5.20.1 Introduction

The purpose of this article is to review the unique challenges that are offered by the development of treatments for acute as opposed to chronic viral diseases. To an extent, the outstanding success of treatments for chronic virus infections including human immunodeficiency virus (HIV) and hepatitis C virus (HCV) detailed in previous articles has served to encourage investment in research and development aimed at the treatment of acute viral infections.

Each acute viral infection offers a unique set of epidemiological and technical characteristics that contribute to the overall possibility of the discovery of useful therapeutic agents. It would be impossible in the space available to examine all acute virus infections so we have chosen to compare and contrast the apparently similar respiratory virus infections caused by orthomyxoviruses (influenza (flu)), rhinoviruses, adenoviruses, and paramyxoviruses including respiratory syncytial virus (RSV). We will consider the challenges of drug discovery in each virus family and how these are being overcome.

We will review in detail the discovery efforts aimed at RSV as a general example of an acute viral infection. This virus illuminates the challenges and promise of working in the field. RSV is also the acute virus infection of most current interest to the industry post the emergence of multiple potent therapeutic combinations to treat HCV.

Finally, we will review the interesting challenges of emerging viral infections. Global warming, the subsequent migrations of viral vectors, and the popularity of global travel are all combining to spread little known viruses around the world and to threaten its human populations.

5.20.2 Respiratory Virus Targets of Research Into Acute Viral Infections

The graph later (Fig. 1) shows an overlay of the epidemics of four common respiratory virus families in the United Kingdom over a 10-year period. The RSV epidemic (*black line*) is a consistent feature every winter. Other paramyxoviruses assume less importance. The rhinoviruses (of which there are more than 150 serotypes) are present through much of the year, while influenza virus epidemics are much less predictable. From this timeline, it is clear that the feared global pandemic of influenza is very much overdue. Adenoviruses become important when groups of seronegative individuals congregate (e.g., army recruits or college students) or when the virus attacks the immunocompromised.

The differences seen in the epidemiology of these four virus families show that one cannot generalize on the "respiratory virus" theme and that each virus needs to be considered from multiple aspects before embarking on a drug discovery project.

The key issues to consider when initiating a discovery project are the following:

- *Prevalence*: the significance of the disease burden caused by the virus
- *Diagnosis*: specimen accessibility and speed and accuracy of testing
- *Alternative therapeutic approaches*: vaccines, immunotherapy, etc.
- *Therapeutic window*: ability to intervene in a timely fashion to significantly improve the outcome for patients
- *Competition*: relative progress of other discovery projects and the opportunity/threat they offer

A common issue for all therapeutic areas in the drug industry has for many years been the choice of target protein(s) suitable for each disease. In the virology field, this has become much less complex. For each virus, multiple targets are available and are well understood. Often, the limiting step in starting an antiviral discovery project is making the commercial case that the return on investment will be sufficient to justify the work. This issue is particularly the case for acute viral infections. The history of such projects is often that they fail to get off the ground because the commercial case is based on attempting to treat the "otherwise healthy" population. This approach is often superficially attractive simply because the numbers of such patients are so large. The real medical need *and* the commercial opportunity lie in finding the patient groups where an acute infection can be catastrophic. These patients may be the very young, the elderly or the immunocompromised.

Table 1 lists the four virus families we have chosen to illustrate the issues in discovery of agents to combat acute virus infections. We will discuss each in turn, followed by the issues around emerging virus infections.

