease states that are in line with the founding member's research interests. This sharp focus provides the organization with an exceptionally high level of expertise in their particular field of interest and allows for concentration of resources. Many of the early academic drug discovery centers were founded using this strategic platform, as they were almost always built on preexisting expertise of established, often tenured, academic scientists. This format was especially popular with the first academic drug discovery centers. In the early days of these ventures (just after the passage of the Bayh–Dole act of 1980) many were skeptical that academic institutions could produce commercially viable therapeutics. By focusing on preexisting expertise, these centers were able to leverage their capabilities to attract grant funding to support their programs.

While this approach can and has been successful, it suffers from the inherent limitation of expertise to a particular disease focus, thereby limiting funding opportunities. In addition, operations of this type often require outside collaboration in order to move programs forward. Biology driven centers, for example, often lack internal medicinal chemistry support, *in vitro* ADME expertise, and other functions required for the successful identification of novel therapeutics. These centers tend to be smaller operations with limited foot prints and infrastructure (faculty and staff of five or fewer), but can be successful in driving academic research into the commercial world through collaborative efforts. The California Center for Antiviral Drug Discovery, for example, was founded in 2010 to take advantage of the founder's in depth knowledge of RNA viruses. Similarly, the Center for Protein Therapeutics at the University of Buffalo's School of Pharmacy and Pharmaceutical Science open its door in 2008 as part of an effort to build on in house expertise in protein science. This organization has attracted sponsorships and funding from numerous industrial partners such as Novartis, Amgen, and Roche.

1.01.2.4 Research Coordination Academic Drug Discovery Centers

The research coordination approach is an alternative to research driven operations. In this scenario, the center is focused on building bridges between research groups within an academic institution and identifying potential external collaborators for on-going research activities within the larger organization. Program management, especially when external resources are required, and technology transfer expertise are key drivers of these operations. They are usually staffed by one to three people who act as contact points, have limited research budgets, and have a portfolio of programs that is heavily dependent on the interest of the faculty of the parent organization. An attractive feature of this scenario is the relatively low cost of entry. A single person or small group of individuals with industrial experience and a network of contacts can run a center of this type without requiring a significant investment in research infrastructure and scientific support staff. The success of this endeavor, however, is predicated upon the willingness of academicians at the parent university/college to work with the center, as the center itself is not a research driven resource.

While this approach can be successful and is attractive to academic institutions unwilling or unable to commitment substantial funds to academic drug discovery, it is clearly limited in scope and capabilities. The Drug Discovery, Development, and Delivery Core (D4 Core) in Hershey, PA, for example, is associated with Penn State College of Medicine was founded in 2002. Currently, this organization has three employees and collaborates with numerous on-site and off-site groups in an effort to pursue drug discovery programs.

1.01.2.5 Fully Integrated Academic Drug Discovery Centers

In some instances, universities have elected to establish independent drug discovery centers that more closely resemble a small to mid-size biotech company than an academic research laboratory. These operations generally consist of several tenured or tenure track faculty members and supporting staff scientists whose collective experience and expertise encompasses the key facets of drug discovery science (e.g., medicinal chemistry, *in vitro* screening science, *in vivo* pharmacokinetics, *in vivo* pharmacology, formulations science, etc.). Significant pharmaceutical industry experience is often available within these centers, as they have attracted numerous scientists who were caught up in the merger and acquisition feeding frenzy of the last 20 years. Research infrastructure and enabling technologies (e.g., high throughput screening laboratories, laboratory animal facilities, chemical screening libraries, *in vitro* ADME screening etc.) is established as part of the on-going operation, and in many cases substantial funding is made available by the parent university to support early stage research (that which is not quite ready for external grant funding).

While these centers have the advantage of direct access to what amounts to a fully integrated drug discovery operation, there is a substantial cost to creating and maintaining this type of organization that is often out of reach of many institutions. As a result, there are only a handful of academic drug discovery centers that qualify as fully integrated. Several of them started out as founder focused centers that built on their success, but this is not always the case. Some of these centers engage in contract research programs to maintain funding for nontenured faculty and staff members that are critical to the day-to-day operation in periods, as grant funds are often insufficient to cover these costs. Still others are benefactors of successful alumni interested in building the research reputation of their alma mater. Irrespective of the source of funding, there can be no doubt that this class of academic drug discovery center is an expensive endeavor, but it is achievable. Prominent examples of successful, fully integrated academic drug discovery centers include the Emory Institute for Drug Development,[28] the Yale Center for Molecular Discovery,[29] the Vanderbilt Center for Neuroscience Drug Discovery (VCNDD),[30] Northeastern University's Center of Drug Discovery (CDD),[31] and the Moulder Center for Drug Discovery Research (MCDDR).[32]

1.01.2.6 US Academic Drug Discovery Centers

In an effort to gain a better understanding of the academic drug discovery landscape in the United States, Frey et al.[33] conducted a survey of 56 academic drug discovery centers. Like their industrial counterparts, academic drug discovery centers maintain an active interest in cancer and infectious disease. Over 85% of centers surveyed reported active programs focused on the identification of novel anticancer agents, while 71% reported an interest in discovering novel treatments for infectious disease. Orphan diseases and maladies primarily found in less developed nations also comprised a significant portion of academic drug discovery centers research portfolios with 36% and 30% of centers reporting active efforts in these areas respectively. Not surprisingly, target selections tended to be higher risk in nature, as only 18% of disease modification targets under investigation were clinically validated. In addition, nearly 50% of targeted biochemical pathways had little or no validation in the literature.

With regard to capabilities, expertise, and funding, Frey's survey demonstrated a wide variation in all of these factors. While almost all of the centers (93%) reported the capacity to run *in vitro* cell based primary assays, less than half (42%) had the capacity to perform pharmacokinetic and metabolism studies on potential lead compounds. Target identification and hit to lead medicinal chemistry capacity was noted at the majority of academic drug discovery centers (77% and 72% respectively), but just over half (51%) reported the ability to perform *in vivo* efficacy studies. Only a handful of centers reported that they could perform all functions of early to mid-stage drug discovery work. This situation is likely the result of funding limitations. While some centers reported annual budget in excess of $10 million, the majority of centers' annual operating expenses were much smaller (>$2 million), some as low as $25,000 per year. Experience gaps may also be a limiting factor. More than half of the responding institutions reported that <25% of their staff scientists had industrial drug discovery experience, and <40% had tenure track faculty members focused on drug discovery.

1.01.2.7 Risks and Rewards of Academic Drug Discovery Centers

While one of the goals of an academic drug discovery center is to provide academic scientists with a method of making their research appealing to an industrial partner, any discussion of this potential value proposition would be incomplete without considering the impact of the second goal of these centers, the training of the next generation of scientists. There should be no illusions regarding the fact the primary goals of the academic institutions and industrial organizations are not the same. At the end of the day, an academic institution's primary operating mandate is to educate its students and help them start their professional lives. As a result of this and the "publish or perish" mentality embedded within many universities, there is often significant pressure to publish results rapidly. In order to mitigate the risk of premature public disclosure of potentially commercially viable research results, academic drug discovery centers often work in close collaboration with university technology transfer offices. Strategically filed patent applications

can protect the intellectual property developed in academic laboratories, while still providing academicians with the opportunity to publish important scientific findings. Importantly, academicians who file provisional patent applications are bound by the same time limitations as any other patent applicant, and failure to meet a patent deadline can have a negative impact on potential patent rights. In addition, although many technology transfer departments will support the cost of a provisional application, the cost of patent cooperation treaty (PCT) and national stage applications can become prohibitively expensive even in the largest academic institutions. As a result, great care must be taken in deciding when, how and if a patent application is warranted.

Irrespective of this risk, there are a number of clinically important therapeutic agents that originated from the academic community. Prezista (Darunavir, **3a**), an important HIV protease inhibitor marketed by Janssen Therapeutics, for example, was discovered by Professor Arun K. Ghosh and his colleagues at the University of Illinois, Chicago.[34] In a similar fashion, Gilead Sciences' nucleoside reverse transcriptase inhibitor HIV therapy Emtriva (Emtricitabine, **3b**) was not originally identified in the pharmaceutical industry. This key drug was first identified by Professor Dennis Liotta's research team at Emory University and the identification of a number of important clinical compounds makes it clear that acadscovery R.[35] The importance of this therapeutic agent is highlighted by its inclusion in the World Health Organization's List of Essential Medicines. Similar recognition is paid to Ziagen (abacavir), an HIV reverse transcription inhibitor originally discovered in the laboratory of Robert Vince at the University of Minnesota and marketed by GSK. Additional success stories include Professor Edward C. Taylor's identification of Alimta (Pemetrexed, **3c**) an anticancer agent marketed by Eli Lilly,[36] Zolinza (vorinostat), the first marketed histone deacetylase inhibitor discovered by Columbia professor Ronald Breslow and Sloan Kettering researcher Paul Marks and Lyrica (Pregabalin, **3d**), a fibromyalgia therapy that produced sales of $3.7 billion in 2011, which was originally identified by Professor Richard Silverman's group at Northwestern University.[37] The financial rewards to the academic institutions and scientists credited with the inventions can be substantial. The discovery and commercialization of Lyrica (Pregabalin), for example, netted Northwestern University and its staff a one-time payment of $700 million, as well as annual licensing fees for the compound.[38]

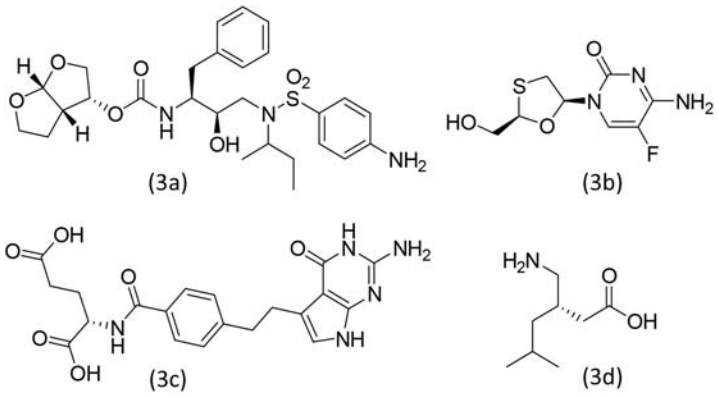

Fig. 3 Prezista (Darunavir) (**3a**), Emtriva (Emtricitabine) (**3b**), Alimta (Pemetrexed) (**3c**), in CAS database.ct as drawn. It is consistent with the structure Lyrica (Pregabalin) (**3d**).

The development of Kyprolis (Carfilzomib (**4c**), Fig. 4) is another interesting success story that began in an academic facility. In the late 1990s, Craig Crews and his colleagues at Yale were investigating the properties of Epoxomicin (**4a**), a microbially derived antitumor compound, and related analogs with the hope of determining a mechanism(s) of action. Their work eventually led to the conclusion that this class of compounds inhibits the proteasome. They also produced an analog designated YU-101 (**4b**), a viable drug discovery lead compound that was licensed to a spin-off company, Proteolix, in Dec. 2003. This company rose over $18 Million in financing to support the eventual identification and early clinical study of Kyprolis(Carfilzomib, **4c**). In late 2009, the company was acquired by Onyx Pharmaceuticals in a deal that included an initial upfront payment of $276 million. Additional payments based on milestones brought the value to over $535 million.[39] The drug was approved by the FDA for the treatment of multiple myeloma in Jun. 2012. A little more than 1 year later, in Aug. of 2013, Amgen bought Onyx for $10.4 billion.[40] Although exact dollar figures have not been disclosed, it is likely that Dr. Crews, his colleagues, and Yale received financial rewards at each of these events.

1.01.3 Concluding Remarks

The long term impact of academic drug discovery centers and academic/industry partnerships on the pharmaceutical industry is likely to be positive and long lasting. The opportunity to commercialize academic research with the potential to earn hundreds

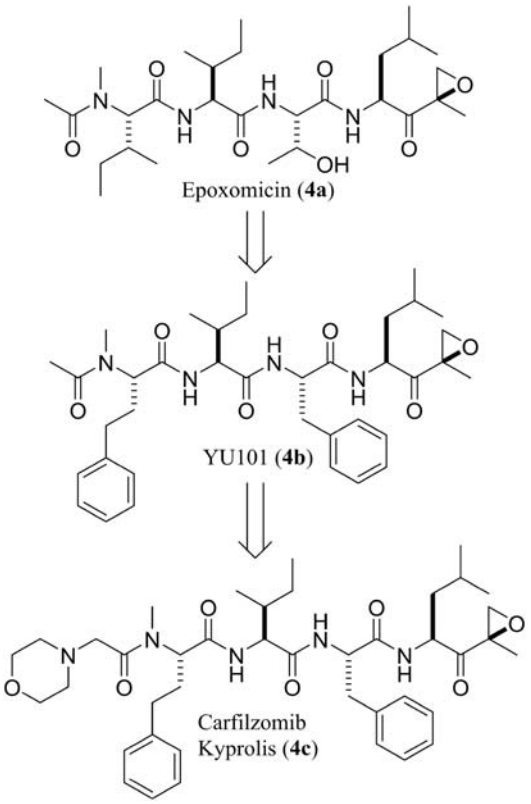

Fig. 4 Identification of Kyprolis (Carfilzomib).

of millions of dollars is a strong, attractive feature that many universities will not ignore. At the same time, the opportunity to better prepare their students to work in the pharmaceutical industry is a highly valuable asset in the competitive job market of the 21st century. Academic drug discovery centers and academic/industry partnerships provide the pharmaceutical industry with two things it needs in constant supply in order to thrive, novel scientific avenues for potential therapeutics and well trained scientists entering the work force to discover the next generation of "wonder drugs."

1.02.1 Historical Perspective

The use to which a medicine could be put has long been of great interest to the practicing doctor, yet (at least until recently) it has not been a primary concern for the medicinal chemist. This review will explore why multiple uses of a drug should be advantageously considered earlier and more thoroughly in the discovery phase of new medicines and the consequences of this approach for medicinal chemistry.

From the earliest times of healthcare, doctors have applied the contents of their medicine cabinet for more than one use. Traditional folk medicines are often proposed for the treatment of a bewilderingly wide range of purposes. The clinician always has been

and still remains central to the discovery of new uses for existing drugs; they approach the issue using the "relatedness principle," whereby a drug might be useful for a related condition to the one for which it is conventionally used. A survey of new therapeutic uses for new molecular entity drugs approved in 1998 revealed 143 examples, of which 57% were discovered by practicing clinicians independent of either pharmaceutical company or university research.[1] This figure demonstrates the special position that clinicians occupy in being able to identify new therapeutic applications for the pharmacopeia and suggests further that there are many more applications we do not currently know about.

As distinct from the historical interest in new use for existing medicines, the modern strategy of drug repurposing suggests that a deliberate search for the ideal indication for a new drug would be a useful exercise before first-in-man studies are performed; it thereby extends our conventional view of medicinal chemistry, which largely takes into account only the chemical and biological properties of a new medicine. Repurposing involves a three-dimensional evaluation of a drug, including its chemistry, its medical use, and the biological target through which the utility is derived.[2] This approach diverges from the traditional discovery approach taken during most of the last century, which follows an investigation of a particular disease-related target. Instead, drug repurposing starts with the drug, follows all the biology around the drug's activities, and ends with the identification of a number of new diseases it might be useful for.

The field of drug repurposing has been confused by its nomenclature: other terms include drug repositioning, reprofiling, and therapeutic switching. It is not clear whether these terms relate to subtly different aspects of essentially the same process, which has been generally described as "the … concept of branching the development of an active pharmaceutical ingredient, at any stage of the life cycle and regardless of the success or misfortune it has encountered so far, to serve a therapeutic purpose that is significantly different from the originally intended one."[3]

In its different guises, drug repurposing may involve the identification for a new indication of a developmental compound, a launched proprietary product, or a generic drug. Repurposing may involve a change of dose, change of route of administration, change of formulation, or none of these, in which case it may represent more of a product line extension. The developmental, regulatory, and commercial aspects (including in particular patent protection) of each of these alternatives differ substantially from each other. The change of indication may involve further optimization of the active principle, and it is this sense that drug repurposing may be of most relevance to the medicinal chemist, although strictly speaking this departs from pure repurposing. This hybrid strategy can benefit from many of the advantages of drug repurposing and indeed in some senses go beyond these advantages. The reasons why this may occur and its consequences are dealt with at the end of this article.

1.02.2 Successes: From Chance Clinical Findings to Determinate Strategy

The historical origins of drug repurposing in clinical practice are one of the main reasons for its current acclaim. In other words, as success in pharmaceutical R&D becomes ever more challenging, investigators have been attracted to this strategy because of the case histories demonstrating benefits for both patients and manufacturers based on products with secondary uses. Many of these findings were serendipitous, but they have revealed more than just another use for an existing drug. The frequency of these experiences has also taught us that one biomolecule is often involved in many different diseases, and it is this pleiotropy that makes repurposing (of a modulator of such biomolecule) a promising strategy.

The use of thalidomide (Fig. 1) in leprosy is a marvelous example. Thalidomide was originally approved for the treatment of insomnia and morning sickness during pregnancy, but banned by the WHO (World Health Organization) for its teratogenicity

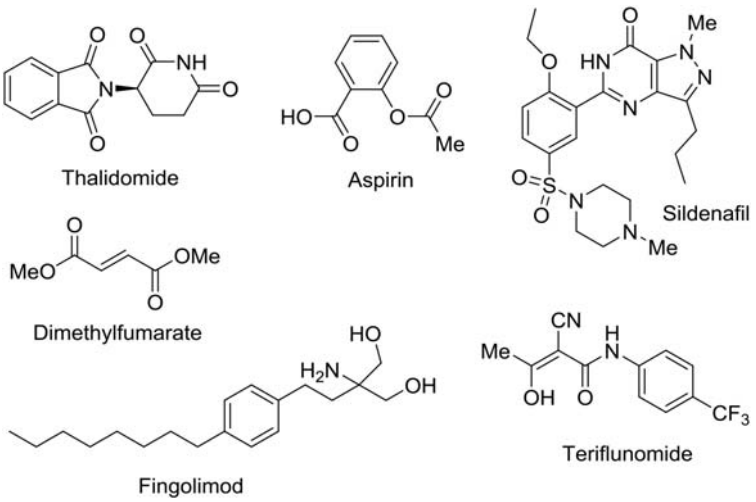

Fig. 1 Chemical structures of compounds mentioned in this section. Clockwise from top left: thalidomide, aspirin, sildenafil, teriflunomide, fingolimod, and dimethyl fumarate.

in 1962 and withdrawn from the market in Europe and Canada. It was almost universally believed that that would be the end of its medical life.

But in 1964, a critically ill patient with erythema nodosum leprosum (ENL), a complication of multibacillary leprosy, was referred to Dr. Jacob Sheskin, who was at the Hadassah University in Jerusalem. The patient was originally from Morocco and was being treated by the University Hospital of Marseilles, France. Leprosy (Hansen's disease) is a chronic, infectious human disease caused by a similar bacillus to that that causes tuberculosis.

Sheskin's patient was on the verge of death for months, he had not slept for more than 2 or 3 h in any diurnal period due to the pain of his condition, and although he had no drug to treat leprosy, the doctor administered thalidomide because he thought that its indication for insomnia would allow his patient to sleep better. In fact, it did much more than that. One day after administering two pills of thalidomide, the patient slept for about 20 h without waking. After 2 days, the pain, which had been so severe, had disappeared almost entirely. After another 3 days, Sheskin decided to withdraw treatment, and the condition rapidly worsened.

To confirm his findings, Sheskin traveled to Venezuela, where leprosy was endemic and thalidomide was still available, where he ended up treating 173 patients in clinical trials in which over 90% were symptomatically cured. The development was taken up by the US pharmaceutical company Celgene, and thalidomide was finally approved in 1997 by the Food and Drug Administration (FDA) for treatment of ENL; it was also subsequently approved for multiple myeloma. Please confirm that the approved product is a single enantiomer of thalidomide. The other stereoisomer is the one leading to the toxicity.

There are many examples of secondary uses for existing drugs, but the case of thalidomide represents the most remarkable. If a product that is the byword for pharmaceutical poison can induce almost a Lazarus-like effect in a life-threatening disease and then become approved for such use, surely there are effectively no existing drugs for which an alternative use cannot be posited. The constraint in this analysis is revealed by the following thought experiment: if thalidomide can be approved for these serious conditions despite its appalling safety record in the context of the original indications, it must equally be the case that an existing drug, deemed safe in an original serious indication, is not necessarily acceptably "safe" in a less serious secondary indication. The product needs to be subject to a new regulatory review and a new safety/efficacy assessment, in the context of this new indication. Thus, it is difficult to countenance the new use of, say, an existing cancer chemotherapeutic for a condition any less severe than cancer (unless there are ameliorating factors such as a lower dose, for instance).

An argument often proposed against drug repurposing is that after a product has been used for a number of years, its effects in patients will have been well appreciated and its utility thoroughly assessed: nothing new remains to be discovered. The flaw in this contention is clearly revealed by the story of aspirin. Aspirin (**Fig. 1**) derives from the bark of the willow tree, the use of which to relieve headaches, pains, and fevers was known to Hippocrates (http://inventors.about.com/library/inventors/blaspirin.htm). Its isolated form was discovered in the early 19th century, and Bayer Aspirin first appeared on the market in 1899. Much later, in the 1960s, the British pharmacologist and Nobel Laureate John Vane discovered that aspirin could disrupt a pathway needed for platelet aggregation.[4] Further studies in the 1980s showed that this effect could be used for the prevention of heart attacks and stroke. Nowadays, low-dose aspirin is used widely for this effect. Beyond cardiovascular properties, there was suspicion that the same pathway could be involved in cancer. A further 30 years was required for the amalgamation of this clinical evidence, so that, in December 2010, important clinical information was reported supporting the benefit of aspirin in preventing colorectal and other cancers.[5] It is now over 100 years since aspirin was first commercialized as a painkiller, showing how long it can take for therapeutic uses to be discovered even with a well-known drug. Even the work on colorectal cancer, based on data from 25,000 patients, is published with the caveat that "further research is needed." The main reason for this very long time interval is the lack of commercial incentive to develop a generic drug for a new indication, since generic substitution removes any commercial exclusivity that might reward a successful innovator. Clinical trials of aspirin in cancer are currently being financed from the public purse, and this takes much longer than if commercial investment were available.

A deterministic approach to the identification of new indications for developmental drugs started to become widespread following the approval of the use of sildenafil for erectile dysfunction in 1998. The commercial success of this product introduction by a large pharmaceutical company and the prospective identification and pursuit of a secondary indication of an incompletely developed drug attracted significant interest in drug repurposing as a strategy.

The discovery of sildenafil (**Fig. 1**) began in 1985 with chemists at Pfizer searching for inhibitors of cGMP phosphodiesterase type 5 (PDE5) enzyme as novel antihypertensives. Test compounds that were shown to inhibit PDE5 activity resulted in vasodilation and platelet inhibition, and the project was shifted toward the therapy of angina. Human trials began in Wales, which were disappointing for their primary end point, but some patients reported the unexpected side effect of penile erections, which ultimately led to the development of sildenafil (Viagra™) as a treatment for erectile dysfunction. Some time later, the role of PDE5 in pulmonary hypertension became better understood, and sildenafil was repurposed for a second time for this condition. Pulmonary hypertension is a general term for a disease process resulting in a progressive increase in pressure in the vessels supplying the lungs, particularly the pulmonary artery. Different from and much more serious than general hypertension, it can be idiopathic, familial, or secondary to a variety of conditions such as rheumatoid arthritis (RA) and Human Immunodeficiency Virus (HIV). Patients with the disease often present with signs and symptoms of right-sided heart failure, including shortness of breath, dizziness, fainting, and leg swelling. It is a life-threatening disease, unlike erectile dysfunction, and left untreated can be fatal with a median survival of 2–3 years from time of diagnosis. In its idiopathic form, pulmonary arterial hypertension is a rare disease with an incidence of about 2–3 million per year; other forms, however, are far more common.

Sildenafil relaxes the arterial wall, leading to decreased pulmonary arterial resistance and pressure. This, in turn, reduces the workload of the right ventricle of the heart and improves symptoms of right-sided heart failure. Pfizer conducted three trials on

sildenafil in pulmonary arterial hypertension, the largest being an international multicenter, randomized, blinded, controlled study involving 278 patients with the disease. Based on the results showing improvements in exercise capacity, the company submitted an additional registration for sildenafil to the FDA, and it was approved for this indication in 2005. The dose of sildenafil required to treat pulmonary hypertension was as low as one-fifth of the dose for erectile dysfunction.

Finally, an example of a determinate development of product for a new use in modern times came to fruition in 2013, when a compound we had known for 200 years was approved both in Europe and in the United States for the treatment of relapsing multiple sclerosis. The product manufacturer was the large biotech company Biogen Idec, who had licensed it from a small German company called Fumapharm.

The product, codenamed BG-12, is more commonly called dimethyl fumarate (**Fig. 1**), known since the early days of organic chemistry and first synthesized as early as 1819. It was therefore nearly two centuries later that the use in multiple sclerosis was approved. For at least 150 years, dimethyl fumarate was considered only as an organic chemical rather than as a pharmaceutical, without plausible beneficial therapeutic effects. It was used for a long while as a mold inhibitor, for incorporation in leather items such as sofas during storage. However, it is also an allergic sensitizer at very low concentrations (down to 1 part per million), producing extensive, pronounced eczema that is difficult to treat. In 2007, 60 Finnish users of leather sofas that had been manufactured with dimethyl fumarate in them were given serious rashes, and as a consequence, the importation of products containing dimethyl fumarate was banned in the European Union in 2009.

Prior to consideration for the treatment for multiple sclerosis, dimethyl fumarate (and other fumarate esters) had been used for the treatment of psoriasis, and a product called Fumaderm™ had been approved in Germany for this use since 1994. Biogen was interested in this product as a substrate for wider use in conditions related to the licensed indication. The pathophysiology of psoriasis is based on various immune and inflammatory mechanisms that are shared with other conditions, and therefore, Biogen undertook a basic investigation of the biochemical pharmacology underpinning the product. They discovered that dimethyl fumarate's mechanism of action involves upregulation of nuclear factor (erythroid-derived 2)-like 2 (Nrf2) and subsequent induction of an antioxidant response. It does this by modifying the cysteine groups of a protein called KEAP-1, which tethers Nrf2 in the cytoplasm. Once modified by fumarate, the KEAP-1/Nrf2 complex dissociates, and Nrf2 migrates to the nucleus, where it activates various antioxidant pathways. With such an understanding in hand, Biogen chose to develop dimethyl fumarate for multiple sclerosis (MS).

While Fumaderm™ was a popular product for psoriasis within Germany, its use was geographically constrained. Once licensed to Biogen Idec, a much larger development resource was allocated to the much longer term studies necessary for multiple sclerosis. They sponsored two main trials to prove the efficacy of the product involving 1200 and 1430 patients with relapsing remitting MS, conducted over 2 years.

The result of this effort was the regulatory approval of an oral product, Tecfidera™, containing a slightly different composition of fumarate esters at a higher dose than Fumaderm™. Many of the existing products for MS require intramuscular or subcutaneous injection, and the oral delivery of Tecfidera™ offers distinct advantages; in addition, compared with other oral MS products, it poses a lower risk of cardiac adverse events relative to fingolimod (**Fig. 1**) and a lower risk of liver toxicity compared with teriflunomide (**Fig. 1**). It is now approved in both the United States and Europe and has recently been allocated 10 years of regulatory exclusivity in the latter territory. This is a remarkable story of the introduction of a valuable new therapeutic option in a very serious disease that has lain unappreciated for nearly 200 years. It proves that major improvements in therapy can derive from evaluating existing compounds in ways that had not hitherto been anticipated. From the patient's perspective, drug repurposing offers huge benefits.

An extensive list of 74 drug repurposing examples of drugs that have been approved or orphan-designated for a secondary use is to be found at http://drugrepurposing.info/index.php.

1.02.3 Advantages and Disadvantages of Drug Repurposing

The 505(b)(2) process is a regulatory pathway applicable in the United States that applies to drugs that have already been approved with small modifications to the product, for instance, either as a new formulation or in terms of a new use. It stands in comparison with the 505(b)(1) pathway that applies to new chemical entities. The proportion of FDA approvals based on the 505(b)(2) regulatory pathway has been increasing markedly in recent years. In 2014, there were 41 FDA approvals via this pathway, surpassing the 505(b)(1) route that registered 35 approvals.[6] Not all of the 505(b)(2) approvals relate to drug repurposing. Another, slightly earlier statistic provides that 20% of the 84 new marketed drug products in 2013 derive specifically from repurposing.[7] It has been estimated that repurposed drugs now generate $250 billion per annum, constituting around 25% of annual revenue for the pharmaceutical industry.[8,9] Some of the most prominent commercial examples are shown in **Table 1**. The last row in the table represents a structural variant of the famous repurposing example, thalidomide, a strategy that is dealt with at the end of the article. These commercial successes have fuelled a growing appreciation of the repurposing strategy.

Differentiated as a modern prospective strategy of R&D, compared with the historical one reliant on clinical serendipity, drug repurposing started to be used widely in the first few years of the new millennium. There are a number of reasons for this, most prominent among them being an attempt to solve the poor, and declining, drug R&D productivity in the pharmaceutical industry over the past 2–3 decades. It has been estimated that it may cost more than USD 1800 million to develop a new drug de novo. In addition, due to regulatory requirements regarding safety, efficacy, and quality, the time required has been estimated to be 10–17 years.[10] Because of the cost, time, and risk of failure, the expected value of a drug discovery program at its inception has been

Table 1 Commercial successes of drug repurposing

Generic name	*Brand name*	*Structure*	*Original indication*	*New indication (year)*	*Company*	*Peak annual sales ($bn)*
Gemcitabine	Gemzar		Antiviral	Cancers (breast, ovarian, lung, and pancreatic) (various)	Lilly	1.72
Raloxifene	Evista		Osteoporosis	Breast cancer (2007)	Lilly	1.09[a]
Finasteride	Proscar		Benign prostatic hypertrophy (1992)		Merck	0.74
	Propecia			Male pattern baldness (1997)	Merck	0.43
Sildenafil	Viagra		Angina	Erectile dysfunction (1998)	Pfizer	2.05
	Revatio		Angina/erectile dysfunction	Pulmonary hypertension (2005)	Pfizer	0.53
Rituximab	Rituxan		Various cancers	Rheumatoid arthritis, Wegener granulomatosis, and microscopic polyangiitis (MPA) (2004)	Biogen and Roche	1.2
Dimethyl fumarate	Tecfidera		Psoriasis	Multiple sclerosis (2013)	Biogen	2.91
Thalidomide	Thalidomid		Antinausea and insomnia	Leprosy (1998) Multiple myeloma (2006)	Celgene Celgene	0.54
Lenalidomide	Revlimid		Structural analog of thalidomide	Multiple myeloma, myelodysplastic syndrome, and mantle cell lymphoma (2006)	Celgene	4.28

[a]Peak annual sales includes both osteoporosis and breast cancer numbers.

estimated as less than zero for a small-molecule drug discovery campaign. According to an analysis from 2009, the estimated net present value for an average small molecule is -$65 million with an internal rate of return (IRR) of 7.5%.[11]

1.02.3.1 Attritional Risk

Approximately 10 drug candidates need to enter into human investigation in order to produce one new molecular entity product launch,[12] and before that, many thousands of molecular library members may need to be screened, structurally optimized, and tested for animal toxicology studies in order for the preclinical candidates themselves to enter first-in-human studies. A reduced risk of R&D failure is therefore to be expected if one starts with a product that has already been through at least part of the process of development. A report by Thomson Reuters suggests improved success rates of around 25% for drug repurposing projects relative to the 10% or so for conventional new drugs.[13]

Most of the risk of failure is associated with uncertain efficacy, but it is also worth pointing out that safety is a relative concept and is not assured for the new indication, even for a well-known approved drug. While it is true that repurposed developments can (normally) take advantage of preexisting data, this does not mean that acceptable safety for the new product is unequivocally established. The safety of a chemotherapeutic agent is quite different from that of a new treatment for insomnia, as pointed out in the discussion around thalidomide. It is actually not easy to repurpose chemotherapeutic drugs because there are scant examples within that class that would be acceptable for another use.[14] Furthermore, certain therapeutic areas have been highlighted by regulatory agencies for detailed examination of safety hazards: a good example is that of new antidiabetic drugs, which are required to undergo extensive safety assessments because of the greater risk of adverse cardiovascular events among diabetic patients. There are also risks in situations where the route of administration is changed in the new development (for instance, in changing from oral to inhaled administration). Therefore, the risks of safety being a reason for discontinuing a repurposing development are reduced, but not eliminated.

1.02.3.2 Cost

The normal regulatory approval process for a pharmaceutical product based on a new chemical entity is discussed earlier.[10] This headline figure ($1.8bn) includes the costs of partly pursuing programs that are ultimately unsuccessful as well as a component associated with the cost of the capital deployed while funds are allocated to these failures. Compared with the cost of a new molecule entirely, new product development costs for drug-repurposed products are limited to the mid- and later stages of clinical development. It has been estimated that these costs amount to around $300 million, assuming that the drug repurposing candidate has to undergo phase II and phase III clinical trials.[15] This figure is predicated on the model proposed by Paul et al., but still represents an approximately 84% saving, compared with the cost of a de novo drug R&D program referred to earlier.

Part of the reason for this dramatic difference in cost is due to the reduction in attrition resulting from better success rates for repurposing projects. Although the bulk of the development costs for a new chemical entity program is also encountered in repurposing projects, the reduced expenditure on failed programs and the associated costs of capital give rise to this substantial cost saving for the repurposing strategy.

1.02.3.3 Time

Relative to the conventional approach, the evaluation of efficacy in a human setting is dramatically brought forward in repurposing programs. New chemical entity projects require years of research and discovery before the utility is even investigated, with substantial expenditure of time and money in the preclinical development phase. Aside from the economic impact, the benefit for the patient is dramatic, with much reduced times for new product innovation and associated improvements in healthcare. The fractional improvement in time taken to proof-of-concept studies is especially dramatic for repurposing relative to NCE discovery. As shown in **Fig. 2**, the time required for preclinical activities can be shrunk to 1–3.5 years compared with the normal expected duration of 4 and 9 years.[16]

Beyond discovery, the formulation of new development plans and their undertaking, market analyses, intellectual property (IP), and regulatory diligence are still required.[16] The time requirements for later drug development and regulatory approval for a repurposed drug program are often comparable with those for traditional R&D,[17,18] so that overall, the drug development cycle for a repositioned drug is expected to require between 3 and 12 years compared with the traditional 10–17 years.

1.02.3.4 Disadvantages

One of the features of drug repurposing that is of substantial advantage is the ability to obtain the so-called "method-of-use" patents framed around the discovery of the secondary use of a compound. Under international patent law, new pharmaceutical uses differ from new uses of other things in their ability to be protected. Such patents are valid in most countries including the major pharmaceutical markets, though "the 'mere' identification of a new use" of a drug in India remains a significant exception. These patents last for the same period as conventional "composition of matter" patents. In some cases, they can be sufficient in themselves to protect a marketed repurposed product; however, they are seen as weaker and more easily challenged.

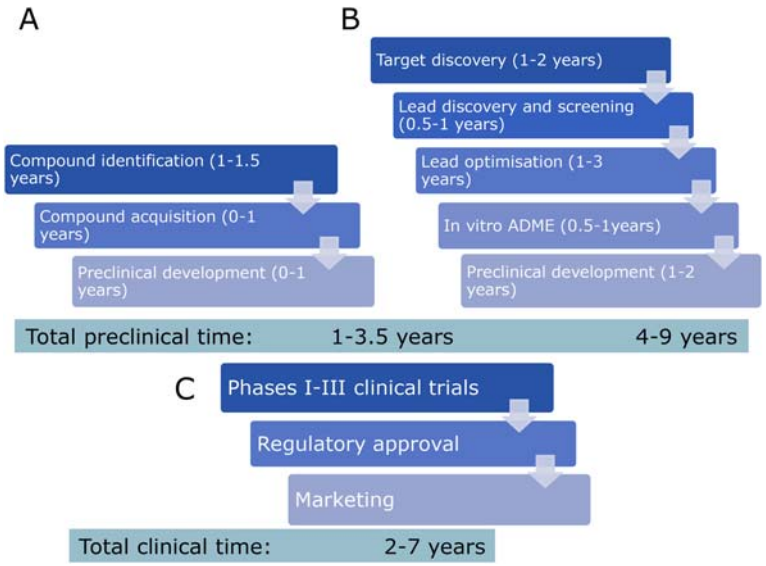

Fig. 2 Comparison of the processes and times for preclinical development of drug repurposing projects (A) with conventional new chemical entity projects (B). The processes and times for clinical development of both types of project are similar (C).

The weakness derives from the greater difficulty for a patent holder in controlling utilization in parallel conditions. For instance, the patent that protected the use of sildenafil for the treatment of erectile dysfunction did not cover its use in pulmonary hypertension, which was the third purpose (taking the original anticipated use in angina as the first) for which the drug was used. This was not a problem for the marketing company, since Pfizer had both indications—erectile dysfunction and pulmonary hypertension—under its control, but could have been a problem if two companies shared the franchise for sildenafil in two separate indications.

The second problem, that of litigatory challenge, is also exemplified with sildenafil, since Pfizer filed a patent both on the compound itself and on its use in erectile dysfunction. After Viagra was approved and it became clear that the use of selective PDE5 inhibitors in this condition would become a major market success, other companies discovered and developed compounds of similar mechanism for the same purpose. However, Pfizer's method-of-use patent claimed not only just sildenafil but also other "selective cGMP phosphodiesterase inhibitors" for erectile dysfunction, and while this patent was in force, it prevented the marketing of these competitors' products. A huge process of patent litigation ensued, which resulted in the invalidation of Pfizer's European patent and restriction of its rights under the US patent 6,469,012 (though the company retained protection for sildenafil itself for the treatment of erectile dysfunction).[19] The challenge was based primarily on an issue of obviousness, that is, whether the effects of sildenafil (and similar compounds) would have been predictable based on prior art publications. Given the breadth of scientific literature that can be cited, this is an issue for any method-of-use patent.

The second major disadvantage of drug repurposing is a commercial one, related to the potential substitution of a repurposed product, often by a generic competitor. Off-label generic substitution can markedly limit the commercial opportunity for a repurposed drug, as is most eminently demonstrated with the use of aspirin referred to earlier. Again, sildenafil also clearly exemplifies this issue, because, in the United States, generic versions that are intended for the treatment of pulmonary hypertension can be used "off-label" for the treatment of erectile dysfunction, although multiple pills are required. Though legally, Pfizer has a monopoly on the sale of products containing sildenafil for erectile dysfunction under the method-of-use patent US 6,469,012, it is a difficult area to police, and some generic substitution occurs. This situation arises from the freedom of a medical practitioner to prescribe a product that, according to his or her professional judgment, best suits the medical needs of the patient. This commercial factor may limit the development of a significant proportion of drug repurposing candidates, and pharmaceutical companies may be quite wary of drug repurposing projects that might suffer from generic substitution due to insufficient market potential.[20]

The repurposing drugs in oncology (ReDO) project is an international collaboration initiated by a diverse group of researchers, clinicians, and patient advocates all working in the not-for-profit sector, seeking new and effective cancer treatments based on existing drugs.[21] From the retrospective evidence listed earlier, there are many examples of drugs used for other purposes that have been associated with reduced rates of cancer incidence. These would make good candidates for investigation for their anticancer properties, at least for their effects in cancer prevention or reoccurrence. However, the process of acquisition of further data and regulatory approval of a specific anticancer product based on these generic substances is very unlikely to be compensated by a preferentially priced product. In this sense, the very existence of generic products acts in opposition to repurposed drug innovation.

1.02.3.5 Off-Label Medicine

When a new medicine is brought to market, the regulatory agencies judge its fitness for use according to a very specific set of conditions, the so-called product label, within which a pharmaceutical company may legally promote the product. This judgment is based

on a careful assessment of the safety and efficacy of the medicine when used under these restricted conditions. However, once approved, a medical practitioner may vary the use of the product outside the regulatory stipulations so long as, in his or her judgment, its prescription is in the interests of the patient. The variation may relate to the medical use, the type of patient, the dose, or the length of time that the medicine is administered.

Off-label prescriptions are written commonly for pediatric use and for certain therapeutic areas such as oncological and psychiatric situations. In all, they are estimated to amount for 20% of pharmaceutical prescriptions.[22] However, around 73–79% of off-label uses lack any, or any good, scientific support.[23,24] A good example of this is the use of antibiotics for viral infections, a form of off-label use that has contributed to the increasing threat from bacterial resistance. In addition to issues related to efficacy, off-label use is associated with two to three times the rate of adverse events, including serious adverse events. In summary, there are less evidence for efficacy and evidence for poorer safety. National acceptance of off-label use varies, with German practitioners restricted to being able to write such prescriptions for serious conditions where there are no alternative approved treatments. A slightly less stringent set of professional rules apply in the United Kingdom, though it is not clear how strictly these rules are followed. In the United States, doctors are comparatively much less bounded, with the FDA prevented by statute from interfering in medical practice and the American Medical Association unwilling to limit the professional freedom of their members to make their own prescription choices. Some of those in support of such freedoms even argue against a requirement for doctors to tell their patients when a product is not labeled for their patient's condition.

Despite the lack of evidential support, and the greater risks of side effects, the freedom to prescribe off-label is a right coveted by practitioners, with some justification. Historically, the successful identification of ancillary medical uses often derives from this freedom, and in rare diseases, for instance, where there are only approved treatments for around 5% of the known conditions, there is often no alternative. The remarkable discovery of the efficacy of thalidomide in leprosy is certainly owed to this freedom, and in this case, many people with leprosy would have suffered and in some cases died if this unlikely treatment had not been discovered to be useful.

Nevertheless, the decision to prescribe in an off-label fashion does not normally lead to a proper evaluation of the results of that prescription, in the same way as would occur in a clinical trial. The freedom to prescribe off-label medicine is generally limited by the lack of an associated onus to collect and report the consequences of such a prescription. The practice is unregulated by the FDA, and it is characterized by poorer safety and efficacy statistics. The use of antipsychotics in dementia patients is one example among many where there are no therapeutic benefit and a greater risk of stroke as a result of the practice. In the United Kingdom, there was a report commissioned into the associated patient harm that estimated 1800 excess deaths per year.[25] In another case, the agent NovoSeven (factor VIIa) was approved for certain forms of hemophilia or congenital deficiencies in the coagulant protein, but the proportion of unregulated prescriptions reached alarming proportions, rising to up to 98% off-label use, and ultimately no clinical benefit in most of these uses, where again excess deaths arose.[26] Similarly, epoetin alfa, an erythropoietin-stimulating agent, was originally approved for patients with anemia in end-stage kidney disease and (later) with HIV. However, it was prescribed much more broadly than these two orphan-designated uses implied, and the market quickly expanded to include nearly all kidney dialysis patients and ultimately many more patients with anemia, not just the very serious cases for which the product was approved. With time, the doses that were used also increased, until in 2006, where the sales of the product Epogen reached $5.6bn. Thereafter, safety concerns were raised because in the less serious cases, and at the higher doses, the safety of the product compared unfavorably with the benefit.[27] Ultimately, the FDA required new warnings to be added to the product label, and since then, sales have dropped off. The drug was also associated with performance enhancement, most notably of the cyclist Lance Armstrong. There are therefore multiple facets of erythropoietin, from the approved lifesaving antianemic product in rare blood conditions to off-label use in general improvement of "well-being and happiness" in much more common and milder cases of anemia to a drug that can be used to cheat in sport.

Off-label medicine is a gray area in which the interests of the patient are often subservient to those of pharmaceutical companies, reimbursement authorities, and doctors. Absent a commercial reward, pharmaceutical companies often choose to pursue alternative avenues of R&D, on the basis of a more assured commercial return, rather than because such alternatives are inevitably likely to deliver better healthcare. Increasingly, the new products deriving from such pharmaceutical R&D present a serious challenge to reimbursement authorities.

1.02.4 Variants

There are a number of different variants of the drug repurposing strategy. Most of these variants differ by virtue of the characteristics of the starting point for the repurposing activity. Each of these variants gives rise to different commercial challenges, patent opportunities, and possible routes to regulatory approval.

1.02.4.1 Repurposing of Generic Drugs

In the simplest case, old, generic drugs without patent protection are used: there are 1527 new molecular entities that have been approved by the FDA since its inception in 1938–2011.[28] Repurposing opportunities that use strictly the same generic drug, in the same formulation and same route of administration, are likely to be encumbered by generic substitution as was demonstrated by the example of aspirin referred to earlier. On the other hand, a number of repurposing developments have been initiated for

different doses, formulations, or routes of administration. In such circumstances, the original preclinical toxicology package may need to be modified or bridged to reflect the new circumstances. In addition, there may be new safety requirements that supersede the regulations in place at the time of the first approval, so that the original toxicology data need to be updated. The process toward clinical testing will therefore need to be carefully assessed on a case-by-case basis. The onus of additional preclinical toxicology is particularly evident for inhaled drug repositioning, where the formulation of a respiratory product and its preclinical toxicology is quite an expensive and time-consuming process.

1.02.4.2 Public/Private Partnerships for Repurposing of Abandoned Assets

The problem of substitution for repurposed generic drugs, coupled with the awareness of the unrealized commercial value in discontinued developments, has engendered an interest in repurposing of programs oriented toward products that have been partially but not fully developed. In such cases, the repurposed product, on success, would represent the only product based on this active ingredient on the market. Some years ago, the opportunity from stalled candidate drugs that have passed phase I but not phase II or III clinical trials was identified as representing a vast pool of repositioning substrates.[29] However, gaining access to collections of failed drugs and the necessary data to progress into clinical trials is typically hard due to intellectual property and confidentiality issues.[30]

A collaborative approach involving a public/private partnership was first broached in the United Kingdom, between the Medical Research Council (MRC) and a single industrial partner, AstraZeneca. The program was called the "Mechanisms for Human Diseases Initiative" and was based on a library of 22 midstage stalled developmental compounds contributed by the pharmaceutical company. At around the same time, in the United States, the NIH convened a round table of leading representatives from academia, government, and private sector R&D to explore new uses for abandoned and approved therapeutics, where pharmaceutical companies would create a pool of compounds for further investigation. This led, in 2012, to the NIH establishing the NCATS (National Center for Advancing Translational Sciences) institute and implementing an initiative called "Discovering New Therapeutic Uses for Existing Molecules." In both cases, the essential model was the deployment of partially developed compounds from industry and financial support from public funds to develop these assets for new uses. A similar collaboration was entered into in 2012 by the Broad Institute and Roche, the latter contributing a collection of 300 compounds with various indications in hopes of identifying alternative uses for the drugs using the research institute's screening technologies.[31]

From the governmental perspective, the advantage lay in the ability to access to high-quality developmental compounds. The MRC and NIH deployed part of their national government-allocated budgets and set up translational grant schemes for which academic investigators would compete; industry contributed their partly developed compounds and associated data. From the industry perspective, this permitted stalled assets with little or no accountancy value to be worked in an efficient manner through a drug repurposing strategy. The value from the remaining patent life in a stalled asset, or from working in an area of chemical space adjacent to the industrial partner's preexisting chemical knowledge, meant that the outcome from successful repositioning by the academic partner might be taken forward with alacrity.

Another unanticipated benefit of the schemes was the use of crowdsourcing to identify new opportunities for these compounds. In the NIH/NCATS scheme, examination of the submissions showed that 15 of the 16 compounds that received five or more applications had been proposed for at least three different indications. The diversity of the proposed developments emanating from one compound supports the potential of repurposing for new therapeutic outcomes.[32] More pertinently, the recent publication of human evidence that the NKB antagonist AZD4901 is a potent suppressor of follicle development and estradiol secretion in women, with potential therefore in polycystic ovarian syndrome, is one of the first reports in support of this kind of partnership between industry and academia.[33]

Other, similar examples of industry–academia partnerships forged with a drug repurposing remit in mind include those between Pfizer and Washington University (St. Louis)[34] and also in Taiwan, with the National Research Program for Biopharmaceuticals (NRPB).[35]

1.02.4.3 Off-Target Versus On-Target

In addition to the stage of development, another dimension in repurposing revolves around whether the mechanism underpinning the new indication is the same or different from that implicated in the original indication. The difference is more than academic in impact.

Most repurposing involves the identification of a new indication for an existing compound working through the original mechanism or target. This is called "on-target" repurposing.[36] The principle is that new biology has connected the old drug to a new indication via the same pathway or protein interaction as is responsible for the original indication. Sildenafil's use in erectile dysfunction and in pulmonary hypertension involves this principle: both indications are effected through inhibition of cGMP PDE5.

Sometimes, however, repurposing involves a new mechanism entirely. The use of doxycycline (**Fig. 3**) for the treatment of periodontitis is such an example. "Off-target" repurposing of this type is rarer because the compound was normally optimized for a mechanism in the original discovery campaign, so it is unlikely to be an optimal compound for another mechanism. In the case of doxycycline, its original antibacterial activity is due to inhibition of protein synthesis by preventing the attachment of aminoacyl-tRNA to the ribosomal acceptor (A) site.[37] Surprisingly, doxycycline also has more potent effects against matrix metalloproteinases and specifically via its effect on collagenase and gelatinase in preventing the infiltration of polymorphonuclear cells

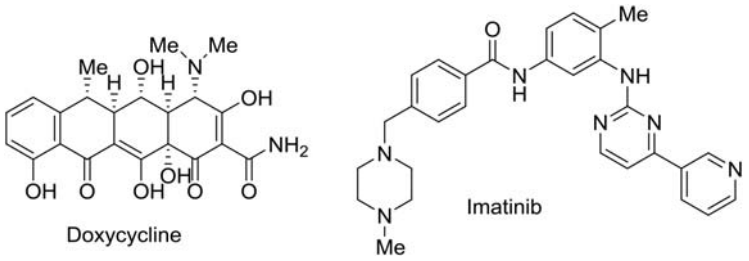

Fig. 3 Chemical structures of compounds mentioned in this section. Left: doxycycline. Right: imatinib.

into gingival tissue of patients affected with periodontitis.[38] The therapeutic benefit of doxycycline in this condition is observed at sub-antibacterial doses, a factor that was crucial in the regulatory approval of the product, since the FDA wanted to avoid the chronic exposure of patients to an effective antibiotic, because of the potential for resistant bacteria to be produced.

Many existing drugs have multiple protein targets to which they bind; some of these targets are currently known, but many more are not. Recent studies have evaluated the extent of polypharmacology by analyzing all known drug–target interactions. A human pharmacology interaction network connecting proteins that share one or more chemical binders has been created.[39] In their database of 276,122 active compounds, 35% hit more than one target. In a second study, Mestres and coworkers integrated seven drug–target interaction databases and found that, on average, each drug interacted with six different targets.[40] However, not only does off-target repurposing require that the repurposing substrate acts at a secondary target but also it does so within a window of therapeutically acceptable dosing. It is, as a result, much rarer than on-target repurposing.

Tyrosine kinase inhibitors are a highly promiscuous therapeutic class of marketed drugs in terms of the number of enzymes they inhibit. These drugs normally bind competitively to the ATP-active site, and there are over 500 similar ATP-binding sites in the human protein kinome.[41] One of the first marketed tyrosine kinase inhibitors was imatinib (**Fig. 3**), which was first introduced for the treatment of chronic myelogenous leukemia (CML). This condition begins in the often asymptomatic chronic phase and over the course of several years progresses through an accelerated phase and ultimately to a blast crisis, by which time it is associated with a very high mortality rate. From diagnosis, the median survival period is just over 5 years. Imatinib is an inhibitor of the tyrosine kinase bcr-abl, and this enzyme is involved in a specific genetic abnormality associated with CML. While imatinib was originally heralded as a breakthrough of a new generation of selective kinase inhibitors, it later became clear that it is also an inhibitor of two other tyrosine kinases through which it produces a useful therapeutic effect. The first of these is PDGF-R, inhibition of which is responsible for use in dermatofibrosarcoma. The second is c-kit; mutations in both c-kit and PDGF-R are central but independent events in gastrointestinal stromal tumor (GIST), and inhibition of both these enzymes proposed to underlie imatinib's benefit in this condition.[42]

1.02.4.4 Rare Diseases

Drug repurposing is a particularly attractive approach for rare diseases, and the term "rare-purposing" has even been trademarked by the company Healx Ltd, which is focused entirely on this strategy. This is so for both scientific and commercial reasons. Scientifically, these diseases are often poorly characterized in their pathophysiology and lack a clear understanding of the biological pathways necessary to interdict or compounds to interdict them with. In silico techniques for predictive repurposing (which are described in more detail in the next section) offer a relatively quick method of identifying testable hypotheses that may be translated into the clinic. In addition, from a commercial perspective, there are specific regulatory measures that are meant to encourage research into rare diseases, and these measures can provide commercial exclusivity in situations where repurposed products cannot be protected by patent or that patent is weak.

From the perspective of unmet medical need, a huge opportunity exists: there are over 7000 rare diseases. Over 95% of these lack an FDA-approved therapeutic agent.[43] Rare diseases are often equated with "orphan" diseases because they lack an approved therapeutic treatment, and various forms of regulatory legislation have been enacted in the major pharmaceutical markets to incentivize the development of drugs for this type of condition.

In the United States, a rare disease is defined as one that affects less than 200,000 persons.[44] The Orphan Drug Act (ODA) was enacted there because the economics for developing a drug for a rare disease, where the costs of R&D can only be amortized over a relatively small number of patients, were unfavorable. As a result of this act, which allocates additional market exclusivity in such situations, over 300 drugs and biological products for rare diseases have been approved by the US FDA since 1983 (compared with fewer than 10 such products in the decade prior to 1983). Orphan products represented 30% of products approved for the first time by the FDA in the 5-year period from 2004 to 2008.[45] Today, the rare disease market is growing rapidly and becomes attractive for pharmaceutical R&D. Despite the small patient populations, significant market sizes can be expected because of high prices. As an example, the drug Soliris (eculizumab) from Alexion Pharmaceuticals is priced at over $500 k per patient per year and recorded sales of over $1bn in 2013.

Table 2 Legislation in major pharmaceutical markets offering commercial incentives for orphan drug developments

	United States	*Japan*	*Australia*	*European Union*
Legislation date	1983	1993	1997/98	2000
Prevalence	Fewer than 200,000 (6.25 per 10,000)	Fewer than 50,000 (4 per 10,000)	Fewer than 2000 (1.1 per 10,000)	Fewer than 5 per 10,000
Market exclusivity	7 years	Reexamination period extended from 4 to 10 years	None	10 years
Fee waiver	Yes	No	Yes	At least partial

The US legislation enables fast-track FDA approval, marketing protection, tax incentives, and funding for clinical research in rare diseases. In particular, once a drug is approved, a generic version in that indication cannot be approved for 7 years (in addition to normal patent protection). The developer may also receive tax concessions, grants, and waiver of regulatory fees. As an indicator of the success of the ODA, similar legislation is now in place in Singapore, Japan, Europe, and Australia, with each jurisdiction having a slightly different definition of an orphan indication and applicable commercial incentive (see **Table 2**). For instance, whereas in the United States, an orphan designation may apply if the prevalence is less than 200,000 (approximately 6.25 in 10,000); in Europe, the corresponding figure is 5 in 10,000 (corresponding to approximately 250,000 patients in the EU28).

The regulatory protection in rare diseases is particularly important given the relative weakness of patent protection for repurposed generic products, which is often confined to "method of use"-type intellectual property. Thus, there is much repurposing activity in this area. A comparison of the FDA approval database with those drugs that have received orphan drug designation revealed 236 that were "promising" for the treatment of a rare disease, though not yet approved for marketing for that condition.[45]

1.02.5 Approaches to the Identification of Drug Repurposing Candidates

1.02.5.1 Experimental Approaches

Experimental screening in drug repurposing involves the parallel testing of compounds against one or more targets or phenotypes in large pharmacological assays. This large-scale approach works on the principle that the greater the number of compounds that are screened, the greater the number of repositioning candidates that should be generated[46]; the most promising candidates can then be progressed to more focused experimental testing. Even if the number of positive hits as a percentage of total compounds screened remains low, the relatively low cost of this initial screening makes this an effective repurposing approach. There are two main approaches to screening in drug repurposing: target-association screening and phenotype-based screening.[30]

1.02.5.1.1 Target-association screening

Target-association approaches aim to associate a target with a disease or drug, measured via in vitro assays in either a one-drug many-target approach (for instance, identifying previously unknown off-targets of a drug) or a one-target many-drug approach. An example of the former is the identification of new targets for the kinase inhibitor gefitinib.[47] In this study, HeLa cellular extracts were washed over immobilized gefitinib (**Table 3**) to determine binding affinity, resulting in the identification of more than 20 new gefitinib targets that were then validated in cellular assays. One of these new targets was the protein kinase RICK. Pretreatment of cells with gefitinib was found to reduce RICK activity by up to half; however, while RICK is known to be involved in immune response, it is not clear to what extent its inhibition would be of therapeutic benefit. This illustrates how the one-drug many-target approach can lead to an "orphan target" problem.

A one-target many-drug approach therefore begins with identification of a disease-relevant target and then attempts to find drugs that modulate its activity. One study targeted the migratory factor AceMIF, inhibition of which could be used to prevent or treat infection by the blood-feeding hookworm parasite[48] (**Table 3**). A high-throughput screening approach was used to assess almost 1000 FDA-approved drugs for AceMIF inhibition. Putative inhibitors identified by the screen were assessed in further in vitro tests, identifying six compounds as AceMIF-specific inhibitors, half of which demonstrated hookworm toxicity in an ex vivo assay. Interestingly, some of these compounds had known antihelminthic activity through other mechanisms: pyrantel pamoate, for example, is known to cause paralysis in parasitic worms through inhibition of parasite cholinesterase. This suggests that AceMIF inhibition may be an additional mechanism of action of pyrantel pamoate. As well as identifying drug repurposing candidates, then, target-based screening can also help to elucidate the ways in which existing compounds work.

1.02.5.2.2 Phenotypic screening

The second type of screening is phenotypic screening. Phenotypic screens are end point-driven, requiring no prior reasoning about targets or disease biology. This can serve as both advantage and disadvantage—on the one hand, such approaches are less hypothesis-driven[49] and can broaden the search space by preventing excessive focus on currently known biology ("looking for one's keys under the streetlight"[49]), increasing the potential for discovery of completely new biology: various examples of its success

Table 3 Overview of drug repurposing candidates from selected experimental approaches

Selected candidates—target/indication	*Structure*	*References*
Gefitinib—RICK (receptor-interacting serine/threonine-protein kinase 2)		47
Furosemide—hookworm infection		48
Pyrantel pamoate—hookworm infection		48
Sodium meclofenamate—hookworm infection		48
Apomorphine—tobacco dependence		53
Topiramate—tobacco dependence		53

are shown in **Table 3**. On the other hand, if a promising candidate is discovered through this end point-driven approach, it may then be required to elucidate its mechanism (for instance, via target identification), which can be a costly and time-consuming process.[50]

Phenotype-based screens can be cell-based (in vitro) or in vivo assays. Cell-based screens allow high-throughput, automated phenotypic analysis, such as that developed by Recursion Pharmaceuticals, in which a phenotypic fingerprint ("phenoprint") of human disease is identified via machine learning methods from thousands of cellular models of genetic disease. These phenoprints can be assessed following drug treatment using automated image analysis techniques, allowing the testing of thousands of drugs in parallel. This platform can be applied to any of an estimated 4500 diseases with a loss-of-function mutation component, with promising applications in the genetic diseases Rett syndrome, Diamond–Blackfan anemia, and cerebral cavernous malformation.[51]

A key advantage of phenotypic screens over target-based screens is their ability to capture biological complexity that cannot be represented in reductionist target-based approaches.[52] Extending this idea further, in vivo phenotypic screens progress directly to screening drugs in animal models of disease. For example, a repurposing study in a zebra fish model of tobacco dependence[53] ran a focused screen of 39 drugs (chosen based on their side effect and contraindication profiles). Six of these medicines, including topiramate and apomorphine (**Table 3**), were found to inhibit the nicotine response in the zebra fish model. The complexity of using animal models means that in vivo screening tends to be lower-throughput and more specialized than what is possible with cellular assays. However, larger-scale in vivo screens are possible: the phenotypic screening platform developed by Melior Discovery uses 40 animal models representing 14 disease areas across a broad range of disease types, from neurological and neurodegenerative diseases to pain, which can be evaluated in parallel. Melior claims that their platform allows compounds to be tested

across the full range of disease models in roughly 10 weeks. Such higher-throughput phenotypic screening has the potential to significantly increase the speed of the early drug discovery process by testing in multiple diseases at once for fast identification of "interesting" versus noninteresting drug candidates.

The disadvantages of phenotypic screening include the risks of missing potentially relevant compounds due to poor absorption, distribution, metabolism, and excretion (ADME) properties or alternatively of identifying "false-positive" candidates (or rejecting candidates that are false-negatives) in a disease model of limited relevance to the human condition.[50] Although target-based screening has received more attention than phenotypic screening in recent decades, phenotypic screening has overtaken target-based screening in the identification of new drugs, with 28 first-in-class small molecules identified through phenotypic screening compared with 17 identified through a target-based approach in the period of 1999–2008.[54] By reducing the need for a strong target hypothesis, phenotypic screens represent a form of "systematic serendipity," enabling the potential for discovery outside of what is predictable from current pharmaceutical knowledge.

1.02.5.2 Knowledge-Based Approaches

There exists a huge body of knowledge about drugs and disease that is qualitative, rather than quantitative, in nature. This knowledge is distributed across various resources such as the biomedical and chemical literature or captured in clinical records. Humans are able to understand and make inferences from diverse sources of information, but this understanding is limited by a problem of scale: the sum total of human knowledge on drug and disease is far too big for any one individual to comprehend. By collecting this information and parsing it into a form that can be "understood" (or mined) by a computer, knowledge-based approaches aim to bring to light new associations between drugs and disease.

1.02.5.2.1 Literature-based

Literature-based discovery treats large sets of scientific literature as a vast system of interconnections between research parameters and navigates through these interconnections to reveal indirect relationships among seemingly unconnected biomedical entities such as genes, signaling pathways, physiological processes, and diseases. In addition to being used to uncover candidates for drug repurposing, it may also be used to describe the basic molecular mechanisms underlying a disease, to better understand the biological effects of a drug, or to evaluate its benefit/risk profile.

In order to achieve this, literature-based approaches make use of the chemical, biological, and clinical knowledge that is held in natural language format ("natural language" refers to any human language as opposed to a language designed to be understood by a computer). Literature mining aims to extract relevant entities from text sources (in this case, scientific literature, clinical trial reports, electronic health records, etc.) and determine the logical relations between entities.

The general principle is that if A is related to B and B is related to C, then it is plausibly true that A is related to C. Interestingly, from a patent perspective, not only is the inference of C to A novel, but also it may in certain circumstances be nonobvious. This type of process is described in Fig. 4. Beginning with an object of interest, A, other objects B can be tentatively related to it within the literature by identifying the co-occurrence of A and B objects within PubMed or MEDLINE records (titles and abstracts). Each B object can then be queried to identify other objects, C, that co-occurred with them in the literature, such as if they occur together in the same sentence. Each of these new objects, C, which are not themselves A or B objects, is related to A only implicitly. In other words, they have no documented relationship with A, but they share one or more second-order relationships with A. This large list of implicitly related objects will contain potential discoveries of new relationships.

However, because of their abundance, it is necessary to prioritize and rank these objects in some manner. For instance, concepts can be expressed as single words or phrases, while the strength of relationships between A and C can be stratified using the number of intermediate concepts B. Spurious links are filtered out by mining a large number of papers, where the "noise" of false associations (e.g., resulting from co-occurrence in a list) is rendered statistically insignificant by the use of a large number of sources.[55] Alternatively, more complex natural language processing approaches can be applied to uncover the semantic relationships present in the text, allowing a deeper understanding of the association between concepts. A review of the alternative methods to link concepts and rank the relationships has been published by Deftereos et al.[56]

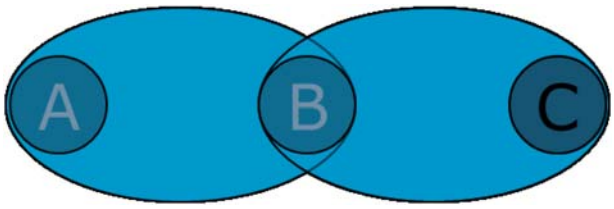

Fig. 4 Swanson's ABC model. Concept A is related to concept B, as reported in one set of papers (indicated by the ellipse on the left), while B is related to C according to another set of papers (indicated by the ellipse on the right). Although A is not known to be directly related to C, one can infer an indirect relation through B. A, B, and C can stand for drugs, targets, diseases, pathways, or any other concept of relevance for the problem to be addressed.

An example of the first approach ("co-occurrence") is the drug–disease knowledge graph created by Gramatica et al.,[55] who combined text mining with graph theory to discover indirect associations spread across three million PubMed extracts. A link is based on the co-occurrence of two concepts in a sentence, with the significance of the link being defined by the number of co-occurrences between the two (the amount of evidence for the association) and the length of the path between them. Longer paths allow for the representation of indirect mechanisms, but long paths also introduce the possibility of spurious connections between concepts. Their graph can link concepts including diseases, drugs, genes, proteins, and biological processes, allowing inference of the mechanism of action of drugs and diseases. Their network linked the tyrosine kinase inhibitor imatinib (approved for use in hyperproliferative disorders including GISTs, mastocytosis, and several leukemias) with Creutzfeldt–Jakob disease (CJD). Through explicit representation of these biological concepts, the system can provide a clear biological rationale for this suggestion: the path imatinib → c-Abl → > apoptosis → CJD indicates that imatinib could work through inhibition of the apoptotic effect of the kinase c-Abl, which has been experimentally linked to CJD. Other methods based on co-occurrence include the natural language approach developed by Weeber et al.[57] and the LitLinker system developed by Yetisgen-Yildiz et al.,[58] which identifies MeSH terms in MEDLINE papers that are closely related to the starting and target concepts, which are then refined to remove synonymous or noninteresting concepts by analyzing word probability distributions. This approach led to the identification of endocannabinoids as potential agents for Alzheimer's disease, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor ligands for migraine, and secretin agonists for schizophrenia.

A more complex literature mining approach was used by Xu et al.,[59] who created a phenotypic measure of disease similarity based on the extent of shared symptoms between two diseases. Over 120,000 disease–symptom associations were extracted from 21 million MEDLINE citations using syntactic patterns such as "*symptom* in *disease*" or "*symptom* associated with *disease*." By learning these syntactic patterns from the literature, spurious or negative associations can be more easily filtered out. Through the creation of a large machine-understandable disease–phenotype database, the authors were able to demonstrate that the number of shared drugs between two diseases showed a positive correlation with the number of shared symptoms. This literature-based correlation was stronger than the correlation obtained from the shared symptoms listed in an existing knowledge base (the Unified Medical Language System). Having demonstrated that shared symptoms between two diseases may also indicate the potential for shared drugs, the authors are now developing a system to use these literature-mined disease–symptom associations for drug repurposing.

1.02.5.1.2 Ontologies

A common problem when working with natural language sources in computational applications is the problem of synonymy, where multiple terms may be used to refer to the same or similar concepts such as the use of generic versus brand names of drugs or the use of the term "dementia" to refer to the symptoms of Alzheimer's or Parkinson's disease. One way in which this can be overcome is by linking to ontologies. Ontologies seek to represent real-world domains in a standardized manner, organizing concepts from natural language in a common system of naming and interrelationships. By specifying relationships between entities—such as "is-a," "has-a," or "part-of"—ontologies can uncover implicit structures in existing resources and make these structures explicitly machine-understandable, aiding the discovery of new associations between diseases and drugs.

A specialized ontology for chemical biology and chemogenomics, Chem2Bio2OWL,[60] has been used in drug repurposing to add semantic annotations to a drug–target interaction network.[61] The network, built from drug and target similarity data and drug–target interaction data, was annotated with "path patterns": for example, "drug *binds* target *binds* drug *binds* target." Paths considered to be significant were used to build a drug similarity network, in which clusters of drugs with different indications could represent repurposing opportunities—for example, the migraine treatment butalbital was clustered with nine insomnia drugs, which the authors suggest is due to its depressant action as a barbiturate. The authors caution, however, that because their method does not yet distinguish between activation and inhibition of a target, drug pairs in the network may represent opposite indications, that is, adverse drug effects.

One problem presented by the use of ontologies is that of a proliferation of ontologies, in which several ontologies seek to represent the same or similar domains, yet use slightly different representations, leading to incompatibility between different sources. Qu et al.[62] created a disease–drug correlation ontology through integration of existing ontologies, standardizing the vocabulary used to relate these terms across different resources. These included MeSH, SNOMED CT, and the NCI thesaurus, which describe disease-associated concepts; GO, which provides a standardized vocabulary for genes and gene products; and the ATC (Anatomic Therapeutic Chemical) classification system, which provides a classification system for drugs. Drug and disease information was compiled from sources such as DrugBank and OMIM and enriched with knowledge from other sources such as GO and KEGG pathways through the retrieval of existing relationships (*is-a* and *has-a*) in these sources. Graph-theoretical approaches were then applied in order to discover significant and interesting links. The authors applied their method to generate a pharmacome–diseasome graph for systemic lupus erythematosus (SLE), ranking tamoxifen as a highly promising candidate for treatment of SLE. Other examples are shown in **Table 4**.

Existing approaches have shown the utility of knowledge-based methods for drug repurposing through extracting information from existing ontologies, from integrating between databases, and from the literature. However, there are still many data sources yet to be exploited, including clinical trial reports, electronic health records, insurance claims, and patients' self-reported effects. These methods have already been used for the detection of adverse drug reaction events and could in the future be extended to detect beneficial drug effects that could lead to repurposing opportunities.[63]

Table 4 Overview of drug repurposing candidates from selected knowledge-based approaches

Selected candidates—target/indication	*Structure*	*Validation*	*References*
Aviptadil—sarcoidosis		Literature support	55
Imatinib—Creutzfeldt–Jakob disease		Literature support	55
Tamoxifen—systemic lupus erythematosus		Literature support for predicted mechanism of action	62

1.02.5.3 Retrospective Analysis

When used in a clinical situation, the co-occurrence of diseases other than those indicated for the prescribed medicine can give clues about other potential applications for the product. Retrospective analysis may occur in any setting; a post hoc analysis can be conducted on the experience of using a drug in the real world, but it may also be conducted on clinical trial data. Such data have the additional advantage of better control and randomization of patients. Retrospective analysis represents a method of uncovering additional uses for a drug that only becomes evident from analysis of the data for an end point that was not anticipated at the time the trial was planned.

Cancer is a particularly common example, which may be identified as a secondary indication, because its frequency of occurrence is almost always recorded as a potential side effect in patients on any prescribed or investigational medication, in order to alert patients and regulatory agencies of a potential carcinogenic effect. Thus, by comparing the incidence of cancer for a cohort of patients when treated with a particular drug, as against a suitable control group, we might identify the potential for this drug as an anticancer agent, in other words, the opposite of a carcinogenic effect. It is important to differentiate the effect from this analysis as a cancer-preventative agent with its utility as a cancer-curative agent, and secondly, the retrospective identification of an association is not proof positive from a prospective viewpoint. But these two issues aside, this type of study is of significant power in drug repurposing.[64]

A survey of retrospective evidence in a variety of possible secondary indications is shown in **Table 5**.

In the field of cancer, some of the retrospective findings of prevention have been extended to prospective clinical trials. Metformin has been studied in a prospective trial for its effect against proliferation in breast cancer, with some benefit attributed.[126]

Caution should be exercised in extrapolating from a retrospective association to a prospective causal relationship, as revealed by the example of the use of HMG-CoA reductase inhibitors (statins) in sepsis. In this case, rosuvastatin was not associated with an improvement in 60-day mortality in sepsis-associated acute respiratory distress syndrome (ARDS),[127] despite the various epidemiological associations of reduced mortality in statin users with sepsis. The difference between the two results can be attributed to the need for long-term dosing with statins for the production of their benefits against vascular leak, through inhibition of RhoA prenylation, an off-target effect of these drugs. A clinical benefit of statins in an emergency situation involving sepsis would require a much more immediate effect than can be produced by this mechanism.

Table 5 Retrospective associations suggesting drug repurposing utility

Mechanism (where known) or drug	*Indication*	*References*
5-HT uptake inhibitor	Myocardial infarction	65
ACE inhibitor	Alzheimer's disease	66
	Cachexia	67
	Immune downregulation	68
Acetylcholinesterase inhibitor	Autism	69
Angiotensin II (AT1) antagonists	Alzheimer's disease	70
Beta-adrenergic antagonist	Alzheimer's disease	66
	Cancer	71
	Cancer metastasis; cancer, breast	72
	Cancer, liver	73
	Cancer, lung	74
	Cancer, ovarian	75
	Cancer, prostate	76
	Melanoma	77
	Osteoporosis	78
Calcium channel blockers	Alzheimer's disease	79
	Cancer, lung	80
Gefitinib	Asthma	81
Glibenclamide	Sepsis	82
HMG-CoA reductase inhibitor	Age-related macular degeneration	83
	Alzheimer's disease	84
	Asthma	85
	Bacterial diseases	86
	Burn injury	87
	Cancer	Esophageal,[88] liver,[89] prostate[90]
	Cataracts	91
ACE inhibitor, HMG-CoA reductase inhibitor	COPD	92
HMG-CoA reductase inhibitor	Depression	93
	Epilepsy	94
	Glaucoma	95
	Influenza, COPD	96
	Osteoporosis	97
	Periodontitis	98
	Pneumonia	99
	Rheumatoid arthritis	100
	Sepsis	101
	Transplant rejection	102
Hydroxychloroquine	Diabetes (type II)	103
Ibuprofen	Parkinson's disease	104
Metformin	Alzheimer's disease	105
	Cancer	Bladder,[106,107] colorectal,[54,108] endometrial,[109] liver,[110] lung,[111] pancreatic,[112] prostate[113]
NSAIDs	Cancer, colorectal	114
Na^+/K^+ ATPase inhibitor (digoxin)	Cancer	Lung,[115] prostate[116]
PPAR gamma agonists	Cancer, colorectal; cancer, liver	117
	Psoriasis	118
Quinolone antibiotic	Cancer	119
SERM (selective estrogen receptor modulator)	Kidney disease, chronic (renal failure)	120
TNF antagonist	Cancer	121
	Diabetes (type II)	122
	Kawasaki disease	123
	Stroke	124
	Systemic vasculitis	123
Tricyclic antidepressants	Cancer	125

An interesting example of retrospective analysis leading to a clinically effective agent is in the area of cachexia. Cachexia is a wasting disease, formally defined as the loss of more than 5% of body weight over a period of less than 12 months, normally in association with a chronic disease. It occurs commonly with not only cancer but also chronic heart failure, kidney disease, and chronic obstructive pulmonary disease (COPD). A reexamination of various clinical trials of therapeutic agents for chronic heart failure, specifically those of angiotensin converting enzyme (ACE) inhibitors[67] and beta blockers,[128] looked at weight as a marker

for cachexia. Both these classes of drug have been formally investigated for the treatment of chronic heart failure. Weight is of course routinely measured in any clinical trial protocol, so the reanalysis could be done without the need for additional measurements. In the case of the beta blockers, a stratification exercise to delineate the mechanistic basis indicated the involvement of beta-1 and beta-2 adrenergic as well as 5-HT1A receptors for optimal activity and identification of S-pindolol as a preferred agent (which possesses all three of these activities) with greater efficacy than other similar agents, including its racemate.[129,130] Interestingly, in the subsequent ACT-ONE clinical trial, at therapeutic doses that do not decrease blood pressure, the product not only is highly effective for alleviation of catabolism but also promotes anabolism and improves functional ability in cancer cachectic patients.[131]

1.02.6 Data Mining Approaches for the Prediction of Drug Repurposing Opportunities

Data mining approaches to drug repurposing take advantage of preexisting data in order to form drug repurposing hypotheses without the need to perform any new experiments. This in silico repurposing takes advantages of the ever-increasing amount of (often publicly accessible) data on drugs, targets, and disease. This section will review examples of these methods and show how they transform biological and chemical data into biologically plausible hypotheses for drug repurposing.

At their core, all data mining repurposing methods (here also referred to as "computational repurposing") share the same basic approach: some process is applied to chemical, biological, and/or pharmacological data in order to form hypotheses about drugs and disease in those different spaces. The ability to derive novel hypotheses (chiefly candidates for repurposing but also hypotheses concerning the mechanism of action of a drug or drug–target interactions) depends both on the input data and on the processing that is applied to that data.

1.02.6.1 Data Types

Computational drug repurposing methods can be broadly classified as either *structure–target-* or *effects*-based, depending on the data type(s) used. Structure–target repurposing is based on the chemical or three-dimensional structures of drugs and their biological targets and the interactions between them. These approaches tend to be drawn from the chemical biology and cheminformatics areas. On the other hand, effects-based repurposing looks at the biological effects of drugs and disease on the body. Effects-based methods use data relating to molecular activity and phenotype, such as -omics or side effect data, to measure the action of a drug or disease on the body without necessarily needing to make explicit its precise mechanism. Repurposing examples in this section have been grouped according to these categories, which will be described in more detail in the relevant section.

1.02.6.2 Data Processing

Given a particular type (or types) of input data, a computational repurposing method generally applies an algorithmic process in order to form new associations or predictions that will be the basis of repurposing hypotheses. Although the choice of algorithm may be influenced by the data used (not only the type of data as described in the previous section but also the size of the dataset and its quality), repurposing algorithms can be broadly classified into three categories independently of the data type:

- *Similarity-based*: Similarity-based approaches work on the assumption that structurally similar drugs bind to similar targets and can be repositioned to treat similar diseases (i.e., diseases with shared disease biology). Similarity-based approaches are appealing in drug repurposing because they are intuitively clear: the rationale behind repurposing suggestions can be easily understood when the suggestion is derived from the similarity between two given drugs or diseases. However, the success of these approaches depends on the strength of the similarity assumption—for instance, a minor structural difference between two otherwise identical drugs could be crucial to the drug effect, or there could be important differences in drug–disease response that are not captured by the chosen similarity metric.
- *Activity-based*: Activity-based methods aim to find some representation of the mechanism or mode of action of a drug or disease effect (e.g., through drug–target interaction or effects on gene expression) and use this information to form new drug–disease associations. These methods are often associated with a reductionist, structure–target-based viewpoint but can also use a more holistic systems biology representation of activity, such as determination of perturbed biological pathways from gene expression data.
- *Misclassification-based*: "Misclassification" here relates to the machine learning task of classification: given data on an item belonging to one of several classes, predict which class the item belongs to. In drug repurposing, the task is often to determine which therapeutic class(es) a drug belongs to. For a classifier with sufficiently high accuracy, misclassifications could be interpreted as repurposing suggestions. The drawback of this method is that it is a "black box" approach—classifiers often use hundreds of features (features are some element of the input data, such as the absence or presence of a particular structural element of a drug), and the way in which classifiers make decisions from these features means that it can be difficult to discover why the drug has been assigned to a particular class. Further, in the drug repurposing task, it could be impossible to measure the true rate of error of a classifier and therefore to discriminate between classifications that are valuable repurposing suggestions and those that are simply errors resulting from model artifacts. Prior biological rationale, or experimental validation, is required to distinguish between the two.

These categories may not be clearly delimited, and one type of approach may form the basis for another, for example, some machine learning approaches use drug–disease similarity or activity as input data and some similarity-based methods use activity as a similarity measure. Further, a huge variety of methods are used within each general type of approach, examples of which will be discussed later in this section.

1.02.6.3 Resources

A key advantage of data mining methods is that they can distill down vast amounts of data into useful hypotheses. For a human, too much data can be overwhelming and hamper our ability to detect any useful signal (the "needle in a haystack" problem), whereas data mining methods often perform better the more data they have as input. The methods presented in this section use upward of hundreds of disease or drug cases, from which hundreds of thousands of associations may be formed. Where do all these data come from? Most computational repurposing methods use data stored in publicly accessible databases or repositories. Each repository is specialized for a different data type or purpose, and methods making use of several different data types may have to integrate data from different repositories, which is not always trivial. **Table 6** details some of the data sources used in the examples in this section.

A data mining method can only ever be as good as the data it uses—the term "garbage in, garbage out" certainly applies here—and the quality of data stored in biological, chemical, and pharmacological data repositories can be variable. Firstly, there are the inaccuracies present in the data itself: data may be noisy, imprecise, biased, or (for data that are not a directly measurable quantity) a model prediction with an associated level of uncertainty. Then, there are the problems inherent in the use of large datasets: due to the volume of data being stored, most data repositories involve automatic annotation to a greater or lesser extent and may be based on literature mining or automatic extraction techniques, all of which introduce some potential for error. Alternatively, the data may rely on a community curation model (such as that used by Wikipedia), with data submitted by individual users with varying degrees of external moderation. Manually curated resources do exist, although these tend to be smaller and more specialized, and of course are subject to human error. Consideration of input quality is therefore essential in algorithm design. Depending on the approach used, however, it may be possible to "average out" any inaccuracies contained in individual entries by the use of large datasets (see, e.g.,

Table 6 Selected data sources used in data mining drug repurposing

Name	*Description*	*Examples of use*	*Size as of 2015*
Drug and target data			
DrugBank http://www.drugbank.ca/	Links drugs (chemical and pharmacological information) to targets (sequence, structure, and pathway information)	20,62,132–134	7759 drugs 4300 proteins
STITCH http://stitch.embl.de/	Chemical–protein interaction database	135,136	300,000 small molecules and 2.6 million proteins from 1133 organisms
Therapeutic Target Database http://bidd.nus.edu.sg/group/cjttd/	Provides information about drug targets and their associated drugs, diseases, and pathways	137	2025 targets 17,816 drugs
MATADOR http://matador.embl.de/	A manually annotated list of drug–target interactions	136	–
Genomic and transcriptomic data			
PharmGKB https://www.pharmgkb.org/	Collates information about the impact of genetic variation on drug response	132,136,138	–
OMIM http://www.omim.org/	Details human genes and genetic disorders and their associated phenotypes	62,139	8000 phenotypes 15,000 genes
Gene Expression Omnibus http://www.ncbi.nlm.nih.gov/geo/	Repository of gene expression studies with associated analysis tools	133,140,141	61,804 experiment series
Connectivity Map https://www.broadinstitute.org/cmap/	Gene expression data from cultured human cell lines treated with small-molecule perturbagens including FDA-approved drugs	140,142–146	1309 small-molecule perturbagens
Other biological data			
NCBI Biosystems	A database of biological pathways linked to other entities in the NCBI system (molecular and chemical data and associated literature)	147	–
KEGG http://www.genome.jp/kegg/	A collection of bioinformatics databases including pathway maps, genes and proteins, compounds, diseases, and drugs, together with shared analysis tools	133 148 140,149	–
SIDER http://sideeffects.embl.de/	Associates marketed drugs with indications and side effect information extracted from packaging labels	133,149–151	1430 drugs 5880 side effects 140,064 drug–side effect pairs

Gramatica et al.[55]), and for many data mining algorithms, it is preferable to use large volumes of "mostly accurate" data than to use smaller amounts of verified data.

1.02.6.4 Validation

If experimental repurposing methods represent in vivo or in vitro repurposing, data mining methods can be thought of as "in silico" repurposing. Just as the in vivo effect of a drug may not perfectly reflect its properties in vitro, its effect as predicted in silico is still further removed from its true activity in a living system, and some method of validation is required to determine how much confidence we should place in these predictions before progressing suggested repurposing candidates to experimental testing. An in silico measure of performance is also required for model selection (to determine which parameters give the best performance) and for training of classifiers in machine learning methods. These performance measures can be loosely categorized into three types:

- *Prediction of existing associations*: Many machine learning-based methods measure predictive performance by the ability to predict (or rather reproduce) the existing associations (to diseases, targets, or other drugs) of drugs, for example, by predicting drug class or drug indication. This ties into the misclassification approach—the better the performance of a method at predicting existing associations, the more confidence we can have in its "errors" (according to existing labels) as potential repurposing candidates.
- *Literature support*: If a suggested drug and indication (or drug and target) are mentioned together in the biomedical literature, this provides a form of confirmation for the prediction. Validation from literature support can be done in two ways. The first is selective support, where a thorough literature search (often manual) is performed for the most promising repurposing candidates in order to discover more about the repurposing rationale before making a recommendation. Alternatively, a large-scale literature mining approach (often automated) can be used, enabling measurement of literature support for all the repurposing candidates to measure the overall performance of the method. Of course, simple co-occurrence of two terms in an abstract or publication does not imply a recommendation for drug repurposing—the two could be in a negative relation to each other (see section "**Knowledge-based approaches**" for a discussion of issues related to automated literature mining methods)—but literature support provides a simple way to measure which suggestions are supported by biological or pharmacological reasoning.
- *Clinical trial support*: If a drug has entered clinical trials for use in a particular disease, this provides an even stronger validation for the repurposing suggestion. Clinical trial support does not necessarily imply that a drug is effective in a disease—entering a clinical trial does not mean the drug has passed the trial!—but it does mean that the recommendation of the predictive method is at least plausible, and the recommendation to reposition can be considered correct.

All of these methods rely on prior knowledge for validation. In some senses, however, this prior knowledge could be considered not validation but invalidation—a method that perfectly predicts all previously known associations of a drug without making any errors (misclassifications according to existing labels) would score highly for accuracy, but is of no use for drug repurposing. Further, when using known associations for validation, it is unclear whether any additionally predicted associations are valuable repurposing suggestions or simply classification errors. This raises the question of whether it is suitable to use the ability to predict what is already known as a proxy to measure the ability to predict what is currently unknown, that is, the ability to make novel and clinically useful repurposing suggestions. Prior knowledge can only measure performance within already explored pharmacological space,[152] and its use as a surrogate outcome may penalize more "exploratory" methods that are less accurate in predicting known drug indications but may come up with a wider range of plausible novel suggestions. While this type of trade-off is a common issue in prediction tasks, the balance must be determined according to the desired outcomes of the system (prediction of useful new repurposing candidates) and should not be biased by the evaluation task. With these limitations in mind, experimental validation of promising repurposing candidates remains the best way to test the practical utility of a computational repurposing method.

1.02.6.5 Structure–Target Data Mining

Structure–target repurposing methods use the structure of drugs and their biological targets, and the known interactions between them, to suggest new associations for drugs. The basis of most structure–target methods is polypharmacology—the binding of drugs to multiple targets. Polypharmacology is increasingly recognized as an important paradigm in the development of new therapeutics, in terms of drugs that can modulate multiple targets at once (in contrast with the highly selective "magic bullet" approach).[153] In structure–target repurposing, polypharmacology generally refers to the association of drugs with new targets distinct from the target involved in the original indication of the drug. This can be achieved through transferring drug–target associations between similar drugs or, vice versa, between target molecules sharing similar ligand-binding sites. However, the polypharmacological profile of a drug (the range of targets with which it interacts or the "interactome") can also be used—for example, as input to a classifier-based approach—to predict new disease indications, bypassing target prediction entirely. This section will describe some of the different approaches used to reposition drugs through their structure and interaction information.

1.02.6.5.1 Chemical structure methods

To find new indications for a drug, it would seem most straightforward to start with its chemical structure—intuitively, we would expect structurally similar molecules to bind to similar targets. SuperPred[154] uses the chemical similarity of drug compounds, including similarity of structural fingerprints (measured by the Tanimoto coefficient, which describes the ratio of the shared structural elements to the total number of structural elements present in both molecules) and of physicochemical properties ("rule of

five" properties[155]), to predict their biological effect (ATC class) and similarity to existing drugs. The system was used to identify drugs with structural similarity to the antihypertensive drug enalapril and found six drugs with Tanimoto coefficient >0.8 (indicating a high number of shared substructures), all of which had literature support for a clinically similar effect. The extent to which structurally similar drugs share similar activities is controversial, however, and it has been stated that there is only a 30% chance that molecules with a Tanimoto coefficient of Daylight fingerprints >0.85 share binding activity and that "similar compounds do not necessarily interact with the target macromolecule in similar ways."[156] Efforts have been made to overcome this by grouping drugs by their targets: one method developed by Keiser et al.[157] represented drug targets by their set of known binding ligands and determined the structural similarity of drugs to each set to predict new targets, including the action of fluoxetine (Prozac) as a beta-1 agonist. Twenty-three out of 30 predictions were experimentally confirmed. However, due to more general problems with the use of chemical structure data—including statistical biases inherent in the most commonly used measure of structural similarity, the Tanimoto coefficient,[158] and the limitation of the search space to drugs structurally similar to the starting set—recent repurposing methods have tended to include chemical structure as a component of integrated methods involving multiple data sources, rather than use chemical structure as the sole predictor.

1.02.6.5.2 Protein structure methods

Rather than using chemical structures to represent the binding capabilities of a drug, the problem can be approached from the opposite direction: using the biological structure of a protein to represent the ligand-binding capabilities of a drug target. Protein structure-based repurposing therefore works through target-to-multiple drug association, rather than through the drug-to-multiple target associations of chemical structure methods. Protein structural similarity has been used to identify treatments for the neglected tropical disease schistosomiasis.[136] Drug–target interaction databases (including DrugBank, the Therapeutic Target Database, PharmGKB, STITCH, and the manually annotated MATADOR database) were interrogated with schistosome protein sequences, searching for homology to known human drug targets to predict interactions with known drugs. As well as six drugs already known to be active against *Schistosoma*, their method identified 115 other drugs inside this schistosomicidal compound space. The authors suggest that all 115 drugs in this active compound space are viable drug repositioning candidates, although it is unlikely that all of these candidates will be suitable for repositioning: this issue relates to the sensitivity–specificity trade-off, which will be discussed later in this section.

One issue with protein structure-based repurposing is that the flexibility of protein–ligand binding means that similar compounds can bind to targets in very different ways, and so structural similarity does not always guarantee similarity of drug binding.[159] One study[160] compared the use of drug-based (chemical structure) similarity and target-based (protein target genomic sequence) similarity for the prediction of novel drug–target interactions and found both to be inferior to a method based on prediction from known interactions. Indeed, it has been shown that pharmacological effects are more closely correlated with drug–target interactions than structural similarity.[161] The next section will describe methods that use drug–target interactions as a starting point for repurposing.

1.02.6.5.3 Molecular docking and binding site similarity

Rather than looking at the structures of drugs or their targets in isolation (as with the methods discussed earlier), it is possible to use the interactions between the two to predict new drug–target associations. Molecular docking models the physical interaction between a ligand (i.e., a drug) and its target (or set of targets)[162] in order to predict binding affinities, measuring the strength of associations between drugs and their protein targets. Molecular docking is important in drug design (see Ref. 163 for a review), and many docking models have been developed (e.g., TarFisDock,[164] BioDrugScreen,[165] and DOCK[166]). The last of these programs, DOCK, was originally developed in 1982 and has been used in a number of drug discovery and repurposing programs, notably in the identification of the antipsychotic agent haloperidol as a highly selective inhibitor of HIV-1 and HIV-2 proteases.[167] This could be considered as one of the earliest examples of computational drug repurposing, although it was technically more of a computational screening approach, using DOCK to assess the binding potential of each of 10,000 molecules in the Cambridge Crystallographic Database to HIV-1 protease.

Molecular docking has also been combined with structural similarity of ligand-binding sites in a drug repurposing study for drug-resistant tuberculosis.[168] Binding-site similarity methods are related to the protein structure methods described earlier, but use the structure of binding sites rather than that of the whole protein. This is a more specific measure of structural similarity than whole-protein structure, as the presence of similar ligand-binding sites enables otherwise structurally different proteins to bind the same drug.[169] This combined approach first finds off-targets of a drug by searching the proteome for molecules with similar ligand-binding sites and then uses molecular docking to evaluate physical interaction of candidates from the first step. This method suggested the antiparkinsonian drug entacapone as a lead compound for the treatment of drug-resistant tuberculosis, but the general idea could also be applied in other disease contexts. Having identified a lead compound, the knowledge of its primary and off-targets can then be used to further optimize the compound for efficacy, selectivity, and ADME properties through selective optimization of side activities.[170]

1.02.6.5.4 Drug–target interaction profiles

Drug–target interaction profiles are a natural extension of molecular docking methods in the drug repositioning task. While molecular docking methods use drug–target interactions to find significant associations of a drug or target of interest, drug–target interaction data can also be combined over multiple drugs and/or targets, forming an "interaction profile" showing binding patterns on

a larger scale. Similarity between interaction profiles can be used for repurposing, on the basis that drugs with similar binding patterns may have similar therapeutic effects.[137,171]

One example of how such an interaction profile can be used in drug repurposing is drug–protein interaction-based repurposing,[135] which is based on drug–protein interactions from STITCH. This method determines the drug–protein interaction profile of drugs indicated for a particular therapeutic effect—essentially a binary drug–protein matrix where 1 represents an interaction (binding, activation, or inhibition) of a drug with a protein and 0 represents no interaction. This matrix was used in a supervised machine learning approach to identify drugs with similar interaction profiles and determine the possibility of their having the same therapeutic effect. Predictions included nitrendipine and nimodipine for hypertension and dexamethasone for malaria (dexamethasone has been anecdotally reported to be beneficial in cerebral malaria, but a literature search later revealed that clinical trials did not show significant effect). Another example of interaction profile similarity methods in drug repurposing is drug repositioning and adverse reactions via chemical–protein interactome (DRAR-CPI),[172] a tool for the prediction of new drug indications (or adverse effects) of a submitted molecule. DRAR-CPI generates a molecule interaction profile (termed the "interactome") and checks for similarity to that of drugs in the library interactome, based on interaction of 254 small molecules with 385 human proteins. Interactome similarity indicated links between a group of antipsychotics and a group of anti-infectives (which are supported by studies showing the antimicrobial effects of the antipsychotics prochlorperazine and chlorpromazine), implying potential for repurposing of others in the same group.

Interaction profile methods can also be combined with molecular docking in order to incorporate binding affinity scores in the interaction profiles. This method has been applied to identify therapeutic targets in Alzheimer's disease (AD),[137] creating an interactome of 10 known AD drugs and 47 randomly chosen "control" (non-AD) drugs docked against 401 human proteins. Proteins that tended to be targeted by the AD drugs but not by the control drugs were therefore assumed to be implicated in AD. As well as the known AD target acetylcholinesterase, the docking-based interactome revealed that two other target families thought to be involved in AD—estrogen receptor, the ligands of which have reported neuroprotective and anti-inflammatory effects, and histone deacetylase—may have already been targeted by existing AD drugs. As well as new drug targets, the similarity of the AD drug interactomes indicates that interactome similarity could be used to reveal drugs sharing therapeutic effects in a multitarget approach to drug repurposing.

Many recent drug repurposing methods have used drug–target interaction data as one component of an integrated approach, often forming the chemical/structural component of methods that attempt to integrate both biological and chemical data types. One such method integrates chemical and protein structural similarity with known drug–target interactions from DrugBank to create a "consensus response score"—a quantitative measure of the association between a drug and its protein target.[173] Using a drug similarity network based on the consensus response scores, new indications were predicted for 185 drugs, of which 72% were supported by literature. Integrated approaches such as this have become popular in computational drug repurposing in recent years and will be discussed in more detail later in this section. Further examples of specific structure–target predictions are shown in **Table 7**.

When considering drug–target interaction-based repurposing methods, it is useful to consider the topology of the network—what the "interaction space" looks like. In a drug–target network linking FDA-approved drugs with their targets, it was found that highly connected nodes were connected to each other at a higher degree than would be expected by chance. This indicates that many drugs target a small number of highly targeted proteins, leading to "follow-on" drugs,[174] which indeed has been a frequent strategy employed in the pharmaceutical industry in recent decades. Conversely, many proteins can be targeted by a small number of drugs. For example, antipsychotics or other drugs acting on the central nervous system are a class that is frequently suggested for repurposing to new indications.[167,172,175] Why should this class come up so frequently? Due to the polygenic nature of central nervous system (CNS) disorders, the most effective therapeutics are those that interact with multiple targets.[176] These drugs may therefore be among the most highly connected in drug–target interaction space, which would lead to a higher rate of repurposing suggestions within this class. On the other hand, CNS-active compounds frequently rely on a fine balance of quantitative activities against these multiple targets, and it is not obvious whether this balance is sufficiently captured yet in computational drug repurposing approaches. Finally, it is worth bearing in mind that drug–target interaction methods only take into account those proteins that are known to be drug targets and therefore cover only a fraction of the entire human protein space,[137] limiting the potential for discovery of drugs that act *via* novel disease-associated targets.

There are a few considerations specific to structure–target repurposing that result from the "reductionist" nature of structure–target methods, namely, that they look at individual aspects of drugs in the system, rather than examining the entire response of an organism. This has its advantages—structure–target methods can provide a neat biological rationale through an explicit mechanism of action, rather than the "black box" of effects-based methods—but by considering only structure and binding, structure–target methods fail to consider the broader systemic effect of drug administration in a biological system. There is a gap between measured structure–target data and the eventual in vivo effect[177] resulting from, for example, metabolism of compounds in the body and unidentified off-target effects. Further data mining approaches to drug repurposing take a more holistic systems biology view of drugs and disease. These "effects-based" methods will be discussed in the next section.

1.02.6.6 Effects-Based Data Mining

Effects-based repurposing methods use biological data to analyze the ways in which a drug or disease perturbs a biological system, providing a systems-level view of drug treatment. These methods are situated along the whole spectrum of biological data

Table 7 Overview of drug repurposing candidates from selected structure–target approaches

Selected candidates—target/indication	*Structure*	*Validation*	*References*
Fluoxetine—β_1 receptor agonist		Experimental validation	157
Ifenprodil—5-HT transporter inhibitor		Experimental validation	157
Delavirdine—histamine H_4 receptor agonist		Experimental validation	157
Aprindine—schistosomicidal agent		Ability to predict known schistosomicidal drugs	136
Clotrimazole—schistosomicidal agent		Ability to predict known schistosomicidal drugs	136
Griseofulvin—schistosomicidal agent		Ability to predict known schistosomicidal drugs	136
Cinnarizine—schistosomicidal agent		Ability to predict known schistosomicidal drugs	136
Nimodipine—hypertension		Literature support	135

Table 7 Overview of drug repurposing candidates from selected structure–target approaches—cont'd

Selected candidates—target/indication	*Structure*	*Validation*	*References*
Verapamil—HIV		Literature support	135
Dexamethasone—HIV		Literature support	135
Entacapone—drug-resistant tuberculosis		Experimental validation	168

(collectively known as -omics), from gene–drug associations (the genome) to drug effects on gene expression (the transcriptome) and the translation into proteins (the proteome) to the eventual range of outcomes of the drug effect (the phenome), each of which can be considered a biological consequence of the one preceding. -Omics data as a readout of a biological system aim to capture a drug or disease effect on multiple components of the system at once. Quantifying drug–disease effect in this way allows comparison between drug and disease that takes the response of the biological system into account and in turn can help to formulate new repurposing hypotheses.

1.02.6.6.1 Genome-based

As modern molecular biology is increasingly able to identify disease–gene and gene–drug relationships, genome-based repurposing aims to reveal the "hidden link" between the two in order to predict novel disease–drug associations. Known drug–gene relationships are listed in databases including the Pharmacogenomics Knowledge Base (PharmGKB, https://www.pharmgkb.org/), which contains drug–gene links derived from co-occurrence in literature, and STITCH (http://stitch.embl.de/), which contains drug–protein (i.e., translated gene) associations based on literature mining. Databases such as OMIM (http://omim.org/) list known disease–gene associations, or predicted associations can be derived from, for example, comparison of mutant phenotypes, as listed in PhenomeNet.[138] The challenge is then to link disease–gene and gene–drug relationships to predict novel, relevant disease–drug relationships. Genome-based methods can be considered as an example of target-to-multiple disease repurposing (the primary target of a drug is involved in multiple diseases),[178] in contrast to the drug-to-multiple target or target-to-multiple drug methods associated with structure–target repurposing.

Many disease–gene relationships have been established through genome-wide association studies (GWAS), which aim to link genetic variants to phenotypic traits using large population studies. Computational drug repurposing methods can combine the results of several GWAS, increasing their power to detect disease–gene associations and creating an informed basis for drug repurposing. One meta-analysis of GWAS in RA identified candidate genes for RA risk and found that these risk genes were enriched for the drug targets of approved RA drugs.[179] This suggested that drugs approved for other indications that targeted RA risk genes could be repurposed for RA treatment—for example, the risk genes CDK6 and CDK4 are targets of approved cancer drugs, one of which (flavopiridol) the authors note has been shown to improve RA symptoms in animal trials. Further, the authors point out that previously approved RA drugs, such as rituximab, were initially developed for cancer treatment, suggesting that repurposing from cancer to RA therapy is biologically plausible.

Other methods for disease–gene association discovery include RNAi screening, which allows identification of loss-of-function mutations associated with particular phenotypic outcomes. A recent RNAi screen[175] identified genes that were modifiers of the proteostasis network involved in the genetic disease alpha-1-antitrypsin deficiency (ATD). Drug–target association databases were then searched to find FDA-approved drugs that targeted these gene products, identifying the antipsychotic fluspirilene, which was shown to be effective against ATD in a mammalian cell line. While genome-based approaches are intuitively appealing due to the apparent simplicity of the drug–gene–disease relationship, it is worth considering that the relationship between a gene and its associated gene

product (i.e., protein) as a drug target is not always clear-cut due to the biological distance between genotype and phenotype, involving, for example, splice variants, posttranslational modifications of the protein, and other factors. The next section will cover an intermediate step between the two: the transcriptome.

1.02.6.6.2 Transcriptome-based

Transcriptome-based repurposing methods can be viewed as an attempt to bridge the genotype–phenotype gap by moving closer to the phenotype of a disease. The transcriptome provides a quantitative measure of the effects of a drug on a biological system, revealing "hidden" information about the effects of a drug[180] that may not be clinically observable or predictable from structure or target information. There are many publicly available gene expression resources, from repositories such as the NCBI's Gene Expression Omnibus (GEO, http://www.ncbi.nlm.nih.gov/geo/) and EMBL-EBI's ArrayExpress (http://www.ebi.ac.uk/arrayexpress/) to curated resources such as GeneSigDB (http://www.genesigdb.org/genesigdb/), which aims to summarize the expression content of published gene expression studies. The release of the Broad Institute's Connectivity Map (CMap, https://www.broadinstitute.org/cmap/) in 2006 provided a valuable source of information about drug transcriptional response, measuring gene expression of cultured human cells following treatment with 1309 small molecules including FDA-approved drugs. The aim of this project was to show the "connectivity" between transcriptional signatures (sets of genes that are significantly up- or downregulated) induced by drug compounds and those of disease—for instance, a high correlation between the signatures of thiazolidinediones and a published gene signature for obesity predicts the observed adverse effect of weight gain resulting from use of thiazolidinediones.

Several transcriptome-based drug repurposing methods have followed the same reasoning in the opposite direction—if positively correlated signatures can predict adverse effects, can a negative correlation of drug and disease signatures predict treatments? Several repurposing studies have been developed around this inverse signature methodology, including that of Sirota et al.,[142] which tested for "oppositeness" of gene expression signatures of disease to drug-induced signatures from CMap using an enrichment-based method, gene set enrichment analysis (GSEA).[181] GSEA tests whether significantly regulated genes in a disease signature fall near the top or the bottom of the ranked list of genes changed in response to drugs. If the genes upregulated in a disease condition are strongly downregulated by drug treatment, this indicates that the drug could be a plausible treatment option for this disease. Their approach was experimentally validated by testing the use of cimetidine as a treatment for lung adenocarcinoma. This group then applied this approach to focus on particular diseases, for example, small-cell lung cancer[182] and inflammatory bowel disease (IBD)[183]; other studies have refined the inverse signature approach to predict treatments for colorectal cancer,[184] skeletal muscle atrophy,[144] leukemia, and breast and prostate cancers.[140]

Information about drug transcriptomic effects can also be used to reveal similarities between the biological effects of drugs. The drug similarity network created by Iorio et al.[180] used CMap transcriptional data, observing that drugs with similar transcriptomic profiles perturb the same biological pathways and therefore may share similar mechanisms of action. Using this approach, they discovered that fasudil—a vasodilator that was thought to have a well-characterized mechanism of action—additionally acts as a promoter of cellular autophagy. Fasudil showed high transcriptional similarity to a known enhancer of cellular autophagy, 2-deoxy-D-glucose (2DOG), and this activity was confirmed in vitro, suggesting its potential repurposing to neurodegenerative disorders. Combining the drug similarity with the inverse signature approach, Hu and Agarwal[143] created a disease–drug network using gene expression signatures from GEO and drug signatures from CMap. Negatively correlated disease and drug signatures were considered as repurposing candidates, including antimalarials for the treatment of Crohn's disease; the network also included disease–disease connections revealing molecular-level relationships between diseases and drug–drug connections that could illuminate drug targets or mechanisms of action.

Although gene expression data have been widely used in computational drug repurposing methods, they suffer from context effects dependent on cell line or species.[149] Providing more specific measurements across parameters including drug dosage and cell type, the Library of Integrated Network-Based Cellular Signatures (LINCS) is being developed as a large-scale successor to CMap. The LINCS will cover over 20,000 compounds (of which ~1300 are FDA-approved drugs) tested in multiple cell lines. While the LINCS will be a valuable resource for transcriptomics-based drug repurposing, it cannot alleviate the problem of noise inherent in the use of gene expression data. As well as biological noise caused by cell cycle stage, transcriptional bursts, and interindividual variation,[64] there is also technical noise caused by imperfect measurement of the amount of RNA present in a given sample. One way to minimize the effect of noise is to map gene expression data onto a higher-level biological space—that of pathways. Converting molecular data to a systems-level representation of pathway enrichment or depletion can strengthen the (sometimes subtle) signals present in the transcriptomic data to give a clearer picture of the drug or disease effect. In one approach, Pan et al.[147] mapped the protein and gene targets (determined from gene expression) of drugs to pathways contained in the NCBI BioSystems database (http://www.ncbi.nlm.nih.gov/biosystems/). As well as revealing the mechanisms of action involved in known drug treatments, some drugs were linked to pathways responsible for other diseases—such as the association of glioblastoma to gefitinib or small-cell lung cancer to celecoxib—suggesting their possible association in a drug repurposing approach.

1.02.6.6.3 Proteome-based

The emergence of newer -omics technologies such as proteomics provides alternative ways to measure the effects of drugs or disease in the body. According to the central dogma of molecular biology, the proteome is a closer molecular approximation to the phenotype than either the genome or the transcriptome, and it is therefore a practically relevant biological space to explore for drug repurposing. Proteomics is less well established than transcriptomics and there is less data available, so repurposing studies using

proteomics tend to focus on specific diseases, rather than the more general multidisease approaches that are possible with transcriptomics. Zhang et al.[145] integrated the results of multiple GWAS, proteomics, and metabolomics studies to create a diabetes metabolite–protein network. The network was searched for potential antidiabetic protein targets with known drug interactions, which were therefore considered to be candidates for repurposing. They then used CMap to compare the gene expression patterns of the repurposing candidates with those of known antidiabetic drugs and to drugs with diabetes-like adverse effects. Four COX2 inhibitors (diflunisal, nabumetone, niflumic acid, and valdecoxib) were proposed for the treatment of type 1 diabetes and two drugs (phenoxybenzamine and idazoxan) targeting ADRA2A (alpha-2A adrenergic receptor) for type 2 diabetes. Note that this is technically repurposing via a meta-analysis of -omics studies rather than a proteomics-based repurposing method; however, this demonstrates the utility of these different data types for drug repurposing alongside more established transcriptomics and genomics techniques.

1.02.6.6.4 Phenome-based

At the opposite end of the scale of molecular biology, the human phenome—which in this context represents the range of drug end points, with regard to both disease progression and side effects—can be a valuable source of information for repurposing, representing in some sense the most relevant measure of drug action. Phenome-based repurposing is a black box model of drug effects, assuming no knowledge about the mechanism of action of a drug. Unlike the genome or transcriptome, the phenome is easily observable in the clinic and—although subject to variation through each clinician's particular classification of observations—does not suffer to the same extent from the problem of noise and measurement error. However, phenomic data present their own problems in terms of appropriate standardization of qualitative observations, and many efforts are under way to create ontologies (Disease Ontology, International classification of disease (ICD), Medical Subject Headings (MeSH)) that standardize the medical language of diseases and side effects.

The phenotypic effects of drugs include their therapeutic effects (their indications), as well as their adverse effects. Chiang and Butte[185] used drug indications (including off-label uses) to link diseases in a guilt-by-association approach—if two diseases share a number of similar therapies, those indicated for either disease but not the other may then be candidates for repurposing. Indeed, they found that drug indications suggested by this method were 12 times more likely to be under evaluation in clinical trials than nonsuggested drugs. Another method used phenome information from SIDER (see **Table 8**) to build a latent variable model based on the interconnectivity of indications and side effects, which was able to generate probabilistic alternative indications for drugs.[150] In this Bayesian model, the phenotypes (drug indications and side effects) represent an observed outcome of drug treatment, and the molecular mechanisms through which drugs exert their action represent hidden variables from which new links between drugs and phenotypes can be inferred. The predictions were validated against literature support—the repurposing of thalidomide to

Mefenamic acid—rheumatoid arthritis		Literature support	150

multiple myeloma, as discussed earlier in this article, was among the candidates proposed by their method. However, another well-known example of repurposing—the antidepressant bupropion (Wellbutrin™) for smoking cessation—was used to illustrate a limitation of their method: the indication "smoking cessation" is not included in the SIDER database and therefore cannot be predicted. This is a more general point about data mining methods—the space in which predictions can be made is necessarily constrained by the data source, meaning that less well-explored areas of pharmacological space may be missed by these methods. This is particularly problematic in the case of rare or orphan diseases.

Side effects are another aspect of the phenome that can be mined for drug repurposing. Campillos et al.[186] used drug side effects to infer drug targets, working from the assumption that two drugs causing similar effects in the body must share a target. By inferring targets from side effects alone, the authors were able to discover associations between chemically dissimilar drugs or drugs with no known targets. They experimentally tested 20 "unexpected" predictions (associations between dissimilar drugs from different therapeutic areas) and confirmed binding to predicted targets in 13 of these drugs, indicating a link between the Alzheimer's treatment donepezil (which has previously been proposed as a treatment of depression) and the antidepressant venlafaxine. Following the success of this approach, the group developed the Side Effect Resource (SIDER) database,[187] which connects drugs to indications and side effect terms. This has been used to develop further side effects-based repurposing methods, such as the large side effect similarity network constructed by Ye et al.,[151] which covered 2183 drugs across nearly 6500 side effects.

Part of the power of effects-based approaches comes from their ability to integrate information about the effects of disease as well as drugs. By combining these different domains, these methods aim to reveal new knowledge that would not be apparent from looking at either domain alone. Extending this concept further, knowledge-based approaches aim to gather information from many different sources in order to form new links between diverse concepts.

1.02.6.7 Integrated Approaches

Integrated approaches combine both effects-based and structure–target methods. By combining these two different data spaces, it is hoped that more can be revealed than from examining either space alone. Luo et al.[172] compared their target-based drug associations with effects-based predictions based on gene expression data and found a high agreement rate of 74%, suggesting that these different approaches are complementary and concordant. High agreement between two data sources strengthens the predictive "signal" against the noise of spurious or false associations: when multiple data sources are used, the common core of agreement can be considered high-confidence predictions, while predictions that are not unanimously supported by all data types could be considered the more "interesting" or less obvious predictions. This section describes examples of data integration, as well as issues relating to data choice and data filtering: examples of the methods used are shown in **Table 9**.

An initial example of this is the classifier-based approach developed by Napolitano et al.[146] This study integrated different types of drug information to quantify drug similarity: similarity of chemical structures, distance of target proteins in a protein–protein interaction network, and transcriptomic effects from CMap. Using machine learning methods, a classifier was created to predict the ATC codes (a classification according to anatomical system and therapeutic effect) of drugs given information on these three features. The method is based on the interpretation of misclassifications as putative drug indications. With classification performance (accuracy) of 78% on prediction of ATC codes, novel misclassifications could therefore be new leads for drug repurposing. An example of a "known misclassification" (i.e., a misclassification that has clinical support) is the diuretic spironolactone, which was predicted to be in the ATC class "sex hormones and modulators of the genital system": spironolactone has known antiandrogenic effects and is sometimes prescribed off-label for hirsutism and other androgenic disorders. One consideration of this method, however, is that it is only able to predict broad therapeutic classes rather than specific uses. While this might be sufficient for some classes—for example, the class "beta blocking agents" indicates a mechanism of action—in some cases, this broad description will not provide enough information to inform a repurposing hypothesis. The description of spironolactone as a "modulator of the genital system," for instance, is not specific enough to be useful in drug repurposing.

Table 9 Data types used by integrated methods

Drug indication	*Phenotypic features of disease*	*Chemical structure*	*Protein sequence similarity*	*Drug–target interaction*	*Disease-related genes*	*Closeness of drug–disease-related genes in a PPI network*	*Side effects*	*Other molecular features of disease, for example, pathway and environmental factors*	*Gene expression following drug treatment*	*References*
X	X	X	X	X						134
	X	X	X		X	X	X			133
X	X				X		X	X		148
		X				X			X	146
		X	X				X			139
				X					X	147

Rather than the narrowness of predicted categories, the description "specific" in a classification context usually refers to the ability of the test to discriminate negative results in a binary classification task (the proportion of predicted negatives that are true-negatives). Specificity is the converse of sensitivity, which is a measure of the proportion of positive results correctly identified—in this case, the proportion of drugs predicted to belong to a therapeutic class that actually belong to that class. In a high-specificity classifier, misclassifications can be more confidently predicted as potential candidates for repurposing. The balance between sensitivity and specificity is given by the "area under the receiver operating curve" (AUC), which plots the true-positive rate against the false-positive rate and is used to measure classifier performance in the following studies.

Recent integrated approaches have included information about disease as well as drug information. One of the first studies to include both of these domains was the PREDICT system developed by Gottlieb et al.,[133] which extended the "guilt-by-association" concept of association transfer. PREDICT works from the assumption that drug–disease associations can be "transferred" between sufficiently similar diseases and drugs. The measures used for drug similarity include chemical structure, drug side effects, and various measures of similarity of their protein targets (similarity of genetic sequence, closeness in a PPI network, and semantic similarity of gene targets). Two different types of disease similarity measures were included: phenotypic, using medical terms from MeSH and HPO, and gene signature-based, using gene expression signatures from GEO and similarity of disease-related genes (as for protein target similarity in the preceding text). Known disease–drug associations allow a classifier to learn the relative contribution of each drug–drug and disease–disease similarity measure to the strength of the drug–disease association; the classifier then balances information from each similarity measure in order to predict new associations. The PREDICT system is particularly notable for its high predictive ability, achieving an AUC of 0.9 in predicting known drug indications using the phenotypic disease similarity measure (rising to 0.93 using the signature-based method) and finding significant overlap of predictions with drugs being tested in clinical trials. Examples of predictions supported by previous studies include the immunosuppressive azathioprine for treatment of the inflammatory disorder familial Mediterranean fever and the use of the dopamine receptor agonist cabergoline to improve migraine symptoms. The authors suggest that their gene signature-based measures of similarity, where a disease is represented purely by its gene expression profile, could be also used for personalized medicine applications.

Also making use of similarity information, the PreDR method[139] integrated drug–drug and disease–disease similarity, using "structure, activity, and phenotype data" (chemical similarity, protein target sequence similarity, and side effects data) for drug similarity and using phenotype data from OMIM for disease similarity. Each type of drug data was found to be predictive individually (with AUC of 0.83, 0.89, and 0.89, respectively); however, data fusion (integrating the three data types) was shown to improve the prediction of drug–disease associations, achieving an AUC of 0.9 and an overall accuracy of 0.82. This seems intuitively clear, but in machine learning, more information does not always lead to better performance: for example, the features may not be fully independent of one another, which can be the case when integrating different biological or pharmacological measurements of the same event. For example, chemical structure affects drug–target interaction, and phenotypically similar diseases share related disease genes, and this relationship between features could potentially affect classification performance.

Whereas these approaches aimed to infer disease–drug associations from measures of disease and drug similarity, more recent approaches have integrated drug–disease associations as another feature from which to infer novel associations (see **Table 10**). The heterogeneous network model developed by Wang et al.[134] represents diseases, drugs, and targets as nodes in a "three-layer graph." Each layer of the graph is constructed from associations between diseases, drugs, and targets (measured by phenotypic, chemical structure, and target sequence similarity, respectively), and connections between the layers are constructed from disease–drug and drug–target interactions from DrugBank. The strength of association between a disease and a drug is computed by an "iterative updating" algorithm, in which the association strengths depend on the other associations in the network. As with PreDR, the authors were interested in the contribution of each data type to the overall accuracy of the method, in this case examining the contribution of target nodes to their initial drug–disease network. Drug target information was found to improve the performance of the network (AUC 0.92 for the target information compared with 0.84 for the drug–disease-only network). The method was able to make predictions even for diseases with few currently available treatments: for non-small-cell lung cancer, which has only one currently known drug treatment, the top three predictions (cisplatin, carboplatin, and temozolomide) were all supported by previous studies.

Through the integration of different types of data, these approaches have aimed to minimize the drawbacks of each individual type. As the data integration approach has grown in popularity, several databases have been developed to aid integrated drug repurposing by collating data from different sources, including PROMISCUOUS[188] and PharmDB.[189] As well as being a function of the explosion of -omics and cheminformatics data resources in recent years, this is part of a general trend toward data fusion approaches in informatics. By combining data on both the biological (gene expression, pathway disruption, and side effects) and chemical (drug structure and target binding) aspects of drug action, we can reach a more holistic view of a drug's effect. The methods covered here have not yet explored all of the potential sources of information on drug effect. Other spaces that could be exploited for drug repurposing could include, for instance, the metabolome: indeed, metabolic networks have been used in a systems biology approach to model the systemic perturbations caused by a drug in order to predict its off-targets.[190] As mentioned earlier, when combining multiple data sources, the contribution of each individual source must be assessed for its contribution to the performance of the method. The utility of different information sources for repurposing prediction tasks could even help to inform the way we think about drug design and lead optimization.

Table 10 Overview of drug repurposing candidates from selected integrated approaches

Selected candidates—target/indication	*Structure*	*Validation*	*References*
Azathioprine—familial Mediterranean fever		Literature support	133
Cabergoline—migraine		Literature support	133
Carboplatin—non-small-cell lung cancer		Literature support	134
Temozolomide—non-small-cell lung cancer		Literature support	134

1.02.6.8 Practical Considerations

Despite the range of different data types and different approaches used in computational drug repurposing, these methods all share common drawbacks that must be considered carefully before making the jump to large-scale experimental validation or thinking about clinical applications. These include the following:

- *Quality of input data*: All of the data sources discussed here suffer to some extent from the problems of missing, incomplete, inaccurate, or erroneous data, especially molecular biology data types (such as gene expression and proteomics data) that are particularly prone to noise and data sources that are generated from computational modeling or prediction (such as molecular docking or disease-related genes) that contain more potential for error. Further, there is a trade-off that must be made between data quality and the number of data points that can be used in a model. While it is generally true that filtering poor quality data will improve performance, overstringent filtering criteria (especially for particularly noise-prone data) may result in such a reduction in the number of available data points that it actually becomes detrimental to performance.
- *Broad versus focused approaches*: Many computational repurposing methods aim to be broad in scope—they aim to suggest drugs for a range of diseases from different disease areas. Although broad-ranging methods are more widely applicable and can be viewed as more challenging and therefore conceptually more interesting, it could also be argued that single-disease studies have more practical utility. More focused approaches (such as the diabetes,[145] schistosomiasis,[136] and RA[179] studies discussed earlier) benefit from increased clinical and commercial focus (see later) and therefore may be more amenable to clinical translation. Another approach is to develop the general method on a large scale and then refine it for specific diseases, such as the work of the Dudley group on "inverse signature" drug repurposing, which was demonstrated to work with a set of 100 diseases from GEO[142] and then used to predict candidate treatments for small-cell lung cancer[182] and inflammatory bowel disease.[183]
- *Experimental validation of hypotheses*: Where authors have experimentally evaluated their repurposing suggestions, this is a good proof of principle of their method, but it is clearly a big step to make between demonstrating a desired effect in in vitro tests and demonstrating efficacy in the clinic. Although repositioned drugs have a slight advantage over novel drugs in that their pharmacokinetic properties have already been determined, the new indication may require a different dosage or delivery method in order to be effective. A case in point is the discovery of the antipsychotic haloperidol as a highly selective inhibitor of HIV-1 and HIV-2 proteases via a molecular docking approach[167] (discussed in more detail earlier). Although haloperidol appeared to be an effective anti-HIV agent, the concentration required to function as an inhibitor was more than 1000 times than that normally given in its use as an antipsychotic, at which dosage it would be highly toxic. In this case, haloperidol was proposed as a useful

lead candidate for drug development; however, this shows the importance of experimental validation even for highly promising candidates.

- *Need for clinical and commercial awareness*: Although computational methods can suggest repurposing candidates, they cannot yet replace expert clinical knowledge. For example, the graph-based method developed by Gramatica et al.[55] suggested the peptide CNP (C-type natriuretic peptide) for treatment of sarcoidosis, even providing a biologically sound mechanism of action through which this treatment would work. However, CNP can in some cases act as a vasodilator and thus could not be considered as a treatment option for sarcoidosis due to its potential to cause serious adverse effects. Similarly, although a repurposing candidate may be biologically plausible and supported by experimental validation, there are still commercial and economic factors to consider when assessing candidates, such as market size versus cost, competitors, and intellectual property issues[20] as discussed earlier in this article.

Data mining approaches to drug repurposing use biological, chemical, pharmacological, and clinical data to reveal new associations between drugs and disease. Benefiting from recent advances in computational data science, including machine learning, natural language understanding, and big data processing, as well as the expansion of large biochemical databases holding diverse drug and disease data types, computational methods can form a valuable first step in drug repurposing efforts. While computational repurposing must always be complemented by experimental validation and human expertise, its strength lies in its ability to take data and, through application of computational analysis, create valuable information that can lead to new repurposing hypotheses. Of course, the value of this information depends on the translation of computational predictions to clinical reality.

1.02.7 Beyond Repurposing: Tailoring an Existing Drug for a New Use

Drug repurposing starts from a compound that has progressed into development; thus, it has been optimized for the original indication for which it was intended; however, in the new indication, the drug is not necessarily optimized. This is certainly the case if the repurposing involves a new target (off-target repurposing), since the basic medicinal chemical optimization will not have been done for this situation. It will also arise when the new indication involves polypharmacological activities, since in this situation also, the balance of pharmacological activities will probably not be right for the new indication. Additionally, the structure–activity relationships that pertained to the original indication may not pertain to the new indication. But even when the target is the same, the pharmacokinetic parameters that were optimized for the original indication may not be right for the new indication. For instance, if the new use requires CNS penetration, whereas the original use was peripheral in basis, there may be a good reason to change the molecule to better suit it for CNS distribution.

In circumstances such as these, and others, a certain amount of structural variation may be required to identify the ideal drug for the new indication. Hybrid projects involving a new use and a new molecule may reduce some of the salient advantages of drug repurposing. Clearly, even with a small chemical change, the opportunity to avert the entire preclinical development stage of the R&D process is lost. In addition, there is a certain amount of drug design and medicinal chemistry optimization to be performed. Set against these disadvantages, the repurposing component has allowed a reduced requirement for discovery chemistry while simultaneously granting a greater degree of novelty in the product by virtue of its twin differentiating characteristics (i.e., both a new molecule and a new indication).[2] The most advantageous strategic balance to be struck between a certain amount of molecular optimization and the alternative product development based entirely on the preexisting molecule for a new use will vary on a case-by-case basis. Additional factors that may influence that choice include the need for reformulation for development in the new use; for instance, in repurposing an oral product for an inhaled use, a substantial formulation and bridging toxicology package will need to be put in place. Repurposing in such cases involves a significant amount of preclinical development.

In Table 11, we see various examples of this strategy. In most of these cases, the new drug derived from a project that originated with the discovery of a new use for the parent drug. For example, gabapentin was originally developed for epilepsy, but after its approval, it became clear that the drug was useful in neuropathic pain. Initially, Pfizer tried to promote it for the secondary use without obtaining regulatory approval, but after significant fines were levied by the FDA for off-label promotion, the company developed a new, but closely related, product (pregabalin) for neuropathic pain. In the case of thalidomide, this is approved for the treatment of leprosy and multiple myeloma, whereas its structural variant lenalidomide is approved for the treatment of multiple myeloma and myelodysplastic syndromes; in addition, it is suggested to have a better side effect profile.

The case of raloxifene, a selective estrogen receptor modulator, is interesting: the story originated with tamoxifen, a drug for the treatment of breast cancer. The initial idea was to find a related drug that would treat breast cancer in patients resistant to tamoxifen. However, early trials were unsuccessful, and Lilly changed tack, choosing instead to develop raloxifene for osteoporosis. Once this tamoxifen analog was on the market, it became clear from retrospective studies that raloxifene did in fact prevent the reoccurrence of malignancy in women with breast cancer; it was later approved for this condition too. Thus, the project had come full circle, from abandonment in the cure of breast cancer to use in its prevention.[26] Finally, one of the most remarkable drug repurposing examples involves the use of prostanoid FP receptor agonists for eyelash lengthening and thickening. Originally, the drug latanoprost was developed as an ophthalmic solution for the treatment of glaucoma, but it was noticed to act as an eyelash growth stimulator, as a side effect, in patients. Rather than develop latanoprost itself for this new indication, Allergan chose to develop the analog bimatoprost to increase the length, thickness, and darkness of eyelashes, and the product Latisse™ was ultimately approved as a cosmetic rather than a pharmaceutical.

Table 11 Examples of new drugs for a secondary use closely related to parents that work for a primary use

Original drug	*Original indication*	*Structure*	*New drug*	*New indication*	*Structure*
Gabapentin	Epilepsy		Pregabalin	Neuropathic pain				Gabapentin enacarbil	Restless leg syndrome	Thalidomide	Leprosy, multiple myeloma		Lenalidomide	Myelodysplastic syndromes	Flupirtine	Epilepsy		Ezogabine	Neuropathic pain	Leflunomide	Rheumatoid arthritis		Teriflunomide (metabolite of leflunomide)	Multiple sclerosis	Tamoxifen	Breast cancer		Raloxifene	Osteoporosis	Latanoprost	Glaucoma		Bimatoprost	To increase the length, thickness, and darkness of eyelashes	
1.02.8 Conclusion

The use of previously discovered drugs for new indications has the potential to revolutionize modern medicine. By exploiting existing pharmacological space, drug repurposing can significantly decrease risk, time, and cost compared with what is possible in de novo drug development. Although drug repurposing has existed in some form for as long as humans have practiced medicine, in recent years, efforts to systematize the traditionally serendipitous route to drug repurposing have led to the development of methods to identify potential drug repurposing candidates at the preclinical stage. These developments have benefited from advances in experimental and computational science, as well as from efforts toward increased sharing and open accessibility of data and pharmacological knowledge. As well as the potential productivity gains for a pharmaceutical industry that is often acknowledged to be undergoing a decline in R&D output, repurposing offers an avenue for the development of drugs for rare and orphan diseases that would otherwise be neglected due to economic factors.

1.03.1 Introduction

1.03.1.1 Historical and Technological Advances

Progress in the field of stem cell research has the potential to be transformative for translational medicine. Human embryonic stem cells (hESCs) and induced pluripotent stem cells (iPSCs) have the capacity for self-renewal in culture and are able, in theory, to differentiate into any cell type of the body, provided that appropriate culture conditions are developed.[1–5] Given these properties and physiological similarities to human cells in situ, stem cell culture has shown great promise as an ex vivo system for studying human development and, most importantly, human disease. An urgent need for better clinicotherapeutic outcomes has directed interest to the use of these physiologically relevant human cells in the drug-discovery process, including early testing of efficacy and toxicity of promising therapeutics, and as a valuable source of specialized cells for regenerative medicine.[6–8]

Pioneers in this field, Yamanaka and colleagues, demonstrated in 2006 that human somatic cells, such as dermal fibroblasts from a skin biopsy, could be reprogrammed into iPSC through the retrovirus-mediated transduction of cells with four transcription factors (Oct3/4, Sox2, c-Myc, and Klf4), now commonly referred to as "Yamanaka factors."[2,3,5] This discovery granted the investigators Dr. Shinya Yamanaka and Dr. John Gurdon the 2012 Nobel Prize in Physiology/Medicine for the discovery that mature cells can be reprogrammed to become pluripotent. With subsequent and continued efforts by several other groups, remarkable improvements in reprogramming strategies, robustness, and iPSC differentiation throughput have been developed with innovations continuing at a rapid pace.[9–17] While the pioneering work by Yamanaka and colleagues relied on the delivery of transcription factors using retroviruses that integrated in the host-cell genome of skin fibroblasts, subsequent innovations have allowed for higher efficiency reprogramming and for additional types of somatic cells, including blood, hair cells, and endothelial cells (e.g., from urine) to be successfully reprogrammed.[18] Beyond increasing efficiency, one significant improvement has been the implementation of integration-free reprogramming methods that do not permanently insert any transgene into the genome (so-called scarless reprogramming), circumventing concerns of mutagenesis or damage to the host-cell genome, and relying on DNA plasmid-based methods and nonintegrating Sendai virus.[9,11,12,19] Thereafter, integration-free mRNA-based transcription factors, micro-RNAs (miRNA), and small molecule-based reprogramming cocktails were successfully developed[13,15] and together have made it feasible to routinely make human iPSCs.

Another area of remarkable advance focuses on direct differentiation of somatic cells into specific cell types such as cardiomyocytes,[20,21] hepatocytes,[22] intestinal and pancreatic cells,[23,24] microglia,[25–27] and neurons.[28–34] In the latter case, variations in induced neurons (iN) protocols involving different transcription factor combinations have shown the potential to further yield defined neuronal subtypes, such as dopaminergic or GABAergic neurons.[35] By eliminating the need to first generate iPSCs, direct reprogramming and differentiation into a specific cell type have the potential to have important, although not yet well established, advantages, including shortening the time frame to obtain the cultured cells of interest. Another significant advantage might be reducing disruption in epigenetic marks associated with iPSC generation, which will be relevant for using these cells as models of human disease. Still, technical restrictions, such as output of relatively small number of cells, are a limiting factor for routine or large-scale studies. This may be resolved with newer approaches, such as generation of induced progenitor cells that retain a replicative capacity allowing expansion of the number of cells from the initial somatic cell population. For example, induced neural progenitor cells (iNPCs)[36] can, similar to NPCs derived from iPSCs,[37,38] be stably kept in culture in proliferative state, differentiated into almost a limitless quantity of neurons with ease while recapitulating key aspects of brain neurogenesis, and allow for long-term differentiation (months).[39–41]

As advantages of certain technologies over others become more evident, continued efforts focus on standardizing and refining the robustness of iPSC models for use in human disease modeling and drug discovery is critical. In parallel, the creation of large cohorts of human iPSCs (e.g., NYSCF Research Institute Stem Cell Repository, StemBANCC, HipSci Consortium, Stem Cells Network DPUK Cohorts) will further accelerate the robustness of findings across different disease models and assay end-points.[42–44]

1.03.1.2 Human Biology Context

Drug screening performed in a variety of human cell lines has contributed significantly to therapeutics progress, particularly in the area of oncology where patient-derived cell lines have been used extensively. But now, patient-specific iPSCs derived models, that recapitulate key aspects of human disease "in a dish," may offer a more relevant, robust, scalable, and cost-effective model of human disease physiology, and an attractive system for drug discovery,[45–47] even though the use of these cells still presents challenges at the level of throughput and capacity for full maturation.

In the context of central nervous system (CNS) disorders, where access to physiologically active and relevant disease-affected cells is extremely limiting, iPSC-derived in vitro culture of specific cell types, such as human neurons and glial cells, is transformative.[35,48] Together with implementation of state-of-the-art phenotyping approaches, including quantitative biochemistry, functional genomics, proteomics, and perhaps most notably, high-throughput (HTS) and high-content (HCS) chemical screening for drug discovery,[6] the potential for understanding and treating human disease is unprecedented, creating a paradigm shift in translational research.[48–50] Focus on patient-specific iPSC-derived neuronal cell models to study molecular and cellular pathophysiological mechanisms has also benefited from growing small molecule and oligonucleotide-based libraries that allow probing gene, protein and molecular pathways' function, and detection of early disease-specific alterations toward identification of disease biomarkers and therapeutic targets. A broad review of human iPSC-derived CNS disease models can be found in expertise literature.[35,48,51–60]

Contrary to traditional approaches, where animal and immortalized cell models are relied upon for drug screening, efficacy readouts, toxicity assessment, and mode-of-action (MOA) studies, and where the "human context" is often only implemented later at the clinical trial phase, patient iPSC-derived models fundamentally introduce the "human context" early in the discovery pipeline. Ultimately, a comprehensive understanding of disease mechanisms, coupled with small-molecule screening, offers unprecedented opportunities for drug discovery, including early testing of drug-target engagement, efficacy against the human target, and toxicity, in a human cell-type and disease-relevant context, at a preclinical trial phase (**Fig. 1**). Such strategies have the potential to increase the probability of success and, perhaps, lower the costs of drug discovery and repurposing.

While many quantifiable phenotypes in human iPSC-derived culture systems may prove adaptable to screening formats, addressing the question of which in vitro phenotypes are ultimately relevant to disease pathophysiology and should be the focus of drug development requires careful consideration.[48,61] Integrative research approaches, across cellular models of the same or related disorders, and in concert with clinicopathological patient data, can offer unique opportunities in recognizing disease-relevant phenotypes, understanding disease in a broader context (e.g., common aspects of neuronal death among related neurodegenerative diseases), and identifying biomarkers and therapeutic targets (**Fig. 2**).

Here, we will focus first on the latest advances in human disease iPSC-derived models, disease etiology phenotyping pipelines, and the potential for preclinical diagnostics. Then, we will address strategies to identify therapeutic targets, HTS/HCS approaches for drug discovery, and drug efficacy and toxicity testing. A number of key challenges will also be discussed, including optimization for cost-effective large-scale culture of iPSCs and iPSC-derived neuronal cultures, standardization of differentiation protocols, throughput and automation of phenotypic assays, and the urgent need for scaling iPSC-derived cellular models to larger patient cohorts with routine integration of clinicopathological information.

1.03.2 iPSCs ex vivo Disease Models

While stem cells are highly relevant for many areas of active therapeutic development and regenerative medicine, a tremendous effort has been directed toward the development of human iPSC-derived models of diseases affecting tissues and cell types that cannot be accessed noninvasively or are of a limited nature in terms of availability. This is particularly the case for neurodegenerative

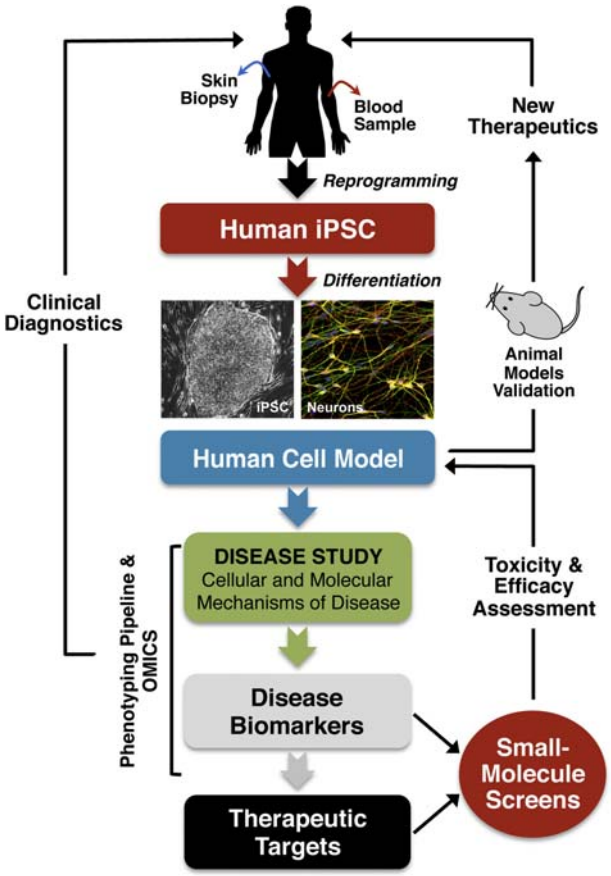

Fig. 1 Human iPSC in drug discovery. iPSC-based models of human disease focus on endogenous physiologically relevant proteins and molecular pathways, with the genetic context associated with disease. Coupled with extensive phenotypic analysis and validation across an increasing number of cell lines, iPSC-derived cells can have an important role in clinical diagnostics and interpretation of genetic variation. Most remarkably, iPSC-derived cell models show increasing potential for small-molecule screening and secondary testing of novel therapeutics' efficacy, toxicity, and mode of action, in a human context and in advance of animal testing and human clinical trials.

and psychiatric disorders where access to living brain tissue is severely limited, and there is a need to investigate the physiology and response of specific cell types to therapeutic agents. Thus, patient iPSC-derived neurons that represent unique ex vivo models of human neuronal networks present the opportunity to investigate disease-relevant genes and proteins at endogenous physiologically relevant levels and in the context of the genomic background associated with disease.[45,62] For these reasons, below we will use the CNS as a case study to point out the value of human iPSC models for ex vivo disease modeling, with similar rationale existing for studies of other diseases and cell types.

1.03.2.1 Human iPSC-Derived Cell Models to Study Disease in Cellular- and Genomic-Relevant Contexts

Traditional approaches for studying pathophysiological mechanisms of human disorders have relied on animal and immortalized cell lines disease models, through overexpression of human transgenes predicted to be causal to disease, in a particular cell type amenable to phenotypic measurements. Although these have been instrumental in initial screening efforts and progression of candidate therapeutics through preclinical efficacy and safety tests, and in elucidating disease mechanisms, these model systems have had poor success in translation to human patient-relevant findings, and ultimately in the registration of new drugs, particularly in the area of CNS disorders.[45,63] This is thought to be partly the result of a concerning disconnect between phenotypic findings and drug pharmacological properties in isolated recombinant model systems versus the actual "native" human system. The physiological and genomic inaccuracy of many disease models might be a fundamental reason for the hindered identification of validated therapeutic targets and the cause of high-cost, failed clinical trials. Justly, research of many diseases was negatively affected by the unavailability and inaccessibility to appropriate cell types, that is, human tissue affected by the disease, carrying the disease-associated genomic background and pathology-relevant altered proteins and biochemical pathways. This translational disconnect has the potential to be overcome by human iPSC-based model systems and screens. Human stem cell-derived neurons allow access to physiologically relevant cell types and protein complexes without the need for overexpression of heterologous genes, representing a reliable system to investigate molecular and cellular disease mechanisms.[35,45,48–50]

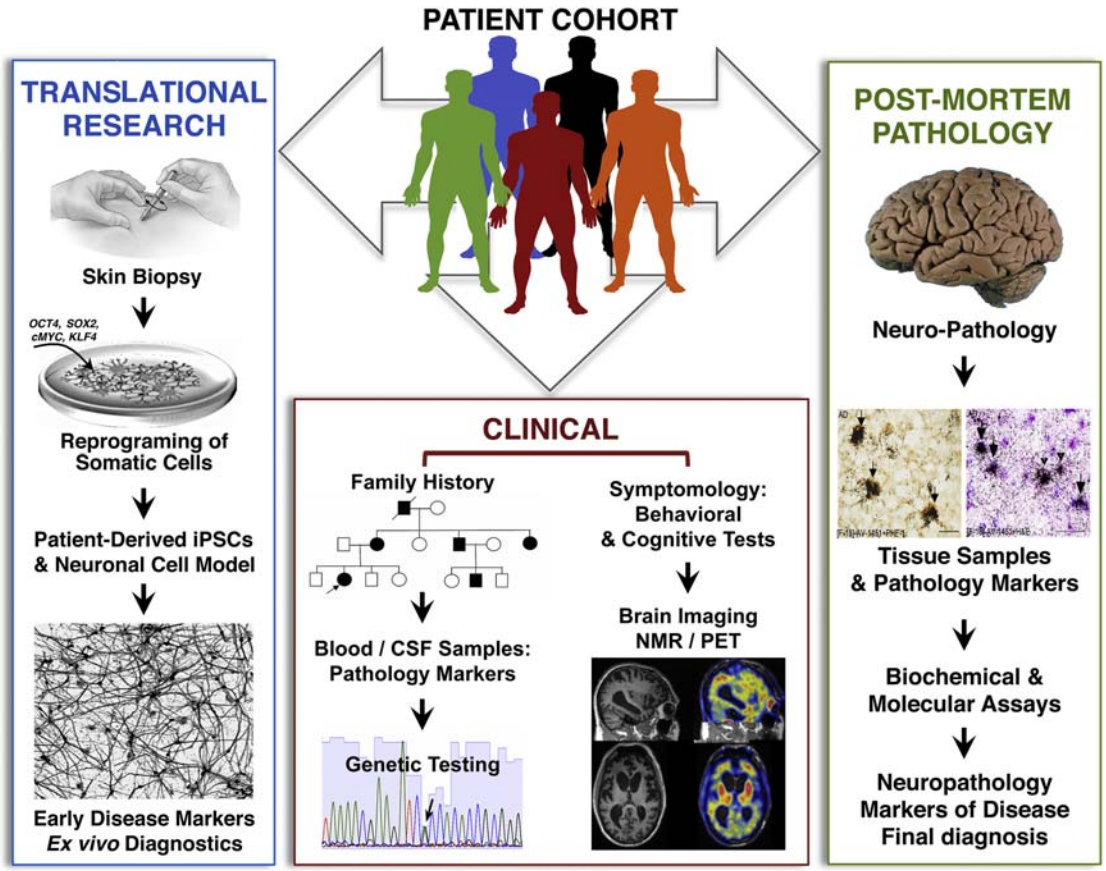

Fig. 2 Translational research integrative approaches: patient cohort-based iPSC-derived cellular models (left), rich and longitudinal clinical phenotyping information (middle), and postmortem pathology data (right). Patient-specific iPSC-derived cell models are a critical tool in the study of early disease molecular and cellular mechanisms. Results interpretation in the context of clinicopathological data allows discerning the most relevant phenotypes, identification of biomarkers with relevance for preclinical and clinical diagnostics, as well as therapeutics development. Brain imaging offers guidance regarding areas of the brain and neuronal circuitries affected by disease, neuronal atrophy, and death, for further studies; NMR (nuclear magnetic resonance) and PET (positron emission tomography) images (Adapted from Ghetti, B.; Oblak, A. L.; Boeve, B. F.; Johnson, K. A.; Dickerson, B. C.; Goedert, M. Invited Review: Frontotemporal Dementia Caused by Microtubule-Associated Protein tau Gene (MAPT) Mutations: A Chameleon for Neuropathology and Neuroimaging. *Neuropathol. Appl. Neurobiol.* **2015**, *41* (1), 24–46). Postmortem pathology data (Adapted from Marquie, M.; Normandin, M. D.; Vanderburg, C. R.; Costantino, I. M.; Bien, E. A.; Rycyna, L. G.; Klunk, W. E.; Mathis, C. A.; Ikonomovic, M. D.; Debnath, M. L.; Vasdev, N.; Dickerson, B. C.; Gomperts, S. N.; Growdon, J. H.; Johnson, K. A.; Frosch, M. P.; Hyman, B. T.; Gomez-Isla, T. Validating Novel Tau Positron Emission Tomography Tracer [F-18]-AV-1451 (T807) on Postmortem Brain Tissue. *Ann. Neurol.* **2015**, *78* (5), 787–800) is relevant to validate the ultimate progression of disease, to ensure that the right processes are being targeted for therapeutics.

1.03.2.1.1 Patient iPSC differentiation into disease-relevant cell types

A major obstacle in developing accurate models of human disease has been, in many cases, the inaccessibility to disease-relevant human tissue, especially if it requires routine patient's sample collection (e.g., biopsy). Even in cases where tissue is available, terminally differentiated cells such as neurons cannot be maintained in culture, prohibiting the possibility of experimental reproducibility and scalable studies. Conversely, readily accessible tissues such as lymphocytes do not necessarily recapitulate all the signaling and molecular pathways that are affected by CNS disorders. With implementation of iPSC technologies, the ability to use genetic and cellular "accurate" human-derived models to investigate the step-by-step molecular and cellular events associated with disease has started to show great impact on the understanding of particular types of neurological diseases. Patient-specific iPSCs and differentiated cells effectively model a human disease genome and proteome in a format amenable to ex vivo investigation, with access to otherwise difficult or impossible-to-obtain living cell types of the human nervous system. Methodology advances in the production of scalable cultures of iPSC-derived specific cell types, including NPCs and neurons,[35–38] represent a significant step forward in the development of platforms for phenotypic HTS-compatible assays, for testing genotype–phenotype correlations in complex genetic disorders, and to support integrated approaches to human chemical neurobiology. Most remarkably, patient iPSCs-derived neuronal cells recapitulate key aspects of human disease ex vivo.

In the context of *psychiatric disorders*, development of effective therapies is one of the greatest 21st century challenges in medicine, affecting millions of individuals worldwide.[64] A major contributory factor is that the causes of mental illnesses are complex and heterogeneous in nature and still not well understood. While risk for common disorders such as bipolar disorder, major depression,

schizophrenia, and autism is clearly polygenic in nature, there is also potential for contribution of both epigenetic variation and environmental factors to disease susceptibility (Fig. 3).[50,65–67] This polygenicity renders it very difficult to create genetically accurate models of psychiatric disorders in animals. Not only do they often lack neuroanatomical regions, and therefore circuitry thought to contribute to pathology, but comparison between mouse and human model systems has exposed real challenges on extrapolation of phenotypes.[50,68] For these disorders, not only access to physiologically active and relevant CNS cell types for research is practically impossible, the precise identity and location of such cells that play a causal role in disease pathogenesis remains, in many cases, unclear. Thus, patient iPSC-derived in vitro NPCs, neurons, and glial cells have paved a new era in psychiatric research since they capture the complex genetic architecture of polygenic susceptibility and allow access to a diversity of neuronal and glial subtypes.[48,50]

Multiple hESC- and iPSC-derived cellular models have been generated for distinct monogenic and polygenic psychiatric disorders, where epigenetic, chemical, proteomic, and signaling pathways dysregulation can be assessed and measured in a cell-specific manner, increasingly providing a powerful means to dissect the underlying disease biology.[39,48,50,69–72] There are now a growing number of human iPSCs models of monogenic psychiatric disorders such as fragile X syndrome[39,73] and Rett syndrome,[74–76] along with a smaller number of human iPSCs models for the polygenic psychiatric disorders schizophrenia[77,78] and bipolar disorder.[79–82] But human iPSC-derived models only demonstrated applicability for modeling psychiatric disorders when reports of cellular phenotypes started to emerge. These include electrophysiological and signaling defects, aberrant neuronal differentiation patterns, and alterations in protein expression in differentiated neurons.[51] For Rett syndrome, a severe childhood onset, neurodevelopmental disorder due to mutations principally in the *MECP2* gene, different iPSC-derived neuronal models have collectively revealed a number of potentially disease-relevant phenotypes, including changes in soma size, glutamatergic synaptic deficits, and altered gene transcription.[83–85] Schizophrenia iPSC-derived NPCs exhibit elevated levels of reactive oxygen species,[77] consistent with proteomic analysis of patients' brain tissue that also revealed disruption of mitochondrial function and oxidative stress.[86] Simultaneously, these models have provided the foundation for developing phenotypic assays suitable for functional genomic and chemical screens.[50] The value of these human in vitro cell models is further corroborated by phenotypic responsiveness to pharmacological agents, and therefore translational potential, including rescue of abnormal calcium signaling with the voltage-dependent L-type calcium channel antagonist nimodipine and rescue of neuronal differentiation patterns by roscovitine in the case of Timothy syndrome, a multisystemic disorder with cardiac, developmental, and autistic features[48,87]; rescue of glutamatergic synapses by the insulin-like growth factor 1 in Rett syndrome cultured neurons[76,88]; and rescue of gene expression abnormalities and connectivity differences in schizophrenia iPSC-derived neurons with the tricyclic dibenzoxazepine antipsychotic loxapine.[77] Meanwhile, targeted small-molecule screens for modulators of pathways affected in psychiatric diseases are beginning to emerge (Table 1). WNT pathway dysregulation has been associated with both psychiatric and neurodegenerative diseases, and a screen by Zhao et al. led

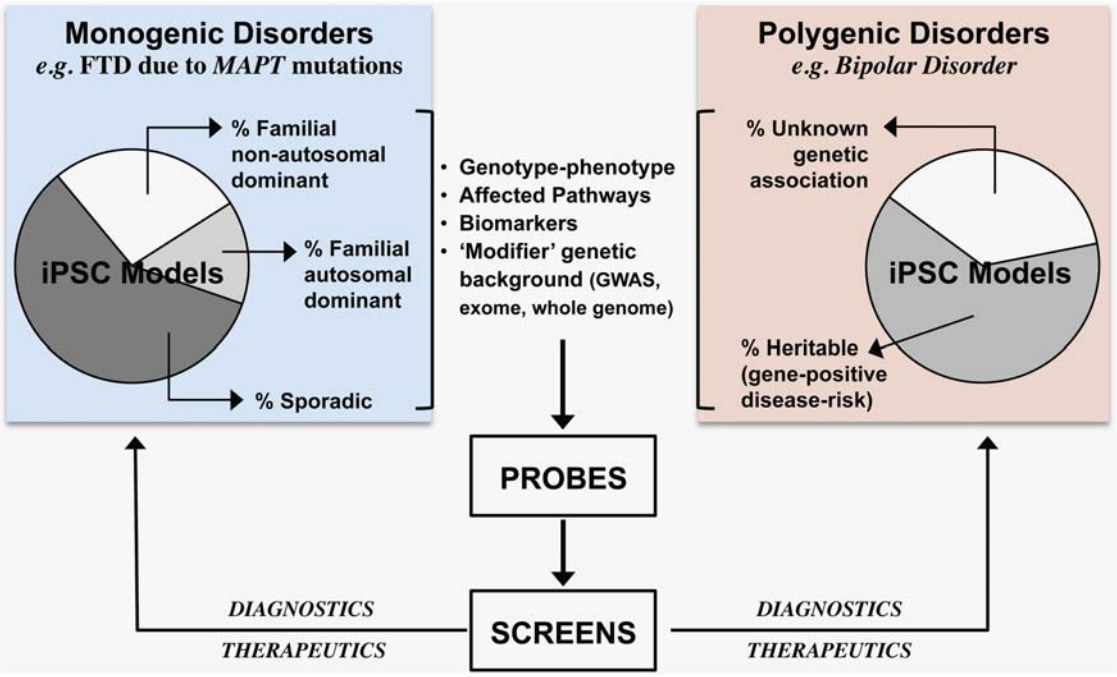

Fig. 3 Genetic variability among CNS disorders (simplified schematic). Patient iPSC-derived models capture the disease-associated genetic variability and allow the study of molecular and cellular phenotypes in a disease-relevant genomic background. Common phenotypes across diseases, independent of heritability class, may reveal the most relevant phenotypes to pursue for biomarker ID and small-molecule screening, with the goal of finding chemical therapeutics effective for a larger number of diseases, that is, by targeting and correcting the "common aspects" of pathogenesis.

Table 1 Examples of low- and high-throughput screens performed leading to lead compounds across stem cell biology and disease areas

Model	*Screening strategy*	*Library size/type*	*Positive hits/lead structure*	*Reference*
ESCs self-renewal (regenerative medicine)	mESCs, Oct4-GFP reporter assay. HTS 384-well plate format	50,000 Compounds	17 Hits Lead class: 3,4-dihydropyrimido[4,5-d] pyrimidines	Chen et al. (2006)[246]
ESC survival[a] (regenerative medicine)	hESC survival in vitro	Candidate approach: caspase inhibitors, growth factors, trophic factors, and kinase inhibitors	ROCK inhibitor Y-27632, most potent inhibitor of apoptosis	Watanabe et al. (2007)[247]
ESC proliferation and differentiation (regenerative medicine)	hESC self-renewal or differentiation. HTS/HCS 384-well plate format, automated laser-scanning confocal microscopy. OCT4/NANOG markers	2880 Small molecules (biologically active and structurally diverse compounds including 748 marketed drugs)	22 Hits: activators of proliferation (THEA, SNM, GTFX, FBP); differentiation inducers (tretinoin, retinoic acid, SLG, CYM, SRM)	Desbordes et al. (2008)[248]
ESC fate (regenerative medicine)	hESC fate regulators, HTS/HCS	1040 Compounds (two commercial libraries)	17 Promoters of differentiation (steroids), 5 promoters of viability (e.g., pinacidil)	Barbaric et al. (2010)[249]
AMPA glutamatergic neuronal potentiation	ESC-derived neurons (mouse and human). Fluorimetric imaging plate reader (FLiPR) Assay	2.4 Million compound library	37 Hits, 7 correspond to two novel molecular series (CE-382349)	McNeish et al. [89]
SMA, motor neuron survival	Rescue of protein survival of motor neuron (SMN) expression. Image-based (antibody-based) HTS/HCS 384-well plate format	3500 Bioactive compounds: LOPAC1280 Collection, Spectrum Collection, Prestwick Chemical Library, and custom set of 289 chemicals	188 Hits validated in SMA patient fibroblasts Mainly RTK-PI3K-AKT-GSK-3 signaling cascade modulator compounds	Makhortova et al. (2011)[250]
Schizophrenia[a]	Patient iPSC-derived neurons. Improved neuronal connectivity (synaptic markers and electrophysiology) in vitro	5 Candidate compounds: Clozapine, loxapine, Olanzapine, Risperidone, and Thioridazine	Loxapine	Brennand et al. [77]
WNT/β-catenin signaling, neuropsychiatric diseases	WNT-reporter assay in iPSC-derived NPCs, HTS 384-well plate format	1500 Compounds (FDA-approved and known bioactives)	45 Hits increased WNT activity (e.g., Riluzole, Trifluridine, Kaempferol, FG7142)	Zhao et al. [40]
ALS motor neurons[a]	Familial and sporadic ALS-TDP-43 patient iPSC-derived motor neurons. Rescue of phenotypes	4 Candidate compounds: trichostatin A, spliceostatin A, anacardic acid, and garcinol	Anacardic acid	Egawa et al. [90]
Familial dysautonomia	Familial dysautonomia patient-derived iPSC neural-crest precursors: rescue of expression of *IKBKAP* gene	6912 Small molecules	8 Hits Lead molecule: SKF-86466	Lee et al. [91]
AD neurons[a]	Suppression of Aβ oligomers-induced cellular stress in familial and sporadic AD patient-derived neurons (ER and oxidative stress phenotypes rescue)	3 Candidate compounds: BSI (β-secretase inhibitor IV), DHA (docosahexaenoic acid), ibenzoylmethane (DBM14-26), NSC23766	BSI, DHA	Kondo et al. [92]
NCS proliferation and viability	iPSC-derived neural stem cell (NCS), proliferation, and viability modulators. CompacT SelecT cell culture robotic platform HTS micro-well plate format	1000 Compounds	5 Potentiators of proliferation and viability (e.g., Cdk-2 modulator)	McLaren et al. (2013)[251]
ALS-SOD1 motor neurons	mESC-derived motor neurons, ALS model with mutant SOD1, survival screen. HTS 384-well plate format.	5000 Small molecules (known drugs, bioactives, and annotated chemicals) × 3 concentrations	Lead: kenpaullone Other hits: MMP inhibitor 1,10-phenanthroline monohydrate; CP55940; MDL 28170; A 77636, 3-Tropanylindole-3-carboxylate methiodide, FPL-64176, Tyrphostin A9	Yang et al. [93]

(Continued)

Table 1 Examples of low- and high-throughput screens performed leading to lead compounds across stem cell biology and disease areas—cont'd

Model	*Screening strategy*	*Library size/type*	*Positive hits/lead structure*	*Reference*
Sporadic ALS	Sporadic ALS patients' iPSC-derived motor neurons. HCS for inhibitors of TDP-43 aggregation (custom-built automated screening system with robotics and automated confocal microscopy)	1757 Bioactive compounds	Four classes of compounds: cyclin-dependent kinase inhibitors, c-Jun N-terminal kinase inhibitors (JNK), Triptolide, and FDA-approved cardiac glycosides, Digoxin, Lanatoside C, and Proscillaridin A	Burkhardt et al. [94]
PD dopaminergic neurons[a]	Neuroprotection of iPSC-derived dopaminergic neurons, by MTT viability assay and PD-rotenone toxicity model. Low-throughput assay, 96-well plate format	44 Compounds	16 Hits (e.g., indomethacin, nicotine, EGCG, resveratrol, taurine, lpoic acid)	Peng et al. (2013)[252]
AD/Aβ neuronal toxicity[a]	Human iPSC-derived forebrain neurons exposed to Aβ1-42 aggregates (insult). HTS for blocking Aβ1-42 toxicity, cell viability assay, and electrophysiology	"Several hundred compounds" from a GSK proprietary compounds library	19 Hits (including Cdk2 inhibitor)	Xu et al. (2013)[253]
Drug-induced arrhythmia[a] (drug development/ toxicology)	Human iPSC-derived cardiomyocytes model for drug-induced arrhythmia. Microelectrode array recordings of beating embryoid bodies exposed to a panel of drugs. Drug toxicology	Candidate approach: drugs prescribed for atrial fibrillation and ventricular tachycardia; other ion channel blockers (e.g., sotalol, quinidine, nifedipine, verapamil)	–	Navarrete et al. (2013)[254]
Cardiotoxicity[a] (drug development/toxicology)	Human iPSC-derived cardiomyocytes from patients with hereditary cardiac disorders to model genotype-dependent cardiac drug toxicity	Candidate approach: cisapride, nicorandil, alfuzosin, verapamil	–	Liang et al. (2013)[255]
Tumorigenesis and safety of hPSC-based treatments	Elimination of hPSCs while preserving progenitor and differentiated cells. HTS in 384-well format, automatic assessment of cell viability	52,000 Small molecules	15 Pluripotent cell-specific inhibitors (PluriSIns); most selective compound, PluriSIn #1 (SCD1 inhibitor) induces ER stress, protein synthesis attenuation, and apoptosis	Ben-David et al. (2013)[256]
Liver disease	Alpha-1 antitrypsin (AAT)-deficiency patient iPSC-derived hepatocytes. AAT expression rescue. IF-based HTS	3131 Clinical compounds (John Hopkins Drug Library)	5 Confirmed hits in multiple lines: carbamazepine, glipizide, lithium, valproic acid, thiamine	Choi et al. (2013)[257]
ALS motor neurons[a]	Familial and sporadic ALS patient iPSC-derived motor neurons electrophysiology (hyperexcitability phenotype)	Candidate approach (Kv7/KCNQ channel activity regulators)	Retigabine (antiepileptic drug)	Wainger et al. [95]
Fragile X syndrome	Rescue of *FMR1* gene expression, in Fragile X patient iPSC-derived neural cells. FRET assay for FMRP detection. HTS 1536-well plate format	5000 Bioactive compounds	6 Compounds	Kumari et al. [96]
Fragile X syndrome	Rescue of *FMR1* gene expression in patient iPSC-derived NPCs. HCS/HTS 384-well plate format	50,000 Compounds	790 Active compounds	Kaufmann et al. [97]
WNT/β-catenin signaling; neuropsychiatric diseases	WNT-reporter assay in iPSC-derived NPCs HTS	300,000 Compounds (NIH-supported Molecular Libraries Program)	Multiple scaffolds	S.J. Haggarty (personal communication)

[a]Small-scale, proof-of-concept studies.
HTS, high-throughput screen; HCS, high-content screen; hESC, human embryonic stem cells; mESC, mouse embryonic stem cells; iPSC, induced pluripotent stem cells.

to the identification of a number of both known and novel small-molecule regulators of WNT signaling in human NPCs, including selective mGLUR1 (metabotropic glutamate receptor 1) antagonists and the FDA-approved drug riluzole (Rilutek).[40] Even though these are examples of targeted studies, the value of psychiatric patient iPSC-derived cell models for small-molecule screening has been established, with the additional potential for follow-up mechanistic studies of the MOA of pharmacological agents in human cells, at a preclinical phase.

Neurodegenerative diseases are another group of heterogeneous devastating illnesses. Symptomatic treatments are available for some diseases, but no effective disease-modifying therapies have been registered. The unmet medical need grows exponentially with the aging population, with prevention and/or timely diagnosis at the forefront of current research.[98,99] These disorders can be familial or sporadic (**Fig. 3**), with onset in adult life and chronic progressive course, leading eventually, to a fatal outcome.[98,100] A main feature is the age-dependent focal and progressive loss of neuronal structure and function, characteristically associated with the presence of aberrant protein inclusions in the affected neurons, leading to neuronal death, astrogliosis, and spongiosis.[100–103] Protein aggregation can result from a mutation in a disease-related gene, leading to expression and accumulation of aberrant misfolded proteins in the cell or, in the absence of genetic alterations, it is thought to be a result of environmental stresses (e.g., head trauma injury) and aging.[100,104] From a disease evolution point of view, it is thought that neuronal cells accumulate aberrant proteins to a certain degree, until a large amount of damage has been sustained, giving place to a progressive proteostasis and cellular "collapse," starting with cells most vulnerable to the protein-mediated toxicity, toward a more global state that affects different functional systems along disease progression.[99,100,104,105] In addition, one of the most interesting but also debated theories today is the so-called protein spreading hypothesis of many neurodegenerative disorders where misfolded/aggregated proteins propagate between neighboring neurons and glial cells.[106–109] This hypothesis is thought to underlie the progression or "staging" of many disorders such as Parkinson's and Alzheimer's disease (AD) across brain regions. Despite the shared features of abnormal protein accumulation, and possibly propagation, leading to neuronal toxicity and death, the correlations between genetics, clinicopathology, and diagnosis are, in some cases, intricate, as revealed by genomic sequencing studies of cohorts of patients.[110–112] Such studies have shown that a given gene or mutation is not necessarily predictive of a single disease.[99,100,102,113,114] In some cases clinicopathological phenotypes can be somewhat predicted by the underlying genetic landscape, for example, polyglutamine expansions in the huntingtin (*HTT*) gene in Huntington's disease (HD)[115] or α-synuclein mutations in Parkinson's disease (PD).[116,117] However, in other cases, such as AD, frontotemporal lobar degeneration (FTLD) and other tauopathies, or amyotrophic lateral sclerosis (ALS), genotyping-based diagnosis is not straightforward as symptoms and associated clinicopathological findings are not always related to the same cytological and postmortem phenotypes.[99,102,114,118–122] Overall, disease variability among individuals of the same genotype and even among individuals with the same exact gene mutation remains poorly understood.

Another key issue, in addition to genotype–phenotype variability, is that of selective vulnerability. The biological mechanisms of neurodegeneration are highly associated with what is referred to as "focal" neuronal death, which means only a select group of neurons are affected in specific regions of the brain, within a tissue that ubiquitously expresses the same disease-associated gene mutation(s), while neurons immediately proximal remain unaffected.[123] Consider the specific examples: AD is associated with the selective damage of neural circuits involved in cognition and memory, including the neocortex, hippocampus, amygdala, basal forebrain cholinergic system, and brainstem monoaminergic nuclei[124]; FTLD affects mainly the frontal, insular, cingulate, and anterior temporal cortex, leading to changes in behavior, personality, and/or language, with relative preservation of memory[101,119,125]; whereas ALS shows a selective involvement of lower motor and pyramidal neurons, leading to muscle atrophy and spastic paralysis. Moreover, within the mentioned neuronal circuits, specific forms of disease can be associated with a strict loss of neuronal subtypes, as is the case of frontoinsular von Economo neurons and fork cell loss in FTLD subtypes.[126,127] The basis for this selective vulnerability, at a specific time in life, is still difficult to address experimentally, but it will require discerning what molecular networks are dysregulated in disease, to determine what predisposes preferentially specific neurons to death, in response to cell stress accumulation.

The identification of gene mutations associated with neurodegeneration prompted investigators to establish in vitro and animal model systems to examine cellular and molecular abnormalities in a genotype–phenotype dependent manner. Transgenic mice expressing human disease-causing gene mutations recapitulate many features of disease and have proved to be very useful in investigating biochemical alterations and pathogenic mechanisms in neural tissues, the evolution of pathology with aging, and in testing potential therapeutic agents.[98] Simpler organisms like the nematode *Caenorhabditis elegans* and the fruit fly *Drosophila melanogaster* also took an important role in the study of the molecular basis of human diseases, offering rapid transgenic model generation, the possibility for genome-wide screens and study of genetic interactions with cellular phenotypes.[98,100,128] Mounting evidence from model systems, together with emerging clinical research and diagnostic tools, such as PET (positron emission tomography) imaging that can detect brain alterations ahead of symptomology onset, and biomarker studies in AD (cerebral spinal fluid (CSF) levels of tau), have revealed that many disease-related cellular and biochemical alterations occur at a presymptomatic stage, turning attention toward the period in the disease when treatment will ultimately prove critical (**Fig. 2**).[129–134] Although postmortem protein inclusions are well accepted as pathological features of neurodegeneration, there has been great controversy about the role of aggregation in the disease process. A growing body of evidence has demonstrated that events preceding the formation of inclusion bodies, including abnormal disease-protein monomers and small assemblies of oligomeric species, might be the actual trigger for neuronal toxicity.[100,104,135] Therefore, a better understanding of the early biochemistry and biophysics of protein conformational change, species formed, and aberrant interaction with cellular components/pathways is indispensable to unravel the cellular toxic events, as well as cellular protective mechanisms that could be exploited from a therapeutics development perspective. Furthermore,

approaches to study the propagation of misfolded proteins are very important and could identify new therapeutic pathways or processes to prevent the spread of toxic protein species.

Patient or gene (mutation)-positive iPSCs are now used to generate cellular models to study early molecular and cellular mechanisms of disease, in a human disease-relevant cell context.[35,47] Notably, lineage-converted cells are able to recapitulate disease phenotypes and provide insight into disease mechanisms. As an example, induced motor neurons derived from ALS patients have been shown to have hyperexcitability due to SOD1 (A4V) mutations,[95] as well as rapid degeneration in culture relative to control neurons.[136] In iPSC-derived neuronal models of tauopathy, multiple groups have reported aberrant tau accumulation and insolubility, posttranslational modifications (PTMs), and subcellular mislocalization as early markers of pathogenesis.[41,92,137–140] Consequences of the early protein accumulation include altered proteostasis pathways, upregulation of stress markers, and increased neuronal vulnerability to cell death. In particular, disruption of protein clearance and endosomal–lysosomal pathways (proteasome and autophagy), endoplasmic reticulum (ER) stress unfolded protein response (UPR), mitochondrial dysfunction, and oxidative stress are strong models for tau-mediated toxicity and neurodegeneration (also seen in AD cases[92]). Consistent with these findings, human studies have identified protein clearance pathway components as CSF markers of neurodegeneration, and mounting evidence shows UPR, mitochondrial dysfunction, and oxidative stress associated with early stages of tauopathy and AD sporadic cases,[92,137,138,141,142] highly reinforcing the validity of iPSC-based cell models in the identification of disease biomarkers.[143] Moreover, overlap in stress markers (e.g., oxidative stress, disruption of protein clearance) and shared increased susceptibility to stress in tauopathy and PD patient-derived neurons, together with clinicopathological information, start to provide larger insight into common processes of neurodegeneration,[144] also supporting the proposition that the onset of cellular pathology occurs earlier than clinical manifestations. In addition, iPSC-derived neurons have also been used to study the spreading hypothesis as related to specific tau species.[139] Finally, increasing advances in iPSC differentiation into defined neuronal subtypes, representative of affected and nonaffected cell types in disease, will allow to probe cell-specific vulnerability to disease proteins, which will be much more challenging than solving gene-phenotype associations.[145]

It is also important to acknowledge that, although not the focus of this article, continued improvement in iPSC methodologies and tissue-specific differentiation have benefited other areas of medical research such as genetic *cardiovascular disease*[146,147] (**Table 1**). Human iPSC-derived cardiomyocyte cells, vascular endothelial cells, and smooth muscle cells that recapitulate key aspects of cardiovascular disease have enabled large-scale chemical and functional genomics screening.[20] Moreover, the potential to derive cardiomyocyte cells is also of great relevance to assess the risk of new therapeutics and dosing optimization, independently of targeted disease, with respect to arrhythmic risk, cardiotoxicity, and myopathy, through plasma markers measurements and cell-specific alterations of molecular and signaling properties.[20]

Overall, findings across human iPSC-derived models of disease are starting to provide more insight into disease mechanisms, guidance for the identification of early disease-relevant phenotypes and potential therapeutic targets, as well as new diagnostic tools, also leading to the development of promising pharmaceutical screens for novel therapeutic agents.

1.03.2.1.2 Assessing disease mechanisms in complex genetic disorders

Understanding the genetic basis of complex human disorders has followed the development of state-of-the-art genomic tools. Remarkable advances in next-generation sequencing (NGS)[111] and genome-wide association studies (GWAS) have led to the identification of disease-causing gene mutations, in addition to gene loci and rare variants that confer either higher or lower risk for disease.[148] For cases where a particular gene or mutation can be directly associated with clinical outcome, the development of animal and cellular models has been somewhat straightforward by simply overexpressing the human gene mutation, and then measuring molecular alterations, cellular phenotypes, and animal behavior. This effort becomes remarkably more complex when the goal is to model diseases that are sporadic, that do not have a clear genetic link or are associated with risk genes, or diseases that are polygenic.[77,92,149,150] Since patient iPSC-derived cells take into account patients' genomic background and allow the generation of both familial and sporadic forms of disease models, there is not a need to have a priori knowledge of the genetic "cause" to create a useful model of a human disease. Moreover, molecular, biochemical, and cellular phenotypes are explored in each patient's own genomic background that through clinicopathological data can be determined to be permissive to the disease state. This is particularly important, as the majority of neurological diseases are sporadic or rare monogenic forms, rendering animal models quite ineffectual. Still, to determine which phenotypes are disease-relevant, and beyond individual inherent variability, it is necessary to study multiple stem cell clones, from multiple patients, and compare phenotypes against multiple healthy individuals. Again, the broader disease relevance of a given phenotype can only be demonstrated by examining cells from patients with different mutations in disease-causing genes, as well as in a large number of sporadic cases (**Fig. 3**).

Advances in genomic tools have contributed to a greater understanding of the genetic architecture of psychiatric diseases,[149] revealing common variants at a large number of loci, but with each variant only having a small contribution to disease risk, that is, a polygenic component (**Fig. 3**). The small contribution of individual common risk variants, together with the rarity of large-effect loci or mutations (Mendelian), mean that accurate conclusions for genetic contribution to disease can only be obtained through large clinical cohorts, specially if the goal is to define causal or contributory role for *de novo* mutations or rare variants.[50,149,151] Moreover, the large heterogeneity and polygenicity in psychiatric disorders makes modeling extremely complex, specifically with respect to connecting the multiplicity of molecular, cellular, and circuit dysfunctions to complex human behavior. Despite the limitations in developing "accurate" model systems of human psychiatric disorders, mouse models of the few large-effect loci or Mendelian risk genes of disease have been developed and contributed significantly to the field, but successful translation has been limited in terms of fundamentally new mechanisms-of-action therapeutics with disease-modifying potential, rather

than affecting only symptomatic aspects.[152,153] As already mentioned, with patient iPSC-derived cell models and increasing access to larger cohorts of psychiatric patients, it will be possible, and potentially more successful, to focus on common phenotypes across models, and disease-modifying or corrective therapeutics. To date, the studies examining monogenic forms of psychiatric disease via patient iPSC-derived neuronal models are encouraging, even though still representative of a small sample size (for representative work see Refs. [39,48,50,51,69,71,76,77,81,83,87]).

For neurodegenerative diseases, the genetic landscape is somewhat different. Diseases are usually associated with a main gene(s) and protein(s), accounting for a percentage of sporadic cases and a percentage of familial cases (Fig. 3). These percentages represent different values for diseases such as Frontotemporal Dementia (FTD), ALS, and PD, whereas HD, for instance, is inherited in a fully autosomal dominant manner.[99,102,114–116,119] Although the principal genes and proteins associated with each disease are thought to account for the vast majority of pathological phenotypes, the underlying genetics do not always match the same pathology. Therefore, efforts to elucidate the link between genetic variation, proteinopathy and neurodegeneration, are critical for finding disease-modifying therapies. In many cases, NGS and GWAS have led to the identification of not only disease-causing gene mutations but also gene loci and rare variants that confer higher or lower risk for disease vulnerability, starting to explain some phenotypic variability and clinicopathological data among individuals with the same gene mutation, emphasizing the concept of modifier genetic background.[119,148,154,155] Also here, patient iPSC models offer the opportunity to study disease etiology in two important ways. First, patient-derived cells offer the "most accurate" cell environment, with disease-relevant genes and proteins expressed at physiological relevant levels, and in the appropriate cellular context, to study molecular and cellular early events leading to neurodegeneration. This aspect is particularly significant when assessing protein accumulation- and aggregation-mediated toxicity, as these are highly dependent on concentration and cell type. Second, with increasing throughput in gene editing technologies (e.g., clustered regularly interspaced short palindromic repeats or CRISPR/Cas9[156]), it is now possible to determine, across otherwise isogenic cellular backgrounds, single gene mutation contribution to cellular phenotypes with relevance for disease.[157,158] When applied to large-scale and integrative research pipelines, these approaches can reveal the most relevant targets for therapeutics (Fig. 3).

1.03.2.2 Integrative and Translational Research of Human Disease Etiology

The era of iPSC-derived cellular models of human disease brought the potential to introduce the human context into the earliest stages of CNS drug discovery. However, investigative approaches usually focus on identifying in vitro phenotypes associated with genetic variation in disease, and then identifying candidate pharmacological agents that rescue these phenotypes in that specific cell model.[48] The challenge is in identifying the most relevant phenotype(s), that is, the determination of a "disease-relevant phenotype," to allow successful pharmacological investigation. A step forward might involve the development of standardized functional and phenotypic cellular assays, which can be run in a pipeline format for iPSC-derived cell models characterization and categorization, with downstream implementation of these same assays in the validation of pharmacological agents (Fig. 4). Observation of similar phenotypes across models of psychiatric and neurodegenerative disorders is promising, but true progress will involve integrative approaches guided by complementary information emerging from biomarker, clinical, and postmortem studies of human disease biology. In this regard, patient clinical cohorts that are extensively and longitudinally phenotyped by a variety of clinical and psychometric assessments, quantitative structural, functional, and molecular neuroimaging measurements, fluid biomarker sampling, and neuropathological analysis, offer a rich clinical-imaging-pathologic phenotype dataset context in which to interpret results from iPSC models. Finally, genomic approaches for patient stratification (NGS and GWAS) may also provide insights into clinical phenotypic variation, contributing to more complete understanding of the genetic architecture and pathways of disease mechanisms (Figs. 2 and 3).

1.03.2.2.1 Phenotyping pipelines in preclinical studies

Human iPSC-derived cell models hold the capability of supporting screening for disease-specific phenotypes and targets, and identifying initial hit structures for therapeutic development.[50] Even so, iPSC-derivation of expandable, self-renewing NPCs, which provide large-scale and consistent sampling of human neurons compatible with large-scale, HTS, has only recently become possible[40,48,97] (Table 1). By allowing a more precise understanding of genotype–phenotype relationship in disease-relevant human cell types, the use of human iPSC- and NPC-derived models in tandem with emerging genome engineering approaches provides a previously "missing link" between basic research and translational efforts. Nonetheless, given the complexity and diversity of biological processes involved in cellular phenotypic assays, it is unlikely that traditional approaches to drug discovery will be successful. In fact, cellular phenotypic assays need to replicate the disease phenotype to such an extent to confidently predict the translation of a given compound to clinically relevant features of illness. This presents challenges, given the relative immature nature of the differentiated cell types from iPSCs and lack of more tissue-like organization, which will be discussed later.

The main point of this section is to overview phenotypic methodologies that have been developed to characterize cellular models of human disease, including cutting-edge, single-cell level resolution, high-content automated imaging for network-targeted chemical genomics, and genotype and cell-type selective vulnerability in CNS disorders. Although harder to implement than to conceptualize, when coordinated in the format of a pipeline and consistently employed in the characterization of patient iPSC-derived neuronal models, standardized assays may help overcome technical issues of variability among same disease cellular models, leading to cumulative evidence of the "real" molecular and cellular disease alterations (Fig. 4). Such effort can also determine, across differently generated models and disease-related models, which are the phenotypes most relevant to a certain disease

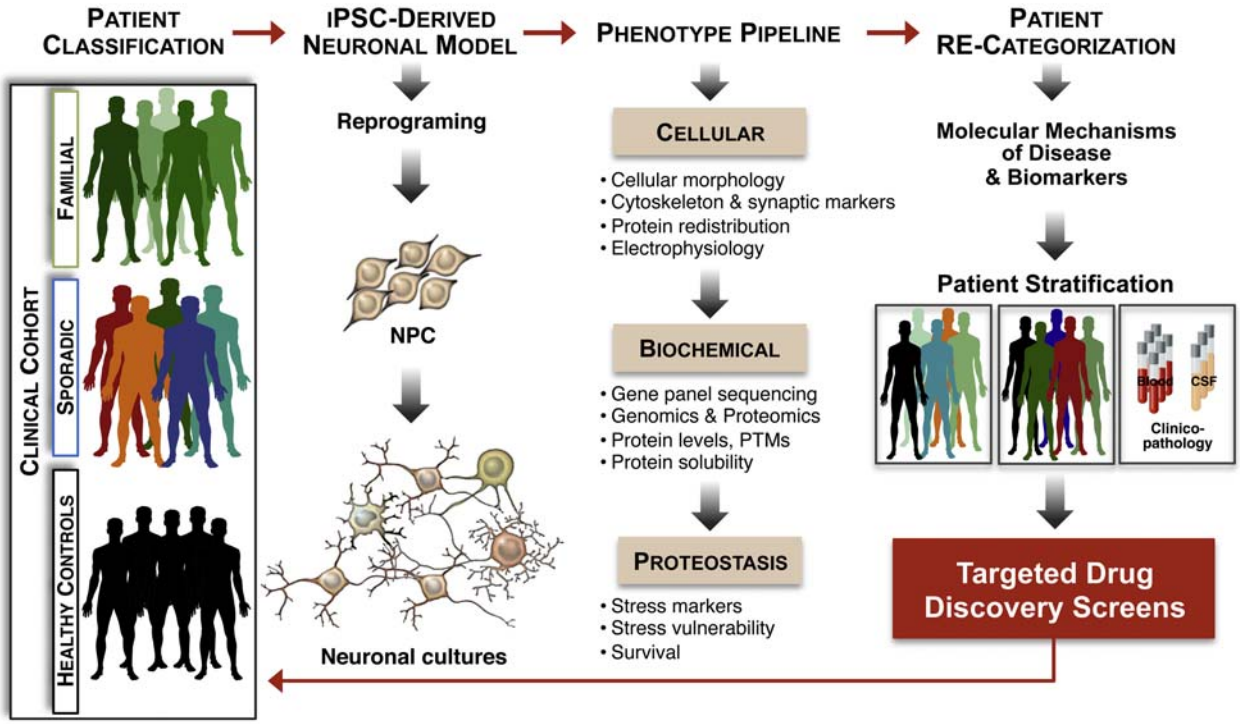

Fig. 4 Clinical cohort-based iPSC-derived cell banking approaches, with development and integration of standardized phenotypic pipelines, for determining molecular mechanisms of disease. Patient stratification based on clinical, genetic, and phenotypic data, for determination of drug screening targets and therapeutic trials in defined subpopulations.

category (e.g., cell stress pathways activated upstream of protein aggregation in neurodegeneration models), and therefore, which are the targets with highest potential for a positive therapeutic outcome (e.g., prevention of cell death in neurodegeneration). Phenotyping pipelines, in concert with clinical assessment and imaging, can ultimately represent valuable preclinical/presymptomatic diagnostic tools. We address here advances in genomic, biochemical, and cellular assays that can be employed toward a scalable platform of preclinical disease evaluation.

1.03.2.2.1.1 Genomics

Remarkable developments in NGS, whole exome sequencing, and GWAS have allowed for high-throughput sequencing of human genomic regions with considerable ease.[102,110–112,155] This has led to the identification of common genetic variants, as well as rare variants (<1% frequency in the population) and high-risk variants segregating with multifactorial, complex genetic disorders.[110,154,159] While the underlying genetics do not necessarily map directly onto specific pathologies, continued efforts to elucidate the link between genetic variability and disease phenotypes are critical to the development of disease-modifying therapies. Currently, sequencing efforts across larger patient cohorts start to offer important interpretive guidance in the mapping of pathways and cellular components with relevance to neuronal integrity, homeostasis, and functionality. As sequence data become available, integration with longitudinal clinical phenotypes, patient iPSC model research and postmortem neuropathology, can guide functional studies toward discovery of disease mechanisms and pathogenicity, and ultimately identification of promising therapeutic targets. Data integration across cohort datasets may also contribute to the development of a gene-panel-based diagnostics. Given the advances in genomics on a population level with efforts to assemble large (>1 million person) cohorts of fully sequenced subjects,[160] perhaps best exemplified by the Precision Medicine Initiative led by the FDA (see https://www.nih.gov/precision-medicine-initiative-cohort-program), one concept that has received much recent attention is the notion of using "experiments of nature" in the form of allelic variants of genes to provide correlative support of whether modulating a specific target will have the desired effect on human physiology and disease biology.[161–163] In certain cases, an allelic series can be identified that supports the directionally of what a therapeutic is desired to do (i.e., loss of function or gain of function), as well as specific structural elements of target that may drive specific physiological outcomes.[161] These observations then set the stage for efforts to identify a therapeutic modality that can mimic the effect of the genetic perturbation. Here, being able to directly measure the biochemical and cellular consequence of specific mutations and allelic series using patient-derived or engineered iPSC models holds tremendous promise for elucidating translatable, pharmacodynamic markers of target modulation; moreover, doing so with human iPSC models allows the potential to simultaneously develop appropriate screening system for drug discovery as discussed later.

1.03.2.2.1.2 Biochemical and cellular phenotypes

In cell models of human diseases where a gene and protein(s) have been associated with pathogenicity, biochemical profiling of patient iPSC-derived cell cultures has relied on techniques, such as quantitative measurement of gene (qRT-PCR) and protein expression (Western blotting), analysis of protein PTMs of relevance to disease mechanisms, and detection of protein species of reduced solubility and increased molecular weight, thought to contribute to disease but still through an unknown mechanisms and unclear timeline. Then, high-resolution, high-content microscopy can reveal a range of quantifiable phenotypes in patient iPSC-derived cells, including developmental/differentiation patterns, expression and subcellular localization of functional markers, as well as (mis)localization of molecules and proteins that are relevant for disease. This is well illustrated by multiple recently described iPSC-derived neuronal models.[35,39,58,138–140,150,157,164,165] Although cultures of specific "purified" cell types are a goal for dissecting disease cell-specific vulnerability, more "mixed" type cultures also allow, with proper cell-type markers, to dissect differential phenotypes within a population of neurons, without losing possible noncell autonomous mechanisms of disease etiology (e.g., glia contribution to neuronal death in ALS[93]). For cell models of psychiatric diseases, with unknown genetics or polygenicity, patient-derived neuronal cultures still allow access to measures of signaling pathway markers, and genotype–phenotype relationships through pathway-selective reporter genes,[40] high-content imaging,[39] and multiplexed gene expression and proteomic profiling assays.[50,166–168] Another remarkable technique uses multielectrode array technology that measures spontaneous bursting activity and evoked action potentials in stem cell-derived neuronal cultures, to capture information processing in an in vitro functional network,[169,170] with crucial relevance in monitoring pharmacological agents effect on network electrical and synaptic activity in studies with patient-derived neurons. Finally, state-of-art genome engineering technologies, such as the CRISPR/Cas9 system,[156] allow correcting or introducing disease mutations in otherwise isogenic iPSC lines, providing a rigorous test of genotype–phenotype correlations.[157,158,171] These tools also complement interpretation of the functional significance of rare genetic variants, as well as probing specificity and target-dependent rescue of phenotypes by any pharmaceutical agent.

1.03.2.2.1.3 Proteomics

Expanding on antibody-based approaches, quantitative methodologies for protein analysis using high-resolution, mass spectrometry (MS) assays have emerged as powerful phenotyping tools for iPSC-derived cells.[172–174] For example, in the case of neurodegenerative disorders involving dysregulation of tau, the FLEXITau MS assay generates MS profiles to detect differences in disease-relevant proteins, in this case tau, from patient iPSC-derived neurons, offering absolute quantification of levels, PTMs associated with neuropathology, and expression ratios between mutant and nonmutant proteins (in heterozygous patients), far surpassing accuracy of any other method.[41,173] Similar approaches with postmortem brain tissue can reveal disease-specific patterns of protein biochemistry (bar-coding), aiding in disease categorization at the preclinical stage with iPSC-derived neurons, and possibly accelerating diagnostics.[173,175]

1.03.2.2.1.4 Proteomic networks and disease nodes

Besides individual protein analysis, implementation of quantitative global proteomic MS profiling of patient iPSC-derived cells, over longitudinal culture periods, has the potential to reveal the dynamic dysregulation of protein networks, directly reveal which nodes in the network are more affected in disease, and identifying the most common alterations across similar diseases. Combined proteomic and pharmacological profiling of patient iPSC-derived neuronal models is an innovative approach to discover network-targeting chemical probes that unveil genotype-specific vulnerability in patient-only cells. That is, to dissect causality and direct link between disease-network nodes and neuropathology, pharmacological tools have the potential to perturb biological pathways in a temporally conditional manner to confirm altered vulnerability, contributing to the dissection of molecular pathways affected in disease. Based on recent studies with neurodegenerative iPSC-derived models,[41,137–140,157,176] patient-derived neurons do reveal dysregulation of specific proteostasis pathways. When further disrupted, by adding pathway-specific "insults," disease neurons' viability dramatically decreases, corroborating pathway involvement in disease and the validity of this research approach.[41,92,164] Development of neuronal stress probes toolboxes might be an efficient and cost-effective manner of validating large sets of proteomic data, to reveal molecular targets in disease.

Overall, phenotypic, disease-specific assays screened against focused libraries allow the entire proteome to be interrogated in a human cell context, to discover candidate therapeutic targets and representing a powerful paradigm shift in drug discovery (**Fig. 4**).

1.03.2.2.2 Integrative approaches across cell models and patient clinicopathological data

With the increasing applicability for iPSC-derived models of disease, it has become critical to quality control the emerging data. If robust disease-relevant cellular phenotypes can routinely be assessed in patient-derived in vitro cell models, it might just become feasible to use these biochemical imaging and physiological "pipelines" as new diagnostic tools for preclinical assessment and guidance of clinical trials.[133,134] Undoubtedly, these efforts will require integrative approaches for data interpretation in the context of clinicopathological data (**Figs. 2** and **4**).

A growing effort has been putting resources into increasing volunteer-based patient cohorts and building patient-iPSC line banks (e.g., NYSCF Research Institute Stem Cell Repository, StemBANCC, HipSci Consortium, Stem Cells Network DPUK Cohorts),[42–44] in order to work with individuals who have been extensively phenotyped by sophisticated clinical, psychometric assessments and imaging.[42,177] In a number of cases, these cohorts include quantitative neuroimaging measurements, fluid biomarker sampling, and, in many cases, patients who have agreed to brain donation. This rich set of clinical data will provide an invaluable context

in which to interpret findings from the iPSC model experiments (Fig. 2). Conversely, emerging disease biomarkers related to specific pathophysiological processes have been corroborated by various biomarker-autopsy correlation studies. Examples include increased uptake of amyloid-specific tracers associated with postmortem fibrillar Aβ deposits in AD patients; increase in tau and phospho-tau burden associated with neurofibrillary tau tangle burden at autopsy of AD and FTD cases; and specific brain areas atrophy on live patients' MRI (magnetic resonance imaging) correlated with neuron loss and tau immunostaining burden at autopsy in AD and FTD. For neurodegenerative tauopathies, ante-mortem MRI and PET scans increasingly report on disruption of brain morphology, (hypo)metabolism, and increased uptake of tau PET tracers often overlapping and correlated with tau inclusions burden at autopsy.[120,133,134,178–180] These promising results represent remarkably powerful methods of diagnosis, even presymptom onset, in living patients. Together with longitudinal clinical follow-up and postmortem neuropathology, this sets the stage for comparison and validation of data from patient iPSC-derived neuronal models that also report on early disruption of molecular pathways and cellular events preonset of disease (Fig. 2). Such integrative approaches have the power to elucidate genotype–phenotype variation and anatomical specificity among diseases, offering powerful guidance for phenotypic rescuing therapeutic targets, and clinical trials design.

Conceptually, testing experimental therapeutics in patient-specific iPSC models provides a powerful proof-of-concept for correlating physiologically relevant models of human disease to preexisting disease biomarkers (e.g., AD[133,134]), establishing the role of iPSC-based models in drug discovery, driven by human disease biology at each step of the process.