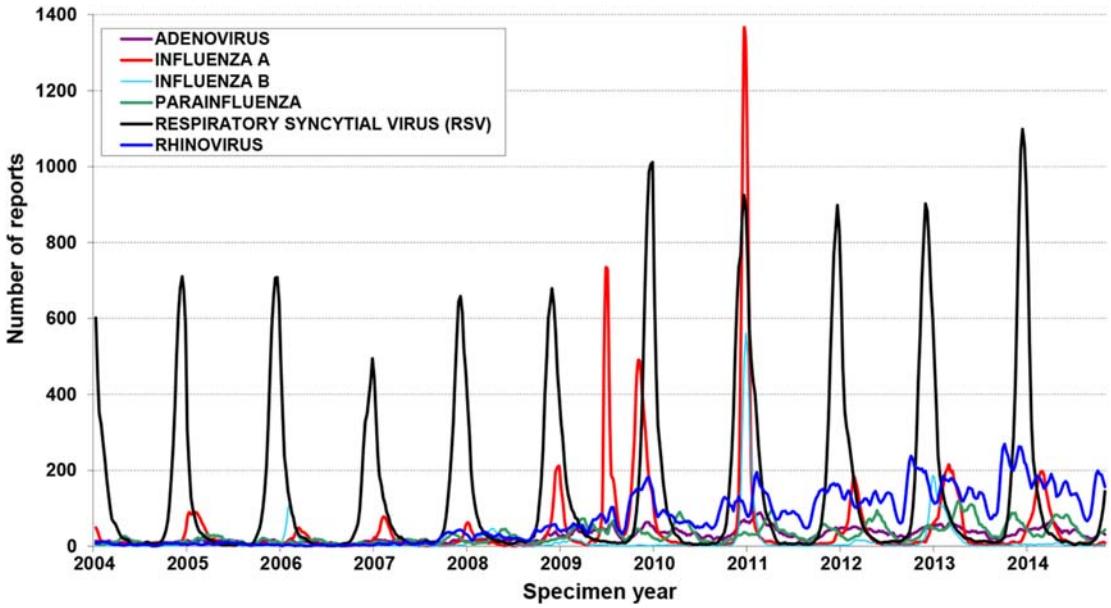

Fig. 1 Six major respiratory viruses reported from PHE and NHS laboratories (LabBase) in England and Wales between weeks 01/2004 and 44/2014 (3-week moving average).

Table 1 Respiratory viruses as targets of drug discovery

Virus family	*Vaccine status*	*Prevalence*	*Approved drugs*	*Active discovery research*
Rhinovirus	None (multiple serotypes)	Very widely distributed; common infection	None	Limited
Orthomyxovirus (influenza)	Multiple	Epidemic and potential for pandemics	Multiple targeting different viral functions	Limited
Adenovirus	Limited (largely for army personnel)	Limited	None	Limited
Paramyxovirus	Passive immunotherapy with Synagis for RSV; multiple vaccines in research phases	Seasonal epidemics with a reliable periodicity	Ribavirin	Active

5.20.3 Rhinoviruses

5.20.3.1 Reasons to Develop Antiviral Drugs for Rhinovirus Infections

Rhinoviruses are known as the cause of the common cold—one of the mildest infections known to medicine. Most adults see two to five infections a year, and although they may cause irritation and some morbidity, they generally are well tolerated. Attempts to treat the common cold with agents like interferons or capsid binders have generally been targeted at the "otherwise healthy" populations. This approach has led to failure, with limited benefits not compensating for the side effects observed. It has also led to a widespread reluctance from the industry to invest in antiviral discovery programs for "the common cold."

Severe outcomes of rhinovirus infections are now widely appreciated in asthmatics, chronic obstructive pulmonary disease (COPD) patients, and those with cystic fibrosis. The problems of developing vaccines or passive immunotherapies for patients who are infected by a virus that may be one of >150 serotypes mandate efforts to develop pan-rhinovirus inhibitors.

Rhinoviruses are a member of the picornavirus family of small single-stranded RNA viruses, and lessons learned through discovery efforts for this group provide useful starting points for research into newly discovered or appreciated small RNA viruses causing significant disease burdens. These include the coronaviruses (SARS-CoV and MERS-CoV) and enteroviruses, which share similar target proteins. A broad-spectrum inhibitor of these viruses would be attractive for use in the life-threatening diseases they can cause.

5.20.3.2 Classes of Rhinovirus Agents

5.20.3.2.1 Capsid binders

Early discovery efforts in several companies identified different types of hydrophobic small molecules that inhibited rhinovirus replication. These compounds were shown to bind to the virus particle and to interfere with the early stages of viral replication. Classic experiments by Rossmann's group determined the three-dimensional structure of example inhibitors bound to virus particles and showed that they were bound to a canyon in the external structure of the viral capsid protein VP1.[1]

A number of structural studies subsequently have confirmed this binding mode with more recently developed compounds on poliovirus[2] and enterovirus 71,[3,4] as well as rhinovirus. In rhinovirus itself, a consistent binding mode can be observed for inhibitors, with a range of interactions with key residues postulated, most notably H-bonding and π interactions with residue Y152. The mutations Y152P and V191L were observed in naturally derived serotypes, and alongside the A150V mutation that is observed across multiple serotypes, all these changes overcome the antiviral effect of inhibitors by reducing the binding affinity of the drug modification at or proximal to the binding site.

In the case of the recently described LPCRW_0005, the distance of the A150 residue from the binding position of the compound (>8 Å) suggests a different effect. The hypothesis proposed is that this mutation stabilizes a collapsed conformation of a portion of the protein that impedes inhibitor access.[5]

As rational as these structural arguments appear, the major feature of drug development in this structural type has been the modification of features that have an effect on both binding affinity and the pharmacokinetic profile. The structures of these inhibitors are long, with multiple freely rotating bonds (Fig. 2). In addition, metabolically labile groups, for example, ester and oximes, are common (CA603 (7), pirodavir (2), and BTA188 (4); Fig. 2). Pleconaril was the first molecule in which these issues were addressed (through the incorporation of the trifluoromethyl-substituted oxadiazole system) and demonstrated satisfactory oral pharmacokinetics.[6] The latest inhibitor BTA798 (5) (vapendavir)[7] utilizes a benzisoxazole replacement for the labile functionality. This isostere appears to provide an orally bioavailable compound, although the bioavailability of 94% in rats is reported at a rather large dose of 50 mg kg^{-1} and retains the potential for the saturation of any metabolic processes that may occur at lower doses closer to the therapeutic range.