1.03.2.3 Human iPSC Models as Potential Preclinical Alternatives to Animal Models

Despite large investments in drug-discovery research, the overall success rate of pharmaceutical drug development for many diseases remains low. This has been debated furiously over the past decade and reviewed extensively elsewhere (e.g., [181]). Within AstraZeneca for example, there has been extensive study of the success rate of programs and implementation of the so-called 5R-criteria to increase the probability of success at each stage of the drug-discovery process.[182] Historically, the primary explanations for the high failure rate of drugs in the clinic were due to toxicology and safety issues but, thanks to the implementation of additional assays for toxicological screening and rigorous optimization of the properties of a molecule earlier in the drug-discovery process, this has become less of a problem. Instead, efficacy of the new therapeutic in the patient is now the main issue. Prominent explanations for this include the use of inappropriate screening assays which do not fully represent the disease state of the target, especially in neuroscience, the (mis)use of animal models, and the wrong patients being selected for the trial, which together contribute to the large gap in translation from bench to clinic.[152,153,183] Traditional drug-discovery approaches use biochemical (in vitro) and animal or human immortalized cell culture models (ex vivo or in cellulo) for initial screening of small-molecule libraries. Animal models are then employed for in vivo testing of drug delivery to target organs and cells, drug efficacy, and toxicity. The "human context" has typically only been implemented late in the discovery process, often during clinical trials, after lead compounds have been identified and thoroughly tested in animal models. Approaches using human stem cell disease models represent a paradigm shift that introduces the "human context" early in the drug-discovery pipeline. It also contributes to "personalized therapeutics/precision medicine" development as increasing patient-specific disease understanding can help select the correct patients for a trial and also predict treatment response (Fig. 4).[20,49,147,184,185]

In the case of CNS disorders, although rodent and human nervous systems share a number of evolutionary conserved properties, there are also critical differences in terms of neurogenesis and neural patterning that are critical when studying human diseases. Moreover, specific types of neurons that are affected in disease (e.g., von Economo neurons in FTD) are found only in humans and other large mammals and not in rodents, clearly highlighting the potential advantage of human iPSC-derived neuronal cultures if appropriate differentiation protocols can be created.[62,127,186–188] Additionally, many aspects of gene epigenetic regulation, particularly relevant in polygenic psychiatric diseases, are unique to the human genome and cannot be adequately investigated in nonhuman systems.[189,190] Finally, the immortalization process of animal or human cells to derive stable cell lines (e.g., HeLa, HEK293, and SH-SY5Y cells) interferes with the normal mechanisms of cell differentiation, and therefore the use of nonimmortalized, iPSC-differentiated cells allows access to a more physiologically relevant state with "human cell context."[48,50]

Replacement of animal-based studies has been strongly pursued also in toxicology studies, which are required to determine the effect of a substance on a tissue/organ at a particular concentration. This allows the determination of safety margins when selecting doses for human trials of a new therapeutic. Studies that convert in vitro results, generated at the tissue, cell, or subcellular level, into dose–response or potency information relating to an organism, that is, the human body (in vitro to in vivo extrapolation), have relied on stem-cell-derived generation of three-dimensional (3D) cultures that closely resemble human tissues/organs in silico, for not only disease studies but also toxicology studies.[191–193] Moreover, early in vitro toxicity testing using iPSC and differentiated specific cell types, such as hepatocytes, cardiomyocytes, neurons, or intestinal tissue, will serve as a cost-effective alternative to traditional in vivo testing (Table 1).[6,194]

Recent examples of successful FDA-approved drug discovery, in disease areas where animal models were deemed inadequate to accurately test efficacy (e.g., Kalydeco for cystic fibrosis[195]), combined with the uncertainties of modeling psychiatric disorders in animals,[153] provide strong motivation to pursue human stem cell-based drug discovery. Large-scale chemical screens in human iPSC models, which provide direct readouts of pathogenicity in vitro and an acceleration of the screening procedure relative to animal models, can lead to the identification of lead compounds that modulate disease-specific molecular processes, in a human cellular context (Table 1). However, the reality might as well be that due to the complexity of disease mechanisms in whole organisms, only a small percentage of initially promising small chemicals may qualify for application in humans. In other words, with

potential for increasing translational pharmacology and accelerate the overall drug development process, these ex-vivo systems may be a powerful step to determine efficacy prior to commencing clinical trials,[147] but it is probable that maximum drug-discovery success could lie within a cooperation between human iPSC-derived cell models and posterior animal testing. At present, validation of drug candidates identified via iPSC chemical screens does not obviate the relevance provided by downstream characterization and validation in animal models (Fig. 1).

1.03.3 Potential Roles for iPSC Models in Drug Development Pipeline

Though human patient-derived iPSC models provide ideal disease-relevant context in which to identify modifying agents of disease-related phenotypes, these can only truly contribute to drug screening if these stem cell-based cultures can be adapted for HTS-compatible formats. Moving beyond the testing of individual drugs, as described in a number of published studies to date, large-scale, HTS has only recently begun to be performed with stem-cell-derived cells. As summarized by the examples from CNS disorders and others in Table 1, gathered evidence so far indicates strong potential for screens to be performed at multiple stages of human cell development with stem cell models.

Two key, interrelated concepts when contemplating the use of human iPSC models in the context of drug screening are: (1) the disease biology supporting the relevance of a particular ex vivo cellular phenotype and (2) the translatability of the phenotypes being measured. These are not concepts unique to the use of human iPSC models but are nonetheless important to address considering the still nascent stage of the use of iPSC models in drug discovery.

In the case of disease relevance, while many cellular phenotypes could in principle be used to support drug-discovery efforts, demonstration of the relevance and specificity of a particular phenotype to the underling disease biology often requires data integration at multiple levels and knowledge that, for many diseases, is presently unknown. For example, since there are only symptomatic treatments of most psychiatric disorders, definitive knowledge of a disease-modifying pathway does not currently exist (but optimistically will in the future). Ultimately, the demonstration of the relevance of the particular phenotype and novel mechanism is only achievable through first-in-human clinical trials. Here, while conceptually powerful, even genetic data for the effect of gain- and loss-of-function mutations in an allelic series providing strong correlative validation of a particular target still requires demonstration that a therapeutic agent can mimic the effect of a protective allele or reverse the effect of a deleterious allele.

In the case of translatability of the phenotypes being measured, a critical question is whether a particular molecular mechanism modulated ex vivo will have the same biological effects when modulated in an in vivo context. With the use of patient-derived models the feasibility of the translation of the specific molecular marker being analyzed, be it an antibody or specific mRNA transcript, is more straightforward than redeveloping probes to measure the human homolog of a rodent or other model system. In many cases, new therapeutic modalities that are being developed will likely benefit from being optimized in the context of human biology. This includes antibodies that target protein–protein interactions, antisense oligonucleotides, and most of all gene editing using CRISPR/Cas9 and related technologies.

1.03.3.1 Examples of CNS-Focused iPSC Drug-Discovery Screening

With the two concepts of disease relevance and translatability in mind, below we summarize specific examples using cases of CNS and peripheral nervous system disorders to highlight ongoing technical approaches to novel therapeutic discovery using human iPSC models.

Landmark studies have highlighted important methodological considerations for investigation of CNS disorders with iPSCs, in particular as we consider these cells for HTS where the assays need to be relevant, robust, and reproducible to enable the more classical design-test-iterate process of early drug discovery.[77] Fortunately, parallel advances in automated microscopy and high-content imaging technologies now allow single-cell and subcellular level analysis of phenotypes with increased throughput in image acquisition, adaptable to iPSC-derived neuronal cell cultures.[196–198] Also, increased sophistication and throughput of computational methods for analysis of large imaging files with elevated number of parameters enables automated quantification of a diverse range of cellular features.[196,199] Furthermore, advances have been made in the generation of robust means to derive NPCs and adapt their use for HTS/HCS, functional genomics, and proteomics.[200–202]

1.03.3.1.1 Psychiatric disorder model screening

One of the first, and still largest scale that has been publicly disclosed, phenotypic screens relevant to multiple psychiatric and degenerative disorders is that of McNeish et al.[89] that aimed to identify novel classes of AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) glutamate receptor potentiators, involving both mouse and human stem cell-derived neuronal cultures subject to a calcium influx assay performed with a fluorimetric imaging plate reader (FLIPR) assay (Table 1). Given the importance of glutamatergic neurotransmission to multiple areas of nervous system plasticity and the challenge of faithfully accessing the biology of ion channels that are composed of multiple subunits and regulator subunits, this work reflects the potential for disease biology-relevant chemical screening with stem cell-derived neurons. That the throughput achieved enabled screening of over 2 million compounds further demonstrates the scalability of such assays.

Rather than targeting a specific neurotransmitter system, but with the goal of identifying novel proneurogenic compounds, McLaren et al.[172] reported on a screen of ~1000 compounds for their ability to enhance proliferation and/or viability of human

iPSC-derived NPCs using a bioluminescence-based assay (Table 1). The compounds identified from this screen hold potential both as research tools to aid in the expansion of NPC to large-scale necessary for HTS and leads for developing proneurogenic compounds that may be relevant to a range of psychiatric and degenerative disorders.

As an example of screening for small molecules that directly target a genetic cause of a psychiatric disorder, HTS for compounds capable of restoring expression of the silenced *FMR1* gene encoding the Fragile X mental retardation protein (FMRP) that causes Fragile X syndrome has recently been reported. Using a homogenous, time-resolved fluorescence resonance energy transfer (FRET) assay to measure FMRP levels in a high-density, 1536-well plate format the first of these from Kumari et al.[96] reported the identification of six structurally diverse compounds out of 5000 screened that were capable of enhancing FMRP expression. As an alternative screening methodology, using high-content imaging, Kaufmann et al.[97] screened over 50,000 compounds yielding a small number of compounds (structures not reported) also capable of reactivating FMRP expression (Table 1). While in both cases the level of FMRP expression obtained was fairly modest and may not be sufficient to rescue neurodevelopmental phenotypes and ultimately be effective in vivo,[39] nonetheless the success of these screening efforts demonstrate the feasibility of screening for additional FMRP enhancers using a range of methodologies as is now underway in both academic laboratories and industry.

An alternative approach to discovering therapeutic targets for psychiatric disorders than the focus on a specific target like an ion channel or gene expression states, as in the case of FXS screens, has been to use phenotypic assays to target the function of entire pathways. For example, the WNT signaling pathway is a key regulator of the nervous system development and plasticity and is modulated by a number of clinically used drugs, including the mood stabilizers lithium and valproate.[203] Dysregulation of WNT signaling has been implicated in the etiology of multiple psychiatric disorders, most notably autism spectrum disorders where strong genetic evidence implicates disruption of the function of genes such as *CHD8* encoding a chromatin remodeling enzyme involved in WNT signaling, and *CTNNB1* encoding β-catenin that interacts with CHD8 complexes.[204] On the basis of these findings, the discovery of novel targets for CNS-selective modulation of WNT/GSK3 signaling has the potential to be relevant for a range of disorders. To this end, Zhao et al. recently described a small-molecule screen for modulators of the WNT/β-catenin signaling pathway in human iPSC-derived NPCs, based on a stably integrated HTS-compatible, luciferase-based WNT pathway reporter system[40,48] (Table 1). After development and optimization for a 384-well plate format, this assay was used to screen a collection of ~1500 compounds from a library of US Food and Drug Administration (FDA)-approved drugs and known bioactive compounds, leading to the identification of a number of both known and novel small-molecule regulators of WNT signaling in human NPCs, including enhancers of lithium. Further optimization of this assay to an automated format has enabled screening of over 300,000 compounds for novel activators and inhibitors of WNT signaling demonstrating the feasibility to perform large-scale screens with human iPSC-derived cells in pathway-directed assays.

1.03.3.1.2 Neurodegenerative disorder model screening

One of the greatest opportunities afforded by human iPSC technology relates to the opportunity to investigate the early steps of disease pathogenesis. For this reason, and owing to the fact that in many cases the relevant cell types affected by the disease pathophysiology are often better understood than in psychiatric disorders, the use of iPSC models for drug discovery in neurodegenerative disorders has begun to see significant attention.

For example, aberrant tau accumulation and PTMs along with dysregulation of proteostasis pathways have now been reported in the context of iPSC models of tauopathies.[41,137–140,157,205] Additional examples of disease-relevant phenotypes have also been reported in iPSC models of multiple other genetic forms of neurodegeneration, including ALS,[90,206] AD,[92,150,207,208] and PD.[209–211] Collectively these observations set the stage for advancing therapeutic screens based upon specific disease hypotheses that are beginning to be realized. For example, Silva et al.[41] demonstrated the ability of mTORC1 inhibition, upon rapamycin treatment, to cause tau clearance through autophagy and rescue the enhanced stress vulnerability of iPSC-derived neurons with an A152T tau variant associated with FTD. Another example of rescuing FTD patient iPSC-derived neuronal phenotypes with pharmacological agents is the demonstration by Lee et al., in the context of a premature stop mutation (S116X) in the *GRN* gene-encoding progranulin (PGRN), that 1-[2-(2-tert-butyl-5-methylphenoxy)-ethyl]-3-methylpiperidine (MPEP) decreases Sortilin (SORT1) expression and rescues extracellular PGRN secretion.[212] Using iPSC-derived cortical neurons from PGRN-FTD subjects with the same mutation, Almeida et al.[164] provided proof-of-concept that *GRN* mRNA and PGRN protein levels can be upregulated through treatment with suberoylanilide hydroxamic acid, a histone deacetylase inhibitor. Taken together, these data provide concrete examples for the potential of FTD iPSC-derived models for novel target discovery.

In the context of the motor neuron disorder ALS, Egawa et al.[90] generated molecularly defined motor neuron subtypes from a panel of familial ALS patients' iPSCs with mutations (Q343R, M337V, G298S) in the Tar DNA-binding protein-43 (TDP-43), which caused aberrant, insoluble, cytosolic aggregates of TDP-43 along with aberrant neurite outgrowth. Screening a small collection of four compounds revealed that anacardic acid, a compound with histone acetyltransferase inhibitory activity among other effects, rescued abnormal ALS motor neuron phenotypes. Based on results from an initial large-scale screen of motor neurons from control and mutant SOD1 (G93A) mouse ESCs (Table 1), Yang et al.[93] demonstrated that the multikinase inhibitor kenpaullone prolonged survival of human iPSC-derived motor neurons with both SOD1 (L144F) and TDP-43 (M337V) mutations, while a second compound that interestingly failed clinical trials in ALS, dexpramipexole, was inactive, and a third compound, olesoxime, that also failed ALS clinical trails was only able to mildly rescue SOD1 (L144F) but not TDP-43 (M337V) survival. Instead of a survival phenotype in ALS, Burkhardt et al.[94] turned to a high-content chemical screen of over 1700 compounds based upon TDP-43 aggregate detection in iPSC-derived motor neuron cultures from sporadic ALS patients (Table 1). This screen led to the identification of the FDA-approved, cardiac glycosides drugs, including digoxin, lanatoside C, and proscillaridin A, two inhibitors of

cyclin-dependent kinase (CDK) inhibitors (flavopiridol, Cdk1/2 inhibitor III), four c-Jun N-terminal kinase (JNK) inhibitors (Incedis-01, BP-11767, NSN01, NSN02), and the natural product triptolide, all capable of reducing TDP-43 aggregates through mechanisms not yet well understood.

Of further note, while not a HTS *per se*, a notable example of the use of iPSC for potential novel therapeutic discovery is the work of Wainger et al. in the context of ALS that identified a hyperexcitable phenotype in ALS patient iPSC-derived motor neuron subtypes, which could be reversed by the existing antiepileptic drug retigabine (ezogabine; Potiga).[95] Here the use of detailed electrophysiology drove the selection of a pharmacological agent for subsequent clinical investigation.

1.03.3.1.3 Pain and sensory neuron disease model screening

Outside of the CNS, pioneering work from the laboratory of Dr. Lorenz Studer and colleagues demonstrated the ability of conduct a screen of over 6000 small molecules in patient-derived neural crest precursor cells for the ability to rescue expression of the *IKBKAP* gene that is disrupted in the rare neurogenetic disorder familial dysautonomia.[91] This screen led to identification of multiple agents targeting cAMP/protein kinase A activity and phosphorylation of the transcription factor CREB that plays a key role in gene transcription and neuroplasticity. Additionally, studies from Pfizer on iPSC-derived peripheral sensory neurons from patients with inherited erythromelalgia, caused by gain-of-function mutations in the *SCN9A* gene encoding the sodium channel Nav1.7, have also demonstrated the utility of iPSC models for drug discovery in the area of pain disorders.[213] Here, the clinical severity presented by patients could be correlated with ex vivo hyperexcitability of neurons, and this altered electrophysiological phenotype could be suppressed by Nav1.7 antagonists providing proof-of-concept of the therapeutic target for a sensory neuron disorder.

1.03.3.2 Quantitative Cellular Pharmacology

Besides the discovery of novel biologically active agents through HTS, another valuable use for human iPSC models in drug discovery is their use in quantitative cellular pharmacology. Here, the notion is to be able to rigorously assess target engagement in a physiologically and disease relevant cellular system, in order to define pharmacodynamic markers that are essential for successful translational studies.[162]

The contemporary approach to identifying lead molecules for drug discovery is based on selecting a target, establishing an in vitro screening assay and then identifying a molecule that interacts with that target, oftentimes through HTS. In many cases, in order to support high-throughput screening platforms, isolated recombinant proteins or even fragments of proteins are used for the screening assay. It is well recognized that isolated proteins or a protein fragment is far removed from the native drug target in a relevant cellular context, and from the molecular and physicochemical environment in which it resides. There are many examples of this disconnect between the pharmacological properties of drugs in these recombinant test systems when compared to the effects of drugs in native systems. The studies of Dr. Peter Sorger and colleagues exemplify this disconnect where drugs acting on components of the PI3K/AKT/mTOR pathway show discrepant dose–response curves and unusual pharmacological properties in native systems compared to activities of recombinant system.[214] Moreover, studies by McDonald and coworkers have shown that AKT signaling complexes associated with the plasma membrane are regulated by drugs such as PI3K inhibitors with high potency, whereas complexes in the nuclear compartment are not.[215] Human iPSC-derived neurons or glia potentially provide access to the native target in physiologically relevant protein complexes without the need for overexpression in a cellular context that may not model the native context appropriately. As such, iPSC-based screening assays promise to provide a more relevant approach as either a primary or secondary screening platform for the identification and characterization of CNS active drugs, particularly with advances in high-throughput generation of cultures of defined neuronal subtypes.[200,202]

These considerations are particularly relevant to CNS targets, many of which are cell-surface receptors or ion channels, often within large protein/lipid complexes, highly regulated by cellular activity and sensitive to the depolarization state of the cell. An interesting example is provided by the NMDA receptor, which is a heteropentameric ligand-gated ion channel of high interest as a target for the treatment of several neuropsychiatric disorders. Recombinant NMDA receptor complexes are extremely difficult to stably express in cell lines suitable for drug screening, at least in part due to their high calcium conductance. Human iPSC-derived neurons can express functional NMDA receptors that can be characterized electrophysiologically and are amenable to quantitative pharmacological assessment. Zhang et al.[216] have shown that the NMDA receptor currents in iPSC-derived neurons are consistent with GRIN2B-containing receptors and are specifically phosphorylated by FYN kinase, providing a platform for screening novel modulators of receptor function. Human stem cells can also provide a platform for the expression of recombinant human targets. For example, using the pluripotent cell line NTERA-2, ionotropic GABA and glycine receptors were successfully expressed as stable cell lines.[217] These receptors have been studied in recombinant systems at the screening level; however, these engineered systems lack the relevant neuronal environment and are limited by the restricted number of receptor subunits that can be coexpressed. Expression in a human iPSC-derived cell system combined with fluorescence imaging provides a potential high-content system amenable to quantitative pharmacological analysis and more closely modeling the native system.

1.03.3.2.1 Advances Enabling Novel Assay Development and Target Validation

Although only a limited number of large-scale screens for novel therapeutic agents have been performed to date (**Table 1**), a number of technical and conceptual advances on the horizon make it highly likely that the number of therapeutic screening efforts utilizing

human iPSC models will continue to expand. These efforts will expand from the beginning of the drug-discovery process involving the identification of novel targets and lead compounds, all the way through the optimization of development candidates for in vivo studies in humans.

A major driver for these efforts is likely to entail the use of CRISPR/Cas9 and related genome-editing techniques for the creation of isogenic cell models to aid in the understanding of genotype–phenotype correlations and the basic function of genes.[218,219] Here, matched sets of isogenic controls will reduce the sample size needed to associate a particular phenotype with a specific genetic alteration. However, the potential for clonal variation and off-target effects of genome-editing process still ideally requires that multiple clones be analyzed.[49] In addition to editing of the genome, adaptations of the CRISPR/Cas9 system are also enabling site-specific modulation of both the epigenome, through recruitment of epigenetic regulatory enzymes, and transcriptional regulation through the fusion of Cas9 to either transcriptional repressor domains for CRISPR inhibition (CRISPRi) or transcriptional activators domains for CRISPR activation (CRISPRa).[220,221] These functional genomic and epigenomic tools, in conjunction with patient-derived iPSC models, hold much promise for creation of innovative tools to assist in therapeutic target identification and validation. The future creation of a complete collection of human iPSC gene knockout (or overexpression) lines using genome-editing techniques will rapidly advance the systematic comparison of genotypes–phenotypes and aid in the performance of "synthetic lethal" and other functional genomic screens currently only possible in model organisms or through pooled CRISPR/Cas screening approaches that are emerging.[222]

Techniques of genome editing also enable the creation of innovative assays for use in drug screening by "tagging" promoters for the creation of endogenous reporter genes or reporter proteins without the need to express them as transgenes, enabling the investigation of physiologically relevant protein complexes with minimized risk of altering their composition and stoichiometry. For example, iPSC lineage-specific reporters for MAP2 (neural lineage specific) or GFAP (astrocyte lineage specific) gene expression have been generated through the targeting of NanoLuc-HaloTag construct to the 3′-prime end of genes of interest to allow normal levels of expression of the endogenous genes with facile detection of protein expression in both live cells for kinetic studies and fixed cells through the luciferase or HaloTag reporters.[223] The near future is bound to provide a suite of molecular and cellular tools for rapid and inexpensive generation of HTS-compatible assays in human iPSC models customized for each disease area.

1.03.3.2.2 Toxicology and Drug Metabolism

There has been considerable effort to establish iPSC-derived cellular models to inform on potential toxicity of drug candidates.[20–34,49,224,225] While a comprehensive review of this area is beyond the scope of the current article, there are a number of applications that are particularly relevant to CNS drug discovery. Through a combination of the nature of many CNS drug targets and the requirement to produce compounds with physicochemical properties consistent with brain exposure, cardiotoxicity has been a major problem in CNS drug discovery. Most approaches to this problem have studied the electrophysiological responses to drugs in iPSC-derived cardiomyocytes.[20,21,231] The use of human iPSC-derived cardiomyocytes in this context provides several major advantages, namely, the expression of a near full repertoire of cardiac ion channels modulating cardiac function and the ability to derive cells from risk genotypes for screening. Patient iPSC-derived cardiomyocytes are increasingly used to evaluate cardiac risk across genotypes and specific syndromes including long QT syndrome and various cardiomyopathies. Recent studies by AstraZeneca using a range of 51 cardiotoxic compounds demonstrated 70% specificity and greater than 85% sensitivity of the screening method for predicting risk, similar to data produced by other investigators.

In addition to cardiomyocytes, iPSC-derived hepatocytes[22,232] and hematopoietic cells have also been used extensively for ex vivo toxicity testing.[49,224] Human hepatocytes and liver microsomal preparations are the mainstay of ex vivo systems used to generate primary predictions of drug metabolism in humans. These methods are now, or could well be, supplemented by several novel iPSC-based methods.[22,193] The potential to induce the expression of drug-metabolizing enzymes, particularly cytochrome P450s, in the liver and intestine can be modeled in iPSC-derived hepatocytes and enterocytes,[226] and a variety of methods have been employed to derive iPSC-derived cell systems for studying drug transport and diffusion,[227] including models of the blood–brain barrier.[225]

1.03.4 Patient Stratification and Disease Diagnosis

Once patient-specific iPSCs were demonstrated as feasible by Yamanaka and colleagues, the concept of "clinical trials in a dish" was immediately recognized as a potential strategy for the identification of subpopulations of patients with a particular disease that may respond to a particular therapeutic agent[49] (**Fig. 4**). Furthermore, patient-specific iPSC generation has also been recognized as a potential means to generate cellular signatures in response to diverse pharmacological or functional genomic perturbations to create diagnostic subgroups of patients.[48,49,228] Together, these concepts have important implications for the future of medicine that have been referred to, appropriately so if they can come to fruition, as "game changing."[49]

1.03.4.1 iPSCs to Predict Drug Responders and Nonresponders

The realization of using iPSC-derived cellular models for patient stratification requires overcoming the dual obstacles of the generation of sufficiently large patient cohort-derived iPSCs to be able to identify responders and nonresponders, and the development of

molecular or cellular biomarkers that have sufficient predictive power and accuracy to translate between ex vivo assays and in vivo treatment of diseases. For diseases where efficacy in the clinic is poorly predicted by existing animal models due to poor evolutionarily conserved biology, for example where causal genetic variation is located in noncoding regions of the genome, or where tissues like the brain are highly elaborated comparing rodents to humans, this strategy may provide an alternative path forward to gain confidence in efficacy. Furthermore, by identifying ex vivo responders based upon the response of patient-specific iPSCs models prior to a Phase II trial, the actual clinical trial itself could be performed with subjects predicted to respond to the drug, based on their specific iPSC-based results. Theoretically, this would increase the power of studies to detect drug efficacy in smaller patient populations and minimize the negative effects of exposing patients to ineffective treatments. While this has yet to be achieved, conceptually the cost and timeline of generation of such a cohort is relatively insignificant compared to the costs and setbacks of a failed Phase II or Phase III trial.

Additionally, such ex vivo patient iPSC-derived cellular responses could be used in advance of patient treatment for already approved drugs where patient response is suboptimal. For example, being able to predict which subjects respond to the mood stabilizer lithium on the basis of iPSC-derived neuronal cell assays in which patients are classified into responder and nonresponder subjects could greatly improve the standard of care in bipolar disorder since roughly half of patients do not respond to this treatment. In the case of lithium, to date such approaches have only been performed retrospectively with the observation of a correlation between clinical response and the ability to suppress a hyperexcitability phenotype in hippocampal-like neurons in lithium responders- and not nonresponders-derived iPSC models.[82] Besides performing such studies prospectively, the sample size analyzed will need to be scaled appropriately to represent the heterogeneity of the disorder. This approach could also be used, for example, to dissect the relationship between gene epigenetic status and drug response (e.g., *FMR1* methylation status and mGluR5 antagonist response in Fragile X syndrome).[229] Most important, assuming faithful recapitulation of the gene epigenetic status in vitro and in vivo in the brain, pretesting of compounds in patient iPSC-derived neuronal cells may help improve prediction of clinical response.

With time, the systematic generation of ex vivo response data in large cohorts for different classes of existing medicines, as well as novel experimental therapeutics, may ultimately allow the discovery of predictive rules for future development of medicines when performed in conjunction with generating full genome sequences and tracking of individuals longitudinally using electronic health records. At the same time, by focusing on the response of individual patients, the use of patient-specific iPSC models and ex vivo drug response provides a practical realization of the concepts of personalized and precision medicine.[160]

Overall, the prediction of whether patients will respond to a particular pharmacological agent based upon ex vivo analysis of iPSC-derived cellular phenotypes, alone or in combination with genetic information, has the potential to impact how modern preclinical studies and clinical trials are performed (**Fig. 4**). While current regulatory policies prevent the replacement of standard clinical trials with an "iPSC clinical trial," it may be feasible in the future to establish such a framework if sufficient prospective predictions of drug response and efficacy are obtained for challenging disorders.[49] Such studies would not obviate the need for careful safety and toxicology studies, which themselves are beginning to benefit from using patient-specific iPSC models,[230] as mentioned earlier for cardiotoxicity,[231] hepatoxicity,[232] and neurotoxicity,[231,233] creating new avenues to demonstrate the efficacy of medicines with the potential for eliminating ineffective ones earlier on in the development process.

1.03.4.2 Role of iPSC Disease Models in Clinical Diagnosis and Prognosis

While the fundamental basis of most current medicine is the treatment of disease symptoms once they manifest, the future of medicine will ideally focus on the development of highly effective, disease-modifying and preventative treatments, along with diagnostic methods that allow the identification of high-risk individuals. This will enable treatment to be initiated early, potentially at a time when it can be most effective, specifically for neurodegenerative disorders where prevention of neuronal cell death is crucial. While molecular and genetic diagnoses for certain disorders are increasingly possible given the availability of specific molecular assays, along with advances in human genome sequencing, many diseases lack precise molecular biomarkers and are polygenic in nature rendering a strict genetic diagnosis not feasible at present. For these collective reasons, beyond the prediction of whether patients will respond to a particular pharmacological agent based upon ex vivo analysis of iPSC-derived cellular phenotypes, there is increasing interest in the concept of generating ex vivo drug-response signatures to diagnose patients and group them into subgroups with the ultimate goal of being able to provide a prognosis (**Fig. 4**).

One strategy being employed to advance this concept is that of using a panel of cellular stressors to reveal susceptibility to disease pathophysiology. For example, using iPSC-derived neuronal models of tauopathy Silva et al.[41] has observed that coupled to dysregulation of tau and enhanced stress-inducible markers, neurons from FTD subjects show increased cell vulnerability to a panel of proteotoxic, excitotoxic, and mitochondrial stressor compounds. This enhanced neuronal vulnerability of neurons to stressors could be rescued upon CRISPR/Cas9-mediated targeting of the *MAPT* locus to knockout tau, demonstrating the causal link to a known pathogenic factor. Since the majority of cases of FTD are sporadic in nature and lack mutations in tau, the application of this panel of cell stressor could conceivably reveal if FTD cases without tau mutations show similar susceptibility. This diagnostic grouping of patients could then be used to predict mechanisms of tau-mediated pathogenesis in cases of sporadic FTD. Beyond assays of cellular viability, the generation of transcriptional signatures using multiplexed gene expression-based screening and proteomic signatures has tremendous potential as drug-response signatures if applied across cohorts of iPSC models.[166–168]

All said, it is still too early to determine whether iPSC models will have a major impact on diagnosis and prognosis of a particular disease. Certainly, iPSCs can be used to analyze the response of a particular cell to a therapeutic, but whether this would predict

a long-term beneficial effect in a human is not known. In terms of diagnosis it is possible that studies of iPSCs could play a role in tandem with other technologies, such as PET-imaging, peripheral blood, or cerebrospinal fluid analysis, to identify patients at very early stages of the disease and then monitor appropriate biomarkers in response to treatment (Fig. 4).

1.03.5 Challenges and Concluding Remarks

On account of a persistent disconnect between phenotypic-driven drug pharmacology from in vitro cellular models or in vivo animal models, and drug efficacy in human trials, the quest for optimized preclinical biological model systems, better predictive of clinical outcome, is a present and urgent challenge in drug discovery. Integral to this quest is the capacity of working with the *bona fide* human disease-relevant cells or tissue.[234,235]

While human iPSC-derived cellular models present promising avenues for pharmacological probes and drug discovery, there are still a number of limitations and challenges.[236] One general limitation is the fact that postmitotic cell types obtained through the directed differentiation of iPSCs are still relatively immature, based on a number of gene expression and physiological markers. This issue is particularly relevant for tissues with limited replicative turnover of cells, for example, the CNS where many cell types in the brain mature over an individual's lifetime. Possible strategies to circumvent this aspect and promote faster maturation and aging of, for example, neural cells in culture are being addressed.[36,237] Additionally, efforts to create 3D cultures of "organoids" with more physiological arrangements of cells into tissue-like structures are gaining traction.[238–240] Certainly assays relying on longer culturing periods and more complex architectures are likely to better capture features of mature cell types, but at the cost of diminished feasibility and scalability. Despite progress in identifying the developmental course of specific cell types, for example, neurons, glia,[241] and pancreatic β-cells,[242] reducing these to practical techniques for drug-discovery efforts still presents challenges.

At present, there is still a lack of robust methodology for reproducible, large-scale production of disease-relevant specific cell types, but current efforts are focused on promoting culture compatibility with HTS modalities, including high-content imaging, multidimensional signature-based screening, and in vitro network activity with multielectrode arrays.[6] These technologies are in active and remarkable development, as is the utility of patient-specific stem models.[35,50,62,90,209,243] Another simple, if very relevant and practical, limitation in human stem cell research for drug-discovery purposes is the relative high cost of cell culture media and supplements, along with the expertise required to reliably generate robust cultures. Together with low scalability for iPSC differentiation, many publications tend to describe and characterize only a minimum number of case and control lines, which can always be susceptible to artifacts introduced by subtle differences in cell line generation, and limited representation of genetically heterogeneous patient populations, particularly for complex, polygenic disorders. Then, it becomes critical for initial findings in small numbers of lines to be replicated in larger cohorts and in multiple lines from individual subjects, with efforts for data integration across genotypes, cell lines, and clinicopathological data, which is currently being addressed with urgency (Figs. 2 and 4).

Another point for consideration has to do with patient-derived cellular models that address mainly cell-autonomous aspects of disease, exploring phenotypes in individual cultured cells regardless of their *milieu*, and without a clear definition of their developmental stage. The concerning aspect is neglecting potentially relevant aspects of the tissue of interest that can certainly influence the outcome of therapeutic interventions. For example, cell-to-cell interactions among neuronal subtypes and glia, synaptic transmission between neurons, and the existence of complex neural networks that creates a circuitry known to be critical to high-order brain function and plasticity are challenging to faithfully mimic with ex vivo cellular models.[187,244] Nonetheless, even if a disease is most apparent at the network level, it does not necessarily follow that deficits will not be observed at the individual cell level. Along these lines, mixed cell populations that result from standard differentiation protocols that were initially considered a limitation might instead represent an opportunity to interrogate multiple cell types simultaneously without losing possible cell nonautonomous mechanisms of disease etiology. Complementary validation of phenotypes with other systems, premortem patient clinical data and postmortem disease pathology, should circumvent many of these concerns (Fig. 2).

In conclusion, in order to improve usefulness of human iPSC modeling for drug-discovery efforts, it is of prime importance to focus on standardization of protocols for iPSCs generation and differentiation,[245] define standards of disease phenotyping in terms of intra- and inter-individual variation, and include strict quality control parameters. The main driving force for advancing human iPSC-derived models in drug discovery will continue to be the concrete demonstration that these cellular systems can: (1) be effectively used to understand the molecular and cellular mechanisms of disease, and possibly the basis for selective cellular vulnerability seen in many diseases and (2) be employed in functional cellular and biochemical assays toward discovery of the next-generation therapeutic agents for the treatment and ultimately prevention of a myriad of human diseases.

1.04.1 Overview of Alzheimer's Disease (AD) Therapy and Diagnosis

Although we savor the promise of a new era of personalized medicine, much of today's drug prescribing is still "trial and error," with a success rate after treatment that is consequently modest. This approach, in addition to the serious medical consequences for the individual patients, has undoubted economic consequences for the healthcare system and the society as a whole. For most serious chronic diseases, early diagnosis and early intervention are two important aspects that are tightly intertwined. The lesson we learned in the cancer field is that an incorrect or delayed treatment decision may result in pathology dissemination with no or very low chances of cure and can even culminate in death. Even worse, for infectious diseases, delay in the recognition of infectiousness facilitates increased transmission.

The same awareness is being acquired in the field of Alzheimer's disease (AD). AD is a major public health problem affecting nearly 35 million patients worldwide with numbers projected to rise to 115.4 million by 2050. In 2013, an estimated 44.35 million people were living with dementia worldwide, predicted to be 75.62 million by 2030, and 135.46 million by 2050.[1] In addition,

with the rise in aging population in the developing countries, the proportion of patients with neurodegenerative diseases is also surging. The prevalence of AD ranges from 6.44% in south India to 4.86% in Shanghai, China to 3.92% in Sri Lanka, for populations above 65 years.[1] These challenges are exacerbated by the lack of effective treatments and by the fact that there is no widely available gold standard for diagnosis.

At present, no effective cure or prophylaxis exists for AD. Four cholinesterase (ChE) inhibitors (tacrine, rivastigmine, donepezil, and galantamine, in Fig. 1) and the *N*-methyl-D-aspartate (NMDA) antagonist memantine (Fig. 1) are the only drugs approved by the US Food and Drug Administration (FDA) and European Medicines Agency (EMA) for AD treatment. The ChE inhibitors were developed on the basis of the cholinergic hypothesis, which correlates the clinically observed cholinergic dysfunction (ie, marked degeneration of cholinergic neurons, loss of cholinergic transmission, and changes in ChE and choline acetyltransferase activity in the cerebral cortex and hippocampus) with the pathology. Memantine is an antagonist of glutamate NMDA receptors (NMDAR) with a peculiar mechanism of action: it preferentially blocks excessive extrasynaptic NMDAR activity while largely sparing the normal synaptic one.[2]

Unfortunately, both drug classes provide only symptomatic treatment, are modestly effective and offer limited temporary benefit, and do not alter the course of the disease.[2] Thus, a number of novel strategies aimed to modify the disease process have been developed. The major developments in this direction of the last two decades are the amyloid-β (Aβ)- and tau-based treatments, which could hold the key to curing AD in the near future. However, reduction of cognitive and functional decline and cortical neurodegeneration, through small molecules or immune-based therapeutics directed toward Aβ, has had little success so far. After focusing on anti-Aβ approaches for many years, the pharmaceutical industry is making major investments in programs designed to discover tau-based therapeutics. Progress has been limited, however, and few such drugs are in clinical development. Several other drugs with different mechanisms of action have been thoroughly investigated in preclinical studies, but most of them have failed to produce any result in the clinical scenario. This makes AD one of the most unsuccessful therapeutic areas of drug discovery,[3] but it also is of great opportunity.[4]

In the battle against this devastating disorder, the tremendous difficulty in developing effective drugs has been attributed to three main factors. First, despite significant advances in understanding the pathological and pathophysiological determinants of AD, such as Aβ, tau, neuroinflammation, oxidative stress, and synaptic dysfunction, we still lack a detailed understanding of the causal roles of these phenomena and the interactions between them. As a result, many potential targets have been identified but not yet validated, so we lack precise knowledge of those that can give rise to disease-modifying treatments.[5] Second, as with all drugs targeting the central nervous system (CNS), AD drugs must cross the blood–brain barrier (BBB) and reach their targets at a concentration sufficient to achieve the desired effect. Indeed, an estimated 98% of systemically administered small molecules do not possess the physicochemical properties required for optimal brain exposure.[6] Third, as for any chronic disease treatment for elderly people with multiple comorbidities and concomitant treatments, these drugs must not be toxic or prone to developing drug–drug interaction.[7]

Ideally, any pharmacological treatment should be timely and rely on an in-depth understanding of the disease biology and the drug's mechanism of action. Better understanding of the disease molecular roots, therefore, is essential, and early diagnosis combined with a comprehensive management strategy initiated early in the course of the cognitive decline will likely be the most effective method of controlling the progression of AD.[8] We are far from being there yet, but recent advances in molecular medicine and molecular diagnostics have given us sufficient confidence about the prospects of personalized medicine in AD.[9]

1.04.2 Diagnosis of AD

Currently, premortem diagnosis of AD relies on clinically documenting decline in memory, cognition, and function over time. However, pathology has already caused severe brain damage in individuals who are diagnosed in this way, as neurodegeneration is estimated to start 20–30 years before the first clinical symptoms become apparent.[10]

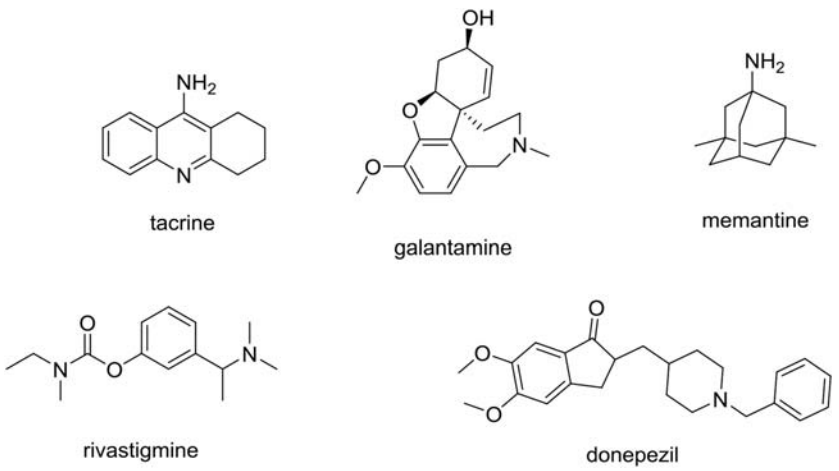

Fig. 1 Chemical structures of drugs approved for AD.

In addition, it is only by actually looking at the affected brain that a pathologist can be able to see exactly what occurred in specific areas and correlate it with the clinical picture of AD. The pathological diagnosis following biopsy or autopsy is thus the only definitive diagnosis of that patient's disease. Considering that brain biopsy is an invasive procedure with evident risk to the patient and also considering that there is currently no cure for AD, brain biopsy is very rarely performed because the risk outweighs the value. Thus, a definitive diagnosis of AD requires both clinically demonstrated dementia and the identification of the two pathological hallmarks of the disease, that is, senile plaques (SPs) and neurofibrillary tangles (NFTs), at autopsy.

In this scenario, researchers have been intensely working to find an easy and accurate way to diagnose AD before the clinical symptoms are evident. In other words, they have been looking for appropriate biomarkers. According to the Glossary provided by FDA, a biomarker is "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention."[11] In the years, several biomarkers have been identified such as serum low-density lipoprotein for cardiovascular diseases, fasting blood glucose level for diabetes, and, more recently, p53 gene and matrix metalloproteinase for cancer. In AD, a number of biomarkers, indicating the presence of pathology and AD-associated neuronal injury in vivo, have been developed. These biomarkers have strong potential not only for clinical use in etiologic determination, predictive prognosis, and monitoring disease progression but also for serving as an outcome measures in disease-modifying therapeutic trials.[12]

1.04.2.1 SPs and NFTs as Biomarkers for AD Diagnosis

Generally speaking, biomarkers can be broadly classified as "diagnostic" biomarkers, used to guide patient selection, and "pharmacodynamic" biomarkers to evaluate target engagement and drug's mechanism of action. Indeed, "diagnostic" biomarkers are indispensable in clinics for distinguishing individuals with prodromal signs of AD from healthy aging adults. Such biomarkers would be also ideal for differentiating AD from other types of dementia, such as mild cognitive impairment (MCI), or mixed forms of dementia, such as vascular dementia (VaD), frontotemporal lobe dementia, or Lewy body dementia. This is important because treatment for these diseases might differ. In parallel, "pharmacodynamic" biomarkers are considered vital at a preclinical level to confirm that a therapeutic agent will reach its intended target and have the desired biological effect. Thus, scientists have also committed to developing "pharmacodynamic" biomarkers to support AD clinical trials.

1.04.2.1.1 Background to the concept of AD biomarkers

There are currently no universally validated biomarkers for AD, but several potential candidates have been identified and began evaluating in preclinical and clinical models.

Biomarkers have been described using several modalities, including magnetic resonance imaging (MRI) scans of brain volume, imaging of cerebral Aβ deposition, studies of cerebral metabolism with fluoro-deoxy-D-glucose (FDG), genotyping of genetic polymorphisms known to be associated with disease risk, and quantification of specific proteins (total tau, phosphorylated tau, and the 42-amino acid form of Aβ ($A\beta_{42}$)) in the cerebrospinal fluid (CSF) or in the plasma.[13]

The best-established method for the detection and tracking of AD pathology relies on structural MRI measurements of regional and whole-brain atrophy. Several studies had demonstrated that structural MRI estimates of tissue damage or loss in characteristically vulnerable brain regions, such as hippocampus and entorhinal cortex, are predictive of progression of MCI to AD. Additionally, the clinical utility of MRI in differentiating AD from other pathologies, such as VaD or non-Alzheimer neurodegeneration, has been widely recognized. However, it has been pointed out that MRI evaluation is based on the assessment of volume change, which is a nonspecific, late feature in disease progression.[14]

Positron emission tomography (PET) is now well established for clinical use in neurodegenerative disorders. Measurements of cerebral glucose metabolism, by using [^{18}F]FDG PET, are of unequivocal value in early diagnosis, differential diagnosis, and the evaluation of drug treatment. In AD patients, neurodegeneration is accompanied by synaptic dysfunction, which is denoted by decreased [^{18}F]FDG uptake on PET scan. Studies consistently find increasing decline in the regional cerebral metabolic rate for glucose in the parietal and temporal cortex in clinically affected patients and in the frontal cortex and whole brain as the pathology becomes more severe.[14]

The search of risk genes that can help in diagnosis is also a very active field: at the moment, investigators have pinpointed three genes (amyloid precursor protein (*APP*), presenilin 1 (*PS1*, also known as *PSEN1*), and presenilin 2 (*PS2*, also known as *PSEN2*)) with rare variations that cause AD and several others that increase risk but do not guarantee that a person will develop the disease. Genetic testing for allele 4 of apolipoprotein E (*APOE-e4*), the strongest risk gene, is included in some clinical trials to identify participants at high risk for the disease. However, as diagnosis unaccompanied by cures is of questionable value, APOE-e4 testing is not currently recommended outside research settings. Nevertheless, it is conceivable that as more effective treatments are developed, genetic profiling will become a solid risk assessment tool for wider use.[10]

Since Alois Alzheimer's seminal report in 1907,[15] the scientific community has considered the defining and main pathological hallmarks of the disease to be extracellular Aβ deposits in SP and intracellular NFT, consisting of paired helical filaments (PHFs) of abnormally hyperphosphorylated tau protein. Of the possible AD biomarkers, SP and NFT are pathological hallmarks that should precede clinical symptoms by several years.[16] This peculiar feature makes in vivo imaging of Aβ and tau particularly suitable for diagnosing patients at risk and detecting AD before dementia occurs, that is, at an MCI stage.

1.04.2.1.2 Amyloid hypothesis supports Aβ as an AD biomarker

According to the "amyloid cascade hypothesis,"[17] the generation of Aβ would happen from the consecutive proteolysis of a large transmembrane protein, the APP, and it would aggregate or deposit in extracellular insoluble SP. β-Secretase produces the NH_2-terminus of Aβ, cleaving APP to provide a soluble version (β-APPs) and a 99-residue COOH-terminal fragment (C99) that remains membrane bound (Fig. 2). Alternatively, α-secretase cuts within the Aβ region to produce α-APPs and an 83-residue COOH-terminal fragment (C83). Both C99 and C83 are substrates for a second proteolytic enzyme, γ-secretase, which performs an unusual cut within the transmembrane domain to produce the amyloidogenic peptide Aβ from C99 and the not amyloidogenic one (p3) from C83 (Fig. 2). Proteolysis by γ-secretase is heterogeneous: most of the Aβ species produced is a 40-residue peptide ($Aβ_{40}$), whereas a small proportion is a 42-residue COOH-terminal variant ($Aβ_{42}$).[18]

The longer and more hydrophobic $Aβ_{42}$ is much more prone to fibril formation than $Aβ_{40}$, and even though $Aβ_{42}$ is a minor form of Aβ, it is the major Aβ species found in SP. In addition to $Aβ_{40}$ and $Aβ_{42}$, another isoform exists, the 38-residue peptide, whose levels in the CSF of AD patients resulted particularly elevated. Experimental evidences consolidated the "amyloid hypothesis"[17] showing that the amount of fibrillogenic Aβ is increased by the vast majority of mutations causing familial AD and that Aβ impairs neuronal functions in a variety of experimental models.[17] These Aβ peptides display an intrinsic tendency to aggregation: soluble Aβ is thought to undergo a conformational change to high β-sheet content, which renders it prone to aggregate into soluble oligomers, larger insoluble fibrils, and finally plaques. In this process, the fibrillogenic $Aβ_{42}$ isoform triggers the misfolding of other Aβ species. Currently, the nature of the neurotoxic Aβ species is very difficult to define because monomers, soluble oligomers, insoluble oligomers, and insoluble amyloid fibrils are expected to exist and accumulate in dynamic equilibrium in the brain. Initially, only Aβ deposited in plaques was assumed to be neurotoxic, but more recent findings suggest that soluble oligomers (amyloid β-derived diffusible ligands or ADDLs) might be the central players. The most widely held view is that aggregation of Aβ peptide in oligomers initiates the vicious cycle that ultimately leads to neuronal death and to the disruption of memory and cognitive functions that characterize AD.[19] This knowledge has been translated into anti-Aβ therapeutic strategies with putative disease-modifying effects, which are being tested in ongoing clinical trials.[20]

1.04.2.1.3 Tau hypothesis supports tau as an AD biomarker

NFTs are fibrillar aggregates constituted mainly by PHFs of the abnormal hyperphosphorylated form of tau protein. Tau is a neuronal microtubule-associated protein, which is involved in microtubule stabilization, and plays an important physiological

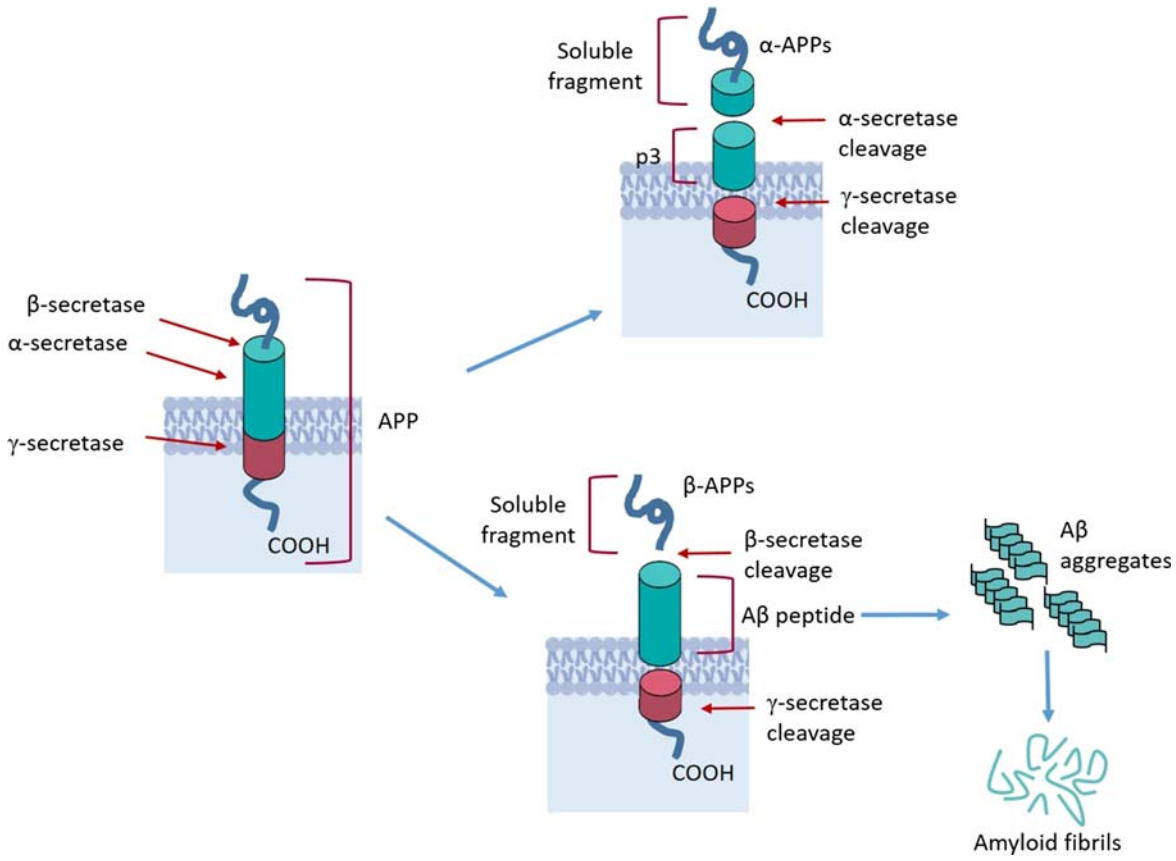

Fig. 2 Schematic depiction of the amyloid cascade.

role in microtubule dynamics and axonal transport. Tau functions can be regulated by its phosphorylation state at ~40 phosphorylatable sites, including serines, threonines, and tyrosines.[21] Tau is abnormally phosphorylated in the brain of AD patients, and there are strong evidences supporting that tau hyperphosphorylation is an early event in the development of neurofibrillary pathology. Tau hyperphosphorylation within the microtubule-binding domain results in its reduced ability to bind and stabilize microtubule assembly, leading to the disruption of axonal transport and ultimately to accelerate synaptic loss and cell death (Fig. 3). Dephosphorylation of tau isolated from NFT restores its ability to bind neuronal microtubules, indicating that the mechanisms regulating phosphorylation/dephosphorylation kinetics are perturbed in AD.[21]

Several kinases have been shown to be capable of phosphorylating tau in vitro, including proline-directed kinases such as mitogen-activated protein kinase 1 (also known as ERK2), glycogen synthase kinase-3 (GSK-3), and cyclin-dependent kinase 5 (CDK5), and non-proline-directed enzymes such as casein kinase 1, protein kinase A, and MAP/microtubule affinity-regulating kinase 1.[22] Recent studies have demonstrated that the majority of tau protein phosphorylation sites can be modified by GSK-3. Furthermore, overexpression of GSK-3 results in tau hyperphosphorylation and disrupted microtubules in transgenic (Tg) mice, suggesting a major role for this kinase enzyme as a validated therapeutic target for AD.[23]

In the hyperphosphorylated form, tau loses its affinity to microtubules and begins to self-assemble, resulting in the formation of PHF and straight filaments, which evolve to NFT.

1.04.2.1.4 Current perspectives

Importantly, the tremendous advances in molecular imaging have allowed us to image the autoptic biomarkers proposed by Dr. Alzheimer in living human brain. With the commercial availability of appropriate tracers, it is nowadays possible to visualize Aβ deposition noninvasively directly in AD patients.[24] The possibility of using amyloid as a biomarker allows, in turn, for the identification of preclinical cases as candidates for early intervention. It also allows for the effectiveness of antiamyloid therapy to be followed in individual patients.[24]

Although Aβ aggregates have been clearly associated with AD pathology,[17] there is still an active discussion as to whether their presence closely correlates with disease progression and severity. If it is not a universally validated biomarker, it has been unequivocally demonstrated that Aβ deposits accumulate in the brain of individuals at risk of developing AD. Consequently, Aβ imaging has not been approved for the diagnosis of AD or for staging disease progression but rather as a diagnostic method for the exclusion of AD in subjects that are cognitively impaired and Aβ PET-negative. Particularly, a negative amyloid scan substantially decreases the odds of having AD and can impact clinical decision-making or treatment. Conversely, in at-risk subjects, a positive amyloid scan is associated with a threefold greater risk of converting to dementia. Currently, it is being evaluated as a diagnostic tool for defining the preclinical stages of AD.[25]

In contrast to SP, the density and neocortical spread of NFT correlate with progressive neuronal degeneration and cognitive impairment,[26] thus potentially making imaging of NFT a more desirable biomarker for AD. Mounting evidence support the central role of tau in the pathogenesis of AD, delineating this protein as both a diagnostic and a therapeutic target.[27] For instance, imaging NFT may allow the early detection of disease, possibly even before the onset of cognitive symptoms, and presymptomatic staging. PET imaging of NFT, especially when done in conjunction with Aβ diagnosis, may also provide a means for distinguishing between AD and non-AD dementias: the presence of NFT and the absence of Aβ would provide support for the latter diagnosis, while the presence of both NFT and Aβ would support the former. In addition, as already pointed out for Aβ, it may allow to investigate the effect of disease-modifying therapies on tau aggregation.

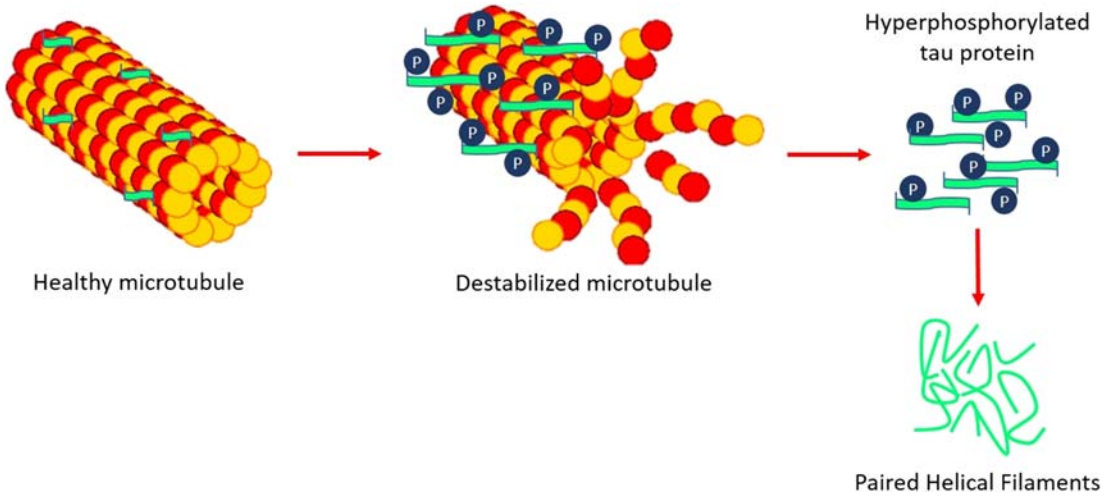

Fig. 3 Schematic depiction of tau cascade.

1.04.3 Development of PET Tracers for AD Diagnosis

Considering the strong premise that imaging of Aβ and tau might advance personalized medicine concepts in AD, provide clinical diagnosis, and ultimately lead to a cure, several small-molecule imaging probes directed to these two biomarkers have been developed and will be discussed in the following. Basically, they belong to two main classes, each of which will be reviewed in this article: PET radiotracers and fluorescent probes (see Section "Development of Fluorescent Probes as Innovative Imaging Agents for AD Diagnosis"). Thanks to their recent approval, PET radiotracers are more promising in terms of their translational applications. However, fluorescent probes hold tremendous capacity for enhancing the delivery of diagnostic procedures and, at the same time, promoting the development of truly innovative therapeutic and diagnostic tools.

PET scan with its widespread applications has emerged as an essential tool in the detection, staging, treatment monitoring, and identification of recurrent disease in a large number of maladies. At the same time, the application of PET had proved beneficial in accelerating drug discovery and development in several therapeutic areas.[28] PET is an imaging technique based on the visualization and quantification of positron-emitting radionuclides. The emitted positrons annihilate nearby electrons, thus generating two low-energy photons (511 keV), which are detected by detectors inserted in PET scanners. Examples of routinely used positron-emitting radionuclides are ^{11}C, ^{13}N, ^{15}O, ^{18}F, ^{44}Sc, ^{62}Cu, ^{64}Cu, ^{68}Ga, ^{72}As, ^{74}As, ^{76}Br, ^{82}Rb, ^{86}Y, ^{89}Zr, and ^{124}I.[29] The short-lived ^{11}C and ^{18}F are ideal for molecular imaging purposes. Given the exquisite sensitivity of PET scanners and the excellent tissue-penetrating properties of photons, radionuclide concentrations in the (sub)picomolar range generally suffice to produce high signal-to-noise ratios and provide useful images and quantitative information. Therefore, PET is routinely used in the clinics.[29]

PET imaging plays also a unique role in drug development because of its ability to quantify drug properties in vivo. The advantages of PET are that, by employing radiotracer principles, it is capable of quantitatively measuring a variety of in vivo processes without perturbing the biochemistry of systems that are easily saturable or operate at low capacity, such as receptors and enzymes.[30] For these reasons, PET is nowadays a key molecular imaging technique that has revolutionized the ability to image molecular processes in the brain.[31]

1.04.3.1 PET Tracers Approved for Aβ Plaque Imaging

Starting from 2000, in vivo imaging of brain amyloid using PET scanning has been extensively used in research studies of dementia.[32] With the passage of time, this methodology has moved rapidly from highly selected centers of excellence to full commercialization with three fluorinated Aβ PET tracers (florbetapir (**1**), Eli Lilly's Amyvid™; flutemetamol (**2**), GE Healthcare's Vizamyl™; florbetaben (**3**), Piramal's Neuraceq™ in Fig. 4) on the market as for 2016.[33] This has allowed wider distribution, with the technique now being available in many countries for clinical practice. All three Aβ imaging ligands have been tested in well-conducted, blinded clinical trials, and all have demonstrated a robust correlation with brain Aβ load, particularly with SP, though they also bind to Aβ in other districts (eg, in blood vessels). It should be emphasized that it is currently unclear whether one of these imaging agents has advantages over the others; they adopt different methods for analyzing and reading scans (flutemetamol uses color and florbetaben and florbetapir provide grayscale images), and they have slightly different tracer kinetics in terms of how scan time relates to time of injection.[32]

As matter of fact, the clinical development of Aβ neuroimaging marks an important step change in our ability to characterize and assess patients with MCI and dementia. Currently, there are clinical situations where it promises to play a crucial role to enhancing diagnostic accuracy. However, the real innovation of Aβ imaging is likely to be not only about improving diagnostics but also about appropriately selecting patients at an early AD stage for disease-modifying therapies once these become available. In addition, as

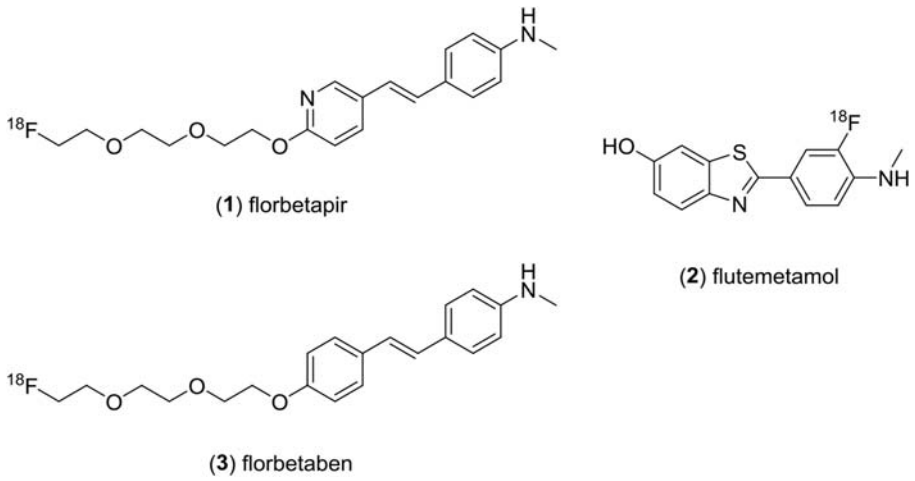

Fig. 4 Chemical structures of PET tracers approved for AD.

part of a wider biological profiling of a complex disease, it promises to drive forward new ways of understanding and classifying dementia.[32]

Motivated by the potential relevance of PET tracers in AD, great medicinal chemistry development has taken place.[34] The last few years have witnessed a great improvement in concepts and methodologies for the design and synthesis of such agents. Learning from the first examples (see the illuminating interview to the brain PET scan pioneer, Louis Sokoloff[35]), today we have set some fundamental prerequisites for a successful radiopharmaceutical directed to Aβ. First, it should effectively bind and image Aβ cerebral deposits. This means that its amount in a given brain area must be quantitatively associated with the amount of Aβ in that area, and there must be a sufficiently high signal-to-noise ratio.[36] Another important consideration is that all currently available imaging agents target fibrillar Aβ in a β-sheet conformation. As already pointed out, Aβ oligomeric species may be a key initiator for AD pathogenic pathways. Although the possibility that these agents bind to Aβ oligomers in a β-sheet conformation after reaching a necessary size (trimer or tetramer) cannot be ruled out, the in vivo signal is not directly representative of these species. This is because of their lower concentration with respect to insoluble Aβ plaques. However, on the basis of the equilibrium existing between monomers, small oligomers, fibrillar Aβ aggregates, and plaques, a relationship exists between the Aβ PET signal and oligomer concentration.[37] In addition to these basic considerations, in general, a PET small-molecule tracer must fulfill a wide range of requirements summarized in **Table 1**.

With specific regard to CNS-directed PET tracers, BBB permeability is an even more crucial issue, as poor BBB permeability remains one of the most frequent causes of failure of promising CNS tracers.[31] Although Lipinski's rule of five[38] for oral availability are applicable for the case of CNS PET tracers,[31] a specific prediction model has been recently developed.[39] This model encompasses calculated distribution coefficients (log *D*) at pH 7.4, molecular weight, topological polar surface area, number of hydrogen bond donors, and protonation constant pK_a of the most basic center. To this respect, it has been verified that low lipophilicity of the tracer reduces BBB permeability, whereas very high lipophilicity results in excessive nonspecific binding, imparting high background signal, which makes the quantitation of the specific binding signal challenging. Furthermore, unspecific binding increases the radiation burden to the patient.[31]

It should be also remarked that brain uptake of PET tracers can also be limited by the presence of several efflux transporters located in the BBB. One of the most relevant is P-glycoprotein (P-gp), situated at the luminal side of brain capillary endothelium, where it functions as an active Adenosine triphosphate (ATP-driven) efflux pump for a wide range of xenobiotics. Hence, brain levels of CNS tracers that are substrates of P-gp might be considerably low, resulting, in turn, in variability of tracer uptake and binding. A number of studies, both in vitro and in vivo, have been performed recently to examine possible interactions of established radiotracers and P-gp.[31]

1.04.3.1.1 Aβ PET tracers derived from Thioflavin T

In this very active area of research, the histopathologic dyes Thioflavin T (ThT, **4**, in **Fig. 5**) and Congo red (CR, **5**, in **Fig. 6**) have provided the structural inspiration for the development of many tracers aimed at the detection of Aβ in living patients. The two dyes show common molecular features that are optimal for Aβ recognition: they are relatively planar, hydrophobic aromatic molecules that can interact with the cross-β-sheet structure found in all amyloid fibrils.

Different from receptors and enzymes, Aβ aggregates are cavity-less proteins that lack a designated binding domain or a substrate binding site. This presents considerable challenges to the development of small-molecule probes. Fibrillar Aβ adopts a cross-β-sheet structure with highly ordered monomers aggregated on the basis of hydrogen bonding, π–π stacking of aromatic residues, and electrostatic interactions (mainly involving glutamate-lysine). $Aβ_{40}$ contains hydrophobic portions both in the middle (residues 17–21) and at the C terminus (residues 30–40). The parallel orientation of β-sheet structures generates small channels and hydrophobic pockets that extend along the length of the filament to which aromatic molecules can intercalate and bind via π–π interactions. Thus, molecules that are known to interact with Aβ plaques all share common structural motifs in that they have planar π aromatic systems. It is thought that their binding involves the molecule entering a hydrophobic pocket or channel and binding via a combination of hydrophobic and π–π interactions. It is likely that there is more than one such binding site on Aβ plaques.[40]

In light of this, it was soon clear that benzothiazole ThT (**4**) could serve as a valuable starting point when searching for new molecules with potential clinical application. It suffers, though, from two major shortcomings: first, ThT has a permanent positive charge, which hampers BBB permeation. Second, its binding affinity to fibrils is quite low. Thus, an optimization campaign was launched in the search for more lipophilic and potent derivatives. Structure–activity relation (SAR) studies on ThT structure revealed that the similar aromatic, planar benzofuran, imidazo-pyridine, benzoxazole, or imidazole scaffolds retained a similar binding

Table 1 Requirements for an ideal PET tracer

- MW < 500
- High target/nontarget binding affinity ratio
- Rapid blood clearance
- Favorable transport between blood and target tissue
- Low peripheral metabolism
- Rapid clearance from nontarget tissues (liver, kidney, and intestine)
- Ideal physical and biological half-life

profile. Additionally, the aniline could be substituted with other flat, rigid moieties (eg, stilbene) without significantly negative effects. Insertion of a planar styrene group between the benzothiazole and the aniline is also well tolerated, while some substitutions, such as bithiophenes, even increase affinity.[9]

Among the several investigated chemical classes of ThT derivatives, benzothiazole aniline (abbreviated as BTA) represents the most widely explored one. To note, these compounds emanated from academic research.[41] Well aware that such a benzothiazolium salt would never cross the BBB, a team based at the University of Pittsburgh modified ThT structure by a simple demethylation (methyl groups in positions 3 and 6) of the benzothiazole ring and of the aniline nitrogen. In 2001, Klunk et al. reported that this neutral ThT analog, named BTA-1, (**6**, Fig. 5) possessed very good brain entry and a higher affinity for Aβ deposits in AD brain.[42] A further SAR campaign identified a hydroxylated derivative (*N*-methyl-2-(4′-methylaminophenyl)-6-hydroxybenzothiazole, 6-OH-BTA-1, **7**) (Fig. 5) with clearance properties that were ideal for a PET radiotracer. Preclinical studies showed that it bound to AD brain with an affinity in the single-digit nanomolar range and, more importantly, entered the brain rapidly and cleared rapidly as well.[43] Therefore, the [^{11}C]-labeled *N*-methyl-2-(4′-methylaminophenyl)-6-hydroxybenzothiazole ([^{11}C]-**7**) was selected for the first human trial of a ThT-derived imaging agent. For simplicity, [^{11}C]-**7** was given the code of [^{11}C]PiB "Pittsburgh Compound-B," the acronym by which it is universally recognized. Thanks to its favorable profile, [^{11}C]PiB has become the benchmark PET Aβ agent, already adopted for the direct visualization of brain SP in thousands of AD patients.

Unfortunately, the 20-min radioactive decay half-life of ^{11}C limits the use of [^{11}C]-**7** to major organizations with an on-site cyclotron facility and ^{11}C radiochemistry infrastructure, making the access restricted and with costs prohibitive for routine clinical use.[44] To overcome these limitations, several tracers labeled with ^{18}F ($t_{1/2}$ of 110 min)—which allow the centralized production and regional distribution, as currently practiced worldwide in the supply of [^{18}F]FDG for clinical use—were developed.[45] This shift from an ^{11}C- to ^{18}F-labeled tracer was expected to significantly enhance the impact of amyloid imaging on research and clinical diagnosis.

Under the proposition of circumventing the aforementioned limitations and allowing a broader application of [^{11}C]PiB, an [^{18}F]-fluorinated derivative was developed. H-to-F substitution of the hydrogen atom in position 3′ of the aniline ring afforded

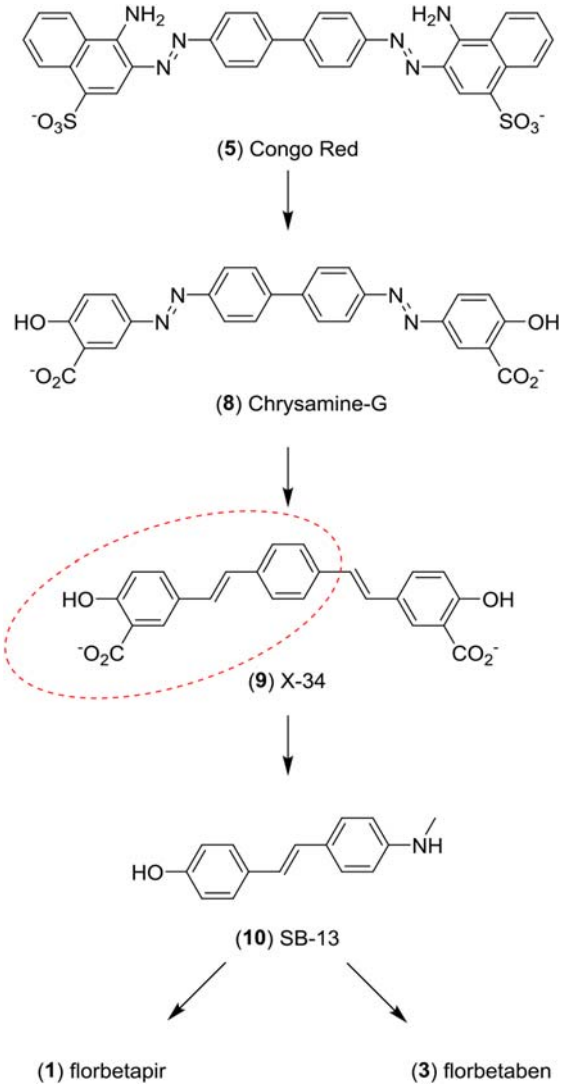

Fig. 6 Congo red (**5**) and its derivatives developed as PET tracers.

[^{18}F]3′F-PiB, also known as flutemetamol (**2**).[41] This compound, also developed at the University of Pittsburgh Medical Center, showed patterns of binding and distribution, in in vivo PET studies, comparable to that of [^{11}C]PiB. After successful completion of clinical trials, in 2014, flutemetamol received marketing authorization from the EMA for imaging of Aβ plaques in suspected AD.

1.04.3.1.2 Aβ PET tracers derived from CR

CR (**5**, in Fig. 6) is another dye widely used for histopathologic staining of SP. More than 100 years after its discovery, CR is still of fundamental importance from a diagnostic point of view. CR staining of fixed tissue and the detection of apple-green birefringence when examined under polarized light remain essential for the diagnosis of amyloidosis.[46] As for the case of ThT (**4**), CR (**5**) served as a starting point for the development of AD PET tracers. To decrease its molecular weight and to increase the metabolic stability and lipophilicity, derivatives of salicylic acid, for example, Chrysamine-G (**8**, in Fig. 6), and divinylbenzene compounds such as X-34 (**9**, in Fig. 6) were developed.[47] Although these compounds showed high log *D* values, they failed to exhibit good brain uptake in preclinical studies.

To enhance BBB permeation, the carboxylic and hydroxyl moieties were removed, and the molecular weight was further reduced, yielding trans-stilbene derivatives as promising lead structures. A cooperative effort between research groups of the University of Pennsylvania and the company Avid Radiopharmaceuticals was set to further optimize the stilbene structure. This intensive effort ultimately resulted in the development of florbetaben (**3**).[48] In 2005, a series of fluoropegylated stilbene derivatives was successfully prepared and tested.[49] Of these, a low-molecular-weight and neutral stilbene derivative, SB-13 (**10**, Fig. 6), demonstrated excellent binding affinity and labeling of SP.[50] A preliminary PET human study with [^{11}C]-SB-13 revealed excellent differential increased uptake and retention in the frontal cortex of AD patients, when compared to control subjects. Notwithstanding these remarkable

preliminary results, no further clinical studies were undertaken, probably due to the technical limitation associated with ^{11}C. However, these data stimulated the search for SB-13 derivatives to be labeled with ^{18}F. In details, by adding three PEG units to the stilbene, a more appropriate lipophilicity was obtained, without loss of specificity. In addition, PEG was shown to be an efficient and effective prosthetic group for ^{18}F labeling. The isosteric replacement of a phenyl ring with a pyridine provided the new classes of styrylpyridines, whose optimized compound was florbetapir (**1**). Both fluorinated tracers, florbetaben and florbetapir, received FDA approval for the estimation of Aβ plaque density in the human brain by means of PET.[31]

1.04.3.2 PET Tracers for Aβ Plaque Imaging Evaluated in Human Subjects

Despite the availability of already three marketed agents, the development of PET amyloid tracers is still attracting considerable attention. Several reviews discussing the status and advances of this class of PET imaging agents have been recently published, to whom the reader is directed for a more comprehensive description.[47,51] The examples reported in the succeeding text are thus intended to provide updates of the progress made in clinical trials.

Interesting Aβ tracers directly derived from the BTA class are [^{11}C]AZD2184 (**11**, in Fig. 7) and [^{18}F]AZD4694 (or [^{18}F]NAV4694, **12**). Their development was motivated by considering that the marketed ^{18}F-labeled tracers have greater nonspecific white matter binding than [^{11}C]PiB and some have even lower cortical binding in AD patients. These characteristics make scan visual interpretation more challenging (particularly for the detection of low levels of cortical SP) and increase the level of expertise required for accurate and consistent scan interpretation in clinical practice.[52] Thus, the guiding hypothesis was that lower lipophilicity (log *D*) than that of previously developed radioligands would translate into lower nonspecific binding. On this bases, the analog of [^{11}C]PiB containing a 2-pyridinyl group instead of 2-phenyl, AZD2184, was synthesized. It displayed a high affinity for Aβ fibrils in vitro. In vivo autoradiography studies showed that [^{11}C]AZD2184 (**11**) exhibits a higher signal-to-background ratio in postmortem brain sections from AD patients, which parallel the reduction of log *D* (1.8 for AZD2184 vs. 2.8 for PiB).[53] The benzofuran isosteres of BTAs have generally showed quite higher binding affinity to Aβ fibrils, together with favorable log *D* and half-life values. [^{18}F]NAV4694 (**12**) is a fluorinated benzofuran derivative with a wider dynamic range than [^{11}C]PiB possibly due to high affinity. Additionally, the ratio between cerebellum and white matter was significantly higher for **12**, which suggests lower nonspecific binding than [^{11}C]PiB. Competition study showed that **12** cannot be fully displaced by [^{11}C]PiB, which suggests binding in early forms of amyloid. Collectively, these robust in vitro and in vivo properties support the unique binding of **12** and highlight its potential for early diagnosis in AD.[54] Indeed, a phase 3 clinical trial to evaluate the efficacy and safety of [^{18}F]NAV4694 (**12**) for detection of cerebral Aβ when compared with postmortem histopathology will end in Dec. 2016.[55] In parallel, a third compound, AZD2995 (**13**), with an even lower log *D* (1.3) than that of AZD2184 (1.8) has been developed. Its development allowed researcher at AstraZeneca to postulate that the specific binding to Aβ plaques is dependent upon the compound ability to form hydrogen bonds with Aβ. They also pointed out that for BTA congeners, the presence of a hydrogen bond donor both on the left-hand and right-hand side of the molecule is essential for the specific binding to brain SP. The preclinical profile of **13** in relation to the reference ligand PiB suggests that the corresponding ^{11}C-labeled compound may enable PET visualization of Aβ deposits in the living human brain, with a higher sensitivity than the currently used PET ligands.[56]

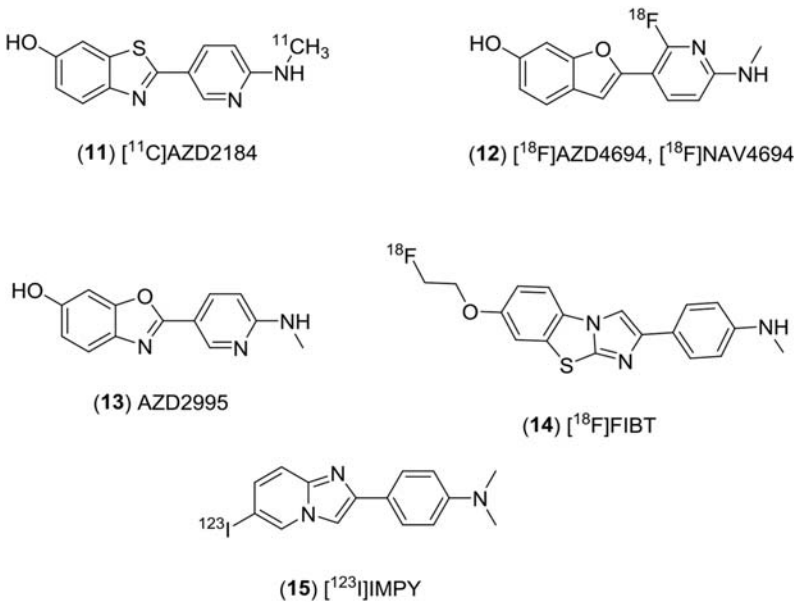

Fig. 7 Chemical structures of **11**–**15**, developed as Aβ PET/SPECT tracers.

Imidazo[2,1-b]benzothiazoles (IBTs) are another promising novel class of Aβ PET ligands. Their good in vivo imaging properties have previously been shown in preclinical studies. Among IBTs, fluorinated [^{18}F]FIBT (**14**) has been selected for further characterization and advancement toward use in humans. [^{18}F]FIBT characteristics have been analyzed in relation to PiB, as reference ligand.[57]

1.04.3.2.1 Aβ single-photon emission computed tomography (SPECT) tracers

To give a more comprehensive view of the subject, the parallel development of SPECT radiotracers should be mentioned. Compared with PET, SPECT has greater accessibility, lower cost, and greater availability as a routine diagnostic method due to the use of easily generated radioisotopes with longer half-lives (eg, [^{125}I], $t_{1/2}$ of 60.1 days, [^{123}I], $t_{1/2}$ of 13.2 h, and [^{99m}Tc], $t_{1/2}$ of 6.0 h). Although several radioiodinated or ^{99m}Tc-labeled probes for Aβ plaques have been described, unfavorable pharmacokinetic properties, such as low brain uptake and slow washout, have prevented their use in AD patients.[58] 6-Iodo-2-(4′-dimethylamino)phenyl-imidazo[1,2-*a*]pyridine (IMPY) is the first SPECT imaging agent to be tested in clinical studies. Although [^{123}I]IMPY (**15**, in Fig. 7) showed excellent features as an Aβ imaging probe in preclinical studies, the preliminary clinical data displayed a low signal-to-noise ratio, possibly due to an excessive lipophilicity and low stability in vivo.[58] Consequently, there is no current SPECT imaging probe useful for the clinical diagnosis of AD.

1.04.3.3 PET Tracers for NFT Imaging

As discussed earlier, the last two decades have been focused on developing numerous Aβ ligands for the noninvasive detection of Aβ deposition in the brain. However, several findings increasingly suggest the progression of tau pathology as a more reliable biomarker. Indeed, a large number of postmortem studies show that the number of NFT in the brain is highly associated with cognitive impairment, and tau deregulation is a key mediator of neurodegeneration.[59] Thus, a selective and specific tau imaging agent will be crucial to achieve a more comprehensive understanding of AD pathophysiology. Moreover, tau imaging could confirm the various stages of tau deposition and assist in the early and differential diagnosis of AD, especially with references to other non-AD tauopathies.[59] In this perspective, tau PET imaging would help not only in the diagnosis but also in the development of anti-tau therapeutics by supporting subject enrollment and evaluation of drug efficacy in clinical trials. As for 2016, approved PET radiotracers are not available. Conversely, tau is widely detected in postmortem histochemistry examination by using two gold standard methods that are AT8 anti-tau antibody and Gallyas silver staining.[59]

Developing imaging agents for tau pathology requires to overcome several obstacles. Similar to Aβ, tau PET tracers should be small, lipophilic, and nontoxic molecules that readily cross the BBB. Ideally, a CNS PET ligand should not form BBB permeable radioactive metabolites and exhibit low nonspecific binding (to avoid low signal-to-noise ratio due to undesired binding). In contrast to Aβ, because most tau aggregates are intracellular, a tau radiotracer ought to cross the cell membrane to reach its target. Moreover, six different isoforms of tau exist, and different combinations of these isoforms resulted in different clinical phenotypes. The wide spectrum of posttranslational modifications at which tau aggregates are subjected (such as phosphorylation, nitration, acetylation, glycosylation, truncation, prolyl isomerization, glycation, and ubiquitination) further complicates the situation.[59,60] Another obstacle in the development of specific tau imaging agents is the coexistence, in AD brains, of Aβ and other misfolded proteins that share the same β-sheet secondary structure. In particular, Aβ and tau proteins colocalize in gray matter areas, and α-synuclein-containing aggregates are sometimes abundant in AD patients' brains. The situation is further complicated by the much lower brain concentrations of tau than Aβ. Depending on the brain region, the concentration of tau is 5–20 times lower, requiring a radiotracer with high Aβ/tau selectivity.[61] Thus, binding affinity is another very important property for an in vivo tau radioligand. Although in vitro studies showed that based on affinity, a 3- to 30-fold selectivity is sufficient, simulation studies suggested that a 20- to 50-fold selectivity for tau over Aβ is required to image tau aggregates in vivo.[61] Finally, and as for any PET candidate, tau radiotracers must be synthetically accessible through quick and efficient processes.[60]

Since Aβ plaques, NFT, and other amyloid aggregates share a similar β-sheet structure, it is not surprising that structural similarities exist between imaging agents for both species. In particular, as the structural diversity of tau protein and its aggregates, as well as their posttranslational modifications, makes impossible studying potential binding sites for a PET ligand, ligand discovery is mainly based on compound screening approaches.[60] These approaches exploit competitive in vitro assays using synthetic tau aggregates or postmortem AD human brain homogenates or sections. Notably, screening campaigns based on synthetic tau aggregates have not been very successful, while assays based on native proteins have yielded the most promising candidates. The reason of such difference could be derived by the fact that synthetic tau aggregates do not have similar hyperphosphorylated or glycated or ubiquitinated residues as the native ones.[60]

From a peculiar medicinal chemistry standpoint, it should be emphasized that few papers describing tau ligands discuss SAR around the different chemotypes.[61] Even, no one provide any robust conclusion about the molecular features required to achieve NFT selectivity over SP.[60] For this reason, the majority of the examples deals with nonselective candidates. The first described potential PET tracer for Aβ and tau was the naphthalene derivative [^{18}F]-FDDNP (2-[1-[6-[*N*-(2[^{18}F]-fluoroethyl)-*N*-methylamino]naphthalen-2-yl]ethylidene]malononitrile, **16**, in Fig. 8), synthesized and characterized by Barrio et al. back in 1999.[62] Importantly, [^{18}F]-FDDNP was used to obtain the first human PET images of AD brain in an 82-year-old woman.[63] However, in vitro evaluation of [^{18}F]-FDDNP at concentrations correspondent to those used for the PET scan showed limited binding to both Aβ and NFT. Thus, its low binding affinity and lack of selectivity hindered further optimization. In light of this, researchers turned their attention to novel probes with higher selectivity.

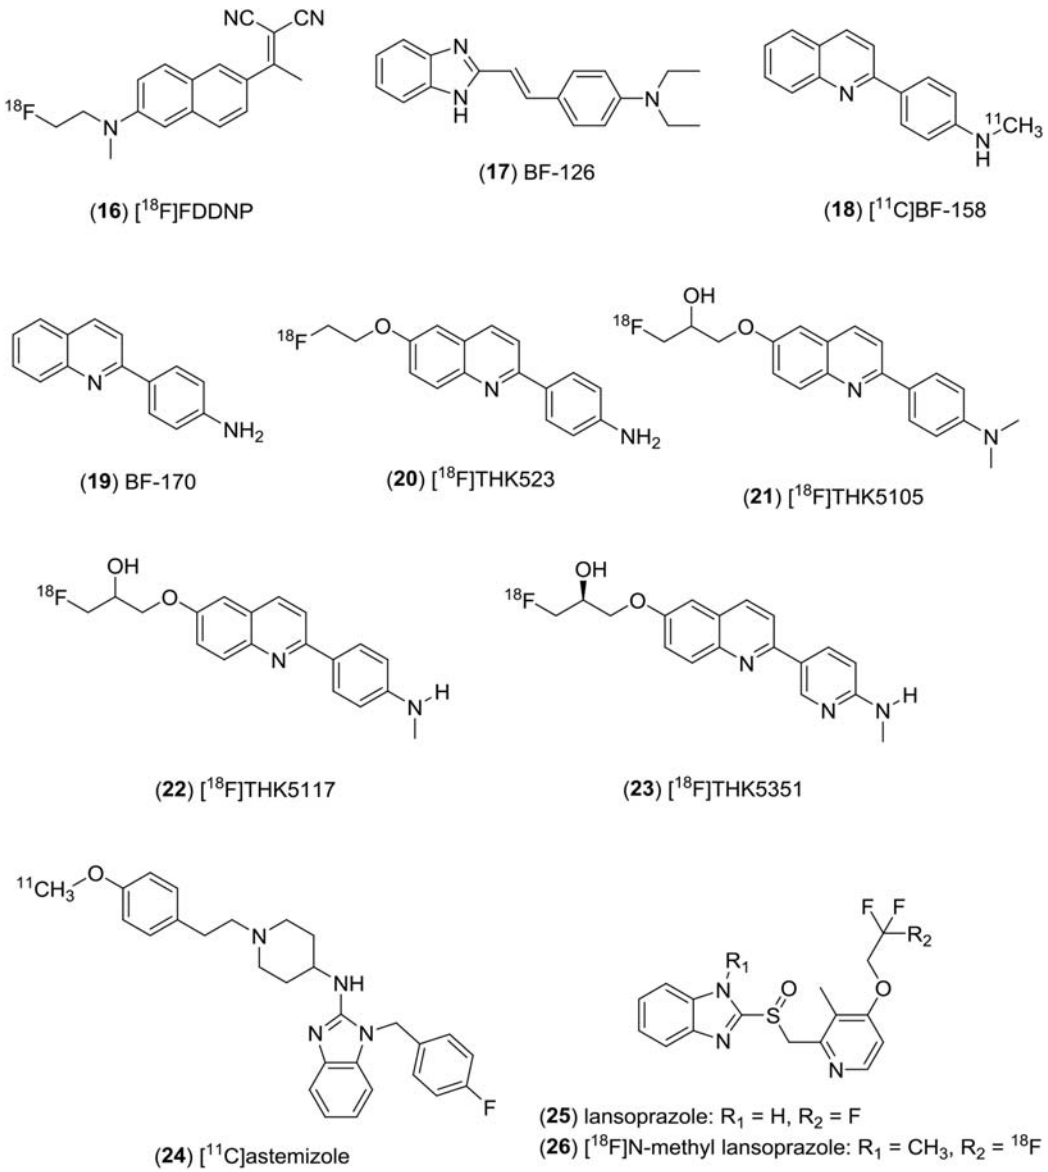

Fig. 8 Chemical structures of **16**–**26**, developed as tau PET tracers.

1.04.3.3.1 Quinoline- and benzimidazole-derived tau PET tracers

One of the earliest ligand screening campaigns for PET tracers targeting specifically tau aggregates was performed in 2005 by Okamura's group.[64] After testing more than 2000 small molecules, they discovered quinolines and benzimidazoles as lead structures. In particular, they proposed the benzimidazole BF-126 (**17**) and the quinolines BF-158 (**18**) and BF-170 (**19**) as candidate probes.[64]

Structurally, BF-126 (**17**) is very similar to [^{11}C]PiB, with the substitution of the benzothiazole ring with a benzimidazole and the insertion of a carbon–carbon double bond spacer between the planar aromatic bicyclic ring and the aniline substituent at position 2. The aniline moiety is present also in the quinoline derivatives **18** and **19**, which do not possess any spacer. Quinolines **18** and **19** emerged as better tau ligands than **17** in terms of binding affinity. Thus, **18** was radiolabeled with ^{11}C for in vitro autoradiographic studies. However, the short half-life of ^{11}C limited its further clinical application.[65]

This led to the synthesis of the first-generation THK series, obtained by labeling quinoline tau ligands derivatives with ^{18}F. In 2011, Fodero-Tavoletti's group reported the identification of [^{18}F]THK523 (6-(2-[^{18}F]fluoroethoxy)-2-(4-aminophenyl)quinolone, **20**).[66] The introduction of an alkyl ether at the position 6 of the quinoline ring allowed the introduction of ^{18}F and at the same time improved affinity and selectivity toward tau.[60] Indeed, in vitro studies showed that [^{18}F]THK523 (**20**) binds selectively to PHF-tau, but it is not able to bind non-AD tau aggregates.[59] Then, after the evaluation of its ability to cross the BBB, [^{18}F]THK523 was tested in vivo in a tau Tg mouse model, confirming its capability to successfully label tau deposits.[67] On these bases, [^{18}F]THK523 was tested in human subjects.[68] In vivo PET imaging showed higher cortical retention in AD patients compared with healthy controls,

and the probe distribution was in agreement with the reported PHF histopathologic brain distribution in AD autoptic specimens. However, a too high retention in white matter precluded the assessment of tau pathology by visual inspection of PET scans.

Thus, the optimization of the alkyl chain at the position 6 of the quinoline afforded a second-generation THK series, reported by Okamura's group in 2013.[69] The two corresponding tertiary and secondary anilines, [^{18}F]THK5105 (1-([2-[4-(dimethylamino)phenyl]quinolin-6-yl]oxy)-3-[^{18}F]fluoropropan-2-ol, **21**) and [^{18}F]THK5117 (1-([2-[4-(methylamino)phenyl]quinolin-6-yl]oxy)-3-[^{18}F]fluoropropan-2-ol, **22**), demonstrated higher binding affinity for tau aggregates than for Aβ plaques in in vitro studies and in AD brain sections. They also showed a more favorable pharmacokinetics than **20**, with no defluorination in vivo. From a chemical point of view, the presence of the secondary alcohol in **21** and **22** introduces a polar moiety, which might be responsible of the observed higher selectivity.[60] Furthermore, the clearance of these derivatives from normal brain was faster than that of **20**, suggesting **21** and **22** suitable candidates for clinical application. First-in-human PET studies with [^{18}F]THK5105 (**21**) revealed its ability to differentiate between AD patients and healthy controls. However, a still slow kinetics and clearance prevented its further investigation. Although [^{18}F]THK5117 (**22**) showed faster kinetics and better signal-to-noise ratio, it was later realized that both probes showed substantial white matter binding, which may lead to misinterpretation of the PET scans. To bypass this shortage, in 2015, the same group developed the single S-enantiomer [^{18}F]THK5351 ((*S*)-1-(fluoro-[^{18}F])-3-((2-(6-(methylamino)pyridin-3-yl)quinolin-6-yl)oxy)propan-2-ol, **23**),[70] by replacing the benzene ring of **22** with a pyridine. Indeed, as observed with Aβ PET tracers, pyridine derivatives show reduced lipophilicity, which correlates with the amount of nonspecific binding.[71] In addition, it is well-known that enantiomers show differences in biological properties, such as affinity for a given target and metabolism.[72] Thus, fast pharmacokinetics, high contrast, and low white matter retention of **23** allowed sensitive detection of tau aggregates in humans.[70]

Two benzimidazole drugs, astemizole (**24**, in Fig. 8) and lansoprazole (**25**), have been found to bind PHF in a repurposing-based approach.[73] However, **24** displayed no selectivity for NFT over SP, together with a low brain uptake and clearance. Although **25** also showed low affinity toward PHF, several of its radioactive derivatives were synthesized and preliminary tested in mice and nonhuman primates. In particular, [^{18}F]*N*-methyl lansoprazole (**26**) has been proposed as a candidate for progression into clinical trials. However, human studies with this tracer have not been reported so far.

1.04.3.3.2 Benzothiazole-derived tau PET tracers

Another screening campaign aimed to identify novel tau-selective probes was performed in 2007 by Kuret and colleagues. The screening of a library of more than 70,000 compounds[74] identified phenyldiazenyl benzothiazole (PDB) derivative **27** (Fig. 9) as novel lead structure. In light of this, Ono and colleagues, in 2011, developed radioiodinated SPECT PDB derivatives by replacing the methoxy group of **27** with a ^{125}I.[75] Among them, [^{125}I]PDB-3 ((E)-4-((6-[^{125}I]-iodobenzo[*d*]thiazol-2-yl)diazenyl)-*N*,*N*-dimethylaniline, **28**) showed high and selective binding affinity for tau aggregates in vitro. However, **28** exhibited poor pharmacokinetics in healthy mice. Therefore, the same group synthesized the PET derivative [^{18}F]FPPDB ((E)-4-((6-(2-(2-(2-[^{18}F]-fluoroethoxy)ethoxy)ethoxy)benzo[*d*]thiazol-2-yl)diazenyl)-*N*,*N*-dimethylaniline, **29**).[76] Interestingly, **29**, which carries the same prosthetic group of florbetapir (**1**) and florbetaben (**3**), showed higher brain uptake and faster clearance than SPECT tracer **28**. Unfortunately, a lower selectivity between tau and Aβ aggregates was found.

More recently, Higuchi and colleagues developed the benzothiazole-derived probes phenyl/pyridinylbutadienyl-benzothiazoles/benzothiazoliums (PBBs).[77] These compounds derived from the stretching of the core structure of ThT (**4**), with two C=C double bond inserts between aniline (or aminopyridine) and benzothiazole (or benzothiazolium) groups. All the synthesized PBBs were able to intensely label NFT and SP in AD brain sections. Thanks to encouraging preliminary data, three potential probes were radiolabeled to conduct PET assays in Tg mice model of tau pathology. [^{11}C]PBB3 (2-[4-(4-methylaminophenyl)-1,3-butadienyl]-benzothiazol-5,6-diol, **30**) yielded the best visualization of NFT and was then selected for exploratory in vivo PET imaging studies in AD patients. **30** showed minimal nonspecific binding and seems able to monitor the temporospatial spreading of tau pathology

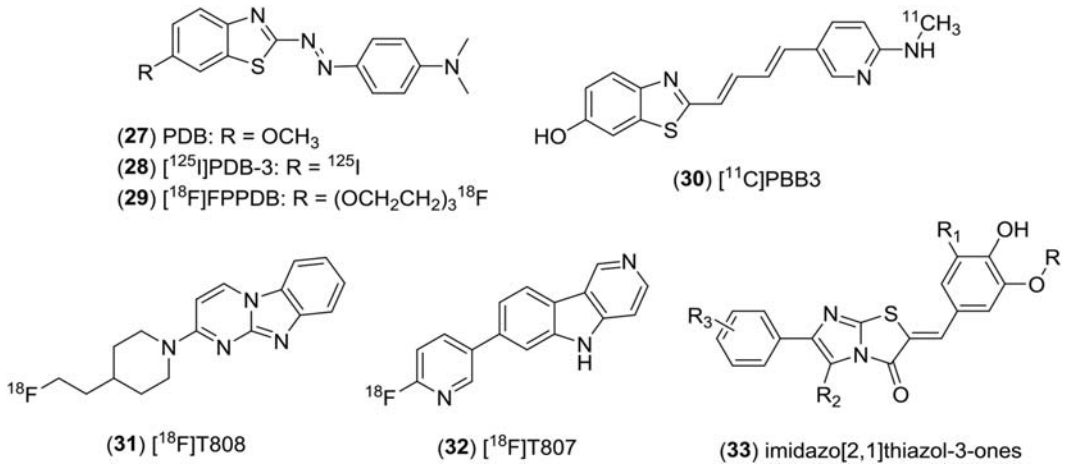

Fig. 9 Chemical structures of **27**–**33**, developed as tau PET tracers.

from the limbic system to neocortical areas, as AD progresses. Moreover, **30** is able to visualize tau deposits also in non-AD tauopathies, emerging as a very promising tool not only in AD diagnosis but also for the differential diagnosis of different neurological conditions.

1.04.3.3.3 Benzoimidazopyrimidine- and pyridoindole-derived tau PET tracers

In 2007, Kolb and coworkers tested over 900 compounds using autoradiographic assays on human brain tissue sections, discovering a novel chemotype, that is, benzo[4,5]imidazo[1,2-a]pyrimidines. Thus, they developed the novel tau PET imaging probe candidate [^{18}F]T808 (2-(4-(2-[^{18}F]fluoroethyl)piperidin-1-yl)benzo[4,5]imidazo[1,2-a]pyrimidine, **31**).[78] **31** rapidly crossed the BBB, followed by rapid clearance, suggesting minimal nonspecific binding in mice. Successively, they developed the related class of 5*H*-pyrido[4,3-b]indoles.[79] After several rounds of optimization, [^{18}F]T807 (7-(6-[^{18}F]fluoropyridin-3-yl)-5*H*-pyrido[4,3-b]indole, **32**) was identified as a favorable tau PET imaging probe.[79] In vitro autoradiography in AD brain sections suggested that **32** binds NFT of human AD brains with high specificity and weak or no interaction with Aβ. On the basis of their encouraging profiles, **31** and **32** have been advanced to clinical tests.

First-in-human PET studies with **32** in AD patients, MCI patients, and healthy participants have shown that its cortical retention matches the known distribution of PHF in the brain. These results were confirmed by postmortem studies showing a strong association of tau pathology with dementia severity. Human studies in three healthy controls and eight AD patients showed better kinetics for **31** than **32**, but substantial defluorination was observed in some cases. A large multicenter study of **32** (renamed as [^{18}F]AV1451) is ongoing, which is expected to validate these initial findings.

Finally, a recent patent application from Hoffmann-La Roche claims imidazo[2,1]thiazol-3-one derivatives (with general structure **33**, in Fig. 9) as potent and exceptionally selective tau aggregate ligands.[80] From a chemical point of view, it is interesting to note the characteristic structure of these molecules, with the highly polar phenolic terminus on one side and a lipophilic aromatic terminus on the opposite side. Indeed, previous studies with these kinds of amphiphilic molecules had suggested that it may be possible to increase potency and selectivity against amyloid aggregates by incorporating lipophilic and hydrophilic features in the same structure.[81] However, it is not possible to estimate the full potential of these molecules, since the affinity and selectivity in human AD brain have not been disclosed yet. These molecules might be included in a recently registered clinical phase 1 study titled "Evaluation of [^{11}C]RO6924963, [^{11}C]RO6931643, and [^{18}F]RO6958948 as tracers for PET imaging of tau in healthy and Alzheimer's disease participants," which, however, does not unveil the chemical structures of the target compounds.[60]

1.04.4 Development of Fluorescent Probes as Innovative Imaging Agents for AD Diagnosis

In addition to radiation-based imaging techniques such as PET and SPECT, optical imaging is one of the most attractive modalities in research and clinical practice, which possesses the advantages of ease of operation, rapid detection, and no exposure to radiation. Although fluorescence microscopy has proved to be one of the most powerful tools in biology and accesses a variety of molecular probes, until the very recent years its application to the intact animal has been limited to imaging few hundred micrometers below the surface. The rest of the animal has eluded investigation at the microscopic level without excising tissue or performing extensive surgery. Therefore, the current ability to perform minimally invasive deep in vivo fluorescence imaging in intact animal studies has represented a breakthrough.

Briefly, when an organic flurophore absorbs light, the molecule will transit from its ground state (S_0) to a higher energy level excited state (S_2). In the excited state, the electrons rapidly, in a few picoseconds, relax to the lowest available energy state (S_1), through a process called internal conversion. Once in this state and after a lag period of several nanoseconds (the fluorescence lifetime), the electrons will relax back to ground state S_0, releasing their stored energy in an emitted photon at a wavelength corresponding to the energy difference of the two energy states ($S_1 \rightarrow S_0$). Because of this relationship, the absorbance and emission spectra are usually mirror images of each other. The energy of emission is lower than that of excitation, which results in a longer wavelength than the excitation light. The difference between the excitation and the emission energy (wavelength) is termed the Stokes shift. The fluorescence quantum yield (QY) is the ratio of photons absorbed to photons emitted. In other words, the QY reflects the probability of the excited state being deactivated by fluorescence rather than by another, nonradiative mechanism.[82]

The so-called "push–pull" organic fluorophores constitute a blueprint in the search for new fluorescent probes for imaging application. They are small molecules in which a π-conjugated bridge (with various lengths and structures) is end-capped with a donor (D) and an acceptor (A) moiety (Fig. 10). The peculiar optical properties of such molecules are due to intramolecular charge transfer. A typical arrangement of these fluorophores is a D–π–A system with strong electron- donating groups ($-NH_2$, $-NR_2$, or –OR) as D and strong electron-withdrawing groups ($-NO_2$ or –CN) as A. These molecules exhibit various degrees of flexibility in

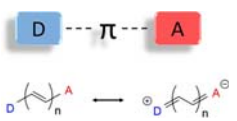

Fig. 10 Typical architecture of a push–pull fluorophore.

the ground and excited state that might be correlated with the fluorescence processes. For a more detailed discussion, please see Staderini et al.[83]

1.04.4.1 Thioflavin T and CR as Starting Points for the Development of Fluorescent Imaging Agents

ThT (**4**, in Fig. 5) is a cationic benzothiazole fluorescent dye widely used to detect Aβ fibrils ex vivo in AD autoptic tissues and to monitor fibril formation in vitro.[84] Structurally, it has a hydrophobic end with a dimethylaminophenyl group, linked to a benzothiazolium containing the polar N and S atoms. Vassar and Culling[85] were the first to unveil the diagnostic potential of ThT, which was shown to detect amyloid in the kidney with high specificity.[85] Following these pioneering studies, considerable advances in understanding the ThT fluorescent response upon binding to Aβ species have been made. ThT is currently universally recognized as a "smart" Aβ probe, thanks to a peculiar fluorescence profile: (i) Its absorption maximum and fluorescence spectrum undergo a redshift when bound, and (ii) the fluorescence emission at 480 nm upon excitation at 440 nm is proportional to the quantity of amyloid fibrils present. This property can be exploited to follow time courses of fibrillation, and such kinetic studies give valuable insight into the underlying molecular mechanisms. Moreover, reduction in ThT fluorescence is often taken to be an indication of the inhibition of the self-assembly process. This behavior was conveniently exploited by LeVine to set up a versatile, inexpensive assay for monitoring fibril formation, which is still the most widely used method for monitoring Aβ aggregation in vitro, and assess the inhibitory potency of newly developed aggregation inhibitors.[86] However, extreme care should be taken when comparing fibril formation under different conditions, since several factors may affect the fluorescence intensity, such as fibrils and ThT concentration and ionic strength. A large number of studies were aimed to correlate the ThT fluorescent behavior with its binding mode with Aβ, but a high-resolution molecular characterization has been hampered by the insolubility and heterogeneous nature of the amyloid fibrils.[87] However, experiments (notably solid-state nuclear magnetic resonance) have provided high-resolution structures of Aβ fibrillar aggregates that can be used in conjunction with computational modeling to probe detailed binding interactions with amyloid dyes. Despite that and the fact that the reported models are somewhat conflicting, two effects occurring upon interaction have been proposed: (1) steric and electronic stabilization (via charge transfer) of the ground-state charge distribution and (2) restriction in the rotational freedom of the carbon–carbon bond between the benzothiazolium and aniline rings in its electronically excited state.[87]

Similarly, staining of amyloid fibrils with the dye CR (**5**, in Fig. 6) has been used since the beginning of the 1920s.[88] CR is a linear and amphiphilic molecule, with a hydrophilic portion encompassing two amino groups and a negatively charged sulfate group (at neutral pH) and a hydrophobic portion consisting of a central biphenyl core, along with a diazo group with two flanking naphthalene rings. Upon binding to amyloid fibrils, CR gives a characteristic apple-green birefringence when examined between crossed polarizer and analyzer, while a distinctive shift in absorbance maximum from 490 to 540 nm is observed.[87] It has been recently proposed that the birefringence might be due to the anisotropic orientation of the CR dipoles resulting from the spatial ordering of these molecules in the grooves along the amyloid fibril axis. The fluorescent enhancement of the bound CR, in turn, should be associated with the torsional restriction of this molecule upon binding. CR is most often applied in diagnosis of amyloid in ex vivo tissue sections using polarization microscopy, although light microscopy and fluorescence microscopy have also been exploited. Although it has been used for the in vitro quantification of Aβ binding by using absorption spectroscopy,[87] CR lacks sensitivity at low Aβ fibril concentration compared to ThT. Furthermore, CR is not well suited for Aβ aggregation inhibitory assays, since it interferes with protein misfolding processes and aggregation.[87]

Following the wide use of ThT and CR in histopathology, the first evidence of the possibility of a fluorescence staining directly in mouse models of AD was provided by Hyman et al. in 2001.[89] The revolutionary goal of this study was to develop a novel imaging approach, using in vivo multiphoton microscopy and the Thioflavin S (ThS, **34**, in Fig. 11) dye, to image SPs in PDAPP Tg mice (APP Tg mice with V717F (Indiana) mutation). Importantly, another aim of this work consisted in exploiting the developed approach for monitoring the effects of an antibody directed to Aβ. Although Thioflavin S (**34**) was effectively able to visualize plaques using this technique, it must be administered topically (direct application to the pial surface) because it does not cross the BBB. It is clear that the lack of a systemic administration prevented its use as in vivo imaging agent in humans.[89]

To overcome this critical limitation, Klunk and colleagues started a broad analog search and synthesis program to obtain more lipophilic, less ionized derivatives of CR. Indeed, this molecule is too highly charged to enter the brain in significant quantities. The analog Chrysamine-G (**8**, in Fig. 6), obtained through the replacement of the sulfonate group by a less ionizable carboxylic group, was tested for the ability to bind to Aβ in vitro and permeate the brain of normal mice.[90] Despite the initial positive results obtained in vitro and in vivo, it was soon realized that the potential of **8** as an in vivo probe was hampered by the still marginal brain entry of this relatively large, acidic compound. On these bases, they started an intense optimization campaign centered on CR and **8**. A systematic series of structural modifications of the pharmacophoric functions resulted in the promising fluorescent probe methoxy-X04 (**35**, Fig. 11).[91] Compared to the parent compounds, **35** has a significantly reduced molecular weight of 344 Da, a value that falls into the optimal range for brain entry. The carboxylic acid groups found in **8** were replaced by the weakly acidic phenols, which, with a pK_a of 10.82, would be uncharged at physiological pH. Furthermore, the log *P* of **35** is 2.6, higher than that of the less lipophilic Chrysamine-G (log *P* 1.8) and significantly higher than that of the charged CR (log $P - 0.18$). After confirming that **35** retained a binding affinity for Aβ fibrils ($K_d = 26.8$ nM) very similar to that of Chrysamine-G ($K_d = 25.3$ nM), it was successfully used to stain plaques, tangles, and cerebrovascular amyloid in postmortem sections of AD brain with good specificity. More importantly, using multiphoton microscopy to obtain high-resolution fluorescent images from the brains of living PS1/APP mice, individual plaques could be distinguished after a single intravenous injection of **35**.[91] In a separate study, **35** has been successfully

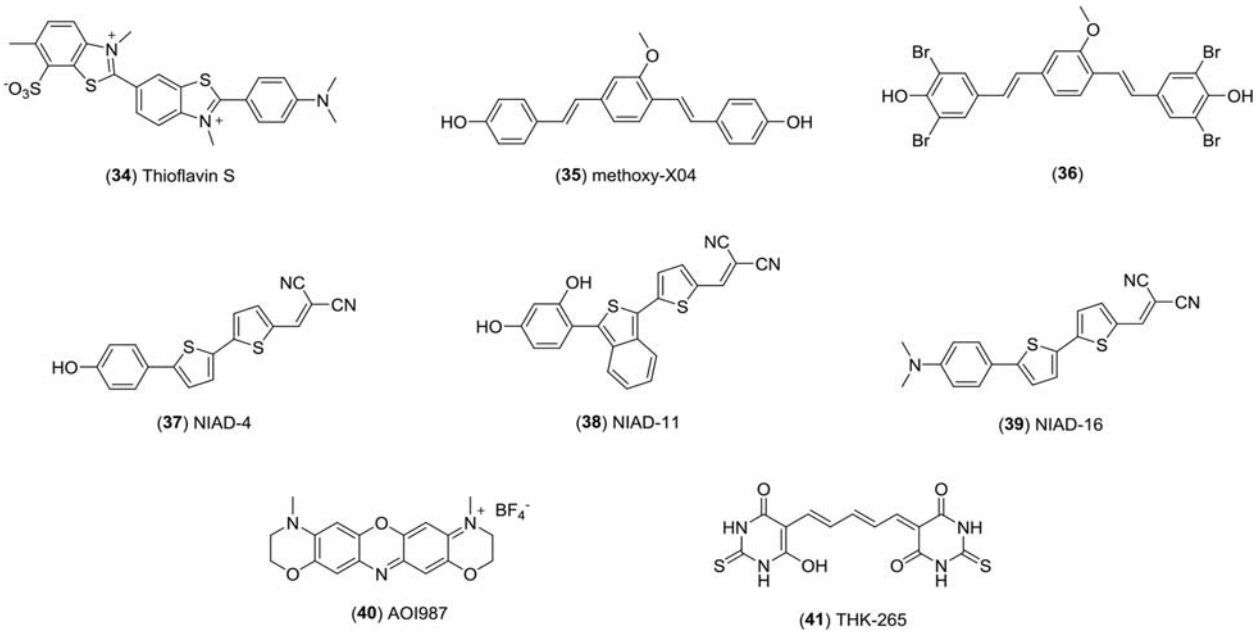

Fig. 11 Chemical structures of **34–41**, developed as Aβ fluorescent probes.

exploited to chart the entire kinetics of growth of a single plaque in Tg2576 mice. It revealed a plateau and/or a sigmoid-shaped progression of Aβ accumulation, confirming previous studies in humans performed with PiB.[92] Despite being a well-established dye, **35** suffers of a slow elimination in vivo. Thus, it has been the starting point for further medicinal chemistry activities by the group of Schmidt. The derivatizations performed resulted in new fluorescent sensors with improved binding properties to NFT and SP, as demonstrated in histochemical staining experiments on human brain tissue and by a Thiazine red displacement assay in vitro.[93] One of these derivatives, **36** (Fig. 11), showed a 24-fold higher affinity for NFT compared to Aβ plaques and thus holds potential to be profiled as a tau-selective fluorescent probe in vivo.

1.04.4.2 First Fluorescent Probes Used for in vivo Aβ Plaque Imaging

As already highlighted, the permanent charge or the ionizable nature of the first developed fluorescent agents hindered their BBB crossing. Besides, the heterogeneous complexes of lipids and proteins in brain tissue are also excitable in the 400–550 nm range, and their emission spectra (550–750 nm) are broad and overlap those of many commonly used dyes. Consequently, researchers moved to the development of neutral probes with a longer emission wavelength, in the near-infrared (NIR) region (650–900 nm).

Thus, in addition to the fundamental prerequisite of BBB permeability, it was increasingly clear that the design of fluorescent dyes for in vivo applications needed to incorporate several other important criteria including (1) a suitable wavelength interval of absorption and emission (NIR range), (2) the ability to rapidly enter the brain after intravenous injection, and (3) specific labeling of the Aβ deposits with concomitant rapid clearing of the unbound dye. Another unique advantage of fluorescence optical imaging is the possibility to attain substantial differences in the photo-physical/optical properties between the bound and unbound forms of the tracer. This would allow a significant increase in imaging contrast, which cannot be exploited with techniques based on radioligands.[94]

1.04.4.2.1 NIAD-4 and derivatives

These concepts inspired the rational design of NIAD-4 (**37**, in Fig. 11) by Swager and coworkers in 2005.[95] They merged the pharmacokinetic requirements with an electronic structure design to produce a compound possessing a suitable spectral range of the absorption and emission bands, with the explicit aim of developing a fluorescent probe to be used in vivo. They employed the typical push–pull architecture with terminal D and A moieties interconnected by a highly polarizable linker. Particularly, **37**, carrying a dithienyl-ethenyl π-conjugated bridge between D and A was purposely designed as one of the simplest possible structures (molecular weight of 334 Da). **37** showed excellent binding affinity ($K_d = 10$ nM) and a dramatic enhancement of the fluorescence intensity (about 400-fold) when labeling Aβ aggregates. Binding studies with fibrillar proteins revealed that **37** binds to the same site as BTA-1 (**6**). The reported affinity is much higher than that of ThT ($K_d = 580$ nM) and not dissimilar to that of high-affinity compounds like PiB (**7**) ($K_d = 4.3$ nM). The increased fluorescence intensity was explained by considering the reduced free rotation of aromatic rings in the excited state. In vivo two-photon imaging experiments in Tg mice demonstrated that **37** readily crossed the BBB after intravenous injection and labeled Aβ plaques in brain and cerebrovascular amyloid angiopathy on blood vessels.[95] In a more recent study, **37** showed a broader pH tolerance than ThT in monitoring Aβ formation, especially under acidic condition.[64]

Although **37** has the undoubted merit of being one of the first rationally designed Aβ probes achieving emission wavelength over 600 nm upon binding with Aβ aggregates, the maximum (603 nm) does not fall within the optimal NIR range of 650–900 nm. Studies with this probe still required the use of the invasive cranial window technique to perform in vivo fluorescence imaging, which is impractical in the clinical setting. To achieve longer emissions, the same group subsequently developed a further series of NIAD-4 analogs, including NIAD-11 (**38**) and NIAD-16 (**39**, in Fig. 11).[96] In details, in **38**, a new push–pull-type NIR fluorophore containing isothianaphthene subunits was synthesized, whereas **39** was obtained by replacing the terminal hydroxyl group of NIAD-4 with a dimethylamino group. As expected, this modification resulted in a bathochromic shift of the emission maximum ($\lambda_{em} = 720$ nm). Thanks to these positive properties, **39** distinguished vascular and nonvascular Aβ plaques through fluorescence lifetime imaging in APP Tg mice.[97]

1.04.4.2.2 AOI987

The pharmaceutical industry naturally was very interested in the development of fluorescent probes. In 2005, researchers at Novartis had defined a target product profile for such new fluorescent probes, which included the following key elements: a low-molecular weight (< 500 Da) and high lipophilicity (log *P* between 1 and 4) to be able to cross the BBB in sufficient amounts for detection and a specific binding to amyloid aggregates without degradation.[98] Moreover, they clearly stated that fluorescence emission maxima should lie in the NIR range, that is, between $650 < \lambda < 900$ nm. Among a series of properly synthesized analogs, the oxazine dye AOI987 (**40**, in Fig. 11) fulfilled all the requirements for selective in vivo Aβ staining. The compound readily penetrated the BBB and bound to Aβ fibrils with a K_d of 220 nM. More importantly, the fluorescence properties were promising, with absorption and emission maxima at 650 and 670 nm, respectively, and a high QY of 41%, an important prerequisite for high sensitivity. Although the researchers could not define the interaction at a molecular level, they proposed intercalation of the planar oxazine with the β-sheet structure of Aβ fibrils as a plausible model. Undoubtedly, the most striking achievement of their study was that they could develop **40** as the first fluorescent Aβ probe for noninvasive NIR detection. Experiments using NIR fluorescence (NIRF) imaging demonstrated that SP could be imaged in living APP23 mice with intact cranium and BBB, after intravenous administration of **40**. For the first time, they were able to quantify the Aβ load by spatial integration of fluorescence intensities, analogous to the quantification of receptor densities in classic receptor neuroimaging studies. In vivo results were confirmed by ex vivo measurements on mouse brains, immediately after acquiring the final in vivo NIRF image. Fluorescence microscopy further confirmed selective in vivo staining of SP in APP23 mice, whereas the brain sections of wild-type animals showed no fluorescence signal. As clearly highlighted by the authors, the noninvasiveness of NIRF imaging with **40** allowed repeated measurements over the lifetime of a mouse, providing an ideal tool for monitoring disease progression in AD animal models and assessing the efficacy of potential AD treatments.[98] Although **40** was reported as an efficient NIR probe for detecting and monitoring SP in a noninvasive way, it still presents two shortcomings, such as a small Stokes shift (25 nm) and moderate binding ($K_d = 220$ nM).

1.04.4.2.3 THK-265

A more recent example is represented by the thiopental dimer THK-265 (**41**, in Fig. 11), which, differently from the previously discussed rational examples, was discovered by screening a large pool of commercial NIRF dye for their binding toward Aβ aggregates.[99] Since the dye exhibited a low toxicity and a good brain uptake, together with optimal optical properties and amyloid affinity, its capability of visualizing Aβ plaques was explored in vivo. Its usefulness as an efficient imaging probe was verified in the APP mouse model, where it provided good discrimination between amyloid deposits in the brain and other nonpathological tissues.[99] When compared with **40**, **41** showed a higher QY and a higher absorption coefficient, together with a higher binding affinity toward Aβ ($K_d = 97$ nM). Building on these promising results and the fact that this molecule is commercially available, Schmidt et al. developed a systematic protocol for staging disease progression by using **41** as NIR probe to evaluate different Aβ aggregation levels in mice of different ages. The intensity of the NIRF signal correlated well with the plaque burden, indicating its utility for direct monitoring of Aβ aggregation progression. Importantly, this study opens up the possibility for efficient, presymptomatic monitoring of Aβ deposition in the aging brain in AD patients.[100]

1.04.4.3 Recent Development of Fluorescent Probes for In vivo Aβ Plaque Imaging

Since these first applications, an impressive development of new NIR fluorescent agents has taken place in recent years, which parallels the enormous technological advances in the optical imaging instrumentations and techniques. In principle, molecular fluorescence-based imaging avoids some technical difficulties of other modalities, such as the use of X-ray in CT and the facility requirements of PET probes (a local cyclotron for generating short-lived positron-emitting radionuclides and a synthetic unit to produce radiolabeled agents).[101] However, as previously discussed, conventional fluorescence methods, such as two-photon fluorescence microscopy and fluorescence molecular tomography (FMT), required craniotomy, cranial windows, and skull thinning. This is due to tissue absorption and light scattering, and scattering is the most significant attenuation factor. Current developments on the hardware and reconstruction algorithms have improved signal localization and quantification by introducing FMT approaches combined with other modalities. The development of optoacoustic tomography is going to allow imaging of physiological and molecular markers at higher resolution.[102] These innovations will further advance the scope of imaging in the area of medicine and biology and certainly have an impact on the drug discovery process. As for the most sophisticated and in vivo effective techniques, resolution and tissue penetration have been significantly improved by combining FMT with CT[103] or MRI[104] (see Refs.[105] and [106] for a more detailed description). As a further implementation, the optical imaging pioneer Ntziachristos recently developed

multispectral optoacoustic tomography (MSOT).[107] MSOT is a high-tech method wherein ultrasound waves are generated in response to the absorption of transient light within the tissue. The feasibility of this approach for the functional imaging of the human brain through the intact skull and scalp has been successfully validated in living mice with glioblastoma, by exploiting the FDA-approved NIR dye indocyanine green.[108]

The impressive technological innovations in fluorescent imaging have stimulated tremendous research efforts to develop novel agents with truly translational potential to be used for in vivo imaging of Aβ plaques. The past experience in the field taught researchers that pharmacokinetic, biophysical, and imaging properties should be simultaneously considered when designing NIR agents. The most comprehensive description of the target requirements has been provided by the group of Moore, who have identified the following requirements for a high-quality probe: (1) specificity to Aβ plaques; (2) reasonable lipophilicity (log *P* between 1 and 3); (3) molecular weight less than 600 Da; (4) emission wavelength > 650 nm and a large Stokes shift; (5) high-affinity binding; (6) high QY; (7) low-affinity binding with bovine serum albumin (BSA); (8) reasonable stability in blood; (9) straightforward synthesis; (10) and, most importantly, upon binding to Aβ plaques, its ability to significantly change its fluorescence properties (ie, fluorescence intensity, fluorescence lifetime, emission wavelength, and QY).[109] Obviously, the simultaneous presence of all these features in a single molecule is not easy, highlighting that the development of these probes is not an easy task to medicinal chemists.

In spite of these challenges, many promising fluorescent imaging probes have been published together with several more recent reviews of a wider scope.[83,94,110] Herein, we focus on very recent (2014–16) examples of fluorescent imaging agents designed to bind Aβ plaques or tau aggregates. Importantly, all the selected agents have demonstrated some utility in in vivo imaging applications. We will show how they substantiate the feasibility of the fluorescent imaging in advancing clinical diagnosis of AD.

The recent work of Cui and colleagues brilliantly exemplifies an iterative design process for achieving NIRF Aβ probes.[111] Starting from a small set of NIR probes based on D (*N*,*N*′-dimethylaniline)-π-A (dicyanomethylene group) architecture, the promising derivative DANIR 2c (**42**, in Fig. 12) was selected as a suitable candidate. **42** displayed high affinity for Aβ plaques and delivered good performances in APPswe/PSEN1 Tg mice in vivo and in fluorescent staining of brain sections from an AD patient. However, its emission wavelength was only 625 nm when bound to Aβ aggregates. To improve **42**'s fluorescence properties, the group

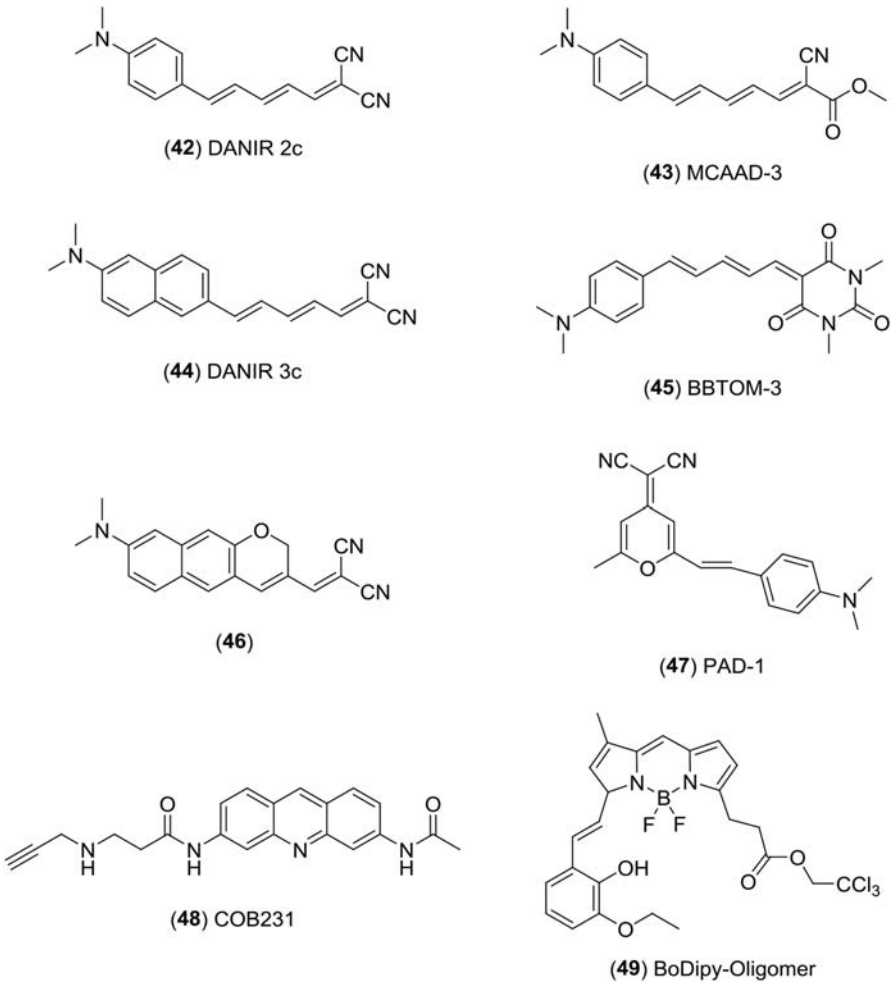

Fig. 12 Chemical structures of **42**–**49**, developed as Aβ fluorescent probes in vivo.

synthesized another set of DANIR-derived probes with different acceptor moieties.[112] The selected NIR probe MCAAD-3 (**43**, in Fig. 12) satisfied most requirements for detecting Aβ plaques in vitro and in vivo. However, it suffered from a low QY. Accordingly, the group recently developed an additional set of DANIR-derived probes by replacing the benzene donor group with a naphthalene ring.[113] Of these probes, DANIR 3c (**44**, in Fig. 12) showed excellent fluorescent properties ($\lambda_{em} > 650$ nm and high QY) and displayed high sensitivity and high affinities to Aβ aggregates. In vivo NIR imaging revealed that **44** is a brain-permeating probe, which efficiently differentiated between Tg and wild-type mice and fluorescently stained Aβ aggregates from an AD patient.

As a further improvement, the same authors reasoned that a coplanar geometry of a probe is a crucial feature for Aβ binding. In addition to this, the emission maximum of **43** and **44** upon binding to SP is below 650 nm, which is not within the NIR optical window. Thus, they envisioned the planar barbituric acid moiety of THK265 (**41**) as a more planar, stronger acceptor to obtain a higher affinity and longer emission wavelength. Indeed, BBTOM-3 (**45**) showed a remarkable binding affinity ($K_d = 13.7$ nM), which was higher than that of **42** ($K_d = 36.9$ nM) and **43** ($K_d = 106$ nM). These results corroborate the initial idea that the planar barbituric acid acceptor moiety (A) makes a significant contribution to the binding affinity. The probe displayed also higher emission wavelength and larger Stokes shift, thus further confirming the rational design applied. Importantly, in pharmacokinetic studies in mice, **45** displayed approximately 20-fold higher brain uptake than parent compound **41**. After confirming the specific binding on brain slices from APPswe/PSEN1 Tg mice and AD patients, in vivo studies were undertaken. As expected, higher fluorescence signals were observed in the brains of the AD mice than in the WT after intravenous injection of **45**.[114]

Kim et al. designed a cyclic analog of **42** and **46** (Fig. 12), as part of a project to develop two-photon fluorophores that can be excited and emit at longer wavelength region ($\lambda_{ex} \sim 900$ nm; $\lambda_{em} \geq 650$ nm), minimizing autofluorescence.[115] The benzo[g]chromene derivative **46** has all the features required for the in vivo imaging of Aβ plaques in the 5XFAD mouse model. Moreover, the fluorescence staining performances are greatly improved with respect to **42** (thanks to the additional conjugation and rigidified structure), particularly upon binding with Aβ aggregates.

Recently, researchers reported the recurrence of a similar acceptor–donor architecture, a chemically different dicyanomethylene-4H-pyran-based dye, namely, PAD-1 (**47**, in Fig. 12).[116] **47** has been described as "smart," thanks to its ability to detect Aβ fibrils in living APP/PS1 Tg mice with a marked turn-on effect.

The proflavine COB231 (**48**, in Fig. 12)[117] was recently identified by exploiting the intrinsic fluorescence of the acridine scaffold. Interestingly, **48** has been evaluated on postmortem human and mice brain slices and in vivo in triple-Tg mice (3xTg-AD), showing a specific labeling of SP over NFT. The originality of **48** is its clickable function, which could be extremely useful for further applications.

A notable and newly discovered fluorescent probe is the oligomer-specific BODIPY-Oligomer (BD-Oligo, **49**, in Fig. 12), which was developed through a diversity-oriented fluorescent library approach and high-content imaging-based screening.[118] This probe allows dynamic oligomer monitoring during in vitro fibrillogenesis and shows Aβ oligomer staining in APP/PS1 AD mice. To date, 49 is the only amyloid probe that discriminates between Aβ monomers, oligomers, and fibrils, raising the possibility of early diagnosis of AD through detecting soluble oligomers.

1.04.4.3.1 Photoswitchable fluorescent probes

As an emerging alternative to the probes described earlier, photoswitchable fluorescent probes constitute a powerful tool for optical imaging.[119] Conventional fluorescent probes are easily photobleached and therefore can only respond irreversibly to one event. Conversely, photoswitchable fluorophore can be reversibly cycled between bright and dark states multiple times. These probes are able to achieve a resolution of ~50 nm or better and limit background interference while maintaining the high molecular specificity and cell compatibility compared to the conventional fluorophores.

The first application of switchable derivatives for Aβ imaging has been recently published by Yi et al.[120] The authors connected an aminonaphthalene-2-cyanoacrylate (ANCA) fragment,[121] which is a well-known Aβ-targeting motif, with diarylethene (DAE) units through a short polyether chain. DAE units, which can reversibly photocyclise upon irradiation with UV and visible light, are promising candidate fluorescent switch systems because of their fast response, excellent thermal stability, and outstanding fatigue resistance. Two interesting probes, T1 (**50**, in Fig. 13) and its corresponding bivalent derivative T2 (**51**), have been characterized as high-affinity probes for Aβ aggregates with a strong increase of fluorescence intensity upon binding and remarkable antiphotobleaching, both in vitro and in tissues. Particularly, **51** showed reversible changes upon switching irradiation of UV and visible light, validating its photoswitchable properties. The associated color change is attributable to the different electrical structures corresponding to the open-ring and closed-ring isomers, which allowed selective staining of Aβ aggregates in brain sections of APP/PS1 Tg mice. Indeed, when **51** is irradiated with 405 nm for 150 s, it specifically highlights Aβ deposits, and the fluorescence of the irradiated deposits was turned off, depending on changing between its open and closed states. Interestingly, the fluorescence of the Aβ deposits could be recovered by irradiating with 633 nm. Although it has not been applied in vivo yet, these encouraging results may provide a new perspective for in vivo high-resolution fluorescence imaging.

1.04.4.4 Fluorescent Probes Used for In vivo NFT Imaging

Despite the previously discussed recent evidence supporting tau pathology as a more reliable AD biomarker, only a few fluorescent probes for NFT have been reported to date. This could be likely due to the fact that most of tau tangles are present inside of the neurons, whereas Aβ has an extracellular localization. Consequently, tau has been less accessible, and fewer fluorescent probes with respect to Aβ have been discovered.[122]

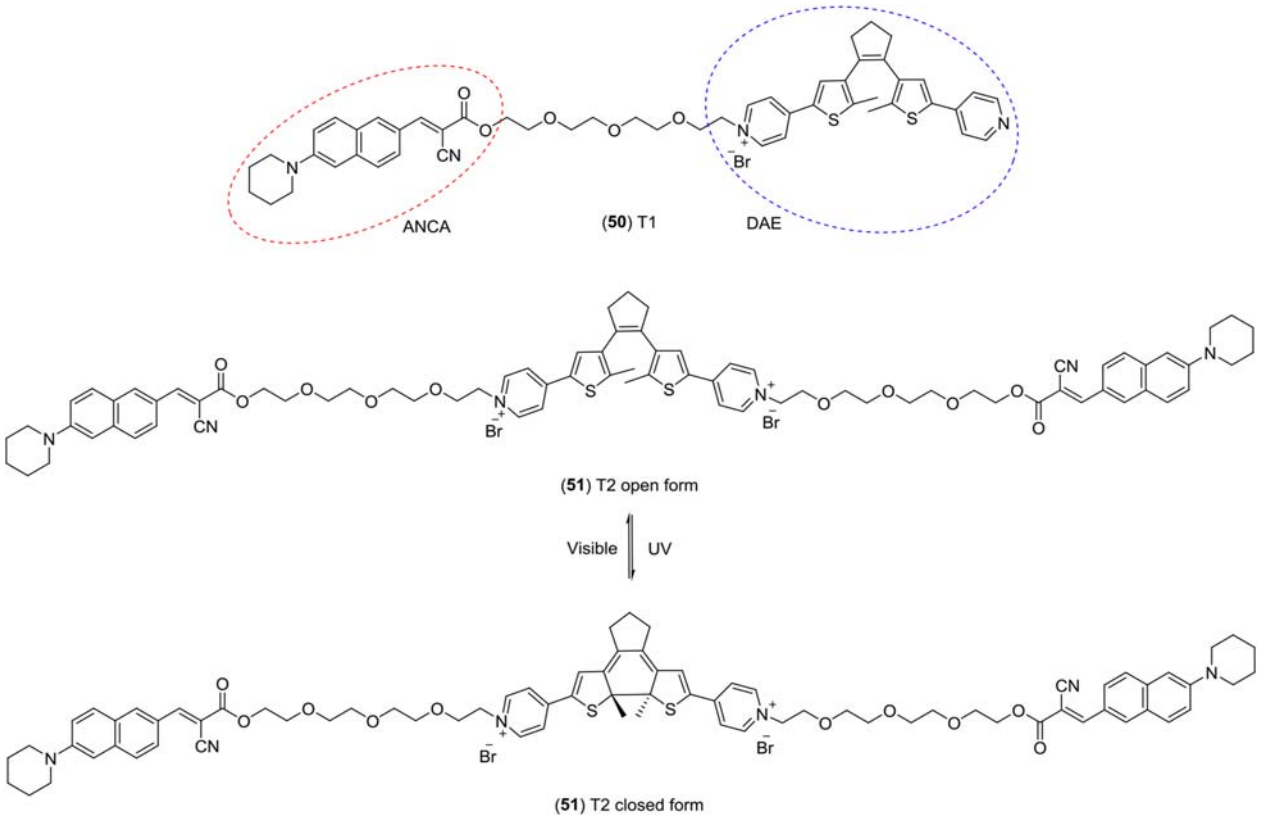

Fig. 13 Chemical structures of **50** and **51** and the photochromism of **51**.

Thus, there is an urgent need for tau imaging tools to complement Aβ imaging tracers that now are widely used. The majority of Aβ imaging agents used for clinical PET studies do not bind to tau lesions. In addition, several candidate tau probes do not bind to tau inclusions in non-AD tauopathy brains without plaque deposition. Therefore, currently, tau aggregates can be clinically characterized only in AD patients with combined Aβ and tau amyloids.

In 2013, Higuchi and colleagues realized that the lipophilicity of β-sheet ligands is associated with their selectivity for tau versus Aβ. The core dimensions of these molecules are major determinants of their reactivity toward a broad spectrum of tau aggregates in different tauopathies.[77] Moreover, these researchers found that affinity for non-AD tau inclusions of different molecules could be attributed to a core structure with a specific extent ranging from 13 to 19 Å. They therefore developed a series of fluorescent and BBB-penetrant compounds, named PBBs (see Section "**Benzothiazole-derived tau PET tracers**"), capable of detecting tau aggregates in AD and non-AD tauopathies. Based on promising in vitro and ex vivo human data, PBB3 (**52**, in **Fig. 14**), with a relatively low log *P*, was characterized through in vivo fluorescence and two-photon laser scanning microscopy imaging. Intravenous administration of **52** in PS19 mice resulted in its rapid transfer to the CNS extracellular matrix and subsequently to the cytoplasm of neurons, where it could bind to intracellular tau inclusions. On the basis of the encouraging preliminary data using this nonlabeled fluorescent compound, some of the synthesized probes were radiolabeled to conduct autoradiographic and PET assays. As discussed earlier, one of these probes, [^{11}C]PBB3 (**30**), was one of the first reported human PET tau imaging tracers.

It has already been highlighted that to precisely monitor the progression of AD, it is desirable to visualize Aβ and tau protein deposits separately. Recently, multispectral fluorescence imaging (MSFI) has been widely used for preclinical applications in microscopy. Moreover, an important application of MSFI is the identification of different protein aggregates, thanks to the fact that some fluorescent compounds show different Stokes shift of the wavelength to various protein fibrils.

Okamura and colleagues, in 2005, found that the previously mentioned benzimidazole derivative BF-126 (**17**) (see Section "**Quinoline- and benzimidazole-derived tau PET tracers**") emitted a different color of fluorescence when bound to Aβ and tau protein.[64] This finding suggested that a single fluorescent probe could differentiate deposits of these two proteins using MSFI technique. Moreover, SAR studies indicated that the backbone of benzimidazole was crucial to show distinctive fluorescence spectra when bound to PHF. Based on this, in 2014, the same group developed a novel fluorescent probe, BF-188 (2-[[4-(4-methylamino)phenyl]-1,3-butadienyl]benzimidazole, **53**, in **Fig. 14**), that can selectively detect Aβ and tau deposits in a wavelength-dependent manner. MSFI imaging with **53** clearly distinguish PHF from Aβ in AD brain sections. Moreover, this molecule shows sufficient brain uptake and rapid washout in normal mice. Thus, they suggested that **53** can potentially be used for selective in vivo imaging of tau and Aβ deposits in AD brain.[123]

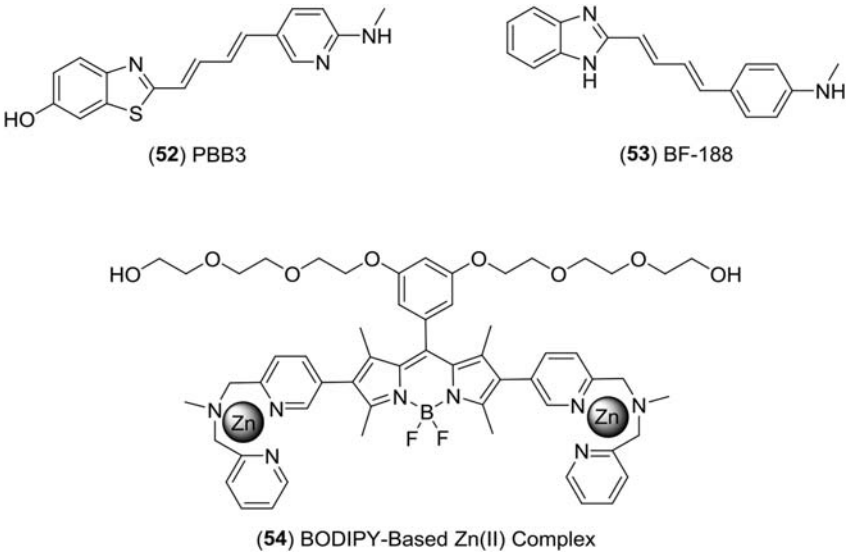

Fig. 14 Chemical structures of **52–54**, developed as tau fluorescent probes.

Despite not encompassing a typical "small-molecule" structure and therefore beyond the scope of this book chapter, the reader should be aware that several coordination complexes have been developed as fluorescent tau imaging agents. As a prototypical example, Ojida et al. reported a well-designed fluorescent BODIPY-based Zn(II) complex (**54**) for selectively detecting hyperphosphorylated tau proteins in brain sections of AD patients.[124] In this book chapter, we did not discuss further these references.

1.04.4.5 Fluorescent Probes Used for Amyloid Imaging in the Retina and Olfactory Epithelium

Another possible approach to a noninvasive NIR optical imaging in AD could rely on the use of neural tissues that are not shielded by the skull. Indeed, while most AD-related pathology occurs in the brain of AD patients and Tg mouse, many pathological hallmarks have been detected in the eye, which is certainly more accessible for imaging than the brain. It is widely accepted that there is high homology between the retinal and cerebral vasculatures and nerve cells and fibers of the retina form a sensory extension of the brain.[125] Thus, the retina could provide a unique opportunity for early diagnosis of AD in animal models and humans by exploiting NIR imaging. By using an advanced optical imaging microscope designed to examine the retina in live rodents, Koronyo-Hamaoui and colleagues were able to in vivo detect the curcumin (**55**, in Fig. 15) fluorescent signal from retinal Aβ in AD mice and visualize individual plaques at an unprecedentedly high resolution.[126] Unfortunately, the same findings were not replicated by Schon and colleagues, who examined postmortem retinas of patients who had suffered from AD. While they could detect hyperphosphorylated tau in Tg mice retina, they did not observe any fibrillar tau or Aβ aggregates in the retina of AD patients.[127] Thus, given the current uncertainties and controversies on the issues related to performance and validation of Aβ deposition in the retina as a biomarker for early detection of AD,[128] further studies are warranted.

The olfactory epithelium, being also an extension of the brain, has emerged as an alternative target for NIR imaging. The lack of a BBB between the nose and brain indicates that the nasal cavity might enable small molecules to access the brain and the CNS by pathways involving the olfactory epithelium and bulb. Therefore, the human olfactory system could be conducive to the diagnosis and treatment of brain disorders, such as AD. While engaged in the development of fluorescent pyrazine, pyrimidine, and pyridazine derivatives for an in vitro and in vivo tau-based diagnosis of AD, Schmidt and colleagues discovered an AD-related deposition of tau aggregates in Bowman's glands of the olfactory epithelium of AD patients. This allowed the authors to propose its use for an endoscopic diagnosis of AD in the olfactory system at very high resolution. The advantages of such a method compared with those of the imaging techniques based on radiotracers, which, as already emphasized, require elaborate infrastructure and on-site radiochemical synthesis of suitable tracers, are apparent. It is interesting to note that the presence of NFT was confirmed by staining, whereas no Aβ deposits could be observed in this region.[129] Whether or not the severity of tau accumulation in Bowman's glands correlates to AD pathology is still a matter of debate. However, this observation has shown potential for the noninvasive diagnosis of AD via changes in the olfactory epithelium in the early stages of disease. Along the same line, the same group developed a series of trimethine cyanine dyes, which were shown to act as efficacious fluorescent probes for the detection of tau deposits in olfactory epithelium tissue. Other concomitant interesting properties, such as good aqueous solubility and negligible cytotoxicity, suggest that these probes hold potential for in vivo applications.[130]

1.04.5 Curcumin as a Versatile Scaffold for the Development of Diagnostic and Therapeutic Agents for AD

Curcumin (**55**, in Fig. 15), the principal curcuminoid of the curry Indian spice, is a brightly colored powder that has been consumed daily for thousands of years in India, Asia, and the Middle East. Similar to many other herbal remedies, people first used **55** as a food

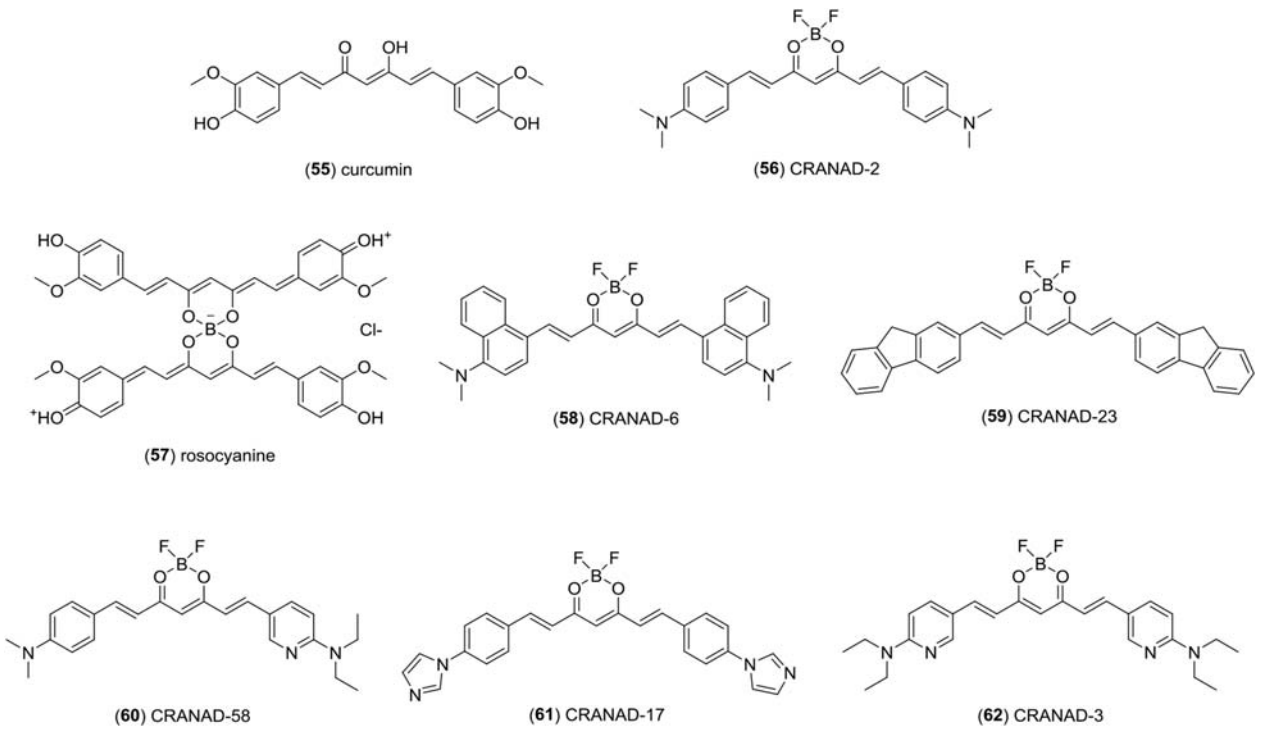

Fig. 15 Chemical structures of curcumin and its derivatives **56–62**, developed as diagnostic and therapeutic agents for AD.

additive and later discovered its several biological properties. **55** is known for its antitumor, antioxidant, antiarthritic, and antiinflammatory properties. Furthermore, it represents a promising tool for delaying or preventing the progression of AD and, at the same time, a promising histological staining reagent for SP.[131] On this basis, Backsai et al. first demonstrated that **55** both labels (by two-photon imaging) and disrupts amyloid plaques in vivo, exerting a neuroprotective effect in an APP–tau Tg mouse model. Indeed, Choe et al. suggested **55** as a potential PET probe for amyloid imaging, thanks to a high-affinity binding for Aβ aggregates ($K_d = 0.20$ nM).[132]

In light of this promising profile, Moore's group started to actively work on this scaffold with the aim of synthesizing new curcumin-derived NIR probes for Aβ. In fact, **55** itself is not an optimal in vivo probe because of its short emission wavelength, limited access to the BBB, and rapid metabolism.

In 2009, they reported the design and synthesis of the first curcumin-based NIR probe, CRANAD-2 (**56**, in Fig. 15).[109]

The rationale behind the design of **56** was based on three considerations. First, it is notorious that **55** reacts with boric acid to form the red-colored compound rosocyanine (**57**), which consists of two curcumins connected by a borate ring. The observed color change from yellow (curcumin) to red (rosocyanine) may be ascribed to the introduction of a boron atom ($\pi \rightarrow \pi^*$ from oxygen to empty orbital of boron) into the rosocyanine fragment. Thus, the authors hypothesized that the redshift benefit of boron incorporation could be used to design boron-containing curcumin derivatives with emission in the desired NIR range. Second, although 2,2-difluoro-1,3,2-dioxaborines are known compounds and their fluorescence properties have been characterized, the fluorescence change caused by difluoroboronate incorporation into diketone remained unexplored. Nevertheless, Moore and Ran noticed that the introduction of difluoroboronate ring into dipyrromethene systems affords the well-documented redshifted BODIPY dyes. Therefore, it was reasonable to speculate that by incorporating a difluoroboronate moiety into **55**, it would generate an appropriate redshift. Finally, *N*,*N*′-dimethyl group is well known as the best absorption redshift pushing group for *para*-substituted aromatic ring. Thus, they modified **55** by replacing the phenolic hydroxyl groups with *N*,*N*′-dimethyl ones, to enable redshifted absorption and, consequently, an additional redshift in emission.[109]

As rationally designed, **56** was able to satisfy all the requirements for a NIR agent for the detection of Aβ plaques both in vitro and in vivo. **56** showed high affinity for Aβ aggregates, a reasonable log *P* value (log $P = 3$), stability in serum, and a weak interaction with BSA. Moreover, after intravenous injection in Tg mice, a significantly higher signal than that from control mice was observed. Thus, **56** could be considered a "smart" probe because it displayed a significant fluorescence intensity increase, an emission blueshift, a lifetime change, and QY improvement upon interacting with insoluble Aβ aggregates. However, **56** lacked the capability of detecting soluble Aβ species.

In order to further optimize **56**, Moore and Ran synthesized several derivatives (eg, CRANAD-6, **58**, and CRANAD-23, **59**) but with no success in terms of fluorescent property improvement.[133] Finally, a longer π conjugation system was exploited for the design of CRANAD-58 (**60**, in Fig. 15). As expected, **60** displayed excitation and emission into the NIR region, and significant fluorescence property changes upon mixing with both soluble and insoluble Aβ species in vitro. In vivo NIR imaging revealed that **60** was capable of differentiating Tg and wild-type mice as young as 4 months old, the age that lacks apparently visible Aβ plaques, and

Aβ is likely in its soluble forms. Thus, the authors suggested that incorporation of PET isotopes into the CRANAD-58 (**60**) molecule could be feasible for the next translational studies.[133]

Moreover, in the same work, the authors took advantages of **55**'s ability to attenuate the $A\beta_{42}$-cross-linking induced by copper. This led to the synthesis of a new derivative, CRANAD-17 (**61**). It is well known that copper coordinates with two imidazoles on His13 and His14 of $A\beta_{42}$ to induce cross-linking with the Tyr position. Thus, **61** was used as an anchoring moiety to drive the compound to the vicinity of His13 and His14, whereas imidazole rings were incorporated to compete with His13/His14 for copper binding. As expected, SDS-PAGE gel and western blot indicated that **61** was capable of inhibiting $A\beta_{42}$ cross-linking induced by copper.[133]

These results corroborate the tremendous potential of the curcumin scaffold as a "privileged" fragment toward the development of small molecules able to both image and inhibit Aβ. In this respect, Moore and Ran demonstrated that the "diagnostic" analog CRANAD-3 (**62**) could be used as an NIRF imaging probe to monitor the Aβ-lowering effectiveness of "therapeutic" CRANAD-17 (**61**).[134]

NIRF imaging is generally more suitable than PET imaging for animal studies, thanks to its low cost, simple operation, and easy data analysis. As previously discussed, **56** was not able to detect soluble Aβ species, which are considered the most neurotoxic species and thus, potentially, could act as biomarkers for presymptomatic stages of AD. Then, the same authors synthesized CRANAD-3 (**62**, in Fig. 15), by the replacement of the two phenyl rings of **56** with pyridyls to introduce the possibility of hydrogen bonding between the engaged Aβ fragment and the nitrogen atoms of the pyridines. **62** displayed an emission peak at 730 nm and showed excellent fluorescence response toward soluble Aβ species. Moreover, in vivo two-photon microscopic imaging and NIRF imaging indicated that **62** is able to penetrate the BBB and specifically labels Aβ aggregates. Based on this encouraging data, first, the authors investigated the ability of **62** to monitor the therapeutic effectiveness of the curcumin derivative **61** and the drug candidate LY2811376, a well-characterized BACE-1 inhibitor. As expected, the fluorescence signal of **61** from APP/PS1 mice after LY2811376 treatment was 33% lower than the signal from the same mice before treatment. Second, they performed a preliminary in vivo therapeutic treatment of APP/PS1 mice with **61** for 6 months. CRANAD-17 is an imidazole-containing curcumin analog developed by the same group in 2013, which is able to reduce copper-induced Aβ cross-linking. After 6 months of treatment, NIRF imaging with **62** indicated that the **61**-treated group showed NIRF signals 25% lower than the signal from the nontreated one. For the first time, an NIR probe was effectively used to monitor AD therapy, and thus, **62** could be considered as one of the first companion diagnostics for AD, that is, an NIRF imaging probe able to monitor the Aβ-lowering effectiveness of therapeutics.[135]

1.04.6 Development of Theranostics against AD

In addition to the "pure" diagnostic role, molecular imaging has potential to move drug discovery toward more effective, individualized interventions. As therapies become directed at specific molecular pathways, personalizing treatments to the "molecular profile" of individual patients will be essential. In this respect, optical imaging should be critical to determine the type and required dose of drug for successful treatment. Imaging can guide customized therapy by envisaging an initial treatment regimen and suggesting a modification in therapeutic plan based on patient response. It will also allow monitoring of side effects during treatment and mapping drug delivery to diseased and normal tissues with the aim of minimizing off-target toxicity in normal tissue.[102]

In traditional approaches, imaging probes and drugs are pursued separately, which is time-consuming and expensive. Key challenges to the pharmaceutical industry today are the ballooning R&D cost and declining productivity driven to a large extent by the ever-increasing need to prove clinical efficacy and cost-effectiveness of new drugs. The need to satisfy these demands before drug approval results in an increasing development time and thereby also in a decrease of the window of opportunity afforded by the drug's patent life. To overcome these disadvantages, developing agents that have potentials for both therapy and imaging is highly desirable.[136] These agents have already been developed at research level with the name of "theranostics": their judicious application to the clinics has the potential to positively impact these challenges, reducing risk and costs, accelerating drug approval, and, ultimately, enhancing medical and commercial success.[136]

The term "theranostics" was first coined by the US consultant John Funkhouser in a press release from the company Cardiovascular Diagnostics in 1998, to describe a material that allows the combined diagnosis, treatment, and follow-up of disease.[137] The advent of theranostics has been in line with ongoing efforts to develop more specific, individualized therapies for various diseases and to combine diagnostic and therapeutic capabilities into a single agent. The use of theranostics is also strongly supported by the fact that most incurable diseases are immensely heterogeneous, and all existing treatments are effective for only limited patient subpopulations and at selective stages of disease development. The great anticipation of theranostics is that the fusion of diagnosis and therapy could provide therapeutic protocols likely to offer improved prognoses.[138] This is because it allows to stratify those patients most likely to respond to a targeted therapy in accordance with their "molecular profile" at a given time-point or, conversely, those patients for whom the risk of adverse effects is higher.

Since its first definition in 1998, the concept of theranosis has expanded, being nowadays quite broad in its meaning. In its most traditional sense of "diagnostics-guided therapy," it can be exemplified by the classical management of type 2 diabetes, whereby glucose blood levels are measured to determine the timing of the treatment and which patients will benefit from the insulin-based therapy. Another classical example relates to radioisotopic forms of sodium iodide, which represents the first molecule used for both diagnosis and therapy, depending on the emission of the chosen isotope. In particular, application of the theranostic approach to thyroid cancers and appropriate cases of thyrotoxicosis involves the possibility of accurate dosimetry with the positron-emitting ^{124}I, so that the appropriate amount of ^{131}I can be administered to destroy the pathological tissue.[139] A more recent

application deals with a test designed to stratify patients with BRAF-mutant unresectable or metastatic melanoma who may be suitable for treatment with a BRAF inhibitor. In this sense, detecting BRAF mutation is equivalent to measuring blood glucose in that it allows identifying which patients would benefit from vemurafenib, a small-molecule inhibitor targeted to mutant BRAF. In both the diabetes and melanoma examples, the diagnostic tool and the therapeutic agent are completely different because they share no molecular components. On the other hand, these two examples differ at least in one regard: while glucose levels represent a "non-targeted" biomarker of the disease state (the true drug's therapeutic target being insulin receptor), detection of BRAF mutation underpins the very presence of the target against which the targeted drug has an inhibitory effect. In fact, the mutated BRAF constitutes both a therapeutic target and a disease biomarker, that is a "targeted" biomarker. In another incarnation of a targeted biomarker, the same agent could be employed in both diagnostic and therapeutic strategies. In this instance, the diagnostic and the therapeutic agents do share at least one molecular component. Following the very elegant definition provided by O'Shannessy and colleagues in 2014, they can be named as "leveraged theranostics." Hence, as schematically depicted in **Fig. 16**, we can describe at least three different theranostic classes: non-targeted, targeted, and leveraged.[140]

1.04.6.1 Theranostic Small Molecules for AD

Despite their recent emergence, a plethora of theranostics are being developed in cancer research.[141] However, although CNS still does not nearly match oncology in either diagnostic or therapeutic prospects owing to a poorer understanding of the disease's molecular roots, theranostic approaches against neurodegeneration begin to be intensively pursued.[142] An analysis of the literature reveals that most of the reported examples deal with theranostics directed to Aβ. As discussed earlier, Dr. Alzheimer identified the amyloid aggregates already a century ago as the postmortem neuropathologic hallmarks of the disease, and more recently, they have been selected as an effective biomarker for clinical diagnosis. At the same time, on the basis of the amyloid hypothesis, amyloid aggregates have been considered as a potential therapeutic target for drug discovery endeavors. Indeed, during the last two decades, tremendous effort has been devoted to the design of small drug-like molecules and antibodies capable of inhibiting Aβ aggregation and deposition. Thus, in the years, Aβ has been undoubtedly regarded from a double diagnostic and therapeutic perspective. This has provided the logical foundation for the development of fluorescent probes able to image Aβ deposition and, at the same time, to provide therapeutic strategies. In other words, such molecules could act as truly targeted or leveraged theranostics against AD.

Interestingly, to these two different categories correspond different design strategies to obtaining them. In particular, the reported lead generation strategy is a rational approach that relies on framework combination. As enunciated in the field of multitarget drugs by Morphy and Rankovic,[143] the framework combination is a medicinal chemistry strategy based on the integration of two molecular frameworks into a new single molecule. They use the terms linking, fusing, and merging, depending upon the extent to which the two starting frameworks are amalgamated. At one end of the spectrum, there are conjugated ligands, which contain separate pharmacophoric moieties connected by a linker. At the other end of the spectrum, there are ligands in which the two pharmacophores overlap or are highly integrated (fusing and merging). Whereas ligands designed by conjugating two distinct pharmacophores are more likely to have high molecular weight and less likely to have oral and CNS drug-like properties, the fused or overlapped compounds are likely to have lower molecular weight and potentially superior drug-like properties. In addition to such rational framework combination, a completely unbiased method could be followed, that is, a screening approach. Despite being less commonly found in the literature, this encompasses compound classes that are already known to be effective Aβ sensors, which are screened for their therapeutic potential and vice versa.[135]

Although huge development is taking place in the field of AD theranostics, it was not until 2012 that the first examples appeared in the literature. To this respect, it should be emphasized that the precision of current bibliographic searches can be undermined by the fact that other terms, such as "multifunctional" and "bifunctional" fluorophores, other than theranostics have been used by some authors. Actually, the literature contains examples where the aim of developing theranostics has not been consciously planned. However, as the reported small molecules are able to simultaneously imaging and inhibiting Aβ peptides aggregates, we can consider them as truly theranostic agents.

Fig. 16 Possible strategies to pursue theranostic approaches. *BM*, biomarker; *Dx*, diagnostic; *Rx*, therapeutic.

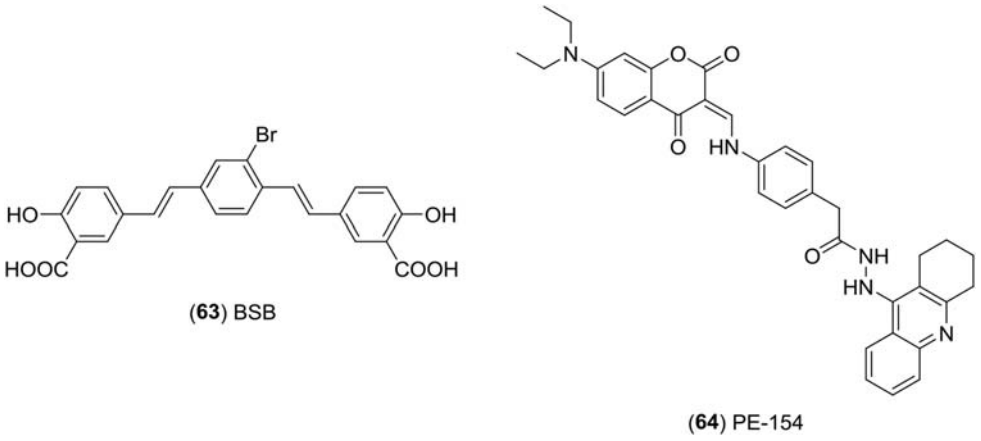

Fig. 17 Chemical structures of **63** and **64**, developed as theranostic precursors.

1.04.6.1.1 BTA-1, BSB, and PE154 as theranostic precursors

This is the case of a very pioneering study published by Ishikawa et al. in 2004.[144] ThT derivative BTA-1 (**6**, in Fig. 5) or CR derivative BSB (**63**, in Fig. 17), known to image Aβ plaques, fluorescently labeled prion plaques in the brain of patients affected by Gerstmann–Sträussler–Scheinker disease, a type of human prion disease. At the same time, both of them were found capable of inhibiting amyloid prion in brain tissues and displaying remarkable antiprion activity in ScN2a cell models ($IC_{50}=4$ nM for **6** and 1.4 μM for **63**).[144] **6** and **63** are therefore examples of potential antiprion theranostic compounds discovered through a screening approach. Despite this promising in vitro potential, neither compound was effective in vivo. Intravenous injection of **63** prolonged significantly but slightly the incubation periods of prion-infected Tga20 mice. However, no significant survival prolongation was observed. Consequently, both BTA-1 (**6**) and BSB (**63**) might be theranostic candidates against prion diseases, but it is likely that these compounds have poor permeability into the brain.[145] A comment is deserved about the capacity of a diagnostic/therapeutic agent to be active toward more than one neurodegenerative diseases. Indeed, neurodegenerative diseases, which encompass highly prevalent disorders such as AD and Parkinson's disease, and other less common ones, such as Huntington's disease, spinocerebellar ataxias, amyotrophic lateral sclerosis, and prion diseases, share several common features. In spite of peculiar clinical manifestation, all neurodegenerative disorders share the presence of cerebral deposits of misfolded protein aggregates. These deposits are a typical disease signature, and, although in each one the main protein component is different, they have similar morphological, structural, and staining characteristics. Compelling evidence suggests that in all these diseases, the accumulation of misfolded protein aggregates is the triggering factor in the pathology and leads to neurodegeneration. If such findings pose interesting questions about the possibility of common strategies for monitoring the amyloid aggregation process and for therapeutic intervention, from a diagnostic point of view, specificity would be mandatory for a differential diagnosis.

Another early example of theranostics was reported by Gütschow and coworkers already in 2009.[146] It deals with the generation of a theranostic small molecule against AD, developed starting from dual binding site acetylcholinesterase (AChE) inhibitors. This class of promising molecules was inspired by the discovery that AChE is one of the several proteins associated with amyloid plaque deposits. It has become increasingly clear that AChE, similar to other chaperone proteins, accelerates the assembly of Aβ peptide into amyloid fibrils.[147] The peripheral anionic site (PAS) of AChE has been identified as responsible for this proaggregating activity. This has provided the rationale for the development of dual inhibitors of AChE, that is, molecules that target the active site of the enzyme and the PAS. Such inhibitors should effectively prevent the aggregation of Aβ into toxic fibrils. Thus, in order to investigate the interplay between fibrils and AChE, Gütschow and colleagues developed a high-affinity, fluorescent ChE inhibitor,[146] PE154 (**64**, in Fig. 17).[148] This molecule originated from previously established heterodimeric ChE inhibitors, with the fluorogenic moiety deriving from the 7-aminocoumarin skeleton. Moreover, the planar electron-rich aromatic system of 7-aminocoumarin was anticipated as a useful interaction partner for Trp286.[149] Detailed in vitro kinetic analysis revealed that PE154 is a picomolar inhibitor of AChE. When characterizing **64**'s fluorescence properties (excitation peak at 405 nm and emission peak at 517 nm), a strong enhancement in fluorescence intensity in the presence of the target protein AChE was observed. Then, competition experiments with drug donepezil provide additional evidence for the binding mode of **64** within the enzyme gorge. The effective properties of **64** as a histological dye toward SP were revealed by confocal laser scanning microscopy in brain tissue sections of triple-Tg mice and an autoptic AD case. This was the first successful report of SP labeling by using a fluorescent, high-affinity AChE inhibitor. However, the authors could not precisely define whether **64** binds to AChE inside the plaques or to the amyloid structure itself.

1.04.6.1.2 SLOH as a theranostic small molecule

Carbazole-based cyanine fluorophores are highly sensitive fluorescent probes for double-stranded DNA and two-photon absorption dyes for two-photon excited bioimaging.[150] Moreover, monocyanine fluorophores were found to bind to Aβ peptide with concomitant strong fluorescence enhancement (>80-fold). On these bases, Li and Wong, in 2012, developed novel molecules

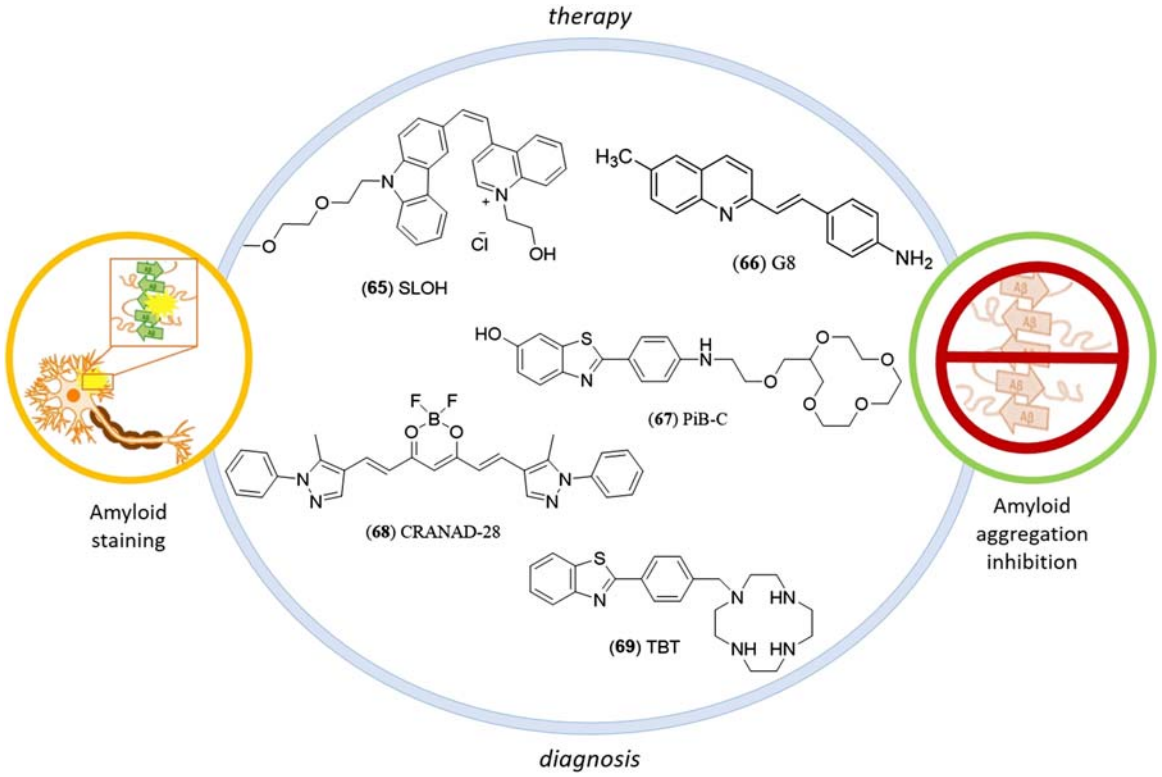

Fig. 18 Theranostic profile of **65**–**69**.

able to directly image and inhibit Aβ fibrillogenesis,[151] thanks to this dual activity they called "bifunctional." Thus, the carbazole scaffold was variously functionalized with the aim of optimizing critical functional properties such as Aβ-binding, cytotoxicity, and BBB permeability. The conducted SAR studies led to the discovery of a new promising compound, namely SLOH (**65**, in Fig. 18). As regards the diagnostic properties, in addition to an optimal intrinsic fluorescence, **65** showed a strong and progressive increase in fluorescence intensity, concomitant with a blueshift of the emission maximum, upon Aβ binding. Importantly, the fluorescence enhancement was much stronger for Aβ fibrils than for Aβ peptide. As regards the therapeutic properties, the authors demonstrated the ability of **65** to inhibit Aβ aggregation, by disrupting both the nucleation and elongation processes. The molecular mechanism of the inhibitory action was also corroborated by a circular dichroism study. A low toxicity together with a strong neuroprotective effect of SLOH toward the Aβ-induced cytotoxicity in SH-SY5Y cell line and mouse primary cortical cells further corroborated its potential. A preliminary in vivo proof of principle was obtained, as the authors demonstrated **65**'s abilities to enter the brain of live Tg mice and to specifically target Aβ plaques. In light of this profile, **65** emerges as a truly theranostic agent for AD.

1.04.6.1.3 G8 as a theranostic small molecule

The very first small molecule proposed as theranostic agent was styrylquinoline G8 (**66**, in Fig. 18), developed by Bolognesi and coworkers.[152] In 2013, they developed a small molecule able to potentially diagnose, deliver therapy, and monitor response to therapy in AD and prion diseases. The starting point of their work was the finding that several styryl derivatives, developed to improve the CNS properties of CR, were employed as AD imaging agents in vivo (see Section "**Aβ PET tracers derived from CR**"). Later, in 2012, styryl-1H-indole and styrylquinoline derivatives were reported as SPECT imaging probes to detect Aβ plaques. Thus, styryl moiety appears as a crucial framework for the ability of small molecules to label and interfere with pathological fibrillar aggregates, while the quinoline moiety is considered a privileged scaffold, displaying good pharmacokinetic properties and a high degree of drug-likeness. In light of this, they synthesized and evaluated (E)-6-methyl-4′-amino-2-styrylquinoline (**66**) as a theranostic agent able to potentially diagnose, deliver therapy, and monitor response to therapy in AD and prion diseases. As their goal was to develop a NIR fluorescent molecule, an amino group was purposely introduced to have an electron-releasing substituent conjugated with the quinoline nitrogen. After the characterization of its fluorescence properties, the authors evaluated **66**'s potential as a dual therapeutic/diagnostic agent. An antiaggregating property in the micromolar range, measured by a ThT-based fluorometric assay, suggested its ability as a moderate inhibitor of the Aβ fibrilization process. More importantly, a strong hypsochromic shift of the emission maximum (from 528 to 490 nm), concomitant with a hyperchromic effect upon Aβ binding, highlighted its potential as an amyloid sensor. Purposely addressed displacement studies suggested that **66** may have a primary high-affinity binding site distinct from ThT and a secondary low-affinity binding site in common with ThT. To substantiate **66**'s theranostic potential at a disease level, a cell-based model of prion diseases was exploited (ScGT1 cells). Fluorescent spots associated to prion fibrils were observed in infected

ScGT1 cells treated with **66**, using a ThS filter, which is within the NIR optical window. At the same time, when assessing the therapeutic antiprion potential in the same cell model, **66** showed a very low toxicity together with a remarkable activity: an EC_{50} of 0.5 μM, which makes it a very potent antiprion drug candidate. In addition, **66** exhibited BBB permeability *in* vitro (PAMPA test), demonstrating its value as CNS-directed agent. Thus, after the findings that **66** is able to stain and modulate both Aβ and prion protein, the authors proposed G8 as a promising theranostic tool to diagnose, deliver targeted therapy, and monitor response to therapy not only in AD but also in prion diseases.[152]

1.04.6.1.4 PiB-C as a theranostic small molecule

In 2014, Moore, Ran, and colleagues[153] exploited a novel approach to inhibit Aβ aggregation through a noncovalent modification at its surface. It is known that crown ethers can form stable complexes with protonated amines through the formation of hydrogen bonds. Moreover, it was reported that positively charged Aβ fibrils and protofibrils are highly cytotoxic and neutralization of the charges could reduce neuronal toxicity. Thus, the authors hypothesized that crown ethers could form noncovalent complexes with Aβ peptides through the formation of hydrogen bonds with protonated amino acids, such as arginine 5 (R5), lysines 16 and 28 (K16 and K28), and histidines 13 and 14 (H13 and H14). To note, previous studies suggested that K16 forms intersheet salt bridges and K28 form intrapeptide salt bridges with aspartate-23, all leading to the stabilization of the misfolded peptides. Thus, it was highly reasonable that breaking down these interactions should attenuate Aβ aggregation process. As a preliminary support to their hypothesis, the researchers verified the antiaggregating ability of a crown ether. 12-Crown-4 ether was chosen over other analogs, due to its low-molecular weight (beneficial for BBB penetration), its effective ability to form complexes with charged amino acids, and its negligible disturbance of physiological ion homeostasis. Both ThT testing and dot blotting indicated that this molecule could efficiently inhibit Aβ aggregation, albeit not in a specific way. Thus, to achieve a targeted effect, the authors planned to link the 12-crown-4 ether moiety with PiB (**7**), the widely used Aβ PET ligand. The new conjugate, called PiB-C (**67**, in Fig. 18), was then synthesized by attaching the 12-crown-4 ether moiety to the amino group of PiB. PiB-C showed an Aβ-aggregation inhibitory effect, as indicated by ThT testing and dot blotting, even stronger than PiB, suggesting the critical contribution of the crown ether moiety to the inhibitory effect. Then, the capability of **67** to reduce Aβ toxicity in SH-SY5Y cells was assessed, in comparison with 12-crown-4 ether. Both molecules lowered the toxicity of Aβ, while PiB did not, demonstrating that the neuroprotective ability of **67** was not originated from PiB. Finally, the authors tested the ability of **67** to specifically interact with Aβ plaques in a biologically relevant environment in vitro and in vivo, using two-photon imaging. As expected, PiB-C could clearly label plaques in APP/PS1 mouse brains not only ex vivo but also in vivo. Thus, the double merit of this study is the proposal of a novel strategy to attenuate Aβ aggregation and the development of the new theranostic agent PiB-C.

1.04.6.1.5 CRANAD-28 as a theranostic small molecule

Another theranostic agent, the curcumin-based CRANAD-28 (**68**, in Fig. 18), was proposed in 2014 by the same authors.[154] Previously, they had developed curcumin analogs able to detect soluble and insoluble Aβ (see Section "Curcumin as a Versatile Scaffold for the Development of Diagnostic and Therapeutic Agents for AD"), but some of them were endowed with low QY. To overcome this limitation, they hypothesized that the replacement of phenyl rings of curcumin with pyrazoles could increase the probe's brightness. This is because the inductive electron-withdrawing effect of one of the nitrogens of pyrazole could lead to a low tendency of electron delocalization in the system, which decreases tautomerization and increases QY. On the other hand, in a previous study, the authors had showed that similar curcumin analogs containing an imidazole ring could interfere with the coordination of copper and thus attenuate Aβ cross-linking (see Section "Curcumin as a Versatile Scaffold for the Development of Diagnostic and Therapeutic Agents for AD").

On this logical basis, they synthesized **68**, where the pyrazole could interfere with the copper coordination, and the phenyl substitution at the N-1 position could further reduce tautomerization and, in turn, improve QY. Thanks to the rationale design, **68** exhibited encouraging fluorescence properties in terms of optical range (excitation peak at 498 nm and emission peak at 578) and QY. Thus, the authors separately evaluated its diagnostic and therapeutic activities. Interestingly, its fluorescence intensity was quenched by Aβ, supportive of a direct interaction. This initial result was confirmed by ex vivo brain slice studies, where **68** provided an excellent contrast for SP. Then, after a positive evaluation of the BBB penetration, the capability of CRANAD-28 for the two-photon imaging of Aβ plaques was effectively validated in APP/PS1 mice. In parallel, western blotting analysis showed that **68** could significantly inhibit natural and copper-induced Aβ cross-linking. Thus, the authors were able to demonstrate the truly theranostic potential of **68**, as a two-photon imaging probe and as an inhibitor of Aβ cross-linking. The great novelty of **68**, although its emission maximum is not within the NIR region, is that it was the first theranostic agent to be successfully tested in an in vivo mouse model. Thus, CRANAD-28 marks an important stage in the search of novel molecules that may contribute to AD diagnosis and therapy in the future.

1.04.6.1.6 TBT as a theranostic small molecule

A more recently proposed theranostic small molecule is TBT (**69**, in Fig. 18), developed in 2015 by Yang, Wang, and colleagues.[155] The rationale behind their study was that metal chelators act as potential therapeutics for AD by reducing metal-induced Aβ aggregation and consequent neurotoxicity and counterbalance metal ion dyshomeostasis. Indeed, metal dyshomeostasis is a contributing cause of AD and of several other neurodegenerative diseases. Particularly, abnormal concentrations of Cu^{2+} and Zn^{2+} have been detected in the neocortex of AD patients, especially associated with Aβ deposits.[156] Interestingly, binding sites for both metal ions have been identified on Aβ oligomers, where they are thought to critically mediate amyloid toxicity.[157] On these bases, the authors

hypothesized that proper modification of chelators with sensing functions would be a promising strategy for developing dual-functional chelators, acting simultaneously as probes and inhibitors of metal-induced Aβ aggregation. To this aim, they developed the novel fluorescent chelator **69**. **69** was designed by following a linking strategy, as it is composed of a metal chelating 1,4,7,10-tetraazacyclododecane (cyclen) group and the Aβ-targeting 2-phenylbenzothiazole group. Indeed, cyclen was selected for its high modulatory efficacy toward metal-induced Aβ aggregation while 2-phenylbenzothiazole as the neutral ThT derivative with a well-known Aβ binding affinity. **69** can tightly bind to Zn^{2+} or Cu^{2+} via coordination interactions between the cyclen group and the metal ions. Moreover, this molecule also exhibited high selectivity for Cu^{2+} and Zn^{2+} over other biologically relevant metal ions. The synergistic effect of the two starting moieties was clearly evident from the profile shown by **69** in the ThT fluorescence competition assay. Additionally, molecular docking analysis suggested that TBT competes with ThT due to overlapping binding sites in Aβ. Then, after confirming that **69** specifically inhibits Zn^{2+}- and Cu^{2+}-induced $Aβ_{40}$ aggregation, the authors were able to monitor the disaggregation of $Aβ_{40}$ aggregates in brain homogenates of APPswe/PSEN1 Tg mice, by using TBT fluorescence behavior. In this respect, **69** is capable of targeting and disaggregating metal-associated Aβ aggregates and self-monitoring the disaggregation by fluorescence decrease even in the brain homogenates of AD mice. All these results, together with TBT's specificity, neuroprotectivity, efficient BBB permeability, and rapid washout, highlighted the potential of this fluorescent chelator as a theranostic tool for AD. However, it is important to highlight that in vivo studies are essential to evaluate the effective applicability of TBT as a theranostic agent in AD.

1.04.6.2 Theranostic Nanomedicine for AD

Although beyond the scope of this book chapter, which is devoted to diagnostic and theranostic small molecules, it should be noted that nanomedicines have been the first theranostics to be developed. In the last two decades, several approaches based on nanoparticles (NPs) ranging in size 1–1000 nm have been successfully brought to the clinic to treat cancer, pain, and infectious diseases. These therapies successfully exploit the general ability of NPs to deliver drugs more precisely, to improve their solubility, to prevent degradation, to increase their therapeutic index, and to reduce the immune response. NPs designed specifically for biomedical applications so far are of different types, mainly liposomes, solid lipid NPs, albumin NPs, polymeric NPs and magnetic NPs, dendrimers, nanogels, and quantum dots. These NPs, in addition to positive features such as biological stability and biocompatibility, have the intrinsic versatility of allowing incorporation of several biological or drug molecules.[158] In spite of these positive features, when referring to the specific development of nanomaterials for CNS applications, a major therapeutic challenge is that they must penetrate the brain, protected by the BBB. The mechanism of uptake and retention of a nanoparticulate system in brain delivery can be through various possibilities: (i) retention of particulate formulation in the blood capillaries of the brain, which, when adsorbed, creates a concentration gradient across the endothelial cells; (ii) suitable surfactant coating, possibly inhibiting the efflux mechanism and allowing the drug to be retained at the site of action; (iii) diffusion of the drug that can be enhanced by opening the tight junction of the endothelial cells; and (iv) release of the drug (normally by endocytosis). Drug delivery is also possible by all of the aforementioned processes.[159] On this ground, researchers have begun to intensively pursue theranostic approaches against neurodegeneration.[160] Some selected examples are provided in the succeeding text. These are only intended to give readers the flavor of the approach and direct them to the original literature or more thorough reviews with several recent reports on the potential applications of theranostic NPs in AD.[161]

Interestingly, a nanotechnological approach has been applied to overcome the low BBB uptake of potential theranostic small-molecule PE154 (**64**). Härtig and coworkers developed carboxylated poly(glycidyl methacrylate) and core-shell polystyrene-block-poly(*n*-butyl cyanoacrylate) NPs both loaded with PE154.[148] Although NPs were directly injected in the hippocampus of triple-Tg AD mice, their clear ability to target Aβ deposits with high specificity was confirmed. This in vivo study provided also the proof of principle of Aβ targeting by using PE154, after its release from NPs in vivo. In addition, the authors consciously considered the possibility of developing a theranostic approach for AD.[162]

Among the various NPs used in AD-related disease research, magnetic iron oxide NPs are particularly promising because of their high biocompatibility, distinctive magnetic properties, relative nontoxicity, biodegradability, and capacity for use as multimodal contrast agents.[163] In this context, Huang et al. developed a biomimetic approach based on superparamagnetic iron oxide glyconanoparticles to inhibit and detect Aβ fibrilization.[164] They build on the finding that carbohydrates, such as gangliosides, have been shown to play significant roles in amyloid aggregation initiation. The binding of Aβ by the glyconanoparticles was demonstrated through several techniques and its detection both in vitro and ex vivo by MRI. Furthermore, the glyconanoparticles were not only nontoxic to SH-SY5Y cells but also greatly reduced Aβ-induced cytotoxicity, highlighting the potential of these NPs for the dual detection and imaging of Aβ.[164] Another theranostic application of Aβ-directed iron NPs is exemplified by the work of Margel et al. These authors reported in 2013 the immobilization of the specific anti-Aβ monoclonal antibody BAM10 to NIR fluorescent maghemite ($γ$-Fe_2O_3) NPs, with the explicit aim of inhibiting Aβ fibrillation kinetics and of detecting Aβ fibrils. Indeed, the developed NP significantly hindered Aβ fibrillation process, such as Aβ-induced cytotoxicity to PC-12 cells. Furthermore, they enabled specific detection of Aβ fibrils ex vivo by fluorescence imaging.[165]

1.04.7 Conclusions

As can be seen from the discussed examples, in the last 20 years, an active and considerable progress has been made in the development and application of tracers for SP and NFT imaging in AD. As amyloid PET has entered into clinical use, we have clearly

understood the potential diagnostic benefits of this tool. The possibility to directly visualize in vivo Aβ deposition, previously only possible at autopsy, undoubtedly represents a major step forward. Equally important is the possibility that PET may facilitate the development of new treatments and of accurate and reliable assessments for diagnosis and for evaluations of the effectiveness of proposed treatments. As an easier and cheaper alternative to PET tracers, fluorescent probes have gained tremendous attention for imaging of both Aβ and tau aggregates. Furthermore, fluorescence imaging has given impetus to the development of theranostics, which combine therapeutic and diagnostic properties in a single chemical entity. In this book chapter, we focused on theranostic small molecules and their applications in AD imaging. The different strategies applied for the design of these molecules were discussed along with the in vitro and in vivo results. Currently, there is no registered theranostics available in the market for AD imaging. This is because there are still many crucial issues that need to be addressed, and their translational potential has been only marginally investigated. Although no one knows if theranostics will reach the clinics, there are already valid argument that these unconventional tools might increase our overall understanding of AD and could be critical for both finding and personalizing its treatment.

1.05.1 Introduction

Nutraceuticals, including functional food, received considerable interest because of their presumed safety and potential nutritional and therapeutic effects in the form of food. It was presumed before 1990 that nutraceuticals are natural foods that provide energy for daily requirement in the body. Later it was realized that nutraceuticals may have beneficial effects on different nutritional disorders.[1] Nutrients are substances that have health-promoting as well as health-protective activity and they can be classified into two types, namely, macronutrients and micronutrients. Macronutrients include protein, carbohydrate, lipid or fat, and crude fiber. Micronutrients include different minerals, vitamins, antioxidants, etc.

According to a survey, diet was rated and considered to be more highly preferred by consumers than exercise or hereditary factors for achieving good health.[2] Further, numerous epidemiological studies suggest that the risks for many chronic diseases are diet related, and hence appropriate use of nutraceuticals can significantly decrease the diet-related chronic diseases, such as heart disease, cancer, stroke, and diabetes. Thus, pharmaceutical and nutritional companies have shown keen interest in bringing these products into the market because they possess potential nutritional value and multiple therapeutic properties. Some popular nutraceuticals include carotenoids, curcumin, gingerol, glucosamine, ginseng, lycopene, folic acid, cod liver oil, omega-3 eggs, calcium-enriched orange juice, green tea, etc. Majority of the nutraceuticals are claimed to possess multiple therapeutic benefits, though substantial evidence about their unwanted effects is lacking for the nutraceuticals.

Hippocrates (460–370 BC) correctly emphasized, "Let food be your medicine and medicine be your food." Currently there is an increased global interest due to the recognition that "nutraceuticals" play a major role in health enhancement. The term "nutraceutical" was coined by combining the terms "nutrition" and "pharmaceutical" in 1989 by Dr. Stephen De Felice, Chairman of the Foundation for Innovation in Medicine.[3] "Nutraceutical" is a marketing term developed for nutritional supplement that is sold with the intent to treat or prevent disease and thus has no regulatory definition.[4] Such products may include isolated nutrients, dietary supplements, and diets to genetically engineered "designer" foods, functional foods, herbal products, and processed foods such as cereals, soups, and beverages.

1.05.2 Rational for the Use of Nutraceuticals

- Regular consumption of synthetic drugs for the treatment of various diseases may cause serious side effects/organ failure whereas the nutraceuticals from natural source is safe.
- Daily intake of food consumed by many people does not have enough fiber, carbohydrate, protein, and the right amounts of vitamins and minerals to maintain good health. Rapidly increasing chronic diseases like cardiovascular diseases (CVDs), cancer, diabetes, and obesity leading to death is mainly due to suboptimal diet quality. Reports suggest that mortality is increasing every year mainly due to insufficient intake of fruits, nuts/seeds, whole grains, vegetables, seafoods, as well as minerals. Thus, nutraceuticals are considered as sources of health promotion.[5]
- Disease treatment by allopathic/modern medicine is highly expensive.
- Drugs derived from plants can be used for treatment or prevention of disease, whereas the food derived from plants enact as nutraceutical by preventing the disease and by eliciting health benefits.

1.05.3 Different Terminologies

There are different terminologies and definitions used by different countries with respect to nutraceuticals as "functional foods," "dietary supplements," "designer foods," "medical foods," "pharmafoods," and "phytochemicals," and there is a thin line of difference between these terminologies in their interchangeable usage by different people on different occasions.

1.05.3.1 Nutraceuticals

Nutrition is the science of how living organisms obtain and use food required for growth and health. De Felice defined "nutraceutical" as a food or part of a food that provides medical or health benefits, encompassing prevention and treatment of diseases.[6] "Pharmaceuticals" may be considered as drugs used mainly to treat diseases, while "nutraceuticals" are those that are intended to prevent diseases. The distinction between pharmaceuticals and nutraceuticals is cute, but superficial and erroneous. Pharmaceuticals are substances that may have patent protection as a result of extensive testing to conform to the specifications of respective governments. Both pharmaceuticals and nutrients can cure and prevent disease(s) but only pharmaceuticals have governmental sanction. Examples of nutraceuticals include fortified dairy products (milk as such is a nutrient and its product casein is a pharmaceutical), citrus fruits (orange juice is nutrient and its constituent ascorbic acid is a pharmaceutical), lutein-containing multivitamin tablets, fish oil capsules, herb extracts, glucosamine, and chondroitin sulfate pills.

1.05.3.2 Functional Foods

Nutraceuticals, sometimes referred to as "functional foods," have caused heated debate because they blur the traditional dividing line between food and medicine. When food is being cooked or prepared using "scientific intelligence" with or without the knowledge of how or why it is being used, then the food is called as "functional food." Thus, functional food provides the body with the required amount of vitamins, fats, proteins, and carbohydrates necessary for healthy survival. When functional food aids in the prevention and/or treatment of disease(s)/disorder(s) other than deficiency conditions like anemia, it is called a "nutraceutical." Tomato fruit packed with a specific type of compound that helps to remove toxic compounds from our body and prevent damage to vital organs like the heart, kidney, lungs, and brain is a typical example of functional food. Other examples of functional foods include soybean, fish, oat meal, cereal bran (wheat, rice), and tea (green and black). Government of Canada for national public health defines functional foods as, "food that is similar in appearance to, or may be, a conventional food that is consumed as part of a usual diet, and is demonstrated to have physiological benefits and/or reduce the risk of chronic disease beyond basic nutritional functions, i.e. they may contain bioactive compounds." The Institute of Medicine's Food and Nutrition Board defined functional foods as, "any food or food ingredient that may provide a health benefit beyond the traditional nutrients it contains."

Functional foods included a wide variety of foods and food components believed to improve overall health and well-being, reduce the risk of specific diseases, or minimize the effects of other health concerns.

1.05.3.3 Dietary Supplement

The US dietary supplement health and education act (DSHEA) of 1994 defines "dietary supplement" as a product (other than tobacco) that is intended to supplement the diet that bears or contains one or more ingredients, like vitamin, mineral, a herb, an amino acid, or a concentrate, metabolite, constituent, extract, or combinations of these.

1.05.3.4 Medical Foods

"Medical foods" are a specific category of therapeutic agents that are intended for the nutritional management of a specific disease. An example of medical foods is formulations intended to manage patients with inborn errors in amino acid metabolism. Newer medical foods are designed to manage hyperhomocysteinemia, pancreatic exocrine insufficiency, inflammatory conditions, cancer, and other diseases.

1.05.3.5 Designer Foods

"Designer food" refers to the food that is designed to have some health benefits other than its traditional nutritional value. "Fortified food is the synonym for designer food," which refers to the food fortified or enriched with nutrient content already present in it or other complementary nutrient. The term was introduced in Japan in 1980s for referring to processed food containing nutrients of some additional health benefits apart from its own nutritional value,[7] whereas in China, designer food (referred to as health foods) is their traditional medicine. The addition of docosahexaenoic acid (DHA) to health drinks for improving brain and visual development and the use of probiotics and nucleotides to enhance immune response and sports nutrition are important examples of designer food.

1.05.3.6 Phytochemicals

Phytochemicals have been used for more than 5000 years in China, Greece, and India for the treatment and prevention of various diseases. Phytochemicals (also called phytonutrients) are the constituents present in plants that may help in reducing the risk of developing certain diseases. For example, consuming tomatoes and garlic that contains phytochemicals lycopene and allicin may reduce the risk of cancer. Consuming grapes that contain resveratrol may reduce the risk of CVDs.

1.05.4 Classification of Nutraceuticals

Nutraceuticals can be classified on the basis of their food sources, chemical nature, and based on the pharmacological action.

Based on natural food source
Based on chemical nature
Based on pharmacological action

1.05.4.1 Classification by Natural Food Source

On the basis of natural food source it is classified as the products obtained from plants, animals, minerals, or microbial sources (Table 1).

1.05.4.2 Classification by Chemical Nature

Based on chemical constitution nutraceuticals can be classified (Fig. 1) into six types, namely, isoprenoid derivatives, phenolic substances, amino acid-based substances, carbohydrates and derivatives, fatty acids and structural lipids, and minerals.

1.05.4.3 Classification by Pharmacological Action

Nutraceuticals can be grouped based on their pharmacological benefits as detailed in Table 2.

Nutraceuticals can also be categorized as traditional nutraceuticals and nontraditional nutraceuticals. Traditional nutraceuticals are natural foods that contain several natural components that deliver benefits beyond basic nutrition, such as lycopene in tomatoes, omega-3 fatty acids in salmon, resveratrol in grapes, or saponins in soy beans. Nontraditional nutraceuticals are artificial foods prepared by adding bioactive components for well-being of humans. It can be subdivided into fortified and recombinant nutraceuticals. Fortified nutraceuticals are the food with agricultural breeding or with added nutrients. Orange juice with calcium, cereals with added vitamins or minerals, flour with added folic acid, and milk with cholecalciferol are some of the examples of fortified nutraceuticals. Energy-providing foods such as bread, alcohol, fermented starch, yogurt, cheese, vinegar, and others that are produced with the help of biotechnology are called recombinant nutraceuticals.

1.05.5 Vitamins as Nutraceuticals

Vitamins are the complex substances of organic origin, which in small quantities are necessary for the maintenance of human and animal life. Fat soluble vitamins A, D, E, and K (Fig. 2) can be stored in the body, whereas the water soluble vitamins (Fig. 3) cannot be stored in the body because they are eliminated through the body fluids like urine and transpiration. Important health benefits of water soluble and water insoluble vitamins are detailed further.

1.05.5.1 Water Insoluble Vitamins

Vitamin A (**1**) exists in several forms, namely, in alcohol form as retinol; in aldehyde form as retinal; in acid form as retinoic acid, where all these forms are known as retinoids. Vitamin A, which is rich in carrots and green vegetables, is essential for growth and

Table 1 Natural food source of nutraceuticals

	Nutraceuticals	*Source*
Plants	Antioxidant vitamins (vitamin C, vitamin E)	Citrus fruits, wheat germ oil, cotton seed oil, peanut oil
	Curcumin	Turmeric
	Dietary fibers	Fruits, barley, oats, lignin, cellulose, pectin
	Lycopene	Tomatoes
	Flavonoids	Grapes
	Isoflavonoids	Soybeans
	Polyunsaturated fatty acids	Flaxseed (*L. usitatissimum*), walnuts, canola oil, soybeans
Animals	Carnitine	Heart, skeletal muscles
	Glucosamine	Bovine
	Methylsulfonylmethane	Meat, milk
Minerals	Calcium	Leafy greens, milk, yogurt, cheese, creams, okra
	Chromium	*Aloe vera*, barley, black pepper, brewer's yeast, broccoli, eggs, mushrooms, green beans, legumes, oats, onions, potatoes, rye, green chili spices, spirulina, tomatoes, whole grains
	Cobalt	Green leafy vegetables, broccoli, nuts, fish, organ meats, oysters, spinach, whole grains
	Copper	Almonds, apples, apricots, beetroot, berries, buckwheat, caraway seeds, cashew nuts, cherries, dates, dried beans, drumstick leaves, egg yolk, fennel, berries, grapes, guava, kiwi fruit, lamb, legumes, lemons, mango, millet, mushrooms, nuts, oats, pears, peas, plums, potatoes, pumpkin, radish, raisins, shellfish, spinach, spirulina, spring onions, strawberries, tea, walnuts, whole grains, yams
	Iron	Meat, fish, poultry
	Iodine	Beetroot, citrus fruits, egg yolk, fish liver oils, garlic, halibut, pears, pineapples, prawns, sea salt, shellfish, spirulina, strawberries, turnip greens, yogurt
	Magnesium	Dark leafy greens, nuts, seeds, fish, beans, whole grains, yogurt, banana, dry fruits
	Manganese	Legumes, cereals, green leafy vegetables, tea
	Phosphorous	Milk, meat, nuts, fish, beans, whole grains
	Potassium	Avocado, potato, sweet potato, tomato, mushroom
	Zinc	Apples, beef, caraway, cherries, chicory, cucumber, drumstick leaves, egg yolk, fennel, flaxseed, garlic, green tea, legumes, melon, milk, mulberries, mushrooms, oats, oysters, peanuts, peas, pine nuts, pork, poultry, prawns, shellfish, spirulina, sweet potato, tapioca, watermelon seeds, whole grains
Microbes	Probiotics	*Lactobacilli*, *Streptococci*, *Bifidobacteria*
	Prebiotics	Oligofructose, inulin, galactooligosaccharide, lactulose

development, maintenance of healthy vision, skin, and mucous membranes. Being an antioxidant it may aid in the prevention and treatment of certain cancers[8] and in the treatment of certain skin disorders.[9]

There are two major forms of vitamin D, namely, vitamin D_2 (**2**), found in plants and better known as ergocalciferol or calciferol, and vitamin D_3 (**3**), found in animal tissues and often referred to as cholecalciferol. Vitamin D is essential for formation of bones and teeth, and helps the body in absorption of calcium. It is essential for the prevention of autoimmune diseases, heart diseases, diabetes, hypertension, and cancer.[10,11] The recommended daily intake of vitamin D is 200 IU for children and adults up to 50 years old, 400 IU for people of 51–70 years old, and 600 IU for people over 70 years old.

Vitamin E (**4**) helps to form blood cells, muscles, nerve tissue, boosts the immune system, and protects oxidation of polyunsaturated fatty acids (PUFAs). It is involved in the maintenance of membrane stability and immune function, inhibition of cancer cell growth and differentiation, free radical scavenging, inhibition of deoxyribonucleic acid (DNA), ribonucleic acid, and protein synthesis in cancer cells.

Vitamin K (**5**) is essential for blood clotting and plays a major role in the prevention of osteoporosis,[12] vascular calcification, and CVD.

1.05.5.2 Water Soluble Vitamins

Daily intake of B-complex vitamins is recommended to combat high level of homocysteine, a known risk factor for heart diseases. B-complex vitamins are generally recommended to those who use caffeine, alcohol, excessive sugar, or oral birth pills in their diet, since they are water soluble and easily excreted from the body.

Vitamin B_1, or thiamine, (**6**) plays an important role in the treatment of Alzheimer's disease, congestive heart failure, and cancer.

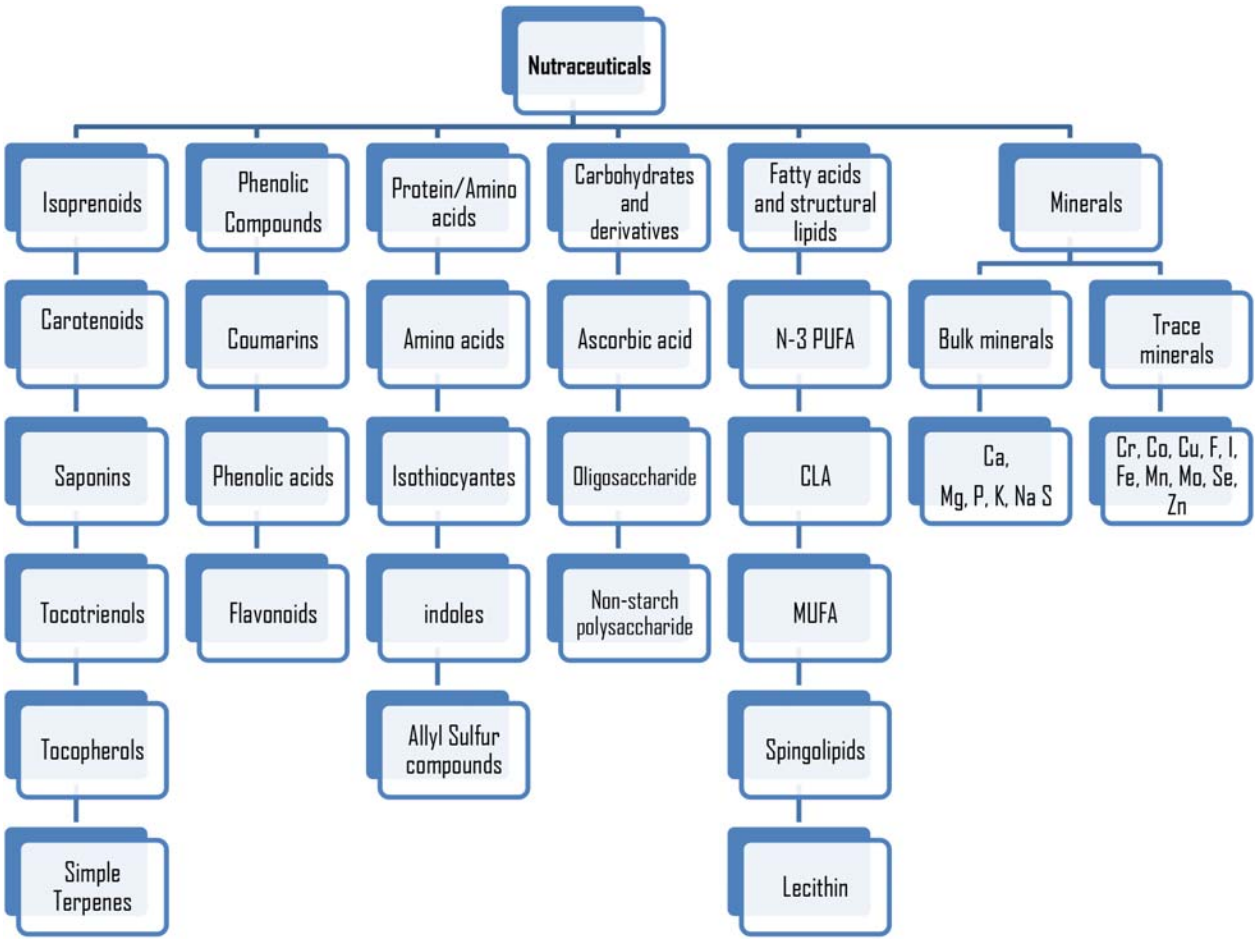

Fig. 1 Classification of nutraceuticals based on chemical nature.

Table 2 Pharmacological action of various nutraceuticals

Pharmacological action	*Nutraceuticals*
Anti-Alzheimer	β-Carotene, curcumin, lutein, lycopene
Antiarthritic	Glucosamine, chondroitin methylsulfonylmethane
Anticancer	Curcumin, selenium present in fruits and vegetables
Antidiabetic	Ethyl esters of omega-3 fatty acids (docosahexaenoic lipoic acid), dietary fibers
Antioxidant	Ascorbic acid, lycopene, tocopherol
Anti-Parkinson's	Ascorbic acid, creatine
Eye health	Lutein, zeaxanthin
Lipid-lowering agent	Polyunsaturated fatty acids
Inhibition of LDL oxidation	Niacin, green tea, resveratrol, garlic, policosanol, sesame
Reduction of total and LDL cholesterol	Plant sterols, flaxseed, garlic, dietary fiber, soy protein
HMG-CoA reductase inhibition	Red yeast rice, green tea, garlic, omega-3-fatty acids, plant sterols
Reduction of triglycerides	Niacin, red yeast rice, orange juice, flaxseed, resveratrol
Increase in total HDL	Niacin, pomegranate, curcumin
Prevention of cardiovascular diseases	Omega-3 poly unsaturated fatty acids, vitamins, minerals, polyphenols, dietary fibers, flavonoids present in onion, vegetables, grapes, red wine, apples, and cherries
Weight loss	Ephedrine, caffeine, ma huang-guarana, chitosan, green tea, 5-hydroxytryptophan, glucomannan, fenugreek, conjugated linoleic acid, capsaicin, *M. charantia*

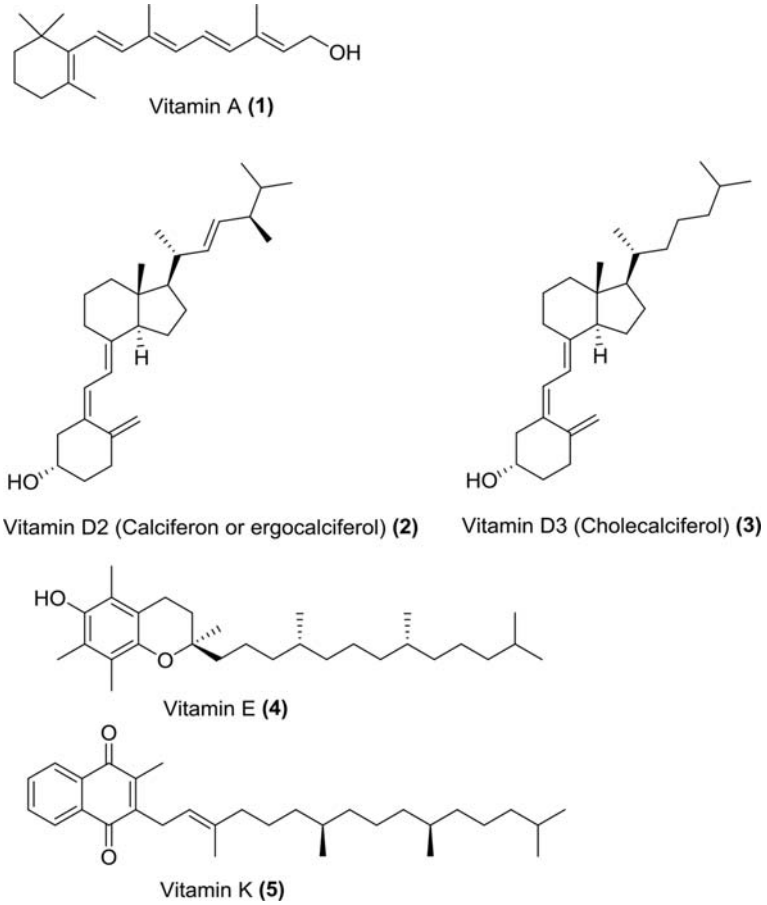

Fig. 2 Chemical structures of water insoluble vitamins.

Riboflavin-5-phosphate is a cofactor for vitamin B_2 (**7**), which is beneficial for people who lack the enzyme to convert vitamin B_2 because of nutritional factors or disease condition. Riboflavin helps in preventing cataracts[13] and is used as a prophylaxis in migraine headaches.

Niacinamide deficiency may cause neurological and skin problems. The major dietary sources of niacin are peanuts, ragi, pulses, soyabean, etc. Niacin(**8**) (vitamin B_3) is chemoprotective[14] and prevents insulin-dependent diabetes mellitus[15] and helps to prevent high cholesterol and CVDs.[16]

Pantothenic acid (vitamin B_5) (**9**) plays an important role in the degradation of fatty acids, and production of sterols and steroid hormones. Dextrorotatory isomer D-pantothenic acid (yellow) is found to possess biological activity and since it is highly unstable in acid, alkali, and in high temperature, it is given in the stable form of calcium pantothenate (white). It is present in peanut butter, almonds, cheese, and lobster. Supplementation of pantothenic acid helps in healing wounds and lowering cholesterol/triglycerides levels.[17]

Vitamin B_6 (pyridoxine) (**10**) is crucial for glucose production, hormone modulation, and neurotransmitter synthesis. Pyrodoxal 5-phosphate is considered as an active form of vitamin B_6, which helps in preventing CVD (by lowering the levels of homocysteine), improving immune and cognitive functions, and reducing the formation of kidney stones.

Biotin (vitamin H or B_7) (**11**) plays an important role in the prevention of diabetes, high cholesterol, and hair loss.[18]

Vitamin B_9 is also called folic acid (**12**), and is important in the prevention of heart diseases (regulates homocysteine levels),[19] colorectal and breast cancer,[20,21] Alzheimer's disease, and cognitive impairment.[22]

Vitamin B_{12} helps in the prevention of CVD,[23] cancer,[24] Alzheimer's disease, and dementia.[25]

Vitamin C (**13**) is required for the growth and repair of tissues in all parts of our body. Vitamin C is essential for the healing of wound and for the repair and maintenance of cartilage, bones, and teeth. Vitamin C deficiency can lead to dry and splitting hair, gingivitis, rough, dry, scaly skin, decrease in wound-healing rate, scurvy, easy bruising, nose bleeds, swollen and painful joints, anemia, etc. Vitamin C combats cancer by promoting collagen synthesis and thus prevents tumors from invading other tissues. Vitamin C, a natural antioxidant, prevents the oxidative DNA damage and also inactivates nuclear factor kappa-light-chain-enhancer of activated B cells (NF-kB) in endothelial cells during the inflammation process and hence can inhibit tumor promotion.[26] As body does not manufacture vitamin C, it is important to include plenty of vitamin C-containing foods in daily diet.

Health benefits, source, and deficiency diseases of all water soluble and water insoluble vitamins are provided in **Table 3**.

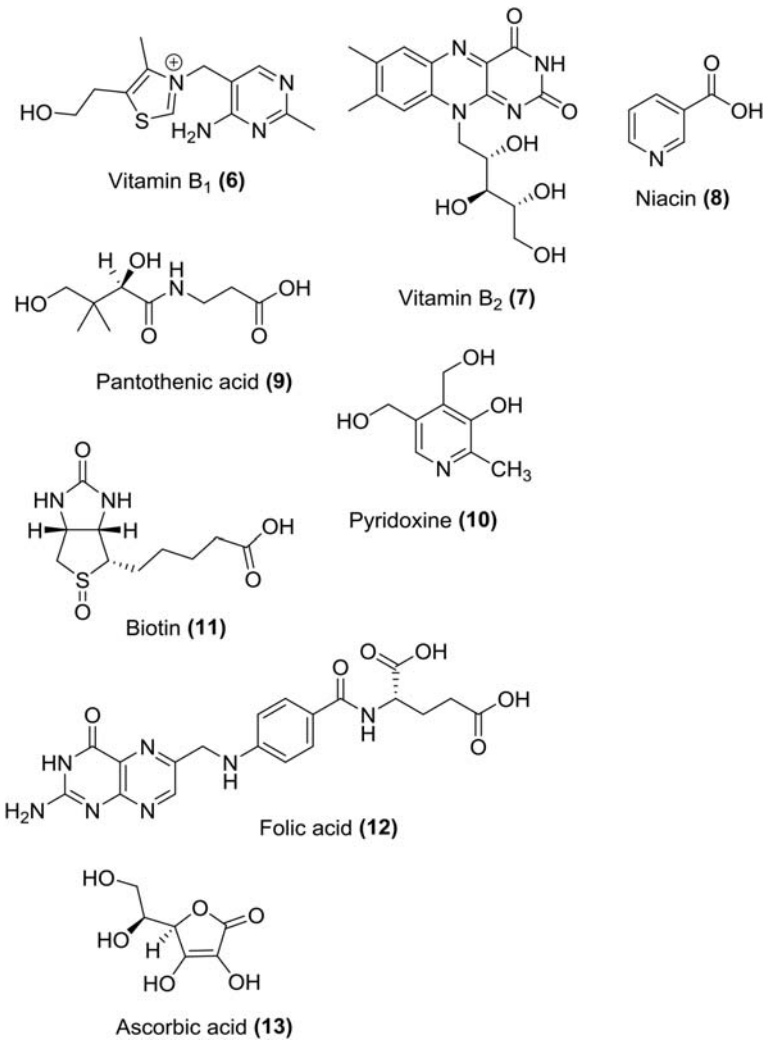

Fig. 3 Chemical structures of water soluble vitamins.

1.05.6 Minerals as Nutraceuticals

Dietary minerals are inorganic elements essential for life, present in the soil and water, which are absorbed by plants. Human body requires some minerals that are essential for normal functioning called as essential minerals, which can be divided into macrominerals (major minerals) and microminerals (trace minerals). The essential six bulk or macrominerals required in relatively large amounts include calcium, magnesium, phosphorus, potassium, sodium, sulfur, and the minerals needed only in very small amounts include chromium, cobalt, copper, fluoride, iodine, iron, manganese, molybdenum, selenium, and zinc.[27] These minerals are essential because they are critical for the production of vitamins, enzymes, and hormones in the body, as well as for the proper blood circulation, fluid regulation, nerve transmission, muscle contraction, cellular integrity, and energy production. These minerals work synergistically with each other and with other nutrients, and minimize the cause of a disease.

1.05.6.1 Essential Macrominerals

1.05.6.1.1 Calcium

The human body needs calcium more than any other mineral, as 99% of the quantity in the body is used for building strong bones and teeth and the remaining 1% is used by the blood, muscles, and nerves. Calcium also plays a role in many other vital physiological activities, including blood clotting, nerve conduction, muscle contraction, regulation of enzyme activity, cell membrane function, and blood pressure regulation. It is present in fruits like blackberries, blackcurrants, dates, grapefruit, mulberries, orange, pomegranate, leafy greens, milk, yogurt, cheese, and okra.

Table 3 Health benefits of vitamins

Vitamins	Source		Deficiency disease	Health benefits
	Plants	Others		
Vitamin A	*Amaranthus* sp. *Brassica oleraceae* *Cucurbita pepo* *Daucus carota* *Pisum sativum* *Spinacia oleracea*	Fish liver oil, milk, cheese, butter	Night blindness, xerophthalmia, keratomalacia	Essential for growth, prevention and treatment of certain cancer, improvement in vision
Vitamin D (calciferol) (also called sunshine vitamin)	*Beta vulgaris* *Cucurbita moschata*, *C. pepo* *Pastinaca sativa* *Solanum tuberosum* *Spirulina maxima*	Fish liver oil, wheat germ oil, egg yolk, milk, butter, mushrooms	Rickets in children osteomalacia in adults	Essential for formation of bones and teeth, helps body to absorb and use calcium, prevents colon cancer
Vitamin E (tocopherol)	*B. vulgaris C. moschata*, *C. pepo* *P. sativa S. tuberosum* *Spirulina maxima*	Wheat germ oil, cotton seed oil, peanut oil, soy bean oil	Sterility, degenerative changes in muscle, aging of skin	Antioxidant, helps to form blood cells, muscles, lung, and nerve tissue, improves immune system
Vitamin K	*Asparagus officinalis* *B. oleraceae* *Cucumis sativus* *D. carota* *P. sativum* *S. oleracea*	Meats, cheese, eggs	Hemorrhagic condition	Essential for clotting of blood, regulates calcium level, and activates proteins involved in bone health
Vitamin B_1 (thiamine)	*Ipomoea batatas* *P. sativum* *P. sativa S. tuberosum*	Cereals, pulses, nuts, yeast	Beriberi, corneal opacity	Essential for functioning of heart, muscles, and nervous system
Vitamin B_2 (riboflavin)	*Amaranthus* sp. *C. pepo* *P. sativum*	Whole grains, milk, eggs	Photophobia, dry itchy eyes, depression, memory loss, fatigue	Essential for growth and reproduction
Vitamin B_3 (niacin)	*C. pepo* *P. sativum* *Glycine max*	Liver, meat, yeast	Chick dermatitis	Helps in functioning of digestive system
Vitamin B_5 (pantothenic acid)	*B. oleraceae*, *Phaseolus vulgaris* *P. sativum* *G. max*	Milk, yeast eggs, whole fish, chicken, grain cereals	Fatigue, insomnia, depression, vomiting, stomach pain	Helps in lowering cholesterol level
Vitamin B_6 (pyridoxine)	*Amaranthus* sp. *B. oleraceae*, *Capsicum annum* *P. sativum* *S. tuberosum*	Rice polishing, yeast, egg, milk	Pellagra, depression, mental confusion, anemia, nausea, glossitis	Plays role in creation of antibodies in immune system, maintains normal nerve function
Vitamin B_7 (Vitamin H or biotin)	*Allium cepa* *B. oleraceae*, *C. sativus* *D. carota* *Juglans regia* *Prunus dulcis*	Egg yolk, peanuts, yeast bread, whole-wheat cheese, cheddar pork, salmon	Anemia, anorexia dermatitis, conjunctivitis	Helps body to metabolize proteins and process glucose

(Continued)

Table 3 Health benefits of vitamins—cont'd

Vitamins	Source		Deficiency disease	Health benefits
	Plants	*Others*		
Vitamin B_9 (folic acid)	*Brassica rapa* *B. oleraceae*, *Phaseolus lunatus* *P. vulgaris*	Chicken giblets, kidney, egg yolk, wheat flour, whole grain breads	Macrocylic anemia	Helps in producing RBC, protects against heart disease by lowering homocysteine, maintains normal brain function
Vitamin C (ascorbic acid)	*Amaranthus* sp. *C. annum* *B. oleraceae*, *P. sativum* Citrus fruits, berries	Milk, egg	Scurvy	Powerful antioxidant plays important role in preventing the body from oxidative damage

1.05.6.1.2 Magnesium

Magnesium is present abundantly in the intracellular fluid of our body and it functions as an important cofactor for more than 300 enzymes in the body. It is important for all energy-dependent transport systems like glycolysis, oxidative energy metabolism, and biosynthetic reactions. It maintains normal muscle and nerve function, keeps heart rhythm steady, lowers hypertension, and reduces the incidence of heart disease. Green leafy vegetables mainly spinach, nuts, avocados, whole grains, legumes, soy beans, and chocolate contain magnesium. Maximum recommended daily intake from supplements is 420 mg day^{-1} for men and 320 mg day^{-1} for women.

1.05.6.1.3 Phosphorus

Phosphorus combined with calcium is necessary to create the calcium–phosphorus balance necessary for the growth of bones and teeth and for the formation of nerve cells. This mineral is also essential for the assimilation of carbohydrates and fats. Being an important component of nucleic acids, it plays vital role in building cellular structure of every cell in the body. In addition, the metabolism of lipids relies on phosphorus and it is an essential component of lipid-containing structures such as cell membranes and nervous system structures. In addition to its role in forming the mineral matrix of bone, phosphorus is an essential component of numerous other life-critical compounds including adenosine triphosphate (ATP).

1.05.6.1.4 Potassium

Potassium is essential to the life of every cell of a living being and is the most widely distributed in all tissues. It plays an important role as a catalyst in energy metabolism and in the synthesis of glycogen and protein. Potassium is most concentrated in the intracellular fluids (117 g) of the body compared with extracellular (3 g) fluids. The gradient, or the difference in concentration within the cell compared with the plasma, is essential in the generation of the electrical impulses in the body that allow muscles and the brain to function. Potassium is necessary for growth, electrical activity of the heart, maintaining normal blood pressure, and muscle function including the heart and nerve impulse transmission. It protects bone mineral density and reduces the formation of kidney stones. Potassium is rich in bananas, cherries, dates, grapefruit, guavas, pomegranates, watermelons, French beans, avocados, potatoes, pumpkins, and sweet potatoes.

Potassium helps

- to overcome fatigue and aids in clear thinking by sending oxygen to the brain
- to regulate body fluids that prevent dehydration
- kidneys to detoxify blood and acts as an alkalizing agent in keeping a proper acid–alkaline balance in the blood and tissues
- in the secretion of hormones and prevent female disorders by stimulating the endocrine hormone production
- in production of sperm in males

1.05.6.1.5 Sodium

Sodium chloride, the chemical name for common salt, which contains 39% of sodium, is an element that never occurs in free form in nature. It is found in an associated form with many minerals especially in plentiful amounts with chlorine. The body of a healthy person weighing about 65 kg contains 256 g of sodium chloride. Of this the major part, just over half, is in the extracellular fluid. About 96 g is in the bone and less than 32 g in the cells. Sodium is the most abundant chemical in the extracellular fluid of the body. It acts with other electrolytes, especially potassium, in the intracellular fluid, to regulate the osmotic pressure and maintain a proper water balance within the body. It is a major factor in maintaining acid–base equilibrium, in transmitting nerve impulses, and in relaxing muscles. It is also required for glucose absorption and for the transport of other nutrients across cell membranes. It

promotes a clear brain, resulting in a better disposition and less mental fatigue. Because of its influence on calcium, sodium can also help dissolve any stones forming within the body. It is also essential for the production of hydrochloric acid in the stomach and plays a part in many other glandular secretions.

1.05.6.1.6 Sulfur

Sulfur in the human body is present in the two sulfur-containing amino acids, methionine and cysteine, or in the double form of the latter known as cystine. The main purpose of sulfur is to dissolve in waste materials. It helps to eject some of the waste and poisons like heavy metals from the system.

1.05.6.2 Essential Trace Minerals/Microminerals

1.05.6.2.1 Chromium

It is an essential trace element required for normal function of insulin and regulation of glucose metabolism. It stimulates the production of proteins in the body, raises immunity against infections, and suppresses the feeling of hunger. It also plays a role in the production of high-density lipoprotein (HDL) cholesterol in liver. With an increase in age the level in chromium decreases, which is one of the factor for developing type 2 diabetes.

1.05.6.2.2 Cobalt

Cobalt is a component of vitamin B_{12}, a nutritional factor necessary for the formation of red blood cells and thus preventing anemia. The presence of this mineral in foods helps the synthesis of hemoglobin and the absorption of iron from food. Vitamin B_{12} with cobalt helps in the production of DNA, choline, and red blood cells, promotes a healthy nervous system, and lowers blood pressure.

1.05.6.2.3 Copper

Copper plays an important role in the conversion of iron to hemoglobin. Copper helps in the synthesis of other proteins and enzymes, supports the functioning of the nervous system, stimulates the growth of red blood cells, and is necessary for the correct functioning of brain cells. It also helps in the maintenance and development of bones, tendons, and connective tissues. Copper, together with zinc, improves the absorption of vitamin D, which in turn aids in the absorption of calcium. It is present in almonds, caraway seeds, cashew nuts, cherries, dates, drumstick leaves, egg yolk, berries, grapes, guava, kiwifruit, mushrooms, nuts, potatoes, and strawberries.

1.05.6.2.4 Fluoride

Fluoride is important for the development of bones and teeth, and helps in the prevention of dental caries and in the treatment of osteoporosis.[28] Fluoridated water, tea, canned salmon, and mackerel are the sources of fluoride.

1.05.6.2.5 Iodine

Table salt is the main source for iodine. Iodine is highly essential to synthesize two vital hormones, thyroxine (T4) and tri-iodothyronine (T3), important for the normal development, growth, and metabolism.

1.05.6.2.6 Iron

Iron rich in green vegetables, lentils, and soybeans is essential for producing hemoglobin (a substance in red blood cells) as the deficiency of the same will cause iron-deficiency anemia. It is essential to carry oxygen to body tissues. Consuming vitamin C together with iron-containing meals can increase or optimize iron absorption. Iron is also a part of myoglobin, which helps muscles to store oxygen.

1.05.6.2.7 Manganese

Manganese is present in trace amounts in the body in bones, liver, kidneys, and pancreas. Legumes, cereals, green leafy vegetables, tea, brown rice, beans, pineapple, raspberries, strawberries, cinnamon, squash, and turmeric are some of the foods that contain rich and high concentration of manganese. Manganese helps the body to form cartilage, bones, and blood clotting factors. Manganese is necessary for normal brain and nerve function and plays essential role in fat and carbohydrate metabolism, calcium absorption, and blood sugar regulation. It is an important cofactor in the key enzymes of glucose metabolism.

1.05.6.2.8 Molybdenum

Molybdenum is a component of several enzymes that plays an important role in sulfur metabolism. It is present in milk and helps in prevention of osteoporosis. Sources of molybdenum include whole grains, beans, and dairy products.

1.05.6.2.9 Selenium

Selenium presents in broccoli, asparagus, red wine, dietary fiber, pepper, peas, soya beans, mushroom, cloves, fenugreek, and ginger reported to decrease the risk of colon cancer. Fruits like banana, lychee, apple, watermelon, mango, guava, and pomegranate also contain selenium. The concentration of selenium in fruits and vegetables depends on the content of selenium in the soil in the region where these foodstuffs are grown.[29] Fish and Brazil nuts are rich in selenium, but it exists in cereals, wheat, and most

vegetables as selenomethionine, showing higher bioavailability than the form found in dairy products and meat. It is an essential component of glutathione peroxidase, which is involved in the reduction of hydroperoxidases. Selenium is required in very little amount of 70 mcg for male and 55 mcg for female to protect their health.

1.05.6.2.10 Zinc

The human body's need for zinc is small but its role in growth and well-being is enormous. Zinc is the healing mineral and part of the enzymes that helps the body to metabolize protein, carbohydrate, and alcohol. It also aids in building bones and healing wounds. Around two grams of zinc is available in the body where it is highly concentrated in the hair, skin, eyes, nails, and testes. Zinc is a cofactor in many enzymes that regulates growth and development, sperm generation, digestion, and nucleic acid synthesis. It plays an essential role in guarding against diseases and infections and is also required to transport vitamin A to the retina. Low levels of zinc can be observed in those who drink alcohol, as alcohol decreases zinc absorption and increases urinary secretion of zinc. Low zinc levels can cause liver deterioration and diminished functioning of the reproductive organs, immune system, and skin. Zinc is present in vegetables, namely, French beans, okra, peas, potatoes, pumpkins, and in fruits, namely, blackberries, dates, pomegranates, and raspberries.

1.05.7 Phytochemicals as Nutraceuticals

Presently, the use of phytochemicals is increasing due to its nutritional and medical importance supported by scientific data. Phytochemicals play an important role in human health as antioxidants and help in preventing various diseases like cancer, CVDs, diabetes, and inflammatory disorders. The major phytochemicals commonly used as nutraceuticals are carotenoids, phenolic compounds, and organosulfur compounds (Table 4).

1.05.7.1 Carotenoids

Carotenoids are biosynthesized by plants and microbes, but not by animals, and hence must obtain them from their food. There are 600 carotenoids reported from nature, where 40 were used in human diet and 14 found blood. It is present in yellow (pumpkin), orange (carrots), and red colored (tomatoes, papaya, watermelon, pink guava, and pink grape fruit) fruits and vegetables. Carotenoids can be classified into two major classes based on their structural elements; carotenes, constituted by carbon and hydrogen (eg, lycopene(**14**), α-carotene(**15**), and β-carotene(**16**)), and xanthophylls, constituted by carbon, hydrogen, and additionally oxygen (hydroxyl, methoxy, carboxyl, keto, or epoxy groups) (eg, lutein(**17**), zeaxanthin(**18**), β-cryptoxanthin(**19**), astaxanthin(**20**), and

Table 4 Sources and health benefits of phytochemicals used as nutraceuticals

Category	*Phytochemicals*	*Source*	*Health benefits*
Alkaloid	Piperine	Pepper	Stomachic
Carotenoids	Zeaxanthin	Wolfberry, carrot, celery, lettuce	Eye health
	α-Carotene and β-carotene	Carrots, pumpkin, orange, apricots, cantaloupe and sweet potato	Prevention of cancer
	Lutein	Spinach, red pepper, mango, papaya, peach	Protection from colon cancer
	Lycopene	Tomatoes, watermelon, papaya, apricot, pink guava, pink grape fruit	Lowers the risk of cancer and atherosclerosis
Glycoside	Withaferin, Withanolides	*Withania somnifera*	Immunomodulator and protects from cancer
Organosulfur compounds	Sulforanes, glucosinloates	Cruciferous vegetables, broccoli, cabbage, cauliflower, radish	Reduce the risk of prostate and colon cancer
	Allicin	Garlic, onion	Antioxidant and prevention of cancer
Phenolics	Anthocyanins	Berry, grape, maize, blackberry, orange	Antioxidant, antiinflammatory
	Rutin	Asparagus, buckwheat, citrus fruits	Strengthen capillary walls
	Catechins	Tea	Antioxidant
	Curcumin	Turmeric	Antioxidant, anticancer
	Quercetin	Tea, onion, grape, buckwheat	Antioxidant, vasodilator
	Resveratrol	Grape, groundnut, blueberry, red wine	Prevents aging, cancer, diabetes, heart disease
	Silymarin	Milk thistle (*Silybum marianum*)	Protect UV induced cancer and hepatoprotective
Phytosterol	Stigmosterol	Soya bean	Prevents arthritis and cancer
Polyunsaturated fatty acids	α-Linoleic acid	Flaxseed	Prevention of cancer and CVD
Terpenes	Zingiberine	Ginger	Carminative, prevents dizziness

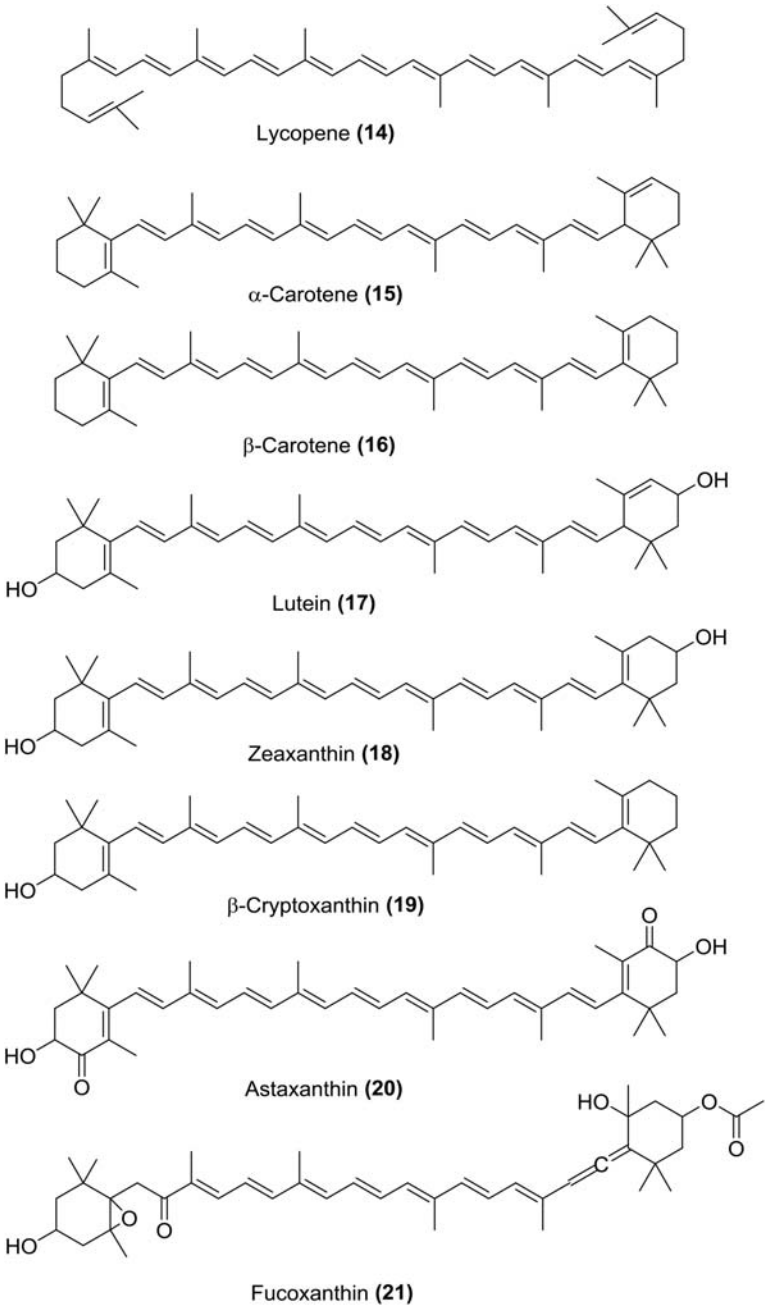

Fig.4 Chemical structures of some important carotenoids.

fucoxanthin(**21**)) (Fig. 4).[30] Among the different types, carotene that contains six-membered rings at the end is found to be active compared with the carotene containing the five-membered rings. Carotenoids are important for human health, as they exert protective effects against serious disorders like cancer,[31] heart diseases,[32,33] and degenerative eye diseases.[34]

Protective effect of carotenoids against cancer is mainly due to the presence of multiple conjugated double bonds which reduces the reactive oxygen species.

1.05.7.2 Phenolics

Phenolics are the most abundant antioxidants in the human diet, and they modulate the activity of a wide range of enzymes and cell receptors. More than 4000 polyphenols have been identified in many plant foods, including vegetables, grains, nuts, cereals, oilseeds (rapeseed, canola, flaxseed, and olive seeds), legumes (barley, corn, nuts, oats, beans, pulses), spices, chocolate, tea, and

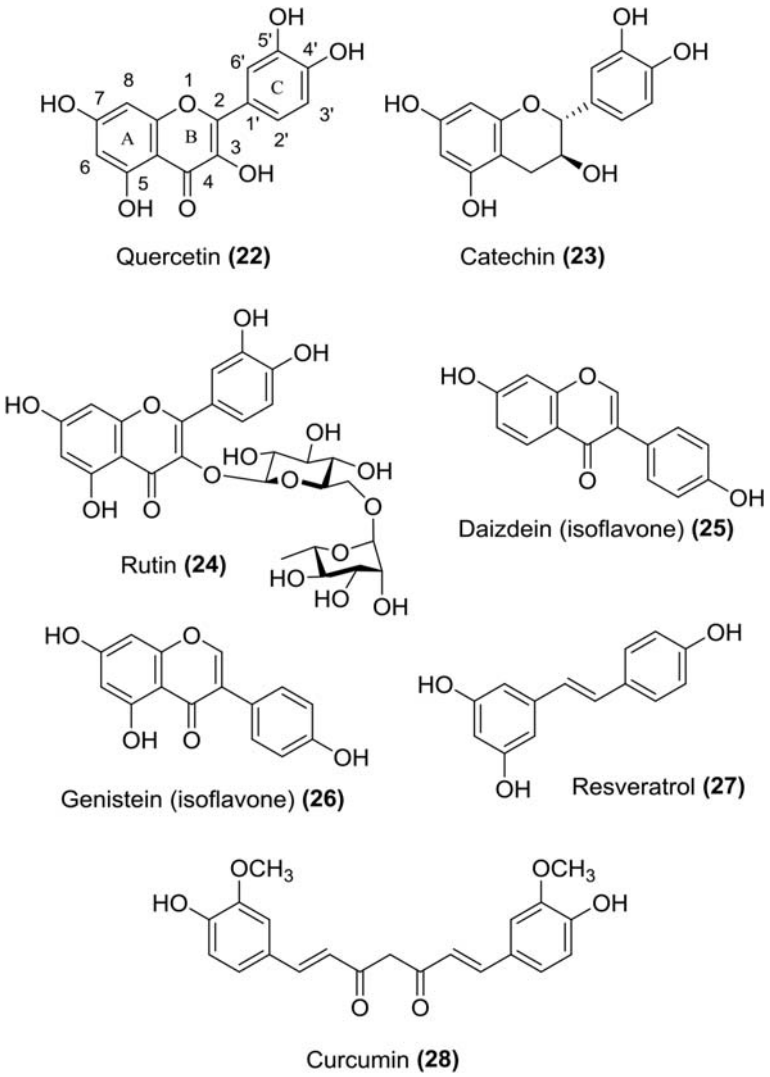

Fig. 5 Chemical structures of some important phenolic nutraceuticals.

beverages (fruit juices, tea, coffee, cocoa, beer, and wine).[35] Fruits such as apple, grape, pear, cherry, and various berries are rich sources of polyphenols.

Plants and food contain large variety of phenolic derivatives as phenolic acids, flavonoids, stilbenes, coumarins, tannins, lignans, and lignins. Dietary fruits rich in polyphenolic compounds reduce the incidence of cancer by inhibiting certain enzymes that promote cell proliferation or promote activities of enzymes that induce cell death.

Phenolic acids like gallic acid and caffeic acid, the derivatives of hydroxy benzoic acids and hydroxy cinnamic acids, helps in preventing the cancer due to its potent antioxidant properties. Caffeic acid in the form of caffeoyl esters is common in apples, pears, grapes, and gallic acid. Grain-derived products are especially significant in human diet as they have higher concentration of phenolic acids in the outer layers of kernel that constitute the bran. Ferulic acid, a phenolic acid present in oats, sweet corn, and tomatoes is a potent antioxidant, helps to reduce blood pressure and protect skin.

Flavonoids are the largest class of polyphenols with a common carbon skeleton of diphenyl propane (C6–C3–C6) representing two benzene rings connected through three carbon atoms. Flavonoids are classified into flavonols (isorhamnetin, kaempferol, myricetin, quercetin(**22**)), flavanols (catechin (**23**), gallocatechin, epicatechin, epicatechin gallate, epigallocatechin), flavones (apigenin, chrysin, luteolin, rutin (**24**)), isoflavones (biochanin A, daidzein (**25**), daidzin, formononetin, genistein (**26**), glycitein) (Fig. 5), flavononols (astilbin, engeletin, genistin, taxifolin), flavonones (eriodictyol, hesperidin, isosakuranetin, naringenin, naringin, taxifolin), anthocyanidins (cyanidin, delphinidin, epigenidin, malvidin, pelargonidin, peonidin, petunidin), and chalcones (butein, okanin) based on the structural variations in the number and positions of OH groups or the presence of ketonic group in the middle ring.[36] Catechins (flavanol) and anthocyanins are collectively known as flavans as they do not have carbonyl group at third position.

Buckwheat (*Fagopyrum esculentum*), rich source of rutin and quercetin (flavonols), also present in high levels in onion, berries, and apples reported to exert protection against inflammation and cancer.[37] Ortho dihydroxy substitution in B ring, double bond between 2 and 3 positions, and carbonyl group in C ring are essential for quercetin to render potent antioxidant activity.[38]

Flavonol and kaempferol are widely distributed in common fruits such as apples and tomatoes, which help in protecting against cancer, inflammation, and bacterial infections.

Flavones like apigenin and luteolin are abundantly present in common fruits such as grapefruit, plant-derived beverages, and vegetables such as parsley, onions, oranges, tea, chamomile, wheat sprouts, and in peppermint, aid in preventing the cancer due to its potential antioxidant, antiinflammatory, and antitumor properties.[39]

The chief flavonoid constituents of green tea are flavanols (catechin (**23**), epicatechin, catechingallate, and epigallocatechin gallate), flavonols (quercetin (**22**), kaempferol, and their glycosides), flavones (vitexin, isovitexin), and phenolic acids (gallic acid, chlorogenic acid), which are able to reduce the risk of cancer, CVD, and inflammations.[40]

Citrus fruits are major sources of flavonones where hesperidin, which is found in abundance (120–250 mg L^{-1}) in orange juice, is a natural free radical agent that gives nutritional tune to the cardiovascular system.

Isoflavones rich in soy help in reducing body weight, improving glucose metabolism, and promoting heart health.

Polymerization of flavonoids into large molecules called tannins include the proanthocyanidins (or condensed tannins) and the hydrolysable tannins. They act as antioxidant by accepting free radicals, but the antioxidant activity depends on their chemical structure.

Resveratrol (**27**), a nonflavonoid polyphenol/stilbene derivative (3,4,5′-trihydroxy-*trans*-stilbene) rich in peanuts, grapes, red/white wine, blueberries, cranberries, cocoa, and dark chocolate, helps in protecting the heart and circulatory system, lowering cholesterol, and protecting against clots, which can cause heart attacks and stroke.

Nonflavonoid polyphenol, curcumin (**28**), chemically known as 1,7-bis(4-hydroxy-3-methoxyphenyl)-1,6-heptadiene-3,5-dione, is an active component of the plant *Curcuma longa* (Zingiberaceae), is responsible for the yellow color, and is known to possess multiple pharmacological effects. It is used in the treatment of inflammatory ailments, obesity, and other metabolic diseases. Its immunomodulatory properties including antioxidant, antiinflammatory, and antitumor properties are well documented.[41] Curcumin interacts directly with cyclooxygenase-2 (COX-2), DNA polymerase, lipoxygenase, glycogen synthase kinase-3b, and cytokines (tumor necrosis factor-α).

Protective roles of flavonoids in human health include heart diseases,[42] eye diseases,[43] diabetes,[44] and neurodegenerative diseases, like Alzheimer's or Parkinson's.[45] The other potential health benefits of flavonoids include antifungal,[46] antibacterial,[47] and antiallergic[48] activity.

Flavonoids also exert a positive effect on the prevention and/or treatment of different types of cancer, namely ovarian, colon, lung, laryngeal, prostate, pancreatic, esophageal, breast, leukemia, renal cell carcinoma, and hepatocellular carcinoma.

1.05.7.3 Organosulfur Compounds

Glucosinloates are nitrogen- and sulfur-containing compounds present in cruciferous vegetables, cress, horse radish, rucola, and mustards, which provide protection against carcinogenesis. Glucoraphanin, the glucosinolates of sulforaphane present in all the cruciferous vegetables like broccoli, cabbage, and cauliflower, is responsible for cancer preventive activity.[49] Studies revealed that broccoli sprouts combined with glucoraphanin powder synergistically enhanced the bioavailability of sulforaphane and proved that regular intake of designer broccoli sprouts enriched with glucoraphanin powder reduces the risk of cancer compared with glucoraphanin powder or sprouts alone.[50]

Mustard, like broccoli and cabbage, belongs to *Brassica* family and is native to Europe having potential benefits against cancer due to the presence of phytonutrient glucosinolate. Among the three varieties of mustard seeds namely black mustard (*Brassica nigra*), white mustard (*Brassica alba*), and brown mustard (*Brassica juncea*), black variety is most popular for its aroma and flavor (due to the presence of sinalbin) and hence it is preferred in cooking. Mustard seed contains minerals such as calcium, magnesium, phosphorus, potassium, selenium, vitamin A, vitamin K, folic acid, and dietary fiber. Mustard oil helps in reducing the levels of glycosylated proteins, serum glucose, aids in reducing lipid peroxidation, and stimulates glucose metabolism.

Garlic and onion belong to allium family reported to contain high amount of sulfur compounds. Garlic is one of the very commonly used ingredient in many cuisines worldwide that contains allicin, alliin, diallyl disulfides (organosulfur compounds), minerals, and vitamins, which help in preventing the various diseases such as cancer, CVDs, obesity, and type 2 diabetes.[51] Onion is an important condiment and vegetable used in every kitchen in the world that contains large amount of sulfur compounds (cepaenes and thiosulfinates), flavonoids (quercetin), vitamins, minerals (calcium, chromium), and dietary fiber. Antioxidant, antitumor, and immune enhancing properties of onions may be due to the presence of flavonoids. High amount of sulfur compounds in onion stimulate the action of amino acids to nervous system, reduce symptoms associated with diabetes mellitus, inhibit platelet aggregation (involved in thrombosis), and prevent inflammatory processes associated with asthma.[52]

1.05.8 Plants as Nutraceuticals

Medicinal plants are being used by indigenous people for many years for the prevention and treatment of various diseases (**Table 5**). Plants synthesize primary metabolites and secondary metabolites, where the primary metabolites like carbohydrates, lipids, and

Table 5 List of medicinal plants used as nutraceuticals

Name of the medicinal plant	*Botanical name*	*Activity claimed*
Amla	*Emblica offficinalis*	Antioxidant, antiinflammatory, diuretic, stomachic, digestive, prevents peptic ulcer
A. vera	*Aloe barbadensis*	Antiinflammatory, emollient, wound healing
Ajowan fruits	*Trachyspermum ammi*	Source of thymol
Aswagantha	*W. somnifera*	Nerve tonic
Bael	*Aegle marmelos*	Chronic diarrhea
Bahera	*Terminalia belerica*	Antidiarrheal, antidiabetic
Baical skullcap	*Scutellaria baicalensis*	Antimicrobial
Bitter guard (Karela)	*M. charantia*	Antidiabetic
Black gram	*Vigna mungo*	Source of proteins, lowers the risk of CVD, helps in maintaining body weight
Boswellia	*Boswellia serrata*	Antiarthritic
Bottle guard	*Lagenaria siceraria*	Reduces total cholesterol, triglycerides (TGS), and low density lipoproteins (LDL) levels. Helps in digestion and reliving constipation
Brahmi	*Centella asiatica*	Brain tonic, improves concentration, and alertness
Coriander	*Coriandrum sativum*	Digestive, stimulant, and flavoring agent
Caraway	*Carum carvi*	Aromatic, carminative
Cardamom	*Elettaria cardamomum*	Carminative
Chamomile	*Matricaria recutita*	Antiinflammatory, spasmolytic, antimicrobial, and wound healing
Cinnamon	*Cinnamomum zeylanicum*	Flavoring agent
Chaulai	*Amaranthus hybridus*	Helps in preventing CVD
Curry leaf	*Murraya koenigii*	Antioxidant, anti tumor, anti inflammatory, anti hyperglycemic, hypoglycemic, and hypolipidemic
Dill	*Anethum graveolens*	Carminatives
Drumstick	*Moringa oleifera*	Antiepileptic, antiinflammatory, antiulcer, antispasmodic, diuretic, antihypertensive, cholesterol lowering, antioxidant, antidiabetic, hepatoprotective, antibacterial, and antifungal
Echinacea	*Echinacea purpurea*	Act as an immune stimulant and treatment of cold and flu symptoms
Ephedra	*Ephedra sinica*	Helps in reducing bronchial edema
Fennel	*Foeniculum vulgare*	Carminative, aromatic, and stimulant
Fenugreek	*Trigonella foenum*	Lowers TGS, total cholesterol, and LDL
Ginger	*Zingiber officinale*	Carminative, antiemetic, treatment of dizziness
Ginseng	*Panax ginseng*	Adaptogen
Green tea	*C. sinensis*	Antioxidant, reduces risk of CVD, enhances humoral and cell mediated immunity
Garlic	*A. sativum*	Prevents atherosclerosis, hypercholesterolemia, high blood pressure
Kalmegh	*Andrographis paniculata*	Protects against all infections including virus
Kidney bean	*P. vulgaris*	Diuretic and flushes out the toxins from the body hypoglycemia
Liquorice	*Glycyrrhiza glabra*	Expectorant, peptic ulcer
Mentha	*Mentha piperita*	Carminative, stimulant, and counter-irritant
Mushrooms	*Boletus* sp.	Helps in preventing CVD, anticancer, antidiabetic property
Mustard	*B. nigra*, *B. juncea*	Helps in prevention of cancer
Myrobalan	*Terminalia chebula*	Digestive, stomachic, laxative
Pepper	*Piper nigrum*	Digestive, stomachic
Pipal	*Piper longum*	Carminative
Neem	*Azadirachta indica*	Antiseptic, ulcers, boils
Nutmeg	*Myristica fragrans*	Carminatives
Oats	*Avena sativa*	Lower cholesterol
Okra	*Abelmoschus esculentus*	Helps in increasing sperm count
Onion	*A. cepa*	Antioxidant, helps in preventing heart disease and cancer
Rasna	*Alpinia officinarum*	Carminatives
Red pepper	*C. annum*	Antiarthritic and antioxidant
Senna	*Cassia angustifolia*	Laxative
Shatavari	*Asparagus* sp.	Tonic and astringent

Table 5 List of medicinal plants used as nutraceuticals—cont'd

Name of the medicinal plant	*Botanical name*	*Activity claimed*
Suran	*Amorphophallus companulatus*	Prevent gastric troubles and rheumatic pain
Suwa	*Anethum graveolens*	Flatulent colic, ulcers
Tea leaves	*C. sinensis*	Antioxidant, helps in prevention of cancer and CVD
Tulsi	*Ocimum sanctum*	Expectorant
Turmeric	*C. longa*	Antiinflammatory agents
Vaj	*Acorus calamus*	Antispasmodic and carminative
Vasaka	*Adhatoda vasica*	Expectorant
Vidang	*Embelia ribes*	Anthelmintic
Wild marygold	*Tagetes minuta*	Antimicrobial

amino acids involve in the growth of the plants. The low molecular weight secondary metabolites have no recognized contribution in the growth of plants but provide health benefits to humans. But the major challenge in herbal nutraceuticals is meeting the requirements of stability as most herbs need low humidity conditions due to their hygroscopic nature.

1.05.9 Microbes as Nutraceuticals

1.05.9.1 Probiotics

Probiotics are live microorganisms such as *Lactobacillis* sp. (*L. acidophilus*, *L. plantarum*, *L. casei subspecies rhamnosus*, *L. brevis*, *L. delbreuckii subspecies bulgaricus*), *Bifidobacteria* sp. (*B. adolescentis*, *B. bifidum*, *B. longum*, *B. infanti*, and *B. breve*), and *Streptococcus thermophilus* present in human body and provides various health benefits on ingestion (World Health Organization). Probiotics inhibit the growth of bad bacteria and help in producing vitamins especially vitamin K and ensure that the immune system works properly. These probiotics are commercially available as spores or in lyophilized forms or in the form of probiotic fortified fermented dairy products. *Lactobacilli* sp. are naturally found in fermented foods like sauerkraut and yogurt. Probiotics are potential in the treatment pediatric antibiotic-associated diarrhea, acute upper respiratory tract infections, chronic and acute enteric infections, and their associated diarrheal complexes.[53] Daily dietary intake of probiotics reduces the incidence and severity of acute and chronic infection, prevents and reduces the recurrence of cancers and incidence of several atopic conditions,[54] and increases the level of liver aminotransferases in patients with nonalcoholic fatty liver disease.[55] Probiotics like *Lactobacillus bulcaricus* help in preventing colon cancer by blocking the breakdown of enzymes β-glucuronidase. They produce lactic acid that lowers the pH of intestine and inhibits harmful bacteria such as *Clostridium*, *Salmonella*, *Shigella*, *E. coli*, and *Helicobacter pylori*. Probiotics decreases the production of a variety of toxic or carcinogenic metabolites and aids in absorption of minerals, especially calcium and magnesium, due to increased intestinal acidity. Calcium and magnesium in turn enhances the dietary nutrition utilization. Probiotics also aids in production of β-D-galactosidase enzymes (that break down lactose) and antimicrobial substances acidophilin, bacteriocin, etc. Some *Lactobacillus* sp. able to break down the bile in the gut, thus inhibiting its reabsorption and lowers the blood cholesterol. Probiotic bacteria ferment dietary fiber to produce short-chain fatty acids, mainly acetates, propionate, and butyrates that increase blood flow to the colon and act as metabolic fuel for the intestinal cells.

Chronic gastritis leading to peptic ulcer is one of the major concern in the long-term infection of *H. pylori*. Treatment of *H. pylori* infection involves expensive therapeutic interventions, which lead to the development of unpleasant side effects and antibiotic resistance.[56] Therefore, the use of food-based products such as probiotics may be a cost-effective way to manage symptoms associated with *H. pylori* infection. The gastric mucosal barrier represents a first line of defense against pathogenic bacteria and the intake of probiotics strengthens this barrier by producing antimicrobial substances, competing with *H. pylori* for adhesion receptors, stimulating mucin production, and stabilizing the gut mucosal barrier. *H. pylori* is known to suppress *MUCI* and *MUC5A* gene expression where probiotics like *L. plantarum* and *L. rhamnosus* can increase the expression of *MUC2* and *MUC3* genes and cause subsequent extracellular secretion of mucin.[57] This property mediates the ability of these strains to restore the mucosal permeability of gastric mucosa or inhibit the adherence of pathogenic bacteria. In addition to antimicrobial effect of lactic acid produced relatively in large amounts by lactobacilli (probiotic), lowering of the pH could inhibit the *H. pylori*[58]; the possible mechanisms by which probiotic bacteria *L. reuteri* inhibits the binding of *H. pylori* to specific glycolipid receptors asialo-GMI and sulfatide.[59]

1.05.9.2 Prebiotics

A prebiotic is a nondigestible component which beneficially affects the host by selectively stimulating the growth and/or activity of one or a limited number of colonic bacteria, thereby improving the health of the host. Prebiotics are called as "colonic food" as they are not digested or absorbed in the stomach and small intestine but gets fermented once they reach the large intestine. Once it enters the colon it become a substrate for the endogenous bacteria and indirectly provides energy and metabolic substrates to the host. Inulin is an example of prebiotic, also known as raftiline, found in several foods such as wheat, onion, garlic, fruits, and vegetables.

Fig. 6 Nutraceuticals used in prevention for various diseases.

Prebiotics are partially soluble in water where it forms slightly thickened product that has a bland neutral taste without any flavor and can contribute to body and mouth feel of food products. Other examples of prebiotics include oligofructose, garlic, onions, chicory root, asparagus, lactulose, whole wheat, rye, and barley. Potential health benefits of prebiotics include increasing the absorption of certain minerals such as calcium, magnesium, and iron, reducing the risk of colon cancer, reduction in cholesterol and blood lipids, and prevention of gastrointestinal tract infections. It helps in increasing the growth of *Bifidobacteria*, which in turn renders beneficial effects by producing nutrients such as B-group vitamins, folic acid, and digestive enzymes, reduces food intolerance by utilizing residual nutrients from the upper gut, and reduces the liver toxins like blood amines and ammonia, by using them as fuels. It alters the colonic microflora toward a healthier composition or selectively stimulates the growth and/or activity of intestinal bacteria associated with health and well-being. Presence of high levels of milk proteins (disulfide bridges) is believed to stimulate the growth of *Bifidobacterium* species, which are known to suppress growth of pathogenic bacteria in the colon. It favors the immune system, improves resistance against infection, and lessens the chances of type 2 diabetes and osteoporosis. Foods containing the combination of probiotics (bacteria) and prebiotics (saccharides) are referred to as synbiotics.

1.05.10 Health Benefits of Nutraceuticals

The use of nutraceuticals, as an attempt to accomplish desirable therapeutic outcomes with reduced side effects, as compared with other therapeutic agents has met with great monetary success. Consumption of plant-based foods, nuts, whole grains, cereals, and marine foods plays a vital role in disease prevention and health promotion.

Some popular nutraceuticals include glucosamine, chondroitin, methylsulfone and *S*-adenosyl methionine (for arthritis), lutein (for macular degeneration), ginseng (for cold), echinacea (antiimmune), folic acid, cod liver oil capsules, etc. The most popular functional food and beverage products include omega-3 eggs, omega-3 enriched yogurts, calcium-enriched orange juice, and green tea, to mention a few. Majority of the nutraceuticals do possess multiple therapeutic benefits; however, in the present article, much effort has been devoted to decentralize them based on their disease-specific major indication.

Nutraceuticals are claimed to possess physiological benefit or protection (Fig. 6) against the following diseases:

CVD
Cancer

Diabetes
Obesity
Chronic inflammatory disorders
Parkinson's disease
Alzheimer's disease

1.05.10.1 Nutraceuticals in CVDs

CVD is the name for the group of disorders of the heart and blood vessels that include hypertension (high blood pressure), coronary heart disease (heart attack), cerebrovascular disease (stroke), heart failure (heart muscle weakness leads to decreased or insufficient flow of oxygen rich blood flow to various organs of the body), and peripheral vascular disease. It was reported that low intake of fruits and vegetables is associated with a high mortality in CVD.[60] Many research studies have identified a protective role for a diet rich in fruits and vegetables against CVD.[61] Nutraceuticals in the form of antioxidants, dietary fibers, omega-3 PUFAs (n-3 PUFAs), vitamins, and minerals are recommended together with physical exercise for the prevention and treatment of CVD. It has been demonstrated that molecules like polyphenols present in grapes and in wine alter cellular metabolism and signaling, which is consistent with reducing arterial disease.[62]

1.05.10.1.1 Polyunsaturated fatty acids

Fatty acids can be categorized as saturated fatty acid, monounsaturated fatty acid, and PUFA. Saturated fatty acids usually contain 14 or more linearly arranged carbon atoms without any double bonds or unsaturation, and these fatty acids are found mostly as triglycerides in edible oils and fats. Monounsaturated fatty acids like oleic acid contain only one double bond, whereas PUFA contain multiple unsaturated double bonds found mostly in fish and plant oils, for example, linoleic acid, eicosapentaenoic acid (EPA), DHA, α-linolenic acid (ALA), and γ-linolenic acid (GLA). EPA, DHA, and ALA are called omega-3 fatty acids or n-3 PUFAs as the double bonds are located at the third carbon atom from its terminal. Linoleic and GLA are called as omega-6 or n-6 PUFAs as they have their first double bond at sixth carbon. Human body is able to synthesize fatty acids except these two omega-3 and omega-6 fatty acids and hence a diet balanced in omega-3 and omega-6 fatty acids is essential for human beings.[63] Long chain omega-3-PUFAs are of great interest because of their effectiveness in prevention of coronary heart disease, hypertension, diabetes, autoimmune disorders, and cancer and are essential for maintenance and development of normal growth, especially for the brain.

1.05.10.1.1.1 Omega-3 fatty acids

Omega-3 fatty acids are unsaturated fatty acids found in green leafy vegetables, vegetable oils, nuts, and fish oil. Tuna or white fish like sole, snapper, and cod contain less amount of DHA and EPA compared to oily fish like salmon, mackerel, and bluefish. Increase in heart failure risk may be possible by eating fried fish as frying destroys the omega fatty acids and increases the trans-fat content. The simplest omega-3 fatty acid is linolenic acid, which has potential health benefits in CVD and in inflammatory disorders. The most common omega-3 fatty acids found in the diet include long chain PUFA, EPA, and DHA. Dietary consumption of omega-3 fatty acid reduces the incidence of CVD, osteoarthritis,[64] and rheumatoid arthritis (RA).[65] Designer diet-based approach will be effective for increasing omega-3 fatty acid.[66]

Omega-3 fatty acids are proved to be beneficial in various disorders such as CVD, hypertension, autoimmune, allergic, and neurological disorders, and it is also essential for normal functioning of the human physiology not only in normal adult but also in pregnant and lactating women. Supplementation with omega-3 fatty acid along with nonsteroidal antiinflammatory drugs (NSAIDs) in juvenile idiopathic arthritis was proved to be effective as it reduces the daily requirements of NSAIDs and the risk of related side effects due to NSAIDs.

Caston and Leeson[67] also reported that it is possible to increase the concentration of omega-3 fatty acid in a hen's egg by adding flaxseed or fish oil in its diet. In the year 2006, Bourre and Galea[68] produced designer egg fortified with omega-3 fatty acid by feeding hens with linseed, minerals, vitamins, and lutein. The nutritional value of 100 g of these eggs contains six times more of the omega-3 fatty acid ALA, three times more DHA, three times more vitamin D, four times more folic acid, six times more vitamin E, six times more lutein and zeaxanthin, 2.5 times more iodine, and four times more selenium. These eggs also contain a little amount of cholesterol and, like standard eggs, are rich in B complex vitamins, vitamin A, phosphorus, and proteins. The consumption of these eggs improved the blood concentration of omega-3 fatty acids, HDL cholesterol, and triglycerides.[69]

DHA is one of the major components present in brain, retina, and testes. Major source of DHA is fish oils and marine algae. Daily dose of 2.5 g is recommended for cardiovascular and eye health.

Dietary supplementation of flaxseed oil (from flax plant *Linum usitatissimum*) that contains 50% ALA, which is an essential omega-3 fatty acid, helps in lowering blood pressure. Candlenut, hemp seed, pumpkin seed, canola, walnut, and soyabean are the other dietary sources of ALA. Recommended dose of this essential fatty acid (EFA) is 1–2 g day^{-1}.

Cardioprotective effects of omega-3 fatty acids include reduction in plasma levels of triglycerides and bad lipoproteins, inhibition of thromboxane A2 synthesis, improved endothelial function, up- and downregulation of genes involved in the synthesis of proteins, prevention of arrhythmias, decrease in plasma homocysteine levels, and increase in nitric oxide (vasodilator) production.

1.05.10.1.1.2 Omega-6 fatty acids

Linoleic acid and arachidonic acid (AA) are the Omega-6 fatty acids that have been found to possess cancer protective properties. The human body converts linoleic acid into GLA, and the latter get converted into AA. EPA synthesized from omega-3 fatty acid and GLA synthesized from omega-6 fatty acid have important roles in the maintenance of good health.

Appropriate balance of these two types of fatty acids, omega-3 and omega-6, should be maintained as these two work together to promote health. EFA deficiency and omega 6/3 imbalance are linked with serious health conditions, such as heart attacks, cancer, insulin resistance, asthma, lupus, schizophrenia, depression, postpartum depression, stroke, obesity, diabetes, arthritis, attention deficit hyperactivity disorder, and Alzheimer's disease.

1.05.10.1.2 Dietary fibers

Dietary fiber is defined as nondigestable carbohydrates and lignin that are intrinsic and intact in plants as an essential nutrient required for proper digestion of foods and proper functioning of the digestive tract. Diets deficient in fiber content may cause constipation, increase in blood glucose, and increase in cholesterol levels. Dietary fiber can be divided into two categories based on solubility and viscosity, where the health benefits are based on these physical attributes. Dietary fiber can be classified as soluble and insoluble based on the chemical properties.[70] Soluble dietary fibers include β-glucans, pectins, gums, barley, and hemicelluloses, which are rich in fruits, oats, barley, and beans. Insoluble dietary fibers include celluloses, some hemicelluloses, and lignins. Research report suggests that consumption of dietary fiber may prevent CVD, diabetes, obesity, lower triglycerides, and blood cholesterol levels. Oat fiber has the tendency to lower plasma cholesterol and low density lipoprotein (LDL) cholesterol. The probable mechanism behind the lipid-lowering effect of water soluble fibers like pectin is that it decreases the uptake of bile acids in the intestine. Readily soluble dietary fibers present in mustard seeds help to improve digestion in the body and make the bowel movements better, thus improving the overall metabolism of the body.

1.05.10.1.3 Flavonoids

Flavonoids are widely distributed in onion, cruciferous vegetables, black grapes, red wine, grapefruits, apples, cherries, and berries. Flavonoids in plants available as flavones (containing the flavonoid apigenin found in chamomile), flavanones (hesperidin-citrus fruits; silybin-milk thistle), and flavonols (tea: quercetin, kaempferol, and rutin grapefruit; rutin buckwheat; ginkgo flavone glycosides—ginkgo) play a major role in curing the CVDs.[71,72]

Flavonoids in regularly consumed foods may reduce the risk of death from coronary heart disease. It protects the vascular system and strengthens the tiny capillaries that carry oxygen and essential nutrients to all cells. Flavonoids exert health benefits by blocking angiotensin-converting enzyme, preventing platelet aggregation, and blocking the enzyme cyclooxygenase.

Hesperidin, a flavanone glycoside classified as a citrus bioflavonoid, is present in high amounts in lemon and orange peels. In combination with a flavone glycoside called diosmin, it is used for the treatment of venous insufficiency and hemorrhoids.

Resveratrol (**27**) occurs naturally in grapes, mulberries, white hellebore, and in peanut butter. It is a constituent of red wine and considered to be responsible for "French Paradox," that is, the observation that people from Southern France suffer a relatively low incidence of ischemic heart disease, although they eat diet rich in saturated fats.[73] It is proven to prevent CVD and cancer in a dose of 15–200 mg day^{-1}.

Proanthocyanidins that are the polyphenolic derivatives that contribute colors to various fruits like plums, grapes, blackberry, cranberry, and cherries have been proved to have protective action against many cardiovascular risk factors.

1.05.10.1.4 Plant sterols

Phytosterols in diet have the potential to reduce the morbidity and mortality of CVD.[74] The most abundant plant sterols include sitosterol, campesterol, and stigmasterol with typical daily intakes ranging from 150 to 400 mg day^{-1}. Plant sterols called as phytosterols, present in green and yellow vegetables nuts, seeds, legume, fruits, and grains in significant amounts, compete with dietary cholesterol due to biochemical similarity, thereby blocking the uptake as well as facilitating its excretion from the body. Statins may be combined with plant phytosterols for additional reduction of LDL cholesterol.

1.05.10.1.5 Policosanol

Policosanol (octacosanol, $CH_3(CH_2)_{26}CH_2OH$), a naturally occurring long chain aliphatic alcohol with 28 carbons, is obtained from superficial waxy layers of fruits, leaves, and epidermis of many plants reported to possess lipid-lowering effect (reduced LDL cholesterol) similar to that of statins, and increasing HDL cholesterol.[75] The recommended dose of policosanol tablet or capsule is 100 mg day^{-1}.

1.05.10.1.6 Vegetables in prevention of CVDs

1.05.10.1.6.1 Garlic

Garlic (*Allium sativum*) belongs to the family Liliaceae and is used as a spice, food, and folklore medicine for more than 5000 years. It contains sulfur compounds (allicin, alliin, allyl sulfides), terpenes (linalool, α-phellandrene, citral, geraniol), and high levels of phosphorous, calcium, iron, selenium, germanium, vitamins like riboflavin, thiamine, nicotinic acid, and vitamin C. Cholesterol in blood and tissues derived from diet or from endogenous synthesis has long been implicated as a significant risk factor in CVD. Allicin, an active constituent present in garlic, reported to have lipid-lowering activity with 9–12% reduction in total

cholesterol level.[76] Garlic blocks the synthesis of cholesterol by acting on the enzyme hydroxy-methyl-glutaryl-coenzyme A (HMG-CoA) reductase, thereby reducing the risk of CVD.

1.05.10.1.6.2 Onion

Consumption of onion with food increases the beneficial HDL cholesterol, lowers total blood cholesterol, triglycerides, reduces blood pressure, thins the blood, and keeps blood free from clots.

1.05.10.1.6.3 Ginger

Ginger, the rhizome of *Zingiber officinalis*, one of the most widely used species of the ginger family, is a common condiment for various foods and beverages. Ginger has a long history of medicinal use dating back 2500 years. Pungent constituents present in ginger and other zingiberaceous plants have potent antioxidant and antiinflammatory activities and also exhibit cancer preventive activity.

1.05.10.1.7 Coenzyme Q10

It is an endogenously synthesized lipid soluble antioxidant and is synonymically called as ubiquinone or ubidecarone. It is present in fish, chicken, cereals, and in spinach. Clinical studies confirmed supplementation of food with Coenzyme Q10, which helps in the prevention of congestive heart failure, hypertension, and myopathy related to statin therapy.[77] It is not only recommended for cardiovascular health but also for cancer prevention with a daily dose of 100–360 mg.

1.05.10.1.8 Potassium

Potassium is the third most abundant mineral in the body. Its primary function is to maintain muscle health, to control the electrical activity of the heart, and to maintain the acid–base balance. Dietary intake of potassium lowers blood pressure, and reduces the risk of coronary heart disease, stroke, and cardiac arrhythmias.

1.05.10.1.9 Fermented red yeast rice

Folk medicine in various countries like China, Japan, and India has the tradition of using fermented food for its health benefits, which includes red yeast rice. In Chinese traditional medicine, red yeast rice has been used as a medicine for digestion and revitalization.[78] Monacolin K (also known as lovastatin) present in monascus (*Monascus purpureus*) fermented red rice reported to inhibit the synthesis of cholesterol.[79–81]

Optimal nutrition, vitamins, antioxidants, minerals, weight reduction, exercise, cessation of smoking, restriction of alcohol and caffeine plus other lifestyle modifications can prevent, delay the onset, reduce the severity, and control CVDs.

1.05.10.2 Nutraceuticals in Cancer Prevention

Oxygen is most important for humans and animals to sustain life, but their metabolic products cause cancer. During the production of cell energy, mitochondria utilize almost 95% of oxygen and throw off unpaired electron called as free radicals. When these unpaired electrons get near the DNA molecules they grab electron (from nitrogen) to balance themselves. This causes damage to DNA molecules, which affects the function of normal cells and when they divide they form new cells causing cancer.

Consumption of regular and large amount of alcohol, smoking, modern lifestyles, change in dietary constituents, high meat consumption, and limited physical activity led to an increasing mortality rate for cancer worldwide. Nutraceuticals were examined for cancer therapy as the synthetic anticancer drugs may often cause adverse effects to the normal organs.[82,83]

Nutraceuticals containing glucosinolates, carotenoids, polyphenolic compounds, and vitamins possess antioxidant property and thus help in preventing the cancer (**Fig. 7**).

Glucosinolates are found in cruciferous vegetables including the *Brassica* crops Brussels sprouts, broccoli, cauliflower, cabbage, watercress, oilseed rape, and mustard are powerful activators of liver detoxification enzymes.[84] Glucosinolates and their hydrolysis products, including indoles and isothiocyanates (−N═C═S), and high intake of cruciferous vegetables have been associated with lower risk of lung and colorectal cancer. They also regulate white blood cells and cytokines. White blood cells are the scavengers of the immune system and cytokines act as "messengers," coordinating the activities of all immune cells. Bio-transformation products of glucosinolates include isothiocyanates, dithiolthiones, and sulforaphane. They block the enzymes that promote tumor growth, particularly in the breast, liver, colon, lung, stomach, and esophagus.

Diets rich with carotenoids like α-carotene, β-carotene, lycopene, lutein, cryptoxanthin, and lycopene present in tomatoes, watermelon, papaya, apricot, pink guava, and pink grape fruit have beneficial effects in human health, such as lowering the risk of cancer and enhancement of immune system function. Due to its potent antioxidant property, carotene helps in cancer prevention (induce apoptosis and inhibit cell cycle progression in cancer cells) and the recommended daily dose is 10–40 mg. Around 40% of human diets we consume constitute of fruits and vegetables are the major source of carotenoids. Thus, consumption of plant-based diets rich in a variety of vegetables (broccoli, carrots, arugula, pumpkins, sweet potatoes, squash, tomatoes, watercress) and fruits (apricots, cantaloupes, mangos, papayas, peaches, persimmons, and legumes) decrease the overall cancer rates to 20%.[85]

Polyphenolic compounds such as anthocyanins and flavonoids in red grape wine were proved to have inhibitory effect on breast cancer cells. A study by Hakimuddin et al.[86] supported the fact that red wine polyphenolic fractions have anticancer property against breast cancer cell lines (Michigan cancer foundation-7, MCF-7) and the authors also reported relatively low cytotoxicity toward

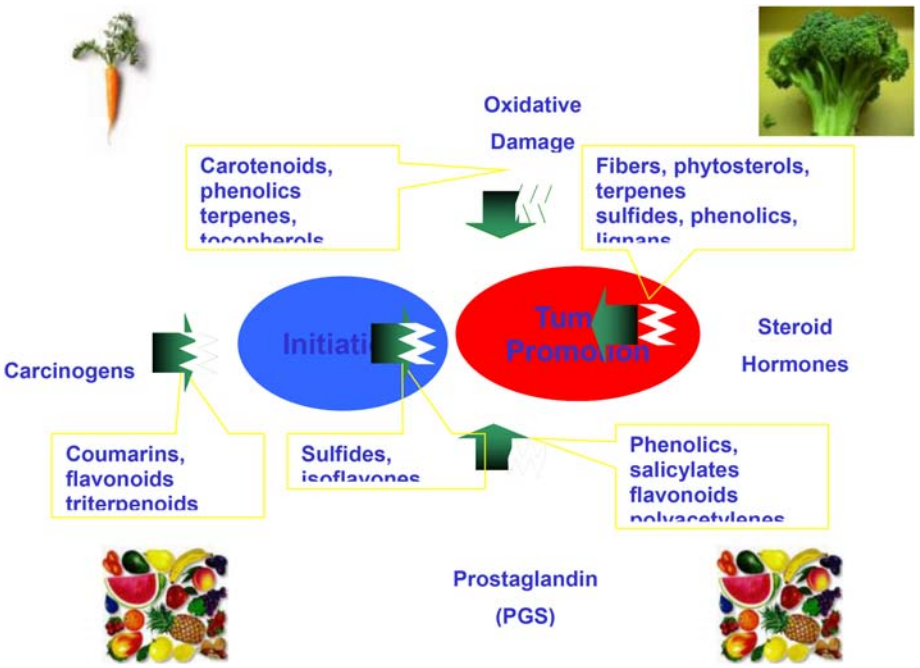

Fig. 7 Role of nutraceuticals in cancer.

normal human mammary epithelial cells (HMEC) and a nontumorigenic MCF-10A cells, which is contrast to the authentic flavonoids such as quercetin, naringenin, and catechin, which inhibited the growth of HMEC much more than that of MCF-7 cancer cells. The polyphenols induced calcium release by disrupting mitochondrial function through membrane damage, which results in selective cytotoxicity toward MCF-7 cells. Apart from its anticancer activity, the polyphenolic fractions showed discrete antioxidant action on cancer cell lines.[87] These studies suggested that consumption of wine, or other polyphenol-rich foods and beverages, could have a beneficial antiproliferative effect on breast cancer cell growth.

Onions, rich in powerful antioxidant, namely, quercetin, prevent the damage of DNA by free radicals, decrease cancer tumor initiation, promote healing of stomach ulcers, and inhibit the proliferation of breast, ovarian, and colon cancer.[88]

Soy isoflavone occurs in nature in glycoside form. Genistein is the major isoflavone present along with other iso flavones, daidzein and glycitein. Recommended dose of 30–50 mg day^{-1} is given for cancer prevention.

Tea is consumed as beverage in almost all the countries in the world. The studies also showed beneficiary effect of tea in reducing the risk of a variety of illnesses such as cancer and coronary heart disease. Tea plant *Camellia sinensis* is cultivated globally, which contains rich source of polyphenols including epigallocatechin 3-gallate. Tea can be of three types namely green tea, black tea, and Oolang tea. Green tea is an unfermented tea that contains high amount of polyphenols like catechin, gallocatechin, epicatechin, epigallocatechin, epicatechin gallate, and epigallocatechin gallate. Worldwide 78% of black tea, 20% of green tea, and 2% of Oolang tea are manufactured and are being consumed by western countries, Asian countries, and in southern China, respectively. Black and Oolang tea are the partially and completely fermented form of tea. Both black tea and green tea were proved to have potential in preventing lung, stomach, esophagus, duodenum, pancreas, liver, colon,[89] and skin cancers and have preventive effect on atherosclerosis, coronary heart disease, high blood cholesterol concentration, and high blood pressure. The health benefits of polyphenols from tea were extended by combining them with other food in the form of designer food.[90] A recommended dose of 5–100 mg day^{-1} is used for cancer prevention.

Phytochemicals (−)-epigallocatechin-3-gallate from green tea, curcumin from turmeric, sulforaphane from broccoli, genistein from soy isoflavone, and lycopene from tomatoes have the potential in prevention of breast cancer.

Triptolide, a diterpene triepoxide isolated from the roots of the Chineseherb *Tripterygium wilfordii*, helps in prevention of cancer.

Ellagic acid, a nonflavonoid polyphenol present in strawberries, raspberry, cranberries, grapes, walnuts, pomegranates, soybean, cabbage, ginger, licorice root, and umbelliferous vegetables, has protective property against cancer.

Allicin, chemically called as cysteine thiosulfinate, is an important constituent present in garlic to reduce the risk of cancer by inducing carcinogen detoxification, inhibiting tumor cell proliferation, scavenging free radicals, inhibiting DNA adduct formation, and inducing cell cycle arrest and apoptosis.

Pectin is a soluble fiber found abundant in citrus fruits, particularly in the peel, and prevents prostate cancer metastasis by inhibiting the cancer cells from adhering to other cells in the body. Naturally occurring phenolic acid derivatives such as ferulic, caffeic, gallic acids, and curcumin are reported to possess anticancer activity.

1.05.10.2.1 Minerals in cancer management

Selenium is an important mineral that has cancer preventive effects. It induces P450 enzyme present in liver that detoxify the cancerogenic molecules. Selenium appears to exert its cancer chemopreventive effects through induction of cell cycle arrest and apoptosis and reduction of angiogenesis.[91] Selenium is present in the active site of many enzymes including thioredoxin, which catalyze the oxidation–reduction reactions thereby causing apoptosis.

Manganese present in trace amounts in the body is an essential component of the antioxidant enzyme superoxide dismutase, which helps to fight against free radicals and prevent heart disease and cancer.

1.05.10.2.2 Vitamins in cancer management

Vitamin C (**13**), an essential nutrient in the human diet and a free radical scavenger, helps in the remedy for gastric cancer. It is important for the development of immune cell system and mobilizes these specialized cells to fight against cancer. The reported mechanism of prevention of cancer by vitamin C is induction of apoptosis through cell cycle arrest, activation of the apoptosis factors, and interference with iron uptake in cells. Vitamin D_3 (**3**) has been shown to reduce the incidence of colon cancer.[92] Vitamins E (**4**) being a powerful antioxidant has been suggested to prevent lung cancer. Since folic acid plays an integral role in DNA methylation and DNA synthesis, it may possess cancer protective effect.

1.05.10.3 Nutraceuticals in Diabetes

Diabetes is a metabolic disorder, where the body is unable to utilize carbohydrate due to lack of insulin, a hormone naturally produced by the beta cells of the islets of langerhans in pancreas. Number of people affected by type 2 diabetes is increasing in every country and this fast-growing metabolic disorder is expected to affect 592 million worldwide by 2035. Apart from pharmaceuticals and lifestyle changes, nutraceuticals played a major role in prevention and management of diabetes. Researchers have proved that cinnamon, garlic, onion, ginseng, *Gymnema sylvestre*, fenugreek, bitter melon, and mushroom such as *Pleurotus obstreatus* have specific health benefits against diabetes.[93,94] The probable beneficial antidiabetic effects of these functional foods may be due to their decreased glucose production in liver, decrease in intestinal glucose absorption, increase in insulin production, and increase in peripheral glucose uptake. Among diabetes, type 2 diabetes is growing rapidly worldwide and nuts enriched with omega-3 fatty acid and cinnamon are potential functional foods for the treatment of type 2 diabetes. Omega-3 fatty acids have been suggested to reduce glucose tolerance in patients predisposed to diabetes.

Diabetic complications due to harmful glucose metabolites may be reduced by diet supplementation of diet with DHA. EFAs during pregnancy are recommended for women with gestational diabetes mellitus.[95]

Lipoic acid (thioctic acid), a naturally occurring dithiol compound and essential cofactor for mitochondrial bioenergetic enzymes, is an important micronutrient with antioxidant properties that can alleviate the pain associated by this diabetic neuropathy.[96]

Leaf extract of *Psidium guajava* (guava) prevents the protein glycation, thereby strongly protects against the complications of diabetes. Gutierres et al.[97] reported that curcumin supplemented with yogurt prevent diabetes.

Fiber-rich foods reported to increase insulin action by increasing insulin receptor binding and by decreasing the rate of absorption of sugar from blood thereby maintaining sugar level in the body. High fiber content cherries believed to have antidiabetic action primarily due to the antioxidant properties and blood glucose reducing properties of anthocyanins and quercetin present in the fruit. Diabetes and associated symptoms are believed to be regulated by the cherries by poor glucose utilization. Fenugreek, a good diabetes-reversing herb because of its high-soluble fiber content, helps to lower blood sugar levels by slowing the digestion and absorption of carbohydrates. Fenugreek contains 4-hydroxyisoleucine and galactomann that helps in increasing insulin production and slowing down the absorption of blood sugar levels respectively.

Supplementation of diet with vanadium decreases fasting blood glucose levels, glycated hemoglobin levels, and cholesterol levels at a dose of 45–150 mcg day^{-1}.

Aqueous extract of *M. purpureus* fermented rice is also reported for antidiabetic activity in streptozotocin induced diabetic rats.[98]

1.05.10.4 Nutraceuticals in Obesity

Obesity is due to excessive consumption of high-fat and energy-rich foods, which leads to the formation of fatty plaques on the inner surface of the arteries that restrict the flow of blood to various parts of the body. The absence of blood circulation in some organs can cause harmful consequences such as angina pectoris, heart attack, cardiac arrest, transient ischemic attack, and stroke. In addition, obesity is accompanied by other complications such as diabetes, fatty liver, cholesterol gallstones, sleep apnea, osteoarthritis respiratory disorders, insulin resistance (diabetes), osteoarthritis, renal dysfunction, cancer, and reduced fertility.[99]

The very high prevalence of more than 50% obese population globally is in need of nutraceutical in addition to continuous and regular physical exercise in its prevention and treatment. Rapid rise in obesity rates is due to excessive consumption of energy-rich foods. Nutraceuticals like conjugated linoleic acid, capsaicin, *Momordica charantia*, and *Psyllium* fiber possess potential antiobese properties.[100] Increase in body weight and fat can be considerably reduced in obese individuals by taking nutraceuticals like ephedrine, ma huang-guarana, chitosan, green tea, glucomannan, fenugreek, and vitamin C in the dietary supplement.

Intake of dietary fibers with meals is important to control obesity where it may decrease body weight, body fat, and body mass index.[101] Dietary fiber reduces the caloric density of foods by physical dilution and by entrapment of nutrients, which reduces the

rate of digestion and absorption (bioavailability) of nutrients, especially glucose and lipids. Glucomannan is a natural gel forming fiber obtained from *Amorphopallus konjac* tubers chemically called beta 1,4-linked D-glucose and D-mannose having high viscosity promote weight loss and is effective in the prevention/treatment of overweight and obesity. Soluble fibers that form viscous hydrated masses suppress appetite better than the less viscous fibers. The high viscosity prolongs the presence of nutrients in the small intestine, downregulates release of appetite stimulating hormones, and leads to reduced appetite. Buckwheat seed proteins have beneficial role in obesity and constipation acting similar to natural fibers present in food.[102]

Supplemenation of food with omega-3 fatty acid has been shown to involve in weight loss, decreased appetite, modulation of lipogenic gene expression, and tissue metabolism.

Curcumin (diferuloylmethane) is a useful phytochemical that attenuates obesity-induced inflammation and obesity-related metabolic complications and weight loss at a dose of 400 mg day^{-1}.

5-Hydroxytryptophan and green tea extract may promote weight loss, while the former decreases appetite, the later increases the energy expenditure.[103]

Studies revealed that two carotenoids namely fucoxanthin and astaxanthin may have significant effect in reduction of body weight.

1.05.10.5 Nutraceuticals in Chronic Inflammatory Disorders

Arthritis is one of the very common inflammatory disorders occurring in elderly population. It was reported that more than 1% of world population is affected by arthritis. It is characterized by pain, swelling, and stiffness in joints due to synovial inflammation and hyperplasia, autoantibody production, cartilage, and bone destruction. Among 100 types of arthritis, rheumatoid and osteoarthritis are most common types of arthritis. Nutrient supplement with glucosamine (**29**), chondroitin (**30**), methylsulfonylmethane (**31**), and *S*-adenosyl methionine (**32**) proved that it can alleviate diseased condition of RA (Fig. 8).

1.05.10.5.1 Glucosamine

It is present in cartilage, tendon, and ligament tissue in humans. Normal diet does not contain this glucosamine and must be synthesized by body and the ability of this synthesis decreases with age. For arthritic treatment, it is given as an oral dose of 1500 mg day^{-1} in sulfate or hydrochloride or *n*-acetyl forms.

1.05.10.5.2 Chondroitin

Chondroitin is a glycoaminoglycan made up of alternative sequences of differently sulfonated units of uronic acid and *N*-acetyl galactosamine. It is a substance that occurs naturally in the body and lubricates joints and maintains healthy cartilage tissue. It can be commercially obtained only from animal sources like bovine, pigs, and chicken cartilage. Daily recommended dose of 1200–1500 mg day^{-1} is orally given for arthritis.

1.05.10.5.3 Methylsulfonylmethane

It is derivative of DMSO, also called as dimethyl sulfone or methyl sulfone. It is present in meat, milk, and in asparagus. It is recommended for healthy joints up to a dose of 2 g day^{-1} available in the form of cream, tablets, capsules, and powders.

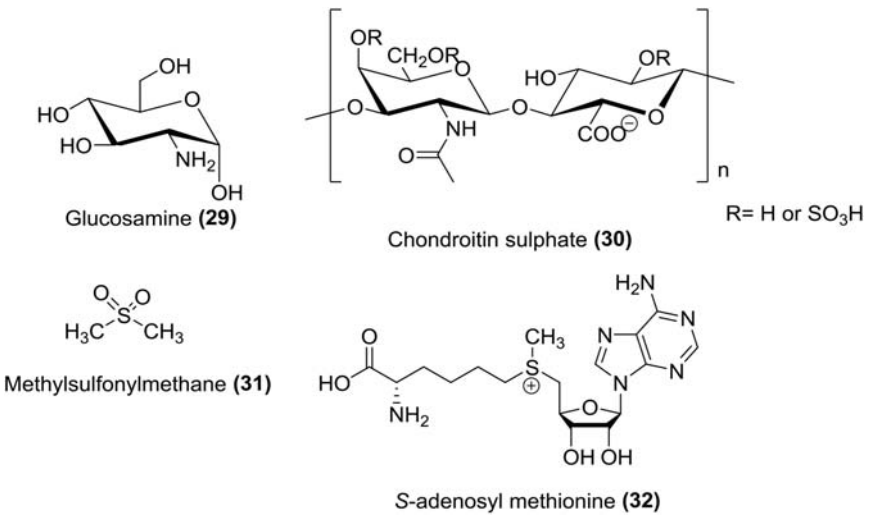

Fig. 8 Chemical structures of some nutraceuticals used in inflammatory disorders.

1.05.10.5.4 S-Adenosyl methionine

S-Adenosyl methionine synthatase is the enzyme responsible for the production of *S*-adenosyl methionine from methionine and ATP. *S*-adenosyl methionine is involved in transmethylation, translation, and aminopropylation reaction. The recommended daily dose of *S*-adenosyl methionine for joints and mental health is in the range of 200–1200 mg.

1.05.10.5.5 Pomegranate

High content of soluble polyphenols, hydrolyzable tannins, anthocyanins, and punicalagins in pomegranate fruit proved to have preventive effect on inflammation, arthritis, and pain.[104] Antiinflammatory activity was reported to exhibit by inhibiting the activity of NF-kB, COX-2, and Prostaglandin E2.[105]

1.05.10.6 Nutraceuticals for Parkinson's Disease

Parkinson's disease is a brain disorder that results from nerve damage in certain regions of the brain causing muscle rigidity, tremor, and akinesia,[106] usually occurring in mid to late adult life. Dopamine-rich foods like meat, milk products, fish, beans, nuts, soy products, and dopamine quinine, a naturally occurring form of dopamine present in banana are recommended for the prevention of Parkinson's disease. Canadian researchers indicated that vitamin E in food may be protective against Parkinson's disease.[107] Creatine is a nitrogenous organic acid produced in liver from amino acids L-arginine, glycine, and L-methionine that helps to supply energy to cells. Researchers have suggested that nutraceuticals such as creatine, glutathione, vitamins C and D, coenzyme Q10, polyphenols, stilbenes, and phytoestrogens prevent or delay the progression of Parkinson's disease (Fig. 9).

1.05.10.7 Nutraceuticals for Alzheimer's Disease

Alzheimer's disease is the first most common aging-related disorder in the world. It is characterized by progressive dementia with memory loss as the major clinical manifestation. Several lines of evidence strongly suggest that oxidative stress is etiologically related to a number of neurodegenerative disorders including Alzheimer's disease. Nutraceutical antioxidants, like β-carotene, curcumin, lutein, lycopene, turmerin etc., may exert positive effects on specific diseases by neutralizing the negative effects, oxidative

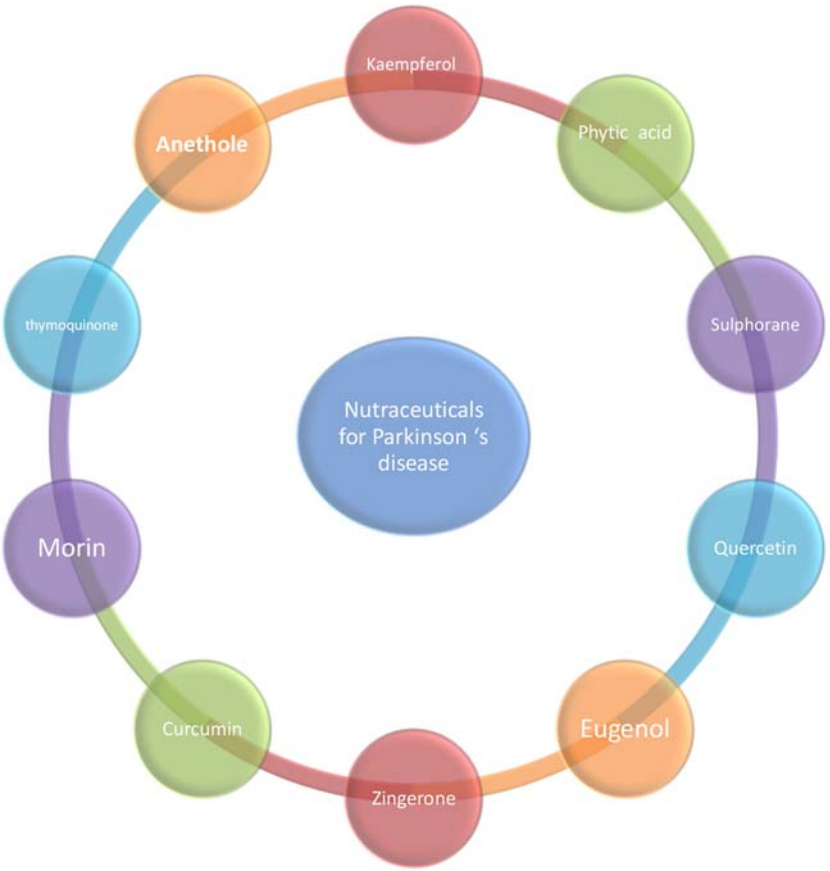

Fig. 9 Nutraceuticals in prevention of Parkinson's disease.

stress, mitochondrial dysfunction, and various forms of neural degeneration. Oleic acid, a monounsaturated fatty acid, has also been proposed to have a potential role in decreasing brain-related disorders such as dementia and Alzheimer's disease. DHA is essential for the maintenance of normal brain function in infants and adults and hence decrease in DHA level may have onset of Alzheimer's disease. Epigallocatechcin-3-gallate, an important constituent of green tea, is suggested as a potential agent for Alzheimer's disease as it has the ability to inhibit aggregation of amyloid-β, which is a major pathogenic factor in the development and severity of the disease. A great deal of research has pointed to deleterious roles of metal ions in the development of Alzheimer's disease, by the augmentation of oxidative stress by metal ion. The growing trend in nutraceutical intake is a result of the belief that they postpone the development of dementias such as Alzheimer's disease.

1.05.11 Conclusion

Nutraceuticals present in a healthy diet provide energy and nutrient supplements to body, which are required for maintaining optimal health. Low intake of vegetables fruits, minerals, and vitamins clearly indicated for the cause of development of various diseases. Antioxidants, dietary fibers, with recommended daily requirement of proteins, vitamins, and minerals together with physical exercise can prevent and treat these diseases. Poor lifestyle habits, consumption of junk food, and low physical activity led to a number of diseases related to nutritional deficiencies. Thus to conclude, optimal nutrition with proper intake of nutraceuticals in maintaining health to combat against acute and chronic diseases due to nutritional disorders will promote optimal health, longevity, and quality of life. However, their success in prevention of diseases and maintaining health mainly depends on purity, efficacy, and safety of nutraceuticals. Assessment of efficacy of nutraceuticals is essential and it is the measure of its ability to improve health and well-being. Assessment of safety can be based on the type of nutraceuticals, that is, if raw materials of nutraceuticals are traditional foods (yogurt, oat meal, and tea), then toxicity study may not be required as they are recognized as safe foods. If the raw materials of nutraceuticals are not traditional, then safety data for genotoxicity, carcinogenicity, teratogenicity, and 90-day toxicity study is required.

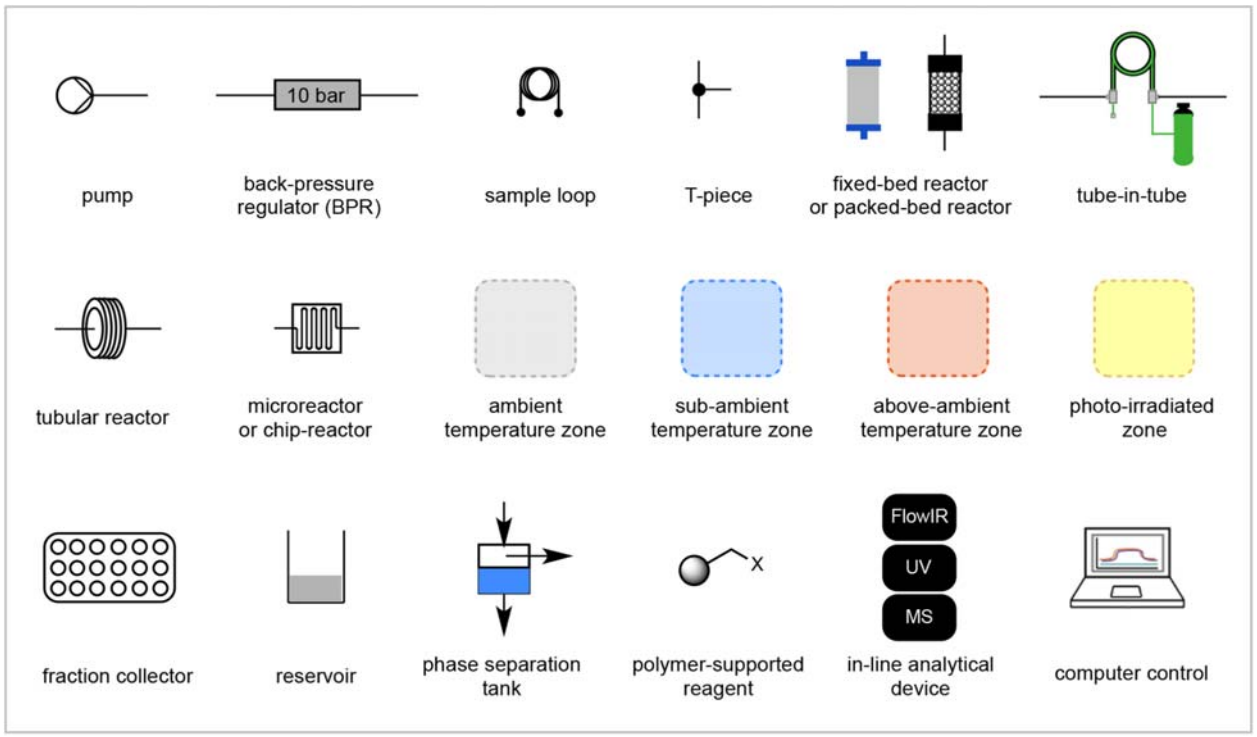
1.06.1 Introduction

Continuous flow processing as applied to the synthesis of fine chemicals is a burgeoning field of research. Specifically, this chemical processing technique has thus far been most closely aligned to the pharmaceutical industry.[1]

There are likely several reasons for this, not the least of which is the ongoing relationship between organic chemists in academia and industrialists in drug discovery and development. The issues and problems sometimes encountered when operating standard round-bottom flask, or "batch" reactions are familiar to all practitioners of synthesis. Indeed these problems typically compound themselves as scales are increased, such as during the early stages of a long natural product synthesis or in the pilot and process scaling for further drug development. A well-optimized and designed flow synthesis machine can negate many of the problems associated with scale-up. This is particularly the case for variation in reaction outcomes and reliability, especially if such results are born of poor control of mixing, heat-transfer, rates of addition, and timing. Essentially flow chemical techniques offer a tighter control on the important reaction parameters that synthetic chemists do not always consider, control, and/or monitor. Moreover, it achieves this through the very method itself, that is, it does not leave room for operator variation. Herein we shall provide a snapshot of some relevant examples of continuous flow processing for medicinal chemistry applications. Our account is by no means exhaustive, and we preemptively apologize for the many excellent examples that we have not incorporated into this overview. We have tried to provide comprehensive referencing to relevant review articles and would refer readers to those for more detailed overviews of more specific areas of interest. This article is designed to provide some initial theory on flow concepts and equipment before presenting a survey of examples as divided up in the subchapters.

Why use continuous flow processing? There are a few key considerations one should be aware of when deciding whether to use flow processing techniques. Unlike a traditional batch reactor where scale is dependent on the volume of the reactor, for a flow process scale is dependent on the length of time for which the process is run. Essentially once the flow process is started, product will be produced at a continuous rate and emerge from the reactor over time. Any point along the flow path represents a unique time point in the reaction process. Conversely for batch—the whole vessel experiences the same time point for the reaction as a bulk from start to finish. This imparts quite profound consequences on how one can start to think about a flow system in terms of space and time. Directly born from this consideration is the notion that continuous flow is inherently safer than batch. For example, if a reaction proceeds through the intermediacy of a hazardous or unstable species then in the flow reactor this will correspond to a single section of the reactor circuit and therefore a subsection of the whole inventory. Essentially, if an incident occurs, then only a small portion of the total inventory will represent the hazard, whereas in the analogous batch reactor the whole reaction vessel will represent the hazard. Incidents caused by these hazards could occur when mixing is insufficient, reaction exotherms are not dissipated, and runaway processes take hold. This brings us to the second inherent safety benefit of flow processing, improved surface area to volume ratios (SA:V). The improved SA:V means that previously uncontrolled exotherms can now be controlled as the heat



Scheme 1 Key of flow components.

generated can be dissipated much more effectively so that thermal runaways are less likely. Conversely the flowing streams can be heated much more rapidly. Heating of reaction streams represents another benefit for flow processing. Not only can materials be heated more rapidly and hazards minimized, but streams can be pressurized and therefore superheated, known as hypothermal conditions. This is simply achieved by adding a back pressure regulator to the system and heating past the standard boiling point. Notably, unlike microwave reactors, pressurized flow systems have no free headspace which can often remove more volatile components from reaction streams or present a hazard themselves. Additional benefits of a flow setup comprise the ability to multistep, daisy-chain, or telescope reactions or chemical processes together. This can allow the avoidance of isolating unstable compounds by advancing them rapidly to the next synthetic step. Rather than running into another reaction, flow processes can also be intercepted for reaction quenching and inline purification. Indeed, designing continuous processes that greatly streamline the separation and purification parts is where significant time and cost savings can be made at scale.

Throughout this article we will provide schematic diagrams that depict the assembled flow components required to make some of the molecules described. Scheme 1 provides a summary of some of the more commonly occurring components that will be used in this article.

1.06.2 Fragments and Heterocycles

Continuous flow processing is effective across a range of scales. The ability to scale up from a segmented discovery setup producing tens of milligrams to a pilot process capable of producing multikilograms per day makes it an important technology for incorporation into medicinal chemistry programs. One machine could produce a diverse variety of fragments and heterocycles incorporating hazardous reagents or high temperatures and then be easily reconfigured to churn out any single one of interest. Owing to this versatility, continuous flow processing of new or stalwart fragments and heterocycles has achieved much attention. In this section we will provide a snapshot overview of some of the capabilities offered by this synergy.

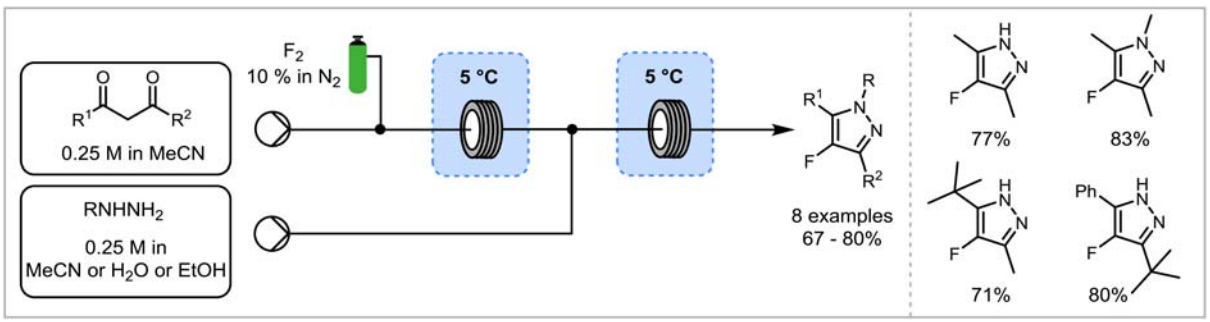
1.06.2.1 Hazardous Gases

The use of reactive gases in a direct chemical transformation is often the most efficient pathway with respect to atom economy. However, it can be highly restricted depending on the hazards of the gas and the pressure involved. Using continuous flow methods has the prospect of allowing much easier handling of gases from a practical point of view. In addition, the mass transfer of gas into the solution is improved, compared to batch reactors, due to the larger surface area. This enables new reaction pathways where otherwise the reaction would not work or be too dangerous using traditional batch methods.[2] There are several ways to introduce

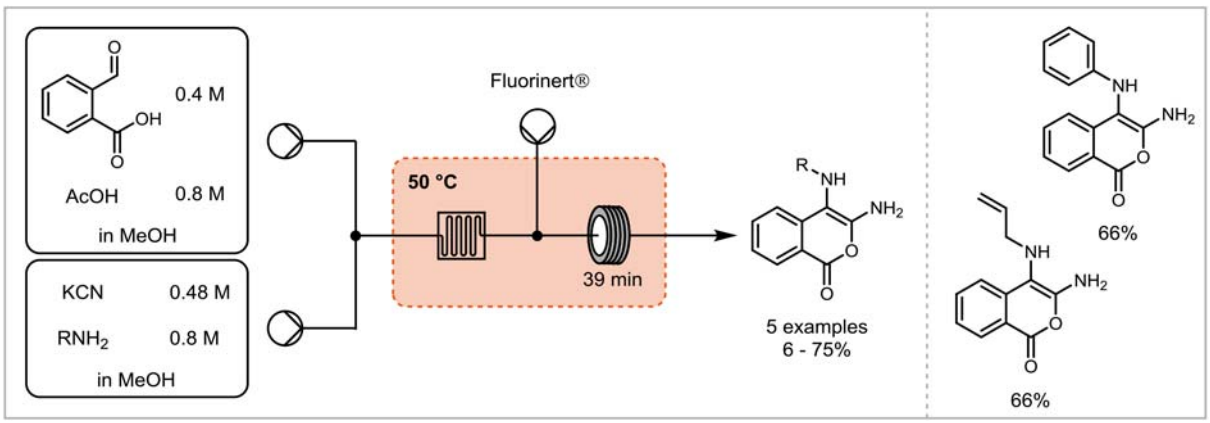
gases to a continuous reaction. The easiest is to simply merge a stream of gas with a stream of the other reactants in solution. Depending on the pressure and flow rate this then leads either to a homogeneous solution with all the gas dissolved or to segmented flow conditions. Another method is the introduction of special reactors such as a falling film or a tube-in-tube reactor. In the falling film reactor the liquid is dispersed over a surface in the reactor to form a thin layer creating a large surface area. The gas is then flowed through from the other side. The tube-in-tube reactor consists of an outer and an inner tube.[3] A original inner-tubing material is the semipermeable membrane Teflon (AF-2400) that enables gas transport from one side to the other. Typically the outer tube is pressurized with the desired gas, while the reaction mixture is pumped through the inner tube. The gas transfer into the solution is thereby dependent on the pressure differential of the gas across the membrane and the flow rate of the liquid. Much work has been reported on the use of tube-in-tube reactors, and we do not wish to reproduce excellent overviews here.[2,3] Instead we have picked just a few examples to highlight the utility of this technology.

The introduction of fluorine atoms into organic molecules is of pharmaceutical and agrochemical interest. However, the most efficient method, direct fluorination using hazardous fluorine gas, is incredibly exothermic and represents a significant safety issue in handling large excesses of fluorine gas. Continuous flow processing offers the prospect of addressing both of these drawbacks.[4] The enhanced safety in handling the gas and the increased reaction and temperature control due to the large SA:V enables the direct use of fluorine gas. One example of direct fluorination to form 4-fluoropyrazoles has been introduced by Sandford and coworkers.[5] The reactor employed has been designed by Chambers and Spink[6] for the introduction of elemental fluorine and is fabricated from nickel-based materials. Sandford and coworkers fluorinated a 1,3-diketone that then cyclized with a hydrazine to give the desired pyrazole derivate (**Scheme 2**). This is the first example of a multistep flow process involving direct fluorination with fluorine gas, or at least 10% F_2 in N_2. Notably such pyrazoles could be prepared by use of selectfluor in the initial 1,3-dicarbonyl steps, but the present method would be much more appropriate at scale from a cost of goods perspective.

Stevens and coworkers introduced a continuous process that would generate and consume HCN in situ but avoid release of the hazardous gas in large quantities.[7] The setup consists of two streams (**Scheme 3**), first, 2-formylbenzoic acid and acetic acid and second, KCN and aniline. These streams are combined and mixed in a microreactor. By separating the cyanide and acid components the hydrogen cyanide is only formed in the reactor and then consumed directly. The aniline and the formylbenzoic acid form an imine followed by addition of the cyanide. This can then ring close and tautomerize to form the product. Interestingly, they introduced a stream of inert immiscible fluorous solvent, Fluorinert, to carry precipitate formed during the reaction through the reactor.



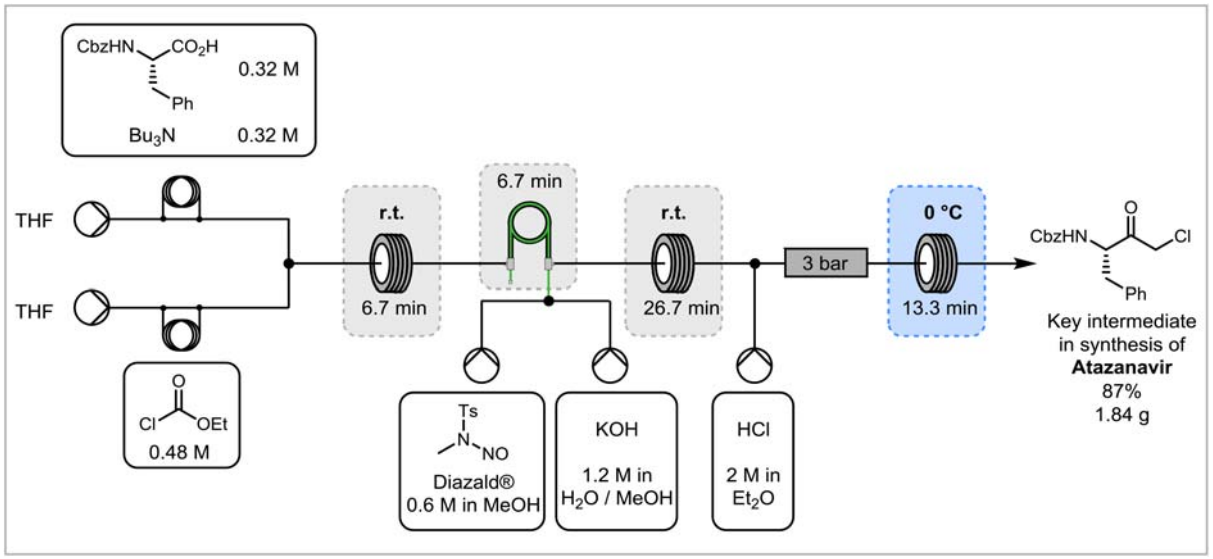
Scheme 2 Fluorination in flow using F_2 gas.[5]



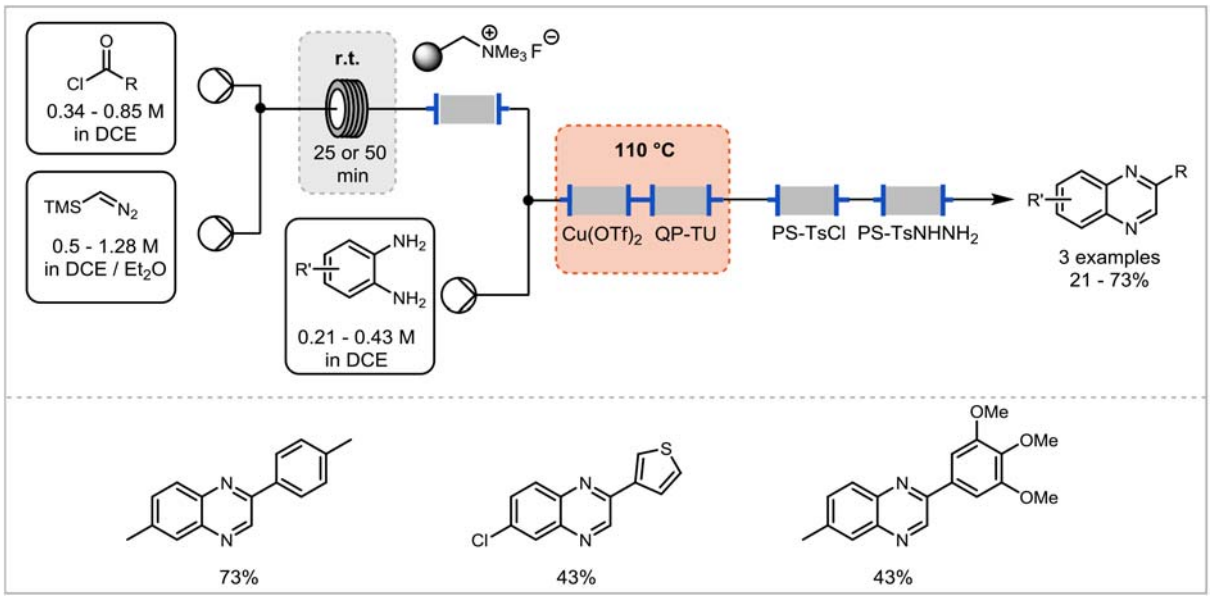
Scheme 3 Flow synthesis of 3,4-diamino-1H-isochromen-1-ones using HCN.[7]

Kappe and coworkers used the tube-in-tube reactor to introduce in situ prepared diazomethane into a reaction.[8] Diazomethane is a C_1 building block that can be used for methylation or acylation. However, due to its hazards, its use is usually avoided. Incorporating its generation into a continuous flow process allows improved safety as it is generated and consumed in situ. Since the first report of its in situ generation from Diazald (*N*-methyl-*N*-nitroso-*p*-toluenesulfonamide) in flow by Struempel and coworkers,[9] many other examples and precursors have been demonstrated, such as the base induced decomposition of MNU (*N*-methyl-*N*-nitrosourea) by Maggini and coworkers.[10] Kappe and coworkers generated diazomethane in a tube-in-tube reactor from *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (Diazald®) and potassium hydroxide in the inner tube and then performed the reaction in the outer tube. This allowed the safe use of anhydrous diazomethane. After finding an appropriate solvent system they performed methylation and acylation reactions. In a subsequent paper this technique was then applied to a multistep reaction to target an intermediate of the antiretroviral agent Atazanavir (**Scheme 4**).[11] First a Cbz-protected amino acid is activated to form an activated species. In a condensation with diazomethane an α-diazo ketone is formed that is then transformed into the α-halo ketone product in a hydrohalogenation reaction.

Martin et al. investigated the formation of diazoketones from acyl chlorides using different diazomethane precursors (**Scheme 5**).[12] They found that the less hazardous $TMSCH_2N_2$ gave better results than Diazald. The concept was demonstrated by synthesizing nine



Scheme 4 Flow synthesis of a key intermediate using diazomethane.[11]



Scheme 5 Flow synthesis of quinoxalines.[12]

different diazoketones (46–98% yield). These diazoketones can then be further converted into different products. They investigated the conversion of phenylenediamines into quinoxalines. From the isolated diazoketones they were able to synthesize 21 different quinoxalines (30–96% yield) including a protein kinase inhibitor. They were also able to demonstrate a telescoped flow process where the quinoxaline was synthesized from the acid chloride via generation and use of the diazoketone (3 examples, 21–73%).

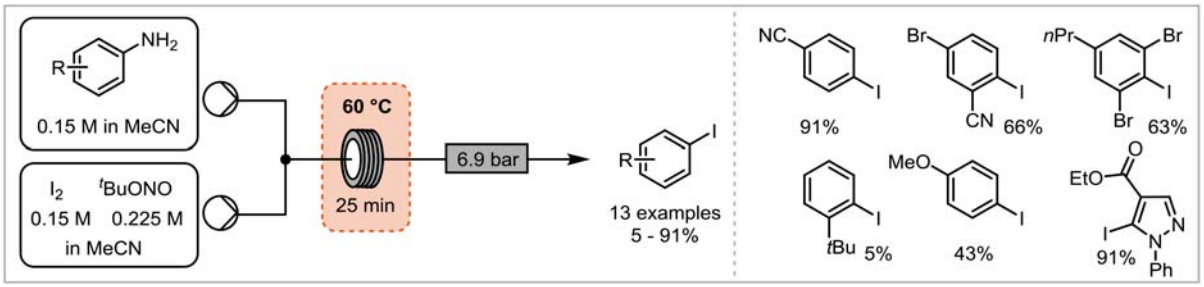
1.06.2.2 Diazonium Salts

Diazonium salts and diazo compounds are important intermediates in organic chemistry given their versatility and wide availability of the required starting materials. However, these nitrogen-rich compounds can lose nitrogen gas if not controlled appropriately. Thermal runaways are dangerous not only because of the heat given off but also because a large volume of gas is evolved causing a pressure build up. One way to control this is to prepare and consume them in situ using flow methods.[13] In this way the temperature is controlled very efficiently, and only a small amount of these hazardous intermediates are present at one time. Flow procedures offer the ability to produce and consume hazardous materials, such as diazonium salts, in situ so that only small quantities of reactive intermediate are present at any one time. This, and the enhanced temperature control, enables safer reaction performance, so many reactions involving diazonium salts and diazo compounds are reported under continuous flow conditions.

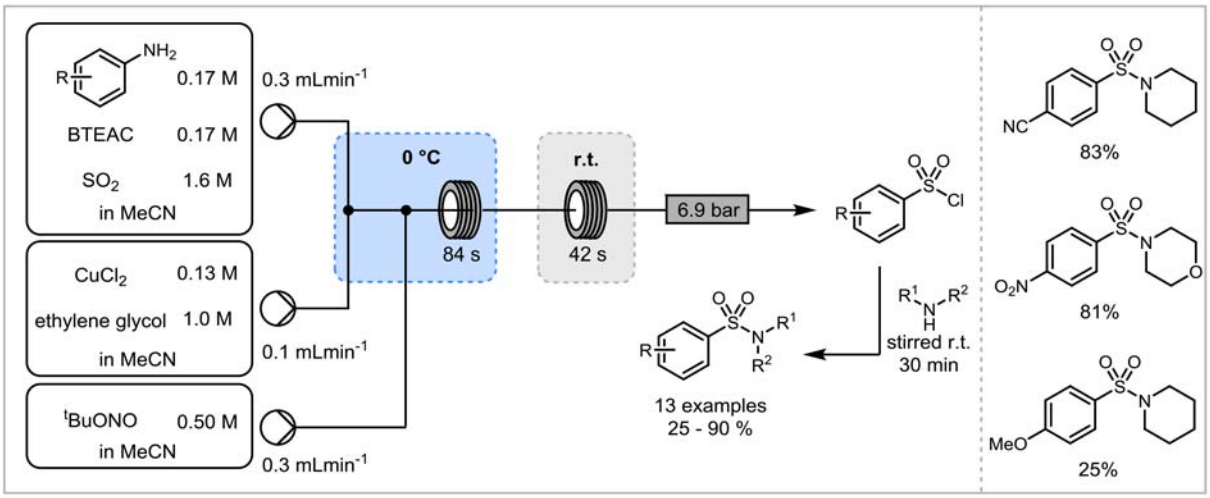
Diazonium salts are usually formed by treating an amine, usually an aromatic aniline, with a nitrite source. Those can then perform various other reactions where the diazonium group is replaced either in a nucleophilic substitution (e.g., Balz–Schiemann reaction) or in a radical mechanism (e.g., Sandmeyer reaction) or intercepted by a nucleophile (e.g., to form a triazene).

Malet-Sanz et al. demonstrated the use of diazonium salts prepared in situ in a copper-free iododeamination (Scheme 6).[14] In contrast to the Sandmeyer reaction this does not require a copper catalyst, as the reaction is performed in neutral conditions proceeding via a triazene intermediate to form radical intermediates. To stabilize the radicals acetonitrile was chosen and molecular iodine acted as the iodine source. The reaction proceeds smoothly, and the application to 13 examples was demonstrated, including those that are sterically demanding and electron-rich, albeit observing generally lower yields with these substrates.

Malet-Sanz et al. also adapted their method to the preparation of arylsulfonyl chlorides in a Meerwein chlorosulfo-de-diazotisation reaction (Scheme 7).[15] The challenge for this reaction setup was the incompatibility of the original reaction conditions with the flow setup due to precipitates and corrosive starting materials. Therefore they substituted the water-soluble nitrite source



Scheme 6 Copper-free iododeamination of diazonium salts in flow.[14]



Scheme 7 Synthesis of aryl sulfonyl chlorides from diazonium salts in flow.[15]

$NaNO_2$, with *t*-BuONO which is soluble in most organic solvents and also does not need the aid of an acid. The delivery of the copper catalyst, which aids the halogen transfer, was investigated, and a homogeneous solution with ethylene glycol as a cosolvent was found to be optimal. This stream was combined with a stream of the aniline, benzyltriethylammonium chloride, and SO_2. Precipitation of a triazene by-product was observed for some examples under neutral conditions. To avoid the formation of the triazene in the first place, the order of reactant streams was changed adding the nitrite last. Using this procedure they were able to generate 13 examples of arylsulfonyl chlorides.

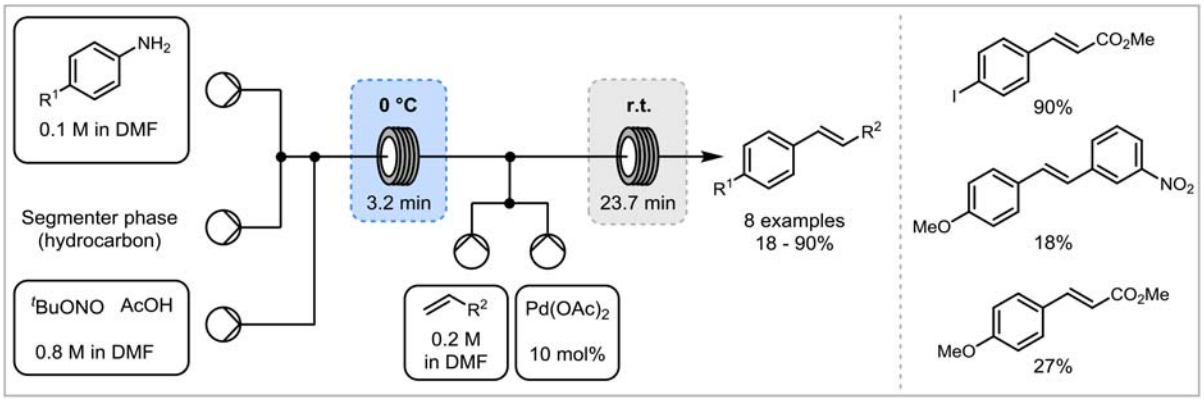
Wirth and coworkers introduced a biphasic, fluorous segmented approach to the diazonium-type Heck–Matsuda reaction in flow (**Scheme 8**).[16] They accelerated the reaction by using segmented flow conditions to enhance micromixing. The aniline stream is thereby segmented by an inert phase before combination with *t*-BuONO for diazotation. The diazonium salt is then intercepted by an alkene in a Heck–Matsuda coupling reaction to form the desired trans stilbene products.

1.06.2.3 Azides

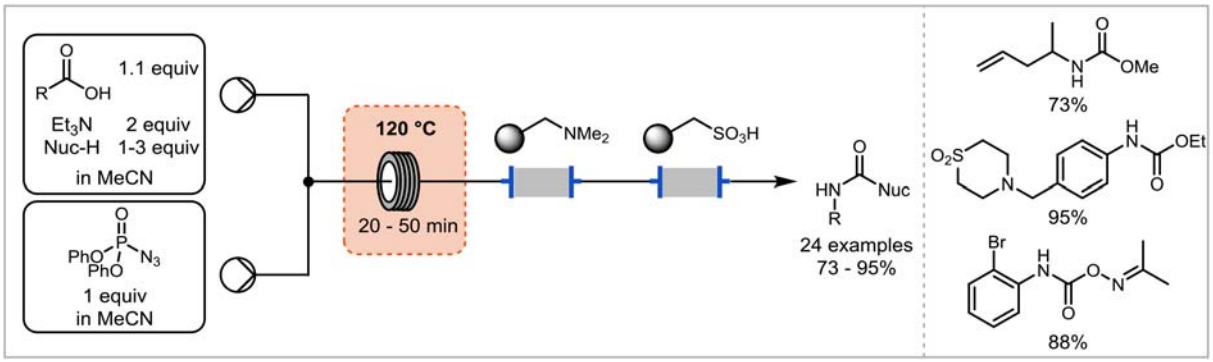
Similar to diazonium salts and diazo compounds, azides are highly versatile yet hazardous materials due to the possible loss of nitrogen gas.[17] Ley and coworkers performed a Curtius rearrangement in flow to safely handle acyl azides. The acyl azides are thereby produced in situ from diphenylphosphoryl azide (DPPA) and the corresponding acid. After reaction with a nucleophile the resultant isocyanate is trapped on a solid support (**Scheme 9**).[18] This enables the inline purification of the product mixture. Using this method they were able to produce 25 g of material, demonstrating the suitability of flow processes to larger scale syntheses.

Jensen and coworkers demonstrated a multistep continuous flow synthesis of carbamates also making use of the Curtius rearrangement (**Scheme 10**).[19] Streams of the acid chloride and sodium azide were combined to form the organic azide. Liquid–liquid phase separation was realized in a microseparator before the reaction mixture was heated where upon nitrogen gas was liberated to form an isocyanate that was then intercepted by an alcohol to afford a variety of carbamate products.

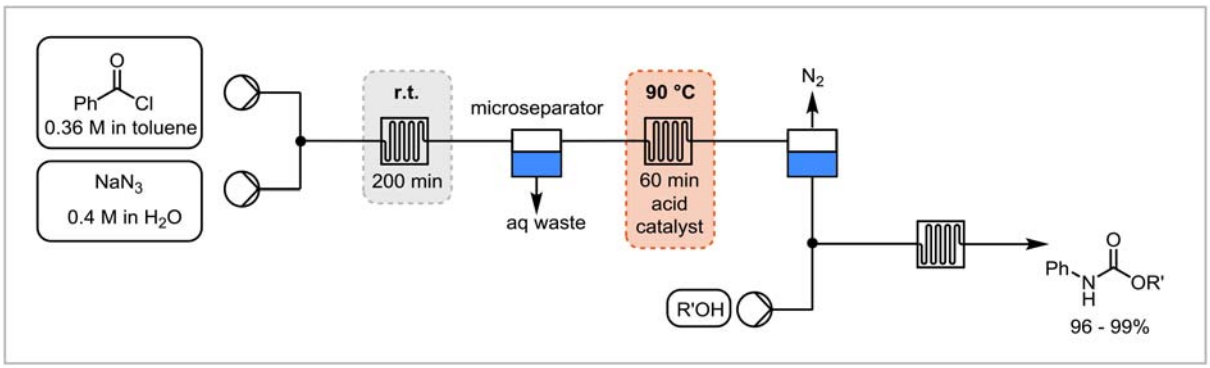
Noël, Hessel, and coworkers performed a catalyst-free Huisgen cycloaddition to synthesize a Rufinamide precursor featuring the triazole heterocyclic moiety (**Scheme 11**).[20] Several dipolarophiles are known to perform this reaction; however these are highly toxic and flammable. Noël and Hessel utilized a greener and less expensive dipolarophile, (*E*)-methyl 3-methoxyacrylate, that



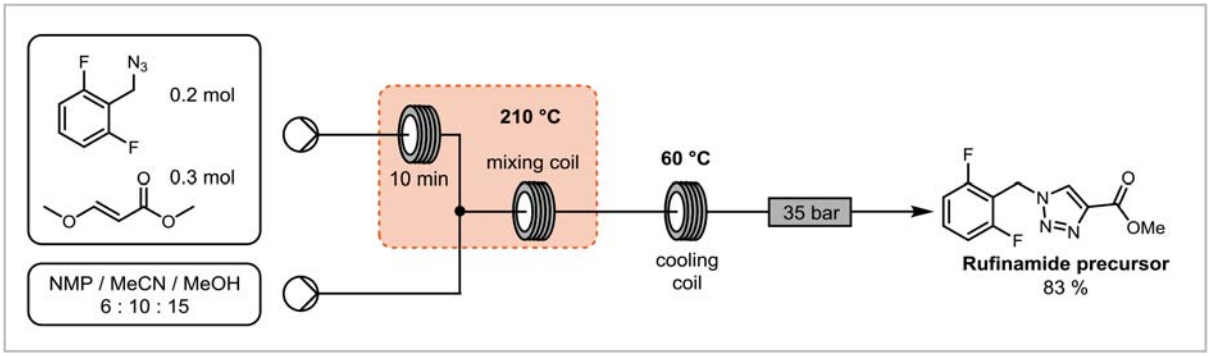
Scheme 8 Heck–Matsuda reaction under segmented flow.[16]



Scheme 9 Curtius arrangement in flow.[18]



Scheme 10 Synthesis of carbamates via a Curtius rearrangement in flow.[19]

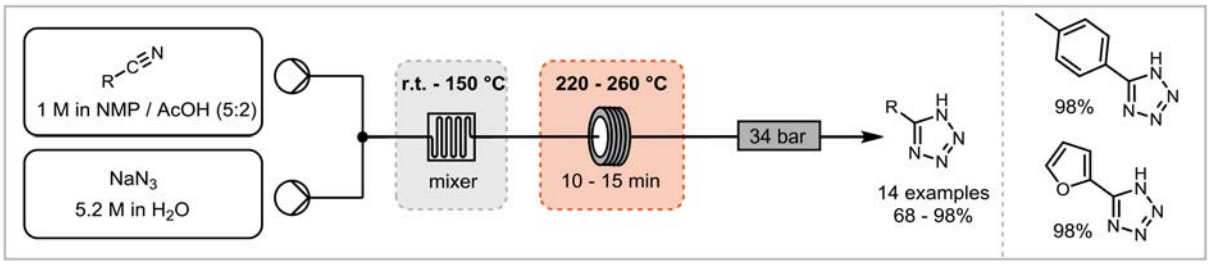


Scheme 11 Flow synthesis of a Rufinamide precursor.[20]

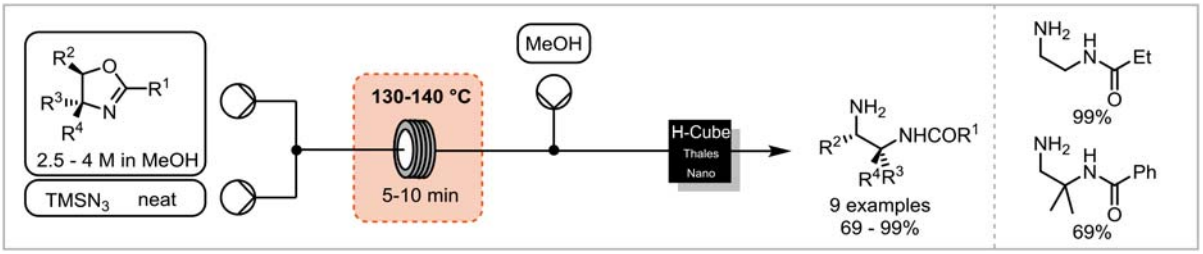
does not require transition metal catalysis. They premixed the neat starting materials, a benzyl azide and their dipolarophile, and passed them through a heated reactor coil. However, they had to take into account that azides readily decompose at elevated temperatures. After investigating the behavior at different temperatures, they found that 210°C and 10 min residence time gave optimal results. This permitted a decrease in the reaction time from 28 h at 135°C in batch to 10 min at 210°C in flow. Interestingly, the reaction worked under solvent-free conditions with a corresponding increase in reaction rate. However, dilution was needed to dissolve the product and prevent precipitation. The reaction proceeded smoothly and gave 83% yield of the Rufinamide precursor after purification.

Roberge, Kappe, and coworkers introduced a process to prepare tetrazoles from nitriles and the toxic and explosive hydrazoic acid (Scheme 12).[21] The hydrazoic acid is generated and consumed in situ by mixing an aqueous sodium azide solution with a solution of acetic acid and nitrile in N-methyl-2-pyrrolidone (NMP). The tetrazole is then formed by reaction with the nitrile. By increasing the reaction temperature to over 200°C, process intensification with decreased reaction times was demonstrated.

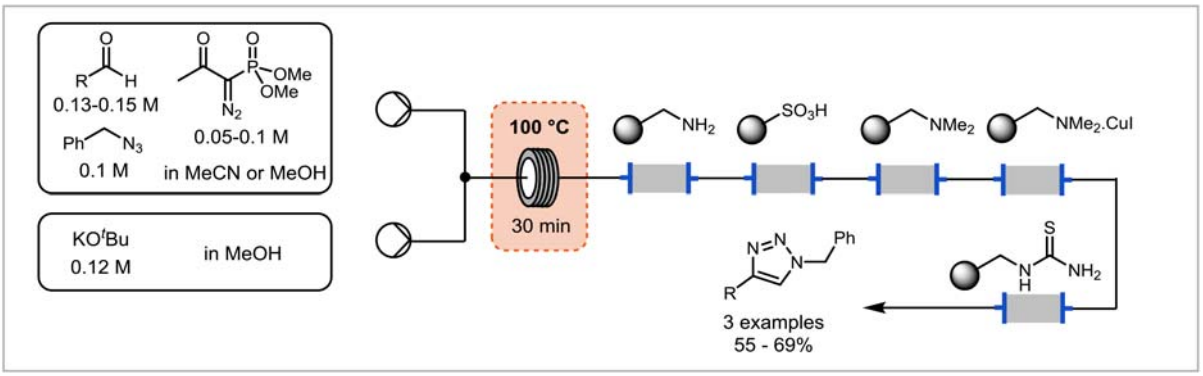
Roberge, Kappe, and coworkers used TMS azide to ring-open oxazolines followed by reduction to the amino amide (Scheme 13).[22] The oxazoline reagent stream and the neat $TMSN_3$ stream were merged prior to heating. The heating-induced ring opening at the C-5 before the azide was reduced in an H-cube to give the amino amide. Thereby the ring is opened by the in situ formed HN_3 gas by solvolysis of $TMSN_3$ with MeOH).



Scheme 12 Synthesis of tetrazoles in flow.[21]



Scheme 13 Ring opening of oxazolines with hydrazoic acid in flow.[22]



Scheme 14 Flow synthesis of triazoles.[23]

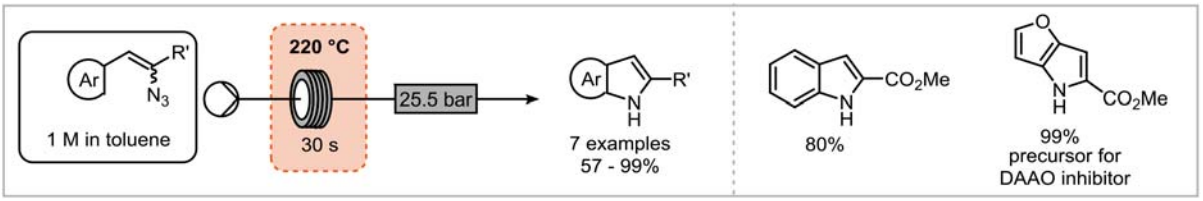
Another method making use of azides has been introduced by Ley and coworkers in their synthesis of triazoles (Scheme 14).[23] Their work focused on avoiding conventional work-up procedures but instead using immobilized reagents and scavenging methods. They used the Bestmann–Ohira reagent, dimethyl (1-diazo-2-oxopropyl)phosphonate, with KO*t*Bu to generate a diazomethyl phosphonate in situ which then formed a terminal acetylene from an aldehyde. The clean product was obtained after passing it through the first three of the packed cartridges. In a telescoped process an azide was mixed into the reagent streams and reacted with the acetylene in a copper-catalyzed cycloaddition to form the desired triazole. The reaction setup could be further modified to also first oxidize an alcohol to the corresponding aldehyde starting material.

Seeberger and coworkers used an azido acrylate to synthesize indoles in a Hemetsberger–Knittel reaction via an aziridine intermediate (Scheme 15).[24] The azido acrylate starting material was prepared in a Knoevenagel condensation beforehand. In the flow reactor it was then thermolytically cleaved to give a nitrene that is then in equilibrium with the aziridine. Importantly, in only 21 min they could produce a precursor for a DAAO inhibitor on an 8.5 g scale.

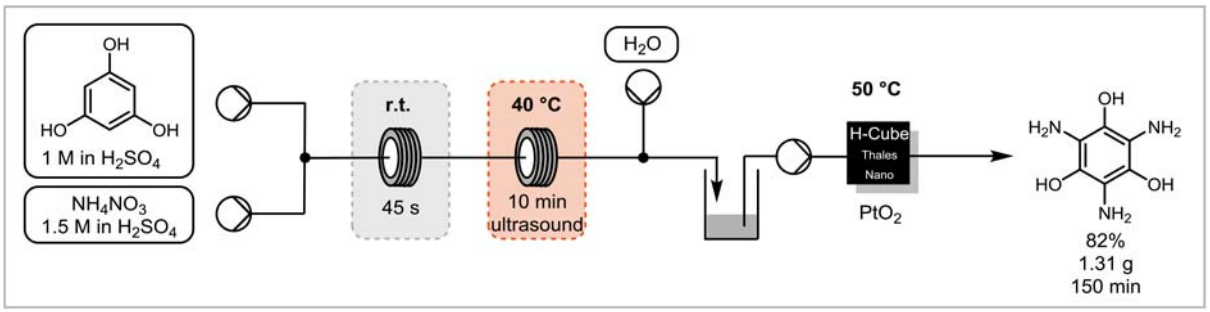
1.06.2.4 Nitration

Nitration reactions can be very hazardous when performed on large scales in batch. They release large amounts of heat, and multiple nitration can be problematic. The products can also be highly explosive. However, the ability to control exotherms in flow allows improved selectivity and safety. As such, there have been many nitration reactions performed using continuous flow.[25]

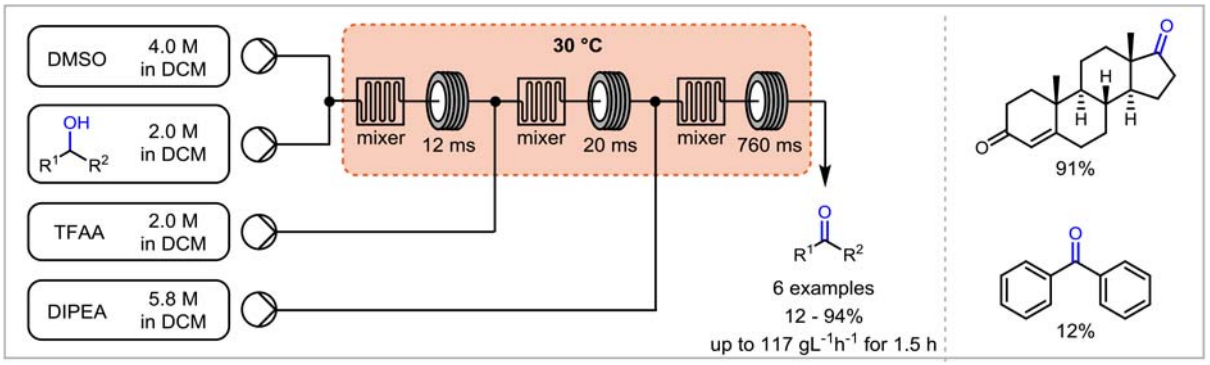
The improved safety is exemplified in the synthesis of triaminophloroglucinol, by Kappe and coworkers.[26] They start from inexpensive phloroglucinol and subject it to nitrating conditions (Scheme 16). An ultrasound bath was used to prevent blocking of the reactor by precipitation of the high energy compound trinitrophloroglucinol. The nitro groups on this explosive intermediate were directly hydrogenated to amines using hydrogen generated from the H-Cube over a PtO_2 catalyst.



Scheme 15 Synthesis of indoles in flow via aziridines.[24]



Scheme 16 Synthesis of triaminophloroglucinol in flow.[26]



Scheme 17 Swern oxidation in flow.[29]

1.06.2.5 Oxidation

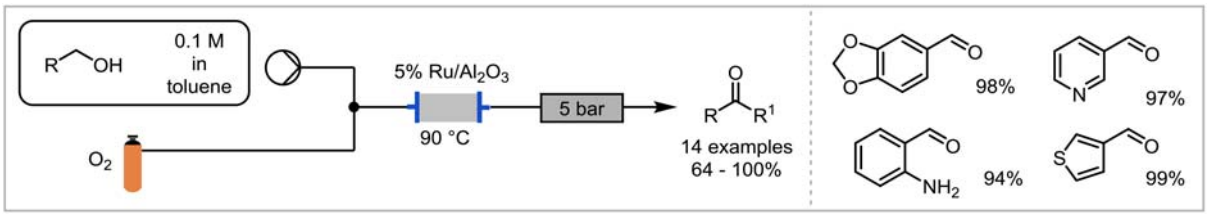
Typical oxidation reactions make use of hazardous oxidizing agents, are often exothermic, and have the potential to form explosive mixtures. Selectivity can also be an issue, especially where overoxidation is possible, or there are multiple potential sites for oxidation. Using flow processes can solve some of these issues, and indeed there are several examples which address these.[27]

The Swern oxidation is a key method for the selective transformation of alcohols to aldehydes, avoiding overoxidation to carboxylic acids. In batch, it is normally necessary to use cryogenic temperatures to avoid side reactions, such as the Pummerer rearrangement. There have been several examples of the Swern oxidation in flow, allowing it to proceed at room temperature with very short reaction times and minimal side product formation.[28] **Scheme 17** shows one example, where trifluoroacetic anhydride was used to activate the DMSO and then oxidize alcohols in less than 1 s at 30°C.[29] The exact order of addition was found to be important to minimize side product formation. The authors have also demonstrated the ability to scale up this method.

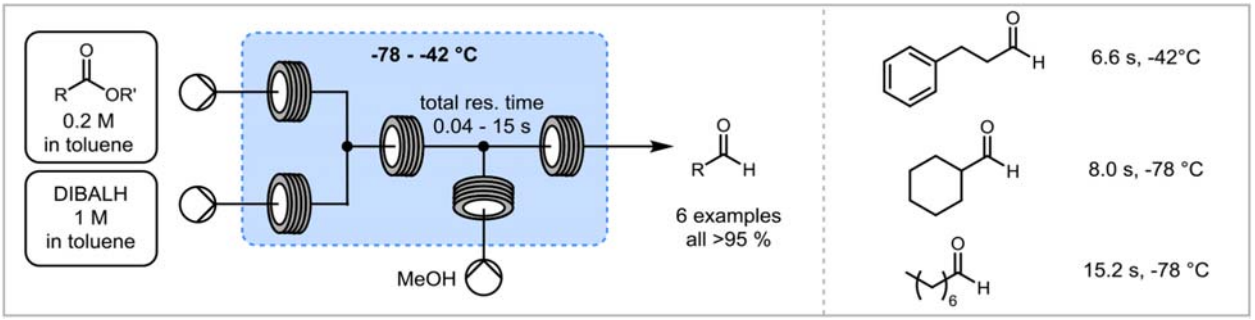
The selective oxidation of alcohols to aldehydes has also been achieved in flow using controlled delivery of oxygen gas (**Scheme 18**).[30] A solution of the alcohol meets a stream of O_2 and passed through a cartridge packed with a Ruthenium catalyst at 90°C. Several alcohols were selectively oxidized using this method and often leading to high yields of the corresponding aldehyde.

1.06.2.6 Reduction

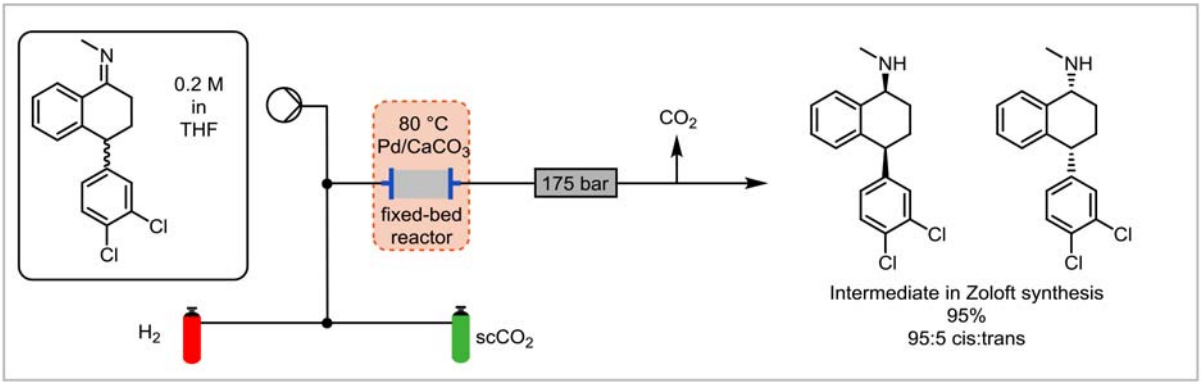
Several of the key issues of oxidation are also present in reduction reactions. Problems of selectivity due to the possibility of overreduction or reduction at different sites exist. Hydrogenation is commonly performed in flow, especially after the introduction of the



Scheme 18 Selective oxidation of alcohols in flow using O_2 gas.[30]



Scheme 19 Selective reduction of esters to aldehydes in flow.[33]



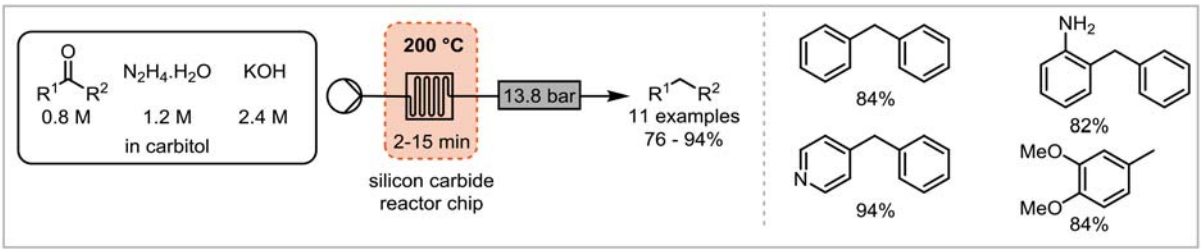
Scheme 20 Hydrogenation of an imine in flow to produce a key intermediate.[34]

H-Cube, which safely generates H_2 gas by in situ electrolysis of water. There are many examples of hydrogenation under flow conditions.[31] Other reductions have also been achieved in flow, some of which are presented later.

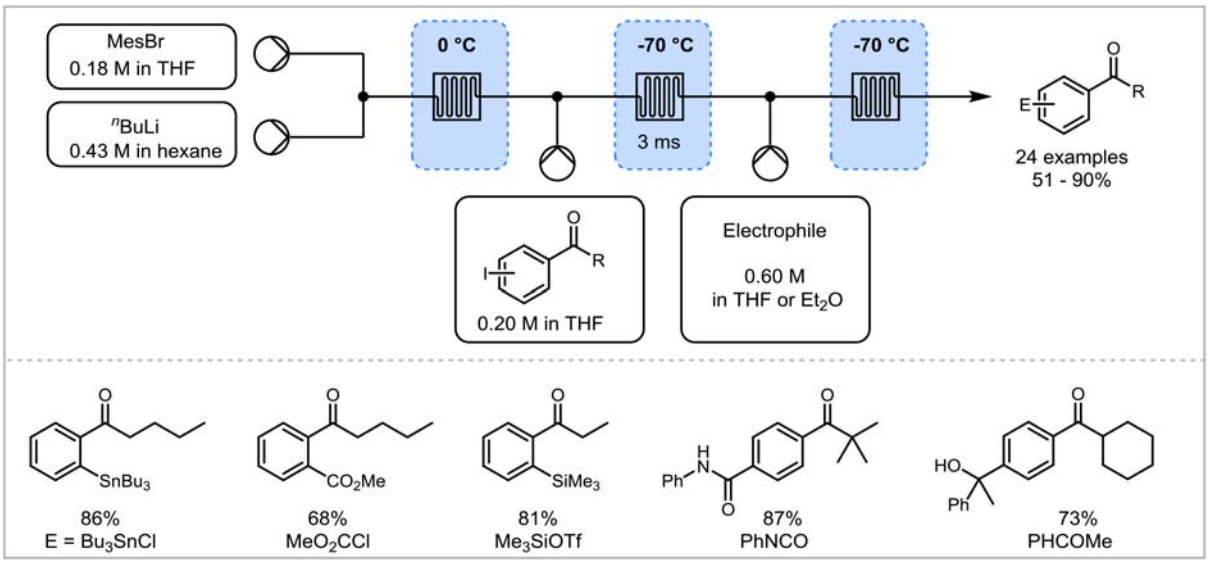
The reduction of esters using diisobutylaluminium hydride (DIBALH) to obtain only the aldehyde, without overreduction to the alcohol, is a challenge. However, using flow processes can improve the selectivity.[32] A report by Webb and Jamison demonstrates that this selective reduction can be achieved in 15 s (Scheme 19).[33] Solutions of DIBALH and the ester were precooled and then allowed to mix and react. A stream of methanol was added to dilute and quench the mixture. This process was found to be extremely selective in forming the aldehyde, with six examples of over 95% yield.

In order to make an intermediate required in the synthesis of the antidepressant Zoloft a continuous flow hydrogenation of an imine was reported by Clark, Poliakoff, and Wells (Scheme 20).[34] Notably, the reaction was performed in supercritical carbon dioxide, which improves the heat transfer properties of the system. A stream of the imine was mixed with hydrogen gas in supercritical carbon dioxide and heated at 80°C over $Pd/CaCO_3$ catalyst. Notably, an improved chemoselectivity was observed in the supercritical carbon dioxide due to prevention of hot-spots on the catalyst bed. The desired product was isolated with excellent yield and diastereomeric ratio.

Jensen and coworkers performed the Wolff–Kishner reduction of ketones and aldehydes (Scheme 21).[35] Initially the carbonyl reacts with hydrazine to form a hydrazone which on treatment with base affords the desired reaction. This requires very harsh reaction conditions, heating the carbonyl with hydrazine and strong base to high temperature. In this case 200°C was used, allowing the reaction time to be decreased in comparison to traditional batch conditions. The use of a resilient silicon carbide microreactor was required in order to achieve these conditions.



Scheme 21 Wolff–Kishner reduction of ketones in flow.[35]



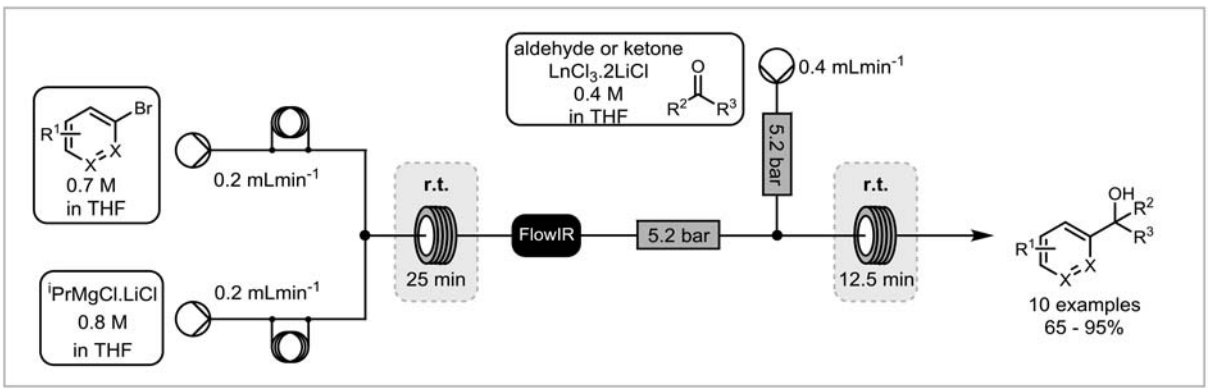
Scheme 22 Lithium halogen exchange followed then interception by an electrophile in flow.[37]

1.06.2.7 Organometallic Reagents

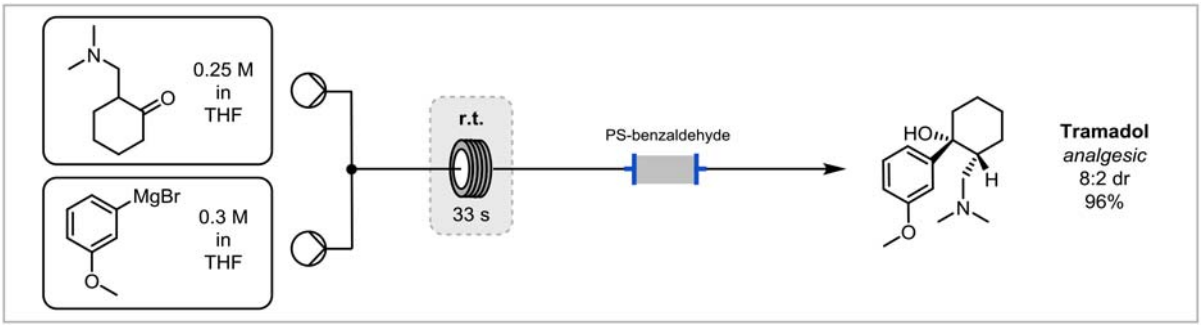
The use of organometallic reagents, such as Grignard reagents, is extremely important in the synthesis of many compounds. These methods are widespread during syntheses due to their versatility. However, there are several issues associated with the use of organometallic reagents. Organometallic reactions in general are exothermic, and the ability to dissipate heat quickly in flow, due to the large SA:V associated with flow reactors, is desirable. This is especially valid when preparing such reagents on large scales. Organometallic reagents are often air and water sensitive, and problems with solubility and precipitates are often encountered due to insoluble by-products, such as magnesium salts after a Grignard reaction. However, these problems can be overcome by the use of peristaltic pumps, which are able to process slurries or the addition of diluting streams to dissolve potentially insoluble materials. Owing to this, the pumps and other hardware used need to be suitable for handling such corrosive materials. There are now many examples of using organometallic reagents in flow including the use of "flash chemistry," pioneered by Yoshida.[36]

Flash chemistry involves using extremely short reaction times in order to prevent reactive intermediates from decomposing, and it has particular applications to organometallic reactions. In this example, an aryl lithium species is intercepted by an external electrophile despite an intramolecular carbonyl being present (Scheme 22).[37] The lithiating species, mesityl lithium, was generated from *n*-butyllithium and mesityl bromide. A stream of aryl iodide was added, and a lithium iodide exchange takes place to form the lithiated intermediate. This reaction takes place at $-70°C$ with a residence time of only 3 ms required to avoid decomposition. This lithiated intermediate was then directly intercepted by a stream of an external electrophile. A range of electrophiles and aryl iodides were successfully transformed using this method.

The preparation of aryl magnesium reagents in flow and subsequent reaction with carbonyls has been demonstrated by Ley, Knochel, and coworkers (Scheme 23).[38] A stream of the aryl bromide was combined with a stream of *i*-PrMgCl·LiCl in order to achieve



Scheme 23 Preparation of Grignard reagent and subsequent reaction in flow.[38]



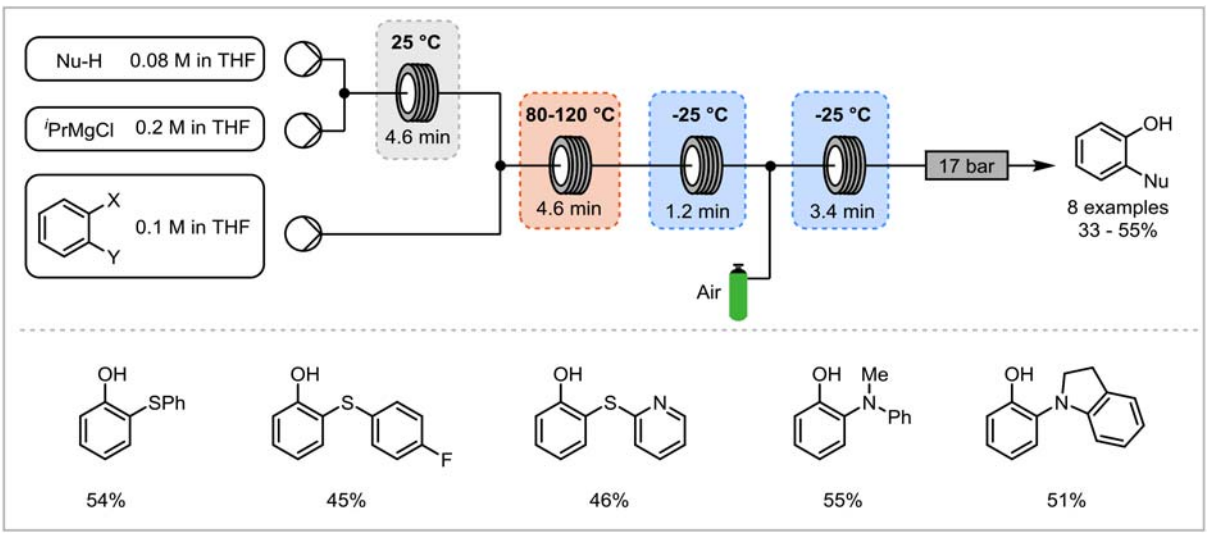
Scheme 24 Preparation of tramadol in flow via a Grignard reaction.[39]

the magnesium/halogen exchange. The mixture was passed through a reactor coil at room temperature for 25 min, and the output was monitored by inline IR to continuously monitor correct Grignard formation via concentration monitoring. The peaks observed due to THF coordination with the aryl magnesium species were used to determine the concentration of active Grignard reagent present. The formation of the protonated species and the homocoupled product were also monitored using characteristic bands in the fingerprint region after calibration. The aryl magnesium formed was then reacted with a range of aldehydes and ketones successfully demonstrating the preparation, monitoring, and reaction of these species in flow.

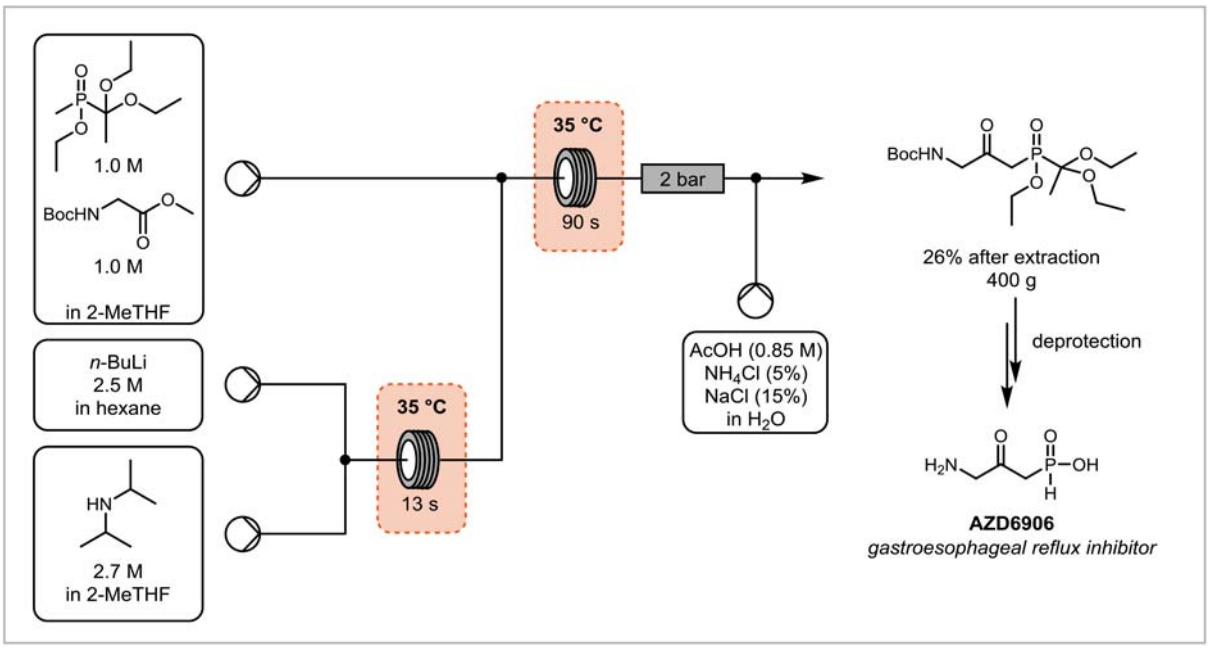
The flow synthesis of the analgesic, Tramadol, was reported by Rencurosi and coworkers in 2010 (Scheme 24).[39] A Grignard reaction was performed under flow conditions, achieving a high yield with a residence time of only 33 s at room temperature. The streams of ketone and Grignard reagent were combined and passed through a reactor coil. The exiting stream then passed through a scavenger column of polymer-supported benzaldehyde to remove any remaining unreacted Grignard reagent. Tramadol was afforded in excellent yield.

Grignard reagents have also been used in flow to synthesize functionalized phenol fragments (Scheme 25).[40] Initially, the relevant nucleophile was deprotonated by the Grignard reagent. This stream was then combined with a stream of the 1,2-dihalobenzene and heated to allow benzyne formation via magnesium halide exchange followed by elimination. The benzyne was then intercepted by the nucleophile resulting in the formation of an arylmagnesium intermediate. The input of air then oxidized the arylmagnesium species to the desired ortho-functionalized phenol. The overall setup provides a convenient method to prepare a diverse array of ortho functionalized phenols, as demonstrated by the eight examples reported.

Another commonly used organometallic reagent is lithium diisopropylamide (LDA). In scaling up the synthesis of a promising reflux inhibitor, Pontén and coworkers used a flow procedure to generate LDA in situ (Scheme 26).[41] Instead of the −78°C required in batch, they were able to generate LDA after 13 s at 35°C in a flow reactor coil. The stream of LDA was then combined with the stream of *N*-Boc glycine methyl ester and methyl phosphinate. The mixture was directed through a heated reactor to afford 400 g of the protected product.



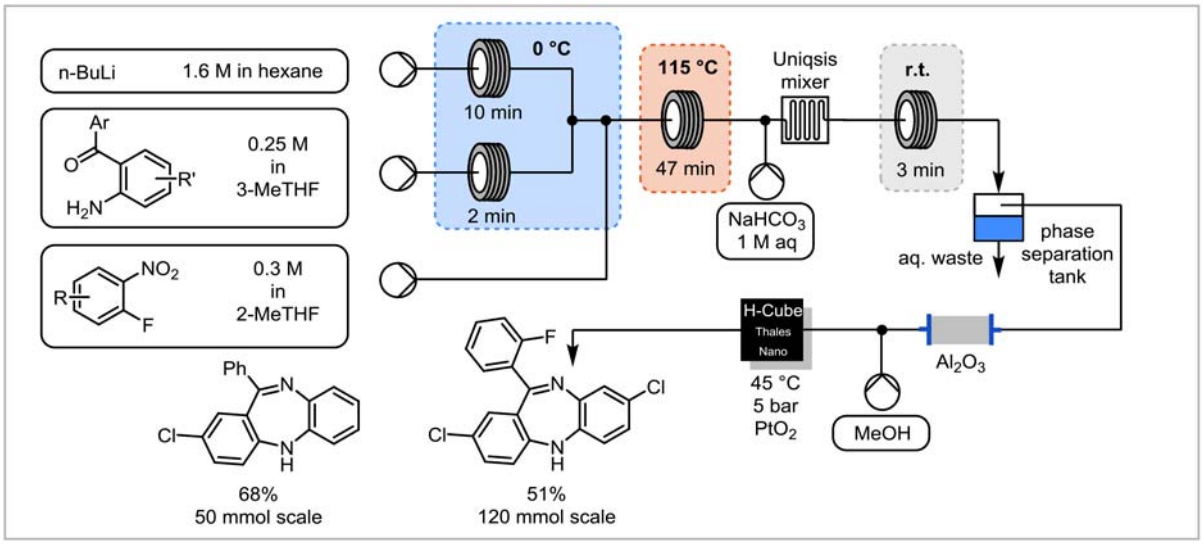
Scheme 25 Synthesis of ortho-functionalized phenols in flow via benzyne formation.[40]



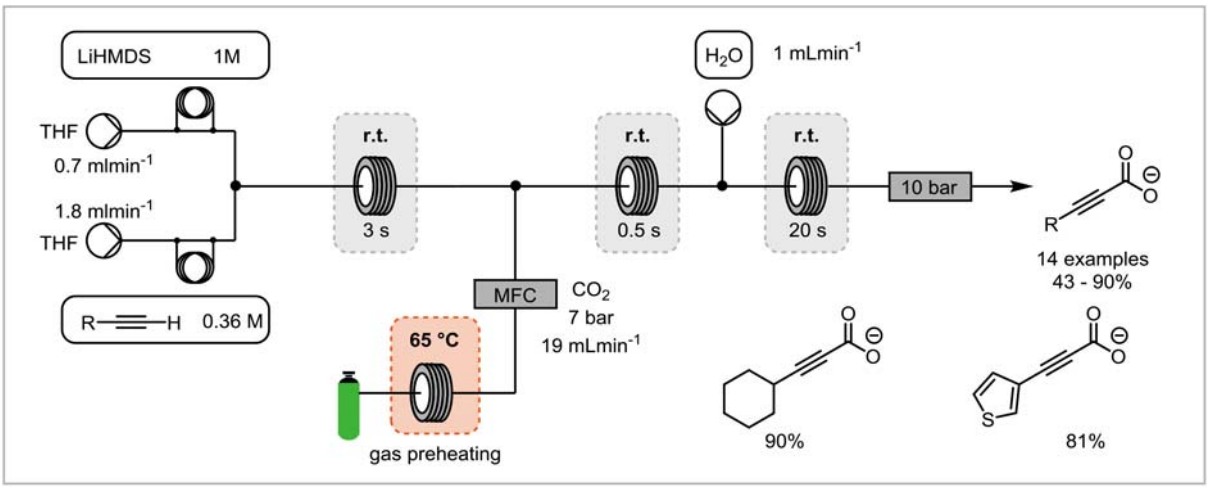
Scheme 26 Formation and use of LDA in flow.[41]

Organolithium species are also often used as strong bases. While synthesizing benzodiazepines in flow, Baxendale and coworkers used butyllithium to deprotonate an amine nucleophile in order to achieve an S_NAr reaction (Scheme 27).[42] The three streams were all precooled before combining at the T-piece and heating to 115°C in the reactor. An inline extraction was then performed, followed by passing the organic layer through a column of alumina to remove any trace water. A stream of methanol was added to dilute the mixture, and the nitro group was reduced to the aniline, which underwent an intramolecular cyclization. This was performed using the H-Cube to generate hydrogen gas with a PtO_2 catalyst. Several benzodiazepines were synthesized continuously by this method.

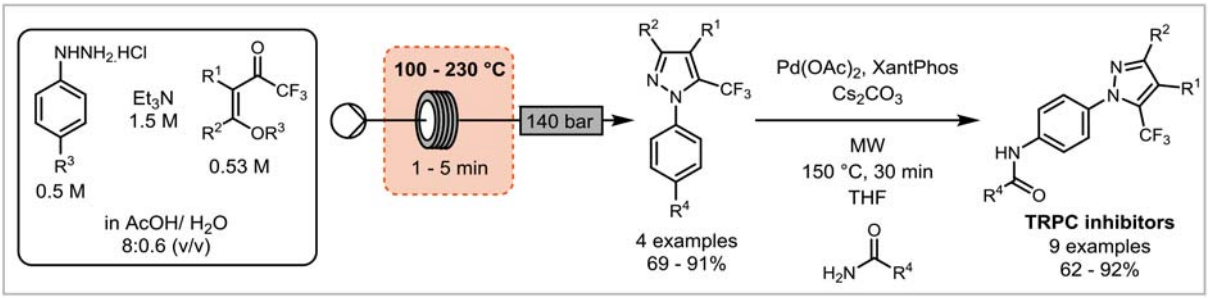
The continuous lithiation of alkynes and subsequent carboxylation with CO_2 has been studied by Kappe and coworkers (Scheme 28).[43] A stream of LiHMDS was combined with a stream of alkyne to form a lithiated species. Gaseous carbon dioxide was then introduced, and the mixture quenched with water forming the carboxylated product after a total residence time of only 23.5 s. This was successfully applied to the synthesis of 14 different carboxylated alkynes.



Scheme 27 Flow synthesis of benzodiazepines.[42]



Scheme 28 Lithiation of alkynes and subsequent trapping with carbon dioxide in flow.[43]



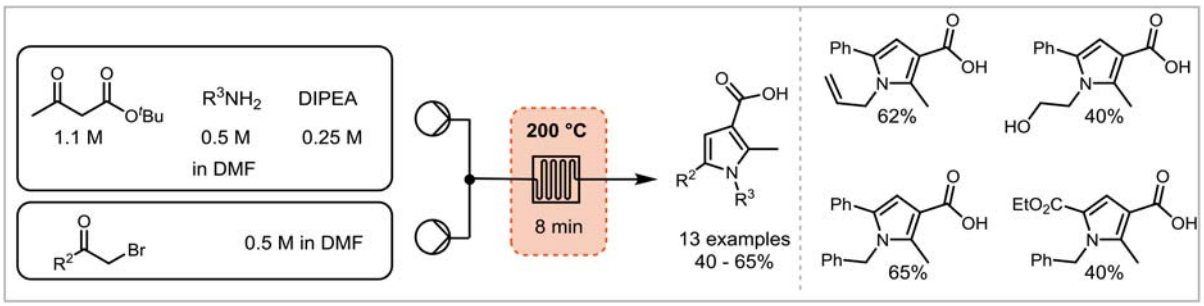
Scheme 29 Synthesis of pyrazoles in flow as an intermediate for TRPC inhibitors.[44]

1.06.2.8 Cyclocondensation

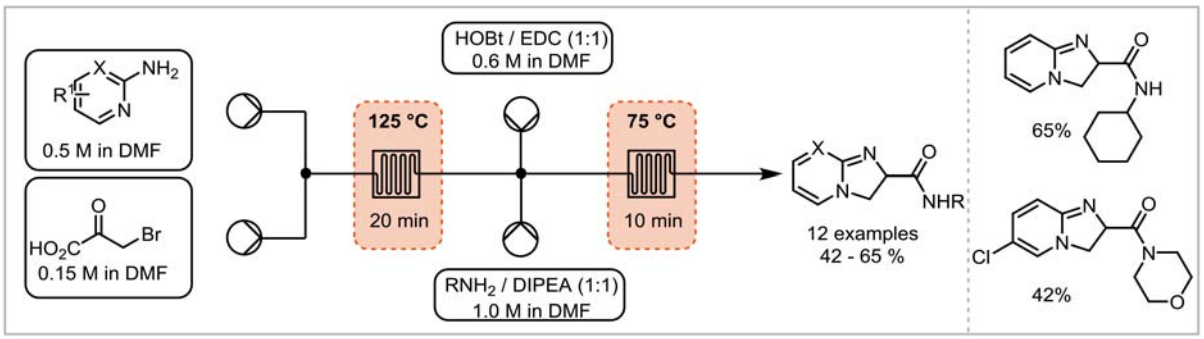
Cyclocondensation reactions are the key method by which heterocycles are synthesized, and there have been several key demonstrations of such reactions under continuous flow conditions. Although no focused review exists for this topic examples are numerous and we will provide an overview of only a few of these here.

In their work synthesizing pyrazoles under high temperature and pressure flow conditions, Kappe and coworkers went on to synthesize nine different inhibitors of canonical transient receptor potential channels (Scheme 29).[44] The use of high temperatures allowed the condensation of hydrazines with enones which then enabled the fast synthesis of several pyrazoles. Subsequent palladium-catalyzed Buchwald–Hartwig amidation under microwave conditions afforded a range of bioactive TRPC inhibitors in good yields.

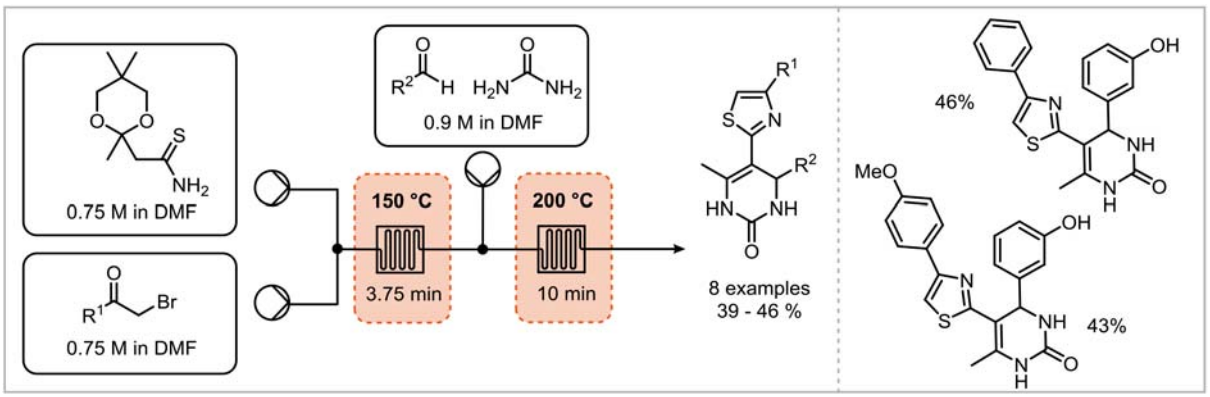
Another application of high temperature flow conditions for heterocycle formation is reported by Herath and Cosford.[45] Microreactors were used to perform a Hantzsch pyrrole synthesis using the HBr generated to directly hydrolyze the ester to the 3-carboxylic acid (Scheme 30). It was also possible to further react the pyrrole-3-carboxylic acid derivatives directly with amines to synthesize the amide. This method was used in the synthesis of two cannabinoid receptor subtype 1 inverse agonists.



Scheme 30 Hantzsch pyrrole synthesis in flow.[45]



Scheme 31 Imidazole synthesis in flow.[46]

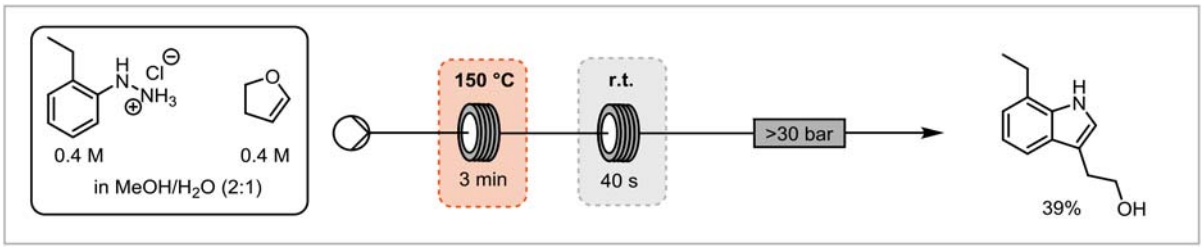


Scheme 32 Flow synthesis of thiazoles.[47]

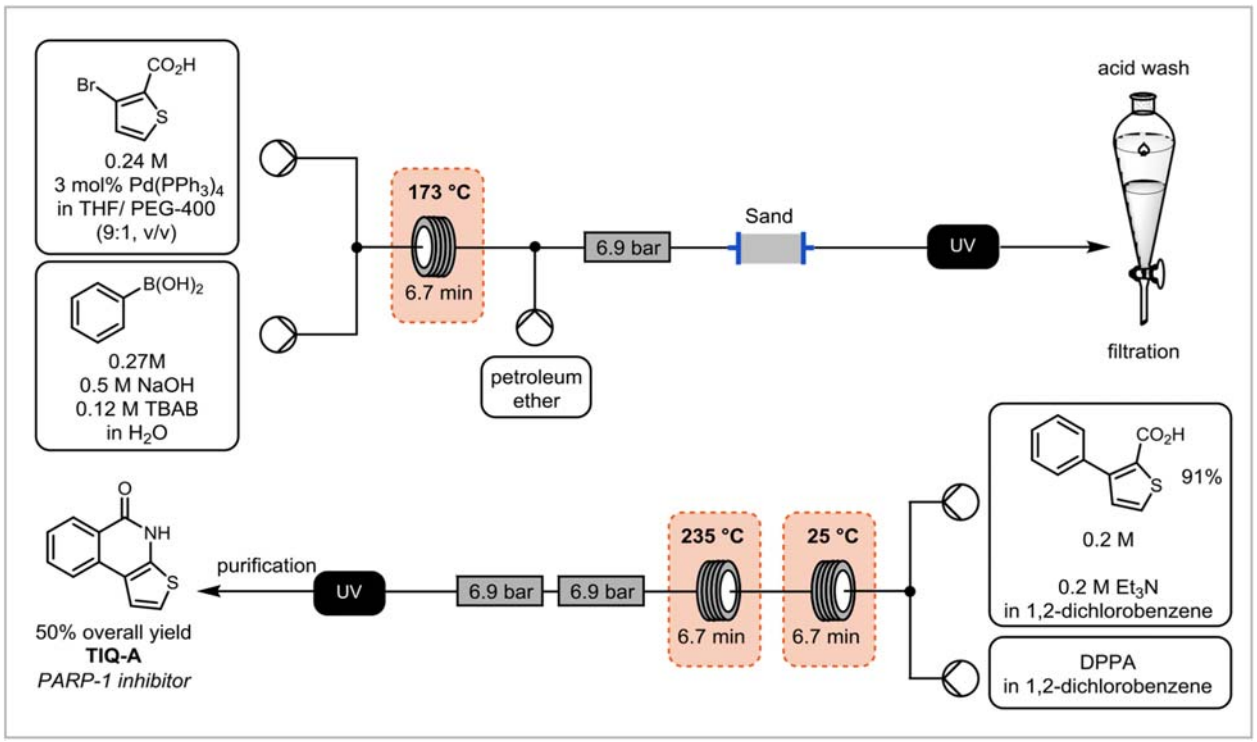
Cosford and coworkers also reported the two-step synthesis of imidazoles using microreactors (Scheme 31).[46] Initially, condensation of bromopyruvic acid with 2-aminopyridines was performed to yield the imidazo[1,2-a]pyridine-2-carboxylic acid. The acid was directly transformed to the amide by addition of a stream of the required amine with N,N-diisopropylethylamine (DIPEA) and a stream of hydroxybenzotriazole (HOBt) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC). This leads to the successful multistep flow synthesis of several imidazo[1,2-a] heterocycles, including a key intermediate for the synthesis of AB530, an FLT3 kinase inhibitor.

A further report from Cosford and coworkers demonstrates the synthesis of thiazoles making use of high temperature microreactors in a two-step synthesis (Scheme 32).[47] Initially, the condensation of an α-bromoketone with a thioamide gives the β-ketothiazole by the Hantzsch thiazole synthesis. A stream of aldehyde and urea was then combined with the main stream and heated for 10 min yielding the dihydropyrimidinone via the Biginelli reaction, catalyzed by HBr from the first step.

Kappe and coworkers report a synthesis of 7-ethyltryptophol, a key intermediate in the synthesis of several pharmaceutically active molecules (Scheme 33).[48] The synthesis involved heating a stream of hydrazine hydrochloride with dihydrofuran in a Fischer-indole synthesis. After carefully analyzing the formation of side products to determine optimal reaction conditions, 7-ethyltryptophol was isolated in 39% yield.



Scheme 33 Flow synthesis of 7-ethyltryptophol.[48]



Scheme 34 Two-step flow synthesis of a PARP-1 inhibitor.[50]

1.06.2.9 Cross-Coupling Reactions

There are many examples of cross-coupling reactions being performed in flow, some of which are presented here.[49] These reactions often form vital key steps during the syntheses of target molecules. In general, catalysts can be homogeneous or heterogeneous, with homogeneous catalysts often serving to mediate more challenging coupling reactions due to an enhanced understanding of their properties.

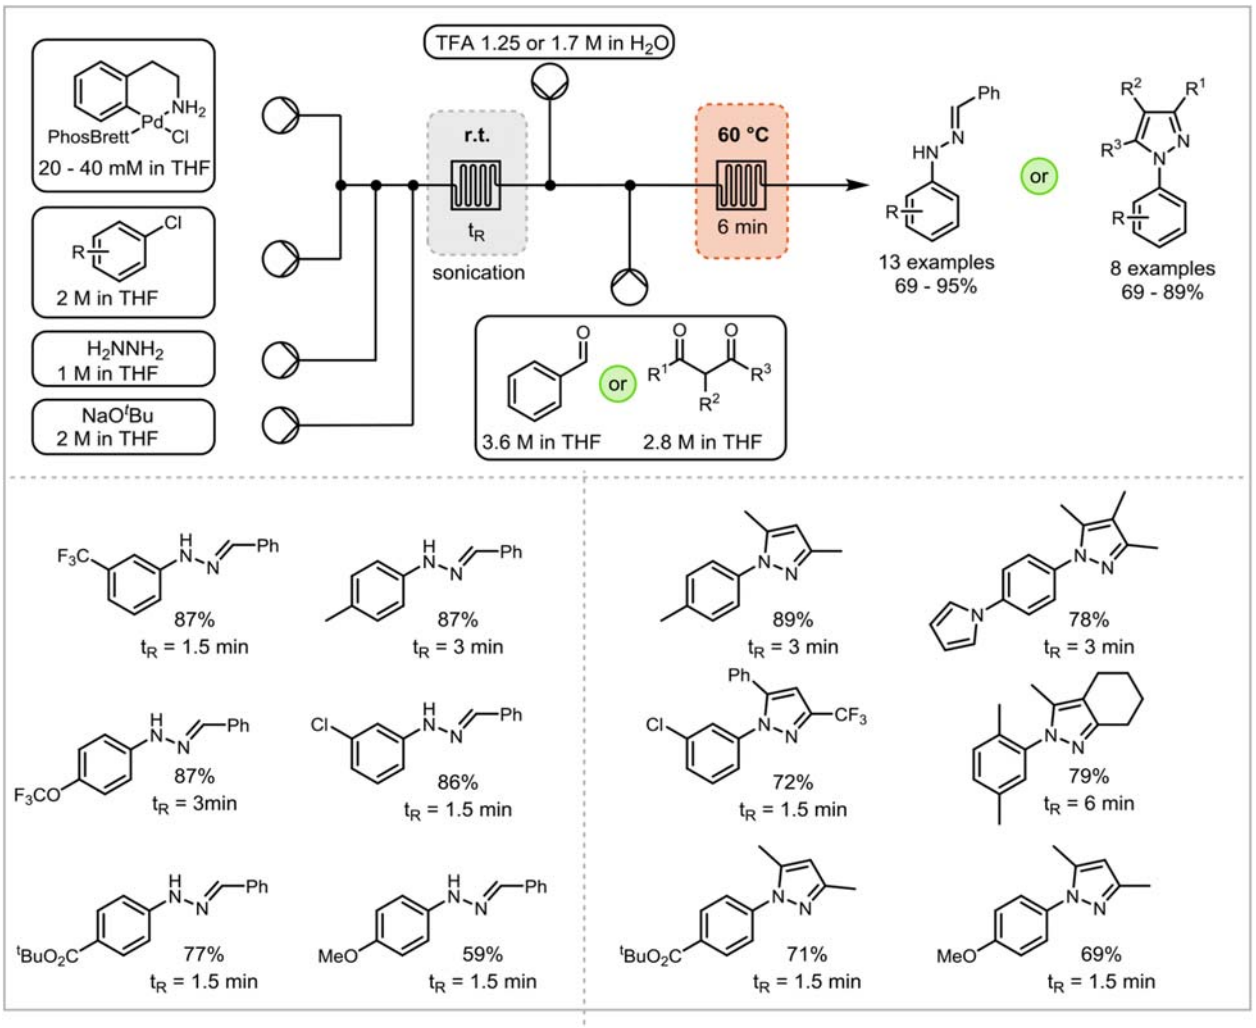
In their synthesis of a PARP-1 inhibitor, Gioiello and coworkers used a Suzuki coupling reaction in the first step (**Scheme 34**).[50] Initially, a stream of the bromothiophene and palladium catalyst was combined with a stream of the boronic acid before entering a heated reactor coil for 6.7 min residence time. After extraction, the coupled product was isolated in excellent yield. Following reaction with a stream of diphenylphosphorylazide and reaction at 25°C, the acyl azide was then heated to 235°C in order to achieve cyclization. The resulting thieno[2,3-c]isoquinolin-5(4H)-one scaffold was isolated with good overall yield.

The palladium-catalyzed C–N coupling of aryl chlorides with hydrazines has been demonstrated by Buchwald and coworkers (**Scheme 35**).[51] Initially, the aryl hydrazine is made by coupling hydrazine with an aryl chloride at room temperature, with sonication required to prevent blocking of the microreactor. It was discovered that BrettPhos was an appropriate ligand for the monoarylation of hydrazine. The aryl hydrazine was then combined with a stream of aldehyde or 1,3-diketone and subjected to 60°C for a residence time of 6 min to afford the corresponding hydrazine or pyrazole products.

The two-step synthesis of benzotriazoles in flow, as reported by Chen and Buchwald, also makes use of a C–N coupling (**Scheme 36**).[52] The initial coupling of an amine to an aryl chloride was performed either by an S_NAr reaction, which was efficient for aryl chlorides with electron withdrawing substituents, or by palladium-catalyzed C–N coupling for other substrates. This stream was then subjected to hydrogenation conditions over Pd/C to reduce the nitro group. Diazotization and subsequent cyclization to the benzotriazole were conducted at room temperature using sodium nitrite under acidic conditions. This method proved versatile for a number of substrates and avoided the issues associated with the use of benzyne and azides.

The Heck aminocarbonylation reaction of aryl iodides has been reported by Ryu and coworkers.[53] The decomposition of formic acid was used to generate CO gas in situ, which was then passed through a tube-in-tube reactor (**Scheme 37**). The aryl iodide and amine substrates, along with the palladium catalyst and ligands, were passed through the tube-in-tube reactor, where it came into contact with the CO for 2.7 h at 80°C to yield the amide fragments.

The Sonogashira coupling reaction was used as a key step in the flow synthesis of 3-aminoindolizines, reported by James and coworkers.[54] In this work, a bromopyridine was coupled with an alkyne, and the resulting alkynylpyridine cyclized by a copper-catalyzed cycloisomerization reaction to yield the aminoindolizine product (**Scheme 38**). In the flow setup, this reaction sequence was realized by simply heating a stream of all reagents to 180°C for 5–10 min. This method allowed the fast synthesis of 31 examples of 3-aminoindolizines, which are a key substructure in many drugs.



Scheme 35 Flow synthesis of hydrazines and pyrazoles.[51]

1.06.2.10 Nucleophilic Substitution

Nucleophilic substitution, including nucleophilic aromatic substitution, is a key reaction in synthesis. Indeed, there are many reports of these reactions in flow. The lack of a headspace void in flow reactors means that mutagenic alkylating agents can be used more conveniently at high temperatures as they can be contained in solution phase.

The two-step synthesis of the proton pump inhibitor, Lansoprazole, has been performed using microreactors by Gangula and coworkers (Scheme 39).[55] The first step is the nucleophilic substitution of a pyridyl chloride by a thiol to yield the thioether, which was then oxidized to the sulfoxide. Both steps were performed at very high flow rates in microreactors so that the residence times were very low. This avoided overoxidation to the sulfone and presumably allowed improved dissipation of an exotherm, thus enabling the rapid synthesis of three benzimidazole drugs.

The nucleophilic ring opening of epoxides by an amine was conducted by Jamison and coworkers during their synthesis of metoprolol.[56] A stream of *i*-propylamine was combined with a stream of an epoxide and heated in a microreactor at 240°C (Scheme 40). The first ring opening afforded the secondary amine intermediate, which attacks another epoxide leading to the tertiary amine, metoprolol, as the final product in 91% yield. It was found that control over chemo-selectivity, that is, mono- or disubstitution could be conveniently controlled by taking advantage of plug flow characteristics.

1.06.2.11 Cycloaddition

Cycloaddition reactions are important in the synthesis of heterocycles and have been used in flow to synthesize a range of nonaromatic heterocycles including particular attention to pyrrolidines. In 2010, Ley and coworkers reported the 1,3-dipolar cycloaddition of nonstabilized azomethine ylides with nitroalkenes.[57] Trifluoroacetic acid (TFA) was required to generate the dipole, so a solution of the alkene and TFA was flowed through a T-piece, where it was combined with a stream of the azomethine ylide

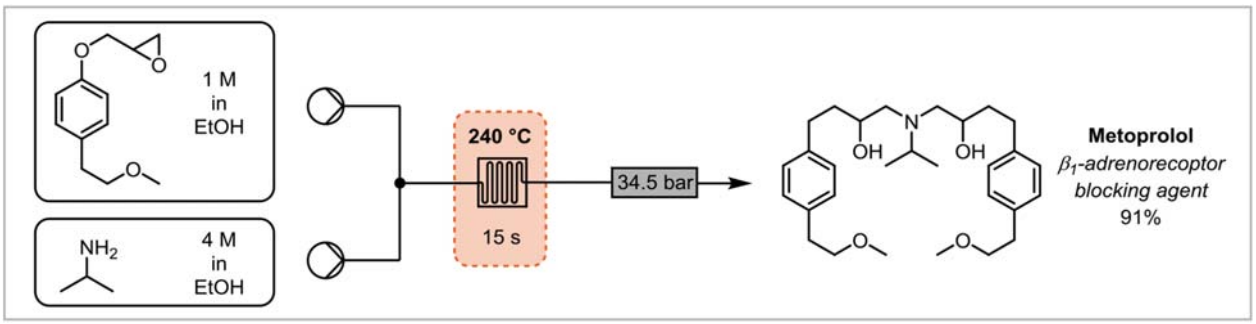


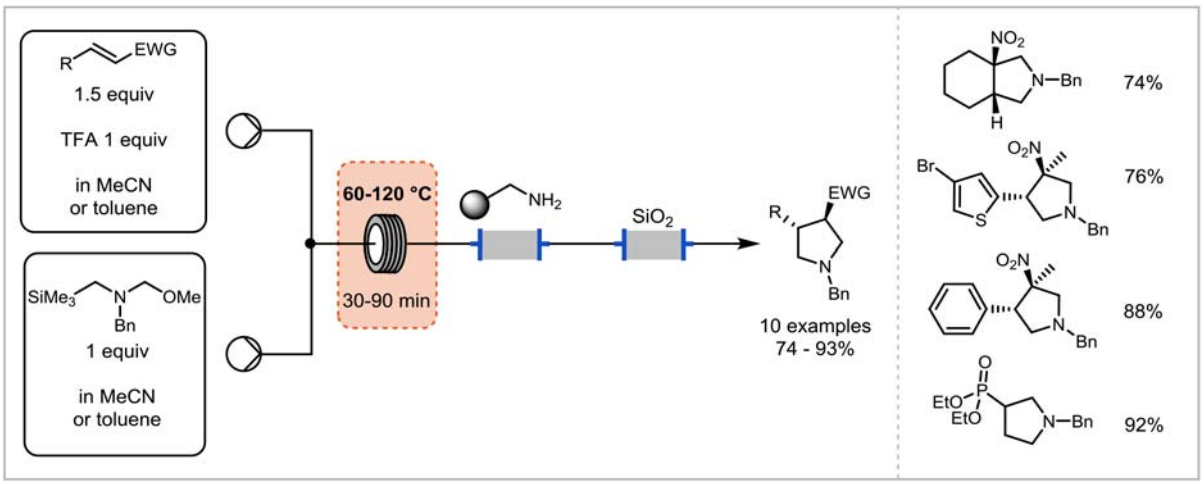
Scheme 40 Flow synthesis of metoprolol.[56]

precursor (Scheme 41). The combined stream was then passed through a heated reactor coil and subsequent scavenger columns in order to remove any unreacted alkene. By using this method, 10 different examples of pyrrolidine scaffolds were synthesized in good yields.

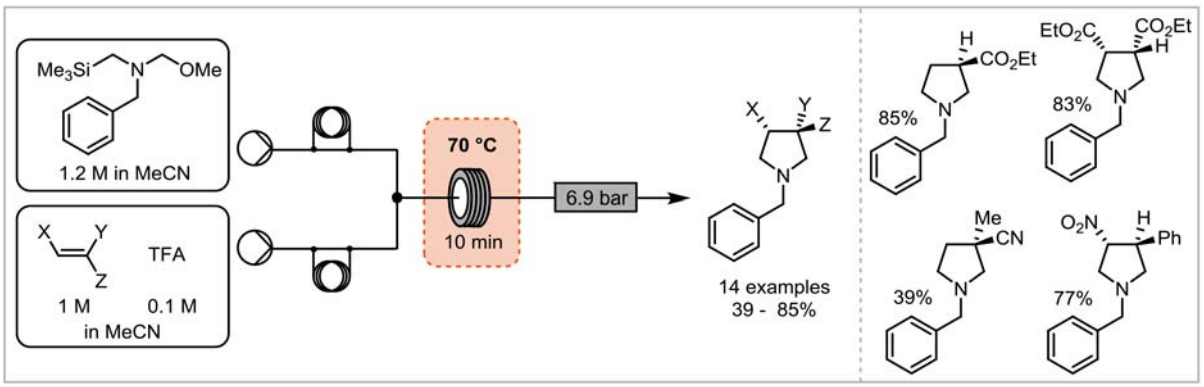
A similar cycloaddition reaction has also been reported in flow by Fray and coworkers.[58] The same azomethine ylide precursor was used to synthesize the pyrrolidine ring. Using different alkene substrates, they were able to perform the reaction at 70°C for 10 min (Scheme 42).

1.06.2.12 Photochemistry

Flow chemistry offers advantages over batch methods in the area of photochemistry. This is due to the Beer–Lambert law, whereby the intensity of light decreases nonlinearly with penetration depth. Therefore, the shape of traditional batch reactors is inefficient and



Scheme 41 Ley's pyrrolidine synthesis in flow.[57]



Scheme 42 Fray's pyrrolidine synthesis in flow.[58]

unreliable for photochemical reactions, as the edge receives full irradiation, and the center of the reactor much less. The large SA:V of continuous flow tubular reactors allows a much greater control of the intensity of light that enters the reaction mixture. As such, there are many examples of light-induced transformations performed in flow conditions, some of which are highlighted here.[59]

Two methods, both thermal and photochemical, for the synthesis of 2H-azirines have been compared by Kirschning and coworkers.[60] The vinyl azide starting material was subjected to either inductive heating or irradiation by a mercury lamp. It was observed that the yield was higher under photochemical conditions, so a one-step process to form a range of dihydropyrroles was developed. In this process, the azirine ring opens photochemically to generate the nitrile ylides, which undergo [3 + 2]-cycloaddition with alkene dipolarophiles (Scheme 43). Eight examples of dihydropyrroles were synthesized using this method.

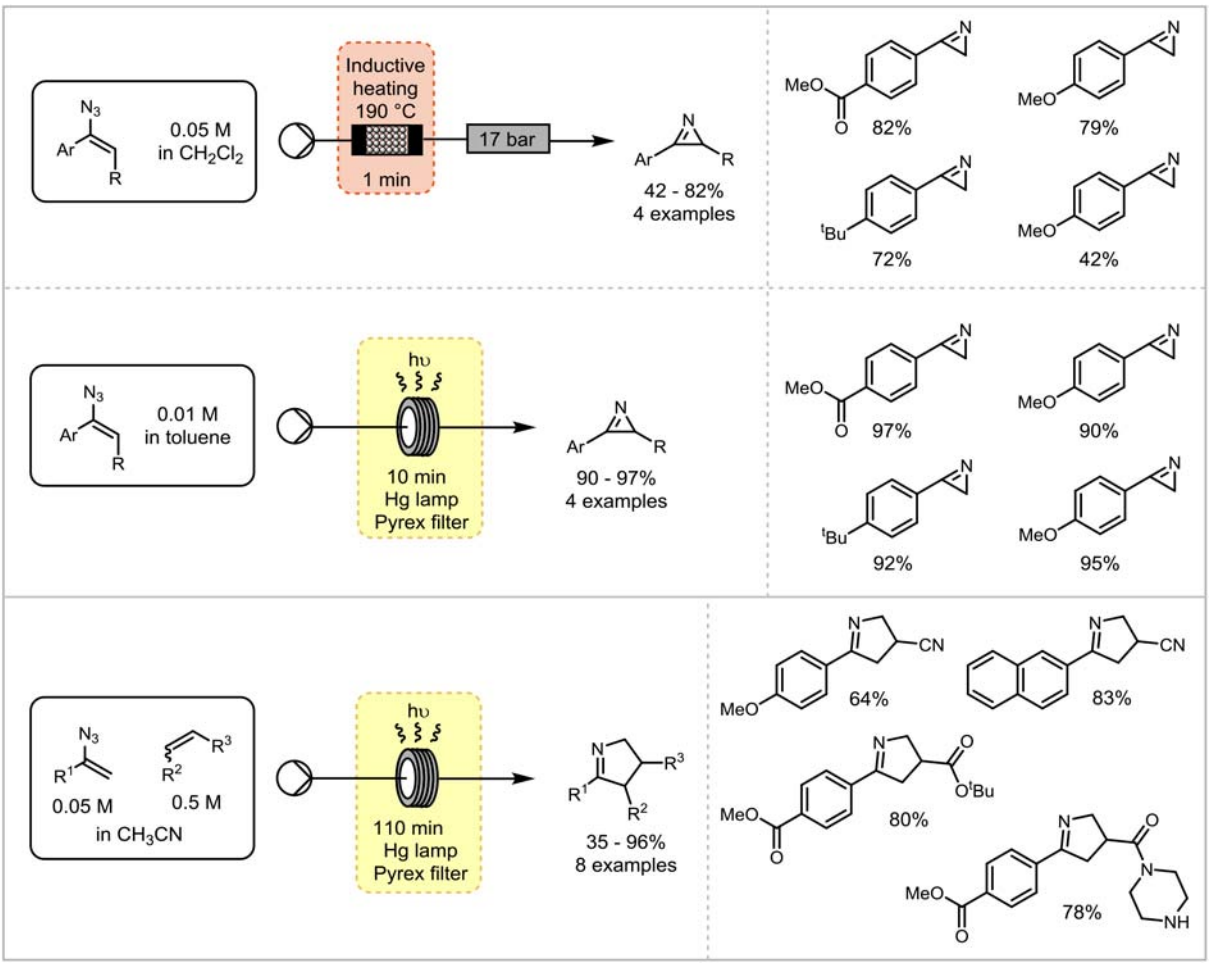
Several carbazole analogues of the antiinflammatory drug Carprofen were synthesized by Collins and coworkers.[61] The use of photochemistry was required to perform the cyclodehydrogenation of diphenylamine derivatives using an I_2/propylene oxide oxidant system (Scheme 44).

Ryu and coworkers have applied photochemistry in flow to the functionalization of cycloalkanes, in this case chlorination using sulfuryl chloride (Scheme 45).[62] They were able to successfully chlorinate different ring sizes of alkanes with reasonable yields. The accurate control of light exposure, molar ratios, and reaction times by using a flow setup allowed good control of the selectivity.

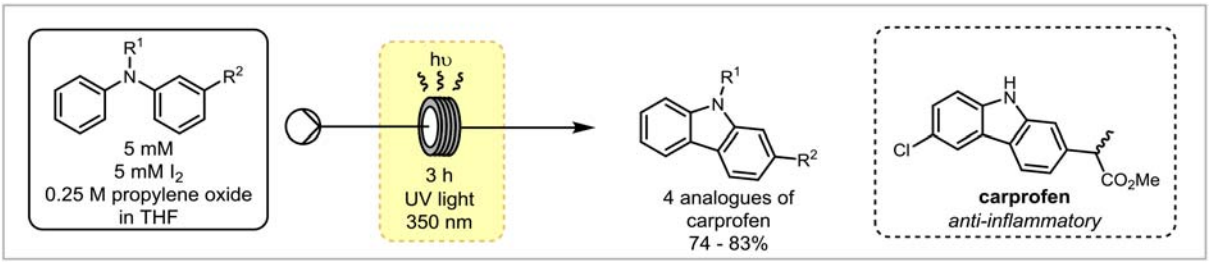
The use of photoreactors has been applied to the generation of nitrenes by Seeberger and coworkers.[63] They report the preparation of 3H-azepinones by the photolysis of aryl azides (Scheme 46). This forms the nitrene which, in the presence of water, rearranges to give the 3H-azepinone. The azepinone scaffold is present in some pharmaceutically active compounds, and some examples are γ-secretase inhibitors for the treatment of Alzheimer's disease.

1.06.2.13 Miscellaneous

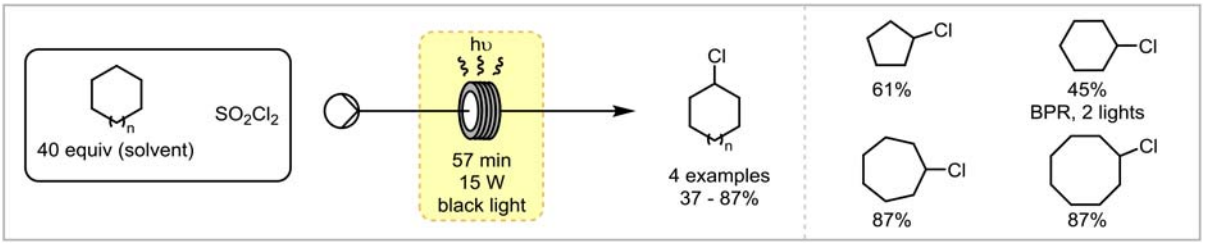
Due to the high SA:V of flow reactors, the heat exchange is more efficient than in batch. This can allow exothermic reactions to be safely controlled and can also allow more control over heating than in batch processes. Polomski and coworkers demonstrated the



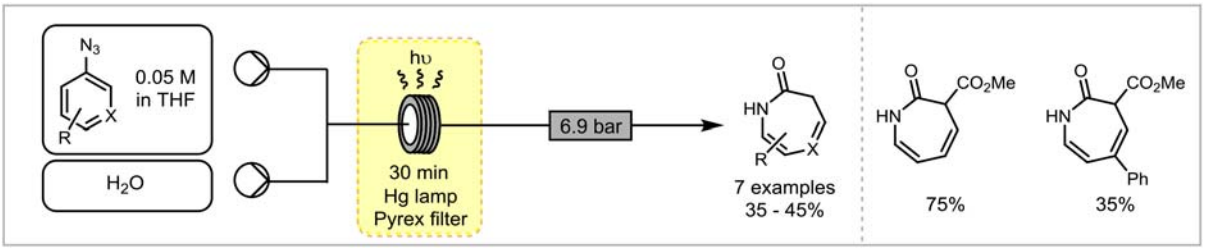
Scheme 43 Flow synthesis of azirines and subsequent cycloaddition.[60]



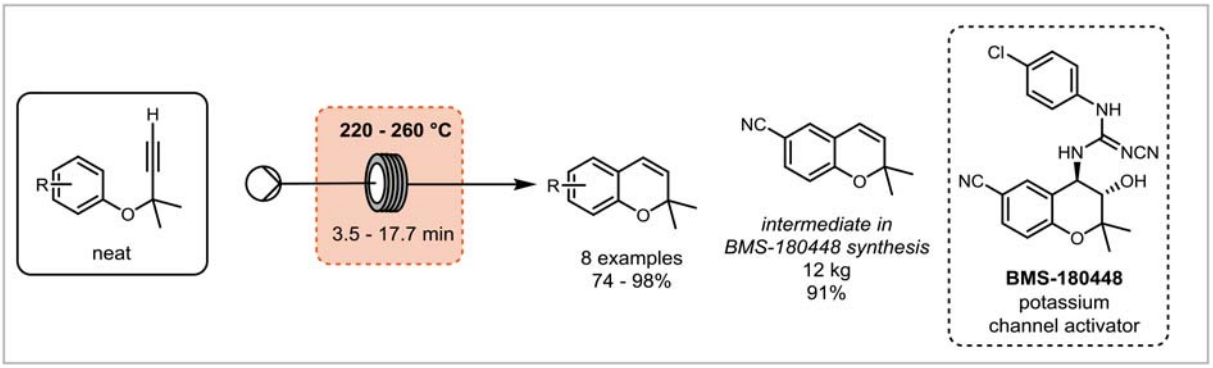
Scheme 44 Flow synthesis of carprofen using a photochemical reactor.[61]



Scheme 45 Photochemical monochlorination of alkanes.[62]



Scheme 46 Flow photolysis of aryl azides.[63]

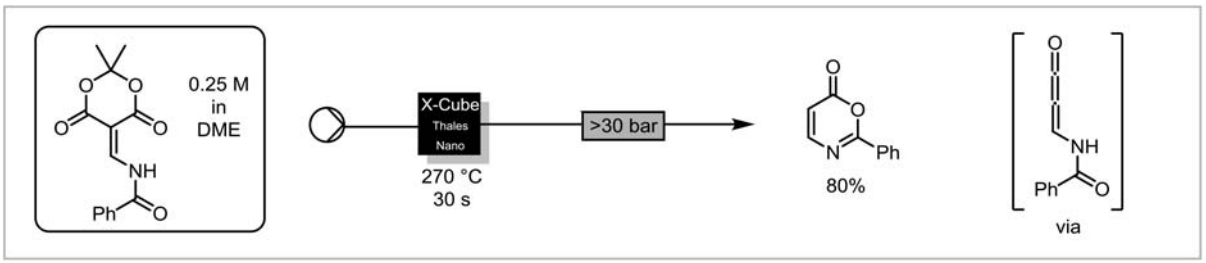


Scheme 47 Large-scale Claisen rearrangement in flow to control the exotherm.[64]

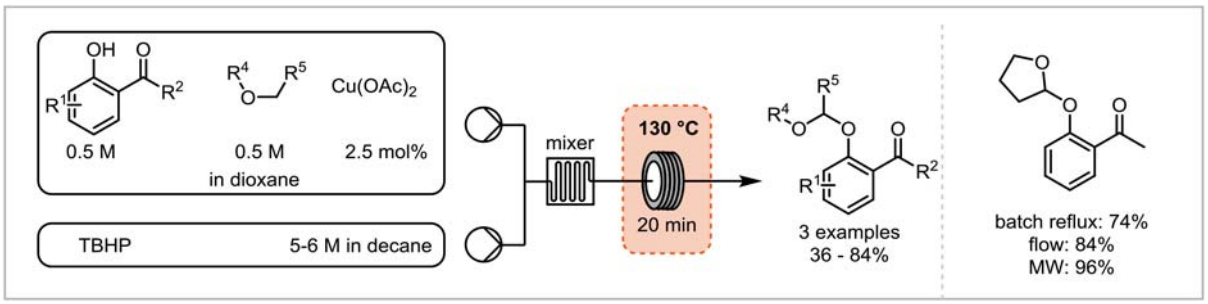
use of a flow process to carefully control the temperature during a Claisen rearrangement (Scheme 47).[64] Heating is required to initiate the reaction, but the overall process is exothermic which can lead to thermal runaways. This makes accurate temperature control, especially on a large scale, challenging. In addition to safety concerns, poor temperature control in batch can lead to degradation. In the flow setup, a neat stream of the precursor was heated accurately in a reactor coil, causing the Claisen rearrangement to occur selectively and in high yields. This setup was able to deliver a large quantity (12 kg) of a key intermediate in the synthesis of a potassium channel activator. This demonstrates the ease of scaling up reactions when performed in flow conditions compared to batch.

The use of high temperatures and pressures is possible in flow conditions by incorporating a back-pressure regulator (BPR) and is often easier than the same process in batch. In batch it is necessary to manufacture vessels capable of operating at high pressures, which is especially difficult and expensive on large scales. In flow, scale-up can involve simply running the system for a longer period of time, or increasing the internal diameter and mixing of the flow tubes. Kappe and coworkers report the high temperature and pressure pyrolysis of Meldrum's acid derivatives (Scheme 48).[65] After loss of CO_2 and acetone, the intermediate ketene undergoes electrocyclization to afford the oxazinone product with 80% yield.

The formation of C–O bonds via C–H activation, disclosed by Kappe and coworkers in 2012, is the first example of C–H activation under continuous flow conditions.[66] They adopted a copper-catalyzed procedure, using tert-butyl hydroperoxide (TBHP) as the terminal oxidant. A stream of ether, the catalyst, and the 2-carbonyl-substituted phenol were combined with a stream of TBHP, passed through a mixer, and then allowed to react at 130°C for 20 min (Scheme 49). The desired acetals were then obtained, demonstrating successful C–H activation.



Scheme 48 Flow pyrolysis of Meldrum's acid derivatives.[65]



Scheme 49 C–H activation in flow.[66]

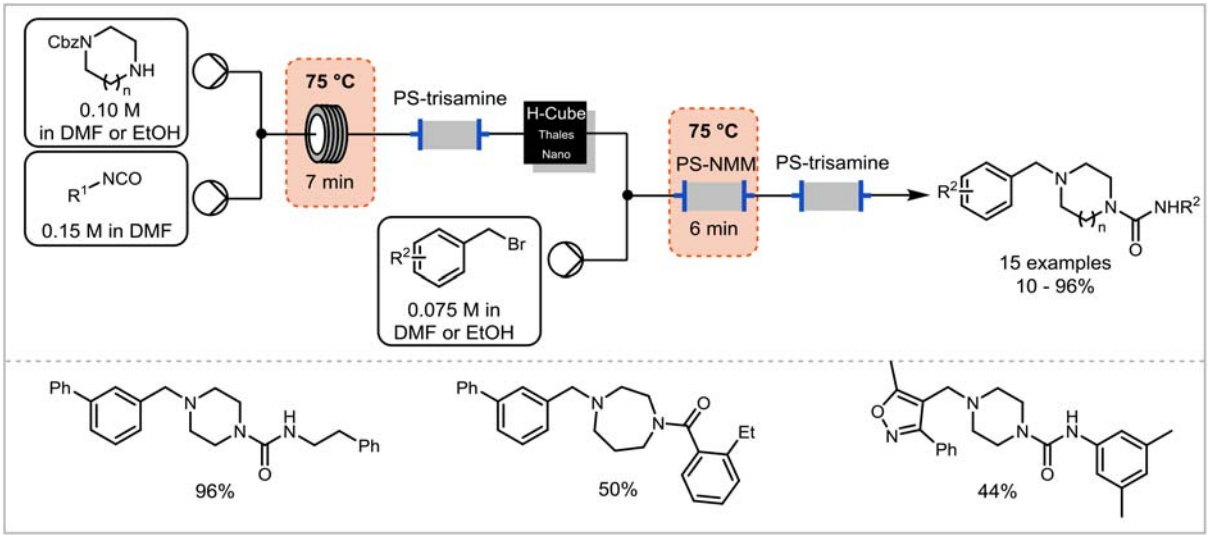
The application of flow chemistry to the synthesis of a range of fragments and heterocycles interesting for pharmaceutical industry has been described briefly. Particular attention is paid to reactivity that can be challenging in batch such as the safe handling of hazardous gases and reagents. This can make it possible to scale-up syntheses to pilot plant scale which would otherwise be challenging.

1.06.3 Library Preparation and Automated Processes

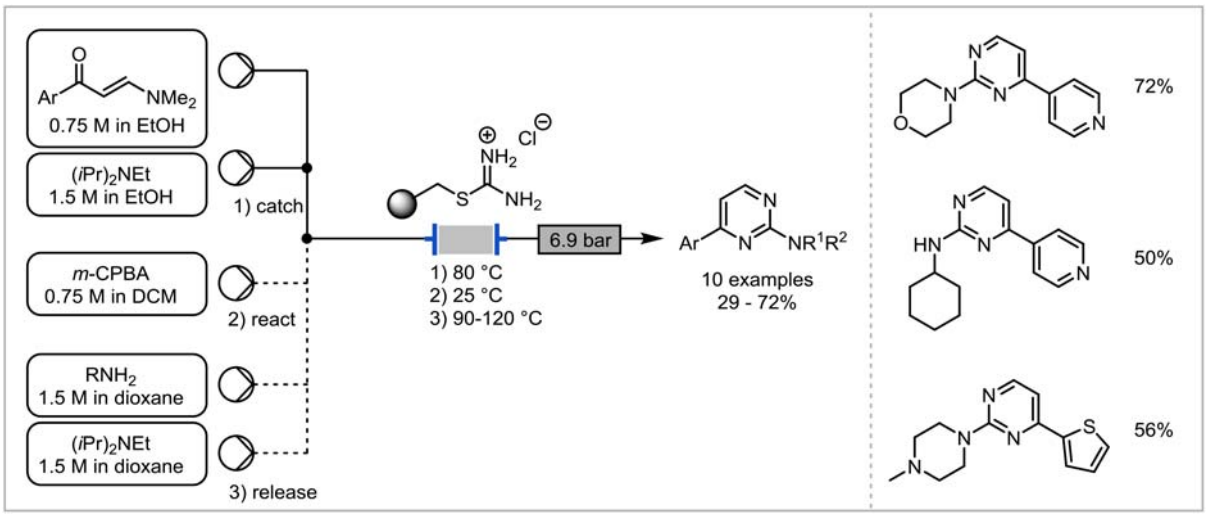
Continuous flow systems are well suited to the synthesis of large libraries of similar compounds. Once good conditions are found for a transformation, it is often straightforward to introduce many different substrates to one reaction setup in order to make many related molecules. This ability is especially relevant to drug-discovery processes, where libraries of potentially bioactive molecules have to be synthesized and screened in order to find a successful "hit." Usually an array of different starting materials is used, leading to more complex products. This process can involve several steps, and it is possible to integrate biological screening into the system. This process can be fully automated in order to improve efficiency and decrease human interaction.

Petersen et al. used a multistep synthesis to rapidly synthesize receptor ligands such as chemokine receptor CCR8 from three building blocks on-demand (Scheme 50).[67] In the first step a diamine, which is mono Cbz protected, reacts with an isocyanate to form a disubstituted urea derivative. Excess isocyanate was scavenged using a solid-supported trisamine before the second amine was deprotected by hydrogenation. This amine was alkylated with a benzyl bromide derivative on solid-supported *N*-methylmorpholine. Excess benzyl bromide was removed on solid-supported trisamine to yield the desired product. This method allows easy access to a library based around the *N*-benzyl-piperazine-urea scaffold, which is present in a number of ligands for receptors, enzymes, and ion channels.

Ley and coworkers developed a process that made use of the "catch–react–release" method to access a library of 2-aminopyrimidines which are precursors to Imatinib (Scheme 51).[68] This method usually decreases downstream processing and delivers clean products directly. This process is comparable to batch mode solid-supported reactions. The starting material, an



Scheme 50 Synthesis of receptor ligands on demand.[67]



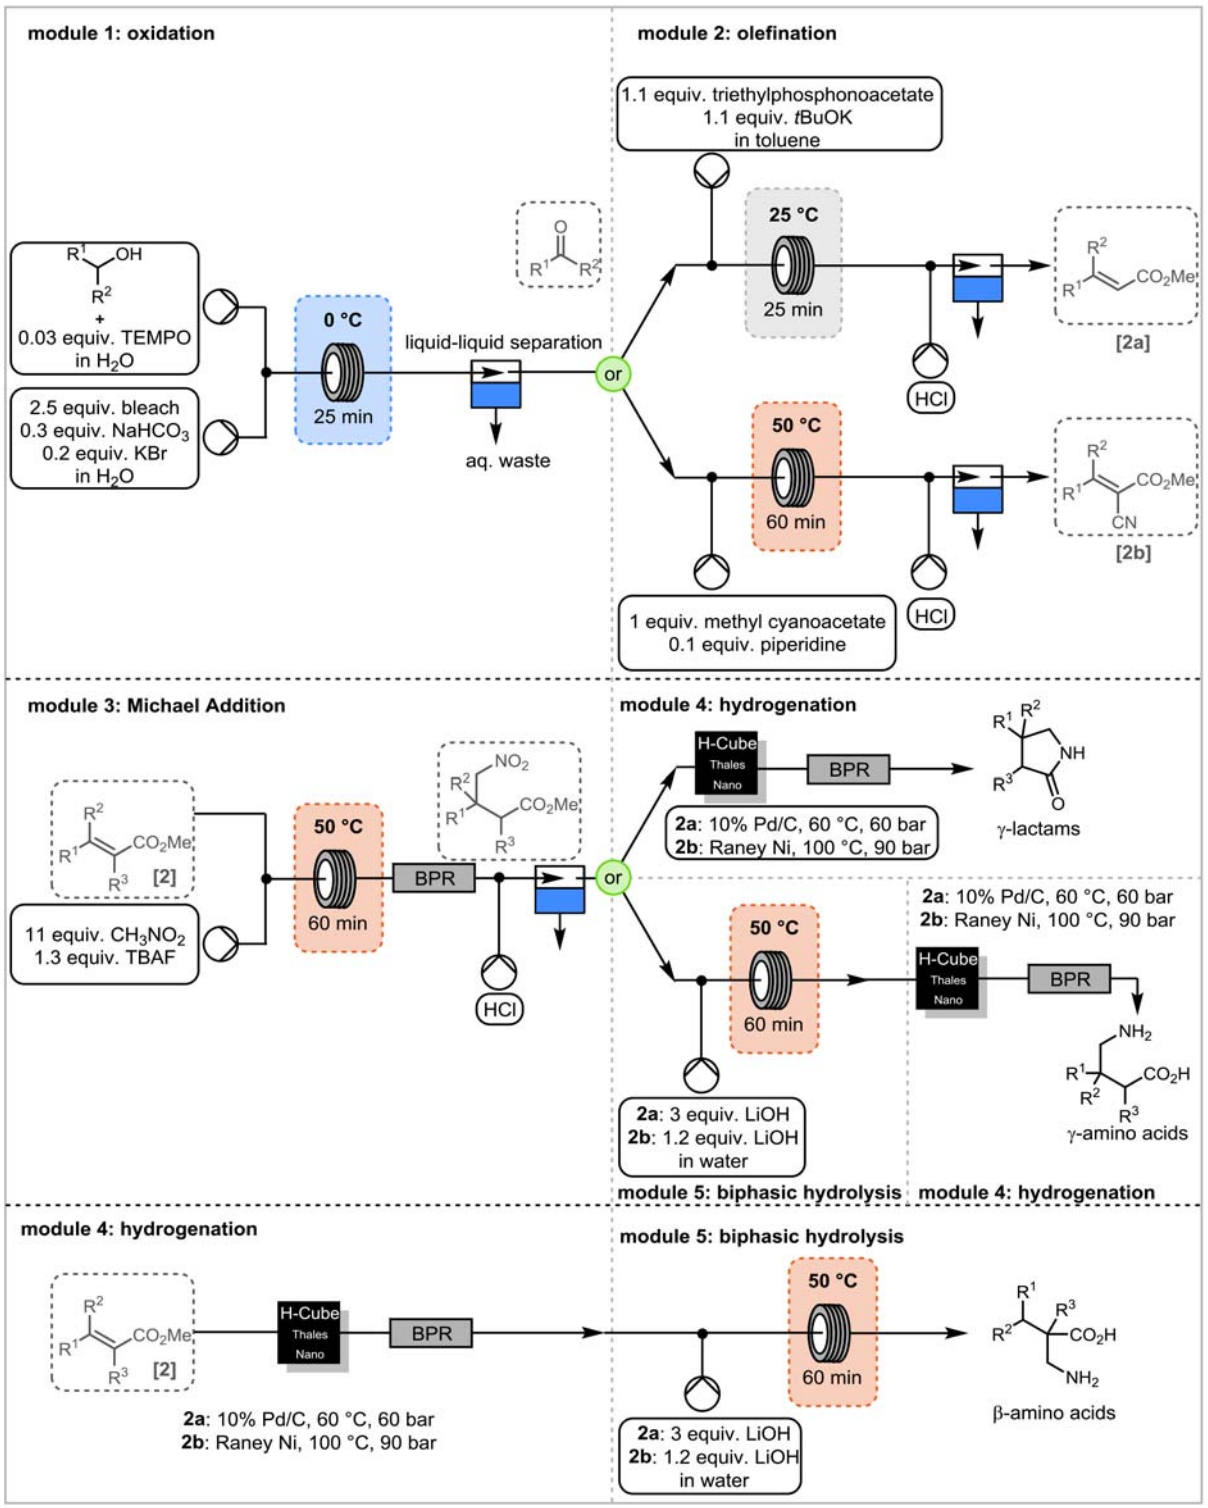
Scheme 51 Use of "Catch–react–release" method in the synthesis of 2-aminopyrimidines.[68]

enaminone in this case, was pumped through the system and caught on a solid support, an isothiouronium chloride-functionalized monolith. Then a valve was switched to deliver the next reagent and perform the subsequent reaction. Ley and coworkers first performed an oxidative activation with meta-chloroperoxybenzoic acid (m-CPBA) before switching to a primary amine input to release the final product. The "catch–react–release" method enables a high throughput of substrates by reducing downstream processes, in this case solvent changes and by-product removal.

A modular reaction approach to not only synthesize one but three different classes of substrates has been developed by Seeberger and coworkers.[69] Five different reaction modules have been developed: module 1 (oxidation with (2,2,6,6-tetramethylpiperidin-1-yl)oxyl (TEMPO) or bleach), module 2 (olefination with triethylphosphonoacetate and *t*BuOK or methyl cyanoacetate and piperidine), module 3 (Michael addition with $MeNO_2$ and tetra-n-butylammonium fluoride (TBAF)), module 4 (hydrogenation using the H-cube with either Pd/C or Raney Ni), and module 5 (saponification with LiOH). Depending on the starting materials, order of the modules and reagent choice different substrates can be targeted (Scheme 52). In all cases a secondary alcohol was oxidized to a ketone in module 1 before olefination in module 2. Depending on the reagent used either a Knoevenagel condensation to yield an α-nitrile ester (**2a**) or a Horner–Wadsworth–Emmons reaction to yield an α,β-unsaturated ester could be performed (**2b**). Both of these intermediates can then either underwent Michael addition in module 3 or hydrogenation in module 4. Michael addition of nitromethane in module 3 led to γ-nitroesters which could be either transformed to γ-lactams via hydrogenation in module 4 or to γ-amino acids initially via hydrolysis in module 5 and then hydrogenation in module 4. Intermediate **2** can also undergo hydrogenation in module 4 directly to give β-amino acids after hydrolysis in module 5. The authors demonstrated how powerful this modular approach can be, as three different classes of substrates, γ-lactams, γ-amino acids, and β-amino acids, can be approached using the same equipment.

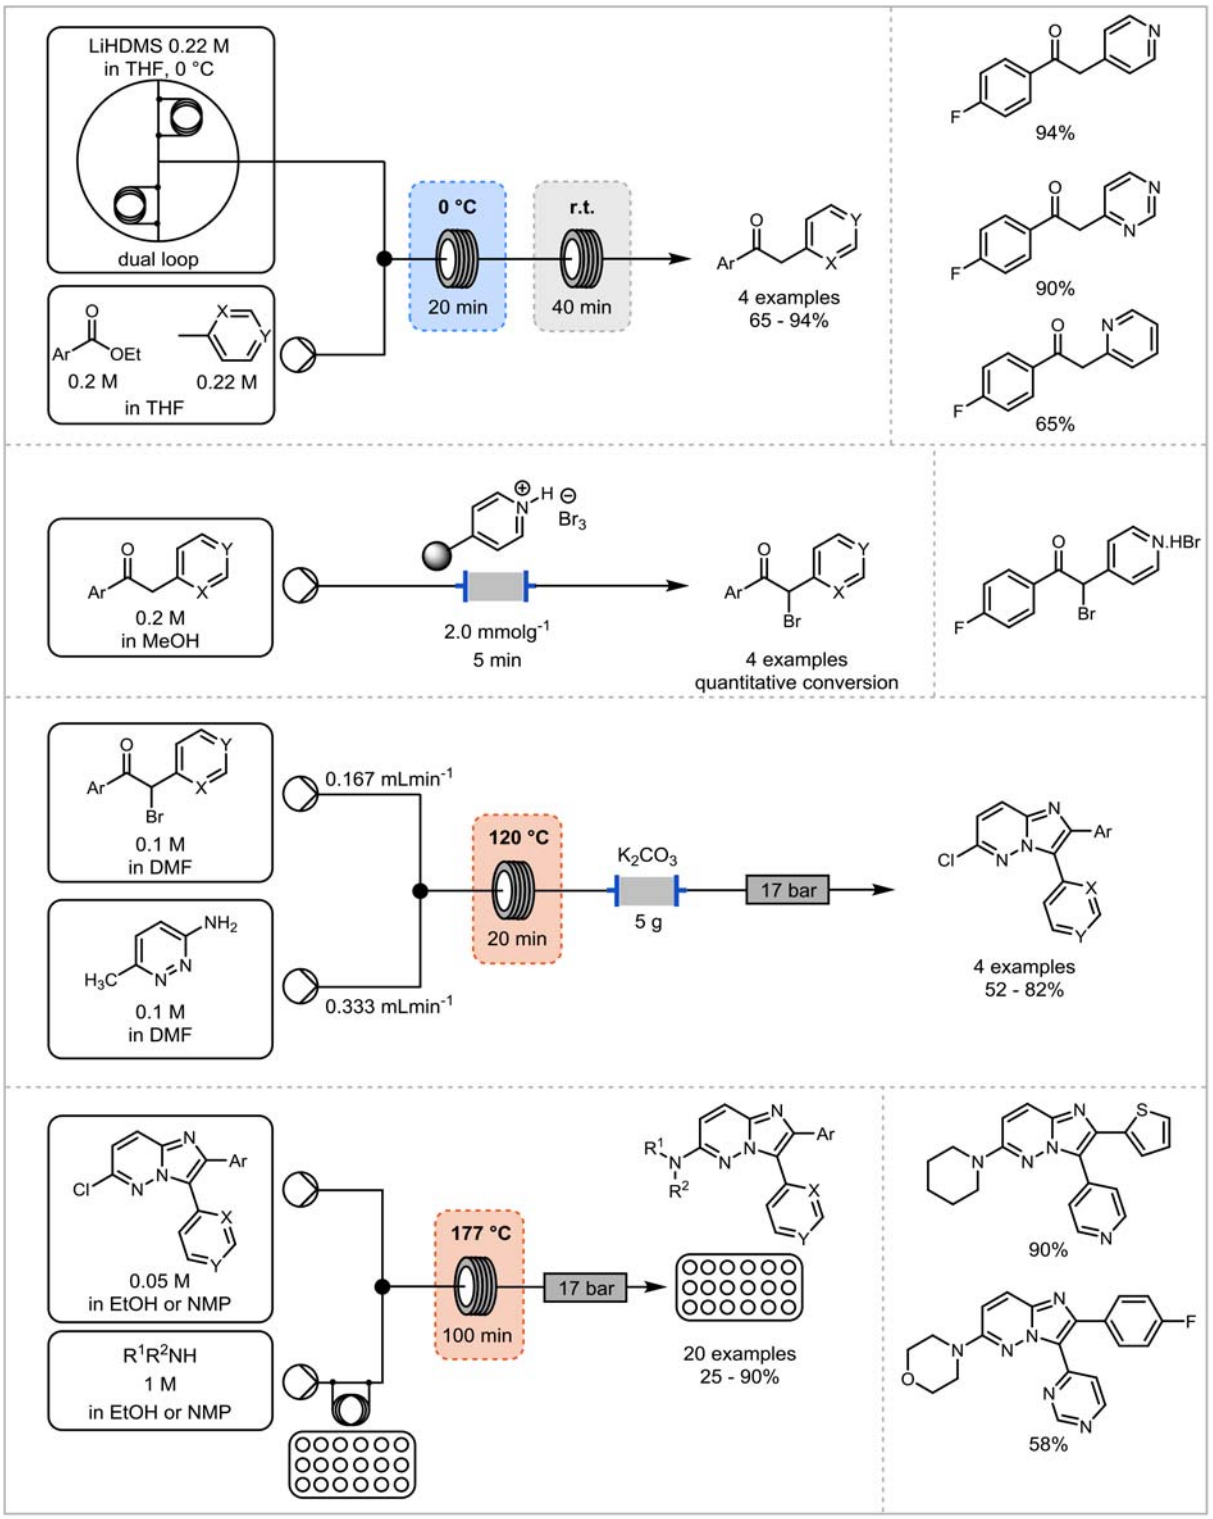
Ley, Baxendale, and coworkers combined several enabling technologies to quickly synthesize a library of imidazolepyridines, a family of casein kinase I inhibitors (Scheme 53).[70] The process has four reaction steps incorporating continuous flow processing with solid-supported reagents, scavenging resins, and autosamplers under fully automated software control. In the first step an organolithium base mediated the addition of a methylated aromatic to an ester. Delivering the organolithium base at scale proved to be a challenge due to its hazards and incompatibility with the seals in high pressure pumps. This was addressed by introducing a "dual sample injection loop" where one sample loop was used to deliver the base while the other was being loaded automatically. The second step was an α-bromination using an immobilized perbromide species to give the monobrominated ketone selectively. This proved to be a more convenient method than using bromine directly as standard flow equipment could be used. In the third step the imidazopyridazine core was generated in a cyclocondensation. Reaction temperature, residence times, and reagent ratios were screened automatically using the Vapourtec Flow Commander software. In the last step structural diversity was achieved by displacing the chlorine substituent with an array of amines using an autosampler at high temperature and pressure using a back pressure regulator. This gave 20 examples of imidazopyridazines in four steps and is a good demonstration of the capability of automated flow processing.

Once a library of compounds have been synthesized, they then have to be screened for biological activity. Baxendale, Ley, and coworkers synthesized a library of substrates, here $GABA_A$ agonists with an imidazo[1,2-a] pyridine structure, and biologically evaluated them in line (Scheme 54).[71] In this case, inline frontal affinity chromatography was used, demonstrating a seamless chemistry–biology interface. The multistep synthesis consisted of three steps. The first step is an immobilized-acid catalyzed condensation between ethyl glyoxylate and acetophenone derivatives leading to unsaturated ketones that cyclize in the presence of aminopyridine derivatives. Incorporating a back pressure regulator enabled superheating of the solvent and therefore a faster



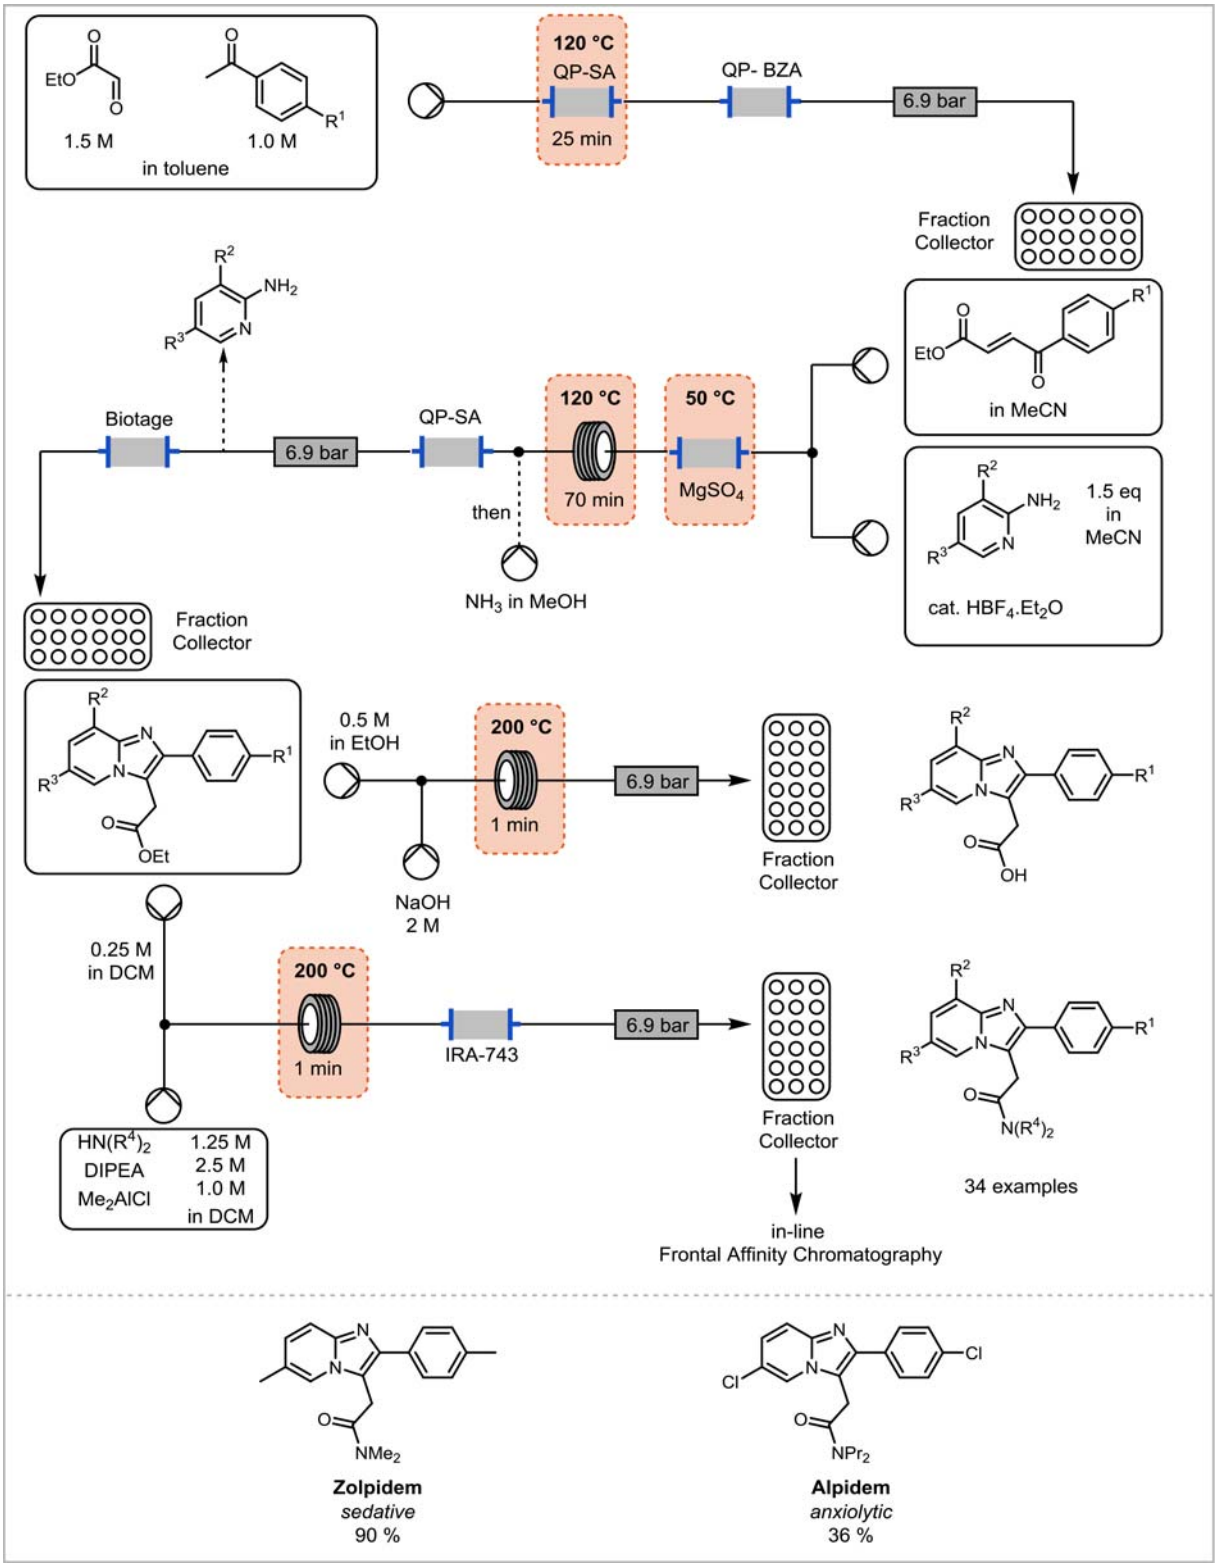
Scheme 52 Synthesis of different classes of compounds using the same five modules.[69]

reaction. Excess aminopyridine was captured on a supported acid resin and could be removed by injecting ammonia in methanol. Column chromatography was then performed to obtain a pure product. For the last step two different reactions were performed as a point to introduce structural diversity on the imidazo pyridine scaffold. The ester could either be transformed into the amide by high temperature amidation, or to the acid by rapid saponification at high temperature. Autosamplers were used to synthesize a library of products, including Zolpidem and Alpidem, that were then tested for biological activity by inline frontal affinity chromatography.



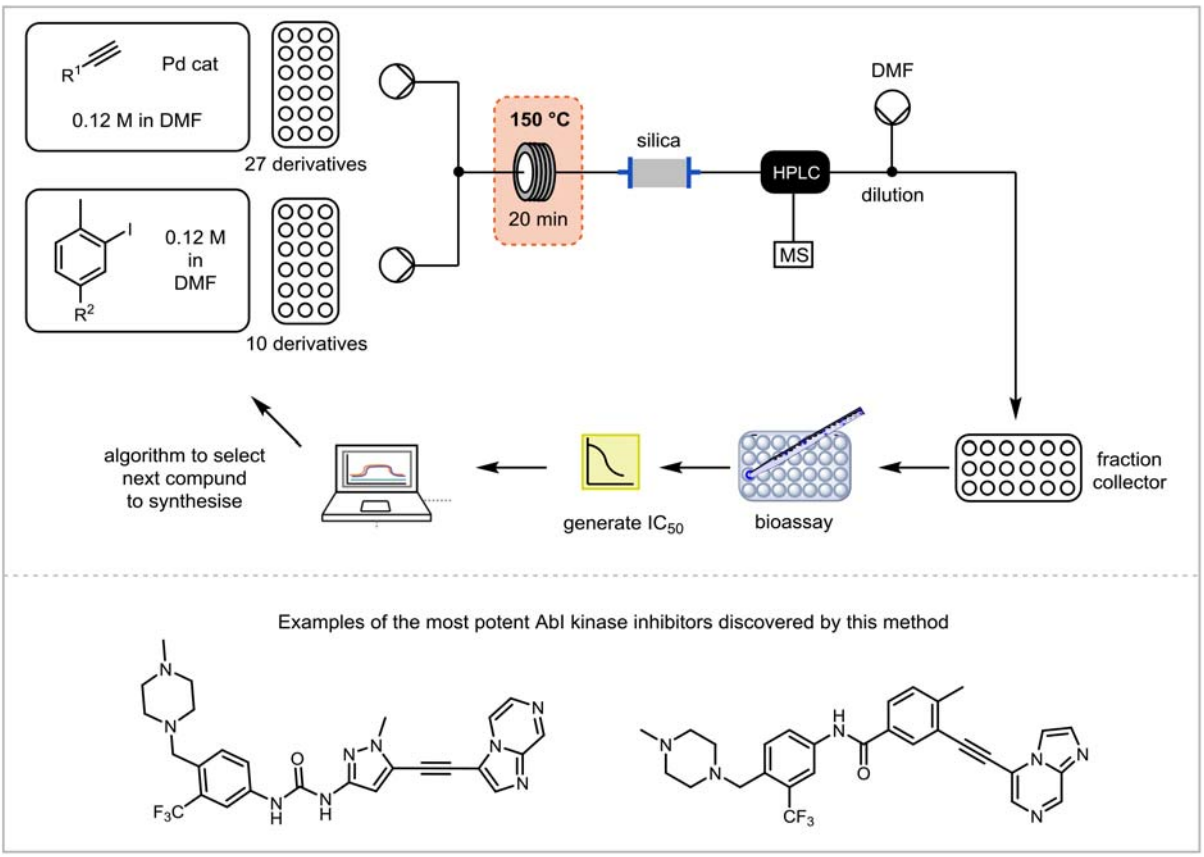
Scheme 53 Synthesis of a library of imidazopyridazines using autosamplers.[70]

A joint collaboration between Cyclofluidic, Sandexis, and Accelerys has resulted in a closed-loop process with a feedback algorithm. This system is capable of synthesizing and evaluating the biological activity of an array of compounds and then choosing the next compound to synthesize (Scheme 55).[72] Two fragments were cross coupled using a Sonogashira reaction in a relatively straightforward reaction setup, purified and analyzed via LC–MS. The product was diluted and then further probed in a bioassay



Scheme 54 Automated synthesis of a library of $GABA_A$ agonists and evaluation of biological activity in line.[71]

to investigate the biological activity. This information was fed into an activity prediction algorithm (Random-Forest regression) which would then determine the next set of starting materials. In this manner 21 compounds were synthesized and evaluated as AbI kinase inhibitors with a novel template being identified.



Scheme 55 Automated synthesis of a library of compounds by the Sonogashira reaction and inline determination of biological activity. By computer control using an algorithm, new leads could be found using this automated feedback loop.[72]

The ability of flow processing to easily generate libraries of compounds has the prospect of leading to a more streamlined drug-discovery approach. The addition of automation leads to further improvement in efficiency, especially when combined with biological screening. The final example presented here adds another level of automation to this process by choosing substrates using an algorithm. Such automated feedback loops can also be used to optimize reaction conditions, be it for yield, cost, or even towards sustainable metrics.

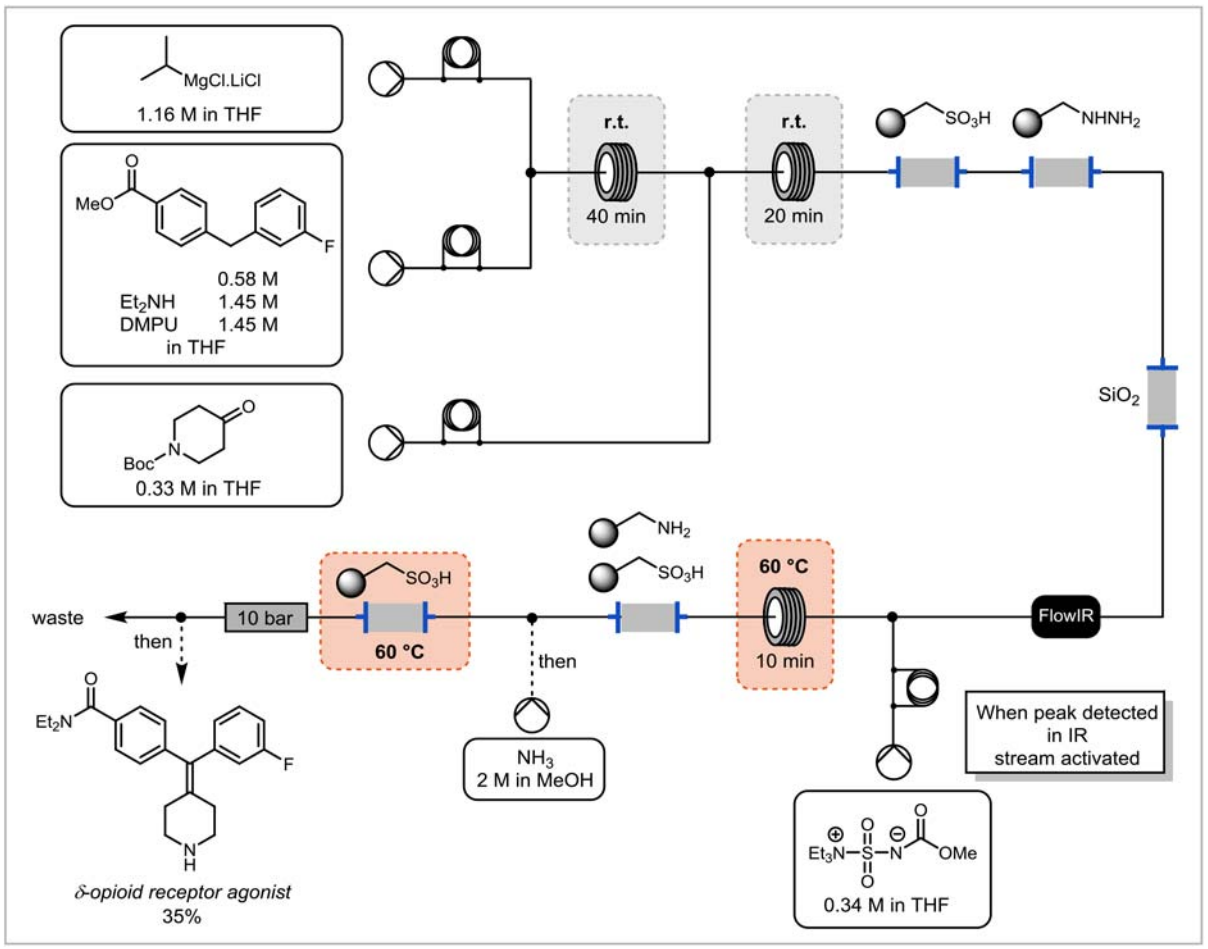
1.06.4 Reaction Monitoring and Self-Optimizing Systems

With the increased availability of inline analysis systems, such as the flow IR cell, monitoring of complex features of reactions as they proceed are becoming more and more attractive. Many standard techniques for offline analysis have now been adapted to inline analysis, with IR, HPLC, GC, mass spectrometry, and NMR available. These monitoring tools allow fast characterization of a reaction mixture and can be used to measure consumption of starting materials, formation of desired products and side products, as well as monitoring hazardous intermediates to prevent dangerous build up.

Automated systems have been used to decrease manual handling steps, such as automatically shutting down a system or switching pumps and valves on and off without requiring the operator to be present. When automated systems are combined with real-time data from inline monitoring and simple algorithms, they can be designed to perform tasks without input from an operator. These tasks vary from simple, such as switching a pump on or off depending on the height of liquid in a reservoir, to performing many experiments in order to optimize reactions automatically.[73] This technology offers the prospect of an enormous reduction in workload to chemists, transferring the burden of reaction optimization to computer algorithms.

Such self-optimizing systems generally follow the same basic steps in order to find optimum conditions for a reaction. An initial set of reaction conditions is chosen, applied to the reaction setup and the data from inline monitoring used by an algorithm to find a new set of conditions. This process is repeated without any manual interaction until optimized conditions are obtained. A few examples for automated self-optimizing systems using different inline monitoring techniques are presented here.

In 2010, Ley and coworkers demonstrated the ability to use inline IR monitoring and automated control to ensure a key reagent was introduced at the correct time during a multistep flow synthesis of a δ-opioid receptor agonist (Scheme 56).[74] Initially, the

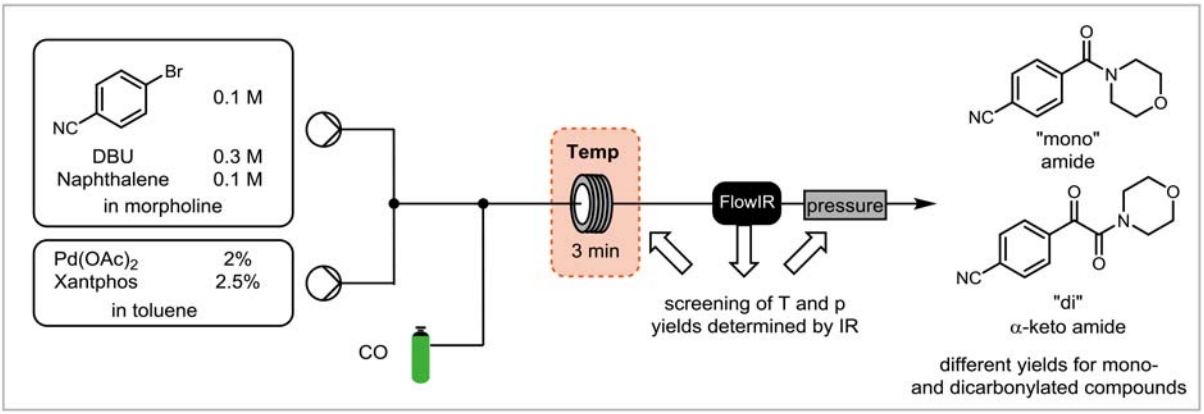


Scheme 56 Inline IR used to automatically introduce a reagent at the correct time during the flow synthesis of a δ-opioid receptor agonist.[74]

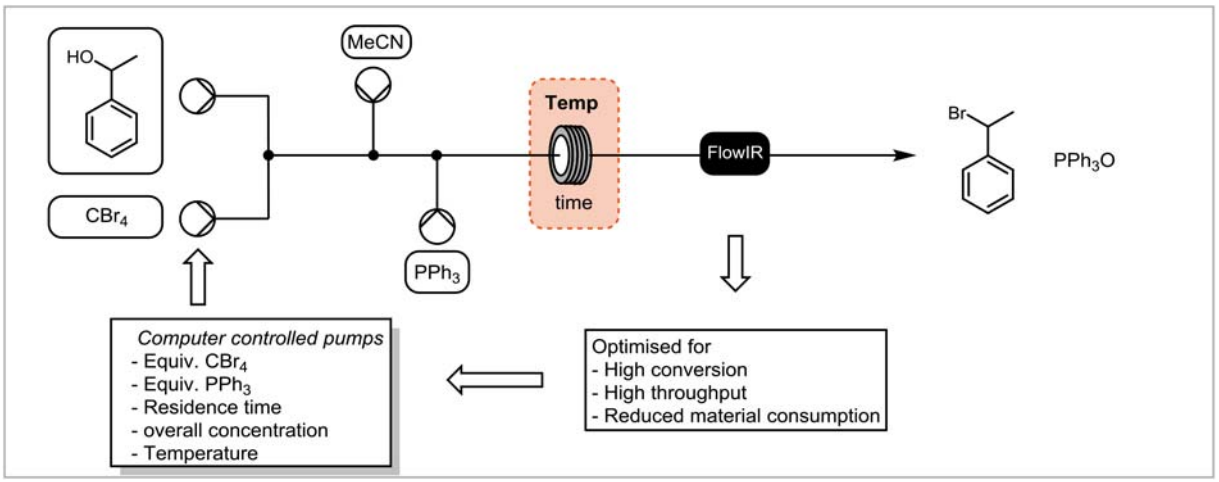
methyl ester is converted to the amide with dimethylamine, using a Grignard reagent as a base. At room temperature, the diarylmethyl proton was removed so that the diarylmethylcarbanion was directly intercepted with a Boc-protected piperidone. This addition could be accurately timed by the strong color of the deprotonated diarylmethyl species. After passing through scavenger columns to remove excess amine, piperidone, and magnesium salts, the stream was directed through an inline ReactIR flow cell. The stream of the Burgess reagent could then be automatically and accurately switched on when the intermediate was being detected in the ReactIR cell. The stream was subsequently heated to 60°C to achieve dehydration, and excess Burgess reagent and by-products were scavenged. The dehydrated product was then directed through a heated column of sulfinic acid, causing Boc deprotection and catching the product. The product was then released by passing a solution of ammonia through the column, yielding the target δ-opioid receptor agonist in 35% overall yield.

The use of IR as an inline monitoring tool is one of the most facile, as spectrometers are compact, and once a characteristic peak has been identified, it can be used to measure concentrations of one component in mixtures of several compounds. As such, there are several examples using IR in self-optimizing systems. Another example, reported by Jensen and coworkers, demonstrates the power of self-optimizing systems to find the conditions required to make different products in an aminocarbonylation reaction (Scheme 57).[75] This reaction takes place under biphasic conditions, with a liquid phase containing the aryl halide substrate and palladium catalyst, and a gaseous phase of CO, taking advantage of good mixing under the segmented flow regime. The two products observed had characteristic, nonoverlapping amide absorptions in the IR spectrum, so the yield of each in the reaction solution could be determined easily. A thorough kinetic study could be performed with minimal operator intervention, and it was found that the selectivity could be controlled by changing temperature and pressure.

Another demonstration of IR monitoring in self-optimization is reported by the Ley group performing an Appel reaction (Scheme 58).[76] This example takes the idea of reduced operator input even further and allows the system to be controlled from anywhere in the world over the Internet.[77] The setup comprised separate streams of alcohol, CBr_4, solvent, and triphenylphosphine. These streams are combined, passed through a reactor coil and then through an inline IR spectrometer. The peaks due to the alcohol starting material and triphenylphosphine oxide by-product could be monitored and tracked simultaneously. The flow rate of each stream and the temperature of the reactor coil could be controlled remotely over the Internet. This permitted the automatic



Scheme 57 Automated investigation of the effect of temperature and pressure on selectivity in an aminocarbonylation reaction.[75]



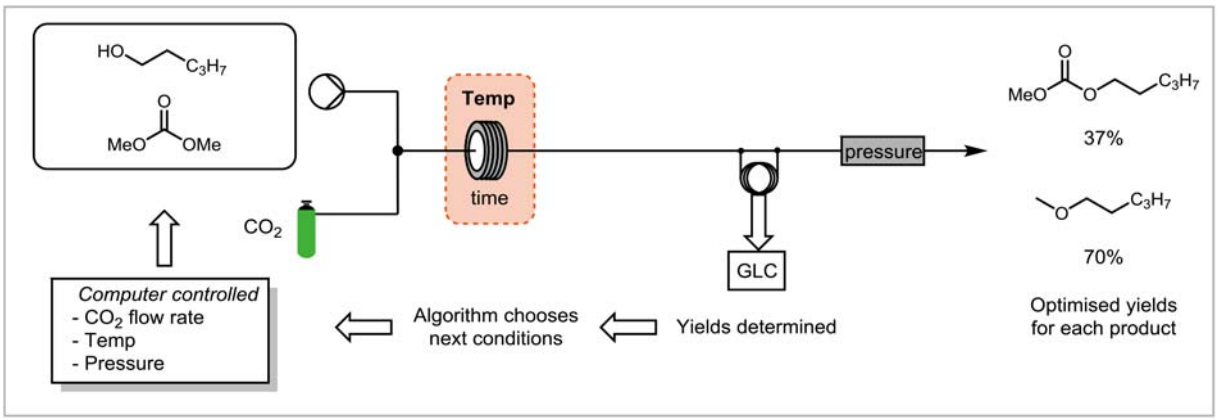
Scheme 58 Self-optimization of an Appel reaction.[76]

optimization algorithm to vary five different parameters. The reaction was optimized for throughput, conversion, and consumption. A simple algorithm can then automatically find conditions that lead to a process with high conversion, high throughput, and low material consumption. A yield of 92% was achieved with productivity of 1.9 g h^{-1} after 30 iterations.

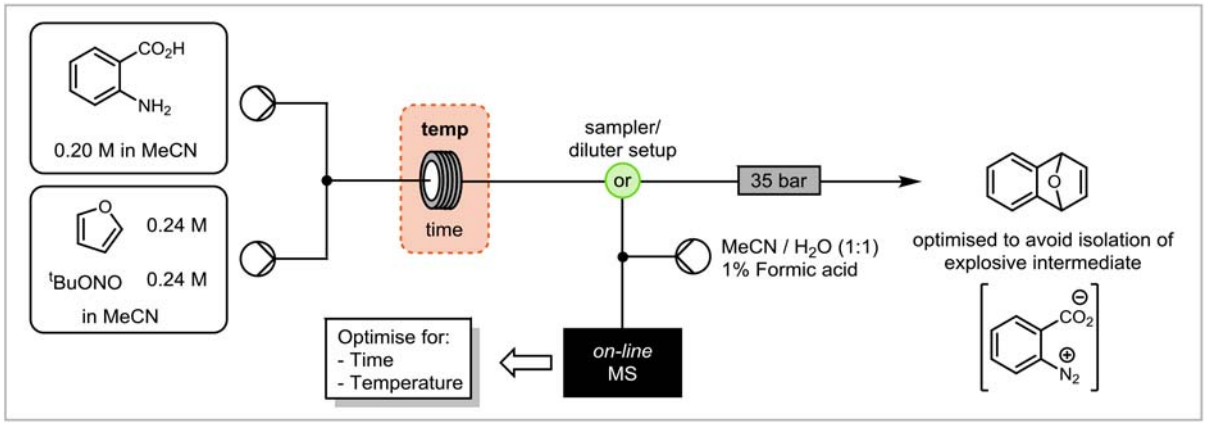
An alternative inline analysis method is liquid or gas chromatography which can be performed online. The reaction outlet is connected to a valve which samples a small slug of the flowing stream and relays it into an offline spectrometer. An example of self-optimization using this online chromatography is reported by Poliakoff and coworkers (Scheme 59).[78] The methylation of an aliphatic alcohol with dimethyl carbonate in super critical carbon dioxide was investigated. The setup comprised of a stream containing both of the starting reagents which was combined with super critical carbon dioxide and subjected to heating. A valve could then inject samples automatically to perform GLC to determine yield. The temperature, system pressure, and CO_2 flow rate were computer controlled. This reaction can yield two different products, both the methyl ether and carbonate. Optimal conditions to form each product were found using the super modified simplex (SMSIM) algorithm, taking approximately 35 h for each optimization.

Inline mass spectrometry is a sensitive technique allowing very small scale reactions to be optimized. This is useful when trying to avoid the use of large quantities of reagents for optimization or if very hazardous intermediates are produced. Ley and coworkers demonstrate the use of inline mass spectrometry to find optimal conditions to minimize the amount of hazardous intermediate exiting the system (Scheme 60).[79] In this setup, a stream of anthranilic acid meets a stream of furan and *tert*-butyl nitrite to form a hazardous diazonium salt. The combined stream is then heated, eliminating N_2 and CO_2 from the diazonium salt to form benzyne. Benzyne then undergoes a Diels–Alder reaction with furan yielding the desired product. After the reactor coil, the stream is diverted to a mass spectrometer where the products were analyzed. Several side products were identified, and the temperature and residence times were optimized to ensure that all diazonium salt is consumed before the stream exits the reactor. This approach also maximized selectivity for the desired product.

An example of optimizing reactions by inline HPLC was reported by Ahmed-Omer and Sanderson during their multistep synthesis of Fluoxetine, an antidepressant (Scheme 61).[80] They demonstrated the use of online HPLC during the enantioselective



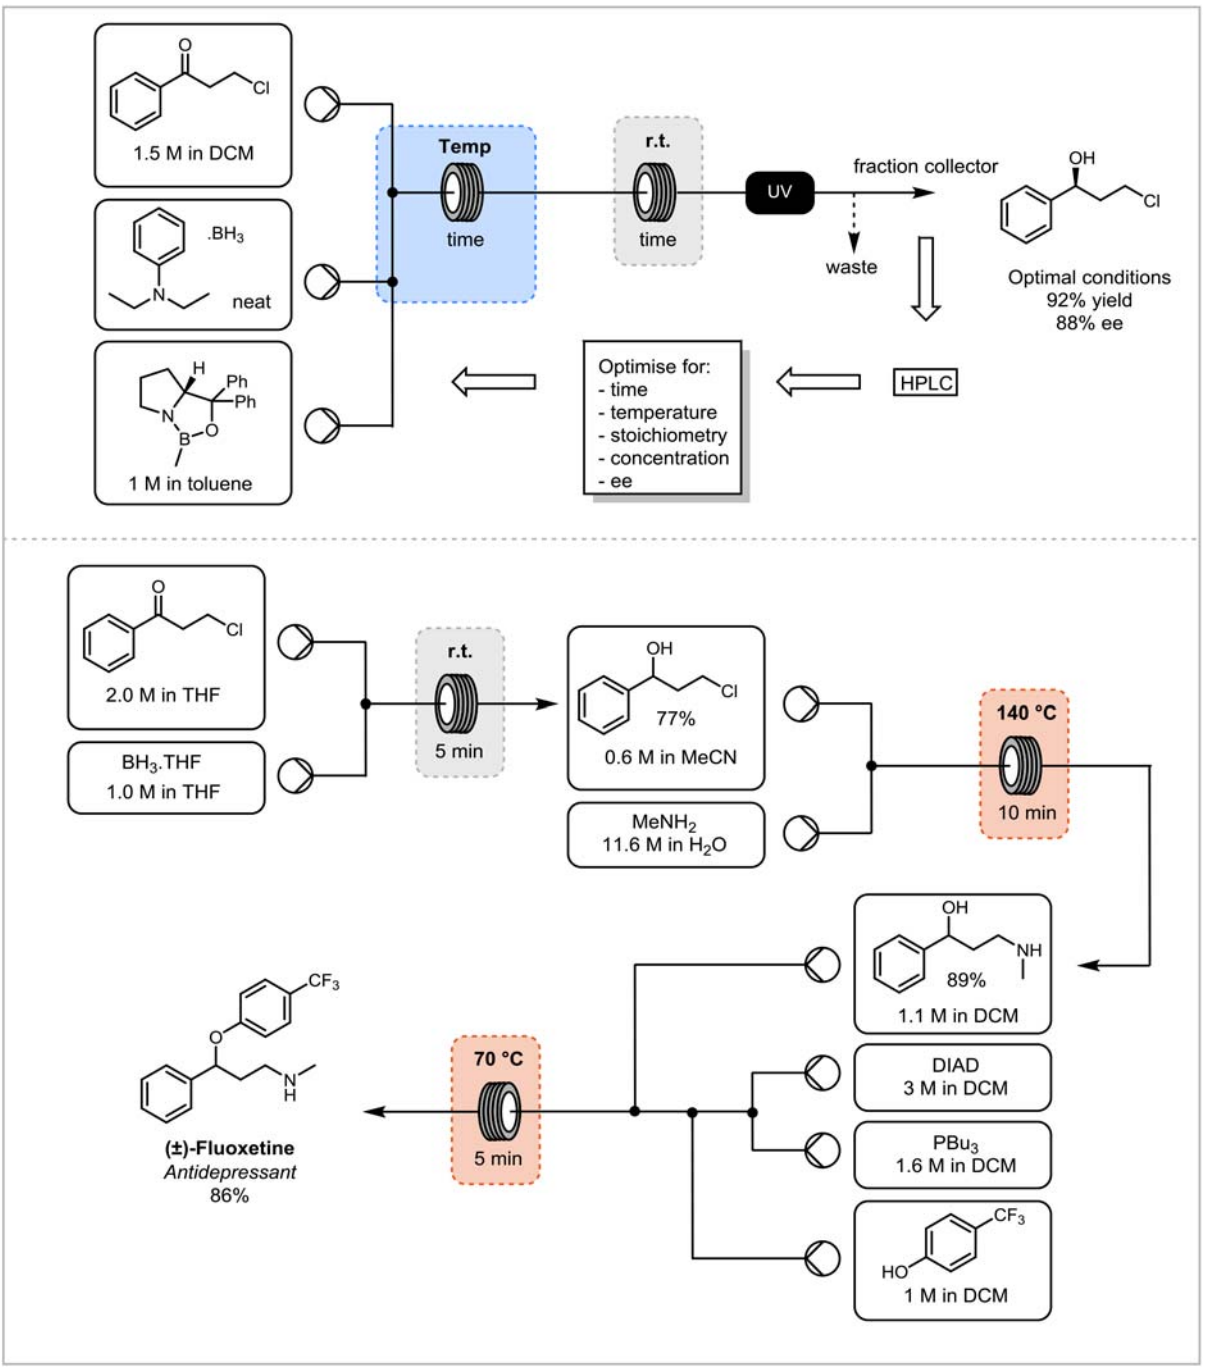
Scheme 59 Self-optimization using online chromatography.[78]



Scheme 60 Optimization using online mass spectrometry.[79]

reduction of a benzylic ketone. The ketone stream was combined with a stream of the diethylaniline borane reducing agent and a chiral oxazaborolidine catalyst before the combined stream passed through two reactor coils with different temperatures. A UV detector was used to determine when the reaction mixture had reached the end of the system, and a fraction collector allowed samples to be taken for HPLC. The residence time, temperature, stoichiometry, and total concentration were varied in order to optimize the yield and enantiomeric excess. Using this method, the enantiomeric excess was increased from 72% to 92%. After demonstrating the use of their method they optimized each step required for the synthesis of (±)-Fluoxetine in the same way. In the first step, a stream of the 3-chloro-1-phenyl-propan-1-one was combined with a stream of BH_3.THF and passed through a reactor coil at room temperature for 5 min to yield the racemic secondary alcohol. Subsequent nucleophilic substitution by methylamine was achieved after 10 min at 140°C, yielding the secondary amine in 89% yield after optimization. The arylation of the benzylic alcohol was achieved by a Mitsunobu reaction first generating the phosphonium, betaine in situ from streams of diisopropyl azodicarboxylate (DIAD) and PBu_3, followed by the addition of streams of the phenol and benzylic alcohol. Optimal conditions of 5 min and 70°C gave the antidepressant Fluoxetine in 86% yield.

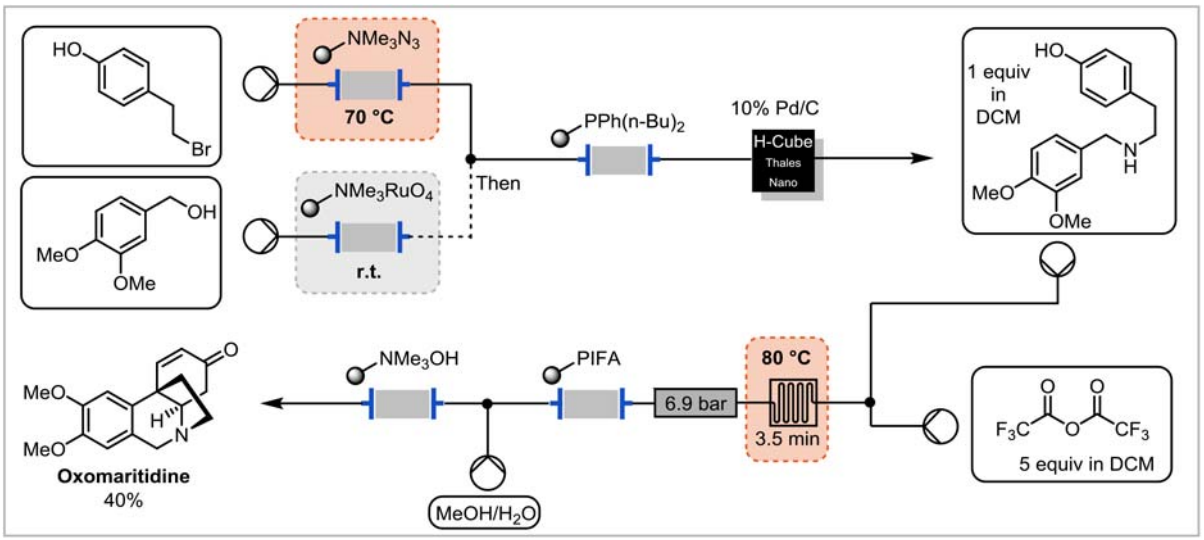
Clearly, the use of reaction monitoring in tandem with automation and computer control to optimize reactions has the potential to speed up the optimization process dramatically. When correctly applied, it can relieve the operator from repetitive work and run experiments continuously without input required. However, it is important to choose parameters and algorithms carefully. Finite numerical parameters are most straightforward such as temperature, pressure, and flow rates. Parameters such as solvents and ligands are more difficult to use in such systems. The problem is twofold: First, numerical values should be assigned to particular attributes, such as dielectric constants, boiling point, or binding affinity. Second, a greater infrastructure is necessary to deliver a variety of solvents, ligands, or additives to the automated reactor system. This would typically consist of an autosampling liquid handling robot but may also use robotic weighing, measuring, and diluting processes. Automatic, self-optimization is a relatively new technique enabled by the increased availability of inline monitoring techniques with the prospect of optimizing ever more complex processes with minimal human input.



Scheme 61 Flow synthesis of Fluoxetine making use of HPLC for optimization.[80]

1.06.5 Multistep Flow Processes

Multistep or telescoped flow synthesis involves directly chaining together multiple reaction steps to form one continuous flow system in order to achieve the synthesis of a target molecule. The finalized process can be a thing of beauty and a form of art where consecutive reaction steps are designed to operate in a flow manner, whereby solvent compatibility, flow rates, coil temperatures, system pH levels, and longevity of operation all need to work in tandem. If all of these attributes are satisfied then this can lead to machines capable of reliably and monotonously performing the same reaction processes. Indeed, it was perhaps owing to the intricacy and elegance of one of the first reports on multistep flow synthesis, targeting the alkaloid natural product Oxomaritidine, that the utility and importance of flow chemistry to this chemical sector was realized.[81]



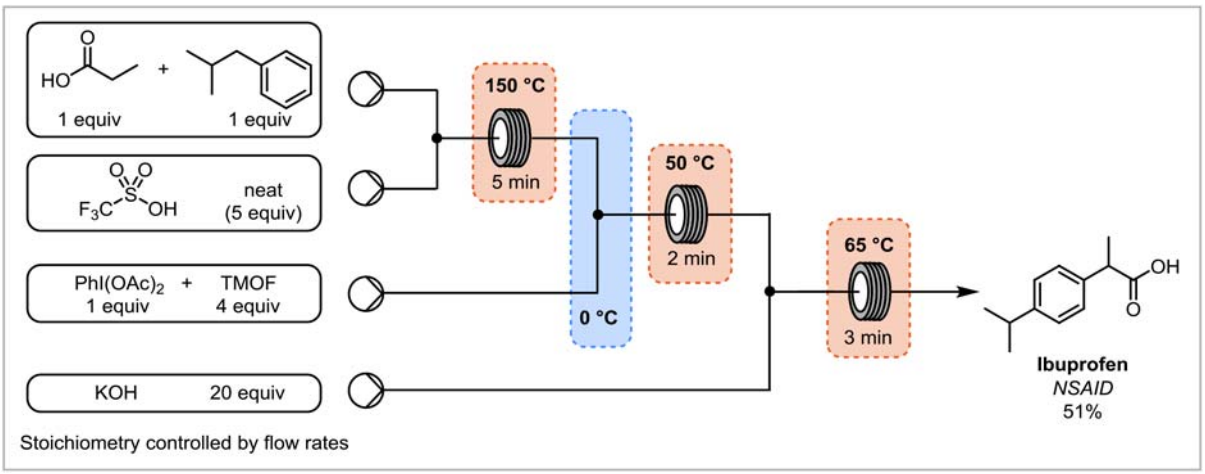
Scheme 62 Continuous flow multistep synthesis of Oxomaritidine.[81]

In 2006, Ley et al. reported the end-to-end preparation of Oxomaritidine using continuous flow technologies and polymer-supported reagents. Many of the principles of polymer-supported reagents that were investigated and understood in the decade prior to this report were key to realizing the continuous flow route. Cartridge charging and loading with reagents along with "catch–react–release" protocols were developed for flow systems for the first time in this synthesis. As shown in **Scheme 62** the alkyl bromide material was first passed through an ion-exchange resin supporting azide anions which effected an S_N2 displacement. The resulting azide species was then caught on a polymer-supported phosphine as an iminophosphorane ready to react in a subsequent step. In tandem to this, a benzylic alcohol substrate underwent Ley oxidation to the corresponding aldehyde, mediated by a PS-RuO_4. The aldehyde then passed through the iminophosphorane column to react in an aza-Wittig process and release the resulting imine from the support (leaving behind the phosphine oxide). The imine was immediately reduced over a palladium on charcoal cartridge to the secondary amine. This material was then collected so as to reset the flow rates and then pumped into a microfluidic chip with (trifluoroacetic anhydride) TFAA in order to acylate the amine prior to oxidation of the phenol moiety using hypervalent iodine (again on polymer support). This reaction resulted in concomitant C–C bond formation between the two aromatic rings. Finally the N-protecting group was removed, allowing conjugate addition of the amine to the quinone in order to furnish Oxomaritidine in an overall 40% yield. This process still stands as one of the more complex examples reported to date. However, more importantly, it paved the way and perhaps inspired others to explore the area of multistep flow approaches. Here, a snapshot of some developments is reported, where we pay particular attention to those attributes that are aligned with a modern medicinal chemistry research laboratory.

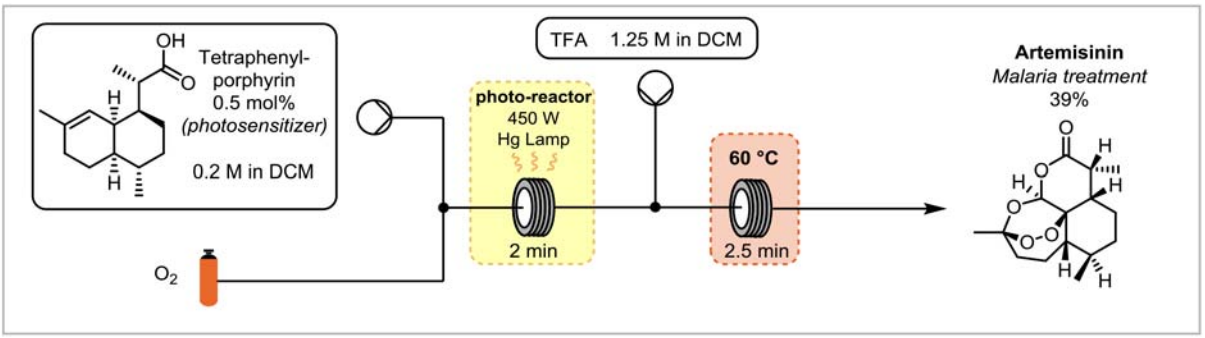
The nonsteroidal antiinflammatory drug Ibuprofen has been the center of attention for several flow syntheses to date.[82] However, the report by McQuade and coworkers in 2009 marks the first multistep approach where all three synthetic steps were run in a continuous process (**Scheme 63**). In the first step a triflic acid-mediated Friedel–Crafts acylation reaction was conducted in a microreactor chip. It was noted that $AlCl_3$ was a viable mediator of this reaction but was not compatible with further processes downstream, an important consideration in establishing a telescoped flow process. The second step, a 1,2 aryl migration, was effected with phenyliodine diacetate (PIDA) in the presence of trimethylorthoformate to deliver the methyl ester which was saponified in the final reactor with potassium hydroxide. Notably the synthesis by this route was complete in 10 min, and it was noted that scale-up could be made with appropriate consideration of pumps, mixers, and reactor channel dimensions. From the three microchip process a 51% yield of Ibuprofen was recovered after recrystallization.

Following the first report of a photochemical flow reaction in 2005 by Booker-Milburn and Berry,[83] 2012 saw the first report of the use of such a processing technology to trigger a reaction cascade toward the antimalarial artemisinin(**Scheme 64**).[84] Here, a stream of dihydroartemisinic acid in DCM is combined with oxygen and a porphyrin-based photosensitizer before passing through a region of tubing exposed to UV irradiation from a mercury lamp. This process results in a photochemical singlet-oxygen ene reaction where the resultant peroxy-ene species then undergoes Hock cleavage in the presence of trifluoroacetic acid (delivered as another stream) to afford artemisinin in 39% yield following column chromatography. Since this report there have been several improvements to the technique toward artemisinin.

There has also been a drive to move away from artemisinin-derived antimalarial compounds due to resistant strains developing. As such, the endoperoxide antimalarial OZ439 was identified as a potent compound toward malaria, including artemisinin-resistant strains. The preparation of this compound has been neatly developed in flow (**Scheme 65**).[85] The reaction sequence commences with the partial, but selective hydrogenation of the bisphenol starting material over a palladium on charcoal catalyst. The resulting phenol ketone material is acylated continuously before feeding the ketone into an ozonolysis reaction with the



Scheme 63 Continuous flow multistep synthesis of Ibuprofen.[82a]



Scheme 64 Continuous flow photochemical synthesis artemisinin.[84a]

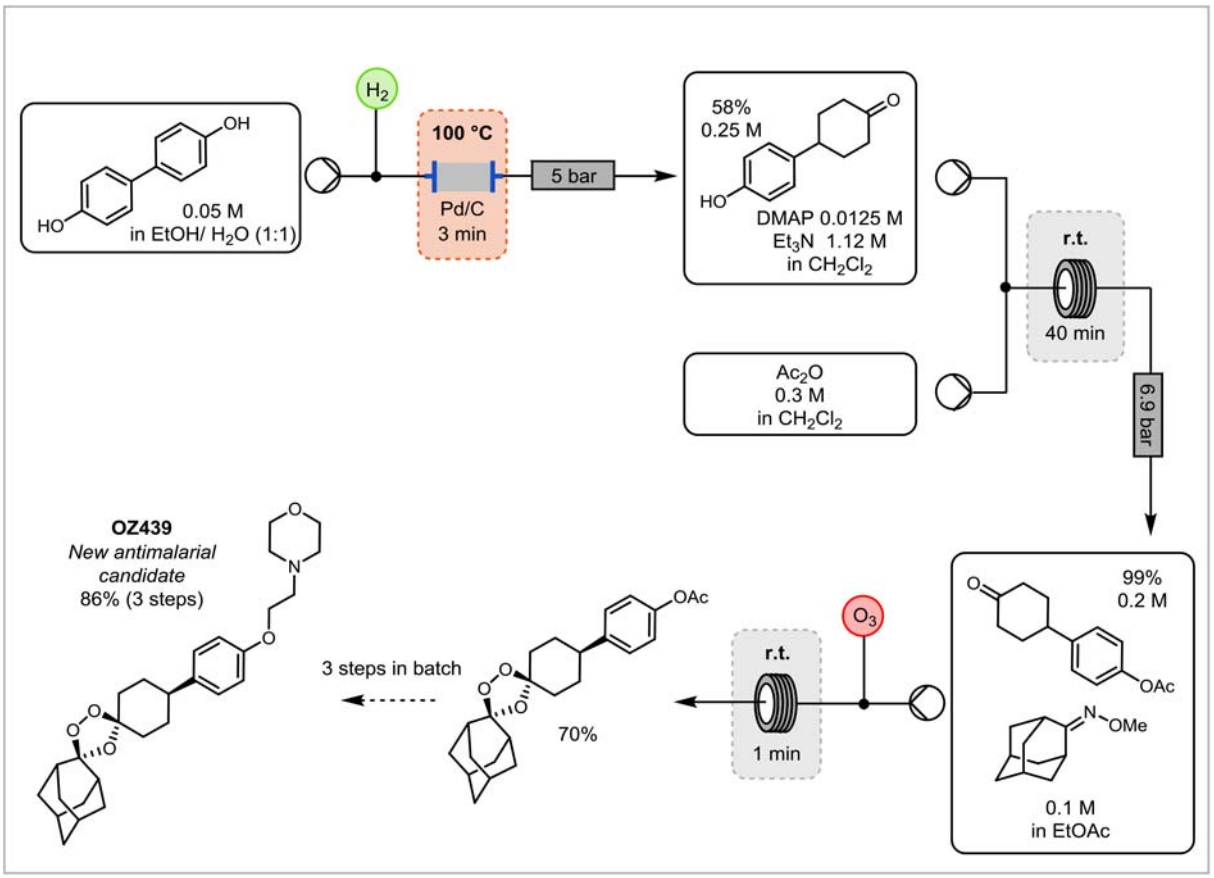
adamantane-derived oxime. Initially ozonolysis of the oxime generates the adamantyl oxido-oxonium which then traps the ketone as a secondary ozonide or endoperoxide. The product is then further elaborated offline.

As an alternative to photo irradiation, electromagnetic induction can be harnessed for synthesis through inductive heating.

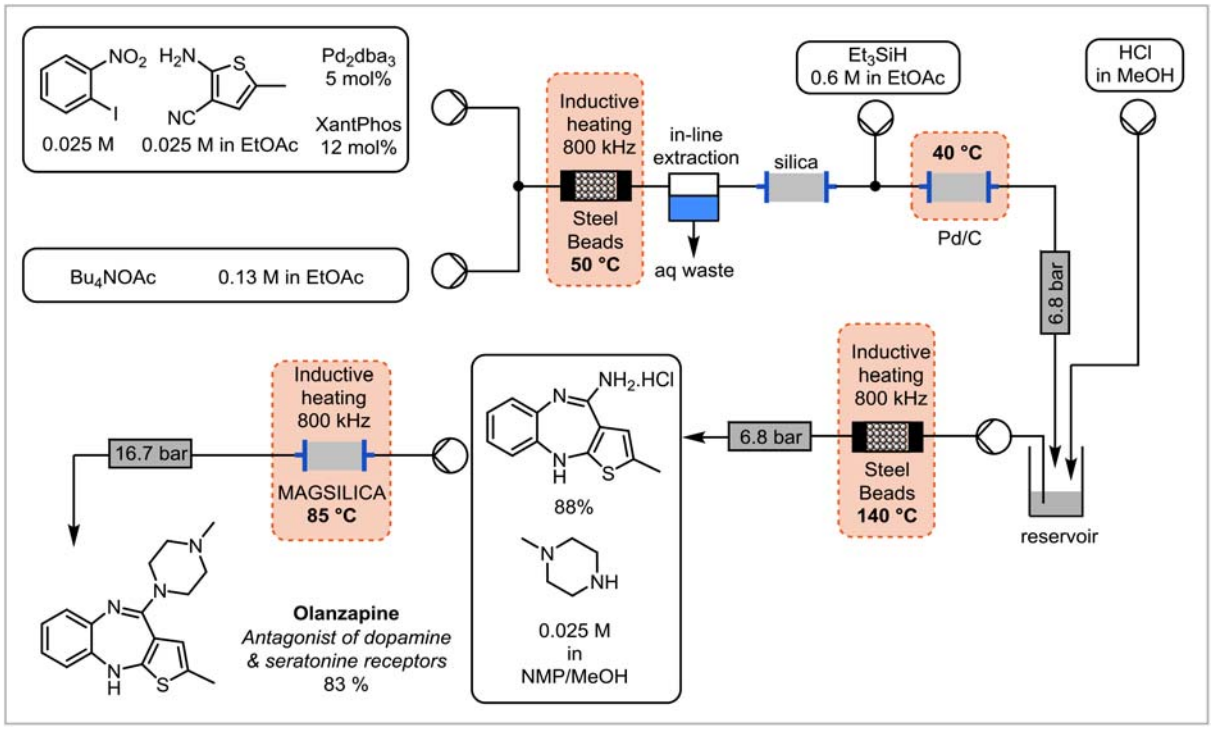
Inductive heating is a phenomenon observed when a rapidly alternating magnetic field is passed through a magnetic, conductive, or superparamagnetic material. The application of this heating technique in continuous flow synthesis has been explored by Kirschning.[86] In general the technique involves the introduction of a column packed with magnetic materials into an induction loop. The flowing stream then passes over the inductively heated particles as it passes through the column.

The method is well suited to reactions at high temperatures and short reaction times although more controlled processes have also been demonstrated. In 2013, the technique was used in the multistep synthesis of the schizophrenia and bipolar disorder therapeutic Olanzapine (Zyprexa).[87] The synthesis commences with a Buchwald–Hartwig coupling of 2-iodo-nitrobenzene with an aminothiophene, using Xantphos as ligand (Scheme 66). It was found optimal to introduce the base for this reaction via a second stream. Inline aqueous extraction of the base was necessary prior to the next step which was a reduction of the nitro group over palladium on charcoal. The product amino nitrile was then cyclized in the presence of acid in the third continuous step where correct solvent choice and acid concentration were critical to the success of the cyclization to the benzodiazepine core. With optimal conditions this material could be isolated in 98% yield. The final step required Lewis acid-mediated trans amination, whereby preparation of a silica/titanium material facilitated the desired reaction. This solid material was homogenized with "Magsilica," a magnetic material, and loaded into the inductive coil so that effective heating could take place to deliver Olanzapine in 83% yield. Inductive heating has also been used in the multistep synthesis of Amitriptyline.[88]

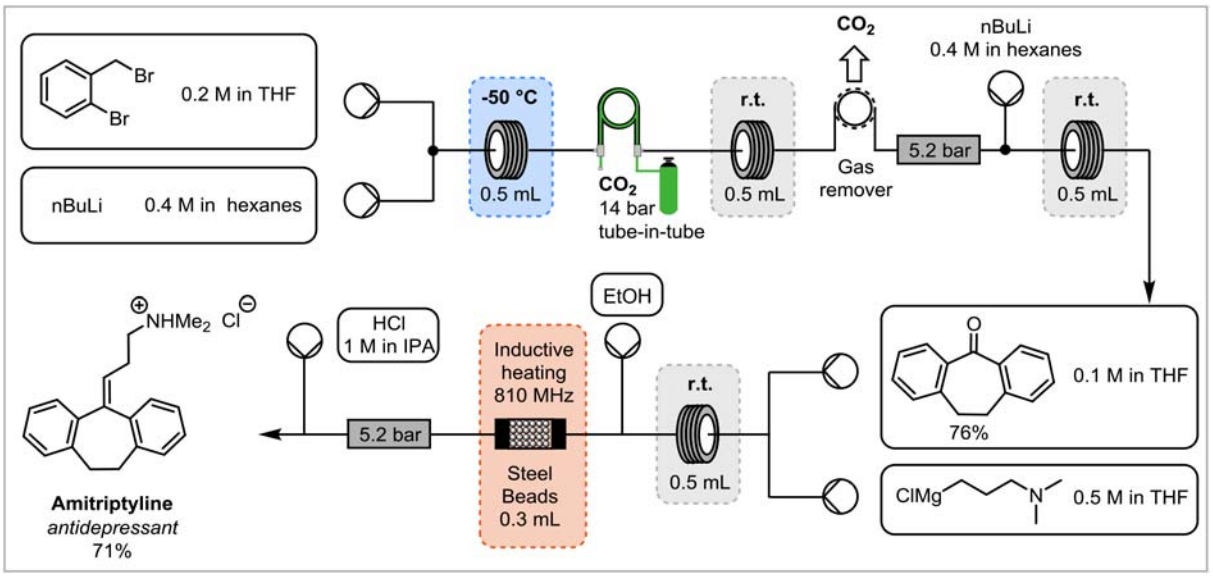
Amitriptyline is on the WHO model list of Essential Medicines and has been used to treat a range of disorders such as depression, migraines, neuropathic pain, fibromyalgia, and nocturnal enuresis. The Kirschning flow synthesis of this important transtherapeutic compound commences with a Wurtz coupling of aryl lithium species generated in situ by the treatment of the bisbromo starting material with butyllithium (Scheme 67). Use of a gas permeable AF-2400 tube-in-tube reactor is then critical for the introduction of carbon dioxide as an electrophile for the preparation of the dibenzosuberone core. For the second phase of the synthesis dibenzosuberone was then mixed with the appropriate Grignard reagent under flow conditions, where room temperature was sufficient to dissipate the exotherm of the organometallic reaction. The output of this reactor was then quenched and kept mobile (by



Scheme 65 Continuous flow synthesis of endoperoxide antimalarial OZ439.[85]



Scheme 66 Continuous flow multistep synthesis of Olanzapine.[87]

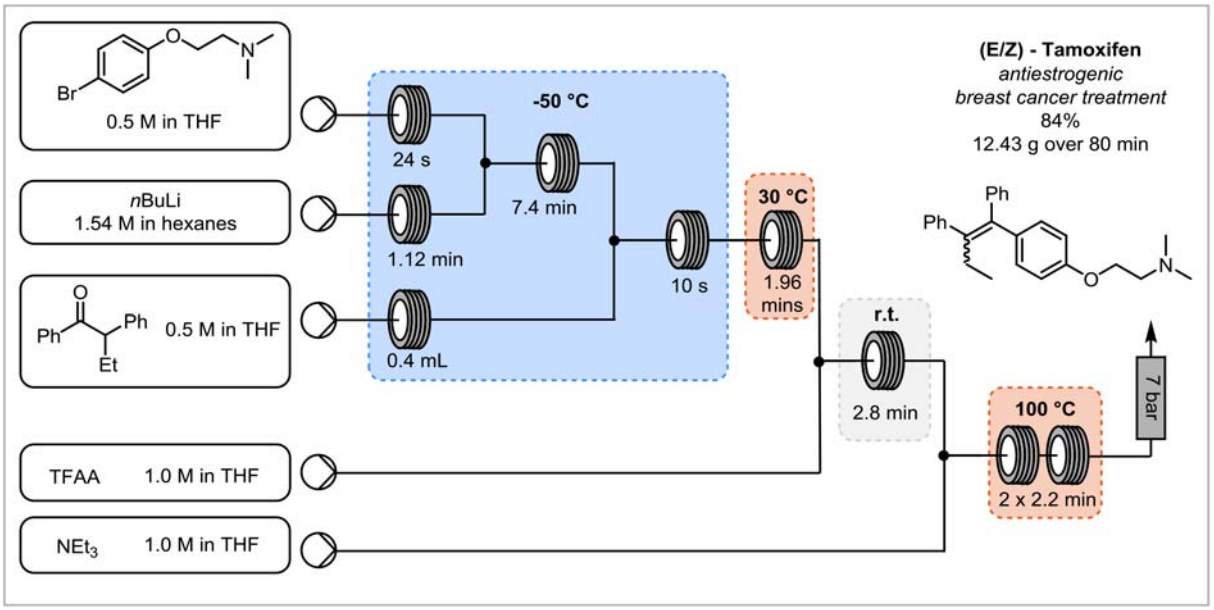


Scheme 67 Continuous flow multistep synthesis of Amitriptyline.[88]

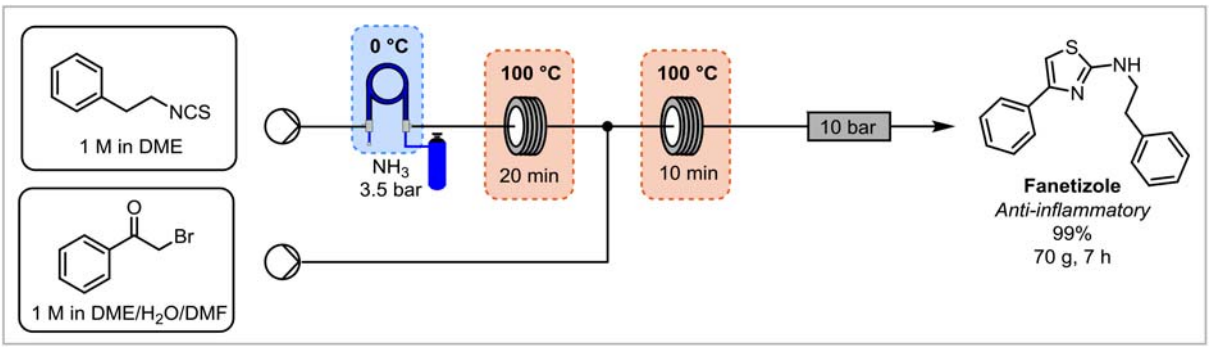
dissolution of potentially problematic magnesium salts) by addition of a stream of ethanol before passing into a high-frequency inductive heating zone to promote the elimination of a tertiary alcohol. Final addition of HCl enabled precipitation and isolation of Amitriptyline·HCl in 71% yield.

Continuous processing of organometallics has been problematic at the early scale-up phase due to pumping issues, where single-shot syringe pumps and HPLC systems can run into problems. In a report aimed at addressing this shortfall by using peristaltic pumping technology Ley and coworkers demonstrate the end-to-end synthesis of Tamoxifen.[89]

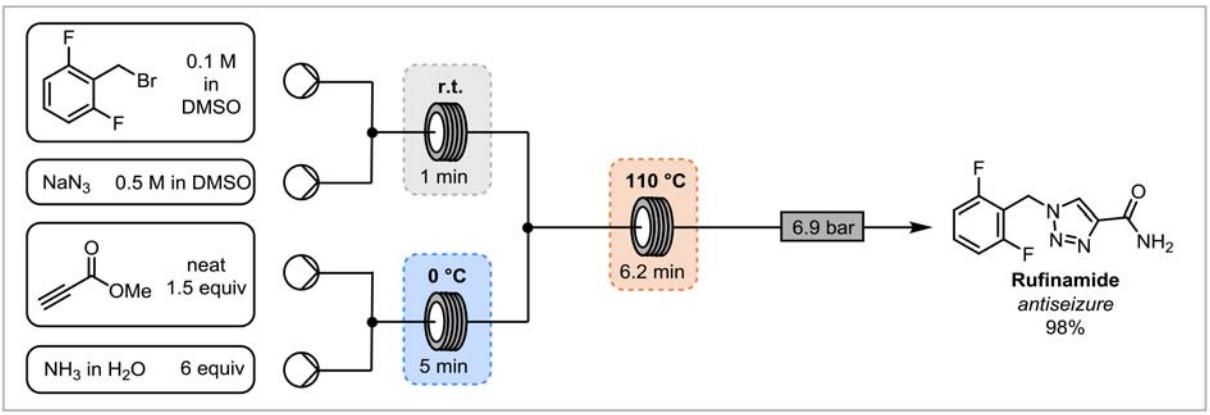
In 2013, Tamoxifen was announced as a preventative treatment measure in the United Kingdom for females at risk of breast cancer, where a 5-year prescription reduces the risk by one-third and protection could last for 20 years. The multistep continuous flow synthesis of this important chemical commenced with a lithium-halogen exchange reaction of bromobenzene starting material (Scheme 68). The freshly formed organometallic was then intercepted with a stream containing a ketone electrophile and passage through a reaction coil at 30°C before interception with trifluoroacetic anhydride to generate the active alcohol leaving group. At this stage the combined flow rates and productivity are relatively high (compared to the previously described methods in this



Scheme 68 Continuous flow multistep synthesis of *E*/*Z*-Tamoxifen.[89]



Scheme 69 Continuous flow multistep synthesis of Fanetizole.[90]



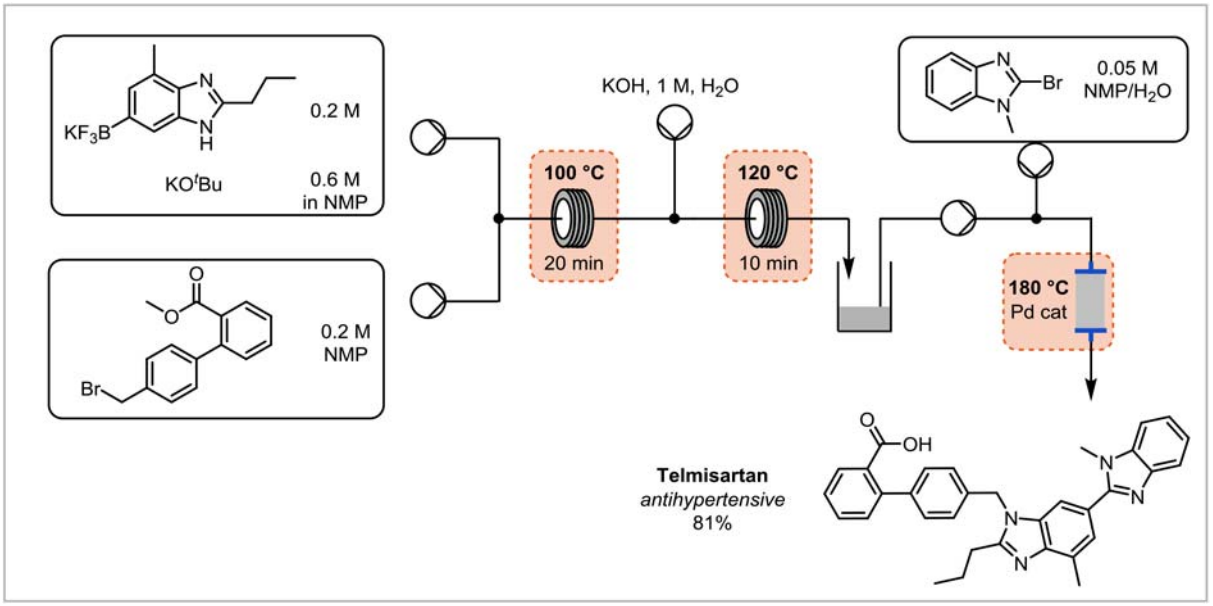
Scheme 70 Continuous flow multistep synthesis of Rufinamide.[91a]

section), and thus the reactor coils used must have a larger volume to provide sufficient residence time. This increases the pressure-drop across the system and would be a problem for pumps with low pressure resistance. Regardless, addition of a stream of triethylamine to the trifluoroacetate material and passage through a 20 mL coil at 100°C was enough to deliver the necessary elimination reaction and afford *E*/*Z*-Tamoxifen in 84% yield. Running this system for an 80 min period produced 12.43 g of material, enough for 900 doses of formulated active pharmaceutical ingredient (API).

Ley has also demonstrated the synthesis of the antiinflammatory compound Fanetizole, incorporating the use of gaseous ammonia through an AF-2400 tube-in-tube reactor (**Scheme 69**).[90] Here the flow system was designed so that colorimetric titration could be used for the determination of ammonia concentration under a range of solvents, pressures, temperatures, and flow rates. It was demonstrated that these could be prepared on demand and remain at reliable accuracy for extended periods. With this setup established, equistoichiometric amounts of ammonia were introduced to an isothiocyanate stream passing through the tube-in-tube reactor. This ammonia-enriched solution was then passed through a heated coil for formation of the thiourea before introduction of an alpha bromo ketone and heating again in a second coil. The desired product Fanetazole then precipitated as a pure solid upon standing, giving 99% yield at a productivity of 70 g delivered over 7 h.

The anticonvulsant drug Rufinamide has also succumbed to flow synthesis and was delivered in short order by Jamison et al. using a three-stage continuous process (**Scheme 70**).[20,91] Combination of the requisite benzyl bromide with sodium azide rapidly delivered the 1,3-dipole, whereas the other component for the click reaction was prepared inline by reaction of excess aqueous ammonia with neat methyl propiolate. Combining the alkynylamide with the azide in standard perfluoroalkoxy (PFA) tubing afforded a 3:1 mixture of triazole regioisomers in low yield. Crucially, it was found that by fabricating the final reactor coil from copper tubing allowed the cycloaddition reaction to progress in both greatly improved yield and selectivity for the desired regioisomer (20:1).

The sartan drugs are angiotensin receptor blockers, used for the treatment of hypertension. Telmisartan represents a recent example to come off patent and features a carboxylic acid as a bioisostere to the tetrazole motif which is common to most other sartans. Indeed, continuous flow preparations of tetrazoles using azide chemistry have been the focus of several flow chemical projects where process safety was a key driving force. In this case however, Gupton and Belecki et al. start their multistep process with the N-alkylation of the trifluoroboronate bearing benzimidazole with the biaryl carboxylate (**Scheme 71**).[92] This was found to proceed at 100°C with a 20 min residence time. The output of the alkylation reactor was then met with a stream of potassium hydroxide for ester saponification. The final step pumped the carboxylic acid material and *N*-methyl benzimidazole through

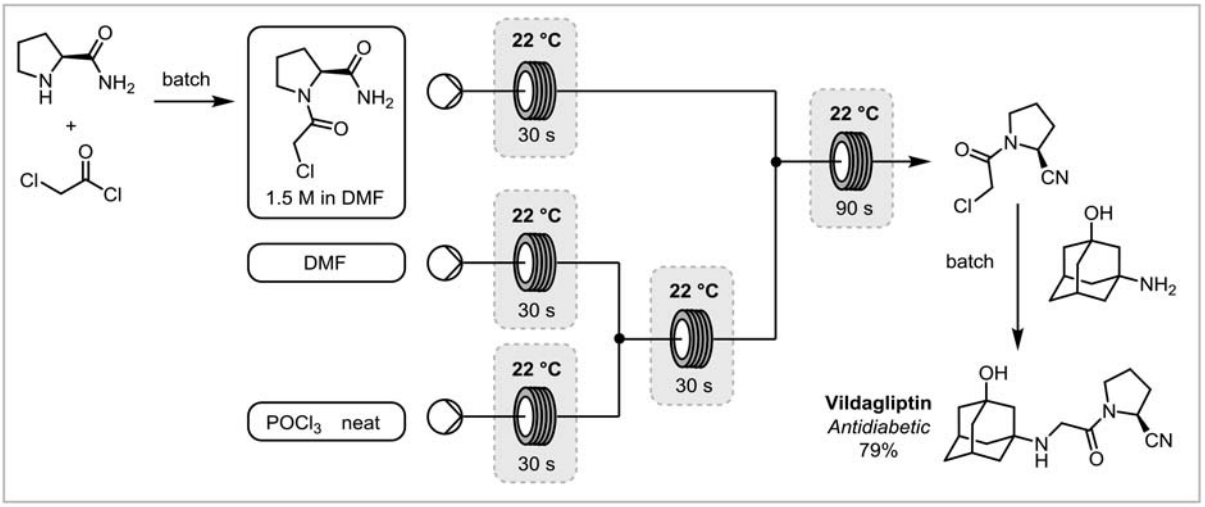


Scheme 71 Continuous flow multistep synthesis of Telmisartan.[92]

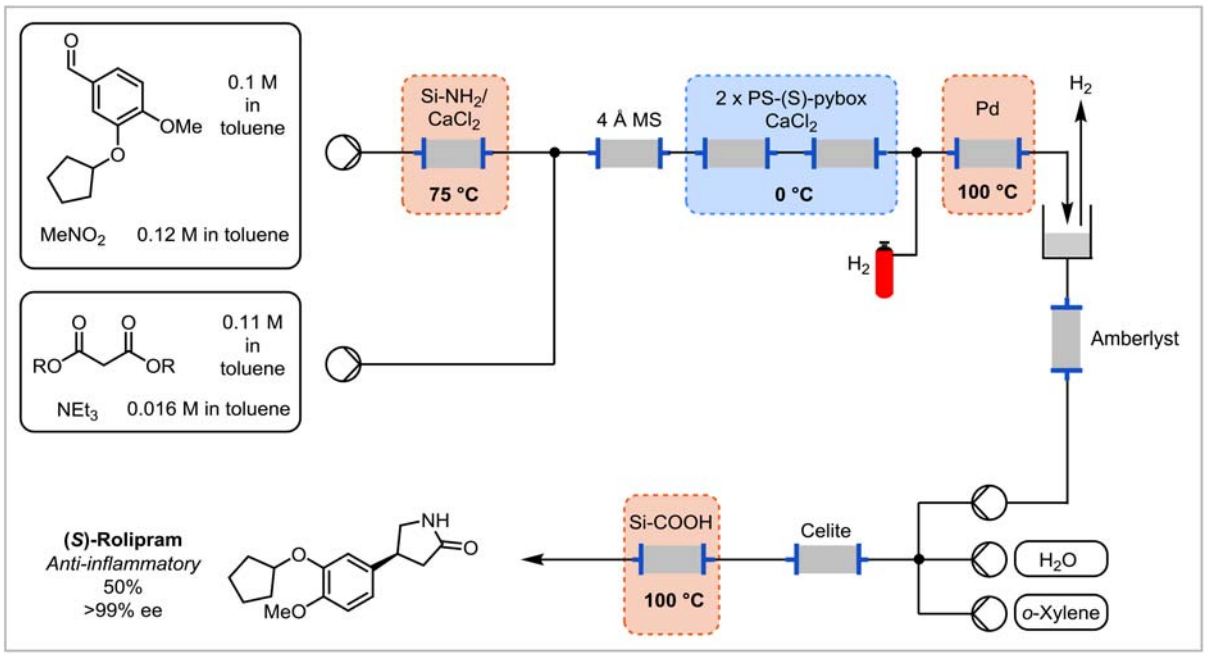
a cartridge containing SiliaCat DPP-Pd to effect Suzuki cross-coupling at 180°C, the final production rate here corresponding to 1 mg min^{-1}.

Vildagliptin is an orally active antidiabetic drug featuring an adamantanol ring system. Novartis have reported an integrated batch and flow process for the synthesis of this compound where the key Vilsmeier reagent is generated safely inline (Scheme 72).[93] The process first commences with a batch acylation of L-proline amide. Upon completion, this material was then pumped out of the reaction pot into a well-monitored flow circuit at 26 mL min^{-1}. Meanwhile dimethylformamide (DMF) was pumped into a mixer and reactor with $POCl_3$ to generate the Vilsmeier reagent which then passes out to the second reactor to effect dehydration of the amide to nitrile. The cyano product was then deposited into a batch reactor ready for alkylation with the amino adamantanol. The overall process was conducted at large scale with the use of pressure sensors, mass flow controllers, and integrated emergency action software controllers. Such controllers permit the machinery to shutdown automatically upon deviation from previously defined conditions.

(*S*)-Rolipram is an important antiinflammatory drug and a member of the GABA series of compounds. Kobayashi and coworkers have demonstrated a succinct asymmetric flow approach to this target compound (Scheme 73).[94] Initially they combined a stream of nitromethane and the appropriate aldehyde before passing this through a basic silica bed to mediate a condensation reaction. The



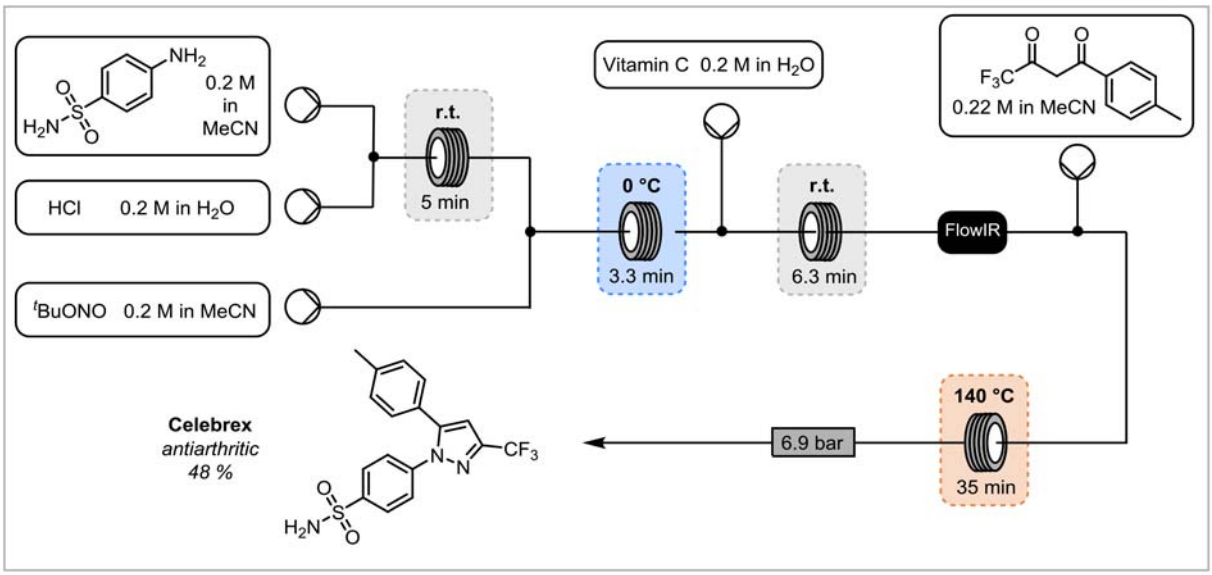
Scheme 72 Continuous flow multistep and batch hybrid synthesis of Vildagliptin.[93]



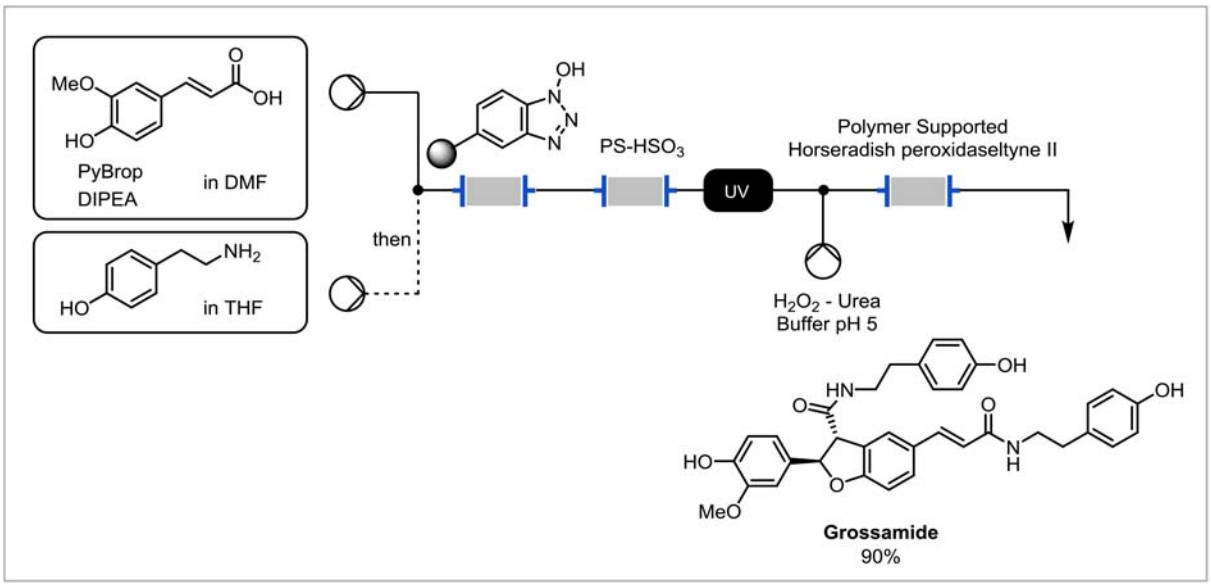
Scheme 73 Continuous flow multistep synthesis of Rolipram.[94]

resulting nitroalkene was then intercepted with a malonate, where a chiral Lewis acid in the form of polymer-supported PyBox-ligated calcium chloride induced an asymmetric conjugate addition reaction. The resulting adduct then underwent nitro group reduction and concomitant cyclization to give the γ-lactam product. In the final step, this material decarboxylates following initial ester hydrolysis to deliver (*S*)-Rolipram in 50% isolated yield and >99% *ee*.

Celebrex, a pyrazole-based antiinflammatory used for the treatment of arthritis, has also been prepared under multistep continuous processing (Scheme 74).[95] In this instance the method hinged on the use of vitamin C for the reduction of diazonium salts as a preferred strategy to the use of tin (II) chloride. This was deemed favorable as it reduces the downstream processing needed to wash away toxic tin residues. The requisite aniline is first diazotized before intercepting with the vitamin C reducing agent. This hydrazine adduct is then combined with a 1,3-dicarbonyl and under acidic conditions passed through a heated coil resulting in cleavage of the hydrazine adduct and cyclocondensation to provide the pyrazole structure. Inline flow IR was used here to monitor



Scheme 74 Continuous flow multistep synthesis of Celebrex.[95]



Scheme 75 Continuous flow multistep synthesis of Grossamide.[96]

the presence and concentration of the formed adduct but also to check that all of the diazonium salt had been consumed. The overall process afforded Celebrex in 48% yield and in high purity following a simple aqueous extraction.

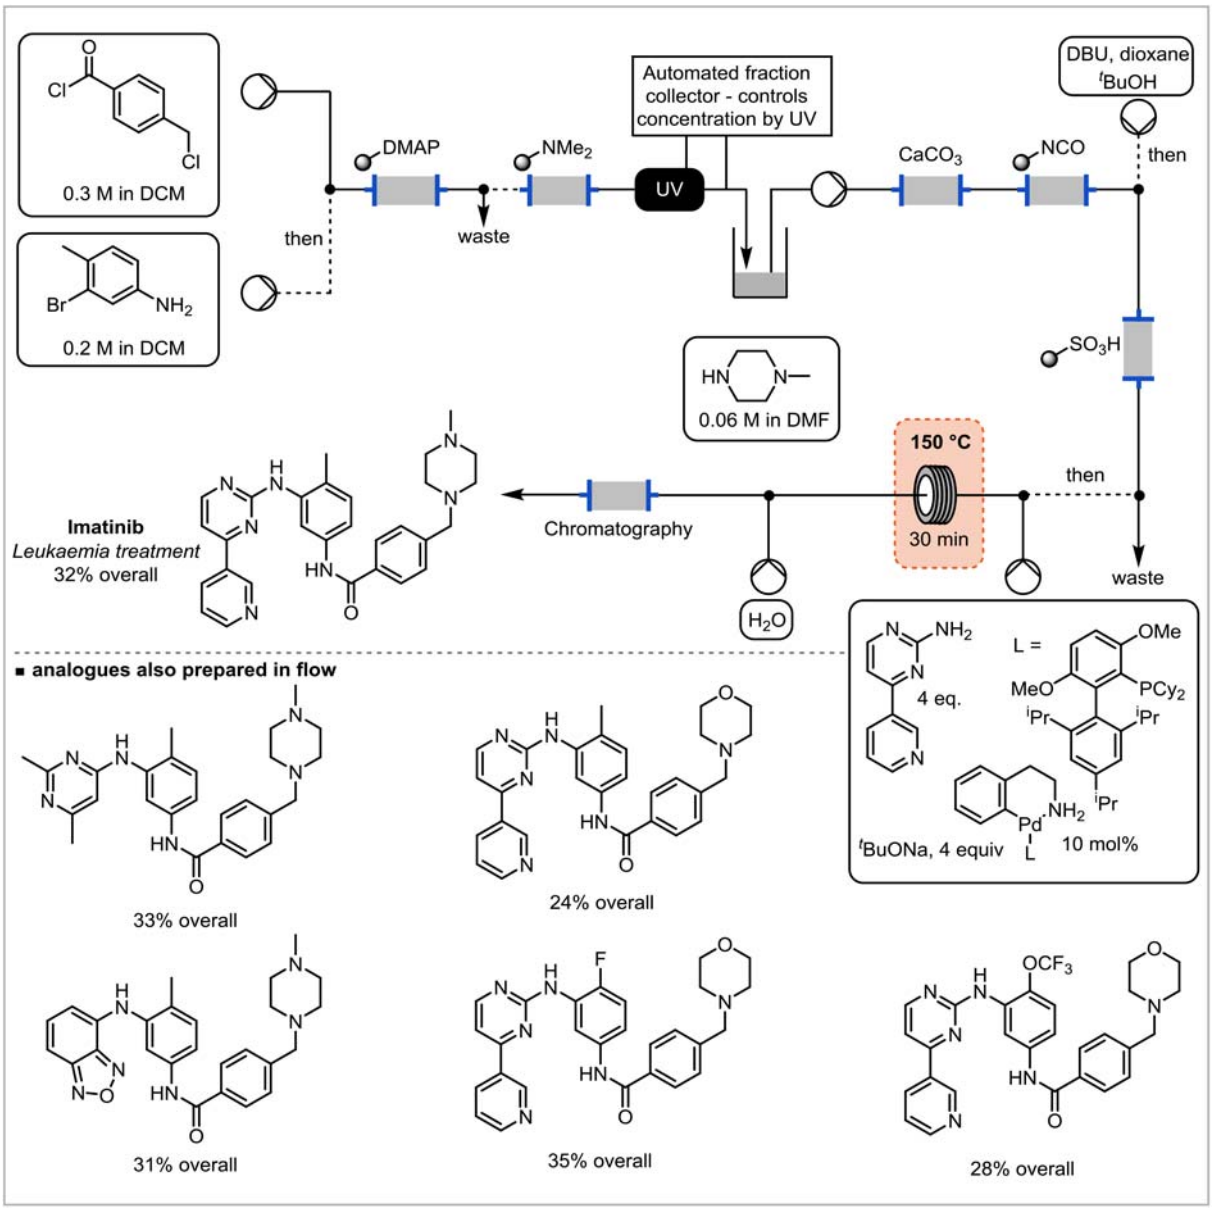
Inline monitoring is now used frequently for flow processes, but perhaps the first example in the context of multistep organic synthesis was in 2006 when applied to the synthesis of Grossamide (Scheme 75).[96] Grossamide was prepared using a catch–react–release approach and also exemplifies the first biocatalyzed flow reaction. The synthetic approach starts by passing a solution of carboxylic acid, DIPEA and PyBroP over a polymer-supported HOBt. This then catches the carboxylic acid in the form of its activated ester. A switching valve then triggers to draw from a stock of amine that then passes through and reacts with the activated carboxylate and thus releasing it as an amide. Any unused amine is then subsequently caught on a PS-acid resin, while the amide product passes through an inline UV cell. The cell triggers the rest of the system, namely, the pumping of a pH 5 buffer solution to aid the biocatalyzed oxidative dimerization to afford Grossamide in 90% yield.

The catch–react–release and UV combination have also been incorporated into the multistep synthesis of the leukemia treatment Imatinib and related analogues (Scheme 76).[97] This time an acid chloride was caught on a polymer supported 4-dimethylaminopyridine (PS-DMAP) as an active amide. This caught carboxylate then underwent the same type of react and release with an aniline nucleophile. The amide product proceeds to a UV-triggered fraction collector ready for the next step. The following steps consist of alkylation at a piperidine nitrogen and a Buchwald–Hartwig cross-coupling. Finally the whole system features inline scavengers and purification with just one automated chromatography step at the end to remove ligands and excess reagents. The overall yield of the process was 32% for Imatinib, with similar yields for a range of prepared analogues.

Capecitibine and indeed 5′-deoxyribonucleosides in general represent a potent compound class, particularly as antiviral and antitumor agents. Jamison and Shen reported a telescoped process for the three-step preparation of these compounds making use of an organic Brønsted acid-catalyzed C—N bond formation through the silyl-Hilbert–Johnson reaction (Scheme 77).[98] The initial reaction step joins a stream containing the 5′-deoxyribose donor and 5 mol% of a pyridinium catalyst with a stream of the silylated pyrimidinone. These combined streams then passed through a heated microfluidic reactor chip to mediate the key bond formation before combination with another stream to form the desired amide in a second reactor chip. Finally, merging with a stream of sodium hydroxide results in global deprotection to furnish Capecitabine in 72% overall yield. Importantly, this method was readily adopted for the preparation of Doxifluoridine and Galocitabine.

The Jamison group has also reported the continuous synthesis of diphenylhydramine, the API of Benadryl, an antihistamine drug (Scheme 78).[99] Remarkably this synthesis demonstrates the processing of a molten ammonium salt without any blockage of the reactor tubing. The salt was generated in situ by reaction of neat *N*-*N*-dimethylaminoethanol with neat chlorodiphenylmethane. These two streams were combined and then heated at 175°C with a residence time of 16 min. Upon exiting the reactor, the neat molten tertiary amine hydrochloride salt was diluted first with aqueous sodium hydroxide and then by hexane before passage through a liquid–liquid phase separating device. The final API product was then secured in 93% yield by addition of HCl to induce crystallization.

The processing of neat reagents was also a key part of the preparation of Aliskiren (Scheme 79).[100] A Novartis-MIT collaboration has resulted in a multistep process for the preparation, separation, crystallization, drying, and formulation of the final Aliskiren product. The process starts with an acid-catalyzed ring opening amide formation where all three channels were pumped neat through a heated tubular reactor. Following this, the stream is diluted and undergoes liquid–liquid extraction. The organic phase,

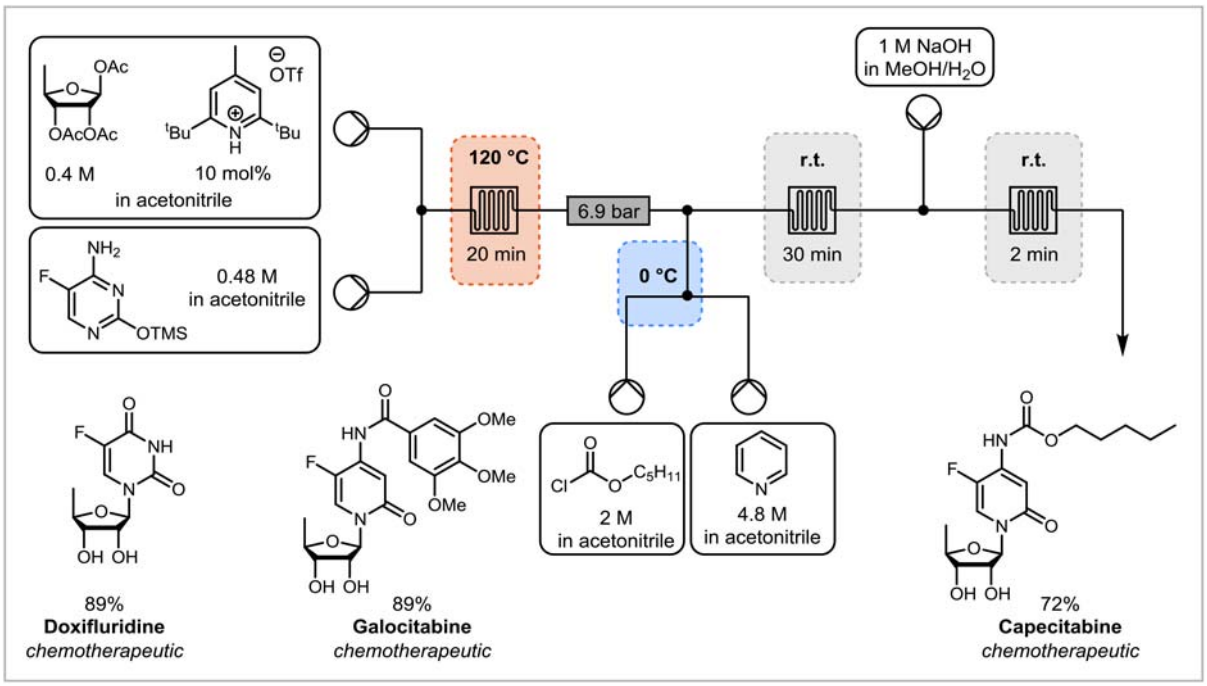


Scheme 76 Continuous flow multistep synthesis of Imatinib and analogues.[97]

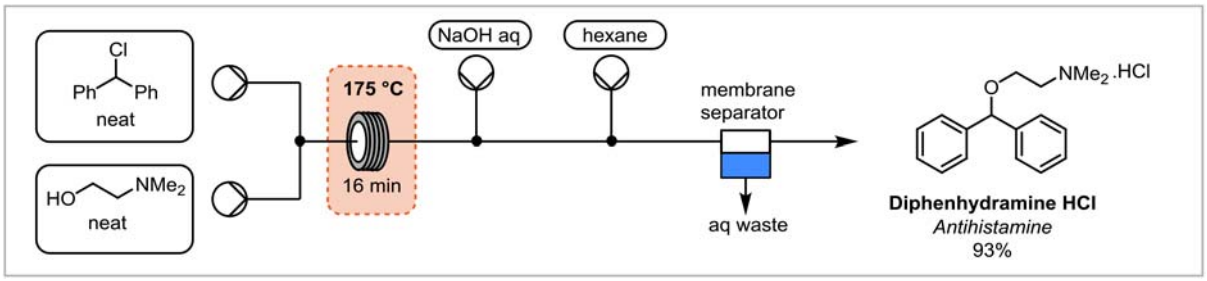
now containing the desired product and remaining starting material, passed into a crystallizing chamber where heptane was added to induce crystallization of the product. The precipitate was then filtered, washed, and automatically diluted to the correct concentration for the following Boc deprotection step. After deprotection, NaOH was added to neutralize, and a liquid–liquid phase separation follows this.

Further addition of ethyl acetate to the resulting organic stream caused precipitation of remaining NaCl, which was removed using a microfilter. In the second crystallization pot, fumaric acid was added to the API material and promoted crystallization as the hemi-fumarate salt. Again the crystals were filtered, washed, and diluted appropriately (again in an automated fashion), before addition of silica which behaves as a glidant material. The slurry was then continuously dried and conveyed through a rotating heated drum with the final drying phase in a vacuum drier. This solid material, which at this point contained 5000 ppm ethyl acetate, passed through a heated extruder in combination with PEG. The extruded mixture was then molded into tablets six at a time. Clearly this is an excellent and exciting demonstration of the capabilities and goes to show that downstream processing is actually where the bulk of time and energy is spent. Achieving regulatory sign-off on such manufacturing processes is a current focus to help bring this technology to the market place.

The same collaborative research team has very recently demonstrated a compact, modular API manufacturing approach. The plug-and-play modules were connected in four different configurations, permitting the multistep synthesis, purification, real-



Scheme 77 Continuous flow multistep synthesis of Capecitabine.[98]



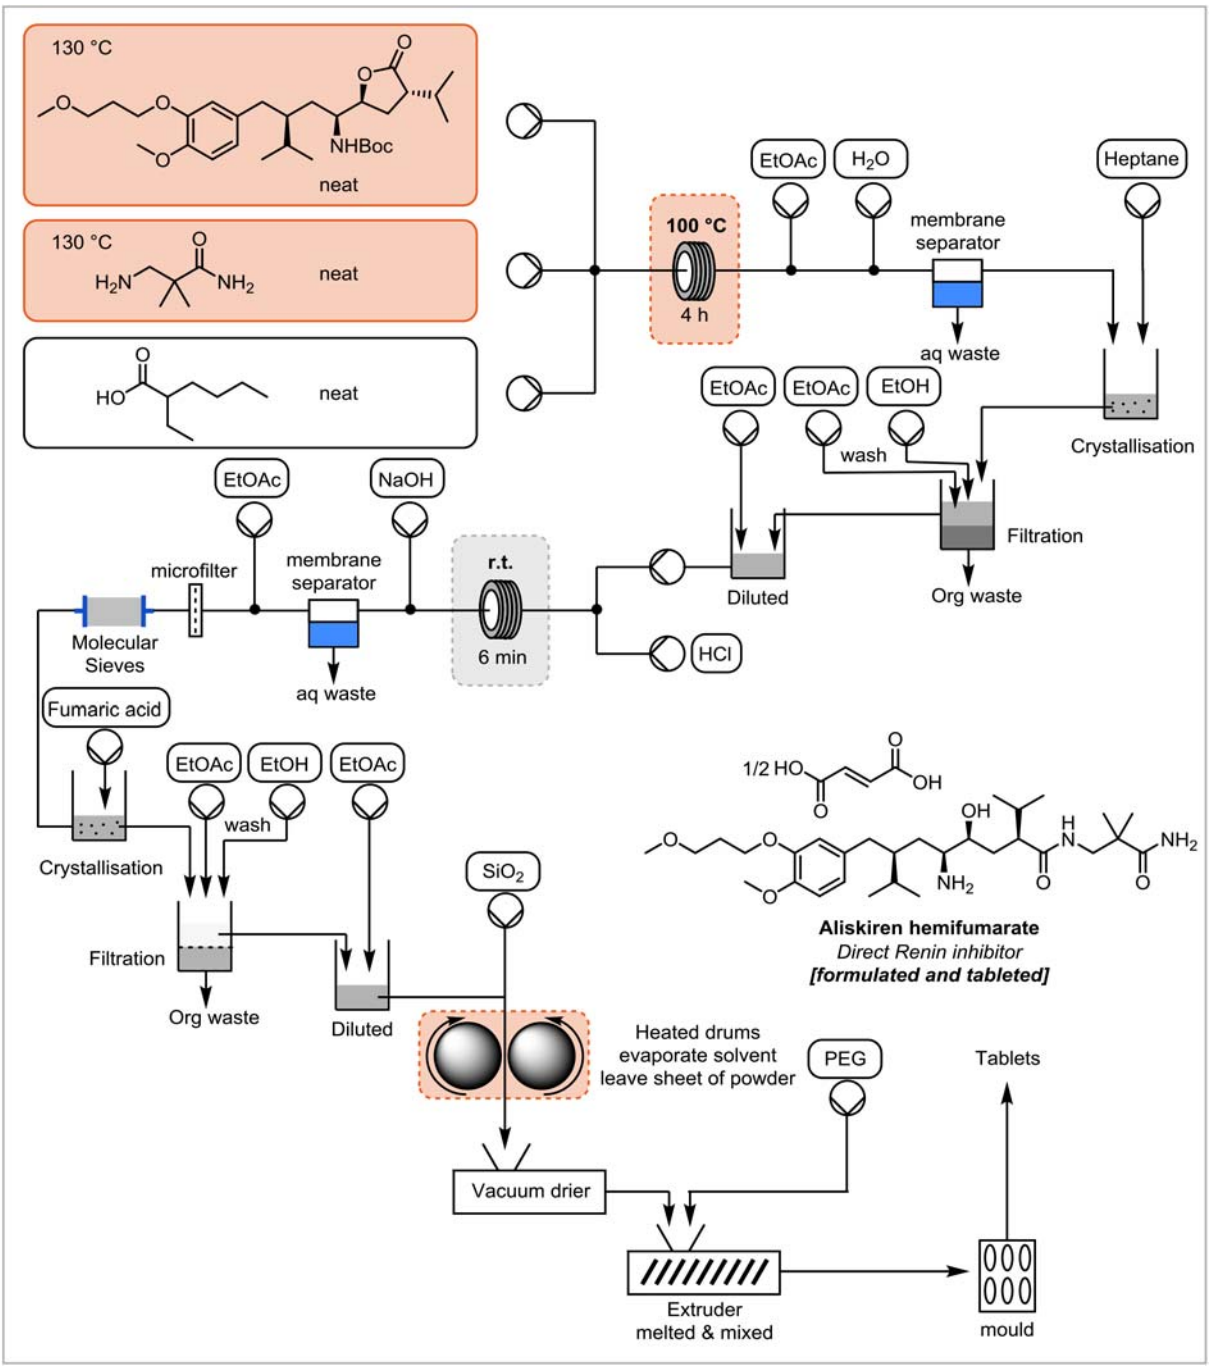
Scheme 78 Continuous flow multistep synthesis of diphenylhydramine.[99]

time monitoring, crystallization, and formulation of four different drug products (Schemes 80 and 81). By connecting a reactor module to a liquid–liquid extractive workup and subsequent charcoal filtration, Diphenhydramine could be crystallized as the hydrochloride salt in the first module. The synthesis of Lidocaine also took place in four modules. This time two reactor modules were required prior to liquid–liquid extraction and crystallization.

For the synthesis of Diazepam a total of six modules were daisy-chained together. In the first two reactor modules the Diazepam was synthesized. This was followed by liquid–liquid extraction (module 3), charcoal-bed filtration (module 4), acidification and extraction (module 5), and final crystallization (module 6) to provide the CNS depressant. Finally, a total of seven modules were used to prepare Fluoxetine. A similar configuration was used to that of Diazepam but now with a liquid–liquid extraction module between the initial two reactor modules. Overall the compact, reconfigurable device for the on-demand synthesis of health-care products is a very exciting prospect. One could imagine these devices serving to support remote or third-world populations.

Efavirenz is an antiretroviral used for the treatment of HIV. It features a trifluoromethyl group, which was discovered through SAR to modulate binding affinity through altering the pK_a of the carbamate H-bond donor. In the continuous flow multistep synthesis of this compound the CF_3 was introduced as an acyl electrophile (Scheme 82).[102] Treatment of 1,4-dichlorobenzene with butyllithium resulted in directed-ortho-metallation at the 2 position before quenching with the morpholino-CF_3-amide to give the desired fluorinated building block in 87% yield. This trifluoroketone then became the electrophile for a lithiated alkyne. The alkynyl alcohol next underwent an impressive O−C and N−C bond formation by passage through a column packed with sodium cyanate. The first step here presumably being attack of the alcohol on the cyanate followed by a ring closing S_NAr process. Overall, Efavirenz was delivered in 45% yield through this process.

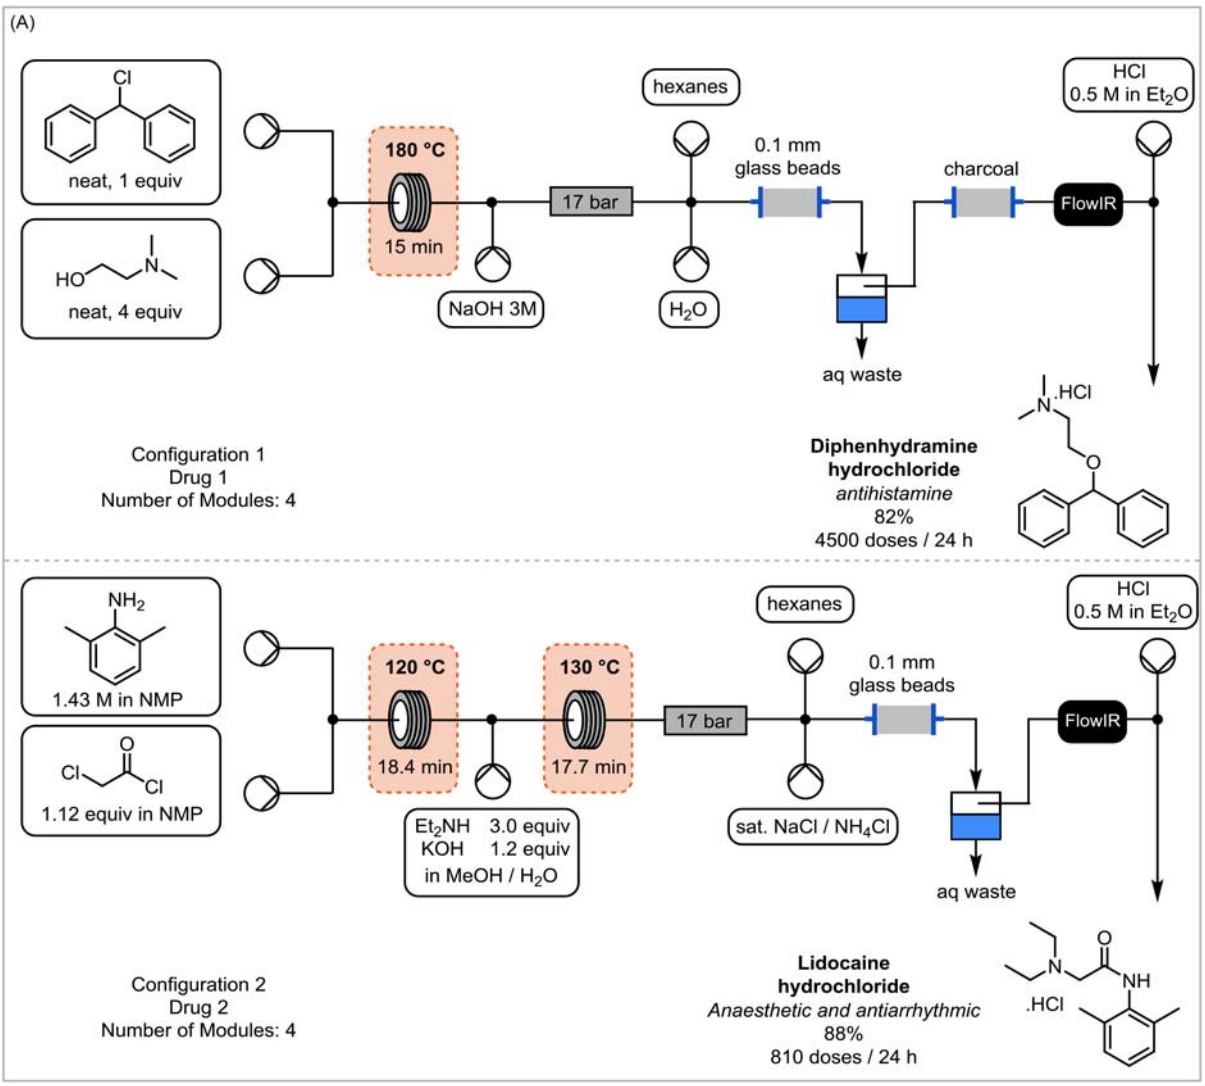
Perhaps the most elaborate and intricate continuous flow synthesis to date is that designed for Merclinertant, a neurotensin receptor 1 antagonist (Schemes 83–85).[104] The synthesis features the flow preparation of two fragments followed by their unison



Scheme 79 Continuous flow multistep synthesis included drug formulation of Aliskiren.[100]

also under flow conditions. The synthesis of the pyrazole fragment commences with the O-acylation of 1,3-cyclohexadione (Scheme 83). This then passed through a column-containing polymer-supported DMAP which induced an O to C acyl migration. The formed tricarbonyl was then treated with iodine to promote iodination, elimination, and aromatization. The resulting trisubstituted diphenol compound was then methylated using dimethyl carbonate prior to undergoing a Claisen condensation with diethyl oxalate. The resultant 1,3,4-tricarbonyl was then transformed into the pyrazole product with a quinolone hydrazine under acidic conditions. Here liquid–liquid phase separation was used for the inline purification of the pyrazole product. To complete the fragment the ethyl ester was saponified at high temperature.

The adamantyl fragment was also prepared continuously (Scheme 84). Starting from the parent adamantanone, ethylmagnesium bromide was added. The formed propargyl alcohol then participated in an acid-induced Ritter reaction followed by a 5-



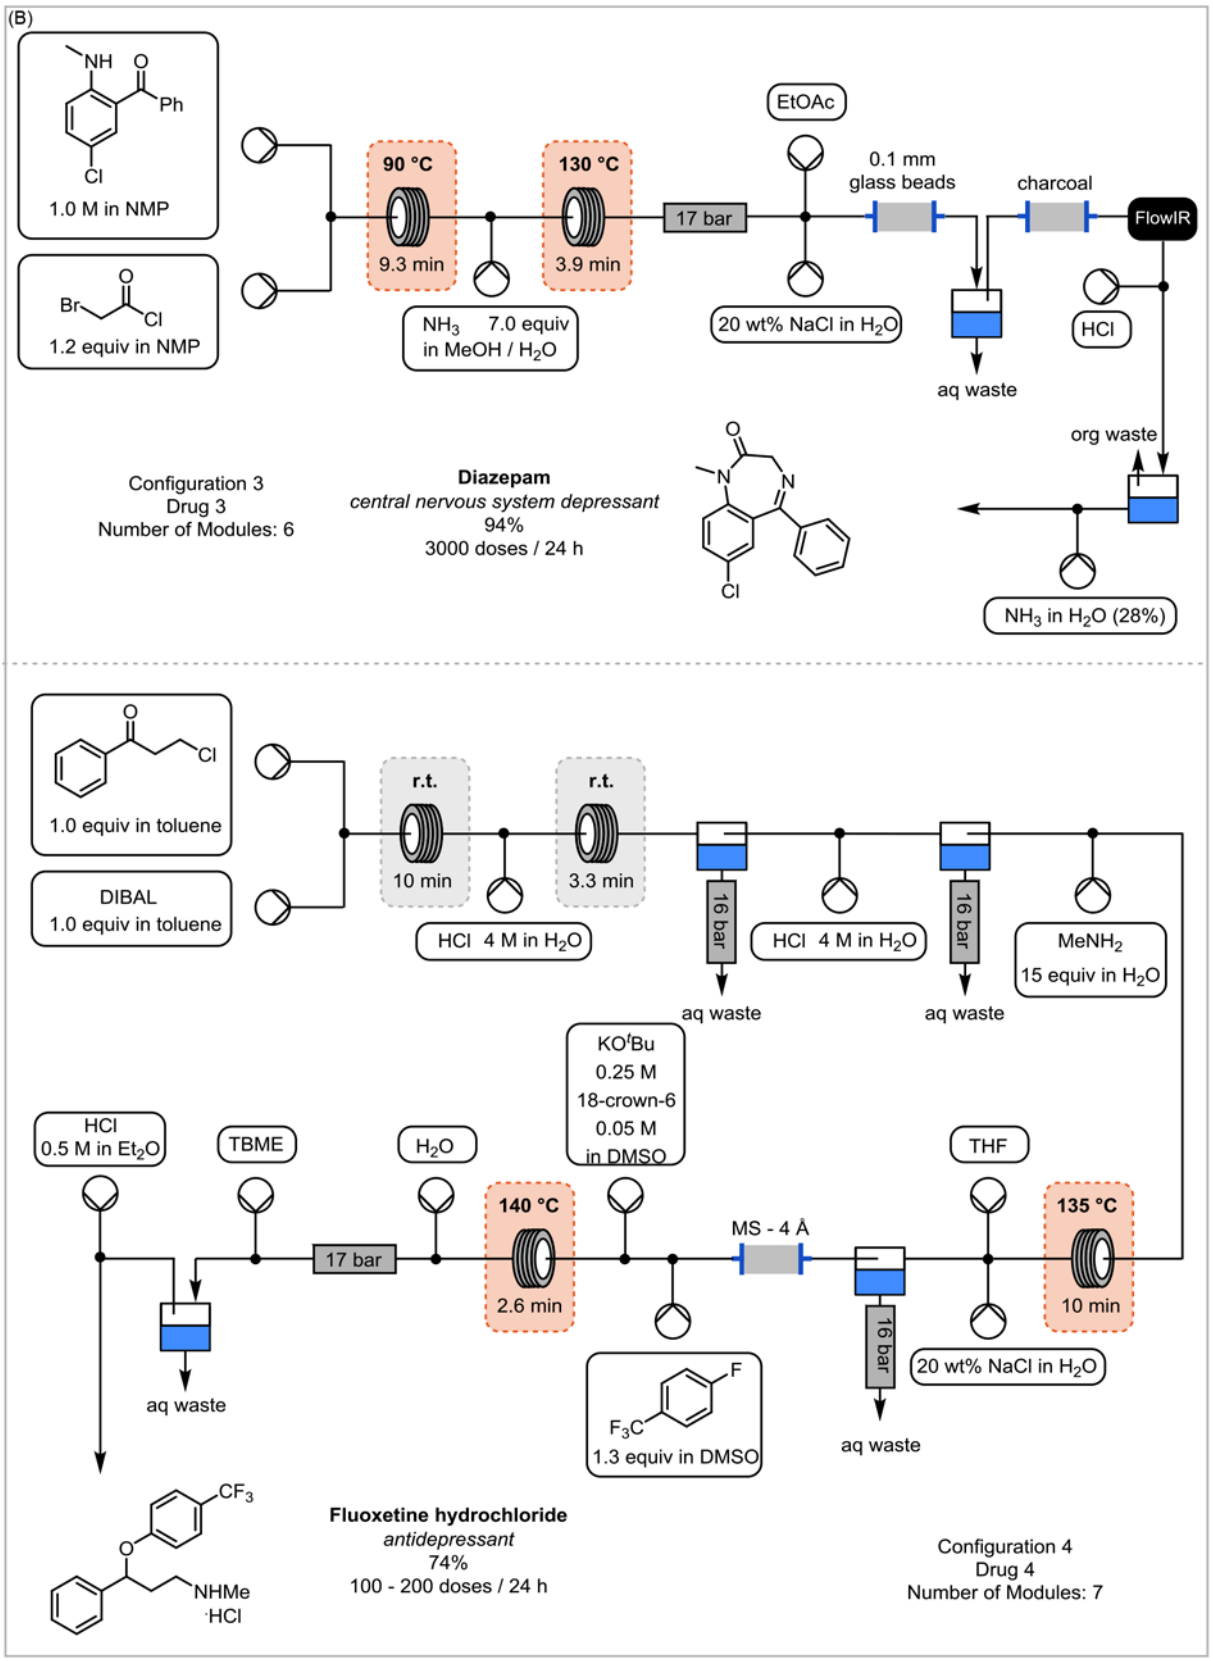
Scheme 80 Modular approach for the production of Diphenhydramine and Lidocaine.

exo-dig cyclization. The spirocyclic product then undergoes ozonoylsis of the exo-double bond before ring opening to provide the 2-aminoadamantane-2carboxylic acid fragment.

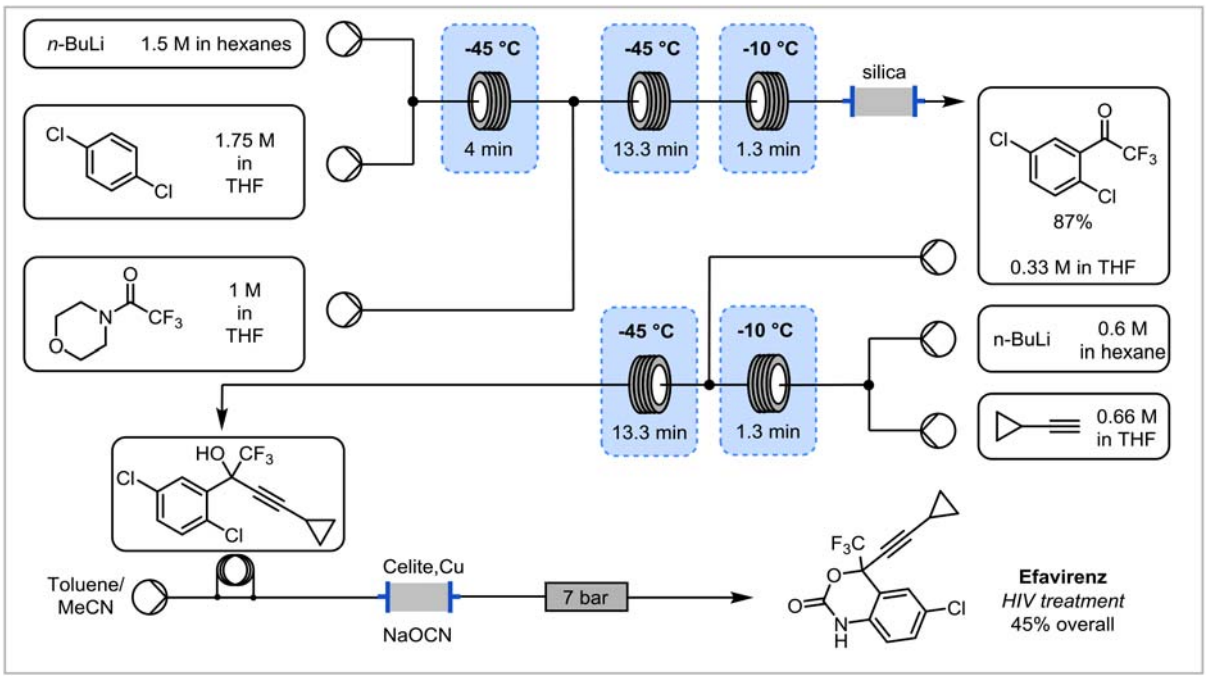
Fragment unison took place through the use of in situ generated phosgene (Scheme 85). Several precautions were put into place to ensure the controlled generation of this material, namely, the use of triphosgene, a more stable equivalent available in solid form. Second, inline flow-IR monitoring was used to monitor phosgene concentration. In the event, passage of triphosgene, DIPEA, and the pyrazole carboxylic acid fragment through a heated initiation coil resulted in the formation of the activated acid. This activated species was then intercepted with the amino adamantane to afford the Boc-protected material. Deprotection was carried out in batch by simply stirring the advanced intermediate over quadrapure (polymer supported) sulfuric acid for 18 h.

This machine-assisted synthesis of Merclinertant demonstrates several of the key considerations required in the planning of a multistep flow process. While other processes described within this section demonstrate some of these aspects, the synthesis of Merclinertant highlights many of them all in one example. Some of these considerations can be quite subtle to those unfamiliar with the practicalities of flow chemical processing.

Resetting of flow rates is a critical practice. As a multistep process moves to higher complexity more streams will be added to the flow circuitry. With more streams comes a higher cumulative flow rate and subsequently, residence times in typical reactor coil sizes (1, 2, 5, 10, and 20 mL) rapidly become shorter. In addition, long lengths of narrow bore tubing can cause "pressure drops" that can be problematic. A common solution to this problem then is to put a break in the flow circuit where the material can be dropped into a reservoir and repumped out to the next stage. This resetting process can be seen in many flow chemistry examples, especially when a continuous process is reported, that is, not using single-shot syringe pumps.



Scheme 81 Modular approach for the production of Diazepam and Fluoxetine hydrochloride.[101]



Scheme 82 Continuous flow multistep synthesis of Efavirenz.[102]

Solvent changes or compatibility planning is another key consideration. Usually the latter is the most demonstrated, where a common solvent is found that is viable for all steps. In instances where this is not possible then solvent switching modules can be used in order to change from one solvent to another.[105] This practice is still far from widespread at the discovery and early pilot flow scales.

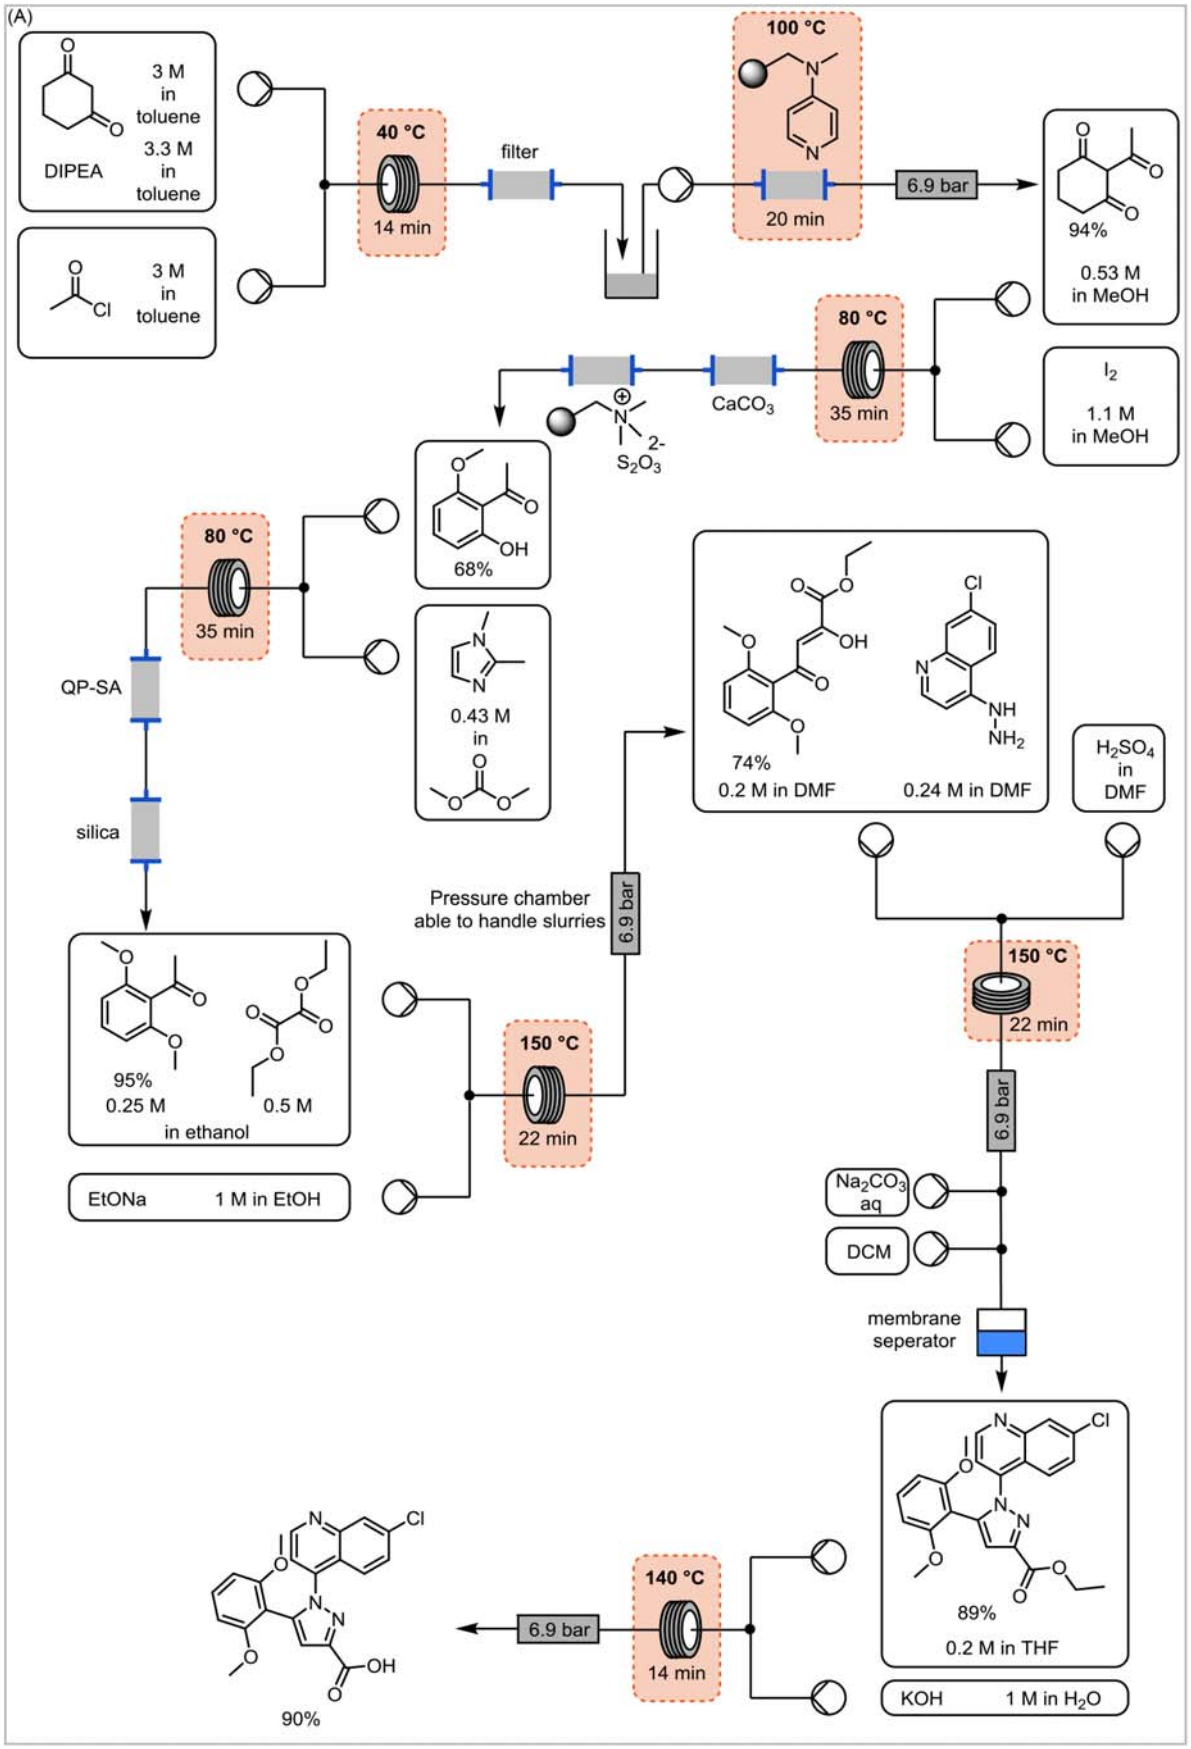
Inline purification through scavenging cartridges, or now, more commonly liquid–liquid extraction is also a critical part of a complex synthesis process. By-products or surplus reagents from one step can negatively affect the subsequent one, and therefore careful planning is needed to ensure that these can be removed.

In addition, attention should be paid to the possibility of forming solid particulates that can block the reactor entirely—this can be catastrophic for the process if the pumps are not pressure respondent.[106] However, with all of these considered several exciting and challenging targets have already been accomplished, and it is clear that the attention is now focused on true manufacturing processes using this exciting technology.

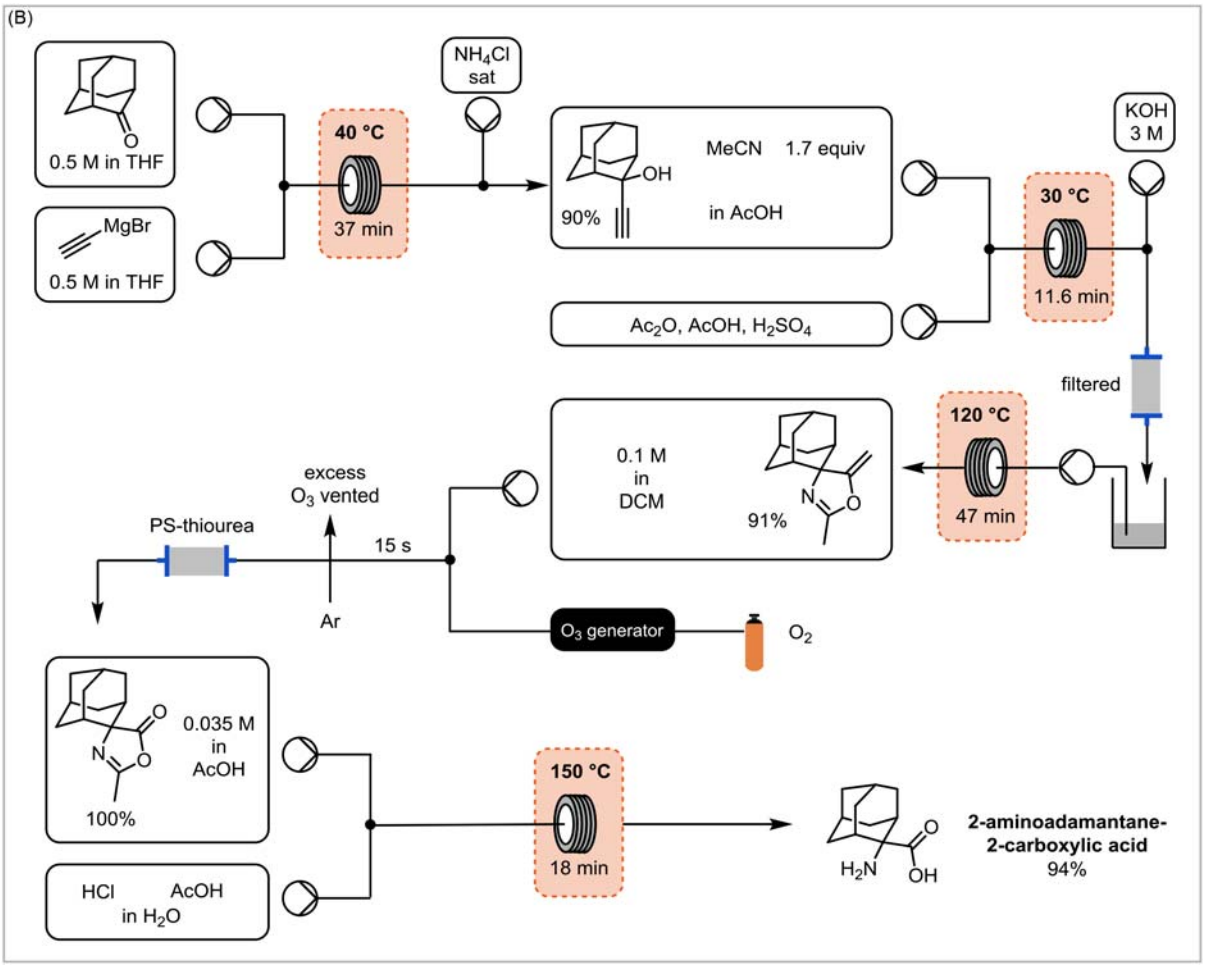
1.06.6 Conclusion and Outlook

We hope to have provided an overview of the capabilities afforded by running reactions in continuous flow mode. While we are not advocating a straight swap of flow for batch (in fact, quite the opposite), we are certainly excited by many of the developments and would advocate careful consideration of flow as an alternative technique to batch. These developments have been driven by open-minded individuals, willing to explore the potential benefits of the technique. Such individuals have either been chemists stepping into the area of chemical engineering or vice versa. Certainly the most impressive feats stem from collaboration between the two disciplines. It is clearly important to encourage more frequent collaborations of this nature in the future.

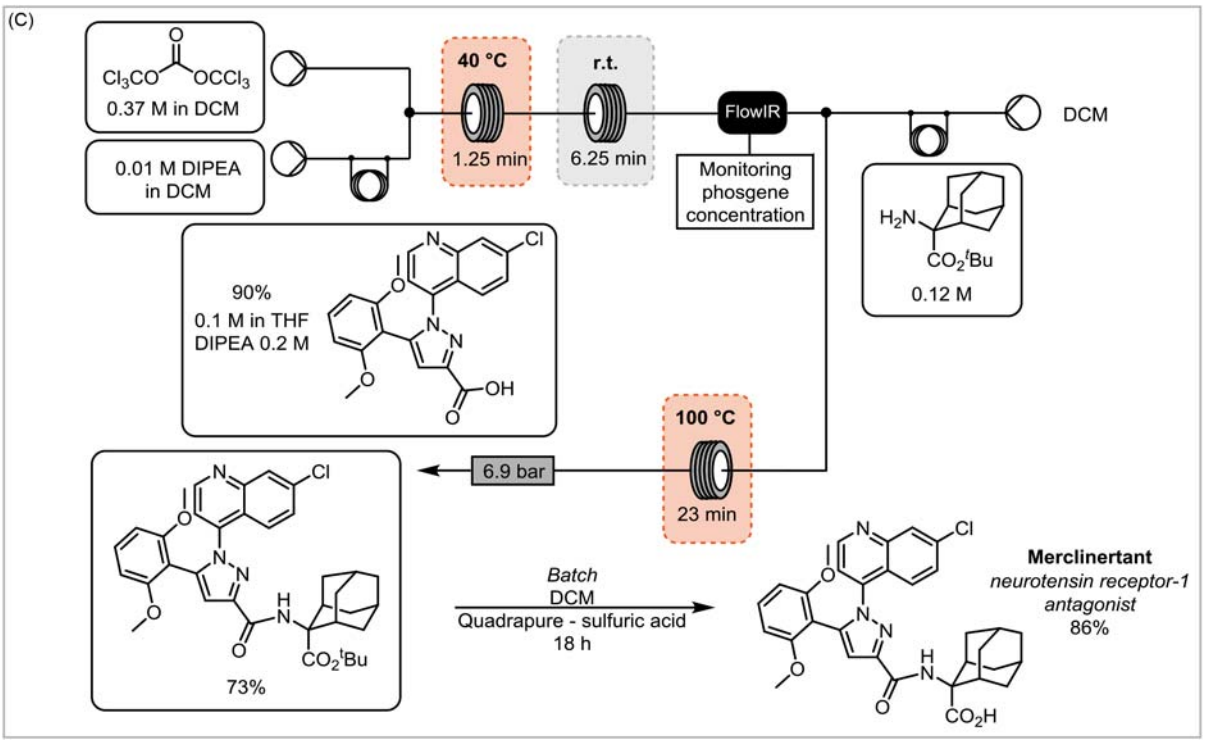
In this article we have provided an introduction to the key drivers for adopting flow, at least those drivers directly relevant to the synthesis and isolation of compounds. We then provided a survey of some of the hazardous chemistry reported before moving on to more elaborate setups that can make and screen compounds, optimize reactions and even synthesize, purify, and formulate tablets. For the latter parts of this article, computer control and statistical modeling have been important to the synthesis process. This trend will likely continue, as machines become smarter and more effective at helping humans perform mundane tasks. It is tempting and even worrying to predict a future where machines make man obsolete in the laboratory. In reality, this is still far from the horizon! Machines, or more specifically, computer control units operating on algorithms, require a reliable set of input data, without which the predictive power and modeling will likely always be "hit-and-miss." Due to nonstandardization of reported data and even a lack of understanding of some seemingly simple reactions, it is unlikely that we will provide sufficiently good input data to the machines in the near future. Machines can however play a critical supporting role though. They can conduct repetitive measuring and manipulation task with far greater accuracy, reproducibility, and even stamina. Machines can work 24/7! Embracing machines to aid us



Scheme 83 Multistep flow synthesis of the pyrazole fragment.



Scheme 84 Continuous flow multistep synthesis of adamantyl fragment.[103]



Scheme 85 Continuous flow multistep synthesis of Merclinertant.[104]

with such tasks will free us up with more time to fulfill tasks that machines cannot (yet) do, such as designing and planning syntheses and processes.

So where next for flow chemistry? Clearly the technique has utility and longevity with industry, but as it is "just" a technique it likely has to become more inventive to maintain ongoing academic development. Certainly continuous flow photochemistry and electrochemical methods have a productive overlap that will continue to develop. For traditional thermal methods, the challenges are now to discover new reactions and reactivity through this technique; "flash" chemistry seems to be an area that can deliver on this front.[107] Adoption and application to other areas of chemistry such as supramolecular materials, inorganic complexes, polymer synthesis, and nanoparticle preparation will provide interest for academics in the years to come.

Another important question is where do the students come from with flow experience to then become industrial chemists? Certainly the active research groups in this area can continue to supply some students—but can they meet the demand, especially as more companies and chemical sectors adopt flow practice? Should flow chemistry be taught at the undergraduate level or should it be taught once employees arrive at a company? Can the setting-up and running of an experiment in flow be carried out by a technician, or technical service? Our experience would suggest that this is not the case; there are always some useful observations made by running processes in flow. Certainly, once you have enough experience you can begin to think in a flow processing mind-set and this can take you in directions that you would perhaps otherwise not consider. We hope that this brief article on the topic has served to whet your creative appetite to flow processing for organic synthesis.

1.07.1 Introduction

The concept of *bioisosterism* refers to frameworks, fragments, atoms, and groups presented in the structures of bioactive compounds that have similar molecular volume, shape, electronic distribution, and physical–chemical properties. It is a molecular modification strategy, based on the replacement of interchangeable molecular fragment(s) (atoms, functional groups, subunits) having similar steric–electronic profile and comparable physical–chemical properties.[1–6]

Bioisosterism is a key strategy in medicinal chemistry aiming to promote molecular modifications in a starting structure (i.e., hit, lead, prototype), in order to improve pharmacokinetic (PK), pharmacodynamic (PD), and toxicological profiles. It is considered also strategic to circumvent intellectual properties issues. In summary, bioisosterism is applied by medicinal chemists to remove unwanted side effects or toxicity, to improve ADME, and to enhance selectivity and potency by a target bioreceptor. In a few cases, the motivation for the use of bioisosterism concept results from the need to overcome patent barriers, being mainly used in the search for novel structural analogues of an innovative drug.[7–10]

A basic principle in medicinal chemistry is that structurally similar compounds have similar physicochemical properties and similar biological activities. This principle is the core for the application of bioisosterism. Consequently, any bioisosteric replacement must consider steric and size attributes, electronic characteristics, comparative solubility, and hydrophobic effects between the elected interchangeable groups or fragments.

However, success by application of bioisosterism requires some knowledge of the structure activity relationships in the parent molecule. In this context, the understanding of pharmacophoric and auxophoric contributions of each of the molecular subunits that comprise the structure of a hit, a lead, or a prototype, is important. Similarly, the metabolic inactivation pathways, as well as the main structural factors determining the physical–chemical properties that regulate their bioavailability and their adverse side effects, direct or not, must be known.

Bioisosterism resulted from the use of the principle of isosterism, developed by Langmuir in 1919, studying the chemical behavior and reactivity of certain atoms and groups with the same number of valence electrons, therefore isoelectronic (e.g., N_2 and CO).[1]

In 1951, Friedman introduced the term bioisosterism to describe the influence of isosteric replacements upon biological activity. He established the concept that if a compound fits the broadest definition for isosteres and has the same type of biological activity, then it can be considered a bioisostere.[11]

Bioisosterism, in its first applications as a molecular modification strategy, has been benefited by the hydride displacement law, an empirical rule formulated by Grimm in 1925.[12] It states that the addition of a hydrogen atom with a pair of electrons (i.e., hydride) to an atom, produces a pseudoatom presenting the same physical properties as those present in the column immediately behind on the Periodic Table of the Elements for the initial atom (**Fig. 1**). In accordance with Grimm's hydride displacement law, any atom belonging to groups IVA, VA, VIA, and VIIA on the periodic table change their properties by adding a hydride, becoming isoelectronic pseudoatoms.

Further work by Erlenmeyer and Hinsberg broadened the principle of isosterism, defining it as atoms, ions, or molecules in which the peripheral layers of electrons can be considered identical.[13]

In 1970, Alfred Burger classified and subdivided *bioisosterism* into two categories: classic and nonclassic.[14] The classic bioisosterism includes atoms, groups, and radicals having peripheral layers of electrons with same valence. They are arranged in mono-, di-, tri-, or tetravalent atoms or groups (**Table 1**). This classification also covers the rings equivalents concept. The nonclassical bioisosterism is the most challenging type of isosteric relationship (**Table 2**). It includes the strategies of retroisosterism, ring opening, ring closure or annelation, and equivalent functional groups.[4–6,9] Another unique contribution of Burger had been the

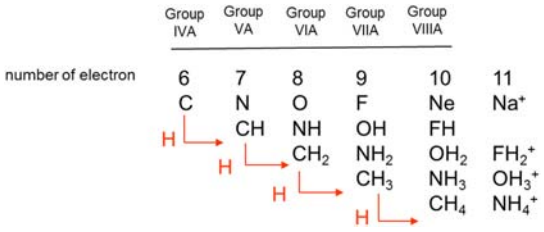

Fig. 1 Grimm's hydride displacement law.

Table 1 Classic bioisosteric groups and atoms

Monovalent	*Divalent*	*Trivalent*	*Tetravalent*
F, OH, NH_2, CH_3, OR	$-CH_2-$	$-CH-$	$=C=$
Cl, SH, PH_2, SiR_3, SR	$-O-$	$=N-$	$=Si=$
Brx	$-S-$	$=P-$	$=N^+=$
I	$-Se-$	$=As-$	$=P^+=$
	$-Te-$	$=Sb-$	$=As^+=$
			$=Sb^+=$

Table 2 Nonclassic biososteres

$-CO-$	$-COOH$	$-SO_2NH_2$	$-H$	$-CONH-$	$-COOR-$	$-CONH_2$
$-CO_2-$	$-SO_3H$	$-PO(OH)NH_2$	$-F$	$-NHCO-$	$-ROCO-$	$-CSNH_2$
$-SO-$	Tetrazole					
$-SO_2NR-$	$-SO_2NHR$		$-OH$		$-$Cathecol	
$-CON-$	3-Hydroxy-isoxazole		$-CH_2OH$		$-$Benzimidazole	
$-CH(CN)-$	3-Hydroxy chromene		$-NHCONH_2$			
R–S–R′	$=N-$		$-NH-CS-NH_2$			$-C_5H_4N$
(R–O–R′)						
R–N(CN)–R′	$-C(CN)=$		$-NH-C(=CHNO_2)-NH_2$			$-C_6H_5$
R–C(CN)(CN)–R′						$-C_4H_4N$
	$-$Halogen					C_4H_4S
	$-CF_3$					
	$-CN$					
	$-N(CN)_2$					
	$-C(CN)_3$					

assumption that to be a bioisostere, compounds need to affect biochemically associated systems as agonists or antagonist. Consequently, for the first time, the bioisosterism concept was not related to similar activity, but with the ability to be recognized by a same bioreceptor.[15]

The Main Factors to be Considered in Terms of a Planned Bioisosteric Substitution Include:

1. Molecular size and volume, electronic distribution of atoms, and considerations on the degree of hybridization, polarity, bond angles and distances, and inductive and mesomeric effects;
2. Lipid and aqueous solubility;
3. Chemical reactivity of the interchangeable isosteric groups or atoms or subunits, anticipating their main changes in the biotransformation process, including those related to the formation of eventual toxic metabolites;
4. Conformational factors, including the differentiating in the ability to form inter- and/or intramolecular H-bonding.

In the following, we will discuss in this article some selected examples of both nonclassical and classical bioisosterism, in order to give an idea of the versatility of this molecular modification strategy, used by medicinal chemists in the steps of ligand design, planning of a congeneric series, lead optimization, and as key tool in the identification of new drugs that are authentic therapeutic copies or me-too.[16]

1.07.2 Bioisosterism in Nature

Bioisosterism is a common phenomenon found in nature as a form of increasing chemical diversity (Fig. 2). The comparison between the structures of serine (1) and cysteine (2) or tyrosine (3) versus hystidine (4) is a nice example to illustrate isosterism

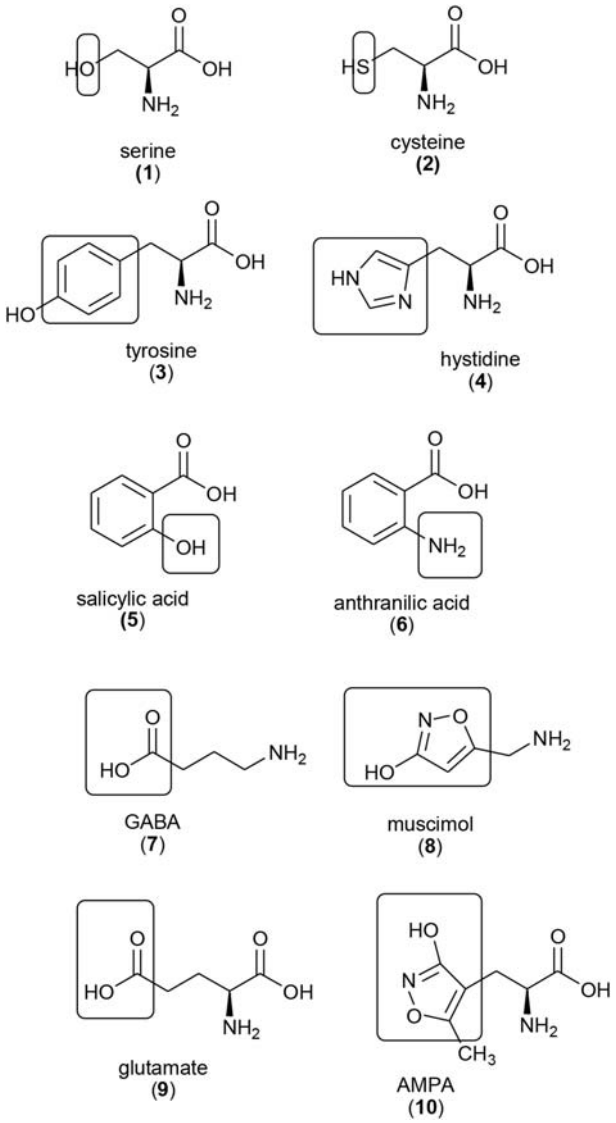

Fig. 2 Examples of classic and nonclassic bioisosterism in nature.

of divalent group (O × S) and equivalent rings, respectively, widely distributed in nature. Salicylic acid (**5**) and anthranilic acid (**6**) are examples of monovalent bioisosteres (OH × NH_2), which boosted the design of important nonsteroidal antiinflammatory drugs. Examples of nonclassic bioisosterism can also be found in nature, as exemplified by the functional group isosterism between GABA (gamma-aminobutyric acid, **7**) and muscinol (**8**), or between neurotransmitters glutamate (**9**) and AMPA (alfa-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, **10**) (Fig. 2).

1.07.3 Functional Bioisosterism

Starting from a peptide-based molecule (**11**) identified as cathepsin K inhibitor with poor metabolic stability, Gauthier and coworkers [17] proposed the bioisosteric replacement of amide function by a trifluoroethylamine subunit, resulting in the design of compound **12** (Fig. 3). This peptide-mimetic derivative (**12**) showed great inhibitory potency against cathepsin K, with improved selectivity profile (cathepsin K versus cathepsin B) and better metabolic stability (Fig. 3). Further optimizations resulted in the discovery of odanacatib (**13**) indicated for the treatment of osteoporosis.

A classical example of functional bioisosterism is the interchangeable relationship between the OH group of phenol subunity and sulfonamide. Larsen and Lish,[18] looking for new compounds able to modulate the catecholamines receptors proposed the replacement of OH-phenolic, presented in the structure of adrenaline simplified analogue **15**, by the NH–SO_2CH_3 group. This structural modification resulted in a phenylmethylsulfonamide fragment (**16**) with a strong structural similarity with

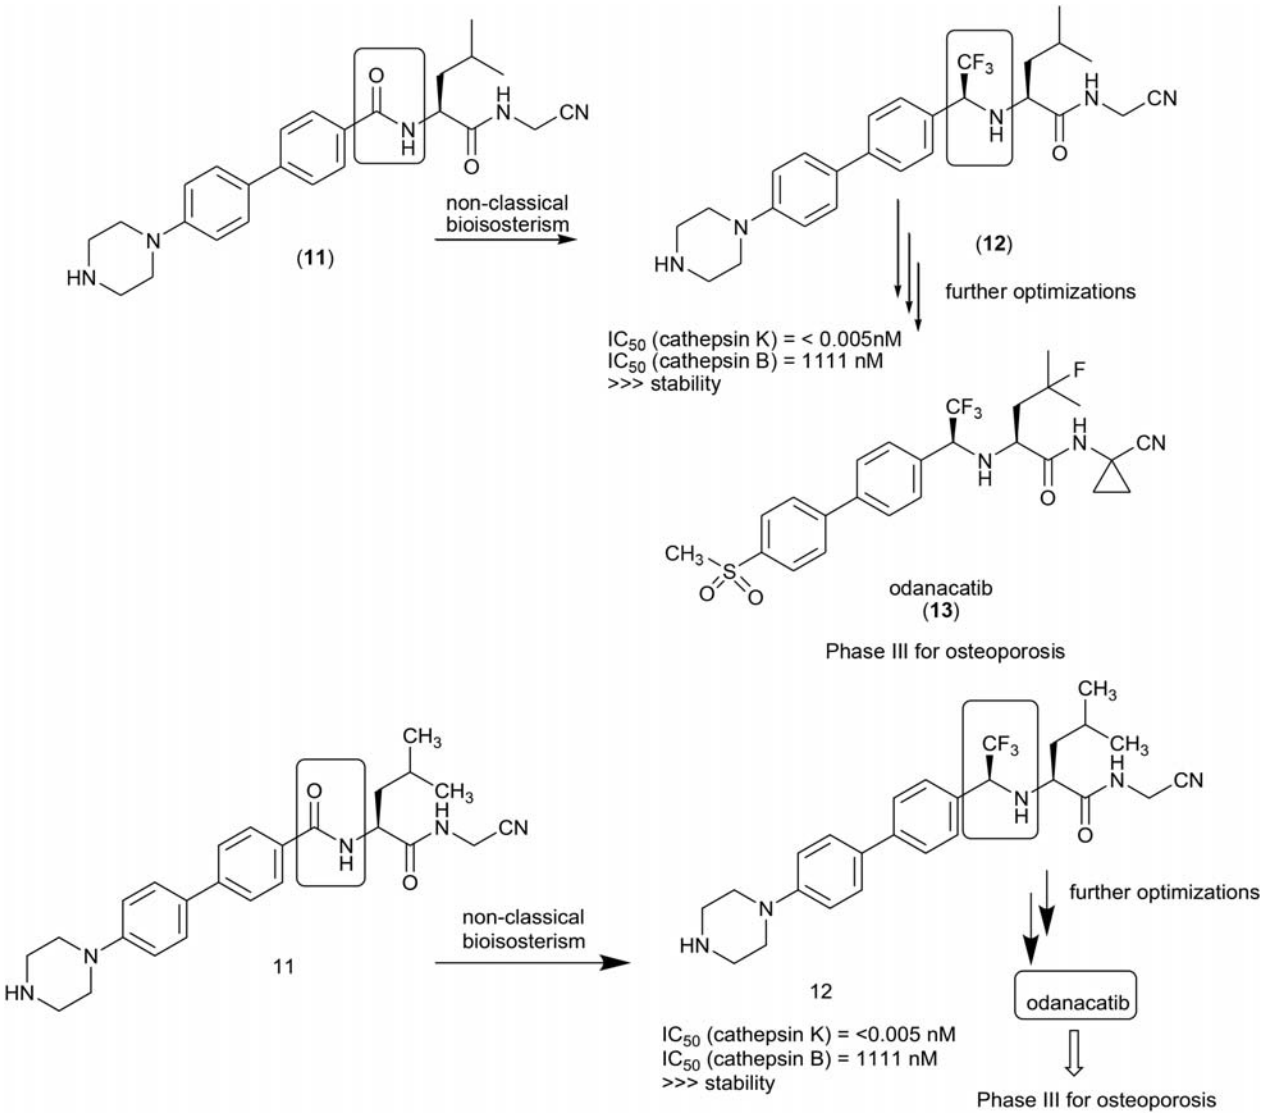

Fig. 3 Nonclassic bioisosteric relationship between the amide (**11**) and trifluoroethylamine (**12**) subunits in the genesis of cathepsin K inhibitors.

adrenaline (**14**) and **15**. Despite the differences considering steric and size attributes, the phenol and arylsulfonamide share similar acidity, due to the similarity between the pK_a of the **OH**-phenol and **NH**-sulfonamide function, that is, 9.1 and 9.6, respectively. Therefore, for catecholamine receptors both fragments are considered interchangeable and constitute a nice example of functional bioisosterism (Fig. 4).

More recently, the same bioisosteric replacement was proposed by Lin and coworkers.[19] The exchange of phenol group (**17**) by an arylsulfonamide (**18**) resulted in a bioisoster fourfold more potent than the parent prototype, acting as an antagonist of gonadotropin hormone receptors (Fig. 5).

An interesting example of nonclassical bioisosterism involving the phenol function, more specifically the 2,6-difluorophenol, was described by Demopoulos from the University of Thessaloniki, Greece. This author and coworkers,[20] searching for new aldose reductase inhibitors had previously indentified the carboxylic acid derivative **19**. From this lead compound and aiming to improve lipophilicity, the authors proposed the replacement of carboxylic acid by a more lipophilic bioisosteric fragment. Therefore, the acetic acid subunit (**19**) was replaced by a 2,6-difluorophenol, resulting in compound **20**, that has been shown to be five times more potent as aldose reductase inhibitor and almost threefold more lipophilic (Fig. 6).

The same parent prototype (**19**) was optimized by Papastavrou and coworkers,[21] with the introduction of 1-hydroxypyrazole ring (**21**) as new acetic acid nonclassical bioisostere (Fig. 7). This interchangeable isosteric replacement resulted in an equipotent inhibitor of aldehyde dehydrogenase (ALDH)-2 and in an expressive increased in the inhibition of ALDH-1. Advantages pointed out in favor of 1-hydroxypyrazole ring (**20**) as an isostere of carboxylic acid (**18**) are that it has less acidic property (pK_a 6.98 versus pK_a 4.37) and higher lipophilicity, resulting in greater potential to permeate more freely through biological barriers.

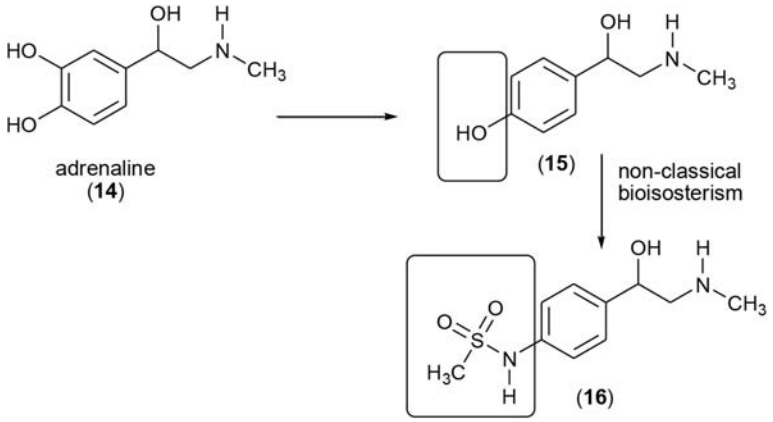

Fig. 4 Nonclassic bioisosteric relationship between the phenol (**15**) and phenylsulfonamide (**16**) in the genesis of adrenaline (**14**) analogues.

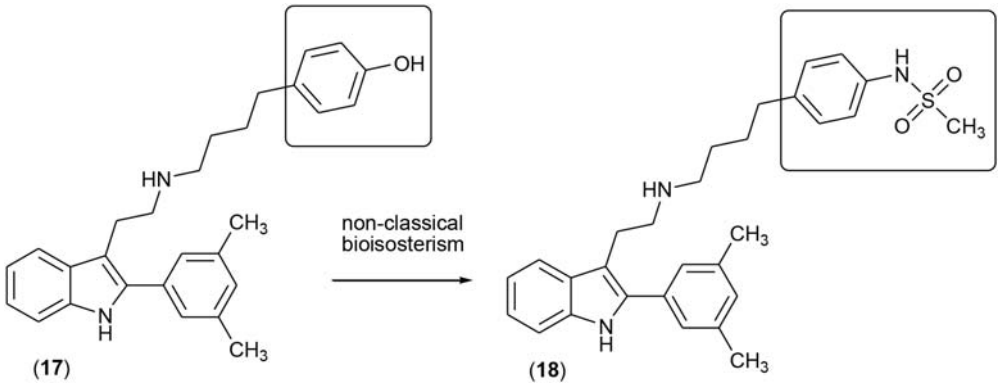

Fig. 5 Example of functional bioisosterism between PhOH (**17**) and $PhNHSO_2CH_3$ (**18**).

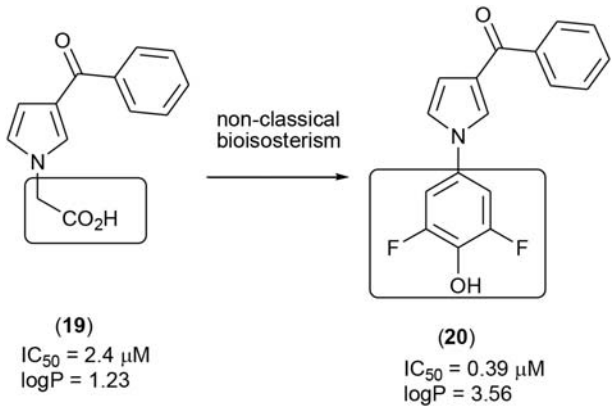

Fig. 6 Example of functional bioisosterism between the carboxylic acid group (**19**) and 2,6-difluorophenol subunit (**20**).

Other important examples of carboxylic acid bioisostere can be represented by the 3-hydroxy-1,2-oxazol-4-yl (**10**), 4-hydroxy-1,2,3-oxadiazol-5-yl (**22**), and 4-hydroxy-1,2,3-tiadiazol-5-yl moieties (**23**). These moieties can be found in the structures of AMPA (**10**) and TDPA (**23**), maintaining a nonclassical boisosteric relationship with carboxylic acid presented in glutamate (**9**), the agonist of ionotropic glutamate receptors (Fig. 8).[22]

Sulfonic and phosphonic acids are considered common carboxylic acid isosteres, and this kind of nonclassical bioisosterism can be identified in nature comparing the structures of the amino acids beta-alanine (**24**), taurine (**25**), and ciliatine (**26**). The same bioisosteric relationship can be also identified comparing the structures of baclofen (**27**), an agonist of $GABA_b$ receptors used as antispastic agent, and saclofen (**28**) and phaclofen (**29**), both identified as a $GABA_b$ antagonists (Fig. 9).[23]

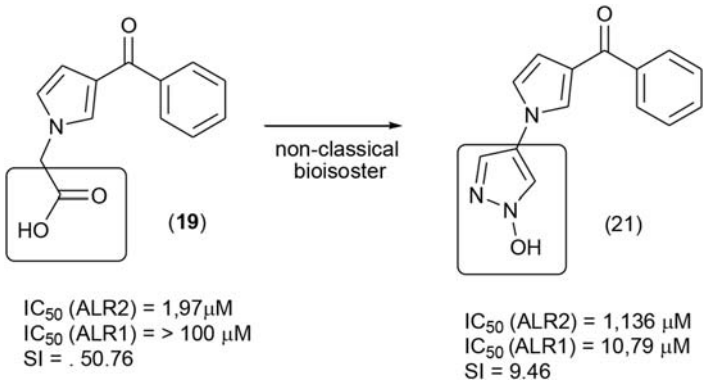

Fig. 7 Example of functional bioisosterism between the carboxylic acid (**19**) and 1-hydroxypyrazole ring (**21**).

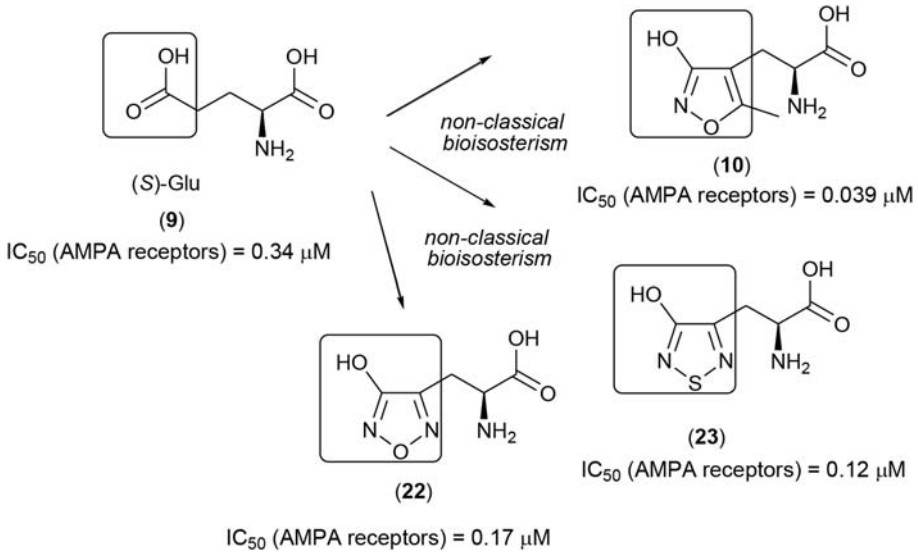

Fig. 8 The nonclassical bioisosterism of functional groups involving a carboxylic acid (**9**) and the 3-hydroxy-1,2-oxazol-4-yl (**10**), 4-hydroxy-1,2,3-oxadiazol-5-yl (**22**), and 4-hydroxy-1,2,3-thiadiazol-5-yl (**23**) moieties.

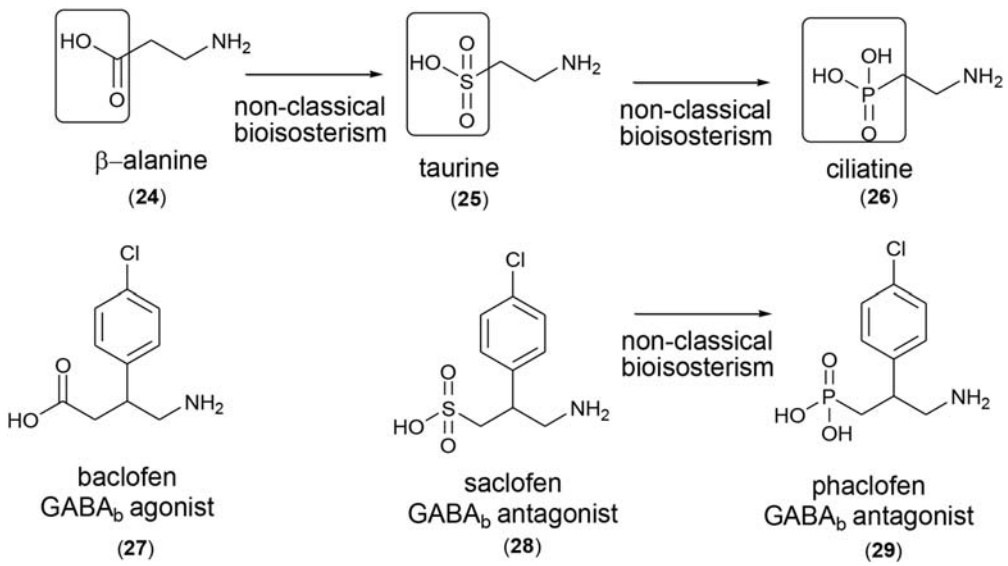

Fig. 9 Examples of nonclassical bioisosterism between carboxylic, sulfonic, and phosphonic acids subunits.

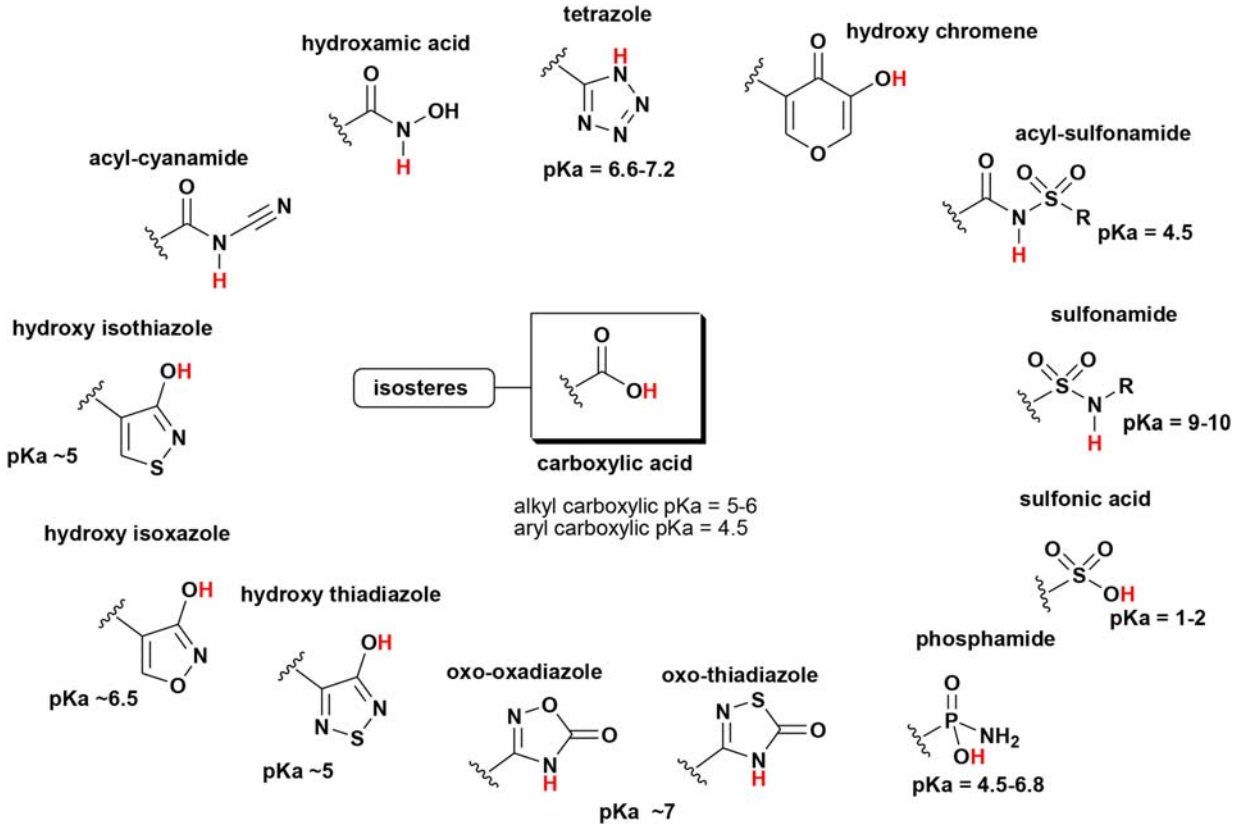

Fig. 10 Examples of carboxylic acid bioisosteres having different pK_a.

In fact, many examples of carboxylic acid bioisosteres have been previously described in the literature.[5,9,24] Fig. 10 illustrates the most common fragments or groups considered interchangeable with carboxylic acid, maintaining a nonclassical bioisosteric relationship with this important functional group in medicinal chemistry.

Others examples of functional bioisosterism can be discussed. An interesting one was reported by Koller and coworkers.[25] The authors described aromatic **N** versus aromatic **F** bioisosterism and their applicability to replace natural bases of nucleic acid structures, generating nonpolar nucleoside isosteres (Fig. 11).

Another example can be demonstrated by the work performed by Sheng and coworkers.[26] Searching for new antifungal agents, the authors proposed the replacement of **O** atom, present in the phenoxyalkylpiperazine side chain contained in the structure of fluconazole analogue **33**, by a triazolone ring (**34**). From these studies, a new nonclassical bioisosteric relationship was established, being demonstrated that the replacement of oxygen by triazolone could improve the water solubility without a loss of hydrogen bonding interaction with CYP51 (Fig. 12).

Guanidine (**35**) is a privileged molecular subunit, having frequently a low oral bioavailability, mainly due its high basicity. The proposal of replacement of the hydrogen atom linked to imine framework by monovalent electron withdrawing groups, such as cyano, nitro, acyl, and sulfonyl (i.e., **36**–**39**), have been demonstrated to be a great strategy to modulate guanidine basicity, resulting in the obtention of new scaffolds maintaining a functional bioisosterim relationship (Fig. 13).

Dmitriev and Ragulin[27] reported a curious potential functional bioisosterism. In order to prepare pseudo dipeptides, having structural similarity with certain fragments of β-amyloid peptides, the authors proposed the design of phosphinic acid oligopeptides (**41** and **43**) as a nonclassical isostere of amide subunit, and then synthesized peptidomimetics analogues of Arg-Glu (**40**) and Gly-Leu (**42**) (Fig. 14).

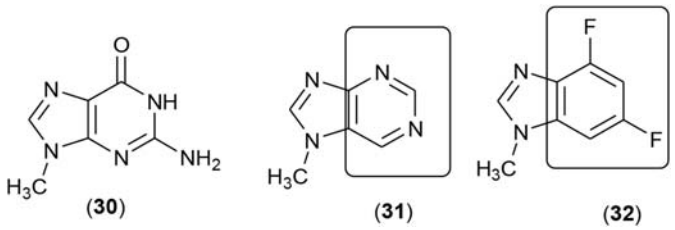

Fig. 11 Nonclassical bioisosteric relationship between aromatic-fluorine (**32**) and aromatic-nitrogen (**31**).

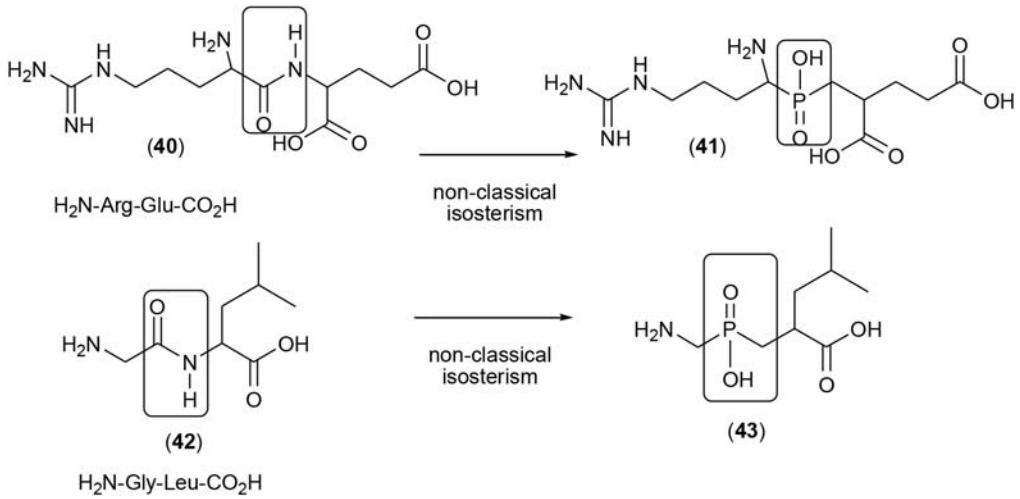

Fig. 14 Structures of dipeptides Arg-Glu (**40**) and Gly-Leu (**42**) and their phosphinic acidic pseudo peptides (**41** and **43**).

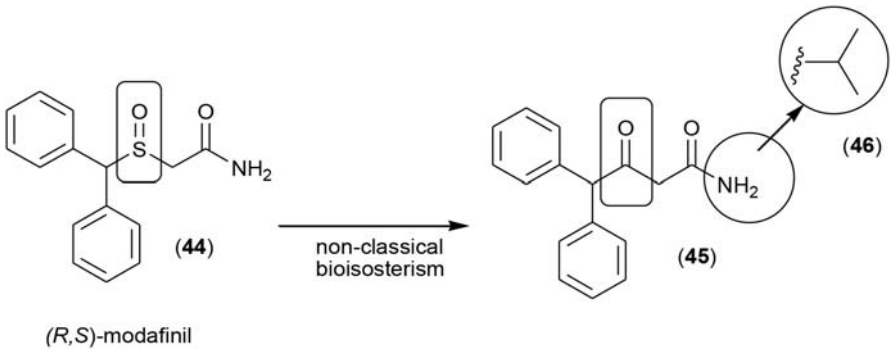

Fig. 15 Structures of (*R,S*)-modafinil (**44**) and its achiral nonclassical bioisosteres **45** and **46.**

A common functional bioisosterism is represented by **C═O × S═O** groups. Modafinil (**44**) is a chiral sulfoxide drug used in the treatment of excessive sleepiness caused by narcolepsy, sleep disorder, and obstructive sleep apnea. Aiming to design nonasymmetric modafinil analogues, Risi and coworkers[28] proposed the isosteric replacement of sulfoxide function by a carbonyl group. Evaluation of the comparative effect on the spontaneous and the electrically evoked tritiated serotonin efflux from rat cortical slices showed a loss of activity for compound **45**, which was restored modifying the primary amide (**45**) into the corresponding *N*-isopropyl derivative **46** (Fig. 15).

1.07.4 Functional Bioisosteres of Esters and Amides

Countless chemotypes or frameworks are isosteres of ester and amide functions.[9,29] The use of this type of bioisosterism is performed, basically, to circumvent metabolic instability of these functional groups, which are vulnerable to hydrolysis catalyzed by different enzymes (e.g., esterases, amidases, carboxyesterases, lipases) widely distributed in humans.

The oxazole ring, present in compound **47**, was introduced as nonclassical bioisostere of the ester group presented in the structure of prototype **48** (Fig. 16). This bioisosteric replacement has advantages like the increase in log*P* values and the enhancement in plasma metabolic stability.[30] Similarly, the pyrrole nucleus (e.g., **50**, Fig. 16) can work as functional and stable amide isostere (e.g., **49**, Fig. 16).[31]

Starting from a series of pyrimidinylthioacetanilides identified as HIV-1 nonnucleoside reverse transcriptase inhibitors, Li and coworkers[32] proposed the nonclassical bioisosteric replacement of amide functionality by a 1,2,3-triazole ring (Fig. 17). The results indicated that despite a better metabolic stability compound **52** was 10-fold less active than the amide prototype **51**.

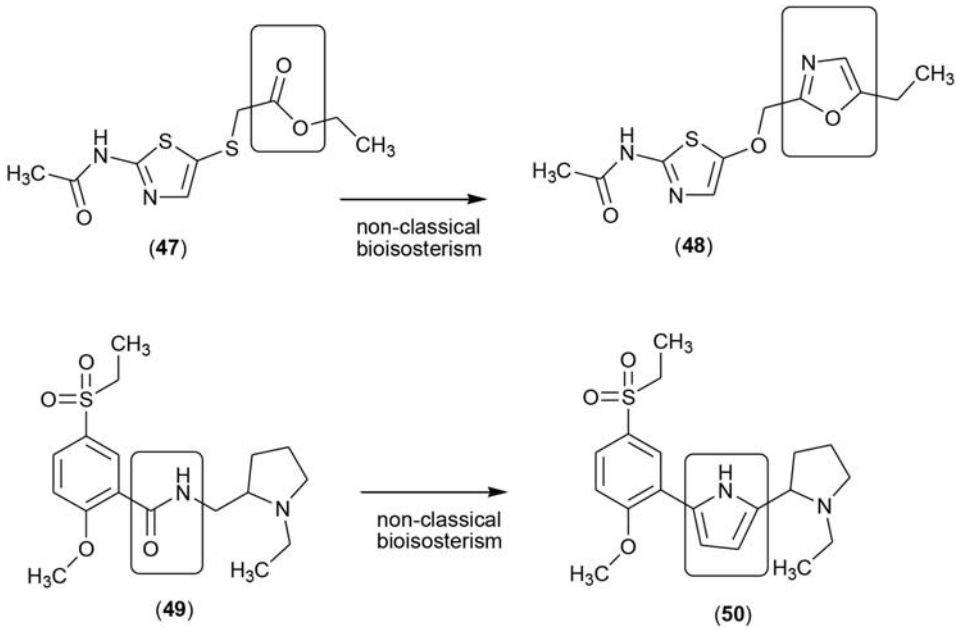

Fig. 16 Functional isosteres of esters and amides.

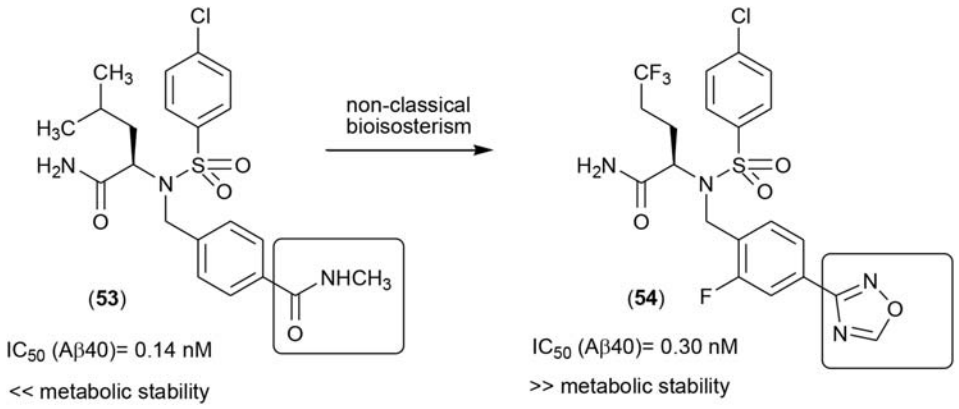

Fig. 18 Inhibitor of γ-secretase **53** and its nonclassical bioisoster **54.**

Aiming to develop a potent and selective γ-secretase inhibitor for the treatment of Alzheimer's disease, Gillman and coworkers[33] previously identified the *N*-methyl-substituted benzenecarboxamide **53**, which showed poor in vitro microsomal stability, indicating the potential for rapid clearance in vivo. In an effort to improve brain penetration and metabolic stability, the authors proposed the nonclassical bioisosterism replacement of the amide function for a 1,2,4-oxadiazole ring, resulting in a compound more lipophilic (**54**) than the parent prototype **53** (Fig. 18). They also demonstrate that the new bioisostere **54** was a potent inhibitor of γ-secretase, presenting good PK profile in rats and dogs.

1.07.5 Retroisosterism

Retroisosterism or reversal of functional groups is a type of nonclassical bioisosterism that is commonly used to improve stability. Retropeptides, for instance, are normally more resistant to enzymatic attacks. From the prototype thiorphan (**55**), a potent inhibitor of neutral endopeptidase (NEP), an enzyme responsible for the hydrolysis of vasoactive peptides, including the natriuretic peptides, angiotensin II, and endothelin-1, the retro-thiorphan (**56**) was designed and prepared (Fig. 19). The reversal of amide position in

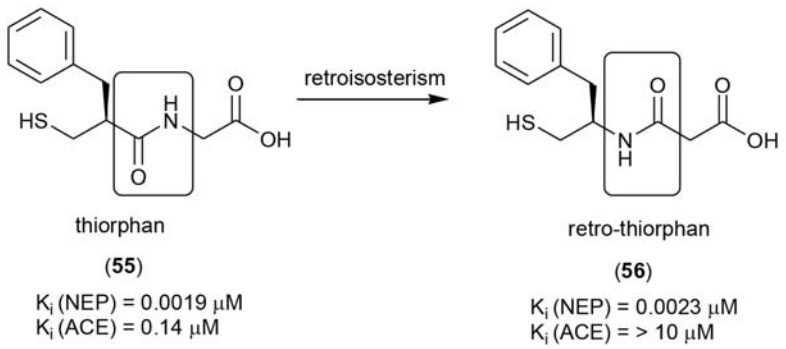

Fig. 19 Retroisosteres of amides: thiorphan (**55**) and retro-thiorphan (**56**).

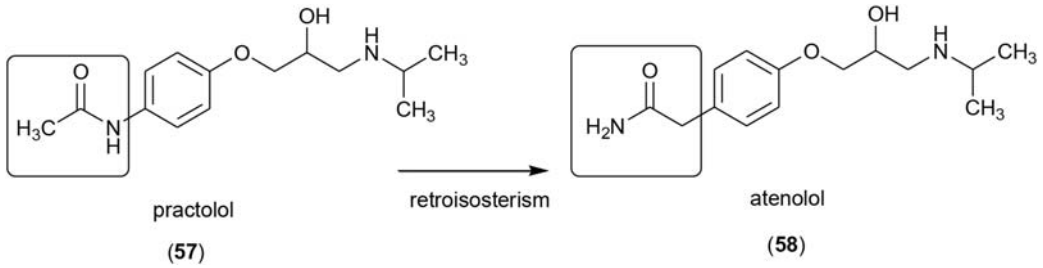

Fig. 20 Retroisosteres of amides: practolol and atenolol.

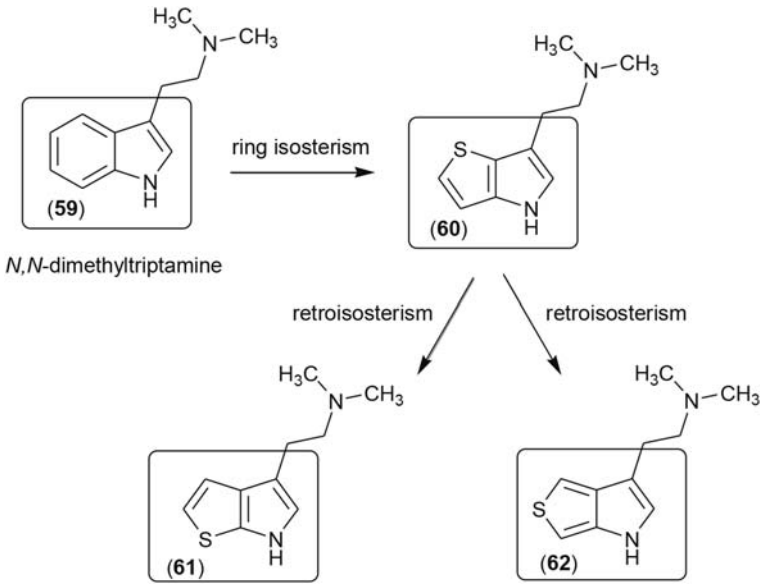

Fig. 21 Retroisosteres of the thienopyrrole system, a classical bioisostere of indole ring.

these peptides (**55** and **56**) resulted in an equipotent inhibition of NEP. However, their effect on the activity of angiotensin-converting enzyme (ACE) was quite different. Retro-thiorphan (**56**) was 71-fold less active against ACE. These results indicated that the retroisosterism strategy was crucial for the selection against NEP and ACE metalloproteins.[34]

Nonpeptidic compounds, as exemplified by the drugs practolol (**57**) and atenolol (**58**), can keep a retroisostere relationship. In fact, atenolol (**58**) differs from practolol (**57**) only for the reversal position of amide subunity (Fig. 20). However, atenolol is a cardioselective β-blocker with fewer side effects than the isomer practolol.[35]

Starting with the prototype *N*,*N*-dimethyltryptamine (**59**), Blair and coworkers[36] proposed initially the classical ring isosterism of the indole system and the 4*H*-thieno[3,2-*b*]pyrrole nucleus (**60**). Following the possibility of two regioisomers of thienopyrrole system, the authors proposed the design of the retroisosteres 6*H*-thieno[2,3-*b*]pyrrole (**61**) and 1*H*-thieno[3,4-*b*]pyrrole (**62**). The results demonstrated that with the exception of the 1*H*-thieno[3,4-*b*]pyrrole (**62**), unstable and hard to synthesize, the other heterocyclic isomeric systems are authentic bioisosteres of the indole nucleus, presenting affinity and selectivity for the serotonin receptors similar to prototype **59** (Fig. 21).

Aiming the discovery of new acetylcholinesterase (AChE) inhibitors, as potential anti-Alzheimer candidate, Barreiro and coworkers[37] designed a novel scaffold from molecular modification of the structure of tacrine (**63**), one of the first therapeutic resources available for the treatment of Alzheimer disease (AD). Starting from tacrine (**63**), the authors proposed the bioisosteric replacement of quinoline ring by the 1-phenyl-1*H*-pyrazolo[3,4-*b*]pyridine system, resulting in compound **64**, that was considerably less active in inhibiting the AChE than the prototype tacrine. Further modification, based on retroisosterism, resulted in compound **65**, presenting the nucleus 1-phenyl-1*H*-pyrazolo[4,3-*b*]pyridine, which was more potent than compound **64**, having a better selective index (AChE vs. BChE) than tacrine (Fig. 22).

1.07.6 Ring Closure or Anelation and Ring Opening

Among the nonclassical bioisosterism strategies, the anelation or ring closure procedure is worth mentioning. Normally this strategy aims to restrict conformational possibilities, creating a more rigid structure that can be better recognized by a hypothetic receptor, if

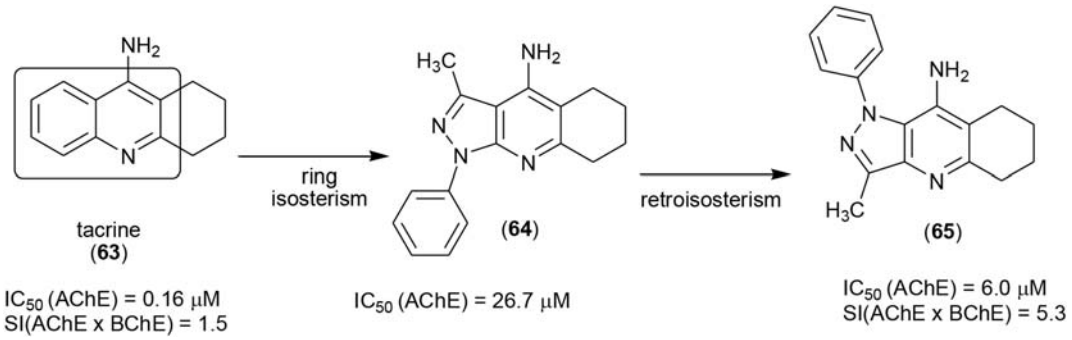

Fig. 22 Classic ring isostere (**64**) and nonclassical retroisostere (**65**) of tacrine (**63**).

it mimics the bioactive conformation, contributing in this case for the enhancement of affinity. Recently, Capparelli and coworkers[38] described the efforts to optimize the activity of the lead-compound MC113 (**66**). This compound was described as a promising inhibitor of P-glycoprotein (P-gp), with good selectivity toward P-gp versus multidrug resistance associated protein 1 (MRP1). Various elongated spacers, between the biphenyl fragment and pyrazine nucleus, were introduced in the structure of MC113. The *O*-butyl spacer resulted in an oxa-homologous derivative **67**, which displayed good potency toward the target protein. Further, aiming to investigate the role of flexibility, conformationally constrained analogues were designed, applying the anelation strategy, resulting in the chromene derivative **68**. This compound was significantly less potent than the parent compound **67**, and was inactive toward MRP1 (Fig. 23). These results indicated that the flexibility could be a requirement to improve P-gp activity and the conformational restriction imposed for compound **68** impairs the recognition by the target protein.

A successful application of ring closure strategy can be exemplified by the discovery of frovatriptan (**71**). This drug was designed by molecular modification on the structure of 5-carboxamidotriptamine (**69**), an analogue of the natural agonist of serotonin receptors. This compound presented soft lability to metabolic oxidation catalyzed by monoaminoxidases, and showed low selectivity against the different isoforms of 5-hydroxytryptamine (5-HT) receptors. Therefore, a lead optimization step was realized and planned based on the application of ring closure procedure, resulting in compound BRL-56905 (**70**).[39] This compound

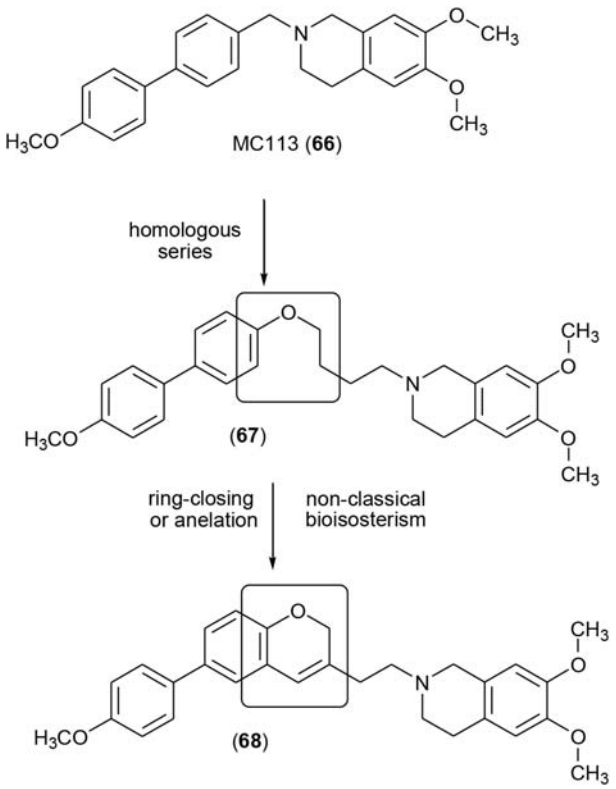

Fig. 23 Structures of MC113, the homologous **67**, and the conformationally constrained analogue **68**.

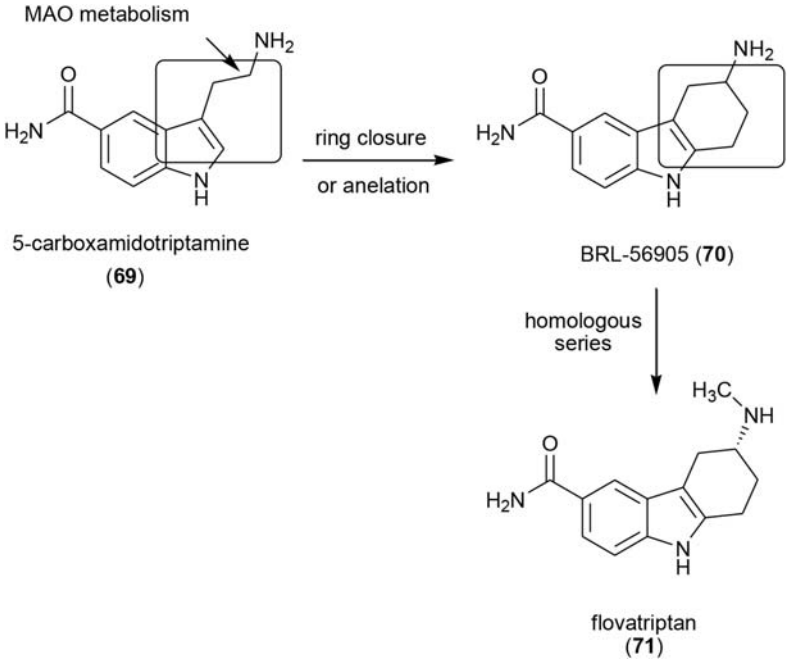

Fig. 24 Genesis of flovatriptan (**71**) and BRL-56905 (**70**) by application of ring closure strategy in the structure of the prototype 5-carboxamidotriptamine (**69**).

presented higher affinity to the 5-HT_{1A} receptors than to the 5-HT_{1D}, and showed remarkable selectivity when compared to the initial prototype **69**. Its metabolic stability was optimized after the introduction of methyl group linked to the amine subunit, resulting in the structure of flovatriptan (**71**), indicated for the treatment of migraine (Fig. 24).

Searching for selective agonists of dopaminergic receptors subtype 2 (D_2), useful in the treatment of Parkinson's disease, schizophrenia and other psychiatric illnesses, compound **72** containing a metabolically labile phenol function, was structurally modified in order to improve its PK profile. Therefore, the tricyclic compounds **73** and **74** were designed by ring closure strategy, eliminating the site of conjugation with phase II metabolizing enzymes, but keeping the heteroatom with unpaired electron, able to be recognized by the target receptor through H-bond interactions. These cyclic analogues presented affinity for D2 receptors and were active by in vivo administration, characterizing themselves as novel nonclassic bioisosteres of OH-phenol (Fig. 25).[40]

The conformational restriction induced by a ring closure procedure is one of the useful approaches to guide biologically active conformations. However, if the restricted structure does not reach the bioactive conformation, the ring closure strategy will result in inactive compounds. To solve that problem, the opposite strategy, namely ring opening, can be employed, restoring the necessary flexibility to interact with bioreceptors in an adequate conformation.

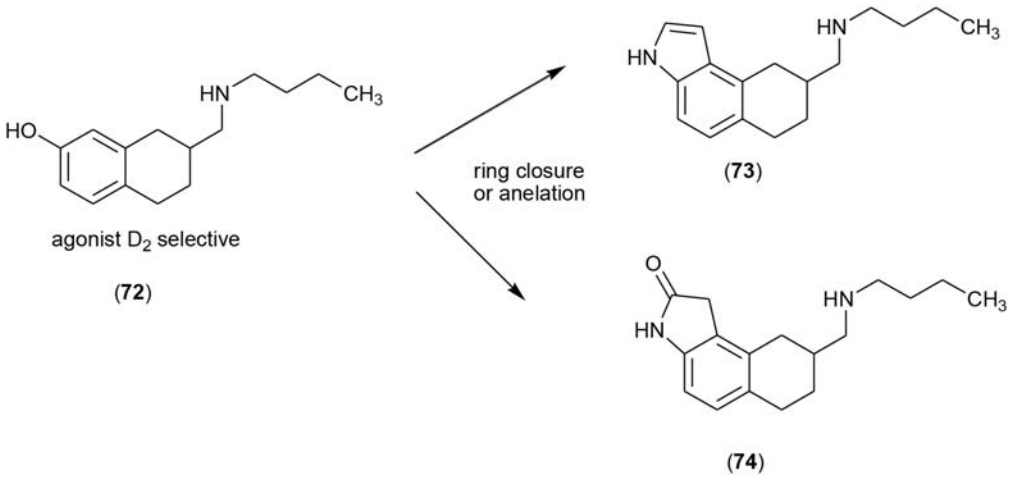

Fig. 25 Structure of the phenol derivative **72** and its bioisosteres **73** and **74.**

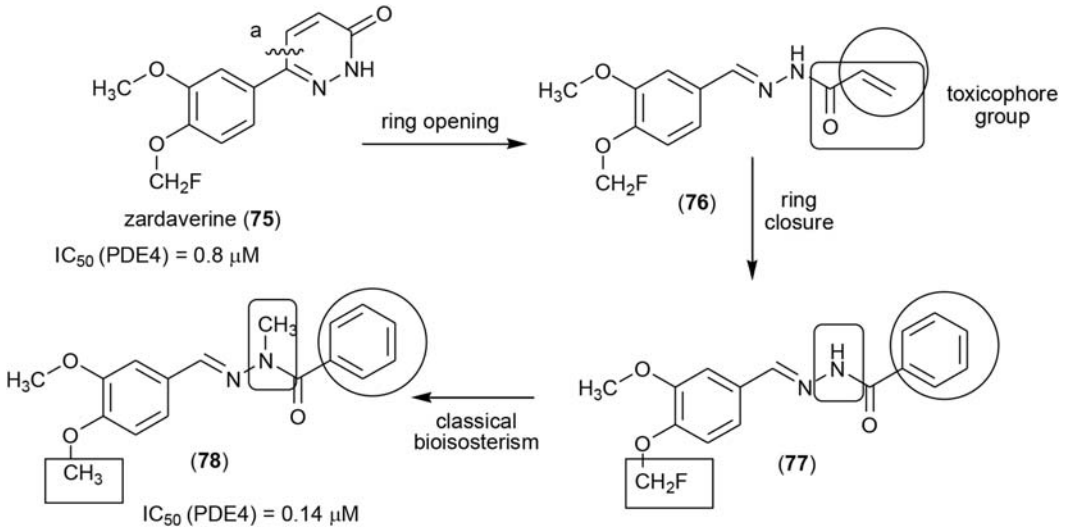

Fig. 26 New PDE4 inhibitor designed from molecular modifications on structure of zardaverine.

Looking for new drug candidate to treat asthma, Kummerle and coworkers[41] selected zardaverine (75) as a prototype for molecular modification. This conformationally restricted prototype was modified applying the principle of ring opening strategy, resulting in the cleavage of the pyridazinone ring (Fig. 26). The opened structure **76** was modified in order to eliminate the toxicophoric profile of α,β-unsaturated carbonyl subunit. Further modifications based on classical bioisosteric replacements resulted in the identification of compound **78**, which was more potent than zardaverine in the inhibition of PDE4.

The analysis of the possible conformers of compound **78** revealed three main conformational possibilities represented by conformers **78a**, **78b**, and **78c**. They differ from the relative orientation between C═O and N−CH_3 and CH═N and NCH_3, as depicted in Fig. 27. Docking studies indicated that conformers **78a**, **78b**, and **78c** are almost isoenergetic and could result in stable complex with the target protein (i.e., PDE4). Aiming to define the bioactive conformation, the authors proposed the design of restricted analogues of conformers **78a** and **78b**, freezing the conformations identified by in silico approach. As illustrated in

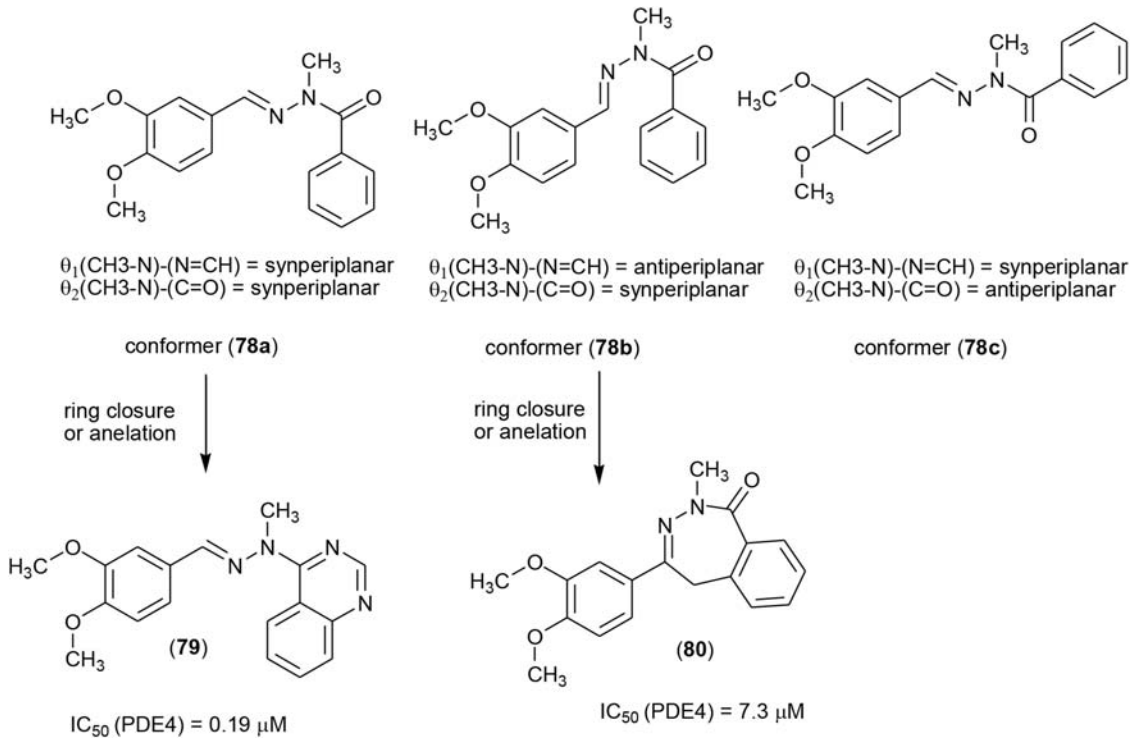

Fig. 27 Design of conformationally restricted analogues **79** and **80** inspired in the different conformers of compound **78.**

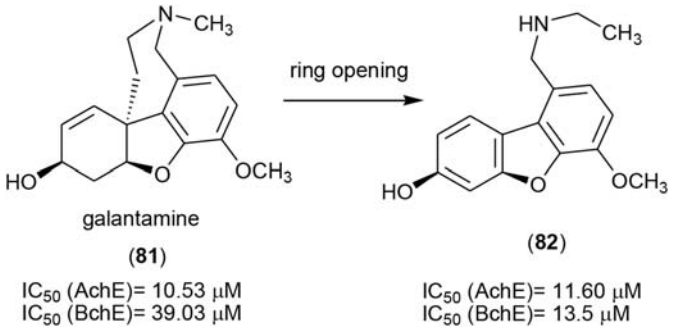

Fig. 28 Nonclassical bioisostere of galantamine (**81**) by opening ring strategy (**82**).

Fig. 27, the frozen analogues **79** and **80** showed different potency in inhibit PDE4 activity, being the quinazoline **79**, 38-fold more potent than benzodiazepinone **80**. These results suggest that the biologically active conformation should be the one represented by conformers **78a**.[41]

Galantamine (**81**) is a natural acetilchoniesterase inhibitor approved drug to treat AD, which is also an allosteric modulator of nicotinic receptors. Based on the hypothesis that the benzofuran fragment and the nitrogen atom of amine group are the pharmacophores responsible for galantamine activity, while the other parts of the structure are auxophoric units, Fang and coworkers[42] proposed the simplification of complex congested quaternary carbon followed by a ring opening strategy on the seven-member azepine ring, generating acyclic amine galantamine analogue **82** (Fig. 28). This compound, having a higher degree of conformational freedom in the amine side chain, was demonstrated to be equipotent to the parent drug.

1.07.7 Classical Bioisosterism

Searching for PDE4D selective inhibitors that could exert pro-cognitive effects with reduced emetic potential, Brullo and coworkers[43] investigated the role of classical bioisosteric replacement of the 3-methoxy group with a 3-difluoromethoxy unit in the PDE4D inhibition activity, and realized the comparison between their blood brain barrier crossing ability (Fig. 29). Authors demonstrated that the 3-difluoromethoxy isostere was the best compound in terms of selectivity and safety, despite having a lower PDE4D inhibitory activity. This isostere (**84**) also enhanced the intracellular cyclic adenosine monophosphate levels more than its nonfluorinated analogue **83**, suggesting that due to the fluorine substitution, it can better cross the cell membrane. This hypothesis was confirmed by preliminary tests, which demonstrated that 3-difluoromethoxy isostere **84** showed a better BBB penetration, its brain/plasma ratio being 20% higher in comparison with its nonfluorinated analogue **83**.

An interesting example of divalent classical bioisosterism between **CH_2/O** was reported in a series of carboxylic acid lipophilic derivatives that work as partial agonists over the PGI_2 receptor (IP2), which are effective as antiplatelet agent. The series originated with the discovery of octimibate (**85**) that was structurally modified to generate compound **86**. This compound was subject of further optimization allowing the identification of the bioisosteres **87** and **88** (BMY-42393), a molecule optimized as a partial IP2 agonist (Fig. 30).[44,45]

The use of this type of bioisosterism has been successfully employed when the cyclic oxygen atom of prostacyclin (PGI_2; **89**), involved in the enol ether function, responsible for the extreme chemical lability of this icosanoid, was substituted by a methylene group providing a stable bioisostere active as agonist of prostacyclin receptors. Further modifications, at ω-side chain of eicosanoid skeleton, resulted in the discovery of iloprost (**90**) (Fig. 31). Cicaprost (**91**) is a me-too drug designed by bioisoteric replacement of **CH_2** by **O**. This exchange in C-3 of α-side chain of cicaprost (**91**) was planned aiming to prevent β-oxidation, an usual metabolic reaction involved in the inactivation of prostanoids and their analogues (Fig. 31).[45,46]

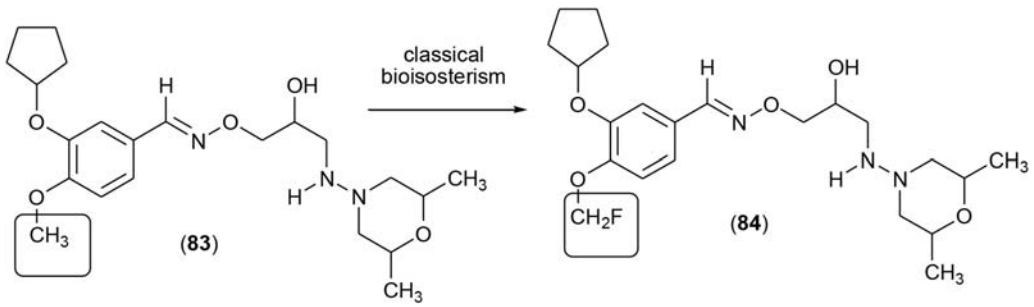

Fig. 29 Structures of classical bioisosteres containing the 3-methoxy versus 3-difluoromethoxy isosterism.

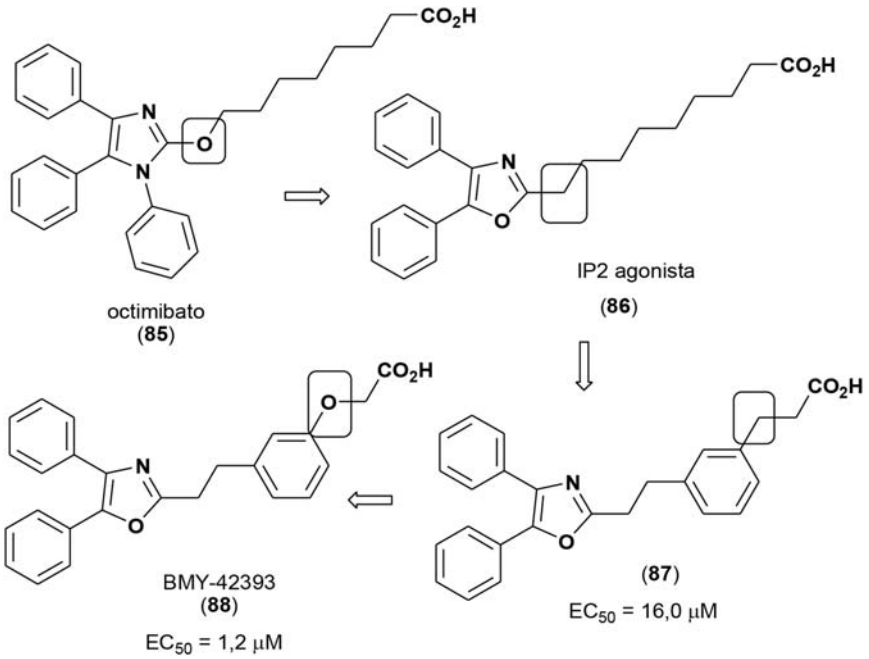

Fig. 30 Classic bioisosterism of divalent group CH_2/O.

Regarding the classical bioisoster of the divalent group, Faustino and coworkers[47] described the characterization of the structure and properties of 6-selenoguanine (**93**), and studied the impact of its introduction in DNA. The 6-selenoguanine was obtained by the isosteric replacement of oxygen atom of carbonyl function presented in guanine (**92**) by a selenium atom (Fig. 32). This seleno-derivative showed promising nanotechnological properties and a unique capability to modulate the equilibrium between different forms of DNA, opening interesting possibilities in antigene-based therapies.

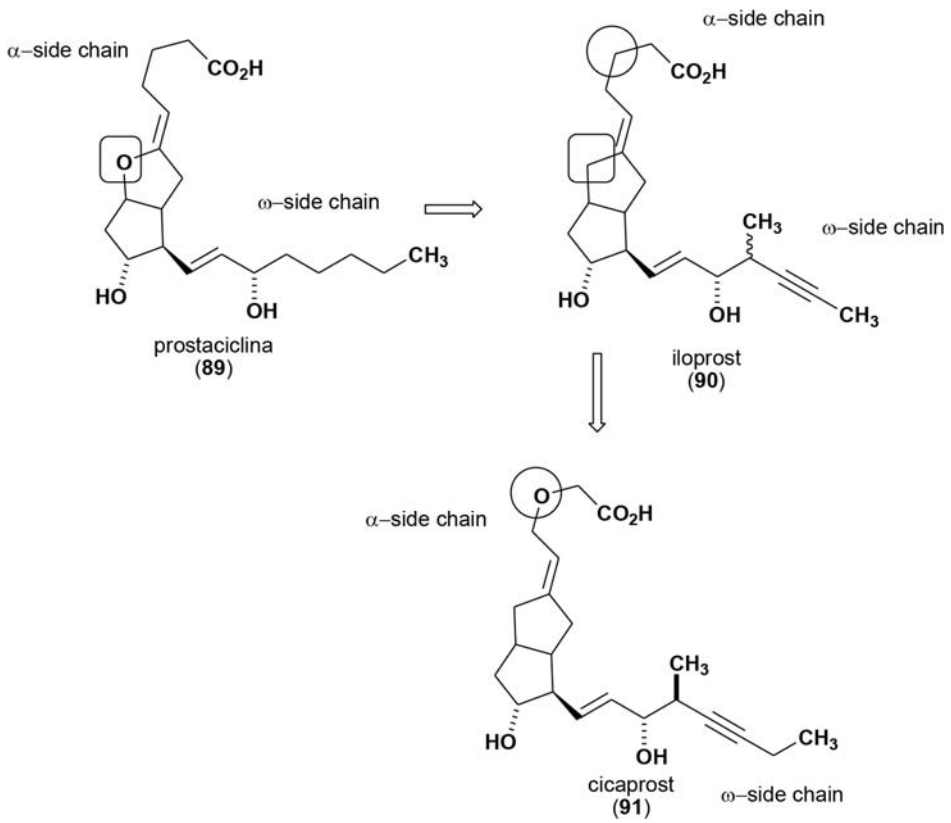

Fig. 31 Classic functional bioisosterism —O—/—CH_2— in prostanoids and analogues.

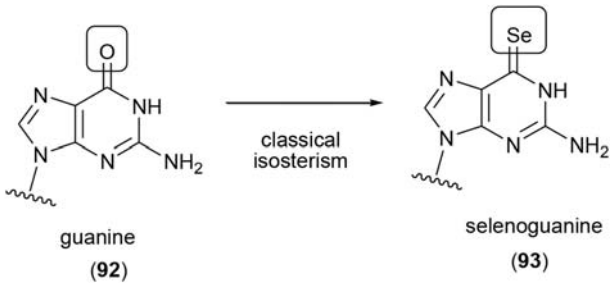

Fig. 32 Structures of the nucleobases guanine (**92**) and its classical isostere selenoguanine (**93**).

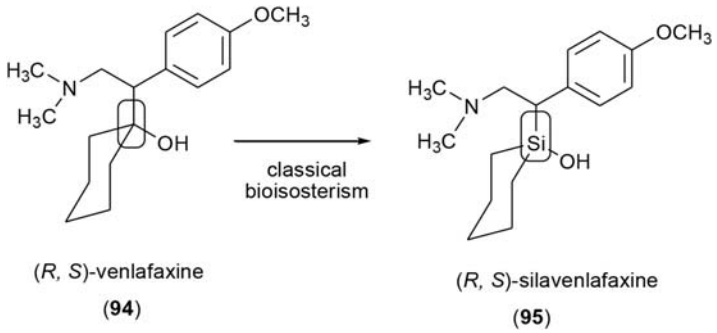

Fig. 33 Structures of (*R,S*)-venlafaxine (**94**) and its classical bioisoster (*R,S*)-silavenlafaxine (**95**).

Considering the classical bioisosterism of tetravalent groups, the isosteric replacement of carbon atom by silicon has gained prominence in the literature. Among the benefits of silicon in medicinal chemistry, the possibility to create a novel chemical space favoring intellectual properties opportunity is remarkable. Furthermore, the replacement of **C** by **Si** can modify in vitro potency and selectivity, alter rate of metabolism, improve in vivo half-life, enhance tissue distribution, and so on.[48] Several silicon bioisosteres of classical drugs have been developed. Daiss and coworkers[49] reported the impact of sila-substitution on the activities of the venlafaxine enantiomers, a potent and selective serotonin reuptake inhibitor (SSRI). The replacement of quaternary carbon of venlafaxine (**94**) by a silicon atom resulted in the respective silavenlafaxine isostere (**95**) (Fig. 33). The comparison between the pharmacological activities of venlafaxine enantiomers and its sila-isostere showed a great difference in their selectivity profile in inhibiting serotonin reuptake and/or noradrenaline and dopamine transporter.

The **C** versus **Si** isosterism was also applied in order to obtain a new active haloperidol analogue. Haloperidol (**96**) is an antipsychotic drug developed by Paul Janssen, which mechanism of action involves blockage of dopamine (D2) receptors in the brain. Therefore, the sila-haloperidol (**97**) was designed, synthesized, and evaluated against recombinant human dopamine receptors (D1, D2, D4, and D5), using radioligand binding experiments. The **C**/**Si** bioisosteres displayed similar potency at D1, D4, and D5 receptors. However, sila-haloperidol (**97**) was 4.7-fold more potent at D2 receptor than haloperidol (**96**) (Fig. 34). Moreover, sila-analogue (**97**) was speculated to be safer than haloperidol, since silicon–carbon double bond is not stable under physiologic conditions and therefore, cannot undergo water elimination to form sila-HPTP (**100**). HPTP (**98**) is considered a key intermediate in the bioactivation of haloperidol (**96**) in the pyridinium-type metabolite (HPP^+, **99**) that has been implicated in the irreversible Parkinsonism-like side effects induced by haloperidol (Fig. 34).[50]

1.07.8 Ring Bioisosterism

Fig. 35 shows classic aromatic ring bioisosterism from the phenyl ring, with 6 electrons π, circled by equivalent isosteric systems represented by several rings of six or five atoms, such as pyridine, pyrazine, pyrimidine, pyrrol, pyrazol, imidazole, thiazole, oxazole, thiophene, furan, and so on. Surrounding this circle are depicted isosteric rings with 10 π, electrons including naphthyl, quinolyl, quinoxalyl, etc. Tricyclic, linear, or angular systems, with 14 π, electrons complete the brief of possible equivalent rings that could be used applying the ring bioisosterism strategy.

Related to the indole system (**A**),[51] illustrated in Fig. 36, it is possible to identify based on the ring bioisosterism, eight equivalent rings (**B–I**) that fulfill the principle of isosterism and, therefore, could be used in an interchangeable way.

Among the myriad of interchangeable rings based on classical isosterism, five-membered heterocycles are noteworthy (Fig. 37). As mentioned in the selected examples previously mentioned, these heterocycles can be considered isosteres of amide and ester moieties with greater metabolic stability. However, for scaffold hopping or lead optimization, special attention should be paid

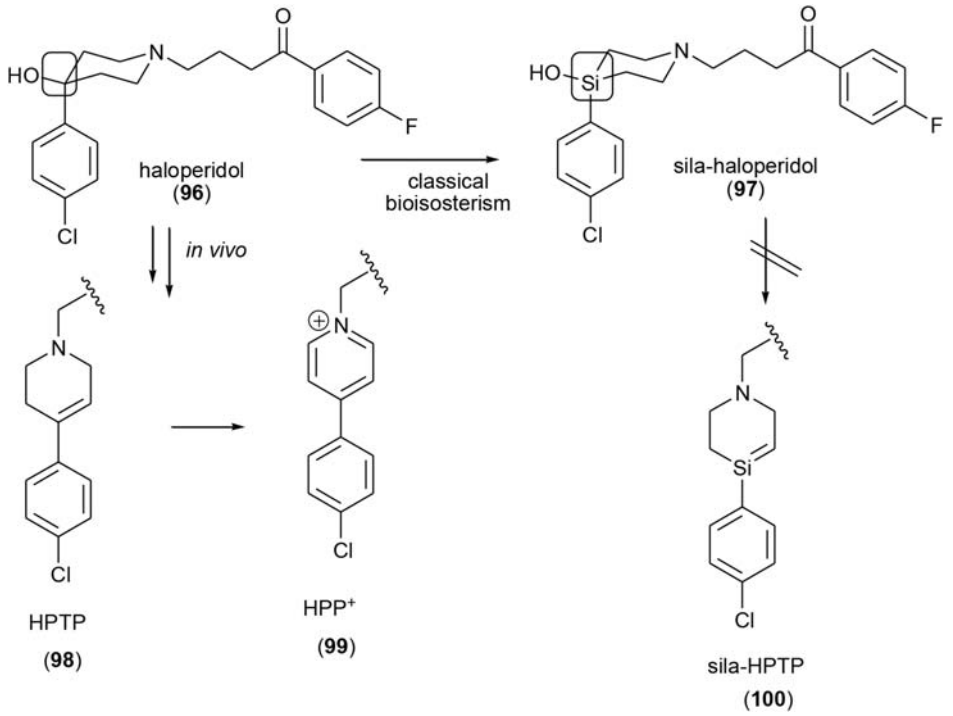

Fig. 34 Structures of haloperidol (**96**) and its sila-bioisostere **97**. Indication of the formation of toxic metabolite HPP^+ from the intermediate HPTP and the inability to form similar intermediate (i.e., sila-HPTP) from the sila-haloperidol isostere.

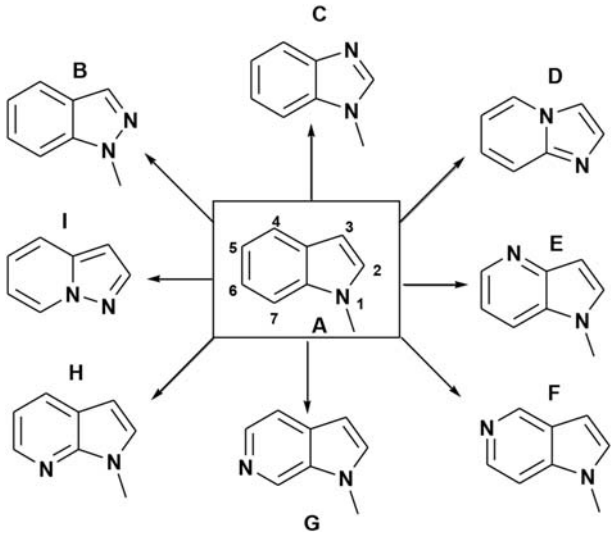

Fig. 36 Indole ring isosteres (**A**).

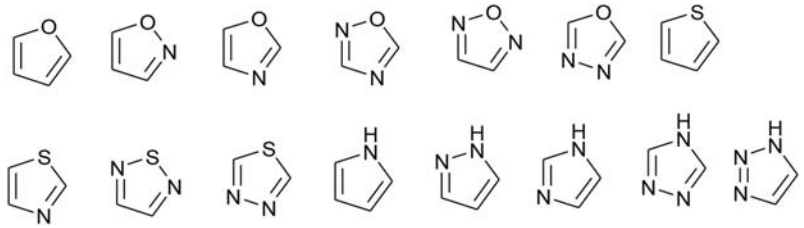

Fig. 37 Examples of five-member ring bioisosteres.

to the unique properties of S-containing heterocycles. It is important to keep in mind that the replacement of O by S atom in a heterocycle will not necessarily result in a bioisosterically equivalent compound. A nice example can be demonstrated by the attempt to replace 1,3-thiazole ring by 1,3-oxazole nucleus aiming to identify new VEGFR2 (vascular endothelial growth factor receptor subtype 2) inhibitors (Fig. 38). Authors demonstrated that the ability of the S atom to engage in donating $n_o \rightarrow \sigma^*$ interaction with the lone pairs of neighboring heteroatoms can lead to conformational and steric effects that are unique of S-containing heterocycles, restraining the capability to identify bioisosteric equivalents.[52]

Ring bioisosterism was used by Francisco and coworkers[53] in an attempt to identify new structural analogues of rimonabant, an antagonist of cannabinoid receptors, approved for obesity control, and withdrawn by Sanofi–Aventis in Jan. 2009. Authors proposed the isosteric replacement of pyrazole ring by 1,3-thiazole and 1,2,4-triazole systems (Fig. 39).[54,55]

An special example of ring bioisosterism was first described by Edwards and coworkers,[56] who described the discovery of ferrocenyl-penicillins and ferrocenyl-cephalosporins designed by replacement of phenyl ring by ferrocene organometallic system. Based on this initial work, and on the demonstration that ferrocene group possesses aromatic properties, and also considering the cytotoxic activity of the ferrocenium cation (Fc+•), which is easily formed by oxidation in biological media, Top and

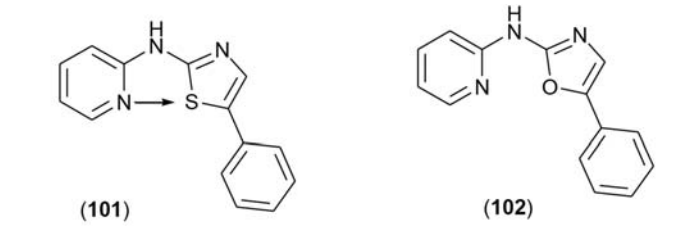

Fig. 38 Structures and IC_{50} values of thiazole versus oxazole isosteres against VEGFR-2, demonstrating the stabilizing of N → S interaction that cannot mimic by the oxazole ring.

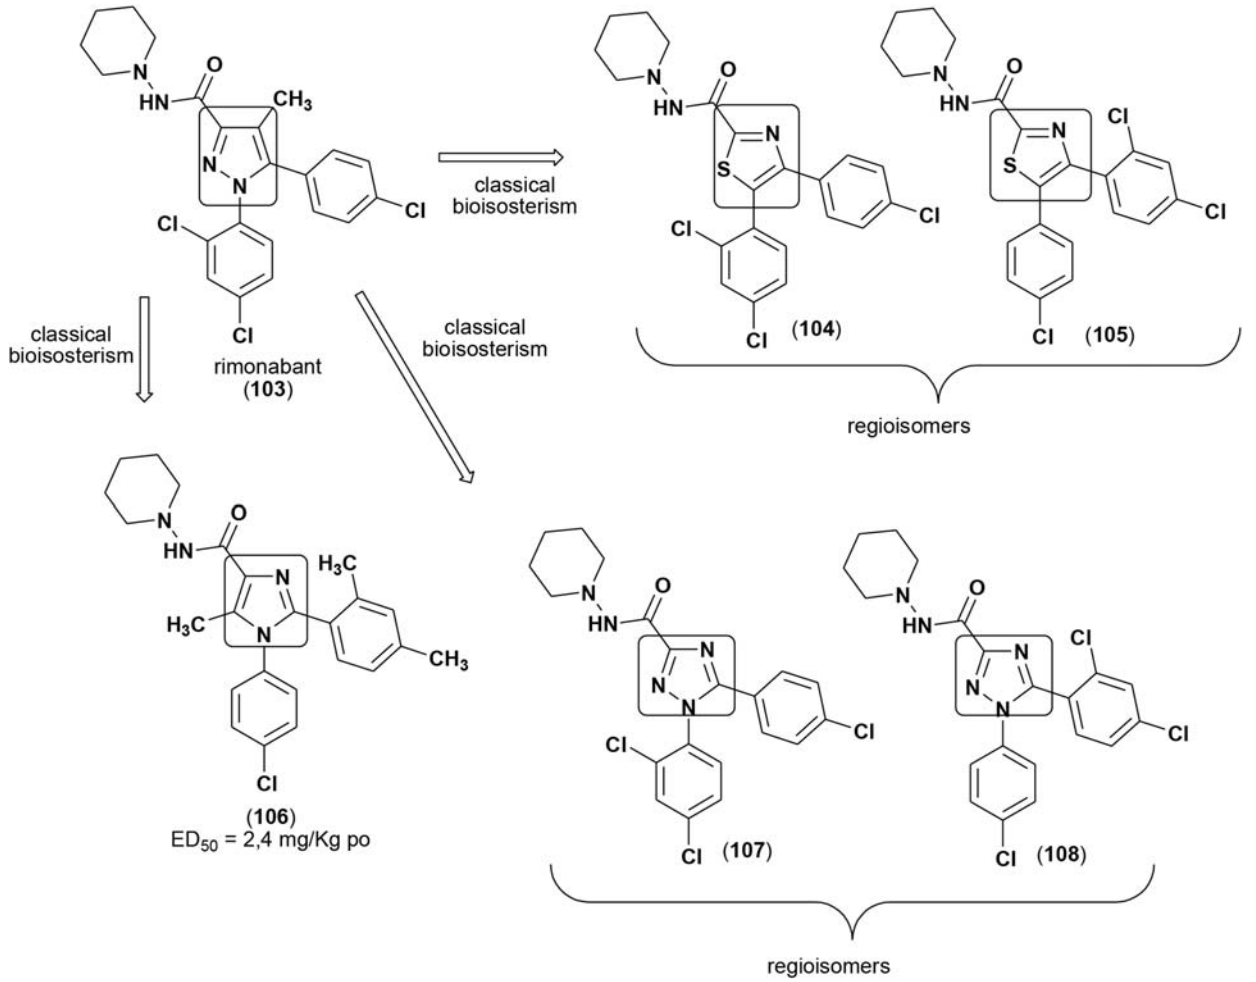

Fig. 39 Five ring bioisosteres with CB_1 antagonist properties.

coworkers[57] proposed the replacement of phenyl ring, presented in tamoxifen (**109**) and its active metabolite (i.e., endoxifen, **110**), by an aromatic ferrocenyl substituent (Fig. 40). This approach resulted in the discovery of ferrocifen (**111**), a new selective estrogen receptor modulator with similar antitumor activity as tamoxifen.

More recently, the same type of ring isosterism was explored in an attempt to optimize the antimicrobial activity of bisacodyl (**112**), a drug originally used as a laxative agent. From this molecular modification strategy, a series of bisacodyl-ferrocene (e.g., **113**) were designed and prepared, being identified as compounds with optimized antimicrobial activity (Fig. 41).[58]

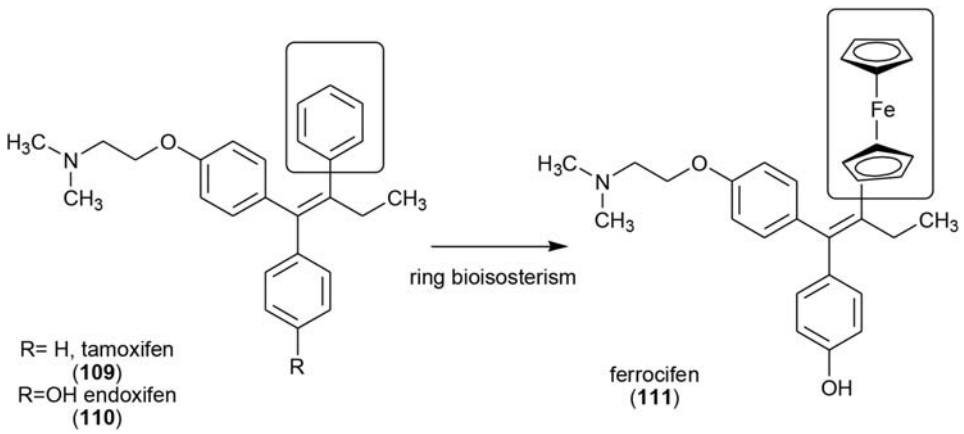

Fig. 40 Ring bioisosterism between tamoxifen (**109**), endoxifen (**110**), and ferrocifen (**111**).

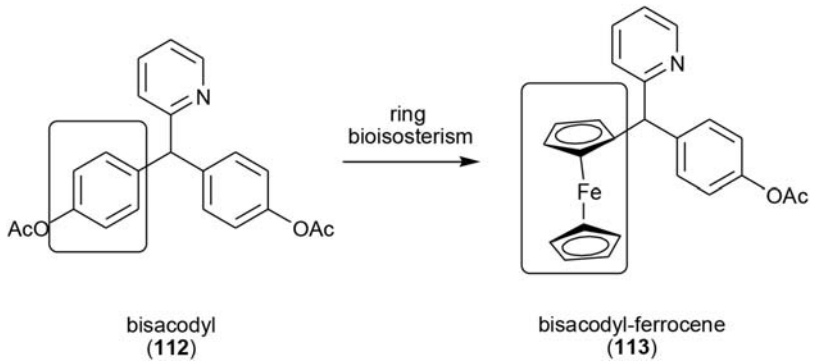

Fig. 41 Ring bioisosterism between bisacodyl (**112**) and its ferrocene analogue **113.**

Ring bisosterism is the most popular molecular modification strategy used by researchers in pharmaceutical industry and academia to discover new me-too drugs. Many examples could be used to fulfill this statement. Nevertheless, just a few examples will be discussed in this article.

Piroxicam (**114**) can be considered the prototype of first-generation nonsteroidal antiinflammatory drug belonging to oxicam class. The replacement of phenyl ring by a thiophene system resulted in the discovery of tenoxicam (**115**), while the same ring bioisosterism strategy applied on the pyridine moiety of pyroxicam resulted in the identification of isoxicam (**116**, Fig. 42).[59,60]

Regarding the class of phosphodiesterase 5 (PDE5) inhibitors, sildenafil (**117**), approved for the treatment of erectile dysfunction, is the innovative drug that was used as prototype for molecular modification resulting in me-too drugs, such as vardenafil (**118**). The 1*H*-pyrazolo[4,3-*d*]pyrimidin-5-yl nucleus presented in sildenafil (**117**) had demonstrated to be a classical bioisoster of 3,5,6,8-tetrazabicyclo[4.3.0]nona-3,7,9-trien-2-one ring in **118** (Fig. 43).[61] It should be pointed out that moving the nitrogen atom in vardenafil (**118**) permits an interaction with the enzyme that is not present in sildenafil (**117**). This contributes to the improved potency of vardenafil.

Fluoxetine (**119**) is a SSRI that represents an innovative drug to treat major depressive disorder and obsessive–compulsive disorder. Applying two consecutive bioisosteric replacements, based on the exchange of phenyl ring by a naphtyl subunit and by a thiophene moiety, duloxetine (**120**) was discovered (Fig. 44).[62] This me-too drug has the same therapeutic indication as fluoxetine.

The structural similarity existing between COX-2 inhibitors, celecoxib (**121**) and etoricoxib (**122**), is detected in the light of bioisosterism. Comparing both structures easily identified the presence of a terphenyl type system, formed by a central heterocyclic ring, such as a pyrazole in celecoxib and a pyridine in etoricoxibe. Exchange between phenyl unit and pyridine ring represents the

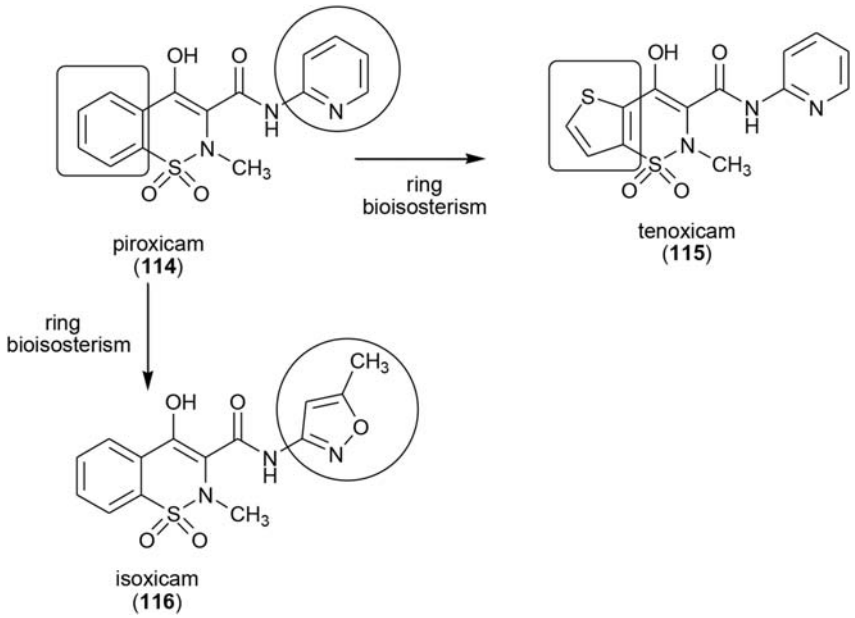

Fig. 42 Bioisosterism of rings and discovery of me-too antiinflammatory of the oxicam class: piroxicam (**114**), tenoxicam (**115**), and isoxicam (**116**).

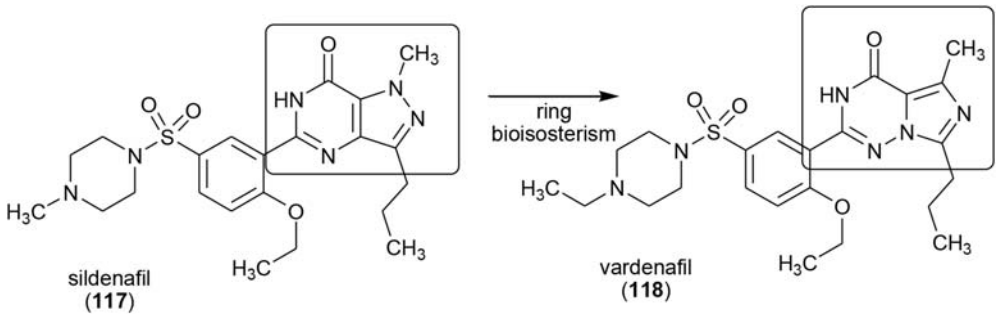

Fig. 43 Ring bioisosterism between sildenafil (**117**) and vardenafil (**118**).

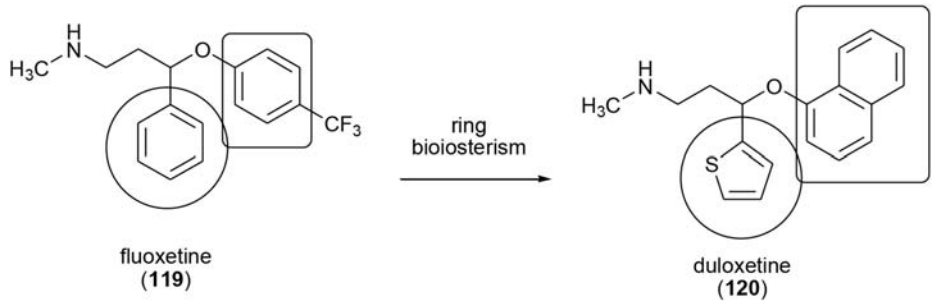

Fig. 44 Ring bioisosterism between fluoxetine (**119**) and duloxetine (**120**).

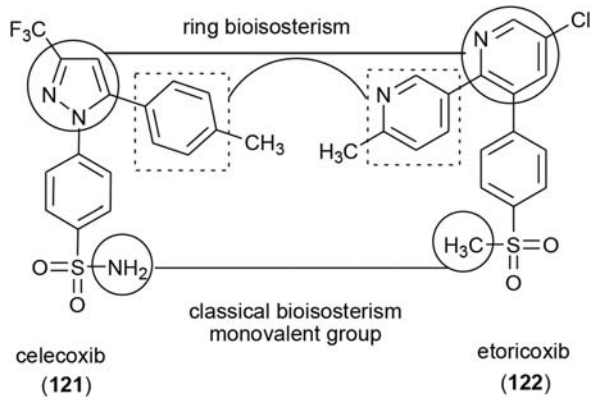

Fig. 45 Bioisosteric relationships between selective COX-2 inhibitors celecoxib (**121**) and etoricoxib (122).

second molecular modification introduced in celecoxib structure based on ring bioisosterism. The replacement of the CH_3 group by a NH_2, both monovalent groups, allowed the design of methylsulfone subunit from a sulfonamide fragment. Therefore, etoricoxib (**122**) can be considered a me-too antiinflammatory drug planned by three consecutive application of classical bioisosterism (Fig. 45).[63]

1.07.9 Final Remarks

The use of *bioisosterism*, as illustrated so far in this article, is an important tool in *Medicinal Chemistry* in order to design new compounds by the application of ligand-based drug design or even structure-based drug design strategies. It is also an amazing approach to optimize the pharmadynamic or PK properties of a previous hit or lead compound. Many researchers in academia and mainly in pharmaceutical companies use bioisosterism as a key strategy to construct a congeneric series, to enlarge chemical space, and to circumvent intellectual property issues.

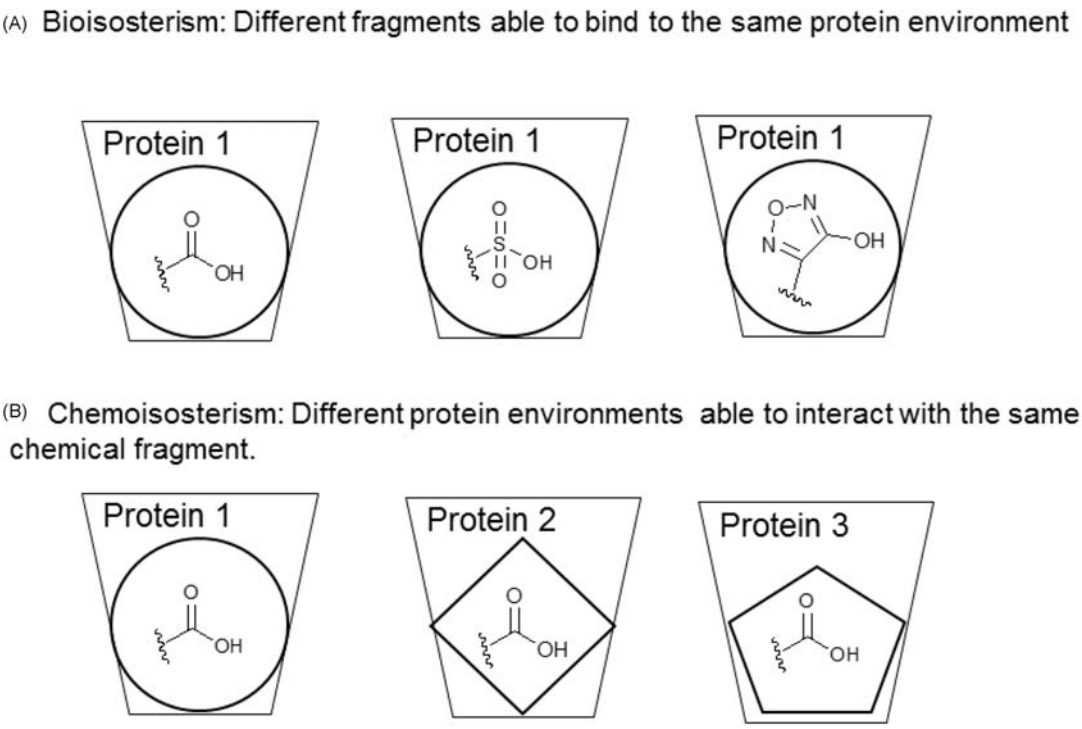

Fig. 46 Schematic definition of bioisosterism (A) and chemoisosterism (B). Adapted from Jalencas, X., Mestres, J. J. *Chem. Inf. Model.* **2013**, *53*, 279; Jalencas, X., Mestres, J. *Med. Chem. Commun.* **2013**, *4*, 80.

As previously mentioned, any bioisosteric replacement must consider steric or size attributes, electronic features, solubility, and hydrophobic effects. Therefore, many theoretical descriptors can be used to characterize properties of groups or fragments or subunits considered interchangeables, indicating if these groups are or not appropriate for a bioisosteric replacement.

Although it is possible to use two dimensional descriptors and chemical intuition to guide bioisosteric replacement, the use of in silico approaches is becoming more common. These approaches can use QSAR strategies, pharmacophore searching, and databases for bioisosteres. Several molecular representations and similarity metrics are available to help the identification of three-dimensional molecular similarities, using measures of 3D shape and electrostatic distribution, facilitating the search for new bioisosteric relationships.[10,64–67]

It is noteworthy that bioisosterism looks at the interaction between chemical fragments or subunits or functional groups and protein environments from the perspective of the latter. However, the assumption that binding sites of different proteins can share a high degree of electronic and steric similarities, easily detected between members of the same protein family, was responsible for the emergence of the concept of chemoisosterism. Chemoisosterism is defined as the property by which different protein environments, sharing similar cavity shapes and features, can tolerate the interaction with the same chemical fragment. Therefore, the understanding of the degree of chemoisosterism among protein environments can help medicinal chemists to make assumptions about potential cross-pharmacology between different protein targets, as well as into the selectivity of bioactive small molecules and its further implications to toxicity and adverse reactions.[68,69] The schematic comparative definition of bioisosterism and chemoisosterism can be easily comprehended by the illustration exemplified in Fig. 46. Combination of both concepts can help medicinal chemists not only to diversify the chemical space for a specific target, but also to anticipate on-target and off-target effects for a specific bioisosteric fragments.

The bioisosterism is a very useful technique used in scaffold hopping strategy,[70] assisting the medicinal chemists to design and discover structurally novel compounds, starting from lead molecules by modifying the molecular backbone of the template, and increasing the chemical space of new chemical entity candidates.

1.08.1 Introduction

Spirocycles are ring systems in which two rings share a single atom known as the spiro atom. Most often, the spiro atom is an sp^3 hybridized carbon atom, although ring systems are known in which the spiro atom is another element, such as a quaternized sp^3 nitrogen.

The nomenclature of spirocycles was originally proposed by von Baeyer.[1] The structures in **Fig. 1** will serve as illustration. The C_{10} molecule **1**, in which a cyclohexane and a cyclopentane share a single atom, is named as spiro[4.5]decane. The numbers within the square brackets indicate the numbers of atoms in chains joining the spiro atom, with the shorter chain listed first. The spiro atom is numbered as position 5 in this case and numbering then continues around the larger ring. Replacement of the carbon atom at position 2 in **1** gives the amine **2**, which is named 2-azaspiro[4.5]decane. Similarly replacement of the carbon atom at position 8 in **2** with oxygen gives aminoether **3** which is named 8-oxa-2-azaspiro[4.5]decane. This review is organized on the basis of formal nomenclature; however, in practice, **2** would often be described as a spiropyrrolidine and this type of informal nomenclature will also be employed.

Spirocycles are well represented among natural products and have attracted the interest of the synthetic community. Seven examples, selected for their structural diversity and biological activity, are depicted in **Fig. 2**. Spiroepoxide fumagillin (**4**) possesses

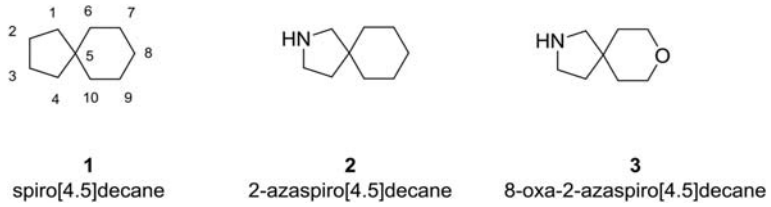

Fig. 1 Nomenclature of spirocycles.

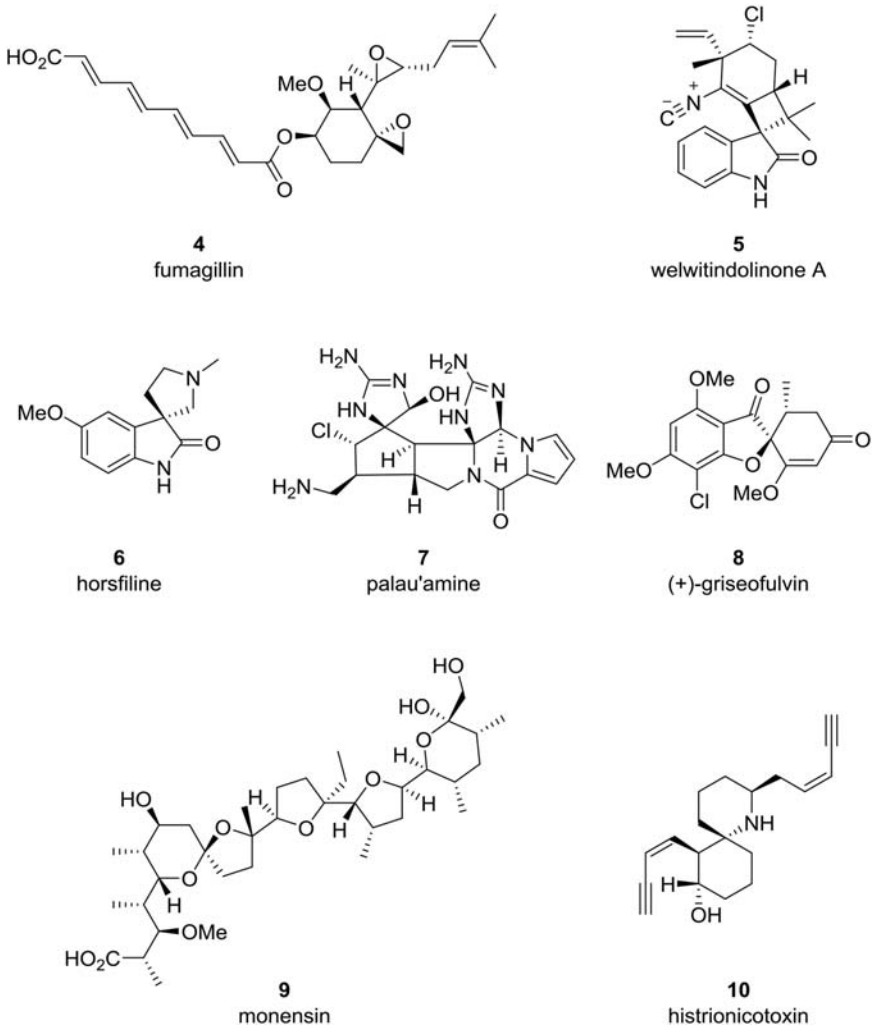

Fig. 2 Selected spirocyclic natural products.

antiangiogenic and amebicidal activity and has been a starting point for medicinal chemistry.[2] Welwitindolinone A (**5**)[3] and horsfiline (**6**)[4] both incorporate spiroindolinone groups, a ring system that has been of considerable interest to medicinal chemists.[5] Palau'amine (**7**)[6] has cytotoxic, antibiotic, and immunosuppressive activity and is reported to inhibit the human 20*S* proteasome.[7] (+)-Griseofulvin (**8**) is an orally bioavailable antifungal drug used in man.[8] The polyether monensin (**9**) is a spiroketal antibiotic used in animal husbandry.[9] Histrionicotoxin (**10**) inhibits nicotinic acetyl choline receptors.[10]

Spirocycles have also captured the imagination of medicinal chemists. Their ability to project substituents in all three dimensions on a generally rigid framework makes them attractive scaffolds for drug discovery and, in fact, some of them have been considered to be privileged structures.[11] In many cases, spirocycles have a high fraction of sp^3 carbons (Fsp3) and can be expected to be more water soluble, and thus more druglike, than aromatic systems of similar molecular weight (MW) and carbon content.[12,13] In addition, spirocycles may offer advantages in terms of patentability.

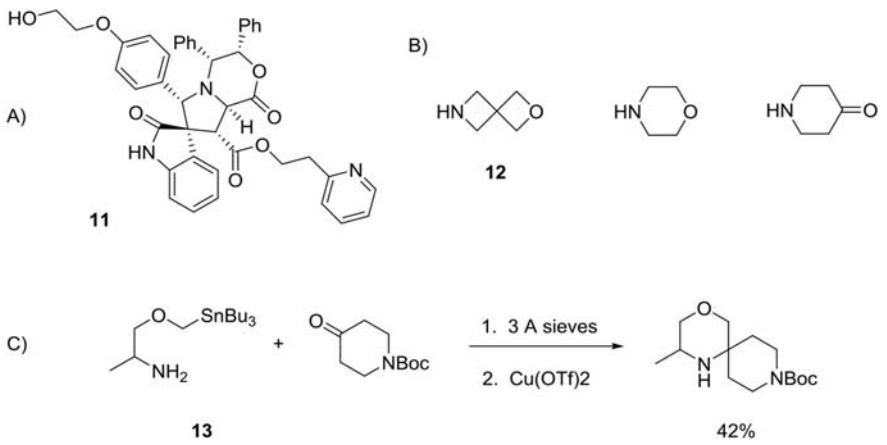

Fig. 3 (A) Biologically active spirocycle discovered using DOS. (B) Spirooxetane. (C) Spirocycle synthesis using SnAP chemistry.

The ability of certain spirocycles, particularly spirocyclic lactams to mimic β-turns in peptides and proteins, may provide a partial explanation for their privileged status.[14] A number of spirocyclic systems have been synthesized and evaluated as β-turn mimetics.[15–21]

Diversity-oriented synthesis (DOS) aims to produce libraries of natural product-like molecules for biological screening.[22] Given their prevalence among natural products and status as privileged substructures,[11,23] it is unsurprising that spirocycles have been exploited in DOS.[24–27] For example, Schreiber's group described the discovery of spirooxindole **11** (Fig. 3A) which synergizes the activity of the actin polymerase inhibitor latrunculin B with an EC_{50} of 550 nM.[28] Spirocycles have also found to use as acaricides[29] and fungicides.[30]

The synthetic literature related to spirocycles is vast. A crude search for the term "spiro" using SciFinder, and limited to the year 2014, retrieved the following numbers of articles from leading organic chemistry journals: *Org. Lett*. 55, *Tetrahedron Lett*. 51, *Tetrahedron* 39, *Eur. J. Org. Chem*. 33, *J. Org. Chem*. 30, *Org. Biomol. Chem*. 21, and *Synthesis* 20. There can be no doubt that development of methods for synthesis of spirocycles continues to interest organic chemists. Various aspects of the synthesis of spirocycles have been reviewed.[31–42] While the synthesis of spirocycles is outside the scope of this article, two recent developments can be highlighted. Firstly, a body of work from the Carreira group describing the preparation of spirocycles including four-membered rings mirrors the general increase in interest in rings of this size in drug discovery.[43–46] For example, spirooxetane **12** was considered as a potential bioisostere of morpholine and 4-oxopiperidine (Fig. 3B).[44] Secondly, the Bode group has recently described bifunctional SnAP reagents, for example, **13**, a number of which are now commercially available, capable of converting cyclic ketones to spirocycles in one pot (Fig. 3C).[47,48] An ongoing challenge to the synthetic community is the control of stereochemistry at multiple positions on spirocyclic scaffolds, allowing full advantage to be taken of the three-dimensional nature of these ring systems.

The focus of this article will be on the conformational analysis of spirocycles, an understanding of which is essential to structure-based drug design involving spirocycles, and selected examples of the deployment of spirocycles in drugs and drug discovery.[49] Both topics are organized based on the International Union of Pure and Applied Chemistry (IUPAC) nomenclature of spirocycles. Due to space limitations it was necessary to exclude many interesting reports of spirocycles in medicinal chemistry.

1.08.2 Conformational Analysis of Spirocycles

1.08.2.1 Overview of Conformational Analysis of Spirocyclic Scaffolds

Spiro ring fusion has been increasingly used to restrict molecular conformation. Smaller spiro structures are rigid with limited or no conformational flexibility. Spirocyclic scaffolds containing a large ring system (larger than seven-membered) are generally highly flexible unless otherwise constrained. Therefore, for drug discovery purposes, we are usually interested in spirocyclic scaffolds that contain rings smaller than eight-membered ring, for example, spiro[*m*.*n*] where $m \leq n$ and *m* and *n* are between 2 and 6.

Apart from spiroketals,[31,50] conformational preferences for spirocyclic systems are generally less well studied than nonspiro ring systems and experimental energetic information is often scarce. Recently, we found that the hybrid density functional theory at the B3LYP/6-31G* level of theory is capable of accurately describing the conformational preferences of geminal disubstituted cyclohexanes. Conceptually spiro scaffolds are just a special case of geminal disubstituted systems. Given the scarcity of experimental energetic information regarding inherent conformational preferences of spirocyclic scaffolds in general, we investigated the conformational preferences of various commonly used spiro[4.5] and spiro[5.5]-ring systems using the B3LYP/6-31G* level of theory. Comparison with available experimental data is made whenever available. In general, the conformational preference of spirocyclic scaffolds can be predicted based on the *A*-values of the corresponding geminal disubstituted cyclohexanes.

1.08.2.2 Spiro[2.*n*] Ring Systems

Spiro[2.2]pentane (where $n=2$), the smallest spirocyclic prototype molecule with two three-membered rings fused together through a spiroatom, is completely rigid. The conformational flexibility of spiro[2.*n*] ring systems, where $n>2$, is determined by the larger ring due to the rigidity of the three-membered ring (Fig. 4). For instance, spiro[2.5]octane (**14**) has similar ring inversion barrier (10.5 kcal mol^{-1}) to cyclohexane itself (10.2 kcal mol^{-1}).[51] Even in this case, the presence of the spirocyclopropane ring can sometimes induce unusual conformational effect, for example, the axial predominance in spiro[2.5]octan-4-ol derivatives. A small spiro ring fusion is generally introduced to improve structural novelty and patentability if presented peripherally in a molecule, in such cases the small ring can often be replaced by geminal dimethyl without losing much binding potency.

1.08.2.3 Spiro[3.*n*] Ring Systems

A four-membered ring can be either planar or puckered. Unsubstituted cyclobutane and azetidine prefer a wing-shaped conformation with small inversion barriers of 1.45 and 1.26 kcal mol^{-1}, respectively, while oxetane is essentially planar.[52] When two four-membered rings are fused together to form a spiro[3.3] system, the two four-membered rings can be either planar or puckered depending on the nature of the rings and their substitution patterns. Both cyclobutane rings of spiro[3.3]heptane containing molecules are normally puckered (eg, CSD code: SPHBAH).[53] Oxetane is planar while azetidine can be either planar or puckered depending on the substituent on N and also protonation state (eg, CSD codes EMUDAS, NUQSEY, AKUQUT). Overall, spiro[3.3] systems do not exhibit a great deal of conformational flexibility.

As with three-membered rings, when a four-membered ring is fused to a larger ring to form a spiro scaffold, the conformational flexibility of the resulting system is determined mainly by the larger ring due to limited conformational flexibility of the four-membered ring (Fig. 5).

1.08.2.4 Spiro[4.4] Ring Systems

Cyclopentane has two low energy conformations: the envelope conformation with four atoms coplanar and the half-chair conformation with three atoms coplanar (Fig. 6). The envelope conformation is about 0.5 kcal mol^{-1} lower in energy than the half-chair conformation with a very small interconversion (pseudorotational) barrier between them; the inversion barrier for the envelope conformation is <5.0 kcal mol^{-1}.[54] For methylcyclopentane, the pseudorotational barrier increases to 3.4 kcal mol^{-1} and in the most stable conformation the methyl group prefers to be equatorial at the flap of the envelope by 0.9 kcal mol^{-1}.[54] Thus in a spiro[4.4] system, the two five-membered rings in principle can be either in half-chair or envelope conformations. Similarly, tetrahydrofuran is puckered with the C_2-symmetrical T form (the envelope conformation with a flap oxygen) being the lowest in energy. Both pseudorotational and inversion barriers are small (0.22 cal mol^{-1} and 4.15 mol^{-1}, respectively).[55]

Also, pyrrolidine is found to undergo rapid pseudorotation with the N–H equatorial envelope conformer being the lowest in energy.[56] There are over 2400 structures in CSD that contain spiro[4.4] scaffolds.[53]

1.08.2.5 Spiro[4.5] Ring Systems

1.08.2.5.1 Isolated ring systems

For spiro[4.5]decane, the conformation of the five-membered ring can in principle be in either the envelope or the half-chair conformation, whilst the six-membered ring would be in the chair conformation. Again, the conformational flexibility of such a spiro system is mainly determined by the six-membered ring. Owing to symmetry, the two low energy conformations of spiro[4.5]decane (**15a**) are equivalent in energy (Table 1). However, the equilibrium between axial and equatorial conformers can be perturbed by changing the nature of X. In 1-oxaspiro[4.5]decane (**15b**), the oxygen prefers to be in the axial position as shown both experimentally[57] and theoretically.[58] In keto compound **15c**, the carbonyl slightly prefers to be in the equatorial position. In amine **15d**, there is little preference for axial versus equatorial; however, the protonated form **15e** shows a slight preference to adopt the axial position.

For spiro lactam **16a**, the axial conformation of the nitrogen is slightly favored (Table 1), however, the presence of an *N*-alkyl group in this conformation (eg, **16b**) would result severe steric clashes between the *N*-alkyl group and the two axial C–Hs at positions 7 and 9. As a result, the equatorial conformation is preferred. A conformational switch of this type can be very useful in controlling ligand conformation in drug design.

Similarly, when both heteroatoms and unsaturation were introduced into the five-membered ring system as in **17** and **18**, the preference of an ether oxygen over a methylene group to adopt the axial configuration still persists according to our calculations at the B3LYP/6-31G* level of theory (Table 2). Even though experimental energetics are not available for these systems, experimental data are available for analogous systems **19** and **20**. In these cases the theoretical results are higher but nonetheless in general agreement with the experimental observations.[59]

Introducing a heteroatom into the six-membered ring of a spiro[4.5] ring system also influences conformational preferences as reported for some spiropiperidine NK2 receptor antagonists.[60]

1.08.2.5.2 Benzo-fused ring systems

For spiro[4.5] systems, the five-membered ring is often fused to an aromatic ring. A ring fusion of this type is expected to affect the conformational preference of the resulting spiro scaffolds. There are two ways to fuse a phenyl ring with the five-membered ring of the spiro[4.5] scaffolds: 1,2 or 2,3-fusion (Tables 3 and 4).

Some examples with a benzo fusion in the 1,2-position are shown in Table 3. For 1,2-phenyl fusion, the phenyl moiety generally prefers to be in the equatorial position. The exception is the lactam **21f** in which the phenyl moiety is predicted to be in the axial position, in agreement with small molecule X-ray crystal structure (CSD code: EBAXIQ, Table 3). However, the magnitude of this conformational preference can be manipulated by introducing a polar group at Z such as oxygen (**21g**) or amine (**21h**).

For 2,3-benzo fusion, the two conformations of the parent compound **22a** are equal in energy due to symmetry (Table 4). The conformational preferences of these systems are usually similar to that of the corresponding unfused scaffolds (**22b** vs. **15b**, **22c** vs. **15c**, **22d** vs. **15d**).

21h	C=O	NH	NH_2^+	−5.86

N-Alkylation appears to be a general conformational switch and can be of great value in controlling ligand conformation in drug design. For the spiroindoxyl ring system (**16a** vs. **16b** in Table 1, 22d vs. **22e** in Table 4), it has been demonstrated N-methylation is sufficient to flip the conformation of the six-membered ring.[61]

1.08.2.6 Spiro[5.5] Ring Systems

1.08.2.6.1 Isolated ring systems

In spiro[5.5] ring systems, since the four atoms attached to the spiroatom can be in either axial or equatorial positions, there are four combinations: eaea, aeea, aeae, and eaae. For the prototypic spiro[5.5]undecane (**23**), those four conformations are energetically

Table 4 Energy differences of benzo-fused spiro[4.5]decane conformers

22eq **22ax**

	X	*Y*	$\Delta E\ X_{ax} - X_{eq}$ (kcal mol^{-1})
22a	CH_2	CH_2	0

22d	NH	CH_2	−0.05
22e	NMe	CH_2	3.9
22f	NH	C=O	−0.37

equivalent (Fig. 7). Interestingly, introducing a spiro ring fusion also introduces an axial chirality,[62] for example, the top two conformations are mirror images, and so are the bottom two. In the case of **23**, they interconvert rapidly and are inseparable.[62]

Changing one of the four atoms attached to the spiroatom of **23** into an oxygen atom results in 1-oxaspiro[5.5]undecane **24** where the two chair conformations are no longer energetically equivalent (Table 5). Both experimental and theoretical investigations of chair conformations demonstrated that the oxygen prefers to be in the axial position by 0.9[50] and 1.3 kcal mol^{-1}, respectively. Introducing a second oxygen atom attached to the spiroatom results in two possible structures **25** and **26**. If the two oxygen atoms are in the same ring (**25**, Table 5), the two conformations are equal in energy due to symmetry. Alternatively, if they are in different rings, the resulting spiroketal 1,7-dioxaspiro[5.5]undecane (**26**, Table 6) has three conformational possibilities: both oxygens in axial positions (**26aa**), one oxygen in an axial and one in an equatorial position (**26ea**), or both oxygen atoms in equatorial positions (**26ee**). Experimentally, it has been demonstrated that only the diaxial conformation **26aa** exists at room temperature,[50] indicating that the other conformations must be at least 2 kcal mol^{-1} higher in energy. Both previous[63] and current theoretical calculations are generally in agreement with the experiment, but the magnitudes of the calculated energy differences regarding the higher energy conformations are significantly different from those estimated by Deslongchamps and coworkers based on steric and anomeric considerations.[50]

[a]Data from Ref.[63].
[b]Data from Ref.[50].

The conformational preference of spiro[5.5] ring systems can also be modulated by the presence of additional polar group or introducing substituent on the rings. Some examples are shown in Table 7. The influence of a protonated basic amine is particularly striking (**29c**, **30c**). Therefore, there is great conformational variation in spiro[5.5] systems.

1.08.2.6.2 Benzo-fused spiro[5.5] ring systems

As with spiro[4.5] ring systems, there are two ways to fuse a phenyl ring to one of the six-membered rings: 1,2-fusion and 2,3-fusion. As discussed above in the case of spiro[4.5] systems, the conformational preferences for 2,3-fusion are similar to the unfused system. Only the 1,2-fusion is considered here and, as in the spiro[4.5] systems, the phenyl moiety prefers to be in the equatorial position (Table 8).

1.08.2.7 Spiro[*m*.6] Ring Systems

Cycloheptane has several low energy conformations: chair, twist chair, boat, and twist boat.[64–66] The twist chair conformation is the most stable one and undergoes pseudorotation via the chair conformation as the transition state. Similarly, the twist boat also undergoes pseudorotation via the boat conformer as transition state with little energy barrier[64] or vice versa depending on the level of theory used in the theoretical investigations.[65] The inherent flexibility of seven-membered ring can be constrained by introducing unsaturation, one or more heteroatom, bridging, benzo fusion, or a combination of these elements. The well-known seven-membered scaffolds in drugs include benzodiazepines and azepinones. For spiro[*m*.6] scaffolds, if *m* is smaller than 5, the conformational flexibility is mainly determined by the seven-membered ring unless the seven-membered ring is highly constrained. For spiro[5.6] systems, both rings can significantly impact the conformational flexibility. Two structures (NUVYUY and RENCIY) from CSD are shown as examples in Fig. 8.

1.08.3 Medicinal Chemistry of Spirocycles

1.08.3.1 Spiro[2.*n*] Ring Systems

Spiro[2.*n*] ring systems include spirocyclopropanes (**32**, Fig. 9), spiroepoxides (**33**), and spiroaziridines (**34**). Cyclopropanes, including spirocyclopropanes, offer the attraction of increased stability to cytochrome P450 (CYP) mediated oxidation as compared to an isosteric geminal dimethyl group.[67] Spiroepoxides (**33**), on the other hand, are reactive to nucleophiles and have enjoyed application as covalent inhibitors. Spiroaziridines (**34**) have rarely been employed in medicinal chemistry.

1.08.3.1.1 Spiro[2.2] ring systems

Spiro[2.2]pentanes have seen occasional use in drug discovery. Spiropentane acetic acid **35** (Fig. 10) is an inhibitor of medium-chain acyl-CoA dehydrogenase with in vivo activity in rat when injected intraperitoneally at 80 mg kg^{-1}.[68] 2-Alkoxyadenosine analog **36** is a potent inhibitor ($IC_{50} = 40$ nM) of bacterial NAD^+-dependent DNA ligase; however, the spirocycle does not impart in vivo stability in this case.[69,70] Replacement of the spiro[2.2]pentylmethyl group with *trans*-4-(trifluoromethyl)cyclohexyl reduced clearance from 96 to 27 mL min^{-1} kg^{-1}.[71]

1.08.3.1.2 Spiro[2.3] ring systems

All carbon spiro[2.3]hexanes have occasionally been employed in medicinal chemistry.[72,73] For example, **37** (Fig. 11) is a positive allosteric modulator of the $mGlu_5$ receptor, a target with possible relevance in the treatment of schizophrenia, with an EC_{50} value of 3.9 nM and 95% efficacy.[72]

Two spirocyclic β-lactams have been reported. Spirocyclopropane **38** inhibits β-lactamases TEM-1 and AmpC with IC_{50} values of 0.65 and 0.02 μM, respectively. It is proposed to be a mechanism-based irreversible inhibitor.[74] Spiroepoxide **39** has antibacterial activity and, in addition, has been shown to irreversibly inhibit β-lactamase I with concomitant covalent modification of the protein.[75]

1.08.3.1.3 Spiro[2.4] ring systems

Compound **40** (Table 9) is a hepatitis C virus (HCV) nonstructural protein 5A (NS5A) inhibitor and was discovered by structure activity relationship (SAR) investigations, including desymmetrization, around dimeric inhibitors of this protein such as daclatasvir. The spirocyclopropane was introduced into **40** in the final optimization of the compound and afforded the drug **41** (ledipasvir) which is now approved for HCV treatment as one component of Harvoni®.[76] This subtle change imparted a small improvement genotype 1a (GT1a) replicon potency and a decrease in protein binding shift. The compound has low clearance, good bioavailability, and long half lives in three species. In healthy volunteers, a single 3 mg kg^{-1} oral dose of **41** had a $t_{1/2}$ of 45 and a 24 h trough concentration of 2.5 nM, 12-fold above the plasma protein-adjusted EC_{50}.

The limited oral bioavailability of the nociceptin/orphanin FQ (ORL1) receptor antagonist **42** was ascribed to its poor metabolic stability (Table 10).[77] An intensive scan of replacements for the essential cyclooctyl hydrophobe identified the spirocyclic bicycle

shown on the right-hand side of **40** as the optimum group. Combination of this group with incorporation of a diol on the left hand side and deletion of the hydroxymethyl group provided clinical candidate **43**.

Polo-like kinase 4 (PLK4) is a kinase involved in the mitotic cycle and is viewed as a potential anticancer target. A lead from screening was subjected to iterative structure-based design, synthesis, and bioassay against PLK4 leading to the discovery of compound **44** (**Table 11**).[78] To overcome configurational instability of the double bond exocyclic to the indolinone ring, the authors replaced the double bond with a spirocyclopropane to give **45**.[79] This change maintained in vitro potency against PLK4 and growth inhibition against two cancer cell lines, MCF-7 and MDA-MB-468. In addition, water solubility, free fraction, and stability in human liver microsomes were increased, while CYP3A4 inhibition was decreased. Further optimization provided **46** which has a GI_{50} value of less than 1 nM against MCF-7 cells and was shown to be orally bioavailable in mice. Oral dosing of **46** at 25 mg kg^{-1} once a day (q.d.) for 21 days resulted in 76% inhibition of tumor growth in a mouse MDA-MB-468 breast cancer xenograft model. Replacement of the dimethylamino group in **46** with 2,6-dimethyl-4-morpholino gave the clinical candidate **47** (CFI-400945).[80,81] In addition to maintaining cellular potency, this compound demonstrated a 35× higher mouse plasma area under the curve (AUC) than **45** when both compounds were dosed at 25 mg kg^{-1} per os (PO).

Compound **48** (AM-1638) is a full agonist of GPR40, a G-protein-coupled receptor (GPCR) target involved in regulation in insulin secretion, with an EC_{50} value of 160 nM (**Fig. 12**). Efforts to constrain the conformation of the phenylpropanoic acid region led to the identification of spirocycle **49** (AM-5262) which possesses improved potency (EC_{50} = 81 nM) and is a full agonist.[82] In addition **49** is more selective than **48** against a panel of 101 GPCRs, ion channels, transporters, and enzymes and has lower clearance in rat. In HF/STZ type II diabetic mice, **49** dosed at 30 mg kg^{-1} provided similarly efficacy in an oral glucose tolerance test to 60 mg kg^{-1} of **48**.

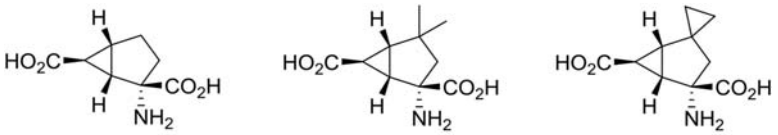
Table 12 Spirocyclopropane agonist of human metabotropic glutamate 2 (hmGlu2) and 3 (hmGlu3)



50 **51** **52**

	hmGlu2 K_i *(nM)*	*hmGlu3* K_i *(nM)*	*hmGLu2* EC_{50} *(nM/%)*	*hmGLu3* EC_{50} *(nM/%)*
50	72	107	7/100	28/100
51	2760	2000	600/92	>25,000/–
52	260	177	8/99	62/88

Compound **50** is a dual agonist of the human metabotropic glutamate 2 (hmGlu2) and 3 (hmGlu3) receptors (Table 12).[83] Geminal dimethyl analog **51** exhibits reduced ability to displace a radiolabeled ligand from receptor preparations, and retains weak agonist activity against hmGlu2 but is inactive as an agonist on hmGlu3. Spirocyclopropane is often deployed as an isostere of the geminal dimethyl group; however, in this instance **52** (LY2934747) retains dual agonist activity, albeit with reduced potency on hmGlu3 compared to **50**.

Spirocyclopropane **53** is highly selective for cyclooxygenase type 2 inhibition over COX-1 and is active in vivo upon oral administration at 30 mg kg^{-1} in three rat assays (Fig. 13).[84] Earlier SAR indicated that the corresponding spirocyclobutyl series was less active in vivo.

Spirocyclic analogs of carbanucleosides have been explored as antivirals by several groups.[85–87] For example, **54** is 4× more potent than the standard compound 2′-*C*-methylcytidine in the HCV RNA replicon Huh7 assay.[87]

Aziridines have not received much attention from medicinal chemists. Steroid derivatives **55a** and **55b** provide rare examples of spiroaziridines.[88] The two compounds are inhibitors of human 17α-hydroxylase/C_{17-20} lyase, a heme containing enzyme, with IC_{50} values of 339 and 372 nM respectively. Related nonspirocyclic compounds were more potent inhibitors.

1.08.3.1.4 Spiro[2.5] ring systems

The spiroepoxide natural product fumagillin (**4**, Figs. 2 and 14) is a covalent inhibitor of methionine aminopeptidase-2 (MetAP-2).[89,90] Several biological activities, resulting from inhibition of MetAP-2 by **4** and its semisynthetic analogs, with potential clinical application have been reported. For example, **56** (TNP-470, AGM-1470) inhibits the growth of tumors in animal models due to its antiangiogenic activity and reached Phase 2 clinical trials.[91,92] Compound **56** also exhibits antiparasitic activity.[93] Carbamate **57** (PPI-2458) resulted from an effort to improve the poor oral bioavailability of **56** and reduce its central nervous system (CNS) penetration (Table 13).[94] In addition to demonstrating improved inhibition of MetAP-2 and more potent inhibition of the growth of human umbilical vein endothelial cells (HUVEC), compound **57** was 9% orally bioavailable in rat and none of the animals displayed CNS toxicity and when dosed at 60 mg kg^{-1} day^{-1} IV for 14 days. More recently another analog, **58** (ZGN-433, beloranib) for the treatment of obesity has completed Phase 2 (Fig. 14).[95]

The natural product FR901464 (**59**) and its *O*-methyl derivative spliceostatin A (**60**) have been shown to bind to the SF3b subunit of the spliceosome and disrupt its functioning (Fig. 15).[96] Compounds with this mode of action are of interest in oncology.

A group at St. Jude Children's Research Hospital has prepared a series of analogs, including **61**, termed sudemycins, with fewer stereocenters.[97] Further optimization of **61** led to carbamate sudemycin D6 (**62**) which displayed cytotoxic activity against several tumor cell lines (SK-MEL-2: $IC_{50} = 39$ nM; HeLa: $IC_{50} = 50$ nM).[98]

Orally bioavailable γ-amino acid pregabalin (**63**) is approved for treatment of neuropathic pain (Fig. 16). It binds to the α_2-δ subunit of voltage-gated calcium channels with a K_i of 19 nM. Spirocyclic β-amino acid **64** binds with a K_i of 13 nM. Like **63**, **64** protected DBA/2 mice from audiogenically induced tonic seizures when 30 μg was injected into the cerebral ventricles; however, **64** was not effective when dosed orally at 30 mg kg^{-1}.[99] Unlike **63**, **64** is not a substrate for active transport into the CNS by the system L transporter.

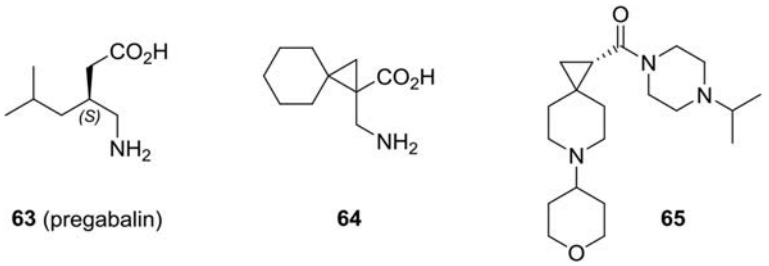

Fig. 16 Selected spiro[2.5] compounds.

Exploration of a 6-azaspiro[2.5]octane core resulted in the discovery of selective histamine-3 receptor (H_3R) antagonist **65**.[100] The compound has a receptor binding K_i of 0.8 nM and a cellular IC_{50} of 8.3 nM. The compound is highly selective for H_3R over other biogenic amine receptors, including H_1R, H_2R, and H_4R. It has oral bioavailability of 99% in rat, a brain to plasma ratio of 3.

1.08.3.1.5 Spiro[2.≥6] ring systems

Dual inhibitors of angiotensin converting enzyme (ACE) and neutral endopeptidase (NEP) are expected to possess superior antihypertensive activity. Geminal dimethyl compound **66a** exhibits double digit nanomolar inhibition of both ACE and NEP (Table 14). The subtle change brought about by constraining the two methyl groups to give spirocyclopropane **66b** maintains ACE potency, but leads to a 6× loss in NEP potency.[101]

1.08.3.2 Spiro[3.*n*] Ring Systems

With the important exception of β-lactams, four-membered rings have been exploited in medicinal chemistry to a lesser extent than three-, five-, and six-membered rings. Similarly, four-membered rings are less numerous in spirocycles, although this situation has begun to change driven by improved methods for their synthesis.[44–46]

1.08.3.2.1 Spiro[3.3] ring systems

2-Oxa-6-azaspiro[3.3]heptane and 2,6-diazaspiro[3.3]heptane have been proposed as isosteres of morpholine and piperazine, respectively,[44,46,102] and they have increasingly appeared in the medicinal chemistry literature in these roles. Three examples follow. Replacement of the morpholine ring in leucine rich repeat kinase 2 inhibitor **67** with 2-oxa-6-azaspiro[3.3]heptane gave **68** (Fig. 17A) which suffered a drastic loss in potency.[103] By contrast, replacement of the piperazine ring in ketohexokinase inhibitor **69** with 2,6-diazaspiro[3.3]heptane provided **70** with slightly improved potency (Fig. 17B).[104] In a series of stearoyl CoA desaturase (SCD) inhibitors, piperazine and 2,6-diazaspiro[3.3]heptane analogs **71** and **72** had comparable potency (Fig. 17C).[105]

1.08.3.2.2 Spiro[3.4] ring systems

Compound **73** inhibits epidermal growth factor receptor (EGFR) kinase with an IC_{50} of 15 nM and is cytotoxic to HCC827 cells, a cell line which contains an EGFR-activating mutation, with an IC_{50} of 28 nM (Fig. 18).[106] In addition, the compound has 34 μg mL^{-1} water solubility. Compound **74**, and its analogs, employs a spirocycle to fill the S2 pocket[107] of HCV protease, in place of the substituted pyrrolidine present in boceprevir and telaprevir.[108] Compound **74** has an EC_{50} of 800 nM against the HCV replicon in Huh7 cells. Cytotoxicity discouraged further exploration of this series.

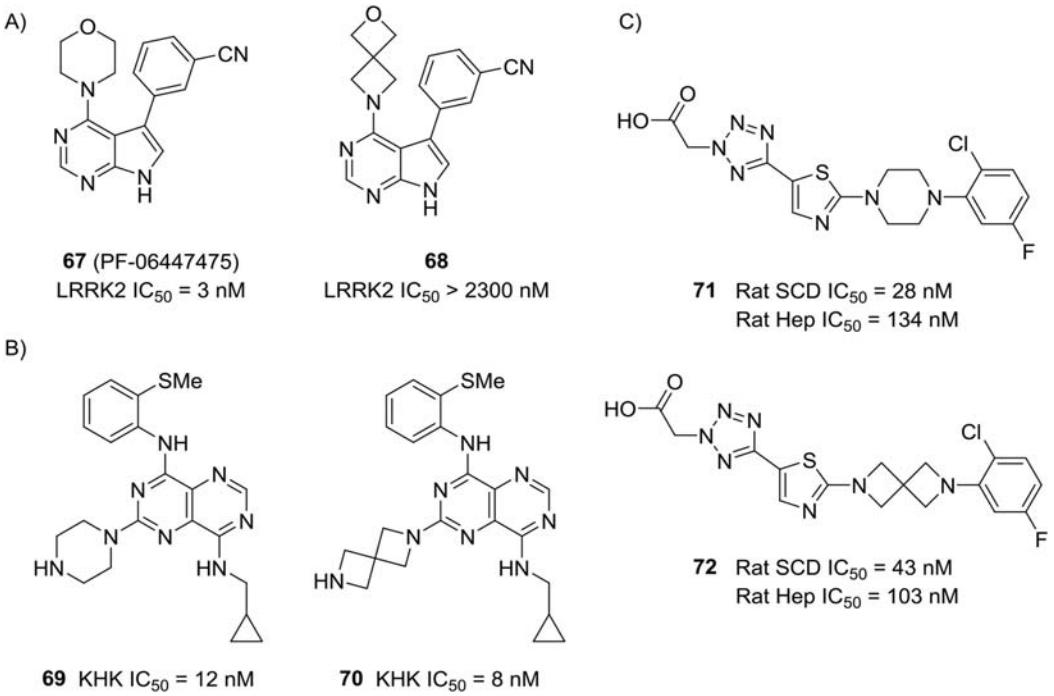

Fig. 17 Examples of the use of spiro[3.3] ring systems.

The prodrug sofosbuvir (**75**) is marketed for the treatment of HCV (Table 15). Two groups have reported analogs of sofosbuvir in which the methyl and fluoro substituents at the 2′ position are replaced with a spirooxetane.[109,110] Both groups initially explored cytidine analogs **76a** and found weak activity in the replicon assay. Conversion to the phosphoramidate prodrugs **76b**[109] and **76c**[110] led to approximately 4× improvements in potency. The uridine analog **77a** is inactive in the replicon assay; however, the derived triphosphate **77b** weakly inhibited NS5B polymerase ($IC_{50} = 39$ μM) and phosphoramidate prodrug **77c** was active in the replicon assay. Replacement of the uracil moiety with 6-methoxypurine and the methyl ester with an *n*-butyl ester afforded **78b** with submicromolar activity in the replicon assay.[109]

1.08.3.2.3 Spiro[3.5] ring systems

Urea **79** (PF-04457845) is a covalent inhibitor of fatty acid amide hydrolase (FAAH) which is orally efficacious at 1 mg kg^{-1} the complete Freunds adjuvant (CFA) rat model of pain and was nominated as a clinical candidate (Table 16).[111] The aminopyridazine moiety functions as a leaving group in **79**. A library synthesis approach was adopted in an effort to replace the methylenepiperidine core with various spirocycles. Compound **80** was identified as the most promising compound from an initial 126-member library constructed from 3 left hand tail groups, 14 spirocyclic cores, and 3 aminoheterocycle leaving groups.[112] Additional rounds of library synthesis were undertaken with the goal of optimizing potency, restoring oral bioavailability, and moving parameters such as MW into optimal ranges for CNS drugs. These goals were met with the discovery of a second clinical candidate **81** (PF-04862853) with MW <400 and a minimum effective dose of 0.3 mg kg^{-1} in the CFA model.[113]

[a] *M2*, human muscarinic acetyl choline M2 receptor.

High throughput screening (HTS) identified spiroazetidine **82** as an inverse agonist of the ghrelin receptor (Table 17). Inverse agonists of this receptor are anticipated to have beneficial effects on body weight and glucose homeostasis. Optimization of the two end groups for potency and improved druglike properties led to **83**.[114] Significant off-target pharmacology of **83** on the human muscarinic acetyl choline M2 receptor was uncovered. Constraining the benzyl substituent on the azetidine nitrogen into an (*R*)-indanyl group reduced binding to the M2 receptor, for example, **84**.[115] Further optimization for potency and M2 selectivity identified the favorable properties of the 6-methyl-4-pyrimidinyl group and led to the discovery of the clinical candidate **85** (PF-5190457).[116] In cultured human whole islets, 1 μM of **85** stimulated insulin secretion more effectively than 11.2 mM glucose.

A group at Amgen has reported on a series of hydroxyethylamine beta-site amyloid precursor protein cleaving enzyme 1 (BACE1) inhibitors that incorporate a spirocyclobutane (Table 18). The genesis of the spirocyclic component, which occupies

the S1′ and S2′ pockets[107] of the enzyme, has not been reported. Compound **86** demonstrated a 32% reduction in brain β-amyloid (Aβ) level, when dosed at 100 mg kg^{-1} PO to rats.[117] The disappointing in vivo efficacy was ascribed to suboptimal pharmacokinetics and poor CNS penetration. Furthermore, **86** is subject to permeability glycoprotein (PGP) mediated efflux, limiting drug levels in brain. Incorporation of a 3,4-methylenedioxy substituent on the benzyl group in place of 4-fluoro imparted potent CYP3A4 inhibition and, as a result, reduced clearance in liver microsomes. Combination of this change with replacement of the acetamide by a methoxypropionamide provided **87** which is slightly less potent than **86** but has reduced PGP efflux and improved bioavailability.[118,119] Compound **87** demonstrated a 44% reduction in brain Aβ level, when dosed at 30 mg kg^{-1} PO to rats, but unfortunately, caused drug-induced tachycardia in dog. A further round of optimization led to thiazole substituted analog **88** with improved potency and a lower rat efflux ratio.[120] This compound retained CYP3A4 inhibitory activity, resulting again in high oral bioavailability and further improved brain Aβ reduction.

Diazacarbazole **89** is a potent, orally bioavailable inhibitor of checkpoint kinase 1. In the course of profiling for off-target activities, **89** was found to be a potent acetyl cholinesterase (AChE) inhibitor (Table 19).[121] An X-ray structure of **89** bound to ChK1 and a model of **89** bound to AChE were employed to guide analog synthesis toward more selective compounds. Spirooxetane **90** demonstrated improved Chk1 cellular activity and a $>125\times$ reduction in inhibition of AChE compared to **89**. Four cycles of treatment of HT-29 xenograft mice with gemcitabine, followed 24 h later by PO administration of 50 mg kg^{-1} of **90**, resulted in complete inhibition of tumor growth.

1.08.3.3 Spiro[4.*n*] Ring Systems

1.08.3.3.1 Spiro[4.4] ring systems

First reported in 1959, spironolactone (**91**) is an antagonist of aldosterone, the major endogenous ligand of the mineralocorticoid receptor (MR) (Fig. 19). Its use in the clinic as an antihypertensive is limited by side effects including gynecomastia, hyperkalemia, and menstrual irregularities, resulting from its lack of selectivity for MR over the androgen and progesterone receptors (AR and PR, respectively). Efforts to improve the selectivity of **91** resulted in the discovery of eplerenone (**92**) which binds to MR with $20\times$ reduced potency than **91**, to AR with $12\times$ reduced potency and to PR with $>140\times$ reduced potency.[122,123] Despite its reduced

binding to MR in vitro, **92** is a more potent aldosterone antagonist in vivo and exhibits reduced antiandrogenic and progestagenic effects. Drospirenone (**93**) is an analog of **91** which has been optimized for PR antagonism, although it retains antimineralocorticoid activity comparable to that of progesterone.[124] Compound **93** is used clinically, in combination with ethinylestradiol, as an oral contraceptive.

Spiroketal amcinonide (**94**) is a topical corticosteroid used for treatment of atopic dermatitis and allergic contact dermatitis.[125]

Researchers at Sanofi hypothesized that an imidazolin-4-one ring could replace the hydroxymethylimidazole moiety in the antihypertensive angiotensin II receptor blocker losartan (**95**, Table 20).[126] Analogs with a single substituent at the 5-position proved to be unstable, so 5,5-disubstituted analogs were investigated. Spirocycle **97a** was more potent than the isosteric 5,5-diethyl analog **93**. Reintroduction of the tetrazole ring gave irbesartan (**97b**) which is a clinically used antihypertensive.

Enalapril (**98a**) is prescribed for the treatment of hypertension (Table 21). It is a prodrug of the active dicarboxylic acid inhibitor enalaprilat **98b**. Incorporation of a spirocyclic amino acid into **98a**, in place of proline gave spirapril **99a**.[127] Both ester **99a** and diacid **99b** were more potent than **98a** and **98b** in vivo. Compound **99a** is marketed as an antihypertensive.

Telcagepant (**100**) is a calcitonin gene-related peptide (CGRP) receptor antagonist which entered clinical trials for the treatment of acute migraine (Fig. 20, Table 22).[128] Development was terminated when elevated levels of the liver enzyme alanine transaminase were found in treated patients. Dealkylation of the azabenzimidazolinone ring from the 4-position of the piperidine ring is a major metabolic pathway of telcagepant, contributing to its rapid first pass metabolism in rhesus.[129] Replacement of this linkage with a suitable spirocycle, incorporating the key cyclic CONH moiety from telcagepant, was expected to block this pathway

while maintaining receptor potency. Scientists at Merck reported a survey of spirocycles which identified spirohydantoin **101** and spiroazaoxindole **102** as compounds with potential for optimization.[130] Replacement of the left hand portion of **101** with other groups lead to compound **103** which is more potent in vitro than telcagepant.[131] Replacement of the hydantoin with an azaoxindole gave **104** which, as expected based on the earlier work,[132] gained potency. The oral bioavailability of compound **104** was limited in rat (12%) and nil in rhesus (0%).[133] Introduction of an NH in the lactam ring and tying back the geminal dimethyl substituents into a spirocyclopentane provided **105a** (MK-3207) with excellent in vitro potency and improved oral bioavailability in both rat (74%) and rhesus (9%).[133] Further modifications afforded ^{11}C PET ligand **105b** (MK-4232)[134] and **106** (MK-8825).[135] The structure of ubrogepant (**107**), a second clinical candidate, has been revealed, but the details of its discovery have yet to be published.[136] Interestingly, the configuration of the spirocycle in **107** is inverted relative to **105a** and **106**. Presumably this is a function of the attachment point of the left hand portion of the molecule as described for earlier compounds.[137]

Compound **108** is potent inhibitor of the zinc metalloproteinase tumor necrosis factor-α-converting enzyme (TACE), albeit with substantially reduced potency in a whole blood assay (WBA) measuring inhibition of TNF-α release (Table 23).[138] Molecular modeling indicated that the 4-position of the cyclopentane ring of **105** is solvent exposed. Spiroketal **109** was equipotent to **108** in binding but was 20× more potent in the WBA.[139] The acid labile dioxolane ring precluded further development of **109**. Spirotetrahydrofurans **110** and **111** both bound tightly to TACE and demonstrated ~4× improved potency in the WBA compared to **108**.[139] Compound **110** retained the same level of oral bioavailability of **108** in a dog.

Based on examination of crystal structures of the mouse double minute 2 homolog (MDM2) protein, also known as E3 ubiquitin-protein ligase, bound to p53 tumor suppressor, Wang and coworkers designed and synthesized densely functionalized spirooxindole **112** as an inhibitor of this protein–protein interaction (Fig. 21, Table 24).[140] Initial optimization led to compound

113 (MI-63) with an in vitro K_i of 3 nM but low oral bioavailability in rat.[141,142] A successful campaign to improve pharmacokinetic (PK) properties identified **114** (MI-219), albeit with a 3.5 × loss in MDM2 binding.[142] A careful study of the stability of the isomers of **115** showed that, under aqueous conditions, retro Mannich opening of the pyrrolidine ring followed by reclosure of the pyrrolidine ring resulted in the formation of all four stereosiomers.[143] Furthermore, the isomer with the syn arrangement of the 2-neopentyl and 4-halophenyl groups (depicted in **115**) is more potent than the anti arrangement (depicted in **114**). Although both **114** and **115** inhibit growth of SJSA-1 osteosarcoma cells in vitro, in the SJSA-1 xenograft model in mice, both compounds required >200 mg kg^{-1} PO doses to inhibit tumor growth and did not achieve complete tumor regression. PK properties were

targeted for further improvement.[144] The side chain 1,2-diol was identified as the major site of metabolism. Removal of one hydroxyl groups and conformational constraint led to aminocyclobutanol derivative **116** (MI-888) and aminocyclohexanol derivative **117**. Compound **116** demonstrated improved potency and PK properties. In SJSA xenograft mice, 30 mg kg^{-1} day^{-1} of both **116** and **117** delivered by oral gavage for 2 weeks inhibited tumor growth, while 100 mg kg^{-1} day^{-1} provided complete tumor regression. Compound **117** was shown to be configurationally stable under conditions that earlier compounds such as **112** and **115** isomerized. This compound has been extensively characterized in cancer cell lines and xenograft models, and entered Phase I clinical trials in 2012, however no results have been reported.[145–147]

Separately, a group at Hoffmann-La Roche hybridized a nonspirocyclic compound MDM2-p53 protein–protein interaction inhibitor they had discovered[148] with **116** to afford **118** (RO8894)[149] and its pyridine and thiophene analogs, **119** (RO2468) and **120** (RO5353), respectively (Table 25).[150] In a homogeneous time resolved fluorescence (HTRF) binding assay, all three compounds bound to MDM2 with single-digit nanomolar affinity and all three had average IC_{50} values of $\leq$20 nM against a panel of three p53 cancer cell lines. Compounds **118** and **120** showed very high oral bioavailability in mice. Compound **118** achieved tumor regression in SJSA xenograft mice when dosed once a day PO at 6.25 mg kg^{-1} for 30 days, while compounds **119** and **120** achieved the same effect at 10 mg kg^{-1} PO once a day.

Spirothiazolidine **121**,[151] designed from MI-219, was further optimized for potency in two cell lines, MCF-7 human breast adenocarcinoma and HT29 human colon carcinoma, to give **122** (Fig. 22).[152]

Fig. 22 MDM2-p53 protein–protein interaction inhibitors from the University of Naples.

Borrowing some features from an earlier series of fused hydantoin antagonists of leukocyte function associated antigen-1 (LFA-1),[153] scientists at Bristol-Myers-Squibb discovered spirocyclic hydantoin **123** (Table 26).[154] This compound was shown to be orally bioavailable in mouse and dog, and, at 10 mg kg^{-1}, it significantly blocked eosinophil accumulation in airways in the mouse ovalbumin lung inflammation model. Compound **123** was advanced into the clinic. Examination of an X-ray crystal structure of **123** bound to LFA-1 indicated that the thiophene carboxylic acid group projected into solvent and does not interact with the protein. Replacement of this group with a pyridine carboxylic acid directly attached to the pyrrolidine nitrogen to give **124** allowed formation of an additional hydrogen bond with the protein and a concomitant 7× increase in binding potency a HUVEC: T-cell binding assay.[155] In addition, **124** was ~4× more potent than **123** in blocking human T-cell activation in a mixed lymphocyte reaction assay and in a human IL-2 whole blood ex-vivo assay. Compound **124** was also advanced into clinical trials.

γ-Secretase inhibitors have been explored as potential therapeutic agents for Alzheimer's disease. Initial optimization of an HTS hit led to butanesulfonamide **125** with an IC_{50} of 610 nM in SHSY5Y cells (Table 27).[156] Replacement of the butyl group in **125** with a trifluoroethylamino group gave 4× more potent sulfamide **126**.[157] Constraining the sulfamide into a spirocycle to give **127** provided a further 8× boost in potency. Following SAR developed in the original sulfonamide lead series, a piperidinoallyl group was appended to **127** to give **128**, which achieved subnanomolar potency. This compound reduced brain Aβ(40) in transgenic APP-YAC mice with an ED_{50} of 17 mg kg^{-1} when dosed orally. Further optimization of **1** targeted the allyl linker and resulted in compound **129** which has ≥35% oral bioavailability in rat, dog, and rhesus and an ED_{50} of 1 mg kg^{-1} in APP-YAC assay.[158]

1.08.3.3.2 Spiro[4.5] ring systems

Investigation of the psychosedative activity of a series of *N*-(4-phenyl-1-piperazinylalkyl) cyclic imides, using animal models, showed that the spirocycle **130b** had superior properties to the geminal dimethyl analog **130a** (Fig. 23).[159] Replacement of the phenyl ring with a pyrimidine and lengthening of the alkylene linker led to the discovery of buspirone (**131**), prescribed for the treatment of anxiety.[160] Compound **131** is a member of the azapirone class of drugs and is a partial agonist of the serotonin 5-HT_{1A} receptor and an antagonist of the dopamine D_2, D_3, and D_4 receptors. It has been a starting point for drug discovery efforts aimed at improving on its receptor selectivity[161,162] and identifying compounds with broader therapeutic uses.[163] Alnespirone (**132**)[161] and tiospirone (**133**)[163] are two prominent analogs which retain the spirocyclic imide ring system.

Spiperone (**135**) was discovered in the early 1960s by C. Janssen and P. A. Janssen and is a typical antipsychotic (Table 28).[164,165] It is the only spirocyclic member of the butyrophenone class of drugs. Benperidol (**134**), another member of this class, can be considered as a nonspirocyclic analog of **132**. Spiperone is an antagonist of the dopamine D_2, serotonin 5-$HT_{1A,}$ and 5-HT_{2A}

receptors. Efforts continue to identify more selective analogs.[166,167] For example, the *N*-methyl analog **136** experiences a 12× reduction in binding to 5-HT_{2A} but much greater losses in binding to 5-HT_{1A} (>170×) and D_2 (440×).

Fluspirilene (**137**, Table 29) is a typical antipsychotic, injected for the treatment of schizophrenia, which was first disclosed in the same patent as **135** (Table 28).[164] Compound **137** is primarily a dopamine D_2 and serotonin 5-HT_{2A} antagonist. Its pharmacology has been compared to 11 other antipsychotics.[168]

Enilospirone (**138**) was discovered as one member of genus of compounds that increased motility in mice (Fig. 24).[169] The compound has been of interest to enhance performance in long duration tasks.[170] At higher doses it causes sleep disturbances.[171] Fenspiride (**139**) is an antitussive.[172] Guanadrel (**140**) is a postganglionic adrenergic blocking agent prescribed as antihypertensive.[173] It functions as a partial agonist of the sodium-dependent noradrenaline transporter. Compared to the nonspirocyclic analog guanethidine (**141**), **140** has a more desirable clinical profile, exhibiting a rapid onset of action and a shorter half-life in the body.[174] The neurokinin 1 (NK1) receptor antagonist rolapitant (**142**) was approved for the treatment of delayed phase chemotherapy-induced nausea and vomiting in 2015.[175]

Selective inhibitors of sodium glucose cotransporter 2 (SGLT2) have been targeted for the treatment of diabetes. Using a pharmacophore query based on the structures of known hSGLT2 inhibitors including **143** (Table 30), researchers at Chugai identified a series spirocyclic *C*-aryl glucosides which they optimized into the highly isoform-selective clinical candidate tofogliflozin (**144**).[176]

Patchett and coworkers at Merck have described the discovery and optimization of spirocycle growth hormone (GH) secretagogues which mimic the effect of the endogenous peptide hormone ghrelin. Screening a collection of compounds prepared during earlier receptor projects uncovered spiropiperidine **145** with an EC_{50} of 300 nM for GH release in a rat pituitary cells (Fig. 25, Table 31).[177] Derivitization of the spirocyclic core led to the discovery of **146** with an EC_{50} of 50 nM as a mixture of four isomers. Concern that the strongly basic quinuclidine ($pK_a = 11$) would hinder oral absorption, prompted a quest for replacements which identified α-aminoisobutyramide. Compound **147** with an EC_{50} of 14 nM is a single isomer.[178] A 2 mg kg^{-1} PO dose of this compound increased GH levels by $\geq 4\times$ in beagle dogs. Incorporation of polar groups at the benzylic position of the spiroindane provided further potency increases as shown by **148a–c**.[179,180] Combination of a polar group at this position with replacement of the indolylmethyl group with a benzyloxymethyl group[181] led to the discovery of clinical candidate **149** (MK-0677) with an EC_{50} of 1.3 nM in the rat pituitary assay and full response in the dog model at 0.25 mg kg^{-1} PO.[177] Additional work afforded ester **150a**, a potent compound with a short half-life in vivo,[182] and amide **150b** with a subnanomolar EC_{50} value and full efficacy in the dog model at 0.06 mg kg^{-1} PO.[183]

Spiropiperidines have also proved to be effective ligands at other GPCRs with endogenous peptide ligands. Compound **151** binds to the oxytocin receptor with a K_i of 780 nM and is $>100\times$ selective over the vasopressin V_1 and V_2 receptors (Fig. 26).[184] Compound **152** binds to human somatostatin receptor subtype2 (sst_2) with a K_i of 1.6 nM and $>1000\times$ selectivity over sst_1, sst_3, sst_4, and sst_5.[185] Compound **153** binds to the tachykinin NK2 receptor with a K_i of 1.25 nM and is an antagonist in vivo.[60]

Weakly basic aminoheterocycles emerged as the favored head group to interact with the catalytic dyad Asp 32 and Asp 228 in beta-site amyloid precursor protein cleaving enzyme (BACE, β-secretase) inhibitors.[186–188] Several research groups have deployed the aminoheterocycle as one ring of a spirocyclic system. Workers at Amgen focused on the 2-aminooxazoline moiety which has a favorable pK_a (Fig. 27, Table 32).[189] Early analogs such as **154** achieved only micromolar potency. Guided by X-ray crystallography, the two phenyl rings were constrained with an ether linkage to form a spirocyclic xanthene core which was optimized to

afford **155** with a >1000× increase in potency in vitro and a 350× increase in cellular potency, while maintaining properties expected to lead to CNS penetration. The oral bioavailability of **155** was 31% in rat and, following a single 30 mg kg^{-1} oral dose, it reduced $Aβ_{40}$ levels in brain and cerebrospinal fluid (CSF) by 76% and 45%, respectively. However, **155** was a low single-digit micromolar human ether-a-go-go-related gene (hERG) inhibitor. Several follow-up compounds (**156–159**), all of which incorporate a 2-fluoro-3-pyridyl moiety to fill the S3 pocket,[107] retain on-target potency while reducing the hERG liability.[190–193] Significant reductions in both rat CSF and brain Aβ levels were reported for these compounds following single oral doses of 30 mg kg^{-1} or lower; notably **158** achieved >70% reduction in both compartments at 3 mg kg^{-1}.

A collaborative effort at Array Biopharma and Genentech started with the racemic spirocyclic acyl guanidine **160** (Table 33).[194] Guided by X-ray crystallography, the bromine atom in **160** was replaced with a pyrimidine ring to give **161** which experienced

a 770 × increase in potency against BACE1 but only an 18 × increase against the important off-target aspartyl protease, cathepsin D (CatD). Despite being a PGP substrate, a single 60 mg kg^{-1} PO dose of **161** to rat reduced the CSF Aβ level by 17% after 3 h. Several modifications, including replacement of the pyrimidine ring with 2-fluoro-3-pyridyl group and the geminal dimethyl substituents with a fused tetrahydropyran ring provided **162** with improved BACE potency, both in the in vitro enzyme assay and in the cell, but decreased CatD selectivity.[195] Compound **162** was also subject to PGP-mediated efflux but nonetheless effectively reduced CSF Aβ levels in guinea pig, rat, and cynomolgus monkey. Further SAR investigation, including replacement of the aspartate binding motif, afforded **163** with BACE potency comparable to **161** but greater CatD selectivity and reduced PGP efflux.[196]

Aldose reductase (AldR) catalyzes the formation of sorbitol which is implicated in the development of diabetic complications. The spirohydantoin sorbinil (**164**) was discovered by a group working at Pfizer and the absolute configuration of the active enantiomer was determined (Fig. 28, Table 34).[197–199] The (−) isomer of spirooxazolidinone **165** was a more potent binder to calf lens AldR than sorbinil but was less effective in an in vivo model that measured sorbitol levels in the sciatic nerve of streptozotocin induced diabetic rats.[200] Aza analog **166** was also a more potent binder but was less potent in the in vivo streptozocinized rat assay, possibly due to reduced metabolic stability.[201] On the other hand, the in vitro potency of spirosuccinimide **167** from Dainippon is reflected in its in vivo efficacy.[202]

Compound **168**, a more polar compound than **164**, is 10 × more potent in vitro than sorbinil; however, the effectiveness of the two compounds at inhibiting polyol accumulation in sciatic nerve is comparable, while **168** is much less effective at reducing polyol accumulation in lens (Table 35).[203] These results suggest that **168** does not penetrate the lens.

Fidarestat (**169**), a carbamoyl analog of **164**, is a 200 × more potent inhibitor of human AldR than **164** and its selectivity over the related enzyme aldehyde reductase is much improved (Table 36).[204] In addition, **169** is 8 × more potent in the streptozocinized rat

model. The origins of potency and selectivity of **169** have been studied by X-ray crystallography.[205–208] Compound **169** progressed to Phase 3 clinical trials.[209,210]

Chromakalim (**170**) acts on cell membrane adenosine triphosphate (ATP)-sensitive potassium channels, opening them and resulting in vasodilation (Table 37). Spirocycle **171** more effectively caused membrane hyperpolarization at 0.1 μM and caused a greater decrease in mean arterial pressure (MAP) and a greater increase in heart rate (HR) when dosed at 0.01 mg kg^{-1} IV.[211] Subsequently, the same authors demonstrated that potency resides in the (S) isomer of **171**.[212]

Conformational restriction of patented cholesterylester transfer protein (CETP) inhibitor **172** by introduction of an ether spirocycle, to give **173**, improved its potency and reduced its liphophilicity (Table 38).[213] Introduction of a second ether provided **174** with a further increase in potency and decrease in clogP. Compound **174** is orally bioavailable and dose dependently inhibited plasma CETP activity in hCETP transgenic mice, leading to a 74% increase in high density lipoprotein (HDL)-cholesterol after 5 days at the 10 mg kg^{-1} dose.

Matrix metalloproteinases (MMPs) contribute to thrombus dissolution; thus, inhibitors of MMPs have potential as for the prevention and treatment of hemorrhage. Using the X-ray structures of two known inhibitors, **175** and **176** bound to MMP13 and MMP3, respectively, spirocyclic lead **177a** was designed (Table 39). Further optimization led to the discovery of the preclinical candidate **177b**.[214] The detailed pharmacology of **177b** has been published.[215]

k Opioid agonists are expected to be potent analgesics without the undesired side effects such as respiratory depression and inhibition of gastrointestinal motility that result from the μ opioid receptor. Methoxycyclohexane **178** was the most potent of several analogs in which the position and stereochemistry of the methoxy group was varied (Table 40).[216] The methoxy group was

constrained into a spiro tetrahydrofuran to give enadoline (**179**), which was both more potent against the μ receptor and more selective over the k receptor. In addition, when dosed IV, **179** is 25× more potent than morphine in the rat paw pressure assay. The closely related compound spiradoline (**180**)[217] was less selective and less effective in the rat paw pressure assay.

Rigid analogs of acetyl choline have been explored as acetyl choline receptor agonists. Cevimeline (**181**, Fig. 28) is a muscarinic M1 and M3 agonist used clinically for treatment of dry mouth (Fig. 29).[218,219] On the other hand, spirocarbamate **182**, another conformationally constrained ACh analog, binds to the nicotinic acetyl choline receptor α7 (nAChRα7) with triple digit nanomolar potency but is selective over other subtypes and is orally bioavailable in rat (Table 41).[220] Substitution of the carbamate NH with a chlorothiophene afforded **183** which was almost 40× more potent than **182** against nAChRα7 but retained 200× selectivity against the α4β2 subtype and oral bioavailability in rat.[221] CYP2D6 inhibition by **183** was associated with the chlorothiophene

moiety. Replacement with a 3-methyl-5-benzothiophenyl group provided **184** with further increased on-target potency but without the CYP2D6 liability.[222] The oral bioavailability of **184** was low in rat but higher in monkey, 83% after a 10 mg kg^{-1} PO dose.

Piperidinopyridine **185** was uncovered in a high throughput screen of 63,040 compounds against the wingless-related integration site (WNT) pathway (**Table 42**).[223] Its favorable physical properties (MW = 274, alogP = 1.6, water solubility >1 mg mL^{-1}) made it an attractive starting point for optimization. Since the biochemical target of **185** is unknown, ligand-based methods were applied to its optimization. Replacement of the piperidine carboxamide with a spirolactam and introduction of a two ring system in place of one chlorine led to the discovery of **186**. This compound had low oral bioavailability and was an inhibitor of CYP3A4 (IC_{50} = 2100 nM). Replacement of the morpholine ring with an *N*-methyl pyrazole gave **187** with improved oral bioavailability in rat and reduced CYP3A4 inhibition. Compound **187** demonstrated a 37% reduction in tumor weight when dosed at 70 mg kg^{-1} bid for 9 days to COLO205-F1756 xenograft mice.

CC chemokine receptor 2 (CCR2) antagonists have been studied for the treatment of inflammatory diseases. An HTS campaign at Merck uncovered α-aminoamide **188** originally prepared during their NK1 program (**Fig. 30**).[224] Replacement of the dimethylamine with a spirocyclic piperidine gave **189** with a 9× improvement in binding and functional activity in a chemotaxis assay (**Table 43**). This compound was, however, more potent against NK1 (IC_{50} = 50 nM) and CC chemokine receptor 5 (CCR5) (IC_{50} = 30 nM) than CCR2. Substitution of the spirocycle with a methyl group and replacement of the 4-fluorophenyl with cyclopropyl gave **190** with improved CCR2 binding, functional activity in a Ca^{2+} flux assay and diminished binding to CCR5 (38% inhibition at 1 μM).[225] Replacement of the flexible linker with a cyclopentane provided **191a** and **191b** with subnanomolar activity in the two functional assays.[226,227] Compound **191a** displayed ~500× selectivity over CCR5. Both **191a** and **191b** had rat oral bioavailability >15%.

Two groups have reported spirocyclic inhibitors of mast tryptase (**Table 44**). Researchers at Sanofi discovered compound **192**; however, this compound was rapidly metabolized by semicarbazide sensitive amine oxidase (SSAO).[228] Consideration of the mechanism of SSAO suggested that reducing the electrostatic potential around the benzylamine would decrease the rate of metabolism by SSAO. This line of thought resulted in the discovery of **193** which was equipotent against β-tryptase and considerably more stable upon incubation with SSAO. It was also stable to rat and human liver microsomes (<20% metabolized at t = 20 min) and was not a hERG blocker. A group at Johnson & Johnson subsequently disclosed **194**, a spirocyclic analog of **192**.[229] Compound **194** is stable in human liver microsomes ($t_{1/2}$ > 100 min), 100% orally bioavailable in rat and was efficacious when dosed PO at 20 mg kg^{-1} bid for 4 days in a guinea pig model of asthma.

1.08.3.3.3 Spiro[4.6] ring systems

Dual antagonist of the histamine H_1 and serotonine 5-HT_{2A} receptors have potential for the treatment of insomnia. Structural modification of mianserin (**195a**) and mirtazapine (**195b**) led to the discovery of **196** with promising dual antagonist activity

against H_1 and 5-HT_{2A} receptors (Table 45).[230] In addition to lacking selectivity toward 5-HT_{2B} and 5-HT_{2C} receptors, the compound suffered from significant off-target activity against cytochrome P450 2D6 (CYP2D6) and hERG potassium channels. Replacement of the dimethylamino group with an azetidine carboxylic acid to give **197** maintained on-target potency but eliminated the CYP2D6 and hERG liabilities.[231] Despite its zwitterionic character, compound **197** was orally bioavailable (Rat $F = 54\%$) and penetrated the CNS. A 3 mg kg^{-1} PO dose of **197** resulted in a statistically significant increase in total sleep time.

Endomorphin-2 (**198**) is an endogenous opioid peptide with affinity for the μ-opioid receptor (Table 46). Compound **199** is an example of successful replacement of a dipeptide with a spirocycle which has been shown to be a β-turn mimetic.[14,232] Compound **199** suffered a 3× loss in binding potency but retained μ selectivity and functional activity as an agonist. Compound **200**, a non-spirocyclic analog of **199** which is not expected to adopt a β-turn conformation, was almost 1000× less potent in binding.

1.08.3.4 Spiro[5.*n*] Ring Systems

1.08.3.4.1 Spiro[5.5] ring systems

Selective monohydrogenation of the spiroketal natural product 5-*O*-demthylavermectin A_{1a} (**201**) affords compound 22,23-dihydroavermectin B_{1a} (**202**), the major component of ivermectin, an antihelminthic used in both human and animal health (Fig. 31).[233]

Artemisinin (**203**) is an important antimalarial drug (Fig. 32).[234] The peroxide moiety is essential for its biological activity. Spirocycles incorporating the 1,2,4-trioxane ring have been explored as one avenue in the effort to discover analogs with superior properties. The adamantane **204** (CDRI 97/98), discovered at the Central Drug Research Institute in India, has entered Phase 1 clinical trials.[235] Compound **205**, recently described by the same group, is orally active against multidrug resistant *Plasmodium yoelii nigerensis* in mice at a dose of 24 mg kg^{-1} for 4 days.[236]

Selective agonists of the δ opioid receptor have shown efficacy in animal models of pain. Compound **206a**, with a K_i of 500 nM against the δ receptor, was discovered by screening a proprietary library (Table 47).[237] Deletion of the 4-chlorobenzylsulfonyl group

to give **206b** provided a 3× increase in potency, while introduction of the double bond in **207** imparted a further 2× potency improvement. While **207** demonstrated promising selectivity over the μ and k opioid receptors, it had a hERG liability. Exploration of substituent SAR around the pendant benzene ring led to the discovery of *N,N*-diethylamide **208a** with improved potency against the δ receptor, retention of isoform selectivity, and a reduced hERG liability. Introduction of a hydroxyl group on the fused benzene ring provided **208b** (ADL5859) with subnanomolar potency, excellent receptor isoform selectivity, and a much improved hERG

211b X = F (cebranopadol)

Fig. 33 δ Opioid receptor agonist and dual nociceptin/orphanin FQ peptide (NOP) and μ opioid receptor agonists.

IC_{50}. Compound **208b** was orally bioavailable (rat $F=33\%$) and efficacious in the rat Freund's complete adjuvant (FCAdj) mechanical hyperalgesia assay with an ED_{50} of 1.4 mg kg^{-1} when dosed PO. This compound was well tolerated in a Phase I safety study and was advanced into a Phase II proof of concept study. An alternative optimization of **208a** gave **209** (ADL5747) which is less potent than **208b** in vitro but has an improved ED_{50} of 0.03 mg kg^{-1} in the fluorescent cytoprint assay (FCA).[238] The oral bioavailability of **209** was 38% in rat and it was free of significant off-target liabilities, including against hERG. Compound **209** was advanced into Phase 1 clinical trials. Unlike the nonspirocyclic δ opioid receptor agonist **210** (Fig. 33), neither **208b** nor **209** causes convulsions in mice.

Spirocycle **211a** binds potently to, and is a full agonist of, both the nociceptin/orphanin FQ peptide (NOP) and μ opioid receptors; however, it has poor PK properties (rat $F=4\%$).[239] The fluoro derivative **211b** (cebranopadol) has much improved oral bioavailability (rat $F=23\%$) and has advanced to Phase 2 for the treatment of pain.[240]

Ligands of the σ receptor have been explored for treatment of various neurological disorders. Spiropipideridines have been a prominent class among ligands for this receptor. Compound **212** was first reported by Merck as a 5 nM ligand (Fig. 34, Table 48).[242] Subsequently, two isoforms of the receptor were discovered and **212** was shown to be selective for σ_1.[241] Introduction of a sulfur into the spirocycle and transposition of the fused benzene ring afforded spipethiane (**213**) with improved σ_1 selectivity.[243] This compound also has $>20{,}000\times$ selectivity over the dopamine D_2 receptor. Further advances in σ_1 selectivity were achieved by the group led by Wunsch with compounds **214a**, **214b**, and **215**.[244–246] On the other hand, a group at Lundbeck introduced an ether linkage into the spirocycle and replaced the benzyl substituent with a larger group to give **216a** which is σ_2

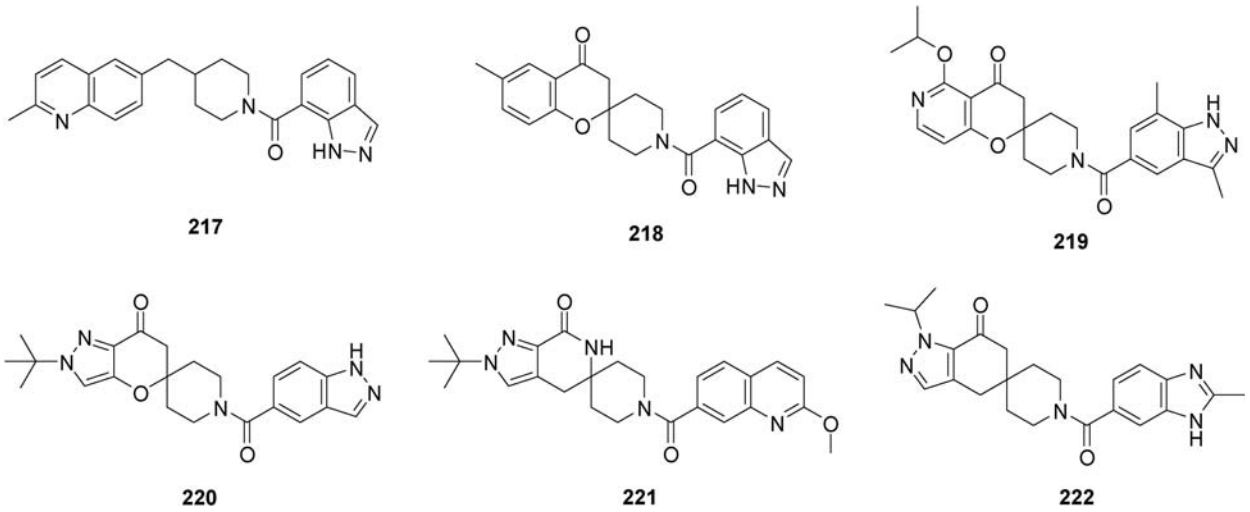

Fig. 35 Acetyl CoA carboxylase inhibitors.

selective. Reducing the cyclic ether from a six- to a five-membered ring provided **216b** with further increased σ_2 potency and selectivity.[241]

Dual inhibitors of acetyl CoA carboxylase isozymes 1 and 2 (ACC1 and ACC2) are expected to decrease fatty acid synthesis in liver and adipose tissue while increasing fatty acid oxidation in liver and muscle, leading to increased energy expenditure, reduced adiposity, and improved insulin sensitivity. Initial follow up of an HTS hit led to compound **217** (Fig. 35, Table 49).[247] The quinoline moiety was replaced with a spirochromanone to afford **218** with ca. 5× improved potency on both isozymes. Further optimization of both chromanone and indazole rings gave **219** which was more potent and orally bioavailable in rat (F=8-52% depending on the formulation). In an effort to reduce lipophilicity, the pyridine ring was replaced with a pyrazole to give **220** which retained potency.[248] The ketone in **220** was observed to undergo reduction in vivo in some species. To avoid this problem, spirolactams, including **221**, were explored.[249] Compound **221** has a clean CYP profile, 71% oral bioavailability in rat, and had an ED_{50} of 1.3 mg kg^{-1} for inhibition of incorporation of ^{14}C acetate into lipids in rats. In an alternative approach, the alkyl substituent on the pyrazole was moved so as to sterically block the ketone.[250] This, combined with other changes, led to **222** which was 40% bioavailable and had an ED_{50} of 7.8 mg kg^{-1} for inhibition of incorporation of ^{14}C acetate into lipids in rats.

223 (RS-504393) **224**

Fig. 36 Spirocyclic chemokine receptors 2 (CCR2) ligands.

Phase I clinical studies demonstrated that **222** has PK properties suitable for once a day dosing and increased whole-body fatty acid utilization.

The CCR2 and CCR5, respectively, have both been addressed with spirocycles. Compound **223** from Roche was one of the first ligands of CCR2 to be described, with IC_{50} values of 89 and 330 nM in binding and functional assays (**Fig. 36**).[251] However, it lacked any selectivity over the human α1a receptor (IC_{50} = 72 nM). Compound **224** is structurally related to CCR2 antagonists described above (**Fig. 30**), and had an IC_{50} of 17 nM in a Ca^{2+} flux assay.[252]

CCR5 is the target site of the antiretroviral drug maraviroc. A group working at Ono Pharmaceuticals employed a library synthesis approach predicated on the privileged status of spirocycles as GPCR ligands[11] to discover **225a** (**Table 50**).[253] The poor oral bioavailability of **225a** was improved by introduction of a carboxylic acid to give **225b**, despite reduced rat liver microsome (RLM) stability.[254,255] Separately it was found that the methylene group connecting the diketopiperazine to the cyclohexane ring was a major site of metabolic hydroxylation.[256] One of the stereoisomeric metabolites, compound **226a**, had good potency.[257] Combination of the carboxylic acid and hydroxyl moieties provided the clinical candidate aplaviroc (**226b**) which progressed to Phase 2 when liver toxicity was encountered.[257,258]

Concurrently, a group working at Roche also disclosed spirocyclic CCR5 antagonists (**Table 51**).[259] Compound **227** has good oral bioavailability in rat, is highly selective over CCR1, CCR2, CCR3, CCR4, CCR6, and CXCR4 (IC_{50} values > 50 μM), and has a clean CYP profile. Interestingly, little difference in the antiviral activities of the enantiomers of **227** was observed. Hybridization of **227** with CCR5 antagonists from other companies, including Ono,[257,258] led to oxazinones **228** with comparable potency.[260] Although the oral bioavailability of **228** in rat was only 10%, it was significantly better in dog (85%) and monkey (42%). The 4-aminopiperidine moiety in **228** was replaced with an azabicycle to give **229** which also demonstrated good antiviral activity.[261]

The orexin system plays a key role in the regulation of sleep and wake.[262] Two related spirolactams, **230** and **231**, were reported as orexin receptor antagonists by workers at Novartis and Aurigene (**Table 52**).[263] While **230** was significantly more potent at both receptor isoforms than **231**, it lacked significant oral bioavailability in mouse. Compound **231** was more selective toward hOX_2R and had much improved oral bioavailability. When dosed orally to mice at 50 mg kg^{-1}, compound **231** clearly increased sleep

time; however, the detailed effect of the compound on sleep architecture differed from that of the suvorexant (**232**) which has modest OX_1R selectivity.

Stearoyl CoA desaturase-1 (SCD1) inhibitor **233**[264] was optimized by replacement of a benzoyl group with a spirocycle to give **234** with significantly improved potency in vitro and in cells (Table 53).[265] Replacement of the $CONHCH_2CH(OH)$ linker with an oxadiazolylmethyl group gave **235a** and **235b**.[266] Both these compounds made further potency gains in the cellular assay and the latter compound had excellent oral bioavailability. Compound **235b** also demonstrated potent, dose-dependent reduction of the plasma desaturation index upon oral administration for 7 days.

A number of spirocyclic barbituric acid derivatives have been studied as bacterial DNA gyrase inhibitors with potential antibacterial utility. PNU-286607 (**236**) was discovered at Pharmacia by whole cell HTS (Table 54).[267] The compound has excellent oral bioavailability in mice and was efficacious against methicilin-resistant *S. aureus* UC9213 in mice ($ED_{50} = 19.5$ mg kg^{-1}; *cf* ciprofloxacin $ED_{50} = 10$ mg kg^{-1}). Scientists at AstraZeneca modified the structure by incorporation of a fused isoxazole ring to give **(−)-237** and subsequently ETX0914 (**238**) which has been advanced as a clinical candidate for treatment of uncomplicated gonorrhea.[268,269]

Compound **239** (MRK-560) is a γ-secretase modulator with selectivity for presenilin-1 (PS-1) over presenilin-2 (PS-2), which may result in an improved therapeutic window (Table 55).[270,271] Extensive investigation around **239** led to the discovery of the unusual spirocyclic phosphonate **(−)-240** which displayed similar or improved potency, and selectivity toward PS-1.[272] This compound possessed a clean hERG and CYP profile, notably demonstrating a much reduced CYP2C9 liability compared to MRK-560. A single 10 mg kg^{-1} PO dose of **(−)-240** reduced Aβ levels in rat plasma, CSF, and brain by 69%, 45%, and 39% respectively after 6 h.

(*S*)-(−)-**241**, an activator of mitochondrial ATP-sensitive potassium channel, displayed similar cardioprotective effect to diazoxide when preadministered IP at 40 mg kg^{-1} to Langendorff perfused rat hearts (Fig. 37).[273,274]

The X-linked inhibitor of apoptosis protein (XIAP) is often overexpressed in cancer cells and is an oncology target. Optimization of a screening hit afforded benzoxazepinone **242**, a selective inhibitor of the BIR2 domain of XIAP (Table 56).[275] Compound **242** was rapidly cleared in vivo by amide hydrolysis. Stability in rat blood was found to correlate with in vivo stability. Installation of a bulky spirotetrahydrofuran ring to give **243** improved both potency and rat blood stability. The napthalene system in **243** was shown to be subject to oxidative metabolism. Replacement with an *N*-phenylindole afforded **244** with further improved potency and reduced clearance.

Inhibitors of SCD1 have been investigated for the treatment of obesity and insulin resistance; however, significant on-target side effects have been observed, including alopecia and partial eye-closure. A group at Merck identified spirobenzoxazepine **245a** as an HTS hit (Table 57). Optimization for potency provided **245b** and **246**. The hypothesis that a liver-selective compound would result

in reduced side effects led to the prioritization of **246**. In vivo testing suggested that a further improvement in liver selectivity would be required to eliminate side effects.[276]

1.08.3.5 Polyspirocycles

Polyspirocycles have received some attention from medicinal chemists (Fig. 38). GSK8853 (**247**) inhibits the NS4B protein and is a clinical candidate for treatment of HCV.[277] Related compound **248**, endowed with a three ring spirocycle, displays comparable in vitro potencies against HCV 1a and 1b.[278] Compound **249** is a potent inhibitor of the MDM2–p53 interaction ($K_i = 0.16$ nM) and is related to compounds discussed above (Fig. 21).[279]

1.08.3.6 Noncarbon Spiro Atom

Trospium chloride (**250**) is a muscarinic M1 antagonist used clinically for the treatment of overactive bladder (Fig. 39).[280]

1.08.4 Conclusions

Spirocycles have been employed by medicinal chemists for over 50 years.[164,281] Spirocycles have been incorporated into molecules that address enzymes, receptors, ion channels, and protein–protein interactions. Targets for which spirocycles have been intensively exploited include HCV NS5B polymerase, grehlin receptor,[282] CGRP,[283] the MDM2-p53 protein–protein interaction,[147] γ-secretase,[284] β-secretase,[285] AR, the σ receptor, and acetyl CoA carboxylase (ACC).[286]

Unsurprisingly, the majority of the spirocyclic ring systems exploited in drug discovery are composed of five-, six-, and to a lesser degree three-membered rings. Spirocycles incorporating four-membered rings have seen more use in recent years as methods for their synthesis have been published.[46] Spirocycles have been introduced on the periphery of molecules[76] and as the central core.[176] Many of the early examples of spirocycles in drug discovery were piperidines in which C4 was the spiroatom.[161,164,172,177] These have the advantage of not necessarily introducing a chiral center into the molecule. However, to fully take advantage of the ability of spirocycles to project functional groups in a wide variety of directions, a sound understanding of conformational preferences of spirocycles and the ability to control stereochemistry at multiple positions around the spirocyclic nucleus are necessary.

A large body of literature describing the synthesis of spirocycles exists and continues to grow as evidenced by continuing publications describing the synthesis of spirocycles in journals focused on organic chemistry. Molecules with new spirocyclic ring systems and different substitution patterns will be added to screening collections. Furthermore, the synthesis of spirocyclic molecules emerging from structure-based drug design is more likely to be undertaken when literature precedent is available. In addition, the increased availability of spirocyclic scaffolds from chemical suppliers will facilitate compound and library synthesis.

Table 58 Spirocyclic drugs on the market and in clinical trials[a]

Identifier (cpd. no.)	*Target*	*Disease*
Marketed drugs		
Amcinonide (**94**)	–	Atopic dermatitis
Buspirone (**131**)	5-HT_{1A}, D_4, etc.	Anxiety
Cevimeline (**181**)	M1, M3	Dry mouth
22,23-Dihydroavermectin B_{1a} (**202**)	GluCl	Helminth infection
Drospirenone (**93**)	PR	Birth control[b]
Eplerenone (**92**)	MR	Hypertension
Fenspiride (**139**)	–	Cough
Fluspirilene (**137**)	5-HT_{2A}, D_2, etc.	Schizophrenia
Guanadrel (**140**)	NET	Hypertension
Irbesartan (**97b**)	AT II	Hypertension
Ledipasvir (**41**)	HVC NS5A	Hepatitis C[c]
Rolapitant (**142**)	NK1	Nausea/emesis
Spiperone (**135**)	5-HT_{2A}, etc.	Schizophrenia
Spirapril (**99a**)	ACE	Hypertension[d]
Spironolactone (**91**)	MR	Hypertension
Tofogliflozin (**144**)	SGLT2	Diabetes
Trospium (**250**)	M1	Overactive bladder
Phase 3		
Beloranib (**58**)	MetAP-2	Obesity[e]
Fidarestat (**169**)	Aldose reductase	Diabetes
Phase 2		
ADL5859 (**208b**)	δ Opioid receptor	Pain
ADL5747 (**209**)	δ Opioid receptor	Pain
Aplaviroc (**226b**)	CCR5	HIV
BMS-587101 (**123**)	LFA-1	Immunological disorders
Cebranopadol (**211b**)	NOP and μ opioid receptors	Pain
ETX0914 (**238**)	DNA gyrase	Gonorrhea
TNP-470, AGM-1470 (**56**)	MetAP-2	Cancer
Ubrogepant (**107**)	CGRP	Migraine
Phase 1		
CFI-400945 (**47**)	PLK4	Cancer
PF-04862853 (**81**)	FAAH	Pain
MI-77301/SAR405838 (**117**)	MDM2-p53	Cancer
BMS-688521 (**124**)	LFA-1	Immunological disorders
CDRI 97/98 (**204**)	–	Malaria
- (222)	ACC1/ACC2	Diabetes

[a]Highest phase of clinical trials reached.
[b]In combination with ethinylestradiol.
[c]Marketed in combination with sofosbuvir (**75**) as Harvoni®.
[d]Prodrug.
[e]Trial halted Dec. 2015.

In the quest for drug candidates with improved physical properties, the reduced aromatic character of spirocycles also renders them more attractive molecular fragments than aryl–aryl coupling products that have been a mainstay in medicinal chemistry over the last 20+ years. It seems certain that spirocycles are not only in some marketed drugs (Table 58) but also they will play a leading role in the future of drug discovery.

1.09.1 Introduction

The definition of nanotechnology varies depending on the source, or even field, but in general it comprises the production, characterization and understanding of the novel properties of materials at the nanometer scale to be used in the design of new systems. The development of nanotechnology in the past few decades has resulted in an explosion of materials, properties and applications able to revolutionize our world. Just a few examples that have resulted in Nobel prizes are the design of the scanning tunnelling microscope (1986, G. Binning and H. Rohrer), the discovery of fullerenes (1996, R. F. Curl, H. W. Kroto and R. E. Smalley) or graphene (2010, A. Geim and K. Novoselov) and the development of super-resolved fluorescence microscopy (2014, E. Betzig, S. W. Hell and W. E. Moerner).

Definitely, nanotechnology is changing our approach to develop new materials and applications, not only in the frame of health, as it would be further discussed later in this chapter, but also in areas that seem so distant as electronics,[1–3] energy,[4] construction and building materials,[5] environmental remediation,[6] sensors,[7] food industry[8] or orthopedic implants.[9]

Nanotechnology will have an impact in the health sector in several different ways. One would be related to the development of nanomaterials with new properties, other associated to the characterization of biological processes and finally other related to the improvement of imaging techniques.

In this book chapter we will focus on the use of nanomaterials in the frame of drug development. In general, nanomaterials can have different physicochemical properties than their bulk counterparts, therefore, resulting in products with new properties, not like those of conventionally-manufactured products. The development of new materials aims at fruitfully succeeding at challenges from conventional medicine as: the use of poorly water-soluble compounds encapsulated in water soluble matrices, the targeted delivery of drugs to specific tissues minimizing the dose required and the impact in other body areas, the delivery of several drugs for combined therapy or the possibility of theranostics, combined diagnosis and treatment.

One of the interesting advantages of using nanomaterials in medicine is related to the same size that these structures have in comparison with biological structures vital to the cell, such as proteins.[10]

In this book chapter we will focus on four different aspects related to the application of nanotechnology to drug development. The first section is devoted to give an overview of the different nanomaterials being used in health treatments. This section aims to provide a general description of the wide variety of compositions being tested, associated at the same time to an extreme range of different properties and possible different applications. The second section is a discussion on the different challenges that the development of nanomaterials for health treatment are facing, ranging from the synthesis of the compound and scale-up for their transference to industry production, theoretical studies to envisage the properties of new possible materials, environmental and geopolitical risks and the difficulties associated to the approval of new drugs by regulatory agencies. The last two sections are devoted to the study of the biodistribution and toxicity of new nanomaterials for health treatment. Regarding the approval by regulatory agencies, these two concerns, drug biodistribution and toxicity, need to be evaluated before any new nanomaterial is transformed into a commercially viable product. Biodistribution studies can be performed *in vivo* and *ex vivo* using a wide variety of techniques. Not all the techniques are appropriated for all the different nanomaterials given the wide variety of properties that they present. We have performed a classification based on the different characterization techniques, indicating which method is adequate for each kind of compound. We have also described a wide variety of toxicological studies that can be performed to assure the safe use of the new developed materials, however, still there is a lack of standardized protocols in the frame of nanomaterials, therefore resulting in difficulties comparing results from different research groups. In the last section of this book chapter we present a detailed description of the approaches to evaluate the toxicity of nanomaterials *in vitro* used in the frame of drug development.

1.09.2 Nanomaterials

1.09.2.1 Description

The European Union Commission Recommendation of 18 October 2011 (2011/696/UE) on the definition of nanomaterial provides de following description "Nanomaterial means a natural, incidental or manufactured material containing particles, in an unbound state or as an aggregate or as an agglomerate and where, for 50% or more of the particles in the number size distribution, one or more external dimensions is in the size range 1–100 nm. (…)."[11]

This definition includes materials so diverse as quantum dots (QD), dendrimers or graphene. Therefore, subsequent classification strategies have tried to order them according to the number of dimensions on the nanometric range. Depending on the shape,

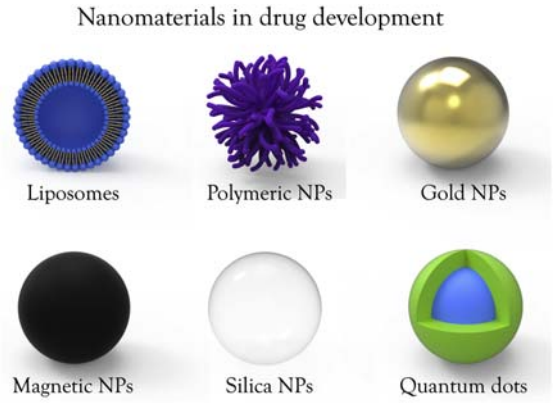

Fig. 1 Most commonly used materials in drug development: liposomes, polymer particles, gold nanoparticles, magnetic nanoparticles, silica nanoparticles, and quantum dots.

nanomaterials could be classified as: 0D, where the three dimensions are below 100 nm, such as nanoparticles or fullerenes, 1D, where one of the three dimensions is above 100 nm, such as nanotubes or nanowires or 2D, where two of the three dimensions are above 100 nm, such as sheets, discs or graphene.[12]

In the case of nanomaterials for biomedical applications, and especially in the frame of drug development, most of the nanomaterials that have been developed or are under clinical studies correspond to 0D compounds where all the dimensions are below 100 nm. In what follows, a brief description of liposomes, polymer particles, gold nanoparticles (AuNPs), magnetic nanoparticles (MNPs), silica nanoparticles and QD, the most commonly used materials in drug development, is provided (**Fig. 1**).

1.09.2.1.1 Liposomes

Liposomes are spherical structures composed of a bilayer of lipids. Their composition makes them good candidates for biomedical applications given their relatively biocompatible and biodegradable properties. Due to their bilayer structure, liposomes can encapsulate drugs either in the phospholipid bilayer or in the entrapped aqueous volume.[13]

Advantages of these materials include, among others, the possibility of carrying hydrophilic or hydrophobic drugs enhancing their solubility, protecting the drug from premature degradation, or improve the selectivity to deliver drugs in targeted tissues.[14]

All these properties have resulted in several nanoformulations based on lyposomes being approved by the FDA (US Food and Drug Administration) and currently available commercially.[14]

1.09.2.1.2 Polymeric nanoparticles

There are a wide variety of materials being used for the synthesis of polymeric nanoparticles, resulting in an infinite diversity of chemical composition and properties. Examples of different compositions include polymer from synthetic origin such as polylactic acid (PLA), polyglycolide (PLG), polylactide-co-glycolide (PLGA), polycyanoacrylate (PCA), polycaprolactone (PCL) or polyalkylcyanoacrylate (PACA) and polymers from biological origin such as chitosan, albumin, gelatin or sodium alginate.[15]

From all these different compositions, some of them, such as PLGA, have been approved by FDA for its use in humans, opening the way to the encapsulations of several drugs for therapeutic use.[16] An example of this would be the encapsulation of Gentamicin by collagen.[17]

Among the advantages of polymeric materials are: the possibility to carry different molecules internally or externally, the release of their cargo under different stimuli such as pH, or temperature and their biodegradability.

1.09.2.1.3 Gold nanoparticles

AuNPs are good candidates for drug delivery applications for several reasons. First, gold is inert, therefore it presents reduced toxicity risks associated to other heavy metals. AuNPs are easily synthetised and their surface easily modified through thiol linkages.[18] Finally, AuNPs optical properties arising from the localized surface plasmon resonance could trigger drug release at remote places.[18]

Gold nanoformulations have not yet been approved by FDA but are already in clinical trials.[19]

1.09.2.1.4 Magnetic nanoparticles

Although magnetic materials for biomedical applications could include a wide variety of compositions including elements such as Co, Fe or Ni in different alloys or forming part of oxides, in the practice, most of the work is being performed using two iron oxides (maghemite or magnetite)[20] specially due to their low toxicity,[21] and the capacity of the body iron metabolism to transform iron released from the particles into ferritin,[22] allowing the recycling of this metal within the body.

Their interest relies in their magnetic properties, being able to: (i) modify local magnetic fields, for example to be used as contrast agents for Magnetic Resonance Imaging (MRI), (ii) act as heat mediators in alternating magnetic fields for magnetic hyperthermia,

or (iii) concentrate in an specific location by the presence of an external magnetic field, to be used as drug delivery systems.[23] MNPs have been already approved by FDA as MRI contrast agents.[19]

1.09.2.1.5 Silica nanoparticles

Silica, an oxide of silicon, has received a wide attention from the research community in the frame of drug transport given its mesoporous structure at the nanoscale that provides large pore volumes to transport different drugs.[24] Advantages of this material include the easy control of their particle size, resistance to temperature and pH, control over the pore size resulting in large pore volumes and an easily functionalized surface.[25]

1.09.2.1.6 Quantum dots

QD are fluorescent nanoparticles composed of semiconductor materials typically in the size range between 2 and 10 nm.[26] QD have unique optical properties that make them especially relevant for imaging techniques. Therefore, linking drugs to these materials becomes an interesting approach to perform both imaging and treatment at the same time. For biomedical applications, particles with a core of CdSe or CdTe, coated by a layer of ZnS have been tested, however, an extra coating layer is required for *in vivo* applications.[26] The main drawback of these materials is related to their toxicity, as the use of heavy metals for *in vivo* applications may have important long-term effects.

1.09.2.2 Advantages of Nanomaterials in Medicine

The use of nanomaterials in medicine offers several advantages over conventional therapeutic treatments (Fig. 2). First, their use allows the possibility to *improve delivery of various therapeutic agents* including drugs, nucleic acids, etc. This is because nanocarriers can: (i) encapsulate poorly soluble drugs; (ii) protect the therapeutic molecules from being degraded in the body before reaching their target; (iii) modify their blood circulation and tissue distribution profile; (iv) enhance the absorption of drugs into the target tissue and target cells by combining passive and active targeting mechanisms; (v) allow for better control over the timing and spatial distribution of drugs to the tissue; and (iv) prevent drugs from interacting with normal cells, thus avoiding usual side effects of conventional administered drugs.[27] Besides, due to their high surface area *it is possible to allocate several therapeutic molecules in a single nanocarrier*. This facilitates the combination of active pharmaceutical ingredients (API), which is commonly practiced in several diseases. Particularly in cancer treatment this could potentially offer synergistic effects to promote the efficacy of therapies, while limiting the risk of resistance. When multiple APIs are administered separately, each one acts according to its own distinct pharmacokinetic and pharmacodynamics properties. Thus, it is not easy to synchronize that each target cells or tissues receive optimal levels of each of them. Conversely, if multiple APIs are combined in a single nanocarrier, the spatiotemporal exposure of each drug can be controlled more precisely.[28]

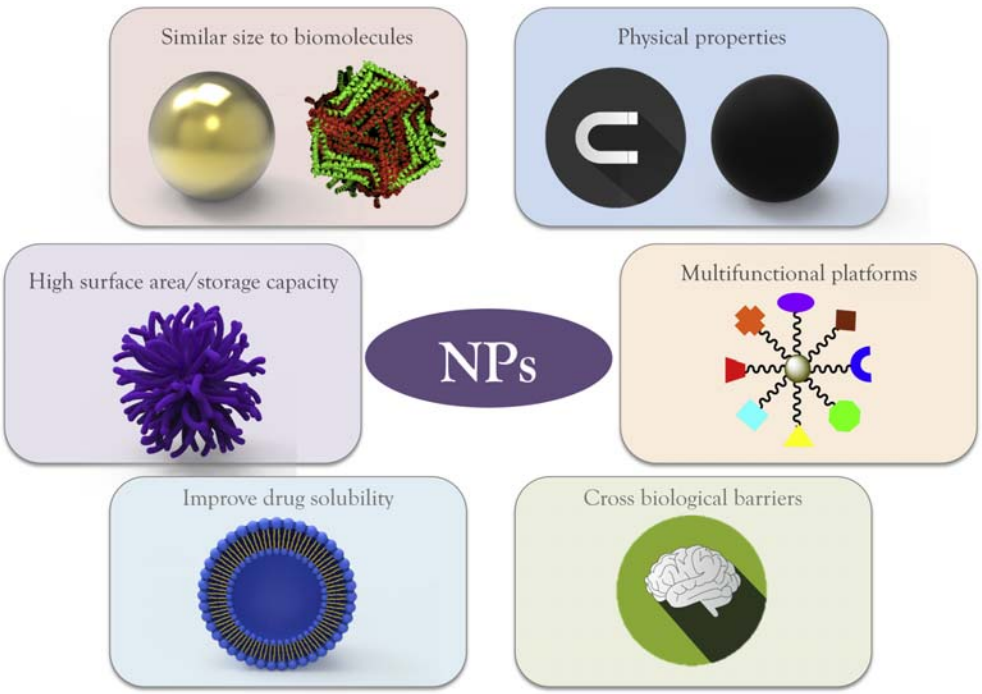

Fig. 2 Key features of nanocarriers for their use in medicine.

Additionally, *inorganic nanoparticles exhibit unique physical properties* due to their nanometer size making them ideal for a host of novel applications in the field of disease therapeutics.[29] For example, as a result of their intrinsic superparamagnetic character, MNPs are valuable in medicine as efficient transversal relaxation (T2) MRI contrast agents. Besides, under the influence of an alternating magnetic field (AMF) they can release localized heat that could be used to trigger drug delivery or destroy cells by ablation. Like magnetic ones, AuNPs could also be efficient agents for targeted cell ablation and remotely controlled drug release due to heat generation in response to light irradiation. In addition, this efficient conversion of light to heat is able to create higher levels of photoacoustic signals and thus AuNPs could also be used as contrast enhancement agents for photoacoustic tomography (PAT). Other applications of AuNPs, due to their physical properties, that could also be combined with the already mentioned include their use as contrast enhancers for computed tomography (CT) and X-ray absorbers for cancer therapy. This clearly shows that the use of a nanoparticle or the combination of different ones in what is named as hybrid nanoparticles has a huge potential for the development of all-in-one nanocarriers. Thus the use of only one type of nanocarrier not only acknowledges for the combined use of different therapies but also different imaging technologies to obtain from structural information to functional imaging.[30] Although nanomedicines at present are in an early stage of development, nanotechnology clearly has a great potential to achieve an overall impact on the medical field with significant advances in patient screening, diagnosis, staging, treatment, and monitoring.

In spite of these advantages for their use in therapy and promising preclinical efficacy results of monotherapy nanomedicines, the overall success rate for drugs moving through clinical trials to FDA approval is near one to ten. This rate is even lower than that from earlier years, that was 1 in 5 to 1 in 6.[31] The discrepancy between preclinical data and clinical outcomes could be explained because until 2010 the main driver of nanotechnology was scientific discovery growing from curiosity-driven research.[32] Consequently, it was not usually taken into account issues of great importance to improve the chances of success after clinical trials during the design of nanodrugs. Among these issues are: proposed clinical use, route of administration, likely dose, and frequency of dosing.[33] Other causes are low accumulation of the NPs in the target tissue due to less pronounced enhanced permeability and retention (EPR) effect, the heterogeneity of human tumors as well as the intrinsic/acquired drug resistance to monotherapy over the treatment course.[34] However, during this new decade it is expected that this tendency will change achieving a real impact of nanomaterials on the improvement of healthcare accelerated by an application-driven research.

Currently, there are several nanotechnology-enabled diagnostic and therapeutic agents undergoing clinical trials, and only few nanodrugs approved by the FDA.[19] Examples of already FDA approved nanoformulations are liposome encapsulated drugs (Doxil,[35] DaunoXone[36]), microemulsions (Cyclosporine[37]), albumin-bound nanoparticles (Abraxane[38]), products using nanocrystal technology (Rapamune[39]) and iron oxides nanoparticles for MRI (Feridex[40]). Other nanoformulations still under study but already in clinical trials are based on AuNPs, gold nanoshells or polymeric micelles.[19] In addition, other nanoformulations have also been approved for other uses, such as silver nanoparticles for antibacterial wound dressing,[41] silica and zirconium nanoparticles as dental composites (3 M ESPE Filtek),[42] liposomes in cosmetics,[43] or titanium dioxide and zinc dioxide nanoparticles for sunscreens (**Table 1**).[44]

1.09.2.3 Actual Research Trends

As it was mentioned, until 2010 most of the nanoparticles that were developed for therapy applications had a relatively simple design, were focused basically on cancer monotherapy and accumulated on the target site mostly by passive targeting mechanisms. However, since then, research focused on the development of more sophisticated high-quality nanomedicines by rational design. What clearly shows that research efforts in the field are growing exponentially is that from the 35.000 articles on "nanoparticles + therapy" reported in Pubmed until February 2016, more than 80% were published since 2010. In order to improve the success of nanomedicines during clinical trials, several key topics have been and are still focus of on-going research: (i) targeted drug release triggered by external *stimuli*; (ii) development of smart nanomedicines able to temporary adapt to changing environments; (iii) multi-biofunctionalization of nanoparticles; and (iv) development of hybrid nanomedicines.

The development of *"smart" nanomaterials able to deliver a therapeutic agent due to environmental causes or remote stimulus* allows to achieve a more precise control, not only temporary but also spatially, of the release of drugs.[45] Several strategies have been reported in order to trigger the target-specific release of the drug such as the use of acidic pH in the tumors, the low pH of endosomes/lysosomes, the intracellular redox potential, the presence of tumor specific proteolytic enzymes, etc.[46,47] Alternative approaches employ physicochemical properties of nanoparticles to develop remote actuation tools for controlled drug delivery. One of these approaches is the use of alternating magnetic field (AMF) to trigger cell death or the release of drugs from MNPs due to heat generation. More recently, it was also shown the effects that a phenomena named as magneto–mechanical has on biomacromolecules, biomembranes, subcellular structures and cells which can be observed using super-low and low AMF in the absence of heating.[48,49] This phenomenon could also be used alone or in combination with hyperthermia for therapy. Another approach for remotely triggered therapy is the use of near-infrared activated plasmonic nanomaterials. The photothermal response of this nanocarriers can be exploited not only for *in vivo* diagnosis (optoacoustic imaging) but also for therapy (drug delivery and photothermal ablation therapy). Besides, playing with the irradiation conditions, it is possible to control the mechanism of cell death from necrosis to apoptosis.[50]

Besides achieving the triggered delivery of drugs, a step forward in the development of high-quality smart nanomedicines is to make them responsive to changing surroundings. Namely to design *nanoparticles able to temporarily adapt* their size, shape, surface chemistry, wettability, adhesive properties, etc. This not only could be used for triggering the release of the therapeutic cargo but

Table 1 Summarizes key characteristics of selected examples of organic and inorganic nanodrugs that were already approved or are still under clinical trials

Nanodrug	*Composition*	*Manufacturer*	*Mechanism of local accumulation*	*Used for*	*Characteristics*	*Disadvantages*	*FDA approval date/ clinical trial status*
Doxyl	Pegylated lyposomal doxorrubicin	Orthobiotech, Schering-Plough	Passive targeting	Ovarian/breast cancer; AIDS-related Kaposi's sarcoma	(i) Enhanced circulation time (4 days) (ii) Improved pharmacokinetic profile	(i)10- to 20-fold more expensive than doxorubicin (ii) skin reactions/ hypersensitivity (iii) more secondary effects than Myiocet	November 1995
Myocet	Non-pegylated lyposomal doxorrubicin	Elan Pharmaceuticals/ Sopherion	Passive targeting	Metastatic breast cancer	(i) different in terms of the lipid composition, size, loading method than Doxyl (ii) enhanced plasma half life (16–50 h) (iii) different tissue distribution profile than Doxyl (iv) different dosing and safety profiles than Doxyl.		2000 in Canada and Europe
ThermoDox	Thermosensitive liposomal doxorrubicin	Celsion Corporation	Passive targeting	Hepatocellular carcinoma	(i) Release their cargo when local tissue temperatures are increased to 39–42°C by application of radiofrequency (ii) allows local concentration of the drug 25-fold more than IV doxorubicin, and up to several times than other liposomal doxorubicin formulations		In clinical phase III
Abraxane	Albumin-bound Paclitaxel nanospheres of 130 nm (Nab). Nab paclitaxel in combination with gemcitabine	Abraxis Bioscience, Astrazeneca Celgene	Glycoprotein 60-mediated endothelial cell transcytosis of Nab and accumulation in the area of tumor by albumin binding to SPARC (secreted protein, acidic and rich in cysteine)	Various cancers Metastatic pancreatic cancer	(i) More effective than paclitaxel at treating tumors because a higher dosage can be delivered (ii) Decrease in side effects from solvent related hypersensitivity reactions (iii) Decrease time of administration (iv) Less toxic than paclitaxel (v) Predictable and linear pharmacokinetics	More expensive than free paclitaxel formulations (Taxol or Onxal)	Jan.–05 Sep. 2013
Aurimmune (CYT-6091)	Tumor necoris factor (TNF-α) bound to colloidal Gold nanoparticles	Cytimmune Sciences	Active vectorization in order to disrupt tumor blood vessels and enable follow-on chemotherapy to penetrate the tumor and kill the cancer cells inside	Head and Neck cancer	Better tolerated and at lower doses causes greater tumor regression than TNF itself		In clinical pahse II

also could help to overcome several biological barriers that could impair therapeutic effectiveness.[51,52] For example, it is well known that nanoparticles with sizes ranging from 100 nm or higher are the ones with best accumulation and retention rates in tumors due to EPR effect. However, recent *in vivo* studies show that particles with less than 100 nm could penetrate better poorly permeable tumors.[53] To solve this limitation, researchers have designed NPs that circulate as large particles and their size is reduced once they reach the tumor.[54] Different stimuli could be used to gain control over extracellular particle transport: (i) internal *stimuli* due specific microenvironment of tumors (low pH, presence of proteases, hypoxia, etc.)[55] or (ii) external *stimuli* (ultrasounds, light, magnetic field, etc.).[56,57] Not only it is possible to gain control over particle size but also over their cellular uptake. In this sense it was already validated *in vivo* a higher uptake by tumor cells of NPs whose surface chemistry could be temporary controlled.[58] This is achieved by masking ligands for targeting or cell internalization by non-ionic hydrophilic polymers during NPs circulation to avoid non-specific interactions with immune cells and normal tissues. This protective layer is linked to the nanocarrier surface by a stimulus sensitive linker. This way, unmasking and promotion of a selective interaction of nanocarriers with tumor cells could be triggered only when they reach target sites. The same internal and/or external stimuli already mentioned could trigger this exposure of cell-interactive ligands.[59–62]

In order to improve the therapeutic effectiveness, another milestone to be reached is the design of *nanomedicines functionalized with different biomolecules*. This allows introducing different bio-capabilities to the nanomaterial such as active targeting, the ability of overcoming several biological barriers, etc.[63] However, the development of appropriate multi bio-functionalization strategies is a big challenge due to the wide variety of nanomaterials and biomolecules available for this purpose.

The biomolecules to be joined to the surface of the nanomaterial could vary significantly in terms of size, chemical composition, 3D complexity, location of its biological active site, and so forth. If properly designed, an oriented functionalization strategy could be a powerful tool to improve the stability, activity, specificity and selectivity of the attached biomolecule, which results in more bioactive materials and in substantial improvements of its subsequent biotechnological or biomedical (biosensing, therapy, theranosis, etc.) application.[64–67] However, a conjugation chemistry that works well with a specific biomolecule could not be adequate for another one. Besides, the wide variety of available nanomaterials shows large differences in terms of size, shape, surface area, net charge, density of reactive groups, colloidal stability, etc. Thus, no universal methodologies exist and the optimization of the most adequate functionalization strategy for each particular combination of nanomaterial and biomolecules is required. Proof of this difficulty is the low number of articles on the topic, as indexed by ISI Web of Knowledge® (keywords combination: biofunctionalization + nanoparticles and multifunctionalization + nanoparticles) (**Fig. 3**).

The importance of selecting an adequate multifunctionalization strategy was highlighted recently by de la Fuente *et al.*[68] Their objective was to develop an optimal multifunctional AuNP to achieve optimal effectiveness of RNA interference for cancer therapy. In this sense, they developed a library of NPs using different bio-functionalization strategies in order to find not only the optimal conjugation methodology but also the optimal combination among different biomolecules (siRNA, biofunctional spacers, cell penetrating peptides as membrane translocating agents and a fluorophore).[68] However, with only one of the obtained nanoconjugates (siRNA/RGD-AuNPs) successful targeting in the lung was achieved using a lung cancer syngeneic orthotopic murine model following direct intratracheal delivery. In this model, significant c-Myc oncogene down regulation followed by tumor growth inhibition and prolonged survival of lung tumor-bearing mice was attained.[69]

Another complementary line of research to bridge the gap between preclinical animal tests and clinical human trial, is *the development of hybrid nanocarriers* composed of at least two different nanomaterials. This kind of nanocarriers allows combining the advantages of purely inorganic and organic nanoparticles. Besides, they also possess unique advantages for imaging and therapeutic applications.[34] For example, it is possible to design nanoparticles with superior pharmacokinetics, multi-stage delivery systems, enhance EPR accumulation and with a combination of therapies in the same nanosystem (eg, co-delivery of chemotherapeutics and biologics plus photothermal ablation, etc.).[70] Besides, accommodating multiple therapies into one single nanocarrier has

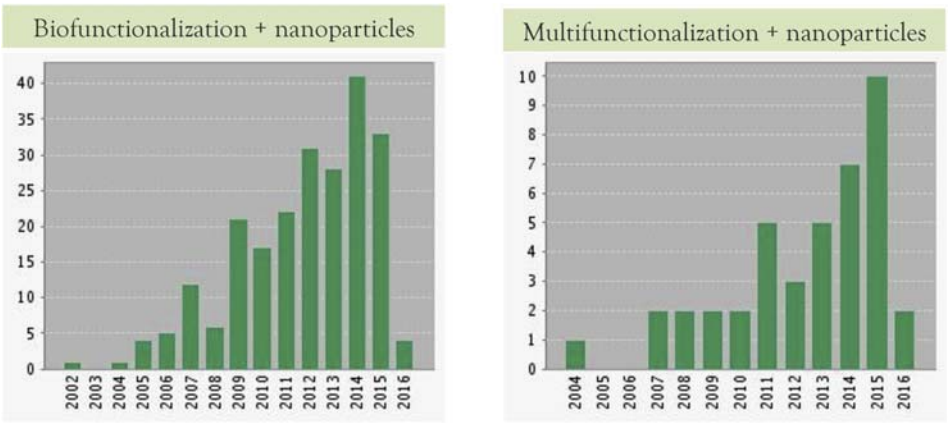

Fig. 3 Number of published articles per year at ISI Web of Knowledge® using biofunctionalization&nanoparticles or multifunctionalization&nanoparticles as keywords.

several advantages, including reduced manufacturing cost, improved patient compliance, and easy-to-monitor release, pharmacokinetics, and biodistribution of different drugs. Although optimized formulations of these complex nanocarries are expected to have a bright future in nanomedicine, the potential safety of each component and/or metabolite that might arise as a result of their *in vivo* degradation or metabolic fate must be studied in detail.

Another step forward in order to revolutionize nanomedicine-based therapy is to *extend research to other diseases than cancer*. Although, still most published articles are focused on cancer therapy, an increasing number of articles are focused on the treatment of other diseases. This is the case of the use of *nanocarriers for Human Immunodeficiency Virus (HIV) infections*. While HIV infections are reducing in incidence since the introduction of Highly Active Anti-retroviral Therapy (HAART), there still remain a number of challenges such as fighting the existence of virus reservoirs, drug resistance and anatomical barriers to antiretroviral therapy. In this sense, the experience acquired during the development of smart nanocarriers for cancer chemotherapy is being used for the design of smart antiretroviral nanocarriers.[71,72] Other application of nanocarriers is their use for *treatment of hepatic diseases* including other pathologies such as hepatic fibrosis and microbial infections in addition to hepatocellular carcinoma.[73] Their prevalence is rising due to the inability to deliver enough concentration of therapeutics and/or contribution to undesirable side effects of standard medication. Therefore this is another field where nanocarriers could have a great potential for improving the delivery of drugs in a more specific manner and by simultaneously minimizing side effects. Nanocarriers have also a potential role in the *early detection and treatment of different neurodegenerative disorders* such as amyotrophic lateral sclerosis,[74] Alzheimer's disease (AD),[75,76] Parkinson's disease (PD)[77–79] and Huntington's disease (HD).[80,81] To date, the blood–brain barrier (BBB) remains one of the reasons for the lack of success in the development of treatments as it prevents the penetration of therapeutic agents and diagnostic tools. It is estimated that more than 98% of small molecular weight drugs and practically 100% of large molecular weight drugs (mainly peptides and proteins) developed for Central Nervous System (CNS) pathologies do not readily gain access to the brain extracellular fluid from the blood. BBB is characterized by tight junctions between endothelial cells, by the absence of fenestrations and low occurrence of pinocytic activity. Transcytosis is the only way for NPs and macromolecules to be captured on one side of the endothelial's BBB cells (bloodstream), drawn across the cell and be ejected on the other side (brain extracellular fluid) or be degraded within lysosomes leading to the drug being released into the brain tissue. There are several transcellular routes that include passive diffusion, carrier-mediated transport (CMT), receptor-mediated endocytosis (RME) and adsorptive-endocytosis (AME).[82] Due to the size limit of passive diffusion, most nanocarriers cannot enter by diffusion. A popular approach to achieve the transcellular passage of NP-linked drugs is to functionalize the NPs with biomolecules that are transported into the brain by the carriers expressed in the brain microvessel endothelial cells. In this sense, more than 20 carrier-mediated transporter proteins have been identified in cerebral capillaries of BBB. Due to their high transport capacity, the most popular carriers used for NP transport are those for large aminoacids (e.g., LAT1) and glucose (e.g., GLUT1).[83] Although these transporter are primarily involved in molecular translocation of relatively small molecules, there are several examples on the bibliography using glucose-modified NPs in order to cross BBB.[84,85] In this sense, a recent example shows how glucose-modified paclitaxel-loaded polymeric nanoparticles, due to their transport via GLUT1, were successfully employed in the treatment of intracranial glioma in mice.[86] However, much more examples could be found in the bibliography targeting receptors that internalize ligands by means of vesicular transport. This is because such transport can readily accommodate nanoparticles with a size of 100–200 nm. Among the most used ligands for the functionalization of NPs in order to reach their translocation by RME are: transferrin, insulin, low-density-lipoproteins (LDL), leptin, thiamine, glutathione, encephalin.[87] Conversely, the concept of adsorptive-mediated transcytosis through the BBB was originally described to occur for cationic proteins (e.g., serum albumin) that can bind the endothelial cell surface but also cross the BBB. This mechanism, applied to NPs, is based on the proper functionalization of their surface with positive charges or positively charged biomolecules (e.g., TAT peptide, albumin, etc.) allowing electrostatic interaction with the negative charges on endothelial cells.[88]

Nanocarriers have been investigated for the development of new effective *antimicrobial therapies for gastrointestinal diseases*.[89] This has a huge impact in developing countries because most of the population lives below the poverty line, making infectious diseases the major cause of morbidity and mortality. The currently available antibiotics or anti-retroviral drugs are specific to certain types of infections and have several limitation such as increasing emergence of antibiotic resistance, high production costs, significant side effects, limited accessibility and adherence of the patient to the treatment. Due to the already mentioned intrinsic features of the use of nanocarriers in therapy, they might be promising to overcome these problems specifically by oral administration of NPs. For example, their incorporation in food or beverages products could be an easy administration of therapeutics with high rates of acceptance and adherence of patients. The use of nanocarriers in the *diagnosis and* as *immunotherapeutic platforms in autoimmune diseases* is also a current field of research. A big advantage of nanomaterials for this application is that they have a natural tendency to accumulate in inflamed tissues, through vascular leakage, macrophage uptake or their active targeting by specific receptors or ligands.[90,91] Another challenging field of application of nanotherapeutics is the *treatment in ocular diseases*. Topical treatment of them is a current challenge as ocular drug bioavailability is less than 5%. This is because to reach the targeted ocular structures drugs applied directly onto the eye need to bypass different biological barriers. The use of nanocarriers to increase ocular drug bioavailability has started in the 80s with the use of liposomes. However, it was during the last decade that this field of research has grown substantially and other type of carriers others than liposomes have been explored including polymeric nanoparticles [chitosan, gelatin, poly-(lactic-co-glycolic acid), hyaluronic acid, etc], nanocapsules, dendrimers, and nanocrystals, etc. Namely, the most important milestones achieved so far are: (i) to show that nanocarriers for this administration route could associate with a wide variety of different drugs, (ii) increase of their residence time onto the ocular surface, (iii) reduction of degradation of labile drugs, and (iv) increase drug bioavailability by improving their interaction with the corneal and conjunctival epithelia.[92] Other interesting

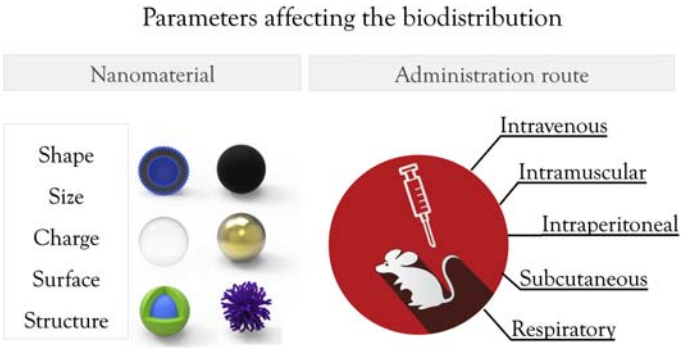

Fig. 4 Parameters that affect the biodistribution of different nanomedicines, classified depending on the physicochemical properties and the administration route.

new field of research is the *improvement of diabetes mellitus treatment* by achieving oral delivery of insulin. The current insulin therapy is via subcutaneous injection, which often fails to mimic glucose homeostasis that occurs in normal individuals. Oral delivery is the most convenient administration route. However, insulin oral delivery is a challenge due to its rapid enzymatic degradation in the gastrointestinal tract (GI), the physiological barrier that represents epithelial cells of GI and the physicochemical properties of insulin that has a large molecular size and tends to aggregate above 100 mM. Nanocarriers have immense potential for the effective oral delivery of insulin and thus different type of nanoparticulate carriers are being currently engineered for this application such as polymeric nanoparticles and micelles.[93] Although some of them have been already through preclinical animal stage testing, there are still many challenges to overcome such as studying the toxicity of these materials administered on a chronic basis.

Among others diseases in which nanocarriers could have a potential to improve their treatment are respiratory diseases,[94,95] Cowel bowel disease,[96] wound healing and skin regeneration,[97] malaria,[98] leishmaniasis,[99] haemophilia, cardiovascular diseases, and rheumatoid arthritis.[100]

1.09.3 Biodistribution

Understanding the *in vivo* biodistribution and degradation pathways of new nanomaterials is fundamental to ensure their safe implementation for biomedical applications. This knowledge would also allow the optimization of the dose required for each treatment.

Several parameters influence the biodistribution of nanomedicines, namely, the physicochemical properties of these compounds, such as shape, size or surface modifications among others or the administration route (Fig. 4). Even the anesthesia used during particle administration may significantly change nanoparticles biodistribution.[101]

This section focuses, not on the parameters affecting the biodistribution, but on the different techniques that are currently being employed to track the biodistribution of different nanomaterials, paying special attention to the advantages and limitations of each technique. Classification of the different techniques has been performed according to the possible use of each approach either *in vivo* or *ex vivo* (Fig. 5).

1.09.3.1 *In vivo* Optical Imaging

Since the fluorescence in the visible light is only applicable for thin tissue samples, the fluorescence based techniques for *in vivo* imaging and therefore possible biodistribution characterization drive into the small spectrum window of the NIR (near infrared) region (650–950 nm). In this NIR window, because of the minimal adsorption of water, hemoglobin and lipids, as well as low autofluorescence and tissue scatter, light penetration is maximal. The depth penetration, normally described as >1 cm, depends highly on imagined tissue type.[102] However it can be increased due to the new microscopy imaging techniques.[103,104] The fluorophores used for NPs labeling must fulfill several requirements, like high brightness and photostability, large Stokes shift, high fluorescence quantum yields (high sensitivity), resistance to degradation in biological systems. Also, they should present preferably low toxicity level. So far only one fluorophore, indocyanine green (ICG), has been accepted by US FDA commission for clinical trials.[105] Because of its several limitations also some derivatives of the ICG are considered.[106] Nevertheless, another polymethines, especially Cy5.5 or Cy7 are one of the most popular organic fluorophores used for NIR imaging.[107,108] Moreover, ultimately several new NIR probes with improved properties have also been described.[109–113]

In vivo biodistribution of several types of NPs can be followed through optical imaging studies. One of the most popular choices for fluorescence imaging applications are QD. This popularity is supported by excellent optic properties, such as narrow and tuneable emissions bands, broad excitation spectra, high fluorescence quantum yields and high resistance to

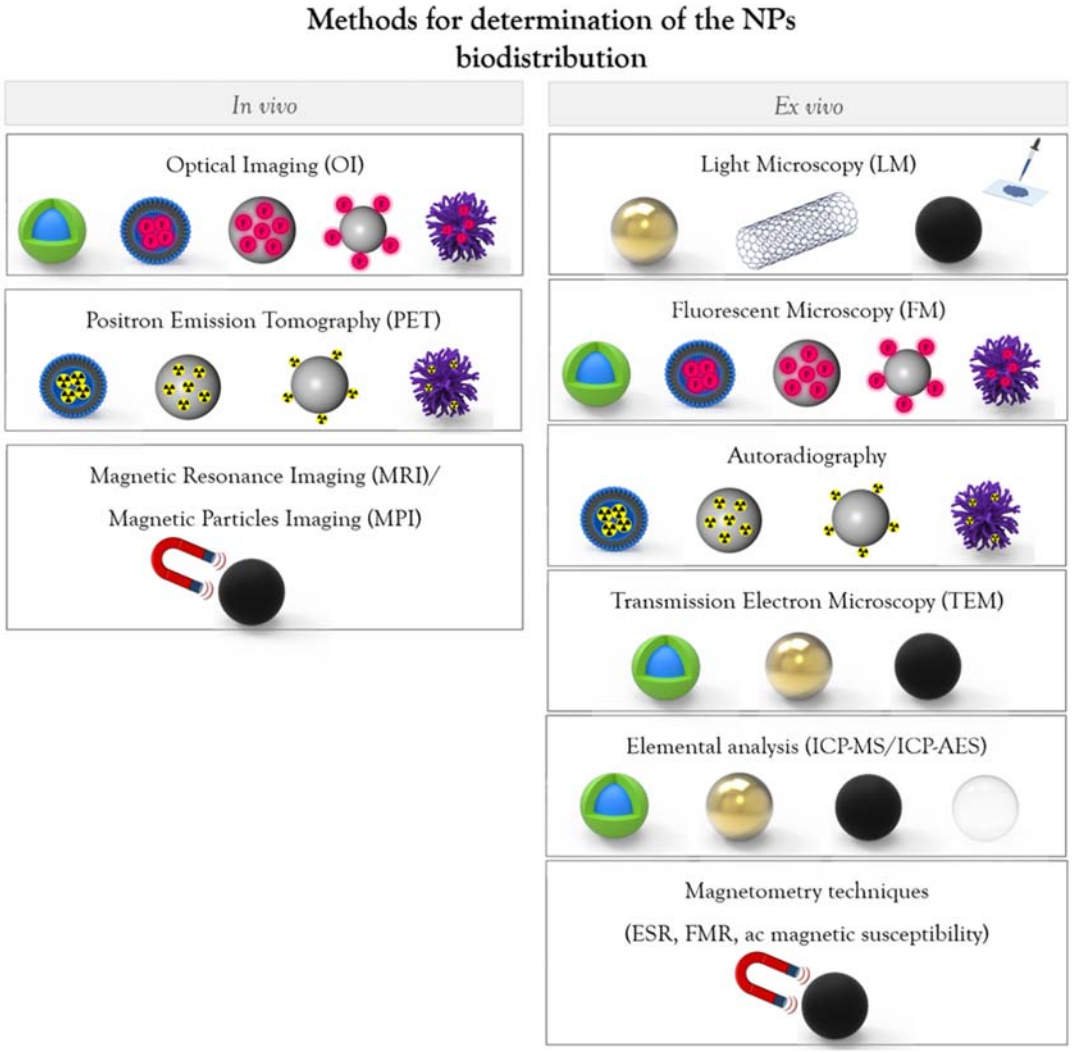

Fig. 5 Methods for the in vivo and ex vivo evaluation of nanomaterials in biomedicine, including the type of material that could be characterized by each technique, as described in **Fig.1**. Gray Nanoparticles are designated as general NPs (including silica, gold or magnetic NPs, and QD).

photobleaching.[114–116] In a single assay with only one excitation source, different colors of QD can be applied enabling multiplexing and simultaneous visualization of different targets.[117] However, the potentially high toxicity of QD resulting from heavy metal ions release[118] limits drastically their potential application in clinical imaging or at least hamper it in case of polymer protected QD as little is known about the mechanism of metabolism or clearance from living organism of this described as stably protected and essentially nontoxic particles.[119,120]

Apart from QD, a wide range of polymer or inorganic matrix- based particles loaded with organic NIR dyes can be localized *in vivo* through optical imaging.[121] However, the combination of several factors makes NIR dye-doped NPs suitable for optical imaging applications, such as brightness of the system resulting inter alia from the efficient fluorophore linking/immobilization strategy.[122]

Dye doped NPs can be fabricated by embedding the fluorophore inside typically the core-shell structured NPs either covalently or noncovalently (mainly: dye-doped silica NPs[123–126]; dye-doped calcium phosphate NPs; dye-containing lipoprotein NPs) or by coupling the fluorophore to the shell/surface of NP (mainly: silica NPs, metallic NPs).

The first case seems to be especially attractive for imaging application for several reasons. High payload of dye molecules per nanoparticle enhance the fluorescence and embedding a fluorophore within the NPs matrix prevents its possible leaching from the particles which can be triggered by the proteins and lipophilic cellular microenvironment and therefore give a false signal. Moreover enclosing dyes within NPs provides its photostability and biocompatibility and the fluorophore high water solubility and toxicity is no more a problematic question, since appropriate surface modification can provide hydrophilicity, stability and multi functionality of the NP.

Within the NIR dye-containing nanoparticles, dye-doped silica NPs seems to be excellent choice for bioapplications, mainly because amorphous silica appears to be a biocompatible and nontoxic material and the surface hydroxyl groups can be easily modified using a conventional silane-based chemistry.[127] What is more, the silica matrix is optically transparent that allows excitation

and emission light to pass through efficiently.[128,129] The *in vivo* biodistribution studies have been performed on a variety of silica NPs (inter alia on ICG-doped mesoporous silica NPs,[130] (red-F)-labeled amorphous silica particles,[131] Ru-BPY doped PEG-Silica NPs[132,133]).

Calcium phosphate (CP) NPs (CPNPs) is another interesting class of inorganic materials which can be doped with fluorophores and therefore show promising properties for animal imaging.[134] Since CP is generally regarded as safe by FDA, it has been widely used to synthesize a novel and no viral systems for targeted drugs or genes effective delivery.[135,136] Also ICG-doped and PEGylated CPNPs has been designed for accumulation studies in breast adenocarcinoma xenografts.[137]

High biocompatibility, biodegradability, payload capacity and nonimmunogenicity make lipoprotein NPs ideal to be used in biomedical fields. Lipoproteins nanocarriers of NIR probes have been reported, enabling *in vivo* validation of the LDL rerouting principle and providing *in vivo* application of enhanced cancer optical imaging in live animals.[138]

Apart from inorganic particles, also organic polymers have been applied for engineering NIR-containing NPs. Optical imaging of intravenously administrated poly-lactide-co-glycolide (PLGA) NPs conjugated with NIR probe (DY-675) and a simil-opioid glycopeptide (g7) showed brain localization.[139] In another approach, NIR-emissive polymersomes were generated through self-assembly of amphiphilic diblock copolymers and conjugated multi(porphyrin) based NIR fluorophores.[140]

In addition to QD and NIR-doped NPs, several nanosized probes can be used as fluorescence imaging agents, where carbon nanotubes (CNTs) are one of them. Although special attention is focused on CNTs mechanical, thermal and electronic properties in terms of electronic devices, their potential application in biomedical imaging began to be explored after discovery of fluorescent semiconducting CNTs. Single-walled nanotubes (SWNTs) present unique features, like emission in the region of 1000–1400 nm (still suitable for optical imaging), photostability, large Stokes shifts and large surface area facilitating functionalization of a large amounts of targeting ligands or drugs.[141]

Coatings and surface modifications of metallic NPs can serve not only to improve their biocompatibility and functionality properties but also to render the fluorescence. Attaching a fluorophore to the NP can be made by depositing additional coatings carrying fluorophore or by immobilizing a fluorophore on the NP surface. The first one can be achieved by the layer-by –layer (LbL) technique,[142] although the *in vivo* stability of the deposited layer remains a problematic issue.[143,144] On the other hand, rich NPs surface chemistry is ideal for straightforward functionalization with desired biomolecules including fluorophores.[145] Although the design of fluorescent NPs especially of small diameters is challenging because multiple fluorophores on the surface of a NP quench each other if they are located within the energy-transfer distance.[146] Moreover, the properties of fluorophore–NP conjugates strongly depend on the efficiency of the fluorophore-linking strategy, the type of immobilization and stability of the fluorophore or even polymer/shell coupled with fluorophore upon *in vivo* administration and cell internalization.[122,147]

1.09.3.2 *In vivo* Positron Emission Tomography

Positron emission tomography (PET) is another imagine technique which enables *in vivo* localization of those NPs which are chelated or incorporated with isotopes without the need for external excitation.[102] This technique relies on recording high energy gamma rays from positron emitting isotope.[148] It characterizes with the highest sensitivity of all imagine modalities and has no tissue penetration limits[149] although the anatomical resolution is rather poor because of spatial resolution limitations.[150] PET, despite being approved by FDA as a clinical molecular imaging technique, exposes living tissues to strongly ionizing radiation and moreover is extremely expensive (positron-emitting isotopes can be generated mostly with a cyclotron or less commonly with a generator source). Nevertheless it is still considered as a highly popular imaging technique potentially improved upon NPs help.

Various isotopes for NPs labeling can be purchased from PET radiopharmacies, which exist through the world and can provide common PET traces on a daily basis.[151] One crucial factor that should be considered in NPs radiolabeling is the radionuclide physical half-life ($T½$). For biodistribution study in a short time frame after NPs administration, short-lived radionuclides such as fluorine-18 ($T½ = 109.7$ min), gallium-68 ($T½ = 67.7$ min) or interestingly even nitrogen-13 ($T½ = 9.97$ min) can be applied. On the contrary, prolonged time frame scanning can be obtained using longer-lived radionuclides, namely copper-64 ($T½ = 12.7$ h), bromine-76 ($T½ = 16.2$ h), iodine-124 ($T½ = 4.1$ d), and arsenic-74 ($T½ = 17.8$ d). Once selected, the radionuclide can be conjugated directly on the NPs surface via different labeling methods. Also it can be indirectly attached through a simple hydrocarbon chain, a peptide, or a polyethylene glycol unit linker to the NP core.[152,153] A vast number or organic as well as inorganic radiolabeled NPs has been successfully traced *in vivo*, among them gold NPs,[154,155] iron oxide NPs,[156,157] aluminum oxide NPs,[158] QD,[159] rare earth containing NPs,[160] silica NPs,[161–163] polymers,[164,165] liposomes.[166] However, because of the poor PET imaging resolution, most of the mentioned biodistribution studies have been supported by incorporation of other imaging modalities and creation of multimodaling approach. Commonly PET technique is combined with computed tomography (CT),[167] NIRF agents (within silica NPs[161]; *International Patent WO 2010/030120* or QD[168]) or MRI (in conjugation with iron oxide NPs[156]). Especially the PET/MRI approach is considered as a powerful combination as both sensitivity and anatomical resolution can be obtained in simultaneous acquisition.[169,170]

Finally for PET application, one more aspect has to be taken into account. Namely, labeling with more than one radioisotope is not possible as all positron emitters lead to 511-keV gamma rays so there is no distinction between them. However this drawback can be overcome by applying another nuclear imaging technique named single photon emission computed tomography (SPECT).[171] For SPECT different radioisotopes such as technetium-99m ($T½ = 6$ h), iodine-123 ($T½ = 13$ h), indium-111 ($T½ = 2.8$ days) or iodine-131 ($T½ = 8$ h) are used. As in this technique single photon emitters decay under the emission of gamma

rays with energies between 100 and 300 keV, various isotopes with different gamma rays energies can be used simultaneously. Despite of the possibility of numerous radionuclides multiplexing, in an order of magnitude this technique is less sensitive than PET (sensitivity lower of about two/three orders of magnitude)[148] and therefore as PET this technique is more often applied together with other imaging modalities such as NIRF or MRI.[169]

1.09.3.3 *In vivo* Magnetic Resonance Imaging

MRI is a non-destructive method applicable for MNPs tracking *in vivo*. This technique is based on the physical phenomenon of protons relaxation in a static magnetic field after excitation pulse application.[172] The magnetic resonance image is generated by monitoring the local variation in relaxation corresponding to image contrast, which results from proton density as well as chemical and physical nature of the specimen tissue. Two different relaxation mechanisms can be distinguished: longitudinal relaxation (T_1-recovery) and transverse relaxation (T_2-decay).[173] MRI per se provides physiological and pathological information about living tissue, however for the enhancement and quantification of physiological information, MRI contrast agents are broadly used and now constitute an integral part of MRI studies.[174] Therefore NPs which are able to increase the T1 signal or reduce the T2 signal, in other words act respectively as a positive or negative contrast agents, can be detected by MRI. The effectiveness of contrasting the MR image by MNPs can be described by its relaxivity, which is the proportionality constant of the measured rate of relaxation, or R1 (1/T1) and R2 (1/T2), over a range of contrast agent concentrations.[102] Its value depends on the NPs magnetic properties, but also on experimental conditions (field strength, temperature, the medium in which the measurements are performed). MRI special advantage over other techniques in NPs *in vivo* tracking is high spatial resolution (micrometers) and tissue penetration depth (NPs can be detected everywhere in the body), however its main drawback is poor sensitivity, high cost and complexity.[148]

Among MNPs that can be traced by MRI, iron oxide NPs (IONPs) and Gd(III)-doped NPs are the most popular ones. Particularly IONPs receive special attention as they are presently being employed in a variety of biomedical applications, inter alia because of the unique magnetic properties they present. Specially NPs with superparamagnetic properties are extremely attractive, as they show fast response to applied magnetic fields with negligible remanence (residual magnetism) and coercivity (the field required to bring the magnetization to zero) what prevents agglomerates formation at room temperature.[175] Superparamagnetic IONPs have been deeply investigated for *in vivo* applications as contrast agents for liver disease diagnosis,[176] lymph-node imaging, angiography and blood-pool imaging.[177] However, the efficiency of IONPs as contrast agents, and therefore the possibility of their *in vivo* tracking depends on many physicochemical characteristics of NPs,[178] where size dependent effect of magnetism is just one of them.[179] One of the biggest drawbacks of IONPs detection via MRI is related to the contrast they generate. As they act as negative imaging agents the produced dark signal can be confused with pathological alternations. Additionally the high susceptibility of IONPs can provoke magnetic field distortion on neighboring normal tissue called susceptibility artifact of "blooming effect." As a result dark images are generated with no background around the lesions.[180] To overcome this limitation various solutions have been proposed,[181–183] although they do not eliminate signal loss or magnetic susceptibility artifacts.

Apart from NPs with a core fully based on iron oxide, systems with other magnetic cores can also be detected by MRI. Alloy-based nanomaterials with high relaxivities are one of them. For instance compounds known as ferrites where one of the Fe ions in an iron oxide has been replaced with a different atom such as Mn, Zn, Co, Ni present high saturation magnetisation and increased relaxation rates, making them good candidates for T2 contrast agents.[184] Particularly Mn-ferrites have been described as highly suitable for MRI imaging.[185]

Another type of nanomaterials that can be visualized by MRI are those incorporated with Gd(III). Gd(III) is the most known example of paramagnetic material which provides bright, positive contrast in MRI. In various reports attachment of Gd(III) complexes to nanostructures based on silica,[186,187] TiO_2,[188] gold,[189] dendrimer,[190] nanodiamond,[191] polymer[192] etc. has been described. The high yield MRI contrast in the case of Gd(III)-doped NPs is provided mostly because of high payload of gadolinium ions and a slow tumbling motion of particles.[102] Moreover, Gd- based NPs gadolinium oxide (Gd_2O_3), gadolinium fluoride (GdF_3), and gadolinium phosphate ($GdPO_4$) have been investigated as MRI contrast agents, although uniformly sized Gd NPs have not yet been obtained.[180]

Other nanomaterials with potential recognition *in vivo* via MRI include gold-iron oxide (Au-Fe_3O_4) NPs, metallic ion NPs, porous hollow Fe_3O_4 NPs and Fe-based alloy nanoparticles, such as iron–cobalt (FeCo) and iron–platinum (FePt) NPs.

1.09.3.4 *In vivo* Magnetic Particles Imaging

As one of the MRI major drawback using MNPs acting as T2 contrast agents is the difficulty in tracking them in tissues with naturally low MRI signals (specially in lungs) a novel imaging modality has recently been proposed. Magnetic Particle Imaging (MPI), introduced in 2005,[193] is based on a direct imaging of the SPIONs intense magnetization in contrast to MRI which indirectly detects the MNPs via the nearby proton relaxation.[194] As a result, MPI identifies only MNPs and not diamagnetic tissue (with zero MPI signal) giving a bright contrast with no obscuring background. As the signal strength is proportional to the MNPs amount, direct measurement of MNPs concentration at certain location is possible. Although for now only a few prototypes of small animal MPI scanners have been constructed, the interest in this new imaging modality is substantial as its utility for *in vivo* MNPs tracking superior over MRI has recently been demonstrated.[195]

1.09.3.5 *Ex vivo* Light Microscopy

Light microscopic evaluation of histological sections is probably the oldest and the most common technique that can be applied for simultaneous toxopathological assessment and visualization of certain NPs types. It requires organ preparation in form of 3–8 μm thickness formalin-fixed and paraffin embedded (FFPE) or more recently cryosectioned tissue samples but at the same time it is sensitive, efficient and cost-effective. However, because of the light microscopy limited resolution to 200–500 nm, single NPs cannot be observed even at the highest microscopic magnification. Therefore only NPs which form aggregates of a major than the resolution limit size and are able to attenuate a visible light can be detected by light microscopy.[196] After a general hematoxylin and eosin (HE) staining[197] that produces blue/violet and pink staining of baso- and acidophilic substances respectively, dark deposits of NPs clusters can be easily detected. Several types of NPs have been successfully detected in HE-stained tissue sections. For example, IONPs forming brown aggregates have been found in glioblastoma sections[198] or in prostate cancer cells[199] in patients after intratumoral injections. Likewise, gold NPs presence in brain of adult albino rat has been detected in HE sections after oral administration.[200] In other studies, tissue sections confirmed CNTs or titanium dioxide deposition in bronchioloalveolar lungs region[201] and on superficial stratum corneum layers of skin[202], respectively.

Depending on the NPs properties, these compounds can be visualized by light microscopic evaluation using specific stains. One of the most popular is Prussian blue staining, commonly used for identifying iron ions in tissue sections.[203–205] The main drawback is that this procedure does not differentiate endogenous iron present in the tissue from the administrated one.[206] To overcome poor sensitivity obtained with traditional Prussian blue staining, an alternative method has been proposed for visualization unlabeled MNPs which employs their intrinsic peroxidase-mimicking activity.[207] Another histological stain named Alcian blue has been successfully applied for negative charged sulfate group detection of dendritic polyglycerol sulfate (dPGS) NPs in Kupffer cells of mice liver.[208] In another approach gold-labeled CNTs have been visualized through light microscopy by silver enhancement method.[209]

1.09.3.6 *Ex vivo* Fluorescent Microscopy

Biodistribution of fluorescently labeled NPs can be determined also *ex vivo* by fluorescent microscopy examination of tissue sections.[210–212] This approach provides resolution similar to that of bright field light microscopy[213] and therefore fluorescently labeled NPs can only be detected if densely packed. Notwithstanding this method enables tracking NPs with much higher spatial and temporal resolution than the one obtained by *in vivo* whole body imaging. For better understanding the NPs localization usually additional approaches are applied, like concurrent counterstain of nuclei with the blue fluorescent dye 4′,6-diamidino-2-phenylindole (DAPI), merging images of fluorescence microscopy and bright field microscopy or immunofluorescent labeling of marker proteins.[214] Moreover, in the last case, the co-localization resolution can be reinforced by employing confocal laser scanning microscopy which enables optical sectioning of the slide for serial 2D and 3D reconstructions of tissues or single cells.[215] Furthermore, recently interesting technique named intravital fluorescence multiphoton imaging has emerged for studying the *in vivo* behavior of fluorescent nanomaterials.[216,217]

As described in the optical imaging section, various NPs classes can be labeled with a wide range of fluorophores and therefore be detected in tissue sections by fluorescence microscopy examination, although the conjugation strategy, in terms of fluorophore stability, has a crucial meaning for signal veracity.[122] As for the bright field light microscopy, the tissue for fluorescent microscopy examination is prepared in the same form of thin sections. Theoretically not only NIR fluorophores can be used for NPs labeling and further detection. However because of the low tissue background autofluorescence in NIR region,[218] using long wavelength fluorophores is still preferable.

1.09.3.6.1 Autoradiography

Distribution of radiolabeled NPs (described in PET section) can also be detected in organs and tissues *ex vivo* by so called whole body autoradiography (WBA) technique.[219] In a standard WBA procedure the whole animal body after the sacrifice is frozen and cryo-sliced into 30–50 μm sections so the radioactivity can be evaluated in different body parts.[220] Phosphor imaging technology permits also semi-quantification of the radiolabeled material with a resolution at organ/suborgan level. Tissues of interest selected from previous WBA imaging can be further applied for another related technique with cellular/subcellular resolution called microautoradiography (MARG)[221] or light microscope autoradiography (LMA).[208] Commonly it requires mounting thin tissue sections onto photographic emulsion coated glass slides and sample examination under light microscopy. As the same tissue can also be stained with HE, pathological examination is possible in the context of autoradiographic NPs signal.[208] Besides, autoradiography can also be adjusted for electron microscopy analysis.[222]

Although mostly used in pharmacology for studying molecules distribution,[223] quantitative WBA and MARG/LMA have been applied for biodistribution examination of several radiolabeled NPs, among others lipid NPs,[224] lyposomes,[225,226] polymer NPs,[208,227] or silver NPs.[228]

1.09.3.7 Transmission Electron Microscopy

Significantly higher resolution than light microscopy can be provided by transmission electron microscopy (TEM). Therefore detailed information of subcellular structures and the precise localization, distribution and morphology of even single NPs inside cells can be obtained.[229] However certain electron density of NPs is required for their unambiguous visualization. For example

organic NPs which characterizes low tissue contrast normally require other visualization techniques.[208] Nevertheless tissue localization of various types of electron dense inorganic NPs have been successfully characterized by TEM, among them titanium dioxide NPs,[202,230] silica NPs,[211] silver NPs,[231] gold NPs,[232] magnetic NPs,[233,234] or QD.[235] NPs with insufficient electron density for TEM detection, can by labeled for example by synthesizing NP around a gold core or covalent binding of colloidal gold.[209] Importantly, it has to be taken into account that standard staining with lead citrate and uranyl acetate for TEM imaging can caused artifacts misinterpreted as NPs. In this context very often supplementary technical refinement is employed. Energy dispersive X-ray (EDX) analysis and electron energy loss spectroscopy (EELS) are techniques which enable qualitative elemental analysis of an electron microscope sample and therefore unambiguous differentiation of NPs from tissue artifacts.[196,232,236] Additionally another tool offered by TEM, namely electron beam diffraction has demonstrated its high utility in MNPs differentiation from ferritin intracellular iron storing protein.[234]

Apart from laborious and costly specimen preparation for TEM, the analytical throughput of samples is one of the major technical difficulties as only small tissue volume of 1–10 μm^3 is usually analyzed. As low NPs doses are administrated *in vivo*, far fewer NPs are accumulated within each cell and far fewer exposed cells are present in exposed tissues.[214] Therefore individual NPs observation in ultra-thin sections of tiny volume tissue samples is sometimes unattainable. To overcome this limitation a scanning transmission electron microscopy (STEM) approach has recently been proposed. In this approach, dark and bright field images were recorded together with control of the image contrast settings to analyse 243,000 μm^3 of liver tissue in a single setting.[237] Moreover, in terms of limited information from selected regions of TEM sample, new method called X-ray scanning analytical microscopy (XSAM) has emerged as an alternative. This non-destructive technique based on the analysis of energy-dispersed fluorescent X-rays in air has been applied for iron elemental mapping in whole mice.[238]

Overall TEM analysis can be most useful for tracking detailed NPs sub-cellular localization as an addition to a series of other detection tools rather than first choice high-throughput imaging technique.[239]

1.09.3.8 Elemental Analysis

Accurate quantification of NPs made of materials natively not found in the body can be obtained by elemental analysis with spectroscopic methods such as inductively coupled plasma-atomic emission spectroscopy (ICP-AES) or inductively coupled plasma-mass spectrometry (ICP-MS). Elemental analysis is a destructive method which requires acidic sample digestion before dilution and analysis which is rather expensive. However, a huge benefit of this technique over other detection methods is its high precision and the possibility of tracing even small amounts of internalized NPs as its detection limits reaches sub-ppb.[240,241] Additionally, in some cases it is possible to convert the mass concentration obtained from elemental analysis into NPs number, as it has been demonstrated for Au NPs.[242] Elemental analysis has been applied for detection of many NPs types in tissues/organs/biological fluids samples, such as QD,[243–245] titanium NPs,[246] Au NPs,[242,247,248] Ag NPs,[249,250] silica NPs,[211,251] or IONPs.[252,253] Importantly in case of IONPs, this technique does not differentiate between iron originated from NPs and endogenous one (in form of transferrin, ferritin or haemoglobin).[254] Therefore magnetometry techniques are considered a better alternative to elemental analysis or optical approaches for magnetic NPs quantification.[255]

As this analysis does not provide any spatial information about NPs localization it is normally preceded by visualization approaches. Moreover, it has to be mentioned that elemental analysis is unable to differentiate between metal species, and therefore does not distinguish elements confined within the nanomaterial from ions leached from the nanostructure.[229]

1.09.3.9 Magnetometry

Alternative to the elemental analysis, magnetometry techniques can provide quantitative and selective determination of MNPs in cells or tissues based on their magnetic properties. Among them, Electron Spin Resonance (ESR), Ferromagnetic Resonance (FMR) and ac (alternating current) magnetic susceptibility are the most popular ones.

ESR is a spectroscopy technique used for studying chemical species with unpaired electrons (including paramagnetic, ferri-/ferromagnetic and anti-ferromagnetic materials)[256] and therefore applicable for MNPs detection. Although ESR is more sensitive for MNPs than for endogenous iron containing proteins,[257] the proper differentiation between them is unattainable as it has been shown in case of superparamagnetic ferrofluids which contribute to the same resonance signal in the EPR spectra as Fe^{3+} ferritin ions.[258] The sample preparation is destructive but this method provides very high quantification sensitivity (ie, nM Fe g^{-1} tissue). Hence ESR served as a robust MNPs detection techniques in several studies.[257,259,260]

FMR is another spectroscopic technique basically consisted in EPR. However in this case dynamics of magnetization of unpaired electrons collectively coupled in a ferro- or ferrimagnetic lattice is followed instead of detecting resonance of individual electron spins.[261] Although not extensively applied its quantitatively and selectivity in *ex vivo* MNPs biodistribution studies have been confirmed.[234,262]

AC magnetic susceptibility is a technique based on the ac magnetic field application and the following recording of the resulting magnetization.[263] Normally the experiment is performed from cryogenic up to room temperatures what enables differentiation of MNPs with even not fully homogenous size and importantly the discrimination between tissue endogenous iron and exogenously delivered MNPs.[264] Besides, MNPs quantification is possible after incorporation into the protocol a collection of precisely prepared standards.[233] In terms of long term biodistribution studies the utility of ac magnetic susceptibility for the evaluation of MNPs transformation over time has been confirmed.[265] Because of its high sensitivity (order of 1 μg Fe g^{-1} dry tissue)[264] and selectivity

superior over traditional MNPs detection methods,[255] ac magnetic susceptibility has been applied in a variety of biodistribution studies.[22,233,234,265,266]

Magnetic measurements are sensitive, specific for transition metals and provide information about MNPs biodistribution from a substantial portion of tissue/organ sample. However as the measurements assess the bulk magnetic properties of the sample no information about the MNPs localization is obtained.[267] Therefore they are normally combined with other visualization approaches.

1.09.3.10 Conclusions

The variety and availability of detection methods for NPs biodistribution studies enable more and more comprehensive understanding of effects caused by NPs delivered *in vivo*. However a single technique is often deficient for unraveling all the questions regarding the NPs biodistribution within a body. Therefore for obtaining reliable information on NPs biodistribution a combination of different detection methods is recommended. *In vivo* approaches provide a non-invasive molecular imaging of NPs whose limited resolution can be overcome by following *ex vivo* studies of dissected organs/tissues. Successively, quantitative determination and subcellular NPs localization can be obtained by employing elemental analysis and electron microscopy studies, respectively. Moreover, in case of MNPs, magnetometry techniques seem to perfectly address the overtime MNPs transformation issues.

1.09.4 Toxicity

Nanoparticles exposure is not limited to NPs developed for biomedical applications; they are present in multiple consumer products such as cosmetic, processed foods, electronic items, etc. That is why, in parallel to investigations concerning the synthesis of new nanomaterials, testing the interactions of these materials with the living world is mandatory for the secure development of nanotechnology.

The special physicochemical properties of nanoparticles (NPs) that show great promise for biomedical applications, may also affect cellular physiology including viability and other critical functions. Apart from specific aspects of each type of NPs such as composition, charge and shape,[268] there are common features that may produce similar mechanisms by which they affect cellular homeostasis or viability.[269] The size of the NPs itself (nano) appears to cause several adverse effects. First of all, because they can reach places where larger particles cannot enter such as placental[270] or hematoencephalic barrier in some cases,[271] enter into cells and be accumulated in endosomes (increasing the local concentration) or in the nucleus.[272] Additionally the high surface/volume ratio increases the surface area available for interaction with signaling pathways or cellular components such as proteins and lipids.[273]

Despite the high number of toxicological studies, the impact assessment of NPs use remains unclear, because the results reported in the literature are ambiguous and the great variety in types of NPs, incubation conditions, assay or cells used, make impossible to compare between different studies.[269] To increase the understanding on this topic standardized protocols to be able to compare different studies are needed.

The toxicity of NPs includes short-term consequences such as loss of cell viability inducing cell death or /and long-term effects such as decreasing cell survival or cell proliferation, inhibiting growth due to cell cycle arrest or senescence, or even they may interfere in cell signaling pathways altering cell activity. Besides the great number of toxicological studies carried out *in vitro*, reliable results are only the ones obtained using different types of cells (different origin), a wide range of concentrations, incubation conditions and all sorts of assays that cover all the aspects that may be affected by NPs. In order to select the appropriate tests, it is important to understand what they really measure and their limitations. In this section we discuss the most popular and interesting assays currently used to determine toxicity *in vitro*.

1.09.4.1 Proliferation Assays

There are a variety of tests used to analyze the proliferation status of the cell. However, common tests that study the NPs effect on cell proliferation only provide evidence of a proliferation decrement if it is caused due to distortion of cell metabolism activity or cell division, besides NPs may affect cell proliferation for many other different reasons.

1.09.4.1.1 MTT

The MTT assay was the first rapid colorimetric assay developed for cell viability high screening in a 96-well format. This assay measures the reduction of yellow MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) to an insoluble blue formazan product by mitochondrial succinate dehydrogenase.[274]

The MTT substrate is added to cells in culture, usually at a final concentration of 0.2–0.5 mg/mL, and incubated for 1–4 h. Then, the cells and formazan product are solubilized with an organic solvent (eg, isopropanol, DMSO, etc.) and absorbance at 570 nm is measured using a multiwell scanning spectrophotometer.[275]

When cells die they lose their ability to convert MTT into formazan, thus, color formation presumably serves as a marker of the viable cells. The MTT assay was developed as a non-radioactive alternative to tritiated thymidine incorporation into DNA for measuring cell proliferation[274] and has been widely used in academic labs for economic reasons and because of their degree of

precision and rapidity, no washing steps are needed. It is very useful for screening a large number of samples at the same time, as the first step to select the range of concentrations (LD50) and the most effective drugs. However, it has some problems and limitations.

Problems: Despite the fact this method was designed for proliferation and cytotoxicity assays, it measures the activity of a mitochondrial enzyme and the signal generated is dependent on the level of cell metabolism.[276] MTT reduction assays are often erroneously described as cell proliferation assay without the use of proper controls to confirm effects on metabolism.[277] Culture conditions may affect the metabolism and consequently the rate of MTT reduction into formazan. For example, in adherent cells metabolism may be reduced when growth is inhibited by contact in a confluence cell culture situation. On the other hand the metabolism may be increased when components of the NPs can be utilized by the cell as nutrients (Fe_3O_4, lipids, carbohydrates, etc.). Other adverse culture conditions are an altered pH or depletion of essential nutrients such as glucose.[278]

As a colorimetric assay, some substances can interfere with absorbance readings, enhancing the signal generating false results. The interference can be produced by the NPs,[279,280] the color of ligands or some medium compounds such as phenol red, which can be reduced using an acid solubilizing solution that changes the color of phenol red to yellow color that may have less interference.[281]

This test is not valid for some NPs (Carbon) because of interactions or absorption of the formazan product used in this assay.[282] This assay measures the product of a reduction reaction (formazan), so, reducing compounds such as paclitaxel, cisplatin, coenzyme A, DTT, or ascorbic acid, among others, may reduce MTT non-enzymatically[283–287] and the high levels of reactive oxygen species (ROS) produced by NPs incubation may alter redox equilibrium of the cell[288] increasing the absorbance values in assay wells independently of cell viability. The assay method must be considered as an endpoint assay because the formazan crystals can harm cells during exocytosis resulting cytotoxic.[289]

Improvements/tricks: Suspected chemical interference of NP should be confirmed by measuring absorbance values from control wells containing culture medium, MTT and various concentrations of the NPs without cells. A variety of formazan solubilizing methods (DMSO, SDS, organic solvents, acidified isopropanol, etc.) have been used to stabilize the color, avoid evaporation, and reduce interference by culture medium components.[290–292] It is possible to change maximum absorbance at other length in order to avoid interference using new tetrazolium compounds as substrates for the MTT assay, such as MTS[293] (absorbance maximum at 490–500 nm).

The amount of signal generated is dependent not only on the number of viable cells and their metabolic activity but also on several parameters including: the concentration of MTT and the incubation time. These parameters should be considered when optimizing the assay conditions to generate a sufficient amount of product that can be detected above background.

1.09.4.1.2 Alamar blue assay

This assay is similar to MTT; it measures the ability of metabolically active cells to convert resazurin (blue) to the molecule resorufin (bright red fluorescence) that can be measured in a plate reader on a fluorescence spectrophotometer (560ex/590em), on a UV–vis spectrophotometer (570 nm) or by flow cytometry.[294]

Problems: The enzymes that mediate the reduction are not well known, they may be mitochondrial or cytosolic and microsomal enzymes.[295] The extensive reduction of Alamar Blue may led to a final nonfluorescent product (hydroresorufin), and hence an underestimation of cellular activity. This test is similar to MTT, so do the problems. The differences for Alamar Blue assay are the higher sensitivity and the non-toxic reactants.[296] However, it has been observed a interference of the carbon NP itself in the fluorescence reading due to a quenching effect.[297]

1.09.4.1.3 Clonogenic assay

The clonogenic assay measures the capability of a single cell to form a colony (Fig. 6). It is a widely used experimental approach to test for the effects of drugs/genes on the growth and proliferative characteristics of cells *in vitro*. After incubation with NPs, the number of cells in each sample are counted and diluted to seed 100 cells per well. Depending on the size of the formed colonies, a 6-well plate or petri dishes (3–5 replicates of each) can be used. The incubation period varies from 1 to 3 weeks depending on the cell line, and it must be equivalent to at least 6 cell divisions to form sufficiently large clones to be visible with the naked eye. The colonies should be fixed, stained and counted.

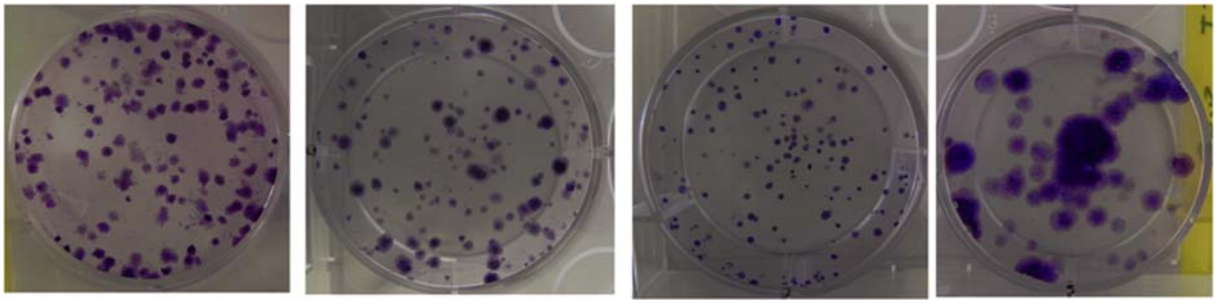

Fig. 6 Difference in the form of the colonies between cell lines. From left to right A549, B16, MiaPaca and MEF cells.

Problems: This assay is the gold standard to analyze cell viability but has the disadvantage that it is limited to adherent cells, additionally not all adherent cells are able to form colonies *in vitro* at low cell density where cell-to-cell contacts and self-produced growth factors are limited. On the other hand this assay is time-consuming and labor-intensive and shows high intra-individual variability because accurate quantification depends on the ability of the operator to visualize and count cell colonies precisely. Additionally, some colonies may be lost during staining and washing steps.

How to solve these problems: In order to reduce operator fatigue, the counting can be done using a stereomicroscope, and to reduce intra-individual variability it can be automatized using a digital imaging software or Image J.[298,299] Cells with low adherence may be grown in collagen matrix, however, some dyes stain collagen (eg, metilen blue), so different staining methods have been developed to reduce background. The most popular dye to direct counting is crystal violet and ethydium bromide which can be used with a UV illuminator.[300]

The major advantage of this method is the low interference of the NPs with the assay reactives, because the only possible interference is with the staining agent, which is used only to visualize automatically colonies or to take images, so the intensity is not important and the colonies can be counted without the necessity of be stained.

1.09.4.1.4 Cell division assay

This assay measures proliferation using flow cytometry. It consists on the incorporation of a fluorescent compound (CFSE) into cells for labeling and tracing them through successive divisions (Fig. 7). Cells are incubated with CFDA-SE (carboxyfluorescein diacetate succinimidyl ester), which diffuses into the cell where it is cleaved into CFSE, a highly fluorescent derivative that is retained in the cell. With each division the fluorescence results in the half and it can be monitored up to 8 divisions before the fluorescence decreases to background levels. In order have a reference value, a control of undivided cells is needed.[301,302]

Problems and solutions: This cell division assay is faster (2–7 days) and less labor-intensive than the clonogenic assay and allows researchers to analyze cell proliferation with other cell-live techniques such as multiparametric analysis, cell sorting, or immunophenotyping. However is more expensive and a flow cytometer is required. High concentration of CFSE is cytotoxic, so a titration of CFSE to obtain an optimal staining concentration is needed. Other fluorescent labels at different ex/em maximum have been developed, such as cell trace violet, yellow or far red to avoid interference with NPs or their ligands.[303]

1.09.4.1.5 EdU proliferation assay

5-ethynyl-2′-deoxyuridine (EdU) is a nucleoside analog dye-labeled which is incorporated into proliferating cells in their DNA during its synthesis, dyeing the cells with a bright fluorescent label that can be detected by flow cytometry or fluorescence microscopy and it can be used in cell cultures or tissues.

The original protocol was developed in the late 1950s and used ^{3}H-thymidine.[304] Due to the inconvenience of the radioactivity and poor sensitivity of this method, it was overtaken by more sensitive, nonradioactive methods, in particular by 5-bromo-2′-deoxyuridine, referred to as (BrdU).[305] The EdU assay is an alternative to traditional BrdU methods for detecting and quantitating newly synthesized DNA.[306] EdU assay is fast and reliable, it also can be used for detection s-phase cell cycle. This method can be performed with other dyes or antibodies even to detect intracellular antigens.

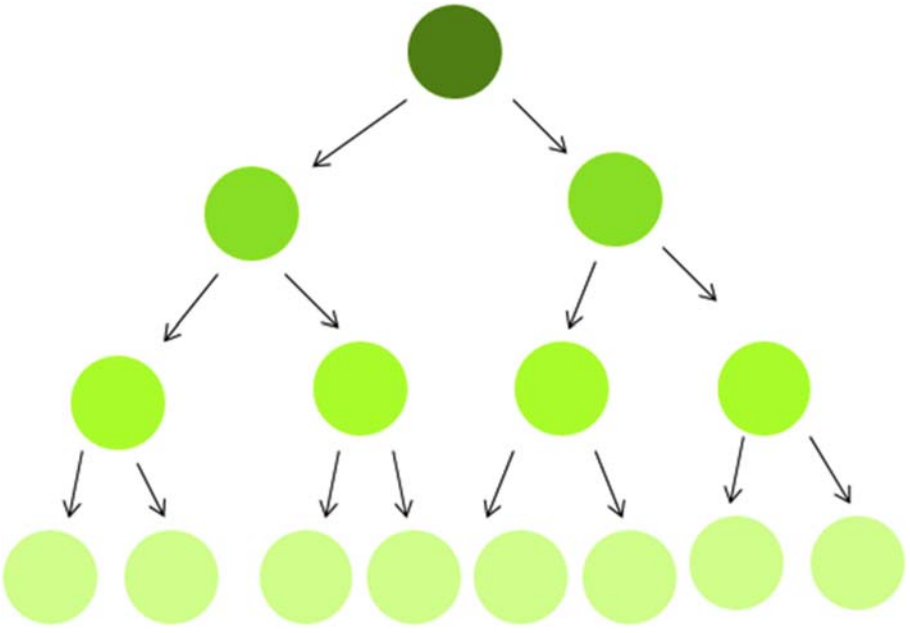

Fig. 7 Cell division assay: The fluorescence is half-decreased in each division.

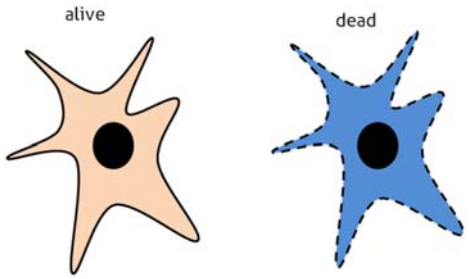

Fig. 8 Schematic representation of Tripan blue staining dead cells.

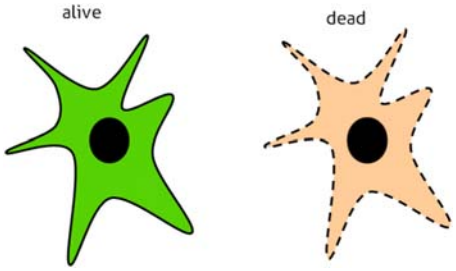

Fig. 9 Schematic representation of fluorescein diacetate staining alive cells.

1.09.4.2 Cell Membrane Permeability

One of the aspects to consider a cell dead is the loss of its membrane integrity. These methods are based on the principle that live cells prevent the entrance of certain dyes because they have intact membrane whereas dead cells are stained or vice versa. Usually the protocols consist on the incubation of the cells with the dye and further visualization.

Problems: The major limitation of these assays is that they cannot distinguish between healthy cells and the cells that are actually dying (in early stage) but still with the intact membrane or alive but losing cell functions, so the results may be underestimated.

1.09.4.2.1 Trypan blue

It is a widely used assay for staining dead cells. Trypan blue enters dead cells and stains their cytoplasm in blue (Fig. 8). Cell viability is determined by counting the unstained/stained cells with a microscope or other instruments. This method is easy and cheap and can be performed in all laboratories, because the only instrument needed is a light microscope.

1.09.4.2.2 Fluorescein diacetate

This compound freely penetrates intact cells where it is hydrolyzed to fluorescein (green), which is retained in the cell due to its polarity. In this method, the cytosol of live cells is stained green and can be detected using a fluorescence microscope or flow cytometer (Fig. 9).

1.09.4.2.3 Calcein acetoxymethyl

Calcein acetoxymethyl (Calcein-AM) is a substrate that passively crosses the cell membrane and in the cytosol is hydrolyzed by the enzyme esterase to a polar green-fluorescent product (calcein) that is retained into cells with intact membrane (Fig. 10). This

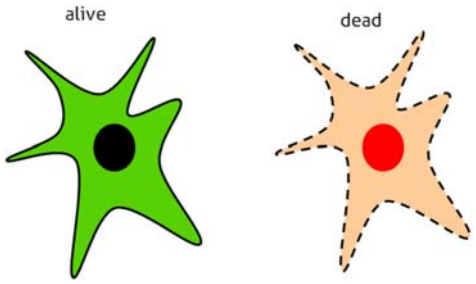

Fig. 10 Schematic representation of a combination of Calcein-AM (staining live cells) and a DNA intercalating agent (staining nucleus of dead cells).

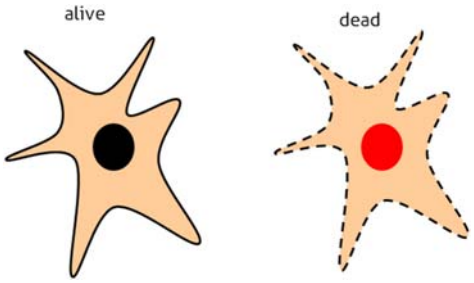

Fig. 11 Schematic representation of intercalating DNA agents staining nucleus of dead cells.

method not only analyses cell membrane integrity but also esterase activity. The fluorophore calcein displays good retention characteristics (several hours after fixation) and low pH sensitivity. This dye is usually used with ethidium homodimer-1 in commercial kits. The test is simple, fast and can be performed using a fluorescence microscope, flow cytometer or fluorescence microplate reader.

1.09.4.2.4 DNA intercalating fluorescent agents

Ethidium bromide, propidium iodine (PI) and 7- amino-actinomycin D (7-AAD) are three red fluorescent dyes that intercalate into DNA of membrane-damaged cells (Fig. 11). Ethidium bromide is considered carcinogenic, that is the reason why it is currently less used. PI and 7-AAD are both excited at 488 nm but the emission range(625 nm for PI and 655 nm for 7-AAD 655 nm), makes the difference, PI has significant spectral overlap with the fluorophore PE (Phycoerythrin) whereas 7-AAD no. Thus, 7-AAD is favorite in multiparameter staining experiments.

1.09.4.2.5 Lactate dehydrogenaze enzyme

The intracellular cytosolic enzyme lactate dehydrogenaze (LDH) can be released to the extracellular media by membrane-damaged cells. LDH activity measured in the culture medium can be used as an indicator of cell membrane integrity. LDH catalyzes the reduction of NAD+ to NADH by oxidation of lactate to piruvate. The formed NADH can be quantified with a second reaction where 2-(p-iodophenyl)-3-(p-nitrophenyll-5-tetrazolium) (p-INT) salt is reduced to a red formazan product in the presence of diaphorase or phenazine methosulfate (PMS) (Fig. 12). The colored product absorbs at 490–520 nm and can be detected spectrophotometrically, with a microplate reader for a large number of samples.[307]

Problem: The serum present in culture medium has considerable LDH-activity and phenol red indicator absorbs at 490 nm causing a significant decrease in sensitivity, thus serum and phenol red should be used also as a control to set up the base line (background). However, the main drawback is that some NPs (CdSe, Au and silicon) can inhibit the activity of LDH.[308]

1.09.4.3 Cell Death Mechanisms

1.09.4.3.1 Annexin-V

Apoptosis is a cell death mechanism characterized by keeping the plasma membrane intact. During apoptosis, phosphatidylserine (PS), a phospholipid usually found in the inner side of the plasma membrane, is translocated to the outer side resulting in its accessibility to annexin-V. This method consists on the incubation of cells with annexin-V joined to a fluorophore to detect apoptotic cell death by flow cytometry.[309]

Problems: When the membrane is damaged (necrotic cells), annexin-V can bind PS in the inner side, therefore in order to distinguish between necrotic and apoptotic cells the experiment should be carried out additionally with 7-AAD or PI (Fig. 13).

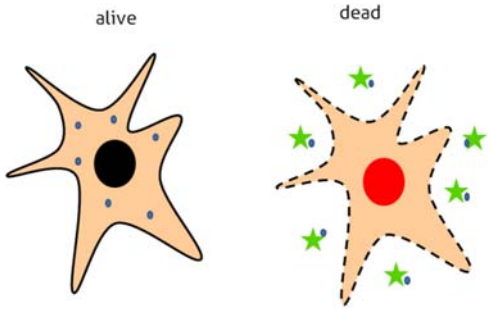

Fig. 12 Schematic representation of LDH activity detection in dead cells.

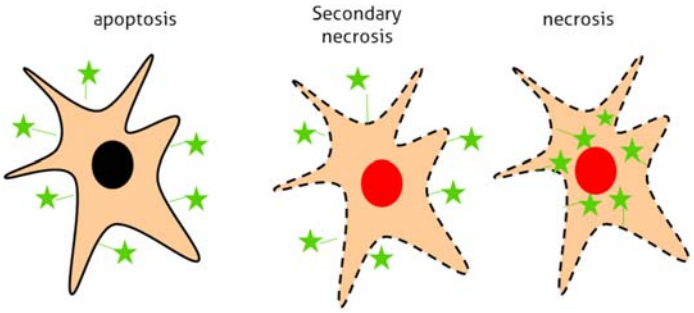

Fig. 13 Schematic representation of Annexin-V staining. In green annexine-V and in red PI/7AAD staining. An apoptotic cell is only stained with annexine-V, however a necrotic cell can be stained by both, because annexine-V not only can bind to PS in the outer side of the plasma membrane but also can enter into the cell and bind the inner PS.

1.09.4.3.2 ROS generation

Upon exposure to NPs, the most common cellular response involves the generation of ROS,[310,311] which has been described as one of the most relevant cytotoxic aspects caused by the internalization of NPs inside the cell.[312,313] ROS encompasses a number of reactive molecules and free radicals derived from molecular oxygen including superoxide ($O_2^{\bullet -}$), hydroperoxy radical ($HOO^{\bullet}$), hydroxyl radical ($OH^{\bullet}$), nitric oxide ($NO^{\bullet}$), hydrogen peroxide (H_2O_2), and peroxynitrite ($ONOO^-$).

The methods used to determine ROS consist on the use of oxidizable dyes that react with different intracellular ROS. The most widely used are fluorometric assays that offer very good sensitivity. Among them the most popular are dihydroethidium (2-HE) and derives forms of 2′-7′-dichlorofluorescein (DCF) such as H_2DCF-DA. 2-HE is oxidized specifically by superoxide anions and the product (red) intercalates with DNA.However, derives forms of 2′-7′-dichlorofluorescein, are oxidized by a wide range of ROS producing DCF (530 nm emission).[314] The fluorescent products can be detected using fluorescence microscopy, flow cytometry or a microplate reader. Some studies have also used oxidized colored compounds or other chemiluminescent substances.[315–317]

Problems: ROS production can be tolerated up to certain levels without side effects because most cells have defense mechanisms to reduce them, such as glutathione redox system.[318] The level of toleration depends on the cell type and it is not well defined.[319] Usually low and transient ROS increase can be tolerated by most cell types,[311] however, when the amount of ROS is excessive and persists over a long period of time, results in cell damage.[320–322] That is the reason why ROS generation results should be considered carefully. In order to analyse whether the effects are transient or long-lasting, ROS levels should be measured at different time points after NPs exposure and other parameters to determine their toxicity such as cell death or proliferation assays should also be determined. Besides, ROS generation assay does not indicate directly cell damage induced by NPs exposure, it is useful to determine the mechanism of a possible toxic effect. The major drawback of this method is that some NPs interfere with the assay.[323–325]

1.09.4.3.3 Loss of mitochondrial membrane potential

Several types of NPs target mitochondria[326,327] so, it is important to study its state. The mitochondrial membrane potential ($\Delta\psi_m$) is a signal of cell health, it provides the charge gradient required for ATP production, Ca^{2+} sequestration and regulates ROS production.[328,329] Loss of mitochondrial membrane potential is a signal of bioenergetic stress and may result in the release of apoptotic factors leading to cell death.

The mitochondrial perturbation can be measured using fluorescent probes [eg, tetramethylrhodamine ethyl ester (TMRE), Rhodamine 123 (Rhod123) and $DiOC_6(3)$ (3,3′-dihexyloxacarbocyanine iodide)].[330,331] These dyes are typically lipophilic positive charged compounds that accumulate into the mitochondrial membrane matrix space according to the Nernst equation (the more negative the mitochondria is charged the more accumulation of the probe).[332] When the mitochondria lost the differential of membrane potential the dye cannot be retained and the fluorescence decrease (**Fig. 14**). Fluorescent probe accumulation in mitochondria is analyzed by optical or confocal microscopy, flow cytometry, or fluorescent plate reader.

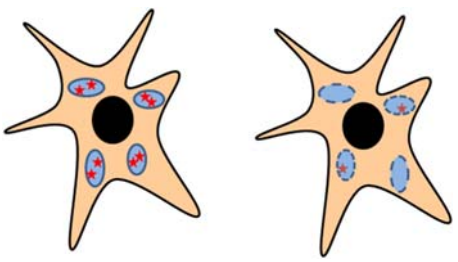

Fig. 14 Schematic representation of mitochondrial potential staining. The mitochondrias are simply represented in blue, the loss of mitochondrial potential in discontinuous line and the fluorescent probe in red.

Problems: High dye concentrations (50–100 nM to several micro molar) form aggregates into the mitochondria quenching some of the fluorescent emissions and once the dye is release, the fluorescence is unquenched increasing the fluorescent signal.[333]

1.09.4.3.4 Cell morphology

NPs occupy an intracellular volume usually inside endosomes or may be attached to the cell membrane. This can alter cellular morphology affecting the structure of cytoskeleton network.[334–337] The NPs effects on cytoskeletal deformations remains uninvestigated, however, as the cytoskeleton participates in cell division, intracellular signaling, exocytosis and endocytosis pathways, among others, NPs may affect them and the elastic and adherent properties of the cell.

On the other hand, the possible adverse effects may be transient, due to the fact the NPs concentration inside the cell decrease each division because they may be divided into both resultant cells and also released from the cell. It is important to evaluate NPs endocytic pathway and intracellular time-dependent location as well as assess the maximal cellular loading capacity without effects. The effect of NPs on cytoskeletal organization can be measured using different techniques:

- *Immunofluorescence analysis of cytoskeleton organization* using fluorescence (confocal/normal) microscopy. Cells are incubated with fluorophore conjugated phalloidin for F-actin and anti-tubulin antibodies for b-tubulin[336] and the results are compared to the control. The major drawback in this assay is the interpretation of the results; it is difficult to detect small differences that cannot be quantified.
- *Cell adhesion assay*[336]: Cells are seeded and sometimes stained with coomassie and the number of adhered cells are counted and refereed to the control.

1.09.4.4 Instrumentation for Detection of Fluorescent Probes

The majority of the fluorescent probes used to analyze cytotoxicity induced by NPs can be detected using different instruments with advantages and disadvantages each one:

- *Fluorescent microscopy*: The results are visual, easy to comprehend and using confocal microscopy, the intracellular location of the labeling can be determined. It is possible to quantify the number of cells affected and even the fluorescence intensity using image treatment software. However, it presents photooxidation problems because light exposure is difficult to control and may not be the same in all samples, for that reason quantifying is not reliable. It is the most-laboring and time-consuming technique.
- *Microplate spectrophotometry*: The advantage respect from fluorescence microscopy is that the photooxidation is the same in all samples, thus the results are comparable and the quantification is accurate. It is the quickest, easiest and less-laboring method, but it is less sensitive and exposure time cannot be modified. Additionally, the value obtained is the mean of the complete well and the results should be done respect to a control.
- *Flow cytometry*: Flow cytometer analyses cells individually and rapidly, the photooxidation is the same in all samples, and therefore quantification is reliable. The fluorescence measurement can be correlated with other aspects of the cells such as size and complexity or granularity and can be performed in the combination of multiparametric experiments.[50,338,339] Thanks to the advances in laser and fluorochrome technology it is possible to detect up to 18 colors at the same time. Nowadays there are more complex cytometers, which recover specific cells after measurement (sorters) or with a camera enclosed acting as a microscope which allows to differentiate between extra and intracellular labeling.

1.09.4.5 General Considerations for the Presence of NPs

The evaluation of nanomaterial safety is not standardized yet, thus, literature is full of conflicting reports, which show different degrees of toxicity with similar nanoparticles.

The NPs themselves may interfere with analytical techniques (fluorescence/absorbance, assay components or reactives, etc.).[340] They can bind to proteins and dyes[341,342] and alter the produced signal affecting their structure and/or function. The consequence can be an enhancement or a reduction in their absorbance or fluorescence. Carbon nanoparticles present the highest levels of interference with the cytotoxic assays because of their absorption ability,[297,343,344] however ionic nanoparticles also interfere with cytotoxic assays[323,325,345]

That is why the use of accurate controls (assay components, analyte and NPs) is needed in order to confirm whether the NPs interfere in the assay. It is becoming evident that these assays have to be standardized and optimized for NPs to avoid misleading results.

A multiparametric study is essential to obtain as much information as possible about the most of the aspects that may be affected by the presence of NPs.

1.09.5 Future Challenges

In spite of the good results already being obtained by nanoformulations for drug delivery and the improvement that these materials provide in comparison with the as-prepared drugs, there is always room for improvement. In this section we present a series of ideas

regarding trends that should be fulfilled in the long-term research associated to nanomaterials for drug delivery. Despite the inherent complexity associated to such a wide variety of nanomaterials being used in the drug industry, it is possible to define general future development trends for all of them.

1.09.5.1 Development of New Materials

It is important to continue developing new materials, synthetic or semi-synthetic with new properties, exploring alternative synthesis routes as the production by biological systems[346] or genetically modified cell factories.[347] Novel materials, which in principle would be used for non-biomedical applications, such as graphene, whose electrical properties led to an explosion of interest in high speed electronics,[348] are recently being tested for biomedical applications[349] such as carriers for anticancer drugs.[350] Regarding the development of new materials or structures, it will be of great importance to predict the advantages of new alternatives by theoretical approaches. Theoretical simulations will identify the properties of new materials, allowing an easier development of new materials. Currently, computational methods are being used to estimate solubility for drug development.[351] These methods allow the evaluation of physico-chemical properties of drugs before entering pre-clinical stages and Phase I safety evaluation. The analysis helps in the prediction of which compounds may fail in these stages, saving time and money in these expensive stages. Similar computational and mathematical tools should be developed for the evaluation of emerging nanomaterials in drug development. However, in many cases, these theoretical approaches are more difficult to achieve than in normal drugs, given the complexity of the new nanomaterials. Theoretical approaches would be able to predict, for example, the magnetic properties of nanoparticles in the frame of cancer treatment.[352,353] More sophisticated approaches should also focus on the interactions with the biological systems.[354]

1.09.5.2 Green Nanoscience

It is also necessary to pay attention to synthesis methods, trying to generate the less amount possible of waste products and approaching Green Chemistry routes.[355] Not just in the production of nanomaterials, but specially for those to be used in biomedical applications and the development of new drugs, we should make an effort to design materials and processes minimizing the hazards throughout the material's life cycle and approaching to a green nanoscience.[356] Synthesis routes should be improved to produce well-defined materials, with reproducible purity profiles, avoiding the use of hazardous materials and minimizing waste products.[356] Some examples of this are the production of silver nanoparticles with antimicrobial activity using leaf extract of *Mimusops elengi*,[357] or the production of AuNPs for drug delivery using water extracts of *Eclipta Alba* leaves.[358] The leaf extract reduces metal ion into metal nanoparticles, avoiding the use of stabilizing agent to prevent agglomeration and requiring less energy consumption than other chemical approaches.

1.09.5.3 Circular Economy

Although this is not commonly something scientists focus on, we should also think of using materials whose essential elements are guaranteed from a geopolitical perspective (Circular economy). Many new nanomaterials being studied in the frame of drug development, such as silver, gold or MNPs and QD, contain metals. Given their extensive utilization in a wide variety of applications and the increased consumer demand from a growing population worldwide, concerns over the security of supply and accessibility of these valuable elements has been raised.

According to a recent study on "Criticality of metals and metalloids,"[359] metals that are present in several nanomaterials for drug development are under different risks associated to imbalances between metal supply and demand in global markets. For example, Selenium, Cadmium and Indium, used as part of QD and Silver, used in the preparation of silver nanoparticles would have a high supply risk, as these metals have small geological resources relative to their current demands.[359] Gold, has high risk in environmental implications given the impacts related to its extraction and processing.[359] Lead, also part of some quantum dot formulations, has high risk to vulnerability to supply restriction, which is related to the degree to which suitable substitutes are unavailable.[359]

1.09.5.4 Biodegradable Products

One of the future challenges would be the production of biodegradable materials that could be degraded by the organism of metabolized and incorporated within the normal metabolic routes. Biodegradable materials would also allow the sustained drug release over a period of time within the target site. There are already several known polymers, both from synthetic or natural origin, with biocompatible properties and whose resorbability is achieved through natural pathways. Biodegradable synthetic polymers that form nanoparticles for drug delivery include, among others, poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and their copolymers, poly(lactide-co-glycolide) (PLGA).[360] Other materials such as porous silicon nanoparticles self-destruct in short periods of time with no evidence of toxicity,[361] therefore releasing drugs in more efficient periods of time than other biodegradable polymers that take longer to degrade.[362] Biodegradable polymers of natural origin include, among others, collagen, that has been used to encapsulate gentamicin and is commercially available,[17] albumin,[363] hyaluronic acid[364] or chitosan.[365] Regarding the use of metal-containing nanoparticles such as silver, gold or MNPs and QD, it should be noted that the human

body has the mechanisms to transfer iron from MNPs into safe storage through normal metabolic routes,[22] however the mechanisms for assimilation or excretion of other metals are not so clear yet.

1.09.5.5 Development of New Applications

We should also investigate new applications with existing materials. A clear example of this would be the new applications being developed using MNPs. These materials have been widely studied as heat generators for cancer treatment by magnetic hyperthermia,[353,366] drug delivery systems[266] or contrast agents for MRI[367,368] and MPI.[369–371] Recently, novel applications of these materials include their use in wound healing,[372,373] stroke treatment,[374] regenerative medicine,[375] transient opening of the blood brain barrier,[376] tissue engineering,[377] non-invasive diagnosis of Alzheimer Disease using MRI,[378] diabetes treatment,[379] or parasite diagnosis.[380]

1.09.5.6 Transference to Industry

Once that the nanotechnology's *discovery* phase,[356] in which new properties, transformations of matter, devices, and applications was the main focus, has passed, the next step is the transference of all the knowledge acquired in the development of new nanomaterials to the industry. Reaching a commercial product involves the production of bigger amounts of materials, prioritizing processes whose scale up is possible, easy and economically viable. Retaining the nanomaterial quality obtained in the small batches usually produced in research laboratories is not easy once the production levels must be reached. Scaling up processes is usually associated with an increase in the inhomogeneities associated, for example, to the reagents concentration or temperature reached. All these inhomogeneities lead to a loose of control of the final product.

In order to solve this, reactions using continuous flow could have an advantage when compared with the use of big volume synthesis approaches. Some examples of continuous flow production have already been described for liposomes,[381] silver nanoparticles,[382] AuNPs[383] or MNPs.[384] The production of materials in larger scales is also associated with new safety concerns. Waste products should be reduced and safety of the material in the frame of the whole society and the environment should be assessed. All these developments should then be performed minimizing the adverse impact of nanomaterials in the environment, especially in biological systems.

Apart from the large scale production, the fundamental step for the obtention of commercially viable products is the approval by regulatory agencies. FDA is the regulatory agency of the US in charge, among other roles, of the regulation and supervision of new developed drugs. New drugs, especially those using nanotechnology developments, should be evaluated and approved by FDA confirming not only their low risk profile but also their benefit. Knowledge of the nanoformulations biocompatibility, biodistribution and production reliability are fundamental for their successful translation into commercially viable products. One of the main hurdles that new developments face is the lack of information concerning the fate of these materials once they have performed their purpose. However, the complex nature of some of the formulations, comprising several different parts such as an inorganic core and the surface coating, comprising a biocompatible molecule and optional bio-conjugates, makes more and more complicated to analyze the biodistribution and degradation of the different parts and also of the whole nanoformulation.[385] It has recently been pointed out that these complex structures should be seen as inorganic/organic/biological nanohybrids with complex distribution and degradation pathways.[385] It could be concluded that although more complex nanoformulations may have better performance than simple ones, it would be much easier for the simple nanoformulations to reach the clinical practice due to regulatory issues.

1.10.1 Introduction

Creating novel drug candidates with improved biological properties and diminished adverse effect for treating human disease such as AIDS and cancer is one of the most important challenges faced by contemporary medicinal chemists.[1–4] Synthetic chemists and biologists initiated the process by taking a lead structure and then finding functional analogs exhibiting the preferred biological activities. Then, medicinal chemist used their experience and chemical insights to eventually choose a functional analog for further development.[5,6] Conventional methods of drug discovery are now being implemented by approaches made possible by identifying the molecular processes involved in disease. In this view, drug design begins with attempting to identify a molecular target (typically a receptor or protein in the body) followed by identification of molecules that affect the function of that target. Making these lead structures without side products and purification is synthetically demanding.[6,7] Click chemistry describes a set of powerful, highly reliable, and selective reactions to generate substances quickly and reliably by joining small units together through heteroatom links (C–X–C).[8–10] Click chemistry in drug design has many advantages and key features of click chemistry can be summarized as follows:[11]

Click reactions progress quickly at low or room temperatures in compatible eco-friendly solvent medium such as water and water-miscible solvents such as THF, methanol, ethanol, DMF, and DMSO and are suitable for microscale solution-phase parallel synthesis without the need for protecting group manipulations. As a result, click chemistry enables the rapid and reliable screening of large library of functional analogs with almost complete chemo-selectivity with broad functional group tolerance.[10,11] The orthogonality of the azide and alkyne functionalities to a diverse range of functional groups and reaction conditions allows the assembly of reactants decorated with diverse unprotected functionalities. The development of new methods for click synthesis is still of interest due to the importance of this function in drug discovery. Several existing methodologies such as copper and ruthenium salt catalyzed describe the regioselective formation of the 1,4-disubstituted triazole unit; efforts also have been made at developing methodologies for the exclusive formation of the 1,5-disubstituted regioisomers that are important in medicinal chemistry (**Fig. 1A**).[12,13] The triazole product is an effective pharmacophore. The 1,2,3-triazole structural motif generated in the click reaction is much more than just a passive linker unit and is considered to be a safe bioequivalent surrogate for amide, which is a widely employed functional group in drug design.[14] The 1,2,3-triazole moiety has several advantages:[14] (i) Its chemical robustness is favorable for adoption in drug discovery programs; (ii) it has a moderate dipole moment (5 debye) and the two H-bond acceptors at N_2 and N_3 can interact with biomolecular targets via enhanced H-bonding interactions, dipole interactions, or pi–pi stacking interactions as shown **Fig. 1A**; (iii) the 1,2,3-triazole offers high chemical stability in biological environments,

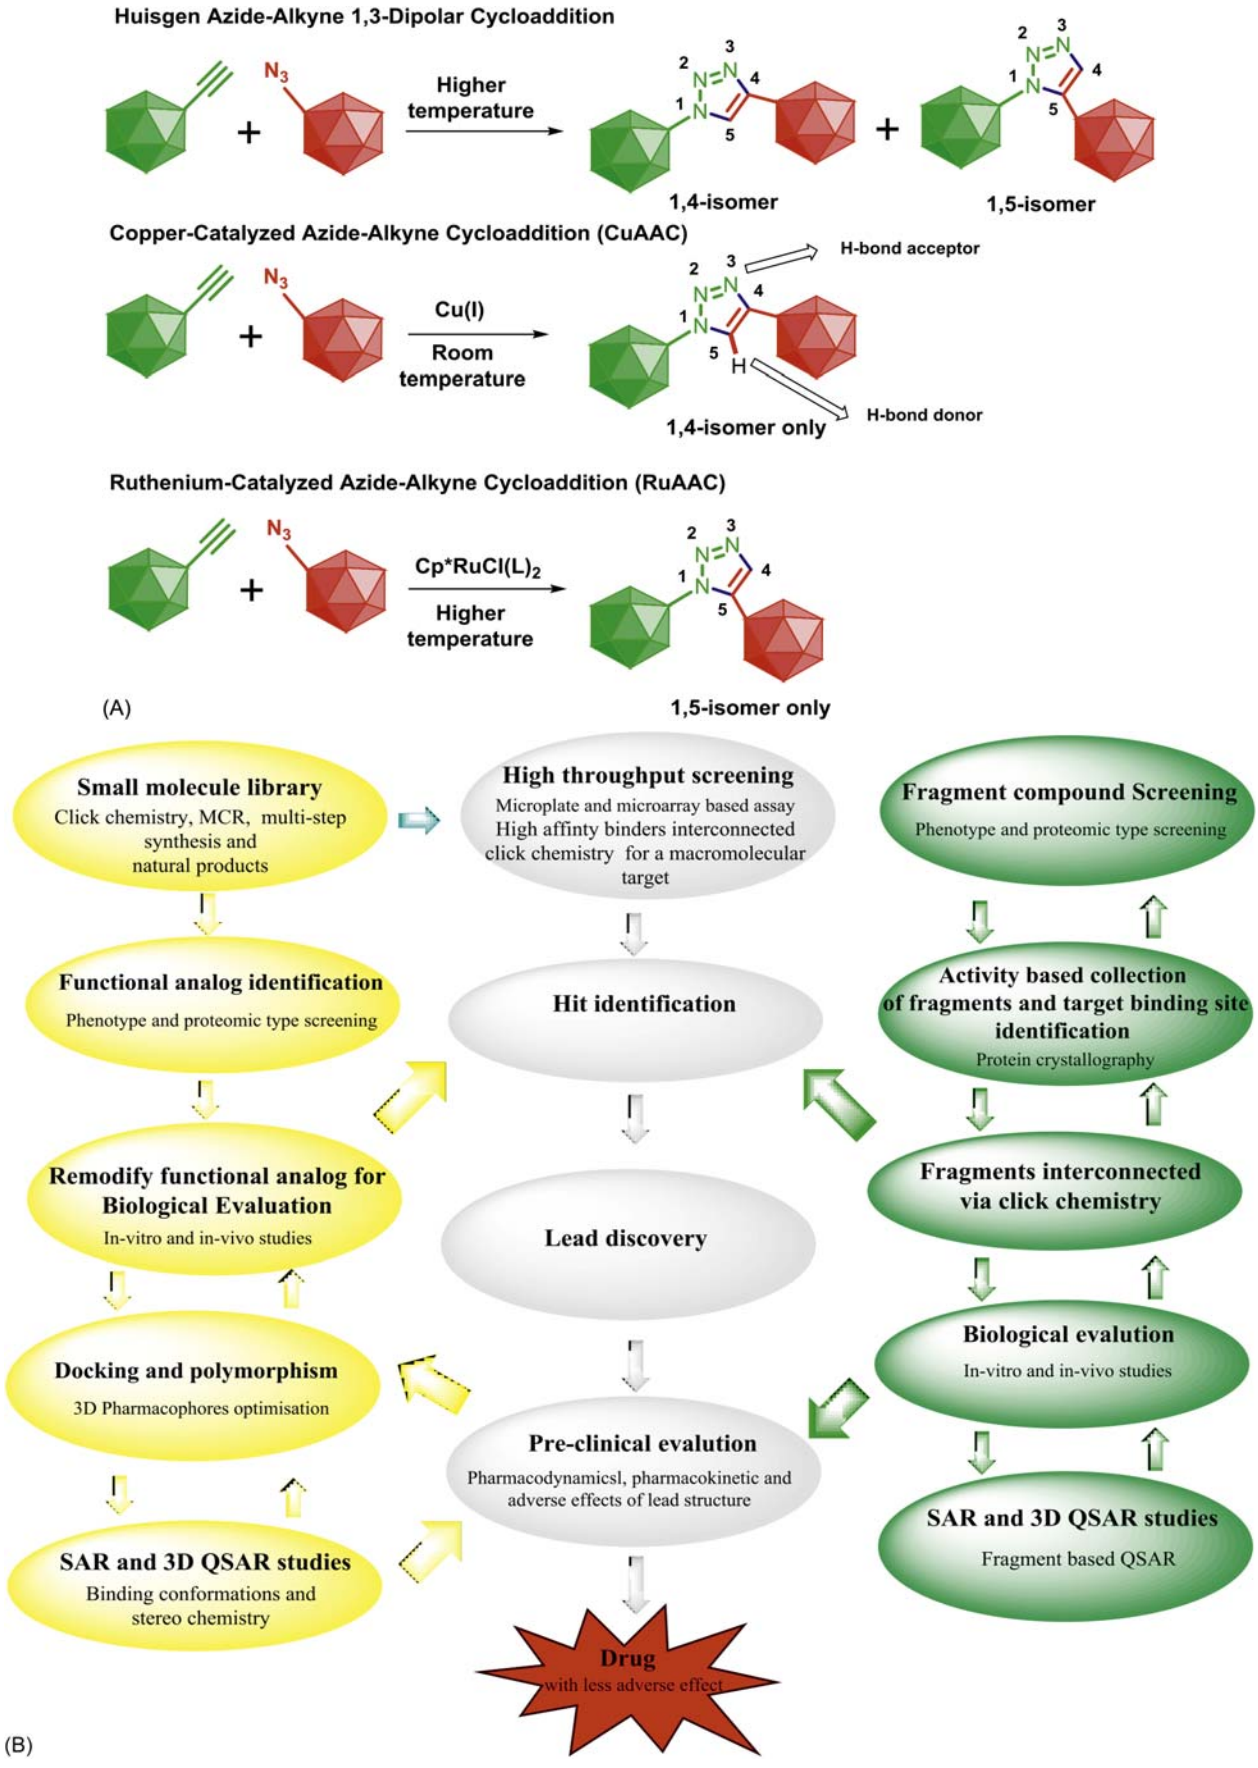

Fig. 1 (A) Schematic representation of (i) Huisgen 1,3-dipolar cycloaddition at higher temperature and (ii) copper (I) salt-catalyzed click reaction at room temperature and (iii) ruthenium-catalyzed azide–alkyne cycloaddition for exclusive formation of 1,5-isomer. (B) Drug discovery process workflow chart: click chemistry employed for various stages of drug candidate development. FBDD, SAR, and QSAR studies are essential elements of drug discovery process. *FBDD*, fragment-based drug design; *QSAR*, quantitative SAR; *SAR*, structure–activity relationship.

including acidic and basic milieus and oxidative and reductive conditions.[15] X-ray crystal structures of protein–triazole complexes are available, which is helpful for drug design, and the pharmacokinetic profile of this moiety has been investigated.[15] Equally important, 1,4-triazoles are metabolically inert, whereas 1,5-triazoles can be metabolized to N-oxides, which are reactive intermediates. Further, 1,4-disubstituted triazoles have a negligible inhibitory effect on the cytochrome P450 family of metabolizing enzymes, compared with the 1,5-isomers, and this is favorable for avoiding drug–drug interactions.[16] These attributes make 1,4-triazole suitable for use either as a potent pharmacophore that can directly participate in drug–receptor interactions or as a nonlabile covalent spacer between discrete N-1 and C-4 or C-5 substituents while maintaining excellent chemical and metabolic stability.[17–19] The triazole analogs are found in a number of biologically active compounds especially anti-HIV, antibiotic, antiviral, and antimicrobial activities.[14,20–22]

A drug discovery process contains several steps that include various chemical and biological screening. Present drug discovery depends on massive screening of chemical libraries against various extracellular and intracellular molecular targets to find novel chemotypes with the desired mode of action. How click chemistry can be effectively applied to drug discovery process is described in Fig. 1B.

1.10.2 Anticancer Agents Generated via Click Chemistry Reaction

Target-based approach in drug discovery is most appealing in contemporary pharmaceutical research, which requires that two key issues should be addressed well for drug development:[23,24] (i) biological targets with an activity that has a causative role in either the onset or progression of a human disease must be identified and (ii) therapeutic agents that appropriately modulate the activity of these targets in humans with limited or no adverse effects must be developed.[25] Conventional drug discovery processes such as high-throughput screening, combinatorial chemistry, and the sequencing of the human genome were remedies for the problems facing the pharmaceutical companies. The utilization of these technologies is well established at most modern pharmaceutical industries; however, the return on investment in terms of marketed products has not met expectations in the early 1990s. Due to severe commercial pressure to increase discovery productivity, medicinal chemists started using advent screening technology such as fragment-based methods for drug development process. Fragment-based drug design (FBDD) is an important tool for lead identification in drug discovery that has emerged in the past decade.[26,27] FBDD is focused on screening smaller numbers of compounds (typically 1000 chemical library) in the hopes of finding low-affinity fragments (with K_d values in the high micromolar to millimolar range). By contrast, conventional screening attempts to evaluate as many compounds as technologically possible (typically 100,000 or more) in the hopes of finding relatively potent drug leads (with K_d values ideally less than 1 μM).

The fragmentation of molecules leads to smaller pieces or even into discrete functional groups (e.g., carboxylate, amine, and alcohol) has been used for some time to simplify the computational analysis of ligand binding and to map out different pharmacophoric elements required for high-affinity binding.[28] The proper optimization of each unique interaction in the binding site and subsequent incorporation into a single molecular entity should produce a compound with a binding affinity that is the sum of the individual interactions.[29]

The efficiency of fragment-based methods can be improved by a combination of other conventional drug discovery techniques with FBDD. The impact of combined drug discovery methods has made in progressing new medicines into clinic.[29] Several enzymes have multiple binding pockets; yet conventional inhibitor development generally focuses primarily on the active site. However, in some cases, the secondary/allosteric binding sites confer selectivity as well as potency. Within this context, click chemistry, due to its highly modular and efficient reaction nature, has been identified as one of the most practical methods toward fragment-based inhibitor assembly where $N+M$ combinations of inhibitor fragments lead to the generation of $N \times M$ potential bidentate inhibitors. Identified small fragments joined together easily without affecting active site using click chemistry reaction or other conventional chemical reactions. Ligands with multiple binding pockets generated via FBDD can be used to selectively inhibit the over expressed protein or enzyme.[17,20]

Click chemistry is an ideal reaction to connect the prodrugs without affecting pharmacological activities. Some of click chemistry reaction-generated drug candidates that reached to clinical trials are shown in Fig. 2. Click-FBDD-based drug screening allows for more efficient lead identification and lead optimization procedures in medicinal chemistry. In this connection, it is easy to predict the usefulness of this reaction in fragment-based ligand design. Triazole peptidomimetic fragments could act as building blocks to be used in fragment-based approaches for drug discovery, thereby rendering this technique feasible in drug discovery. Hence, we go through here some of the lead drug-like molecules generated via click chemistry reaction described in the literature as novel drug development toward many incurable diseases like anticancer, antiviral, and anti-TB.[17,20] Some of triazole derivatives shown in Fig. 2 are under clinical trials for cancer therapy. Radicicol triazole (i) is a promising heat shock protein 90 (Hsp90)-based anticancer agent prepared from synthetically modified natural product of radicicol (dienone of cycloproparadicicol replaced with a triazole).[30] The conformational constraints of **r**eceptor-**a**ssociated **p**rotein 1 are important for binding to the Hsp90 N-terminal domain, and triazole analogs showed a significant drop-in activity compared to radicicol itself, and interestingly, radicicol triazole inhibits Kasumi-1 leukemia cells (IC_{50} value of 620 nM).[30] Letrozole (ii) and anastrozole (iii) are nonsteroidal aromatase inhibitors for the treatment of hormonally responsive breast cancer after surgery.[31] Both drugs work by inhibiting the synthesis of estrogen primarily in the body. This helps to starve cancer cells by depriving them of estrogen. Carboxyamidotriazole (iv) is an orally active potential antineoplastic agent, and it binds non-voltage-operated calcium channels, blocking both Ca^{2+} influx into cells and Ca^{2+} release from intracellular stores, resulting in the disruption of calcium channel-mediated signal transduction.[32]

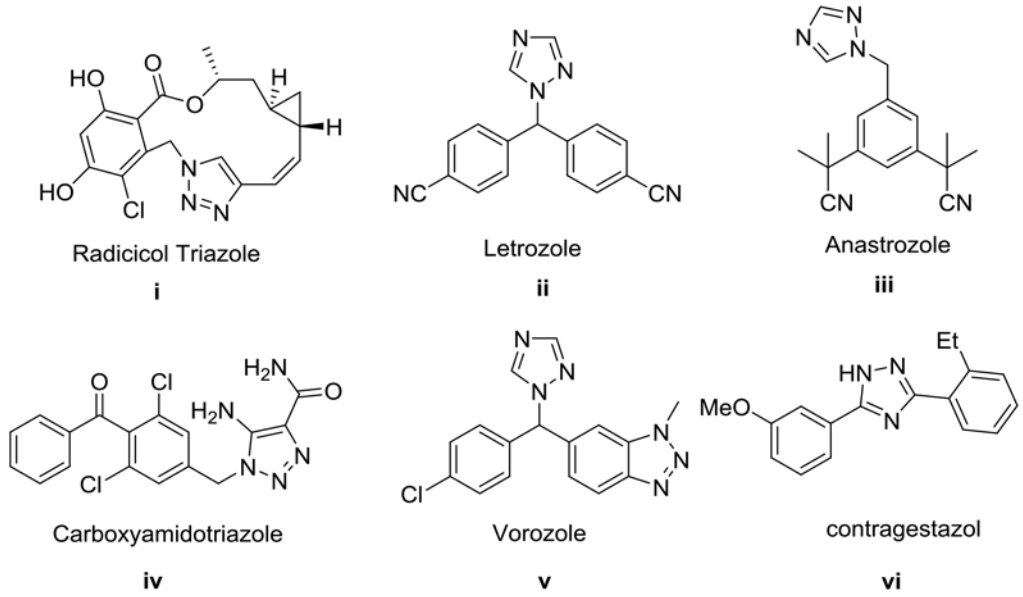

Fig. 2 Triazole-based analogs under clinical trials as cancer therapy agents.

Carboxyamidotriazole derivative also may inhibit tumor cell growth, invasion, and metastasis. Vorozole (v) is an imidazole-based specific, selective, and potent aromatase inhibitor and useful for postmenopausal patients with advanced breast cancer.[33] Vorozole is a triazole derivative, which binds to the cytochrome P450 moiety of aromatase, thus causing reversible inhibition of the enzyme. Plasma estradiol levels are reduced by about 90% in postmenopausal women treated with vorozole. Phase II clinical studies found vorozole to be an effective agent for the treatment of postmenopausal women with advanced breast cancer, achieving objective responses in up to 35% of patients. In two large phase III studies, vorozole 2.5 mg day^{-1} demonstrated favorable clinical efficacy compared with aminoglutethimide and megestrol. Vorozole improved patients' quality of life to a greater extent than aminoglutethimide.[34] Contragestazol is a nonhormonal antifertility agent and displayed a high activity on arresting early pregnancy in animals. Recently, contragestazol also exhibited outstanding effect on the suppression of ovarian cancer cell growth in human cell tumor models.[35]

A collection of triazole-dithiocarbamate derivatives were synthesized and evaluated for anticancer activity against four human tumor cell lines (MGC-803, MCF-7, PC-3, and EC-109). Most of the synthesized compounds exhibited moderate to potent activity against MGC-803 and MCF-7. The synthesized triazole analogs showed excellent broad-spectrum anticancer activity with IC_{50} values ranging from 0.73 to 11.61 μM (MGC-803, MCF-7, PC-3, and EC-109 cell lines). Particularly, compound **1** (Fig. 3) was more potent than 5-fluorouracil against all tested human cancer cell lines. Flow cytometry analysis demonstrated that treatment of MGC-803 with 3c led to cell cycle arrest at G2/M phase accompanied by an increase in apoptotic cell death after 12 h.[36]

Girard and his coworkers recently prepared mono- and bis-triazole derivatives from propiolic acid. All mono- and bis-alkyne triazole compounds were tested in vitro for their cytotoxic activity using B16 melanoma cells. Compound **2** ($IC_{50} = 0.28$ μM; Fig. 3) showed nanomolar level of cytotoxic activity using B16 melanoma cells.[37]

Kumar and Kalivendi et al. prepared a series of podophyllotoxin derivatives by using azide–alkyne click chemistry. Podophyllotoxin derivatives were evaluated for their cytotoxicity against a panel of four human cancer cell lines and their IC_{50} values were found to be in the range of 2.4– 29.06 μM. The cytotoxicity exhibited by the majority of tested compounds was found to be comparable and often more effective than doxorubicin, and compound **3** (Fig. 3) exhibited good cytotoxicity on A-549 cell lines.[38]

Triazole derivatives of epipodophyllotoxin–chalcone were generated toward the development of better anticancer agents. These hybrids consist of structurally different but functionally similar topoisomerase-II inhibitors, which were conjugated together through click chemistry. Evaluation of the anticancer activity of these synthesized conjugates against a panel of six human cancer cell lines proved their potential cytotoxicity. Among evaluated compounds, compound **4** (Fig. 3) was found to be the most potent, especially selective against SW-620 and SKN-SH cell lines.[39]

Bertrand and coworkers recently reported the synthesis of clickable pH-responsive pH-mediated release of histone deacetylase inhibitors. HDACi are an important class of molecules belonging to the epigenetic modulators used for innovative cancer strategies. The behavior of these prodrugs was determined by a bioluminescence resonance energy transfer assay in living tumor cells. Innovative type of clickable prodrug (5; Fig. 3) entered cancer cells and showed restored antiproliferative properties attributed to the effective release of the HDAC inhibitors. A correlation between kinetic studies, dose responses, and biological activities was obtained, making such clickable prodrug good candidates for new strategies in epigenetic-oriented anticancer therapies.[40]

A series of triazole-linked osthol derivatives were synthesized using click chemistry approach. All the derivatives were subjected to 3-(4,5-dimethylthiazol-yl)-diphenyl tetrazolium bromide (MTT) cytotoxicity screening against a panel of seven different human

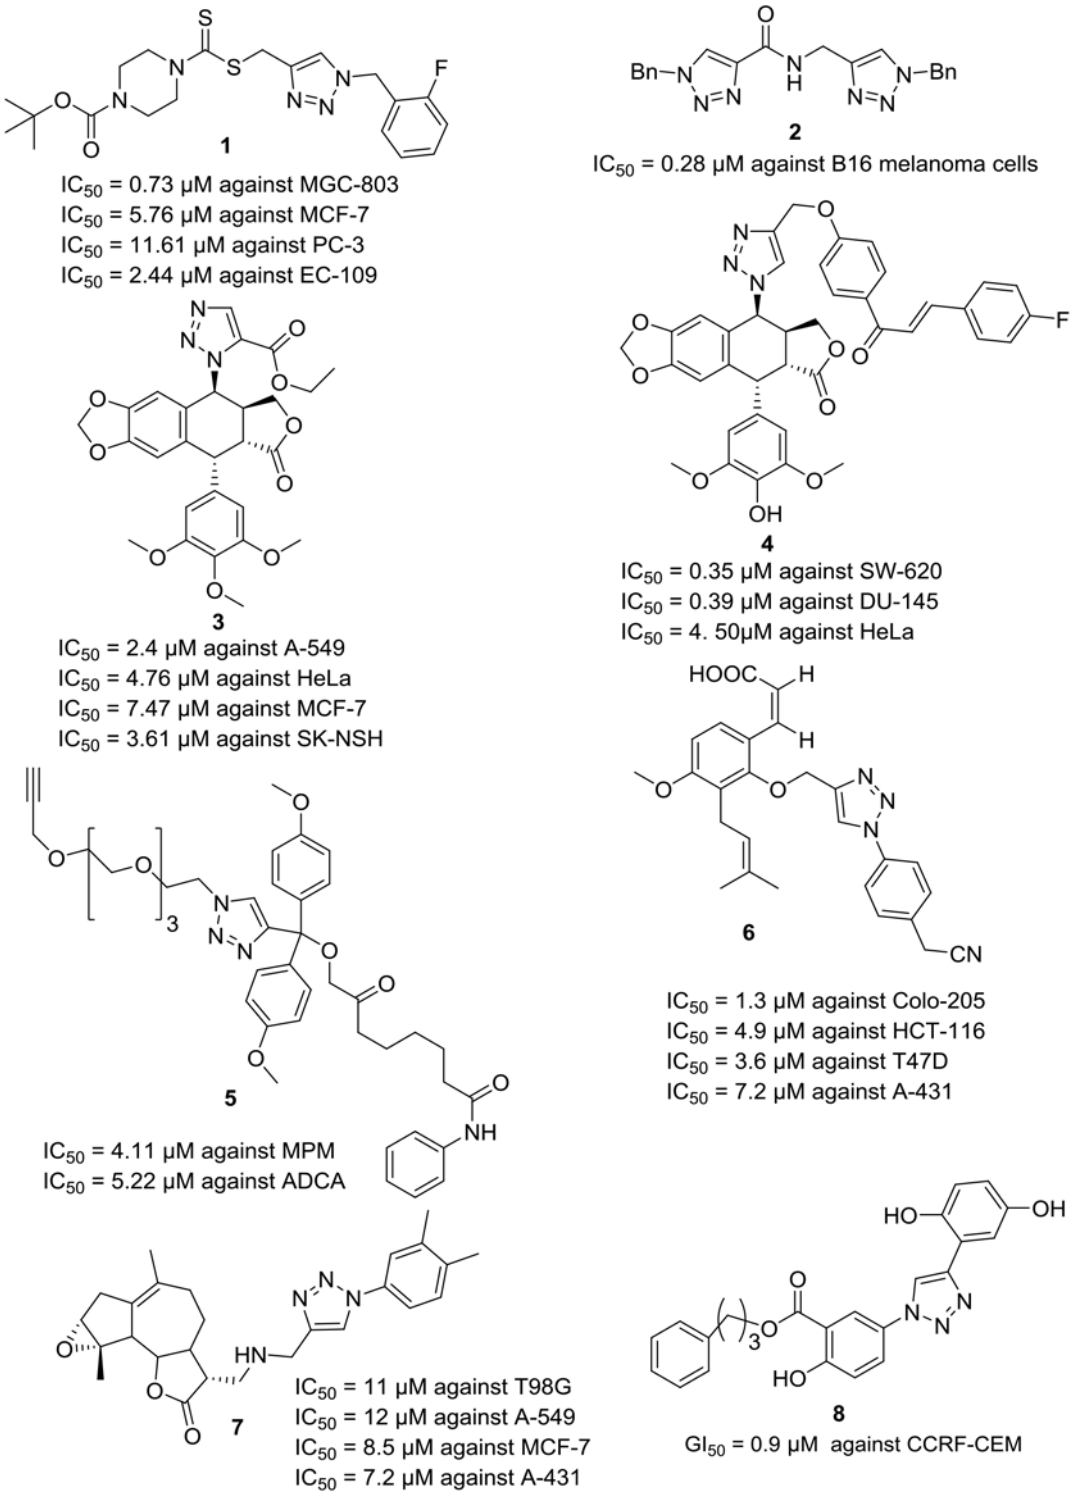

Fig. 3 Potent click functional triazole generated for anticancer activity with low IC_{50}.

cancer cell lines, viz., colon (colo-205 and HCT-116), breast (T47D), lung (NCIH322 and A549), prostate (PC-3), and skin (A-431) to check their cytotoxic potential. Interestingly, among the tested molecules, most of the analogs displayed better cytotoxic activity than the parent osthol. Of the synthesized triazoles, compound 6 (Fig. 3) showed the best activity with IC_{50} of 1.3, 4.9, 3.6, 41.0, 35.2, 26.4, and 7.2 μM against colon (Colo-205 and HCT-116), breast (T47D), lung (NCI-H322 and A549), prostate (PC-3), and skin (A-431) cancer lines, respectively. Compound **6** induced potent apoptotic effects in Colo-205 cells. The population of

apoptotic cells increased from 11.4% in case of negative control to 24.1% at 25 μM of **6**. Compound **6** also induced a remarkable decrease in mitochondrial membrane potential (LJm) leading to apoptosis of cancer cells used.[41]

Bhat and his coworkers synthesized a series of 1,4-disubstituted 1,2,3-triazoles of Ludartin for their behavior against a panel of five human cancerous cell lines. Sulforhodamine B cytotoxicity screening of the resulting products against a panel of five human cancerous cell lines revealed that few of the analogs display promising broad-spectrum cytotoxic effect. Among all synthesized compounds, only **7** (Fig. 3) displayed the best cytotoxic effect with IC_{50} values of 12, 11, 38, 39, and 8.5 μM but less than the standard Ludartin (1) with IC_{50} values of 6.3, 7.4, 7.5, 6.9, and 0.5 μM against human neuroblastoma (T98G), lung (A-549), prostate (PC-3), colon (HCT-116), and breast (MCF-7) cancer cell lines, respectively.[42]

Click-based approach for rapid synthesis of lavendustin triazoles is used by Ryu and his coworkers. Lavendustin substituents were varied to investigate chemical space and the auxophoric $-CH_2-NH-$ was altered to a 1,2,3-triazole for rapid click conjugation. Lavendustin triazoles were evaluated against HCT116 colon cancer and CCRF-CEM leukemia cell lines. Among 28 analogs, compound **8** (Fig. 3) inhibited CCRF-CEM leukemia cell growth with the GI_{50} value of 0.9 μM.[43]

Phenyl-substituted berberine triazolyls was generated using click cycloaddition. The synthesized berberine triazolyl compounds were evaluated for anticancer activity against a panel of three human cancer cell lines, including MCF-7 (breast), SW-1990 (pancreatic), and SMMC-7721 (liver) and the noncancerous human umbilical vein endothelial cell (HUVEC) cell lines. The screening results indicated that most of the compounds displayed notable anticancer activities against the MCF-7 cells compared with berberine. Triazole analog **9** (Fig. 4) showed potent inhibitory activity against the SW-1990 and SMMC-7721 cell lines, with half-maximal inhibitory concentration (IC_{50}) values of 8.54 ± 1.97 μM and 11.87 ± 1.83 μM, respectively. Compound **10** exhibited the most potent inhibitory activity against the MCF-7 cell line, with an IC_{50} value of 12.57 ± 1.96 μM. Compound **9** and compound **10** (Fig. 4) exhibited low cytotoxicity in the HUVEC cell line, with IC_{50} values of 25.49 ± 3.24 μM and 30.47 ± 3.47 μM, respectively.[44]

A series of 2-pyridone triazole derivatives evaluated their antitumor activities in vitro. The bioassays showed that most of the synthesized compounds exerted inhibitory effects on six human cancer cell lines to various extents. Especially, compound **11** (Fig. 4) showed good antitumor activities (IC_{50} values of A549, HeLa, and SW480 cancer cell lines were 0.86, 0.54, and 0.21 μM, respectively).[45]

Ursolic phenyl triazolyl derivatives were synthesized via click chemistry and the synthetic compounds were evaluated for anticancer activity against a panel of four human cancer cell lines including A-549 (lung), MCF-7 (breast), HCT-116 (colon), THP-1 (leukemia), and normal human epithelial cell line (FR-2) using sulforhodamine B assay. The pharmacological results showed that most of the compounds displayed high level of antitumor activities against the tested cancer cell lines compared with ursolic acid. Compound **12** (Fig. 4) was found to be the most potent compound among the synthesized compounds.[46]

A library of podophyllotoxin 4β-[(4-alkyl)-1,2,3-triazol-1-yl] derivatives were synthesized by employing click chemistry approach and evaluated for cytotoxicity against a panel of human cancer cell lines (SF-295, A-549, PC-3, Hep-2, HCT-15, and MCF-7). Majority of the compounds proved more potent than etoposide, and selected compounds **13** and **14** (Fig. 4) exhibited significant anticancer activity with IC_{50} values in the range of 0.001–1 μM. DNA fragmentation and flow-cytometric results reveal that 4β-[(4-alkyl)-1,2,3-triazol-1-yl] podophyllotoxin derivatives induce dose-dependent apoptosis. Docking experiments showed a good correlation between their calculated interaction energies with the topoisomerase II and the observed IC_{50} values of all these compounds.[47]

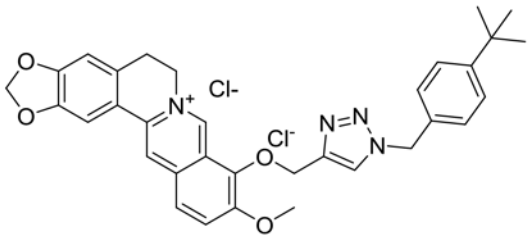
Click chemistry employed for the synthesis of novel heat shock protein 90 (Hsp90)-based anticancer agent, triazole-cyclopropradicicol derivative. Preliminary biological evaluations revealed triazole-cyclopropradicicol 15 (Fig. 4) potent inhibitor of Hsp90, with $IC_{50} = 400$ nM. Triazole-cyclopropradicicol 15 also displayed significant in vitro inhibitory activity against the leukemia cell line Kasumi-1 ($IC_{50} = 650$ nM).[48]

Chang and his coworkers employed click chemistry for the synthesis of a library of carbohydrate–cyclopamine derivatives with various structural motifs for exploring the desired activity. From this initial library, we have observed one derivative that exhibits improved activity against lung cancer cell as compared to cyclopamine. Compound **16** (Fig. 4) expressed potent activity against lung cancer cell lines with IC_{50} value of 33 μM.[49]

A library of 1,2,3-triazole-pyrrolo[2,1-c][1,4]benzodiazepines functional derivatives were synthesized by employing "click" chemistry. These molecules exhibited promising DNA-binding affinity and evaluated for their in vitro anticancer activity in selected human cancer cell lines of breast (Zr-75-1 and MCF7), oral (KB, DWD, and Gurav), ovary (A2780), colon (Colo205), lung (A549), prostate (PC3), and cervix (SiHa) by using the sulforhodamine B (SRB) method. Especially, compound **17** (Fig. 5) showed good inhibition against various cancer cells like oral, ovarian, colon, lung, prostate, and cervical.[50]

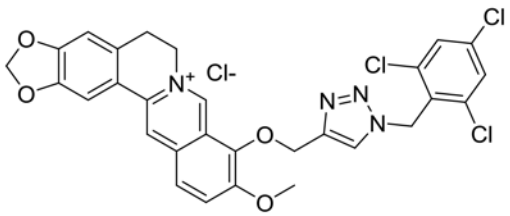
Benzo-macrolactone derivatives were prepared by click chemistry reaction and evaluated as inhibitors of Hsp90, an emerging target for novel cancer therapeutic agents. The synthesis of resorcylic acid macrolactone analogs of the natural product radicicol was described in the literature in which the key steps are the acylation and ring opening of a homophthalic anhydride to give an isocoumarin, followed by a ring-closing metathesis to form the macrolactone. The novel triazole-macrocyclic lactones were evaluated for Hsp90 inhibition in two Hsp90 binding assays: the fluorescence-polarization (FP) assay and the TR-FRET assay. Their growth inhibitory potency in HCT116 human colon cancer cell line, as measured by the SRB assay, was also determined. Compound **18** (Fig. 5) showed good inhibition of Hsp90 in the FP assay in the series.[51]

Click chemistry was employed for the synthesis of a series of triazole-containing novobiocin analogs. The antiproliferative effects of these compounds were evaluated against two breast cancer cell lines (SKBr-3 and MCF-7) and manifested activities similar to their amide-containing counterparts. In addition, Hsp90-dependent client protein degradation was observed via western blot



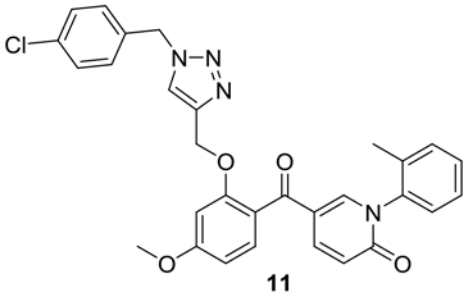
9

IC_{50} = 8.54 μM against SW-190
IC_{50} = 11.87 μM against SMMC-7721
IC_{50} = 25.49 μM against HUVEC



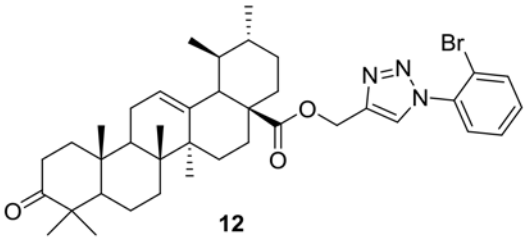
10

IC_{50} = 12.57 μM against MCF-7
IC_{50} = 30.47 μM against HUVEC



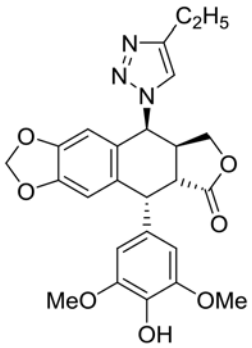
11

IC_{50} = 0.86 μM against A549
IC_{50} = 0.54 μM against HeLa
IC_{50} = 0.21 μM against SW480



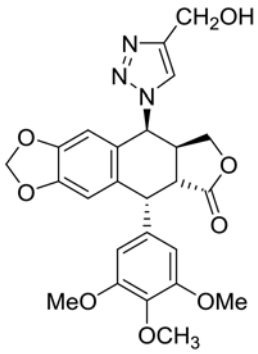
12

IC_{50} = 2.89 μM against A549
IC_{50} = <0.1 μM against MCF-7
IC_{50} = <0.1 μM against HP-1



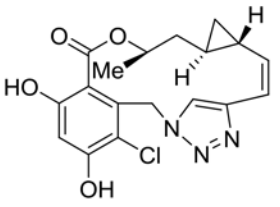
13

IC_{50} = 0.06 μM against PC-3
IC_{50} = 0.05 μM against Hep-2
IC_{50} = 0.04 μM against MCF-7



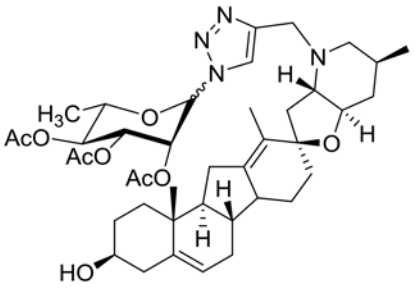
14

IC_{50} = 0.06 μM against PC-3
IC_{50} = 0.06 μM against Hep-2
IC_{50} = 0.01 μM against MCF-7



15

IC_{50} = 400 nM against Hsp90
IC_{50} = 650 nM against Kasumi-1 leukemia



16

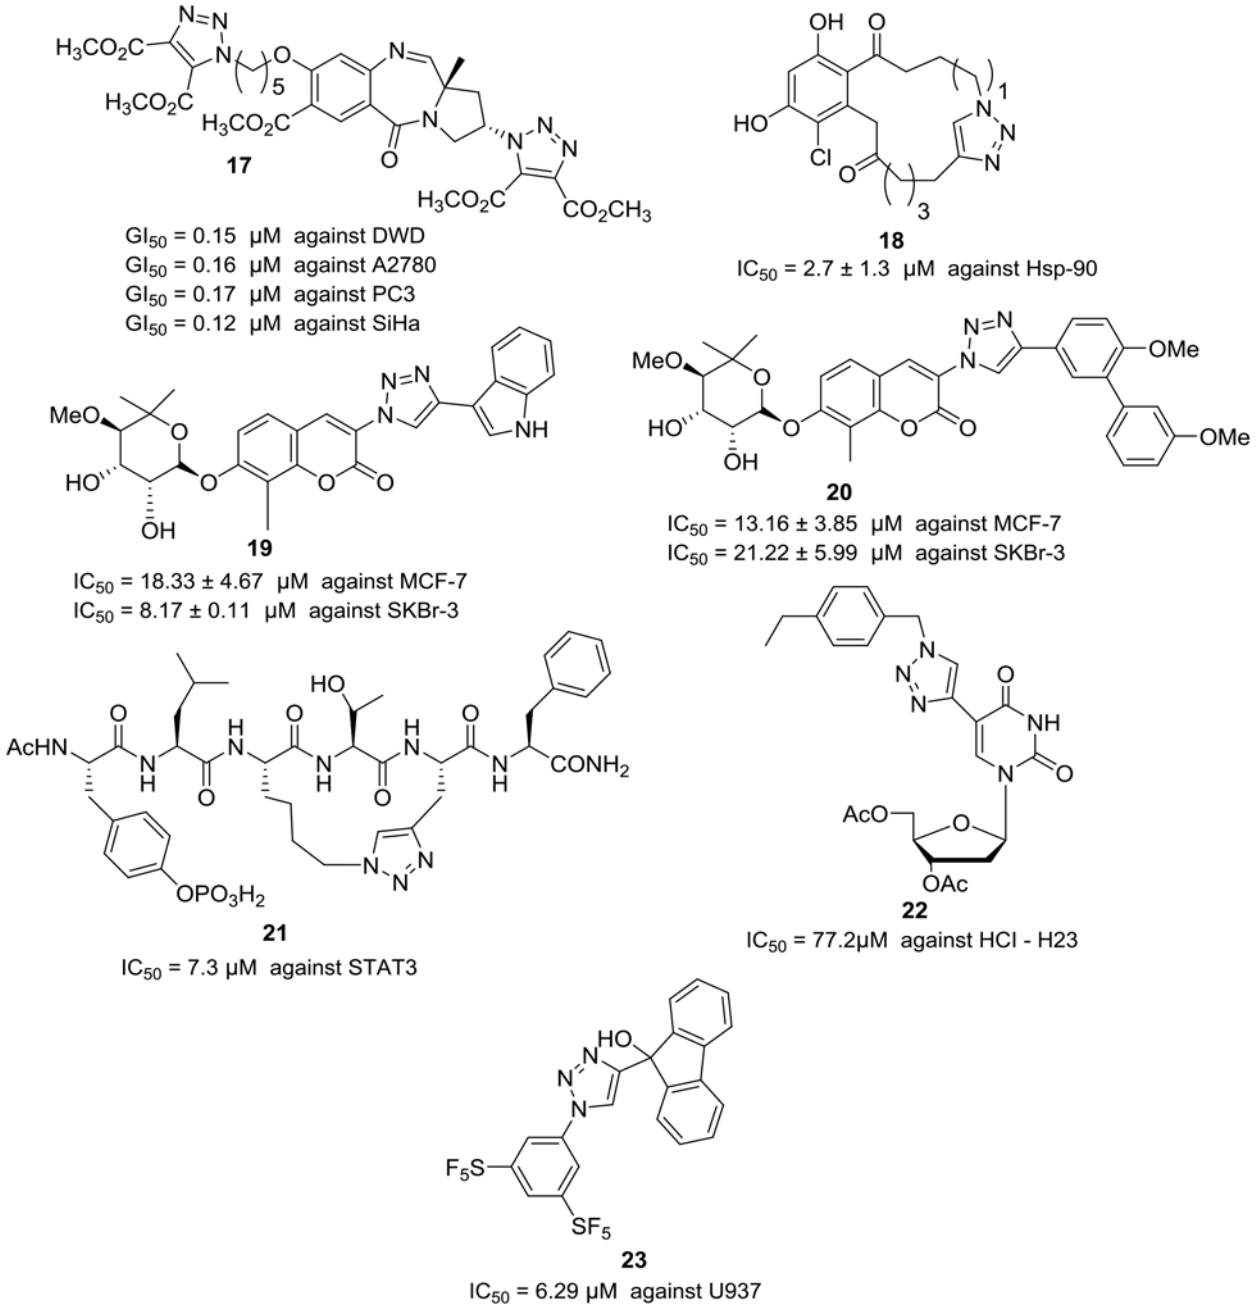

Fig. 5 Potent anticancer lead structures generated via click chemistry reactions.

analyses, supporting a common mode of Hsp90 inhibition for both structural classes. Compounds **19** and **20** showed most potent inhibition against SKBr-3 and MCF-7 among homologous series (Fig. 5).[52]

STAT3 (signal transducers and activators of transcription 3) is a promising molecular target for design of new anticancer drugs. Wang and coworkers reported the synthesis of conformationally constrained macrocyclic peptidomimetic analogs via click chemistry. Compound **21** (Fig. 5) was revealed to bind to STAT3 with a K_i value of 7.3 μM in a competitive fluorescence-polarization-based binding assay, representing a promising initial lead compound.[53]

Kim et al. employed click chemistry for the synthesis of C5-modified nucleosides from 5-iodo-2′-deoxyuridine and their activity against six types of human cancer cell lines (HCT15, MM231, NCI-H23, NUGC-3, PC-3, and ACHN). Researchers synthesized several azides from benzylic bromides and their click reactions with 5-ethynyl-2′-deoxyuridine provided triazole derivatives anticancer development. Compound **22** (Fig. 5) revealed good inhibition against lung cancer lines (NCI-H23) with $IC_{50} = 77.2$ μM.[54]

Pentafluorosulfanyl-containing 1,4-disubstituted 1,2,3-triazoles were synthesized by click reaction in good yields, and their biological activities were evaluated against human leukemic monocyte lymphoma U937 cells. An analogous fluorenol-substituted triazole (**23**; Fig. 5) exhibited promising cytotoxic effects against U937 cells, with an IC_{50} value of 6.29 μM.[55]

1.10.3 Antiproliferative Agents Synthesized Using Click Chemistry

Sekhar and coworkers recently prepared a series of novel 6-(4-((substituted-1*H*-1,2,3-triazol-4-yl)methyl) piperazin-1-yl)phenanthridine derivatives using click chemistry reaction and evaluated them as antiproliferative agents against four cancer cell lines by MTT assay. Among the synthesized triazole derivatives, **24** and **25** (Fig. 6) showed good activity against all the test cell lines. In particular, **24** ($IC_{50}=9.73$ μM) exhibited excellent activity against THP1 cancer cell line, and **25** ($IC_{50}=7.22$ μM) emerged as more active compound than the standard drug etoposide against HL60 cancer cell line.[56]

A series of salinomycin or monensin and cinchona alkaloid derivatives were obtained by click chemistry of respective N-propargyl amides of salinomycin or monensin with four different cinchona alkaloid-derived azides. In vitro antiproliferative activity of these conjugates evaluated against three cancer cell lines (LoVo, LoVo/DX, and HepG2) showed that four of the compounds exhibited high antiproliferative activity (IC_{50} below 3.00 μM, compound **26**; Fig. 6) and appeared to be less toxic and more selective against normal cells than two standard anticancer drugs.[57]

Pertino and his coworkers prepared dehydroabietic acid (DHA) triazole derivatives using click chemistry. The antiproliferative activity of the new DHA triazole derivatives was assessed toward human cell lines, namely, normal lung fibroblast (MRC-5), gastric epithelial adenocarcinoma (AGS), lung cancer (SK-MES-1), and bladder carcinoma (J82) cells. Better antiproliferative effect was found for compound **27** (Fig. 6), with an IC_{50} of 6.1 μM and selectivity on SK-MES-1 cells.[58]

A series of 1,2,3-triazoleedithiocarbamate urea triazoles were synthesized and their antiproliferative activities against four selected human cancer cell lines were evaluated. The results showed that the synthesized triazole derivatives exhibited potent activity in selected human cancer cell lines. Among them, compounds **28** and **29** showed broad spectrum of anticancer activity with IC_{50} values ranging from 1.62 to 20.84 μM and 0.76 to 13.55 μM, respectively. Interestingly, compounds **28** and **29** (Fig. 6), being very potent against MGC-803 cells, exhibited no significant cytotoxicity against normal human embryonic kidney cells at up to 55 and 70 mM, respectively.[59]

Nagarapu and his coworkers recently reported a series of novel 1,2,3-triazole-1,4-benzoxazine hybrids synthesized via click chemistry approach and evaluated for antiproliferative activity against four cancer cell lines such as HeLa (cervical), MIAPACA (pancreatic), MDA-MB-231 (breast), and IMR32 (neuroblastoma). Compound **30** (Fig. 6) exhibited antiproliferative activity with GI_{50} values ranging from 0.1 to 1.1 μM, respectively, against all cell lines, like HeLa, MDA-MB-231, MIAPACA, and IMR32, whereas compound **31** (Fig. 6) showed significant activity against MDA-MB-231 and IMR32 with GI_{50} values ranging from 1.1 and 1.4 μM.[60]

8-Hydroxyquinoline derivatives were synthesized with good yields by performing copper-catalyzed Huisgen 1,3-dipolar cycloaddition between an 8-O-alkylated-quinoline containing a terminal alkyne and various aromatic azides. These compounds were evaluated in vitro for their antiproliferative activity on various cancer cell types. Among the halogenated derivatives, the chlorinated ones showed the best overall activity, with **32** (Fig. 6) showing the lowest MG MID GI_{50} value of 0.7. Protected sugar triazole derivative **33** (Fig. 7) was the most active against and highly selective for ovarian cancer cells (OVCAR-03, $GI_{50}<0.25$ μg mL^{-1}), showing greater activity against these cells than doxorubicin.[61]

Bis-prolinamide pyridine derivatives were generated via click chemistry by Dash and coworkers. Pyridine analog (compound **34**; Fig. 7) showed better *c*-KIT1 G-quadruplex binding ligand than the benzene-substituted bis-prolinamide derivatives, suggesting that H-bonding plays a key role in controlling the conformation of the pyridyl ligand for the selective recognition. The FID assay revealed that the pyridyl ligand (compound **34**; Fig. 7) binds with high affinity to *c*-KIT1 and displays moderate to high *c*-KIT1 specificity over c-MYC, h-TELO, and c-KIT2 quadruplexes. In addition, the pyridyl ligand effectively inhibited the cell growth and induced cell death of HepG2 cancer cells.[62]

Functionalized flavone–triazole–tetrahydropyran conjugates were generated via click reactions by Ahmed and coworkers, and these flavone–triazoles were screened in vitro for their antiproliferative activity against three human cancer cell lines (MDA-MB 231, KCL22, and HeLa). Compounds **35** (IC_{50} 0.61 μM; Fig. 7) and **36** (IC_{50} 0.70 μM; Fig. 7) exhibited antiproliferative activity better than the reference drugs against the KCL22 cells and MDA-MB 231 cells, respectively.[63]

A series of estrone derivatives substituted 16α-triazolyl on ring D were synthesized by click chemistry and investigated for their antiproliferative action on human adherent cell lines. Estrone derivatives (compound **37**, Fig. 7) exhibited in vitro potencies comparable to that of the clinically utilized reference agent cisplatin.[64]

Steroidal 15β,17β-triazole alcohol derivatives were generated via click chemistry and these synthetic steroidal triazoles tested for antiproliferative activity. Structures **38** and **39** showed good antiproliferative activity with MCF-7, HeLa, and A431 cell lines among tested series of steroidal triazoles.[65]

Hu and his coworkers reported the synthesis of indole N-hydroxyarylamide alkyl substituted triazole, and their in vitro biological activities were examined. Most of triazole derivatives showed promising anticancer activities; particularly compound **40** shown in Fig. 7 had a significant HDACs inhibitory and antiproliferative activities comparable to or slightly stronger than SAHA against human carcinoma cells. Furthermore, compound **40** exhibited much better selectivity for HDAC1 over HDAC6 and HDAC8 than SAHA. In addition, compound **40** also could dose-dependently induce cancer cell cycling arrest at G0/G1 phase and promote the expression of the acetylation for histone H3 and tubulin in vitro.[66]

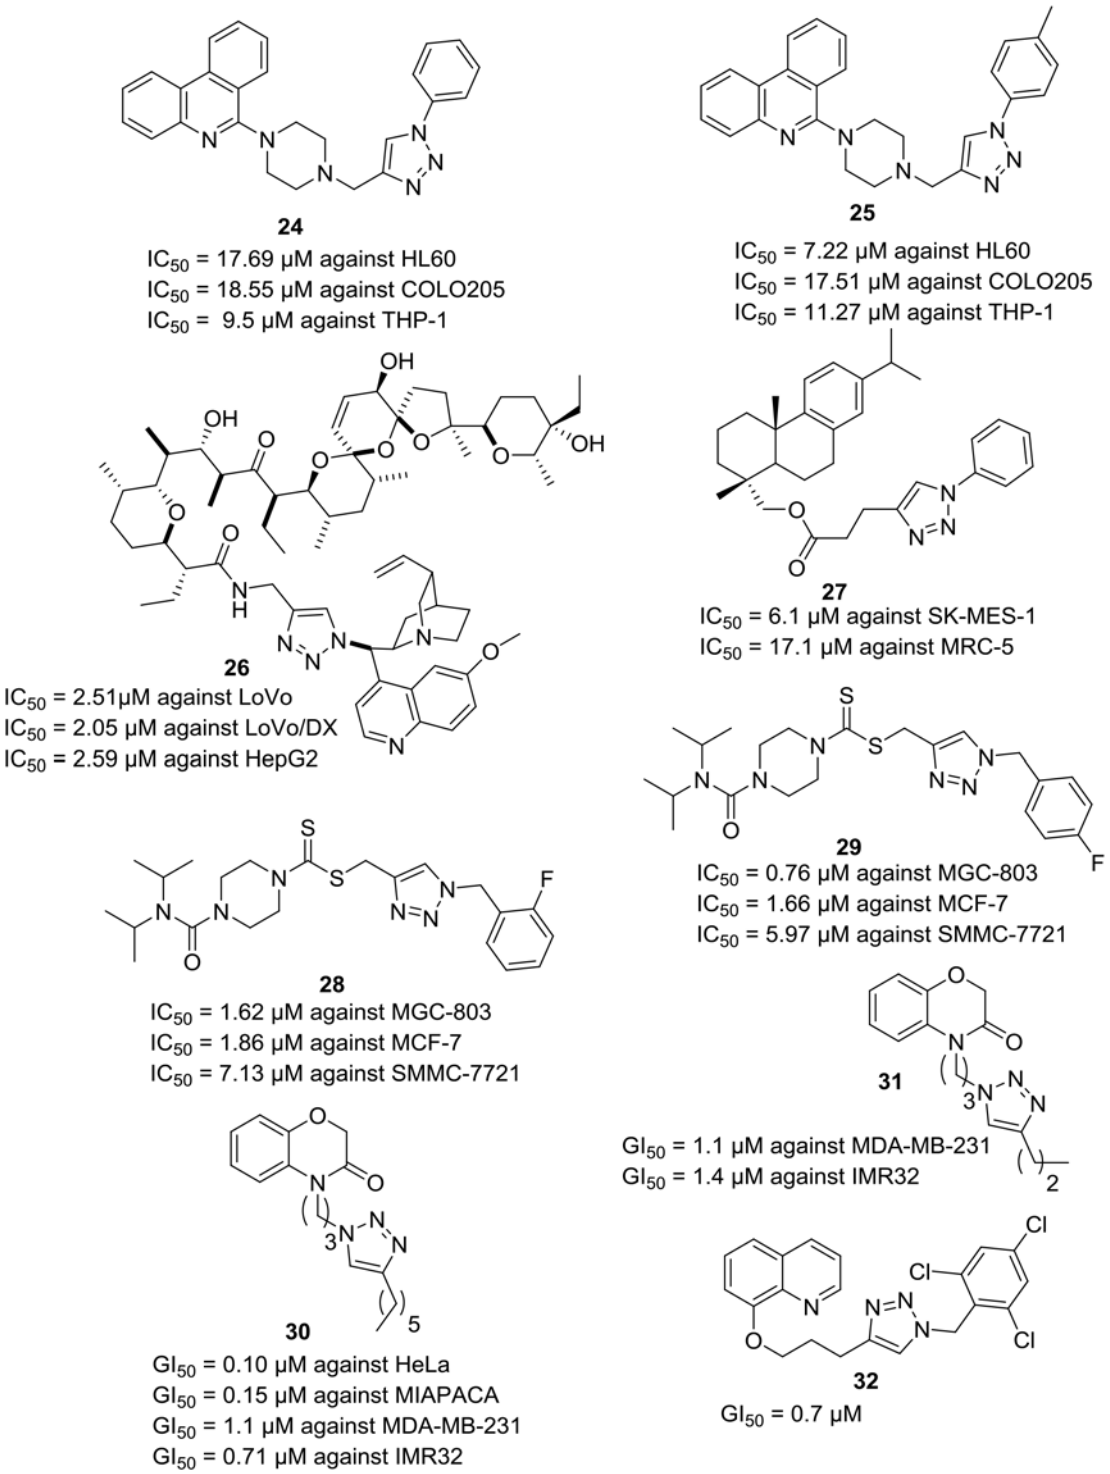

Fig. 6 Click triazole lead structures generated for antiproliferative agents (IC_{50} is the drug concentration causing 50% inhibition of the desired activity and GI_{50} is the concentration for 50% of maximal inhibition of cell proliferation and should be used for cytostatic (as opposed to cytotoxic) agents).

1.10.4 Antiviral and Other Lead Small Molecules Synthesized From Click Chemistry

A library of 2′-deoxy-2′-fluoro-4′-triazole cytidine nucleosides were synthesized via click chemistry by Song and coworkers. These nucleoside analogs exhibited potent anti-HIV-1 activity with no cytotoxicity observed at the highest tested concentration up to 25 μM. Among them, compounds **41** and **42** (Fig. 8) exhibited extremely potent antiviral activity and thus had a great potential for further development as novel nucleoside reverse transcriptase inhibitors (NRTIs) for the treatment of HIV-1 infection.[67]

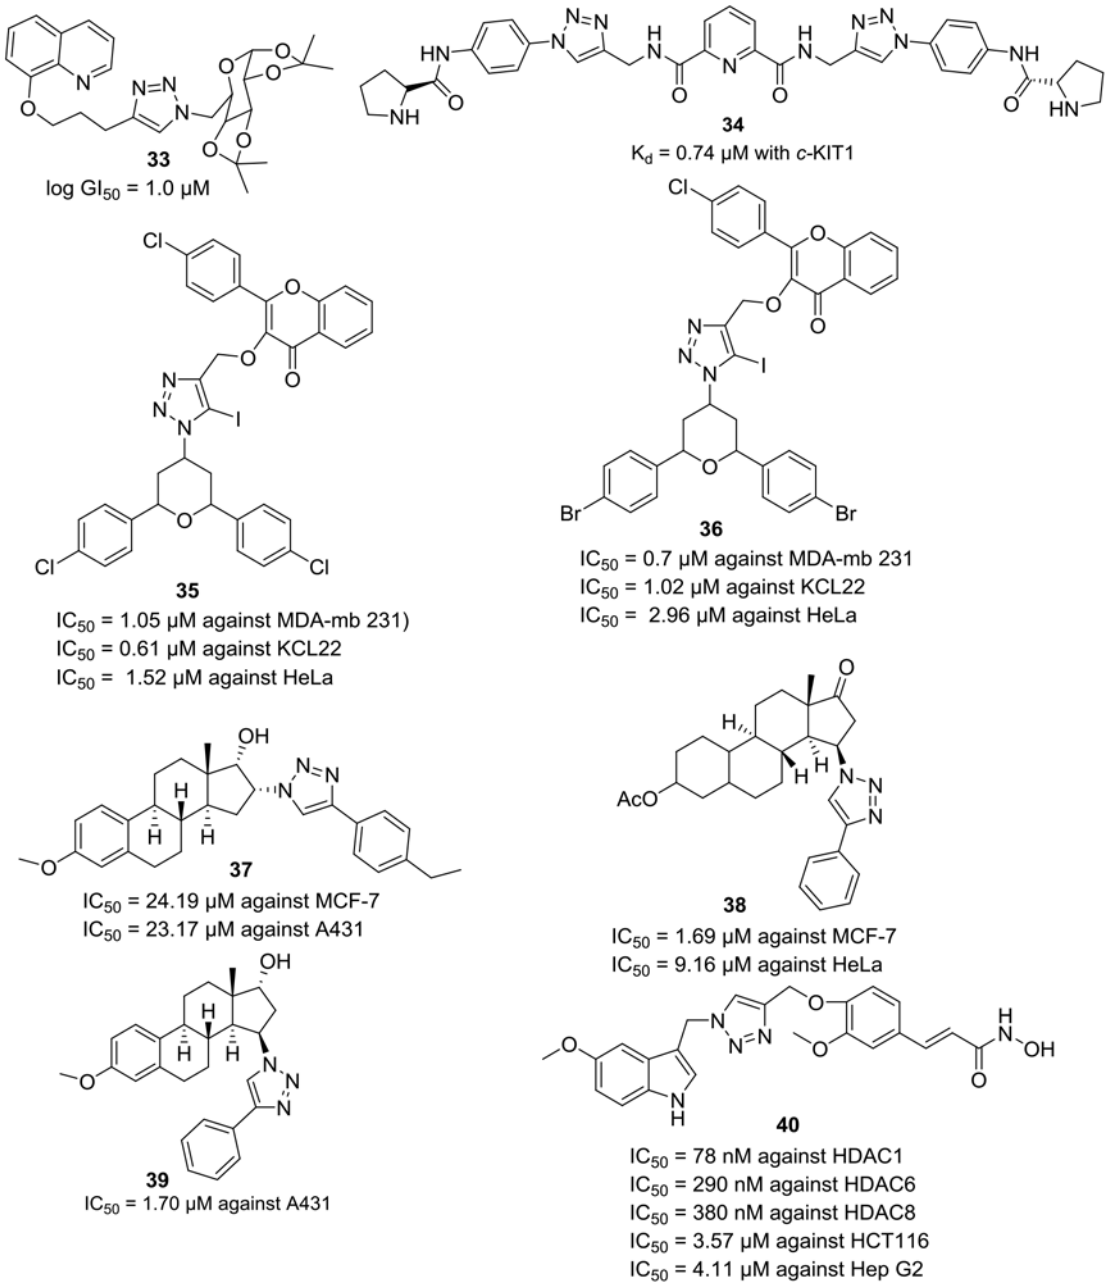

Fig. 7 Lead chemical structures with antiproliferative agents generated via click chemistry reaction.

A library of rupestonic acid triazole derivatives were generated using click chemistry, and these compounds were subjected for in vitro activities against various strains of influenza A virus (H1N1, oseltamivir-resistant H1N1, and H3N2) and influenza B virus. The results showed that most of structures were active against the H1N1 strain of influenza A virus. The screening results showed that **43** and **44** (Fig. 8) were better than ribavirin in inhibiting plaque formation, in good accordance with their anti-influenza B activities.[61]

A series of naphthalene-1,4-dione substituted triazoles were generated via click reaction and screened against broad spectrum of viruses. The screening results of identified compound **45** showed good inhibition against five viruses such as West Nile virus (WNV), dengue virus type 2 (DENV-2), Western equine encephalitis virus (WEEV), vesicular stomatitis virus (VSV), and yellow fever virus (YFV).[68]

Sugar derivatives of ristocetin from azido-ristocetin aglycon and various propargyl glycosides were prepared for employing click chemistry. Triazole sugar derivatives were found active against gram-positive bacteria and showed favorable antiviral activity against the H1N1 subtype of influenza A virus. Compound **46** (Fig. 8) showed good inhibition activity against H1N1 subtype of influenza A virus with EC_{50} value of 4.0 μM.[69]

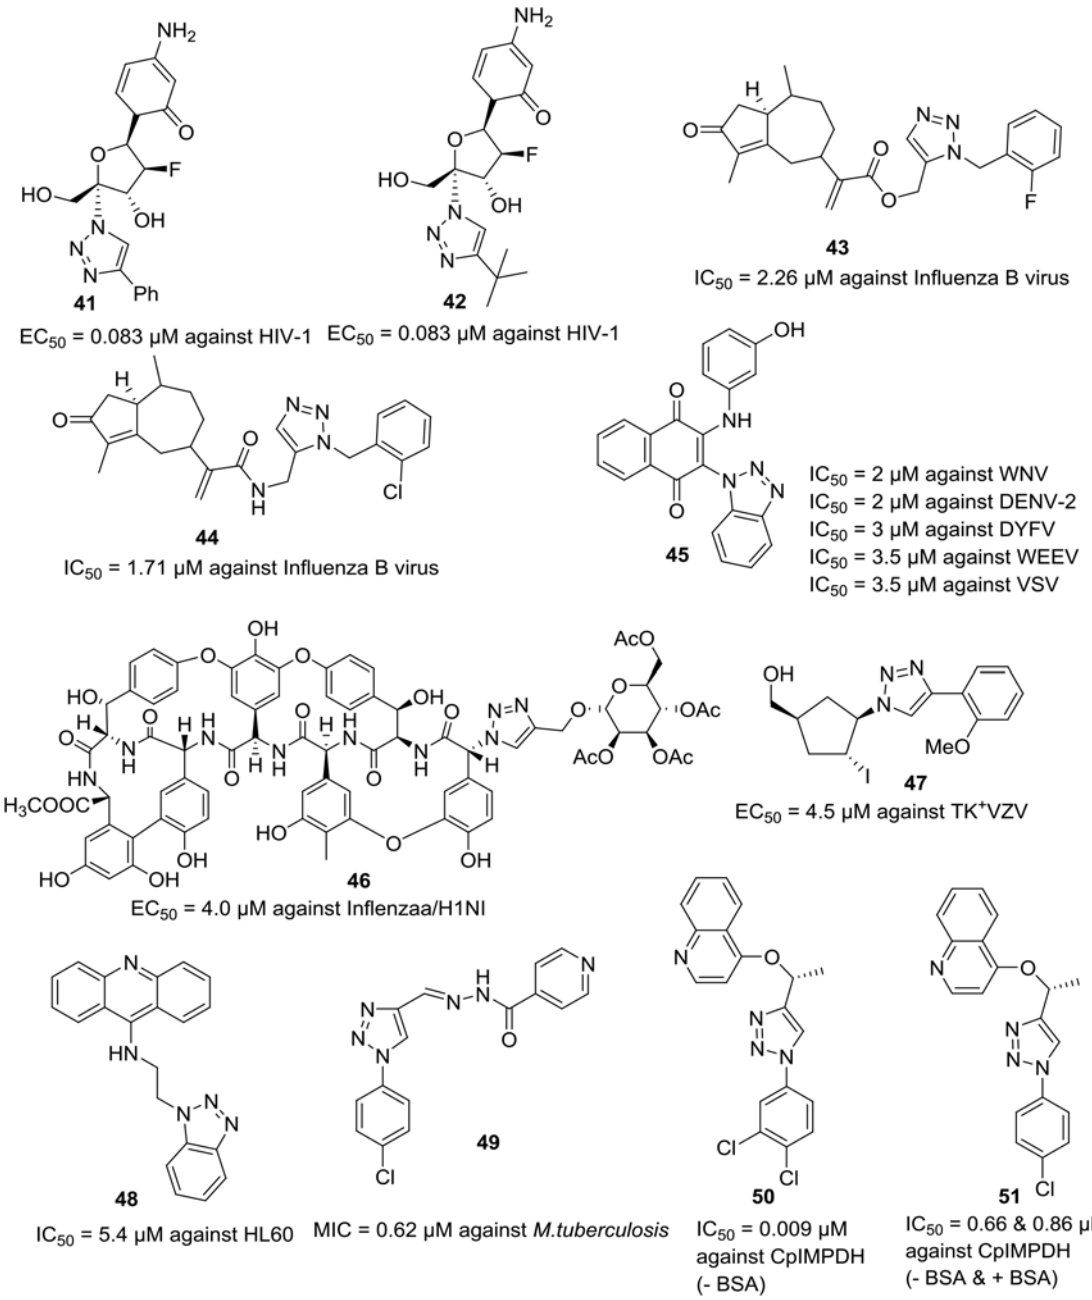

Fig. 8 Chemical lead structures of antiviral, antibacterial, and some other drugs synthesized via click chemistry.

A series of racemic 4-aryl-1,2,3-triazolo-2′,3′-dideoxy-2′-iodocarbanucleosides and 4-aryl-1,2,3-triazolo-2′,3′-dideoxy-2′,3′-didehydrocarbanucleosides were prepared using click chemistry reaction by Caamaño et al. These compounds were evaluated for their inhibitory activities against cytomegalovirus (CMV Davis strain) and varicella-zoster virus (TK^+VZV, thymidine kinase-positive strain, and TK^-VZV, thymidine kinase-deficient strain) in human embryonic lung (HEL) cells. Compound **47** (Fig. 8) exhibited specific inhibitory potential against TK^+VZV ($EC_{50} = 4.5\ \mu g\ mL^{-1}$).[70]

DNA intercalators have found great utility as antitumor agents, from natural products such as doxorubicin and actinomycin D to synthetic agents such as mitoxantrone and amsacrine. Amsacrine is an acridine that binds to DNA and inhibits the enzyme topoisomerase. A small set of 9-aminoacridine-3- and 4-carboxamides were synthesized efficiently using the benzyne/azide click chemistry. The synthesis of threading intercalators was bound to DNA with reasonable affinity and had up to low micromolar antitumor activity. Compound **48** (Fig. 8) revealed good antitumor activity with HL60 cell line.[71]

4-Substituted N-phenyl-1,2,3-triazole derivatives were prepared using click chemistry reported by Boechat and coworkers. The phenyl triazole derivatives were screened in vitro for antimicrobial activity against *Mycobacterium tuberculosis* strain H37Rv

(ATCC 27294) using the Alamar Blue susceptibility test. The activity was expressed as the minimum inhibitory concentration (MIC) in $\mu g\,mL^{-1}$ (μM). Derivatives of isoniazid (INH), (*E*)-N′-[(1-aryl)-1*H*-1,2,3-triazole-4-yl)methylene] isonicotinoyl hydrazides (**49**; Fig. 8), exhibited significant activity with MIC values ranging from 2.5 to 0.62 $\mu g\,mL^{-1}$. In addition, they displayed low cytotoxicity against liver cells (hepatoma HepG2) and kidney cells (BGM), thereby providing a high therapeutic index.[72]

A library of 1,2,3-triazole-containing ether cryptosporidium parvum inosine 5′-monophosphate dehydrogenase (CpIMPDH) inhibitors were prepared using click chemistry by Cuny et al. Compounds **50** and **51** (Fig. 8) showed most potent CpIMPDH inhibitors among the tested compounds. These 1,2,3-triazole CpIMPDH inhibitors are used as potential therapeutics for treating cryptosporidiosis.[73]

A series of 1,2,3-triazolylsterols were prepared from pregnenolone through reductive amination and azide–alkyne click chemistry by Labadie et al. Triazolyl sterols were screened in vitro against different parasites and compound **52** (Fig. 9) showed low micromolar IC_{50} value against *Leishmania donovani*.[74]

Synthetic mimics of triazole peptide linkers were prepared using click chemistry. An enhancement antimicrobial activity against *Staphylococcus aureus* and *Escherichia coli* was observed when these triazole peptide linkers were administered in the presence of mouse serum. Compound **53** (Fig. 9) had minimum inhibitory concentrations (MICs) of 0.39 and 6.25 $\mu g\,mL^{-1}$, respectively, and an HC50 of 693 $\mu g\,mL^{-1}$.[75]

A series of benzene-substituted triazole amides were prepared via click chemistry and these compounds were tested for their antiepileptic activity. Epilepsy is a neurological disorder characterized by unprovoked seizures affecting at least 50 million people worldwide. There is a continuing demand for new anticonvulsant agents as it has not been possible to control every kind of seizure with the currently available antiepileptic drugs. Compound **54** (Fig. 9) exhibiting antiepileptic activity was generated via click chemistry.[76]

Click chemistry employed for interconnecting lead functional analogs of antibiotics in order to improve the pharmacokinetic properties. Compound **55** showed good antibacterial activity with improved efficiency.[77] Among the best-known examples of triazole-containing structures is tazobactam, a β-lactamase inhibitor that is marketed in combination with the broad-spectrum antibiotic piperacillin. Tazobactam (**56**) and related triazole-containing compounds (**57**, **58**, and **59**; Fig. 9) turned out to be potent β-lactamase inhibitors with higher potency than clavulanic acid and sulbactam, and the triazole ring appears to play a pivotal role for its potency.[77]

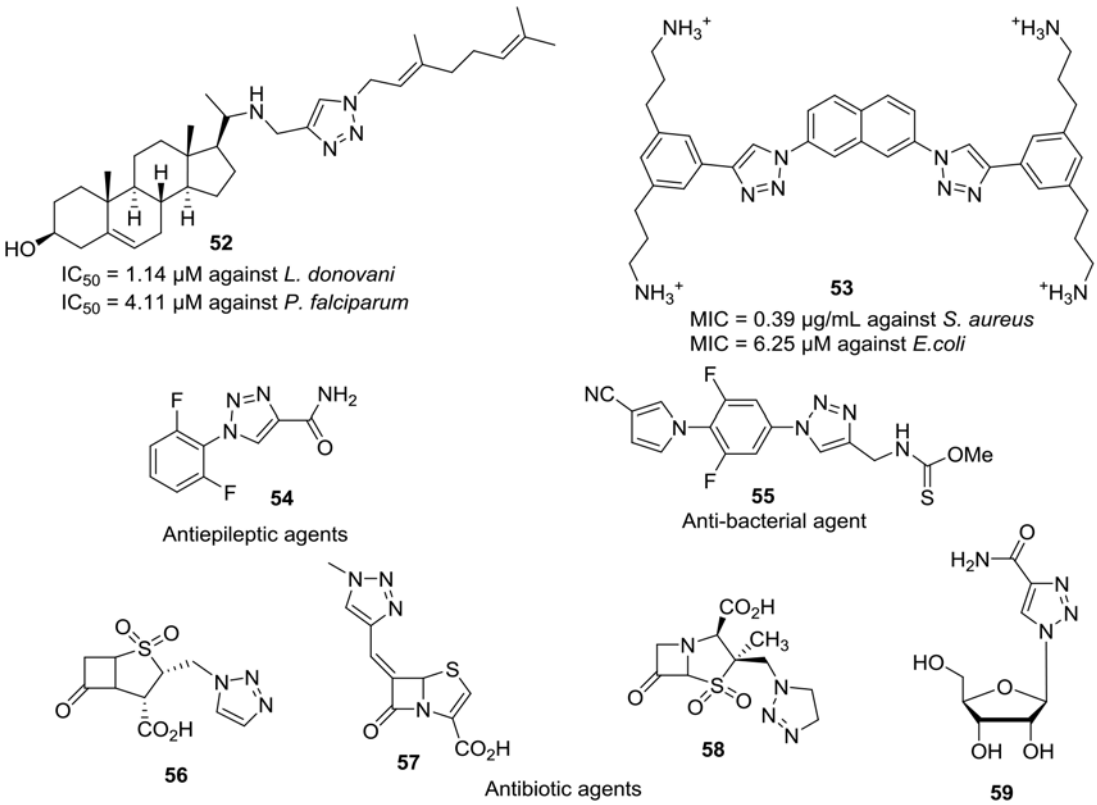

Fig. 9 Chemical lead analogs of antimicrobial, antibiotic, and some other drugs constructed via click chemistry.

1.10.5 Click Chemistry in Receptor–Ligand-Binding Studies

Receptor–ligand interactions play an important role in biological systems and their studies form an important part of contemporary drug development. Cells are activated by the binding of specific ligand molecules to cell-surface receptors. The interaction between the ligand and the receptor is characterized by association and dissociation rate constants and by processing of the ligand–receptor complex what may involve internalization, recycling, and ligand degradation steps. All of these processes may contribute to the means by which the ligand–receptor interaction ultimately generates the signals necessary for cellular responses.[78]

Receptors that couple to G-proteins communicate signals from a large number of hormones, neurotransmitters, chemokines, and autocrine and paracrine factors. G-proteins play a significant role in signaling pathways.[79] It regulates important cellular components, such as metabolic enzymes, ion channels, and the transcriptional machinery. The resulting alterations in cellular behavior and function are manifested in many critical systemic functions, including embryonic development, learning and memory, and organismal homeostasis. These results are in the propagation of regulated activities through increasingly complex layers of organization to serve as the basis of integration at the systemic level. Among the many receptors, GPCRs in humans are all potentially very important drug targets.[80,81]

Several research groups employed click chemistry reaction for the development of selective agonist and antagonist and efficient binding ligand synthesis for various GPCR receptors–ligand binding. These developments of the new agonist and antagonist and efficient binding ligands are very useful in the new drug discovery for the uncured diseases. Here, we are outlining some of the effective synthetic triazole generated via click chemistry used triazole for selective agonist and antagonist and efficient binding ligand development.[20]

1.10.5.1 Agonist

A series of N-arylpiperazinylmethyl triazoles were synthesized, and they were evaluated for dopamine and serotonin receptor binding. A brief library of triazoles substituted fluoroalkyl, fluoroalkoxy, fluoroalkoxyphenyl, and deoxyfluoroglucosyl derivatives was tested for D4 receptor affinity and selectivity. The D4 receptor affinity and selectivity tuned by altering the chemical moiety attached to the triazole unit. Among the screened triazole derivatives, fluoroethoxyphenyl triazole derivative **60** (Fig. 10) showed weak partial agonism at D4 with an binding affinity (K_i) of 14 nM.[82]

Gmeiner et al. reported aminomethyl-substituted biaryls bearing a triazole moiety synthesized and investigated for dopamine and serotonin receptor binding. SAR experiments on dopaminergic arylazole derivatives lead to highly active D4 partial agonist showing substantial 5-HT_{1A} binding as well. N-arylpiperazine triazole derivative **61** (Fig. 10) showed good high affinity for the D_4R ($K_i = 2.7$ nM) besides being moderately selective over the D_2 and D_3 receptor subtypes.[83]

Click chemistry was employed for the peptide–peptide conjugate ligand synthesis for full activator of corticotropin-releasing factor type 1 receptor (CRF1R) using a high-throughput approach. An acetylene-tagged peptide library was synthesized and conjugated to an azide-modified high-affinity carrier peptide derived from the CRF C-terminus using copper-catalyzed dipolar cycloaddition. The resulting conjugates reconstituted potent agonists and were tested in situ for the activation of the CRF1 receptor in a cell-based assay. Compound **62** (Fig. 10) showed good activation and binding affinity toward CRF1 receptor. Unnatural amino acid peptide–peptide analogs also were synthesized using click chemistry, and these conjugates showed good binding affinity and activation with CRF1 receptor with IC_{50} values of 1.6 ± 1.0 nM. By the use of this approach, researchers (i) defined the minimal sequence motif that is required for full receptor activation, (ii) identified the critical functional groups and structure–activity relationships, (iii) developed an optimized, highly modified peptide probe with high potency ($EC_{50} = 4$ nM) that is specific for the activation domain of the receptor, and (iv) probed the behavioral role of CRF receptors in living mice.[84]

A series of 1,4-disubstituted 1,2,3-triazoles were generated and tested for their ability to increase oleic acid oxidation in human myotubes using a high-throughput multiwell assay. Compounds **63** (Fig. 10) exhibited potent agonist activities with peroxisome proliferator-activated receptors (PPAR). Compound **63** exhibited dual agonist effects for both PPARα and PPARδ in a luciferase-based assay.[85]

1-Aryl-3-benzazepine arylpiperazinyl functional analogs were synthesized by combining a D1 receptor agonistic pharmacophore and a $5HT_{1A}$ receptor pharmacophore through click reaction. Compound **64** (Fig. 10) showed the highest affinity at the $5HT_{1A}$ receptor with K_i value of 85 nM. Functional assays indicated that compound **64** showed full agonistic activity with 5-HT_{1A} receptor.[86]

The cytokine macrophage migration inhibitory factor (MIF) is involved in inflammation and cell proliferation via pathways initiated by its binding to the transmembrane receptor cluster of differentiation 74 (CD74). MIF also promotes 5′ AMP-activated protein kinase (AMPK) activation with potential benefits for response to myocardial infarction and ischemia–reperfusion. Jorgensen et al. reported the synthesis of agonists for MIF–CD74 receptors using click chemistry. The three compounds (**65a**, **65b**, **and 65c**; Fig. 10) showed full agonist effect with MIF–CD74 receptor.[87]

Adenosine receptors (ARs) regulate the release of neurotransmitters in the central nervous system. ARs are G protein-coupled receptors (GPCRs) and found in myocytes, astrocytes, neurons, neutrophils, eosinophils, and other cell types. Both A_3AR agonists and antagonists are proposed for the treatment of cancer and inflammatory diseases. Click chemistry was employed for the synthesis of 2-dialkynyl derivatives of (N)-methanocarba-triazole nucleosides for A_3 adenosine receptor-selective agonist development. Most potent and selective novel compound was a 1-adamantyl derivative **66** ($K_i = 6.5$ nM; Fig. 10), which suggested the existence of

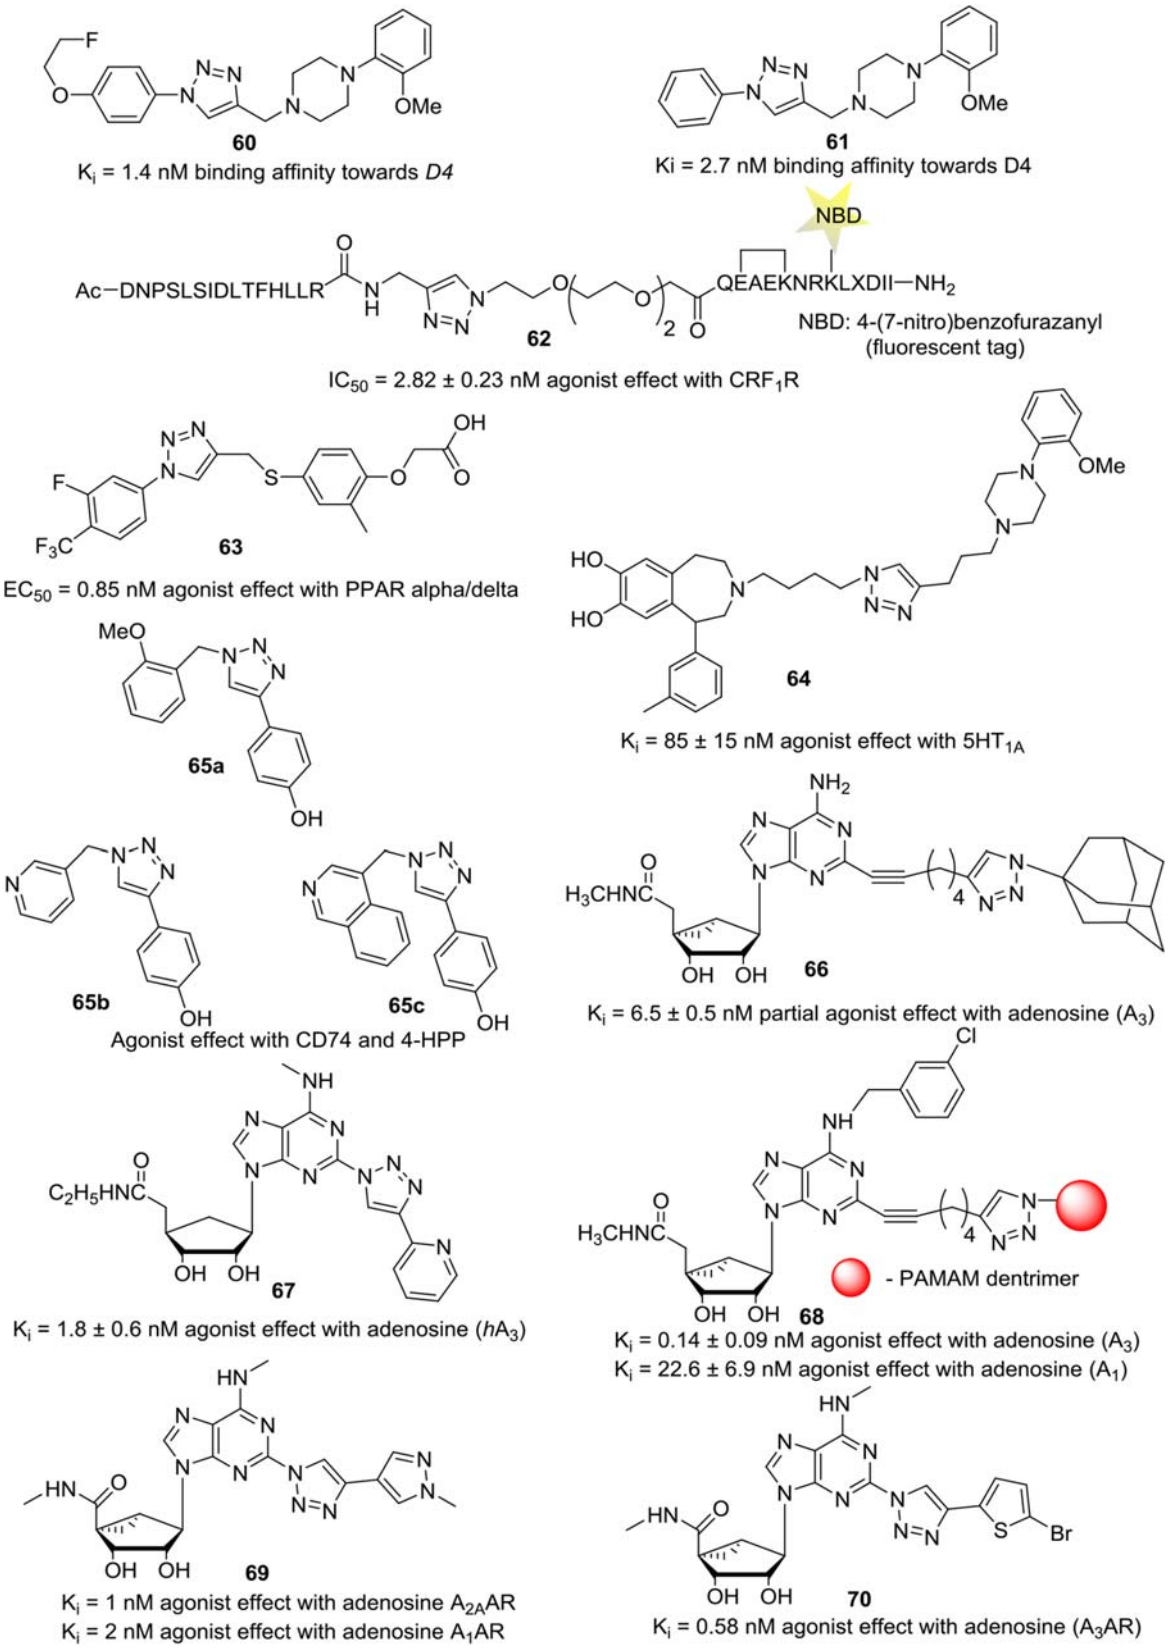

Fig. 10 Chemical lead functional analogs with agonistic effect on various receptors generated by click chemistry.

a hydrophobic binding pocket in this region of the receptor. Curiously, compound **66** proved to be a partial agonist of the A_3AR with only 27.8% of the maximal efficacy in comparison with 5′-N-ethylcarboxamidoadenosine.[88]

Two series of 2-(1,2,3-triazolyl)adenosine derivatives were prepared via click chemistry, and the binding affinity at the human A_1, A_2, and A_3ARs (adenosine receptors) and relative efficacy at the A_3AR of these compounds were determined. Some triazol-1-yl analogs showed A_3AR affinity in the low nanomolar range, with a high ratio of A_3/A_2A selectivity and a moderate-to-high A_3/A_1 ratio. The 5′-OH ethyluronamide analogs showed increased A_3AR affinity and behaved as full agonists, that is, compound **67** (Fig. 10), with 910-fold A_3/A_1 selectivity.[89]

Polyamidoamine (PAMAM) dendrimer triazole conjugate series was prepared using click chemistry reaction from alkyne of a 2-octadiynyl nucleoside and azide-derivatized G4 (fourth-generation) PAMAM dendrimers. A_3AR activation was preserved in these multivalent conjugates, which bound with apparent K_i of 0.1–0.3 nM. A bifunctional conjugate **68** (Fig. 10) activated both A_3 and A_1 with selectivity in comparison with other AR receptors.[90]

Aryltriazole derivatives of (N)-methanocarba adenosine 5′-uronamides were prepared toward adenosine receptor binding reported by Jacobson et al.[86] Derivatives of selective A_3AR agonists containing a triazole linker in place of an ethynyl group, a preferred substitution as predicted using molecular modeling, were prepared and shown to parallel the ethynyl series in receptor affinity and selectivity, due to its ability to fit a narrow cleft in the receptor. The triazole analogs with various N6 and C2-aryltriazolyl substitutions were synthesized and characterized in binding (K_i at hA3AR 0.3–12 nM) and in vivo to demonstrate efficacy in controlling chronic neuropathic pain. Especially, compound **69** showed agonistic effect with A_2AR and A_1AR receptors, whereas compound **70** (Fig. 10) showed selective agonism to the A_3AR receptor.[91]

1.10.5.2 Antagonist

A series of N-arylpiperazinylmethyl triazolyl derivatives synthesized and these compounds were tested for their preferential affinity for the D4 receptor. Fluoropropoxyphenyl homologue **71** turned out to act as a neutral D4 antagonist ($K_i = 5.1$ nM). Compound **71** (Fig. 11) revealed an excellent balance between D4 receptor affinity and subtype selectivity, providing lead candidates for the development of ^{18}F-labeled radioligands for D4 receptor imaging studies by positron emission tomography (PET).[82]

The $P2Y_{14}$ receptor (purinergic receptor P2Y, G-protein-coupled, 14 ($P2Y_{14}R$)), one of eight P2Y G protein-coupled receptors (GPCR), is involved in inflammatory, endocrine, and hypoxic processes and is an attractive pharmaceutical target. The newly synthesized compound series was consistent with the structural insights gained from $P2Y_{12}R$-based homology modeling and docking at this closely related receptor. The resulting $P2Y_{14}R$ model with its ECLs (extracellular loops) defined conformationally allows prediction of specific interactions with antagonist analogs. Chain-elongated alkynyl or amino derivatives for click coupling were synthesized, and their antagonist activities were measured in *h*$P2Y_{14}R$-expressing CHO cells. Moreover, a new Alexa Fluor 488 (AF488)-containing derivative **72** (MRS4174, $K_i = 80$ pM; Fig. 11) exhibited high affinity, as compared to 13 nM for the alkyne precursor.[92]

Click chemistry has been employed for the synthesis of cyclopeptidic second mitochondria-derived activator of caspase (Smac) mimetics by Wang et al.[88] Two compounds bind to X-linked inhibitor of apoptosis protein (XIAP) and cIAP-1/cIAP-2 with low nanomolar affinities and restore the activities of caspase-9 and caspase-3/caspase-7 inhibited by inhibitors of apoptosis proteins (XIAP). Especially, compound **73** (Fig. 11) potently inhibits cancer cell growth and is five to eight times more potent than the initial lead compound.[93]

Endothelin (ET) receptors play an important role in the expression and function of abnormal in cardiovascular diseases, tumor progression, and tumor metastasis. Michel et al.[89] explored click chemistry for the synthesis of high-affinity ET_A-selective receptor ligands with clogD values ranging from 1.50 to 3.90, which allow systematic investigations of pharmacokinetic properties and metabolic stability. Compound **74** (Fig. 11) showed good selectivity toward ET_B/ET_A.[94]

Labeled molecular probes are powerful pharmacological tools to study and characterize ligand–receptor interactions. Click chemistry was used as a tool to facilitate the access to labeled novel pirenzepine derivatives. The incorporation of a fluorophore (lissamine rhodamine B), a nonfluorescent dye (Patent Blue VF), or biotin into a muscarinic antagonist pirenzepine scaffold was done by using click chemistry. The affinity of the compounds for the *human* M1 muscarinic receptor fused to enhanced green fluorescent protein (EGFP) was checked under classical radioligand and FRET binding assays. Pirenzepine triazole (**75**; Fig. 11) displayed a nanomolar affinity for the M1 receptor. In addition, both dye-labeled derivatives behave as potent acceptors of energy from excited EGFP with a very high quenching efficiency.[95]

1-Phenyl-1*H*-1,2,3-triazoles were prepared via click chemistry for selective antagonist development for β3 over α1β2γ2 GABA receptors by Ozoe and his coworkers. Among screened triazole analogs, the 4-n-propyl-5-chloromethyl analog of triazole (**76**; Fig. 11) showed antagonist affinity for both β3 and α1β2γ2 receptors with K_i values of 42 ± 5 nM, respectively.[96]

Dopamine D2 receptor homodimers are the promising target proteins for the discovery of a typical antipsychotics. To investigate and control GPCR, dimerization may be provided by the exploration and characterization of bivalent ligands, which can act as molecular probes simultaneously binding two adjacent binding sites of a dimer. The synthesis of bivalent D_2 receptor ligands was performed, incorporating the 1,4-disubstituted aromatic piperidines/piperazines (1,4-DAPs) and triazolyl-linked spacer elements. Radioligand-binding assays revealed that the bivalent ligands exhibited a distinct binding profile compared with monovalent ligand. Bivalent ligands **77** and **78** (Fig. 11) revealed a most potent binding affinity toward the D_2 receptors.[97]

Substituted aryl-1,2,3-triazoles were synthesized using click chemistry for binding of the cytokine macrophage migration inhibitory factor (MIF) to its receptor CD74. Especially, compound **79** (Fig. 11) showed antagonist effect with CD74 receptor.[87]

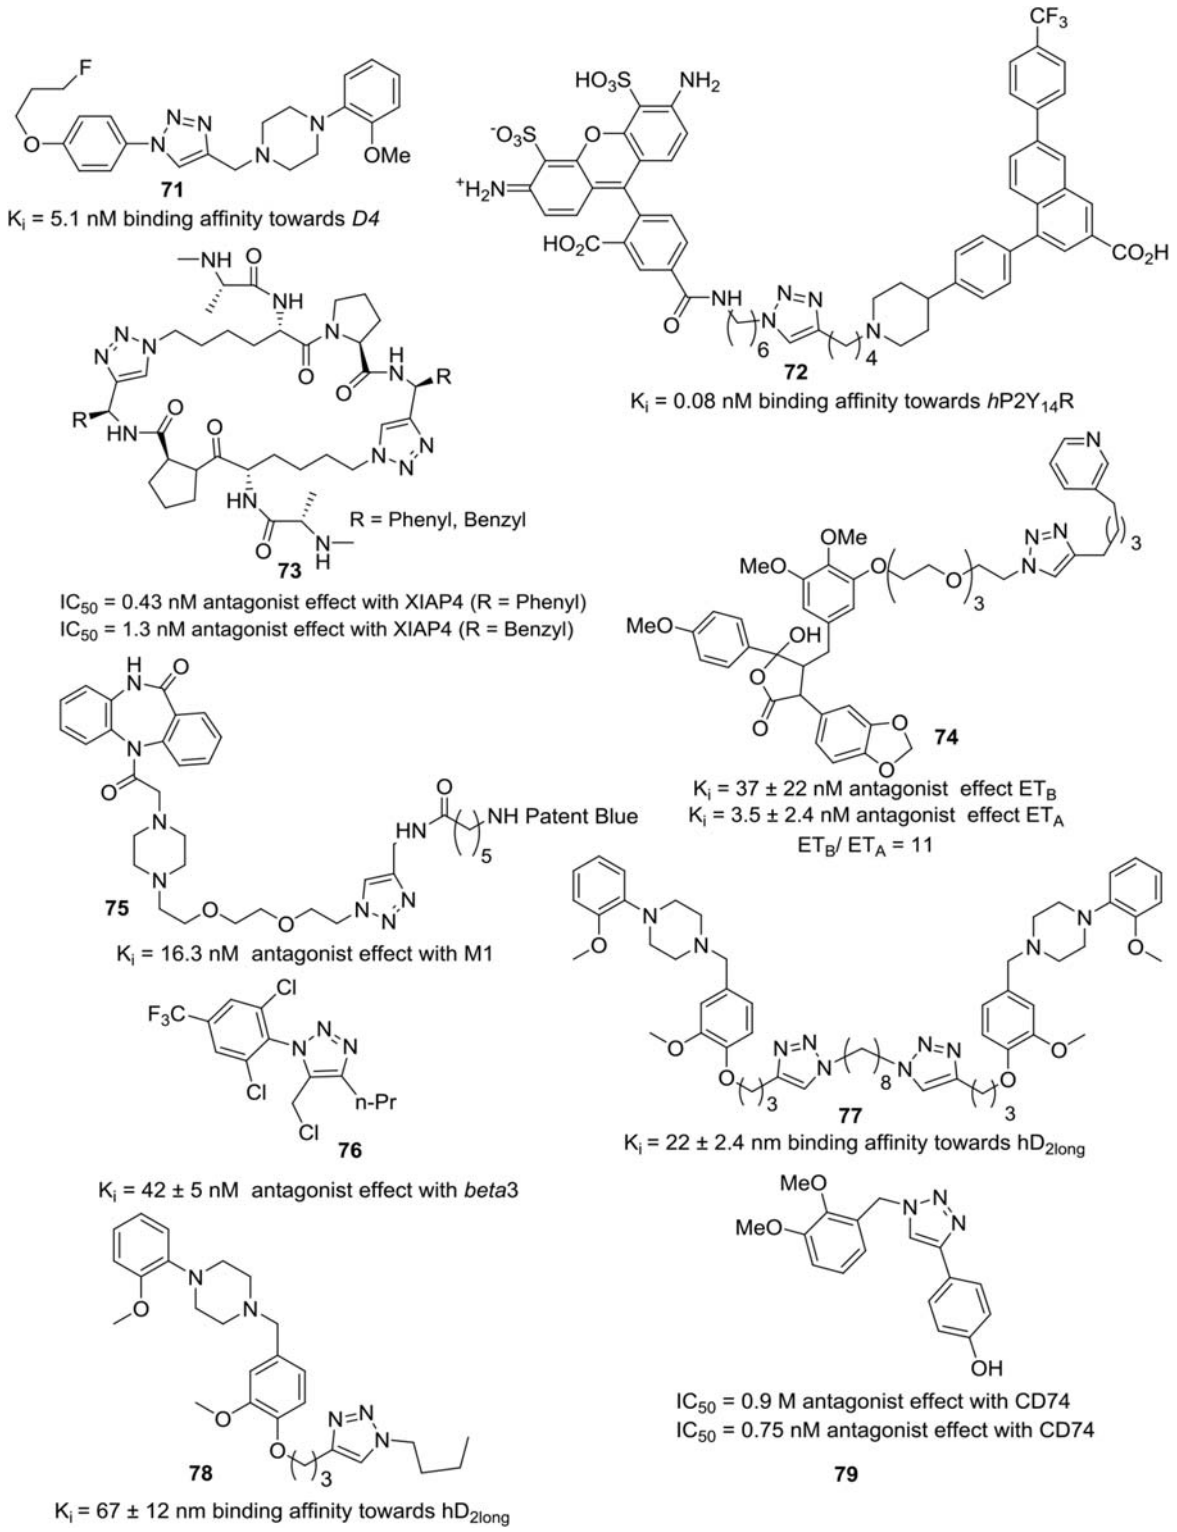

Fig. 11 Lead chemical triazole functional derivatives with antagonistic effect on various G-protein-coupled receptors synthesized via click chemistry.

1,1′-Substituted ferrocene triazole derivatives were generated via click chemistry for the development of novel antagonist for dopamine receptor by Gmeiner and his coworkers. 1,1′-Substituted ferrocene triazoles were used for the fine-tuning of biological activity and for the attachment of linker units generating bivalent GPCR ligands. Receptor binding assay was evaluated by radioligand displacement experiments, revealing super-affinity with sub- to single-digit nanomolar K_i values for particular test

compounds. As a neutral antagonist at the dopamine receptors D_3 and D_4 and a potent partial agonist at the D_2 subtype (intrinsic activity = 57%, EC_{50} = 2.5 nM), the bifunctional ferrocene **80** (Fig. 12) revealed a unique activity profile.[98]

Peptide triazole functional derivatives were constructed via click reaction of both aryl and alkyl acetylenes with an internally incorporated azidoproline derived from the parent peptide. These triazole conjugates were found to exhibit several orders of magnitude increase in both affinity for HIV-1 gp120 and inhibition potencies at both the CD4 and coreceptor binding sites of gp120. Structural factors in the added triazole grouping were responsible for the increased binding affinity and antiviral activity of the dual inhibitor conjugates. Peptide conjugate potencies were measured in both kinetic and cell infection assays. High affinity was sterically specific, being exhibited by the *cis*- but not the *trans*-triazole. Aromatic, hydrophobic, and steric features in the residue side chain are important for increased affinity and inhibition (compound **81**; Fig. 12).[99]

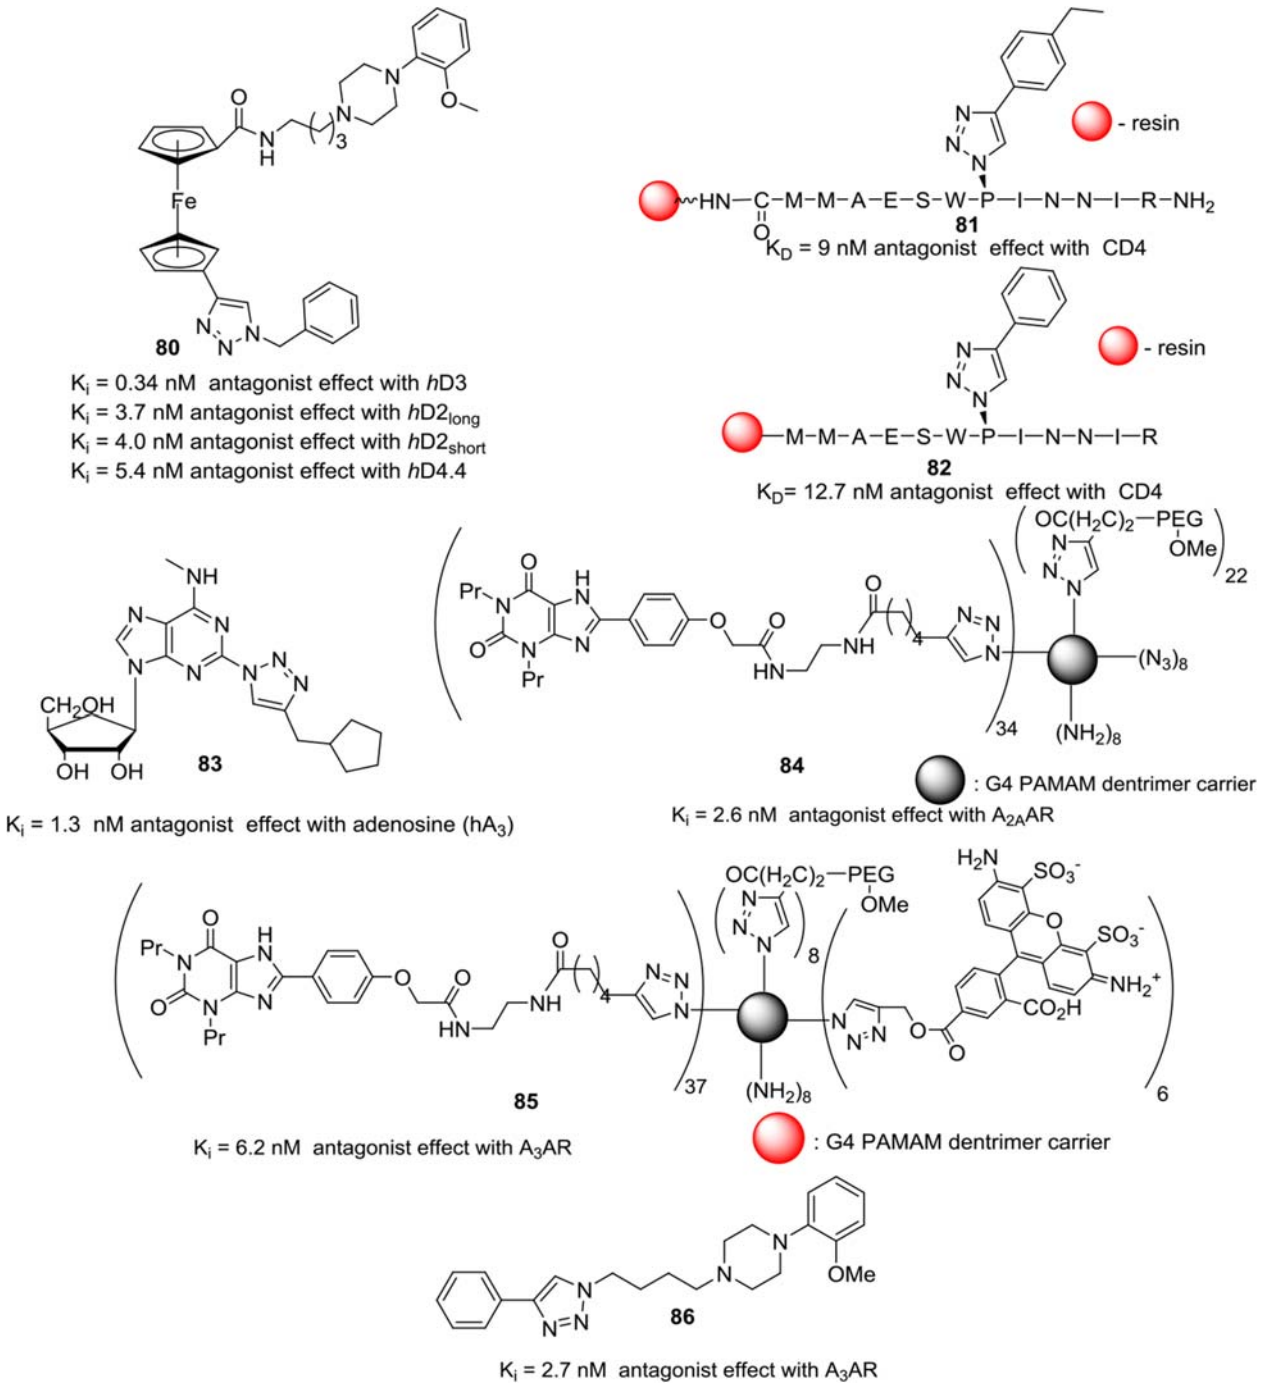

Fig. 12 Click triazole functional analogs generated for antagonist effect on various receptors.

Click chemistry was employed for the synthesis of high-affinity dual antagonist for HIV-1 envelope glycoprotein gp120 by Chaiken and his coworkers. The peptide analog **82** (Fig. 12) of (2*S*,4*S*)-4-(4-phenyl-1*H*-1,2,3-triazol-1-yl)pyrrolidine-2-carboxylic acid at residue position 6 was binding to gp120 with an affinity two orders of magnitude greater than that of the parent peptide and strongly inhibits the interaction of gp120 with both CD4.[100]

2-(1,2,3-Triazolyl)adenosine derivatives were prepared via click chemistry, and their binding affinity of the human A_1, A_2, and A_3ARs (adenosine receptors) and relative efficacy at the A_3AR were examined. 2-Triazole analogs with an unmodified ribose moiety **83** (Fig. 12) showed good antagonist activity at the A_3AR.[89]

GPCR ligand–dendrimer (GLiDe) conjugates were prepared for a potent adenosine receptor (AR) antagonist for treating Parkinson's disease, asthma, and other diseases by Jacobson and his coworkers. Xanthine amine congener (XAC) was appended with an alkyne group on an extended C8 substituent for coupling by Cu(I)-catalyzed click chemistry with azide-derivatized G4 PAMAM dendrimers to form triazoles. These conjugates also contained triazole-linked PEG groups for increasing water solubility and optionally prosthetic groups for spectroscopic characterization and affinity labeling. Human AR binding affinity increased progressively with the degree of xanthine substitution to reach K_i values in the nanomolar range. The order of affinity of each conjugate was hA$_2$AR > hA$_3$AR > hA$_1$AR, while the corresponding monomer was ranked hA$_2$AR > hA$_1$AR ≥ hA$_3$AR. The antagonist activity of the most potent conjugate **84** (34 xanthines per dendrimer; Fig. 12) was examined at the G_i-coupled A_2AR, and it showed significant binding affinity toward A_2AR at low nanomolar concentration. The conjugate **85** (Fig. 12) showed most potent antagonist activity toward A_3AR with K_i value of 6.2 ± 0.9 nM.[101]

A series of 1,4-disubstituted triazoles were synthesized via click chemistry by Carro et al. 1,4-Disubstituted triazoles derivatives were evaluated as potential ligands on several subtypes of dopamine receptors in in vitro competition assays, showing high affinity for dopamine D_3 receptors, lower affinity for D_2 and D_4, and no affinity for the D_1 receptors. Triazole derivative **86** (Fig. 12) displayed the maximum affinity toward D_3 receptor with a K_i value of 2.7 nM, selectivity over D_2 (70-fold) and D_4 (200-fold), and behavior as a competitive antagonist in the low nanomolar range.[102]

1.10.5.3 Selective Binding Ligands

A series of 4-phenylpiperazines triazole derivatives were generated via click chemistry to explore the triazole as a bioisosteric substitution for the amide linker commonly found in this chemical class of D_3R (dopamine D_3 receptor)-selective ligands. Several 1,2,3-triazole-synthesized compounds had high (K_i = 1–10 nM) affinity for D_3R and >80-fold selectivity for D_3R over D_2R. Compounds **80**, **81**, and **82** (Fig. 13) showed good affinity toward D_2R, D_3R, and D_4R, respectively.[103]

Integrin receptors consist of heterodimeric glycoproteins involved in cell–cell and cell–extracellular matrix adhesion and signal transduction. Many integrins, which are glycoproteins, contain the arginine–glycine–aspartic acid (RGDa) tripeptide sequence, found in a series of peptide-based ligands such as vitronectin, fibronectin, and osteopontin. Regarding RGD-dependent integrins, $\alpha_v\beta_3$ and $\alpha_v\beta_5$ receptors have received increasing attention as therapeutic targets, as they are expressed in various cell types and are involved in inflammatory and tumor-related processes. $\alpha_v\beta_3$ integrin expression is upregulated in many solid tumors and contributes to the mechanisms involved in tumor growth and metastatic dissemination. During the progression from a benign melanocytic disease to a metastatic malignant melanoma, melanocytes undergo a series of changes in the expression of cell-surface molecules, including $\alpha_v\beta_3$ integrin. Guarna and his coworkers employed click chemistry for the discovery of triazole-based arginine–glycine–aspartate (RGD) mimetics, which showed binding affinity properties toward $\alpha_v\beta_3/\alpha_v\beta_5$ integrins. Biological assays showed compound **83** (Fig. 13) capable of binding $\alpha_v\beta_3$ integrin with nanomolar affinity according to a two-site model, and molecular modeling studies revealed a peculiar π-stacking interaction between the triazole ring and Tyr178 side chain. Accordingly, compound **83** inhibited the adhesion of integrin-expressing human melanoma cells to RGD-containing proteins of the extracellular matrix, such as vitronectin, fibronectin, and osteopontin, and also angiogenesis in vitro and in vivo experimental models. The relevant biological effects exerted by compound **83** suggest its potential application as an antiangiogenic agent in the diagnosis and therapy of tumors where $\alpha_v\beta_3$ integrin expression is upregulated.[104]

Neurotensin (NT) is a secreted tridecapeptide, which is widely distributed throughout the central nervous system, and function as a neurotransmitter or a neuromodulator. NT binds to the neurotensin receptor (NTR) where of three different subtypes, NTR1, NTR2, and NTR3, are characterized. NTR1 and NTR2 belong to the family of G-protein-coupled receptors, and their internalization mechanism via receptor-mediated endocytosis is well described by Mazella and Vincent. NTRs as promising target for cancer diagnosis and therapy were well reported in the literature. Wuest and coworkers employed click chemistry for the synthesis of neurotensin-containing peptide heterodimer analogs. Neurotensin-containing peptide dimer analogs were used in an in vitro binding assay to determine binding affinity toward the neurotensin receptor-1 (NTR1). The determined IC_{50} values of 0.7 μM indicated only very low binding affinity of the neurotensin (compound **84**; Fig. 13)-containing peptide heterodimer toward the NTR1.[105]

1,4-Substituted triazole-based peptidomimetics were prepared for binding affinity toward somatostatin receptor (SSTR). Stereoisomeric peptidomimetics were synthesized by click chemistry, using the ligand TBTA (tris-(benzyltriazolylmethyl)amine) to suppress competing homodimer formation (compound **85**; Fig. 13). NMR analysis showed that all compounds existed in a single conformation on the NMR timescale. The compounds exhibited diverse selectivity against the five human SSTR subtypes 1–5. In an attempt to define the three-dimensional pharmacophoric requirements for receptor binding, the most potent human SSTR subtype 4 peptidomimetic was overlaid with all the other peptidomimetics. Three ligand groups were thus identified: selective ligands, broad-spectrum binders, and low-affinity ligands.[106]

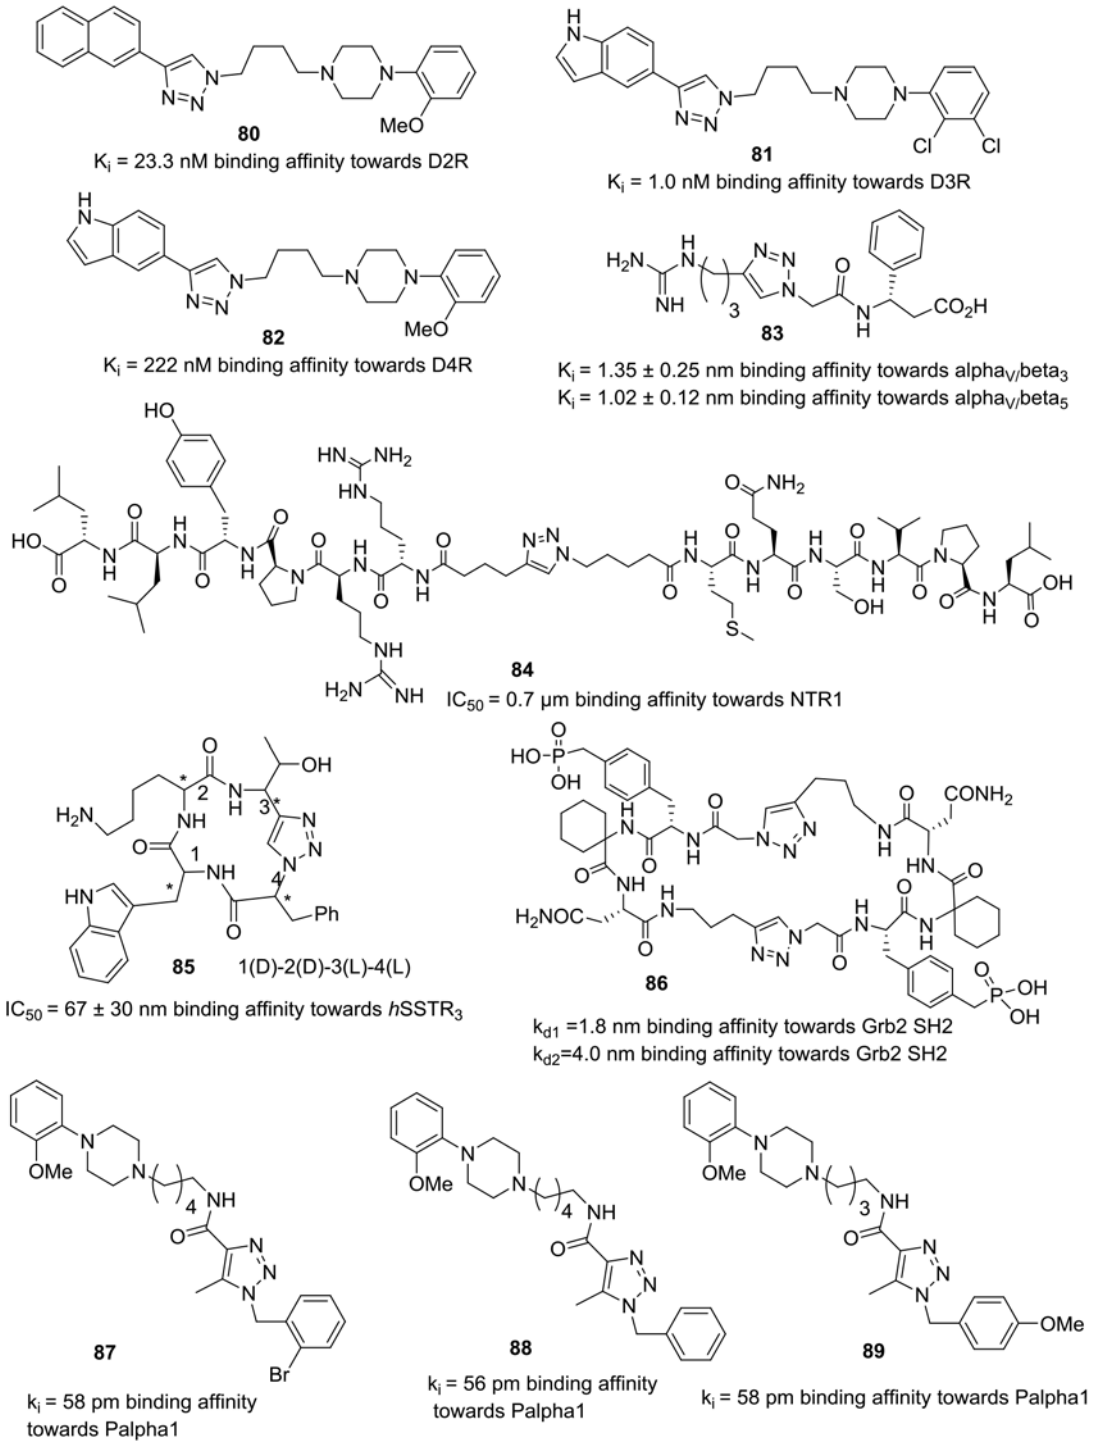

Fig. 13 Triazole lead structures of receptor-selective binding ligands explored via click chemistry.

Growth factor receptor-bound protein 2 (Grb2) is a SH2/SH3 domain-containing adaptor protein that links growth factor receptor tyrosine kinases to the Ras signaling pathway. For Grb2 SH2 domains, where open-chain "pTyr-Xxx-Asn" sequences are preferentially recognized in type-I β-turn conformations, induction of turn geometries through macrocyclization using ring-closing olefin metathesis2 (RCM) has resulted in a number of potent binding inhibitors. Burke and his workers employed click chemistry for the synthesis of triazole-containing macrocycles based on the Grb2 SH2 domain-binding motif, "Pmp-Ac6c-Asn," where Pmp and Ac6c stand for 4-phosphonomethylphenylalanine and α-amino cyclohexane carboxylic acid, respectively.

In Grb2 SH2, domain-binding assays revealed that compound **86** (Fig. 13) showed most binding affinity toward Grb2 SH2 of the series.[107]

Parallel solid-supported synthesis of formyl aryloxymethyltriazole (FAMT) resins was prepared using click chemistry by Gmeiner and his research group. A library of test compounds revealing three points of diversity were generated by a four-step BAL-based strategy including reductive amination, acylation, 1,3-dipolar cycloaddition, and TFA-induced cleavage. The target compounds were screened for neuroreceptor binding employing eight different GPCRs, whereas high-affinity dopamine D_3 and α1-receptor binders were identified. The library members **87**, **88**, and **89** (Fig. 13) revealed K_i values for the α1 receptor in the medium picomolar range.[108]

α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPAs) are hetero-tetrameric combinations of GluR1–4 subunits that provide the major fast excitatory inputs in the CNS. Regulation of AMPA receptor number at the postsynaptic membrane contributes to changes in synapse strength and to synaptic plasticity. Such regulation requires a synaptic infrastructure that controls the trafficking and localization of receptors, such as through the interaction of receptors with synaptic scaffolding proteins. The central nervous system glutamate receptors are an important target for drug discovery. Abell and his coworkers reported synthesis and glutamate receptor activity of 1,4- and 1,5-disubstituted 1,2,3-triazolyl amino acid glutamate homologues. In vitro screening indicated selective binding for **90** (Fig. 14) at AMPA receptors of the series with IC_{50} value of 49 μM.[109]

Pharmacological effects of cannabinoid and endogenous cannabinoid ligands are mediated by two subtypes of transmembrane G-protein-coupled receptors: CB1 and CB2. CB1 receptors are expressed in the central nervous system (CNS) with high density in the cerebellum, hippocampus, and striatum. CB1 receptors are found in some peripheral tissues (the urinary bladder, testis, and ileum) as well. CB2 receptors are predominantly located in the immune system (tonsils, spleen, and immune cells) with very low concentration in the CNS. CB1 agonists have potential therapeutic applications in developing drugs for pain, nausea, glaucoma, stroke, cancer, and neurological disorders such as multiple sclerosis and Parkinson's disease. The potential applications of CB1

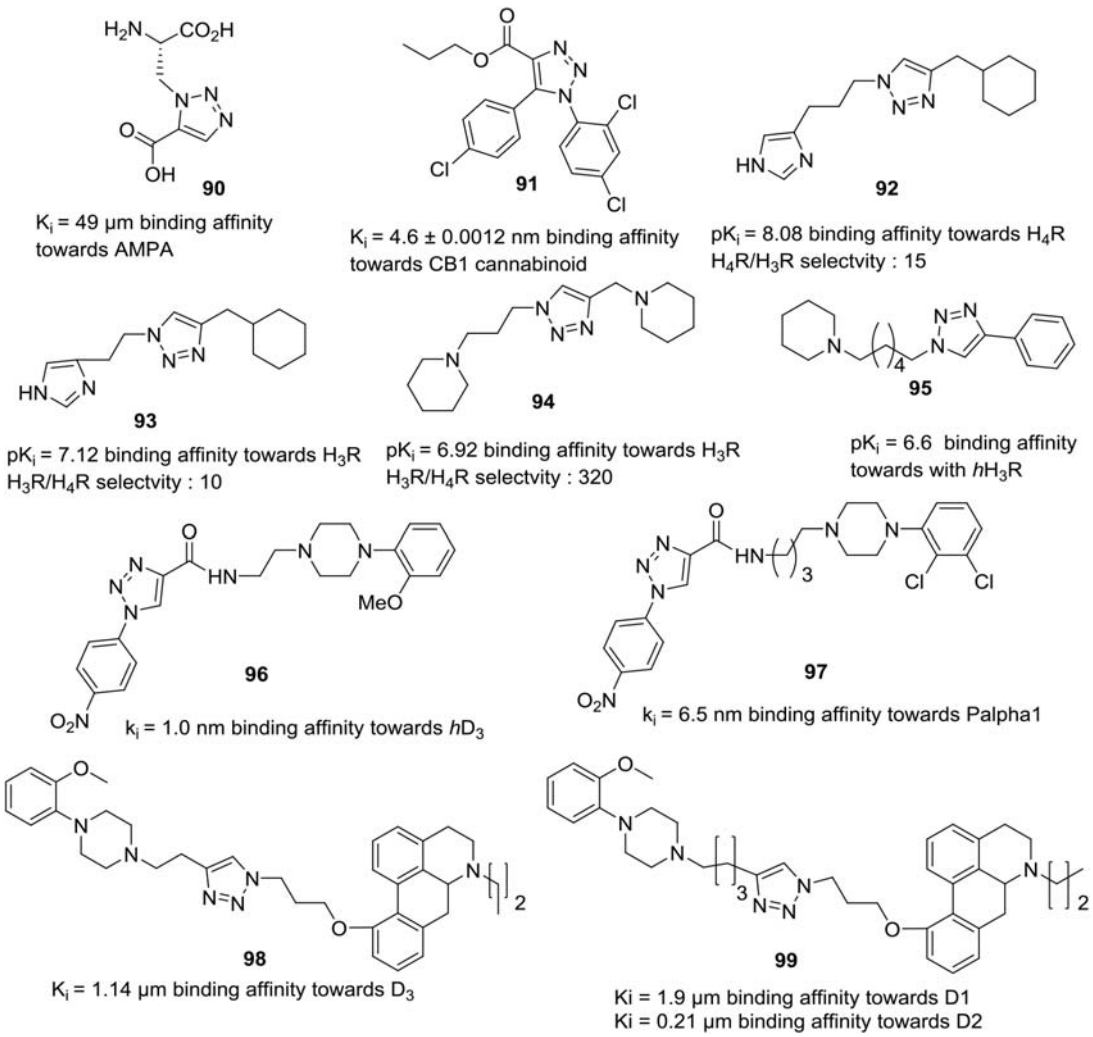

Fig. 14 Chemical triazole lead structures of receptor-selective binding ligands generated via click chemistry.

antagonists include the therapeutic treatment of obesity and related metabolic disorders as well as medications for drug addiction. Trudell and his workers employed click chemistry for the synthesis of a series of 4-alkoxycarbonyl-1,5-diaryl-1,2,3-triazoles and evaluated as a novel class of potent cannabinoid receptor ligands. The *n*-propyl ester **91** ($K_i = 4.6$ nM, Fig. 14) exhibited the most potent binding affinity toward cannabinoid receptor of the series.[110]

The histamine H_3 (H_3R) and H_4 (H_4R) receptors attract considerable interest from the medicinal chemistry community. It is playing an important role in inflammation and immune responses with possible applications in diseases such as inflammatory bowel disease, allergic asthma, and pruritus. Wijtmans and his coworkers employed click chemistry to assemble diverse triazole compounds containing a peripheral imidazole group. The imidazole ring posed some problems in the click chemistry putatively due to Cu(II) coordination, but Boc protection of the imidazole and removal of oxygen from the reaction mixture provided effective strategies. Pharmacological studies of triazole scaffold proved remarkably sensitive H_4R affinities. With subtle changes in aliphatic group, **92** and **93** (Fig. 14) were obtained, which boosted high H_4R affinity ($pK_i = 8.08$ and 7.12) and a good H_4R/H_3R selectivity of 15 and 10 noteworthy for a monosubstituted imidazole compound. In contrast, a replacement of both peripheral groups by piperidines led to compound **94** (Fig. 14) with good H_3R affinity ($pK_i = 6.92$) and excellent H_3R/H_4R selectivity (320).[111]

Human histamine H_3 receptors (hH$_3$R) in the central nervous system (CNS) are auto- and heteroreceptors modulating the synthesis and the release of histamine as well as the liberation of various other neurotransmitters. Hence, histaminergic neurons, which spread from the tuberomamillary nucleus into most parts of the brain, influence the neurotransmitter balance in the respective compartments in dependence of colocalized neurons. Central functions like vigilance, attention, and learning are affected. Modulation of this neuronal interplay by hH$_3$R antagonists/inverse agonists might be an effective approach in the therapy of neuronal diseases, for example, cognitive impairment, sleep/wake disorders, epilepsy, and obesity. The diversity of potential indications gives a hint of the complexity of hH$_3$R modulation. Stark and his coworker employed click chemistry for the synthesis of human histamine H_3 receptor (hH3R) binding ligands using ω-piperidinylalkayl azide derivatives. Compound **95** (Fig. 14) showed the most binding affinity toward hH3R within this series, showing receptor binding affinity in the nano- and subnanomolar concentration range.[112]

Dopamine (DA) D_3 receptor belongs to the D_2-like subfamily of dopamine receptors, including D_2, D_3, and D_4, functionally distinct from the D_1-like subfamily (D_1 and D_5). D_3 receptor is implicated in a variety of brain functions and proposed as a promising therapeutic target for a number of neurological and psychiatric disorders, including schizophrenia, depression, drug abuse, Parkinson's disease, and restless leg syndrome. Gmeiner et al. successfully applied click chemistry for a parallel synthesis of dopaminergic phenyltriazoles utilizing the triazolylmethylcatechol (TMC) resin. A focused model library of 20 test compounds revealing three points of diversity was generated by a three-step SPOS approach. Product purification was performed employing a solid-supported carboxylic acid anhydride as a scavenger. GPCR-ligand-binding screening revealed dopamine D_3 ligand (**96**, Fig. 14) with K_i values in the single-digit nanomolar range. Also compound **97** showed good binding affinity toward Pα1 with K_i value of 6.5 nM.[113]

Click chemistry was employed for the synthesis of a series of aporphine analogs from appropriate precursors and aryl piperazines. These compounds displayed good to high affinity at the D_3 receptor and low or no affinity at the D_1 and D_2 receptors. Compound **98** (Fig. 14) showed good affinity at the D_3 receptor and low affinity at the D_1 and D_2 receptors with $K_i = 1.14$ nM against D_3 receptor. Compound **99** (Fig. 14) was identified as the most potent at the D_1 and D_2 receptors among our newly synthesized analogs with K_i values of 1.9 and 0.21 μM against D_1 and D_2 receptor, respectively.[114]

1.10.6 In Situ Click Chemistry

Modern medicinal chemists mainly are applying fragment-based approaches to find lead molecules more efficiently to facilitate the drug discovery process.[6,115] The conventional approach used by medicinal chemists in drug discovery consists of the synthesis of a collection of compounds and subsequent biological screening. The procedure would be shortened and optimized if the biological target could actively choose its best ligand. Indeed, the target would act as the ideal template to generate the perfect hit. In this specific context, it is therefore possible to envisage that, at room temperature, an enzyme could bring azide and alkyne containing molecules in close proximity so as to overcome the high energetic barrier allowing the click chemistry reaction to occur in room temperature catalyzed by an enzyme. In this manner, only compounds that fit correctly into the active site of the enzyme should react to give new potent ligands of the enzyme. The schematic pictorial representation of in situ click chemistry[116–119] of enzyme inhibitor is shown in Fig. 15.

Several reports have appeared in which fragment-like monomers are allowed to react together in the presence of target protein. In certain cases, the rate of formation of a few possible products from a potentially large number is dramatically accelerated by sequestering the two components inside a host structure due to the appropriate orientation of the fragments. The resulting compounds always have good potency because they are preselected to be good binders. This approach has been effectively applied to the click triazole-forming reaction of azides and acetylenes, because the reactive partners appear to snap together when properly oriented.[120]

Many examples of the in situ click chemistry concept are present in the literature and have been reviewed in details in our review article in 2013.[20] Some of the recent updates are described in the succeeding text. In principle, the "click chemistry" approach to drug design is applicable to almost any target. If it is possible to use a pure enzyme, the function of which can be measured easily, then the techniques are easier to apply. However, Finn stresses, "the in situ approach has the virtue of being potentially useful when

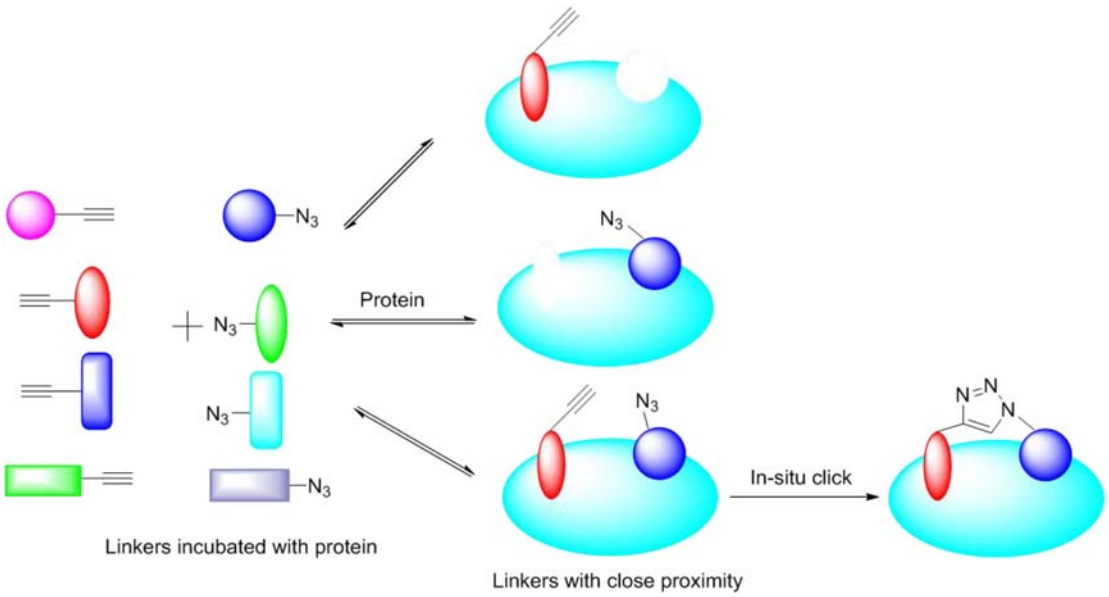

Fig. 15 Schematic diagram of the development of enzyme inhibitors using in situ click chemistry strategy.

these conditions were met. If everything works perfectly, one can even imagine administering a set of pieces of a drug to a patient and having the drug assembled itself at the desired site (e.g., a tumor tissue) in response to the specific nature of the target." Further development work with enzyme inhibitors is now in progress in many research groups, on a variety of diseases including AIDS, cancer, anthrax, and Huntington's disease.[116]

1.10.6.1 Screening and Identification of Biotin Protein Ligase (BPL) Inhibitors

In situ click chemistry was employed for screening and to probe the binding sites of biotin protein ligase inhibitors by Abell. This technique is the elegant approach for identifying enzyme inhibitors, where the target enzyme is used to select the appropriate combination of azide and alkyne analogs from a library. Once bound in the active site, they assemble via click chemistry reaction into the corresponding triazole-based inhibitor. BPL is the clinically important bacterial pathogen *Staphylococcus aureus* (Sa). The function of BPL is to catalyze the stepwise formation of biotinyl-50-AMP from biotin and ATP. Biotinyl-50-AMP then enables biotinylation of enzymes central to fatty acid biosynthesis and the tricarboxylic acid cycle. The triazoles are prepared by click of biotin alkyne and adenosine azide fragments. A leaky mutant (SaBPL-R122G) of wild-type SaBPL was used to enhance the turnover rate for the reaction of biotin alkyne with an azide to give a triazole. That allowed the enzyme to select the optimum triazole-based inhibitor using a library of such azides in a single experiment, with improved efficiency and sensitivity of detection, difficulties which could restrict the general utility of a multicomponent in situ click approach to ligand optimization. The leaky mutant had a 40-fold enhanced rate of product dissociation relative to the target enzyme (SaBPL). Particularly, compound **101** (Fig. 16) indented in this library-based experiment was the most potent inhibitor. Enhancing the efficiency of a target enzyme is an important approach for improving the utility of multicomponent in situ click beyond the few examples reported to date.[121]

1.10.6.2 Probing the Binding Site of Abl Tyrosine Kinase

Passarella and his coworker successfully applied in situ click chemistry for ligand-binding site of Abl and the ability of this enzyme to form its inhibitor. The selection of coupling analogs was incubated with the enzyme based on the structure of "hits" originating from docking studies and/or high-throughput screens. For example, many of the known inhibitors of tyrosine kinase could be dissected in frameworks and properly functionalized with azide/alkyne moieties to be used as libraries of building blocks for in situ click reaction, in the presence of any available tyrosine kinase. The detection of the Abl-bound compounds is favored by HR-ESI-MS. Especially, compound **102** (Fig. 17) bound with Abl was detected by HR-MS at lower concentration of azide (0.25 μM), alkyne (0.25 μM), and Abl (0.0185 μM). This detection method will open the way for the preparation and in-depth biological evaluation of selective molecules as lead structures.[122]

1.10.6.3 Antibody-Like Protein-Capture Agents

Antibody-based capture agents are important novel method to detect most proteins. A good antibody displays high affinity and selectivity for its related protein, though antibodies are often costly and they may appear unstable toward chemical and biochemical

processes. Several alternative protein-capture agents, including oligonucleotide aptamers and phage-display peptides, were reported, each of which had advantages as well as significant limitations.[123]

Agnew and coworkers first developed a triligand capture agent against bovine carbonic anhydrase II (bCAII).[124] In situ click chemistry approach was applied for the building of multiligand protein-capture agents and triligand capture agent screened against *human* bovine carbonic anhydrase II (h(b)CAII). Bead-based combinatorial synthesis of oligopeptides was employed for attaching alkyne group at the terminal of each library analog. Hexapeptide anchor sequence was confirmed from beads bound the protein most strongly, followed by Edman sequencing. The anchor ligand exhibited a weak affinity ($K_D \approx 500$ mM) against bCAII. The anchor compound was then incubated with bCAII and a second D-amino acid peptide library bearing azido-amino acids of variable side-chain length. After two screens, a consensus 2° peptide was identified and conjugated to the anchor peptide by the click reaction to yield a biligand with significantly improved affinity ($K_D = 3$ mM) as determined using surface plasmon resonance. The process was repeated to generate a high-affinity triligand (**103**) as measured by SPR techniques ($K_D \approx 45$ and 64 nM) that could function as a drop-in antibody replacement in immunoblotting experiments. Importantly, the triligand was formed on-bead only in the presence of bCAII or human carbonic anhydrase II (hCAII). Recent years, two more triligands (**104** and **105**; $K_d = 0.5–5$ μM; Fig. 18) were developed for human carbonic anhydrase II inhibitors.[125] Similarly triligand (**106**, Fig. 19) was developed by Millward and coworkers for prostate-specific antigen-binding peptides (anti-PSA triligand with cyclic anchor peptide) generated via click reaction from modification cyclic peptide reported in the literature.[125]

Iterative in situ click chemistry was applied to generate Akt-specific branched peptide triligand (**107**; Fig. 19) with mid-nanomolar affinity for protein kinase B (Akt1). Each peptide module in the branched structure made unique contributions to affinity and/or specificity resulting in a 200 nM affinity ligand that efficiently immunoprecipitated Akt from cancer cell lysates and labels Akt in fixed cells. The resulting branched triligand was found to inhibit the catalytic activity of Akt1 without directly binding to the ATP or peptide substrate pockets, suggesting an allosteric mode of inhibition. The triligand immunoprecipitated Akt from OVCAR3 ovarian cancer cell lysates and a fluorescent variant was used to image membrane-localized Akt in cell culture after stimulation with insulin and EGF. In both cases, the triligand compared favorably with commercial monoclonal antibodies.[126]

1.10.7 Conclusion and Future Directions

In this article, we provided an overview in medicinal science applications for the researchers that intend effective utilization of click chemistry. Innovative and more efficient chemical reactions (click chemistry) and methodologies, which may override the laborious protection/deprotection and purification steps in conventional total synthesis, could revolutionize the next-generation chemical and biological research. We have demonstrated from this article that click chemistry is one of the powerful tools for the construction of heteroatom links for chemistry and biology in drug development and investigation of biological system. The copper(I)-catalyzed 1,2,3-triazole-forming reaction between azides and terminal alkynes has become the gold standard reaction due to its reliability, specificity, and biocompatibility. Research in drug development in this click chemistry field is still increasing exponentially. We have discussed the use of click chemistry in the area of the synthesis of agents with anticancer activity, antiproliferative, antiviral, antimicrobial, etc., and have intended to demonstrate the diversity of applications of this chemical strategy in the area of drug discovery. Lead triazole functional analogs are used for anticancer agents, antiproliferative, antiviral, and antimicrobial development. On the other hand, click chemistry has been effectively applied for the development of agonists, antagonist, and selective ligand in receptor–ligand-binding studies for drug development in the field of medicinal chemistry. Lead triazole structures were used in the literature for various receptor–ligand-binding studies for effective drug development. Additionally, in situ click chemistry ingenious strategies are effectively applied into new ways of generating extremely potent inhibitors against certain enzymes. Especially, in situ click chemistry is used for protein ligase, Abl tyrosine kinase, carbonic anhydrase II, and protein kinase B (Akt1) potent enzyme inhibitor development.

In contemporary drug discovery research, click chemistry is playing important role for generating drug-like candidates to understand biochemical pathways and access the information of the drug-binding sites in the receptor site in the cell membrane. Click chemistry can be applied in several areas and is rapidly increasing with possibilities of exciting discoveries on the horizon. Apart from the general areas of materials science, nanoscience, and bioconjugation, the concept has already made huge impact in drug discovery. A constant drive toward simpler chemical reactions such as click reaction with a wide scope is in progress. Due to the simplicity of click reactions, biochemists and molecular biologists are able to make complex molecular systems without much bothering about the synthetic chemistry. Click chemistry in the future will reach the level of ready-made chemistry like many kits available in the market to make it easy to use. On the other hand, click chemistry reaction is used to site-specific functionalization biological macromolecules (protein, DNA, glycans, lipids, and cell surfaces) and living systems (virus nanoparticles, bacterial-like microorganism, and zebrafish embryos) under physiological conditions. These click modified bimolecular assemblies can be effectively used in target-based drug delivery in the future. Click activity or affinity-based protein profiling methods facilitate the detection of many disease applicable enzymes and careful pharmacological probes to perturb and characterize these proteins in cells. Activity-based proteomics can provide insight into the metabolic and signaling pathways that support illuminate new strategies for disease diagnosis and treatment.

1.11.1 Introduction

The practice of modern medicinal chemistry can be described as forced Darwinian evolution in chemical space. It is marked by iterative cycles of chemical modifications to organic molecules, followed by the biological testing of these compounds. Successive iterations of synthesis and biological testing gradually build up a picture of "structure–activity relationships" (SAR) that reveal how structural changes impact the biological properties of organic compounds. SAR studies are the navigational tools that help guide the medicinal chemist across the chemical landscape. They identify the promising chemical structures that have the right blend of chemical, physical, and biological properties for human clinical testing with the eventual goal that one of these compounds becomes an approved "drug." It is inherently implied in this paradigm that in order to practice their craft and generate useful SAR data, medicinal chemists have the ability to manipulate chemical structures in a controlled and defined manner. Thus, not

surprisingly, the practice of medicinal chemistry has evolved in conjunction with advances in modern organic synthesis, molecular modeling, and analytical chemistry, which has given chemists tools for precise structural manipulations in heterocyclic organic molecules. Over the past century, low molecular weight heterocyclic compounds that can be orally administered have been the dominant class of molecules in pharmaceutical pipelines. In contrast, despite delivering significant clinical and medical benefits, drugs made of relatively larger, more complex compositions such as peptides, antibiotics, naturally derived proteins, and serums have not been a major focus of pharmaceutical industry. These molecular modalities have been at the periphery, or even outside the scope, of the traditional medicinal chemist's remit.

However, the pharmaceutical landscape started to shift over the last 40 years due to advances in molecular biology and recombinant protein expression. These technologies, along with protein purification and characterization tools, gave birth to the biotechnology industry and ushered in the era of engineered protein drugs. Early biotech companies such as Genentech, Celltech, Hybritech, MedImmune, Biogen, Amgen, Genzyme, and Genetics Institute, to name a few, were pioneers on this new frontier. In contrast to orally delivered and synthetically produced small molecules, these companies were developing high molecular weight protein drugs that could not be delivered orally, but rather as injectables. In 1982, the US FDA approved the first recombinant protein therapeutic, human insulin. Since then, biologics have been steadily growing as a successful class of drugs, delivering medications such as human growth hormone (GH), interferons, and engineered antibodies. While the acceptance of biologics as drugs was slow in the beginning, the pharmaceutical industry has seen an accelerated shift over the past decade toward embracing them.

Biologic drugs represent a tremendous investment value for the industry as they provide highly differentiated therapeutic options for difficult-to-treat diseases that can command higher prices. Unlike small molecules, it is not trivial to create "generic" versions of biologics, since they are made by living organisms and are characterized by inherent batch to batch variability. In addition, their development involves significantly more complex manufacturing and chemistry, manufacturing, and controls components compared to small molecules, and once approved, they are granted an extended regulatory exclusivity period. Historically, this has provided financial and commercial incentives for developers of biologic drugs. In 2015, there were 7 biologics among the top 10 selling drugs (**Table 1**).

According to a recent report from the Tufts Center for Study of Drug Development, clinical trials of biologic drugs have risen by over 155% from 355 in 2001 to more than 900 in 2012.[2] The worldwide sales have increased from $36 billion in the early 2000s, to $165 billion by 2013, and it is projected that the overall worldwide sales from biologic drugs will exceed $300 billion by 2020.

In order to lower costs for biologic drugs, under the Affordable Care Act, the FDA has required fewer clinical and preclinical data submissions for biosimilars, products that are highly similar to an original biologic. In 2015, the FDA approved the first biosimilar product in the United States—zarxio™ (Sandoz)—which is used for boosting white blood cells in cancer patients, and is a less expensive version of neupogen (Amgen). Shortly after, the FDA-approved Celltrion's Inflectra™ (infliximab), which is a biosimilar molecule of the original product Remicade® (infliximab). Inflectra™ is now the first biosimilar monoclonal antibody (mAb) therapy approved in the United States (see listed Websites 1 and 2 for reference).

Today, there are more than 50 biosimilars in the development pipeline. It is expected that these generic-like products will enter the market in the near future. Nonetheless, there are still a number of regulatory hurdles in place that prevent approved biosimilars from immediate access as a substitute. Most importantly, due to growing patient needs, innovators will keep delivering creative solutions and make differentiated and enhanced products. This will continue to challenge "me-too" alternatives and "biosimilar" products.

The advent of biologic drugs has also coincided with a bleak period of productivity for small molecule drugs. The promise of technology-focused initiatives such as high-throughput screening (HTS), genome mapping, computer-aided drug design, and combinatorial chemistry has resulted in a significant increase in investments and input costs for R&D programs. A number of excellent articles have dissected the various causes for the productivity decline in drug discovery focused on small molecule medicinal chemistry.[3–8] These reviews drive home the point that the technology-driven, target-focused, reductionist approaches have been

Table 1 Top 10 products[1]

Trade name	*Type*	*Marketer*	*Medical use*	*Estimated 2015 sales ($ billions)*	*Change from 2014 (%)*
Humira®	Antibody	AbbVie, Eisai	Inflammation	14.2	13

a letdown in drug discovery research and recommend strategies that rely more on phenotypic screening and predictive animal models as a way out of the productivity crisis; but, these approaches come with challenges of their own.

The rise of biologics coupled with the poor productivity of small molecule discovery programs has significantly altered the role of medicinal chemists as the drivers of innovation and value creation for the early stage R&D in biopharma industry. The synthesis of organic molecules is regarded as a commodity that is readily purchased in cheaper overseas markets such as China or India. At the same time, the spotlight has shifted to molecular biologists and protein engineers, who can help design and create highly lucrative biologic drugs. In 2002, Paul Earhardt authored a forward-looking, exhaustive review titled *Medicinal Chemistry in the New Millennium: A Glance Into the Future.*[9] The review presented a picture of how the practice of medicinal chemistry would evolve in 21st century and predicted a number of trends and strategies that would be adopted by medicinal chemists. However, the discussion almost exclusively focused on orally administered small molecules as the singular modality of operation for medicinal chemists. Yet, by the end of the first decade since the publication of that review, it is evident that this view is no longer relevant.

The shift toward biologic drugs has also increased the acceptance and representation of injectable drugs in development pipelines. Novel formulation technologies, reduced dosing frequencies, smaller injection volumes, and friendly delivery devices have dramatically improved patient compliance and thus enabled greater acceptance of these nontraditional modalities. Alternative routes of administration have the potential to become convenient and cost-effective delivery systems, hence allowing for the development of next-generation biologic drugs. Thus the chemists, to a certain degree, have been liberated from the high barrier to design molecules that need to be orally administered. The increased acceptance of the nonoral delivery modalities will continue to open new areas of opportunities for drug design.

A detailed discussion of the drug design and optimization strategies of the various modalities is too broad of a topic and is beyond the scope of this discussion. However, herein we attempt to present the drug design opportunities at these interfaces not from a modality or a product perspective, but rather from a solutions perspective. In other words, the motivation to design new classes of therapeutics beyond small molecules is driven by the promise of (a) expanding druggable target space, and (b) targeted delivery of next-generation drugs. Each of these areas is discussed here with a view toward the future (rather than an exhaustive review of the literature) and it is important to recognize that there are number of programs or examples that will overlap significantly between these topics.

1.11.2 Expanding Druggable Target Space

The practice of drug discovery is at an interesting crossroads. The completion of the Human Genome Project in 2001 coupled with recent advances in computational tools, data science, chemical biology, proteomics, and analytical methods gave us unprecedented insights into human physiology and disease biology. We have gained a greater understanding of molecular mechanisms for human diseases, and this knowledge has opened up possibilities for new therapeutic treatments. Synthetic small molecules, which have been the main source of leads in drug discovery pipelines,[10,11] successfully address traditional targets such as G-protein-coupled receptors (GPCRs), nuclear receptors, kinases, and voltage-gated or ligand-gated ion channels[12]; but the vast majority of the proteins encoded in the human genome remain "undruggable." The emerging biological target space has triggered the need for complex synthetic drug modalities that can effectively modulate intracellular protein–protein interactions (PPIs), the immune system, or manipulate gene function at the RNA level. The following section briefly describes newer targets spaces, opportunities for new modalities, and how new design approaches can impact them.

1.11.2.1 PPIs and Their Modulators

The interactions between two proteins represent a fundamental step in driving signaling pathways and cellular processes both inside and outside the cell. The modulation of such PPIs, in turn, provides significant opportunities to control dysregulated proteins in a disease state. For example, intracellular PPIs play a key role during tumor progression. They link oncogenic networks that trigger a cascade of events fostering tumor growth, invasion, and metastasis.[13] The central role of PPI networks, the so-called interactome, is a vast source of new therapeutic targets in drug discovery. Some examples include an amplified c-myc interaction with Max that regulates tumor cell proliferation, differentiation, and apoptosis,[14] and the interaction of the protein eIF4E with eIF4G to increase mRNA translation and to promote tumorigenesis.[15] Recent studies have shown the importance of specific PPIs in a number of different diseases such as multiple sclerosis and Alzheimers.[16] At present, more than 14,000 PPIs have been characterized in humans.[17] PPI interfaces are characterized by relatively featureless and large interaction surfaces of $\sim$1000–2000 A^2 which make it difficult for small molecule drugs to effectively target them.[18–24] Small molecules are better suited for protein targets that present deep cavities and hydrophobic grooves of $\sim$300–500 A^2. The work in the PPI field has led to a better understanding of various types of interactions based on their complexity. Furthermore, the realization that only a small number of residues, referred to as hot spots, are likely to contribute the majority of the binding energy has also helped drive progress; advances in screening technologies, and a combination of computational and biophysical tools, have helped identify a number of successful synthetic PPI modulators.[18–23] Venetoclax or ABT-199 is an orally active, potent, and selective PPI inhibitor of BCL-2, with proapoptotic activity. It was approved in 2016 for treatment of patients with chronic lymphocytic leukemia ith 17p deletion. The development of ABT-199 is the culmination of over a decade's worth of work, and demonstrates the ability of fragment-based screening, structural biology, and focused medicinal chemistry, in delivering a successful PPI inhibitor. In spite of the success with Venetoclax, the challenge with PPI targets still

looms large in the coming years. It will demand innovation in the screening, designing, and delivery of suitable chemical matter, which will likely be outside the rule-of-five (Ro5) space.

Peptides, proteins, and antibodies, all of which offer larger interaction surface areas, are better suited as PPI inhibitors. They have the ability to mimic protein fragments and functional motifs at PPI interfaces. These modalities demonstrate exquisite potency and an exceptional ability for highly selective targeting, which leads to a lower risk of toxicity and side effects. In the 1980s, production of fully human therapeutic mAbs facilitated the transformation of mAbs into the most successful drugs among protein-based therapies. Today, most biologic drugs in development pipelines are antibody-based proteins, and there are a number of blockbuster mAb drugs on the market that target extracellular proteins.[25]

However, as their large size restricts their diffusion across the cell membrane, it is a challenge for proteins and antibodies to address biological PPI targets in the intracellular space. Peptides and macrocycles are alternative classes of molecules that are uniquely suited to impact PPI targets in the intracellular space. These classes of compounds have the ability to modulate targets with extended binding interfaces. The challenges and the opportunities for medicinal chemists lie in their ability to design these molecules so that they (a) effectively permeate the cell membrane, (b) access the intracellular compartments, and (c) devise new ways of identifying viable hits as starting points for chemical optimization efforts.

1.11.2.1.1 Macrocycles

1.11.2.1.1.1 Synthetic macrocycles

Natural products which feature a macrocycle, that is, a ring system made of 12 or more atoms, have been successfully developed as drugs. There is evidence that macrocyclic structures that are not Ro5 compliant can nevertheless demonstrate good physicochemical properties and permeability comparable to smaller molecules. Thus, they can be viable chemical matter for targeting intracellular PPIs and even be developed as orally bioavailable drugs. The current compound collections that are screened to identify initial hits are biased by binding pockets of traditional targets, and they sample a narrow range of the chemical space and physicochemical properties. Consequently, they do not effectively complement PPI interfaces. There are a number of new technologies that create macrocyclic libraries of "beyond Ro5 compounds" to allow for the fast and extensive search of chemical space for hit identification.[26,27] Screening libraries can be generated using synthetic platforms that utilize amphoteric reagents for small peptidomimetic macrocycles,[28,29] macrocyclic template chemistry,[30] chemical linkage of peptides onto scaffolds,[31] and DNA-programmed chemistry.[32] In addition, advances in diversity-oriented synthesis strategies have enabled a generation of screening libraries of complex natural-product-like macrocycles. A better understanding of the chemical space of PPI inhibitors will help to create new and focused chemical libraries that could ensure more successful HTS in the future.[33,34]

1.11.2.1.1.2 Peptide macrocycles

Peptide macrocycles are uniquely positioned to target PPIs for drug development. The effective modulation of these challenging therapeutic targets often requires structurally complex ligands. Such complexity has been successfully afforded by antibodies and proteins. However, large biologics cannot efficiently cross the cellular membrane, thus placing the intracellular target space beyond their reach. Peptide-based macrocycles are the smallest biomolecules that have the molecular complexity to effectively recognize the large interaction surfaces of challenging biological targets. These modalities are amenable to biological display tools such as phage and mRNA libraries. In addition, well-established cyclization and medicinal chemistry strategies can be employed to improve selectivity, potency, stability, and the permeability of peptide macrocycles, making them an attractive class of molecules outside of the Ro5 space.

It is well established that many naturally occurring cyclic peptides penetrate the cell by passive membrane diffusion, the most prominent example of which is the orally administered drug cyclosporin A (CSA). The permeability mechanism of natural cyclic peptide products originates from their remarkable chemical diversity, as many of them are biosynthesized via nonribosomal peptide synthetases (NRPSs) and are often modified by "tailoring" NRPS enzymes. This class of compounds incorporates features such as nonproteinogenic amino acids, depsipeptide linkages, *N*-methylation, thiazole/oxazole rings, and backbone cyclization. These diverse structural elements enable the tuning of the pharmacokinetic properties of macrocycles, while ensuring their effective target engagement. Specifically, macrocyclization increases the enzymatic stability of a peptide as compared with their linear precursors—partly by eliminating charged N- and C-termini, and partly due to the fact that conformationally distorted cyclic structures do not usually fit into endopeptidase recognition sites. In addition, cyclization preorganizes peptides, significantly reducing entropic penalty upon binding, which can translate into improved target affinity and specificity. The delineation of the structural features that govern and fine-tune cell-permeability is more challenging. A number of studies have shown that the conformational flexibility of macrocycles is one of the key facilitating factors for passive membrane permeability. Using simple model systems, it was previously demonstrated that the formation of internal hydrogen bonds in nonpolar media correlates with passive diffusion.[35–39] To further elucidate the determinants of passive cellular permeability, 62 systematically modified cyclic hexapeptides were studied via Caco-2 and parallel artificial membrane permeability (PAMPA) assays.[40] The study correlated cell-permeability with experimentally measured physicochemical properties, such as lipophilicity and solvent interactions. The authors proposed an "island of permeability" to understand the peptide features contributing to cellular uptake. The developed model was supported by molecular dynamics simulations, which related experimental observations to predicted three-dimensional (3D) structures.

In the most recent study, Jacobson and Lokey elucidated the passive membrane diffusion of 39 cyclic peptide natural products using a PAMPA assay. Additionally, they applied a computational algorithm to predict the passive permeability of the same peptides based on their known or predicted 3D structures. The study highlighted a few conformational and structural features that were

common characteristics of permeable cyclic peptides. Consistent with previous findings, they emphasized the importance of peptide conformation with respect to cellular permeation. Specifically, *N*-methylation patterns, modified backbone stereochemistry, and stabilized structures with intramolecular hydrogen bonding were frequently observed. Furthermore, depsipeptide linkages and thiazole/oxazole rings were highlighted as new strategies to eliminate or tie-up backbone amide NH groups. Interestingly, the structure-based in silico model was successful in predicting permeation for only those molecules where experimental 3D structures were known. This fact emphasizes that structure determination methods, such as NMR and X-ray crystallography, are essential sources of experimental data because it remains challenging to accurately predict relevant 3D conformations of macrocyclic molecules. The study also reported a number of new chemical scaffolds that demonstrated passive membrane permeability. These results highlight that peptides derived from natural sources could be used as the basis for structural information to guide the design of compounds with drug-like properties. However, the challenge remains in understanding, at a molecular level, what makes macrocyclic peptides cell-permeable.

In the past, backbone-modified macrocyclic peptides were mainly isolated form living organisms. The discovery and development of such ligands required the synthesis of large macrocyclic libraries with diverse backbone modifications, which was a challenge for synthetic chemists. Today, advances in biological selection technologies, coupled with creative synthetic approaches, allow us to pursue the systematic exploration of the macrocyclic peptide chemical space for drug discovery. In the following section, we will highlight a few ongoing developments in the field.

1.11.2.1.2 Biological selection of backbone-modified macrocyclic peptides

It is not trivial to conduct a fast and extensive search of the backbone-modified macrocyclic peptide space for hit identification. While various synthetic platforms can generate diverse macrocycles, biological selection methods remain powerful alternatives for peptide library generation and screening. The selection techniques (e.g., phage-, ribosome-, yeast-, mRNA-display) allow for fast and cost-effective screening of very large libraries (10^9–10^{13} compounds) with the amplification of target-bound peptide sequences during iterative selection rounds. In recent years, the selection methods that produce ribosomally synthesized macrocyclic peptides have been able to generate functional diversity beyond proteinogenic amino acids by integrating synthetic groups in the displayed peptides. They usually exploit two different approaches for posttranslational peptide cyclization and chemical modification. One of them employs the selective cross-linking of natural amino acid side chains with chemical reagents. This approach constrains the linear peptide library via a synthetic linker, yielding a genetically encoded library of peptide derivatives. A remarkable number of macrocyclization chemistries have been successfully integrated with phage- and mRNA-displayed libraries.[41] Using this methodology, genetically encoded linear peptides have been converted to cyclic and bicyclic derivatives that carry various nonproteinogenic recognition moieties and functional groups.[42,43] In the most recent study, the Derda group proposed an elegant posttranslational modification of phage-displayed peptides.[44] The synthetic approach was inspired by the cyclization chemistry that utilizes 1,3-dichloroacetone, recently described by Dawson and coworkers to enhance helical secondary structures.[45] The Derda group reported phage-displayed libraries of macrocylic glycopeptides for selection of ligands for glycan-binding proteins. However, the approach could incorporate any known inhibitor, enzyme substrate, or small molecule to generate displayed libraries of macrocyclic peptide-fragment conjugates. A detailed overview of the novel strategies for cyclization of phage libraries displayed on the pIII protein of M13 phage libraries is depicted in **Fig. 1**.

In vitro selection of hybrid peptide–drug conjugates has been performed on mRNA-display libraries as well.[48] Other studies have demonstrated that high-diversity mRNA-displayed peptides can be covalently cyclized, as illustrated via the posttranslational cross-linking of the N-terminal amine and the ε-amine of a lysine side chain.[49] One of the limitations of this approach is the fact that only one chemical modification is possible per displayed library, which makes it difficult to find an optimal combination of chemical linker and peptide sequence. In their latest publication, the Derda group introduced a method of "silent barcodes" to trace the identities of multiple synthetic linkers within a mixed modified library.[50] The approach can be extended to other in vitro display technologies, such as mRNA or T7-phage.

Alternatively, to incorporate nonproteinogenic groups in the peptide chain, genetic code reprogramming is used. An mRNA-display generates large libraries ($>10^{13}$) of peptides that are covalently linked with their corresponding mRNAs.[51] The unique feature of this technology is that, when coupled with the customized in vitro translation systems, it is capable of incorporating nonnatural building blocks in macrocyclic peptides. Namely, in the reconstituted in vitro translation system protein synthesis using recombinant elements,[52–54] natural amino acids can be replaced with chemically similar and tRNA-synthetase compatible nonnatural residues. Alternatively, the flexible in vitro translation[55,56] approach relies on "flexizyme," an engineered flexible ribozyme that does not recognize the side chain or the amino group of the activated amino acid, and therefore is able to charge a wide variety of nonproteinogenic building blocks.[57]

While the selection methods described earlier can produce large lists of potential binders, it remains a challenge to rank the peptide affinities in a high-throughput manner. To address this issue, the Roberts group developed a novel approach by combining next-generation DNA sequencing and mRNA display.[58] Specifically, their high-throughput sequencing kinetics method could determine the K_{on} and K_{off} rates for thousands of ligands simultaneously without synthesizing and purifying individual peptides. A few years ago, the same group reported a two-step selection process that simultaneously selected for protease resistance and target binding.[59] These scientific advances offer a powerful technology platform with the potential to discover macrocyclic ligands with drug-like properties for a wide variety of therapeutic targets. Based on a report from 2014, 68 macrocyclic drugs on the market were almost equally distributed between two classes of compounds—cyclic peptides and macrolides; all peptides were delivered parenterally, except for CSA.[60] It is promising that, in clinical trials, cyclic peptides represented the largest group of macrocycles,

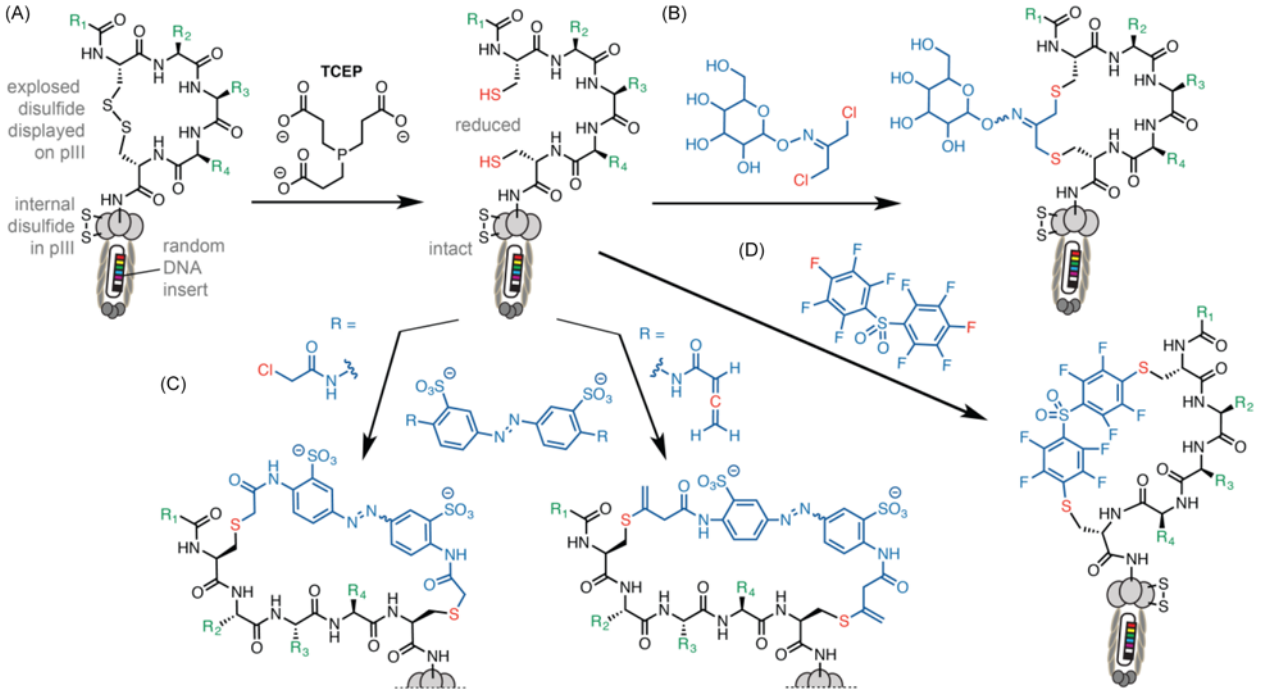

Fig. 1 Overview of the strategies for cyclization of phage libraries displayed on pIII protein of M13 phage libraries produced from commercially available vector M13KE (New England Biolabs). (A) The most critical step is regioselective reduction of phage-displayed disulfides. The bulky hydrophilic reducing agent (tris(2-carboxyethyl)phosphine) (TCEP) affords this reduction while leaving the disulfide bonds inside protein pIII intact.[42] (B) Reduced thiols can be alkylated using various dichlorooximes[44]; for example, dichlorooxime displaying a monosaccharide yields a cyclic glycopeptide. This reaction occurs specifically on displayed thiols and not on the internal thiols or any nucleophiles on phage. (C) Libraries of macrocycles that change conformation reversibly in response to light can be produced by cross-linking the thiols with light-responsive azobenzene linchpin (AZL). Bis(allenamide) AZL (left)[46] is ~30 times more reactive than bis(chloroacetamie) AZL (right).[42] (D) Modification of phage libraries by decafluorodiphenylsulfone yields libraries of macrocycles that contain hydrophobic "perfluoro-staple."[47] This figure is a courtesy of the Derda Group.

with three orally administered candidates.[60] Current research shows that CSA is not a unique example in demonstrating passive permeability in the macrocyclic peptide chemical space; there have been a number of non-CSA scaffolds reported with drug-like passive membrane transport.[37,40,61] Yet, it remains to be seen if we can discover and develop new peptides into orally bioavailable drugs. The challenge to understand how to find and validate successful cell-permeable macrocyclic inhibitors for intracellular targets with desired in vivo activities still remains. Correlating structural features with permeability and bioavailability will be an important driver in this field; it will help design macrocyclic structures that are well suited for targeting intracellular PPIs that remain out of the reach of antibody or protein therapeutics.

1.11.2.1.3 Stable peptide frameworks for therapeutic applications

Chemically constraining peptide secondary structures to their biologically active conformations is a well-established approach in peptidic drug design. Carefully mimicking and/or stabilizing specific structural elements at PPI recognition interfaces has become the main strategy for the rational design of synthetic ligands which selectively modulate PPIs.[62] A number of computational methods were developed to find druggable pockets on protein targets,[62a] or to identify the residues and/or peptide segments that have the highest impact on binding interactions. Recently published algorithms allow for a systematic search of the Protein Data Bank database using customizable parameters[63] to find α-helix-,[64,65] β-strands-, or loop-mediated PPI interfaces.[63] Validated in silico tools are routinely used to select peptide fragments that are viable starting points for PPI inhibitor design.[66] Numerous synthetic approaches have been developed for peptide stabilization; this stabilization mimics specific secondary structures and confers chemical/enzymatic stability, as well as increased potency and selectivity.[67,67a] These methodologies have delivered a number of successful PPI inhibitors with remarkable in vitro and in vivo bioactivities when it comes to extracellular targets. However, reaching the desired in vivo efficacy is still a challenge when targeting intracellular PPIs, since designing cell-permeability rationally within an active molecule is not a straightforward task.

Disulfide-rich peptides with well-defined 3D frameworks are a fascinating class of molecules with tremendous potential for therapeutic applications (Fig. 2). Sunflower trypsin inhibitors (SFTI), Θ-defensins, and cyclotides are peptide families of various size and complexity that naturally incorporate not only disulfide bonds, but also head-to-tail cyclization. These molecules are characterized by exceptional stability and low toxicity. Their loop regions, which are important for molecular recognition, are very tolerant to sequence substitutions. This allows for the grafting of various bioactive peptides into their stable frameworks, making them

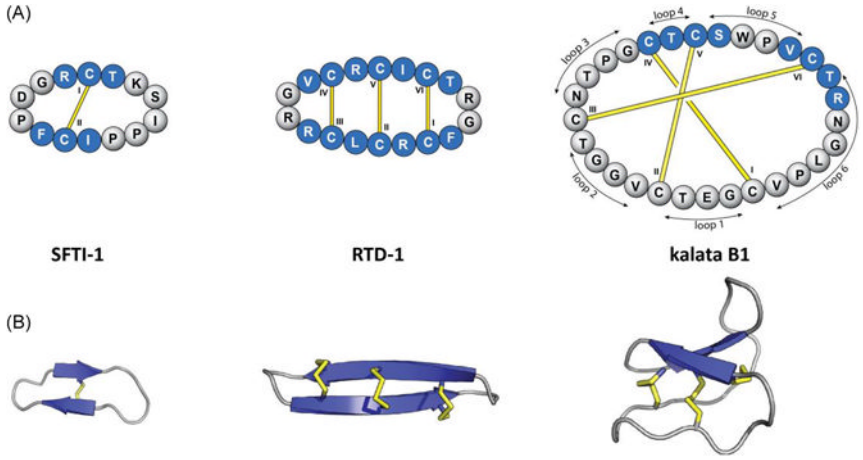

Fig. 2 Sequences and structures of three disulfide-rich peptide families, represented by SFTI-1 (PDB ID: 1JBL), RTD-1 (PDB ID: 2LYF), and kalata B1 (PDB ID: 1NB1). (A) β-Sheets are depicted in *blue* and disulfide bonds in *yellow*. For the disulfide connectivity, cysteine residues are identified using roman numerals. The sequences are drawn in a clockwise direction for each peptide. (B) Secondary structures of the three disulfide cyclic peptides, showing β-sheets as *arrows*. The structure of RTD-1 has been flipped 180 degrees in the horizontal plane to better show the disulfide connectivity.[68]

attractive scaffolds for drug development applications. Grafting an active peptide epitope into a well-defined 3D scaffold potentially reduces binding entropy and harnesses the intrinsic stability of the framework. Since the discovery of disulfide-rich molecular frameworks, an immense amount of research has been done on these molecules by David Craik and his team, as well as others.[68,69]

A number of successful examples have been reported for engineered cyclotides—the largest known family of cyclic peptides found in nature. This class of molecules is ribosomally produced in plants; they are defined by head-to-tail cyclized backbone and a cyclic cystine knot motif that confers exceptional thermal, chemical, and proteolytic stability. In a recent study, engineered cyclotides were designed for the treatment of multiple sclerosis.[70] Namely, a peptide epitope with the immunoregulatory function (from myelin oligodendrocyte glycoprotein) was grafted into the kalata B1 scaffold (loop 5). The results obtained in a mouse model suggest that an engineered cyclotide could be used as a stable vaccine to treat immune-mediated diseases. In another study, Craik et al. showed that cyclotides kalata B1 and MCoTI-II, as well as trypsin inhibitor SFTI-I, cross the cellular membrane by various mechanisms, hence identifying a new class of cyclic cell-penetrating peptides (CPPs).[71,72] Recently, Camarero and coworkers reported that grafted cyclotide could efficiently modulate intracellular PPI.[73] Specifically, engineered cell-permeable MCoTI-II could antagonize the interaction between the transcription factor p53, and its binding oncogenic proteins, HDM2 or HDMX, in vitro and in vivo. These findings extend the potential realm of application for disulfide-rich cyclic peptide scaffolds for intracellular targeting.

Knottins are another interesting family of disulfide-rich peptides found in fungi, plants, and animals. They possess a cystine knot core, but no head-to-tail cyclization. Native and engineered knottins are studied for diagnostic and therapeutic applications. Their engineered frameworks were shown to be effective modulators of various therapeutic targets. Several knottins have already reached clinical trials. The first FDA-approved knottin on the market is a synthetic version of the MVIIA conotoxin that originates from the cone snail venom. The peptide was approved for intrathecal use to treat chronic pain under the generic name Ziconotide (distributed as Prialt®).

Another native knottin chlorotoxin, derived from scorpion venom, was found to preferentially bind malignant glioma cells when conjugated to a near-infrared dye. The chlorotoxin is being developed in the clinic as "tumor paint"—an optical imaging contrast agent to help surgeons differentiate between cancerous and healthy tissues during surgery.[74]

In the most recent study, the Cochran group synthesized and studied a series of knottin peptide–drug conjugates (KDC) (**Fig. 3A**). The results demonstrated that the KDC could deliver gemcitabine to malignant cells, which express tumor-associated integrins.[75] The evidence shows that this knottin–drug conjugate binds to tumor cells with low nanomolar affinity, is internalized by an integrin-mediated mechanism, and acts as a highly potent inhibitor of several malignant cell lines as the drug payload is released intracellularly. The same team has previously labeled knottins with various tags including fluorescent small molecules, radioisotopes, and ultrasound contrast reagents (**Fig. 2B**). They demonstrated that labeled knottins can be used for the in vivo imaging of tumors in mice.

Due to their small size, knottins allow for easy synthesis and have the potential for better tumor penetration.[76] If cell- and tissue-specific targeting is tuned effectively, these peptide-small molecule constructs can potentially overcome the limitations of antibody–drug conjugates (ADCs).

1.11.2.2 Immune Targets and Vaccines

Targeting of the immune system with vaccines for treating infectious diseases is probably one of the most successful medical innovations to date. Prophylactic vaccines have helped us combat and eliminate the morbidity associated with several deadly infectious

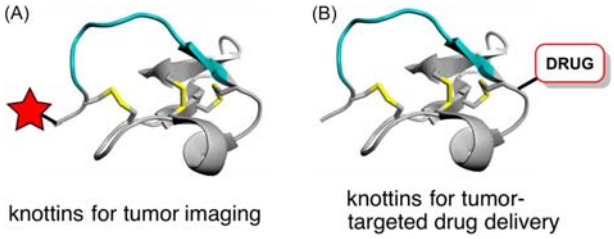

Fig. 3 (A) Knottins labeled with fluorescent small molecules, radioisotopes, or ultrasound contrast reagents for tumor-imaging. Integrin-Targeting Knottin Peptide-Drug Conjugates Are Potent Inhibitors of Tumor Cell Proliferation. *Angew. Chem. Int. Ed. Engl.* **2016**, *55*, 9894–9897. Copyright Wiley-VCH Verlag GmbH & Co. KGaA.

diseases such as diphtheria, smallpox, polio, measles, mumps, and rubella. Vaccines were traditionally made from attenuated live organisms (bacteria or viruses) or whole inactivated pathogens.[77] For example, the bacillus Calmette-Guérin vaccine is an attenuated form of the *Mycobacterium bovis*. This vaccine, initially used against tuberculosis, is widely used today in the treatment of non-muscle invasive bladder cancer due to its ability to enhance tumor immune responses.[78] The early generations of vaccines involved the creation of inactivated or attenuated pathogens, or toxoids from pathogens, as therapeutic agents. However, these strategies carry a number of challenges, including the risk of infection, the reversion of the virulence induced by mutations, undesirable reactions to the vaccine components, and the inability to develop effective vaccines against pathogens that are difficult to grow in cultures or ones that present hypervariable antigens. The variability between batches and strains, the heterogeneity in vaccine mixtures, and the strict conditions in manufacturing, storage, and handling[79] create additional development and production challenges, not to mention that the development process can be slow and time-consuming. In response to these challenges, the field has moved on to the concept of "subunit" vaccines, where specific portions or subunits of antigens are used as immunostimulatory agents. One of the limitations of subunit vaccines is that they are not as immunogenic as those with whole pathogens.

One way of boosting immunogenicity of subunit vaccines is to use them in conjunction with "adjuvants" which serve to boost host immune responses. There are two types of adjuvants, namely immune potentiators that stimulate the immune system, and delivery systems that deliver and present antigens to the immune system in an effective manner. In 2014, the NIH reported that better adjuvants are needed, and committed up to $70 million over the next 5 years to new adjuvant research.[80] The field of adjuvant research presents some interesting opportunities for chemical design approaches, as highlighted by a recent study that demonstrated that the efficacy of vaccines can be improved through the proper design and modulation of physicochemical properties, and through the formulation of polymer carriers of toll-like receptor agonists, which are a form of vaccine adjuvants.

In order to improve immunogenicity, subunit antigens have been chemically conjugated to protein carriers such as the tetanus toxin, diphtheria toxin, or CRM197, a nontoxic variant of diphtheria toxin. Bioconjugate vaccine strategies have been fundamental to the development of highly successful vaccines such as Prevnar-13, Menactra, Menomune, and HibTiter. These were created by conjugating bacterial polysaccharides to immunogenic carrier proteins. The evolution of conjugation strategies and its impact on therapeutic practice is evident in the development of Prevnar, Synflorix, and Prevnar-13, which are conjugate vaccines of cell capsule sugars from 7, 10, and 13 serotypes, respectively. The field of generating antigen conjugates, where the antigens are displayed in specific repetitive arrays on various polymers and carrier proteins, is a growing area of research and promises the opportunity to create more effective and potent vaccines. Another advancement in the vaccine field is the concept of reverse vaccinology and structural vaccinology, wherein the combination of human immunology, structural biology, and bioinformatics is applied rigorously to identify antigenic epitopes. The rational design of vaccines is challenging and requires crystallographic analyses and computational modeling, along with a good understanding of immune biology, to effectively help advance the development of synthetic vaccines.[81,82] There is a growing effort to create homogeneous molecular vaccines. For example, using genetic code expansion methods (including the amber suppression technique or the rare sense codon reassignment), peptide or protein engineering can be done in a manner that allows for the break of self-tolerance.[83,84] These approaches will allow for the preparation of highly immunogenic synthetic vaccines without the need for carrier protein bioconjugations.

The success with prophylactic vaccines and the advances in knowledge-based immunogen design and conjugation strategies have created opportunities for deploying "therapeutic vaccines." Therapeutic vaccines are intended to activate the immune system to recognize and combat existing infections or diseased cells. Much of the work in the therapeutic vaccine space to date has focused on trying to harness the immune system to recognize and eliminate cancer cells. Dendreon's Provenge (Sipuleucel-T) became the first FDA-approved therapeutic vaccine when it received approval for treatment of metastatic prostate cancer in 2010. Since then, there have been others: a cholesterol-lowering vaccine that targets pcsk9, antinicotine vaccines to aid in smoking cessation, and anti-cocaine vaccines for treating cocaine addiction. There are multiple cancer vaccines currently in clinical trials for a range of different solid tumors. Carbohydrates, proteins, peptides, glycopeptides, and glycolipids have been used as antigens in these approaches. For example, recent progress has been made in the field of peptide vaccination to mimic T-cell epitopes and to trigger an effective engagement of the immune system, particularly in combinatory regimens.[85,86] As a result, a large number of peptide vaccinations for solid tumors are currently in clinical trials, such as those targeting HER2, IDO, and IDH1. The design of such peptides takes advantage of the new immunoinformatic tools that combine both computational and experimental epitope mapping for optimal

immunogenicity prediction.[87–89] Yet, the peptide vaccination field is still experiencing some difficulties, such as the delivery route, the low intrinsic immunogenicity of individual peptides, the ability to predict the immune response of a pool of epitopes, and also the need to mimic both linear and conformational B-cell epitopes.[90] Answering these questions will be an exciting challenge to be met in the effort to broadly increase the use of peptide vaccination in cancer therapy and in combinatory regimens in the coming years.

In addition to vaccines, the field of immunooncology has seen an explosive growth, as strategies to activate patients' immune system by blocking immunosuppressive checkpoints in the tumor microenvironment have been successful in the clinic.[91] The FDA-approved anti-CTLA4 and anti-PD1 antibodies for the treatment of melanoma greatly improved the overall survival of patients.[92,93] There are growing opportunities for small molecules to become important players in the immunooncology space. Similarly, peptides, macrocycles, or tumor-directing bispecific constructs and conjugates could also present interesting opportunities for medicinal chemistry approaches in this field.

1.11.2.3 Oligonucleotides and Oligonucleotide Drugs

The number of small molecules or natural products which target and interact with nucleic acids are relatively limited. They include a few cytotoxic chemotherapeutic agents that target DNA, a few aminoglycoside and macrolide antibiotics that target bacterial RNA, and antimetabolites, which interfere with DNA synthesis and are used as anticancer and antiviral agents.[94] Over the last two decades, there has been a tremendous explosion in the understanding of RNA biology. This has led to surprising insights into the structure, function, and mechanism of how RNA molecules control and regulate various cellular processes. RNA can be broadly grouped into molecules that are directly involved in translating and coding for proteins, exemplified by mRNA and the noncoding RNAs that do not directly encode proteins but regulate gene expression through indirect mechanisms. The increased understanding of the role that RNA plays in cellular processes and its role in disease biology has opened up the RNA field as an exciting therapeutic target. RNA targeting is an attractive approach for protein targets that are inaccessible to small molecules, proteins, and peptides, and it has the potential to significantly expand the universe of druggable targets.[95] Antisense oligonucleotides (ASOs) represent a broad class of oligonucleotide (ONT) drugs that bind a target RNA and modulate its function by interfering with its translation, or by causing a degradation of target RNA. There are two main types of ASOs, namely RNAse H-dependent ASOs and small-interfering RNAs (siRNAs). RNAse H-dependent ASOs are single-stranded ONTs that bind target mRNAs and reduce gene expression by sterically blocking the ribosomes and RNAse H-mediated cleavage of the mRNA. siRNAs, on the other hand, are double-stranded RNAs which inhibit gene expression by causing the destruction of the target RNA via RNAse Argonaute 2. In addition to mRNA, other RNA targets that are of great interest include micro RNA (miRNA), exon skipping RNAs, and long noncoding RNAs.

There are tremendous opportunities for medicinal chemistry in the RNA field. It has been clearly demonstrated that it is possible to modulate the potency, stability, toxicity, biodistribution, and pharmacokinetic behavior of ONTs through chemical design and structural modifications. SAR studies can be built around the design of a specific ONT sequence and combinations of specific structural modifications in the nucleobase, sugar, or the phosphodiester linkages. ONT drugs need to be taken up in cells in order to be active. There are opportunities for chemists to modify the physicochemical properties of ONT, as well as to design and develop such formulation and delivery vehicles that increase cellular uptake, as well as target the delivery of ONTs to specific tissues. Over the last 13 years, two single-stranded ASO drugs (fomivirsen and mipomersen) have reached the market. Fomivirsen was developed in 1998 to block the translation of viral mRNAs in immunocompromised patients with cytomegalovirus retinitis, but was discontinued due to low demand.[96] Mipomersen was approved by the FDA in 2013 to inhibit apolipoprotein B mRNA in patients with familial hypercholesterolemia, a rare genetic disorder that leads to excessive levels of low-density lipoprotein cholesterol.[97] More than 30 ASOs are currently at various stages of clinical development in efforts to reduce the overexpression of genes associated with cancer, diabetes, cardiovascular, and inflammatory disorders, and other rare diseases.[98] For example, mongersen, an oral SMAD7 ASO, targets SMAD7 overexpression leading to Crohn's disease-related inflammation.[99] Other examples include oblimersen, an intravenous infusion of bcl-2 antisense oligodeoxynucleotide in Phase 1 clinial trials for patients with solid tumors,[100] and BL-7040, an orally available synthetic ONT in development for the treatment of inflammatory bowel disease.[101] To date, half of these studies correspond to the development of ONT therapeutics targeting hepatocyte-expressed genes in the liver (an organ that plays a major role in metabolism and secretion of carrier proteins, coagulation factors, hormones, and apolipoproteins).[102] In addition, it has been shown that phosphorothioate-modified ASOs accumulate in the liver, rendering it an attractive space for this class of drugs.[103] However, a broader clinical translation of ONT therapeutics is still hampered by their challenging delivery.

Alternatively, nonnucleotide small molecules that selectively target specific RNAs were also developed. For instance, some antibiotics, such as aminoglycosides and tetracyclines, are able to target RNA structures in the ribosome (rRNA) of bacteria, and thereby alter their growth.[104] Synthetic small molecules were also used to target DM1, a mutated gene in the context of myotonic dystrophies.[105] Increasing the affinity of synthetic small molecules to RNA could be achieved by rendering them positively charged, allowing them to bind strongly to negative-charged RNA. It remains challenging, however, to optimize the physicochemical properties of small molecules, such as hydrophobicity and aromaticity, to make them more selective to specific RNAs.

Nonetheless, RNAi-based biologic therapies can provide greater target specificity than small molecules and they can also target intracellular proteins that are difficult to reach with mAbs. Significant efforts are underway for modulating their tissue distribution and toxicity profile. For instance, siRNAs can be covalently conjugated with *N*-acetylgalactosamine (GalNAc), a ligand for the asialoglycoprotein receptor (ASGPR) which is expressed on the cell surface of hepatocytes, allowing a specific delivery of RNAi to target tissues.[106] siRNAs can also be complexed with peptides designed to penetrate tumors and pass through the tumor cell membranes.

Table 2 Injectable programs in Phase 2 and Phase 3 clinical trials by molecule type[109]

Modality	*Phase 3 (%)*	*Phase 2 (%)*

PharmaCycle products and pipeline module.

For instance, siRNAs targeting the ID4 oncogene, coupled with specific tumor peptides containing cyclic nonapeptide LyP-1 (CGNKRTRGC) and capable of tumor-homing and penetration, were shown to be effective in treating ovarian tumors in mice.[107] siRNAs could be also wrapped in lipopeptide nanoparticles (NP), which have been shown to offer 100 times the potency of naked design, and would thereby allow lower doses of ONT molecules as well as a better toxicity profile in rodents and primates.[108] Further investigations around the delivery of RNAi biologic therapies could help broaden their use in cancer therapy and beyond.

1.11.3 Targeted Delivery of Next-Generation Therapeutics

Significant advances have been made in the discovery of highly potent and selective biologic drugs in the past few decades. This progress, in combination with the decline in small molecule discovery programs, has led to an increased acceptance of injectable drugs. Not surprisingly, all 7 biologics from the top 10 selling drugs (see **Table 1**) are injectables. Moreover, the majority of the developing pipeline for injectables consists of various biologics, including siRNA, peptide, protein, and antibody therapeutics (**Table 2**).[109] mAbs, for example, are routinely administered via intravenous or subcutaneous injection. Given the long-circulating half-life of most mAbs, weekly, monthly, or even less frequent injections is adequate to get the desired exposure with these therapeutic agents. Thus, injectables in patient friendly formats can significantly improve compliance and potentially bypass the problem of poor oral bioavailability for biologics. Yet, achieving adequate exposure and distribution of peptide, protein, and ONT-based therapeutics remains a key issue in drug development, as these molecules often exhibit a short plasma half-life and low cellular uptake. The short exposure/PK profile is generally due to proteolysis and poor metabolic stability,[110] while the low cellular uptake is associated with the large molecular weight and physicochemical properties of biologics. A wide range of methodologies are continuously being explored to overcome these challenges, leading to the development of novel formulations and delivery technologies.

To create peptide/protein drugs that have longer duration of action, improved PK profile, and more compliant dosing regimens, the bioconjugation to polymeric carriers has been used routinely.[111–116] The most advanced bioconjugation technology is PEGylation, with the first PEGylated molecule, Adagen®, having been approved by the FDA in 1990. Since then, more than 10 PEGylated biologics have been approved by the FDA, with a similar number going through clinical trials.[116] Bioconjugation to other carriers such as antibodies, Fc-fragments, sialic acid polymers, lipids, and polypeptide fragments continues to be investigated as an alternative to the PEGylation strategy. Other technologies being explored include lentiviral particles (e.g., MS2-chimeric retrovirus-like particles),[117] lipid-based technologies (e.g., liposomes, Saint-PhD)[118,119] NP (e.g., Nanocin),[120] supercharged proteins (e.g., β-defensin-3),[121] inactivated toxins (e.g., anthrax toxin),[122] and CPPs (e.g., PepFects).[123,124] These strategies may help to improve the bioavailability of different types of biologics (DNA, RNA, peptide, protein, vaccines) by preventing proteolytic and enzymatic degradation, or by increasing their cellular uptake via different mechanisms of cell entry, including direct membrane translocation and endosomal entry/escape.

Another aspect, as important as the PK profile and cellular uptake, is the delivery of drugs specifically to cells of interest. When a therapeutic agent affects healthy tissue, patients may experience side effects which limit the dose of the drug. One way to improve the efficacy and tolerability of therapeutics is to alter their biodistribution by selectively delivering them into diseased cells. Targeted delivery is a strategy that is used to achieve cell-specific drug delivery via receptor-mediated endocytosis or transcytosis. Receptor-mediated endocytosis is the key mechanism that facilitates internalization of the receptor–ligand complexes. Receptor-mediated transcytosis (RMT) is defined as transporting macromolecular cargo from one side of the cell to the other within

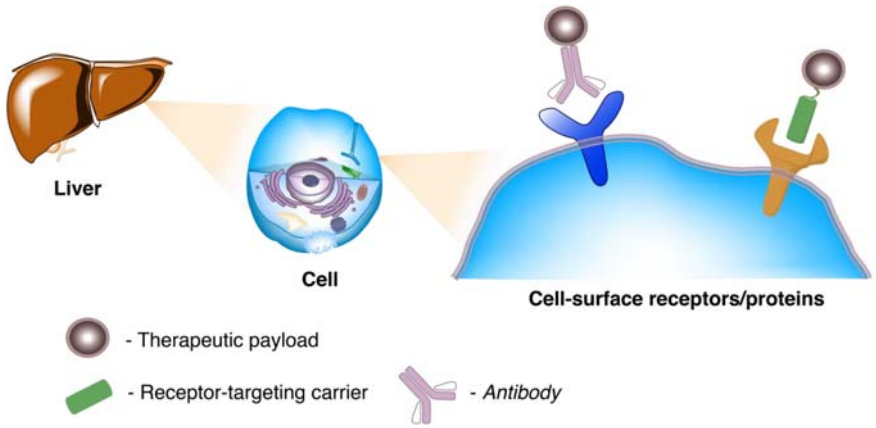

Fig. 4 Cartoon diagram illustrating targeted drug delivery to liver.

membrane-bound carriers(s).[125] Receptor-mediated endocytosis is the key mechanism that facilitates internalization of the receptor–ligand complexes. The approach takes advantage of cell-surface receptors or proteins that are overexpressed in different tissue types, malignant cells, or tumor microenvironments. Ligands, which bind to these proteins, act as targeting agents and transport conjugated therapeutics to the specific cells. Cytotoxic dugs, imaging agents, radionuclides, and miRNAs are some examples of therapeutic cargos that have been successfully delivered by this approach. The receptor-targeting moieties, as shown in Fig. 4, include antibodies and their derivatives, peptides, carbohydrates, aptamers, and nonantibody proteins.

In this section, we discuss current research in efforts to deliver biotherapeutics to the intracellular space. Initially, we review CPP-mediated delivery of drugs, their cellular uptake mechanisms, and the design principles that guide peptide cell-permeability. In subsequent sections, we highlight recent developments and challenges in those targeted therapies that utilize transcytosis or endocytosis, the internalization mechanism of overexpressed receptors, to deliver bioconjugates to the site of action.

1.11.3.1 CPPs as Delivery Vectors

Living cells tightly and selectively control the translocation of various molecules through the plasma membrane by utilizing ion channels, carrier proteins, or their innate endocytic uptake mechanism. However, it is known that chemically intractable proteins, which represent a vast majority (>80%) of the human proteome, reside in the intracellular space.[126] Therefore, it is essential that we find a way to efficiently deliver bioactive molecules into the cytosol and nucleus of the cell. Most small, hydrophobic organic molecules easily cross lipid bilayers by passive diffusion or carrier-mediated transport. However, as published data suggest, small molecule drugs can only target about 10% of the druggable genome.[127] For biologic drugs, on the other hand, cell-permeability is a major hurdle that impedes the realization of their full potential as pharmaceuticals. In fact, the vast majority of proteins cannot penetrate the cell.

Peptides have an inherent advantage over large biologics in crossing the cellular membrane. CPPs, also referred to as protein-transduction domains, are a specific class of molecules that are typically less than 30 amino acids long and can permeate the phospholipid bilayer without significant toxicity. CPPs can be derived from natural proteins, large combinatorial libraries of plasmid or phage displays, phylomers, as well as from de novo synthesis. A number of excellent reviews have described and classified known CPPs based on their origin and physicochemical properties.[128–130]

CPPs are used for a number of applications such as: (1) elucidating the mechanism of cell entry; (2) acting as vectors to transport various attached cargos, including small RNA/DNA, antibodies, and NP; and (3) designing functional cell-permeable peptides by incorporating bioactive motifs within the CPP sequence. The design rules, however, of grafting active domains remain elusive and difficult to distill. Currently, one of the most popular approaches for the intracellular delivery of biologic drugs in vivo is their fusion to CPPs, as are described in recent reviews.[129–131] Other approaches have also been studied and reported, including the conjugation of biologics to receptor ligands, cell-penetrating proteins, and lipid NP.

1.11.3.1.1 Cellular uptake pathways for drug delivery with CPPs

In the past, understanding the mechanism for the cellular uptake of CPPs has been a topic of debate as earlier experiments reported contradictory results. This was due, partly, to the unrecognized artifacts of flow cytometry and fluorescence microscopy of fixed cells. It was not trivial to distinguish between fluorescent groups that are bound to the cell surface and those that are taken up by the cell.[132] Furthermore, while labeling CPPs fluorescently is one of the most convenient ways to monitor cellular uptake, it was demonstrated that the addition of a hydrophobic fluorescent dye could in fact alter the cellular interaction mechanism.[133] Another common practice to study various routes of endocytosis is the use of chemical inhibitors. However, these methods have limitations, and they are often highly dependent on the specific cell line used.[132] Therefore, the experimental results should be interpreted

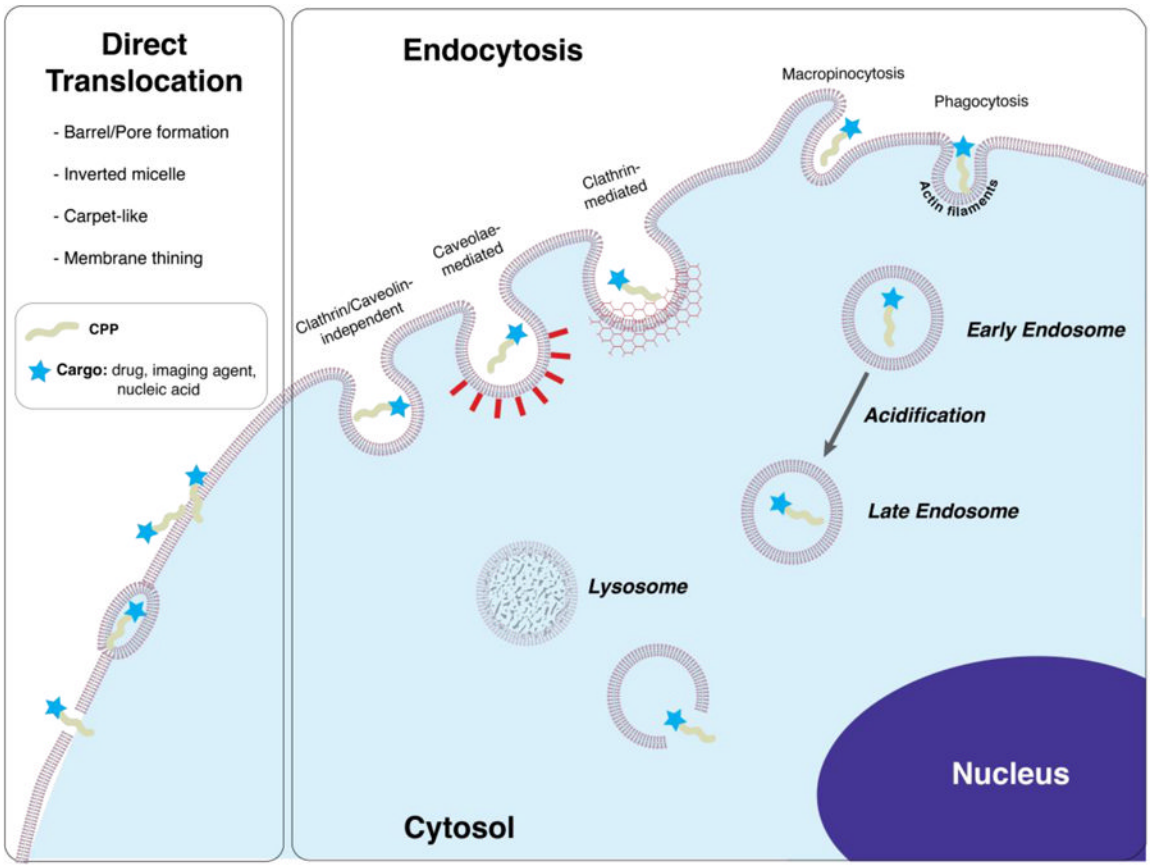

Fig. 5 Entry pathways of cell-permeable peptides.

carefully. Based on accumulated data and experience, subsequent studies of the permeability mechanism were better able to differentiate between cellular binding, cellular endocytic uptake, and direct translocation.[131,134] It was consequently recognized that the uptake mechanism depends on the CPP sequence, its concentration, the physicochemical nature of the attached cargo, the type of cell line, the incubation time, and the temperature. It has been reported that each CPP could utilize more than one uptake mechanism depending on the conditions. In addition, endocytosis and direct translocation could occur at the same time. These considerations make it difficult to describe the complex process of cellular uptake with a common set of rules.

For arginine-rich CPPs, direct translocation is the primary mechanism at low CPP concentrations, which is a receptor-independent route of cell entry. Above 2 μM, this mechanism is replaced by endocytosis, and at concentrations higher than 10 μM, rapid cytoplasmic entry takes place via transduction.[135]

Fig. 5 provides a summary of major cellular uptake mechanisms, such as direct translocation and endocytosis. The latter includes different mechanistic pathways such as macropinocytosis, clathrin- or dynamin-dependent uptake, and caveolae/lipid raft-mediated endocytosis. A number of review papers delve into the subject in more detail.[136–139]

1.11.3.1.2 Molecular determinants of cell-permeability

Despite extensive research conducted within the past decade, the general requirements of the structure–transport relationship for cellular permeability of peptides are not well understood. Nevertheless, it is widely recognized that the internalization pathway is chosen depending on the character and the strength of the initial interaction of a CPP with the plasma membrane.[140] The initial step in cellular uptake often involves the electrostatic interaction between positively charged peptides and negatively charged phospholipids or the proteoglycans on the cell surface. While this step is not required for cellular entry, the number and nature of positively charged groups can have a tremendous effect. Experimental data have demonstrated that the uptake rate is higher for those CPP sequences that contain arginine instead of lysine. This phenomenon is attributed to the unique ability of guanidinium headgroups to form bidentate hydrogen bonds with negatively charged groups on the cell surface.[137,141] Interestingly, as described in a recent review by Lonn and Dowdy,[142] efficient transduction of TAT (peptide responsible for the uptake of transactivator protein) can occur in cell lines that are deficient in glycosaminoglycans and sialic acids. However, enzymatic removal of cell-surface proteins completely abrogates TAT-mediated transport. The data suggest that interaction with cell-surface proteins is an important step for initiation of macropinocytotic TAT uptake.[143]

Furthermore, hydrophobic side chains—especially aromatic groups—are also believed to enhance the translocation ability of CPPs, as they strongly influence peptide–lipid interaction. It has been shown that intracellular localization and the efficiency of oligoarginine-based CPPs could be tuned via the introduction of tryptophan residues.[144] Specifically, the number and distribution of tryptophans has affected the cellular uptake mechanism as CPP analogs were internalized via endocytic and/or nonendocytic pathways.

The correlation between the secondary structure of peptides and their ability to permeate the cell remains unclear. While most CPPs are unstructured in aqueous solution, many adopt a range of conformations (α-helix, β-strand, β-turn) during their interaction with various lipid environments and membrane mimetics.[145] This variability in their structure could be detected within the same peptide sequence due to different cellular environments and experimental conditions. One commonly observed feature is amphipathicity, which leads to the classification of CPPs in three structural classes: primary amphipathic, secondary amphipathic, and nonamphipathic. Specific peptide sequences and their uptake mechanisms are well documented in recently published comprehensive reviews.[146,147]

Various structural elements are found in secondary amphipathic peptides, including polyproline II, β-sheets, and α-helices. One of the common motifs, the amphipathic α-helix, has a hydrophobic patch on one face. However, the other faces of helical CPPs vary between cationic, anionic, or polar.[128] Hence, when it comes to efficient cellular entry, the general rules and requirements for secondary structure elements are difficult to delineate. Evidence suggests that helix stabilization often results in more efficient membrane translocation.[148] In a recent study, an arginine-based peptide was elegantly designed into an α-helical shape by incorporating novel nonproteinogenic amino acids.[149] When intracellular uptake was examined, the data showed that stable α-helical structures entered cells more efficiently than the corresponding nonhelical arginine nonapeptide (R_9). Nonetheless, helicity is not generally necessary to achieve efficient cellular uptake, as different peptide conformations can trigger different uptake mechanisms. A number of studies have found that cyclization could also enhance cell-permeability of arginine-rich CPPs.[148] In contrast, Medina et al. recently reported a constitutively disordered, arginine-rich peptide, CLIP6, which directly translocates through the cell membrane without folding. CLIP6 demonstrated an exclusively nonendosomal cell entry mechanism, and avoided lytic conformation due to its disordered state.[150] Hence, conformational flexibility might be the most important feature of CPPs when interacting with various lipids, because peptides can adapt their structure to specific environments and determine their route of entry.[137] More importantly, experimental evidence obtained so far suggests that each cellular uptake mechanism might have its own structure–transport relationship.[135] However, without a full understanding of the molecular interactions that trigger efficient internalization of peptides, it remains a pervasive challenge to rationally design and tune cell-permeability.

1.11.3.1.3 Enhancing endosomal escape of biologic drugs

Endocytic trafficking is one of the major challenges that limit the intracellular delivery of therapeutic agents. While some advances have been made, novel methodologies are developed continuously to improve the efficient cytosolic entry of biologic drugs.

At high concentrations (>10 M), some CPPs have been shown to predominantly penetrate the cellular membrane via direct transduction.[135] However, it is generally believed that most positively charged CPP sequences, which bind to the cell surface, enter the cell by at least one of the endocytic mechanisms that form endocytic vesicles. As a result, the CPP-cargo conjugate is predominantly entrapped in the endosomes, and eventually it either becomes enzymatically degraded in the lysosomes or recycled back to the cell surface. Therefore, a large fraction of biological agents does not reach intracellular target proteins in vivo. Consequently, a high concentration of an active compound is required for efficient cytosolic delivery and for the desired biological efficacy on intracellular targets.

It has been shown that certain types of proteins are also able to deliver attached cargos (proteins, peptides, and nucleic acids) into mammalian cells. An example is a class of superpositively charged proteins such as +36 GFP.[151] These proteins have demonstrated effective intracellular delivery of conjugated cargo, but a significant fraction of them remains trapped in endosomes.

Endosomal release has been studied extensively in recent years to address the problem of endosomal localization of biologics. New technologies have enabled the identification of a number of mechanisms, including pore formation, the pH-buffering effect, conformational change, and the photochemical disruption of the endosomal membrane. Based on this knowledge, various chemical agents have been designed and tested to achieve the safe and efficient release of therapeutics into the cytosol. Some important considerations for the escape agent include low immunogenicity and toxicity, as well as affordable manufacturing cost for large-scale production. Furthermore, the endosomal escape properties of the agent should not depend drastically on the nature of the attached cargo. We will highlight a few examples in this article, while more detailed reviews on this topic can be found in recent publications.[152,153]

One of the strategies used to achieve efficient cytosolic delivery is based on the discovery of peptide sequences that can facilitate the early endosomal escape of conjugated cargo molecules. A recent study demonstrated the successful use of such peptides to enhance the endosomal escape of protein cargos fused to +36 GFP.[154] In order to find endosomolytic peptide sequences, authors cleverly screened a panel of known antimicrobial peptides which disrupt microbial membranes without mammalian cell toxicity. One of the key challenges in testing such peptides is the lack of general assays that can differentiate between proteins that are trapped inside the endosomes, from proteins that have been released into the cytosol. It is usually necessary to assemble multiple independent assays, and to combine the results with mutational studies. As a result of these efforts, a 13-residue peptide called aurein 1.2 was discovered. This peptide was able to significantly enhance the cytosolic delivery of proteins and their cargos in cell culture and in vivo. It was shown that aurein 1.2 facilitates endosomal escape in a cargo-independent manner.

A recent study has reported the discovery of rationally designed miniature proteins with arginine residues at various positions on the helical surface of the hairpin fold.[155] These miniproteins reach the cytosol through rapid internalization, followed by early endosomal release. A similar uptake pathway was detected for a novel cyclic amphipathic peptide, cFΦR4, which enters cells through multiple endocytic mechanisms and promotes an early endosomal release of its cargo.[156] cFΦR4 is one of the most active transporter peptides known today that delivers active biologics directly into the cytoplasm. However, the exact mechanism of endosomal escape remains to be determined.

Other strategies that can improve endosomal escape efficiency include the proton-sponge effect, multivalent CPPs, and those that mimic the mechanisms of enveloped viruses releasing viral capsid into the cytoplasm.[142] While some progress has been made with these strategies, the endosomal entrapment remains one of the major hurdles of CPP-mediated delivery of biologic drugs.

1.11.3.2 Targeting Specific Tissues

Targeting tumor cell-specific receptors is an approach widely used to deliver ligand-conjugated therapeutic payloads to malignant cells. When ligand binds to a cell-surface receptor, receptor-mediated endocytosis takes place triggering innate internalization of the receptor–ligand complex within clathrin-coated vesicles (Fig. 6). This process is usually preceded by downstream signaling. Often, the ligand dissociates from the receptor in the acidic environment of the late endosome. Subsequently, the receptor can be either recycled to the membrane for another round of signaling/internalization, or transferred to the lysosomes, along with the ligand, for degradation. The fate of the ligand internalized via receptor-mediated endocytosis tends to be degradation via the lysosomes. Therefore, endocytic escape is required if the drug needs to reach its biological target inside the cell. While the therapeutic effect of a ligand-conjugated payload depends on the potency of the payload, the drug should also be metabolically stable, and there should not be any loss due to its excretion. In addition, it is important to estimate the minimal level (or absolute number) of receptor expression that is necessary to deliver the sufficient amount of a drug, as well as the ratio of receptor expression in diseased versus healthy tissue, and the rate of internalization and recycling.

Ligands that internalize via receptor-mediated endocytosis include hormones, growth factors, small molecules, toxins, lectins, viruses, antibodies, and serum transport proteins.

The main criterion for the selection of a receptor is its distribution pattern. The higher the receptor upregulation level on malignant relative to normal cells, the better the specificity of targeted delivery and the lower the toxic side effects from the exposure of healthy cells to the drug. While a high overexpression ratio (tumor vs. normal) is required, many receptor-targeted therapeutics in

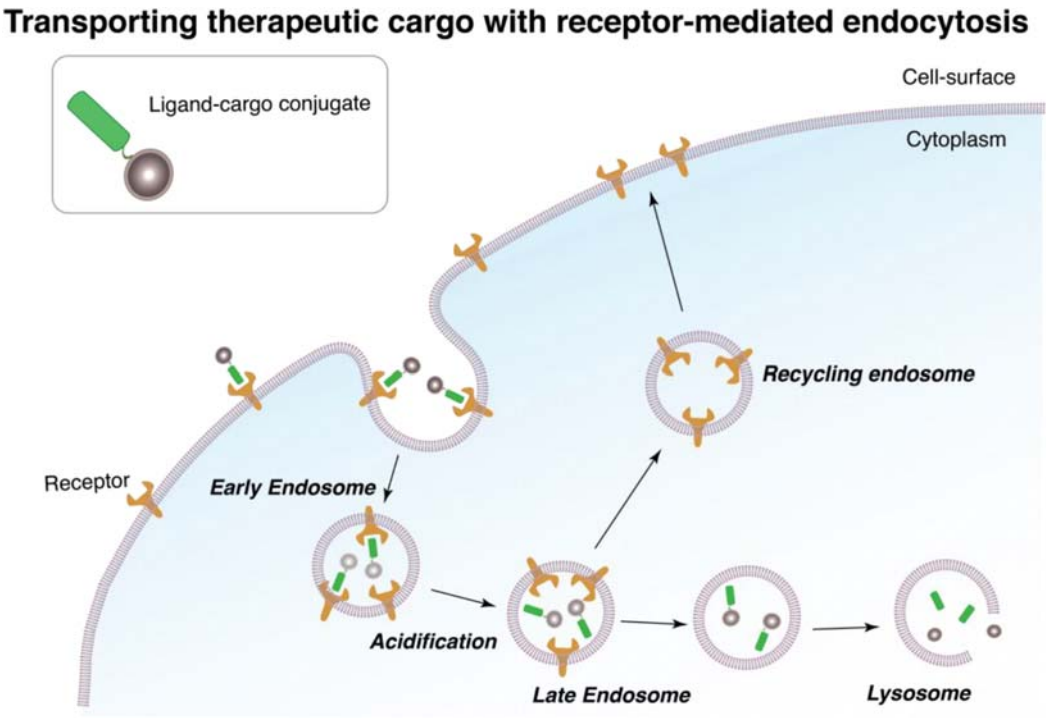

Fig. 6 Schematic representation of receptor-mediated endocytosis: a ligand in the extracellular space binds to its target receptor and triggers signaling/internalization of the receptor–ligand complex. Common compartments during the intracellular trafficking are shown: early endosome, late endosome where dissociation of the receptor–ligand may happen, recycling of receptors to the cell surface, and releasing the attached payload into the cytoplasm.

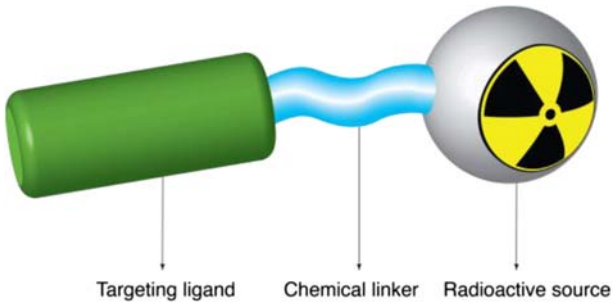

Fig. 7 A schematic representation of a conjugate with a radioactive source as a therapeutic, diagnostic, or imaging agent.

the clinic only show a two- or threefold difference in receptor upregulation, which is still an improvement in comparison to non-targeted therapy.[157] One factor that amplifies specificity of targeted delivery besides the overexpression ratio is the receptor recycling rate, which is usually greater in malignant cells and translates into increased drug transport.

It is important to note that receptor internalization is not always a necessary step in achieving the desired therapeutic effect. For example, cell-surface receptor antagonists are generally not internalized via endocytosis. Yet, they have successfully delivered drugs to tumor-specific receptors. For example, radiolabeled receptor-binding somatostatin analogs are used in peptide receptor radionuclide therapy for the treatment of neuroendocrine tumors (NETs). These antagonists have shifted the paradigm by demonstrating more favorable pharmacokinetics and better tumor visualization than agonists did. Subsequently, gastrin-releasing peptide receptor targeting antagonists showed better PK profiles and fewer side effects, showing promise in early clinical trials for prostate cancer imaging.[158]

In radionuclide therapy, a radioactive source is covalently attached or chelated to a targeting ligand via a chemical linker (**Fig. 7**), sometimes referred to as "PK modifier." The physicochemical properties of the linker dramatically influence the PK, biodistribution, tumor uptake, and rate and route of conjugate excretion, while the effectiveness of the therapy depends on the expression of the targeted receptor and the nature of the radionuclide.

Recent years have seen a tremendous growth of biological data generation. The input provided by bioinformaticians in analyzing these data creates great potential for the discovery of new clinical targets. The profiling of proteins or receptors for ectopic expression and overexpression in tumor/disease tissues, with little or no expression in healthy tissues, provides new opportunities for the development of therapeutics that can target malignant cells, reducing side effects and improving the therapeutic index.

In this section, we highlight a few examples of how the distribution of cell-surface receptors and proteins has been used for the specific targeting of pathologic cells. We emphasize cases that involve crossing various biological barriers in order to deliver therapeutic cargos to the brain, pituitary gland, liver, pancreas, and to tumor tissues.

1.11.3.2.1 Delivery of therapeutics across the blood–brain barrier

Treating neurological disorders such as Alzheimer's, Parkinson's, strokes, lysosomal storage disorders, schizophrenia, depression, and brain tumors require the transport of a drug through the blood–brain barrier (BBB).[159] There are tremendous unmet patient needs when it comes to central nervous system disorders, as crossing the BBB remains a significant hurdle for delivering biotherapeutics. The BBB is a protective barrier that separates the brain from circulating blood, allowing water and other essential molecules in, while excluding macromolecules and potential neurotoxins from entering the extracellular fluid of the brain. For biologics, the main physiological entry mechanism into the brain is RMT. There are a number of known receptors associated with RMT, including the transferrin receptor (TfR), insulin receptor, lipoprotein receptor, and the diphtheria toxin receptor.[160] The ligands that bind to these cell-surface receptors have been frequently used for targeted cargo delivery across the BBB. A specific example of this is the delivery of protein drugs fused to a mAb of the TfR.

The TfR transports iron-bound Tf into the brain. When the Tf–TfR complex is formed, the process of endocytosis is initiated. When the complex reaches the late endosome's acidic environment, iron dissociates and the Tf–TfR gets recycled back into the plasma membrane of the brain endothelial cells.

The transferrin receptor monoclonal antibody (TfRMAb) has been used as a shuttle to deliver therapeutics into the brain. The TfRMAb binds an epitope within the extracellular domain (ECD) of TfR1 with low affinity and gets internalized via RMT at a similar rate as transferrin itself.[159] Importantly, the TfRMAb-binding epitope is spatially removed from the endogenous Tf binding site, therefore it does not interfere with the transport of iron into the brain.[159,161]

Several examples in the literature illustrate how TfRMAb can be engineered as a fusion protein to successfully deliver therapeutic antibodies,[162,163] neurotrophins (the glial-derived neurotrophic factor and erythropoietin), decoy receptors (ECD of the type II TNFR), and lysosomal enzymes (iduronidase (IDUA)), and iduronate 2-sufatase. The TfRMAb has also been engineered as a fusion protein with avidin to allow the delivery of a biotinylated β-amyloid peptide radiopharmaceutical used for the imaging of amyloid plaques in the brain of patients with Alzheimer's disease. In all of these examples, the TfRMAb was engineered to retain its binding affinity to the TfR1 as well as the activity of the therapeutic protein.[159] If clinical trials prove successful, this approach can be applied to almost any class of recombinant protein to produce a BBB-penetrating IgG-therapeutic fusion for the delivery of biologics into the brain.

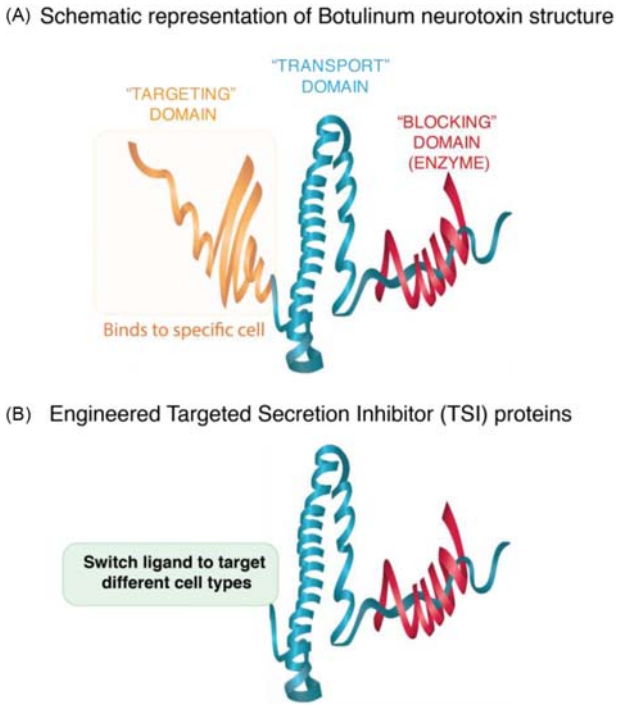

Fig. 8 Schematic representation of BoNT and TSI proteins. Adapted from Foster, K.; Chaddock, J. A. Targeted Secretion Inhibitors-Innovative Protein Therapeutics. *Toxins* **2010**, *2*, 2795–2815.

1.11.3.2.2 Targeting the pituitary

Acromegaly is a disease resulting from excess GH secretion, nearly always originating from a benign tumor of the somatotroph cells in the pituitary gland. A targeted secretion inhibitor (TSI), a botulinum neurotoxin (BoNT) engineered protein, was developed to treat acromegaly. It specifically targets the GH-releasing hormone (GHRH) receptor, which is overexpressed on somatotroph cells.

BoNT is a highly effective therapeutic drug due to its specificity and duration of action in targeting the neuromuscular junction. It contains three domains: a neuronal targeting domain (H_C), a translocation domain (H_N), and an enzymatic domain (LC). It is the enzymatic domain of BoNT that carries out the therapeutic action inside the cell and causes neuroparalysis (Fig. 8).[164] This enzymatic domain targets SNAREs (soluble *N*-ethylmaleimide-sensitive factor-attachment protein receptors), the polypeptides responsible for vesicle fusion to the membrane that causes neurotransmitter release.[165,166]

TSIs are engineered proteins where the neuronal cell-targeting domain (H_C) of BoNT is replaced with a peptide or protein that targets a specific cell-surface receptor, while retaining the enzymatic (LC) and translocation (H_N) domains. A detailed description of the research has been reviewed.[167]

For the treatment of acromegaly, the targeting domain of BoNT was replaced by the GHRH peptide, which binds the GHRH receptor. This TSI construct showed in vitro and in vivo efficacy, as GH secretion inhibition was observed with cleavage of the SNARE of interest, in this case the vesicle-associated membrane protein, which is associated with GH release.[168–170] While the studies explored thus far show promising in vivo efficacy results, a safety window for systemic administration of TSIs is still to be determined. Delivering TSIs to nontarget tissues that have a marginal expression of the targeted receptor remains a concern. However, due to the fact that the TSIs act on specific SNAREs, in order to observe a toxin effect, nontargeted tissues would have to contain the targeted SNAREs.

If this approach proves successful, the engineered TSIs could lead to a new class of biologics for the treatment of disorders that are characterized by overproduction of a particular hormone or neurotransmitter, such as endocrine secretory disorders, neuropathic pain, or overactive bladder.[158]

1.11.3.2.3 Targeted delivery to the liver

Gene silencing has been developed as a therapeutic treatment for many infectious, metabolic, and genetic diseases such as hemophilia, hepatitis, and transthyretin (TTR)-related amyloidosis, which are controlled by processes of the liver. Due to its potential for treating a variety of diseases, including cancer, gene silencing has generated a lot of interest in the field since the discovery of siRNA in 1999.[171] There are, however, many challenges in developing siRNA therapeutics, some of which include poor in vivo stability, efficient delivery to the desired tissue to avoid off-target effects, and intracellular delivery. Some of these challenges have been addressed with the use of NP, which protect ONTs from proteases and facilitate the intracellular delivery of these negatively charged molecules.

Kupffer cells, which form part of the reticuloendothelial system, are responsible for a large uptake of NP by the liver. The use of lipid NP has proven efficient for a few treatments, but the development of targeted delivery to hepatocytes has improved the therapeutic potential of siRNAs. Targeting the liver can be achieved through the ASGPR, which is expressed on hepatocytes. The ASGPR facilitates the uptake and clearance of glycoproteins with terminal galactose and GalNAc via clathrin-mediated endocytosis (as shown in Fig. 5).[172–174] Multivalency presentation can yield ligands that bind in the low nanomolar range, depending on their valency and spatial orientation.[175]

Galactose-modified cationic liposomes have been used to deliver siRNA to the liver via binding to the ASGPR.[174] Liposomes containing a higher ratio of the galactose-modified lipid showed increased uptake of the siRNA by HuH-7 cells, a hepatocellular carcinoma cell line. Gene silencing was demonstrated in this cell line with a twofold higher suppression of hVEGF-A protein expression over nongalactosylated cationic liposomes. Five and sixty minutes post administration of the galactose-modified cationic liposomes, enhanced transfer to hepatocytes was demonstrated in mice, with a higher content of ^{3}H-labeled siRNA found in the liver. The enhanced siRNA accumulation in the liver was eliminated by pretreating mice with asialofetuin, an ASPGR ligand, providing evidence that the higher uptake was due to the ASGPR. Other reports have also demonstrated targeted delivery of siRNA or oligodeoxynucleotides to the liver via liposomes containing galactosylated cholesterol derivatives.[176,177]

A similar concept was used by Jiang et al. to demonstrate in vivo gene silencing.[172] siRNA was encapsulated in cationic liposome NP and the surface of the NP was decorated with a galactose-modified PEGylated lipid to produce galactose-modified liposome nanoparticles (Gal-LipoNP). Fas siRNA was successfully delivered to the livers of mice in a ConA-induced fulminant hepatitis model, in which liver injury was induced at the predetermined peak time of gene silencing. Gene silencing peaked at ~90% 3 days after tail-vein administration of the Gal-LipoNP/Fas siRNA complex. However, the effect was still observed on the seventh day postadministration, with ~50% gene silencing. Administration of LipoNP/Fas siRNA (particles not modified with galactose) yielded only ~25% gene silencing 24 h postinjection.

In vivo gene silencing in the liver has been demonstrated by Alnylam Pharmaceuticals. Direct conjugation of triantennary GalNAc ligands to stabilized siRNA has led to the development of various drug candidates. The enhanced stabilization chemistry is used to prepare the siRNA–GalNAc conjugates which deliver compounds via subcutaneous administration with improved tissue-specific delivery and efficacy relative to intravenous administration.[175] Alnylam's most advanced product utilizing this technology, revusiran (ALN-TTRsc), is currently in Phase 3 clinical trials to evaluate its efficacy and safety in patients with TTR-mediated familial amyloidotic cardiomyopathy.

GalNAc has also been used by Arrowhead Research Corporation to facilitate in vivo delivery of siRNA to the liver for the treatment of hepatitis B virus (HBV). However, in this case, the GalNAc is conjugated to a melittin-like peptide (NAG-MLP) instead of being conjugated to the siRNA. This conjugate is coadministered with a cholesterol-conjugated siRNA (chol-siRNA) targeting HBV.[178] The product, ARC-520, is currently in Phase 2b clinical trials for the treatment of chronic HBV. The drug consists of two vials, one of which contains the NAG-MLP that targets hepatocytes and promotes endosomal escape; the second vial contains two chol-siRNAs for broader genotype coverage, and is coadministered intravenously.

1.11.3.2.4 Targeting the pancreas

Vesicular monoamine transporter-2 (VMAT-2) is a tissue-specific marker that is expressed in the brain and endocrine tissues. (+)-Dihydrotetrabenazine (DTBZ) is a selective ligand for VMAT-2 that is used for pancreatic beta cell imaging in rodent and human studies. Wu et al. took advantage of the tissue specificity of DTBZ to deliver specific payloads to pancreatic cells. Aminopyrazines (AP), known to have stimulatory and proliferative effects on pancreatic beta cells, were conjugated to DBTZ. This was done in a manner that allowed the conjugates to retain both the binding affinity for VMAT-2 and proliferative effects on beta cells. Tissue distribution studies in rodents revealed that the concentration of DTBZ-AP conjugates were 15-, 2- and 5-fold higher in the pancreas, liver, and kidney, respectively, than in the plasma. The clearance rate of the conjugate was similar to DTBZ. The conjugate demonstrated a much higher volume of distribution at steady state compared to DTBZ, resulting in a significantly increased half-life for the conjugates and a prolonged duration of exposure in the target tissue. This early stage study demonstrated the enhanced delivery of a beta cell proliferating agent to the pancreas by conjugating with a validated imaging agent. However, more work needs to be done to translate the potential of this approach into a clinical application.[179]

1.11.3.3 Targeting Tumors

1.11.3.3.1 Antibody–drug conjugates

Bioconjugation has made it possible to bring together the precise targeting and the long half-lives of mAbs with the cell killing power of highly potent toxins. This has created a new class of drugs called antibody drug conjugates, also known as ADCs. The approval of two ADCs, namely brentuximab vedotin (SGN-35, Adcetris) for Hodgkin's and anaplastic large cell lymphoma, and trastuzumab emtansine (T-DM1, Kadcyla) for HER2^{+} breast cancer, has validated the ADC concept and triggered intensive R&D efforts in all aspects of ADC research.[180] ADCs have created tremendous excitement in the oncology-targeted mAb space; at present, there are over 90 different ADCs in preclinical and over 50 in clinical development for the treatment of both solid and liquid tumors.

An ADC consists of a mAb and a cytotoxic payload that are connected via a chemical linker that result in a molecule that is greater than the sum of its parts. The combination with a cytotoxic agent can significantly enhance the potency and tumor killing potential (increased efficacy) of a mAb. Similarly, the combination with a targeted antibody can increase selective delivery of cytotoxic agent to the tumor cells, while minimizing the exposure to normal, tissue resulting in improved safety and tolerability. The choice of the

linker and conjugation chemistry has a major impact on the efficacy, disposition, and toxicity of ADCs. The chemistry for making the first generation ADCs has been dictated by the limitations of working with proteins. For example, trastuzumab emtansine[181] and brentuximab vedotin[182] were generated by conjugating cytotoxic drugs to native (exposed) lysine or cysteine residues in the antibody backbones. These early conventional conjugations were not site-selective and resulted in highly heterogeneous drug products composed of number of distinct molecular species, differing both in the number and location of conjugation sites.[183,184] This high level of heterogeneity complicates the interpretation of preclinical data as well as the analytical characterization of the ADC molecules. Studies have demonstrated that different molecular species within the same ADC product can have different stability,[185] pharmacokinetic,[186] and efficacy profiles.

In an attempt to reduce ADC heterogeneity and improve product profiles, site-specific conjugation of payloads to proteins has been an intense area of research. New site-specific conjugation technologies have used protein antibody engineering to build unnatural anchoring elements in the antibody sequences followed by an orthogonal conjugation chemistry to selectively attach payloads to these anchors. In addition, there are a few methods that have been able to reduce product heterogeneity by controlled and selective conjugations to native cysteines or lysines. The methods that rely on protein engineering have an inherent advantage as they offer the opportunity to find the optimal site of conjugation for a given antibody and toxin combination. These methods take advantage of protein engineering to move the conjugation site across any region of the antibody and enable a true exploration of the impact of conjugation site on the biological properties of ADCs. The work with the site-specific ADCs has definitively shown that the site of conjugation has a major impact on the pharmacological properties of an ADC and is a critical parameter in the design of ADCs. There are tremendous opportunities for continued medicinal chemistry design inputs in evolving these methods and developing SAR with appropriate linkers and toxins.

In addition to ADCs cytotoxic conjugates, polymers, NP, protein fragments, peptides, and small molecules are also actively being pursued with the goal of selective delivery of therapeutic agents to tumor cells. The potential advantage of using nonantibody carriers could include improved tumor penetration, ease of manufacturing, access to novel targets, and potential differentiation with regards to dosing schedules and toxicities. The lessons learned in the design and development of ADCs and similar conjugates can be applied to the broader field of conjugates for targeted delivery to other tissues, and will continue to be a fertile arena of research for trained chemists.

1.11.3.3.2 GPCRs as targeting vectors

GPCRs are the largest family of cell membrane receptors with ~900 members, and are characterized by their seven transmembrane domains. This family of receptors can be subcategorized into different classes depending on their structure and function. Most GPCRs are internalized via clathrin-dependent endocytosis upon agonist binding/stimulation, although it has been demonstrated that some receptor families are constitutively internalized via clathrin-independent endocytosis. Following internalization, the receptor can be either recycled back to the plasma membrane for another round of signal transduction, or transported to the lysosomes for degradation.[187–190]

GPCRs control a wide variety of physiological and pathological processes. Their signaling pathways are implicated in the pathophysiology of various diseases, including tumor growth and metastasis, infectious diseases, and metabolic, immunological, and neurodegenerative disorders. A large proportion of clinically approved drugs, between 30% and 40%, target GPCRs as ligands modulating their signaling pathways. GPCR endogenous ligands include cations, neurotransmitters, lipids, peptide hormones, and glycoproteins.[187]

The overexpressed receptors can also be used as targeting vectors to bring cytotoxic drugs specifically to cancer cells, thus reducing side effects caused by systemic administration. Some examples of this include the Peptide–drug conjugates Zoptrex™ (AEZS-108), a luteinizing hormone-releasing hormone (LHRH)–doxorubicin conjugate, and AEZS-138, a LHRH–disorazol Z conjugate. AEZS-108 has completed Phase 2 trials for the treatment of ovarian cancer and prostate cancer with positive results, and is undergoing Phase 3 trials for endometrial cancer. AEZS-138 is still in preclinical studies and has shown positive results against various tumor cell lines. Both of these conjugates target the LHRH receptor, which is overexpressed in various tumor tissues; the receptor is not commonly found on normal tissue, with the exception of the pituitary gland.

Following the same approach, there is increasing interest in taking advantage of GPCR overexpression for imaging and therapy of different types of tumors. The approach involves attaching the appropriate radionuclide (diagnostic or therapy purposes) to specific ligands that target overexpressed receptors. OctreoScan, an octreotide analog labeled with ^{111}In which targets the somatostatin receptor, was approved in 1994 for SPECT imaging of NETs and other neoplasms expressing somatostatin receptors. More recently, it was demonstrated that antagonists targeting somatostatin receptor 2 (SSTR2) and SSTR3 have higher uptake and longer retention than the somatostatin agonists.[191] A Phase 1/2 trial has completed for OPS202, a ^{68}Ga-labeled SSTR2 antagonist being developed by Ipsen for the detection of NETs; a Phase 1/2 trial is planned for the therapeutic analog labeled with ^{177}Lu (OPS201) for the treatment of gastroenteropancreatic NETs.

1.11.4 Concluding Remarks

A detailed knowledge of gene–protein pathway networks in the human body is essential for biomedical research. Emerging biological target spaces, such as PPIs, the immune system, or RNA/DNA, are opening new opportunities for drug discovery. Designing next-generation therapeutics to modulate these targets demands an understanding of their mechanisms on a molecular level.

To date, the Human Genome Project has identified 20,687 protein-coding genes.[192] However, the experimentally determined map of proteins and peptides that are expressed by the genome does not yet exist. It is still not clear which human genes are translated into proteins, what the expression patterns in specific cell types are, or what the PPI network looks like. With the development of new analytical and bioinformatics technologies, systematic mapping of the human proteome will continue.[193] In the coming years, its integration with genomic data will provide a better insight into human disease biology, which is essential for more informed target selection, derisking, and validation in the early stages of drug discovery.

Understanding various biological barriers and designing molecular transporters or therapeutics that are able to cross these barriers is one of the key challenges of postgenomic drug discovery.

Powerful therapeutic tools, such as siRNA or cytotoxic agents, require cell-specific delivery. Receptor-mediated targeting for imaging and therapy of different types of tumors can reduce unwanted side effects. However, an understanding of the overexpression patterns and the distribution of protein targets in malignant and normal tissues is essential for cell selectivity.

The chemical modalities in today's drug development are becoming increasingly complex. The modular nature of peptide and protein chemistry opens up opportunities to create multifunctional molecular modalities with diverse properties, such as peptide-antibodies or peptide–small molecule conjugates. Due to this complexity, the traditional medicinal chemist's skills are no longer sufficient to guide chemistry efforts in the pharmaceutical industry. In order to design innovative conjugates, multifunctional ligands, novel delivery systems, an understanding of structural biology, molecular modeling, and bioinformatics has become as essential for medicinal chemists as skills in synthetic chemistry. Drug development is a multidisciplinary field with a multiparametric design space. This development is advanced by a continuous chain of decisions which constantly balance risks and benefits. Consequently, it has become imperative for chemists and biologists to think across the aisles. Those who are able to stand at the crossroads of this multidisciplinary vision will reap the benefits of the promise held by next-generation therapeutics.

1.12.1 Introduction

Average human longevity has dramatically increased in the course of humanity's history.[1] The most drastic changes have occurred in the last century when implementation of vaccination, disinfectants and antibiotics led to a substantial reduction of infectious diseases as a cause of death. The continuing decline in mortality over the last decades among the elderly is most probably owing to the preventative factors, such as improved diets, as well as a reduction in smoking and exercise.[2] Kennedy and Pennypacker noted in their recent paper that if current demographic trends continue then 20% percent of the global population of 9 billion will be over the age of 60 by 2050.[3] As a consequence, most modern nations undergo rapid population aging. Although the life expectancy has enhanced dramatically in modern generations, this process has not been accompanied by an equivalent increase in healthy life expectancy.[4] Since aging is a major risk factor in most chronic diseases, the prevalence of age-associated disorders, such as neurodegenerative disease, type 2 diabetes, cardiovascular disease, osteoporosis and cancer, rises considerably with the increasing average age in populations of developed countries, representing a great socio-economic challenge. It has been estimated that in the U.S., there will be more than 30 million people over the age of 80 by 2050; half of them will suffer from different forms of dementia, and at least 3 million of all adults in the U.S. will be diagnosed with Parkinson's disease.[5] The expected increase in these and other age-related conditions will have substantial consequences for future society including increased financial and psychological burden for families and greater pressure on government health care programs and entitlement budgets.[6,7] Eric Le Bourg recently pointed that 'the increased proportion of elderly people in the population of developed countries — the so-called demographic aging — explains a part of the now observed enormous interest of country leaders and lay public for aging matters, and thus for biogerontology research'.[8]

Life span extension research has traditionally raised concerns that it may lead to increasing the size of the elderly population and, thereby, to the high prevalence of aging-associated chronic pathologies. Numerous experimental studies have, however, showed that extension of life span is usually accompanied by delayed or reduced morbidity including cardiovascular disease, neurodegeneration, and tumors.[9] There is also evidence from human epidemiological studies which is consistent with these findings from animal models. For example, it has been found that centenarians, in particular those who live in so-called 'Blue Zones' (five regions in Europe, Latin America, Asia and the U.S. with unusually high concentrations of centenarians), not only exhibit exceptional longevity, but also often remain free from disability and chronic disease until very advanced ages.[10]

For the last decades, the primary strategy in gerontology and geriatric research has been the compression of morbidity. This strategy claims that we may limit morbidity to a shorter period closer to the natural end of life, thus reducing the burden of illness and disability, by delaying the age of onset of major age-related chronic diseases.[11] Geroscience, a novel field within biological aging

research, is centered on healthspan extension.[12] Extending healthspan is a critical component of achieving optimal longevity, defined as living long, but with good health and quality of life, including improved functioning, productivity and independence. The efforts to increase healthspan are currently focused on slowing the basic biological processes of aging such as cellular senescence, mitochondrial dysfunction, age-related decline of stress resistance, dysregulated cellular energy sensing/growth pathways, impaired proteostasis, deteriorated stem cell function/bioavailability, as well as inflammation/oxidative stress.[11–14] All these processes interfere with the normal physiological cellular signaling pathways, demanding compensatory adjustments with aging to maintain homeostasis. A good example is intensification of insulin secretion by the beta cells of the pancreas in order to counteract the peripheral insulin resistance. Another example is the recruitment of additional neural circuits in prefrontal regions of the brain to maintain cognitive functioning in the face of pathological neural changes. At a certain stage, however, these compensatory mechanisms become exhausted and the effects of aging are manifested, thereby increasing the risk for functional decline and the development and progression of chronic diseases.[15]

Research on life extension is a part of a larger investigation field widely known as 'anti-aging medicine'. Emerging in the beginning of 1990s as a new speciality in medical practice, anti-aging medicine became the increasingly discussed and debated topic over the past years.[16] The main goal of anti-aging medicine is to prolong both a healthspan and life span by specific regimes of exercise and dieting, as well as by advanced biomedical interventions aimed at slowing, stopping or reversing the aging process.[17,18] The major assumption underlying anti-aging research is that age-related senescence can be considered as a pathophysiological phenomenon that can be prevented or even reversed,[19] and modern anti-aging medicine promotes biomedical technologies that have the potential to delay or postpone this process.[2] Traditionally, aging is considered to be 'natural' and therefore inevitable. However, in the view of many authors, the idea that aging is indefeasible part of human nature is quite questionable.[20] In accordance with many modern evolutionary theories of aging, it has emerged as a by-product of evolutionary processes and does not have a specific function.[21] If aging is really not an intrinsic, irrevocable component of life, then it could be manipulated similarly to other processes which are generally deemed to be unnatural or pathological.[20] The rapid progress in understanding the mechanisms underlying aging and longevity over the last decades and first successful pharmacological interventions to extend healthy life span in various model organisms now indicate that the process of aging is malleable.

There are two main tasks in biogerontology research. The first one is life extension and the second one is prevention of age-associated pathologies. Since numerous studies indicate that many genetic pathways determining aging and longevity are highly conserved across species, it can be suggested that life-extending treatments which are effective in invertebrates might also be effective for vertebrates including humans. Therefore, a number of experiments in this field were performed on invertebrate model systems, including the nematode *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, and the yeast *Saccharomyces cerevisiae*. The main advantage of using such short-lived models is that they allow quickly evaluate the effects of such treatments on the pathways involved in the aging process. Moreover, these models seem suitable because there are organisms whose genomes have been fully sequenced and annotated. Rodent models are also widespread in anti-aging studies because they are relatively inexpensive, easy to maintain and manage, and may be used to investigating such important areas in aging research as behavior, cognition and memory. Studies on life span extension in nonhuman primates are of interest as well because they may be successfully used for better comprehension of the aging process in human beings. However, without denying the importance of such studies, it should be noted that the extension of longevity per se, not accompanied by a decrease of the risk of age-associated pathologies, would certainly not be adequate.

The development of pharmacological agents targeting aging-related functional declines and pathological manifestations ('anti-aging drugs') is now in the spotlight in geroscience. Over the last 20 years, an exponential growth of research in the field of geriatric pharmacology, including the study of prospective anti-aging drugs, is observed.[22] The first step in the drug development process involves the selection of druggable targets.[23] The situation when gene targets are determined by the study of genetic variations linked to either gain-of-function or loss-of-function phenotypes, is especially useful because these targets may be considered as those which had been reliably validated.[24] Over the past two decades, a number of genes have been identified that play an unequivocal role in the control of aging and longevity,[25–27] and all of these genes represent attractive drug targets. Currently, many pharmacological agents targeting the putative mechanisms of aging mentioned above are under development. Another way for anti-aging drug discovery is evaluating the pharmacological agents already approved by the FDA and other regulatory agencies for the treatment of particular conditions associated with aging, such as beta-blockers, metformin, statins, renin-angiotensin-aldosterone system inhibitors, thiazolidinediones, as well as anti-inflammatory medications.[11] These classes of drugs are commonly used in the treatment of patients with chronic medical illnesses and their efficacy and safety has been proven in many clinical trials. They have been also shown to improve physiological functioning, health, and well-being in middle to old age patients with chronic disorders.[28] Such agents are presently not used in treatment of age-related physiological dysfunctions in the absence of clinical manifestation of disease. However, these medications might theoretically be redirected to treating or preventing conditions or syndromes typically associated with aging. Therefore, the longevity dividend, that is an idea that extending healthy life by slowing aging may prove to be the most efficient way to combat the fatal and disabling diseases that plague us today, [29,30] can provide an opportunity to revitalize the drug development pipeline. By delaying the aging process per se, it likely would be possible to delay or prevent all age-associated pathologies rather than to overcome them one by one, which is the current approach of the disease-based paradigm of drug development. Furthermore, delaying the progression of a particular age-related chronic disorder, for example, cardio-vascular disease, will apparently have only a modest effect on the population life expectancy because comorbidity, for example, cancer, will to a great extent substitute the reduction in mortality risk caused by preventing the targeted pathology. The main idea of geroscience is that delaying the clinical manifestation of all of age-associated diseases as a group by inhibiting the basic

aging mechanisms can be far more effective than preventing the individual chronic disorders.[31] A recent analysis conducted by Goldman et al.[32] demonstrated that substantial socio-economic benefits might be derived from this approach in comparison with current public health strategy targeted to prevention of particular diseases. According to this analysis, the economic impact of delaying aging and increasing healthspan in the U.S. is estimated at ~$7 trillion dollars over the next 50 years. Hence, it is evident that discovery of new drug targets based on biogerontological research represents an incredible opportunity for the pharmaceutical and healthcare industries.[33]

1.12.2 Antioxidants

The free radical theory of aging (now more commonly termed the oxidative damage theory of aging) first postulated by Denham Harman in 1956,[34] was historically perhaps the most influential theory of aging. It was one of the earliest concepts to try to explain the basic cause of age-related functional decline and aging-associated pathologies. This theory suggests that free radicals and other reactive oxygen species (ROS), formed unavoidably in the course of normal metabolism in mitochondria as undesirable side products of the oxidative energy metabolism, and arising due to the action of adverse exogenous factors, can damage various biomolecules, and accumulation of these damages is the proximal cause of aging and age-associated diseases.[34] As a consequence, it is supposed that life span is determined by the rate at which these damages occur (Fig. 1).

1.12.2.1 Oxidative Damage Theory of Aging: Conceptual Basis and Clinical Expectations

It has been well established since the free radical theory of aging was first formulated that advanced ages are linked to elevated production of free radicals and other ROS including superoxide anion ($O_2\cdot^-$), hydroxy (HO·), peroxy (ROO·), alkoxy (RO·), and hydroperoxy (HOO·) radicals, mostly from mitochondria, and with increased markers of oxidative injury, such as carbonylated proteins, lipoperoxides, and oxidized DNA.[35–38] Under physiological conditions, excess ROS in the body are eliminated by endogenous antioxidative defense systems, including, among others, superoxide dismutase (SOD), enzyme detoxifying superoxide radical ($O_2\cdot^-$), catalase (CAT) and glutathione peroxidase both involved in the detoxification of peroxides, and glutathione reductase involved in the regeneration of glutathione (Fig. 2).

Together, these antioxidant systems allow keep the cellular equilibrium between oxidation and antioxidation processes. However, the endogenous antioxidant systems may be insufficient, especially in conditions of chronic oxidative stress, that generally accompany aging and degenerative age-associated disorders.[35] In such conditions, exogenous antioxidant compounds may play a substantial role in maintaining the homeostatic balance in living organisms. They include, among others, vitamin E, vitamin C, beta-carotene and other carotenoids, lipoic acid, glutathione, coenzyme Q10, flavonoids, phenols, polyphenols, phytoestrogens, as well as several minerals such as zinc, selenium and manganese. Therefore, there is continuous demand for exogenous antioxidant compounds in order to prevent the oxidative damage of biomolecules under the conditions of a disequilibrium redox state in favor of oxidation. However, high doses of such agents can be toxic due to their prooxidative effects at high concentrations or their potential to react with beneficial concentrations of ROS normally occurring at physiological conditions and required for effective cellular functioning.[36]

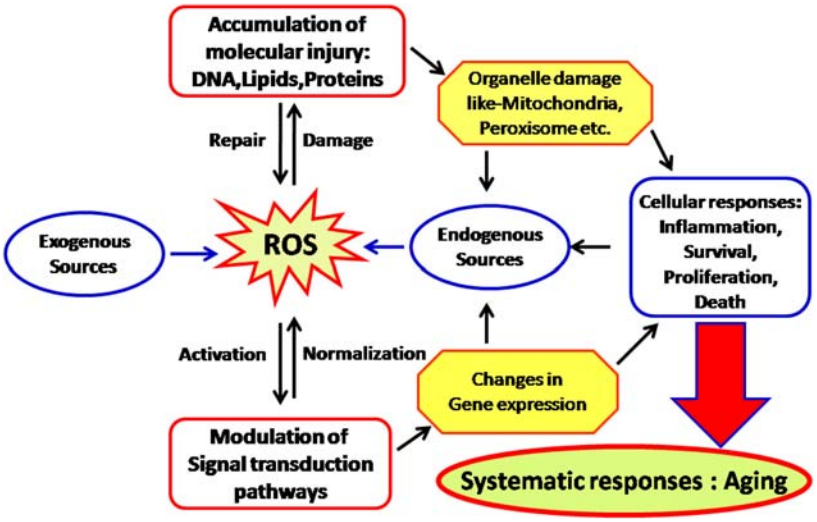

Fig. 1 Reactive oxygen species (ROS) generated by endogenous as well as exogenous sources, cause damage and accumulation of proteins, lipids and DNAs, when defensive (repair) mechanisms of body become weak. These ROS also modulate the signal transduction pathways. These disturbances cause organelle damage, changes in gene expression followed by altered cellular responses which ultimately results into aging (The figure is reproduced with permission of the copyright holders from Pandey and Rizvi[35]).

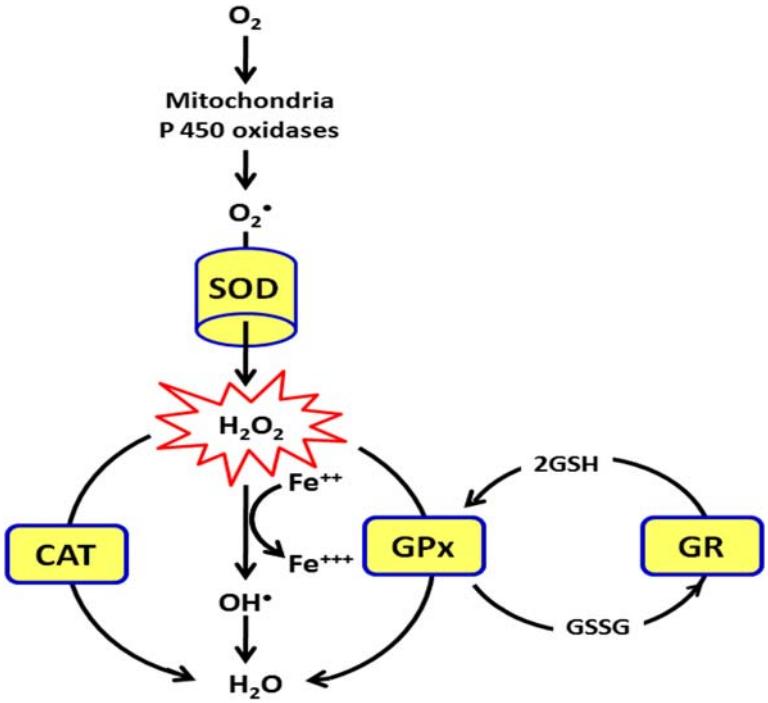

Fig. 2 Superoxide dismutase (SOD), glutathione peroxidase (GPx), glutathione reductase (GR) and catalase (CAT) are the main endogenous enzymatic defense systems of all aerobic cells. They give protection by directly scavenging superoxide radicals and hydrogen peroxide, converting them to less reactive species. SOD catalyzes the dismutation of superoxide radical ($\bullet O_2$) to hydrogen peroxide (H_2O_2). Although H_2O_2 is not a radical, it is rapidly converted by fenton reaction into $\bullet OH$ radical which is very reactive. GPx neutralizes hydrogen peroxide by taking hydrogens from two glutathione (GSH) molecules resulting in two H_2O and one *glutathione disulfide* (GSSG). GR then regenerates GSH from *GSSG*. CAT the important part of enzymatic defense, neutralizes H_2O_2 into H2O (The figure is reproduced with permission of the copyright holders from Pandey and Rizvi[35]).

If the oxidative damage theory of aging is true and if aging is really due to free radical reactions, it should be possible to extend the organismal life span by activation of antioxidant defence. Based on this assumption, a number of studies in various experimental models have attempted to delay aging and prolong longevity using dietary supplementation with natural or synthetic antioxidants or by manipulating the antioxidant genes.[39,40] A large number of studies have been performed to investigate whether supplementation with antioxidants, especially vitamins C and E, may extend the life span of different model animals. Vitamin C, also referred to as ascorbic acid, L-ascorbic acid and ascorbate, is the major hydrophilic (water-soluble) antioxidant. In cell membranes, it may rapidly reduce the α-tocopheroxyl radicals and level of low-density lipoprotein (LDL) to regenerate α-tocopherol and to inhibit the generation of free radicals.[41] Vitamin E (α-tocopherol) is the main hydrophobic (fat-soluble) antioxidant in cell membranes and circulating lipoproteins. The antioxidant function of vitamin E is strongly supported by regeneration promoted by vitamin C. Vitamin E is known to prevent atherosclerosis due to the reduction of oxidative stress and inhibition of LDL oxidation.[42] In addition to vitamins, other substances such as melatonin,[43] ubiquinone (coenzyme Q)[44] and lipoic acid[45] also considered to be efficient efficient antioxidants.

It is believed by many researchers now that development of novel means of delivery of antioxidants into cells or construction of novel antioxidant compounds may open new perspectives for modulation of aging and healthspan extension. Since mitochondria are the main source of ROS in the cell, mitochondrially targeted antioxidants might be more effective than traditional ones.[46] The most demonstrative indications favoring this conclusion originate from recent discoveries of in vivo effects of mitochondria-targeted antioxidants including MitoQ and plastoquinone (SkQs).[47] Chemical structures of main antioxidant substances are presented in Fig. 3.

1.12.2.2 Life Extension by Antioxidants

Findings on the effects of antioxidant supplementation on life span of experimental organisms such as the fruit fly, *Drosophila melanogaster*, the nematode worm, *Caenorhabditis elegans*, and rodents are summarized in Table 1.

As it is seen from the Table 1, supplementation with substances having antioxidant properties resulted in controversial effects on life span of different model organisms. In most cases, it caused life extension accompanied by reduced age-associated oxidative stress,[93–96,98] increased antioxidant enzymes activity,[77,79,80] enhanced stress resistance,[58–61,64,66,69,70] increased reproductive activity,[54,85] and modulated expression of aging-related genes.[78,81,83–86] In several studies, however, the life span and fertility were unchanged or even decreased.[55,65,87,88,92,95] Furthermore, in some cases the life-extending capacity of substances with potent

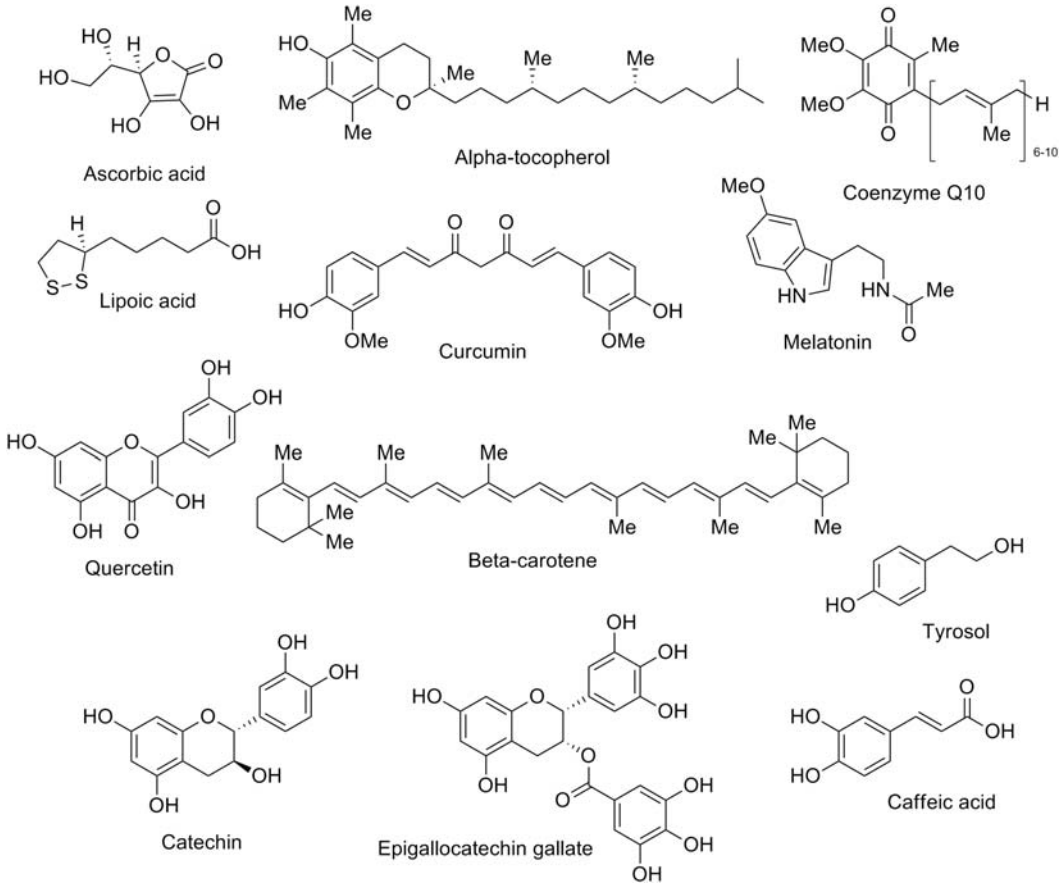

Fig. 3 Main antioxidant substances.

Table 1 Summary of the effects of substances having antioxidant properties on the life span and associated functional traits of model organisms

Experimental del/Agent	*Effects observed*	*Reference*
Rotifer		
Vitamin E	Extended pre-reproductive stage	Sawada et al.[48]
Indolepropionamide	Increased life span	Poeggeler et al.[49]
Caenorhabditis elegans		
Vitamin E; CoQ	Increased life span; reduced superoxide anion levels	Ishii et al.[50]
Vitamin E	Increased life span; delayed reproduction	Harrington and Harley[51]
Polydatin, a natural resveratrol glycoside	Increase of mean life span by 31% and 62% under normal and acute stress conditions, respectively	Wen et al.[52]
Curcumin	Increased life span	Liao et al.[53]
Quercetin, a major flavonoid in the human diet	Increased life span; increased reproductive capacity; enlarged body size	Surco-Laos et al.[54]
Quercetin-3-O-glucoside	Increase of mean life span by 23% by low concentrations, decrease of life span by high concentrations	Dueñas et al.[55]
Flavonoids myricetin, quercetin, kaempferol, naringenin	Increased life span in wild-type worms	Grünz et al.[56]
Caffeic acid; rosmarinic acid	Increased life span; reduced body size; altered lipid metabolism; delayed reproduction	Pietsch et al.[57]
Flavanol catechin	Increased life span; enhanced stress resistance; reduced body length	Saul et al.[58]
Epigallocatechin gallate	Increased life span; enhanced stress resistance	Abbas and Wink[59]
Epigallocatechin gallate	Increased life span under stress conditions; no effect under normal conditions	Zhang et al.[60]
Ferulsinaic acid	Increased life span; improved resistance for heat and oxidative stresses; attenuated lipid peroxidation	Sayed[61]
EUK-8 and EUK-134, SOD/CAT mimetics	Increased mean life span of wild-type worms by 44%, and prematurely aging worms by 67%	Melov et al.[62]
Tyrosol, an olive oil phenol	Increased life span	Cañuelo et al.[63]

(Continued)

Table 1 Summary of the effects of substances having antioxidant properties on the life span and associated functional traits of model organisms—cont'd

Experimental del/Agent	*Effects observed*	*Reference*
KPG-7, herb mixture complex	Increased life span; protection against oxidative stress	Moriwaki et al.[64]
EUK-8	Dose-dependent reduction of life span and fertility	Keaney and Gems[65]
Ginkgo biloba extract, EGb 761	Increased life span; increased stress resistance	Wu et al.[66]
Royal jelly	Increased life span	Honda et al.[67]
Platinum nanoparticles (nano-Pt), a SOD/CAT mimetic	Increased life span; reduced accumulation of lipofuscin and ROS induced by paraquat	Kim et al.[68]
N-acetyl-L-cysteine	Increased life span; increased resistance to oxidative, UV and heat stresses	Oh et al.[69]
Extract from Acanthopanax sessiliflorus	Increased life span; increased resistance to heat shock and UV irradiation; reduced oxidative DNA damage	Park et al.[70]
Drosophila melanogaster		
Lipoic acid and resveratrol	Increased life span	Bauer et al.[71]
Melatonin	Increased life span	Izmaylov and Obukhova[72]
EUK-8 and EUK-134; MitoQ	Increased life span in SOD-deficient flies; no effect in wild type flies	Magwere et al.[73]
SkQ1	Increased life span	Krementsova et al.[74]
Epitalon	Increase of mean life span by 11–16%	Khavinson et al.[75]
Carnosine, S,S-Trolox-carnosine, STC	20% increase of male mean life span, no effect on females; increase of male mean life span by 16%, female by 36%	Stvolinsky et al.[76]
Curcumin	Increased life span; enhanced SOD activity	Suckow and Suckow[77]
Curcumin	Increased life span; reduced oxidative stress; improved locomotion; modulated expression of aging-related genes	Lee et al.[78]
Curcumin	Increased life span; increased SOD activity; reduced accumulation of malondialdehyde and lipid peroxidation	Shen et al.[79]
Aloe vera extract	Increased life span; increased antioxidant enzymes activity; increased locomotor activity	Chandrashekara and Shakarad [80]
Black rice extract	Increase of mean life span by 14%; up-regulation of SOD1, SOD2, CAT and Rpn11, and down-regulation of Mth genes	Zuo et al.[81]
Cocoa	Increased life span; metal-chelating effects	Bahadorani and Hilliker[82]
Blueberry extract	Increased life span; up-regulation of SOD, CAT and Rpn11, and down-regulation of Mth genes	Peng et al.[83]
Cranberry anthocyanin extract	Increase of mean life span by 10%; up-regulation of SOD1 and down-regulation of MTH, InR, TOR and PEPCK genes	Wang et al.[84]
Cranberry extract	Increased life span; increased reproduction; higher expression of oxidative stress and heat shock response genes	Wang et al.[85]
Sesamin, a major lignan in sesame oil	Increase of mean life span; up -regulation of SOD1, SOD2, CAT and Rpn11 genes; attenuation of neurodegeneration	Zuo et al.[86]
Musca domestica		
EUK-8 and EUK-134	No effect on life span under normoxic conditions; shortened life span under hyperoxic conditions	Bayne and Sohal[87]
Mus musculus		
Vitamin E	Increased median life span in C57BL/6 mice by 15%; anti-cancer effect via inducing the P21 signalling pathway	Banks et al.[88]
Vitamin E	No effect on life span	Morley and Trainor[89]
Vitamin E	Increase in mean but not maximum life span; lower fatal tumour incidence	Blackett and Hall[90]
Tetrahydrocurcumin; polyphenol from green tea	Increased survival in male C57BL/6 mice	Kitani et al.[91]
Commercial nutraceutical combinations	No or detrimental effect on life span	Spindler et al.[92]
Carboxyfullerene, SOD mimetic	Increased life span; reduced age-associated oxidative stress; rescued age-related cognitive impairment	Quick et al.[93]
Royal jelly	Increase of mean life span of C3H/HeJ mice by 25%, no effect on maximum life span; reduced oxidative damage	Inoue et al.[94]
Alpha-lipoic acid	Decreased life span in senescent prone SAMP8 mice; reduced oxidative stress and improved memory in old mice	Farr et al.[95]
Melatonin	Increased life span; normalized redox status of the mitochondria and increased ATP levels in SAMP8 mice	Rodríguez et al.[96]
SkQ1	Increased life span; prevented age-dependent disappearance of estrous cycles; retardation of age-linked immune decline	Anisimov et al.[97]
Rattus norvegicus		
Epigallocatechin gallate	Increased life span; reduced liver and kidney damage; improved age-associated inflammation and oxidative stress	Niu et al.[98]

antioxidant activity have been manifested in superoxide dismutase (SOD)-deficient mutants with compromised antioxidant defence[73] or in normal animals under stress conditions,[60] but were not shown if wild-type animals reared in normal conditions were investigated. In addition, antioxidant compounds have commonly been shown to be able to affect the mean life span but they were failed to show consistent effects in extending a maximum life span of wild-type animals,[90,94] suggesting that these effects could be caused by reduction of mortality owing to the prevention or delay of age-related diseases rather than due to the interference with the aging process per se. Generally, life-extending effects have been observed so far in species that are evolutionarily distant from mammals. All of the life-extending strategies used, however, did not induce a similar extension of the longevity in mammals, where more complex control systems are likely working over the aging process, probably requiring more elaborate and specific interventions.

1.12.2.3 Antioxidant Supplementation: Contradictions, Controversies and Paradoxes

Taken together, the findings from research of antioxidant compounds suggest that the mechanisms underlying the effects of these agents are complex and interacting in ways that are difficult to address experimentally. Theoretically, the effects of supplementation with exogenous antioxidants may be explained by mechanisms other than antioxidant activity of itself. It is known that endogenous and exogenous antioxidants act interactively (e.g., synergistically) to maintain or re-establish the redox homeostasis.[36] In some cases, the effects of substances with potent antioxidant capabilities could be related not with their own antioxidant action, but with induction of endogenous antioxidant mechanisms; the intake of high levels of exogenous antioxidants can, however, suppress the synthesis of endogenous antioxidants as well.[40] This is an important point as a fine-tuned balance between oxidative and anti-oxidative processes is critical in maintaining healthy biological systems.[36] The excessive supplementation of antioxidants may lead to destroying the delicate control mechanisms of homeostasis resulting in deterioration of health status and life shortening.[99] Since it is difficult to assess the quantity and quality of food consumed by experimental organisms, it may be suggested that the intake of high amounts of antioxidants can modulate their feeding behavior and thus lead to malnutrition or even starvation.[100] If so, it can be assumed that life-extending effects of exogenous antioxidants might be explained, at least partly, by the mechanism of calorie restriction (CR). Indeed, it is well known that severe lowering of calorie intake may dramatically slow the rate of aging and delay the onset of various age-related disorders such as type 2 diabetes, cardiovascular disease, cancer, and neurodegenerative disease in a number of experimental models (see the respective subsection below). Moreower, the life-extending effects of antioxidants and other substances may be a by-product of other, rather deleterious, effects such as decreased rate of development, lower weight, and reduced level of metabolic rate.[100] This is all the more true that most compounds having anti-oxidant properties are multi-functional: the mechanisms that are operative or dominant in a particular situation are dependent on the certain biological conditions and thus these conditions can affect the kinetics and hence the antioxidant activity. For example, ascorbic acid can act, depending on particular conditions, not only as an antioxidant, but also as an oxygen scavenger, a metal chelating agent, and a reducing agent.[101] Similarly, although curcumin demonstrates superior antioxidant activity, its life-extending properties may be caused by its indirect antioxidant action, namely, induction of exogenous antioxidant enzymes, or by interference with various cellular signaling pathways such as inflammatory cytokines, growth factors and their receptors, adhesion molecules, apoptosis-associated and cell-cycle proteins, several transcription factors including NF-kappaB (a major transcription factor for inflammatory responses), activator protein 1 (AP-1) and signal transducer and activator transcription factor as well as with several longevity-associated enzymes like mitogen-activated protein kinase (MAPK), mammalian target of rapamycin (mTOR), and protein kinase B (Akt).[40]

Another important point is that antioxidants show contradictory behaviors in differing biological environments, depending on their concentration and the nature of neighbouring molecules, they may act as pro-oxidants.[102] In addition, whereas high concentrations of ROS are hazardous for all living beings and damage all major cellular constituents, numerous evidence have been reported that at proper cellular concentrations they play a significant role as regulatory mediators in various signaling processes such as signal transduction from membrane receptors and control of gene expression, as well as in cell cycle regulation, cellular proliferation and differentiation, and autophagy stimulation.[103,104] Therefore, the intake of high doses of exogenous antioxidants can result in the disruption of the pro/antioxidant balance and to adverse health effects. Moreover, the life-extending effects induced by antioxidants can also be explained by the hormesis phenomenon, that is, a dose–response relationship characterized by low-dose stimulation and high-dose inhibition.[105] Similarly to the hormesis-inducing compounds (hormetins), antioxidants act in some concentration range, and their high concentrations are generally toxic to most organisms. Paradoxically, the effect of longevity hormesis can be mediated by increased formation of ROS.[40,103] According to the concept of mitochondrial hormesis ('mitohormesis'), whereas high levels of ROS generated in the mitochondria may cause cellular damage and promote aging, their moderate levels can induce an adaptive response and thus improve the systemic defense mechanisms. This hypothesis postulates that ROS act as essential signaling molecules to promote healthspan and longevity, and that intake of exogenous antioxidants can be useless or even harmful.[106]

On the basis of these facts, Bouayed and Bohn[36] pointed in their review that supplementation with exogenous antioxidants can lead to the double-edged effects depending on their concentrations: physiologic doses cause beneficial effects while high doses lead to harmful effects. The schematic presentation of these ideas is reproduced from the article by Bouayed and Bohn[36] in Fig.4.

Given all these contradictions, it is no wonder that conflicting data are reported on the health effects of long-term dietary antioxidant supplementation in human populations. It has been indicated in a number of investigations that oxidative damage is substantially involved in the pathogenesis of many aging-associated disorders including neurodegenerative Alzheimer's and

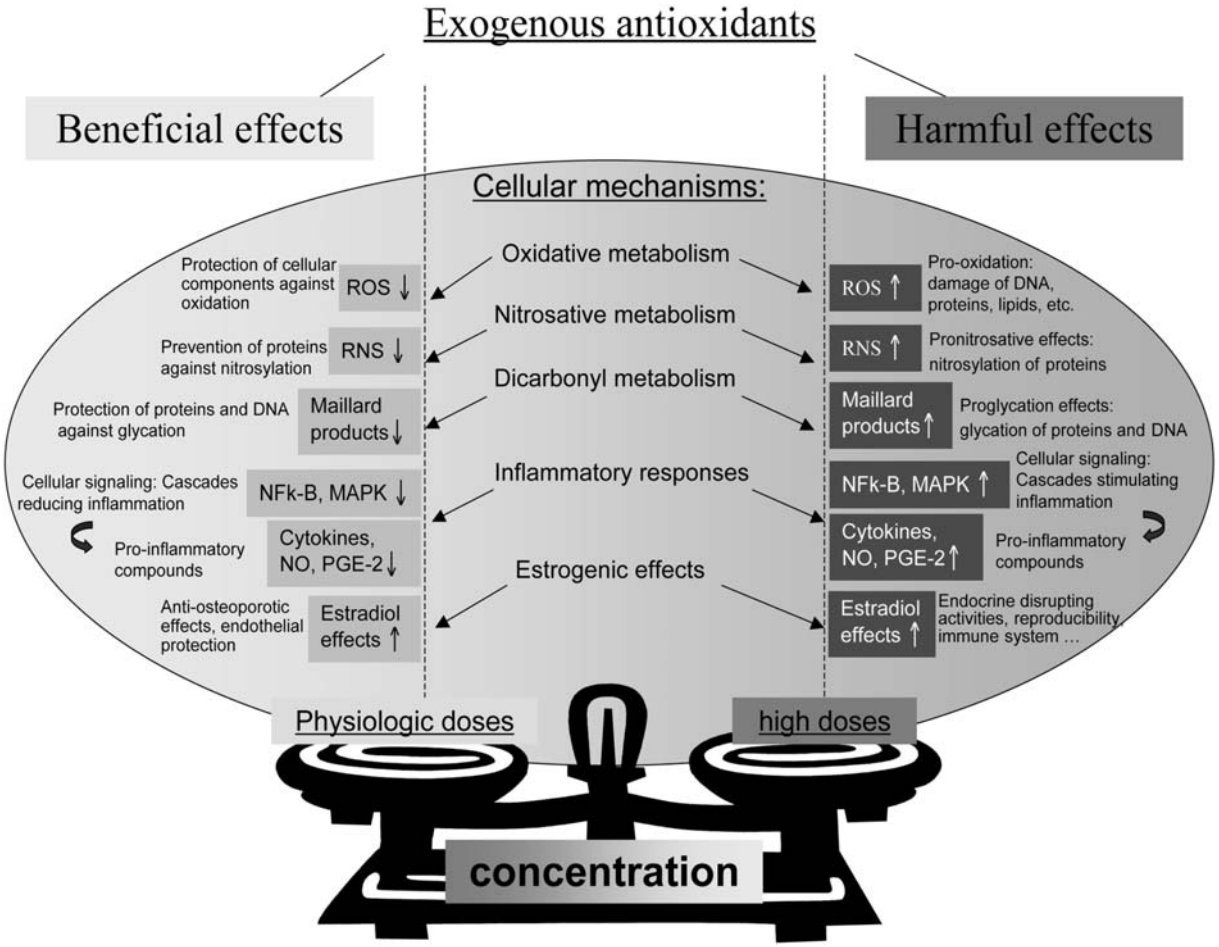

Fig. 4 Double-edged effects of exogenous antioxidants on cellular responses including oxidative, nitrosative and dicarbonyl metabolisms and other pathways such as inflammatory processes depending potentially on their concentrations: physiologic doses leading to beneficial effects whereas high doses may result in harmful effects. Specifically, 'beneficial or harmful effects of natural compounds may also occur independently from their (anti-) oxidative properties e.g., as a result of the activation of particular cellular pathways including inflammatory processes, nitrogen and dicarbonyl metabolisms for which a close relation exists. Indeed, inflammation, nitrosative stress (resulting from excessive production of reactive nitrogen species) and carbonyl stress (resulting from excessive accumulation of reactive dicarbonyl compounds) may exacerbate or provoke oxidative stress and vice versa. Besides the biphasic effects of antioxidants on oxidative metabolism, it has also been reported that natural compounds can display double-edged effects on inflammatory reactions… Other activities of natural compounds might result in beneficial as well as harmful effects such as due to the estrogen-like activity of isoflavones, as they are able to bind to ß-estradiol receptors. Independently of their antioxidant activity, polyphenols are also able to exert modulatory effects in cells, resulting in outcomes depending on the activated pathways among others, e.g., by interacting with intracellular signaling cascades [e.g., the nuclear factor kappa B (NFkB) and the mitogen-activated protein kinase (MAPK)] or by binding to the ATP-binding sites of a large number of proteins, including mitochondrial ATPase, calcium plasma membrane ATPase, protein kinase A, protein kinase C and topoisomerase. It also has been revealed that some antioxidants (e.g., quercetin and naringenin) are able to inhibit certain cytochrome P450 enzymes (CYP1A1 and CYP3A4, respectively) involved in the bioactivation of chemical carcinogens, constituting another proposed chemopreventive mechanism of polyphenols against cancer development including lung cancer. In addition, it has been demonstrated that polyphenols (e.g., chlorogenic acid, EGCG and rutin) at pharmacological (non-nutritional) doses could interact with GABAA receptors or modulate neurotransmitters (e.g., serotonin and noradrenaline), resulting in interesting pharmacologic properties on the central nervous system including anti-anxiety and antidepressant activities.. The figure is reproduced with permission of the copyright holders from Bouayed, J.; Bohn, T., Exogenous antioxidants – Double-edged swords in cellular redox state: Health beneficial effects at physiologic doses versus deleterious effects at high doses, Oxid Med Cell Longev 3 (4) (2010) 228–237.

Parkinson's diseases,[107,108] type 2 diabetes,[109] atherosclerosis and other cardiovascular complications,[110–112] as well as sarcopenia[113] and osteoporosis.[114] Some authors therefore suggest that enhancing the antioxidant defense system in relevant organs can be useful in reducing the oxidative stress and the impact of age-related pathologies. In animal models, it has been really demonstrated that dietary supplementation with exogenous antioxidants may attenuate the development and progression of various age-related disorders, including amyotrophic lateral sclerosis, Parkinson disease, and heart failure.[115–120] Application of that idea for human beings has, however, turned out to be rather problematic. Most controlled clinical trials failed to demonstrate any clinical benefits of antioxidant-based therapies for aging-associated diseases such as cardiovascular disease,[121,122] stroke[123]

and type 2 diabetes.[124,125] This controversy may be linked to the excessive intake of antioxidants or with insufficient bioavailability of the antioxidants in the relevant organs to reduce the oxidative damage.[126]

The excessive levels of exogenous antioxidants may interfere with endogenous cellular signaling mechanisms and thus can be harmful.[127] Indeed, in a large-scale study the use of multivitamins more than seven times per week was shown to be linked to a substantial increase of prostate cancer risk when compared to never users.[128] Supplementation with antioxidants (vitamin C and E combined) precluded the health-promoting effects of exercise in humans.[129] In a large trial of beta-carotene conducted among heavy smoking men in Finland who were at high risk for developing lung cancer, a significant increase in lung cancer diagnoses among those taking the supplement compared to those taking a placebo has been revealed.[130] In another trial among heavy smokers and people exposed to asbestos, an increased incidence of lung cancer and elevated risk of death from lung cancer, cardiovascular disease, and any cause were found in both smokers and workers exposed to asbestos who took the combination of beta carotene and vitamin A.[131] In meta-analyses of observational studies and randomized controlled trials conducted in well-nourished and healthy populations, antioxidant supplementation has been repeatedly associated with undesirable consequences for the health and all-cause mortality.[132–135]

Taken together, these findings indicate that antioxidant intake may not always be advantageous to human health.[136] The paradoxical situation when oxygen radicals and other ROS are involved in various human diseases, but supplementation with large doses of dietary antioxidants to human individuals has resulted, in most cases, in little or no preventative or therapeutic effect, is commonly referred to the term 'antioxidant paradox'. The manipulation of level of endogenous antioxidants (eg, by supplying mild pro-oxidants) seems a more useful approach to prevention and treatment of disorders in which ROS play an important role than the consumption of large doses of exogenous dietary antioxidants.[137] From this, Bast and Haenen[138] have recently concluded that 'initial excitement regarding the potential health benefits of antioxidants has diminished. Currently, it is even claimed that antioxidants increase mortality. The antioxidant pendulum appears to swing from healthy to toxic and from general panacea to insignificant ingredient. Owing to the polarity of views towards antioxidants, nutritional recommendation ranges from advice to increase antioxidant status in plasma to the notion that it is a useless measurement.

In summary, while benefits of supplementation with exogenous antioxidants seem obvious in case of increased oxidative stress and endogenous antioxidant deficiency, additional studies are required to determine the potential risks and benefits associated with intake of antioxidants by healthy persons.

1.12.3 Pharmacological Interventions Mimicking Calorie Restriction

The raised doubts about the effectiveness of antioxidant treatments have currently led to an increased interest in alternative anti-aging therapies. Among them, calorie restriction (CR)-based therapeutic strategies seem to be the most promising now. CR is defined as a restriction of food intake without malnutrition in organisms normally fed ad libitum.[139] Presently, CR, a diet providing all the essential nutrients and vitamins but having significantly (30%–70%) lower amount of calories, is accepted as a well-known and established experimental procedure for life extension, although some authors suggest that the restriction of specific nutrients including protein and particular amino acids such as methionine may play a crucial role.[140] It is well known, since the pioneering work of McCay and co-workers, that CR may promote longevity and slow aging. In this study, it has been found that rats subjected to 40 % CR had up to 50 % longer median and maximum life span than animals fed a standard diet.[141] From that time, a number of studies have demonstrated that CR may retard aging or extend life span in many experimental models including yeast, worms, insects and rodents.[142–144] More recently, evidence was obtained that CR may lead to a delayed onset of various age-related disorders in non-human primates such as rhesus monkeys.[145–147] Specifically, prolonged CR resulted in lowered body fat, decelerated rate of muscle loss with age, lowered incidence of cancer, cardio-vascular disease and type 2 diabetes, as well as in improved insulin sensitivity and glucose tolerance. In addition, in conditions of CR the age-related and all-cause mortality of monkeys was substantially reduced.[148] In recent years, accumulating data indicate that moderate CR with qualitatively adequate diet can cause a powerful protective effect against inflammation, hypertension, obesity, type 2 diabetes, and cardio-vascular disease, and also reduce the metabolic risk factors linked to cancer in humans.[149,150] However, although CR has been established to clearly reduce risk factors linked to aging in humans, it is still a matter of debate whether CR can result in increase of human life expectancy.

The important point is that since the human maximum longevity is substantially greater relative to that of closely related non-human primate species, it is likely that humans have acquired genetic variations mimicking the effects of CR. By testing this assumption, Rizza et al.[151] have compared the transcriptome differences between humans and other primates, with the transcriptome changes observed in mice subjected to CR. Findings from this research show that evolution of human life span is likely independent of CR-induced mechanisms of life extension. Based on these and other findings, it can be assumed that application of CR can be a promising direction to the human life extension.[152]

Converging lines of evidence indicate that beneficial effects of CR are mediated by the same pathways which are also involved in the control of tissue repair, immunity, appetite, thermoregulation, and metabolism. [153] Importantly, these effects of CR likely result not from passive metabolic changes, but rather from processes that are highly regulated and depend on the activation of specific effectors.[154] Major nutrient-sensing pathways linked with regulation of the life span by CR are the insulin/insulin-like growth factor signaling (IIS), the adenosine monophosphate (AMP)-activated protein kinase (AMPK) and mTOR pathways, as well as sirtuins, especially SIRT1. These signaling pathways also represent important regulators of cell growth and proliferation, mitochondrial

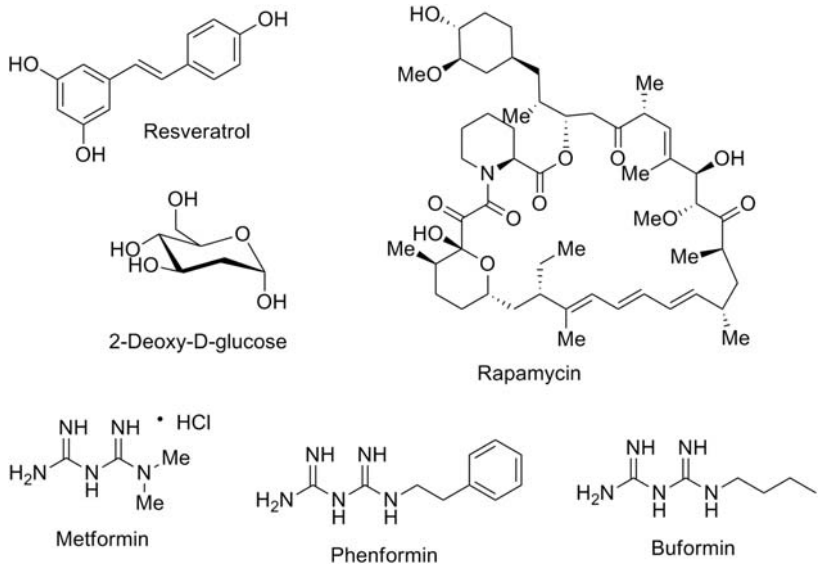

Fig. 5 Chemical agents able to mimick calorie restriction.

function, autophagy, and survival. In addition, the nutrient-sensing pathways involved in CR are known to be regulated by cross talk with one another.

To produce the beneficial effects on healthspan and life span reported in experimental conditions, the long-term CR is necessary. It can be obviously problematic for most modern people. When discussing the clinical trials initiated to assess the therapeutic potential of CR in humans, Ingram et al.[152] stressed that 'even if results from these studies could eventually substantiate CR as an effective pro-longevity strategy for humans, the utility of this intervention would be hampered because of the degree and length of restriction required.' These challenges have generated interest in developing alternatives to CR, which may provide pro-healthspan and pro-longevity benefits of CR without the significant reduction in the long-term food intake. Such agents are referred to as CR mimetics. Ingram et al.[152] defined the characteristic properties of CR mimetics as follows: (1) inducing the hormonal, metabolic and physiological effects similar to those of CR; 2) activation of the stress response pathways like the CR; 3) life span extension and reducing the incidence or delaying the onset of age-associated disorders.

The signaling pathways mediating the effects of CR and most promising pharmacological agents modulating these pathways, such as resveratrol, rapamycin and metformin (Fig. 5), are described in detail in the subsections below.

1.12.3.1 Inhibitors of Glycolytic Metabolism

Hyperglycemia and hyperinsulinemia are widespread in advanced ages. The age-related metabolic disorders such as type 2 diabetes, which are commonly accompanied by disturbance in insulin signaling and glucose homeostasis, are known to produce various aging-like phenotypes such as cancer and other age-associated disorders. Untreated diabetes patients typically have elevated glucose levels and they are more susceptible to certain diseases, such as neurological degeneration, kidney problems, heart disease, vascular and microvascular damage, impaired wound healing and cataracts, which typically occur in most non-diabetics much later in life.[155,156] Hyperglycemia-induced oxidative stress is known to promote the generation of advanced glycosylation end products (AGEs), thereby substantially affecting the rate of aging.[155] The accumulation of AGEs has been shown to be accelerated in diabetes patients and it was suggested to be a credible biomarker for both aging and 'metabolic memory' (the persistence of deleterious effects of prior hyperglycaemia on the initiation and progression of diabetic vasculopathies even after glucose normalization).[157,158] Moreover, hyperinsulinemia, a marker of insulin resistance which is also known to increase with age, is an important causal factor in the pathogenesis of cancer.[159]

CR has been repeatedly shown to reduce the levels of glucose and insulin, and to improve the insulin sensitivity.[160] Therefore, the inhibition of particular enzymes within the glycolytic pathway is assumed to be promising strategy to produce CR-like anti-aging effects.[161] The first candidate agent in this pharmacological category is 2-deoxy-D-glucose, an analog of glucose having a hydrogen atom instead of a hydroxyl group at its C2 position, which may be taken up by cells through the glucose transporters.[162] Within the cell, 2-deoxy-D-glucose is converted to 2-deoxyglucose 6-phosphate by hexokinase in the first step of glycolysis. 2-deoxyglucose 6-phosphate can in turn inhibit phosphoglucose isomerase at the second step of glycolysis and imped processing of glucose to fructose 6-phosphate. Due to these properties, 2-deoxy-D-glucose was applied for decades to affect glycolysis in a variety of organisms from bacteria to mammals, and it was repeatedly shown to have therapeutic benefits for treating epilepsy, viral infection and cancer.[163] This preparation is considered to be particularly promising in anti-cancer therapies. Indeed, since cancerous cells exhibit enhanced glycolysis and use this metabolic pathway for generation of ATP as a main source of their energy supply, the elevated

dependence of cancerous cells on glycolytic pathway for ATP generation provides a biochemical basis for the development of therapeutic strategies to preferentially kill malignant cells by the pharmacological inhibition of glycolysis.[164,165] This drug was also shown to recapitulate several aspects of the CR phenotype such as reduced levels of circulating insulin and body temperature in short-term rodent trials, while obvious toxic effects of 2-deoxy-D-glucose have been demonstrated in one chronic feeding study conducted up to now. In this research, a remarkable CR-like phenotype was revealed in rats treated with this drug, such as reduced food intake and decreased weight gain. These changes, however, were accompanied by cardiac vacuolization and increased mortality in treated animals.[162] Thus, the potential toxicity of 2-deoxy-D-glucose leads to serious challenges in the CR-based therapeutic application of this medication.

1.12.3.2 Inhibitors of GH/IGF-1 Pathway

Among the signaling pathways associated with CR, insulin/insulin-like growth factor-1 (IGF-1) pathway is known to play an important and evolutionary conserved role in the regulation of longevity. There is plenty of research evidence to suggest that CR, as well as protein and amino acid restriction and intermittent fasting, may extend the mammalian life span via modulation of IGF-1 signaling.[166] Accumulating evidence from animal models indicates that reduction in the level of IGF-1 may result in life extension. Particular polymorphic variants of the IGF-1 receptor gene have been shown to be related to the human life span,[167,168] in particular, to the exceptional longevity of centenarians.[169] In addition, low circulating IGF-I bioactivity was shown to be associated with longevity of the exceptionally long-lived individuals,[170] and their offspring.[171]

Remarkably, the long-lived growth hormone (GH) receptor knockout Laron dwarf mice (GHR−/−) were shown to be insulin sensitive despite obesity, and were also found to have significantly reduced IGF-1 levels and decreased risks for diabetes and cancer.[172,173] Similarly, Laron syndrome patients who have low IGF1 levels despite normal or increased levels of GH, have been shown to be protected from cancer and diabetes.[174,175] As a consequence, it can be assumed that treatments targeted at lowering IGF-1 levels could be a promising pharmaceutical strategy for healthspan extension.

Recently, several pharmacological inhibitors of the GH/IGF-1 axis have been proposed for the treatment in patients with acromegaly.[176] Such agents include, for examole, analogues of somatostatin which can reduce the serum levels of GH by suppression of GH secretion by pituitary somatotrophs, thus resulting in reduced serum IGF-1 levels. Although such therapy may potentially lead to adverse effects because these substances are known to suppress secretion of several hormones including the insulin, unfavorable consequences such as anorexia, diarrhea and gallstones, were observed only in 20–50% treated acromegalic patients. Another drug from this pharmacological class to be approved for treating acromegaly is the antagonist of the GH receptor, pegvisomant, which is known to inhibit GH secretion and also inhibit GH action by binding to and blocking the GH receptor.[177,178] In patients treated with pegvisomant, a dose-dependent decrease of IGF-1 levels (up to 90%) has been demonstrated.[177,179] Thereby, since pegvisomant can cause advantageous effects on glucose metabolism by reducing the serum IGF-1 and increasing the insulin sensitivity, it is believed to be a promising agent for health- and life span extension. However, even though no substantial harmful effects of pegvisomant have been observed in the long-term research by van der Lely et al.,[180] further studies are needed to prove its safety. Modulation of IGF-1 availability may be another mode to inhibit IGF-1 action. For this purpose, pharmacological agents modulating the pregnancy-associated plasma protein-A (PAPP-A), a zinc metalloproteinase that enhances the local bioavailability of the IGFs, may be developed. Indeed, it has been reported that PAPP-A knockout mice have significantly extended healthy life span, suggesting an important role of PAPP-A in aging and age-related disease.[181,182] Healthspan-promoting effects of such preparations, however, have not been studied yet and will likely be the subject of future research.

1.12.3.3 Sirtuin-Activating Compounds

Sirtuins, also known as Silent Information Regulators (SIRs), are nicotinamide adenine dinucleotide (NAD+)–dependent protein deacetylases which are thought to play a fundamental role in epigenetic regulation of gene expression by mediating the assembly and maintenance of the silenced chromatin. Sir2, a NAD+−dependent class III histone deacetylase, has been initially identified as a molecule with potent anti-aging properties in yeast studies.[183] Subsequently, Sir2 has been shown to be implicated in control of life span in yeast, the nematode *Caenorhabditis elegans*, and the fruit fly *Drosophila*. In mammals, SIRT1, a homologue of Sir2, has been revealed to act as anti-aging molecule in the context of CR.[184] SIRT1 has been repeatedly found to regulate various biological processes such as gene silencing, mitochondrial biogenesis, stress resistance, inflammation, glucose and lipid metabolism, cell survival, apoptosis and autophagy.[185,186] The important role of SIRT1 in the effects of CR has been revealed in SIRT1 transgenic mice that manifest a CR-like phenotype, exhibiting decreased levels of insulin, fasting glucose blood cholesterol, adipokines, and greater glucose tolerance than the control animals.[187] In addition, in a controlled intervention trial conducted in healthy humans, with measurements before and after the intervention, it has been found that 25 % reduction in calorie intake during six months caused overexpression of peroxisome proliferator-activated receptor (PPAR)-γ coactivator-1α (PGC-1α) and SIRT1 in the skeletal muscle, accompanied by enhanced mitochondrial function and decreased levels of the oxidative stress, body temperature, metabolic rate, visceral fat mass and insulin resistance in non-obese young adults.[188] However, in several studies in yeast, nematodes and *Drosophila*, CR was shown to be able to extend life span in the absence of Sir2.[189–191] Therefore, the importance of sirtuins, particularly SIRT1, in CR-related life extension is still unclear. However, since the activation of SIRT1 is known to decelerate the progression of age-associated diseases and conditions thus extending healthspan, SIRT1 is a potential target for CR mimetics.[192] In addition, the control of SIRT1 activity is closely linked to that of the AMPK, which regulates lipid, cholesterol

and glucose metabolism in specialized metabolic tissues, such as liver, muscle and adipose tissue, and is one of the central regulators of metabolism in eukaryotes.[193] AMPK is known to be activated in conditions where nutrients are limited and promotes oxidative metabolism. It is also known that AMPK can be activated by increasing NAD+ production, and activation of SIRT1 leads to increased AMPK activation via the deacetylation of liver kinase B1 (LKB1), which is the major upstream AMPK kinase.[194,195]

1.12.3.3.1 Resveratrol

Large-scale screening of compounds which are capable of activating SIRs led to the discovery of 18 small molecules demonstrating such properties.[196] Among them, resveratrol, which is a naturally occurring polyphenolic phytoalexin present mostly in grape skins and red wine, but also in peanuts and berries, has been studied most extensively.[197] The investigation of this chemical initially started through the "French paradox" which describes improved cardiovascular outcomes despite a high-fat diet characteristic of Mediterranean countries, including France.[198] In experimental studies, administration of resveratrol in doses of 100–1000 1000 μM mu;M resulted in life extension of short-lived models, such as yeast, worms, fruit flies, and honey bee (for a summary of these studies, see **Table 2**).

The resveratrol-induced life extension in these model organisms was shown to be dependent on the functional Sir2, and was not observed when nutrients were restricted.[199] Resveratrol has been also demonstrated to prolong the life span and retard the onset of age-related markers in short-lived vertebrates such as fish.[200,201] In mice model, resveratrol exerted the beneficial effects on life span and metabolism in high-fat diet-induced obese animals.[202] In mice fed a standard diet, resveratrol delayed age-related deterioration and mimicked transcriptional aspects of dietary restriction without extending life span.[203] In mammals, resveratrol also exhibited the ability to protect against a variety of age-related diseases including Alzheimer's disease, type 2 diabetes and cancer.[208] In obese male patients, 30 days of resveratrol supplementation (150 mg per day) resulted in CR-like effects manifested in prevention of obesity-associated metabolic dysregulation by activating the AMPK/SIRT1 pathway in the skeletal muscle.[209] In addition, resveratrol caused enhanced intramyocellular lipid levels and decreased circulating glucose, intrahepatic lipid content, alanine-aminotransferase, triglycerides and inflammatory markers. More recently, 30-day supplementation with the same dose of resveratrol led to a significantly decreased adipocyte size, with a shift toward a reduction in the proportion of large adipocytes and an increase in the proportion of small adipocytes.[210] Today, resveratrol is one of the most popular dietary supplements on the market. In the U.S., two-thirds of people who consume multiple dietary supplements, consume resveratrol.[211] It should, however, be noted that, despite the high expectations placed on resveratrol as a promising anti-aging drug, some challenges are associated with its application. In recent commentary published in Ann NY Acad Sci, Vang has stressed that: '(1) many different cellular effects are observed for resveratrol, but it is not known whether they arise from one point of action (or a few) or whether resveratrol is non-specific in its action; (2) the health-promotion effect of dietary resveratrol is likely a combinatory effect of various bioactive components in the mixture (diet); (3) the known cell biological response to resveratrol is presently based on exposure to short-term high levels, and better in vitro analyses have to be developed; (4) the actual level of resveratrol and resveratrol metabolites present in vitro

Table 2 Summary of the effects of resveratrol on the life span and associated functional traits of model organisms

Model organism	*Effects observed*	*Reference*
Saccharomyces cerevisiae	Extension of replicative life span by 70%	Howitz et al.[204]
Caenorhabditis elegans	9-18 % increase in mean life span; transcriptional induction of a family of genes encoding prion-like glutamine/asparagine-rich proteins involved in endoplasmic reticulum stress response to unfolded proteins	Viswanathan et al.[205]
	10-14 % increase in mean life span without reducing fecundity	Wood et al.[199]
Drosophila melanogaster	29 % increase in mean life span, 20–22 % increase in maximum life span without reducing fecundity	Wood et al.[199]
	10-17 % increase in mean life span	Bauer et al.[71]
	10-15 % increase in mean life span; downregulation of genes in aging-related pathways, including antioxidant peroxiredoxins, insulin-like peptides involved in insulin-like signaling and several downstream genes in Jun-kinase signaling involved in oxidative stress response	Wang et al.[206]
Apis mellifera	33-38 % increase in mean life span; ingestion of fewer quantities of food under ad libitum feeding conditions	Rascón et al.[207]
Nothobranchius furzeri	33-56 % increase in median life span, 27–59 % increase in maximum life span; delaying the age-dependent decay of locomotor activity and cognitive performances and reducing the expression of neurofibrillary degeneration in the brain	Valenzano et al.[200]
Nothobranchius guentheri	19 % increase in mean life span, 28 % increase in maximum life span; enhanced cognitive ability and locomotor activity; protection from neurodegeneration; reduced rate of lipofuscin formation	Yu and Li[201]
Mus musculus	31% reduced risk of death from the high calorie diet until the 114 weeks of age; increased insulin sensitivity, reduced insulin-like growth factor-1 levels, increased AMPK and peroxisome proliferator-activated receptor-gamma coactivator 1alpha activity, increased mitochondrial number, improved motor function	Baur et al.[202]
	No effect on life span, but a marked reduction in signs of aging, including reduced albuminuria, decreased inflammation, and apoptosis in the vascular endothelium, increased aortic elasticity, greater motor coordination, reduced cataract formation, and preserved bone mineral density	Pearson et al.[203]

and in vivo during experiments may be over- and underestimated, respectively, because resveratrol is not very soluble in water; and (5) only a few small clinical studies have been published to date, focusing on the therapeutic effects of resveratrol.' [212]

1.12.3.3.2 Synthetic activators of sirtuins

Over the last decade, several synthetic activators of SIRT1 such as SRT1460, SRT1720, SRT2104 and SRT2183 (Fig. 6) have been synthesized by a biotechnology company Sirtris Pharmaceuticals. The most studied among them is SRT1720, a specific SIRT1 activator that has been shown previously to cause life extension and amelioration of metabolic impairments in mice fed a high-fat diet.[213] More recently, it has been found that SRT1720 supplementation can result in life span extension and delayed onset of age-associated metabolic diseases in mice fed a standard diet.[214] In a mice model, SRT1720 has been also demonstrated to be able to reverse the adverse age-related changes such as excessive superoxide production, vascular endothelial dysfunction and inflammation.[215] Recently, beneficial effects of another SIRT1 activator, SRT2104, on bone and muscle mass, as well as on survival of male mice have been revealed.[216]

1.12.3.4 Pharmacological Inhibition of mTOR Pathway

The mechanistic (also known as mammalian) target of the rapamycin (mTOR) pathway is another nutrient-sensing pathway playing an important role in mediating the beneficial effects of CR on the rate of aging and longevity.[217] mTOR is a serine/threonine protein kinase that is evolutionarily conserved in all species. It has been repeatedly found to be involved in the processes of cell growth, metabolism and regulation of energy homeostasis.[218] Within the cell, mTOR exists as a part of two distinct multiprotein complexes called mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2).[219] mTORC1 is controlled by numerous signals including amino acids, growth factors and cellular energy and is known to regulate various important cellular processes such as transcription, translation and autophagy.[220] There is ample evidence to indicate that mTORC1 is the main mTOR complex involved in regulating longevity.[221] In the presence of sufficient nutrients, growth factors and energy availability, mTOR switches off autophagy and stress resistance, and switches on cell growth pathways, including translation and ribosomal biogenesis.[222] Since the rate of protein synthesis is known to inversely correlate with longevity,[223] inhibition of protein synthesis mediated by reducing mTOR pathway activity may likely be involved in the life-extending effects across species.[222]

The observation that mTOR is activated by particular amino acids can provide a causal mechanism for the recent findings that decrease in the proportion of protein in the diet, rather than CR per se, can cause a longevity-promoting effect in different experimental models.[224–226] In addition, mTOR signaling is known to play a crucial role in mediating aging and age-related metabolic disorders, such as obesity, type 2 diabetes and cancer.[227] Therefore, mTOR is believed to be a leading target for the pharmacological interventions to modulate the nutrient response pathway and to slow aging. Inhibition of this pathway was repeatedly shown to

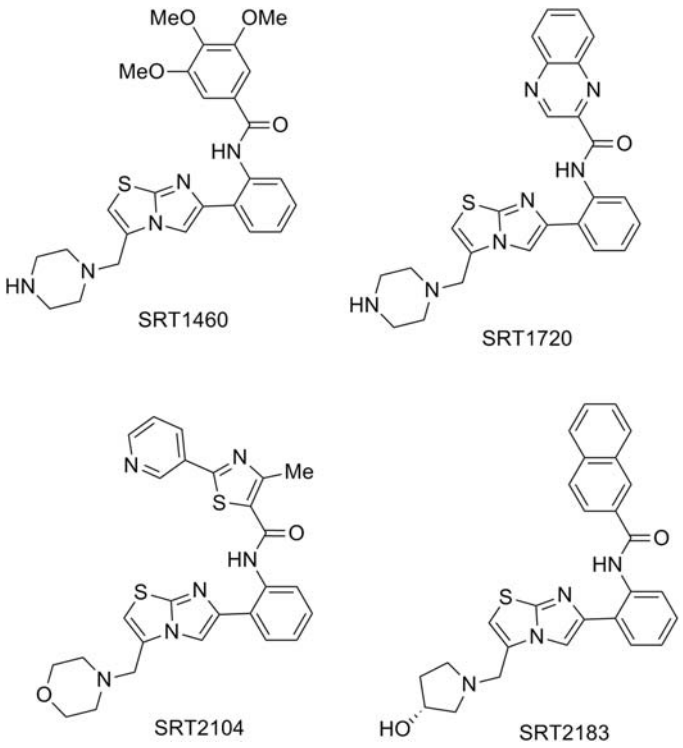

Fig. 6 Sirtuins activators.

confer protection against a growing list of age-related pathologies and to extend life span in a wide spectrum of model organisms.[228] Genetic inhibition of mTOR signaling resulted in life extension in worms,[229,230] fruit flies,[231] and mice.[232] Recently, it has been shown in the gene expression analysis of mTOR pathway, that this pathway not only plays a role in the regulation of aging in animal models, but also in human health and longevity.[233]

1.12.3.4.1 Rapamycin

A commonly used inhibitor of mTOR is rapamycin. It is a natural compound produced by bacteria *Streptomyces hygroscopicus* that was first found in an Easter Island soil sample around 1970. This substance was initially developed as an antifungal agent but was subsequently demonstrated to have significant regulatory effects on many important biological processes including cell growth, proliferation, and inflammation via its inhibitory action on mTOR.[234] Since rapamycin was found to inhibit the immune response, it has been subsequently adopted as a standard therapy to prevent graft rejection in transplant recipients and to treat autoimmune disorders.[235] Currently, rapamycin is approved by FDA for use as an immunosuppressant following transplant surgery and for the treatment of renal cell carcinoma.[234] Due to these properties, rapamycin is suggested to be the most promising anti-aging agent now.[236] Life-extending properties of rapamycin were investigated in several studies conducted in yeast, worms, fruit flies and mice.[221] Supplementation with rapamycin, mostly in doses of 14 ppm ($\sim$2.24 mg kg^{-1}/day) to 42 ppm ($\sim$6.72 mg kg^{-1}/day), lead to significant increase of both mean and maximum life span in these experimental models. A brief summary of these studies is presented in the **Table 3**. Therapy with rapamycin has been also demonstrated to delay variety of aging-associated changes in mice, including liver degeneration, tendon stiffening, accumulation of subcellular alterations in the myocardium, endometrial hyperplasia, and decline in physical activity.[250] In addition, it proved to be effective against other age-related pathological conditions such as retinopathy,[251] cardiac hypertrophy,[252] neurodegenerative disorders,[253] cognitive decline,[254] and loss of stem cell function.[255]

On the basis of the data obtained, it is suggested that potential mechanisms of life extension by rapamycin include antitumor effects,[256,257] induction of autophagy,[258] stem cell guidance,[259] as well as immune-modulating and anti-inflammatory activity.[260] Moreover, the reduction of the rate of protein synthesis can likely mediate the life-extending effects of rapamycin because of decrease of the overall translation rate can prevent the accumulation of damaged or misfolded proteins which could in turn affect longevity.[261] In addition, mTOR is known to be negatively regulated by other nutrient-sensing pathways such as the AMPK and SIRT1 pathways.[262]

Although chronic treatment with rapamycin is known to inhibit both mTORC1 and mTORC2, the life-extending effects of rapamycin are believed to be mediated by the inhibition of TORC1 activity. At the same time, suppression of mTORC2 by rapamycin may lead to impaired glucose homeostasis and insulin resistance owing to unfavorable effects on hepatic gluconeogenesis.[232] Potentially detrimental side effects of chronic rapamycin administration, including hyperglycemia, glucose intolerance and insulin resistance, have been demonstrated in several rodent studies.[263,264] The substantial side effects of rapamycin were also shown in

Table 3 Summary of the effects of rapamycin on the life span and associated functional traits of model organisms

Model organism	*Effects observed*	*Reference*
Saccharomyces cerevisiae	Extension of chronological life span up to 54%	Powers et al.[237]
	15% increase in replicative life span	Medvedik et al.[238]
	19% increase in replicative life span	Ha and Huh [239]
Cenorhabditis elegans	19 % increase in mean life span	Robida-Stubbs et al.[240]
Drosophila melanogaster	Extension of female life span up to 17% and 23% (median and maximum, respectively) on rich media and up to 54% and 36% during starvation; increased resistance to starvation and paraquat stress	Bjedov et al.[241]
	Standard diet: increase in the male mean life span on 6% and increase in the female mean life span on 26%;	Sun et al.[242]
	Low-calorie diet: decrease in the male mean life span on 12% and increase in the male mean life span on 57%	
Mus musculus	14% increase in 90% mortality for female and 9% for male genetically heterogeneous mice fed rapamycin beginning at 600 days of age heterogeneous mice	Harrison et al.[243]
	Increased mean life span (male: 10%; female: 18%) in genetically heterogeneous mice fed rapamycin from the age of 9 months; attenuating age-associated decline in spontaneous activity in males but not in females	Miller et al.[244]
	Increase of mean life span of genetically heterogeneous mice by 23% (males) to 26% (females)	Miller et al.[245]
	11% increased maximum life span in females, prevention of age-related weight gain, decreased rate of aging and suppressed carcinogenesis in transgenic HER-2/neucancer-prone mice	Anisimov et al.[246]
	8% increased maximum life span, inhibited age-related weight gain, decreased aging rate, and delayed spontaneous cancer in inbred females	Anisimov et al.[247]
	Improved survival of C57BL/6 mice after the late-life rapamycin feeding; reduced total and resting metabolic rate during the light (inactive) phase.	Zhang et al.[248]
	Increased median life span in male C57BL/6J mice	Neff et al.[249]

humans from clinical trials with cancer patients in which it has been used as a monotherapy.[265] Side effects of rapamycin in humans include metabolic changes, such as hyperlipidemia, decreased insulin sensitivity, glucose intolerance, hypertension and an increased incidence of new-onset diabetes,[234] as well as diarrhoea, anaemia, nausea or vomiting, thrombocytopenia, skin rash, stomatitis and malignancies (lymphoma and skin cancers).[234, 266,267] The rapamycin-induced metabolic defects were demonstrated, however, to be fully reversible. In both lean and obese mice, these effects have been shown to be almost completely lost within a few weeks of cessation of rapamycin treatment, indicating that chronic treatment with rapamycin does not induce permanent impairments in glucose metabolism.[268]

The important point is that treatment with rapamycin starting late in life is sufficient to extend life span, and, moreover, that transient late-life treatments can yield similar benefits.[221] Indeed, the findings from mice studies suggest that rapamycin supplementation initiated late in life (20 months of age) is nearly as effective as beginning at 9 months of age.[243,244] Late-life transient rapamycin intervention was also shown to reverse the age-associated heart dysfunction, and it also led to the beneficial behavioral, skeletal, and motor changes in 24-month-old female C57BL/6J mice.[269] The opportunity for the benefits of a mid- or late-life rapamycin therapy seems crucially important since mid- or late-life interventions are preferable when considering potential translation of any anti-aging therapy to humans.[221] Characterized inhibitors of mTOR pathway are already clinically approved, and others are under development. Johnson et al. recently pointed out that 'although adverse side effects currently preclude use in otherwise healthy individuals, drugs that target the mTOR pathway could one day become widely used to slow aging and reduce age-related pathologies in humans.' [228]

1.12.3.5 AMPK Pathway

The mTORC1 complex of mTOR is known to be regulated by cellular energy levels through the metabolic sensor, AMPK, which has emerged as another potentially important target in CR-based therapies. AMPK signaling pathway maintains the energy balance in the cell by modulation of ATP production. AMPK is a cellular energy sensor that monitors the AMP/ATP ratio inside the cell. The reduced ATP concentrations in the cell result in increase of AMP levels and to activation of AMPK.[195] Recent studies revealed that, apart from AMP, adenosine diphosphate (ADP) may also be crucially contributed to AMPK activation.[270] Activated AMPK coordinates an energy-conserving program by increase of cellular ATP production and reduction of ATP consumption by shutting down energy-consuming processes such as the mTOR-dependent protein translation.[271] Upon activation, AMPK switches on catabolic pathways that generate ATP, both in a short time frame, by promoting glycolysis and fatty acid oxidation, and in a long time frame, by increasing mitochondrial content and the use of mitochondrial substrates as an energy source, and also switches off the ATP-consuming processes such as biosynthesis as well as cell growth and proliferation.[272] Although these processes can occur to respond to metabolic stress at the cellular level, cytokines and hormones such as leptin, insulin, and adiponectin may interact with this system, and it likely can play a crucial role in maintaining energy balance at the whole body level. AMPK responds to energy stress by suppressing the cell growth and biosynthetic processes, partially via the inhibition of the mTORC1 pathway.[273,274] Moreover, AMPK activation leads to an increased glucose uptake in skeletal muscles, and to a decreased hepatic glucose production and enhanced fatty acid oxidation in various tissues.[275] Numerous data indicate that AMPK inhibits mTOR through the phosphorylation and activation of the tuberous sclerosis complex (TSC) as well as via the direct phosphorylation of the RAPTOR subunit of mTORC1.[276] Recent results suggest that activation of AMPK by the upstream kinase, the tumor suppressor LKB1, in response to nutrient lack occurs at the surface of the lysosome.[277] Thereby, AMPK is an important player in regulation of energy balance at both cellular and whole-body levels via the regulation of insulin sensitivity and mitochondrial biogenesis, as well as in processes of autophagy and stress resistance.[278]

The AMPK system may be partly responsible for the health benefits of exercise. It is a key player in the development of new treatments for obesity, type 2 diabetes and the metabolic syndrome. In addition, it is known as the key integrator and mediator of processes linking metabolism to longevity.[279,280] Because modulation of AMPK signaling is also known to contemporaneously modulate other biochemical pathways which are considered as key anti-aging pathways, including the PPAR gamma coactivator a (PGC-1a), SIRT1 and TOR,[22] AMPK pathway is assumed to be a promising drug target for healthspan and life span extension.

1.12.3.5.1 Metformin

A number of drugs have been developed demonstrating the AMPK-activating properties, including several FDA-approved drugs such as resveratrol, biguanides, salicylates, thiazolidinediones, and glucagon-like peptide-1 receptor agonists.[281] Among them, metformin (1,1-dimethylbiguanide hydrochloride), a biguanide antidiabetic medication derived from French lilac, is in the focus of research activity. Currently, it is considered to be one of the most effective medications for treating type 2 diabetes because it is known to be able to specifically inhibit the hepatic gluconeogenesis without increasing insulin secretion, inducing weight gain or posing a risk of hypoglycaemia.[282,283] It might also act as a CR mimetic since it has been shown to acutely decrease hepatic glucose production, mostly owing to mild and transient inhibition of the mitochondrial respiratory-chain complex 1.[284]

Several studies have shown that administration with metformin and other biguanides, such as phenformin and buformin, can extend the life span of experimental animals such as worms, fruit flies and rodents, although the results have been somewhat inconsistent (**Table 4**).

Increasing evidence for beneficial effects of metformin has been obtained in human studies as well. For example, in a very recent study by Luong et. al.,[298] metformin treatment resulted in significant improvement in body mass index, total cholesterol, low-density lipoprotein cholesterol, and non-high density lipoprotein cholesterol in children with metabolic syndrome. The

Table 4 Summary of the effects of biguanides on the life span and associated functional traits of model organisms

Model organism	*Biguanide*	*Effects observed*	*Reference*
Caenorhabditis elegans	Metformin	Extended median life span, slowed lipofuscin accumulation, prolonged youthful locomotory ability	Onken and Driscoll[285]
	Metformin Phenformin	Increase of mean life span by 18%, 36%, and 3% in worms treated with doses of 25, 50, and 100 mM, respectively; altered microbial folate and methionine metabolism; Increase of mean life span by 5%, 21%, and 26% in worms treated with doses of 1.5, 3, and 4.5 mM, respectively	Cabreiro et al.[286]
	Metformin	Significant life extension; 45% increase in respiration and 38% increase in metabolic heat production	De Haes et al.[287]
Drosophila melanogaster	Metformin	Males: no effect on life span of flies supplemented with 1 to 50 mM, decreased life span at 100 mM; Females: no effect on survival of flies supplemented with 1 to 10 mM, dose-dependent decrease in life span at doses above 10 mM; activation of AMPK and reduced lipid store	Slack et al.[288]
Mus musculus	Metformin	C57BL/6 strain: 5.83%, increase of mean life span in males treated with 0.1%; 14.4% decrease of mean life span in mice treated with 1%; B6C3F1 strain: 4.15% increase of mean life span in males treated with 0.1%	Martin-Montalvo et al.[289]
	Metformin	8% increase of mean life span in female transgenic HER-2/neu mice supplemented with 100 mg kg^{-1}; decreased food consumption; slowdown of the age-related rise in blood glucose and triglycerides level, as well as the age-related switch-off of estrous function	Anisimov et al.[290]
	Metformin	Increase of mean life span up to 37.8% and maximum life span up to 10.3% in female outbred SHR mice supplemented with 100 mg kg^{-1}; slowdown the age-related switch-off of estrous function	Anisimov et al.[291]
	Metformin	8% increase of mean life span in transgenic HER2/neu mice supplemented with 0.5 mg ml^{-1}; increased latency of mammary adenocarcinoma by 13.2%	Anisimov et al.[292]
	Metformin	13.4% decreased mean life span of inbred 129/Sv male mice treated with 100 mg kg^{-1}; no significant effect on female life span; 3.5 times decreased incidence of malignant neoplasms in female mice	Anisimov et al.[293]
	Metformin	Decreased body temperature and postponed age-related switch-off of estrous function in female outbred SHR mice; 14% increase of mean life span in mice treated started at the age of 3 months; no effects on longevity in mice treated starting from the ages of 9 or 15 months. Delayed detection of the first tumor by 22% and 25% in mice treated since the ages of 3 and 9 months, respectively.	Anisimov et al.[294]
	Phenformin	Increase of mean life span of female C3H/Sn mice by 21.1% and the maximum life span by 26%.	Anisimov et al.[295]
Rattus norvegicus	Buformin	9% increase of mean life span in LIO rats, 1.6-fold reduction in cumulative incidence of spontaneous tumors	Anisimov[296]
	Metformin	Reduced body weight, no effect on life span in Fischer-344 rats	Smith et al.[297]

anti-cancer effects of metformin among both diabetic and non-diabetic patients have been also observed.[299–301] In addition, treatment with metformin caused the 30 % reduction in the lifetime risk of cancer incidence in diabetic patients.[302] Remarkably, microarray analysis revealed a considerable similarity between the gene expression patterns generated by both metformin and CR.[303]

There is an increasing recognition that metformin can directly act on tumor cells, primarily affecting the mitochondrial respiratory chain, thereby resulting in the activation of AMPK. Recent research findings, however, indicate that AMPK-independent pathways may also explain both beneficial and unfavorable effects of metformin.[304] These pathways include suppression of glucagon signaling, alteration of intestinal microbiota, inhibition of mitochondrial shuttles, induction of mitochondrial stress, activation of autophagy, attenuation of inflammasome activation, induction of incretin receptors and reduction of terminal endoplasmic reticulum stress.[305] Thus, therapeutic and pro-healthspan effects of metformin have been well established. However, as it was recently stressed by Longo et al., 'to consider metformin for clinical trials testing its potential anti-aging effect, it will be important to closely examine the known effects of long-term use on a wide range of subjects and particularly those who are relatively healthy, but also those with specific conditions for whom chronic metformin use may have been shown to be detrimental.' [161]

Summarizing the research findings on the effects of CR mimetics, it should be noted that, despite the increasing interest in applying these substances in anti-aging medicine, any proven CR mimetics have been identified until now. Several candidate medications, such as resveratrol, rapamycin and metformin, however, appear highly promising. By arguing that both CR and CR mimetics induce their beneficial effects through numerous signaling pathways, Ingram and Roth (2015) have recently proposed to use the "cocktails" of CR mimetics to simultaneously affect multiple pathways. [144] For example, metformin might be expected to block the glucose dysmetabolism caused by rapamycin treatment via inhibiting the gluconeogenesis by downregulating expression of glucose-6-phosphatase and phosphoenolpyruvate carboxykinase.[306] Such combined strategy would likely be more secure and provide a more balanced therapeutic approach, especially in relatively healthy subjects.

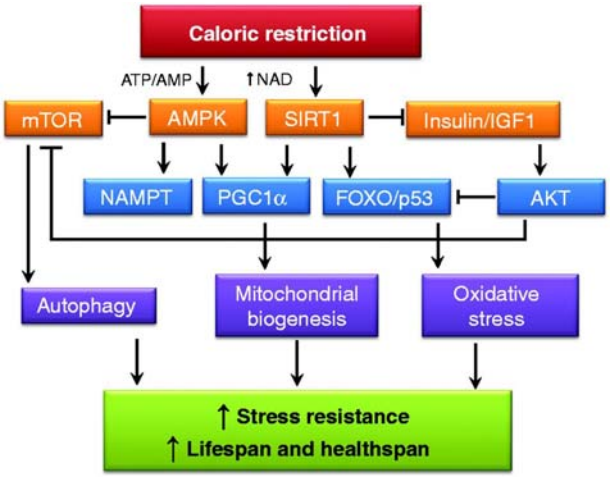

Fig. 7 The complex metabolic network of potential players in the mechanism of CR. A reduction in energy intake influences cellular energy levels, activating the AMPK and SIRT1 pathways. Antagonistic responses include the inhibition of the anabolic pathways mTOR and insulin/IGF1. Downstream effects result in increased stress resistance and improved life span and healthspan. The figure is reproduced with permission of the copyright holders from Solon-Biet, S.M.; McMahon, A.C.; Ballard, J.W.; Ruohonen, K.; Wu, L.E.; Cogger, V.C.; Warren, A.; Huang, X.; Pichaud, N.; Melvin, R.G.; Gokarn, R.; Khalil, M.; Turner, N.; Cooney, G.J.; Sinclair, D.A.; Raubenheimer, D.; Le Couteur, D.G.; Simpson, S.J., The ratio of macronutrients, not caloric intake, dictates cardiometabolic health, aging, and longevity in ad libitum-fed mice, Cell Metab 19 (3) (2014) 418–430.

The complex metabolic network of potential players in the mechanism of CR and CR-mimicking interventions is presented in Fig. 7.

1.12.4 Autophagy

Autophagy is a cytoplasmic catabolic process of protecting cells against stressful conditions. By this process, damaged or defective cellular components are engulfed into the lysosomes for degradation and recycling of their components; then they can be used for protein synthesis and cellular repair.[307] Depending on the mode of delivery of cellular material to lysosomes, autophagy is generally classified into three major categories: microautophagy, macroautophagy, and chaperone-mediated autophagy.[308] Among them, macroautophagy (usually referred to as 'autophagy'), a degradative pathway wherein cytoplasmatic components such as aggregated/misfolded proteins and organelles are engulfed within double-membrane vesicles (autophagosomes) and then delivered to lysosomes for degradation, is the most prominent and best-studied form of autophagy. This process is involved in degrading and recycling macromolecules and damaged organelles to maintain intracellular homeostasis in conditions of metabolic stress.

The autophagy pathway is evolutionarily conserved across diverse species ranging from yeast to mammals. For decades, this process has been regarded as a predominantly unspecific and destructive, contributing to 'autophagic cell death'. However, recent research has uncovered important cytoprotective functions of this pathway including fuel utilization, cellular differentiation and protection against cell death.[309] The cytoprotective effects of autophagy are generally attributed to the digestion of potentially harmful intracellular structures, including aggregates of misfolded proteins and damaged organelles.[310,311] Madeo et al.[312] speculated in their recent review that major mechanistic pathways contributing to cytoprotection by autophagy are: '(a) buffering of cellular stress in conditions of fluctuating nutrient availability by enhanced provision of substrates for bioenergetic metabolism and anabolic reactions, (b) removal of dysfunctional and harmful organelles, including uncoupled mitochondria, and (c) clearance of aggregate-prone, potentially toxic proteins.' On the whole-organism level, these pathways can be expanded by the immunoregulatory effects of autophagy, suppression of carcinogenesis as well as by hormetic responses.[312]

The autophagic cytoprotective response allows cell to mobilize the energy resources from recycled organelles in order to cope with stress, particularly in conditions of hypoxia, amino acid and/or glucose deprivation, genotoxic stress and viral infection.[313–315] As a consequence, autophagy induced by hypoxia or nutrient deprivation enhances cellular survival, and thereby improves cellular fitness, while inhibiting this pathway can precipitate bioenergetic failure and cell death.[316] The autophagy-induced enhanced stress resistance has been revealed at the organismal level as well. The induction of autophagy is believed to be contributed to the beneficial effects of fasting,[317] low-dose radiation (radiation hormesis)[318] and low doses of toxins and other stressors.[311] It can also play an important role in aging process because they counteract the age-associated accumulation of damaged organelles and proteins. Since the capacity of the cell for autophagic degradation is known to decline with age, it is not surprising that autophagy has an important impact on pathological processes common to the elderly. A deficient autophagy is suggested to

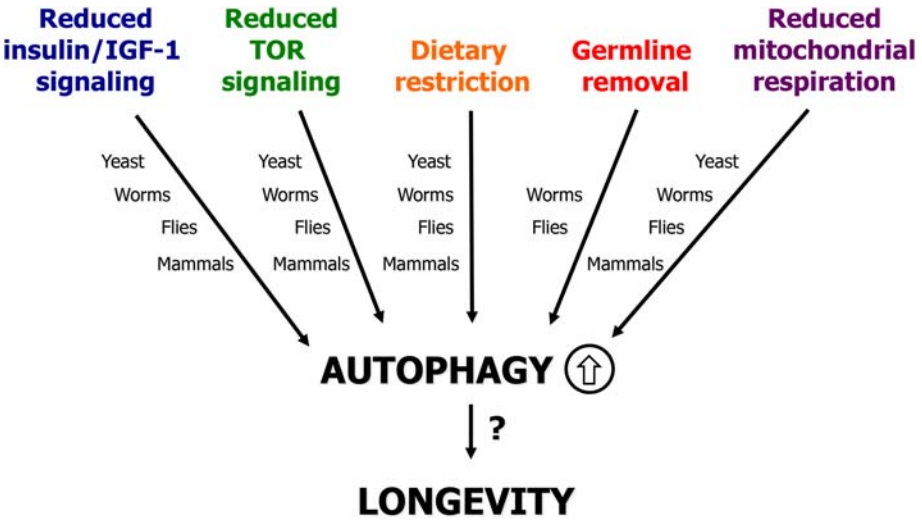

Fig. 8 Conserved longevity pathways and processes, which modulate aging via autophagy. Additional interventions not listed here, e.g., the polyamine spermidine may also engage autophagy as a possible effector mechanism to extend life span. For simplicity, the interactions between the pathways are not shown, whereas the degree of conservation is indicated. While the mechanisms by which autophagy affects aging through these longevity paradigms are not yet fully elucidated, several positive regulators of autophagy have been identified, including the forkhead transcription factor FOXO, the histone deacetylase SIRT1, the energy sensor AMPK, and the forkhead transcription factor PHA-4/FOXA. The figure is reproduced with permission of the copyright holders from Gelino, S.; Hansen, M., Autophagy – an emerging anti-aging mechanism?, J Clin Exp Pathol (4) (2012) pii:006, with correction.

contribute to a variety of age-related pathological conditions such as excessive lipid accumulation, glucose intolerance, reduction of muscle mass (sarcopenia), neurodegeneration and cardiac malfunction.[309]

Autophagy-related genes (ATGs) have been shown to be significantly implicated in the life extending effects observed in fruit flies, nematodes and mice.[319] In experimental models, autophagy has been demonstrated to be induced by the same genetic manipulations that are known to extend longevity, such as mutations in crucial signaling pathways like the TOR, SIRT1 and insulin/IGF-1 pathways.[307,320] Moreover, life extending effects have been repeatedly obtained by the pharmacologic induction of autophagy in experimental studies.[312] The schematic presentation of autophagy-mediated pathways potentially influencing longevity is presented in Fig. 8.

Biological mechanisms underlying the role of autophagy in health and disease are not properly understood to date, however there are several plausible explanations for this. Enhanced autophagy can improve the resistance of the cell to stress by increasing its metabolic buffering capacity or, alternatively, it can enhance the organelles' turnover, thereby preventing the accumulation of old or damaged organelles.[321–323] Moreover, the reduced autophagy can contribute to the progression of cancer, whereas the increased level of autophagy is characteristic to cancerous cells where the availability of nutrients and oxygen is restricted and represents a mechanism of cell survival aimed to overcome the cellular stress and cytotoxicity induced by drugs.[324]

1.12.4.1 Pharmacological Induction of Autophagy

Depending on the pathophysiological context, pharmacological suppression or induction of autophagy can cause therapeutic effects through promoting either survival or death of particular cell groups which may be critically important when attempting to treat chronic human disorders, including cancer.[325] Currently, it is commonly believed that modulating the autophagy activity via targeting specific components of its molecular machinery can affect the development and progression of the chronic pathological processes, thereby representing a promising pharmacological target for therapeutic application in treatment of age-associated diseases. Many recent data indicate that autophagy can mediate CR-dependent life span extension, and also that induction of autophagy may contribute to the pharmacologically-induced life extension in various experimental models.[326]

Involvement of autophagy in life-extending effects of rapamycin has been demonstrated in yeast, worms and fruit flies. In yeast, rapamycin was not able to extend the chronological life span of mutants lacking the essential autophagic genes, *ATG1* and *ATG7*.[327,328] Autophagy was also found to be required for life span extension by rapamycin in *C. elegans*: no positive effect on longevity was observed when the essential autophagy genes, *VPS34* and *BEC-1*, were knocked down.[329] Role of autophagy in rapamycin-induced life extension has been also found for *Drosophila melanogaster*.[241]

Resveratrol is another commonly used drug whose health-promoting effects are believed to be mediated by autophagy. In many organisms, including humans, resveratrol was found to substantially increase the level of SIRT1, which is a key regulator of both autophagy and longevity, but failed to extend life span under the lack of SIRT1. For example, resveratrol treatment caused life extension in the autophagy-proficient nematodes in conditions of CR. These beneficial effects, however, were abolished by the

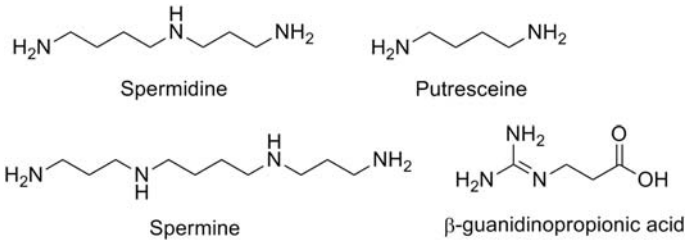

Fig. 9 Autophagy-inducing agents.

knockdown of the essential autophagic modulator Beclin-1.[330] These findings indicate that life-extending effects of resveratrol are consistent with SIRT1-dependent induction of autophagy.

Similarly to the resveratrol, which is the histone deacetylase activator, the histone acetylase inhibitor, spermidine, can induce autophagy by upregulation of ATG genes and extend life span in a range of model organisms from yeast to mice.[326,331–333] This ubiquitous molecule is a naturally occurring polyamine interacting, along with other polycations, with negatively charged molecules, including RNA, DNA and lipids, thereby substantially influencing basic cellular functions such as DNA stability, as well as cell growth, proliferation and death. The intracellular concentrations of spermidine have been shown to decline through the aging process.[334] Recently, spermidine has been emerged as promising anti-aging substance.[334–336] The supplementation with this agent was shown to increase the resistance to stress and life span in yeast, nematode worms and fruit flies, as well as to decrease the loss of age-related locomotor activity and the incidence of age-related pathological changes.[334,336,337] Supplementation with spermidine and other physiologically relevant polyamines, putrescine and spermine (**Fig. 9**), also increased both healthspan and life span in mice,[332,333] although implication of autophagy has not been examined in this research.

Since spermidine can affect the acetylation profile of many proteins (mostly belonging to the autophagy protein network), autophagy is currently believed to be the main mechanism mediating the anti-aging effects of this substance. Involvement of autophagy in the life-extending effects of spermidine is evident from the fact that these effects were abolished in yeast, worms and fruit flies if autophagy was blocked by knockout or knockdown of the essential autophagy genes, *ATG7* or *BECN1*.[326] Remarkably, the deletion of SIRT1 did not abolish the life-extending capability of spermidine, indicating that spermidine can promote longevity by pathways other than SIRT1.[326] Other candidate pathways, mTOR and AMPK, are also unlikely to play a crucial role, because of spermidine does not alter the phosphorylation status of mTOR, AMPK and their substrates.[338] In addition, recent research has demonstrated that spermidine may act through mechanisms such as control of inflammation and lipid metabolism, as well as regulation of cell growth, proliferation and death.[337] It is currently believed that another important signalling pathway mediating the effects of spermidine is the MAPK pathway, which is known to interact with polyamines. This pathway was shown to be involved in the control of cellular functions such as cell proliferation, inflammation, and programmed cell death, and also in autophagy modulation.[339,340] It should be, however, noted that since the health benefits and life-extending effects of spermidine are generally mediated by inhibition of histone acetylase activity, whereas similar beneficial effects of resveratrol are due to the activation of the histone deacetylase, SIRT1, it may be indicative of the important role of histone acetylation in both the autophagy and longevity pathways. Supplementation with spermidine can cause histone deacetylation, thereby inducing changes in gene expression.[334]

In recent years, other potent autophagy-inducing agents have emerged as exhibiting life-extending properties. For example, it has been demonstrated that β-guanidinopropionic acid (a creatine analog that causes ATP depletion) (**Fig. 9**) can extend the life span of *Drosophila melanogaster* via an AMP-activated protein kinase-dependent increase in autophagy.[341] Administration of ethanolamine (a precursor of phosphatidylethanolamine which is an essential component of most biological membranes) was also shown to positively regulate the autophagy and longevity in yeast.[342] Experimental findings on the life span-modulating effects of autophagy-inducing agents are summarized in **Table 5**.

1.12.5 Melatonin

Melatonin (**Fig. 3**) is a natural hormone produced predominantly by pineal gland in the brain and released into circulation in a pulsatile fashion with the sharpest peaks in the early morning hours.[343] It is a highly pleiotropic agent acting not only as an orchestrating chronobiotic required for some high-amplitude rhythms, but also a potent antioxidant that prevents excessive free radical formation thus supporting the redox balance, a modulator and protectant of mitochondrial electron flux, a coregulator of metabolic sensing and antagonist of insulin resistance, as well as an immune modulator.[344] In addition, its effects appear to be mediated by autophagy and regulation of some signaling pathways that influence energy metabolism, including insulin/IGF1, Akt and phosphoinositide 3 kinase (PI3K), as well as mTOR signaling pathway.[345]

The role of melatonin in aging process is evident from the observation that both aging and age-associated disorders are linked to loss in melatonin secretion and decline of circadian amplitude of the melatonin rhythm. Recently, it has also been suggested that life span-modulating effects of melatonin may be attributed to SIRT1 activation.[346] On this background and since melatonin is shown to be a safe and well tolerated substance, it attracts great interest for the application in anti-aging medicine. Its potent aging-

Table 5 Summary of the effects of autophagy-inducing agents on the life span and associated functional traits of model organisms

Model organism	*Substance/dose*	*Effects observed*	*Reference*
Saccharomyces cerevisiae	Rapamycin (0.1–40 nM)	Extension of chronological life span accompanied by induction of autophagy in wild-type strain; no effects on life span in autophagy-deficient mutant strains, ATG1 and ATG7	Alvers et al.[327,328]
	Spermidine (1 mM)	Extension of chronological life span in an autophagy-dependent fashion	Eisenberg et al.[334]
	Ethanolamine (10 mM)	Extension of chronological life span in an autophagy-dependent fashion	Rockenfeller et al.[342]
Caenorhabditis elegans	Spermidine (0.2 mM)	Extension of life span in an autophagy-dependent fashion	Eisenberg et al.[334]
Drosophila melanogaster	Spermidine (1 mM)	Extension of life span in an autophagy-dependent fashion	Eisenberg et al.[334]
	Spermidine (0.1 and 1 mM)	Increased median life spans, enhances starvation resistance, improved survival on paraquat, reduced female fecundity; abolished life extension by downregulation of autophagy through the reduction in expression of ATG5 gene by RNA interference	Bjedov et al.[241]
	β-guanidinopropionic acid (>900 mM)	Life extension via an AMP-activated protein kinase-dependent increase in autophagy; abolished life extension by downregulation of autophagy through the reduction in expression of ATG5 gene by RNA interference	Yang et al.[341]
Mus musculus	Mixture of spermine, spermidine and putrescine (374 to 1540 nmol g^{-1})	Increased survival, lower incidence of glomerulosclerosis in kidney	Soda et al.[332]
	Mixture of spermine, spermidine and putrescine (374 to 1540 nmol g^{-1})	Reduced mortality in advanced age; decreased age-associated pathological changes, suppressed age-associated increase in pro-inflammatory status, inhibited age-associated global alteration in DNA methylation status and 1,2-dimethylhydrazine-induced tumorigenesis	Soda et al.[333]

modulating properties were investigated in a range of model systems.[347] Life-extending capabilities of melatonin have been repeatedly demonstrated in *Drosophila melanogaster* and in mice.[348] Findings from these studies are summarized in the **Table 6**.

1.12.6 Perspective and conclusion

This chapter is devoted to review literature related to the development of theoretical concepts, as well as advances and perspectives in the field of anti-aging pharmacology. Based on analysis of research findings reviewed in the chapter, the conclusion can be made that this research field has evolved from the reductionistic to more systemic holistic thinking and approaches. It seems increasingly clear that a single cause cannot properly explain the anti-aging and longevity-promoting effects of various pharmacological classes. In the middle of the past century it was generally believed that cellular damages induced by free radicals are the main cause of aging and that supplementation with exogenous antioxidants can protect against such damages, thereby slowing the aging process and preventing the age-related chronic pathologies. Presently, however, it is becoming increasingly obvious that pro-longevity effects of most potential anti-aging drugs are complex and may be attributable to multiple interacting signaling pathways. For example,

Table 6 Summary of the effects of melatonin on the life span and associated functional traits of model organisms

Model organism	*Effects observed*	*Reference*
Drosophila melanogaster	Increase of life span up to 19% in males and up to 12% in females	Izmaylov and Obukhova [72]
	13.5% increase in median life span; 33.2% increase in maximum life span; increased resistance to paraquat and to heightened temperature (36°C)	Bonilla et al.[349]
	27.8% decrease in mean life span, 25.4% increase in maximum life span; increased eclosion rate and the locomotor activity; decreased concentration of malondialdehyde	Terán et al.[350]
Mus musculus	5.4% increase in mean life span of female CBA mice; decreased locomotor activity and body temperature; delay of the age-related switching-off of estrous function; 20% increase in malignant tumor incidence	Anisimov et al.[351]
	10% increase in maximum life span of female SHR mice; delay of the age-related switching-off of estrous function	Anisimov et al.[352]
	17.4% increase in maximum life span of SAMP8 mice; normalized redox and bioenergetic status of the mitochondria and increased ATP levels	Rodríguez et al.[96]

resveratrol, in addition to being the well-known sirtuin-activating substance, also showed other beneficial properties, such as antioxidant activity. Moreover, both resveratrol and other promising anti-aging drug, spermidine, can induce autophagy by differing pathways, the first one by SIRT1 activation and the second one through protein hypoacetylation. In addition, hormesis (beneficial effects from low doses of potentially toxic substances) may also be involved in pro-longevity effects of various compounds.[105,353,354] Such substances can cause the mild stress-induced activation of several stress response pathways and stimulation of repair mechanisms, thereby reducing the age-related accumulation of molecular damage.[355] Thereby, it can be assumed that, taking into account the complexity of the aging process, application of hormesis-based systemic approach addressed primarily to mechanisms of central regulation of the aging process could be a novel promising strategy to slow down aging and to extend the healthspan and life span.[99]

Taking into account the extraordinary complexity of mechanistic pathways underlying aging process, the recognition of these pathways and development of anti-aging interventions seems a challenging task. Significant progress, however, has been achieved in this research field during the past years. A number of pharmacological agents with the potential to target particular pathways associated with aging and to produce protective responses against age-related pathologies are currently under investigation. Nowadays, there is an active search for new classes of pharmacological agents capable of modulating the rate of aging. Apart from the substances with potential clinical value in the treatment of aging-related conditions, which are described in detail in this review, other agents also may be classified as potent anti-aging therapeutic compounds. All these compounds are multi-functional and targeted at multiple signaling pathways affecting aging. Among them, there are phytochemicals such as curcumin, a natural extract from the turmeric spice which is a powerful antioxidant and efficient inhibitor of mTOR and NF-kappaB,[356] as well as epigallocatechin gallate (EGCG), a flavonoid extracted from green tea shown to prevent age-related inflammation and oxidative stress via the inhibition of NF-kappaB signaling by activation of the pro-longevity factors including forkhead box transcription factor FoxO3a and SIRT1 (Fig. 6).[98] A lot of hope is also being pinned on pharmacological agents targeted to epigenetic regulators of gene activity, such as inhibitors of DNA methyltransferases and histone deacetylases (HDACs). Life-extending properties of HDACs including sodium buthyrate, trichostatin A (TSA), sodium 4-phenylbutyrate (PBA) and suberoylanilide hydroxamic acid (SAHA) (Fig. 10) have been reported repeatedly in *Drosophila* studies.[357–359] The evidence remains however limited regarding the overall health benefits of these substances, including epidemiological studies exploring the impacts of various intake levels on human health.

In summarizing it can be concluded that targeting aging per se can be more effective approach to postpone or prevent age-associated disorders than treatments targeted to specific pathological conditions. Because of the aging population, such therapeutic strategy is undoubtedly an area of enhancing relevance for pharmaceutical industry and public health organizations. Longo et al. concluded in their recent review that 'the time has come not only to consider several therapeutic options for the treatment of age-related comorbidities, but to initiate clinical trials with the ultimate goal of increasing the healthspan (and perhaps longevity) of human populations, while respecting the guiding principle of physicians primum non nocere.[161] Currently, this is the consensus among physicians and health professionals that the optimization of physiological and mental functioning throughout the life span should be a major emphasis of any contemporaneous biomedical policy addressing global aging. The healthy lifestyle comprising proper diet and physical activity represents the first-line function-preserving strategy. Pharmacological compounds, both existing and potential, can serve as prospective complementary approach.[11]

In a modern pharmacy, anti-aging is likely one of the most promising markets because the target group can potentially include each person. Current marketing research indicates that most people are willing to pay for long-term pharmacological therapy to prevent or delay the aging-related decline in physical and mental functions.[153] Optimistic predictions of the feasibility of health- and life-extending interventions, however, should certainly be critically discussed in the light of their ethical, economic and social implications. Only after in-depth examination and following comprehensive debates, the implementation of such approaches in clinical practice will be possible. To meet the requirements created by the rapid aging of the population in both developed and developing countries, a new emphasis in physiological geroscience is needed that will demand the joint efforts of interdisciplinary researchers working throughout the continuum of translational research from basic science to health care.

1.13.1 Introduction

Stemistry[1] is the term given to describe the search for, and use of, small molecules able to affect the behavior of endogenous stem, stemlike, or progenitor cells. "Affecting the behavior" includes the stimulation of the proliferation of these cells, their directed differentiation to specific cells, their migration, and the dedifferentiation/transdifferentiation of differentiated cells. Such molecules could be used in regenerative medicine to repair tissue in two general ways. The ex vivo approach would remove cells from the patient and expand and differentiate them in vitro before transplanting into the patient. A particular medical advantage of this approach is that the cells to be transplanted could be subjected to rigorous quality control and inspection to ensure that only the desired cells were present and that teratoma formation would be highly unlikely. In the clinical situation, however, the resources needed for this are, except in a research environment, likely to be high and possibly difficult to justify at a time when all health systems are under significant financial pressures. There have been reports of successful applications of this procedure although definitive treatments

have yet to be confirmed. The alternative approach that would be much simpler for both the health professional and the patient is the in vivo one in which the transforming drug(s) were dosed directly to the patient.

Current research reviewed by us[1] and others[2,3] has shown considerable progress in identifying small molecules able to affect cell behavior in the desired manner. Whereas the major emphasis in this article are studies toward finding in vivo active small molecules, and several pioneering examples have been described in recent years, a significant body of work published to date has come from in vitro studies. In many instances these latter studies have found utility in cell-based transplantation therapies. While a full discussion of cell transplantation therapies is beyond the scope of this review, these systems also represent useful models and selected examples are discussed in this context. Before reviewing some of these findings it will be helpful to define the terminology used in this research.

1.13.1.1 Definitions

The terms and their definitions that are used in this article are as follows (Fig. 1).

Self-renewal is the process whereby a stem cell divides to produce at least one copy of itself.

Proliferation is the production of multiple exact copies of any cell.

Differentiation is the process whereby a cell is transformed into a new cell type. In the context of this article it refers to the change of a stem or progenitor cell into a particular cell type.

Dedifferentiation or transdifferentiation is either the reversion of a cell type to a progenitor cell or directly to a different, differentiated cell type.

Stem cells possess two critical properties, namely, the ability to repeatedly self-replicate through cell division while maintaining an undifferentiated state and the capacity to differentiate into specialized cell types. They are conveniently divided into a number of types depending on their location and ability to produce differentiated cells. In decreasing ability to produce different cell types, these are:

Totipotent stem cells are only found in the fertilized egg and the first few cell divisions. They are able to produce all the 200+ cell types of the adult human as well as the placenta and extra-embryonic tissue.

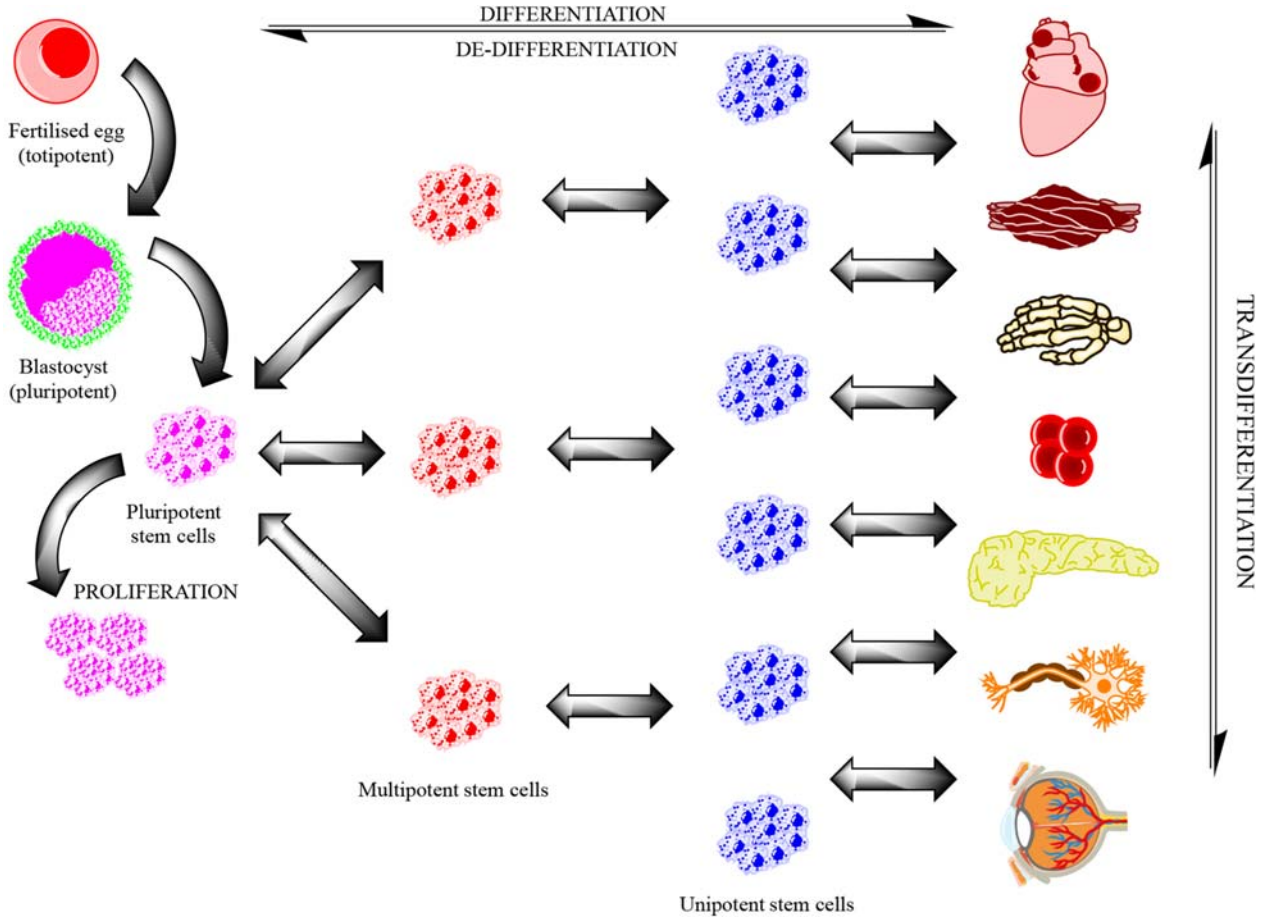

Fig. 1 Stem cell ontogeny and manipulation.

Pluripotent stem cells are derived from the epiblast tissue of the inner cell mass of the very early stage, that is, less than 5 days old, embryo and are capable of producing all the cells of the embryo and the adult except for the placenta and the extra-embryonic tissue. Historically, these cells could not be isolated without bringing about the death of the embryo and this has made the use of human embryonic stem cells (hESCs) problematic or unacceptable to a number of cultures and religions.

A major breakthrough occurred with the finding that adult terminally differentiated cells could be reprogrammed to produce pluripotent stem cells. These so-called induced pluripotent stem cells were initially derived from skin fibroblasts and later from those of the stomach, liver, skin, and blood. They were reprogrammed using the transcription factors (TFs) Oct 3/4, Sox2, c-Myc, and K1f4, but this procedure is complicated, inefficient, and carries the risk of tumor formation.[4] It is of particular relevance to this article that recently Deng and coworkers have been able to replace the TF Oct 4 by one of three candidate molecules (**Fig. 2**; forskolin (1), 2-methyl-5-hydroxytryptamine (2), D4476 (3)) and, in a separate study, the TFs Sox2, c-Myc, and K1f4 by a combination of four small molecules (valproic acid (4), CHIR99021 (5), 616452 (6), and tranylcypromine (7)). They went on to optimize this small molecule cocktail to develop a chemically induced reprogramming protocol, albeit with only 0.2% frequency.[5]

Multipotent/unipotent stem cells can only produce one or more differentiated cell types usually associated with specific tissues or organs. Examples include hematopoietic stem cells found in the bone marrow that give rise to red and white blood cells and platelets. Mesenchymal stem cells (MSCs) are also found in the bone marrow and give rise to stromal cells, fat cells, and bone cells. Epithelial stem cells give various types of skin cells while satellite cells contribute to differentiated muscle cells.

Progenitor cells have a tendency to differentiate into a specific target type of cell, although unlike the case with stem cells this cannot occur indefinitely and is restricted to a limited number of stages.

Adult or somatic stem cells are found in both children and adults and occur throughout the body and their role in natural repair processes is a subject of ongoing research. They can self-renew and generate the cell types comprising the organs where they reside including the hematopoietic system, bone marrow, central nervous system, liver, skin, cornea, gut, skeletal muscle, and adipose tissue. While compared with hESC and hiPSC they do have limited proliferation and differentiation capacity in vitro they confer a low risk of tumor formation after being transplanted to patients. In fact, a number of clinical trials are currently in place to investigate the use of adult stem cells to restore normal functioning in neurodegeneration, spinal cord injury, graft-*versus*-host disease (GVDH), and diabetes.[3]

To reiterate, the medicinal chemistry approach to regenerative medicine is to identify small molecules able to selectively influence stem cells in vivo in a therapeutically valuable way to produce new, healthy tissues, a process that has been termed "molecular organ repair."[6] The obvious question that a critic could pose is "is there any evidence that such an approach is at all feasible?" Poss[7] has discussed known in vivo tissue repair such as that seen in the liver while pointing out that mammalian tissues such as cardiac muscle and the spinal cord appear to have little regenerative capacity. He did also note that stem cells are not necessarily involved even in well-established instances of tissue regeneration. In particular, in the salamander, which is usually taken as the example *par excellence* of regeneration, the process seems to be one of dedifferentiation of tissue-specific cells rather than stem cell differentiation. These studies indicate that test systems designed to detect activity arising from a range of cell types can be established and could be used for the detection of small molecules that influence their behavior.

The hESCs contain the potential to produce exact daughter cells and to differentiate into all other adult cell types, which have only limited ability to change further. Thus the stem cell under the influence of the correct signaling factors is able to produce gene products that cause the cell to proliferate or to begin the differentiation process leading to the new cell lineages. A key feature in

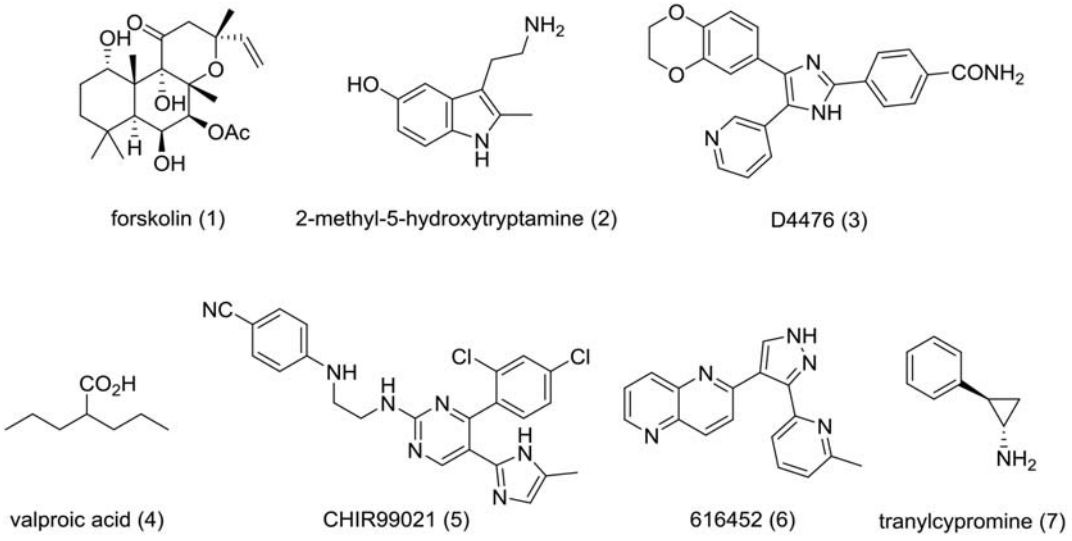

Fig. 2 Small molecules which used in combination are able to reprogram differentiated cells to pluripotent stem cells.

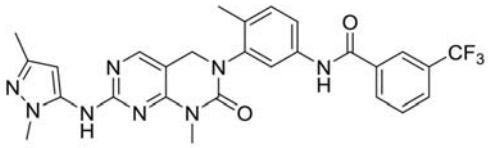


(8)

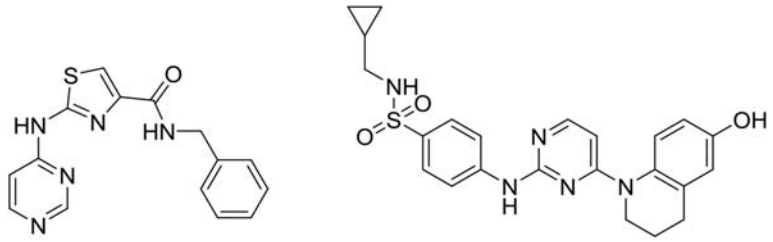
Fig. 3 Chemical structure of Pluripotin SC1 (8).

development is that conversion of a pluripotent stem cell to, say, a kidney cell, takes place through a number of steps all of which require the sequential production of signaling factors. Each of these processes produces only the targeted cell in a specific location so that, for example, a kidney cell ends up in the kidney and not the heart. Since in vitro studies demonstrate that the stem cell cannot itself "decide" to make a particular cell, this must mean that at a certain point in the development of the embryo signaling from other cells in the vicinity must play a role in the differentiation process. This microenvironment in which a stem cell resides has been designated the "niche" and it seems highly likely that growth factors either released into the niche or present in the extracellular matrix or on the surface of adjacent cells are responsible for the differentiation of the stem cell. In the later section of this article dealing with the pancreas, work will be described in which a prepared extracellular matrix is able to direct the differentiation of a stem cell to a pancreatic β-cell during in vitro culture.

Thus differentiated cells are produced as a result of growth factor interactions, that is, by protein–protein and ligand–receptor interactions and modulation of enzyme activity; medicinal chemistry has a substantial history at being able to find agents capable of interrupting such interactions to great therapeutic benefit. But how might such compounds be discovered? Initially with little information on the biochemistry/cell biology of the stem cell being known the way forward was via high-throughput screening of libraries of compounds using stem cell proliferation or differentiation readouts. Our previous perspective[1] discusses a number of such studies so one example will suffice here to show the principle involved. Schultz et al. used a reporter murine embryonic stem cell line from transgenic OG2 mice, which had been transfected with the regulatory region of the Oct-4 gene (a widely used pluripotency marker) fused with that for green fluorescent protein (GFP).[8] Under incubation conditions such cells lose both GFP expression and their compact colony morphology completely in 4–6 days in the absence of feeder cells and leukemia inhibitory factor so the maintenance of GFP expression in the presence of test compounds is a good indication of maintaining pluripotency of the stem cells. One active compound found in a library of 50,000 compounds was SC1 (pluripotin) ((8), Fig. 3), which on further biochemical investigation showed to be a dual function inhibitor of both extracellular signal-related kinases (ERK) and Ras GTPase activating protein (Ras GAP). Thus pluripotin allows the propagation of murine ESCs in an undifferentiated pluripotent state under chemically defined conditions and also gives ideas about some of the biochemical pathways involved in this process, which might be further exploited in the search for new agents.

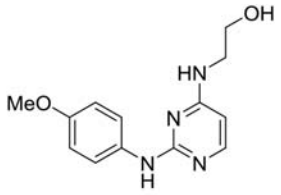
Lu and Atala[3] give lists of compounds that cause self-renewal of stem cells, of others that affect differentiation of stem cells or generation of iPSCs from other cell lines and dedifferentiation of cells along with possible modes of action. Most of these have been discovered using variations of the original work described earlier. Once active molecules have been identified the next stage is to try to determine its mode of action but of course the fact that a compound is an inhibitor of, say, a kinase does not necessarily mean that the inhibition of that kinase actually causes the cellular changes. Questions relating to both the potency and specificity of the compounds naturally arise in the mind of the medicinal chemist, thus investigations into the action of other inhibitors of the kinase on stem cells should at least take place. In many instances such studies have not yet been undertaken or reported.

A word of caution regarding the use of murine stem cells as model for the human is necessary. Significant differences in behavior between the two species have been discovered including responsiveness to different signaling pathways and the vulnerability of human cells toward apoptosis following single cell dissociation. As this represents a significant hurdle to the use of hESCs a search was made to discover molecules able to enhance cell survival after dissociation and to maintain pluripotency.[9] From a library of 50,000 compounds, thiazovivin (9) and pyrintegrin (10) had the desired activities (Fig. 4) and it was suggested that the mechanism



thiazovivin (9) pyrintegrin (10)

Fig. 4 Compounds reported to enhance hESC survival and maintain pluripotency.



(11)

Fig. 5 Chemical structure of Cardiogenol C (11).

of activity is the enhancement of ECM-cell adhesion-mediated integrin activity. Thiazovivin was subsequently shown to inhibit Rho-associated kinase and to stabilize E-cadherin, thus promoting E-cadherin mediated cell–cell adhesion. Again the importance of interactions with elements of the niche is emphasized.

The discovery of agents able to control differentiation of stem cells is illustrated by the use of the mouse embryonic carcinoma cell line, P19, transfected by the promoter region of the rat atrial natriuretic factor, a polypeptide hormone synthesized primarily in cardiac myocytes[10] fused with a luciferase gene. As the natriuretic factor is considered as a specific cardiomyocyte (CM) marker, an increase in luciferase activity was taken as indicative of differentiation to cardiac cells. From a library of 100,000 compounds the most active was cardiogenol C ((11), Fig. 5) and cardiac activity was supported both by the detection of sarcomeric myosin heavy chain, one of the motor proteins essential for cardiac muscle contractibility and also the production of GATA-4, a TF expressed in the developing heart.

Small molecule-mediated or -enhanced dedifferentiation has been investigated mainly as an alternative route to iPSCs particularly from fibroblasts or keratinocytes, examples being the TGF-β inhibitor SB431542 (12) and MEK inhibitor PD0325901 (13).[11–13] Myoseverin (14), which binds tubulin, thus causing degradation of the microtubule cytoskeleton, was reported to convert muscle cells to a myoblast-like phenotype and, later, reversine (15) was shown to induce myogenic lineage-committed cells to become multipotent progenitor cells (Fig. 6).[14] Further examples of all of the earlier processes are discussed in the following sections.

In vivo test systems are of course essential in the route from in vitro findings to animal studies to clinical trials and a number of results are described further. In particular, the zebrafish and its embryo have been used as a test system due to its innate ability to repair many types of tissue damage. Examples of specific in vivo investigations are also discussed in the later sections of this article.

1.13.1.2 Literature Trends in This Research Area

Recent years have seen a significant rise in publications relating to stem cells and their application in regenerative medicine. While many of these refer to cell-based therapies, and are therefore outside the scope of this article, the utilization of small molecules to modulate stem cell function and fate is on the rise. As already described, this enables the medicinal chemist to contemplate a rather more conventional Design-Make-Test-Analyse (DMTA) drug discovery project paradigm akin to the well-established workflow illustrated in Fig. 7.

It can be seen that the term "stem cells," while first described in the literature around 1900, has only really started to come to prominence during the late 1990s (Fig. 8, searches conducted using SciFinder™). Interestingly, a similar trend applies to the patent literature, though as one might expect, the rise in publications relative to the primary peer reviewed literature lags by a few years.

When a more applied stem cell paradigm is considered, in this case colocation of the terms "stem cells" and "small molecule" one can see that this only really emerges in the 1990s, and starts to increase in the mid 2000–10 decade (Fig. 9).[1] Again, as shown in a recent review, the patent literature lags somewhat behind the primary literature,[15] and while filings in this area are on the rise, one could expect this to be the growth area of the next decade, as true industrial application and drug discovery opportunities begin to be fully realized.

1.13.2 Studies on Specific Organs

1.13.2.1 Blood and Bone

1.13.2.1.1 Hematopoietic stem cells

The blood system is one of the organs of the body with the greatest capacity for regeneration and is maintained by a small pool of multipotent hematopoietic stem cells (HSCs), which is sufficient for replenishing all human blood cell lineages at a rate of millions of cells per second throughout life. Within the HSCs there are two large and distinct subsets responsible for the production of myeloid cells including monocytes, macrophages, neutrophils, basophils, eosinophils, erythrocytes, and dendritic cells and lymphoid cells producing T and B cells and natural killer cells. Recently it has been shown that there exists in the mouse a distinct HSC subset primed for platelet-specific gene expression with enhanced propensity for short- and long-term reconstitution of platelets.[16] As platelets are crucial for preventing bleeding, the discovery of specific targets with the potential to be targeted by drugs could be essential to medicinal chemistry programs aimed at enhancing their production following bone marrow transplantation or chemotherapy. Since the platelet-biased HSCs also frequently have a long-term myeloid-lineage bias and can give rise to lymphoid-biased HSCs, it was suggested that these cells could lie at the apex of HSC subtypes.

The self-renewing HSCs occupy the top of a hierarchical population of multipotent and progenitor cells, which differentiate along defined pathways via increasingly lineage-restricted cell types in response to various signaling events, thus giving rise to all the specialized functional cells of the bloodstream. Studies in mice have indicated the presence of both long-term (LT) and short-term (ST) HSCs.[17] Engraftment of human HSCs into immune-deficient mouse strains such as the nonobese diabetic/severe combined immunodeficiency (NOD/SCID) mouse has allowed the characterization of human HSCs.[18] Combinations of cell surface markers have been used to identify both human and mouse HSCs but, unfortunately, these are not conserved between species.[19] A number of endogenously synthesized growth factors including erythropoietin (EPO), thrombopoietin (TPO), granulocyte-macrophage colony stimulating factor (G-CSF), macrophage colony stimulating factor (GM-CSF), stem cell factor (SCF), and various interleukins (IL) have been shown to influence the proliferation, survival, and differentiation of HSCs.[20] A full review of the activity of TPO as the primary regulator of megakaryocyte progenitor expansion and differentiation, its activity, structure, mechanisms of action, and therapeutic use to increase platelet production has been produced.[21] The expectation that it should be possible to find small organic molecules able to influence the behavior of HSCs is perhaps given credence by the report that compounds P18IN003 (16) and P18IN011 (17), which block the activity of the G1 phase regulator protein, P18, are able to enhance ex vivo expansion of HSCs (Fig. 10).[22]

The details of endogenous hematopoiesis mechanisms in animals, particularly mice, have only recently been addressed. Earlier studies had involved following cells after transplantation and it is proposed that the stresses involved in such studies may give results different from the normal situation. In fact, Camargo et al. have shown that a large number of long-lived progenitors rather than classically defined HSCs are the main drivers of steady-state hematopoiesis during most of adulthood.[23] An even more recent report[24] agrees with the idea that the transplantation model is unlikely to give results showing the situation in the normal animal but believes that adult hematopoiesis is largely sustained by short-term stem cells downstream of HSCs, which nearly fully self-renew and receive rare but polyclonal HSC input. The authors postulate that the reservoir property of the ST-HSCs might explain the differences between their results and those of Camargo.[23] In any event, it is clearly very difficult to gain a full picture of the complex events taking place inside the bone marrow.

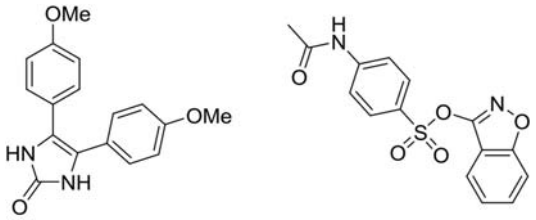

Fig. 10 Compounds reported to enhance ex vivo expansion of HSCs.

While HSCs self-renew indefinitely, their functional activity declines over time, which results in degraded blood production. Evidence has recently been reported to support this decline being due to replication stress and that the minichromosomal maintenance DNA helicase could be a potential molecular target for agents designed to alleviate this process.[25] In mice, HSCs divide significantly more frequently in female than in male mice. Further, estrogen levels increase in pregnancy and increase HSC division, frequency, cellularity, and erythropoiesis in the spleen via the estrogen receptor-α.[26]

1.13.2.1.2 Mesenchymal multipotent stromal cells

This is an overarching term used to describe multipotent cells able to produce other differentiated cells of which MSCs may be a subset.[27] These cells are also found in the bone marrow and are responsible for sustaining the integrity of the adult skeleton by the maintenance of the bone-forming osteoblasts and bone resorbing osteoclasts. Additional cell lineages produced by MSCs are chondrocytes and adipocytes for the maintenance of cartilage and lipid, respectively. In vitro populations of mesenchymal multipotent stromal cells, which self-renew and differentiate, can be derived from multipotent mesenchymal stem or progenitor cells. However, MSCs are significantly less well characterized than HSCs and as yet, appear to have no universally accepted unique surface markers. They may in fact be a heterogeneous population.[28] Bara et al.[29] have recently produced a detailed review of MSCs in their native environment focusing on the distinct phenotypic differences between them and MSCs cultured in vitro. The implications of these changes on potential clinical use are discussed.[29] Their possible interaction with HSCs is discussed in the next section.

1.13.2.1.3 Bone marrow stem cell niche and signaling pathways

The concept of a niche is that there is a defined area in which a particular cell exists and interacts with the cells and structures within the local microenvironment, this interaction controlling the behavior of the cell. The idea of the HSC niche was first introduced by Schofield in 1978[30] as a microenvironment in which stem cell populations reside and are maintained through a variety of cues. Of all adult stem cell niches, bone marrow HSC niches have been the most extensively studied, although many aspects remain poorly understood.[31,32] The main problem seems to lie in the difficulty with trying to get a clear picture of the nature of the cells and their precise status deep inside the bone marrow and in deciding which interactions are likely to be important under which circumstances. Morrison et al. have used GFP linked to the gene for α-catulin allied to deep confocal imaging to indicate that HSCs were more common in central marrow than near bone surfaces and that most HSCs, both dividing and nondividing, were located near sinusoidal blood vessels and distant from arterioles, transition zone vesicles, and bone surfaces. It was concluded that these cells reside mainly in perisinusoidal niches.[33] A very detailed review of the niche has been presented by Morrison and Scadden,[34] who suggest that HSCs reside in a specialized niche that is distinct from those that nurture other hematopoietic progenitors. Each niche may be created by multiple cell types that contribute to the niches in unique as well as redundant ways. Overall, the niche is perivascular and is created partly by mesenchymal stromal cells and endothelial cells. How these niches react in response to factors such as stress from infection, myeloablation, or neoplasia could shed light on disease progression or suggest ways of treating the condition. Mendez-Ferrer et al. have discussed the difficulties in precisely identifying the role of MSCs in the niche, difficulties caused by partial characterization of cell lines, redundancy and compensatory effects of the cells, and technical difficulties in the experimental procedures.[35] The role of interactions with the extracellular matrix components and adhesion molecules released from surrounding cells has been discussed by Klamer and Voemans.[36] They point out that normally the majority of HSCs are present in a quiescent state with, in mice, division only taking place on average once per 32 days while a subpopulation only divides five times during the lifespan of the mouse. However, these cells are reversibly activated upon massive hematopoietic cell loss. Presumably, this takes place following input from surrounding cells and tissue. Among the signaling molecules identified as playing a role in HSC stimulation are VLA4, VCAM1, CD44/hyaluronic acid, CXCR4/SDF1, SCF, ANG1, TIE2, TPO, MPL, Notch, and hedgehog signaling.[37] As well as these biochemical modulators, the physical environment imposed by the extracellular matrix within the niche such as shear stress and rigidity have also been reported to play a role in the regulation and maintenance of HSCs.[38] Furthermore, the changing role of the HSC niche through ontogeny to adulthood has been discussed by Fraser et al.[39]

1.13.2.1.4 Diseases involving these cells

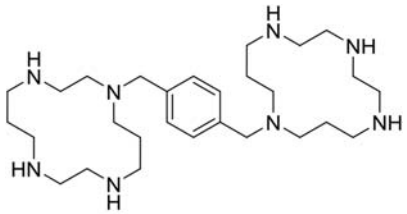
HSCs and mesenchymal stem/progenitor cells are essential for maintenance of blood and bone and thus it is to be expected that faults in the functioning of either could lead to human diseases. These include myeloproliferative neoplasms such as leukemia, cell-based anemia, for example, thrombocytopenia (platelet deficiency) or osteoporosis in which osteoclast destruction is not matched by osteoblast mediated bone formation.[40,41]

1.13.2.1.5 Current therapies

HSCs form the basis of one of the oldest and most widely employed stem cell-based therapies, namely, their transplantation into patients suffering from bone marrow failure or myeloablative chemo/radiotherapy for leukemia. These transplantations may be autologous, where the bone marrow is sourced from the patient before myeloablation or allogenic, where the HSCs are sourced from a human leukocyte antigen (HLA) matched donor. Autologous donations hold the promise of a successful engraftment without the appearance of dangerous GVDH, while allogenic donations are preferred in cases of acute myeloid leukemia where the reintroduction of the patient's own cells is likely to lead to the reappearance of the cancer.[42] Aspiration of bone marrow, peripheral blood, and umbilical cord blood (UCB) are the three main sources of HSCs for transplantation. As harvesting bone marrow is an invasive procedure that requires the use of general anesthetic, its use has largely been replaced by the use of peripheral blood. This seems surprising as the number of HSCs circulating in peripheral blood is generally very low but it has been found that administration of G-CSF prior to harvesting promotes migration of HSCs out of the bone marrow.[43] This would seem to be an attractive case for small molecule intervention and indeed AMD3100 (plerixafor; marketed as Mozobil, (18), Fig. 11), a CXCR4 agonist, has been shown to promote mobilization of HSCs either alone or in combination with granulocyte-colony stimulating factor (G-CSF).[44] AMD3100 was approved by the FDA for the mobilization of HSCs to peripheral blood for autologous transplants in non-Hodgkin lymphoma and multiple myeloma patients.[45]

UCB has the advantage of availability from a variety of donors of different genetic background, who are otherwise underrepresented among donors and has been found to be more tolerant of HLA mismatches between donor and recipient. However, the small quantities of UCB available from each donor have historically limited transplants to children or very small adults. Even in these cases the low number of HSCs leads to a delay in hematopoietic reconstitution leaving recipients with reduced immune cell and platelet numbers with the associated risk of infection and bleeding. Cells from more than one source could be used but this increases the risk of GVHD. Thus strategies to expand the HSC populations from these sources are being investigated.[46,47] Recently O'Brien et al. have taken earlier findings that UCB derived hematopoietic progenitor cells (HPC) are depleted of Wnt signaling and proposed that inhibition of GSK-3β could reactivate this. They showed that culture of ex vivo expanded HPC in the presence of BIO ((19), Fig. 12), a GSK-3β inhibitor (albeit a relatively nonspecific one), increased engrafting of human cells into the NOD–SCID mouse and suggested that this could be a way of increasing the clinical usefulness of UCB.[48]

MSCs have also shown promise for cell-based therapy. Their therapeutic effects are increasingly being recognized as arising as a result of paracrine signaling in situ. For instance, the immunomodulatory activity of MSCs has led to them being used in clinical



(18)

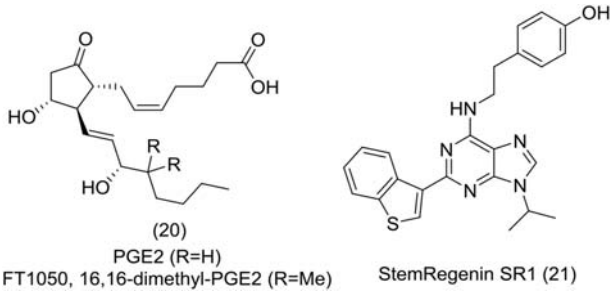

Fig. 13 Compounds reported to promote HSC expansion in vivo and ex vivo.

trials against various inflammatory diseases including GVHD and Crohn's disease. MSCs have also been shown to exhibit a paracrine effect to promote healing in other organs including the heart following myocardial infarction. Cell-based therapies in which MSCs/progenitor cells or chondroprogenitors are used to improve fracture healing or cartilage regeneration in osteoarthritic joints are also under investigation (see below).

1.13.2.1.6 Chemical manipulation of HSCs

While growth factors such as EPO and TPO stimulate HSCs and their progeny, small molecules would have the advantage of easier production and dosage and the search for such agents has been pursued with vigor. Prostaglandin E2 (PGE2) ((20), R=H, **Fig. 13**) and its more stable chemical analog 16,16-dimethylPGE2 ((20), R=Me, dmPGE2, FT1050) were found in a high-throughput screen using zebrafish embryos to enhance HSC expansion during embryogenesis.[49] This molecule, dmPGE2, was subsequently found to promote recovery of kidney marrow in sublethally irradiated zebrafish, which suggests a role also for this agent in adult HSC homeostasis. Human HSCs are also expanded by dmPGE2,[50] and the ex vivo dmPGE2-treated CB (ProHema®-modulated CB), very recently completed a Phase 2 clinical trial to evaluate its effects in a double CB transplant in patients with hematological malignancies (Clinical Trials.gov ID: NCT01627314). Further in 2011 the FDA granted this compound orphan drug status for the ex vivo treatment of human allogenic HSCs to enhance stem cell engraftment by treating neutropenia, thrombocytopenia, lymphopenia, and anemia.

In an approach similar to a number of others described in this article, Schultz and coworkers identified StemRegenin (SR1, (21)) from 100,000 heterocycles in a cell-based assay assessing ex vivo expansion of primary human CD34+ cells derived from HSC-mobilized peripheral blood.[51,52] SR1 acts as an agonist of the aryl hydrocarbon receptor (AhR), thus identifying another target for the design of molecules able to promote the ex vivo expansion of HSCs. It should be noted that SR1 did not promote the ex vivo expansion of mouse HSCs due to a lack of activity on the murine AhR, thus underlining another difference between human and murine cells.

Inhibition of p53 activity has been shown to enable the expansion of HSCs and it was found that pifithrin β ((22), **Fig. 14**), an inhibitor of p53, acts in mice to increase numbers of HSCs in vivo and promotes their mobilization into peripheral blood.[53,54] Given the widely studied role of p53 as a tumor suppressor, the strategy of inhibiting p53 activity for expansion of stem cell populations could, in principle, give rise to safety concerns. However, Gudkov et al.[53] found that administration of a single dose of pifithrin β to p53+/− heterozygous tumor susceptible mice prior to a dose of total body radiation did not lead to increased tumor incidence compared to control. Their conclusion was that short-term inhibition of p53 may not lead to increased incidence of tumors and it therefore could represent a viable strategy for HSC expansion.

From a 50,000 member library, MK1 ((23), **Fig. 15**) was identified as enhancing differentiation of primary human mobilized peripheral blood-derived CD34+ HSCs into CD41+ megakaryocytes.[55] MK1 was found to inhibit platelet-derived growth factor receptor (PDGFR), which leads to the production of megakaryocyte/erythrocyte progenitors (MEP). In a separate study, the natural product, euphohelioscopin A (24), was found to promote differentiation of CD34+ cells to the granulocyte/monocyte lineage at least in part via activation of protein kinase C.[56]

1.13.2.1.7 Eltrombopag: a case study in drug discovery of small molecule stem cell modulation

The existence of TPO as a growth factor released from the liver and kidneys and involved in the production of platelets was first hypothesized over 50 years ago but this was only experimentally confirmed in 1994.[57] It is a 332-amino acid protein that has ca. 23% homology in its N-terminal region to EPO. However, its C-terminal region has homology to no known proteins and is thought to provide in vivo stability against proteolytic breakdown. Binding of TPO to its receptor, c-mpl, initiates multiple signaling pathways that lead ultimately to the production of megakaryocytes and thus to increased production of platelets (Fig. 16).

Following the isolation of TPO, a first generation of recombinant human TPO (rhTPO) and pegylated recombinant human megakaryocyte growth and development factor (PEG-rhMGDF) entered clinical trials and increased platelet counts in humans undergoing nonmyeloablative chemotherapy, but not in those undergoing stem cell transplantation. However, several healthy volunteers were found to develop neutralizing antibodies against PEG-rhMGDF, paradoxically leading to a drop in platelet levels and development of these proteins was halted. Another large molecule, romiplostim (AMG531) a conjugate of a peptide, which binds to the TPO receptor and an antibody Fc domain, which increases its half-life in the bloodstream, has been approved by the FDA and NICE for long-term treatment of chronic idiopathic (immune) thrombocytopenic purpura (ITP). Clinical use does require monitoring for thrombocytosis, the overproduction of platelets, which can lead to potentially hazardous blood clots.[58]

In view of the positive clinical activity of these macromolecules, the discovery of a safe, effective, and orally available, nonpeptidic TPO mimetic would seem to be highly desirable. Researchers at SmithKline Beecham in collaboration with Ligand Pharmaceuticals used high-throughput phenotypic screening of their in-house libraries to identify a number of classes of compounds, which upregulated TPO-responsive signaling pathways using a luciferase reporter assay.[59] From initial hit structure ((25), Fig. 17) extensive lead optimization led to the identification of eltrombopag (26), which was shown to be a potent TPO receptor agonist.[60,61]

Eltrombopag stimulates megakaryocyte proliferation and differentiation and increases platelet counts without activating them. Interestingly eltrombopag binds to the TPO receptor at a different site from that bound by TPO itself and the two agents act additively.[62] A histidine residue within the transmembrane region of the TPO receptor was found to be critical for binding of eltrombopag; only the human and chimpanzee TPO receptors have this residue and this may provide a rationale for why

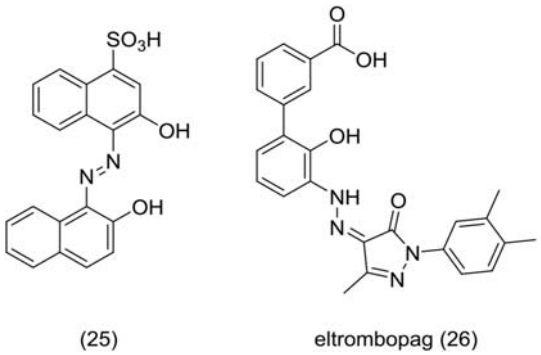

Fig. 17 Lead structure and final TPO receptor agonist.

eltrombopag only shows efficacy in these species. Binding to the receptor leads to activation of the Janus kinase (JAK) and signal transducer and activator of transcription (STAT) pathways but in a response distinct from that produced by TPO or romiplostim (Fig. 18).

Eltrombopag was granted orphan drug status and was approved by the FDA in 2008 for the treatment of thrombocytopenia (platelet deficiency) and in 2014 for the treatment of aplastic anemia. Numerous clinical trials have established that it is effective, and safe, for the treatment of both adult and childhood thrombocytopenia and in severe aplastic anemia.[57] In addition, it has been

found to be of use in the treatment of thrombocytopenia in patients with chronic hepatitis C.[63] A very interesting finding was that of Desmond et al. who found that eltrombopag treatment was successful in patients with severe aplastic anemia, but remarkably the hematological responses were maintained even after discontinuation of drug treatment.[64] It was hypothesized that the drug was acting by the stimulation of residual HSCs, which would represent a new approach to the treatment of aplastic anemia.[65] It would also represent a further successful application of medicinal chemistry to the modulation of stem cell behavior to the benefit of the patient.

Other TPO mimetics have been progressed to clinical trials. Eisai have developed avatrombopag ((27), **Fig. 19**), which is claimed to have greater pharmacological activity than eltrombopag as a TPO agonist.[66] It is reported to be in Phase III trials in patients with thrombocytopenia associated with liver disease. Positive results have also been reported in patients with chronic immune thrombocytopenia[67] and in increasing platelet counts in patients with cirrhosis undergoing invasive procedures.[68] Another compound is LGD-4665 from Ligand that, despite being in development, has not yet had its structure disclosed.

1.13.2.1.8 Bone

Mesenchymal multipotent stromal cells and their role in sustaining bone and cartilage structure were introduced earlier. Here their potential role in correcting diseases of bone and cartilage is examined. The main disease of bone is osteoporosis, where the balance of bone resorption and reformation is disturbed, resulting in loss of bone mass and eventually severely weakened bone structure. In the case of cartilage, the main disease is osteoarthritis where damage results in pain and inflammation of the joint. Both of these conditions are widespread, cause significant levels of distress to the patient, and are largely treated by palliative interventions or significant invasive surgery. Thus drug treatments capable of giving bone and/or cartilage regeneration would be of significant benefit. A very recent review of orthopedic tissue regeneration using cells, scaffolds, and small molecules has appeared.[69]

As stated earlier, MSCs are adult stem cells capable of giving rise to tissues of mesodermal origin including bone, dentine, and ligament and so have been the most widely studied stem cell in this area. The ex vivo osteogenic differentiation of MSCs was discussed in our previous review.[1] One proosteogenic compound, purmorphamine ((28), **Fig. 20**), identified by high-throughput screening of a 50,000-member library, was shown to act by activation of the Hedgehog (Hh) signaling pathway as an agonist of the transmembrane receptor Smoothened (Smo). This compound acts synergistically with bone morphogenetic protein 4 (BMP-4) in osteogenic activity. The bone morphogenetic proteins are a group of 20 growth hormones initially identified by their ability to induce the formation of bone and cartilage. Recombinant BMP-2 and BMP-7 are approved by the FDA to stimulate the production of bone in orthopedics and dentistry. Other small molecules identified included H-8 (29), an ATP competitive inhibitor of protein kinase A, C, G and myosin light chain kinase, N6-benzoyladenosine-3′5′-cyclic monophosphate (30), a PKA-selective cAMP analog, CW008 (31), an inducer of cAMP production and SKL2001 (32), a specific activator of Wnt/β-catenin signaling. More recently, Ito et al. identified by means of a phenotypic screen the flavonoid natural product kaempferol (33) as being effective in the induction of osteogenesis in MSCs and as possessing in vivo activity in an ovariectomised mouse model, although the mechanism is as yet unclear.[70] As part of an excellent survey of the use of stem cells in the treatment of osteoporosis, Gazit et al. commented that Phase I trials investigating the ability of the anabolic agent, parathyroid hormone (PTH), with alendronic acid (34) to recruit MSCs to the sites of bone fractures were underway.[71] Finally, Cashman and coworkers reported that two small Wnt signaling modulators, THQ-1a (35) and PP-9 (36), increased the differentiation of C2C12 cells synergistically in the presence of an osteoinductive TCP ceramic.[72] C2C12 is a myoblast cell line that has been used for in vitro studies of osteoporosis and these results may even suggest an approach to directing cell lineage commitment for bone regeneration in vivo using a mixture of these sorts of small molecules along with osteoinductive ceramics.

The direct use of MSCs in dentistry has been recently reviewed; however, clinical trials conducted to date in this area have not yet allowed conclusions as to their utility to be drawn.[73]

It has been shown that cartilaginous grafts could be assembled from fat pad-derived stem cells by incorporating them onto fiber membranes, thus opening up the possibility that similarly engineered tissue derived from the cells of patients with osteoarthritis could be used in the treatment of damaged joints.[74] In the field of cartilage repair, Denaro et al. have cautioned that the limitations in animal models of osteoarthritis are rarely predictive of the equivalent disease in humans and that this is hindering the use of stem cells and gene therapy for the management of cartilage lesions.[75] The stepwise, controlled large-scale and effective differentiation of

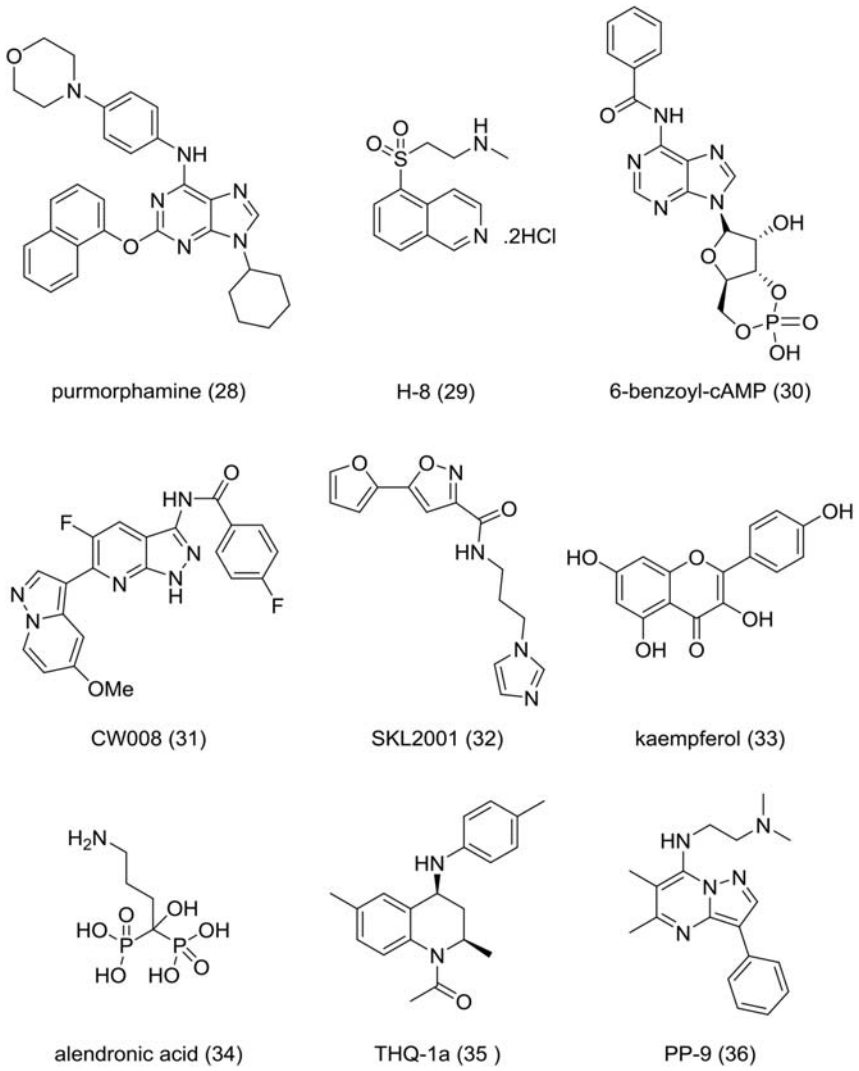

Fig. 20 Compounds with osteogenic properties.

mouse embryonic stem cells (mESC) and mouse- and human-induced pluripotent stem cells (hiPSCs) into osteoblasts has been described.[76] The four compounds (**Fig. 21**) used in the sequential steps for this process were CHIR99021 (5), cyclopamine (37), a smoothened/Hh antagonist, TH (38), and SAG (39), a smoothened/Hh agonist. While the molecular target for TH is unknown, this potentially offers a tool for mechanistic studies of osteoblast development and cell-based therapies for bone defects.

As might be expected, the BMP family of proteins has attracted considerable interest in their use in bone repair or as targets for the design of small molecule mimetics. A recent review[77] has discussed the complications involved in using both growth factors themselves in the clinic and small molecule mimetics. Difficulties with the proteins themselves include manufacture, specificity, and immunogenic potential while small molecules do have tremendous possibilities; of the BMP mimetics described to date several questions relating to their mode of action, specificity, and delivery remain. BMP acts on MSCs to stimulate differentiation into osteoblasts and as osteoporotic patients show reduced capacity for bone healing; it was surmised that impaired signal transduction and reduced osteogenic differentiation capacity in response to BMP-2 could be the cause of this.[78] In fact, while changes in BMP-2 signaling were observed, nonetheless osteogenic differentiation was retained in response to BMP-2 suggesting that this cytokine could be of use in the treatment of this disease.

The quinoline KM 11073 ((40), **Fig. 22**) was found to enhance the induction of BMP-2 stimulated effects in vitro and demonstrated in vivo osteogenic activity in zebrafish and mouse models suggesting its use in the stimulation of bone formation either alone or in combination with BMP-2.[79]

Lee et al. showed that a combination of BMP-2 and phenamil (41) promotes the osteogenic differentiation of adipose-derived stem cells in vitro and confirmed in a mouse calvarial repair model the usefulness of this combination in vivo. It was suggested that this combination using slow-release technology could represent a cost-effective, efficient approach to clinical bone repair.[80] An excellent overview of the state of research on regenerative medicine in osteoarthritis has been presented by Osch.[81]

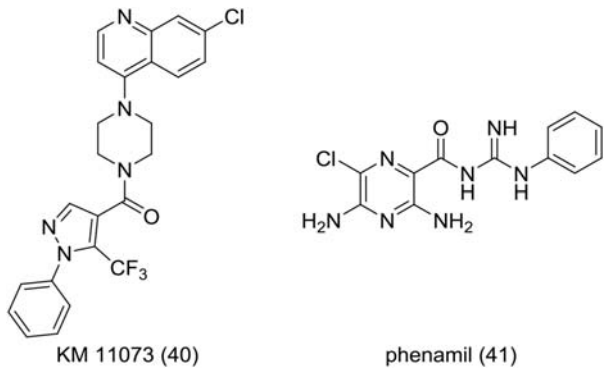

Fig. 22 Osteogenic agents.

1.13.2.2 Cardiac Regeneration

Progression to heart failure is usually coupled with a severe loss of CMs, the contracting muscle cells of heart tissue.[82] After injury, the heart undergoes a series of steps in wound healing. As adult mammalian CMs have little regenerative capacity, the result of the wound healing in the heart is the formation of a scar at the injury site that is mainly comprised of fibroblasts. These fibroblasts help maintain the structural integrity of the heart after an injury but have no contractile ability.[83] As a consequence the surviving CMs work more to compensate and support cardiac output. Over time, the CMs become hypertrophic, which eventually leads to heart failure.

Although today's medical and device therapies aim to optimize the cardiovascular hemodynamic, they do not account for the loss of the functional CMs, which are the cause of the failing myocardium. In general, embryonic cardiac development can be simplified into four key steps involving mesoderm induction, mesoderm structuring, cardiac mesoderm formation (cardiac progenitor cells) followed by CM induction and maturation. The prospect of being able to regenerate human heart tissue either in vivo by controlling the differentiation of stemlike/progenitor cells in situ, or ex vivo by subsequent implantation of the generated CMs is of great interest. The ability to achieve this goal by screening small molecules represents an important challenge and opportunity for medicinal chemists. Many cardiopoietic factors involved in CM generation are known and multiple publications have reported the effect of small molecules on this process.

1.13.2.2.1 In vitro chemically guided cardiac differentiation

1.13.2.2.1.1 Unspecific mode of action

Until relatively recently, few small molecules affecting cardiac differentiation from pluripotent stem cells had been reported and many of these had unspecific modes of action.[84] Among one of the first examples was ascorbic acid (AA).[85] More recently, in 2015, two research groups have reported the use of AA ((42), Fig. 23) to enhance differentiation of stem cells into CMs.

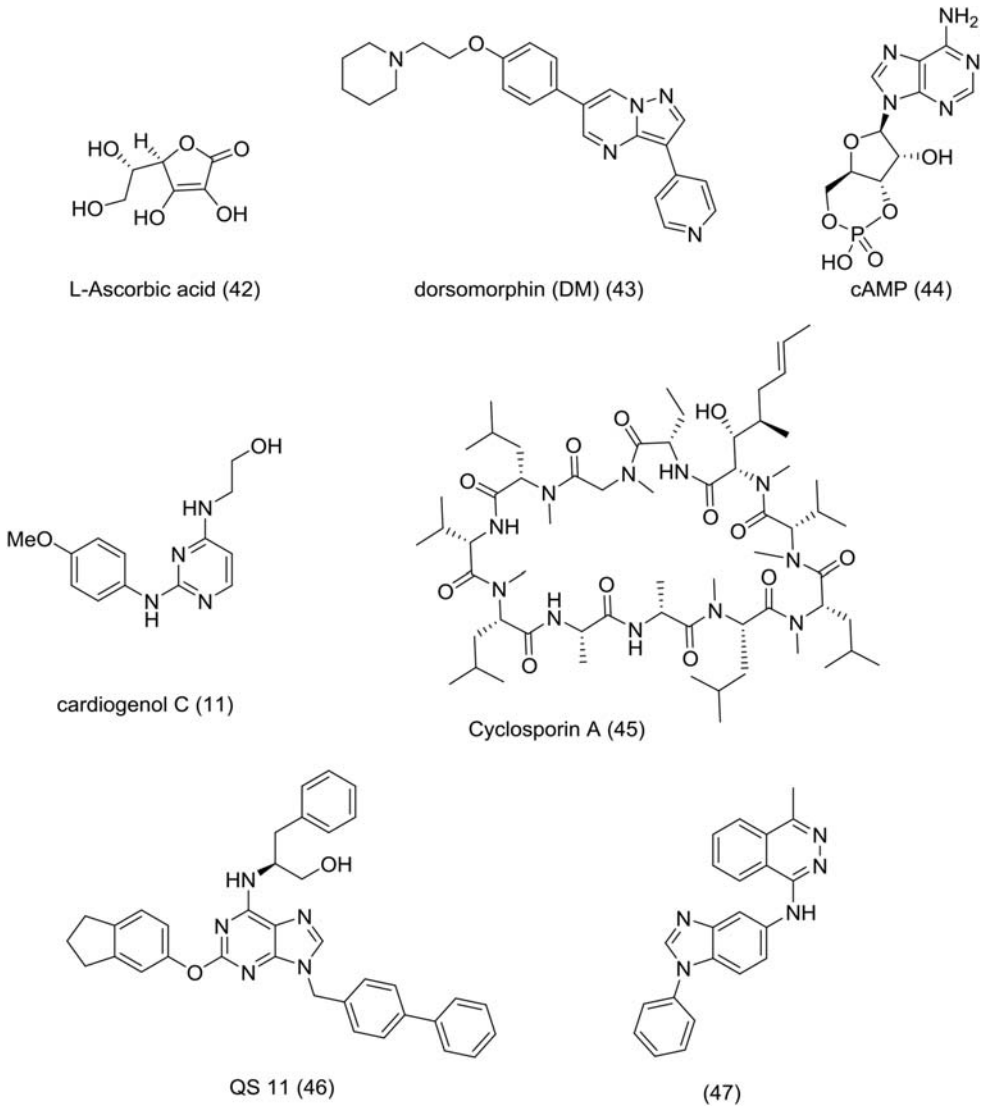

Fig. 23 Compounds reported to be able to differentiate iPSCs into cardiomyocytes.

In the paper published by Talkhabi et al., retrovirally transduced fibroblasts with reprogramming genes encoding all four TFs *Oct4*, *Sox2*, *Klf4*, and *c-Myc* and used these to screen small molecules that could augment the direct conversion of mouse fibroblasts into beating CMs.[86] Daily observation of the cells allowed the identification of AA as an efficient inducer. Moreover it was noticed that pretreatment of cells with AA at days 6–9 followed by cotreatment with both AA and recombinant BMP4 enhanced the conversion. Flow cytometry analysis showed that the cotreatment also increased the number of cardiac lineage cells (Flk1+, GATA4+, and MHC+) when compared to the control, leading to approximatively 20–30% of Flk1+ cardiac progenitors at day 14. The resulting directly converted beating CMs exhibit mature cardiac electrophysiological activity.

Ivanyuk et al. have evaluated the cardiac enhancing properties of small reported molecules such as AA, dorsomorphin (43), cyclic adenosine 3′,5,-monophosphate (cAMP, 44), cardiogenol C (11), and cyclosporin A (45) on ESC and iPSC lines.[87] Of concern was the observation that cardiogenesis induced by previously reported compounds was not reproducible from one pluripotent stem cell line to another, serving to underscore the significant differences between these lines. Among these five compounds, the most reproducible cardiogenic effect was only observed in the CGR8 ESC line when treated with AA alone. Further experiments have shown that AA treatment during the first 2 days of differentiation was sufficient to efficiently enhance differentiation of ESCs into CMs. When identifying functional categories enriched by AA-induced gene expression, cardiac-specific transcripts (Mef2, Myl7) along with early mesodermal marker T-brachyury were upregulated in day 5 embryonic bodies (EBs). TFs involved in angiogenesis, hematopoiesis, and vasculature development were also induced. In addition, what appeared to be an additive effect was observed when treating cells with both AA and QS11 (46), a small molecule synergist of the Wnt/β-catenin signaling pathway, significantly increasing the expression of TnnT2, cardiac α-actinin (Actn2), α-myosin heavy

chain (αMHC), and Nkx2.5 transcripts. No significant differences were found between control CMs and AA/QS11 CMs in electrophysiological analyses, suggesting that these chemically induced CMs were functionally intact.

To identify small molecules that stimulated stem cell differentiation, Okolotowicz et al. have screened chemically diverse compounds in a high-content cell-based assay using mESC.[88] The hit followed up from the small molecule screen was 1-phenyl-5(4′-methylphthalazin-1′-yl)aminobenzimidazole, (47), a robust and reproducible inducer of cardiomyogenesis: mESCs were differentiated into CMs upon chemical treatment from days 2 to 6. In addition to αMHC activation observed in mesoderm-derived cardiac muscle from day 10-differentiated mESC cultures, this new benzimidazole hit enhanced other biological markers such as Cer1 and Sox17 for the endoderm linage and Cdx2 and MesP1 for the mesoderm linage. Structure activity relationship studies and medicinal chemistry optimization afforded more potent and drug-like derivatives that stimulated differentiation of CMs upon a more restricted time window from days 2 to 4.

1.13.2.2.1.2 Targeting cardiopoietic signaling pathways

1.13.2.2.1.2.1 TGFβ pathway

The TGFβ superfamily is known to influence several cellular functions such as proliferation, apoptosis, and differentiation. Ifkovits et al. have reported that inhibiting the TGFβ pathway increased the direct conversion of both mouse embryonic fibroblasts (MEFs) and adult cardiac fibroblasts to induced cardiomyocytes (iCMs).[89] It was shown that treatment with SB431542 ((12), **Fig. 24**) in conjunction with ectopic expression of the TFs *Hand2*, *Nkx2.5*, *Gata4*, *Mefc2*, and *Tbx5* (HNGMT) increased the conversion of MEFs to iCMs in a dose-dependent manner. SB431542 (12) is a small molecule known to inhibit the Activin/Nodal/TGFβ signaling pathways, showing specificity for the Alk4, Alk5, and Alk7 components of the TGFβ signaling pathway. The authors reported that adding (12) prior to inducing HNGMT expression (day 1) resulted in a 3.5-fold increase of iCMs with Troponin T-GCaMP activity at day 14 post-HNGMT induction. Inhibition of this signaling pathway by (12) in the cardiac fibroblasts led to converted iCMs displaying several CM markers such as Troponin-T, α-actinin, αMHC, MHC-2, and beating of the iCMs was evident as early as day 16 postinduction. Interestingly, generation of iCMs was also observed when adding LY364947 (48), a known inhibitor of TGFβ but not Activin or Nodal components, on day 1.[90] Taken together these findings strongly suggest that the increase in iCM yield associated with (12) or (48) treatment is due to inhibition of TGFβ signaling as opposed to inhibition of Activin or Nodal family members.

Embryonic Nkx2.5+ cells are potent for both CMs and smooth muscle differentiation. In contrast neonatal Nkx2.5+ cells, which lack the capacity to differentiate into CMs nonetheless retain a limited ability to generate smooth muscle cells.[91] Using transgenic Nkx2.5 cardiac enhancer eGFP mice (Nkx2.5-eGFP) to label Nkx2.5+ cardiomyoblasts with eGFP, Chen et al. have demonstrated that A83-01 (49), a pharmacological inhibitor of type 1 TGFβ receptor (TGFβR1), could induce proliferation of

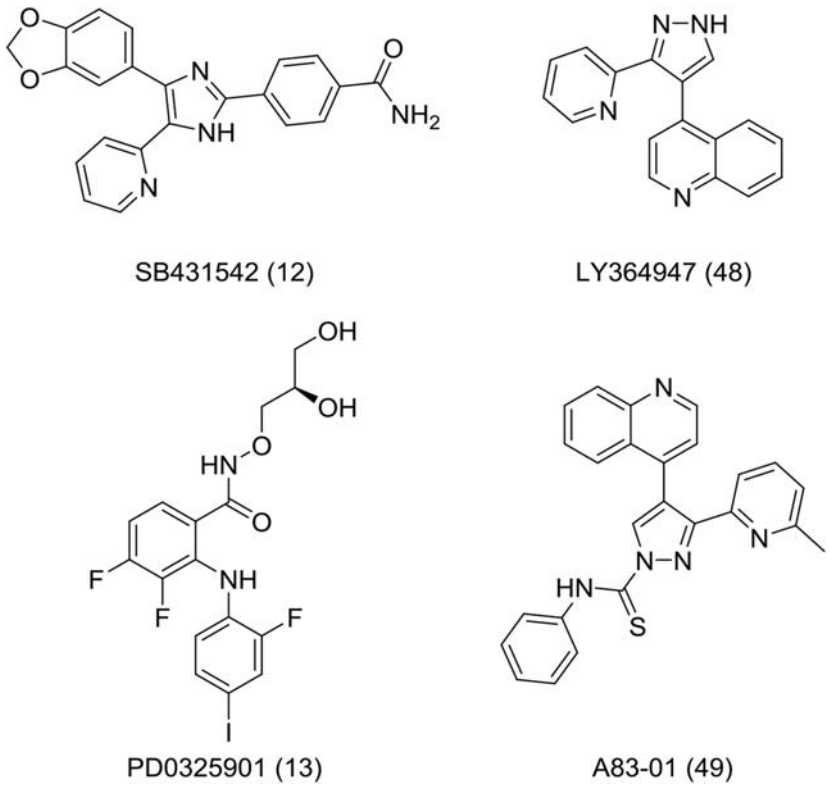

Fig. 24 Compounds affecting the TGFβ pathway in cardiac fibroblasts.

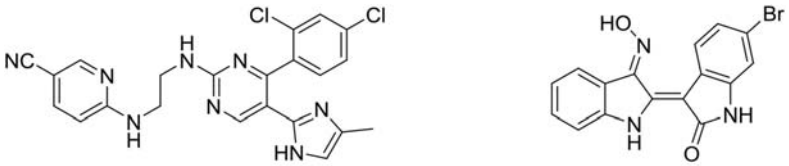

Fig. 25 Compounds affecting the Wnt signaling pathway in cardiogenesis.

postnatal Nkx2.5+ cardiomyoblasts in vitro and improve their cardiomyogenic differentiation.[92] After 7 days of culturing, A83-01 was shown to increase the percentage of eGFP+ cells up to 49% in a dose-dependent manner. The authors also demonstrated that A83-01 inhibited smooth muscle cell differentiation of Nkx2.5+ cardiomyoblasts but stimulated their differentiation into CMs. In addition, it was suggested that a direct cross-talk between TGFβ and FGF signaling pathways are necessary to retain the Nkx2.5+ cardiomyoblast phenotype as cotreatment with PD0325901 (13) an inhibitor of the mitogen-activated protein kinase kinase (MEK), a component of the FGF signaling, abolished the effect.

1.13.2.2.1.2.2 Wnt pathway

The Wnt signaling pathway is known as one of the key regulators of cardiogenesis in vitro and in vivo. A mechanism of activation of canonical Wnt signaling is via inhibition of the glycogen synthase kinase 3β (GSK3β), which leads to β-catenin nuclear accumulation and specific gene transcription activation. Canonical Wnt ligands induce cell proliferation and determine cell fate during embryonic development. Lian et al. have reported the use of CHIR99021, a GSK3β inhibitor ((5), **Fig. 25**), to modulate regulatory elements of the Wnt/β-catenin signaling pathway.[93] Populations of up to 98% of cTnT+ CMs were generated by chemically manipulating Wnt signaling activity during hPSCs differentiation under growth factor-free conditions. In this same article knockdown studies have shown the importance of β-catenin in hPSC differentiation to mesoderm and cardiac progenitors induced by GSK3β inhibitors. Various chemotypes of GSK3β inhibitors have been explored and in addition to CHIR99021, BIO (19) was also found to induce cardiac differentiation.[94]

In contrast to Wnt pathway stimulation, Wnt inhibition is also feasible for cardiac induction. Indeed, Willems et al. have reported the use of *endo*-IWR-1 ((50), **Fig. 26**) to induce beating foci from monolayer cultures of MESP1+ and KDR+ cardiac

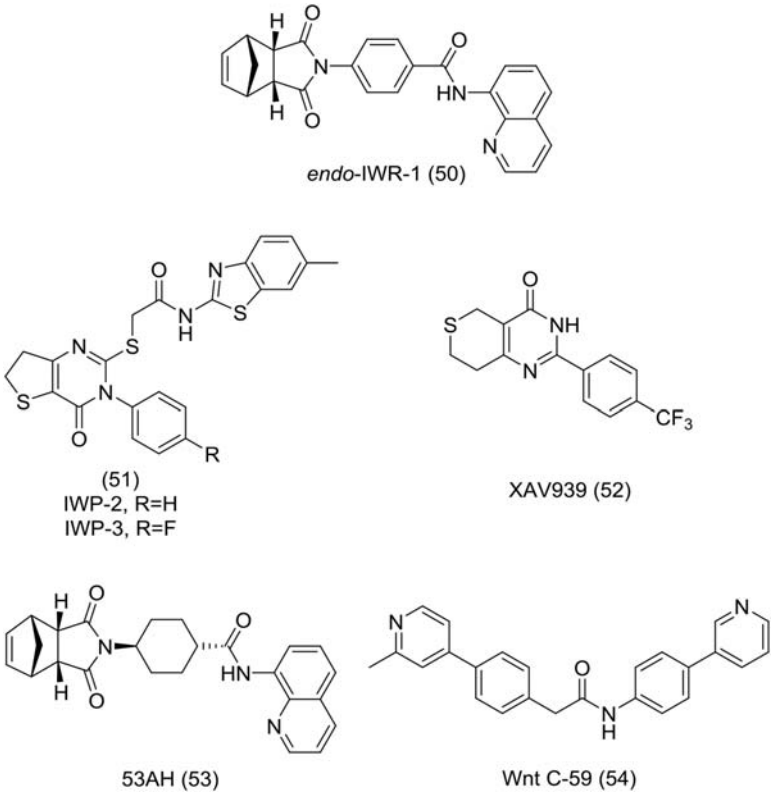

Fig. 26 Compounds affecting the Wnt signaling pathway in cardiogenesis.

mesoderm cells derived from hESCs.[95] *endo*-IWR-1s maximal cardiac induction was observed when added from days 4 to 5. Up to 30% CMs were generated, which was a 200-fold increase in yield over control cultures. Further analysis demonstrated that cardiac TFs (Mef2c and Nkx2.5) as well as CM structural genes (Myh6, Actn2, and Tnnt2) were increased upon treatment with *endo*-IWR-1. Other inhibitors of the Wnt pathway able to induce cardiogenesis were also used as examples. The porcupine inhibitors ((51); IWP-2, R=H and IWP-3, R=F), which prevent Wnt ligand palmitoylation[96]; the tankyrase inhibitor XAV939 (XAV, 52), which is cardiogenic in mESCs; and the most potent *endo*-IWR-1 analog 53AH (53) were tested and all three classes were found to promote cardiogenesis. Together these data strongly support a role for Wnt inhibition in cardiac induction using this system.

In an attempt to optimize a chemically defined medium, Burridge et al. have analyzed the importance of the timing of activation or inhibition of the Wnt signaling pathway, which may go some way to account for the apparent discrepancies in the examples described earlier.[94] Interestingly, treatment with Wnt activator CHIR99021 (5) for 2 days followed by its inhibition with Wnt-C59 (54) in CDM3 medium resulted in the production of TNNT2+ CMs.

1.13.2.2.1.2.3 Bone morphogenetic protein (BMP)

In 1997, the role of BMP in cardiac myogenesis was demonstrated by Schultheiss et al.[97] A fine balance between BMP, Nodal/Activin, and Wnt is desired for optimal mesoderm induction requiring BMP stimulation using recombinant BMP4 and Activin A. Interestingly, Hao et al. have reported that timely application of dorsomorphin (DM, (43), **Fig. 27**) in the early stages of mESCs induced cardiac differentiation, which they initially attributed to BMP inhibition.[98] However, in a series of studies prior to and following this report, (43) was shown to be nonspecific for Smad-dependent BMP signaling and also affected non-BMP signaling (AMP-kinase, receptor tyrosine kinases for PDGF and VEGF signaling) accounting for the delayed induction of early cardiac progenitor cells. The highly potent and selective analog (dorsomorphin homologue 1, DMH-1, (55)) was synthesized and characterized in a detailed in vitro study, and was reported to be a more selective inhibitor for the BMP Type 1 receptors compared to DM and LDN-193189 (56) inhibitors.[99] More recently, Ao et al. have compared the use of (55) with (43) to increase CM progenitors and promote cardiac differentiation in mESCs.[100] The authors reported that both (43) and (55) significantly increased beating EBs formation and reached a peak at about 70–75% efficiency on days 9 to 10 after induction; both compounds showed a fivefold induction increase. However, when (55) was compared with (43), it was observed that (55) induced beating EBs began to beat a day earlier than those induced by (43). As shown by rt-PCR the main difference between the two compounds appeared to be in their ability to modulate cardiac progenitor markers. Whereas (55)-treated cells expressed premesoderm (Bry-T) and mesoderm lineage (Mesp1) markers on days 3 and 4 in an upregulated manner, the expression of these factors was delayed or limited in (43) treated samples. Expression of CM-specific Nkx2.5 markers was also significantly increased in (55)-induced cells but showed less robust expression in samples treated with compound (43). It was suggested that (55)-induced cardiomyogenesis involves a canonical pathway requiring known premesoderm and mesoderm-specific TFs. Moreover, due to these differences in expression profiles, Ao et al. speculated that DM-induced CMs require a noncanonical pathway that remains unknown.

1.13.2.2.1.2.4 Small molecule cocktails

To circumvent the carcinogenicity and genetic insertion of the iPSCs obtained by viral-based methods, Hou et al. generated chemical-induced pluripotent stem cells (CiPSCs) from MEFs with a small molecule combination CRFVPTZ (C, CHIR99021 (5); R, RepSox (6); F, forskolin (1); V, valproic acid (4); P, parnate (7); T, TTNPB (57); Z, DZnep (58), **Fig. 28**).[5] A few years later,

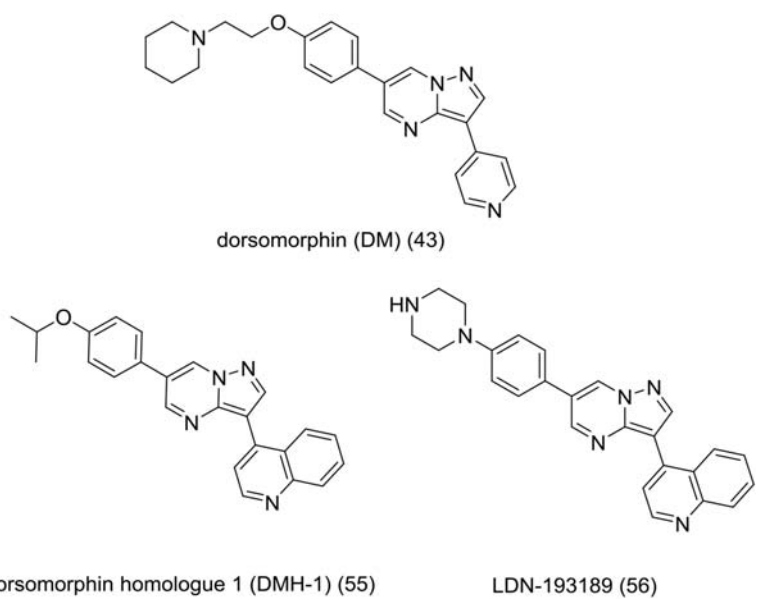

Fig. 27 BMP Type 1 receptor inhibitors.

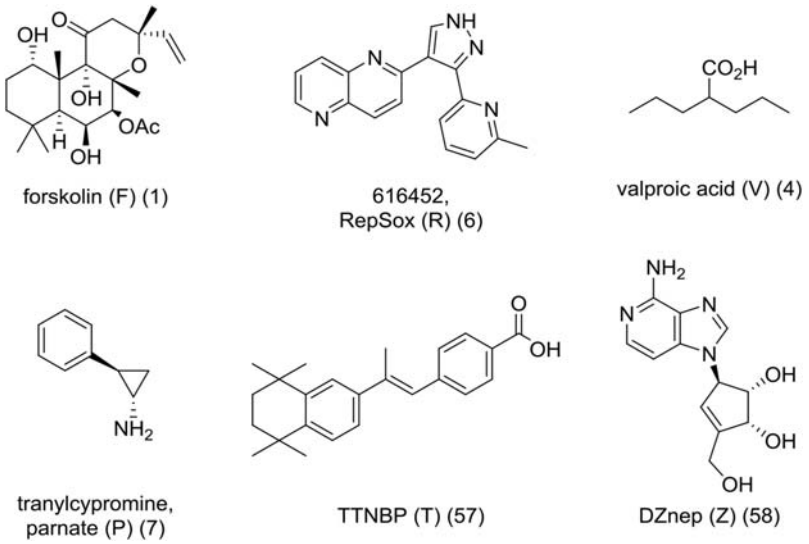

Fig. 28 Compounds inducing production of chemically induced cardiomyocyte-like cells.

Fu et al. also reported the use of a chemical cocktail to directly reprogram MEFs and neonatal mouse tail-tip fibroblasts (TTFs) into contracting cells named chemically induced cardiomyocyte-like cells (CiCMs).[101] However, their results suggested that the use of the CRFV cocktail was sufficient to generate CiCMs from MEFs after optimization of media.

Having identified conditions to produce CiCMs from MEFs, several additional compounds were trialed to enhance the transdifferentiation process including modulators of pathways that affect cardiac development or somatic cell reprogramming (Fig. 29). Both icariin (59) and PD169316 (60) were found to be effective. Phosphodiesterase (PDE) 4 inhibitors such as rolipram (61) and cilomilast (62) were also highly effective. Other PDE 1, 2, and 3 inhibitors were less efficient, while PDE 5 inhibitors were similarly found to be ineffective.

When using TTFs, the cells had to be treated with the CRFVPT cocktail. However, the reprogramming efficiency from TTFs to CiCMs was lower than from MEFs. With the aim to enhance the efficiency of CiCM generation from TTFs, numerous growth factors and chemicals were trialed. Addition of NRG1 and/or G-CSF and rolipram significantly enhanced the number of beating cells.

Further characterization of the CiCMs has shown that they express CM-specific markers. Important TFs for both cardiac development and function, including Mef2c, Gata4, and Nkx2.5 were expressed in the MEF-CiCMs whereas the TTF-CiCMs

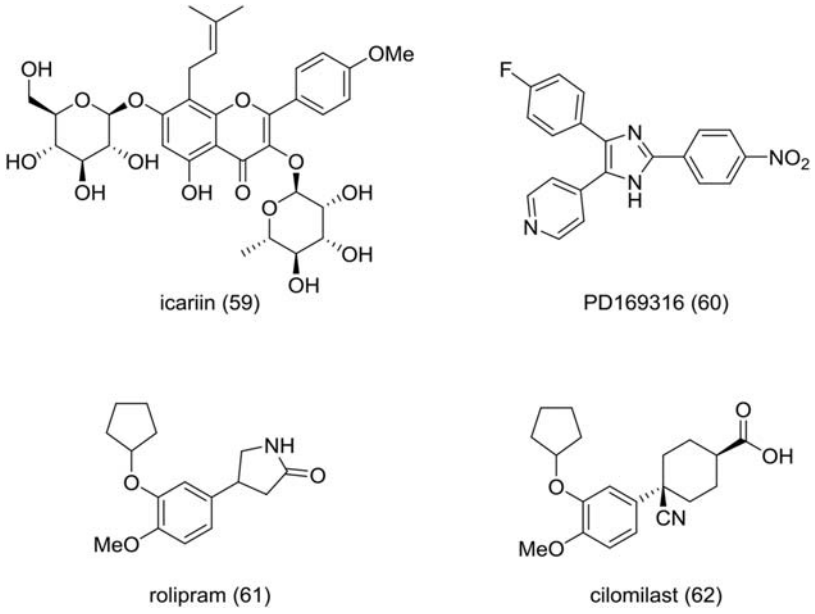

Fig. 29 Compounds reported to transdifferentiate cells to chemically induced cardiomyocyte-like cells.

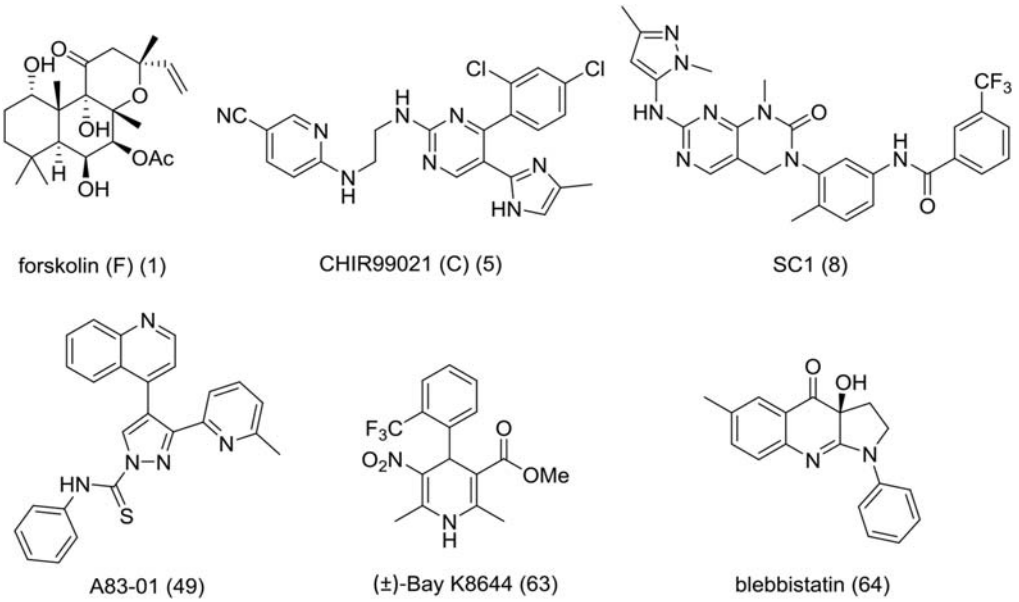

Fig. 30 Compounds reported to transform mouse embryonic fibroblasts to cardiomyocytes.

expressed Mef2c, Gata4, cardiac troponin-T, α-MHC, and α-actinin. Furthermore, these cells exhibit sarcomeric organization and possess typical cardiac calcium flux and electrochemical features.

It is noteworthy that both atrial-like and ventricular-like cells were found in the culture. These results suggest that specific cell types could be generated with further manipulation and optimization of both the chemical cocktail and culture conditions.

Park et al. have reported the conversion of MEFs into spontaneously contracting, cardiac troponin T-positive (cTnT+) cells using a combination of small molecules.[102] After treating MEFs for more than 2 weeks with the small molecule cocktail, features of CMs such as contraction and cTnT expression were observed. Flow cytometry analysis showed that the treatment of MEFs with five small molecules, termed FASCB (forskolin, F (1), A83-01, A (49), SC1, S (8), CHIR99021, C (5), (±)-Bay K8644, B (63), **Fig. 30**) significantly increased the percentage of cTnT+ cells. The authors were also able to report the importance of culture medium supplements; fibroblast growth factor 2 (FGF2), AA, and insulin transferrin-selenite (ITS) were indispensable to induce the differentiation of MEFs into cTnT+ cells. Further analysis using alternative chemotypes targeting common pathways to the FASCB components was consistent with cTnT+ cell induction by FASCB being mediated by the modulation glycogen synthase kinase 3 (GSK-3), activating receptor-like kinase 5 (ALK-5), and cyclic AMP (cAMP), although it suggested other pathways were also involved. The treatment with this small molecule cocktail also enabled the induction of both mesodermal (Flk-1, c-kit) and cardiac progenitor (Mesp1, Isl1, Nkx2.5) markers in MEFs. Further to these results, the role of each molecule in the FASCB cocktail was investigated. While the expression of most cardiac genes was induced by CHIR99021 (5) and A83-01 (49), forskolin (1) on the other hand suppressed the expression of mesoderm/cardiac progenitor markers but promoted the expression of CM markers. Based on these results, ASCB small molecules were used in the initiation stage to induce cardiac progenitors whereas medium supplement with FASCB would preferably enable cardiac differentiation. This suggests that treatment of fibroblasts with the appropriate small molecule cocktail allows the formation of small molecule-induced cardiomyocyte-like cells (smiCLCs).

In work from Karakikes et al., the authors have put in place a combination of small molecules and growth factors to develop a direct differentiation system to induce ventricular-like-cardiomyocytes (VCMs) from hESCs.[103] The chemically defined protocol was divided into two steps. In stage 1 (days 0–4.5), EB formation was initially induced by blebbistatin ((64), **Fig. 31**), a small molecule inhibitor of programmed cell death. As a result, apoptosis was inhibited and EBs formation was increased. A combinatorial activation of the BMP and Nodal/Activin signaling pathways by BMP4 and Activin A generated a multipotent cardiovascular

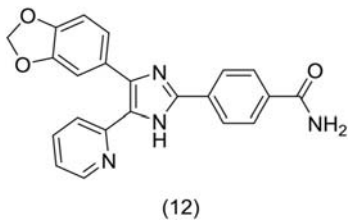

Fig. 31 Chemical structure of SB431542 (SB) (12).

progenitor population. In stage 2 (days 4.5–8), inhibition of the Wnt signaling pathway was realized by a small molecule IWR-1 (50) and yielded up to 90% terminally differentiated ventricular-like CMs as indicated by the expression of cardiac-specific (TNNT2) and ventricular CM (MLCV2) markers and the ventricle-specific TF (IRX4).

Wang et al. have screened for small molecule conditions that replaced TFs and enabled cardiac reprogramming of mouse fibroblasts with only one TF, Oct4.[104] A small molecule cocktail consisting of SB431542 ((12), Fig. 31, Alk4/5/7 inhibitor), CHIR99021 ((5), Fig. 30, GSK-3 inhibitor), parnate ((7), Fig. 28, LSD1/KDM1 inhibitor), and forskolin ((1), Fig. 30, adenylyl cyclase activator) was discovered. The fibroblasts were converted to spontaneously beating CMs that exhibit a ventricular phenotype. Immunocytochemistry analysis of the cells was consistent with the expression of cardiac troponin-T and α-actinin while qRT-PCR revealed the expression of cardiac-specific genes such as Myh6, Tnnt2, Gata4, and Nkx2.5. In addition, these chemically induced CMs also exhibited typical electrophysiological properties.

1.13.2.2.1.2.5 microRNAs

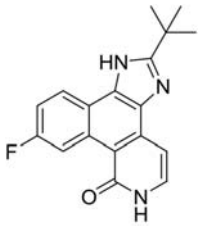
An alternative strategy for reprogramming is the use of microRNAs, as over the past several years, mounting evidence has indicated that virtually all aspects of cardiac function and adaptation are under the control of the microRNA (miRNA) network.[105,106] Four muscle-specific miRNAs—*miR-1*, *miR-133*, *miR-208*, and *miR-499*—are abundantly expressed in CMs, regulating many aspects of cardiac biology. In their study to redirect cardiac cell fate, Jayawardena et al. have developed a strategy to identify specific miRNAs capable of reprogramming cardiac fibroblasts directly to the cardiac lineage. miRNAs were selected based on their roles in cardiac muscle development and differentiation.[107–109] Synthetic and chemically modified mimics of miRNAs 1, 133a, 208a, and miRNA-499 were introduced into the mouse cardiac fibroblast via a single transient transfection. Using αMHC-CFP (cyan fluorescent protein, CFP) transgenic mice as cardiac reporters, they found that the in vitro transfection induced 5% of αMHC-CFP+ cells; this percentage was higher than the expression obtained in the control. Furthermore, RT-PCR revealed a shift in fibroblastic cells (Ddr2 and Vim) to early CMs (Isl1, Nkx2.5, Gata4, Hand2, and Mef2c) and late cardiac myocytes (Tnni3, Cx43). The starting cells were able to be converted to a CM-like lineage in vitro albeit with low efficiency. However, a 10-fold enhancement of miRNA-mediated reprogramming was realized upon treatment with Janus tyrosine kinase (JAK) inhibitor I ((65), Fig. 32). CM-like cells can be induced from noncardiac cells by ectopic expression of TFs and microRNAs. While these findings represent a promising avenue for future research, at the current time these methods have significant drawbacks that limit their application in therapies.

1.13.2.2.2 In vivo

1.13.2.2.2.1 Murine model

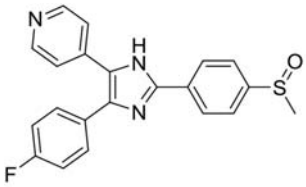
Chen et al. have described the effect of A83-01 (49) treatment on in vivo cardiomyogenesis using inducible Nkx2.5+ enhancer Cre transgenic mice to label postnatal Nkx2.5+ cardiomyoblasts and their differentiated progenies after myocardial injury.[110] Indeed, a recent study has demonstrated that Nkx2.5+ cardiomyoblasts may participate in the ability of neonatal heart to regenerate after induced injury. Treatment of Nkx2.5-GFP mice with A83-01 expanded postnatal Nkx2.5+ cardiomyoblasts contributing to the maintenance of ventricular wall thickness and cardiac function in post MI-mice.

Graichen et al. have generated CMs with promising efficiency when treating human ESCs with SB203580 ((66), Fig. 33), a p38 MAP kinase inhibitor, in the presence of factors released from endoderm-like (END-2) cells.[111] In addition, a synergistic effect was

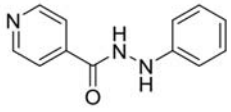


(65)

Fig. 32 Chemical structure of JAK Inhibitor 1 (65).



SB203580 (66)



PluriSIn-1 (67)

Fig. 33 Compounds involved in cardiomyocyte differentiation in vitro and in vivo.

observed when using the same p38 MAP kinase inhibitor in combination with FGF1. While in vitro studies showed that mitosis was induced in cultured CMs, in vivo experiments showed reduced scarring and improved cardiac function in rats after acute myocardial infarction. In a separate study, Low et al. designed and prepared a series of imidazole analogs and tested them for their ability to both inhibit MAP kinase and to induce CM differentiation.[112] Although they demonstrated that analogs of SB203580 could induce CM differentiation from ESCs, the correlation between this and MAP kinase inhibition could not be established. Further work in this area is needed.

While the earlier examples illustrate the successful translation of in vitro active modulators of CM production to in vivo models, in general of the numerous examples of small molecules acting in vitro there have been very few reports of translation to achieve efficacy in vivo. This may be due to the inherent limitations of in vitro screening systems, but may also be due to controversies as to which cell populations within the adult heart are most relevant or susceptible to target to promote cardiac regeneration in vivo. In the past few years, several studies have demonstrated that epicardial-derived cells (EPDCs) can contribute either directly or indirectly to cardiac regeneration in vivo in animal models post injury, and that this effect can be augmented by treatment with exogenous agents. For instance, it has been shown that in response to injury resident adult EPDCs treated with the peptide thymosin β4 undergo migration and differentiation in vivo into what appear to be structurally and functionally coupled CMs.[113] Thymosin β4 has multiple potential applications in regenerative therapies, and RegeneRx are currently conducting a Phase 3 clinical trial on this agent for neurotrophic keratopathy (RGN-259, Clinicaltrials.gov ID NCT02600429).

Another significant challenge in regenerative therapies is that in adult mammals the wound healing response also involves inflammation and scarring. This response allows the maintenance of the structural integrity of the heart after an injury but, as the scar tissue has no contractile ability, significantly impacts on heart function. To regenerate cardiac tissue to restore functional capacity it will likely be necessary, to some extent, to intervene in the inflammation process to either reduce or reverse scar formation. A very recent study has revealed insights into how this may be achieved.[114] The cardiac lymphatic system is a crucial component of the immune system, and in 2015 it was shown that myocardial infarction in adult mice stimulated a significant lymphangiogenic response. Importantly, this response was shown to be enhanced by treatment with vascular endothelial growth factor C (VEGF-C) and led to an unprecedented 40% increase in functional recovery.

One crucial hurdle for therapeutic application of iPSCs or iPSC derivatives (iPSCD) can be the risk of teratoma formation after transplantation if residual undifferentiated iPSCs are not fully eliminated by cell differentiation or purification protocols.[115] As inhibition of stearoyl CoA desaturase (SCD) was recently reported to eliminate undifferentiated hESCs, Zhang et al. have tested the effect of PluriSIn 1 (67), a small molecule inhibitor of SCD, on iPSC-derived CMs.[116] Moreover, Nanog-positive cells have also been correlated to tumorigenicity. As a result, the authors asked whether (67) would eliminate Nanog-positive iPSCD, thus preventing tumorigenicity of transplanted cells in mouse model of myocardial infarction. CMs were differentiated from ESCs and inhibition of SCD with (67) resulted in a decrease of nearly all cultured iPSCD spheroids after 4 days of treatment. As shown by immunoblots and qRT-PCR, Nanog level was downregulated 16-fold by (67) treatment in comparison to DMSO. Moreover, treatment with (67) prevented in vivo tumorigenicity of iPSCD in a mouse myocardial infarction model. Indeed, 2 weeks after cell transplantation, tumor formation was observed in hearts injected with DMSO-treated iPSCD, while no tumor formation was detected following injection of (67)-treated iPSCD, thus enhancing the safety of iPSCs transplantation in mouse ischemic myocardium.

1.13.2.2.2.2 Zebrafish model

Zebrafish represent an interesting model to identify manipulation of, blocking of, or enhancement of CM proliferation, since the animal husbandry is straightforward and embryos are transparent. Indeed, in contrast to adult mammalian cells, zebrafish CMs have the capacity to proliferate in response to injury. Ni et al. have developed an in vivo small molecule screen that modulates heart size and CM generation.[117] To test these compounds, the authors have carried out a screen using transgenic zebrafish embryos (cmlc2:EGFP). Three related compounds, cardionogen-1 ((68), **Fig. 34**), cardionogen-2 (69), and cardionogen-3 (70), induced cardiomyogenesis and were subsequently shown to act by inhibiting Wnt/β-catenin-dependent transcription in both zebrafish embryos and murine ESCs. Further it was shown that the cardionogens increased the expression of Nkx2.5, cmlc2, and vhmc at only 17 h post fertilization leading to expansion of cardiac progenitor cells. Similarly, the authors have observed that in IWR-1 (50)-treated embryos, expression of the cardiac progenitor cell marker Nkx2.5 was increased. However, in contrast to the cardionogens, IWR-1 caused anterior–posterior axis development defects.

In another example of the use of phenotypic assay in zebrafish embryos, Choi et al. have adapted transgenic zebrafish lines that utilize the fluorescent ubiquitylation-based cell cycle indicator (FUCCI) system.[118] The cmlc2:FUCCI line was developed to monitor CM proliferation allowing the discovery of chemical modifiers of heart regeneration. When 3 days postfertilization embryos were exposed to a variety of compounds targeting developmental signaling pathways, only drugs targeting the Hedgehog (Hh), Insulin-like growth factor (IGF), and TGFβ signaling pathways seemed to modify CM proliferation. Indeed, similar results were obtained when modulating these signaling pathways. Modulation of the Hh pathway in CM production has demonstrated that a Smoothened agonist (SAG) (39) enhanced the proliferation of CMs up to 60% whereas cyclopamine (37), a Smoothened antagonist decreased this production to 27%. Treatment with IGF signaling agonist NBI-31772 (71), a potent inhibitor of IGF-binding proteins, increased the number of CMs by 41% while cardiomyocyte production was reduced to 31% in the presence of the IGF receptor antagonist NVP-AEW541 (72). It was also found that SB431542 (12), a TGFβ inhibitor, reduced the number of proliferating cells by 30%. Consistent with these findings, these pathways were also found to be activated in adult zebrafish following partial ventricular

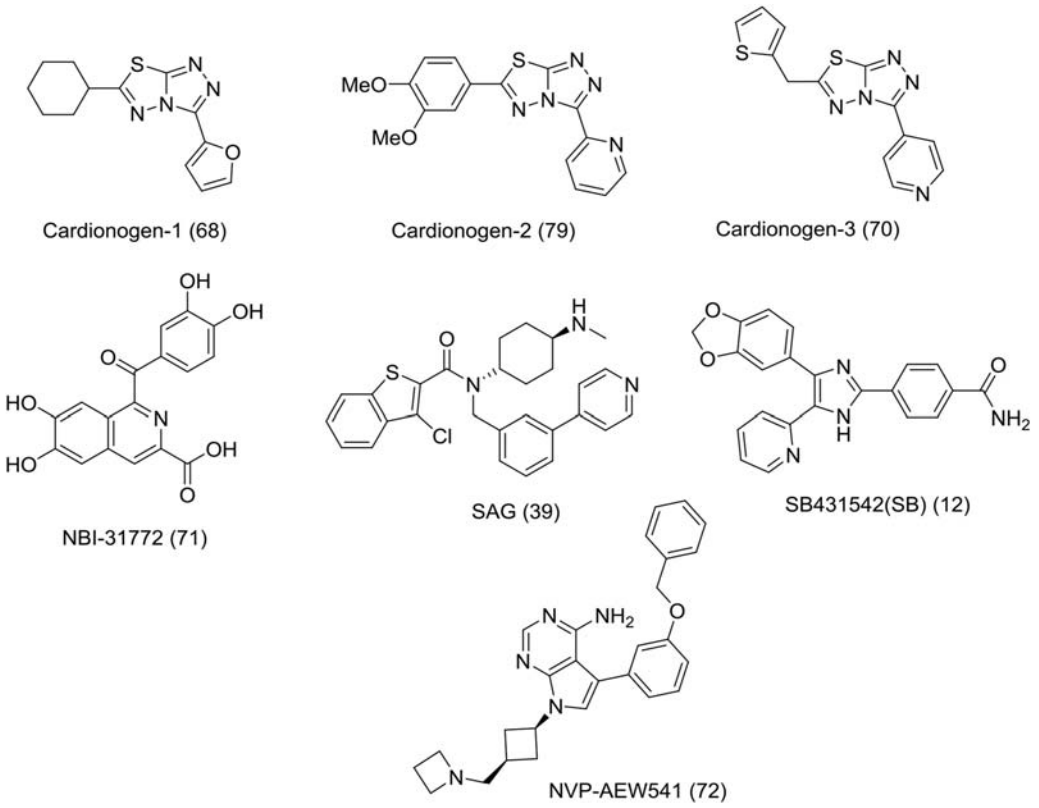


Fig. 34 Compounds involved in in vivo cardiomyocyte formation.

resection and genetic ablation of cardiac muscle and their effects on cardiomyocyte proliferation could be augmented by Hh and IGF agonist treatment. Interestingly, no response was observed in uninjured adult zebrafish.

1.13.2.3 Neuronal System

1.13.2.3.1 Neuronal regeneration: neuronal stem cells and drug discovery

Neurogenesis is the process whereby neurons are generated from precursor cells, namely neural stem cells (NSCs), and progenitor cells (NPCs). In addition, differentiated cells, in particular fibroblasts, have been transdifferentiated into neurons and this is discussed later in this section. While the process of neurogenesis is most active during prenatal development where it is responsible for populating the growing brain with neurons, there is now convincing evidence that the process continues in defined brain areas into adulthood. The precise details of neurogenesis, particularly in the adult human brain, are still being discovered and understood but what is clear is that cell signaling using factors from the stem cell niche, from other cells including neurons and from the bloodstream are involved in controlling the behavior of NSCs. As further details are revealed, the scope and potential of drug intervention in the process should also become clearer.

It is well-known that damage to the central and peripheral nervous systems affects large numbers of individuals with estimates of perhaps 1 billion sufferers throughout the world. In view of the fact that the average lifespan in many countries is increasing, it is predicted that these numbers can only increase in future. These disorders include the widely prevalent Parkinson and Alzheimer's diseases and less common conditions such as motor neurone disease, multiple sclerosis, and rare diseases such as spinal muscular atrophy. Also there are numerous psychiatric conditions for which a neurodegenerative component is being increasingly recognized. As many of the physical and psychiatric conditions are often imperfectly helped by current drug treatments, there is a pressing need for novel therapies to alleviate the suffering. The deliberate stimulation of neuronal stem cells/progenitor cells to produce new neurons or to repair existing, but damaged, ones could offer a route to such novel treatments.

The growth of understanding of adult mammalian NSCs and neurogenesis over the past 50 years has recently been authoritatively reviewed by Bond, Ming, and Song.[119] They titled their review on the fact that it was in the 1960s that Altman first suggested that neurogenesis takes place in the adult brain[120] with NSCs and NPCs being detected in 1989 and widely accepted during the 1990s.[121,122] NSCs are self-renewing multipotent cells that can generate neurons, astrocytes, and oligodendrocytes.[123] Endogenous NSCs have been shown to reside in three neurogenic niches in the adult mammalian brain. Of these the two most widely studied are the subventricular zones (SVZs) lining the lateral ventricles and the subgranular zone (SGZ) within the dentate gyrus of the

hippocampus, but there is also recent evidence to support a neurogenic niche within the hypothalamus. From their position in the SVZ NSCs are able to access both the cerebrospinal fluid and blood vessels from which presumably they receive growth factors and other stimuli essential to their development. NPCs differ in that while they are multipotent they do not self-renew indefinitely and appear to exist between NSCs and differentiated cells. It is also becoming clear that the population of NSCs at any time is very heterogeneous with, in particular, cells from different locations giving markedly different differentiated cells. This must be dependent on different signaling molecules in the niches as NSCs from both niches generate all three cell lineages when propagated in vitro in the presence of high concentrations of growth factors. Thus, in vivo SVZ NSCs generate olfactory bulb interneurons and corpus callosum oligodendrocytes while SGZ NSCs generate dentate granule neurons and astrocytes.

Elsewhere in this article the importance of the niche in which the particular stem cell exists has been stressed and this is true also for NSCs. NSCs in the SVZ are in close contact with cerebrospinal fluid (CSF) and the ependymal cell layer which excretes, inter alia, noggin, an inhibitor of bone morphogenetic protein signaling, whose presence allows the activation of the stem cell. NSCs are also exposed to signaling factors such as VEGF from endothelial cells, which promote self-renewal; and neurotrophin-3 (NT-3), which further promote quiescence and long-term maintenance. These signaling processes are not one-way streets and NSCs release signaling factors, which affect the structures that make up the niche. Also, and very remarkably, NSCs are regulated by neurotransmitters released by mature neurons and they express receptors, which respond to a variety of neurotransmitters including γ-aminobutyric acid (GABA), which also promotes quiescence. Many factors have been identified as affecting NSC behavior and no doubt many more remain to be detected but this surely shows the potential for discovering molecules able to affect the interactions involved in these signaling pathways.

Quiescence is an important state for the NSC, but it is not a dormant or passive state as there appear to be active expression of various receptors for niche signals and downstream signals. After activation most, if not all, of these are downregulated. Once the cell is activated a whole range of signaling processes, many of them acting in combinations, generate progression through NPCs to the final neuron or glial cell. Thus, for example, NSCs from the SVZ give rise first to transient amplifying progenitors, which divide a number of times to form neuroblasts. These neuroblasts then migrate to the olfactory bulb where they migrate radially and differentiate into different subtypes of interneurons. In a very interesting study, which perhaps sheds some light on normal ongoing processes in the central nervous system, Song et al.[124] have shown that in the adult mouse nestin (an intermediate filament protein expressed mainly in nerve cells where they are implicated in the radial growth of the axon)-expressing radial glia-like quiescent NSCs respond to GABA via the γ_2-subunit-containing $GABA_A$ receptor. Depletion of this subunit causes the cells to leave quiescence and undergo self-renewal. As stated earlier, decreasing GABA leads to quiescent NSC activation. The GABA responses are potentiated by diazepam, which specifically enhances γ_2-containing $GABA_A$ receptor responses to GABA.

It was the initial theory that the role of NSCs was to produce new neurons, which could repair or replace those damaged by disease or injury. It now appears that neurogenesis rather confers a unique mode of plasticity to the adult mammalian brain. However, this does not mean that with the right reagents the role of repair could not be achieved and that NSCs and NPCs could be stimulated to replace damaged neurons with functioning normal ones and that this approach could also be applied to conditions resulting from trauma injury to the CNS. As with other organs, at least three potential approaches are being actively investigated:

(1) The manipulation of NSCs and NPCs in vitro to generate tissue types for disease modeling and drug efficacy and toxicity testing
(2) Stem and progenitor cell therapy approaches involving ex vivo stimulation and differentiation followed by transplantation back into the patient and
(3) In situ stem cell modulation

However, obtaining neuronal stem cells from the patient would not be straightforward and it is likely that approach [3] will be more clinically acceptable. Alternatively, redifferentiation or transdifferentiation of more readily available adult cells into neuronal cells, or using cells from donors, would seem to be an attractive approach.

1.13.2.3.2 Neural stem cell culture

NSCs have proved difficult to culture in vitro as single cells and most work has involved the use of 3D aggregations of free-floating clusters of cells, which only contain a small percent of NSCs known as neurospheres. These are formed by suspending putative NSCs in a medium lacking adherent substrates but containing necessary growth factors such as epidermal growth factor (EGF) and fibroblast growth factor (FGF). A detailed protocol for producing neurospheres from mouse brain has been published by Pacey et al.[125] While neurospheres have proved to be highly useful in studying NSCs, there are problems that have to be taken into account. For instance, the culture formation is highly sensitive to the procedure so that different neurospheres can contain differences in composition of cell types and properties thus making interpretation of results obtained by their use difficult to interpret. It is known that neurospheres contain cells at multiple stages of differentiation, including stem cells, NPCs, neurons, and various glial cells. Nonetheless animal studies on the use of neurospheres or NSCs obtained from them are under investigation. Recently, Liebl et al. have published a detailed procedure for the preparation of cultures of adherent monolayer cells, which may act more consistently.[126] Also, the signaling pathways involved in NSC self-renewal and differentiation are becoming clearer with EGF, Hedgehog, vascular endothelial growth factor (VEGF), BMP, Notch, LIF-JAK-STAT identified to date.

1.13.2.3.3 Directed differentiation of NSCs and NPCs in vitro

As with any stem cell differentiation, the initial challenge is to prevent self-renewal and to initiate the differentiation pathway; in effect to inhibit one set of signaling pathways and/or stimulate the appropriate one. Rolfs et al. showed that inhibitors of glycogen

Fig. 36 Compounds causing neuronal differentiation.

synthase kinase-3 (GSK-3), in particular SB216763 ((73), Fig. 35) and kenpaullone (74), enhance neurogenesis in human NPCs.[127] GSK-3 is a multifunctional enzyme, which is involved in glucose metabolism, Wnt/β-catenin, Sonic Hedgehog, Notch, and FGF signaling. It was proposed that these two compounds stimulate the Wnt/β-catenin pathway and that stimulation of this pathway is one route to differentiation.

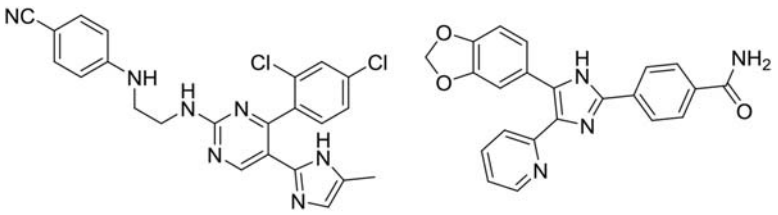
Earlier, Schultz et al. had found that neuropathiazol ((75), Fig. 36) was able to enhance neurogenesis while suppressing astrogliogenesis in rat NPCs albeit via an unknown mechanism.[128] (+)-Cholesten-3-one (76) has been shown to induce the differentiation of NSCs from embryonic rat forebrain into dopaminergic neurons.[129] (+)-Cholesten-3-one (76) was shown to increase BMP receptor expression leading the authors to conclude that its effect is mediated through indirect stimulation of BMP signaling. Finally, N-docosahexaenoylethanolamine (77) promotes neuronal differentiation of NSCs both in vivo and in vitro.[130]

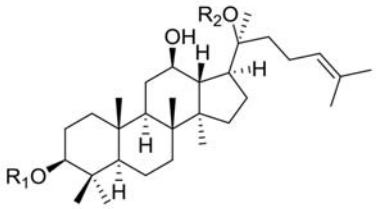
1.13.2.3.4 Directed differentiation of other cell types

1.13.2.3.4.1 Embryonic stem cells

A recent report describes the use of a cellular model involving hESCs first cultured toward a dopaminergic lineage, which are then treated with candidate molecules to detect those able to complete the differentiation to dopaminergic neurons.[131] From a range of tea catechins and ginsenosides, compound Rb1 ((78), Fig. 37) was found to be the most effective at generating dopaminergic neurons. It would appear that this approach could also be used to screen a wider range of structures. A different approach grew hESCs on monolayers in the presence of human leukemia inhibiting factor (LIF) and two small molecules, CHIR99021 (5), an inhibitor of GSK-3, and SB431542 (12), a TGF-β inhibitor. This produced primitive NSCs that can self-renew and respond to neural patterning cues toward midbrain and hindbrain neuronal subtypes. The authors subsequently showed that these cells could be transplanted into the lateral ventricle of neonatal mice and, satisfyingly, were then found to be distributed in many brain areas including the corpus callosum, the subcallosal zone, and the caudate-putamen.[132] A compound that had previously been reported to possess antiaging activity, icaritin (79), has been found to increase the differentiation of mESCs into cholinergic neurons in vitro[133] while isobavachin (80) also induced the differentiation of mESCs into neuronal cells.[134] Mechanistic studies were consistent with isobavachin acting via modulating protein prenylation.

Noggin is a protein that inhibits signal transduction within the TGFβ superfamily, and when present in the growth medium for hESCs the cells produce neuroectoderm. Further it was shown that treatment with FGF2/EGF gives neurospheres, which in the presence of Y-27632 ((81), Fig. 38), a Rho kinase inhibitor, produces increased levels of migrating neural cell-like cells, which were able to colonize explants of embryonic mouse gut and there to differentiate into enteric neurons.[135]





Rb1 R_1= glc-β(1-2)glc; R_2= glc-β(1-6)glc (78)

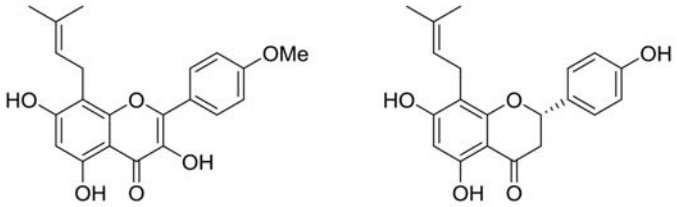


Fig. 37 Compounds causing the differentiation of mouse embryonic stem cells into neuronal cells.

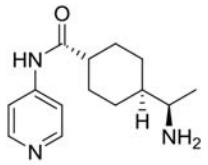

Fig. 38 Chemical structure of Y-27632 (81).

Inhibition of a different signaling pathway, namely Notch, by the γ-secretase inhibitor DAPT in hESC-derived NSCs markedly accelerates neuronal differentiation of the cells.[136] Further, hNSCs pretreated with DAPT ((82), Fig. 39) before transplantation into the mid-striatum of 9–12-week-old SCID-beige mice showed increased doublecortin staining, indicating that DAPT treatment also enhances neuronal differentiation in this context.

Two clinically useful drugs have also been found to have distinct effects on the differentiation of hESCs. The urinary analgesic drug phenazopyridine (83) was found using a high-throughput screen to increase total neurite outgrowth from hESCs and to produce a neuronal precursor cell population. After 1 week of incubation glutamatergic, GABAergic, and tyrosine hydroxylase-positive neurons were seen while after 4 weeks additionally nestin, β3-tubulin, SOX1, and vimentin-positive neurons were detected along with mature neurons and astrocyte and oligodendrocyte progenitors.[137] Zeng et al. showed that the antiarrhythmic drug, amiodarone ((84), Fig. 39), is selectively toxic to NSCs but not to dopaminergic neurons derived from hESCs, thus providing a way of producing a purer enriched population of desired neurons from these precursors.[138]

Of course, the generation of neurons from stem cells will only be of use if the resultant neurons can recapitulate the properties of native cells. A review has detailed the evidence that spinal motor neurons and cortical pyramidal neurons derived from stem cells show a remarkable degree of fidelity with those produced in normal embryonic development.[139] Further, it has also been shown that spinal motor neurons generated from hESCs show expected morphological and electrophysiological development along with neurite outgrowth and increased soma area.[140,141]

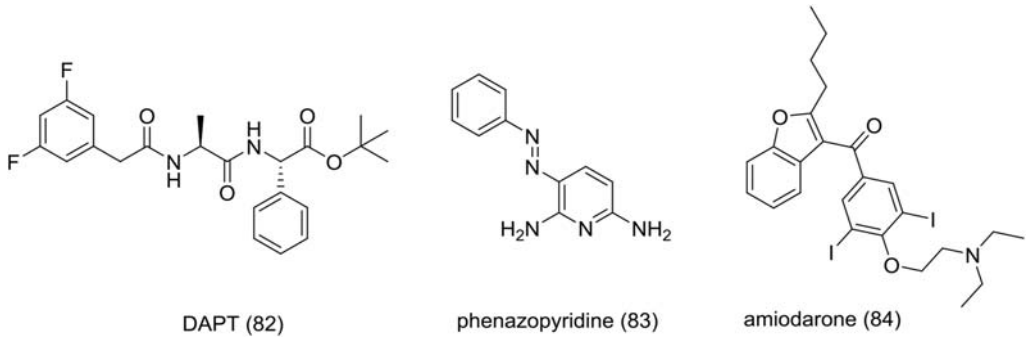

Fig. 39 Compounds causing the differentiation of hESCs into neurons.

Recently, Shin et al. took a mouse embryonic carcinoma cell line, P19, which, on treatment with appropriate growth factors and small molecules, could be differentiated into a range of cells including neurons, glia, cardiac, and skeletal muscle cells, and using a high-throughput screen found that two imidazoles, neurodazine ((85), **Fig. 40**) and neurodazole (86), promote the production of functional neurons.[142] Interestingly, these compounds do not also promote formation of astrocytes and this distinguishes them from other endogenous and synthetic mediators such as retinoic acid.

1.13.2.3.4.2 Induced pluripotent stem cells

In view of the ethical, sociological, and political difficulties arising from the use of hESCs it is not surprising that much work has been concentrated on the use of human iPSCs as potential sources of neurons for pharmacological studies and, hopefully, clinical use. A detailed review of the potential role of iPSC technology in understanding in vivo neurogenesis, neurological disorders, and in the discovery of potential new treatments for these disorders has been produced by Compagnucci et al.[143] In particular, they highlight how advances in carefully controlled culturing and differentiation of iPSCs in vitro feed into advances in the understanding of neurogenesis in vivo and vice versa. The differences between mouse and human cells are noted along with words of caution on extrapolating from one to the other.

Among other studies, Eggan et al. showed that 16 iPSC samples isolated from 7 individuals gave functional motor neurons with a range of efficiencies similar to that given by hESCs.[144] A detailed description of the rapid conversion of both hESCs and hiPSCs into motor neurons with defined subtypes of activities potentially useful for the study of neurodegenerative diseases has been published.[145,146] These studies used the small molecules Y-27632 (81), SB435142 (12), and LDN193189 ((56), **Fig. 41**) along with growth factors in the culturing media. Compound (12) was also used in combination with dorsomorphin (43) to enhance the neural induction of hESCs and hiPSCs.[147,148] A more specific BMP inhibitor than dorsomorphin, DMH1 (55), has been used with (12) and, separately, with SB218078 (87) in inducing neuronal differentiation of hiPSCs.[149,150] Gonzalez[150] used hiPSCs grown on Matrigel in N2B27 medium supplemented with primitive neuroepithelium to produce a highly enriched population of NSCs with concomitant downregulation of markers for pluripotency. These cells were found to be particularly suitable for the formation of dopaminergic cells.

The problem of producing sufficient specific neurons for clinical use has also been addressed by Iwata et al.[151] These authors used aggregates of dopamine neuron precursor cells in alginate-Ca^{+} microbeads followed by 25 days culturing to ensure cell maturation. The long maturation process has been shown to avoid teratoma formation following implantation into test rodents. This process gave dopamine-releasing neurons and the aggregates could be transplanted into rat brains where they were found to

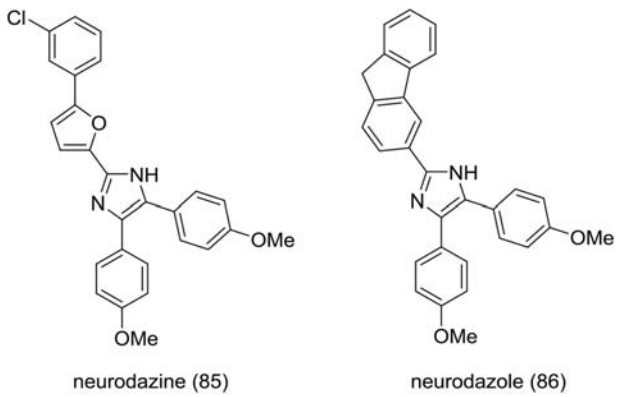

Fig. 40 Compounds involved in the production of functional neurons.

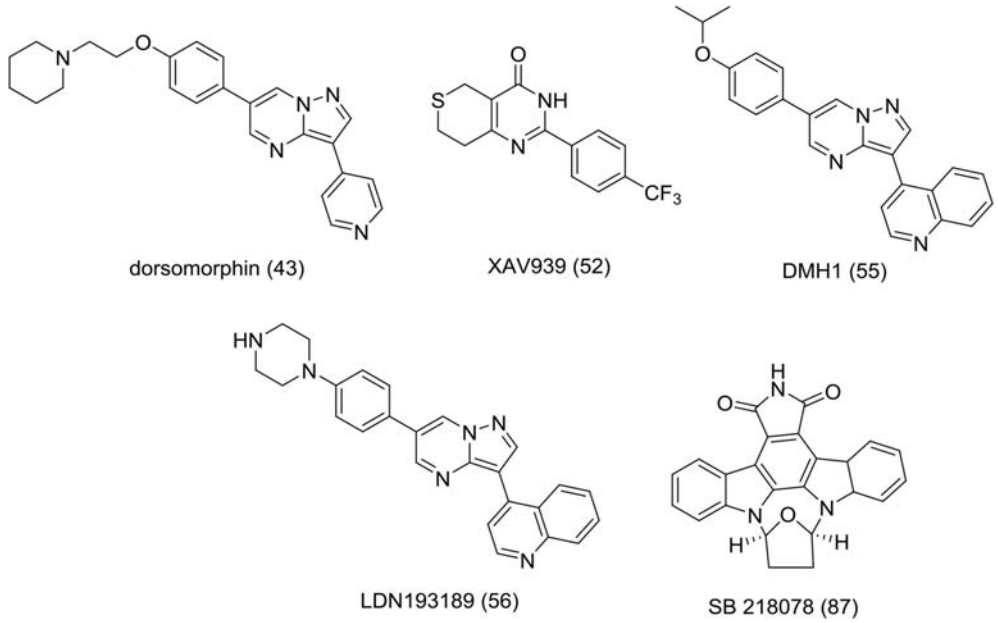

Fig. 41 Compounds differentiating hIPSCs to neurons.

produce neurites extending into the host tissue. Further studies are underway to investigate their functionality following transplantation.

Neurons in the hypothalamus are known to secrete a significant number of neuropeptides, which play roles in human health and disease. Among these are melanin-concentrating hormone, oxytocin, arginine vasopressin, corticotropin-releasing hormone, thyrotropin-releasing hormone, pro-opiolemelanocortin, agouti-related peptide, hypocretin/orexin, and melanin-concentrating hormone. Thus these neurons are under investigation as the basis of cellular models of the functioning of the hypothalamus, as potential screens in the discovery of new drugs to treat a number of human diseases or as cell-based therapies. Eggan et al. have described the generation of significant quantities of these neurons from hiPSCs by both a self-patterning strategy and, better, by a directed differentiation technique in cell culture. In the latter approach the hiPSCs were cultured on the growth medium in the presence of SB431542 (12), LDN193189 (56), and XAV939 (52) followed by purmorphamine (28) and SAG (39) and the resultant neurons were found to possess the characteristic morphological properties and gene expression patterns with in vivo neurons and were able to integrate into the mouse brain upon transplantation.[152] A similar approach to the study of hippocampal neurons was reported by Gage et al.[153] who produced dentate gyrus granule neurons from hiPSCs by culturing in the presence of, inter alia, Dkk1, SB431542 (12), Noggin, cyclopamine ((37), Fig. 42), and a number of growth factors. The final neurons that were shown to express characteristic expression factors were able to integrate into the dentate gyrus of the mouse and, very interestingly, the use of iPSCs derived from patients with schizophrenia showed lower levels of neuronal marker expression, reduced neuronal activity, and transmitter release by comparison with those from their healthy volunteer counterparts.

One feature of the development of a particular cell type from both ESCs and iPSCs is that different signaling pathways are operating at different times in the culture medium. A recent report[154] has generated transcriptomic data sets containing the expression levels from three ESC lines and two iPSC lines at four stages of differentiation. These were undifferentiated stem cells, NSCs, dopaminergic precursor cells, and dopaminergic neurons and showed clear differences in gene expression between the four stages. Thus they were able to systematically analyze the gene/pathways, networks, and cellular/molecular processes

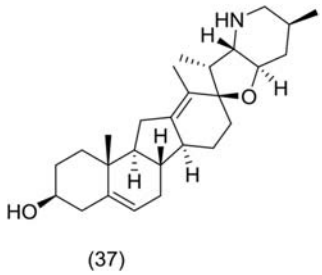

Fig. 42 Chemical structure of Cyclopamine (37).

controlling cell fates and the resultant information should provide great insights into how these processes could be improved by use of chemical mediators.

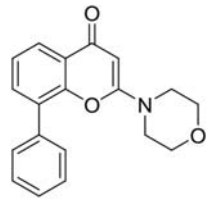
1.13.2.3.4.3 Bone marrow-mesenchymal stem cells

Mesenchymal multipotent stromal cells, of which MSCs are thought to be a constituent subtype, can be isolated from bone marrow and other tissues such as fat muscle and umbilical cord.[155] In fact the use of Wharton's jelly, the umbilical cord matrix, as the source of MSCs is regarded as a highly suitable source thanks to the primitive nature of the cells and their easy isolation without particular ethical concerns. The direct use of MSCs in animals and the clinic is discussed further, but they have also been used to produce neurons and other cells including osteocytes, adipocytes, chondriocytes, CMs, and endothelial cells. While a number of combinations of small and large molecules have been identified as directing cultures of MSCs to neurons, a recent paper claims that the presence of FGF2 alone is sufficient to generate dopaminergic neurons.[156] Previously a small molecule inhibitor of PI3K (phosphatidylinositol 3-kinase)/AKT signal pathways, LY294002 ((88), **Fig. 43**), was also shown to inhibit MSC proliferation and direct the neuronal differentiation of MSCs.[157]

Petri et al. [158] used human cord-blood-derived induced pluripotent stem cells, which hold the promise of lower genetic mutation burden or epigenetic alterations than iPSCs, to generate motor neurons by culturing in the presence of SB431542 (12), dorsomorphin (43), CHIR99021 ((5), **Fig. 44**), and purmorphamine (28). The resultant neurons showed characteristic functional neuronal properties such as sodium-inward currents and the ability to fire action potentials.

1.13.2.3.4.4 Transdifferentiation of other cell types

As has been mentioned elsewhere in this article, a potential problem arising from the use of transplanted ESC and iPSC-derived neuronal, and other, cells in the clinic is the potential for uncontrolled growth and teratoma production, which has been ascribed in part to the proliferative capacity of contaminating undifferentiated precursor cells. One means of circumventing this problem is to derive the target cells directly from a nonpluripotent, less/nonproliferative cell type, in particular from fibroblasts. Initial studies used the growth factors Asc11, Brn2, and Myt11 on mouse fibroblasts,[159] while Eggan et al. converted fibroblasts from both the mouse and human to motor neurons by using a limited number of TFs, namely, Asc11, Brn2, Myt11, Lhx3, Hb9, Isl1, and Ngn2 for the mouse and with one more, NEURODI for the human.[160] Interestingly, this conversion does not appear to involve a neural progenitor stage but the resultant neurons behave normally. Subsequently, a member of the forkhead box class O (FoxO) TFs, FoxO3a has been shown to be a critical regulator in the reprogramming of MEFs to iPSCs and thence to NSCs.[161] More recently, two groups have used only small molecules to achieve this transformation (**Fig. 45**). Cheng et al.[162] first used a combination of valproic acid ((4), histone deacetylase inhibitor), CHIR99021 ((5), a GSK-3 inhibitor), and RepSox ((6), an inhibitor of TGF-β pathways) under hypoxic conditions to produce neural progenitor cells. They then added a number of small molecules, forskolin (1), SP600125 (89), Go6983 (90), and Y-27632 (81) known to promote neural differentiation of NPCs[163]



(88)

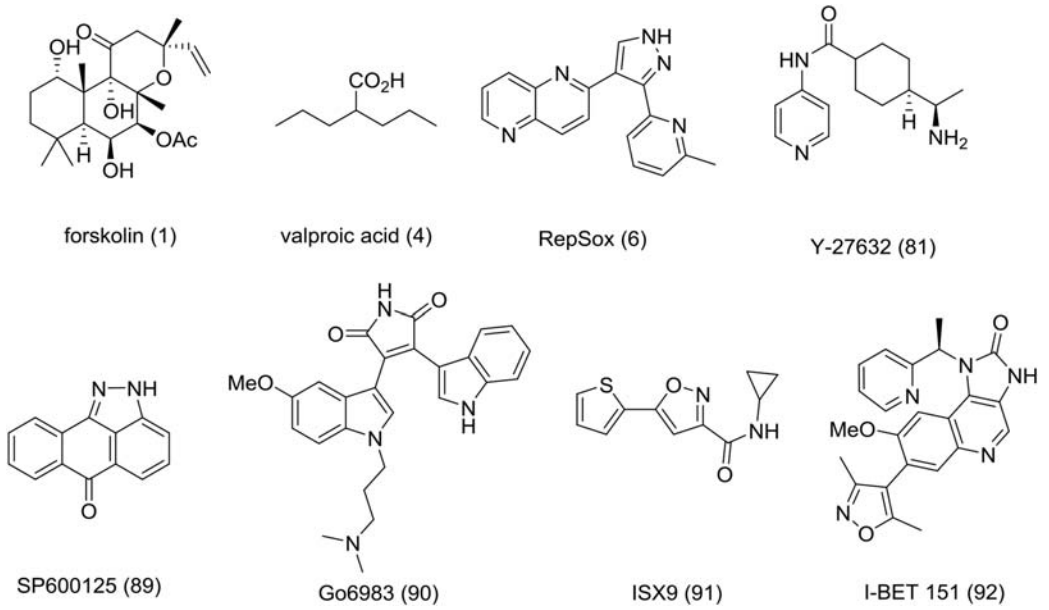

Fig. 45 Compounds reported to differentiate fibroblasts to neurons.

and produced mainly glutamatergic neurons from human fibroblasts. Fibroblasts from patients with familial Alzheimer's disease could also be differentiated and produced neurons with the expected elevated extracellular Aβ42 levels and Aβ42/Aβ40 ratio. A second Chinese group[164] has found that a combination of forskolin (1), ISX9 (91), CHIR99021 (5), and 1-BET151 (92) was able to generate with a very high-efficiency functional neurons from mouse fibroblasts. As was found earlier, these processes do not seem to involve the neural progenitor stage. Dopaminergic neurons were produced from mouse fibroblasts by use of a combination of transcription and neurotropic factors.[165]

It has been recently shown that adult neuroprogenitor cells can be isolated from subcortical white matter very much more conveniently than from the hippocampus and that they are able to produce neurons, astrocytes, and olidodendrocytes in amounts comparable to fetal NSCs.[166] Human dental pulp stem cells have been isolated and cultured to give first neurospheres and then cells with neuronal characteristics.[167] These may prove more readily accessible sources of human precursor cells in the future.

1.13.2.3.5 Cell-based therapies for neurological disorders

Since many neurological disorders and traumas involve irreversible damage to some brain tissue and as most current therapies provide only limited symptomatic treatments, the idea of replacing or regenerating the damaged tissue is a highly attractive one. The use of neuronal cells from a variety of sources has been reviewed by Das et al. [168] and, very recently by Steinbeck and Studer[169] who discussed in detail the history of cell-based treatments for neurological disorders, in particular Parkinson's disease (PD), and the switch to cells generated in vitro and the difficulties of establishing that the transplanted cells in both animal models and humans are functioning as anticipated. Initial studies in PD used fetal cell transplants and gave some indications of positive results. A recent paper has described the situation of two patients who, 15 and 18 years posttransplantation, show positive clinical improvements in their condition along with abandonment of any pharmacological dopaminergic therapy.[170] Two cases are hardly sufficient to draw definitive conclusions; nonetheless, this is a dramatic result for these two individuals. More recently the ethical and practical difficulties of this approach caused a shift to the use of neurons or neuron precursor cells derived from stem cells. These have their own difficulties such as ensuring proper quality control of cultivated cells and again establishing that any transplanted cells are behaving as required in the brain of both animal models and humans. For example, human adipose tissue-derived stromal cells (hASCs) were cultured and grafted into severed sciatic nerves of athymic nude female rats and found to significantly improve functional recovery in the damaged limb.[171] However, it was found that the hASCs did not differentiate into neurons and it was suggested that improvement was due to the production and local secretion of neurotrophins such as neural growth factor. Due to these difficulties, the number of clinical trials currently underway is very small but Asterias Biotherapeutics are running Phase 1/2 trials of a preparation of cells containing oligodendrocyte progenitor cells for patients with severe spinal cord injury. A detailed discussion of the potential and challenges of using NSCs in the treatment of neurological disorders along with a listing of clinical trials in the area has been given by Conti et al.[172] These authors stress that improving knowledge of the CNS microenvironment following injury will affect future treatment protocols and emphasize that the potential of NSCs to regenerate the brain also relies on the competence of other cells to be involved in the process. Lo et al. have discussed biomaterials, which might help the dosing and integration of transplanted cells.[173]

In other work, the direct transplantation of bone marrow MSCs to lineage stroke–prone spontaneously hypertensive rat resulted in levels of superoxide, apoptotic cells, and the by-products of lipid peroxidation fell to control levels and there was evidence of repair of morphological damage at the hippocampal region.[174]

A crucial feature of any cell-based treatment is that the transplanted cells should integrate into the recipient nervous system. Evidence that this is possible was provided by Ding et al. [175] who took human primitive NSCs transfected with GFP under the control of the elongation factor-1α promoter to show that following injection into the site of injury of athymic nude rats with lesioned spinal cords, the cells survived and largely differentiated into neurons. Further they grew away from the injury site and were also found to be predominantly serotonergic neurons. A different class of neurons, the inhibitory interneurons, has been discussed by Alvarez-Buylla et al.[176] These neurons are of particular interest because in their development they migrate through the brain to form inhibitory neural circuits and transplanted embryonic interneurons are found to do likewise. They therefore may be of interest in their own right as treatments for neurological disorders but also for what they can reveal about the formation of neurological circuits.

1.13.2.2.5.1 In situ stem cell modulation

It is an intriguing thought that existing drugs may exert some or all of their effects by promoting effects, including neurogenesis, on brain cells and the potential relationship between antidepressants and neurogenesis has been reviewed.[177,178] Antidepressants from multiple pharmacological classes have been shown to increase neurogenesis in human and animal models, although the link between neurogenesis and antidepressant activity remains controversial. Sertraline ((93), **Fig. 46**), an antidepressant, has been shown to increase adult human hippocampal neurogenesis via a mechanism that appears, at least in part, to involve activation of glucocorticoid receptors, which requires PKA signaling, glucocorticoid receptor phosphorylation, and gene activation.[179,180] Interestingly and importantly, the effect of such agents appears to be restricted to one NSC nest within the brain rather than exerting pleiotropic effects on other resident stem cell populations, an observation for which a possible explanation could be the reported synergy between sertraline and endogenous glucocorticoids,[179,180] thus raising the prospect of being able to find selective agents. Chronic fluoxetine (94) treatment of middle-aged rats increases the volume of the hippocampus and increases the expression of molecules related to structural plasticity and inhibitory neurotransmission with lesser effects in the amygdala.[181]

Allopregnanolone (95), a metabolite of progesterone, significantly increases neurogenesis in the SGZ of the dentate gyrus and the SVZ of a mouse model of Alzheimer's disease (3xTgAD mouse) and thus is currently the only small molecule with the ability to promote neurogenesis, to reduce cognitive defects, and to reduce the AD pathology burden.[182] A different class of active molecules, the histone deacetylase inhibitors, is effective neuroprotective agents following acute traumatic brain injury (TBI) in rodent models. LB-205 (96) treatment was reported to increase expression of CNS survival factors such as nerve growth factor (NGF) and activate the neurotrophic tyrosine kinase receptor type 1 (TrkA), repress astrocyte production, and augment the proliferation of nestin-expressing stemlike cells.[183]

Also active in models of TBI is LM11A-31 ((97), **Fig. 47**), a ligand for the p75 neurotrophic receptor, which is a major contributor to pathological processes in the CNS, and which decreases impairment of learning induced by injury, promotes neural progenitor cell survival, improves the outcome of TBI, and enhances the production of mature neurons from adult hippocampal neural progenitors in vitro.[184] The antiepileptic drug ethosuximide (98) has been shown to increase GABAergic neurons in rat forebrain cortex stem cells in vitro, but whether this could be the basis of its clinical effects has not been established.[185]

1.13.2.2.5.2 Augmenting neurogenesis in vivo

An attractive strategy to tackle neurodegenerative disease would be to promote differentiation of neural stem/progenitor cells especially as promotion of terminal differentiation rather than self-renewal of disregulated cancer stem/progenitor cells could

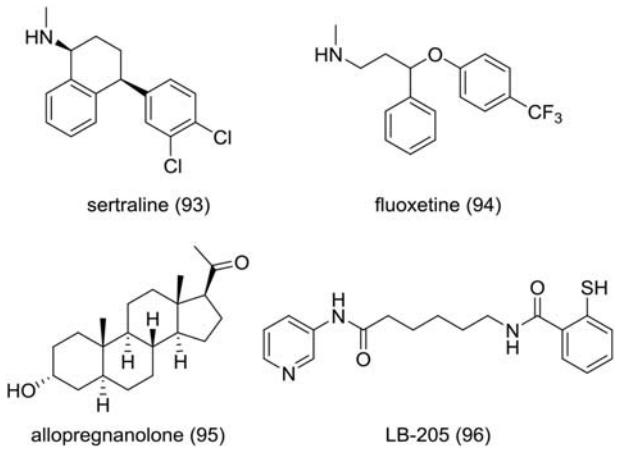

Fig. 46 CNS active agents able to induce neurogenesis.

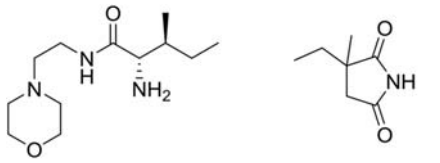

Fig. 47 Compounds active against traumatic brain injury and epilepsy.

play a key role in halting the progression of various neurological malignancies. However, it is apparent that the use of such agents discovered using in vitro methods in an in vivo pharmacological/clinical situation is likely to be particularly complicated due to the usual pharmacokinetic constraints, including the need to penetrate the blood–brain barrier. Notwithstanding these caveats, in vivo active compounds have been discovered. A group of molecules including P7C3 ((99), Fig. 48) and its derivative P7C3A20 (100) were discovered in an in vivo study monitoring hippocampal neurogenesis in neonatal mice. The authors went on to demonstrate that these molecules act through inhibition of apoptosis of new-born neurons in the subgranular zone of dentate gyrus, an effect mediated through activation of NAMPT, a key mediator in the NAD salvage pathway.[186] In addition, the compounds were able to protect adult mice against the effect of the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP, (101)), especially on dopaminergic neurons.[187] Further, P7C3A420 (100) was particularly active in the G93A-SOD1 mutant model of amyotropic lateral sclerosis (ALS) in protecting ventral horn spinal cord motor neurons,[188] indicating that this class of compounds do possess an exciting range of neuroprotective activities, although their broader specificity has yet to be reported.

1.13.2.2.5.3 NSC differentiation in vivo

To illustrate that this differentiation is possible, it should be noted that perfluorooctane sulfonate at environmentally relevant levels decreases proliferation and increases neuronal differentiation in NSCs in vitro via PPAR-γ (peroxisome proliferator response element) and in utero in the developing mouse brain.[189] The effect of hypoxia on neural development has been reviewed[190] and Fuller et al. showed that the NPCs isolated from SVZ tissue from 4 day old C57BL/6 mice, which had been exposed to intermittent hypoxia had greater capacity for expansion, increased cellular metabolic activity, and an increase in hypoxia-inducible factor 1-α signaling.[191] Novel medicinal chemistry discoveries may be facilitated by discovering the details of the biochemical processes involved in a particular target organ or tissue. Among such targets are the Notch/RBPJk (recombining bonding protein suppressor of hairless)-signaling pathway, which is highly active in NSCs and its inactivation leads first to increased neuronal differentiation and later, suppression of hippocampal neurogenesis,[192] which is accompanied by loss of expression of Sox2 (sex determining region-Y-box 2). A crucial role for cGMP in the in vivo differentiation of NSCs to neurons in rat prefrontal cortex and hippocampus has been shown and treatment of pregnant rats with L-NAME ((102), Fig. 49), a nitric oxide synthase inhibitor, which significantly reduces levels of cGMP in the fetus brain results in reduced neuron production and increased production of nonneuronal cells.[193] The effect was reversed on concomitant treatment with sildenafil (103), a cGMP-specific phosphodiesterase-5 inhibitor.

Schultz et al.[194] developed KHS101 ((104), Fig. 50) from a group of thiazoles identified in a phenotypic screen for compounds able to promote the neuronal differentiation of rat hippocampal NPCs. Further studies using chemical proteomics identified transforming acidic coiled-coil-containing protein 3 (TACC3) as a protein target bound by KHS101 leading to increased nuclear localization of the TF ARNT2. KHS101 also suppressed NPC proliferation and BMP4 induced astrogenesis in vitro and on subcutaneous injection into rats crossed the blood–brain barrier and promoted neurogenesis of NPCs in the subgranular layer of the dentate gyrus at the expense of proliferation.

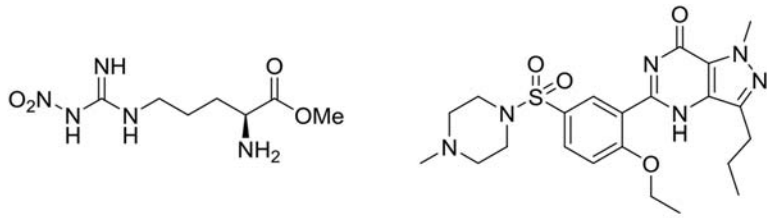

Fig. 49 Compounds involved in in vivo differentiation to neurons.

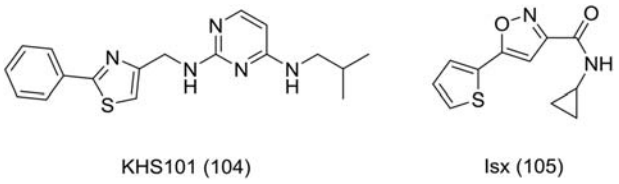

Fig. 50 Neuroactive isoxazoles.

A series of isoxazoles, exemplified by Isx (isoxazole stem cell modulator of small molecules) (105), which promote neurogenesis in NSCs in vivo were linked through a chemical proteomics study to the activity of a protein GPR68, a proton sensing G protein-coupled receptor with no previously reported function in the brain.[195] Isx and GPR68 were both found to increase levels of neuronal target genes such as Bex 1 (brain-enriched X-linked protein-1) in hippocampal progenitor cells. Furthermore, after TBI cerebral cortical astrocytes express GPR68 indicating a crucial role for the effect of brain pH and the authors speculate that lactic acidosis could explain the beneficial effect of exercise on Alzheimer's disease. Microarray gene expression analysis showed that Isx promoted upregulation of genes associated with neurogenesis and cell cycle progression in primary mouse dentate gyrus cells in vitro, which would be consistent with the conversion of quiescent NSCs converting to proliferative transit amplifying progenitors prior to terminally differentiated neurons. Isx is able to penetrate the blood–brain barrier and can promote enhanced hippocampal neurogenesis following intraperitoneal injection in young mice with an associated decrease in NSC populations. However, while Isx-treated mice increased neurogenesis as assessed by dentate gyrus volume combined with nestin-GFP + cell count and cell lineage tracing, they did not display any learning or memory enhancement over controls in behavioral tests likely due to the young age of the mice tested. It would be interesting to see the effects on cognitive behavior of these compounds in aged animals. Taken together these studies suggest a link between pH, which is often linked to hypoxia, and regulation of neurogenesis and that this may play part of the coordination of the body's response to injury. These findings may also pave the way for other opportunities for small molecule therapeutic intervention.

1.13.2.2.5.4 Neural cell migration in vivo

Neurogenesis in both embryonic and adult zebrafish has been the subject of a recent review[196] and methods of imaging the neural migration, axonal, and dendrite formation have also been described.[197] Clearly, being able to understand the mechanisms of these processes could lead to the discovery of agents able to constructively affect them and to influence the migration of neurons into functioning brain structures. N-Cadherin is known to regulate β-catenin and Wnt signaling, and has recently been shown to maintain β-catenin signaling via AKT (protein kinase B) in mouse cortical development.[198] Further, inhibition of AKT signaling in neural precursors in vivo leads to reduced β-catenin-dependent transcriptional activation, increased migration from the ventricular zone, premature neuronal differentiation, and increased apoptotic death. The growth factor, insulin-like growth factor-1 (IGF-1), has been found to act on SVZ-derived adult neuronal precursor cells in mice to induce migration along the rostral migratory stream (RMS) through both chemokinesis and chemotaxis.[199] Although less migration has been observed for human SVZ-derived neurons compared to mouse, this nonetheless suggests a possible target for further exploration to increase precursor cell recruitment into areas of cellular damage resulting from brain injury or illness.

Interestingly and in contradiction of previous claims, it has been shown that AMP-activated protein kinase activity (AMPK) is not required for proper cortical neurogenesis, radial migration, cortical layer formation, and axon-dendrite formation both in vivo and in vitro.[200] Hyperactivation of this enzyme complex does however have profound consequences on early neural development with inhibition of axon specification via the mTOR-dependent pathway (mammalian target of rapamycin complex-1).

1.13.2.2.5.5 Reprogramming in vivo

Evidence of the natural processes involved in neuronal development was provided by Lie et al.[201] who showed that in the adult mouse hippocampus expression of the SoxC TFs Sox4 and Sox11 is initiated at the time of neuronal commitment to adult

NSCs and is maintained in immature neurons. Further, both of these factors work with Ngn2 to reprogram astrocytes into neurons and understanding these processes is likely to lead to fresh targets for drug intervention.

1.13.2.3.6 Disease screening and drug discovery

The ability to produce the neurons and glial cells that are possibly involved in neuropathies and then use them in high-throughput screening could represent a highly significant approach to the discovery of new therapeutic agents. Thus for example the groups of Eggan and Wichterle have shown that hiPSCs generated from patients with amyotrophic lateral sclerosis (ALS) could be differentiated into motor neurons, thereby giving a route to the understanding of the molecular details of this disease.[202] The problems of such approaches to "in vitro disease modeling" have been discussed in thoughtful and comprehensive reviews by Eggan.[203–205] In particular, these reviews show how detailed studies of the cell type-specific gene expression of the damaged neurons could lead to an understanding of the true molecular nature of the disease and consequently the discovery of agents able to correct or alleviate this. Further, the potential problems arising from the use of hiPSCs from individuals, the variable behavior of such cells in culture, and epigenetic variations are discussed. It is possible that recent advances in reprogramming techniques and more stringent quality criteria will allow the production of large cohorts of disease and control subject pluripotent cell lines and that this should reduce the possibility of the results being distorted by the presence of aberrant cell lines.[206]