The most recently described inhibitor type (6) (LPCRW_0005)[5] certainly demonstrates a different perspective on site binding mode for capsid inhibitors. Due to the compound's decreased size over other inhibitors, it occupies a fraction of the conventional binding pocket. As such, it provides an interesting new template for further medicinal optimization.[8]

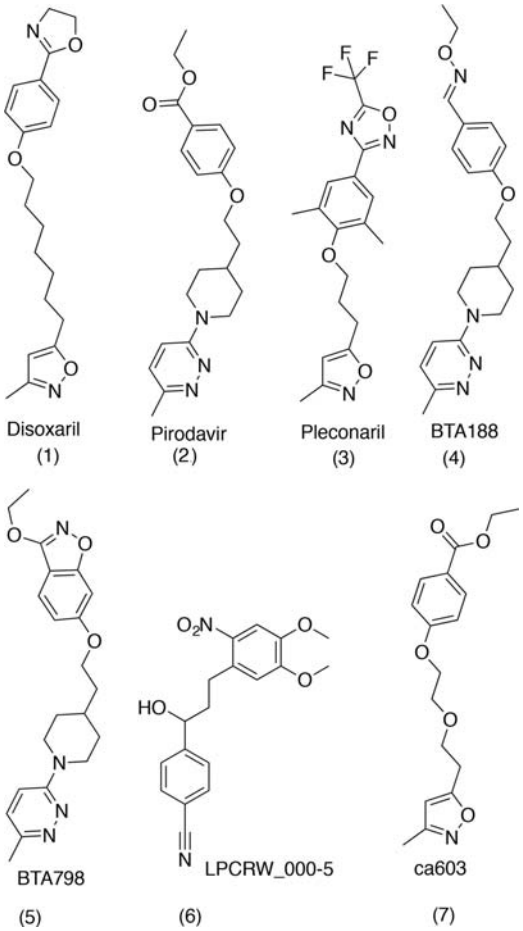

Fig. 2 Capsid inhibitor structures.

The Janssen group developed a series of capsid binders that showed potent activity against selected strains of rhinovirus. As the series developed, an appreciation emerged of variation in the sensitivity of various rhinovirus serotypes and the need for compounds with a wider spectrum of activity.[9] This work culminated in pirodavir (2) (R77,975), which entered clinical trials in challenge studies.[10] As with most capsid binders, the physicochemical properties of the compound made formulation difficult, and an intranasal spray was developed. The compound was tested both in the prophylaxis and treatment modes. There was a clear antiviral effect when the compound was used six times a day in the prophylactic mode, but the treatment data and the effect on the symptoms of the "cold" were disappointing.

Pleconaril originated from research at Winthrop that was later acquired by Sanofi, and pleconaril was licensed to ViroPharma. Using clinical trial data obtained with an oral formulation of the drug ViroPharma attempted to obtain an new drug application (NDA). The trials[11] showed a clear effect on the outcome of a common cold with a benefit of about a day in the resolution of clinical symptoms. Unfortunately, the side effects, although moderate (largely GI-related), were considered too severe by the FDA for the limited benefit. The drug also induced the metabolism of contraceptives, and two women on the trial became pregnant. This outcome very clearly demonstrates the uphill task of developing a medicine for what is considered to be a "trivial" infection.

Detailed analysis of the clinical trial and laboratory data on pleconaril highlights some other interesting challenges for this type of rhinovirus inhibitor. There was very wide variation in the sensitivity of the various serotypes of rhinovirus to the drug, with some insensitive to inhibition. Resistant virus variants were readily isolated during therapy although their relative "fitness" was not assessed (in a recent paper extending the interest in capsid binders to other picornaviruses, Kelly et al.[12] clearly demonstrate the fitness cost of VP1 resistance mutations to the virus.).

In 2007, Schering-Plough in-licensed pleconaril from ViroPharma and began developing an intranasal formulation for the prevention of rhinovirus-induced exacerbation of asthma. A recent update of the results on the https://clinicaltrials.gov website (NCT00394914) show that although patients were entered on the trial when they came into contact with a family member with a proven rhinovirus infection, only 8 out about 600 recruits were found to be infected.

Vapendavir (5) (from Aviragen Therapeutics, previously known as Biota Pharmaceuticals), described earlier, is currently in a phase II trial in asthmatics. Vapendavir displays a broader spectrum of activity against virus isolates than pleconaril. The phase

II study seeks to monitor moderate-to-severe asthmatics during the rhinovirus season and to start dosing with drug or placebo when they are proven to be infected, and its outcome, including measurements of asthma exacerbation, is anticipated in late 2016 (http://www.aviragentherapeutics.com).

Various groups are exploring the possibility of challenge studies in asthmatics to provide more controlled and hence more clear-cut results. The Rega group is continuing to explore the possibility of more advanced capsid binders.[3] Further work in this area is also exploring the possibility of extending the activity to other members of the picornavirus family.[12,13] Mello et al.[14] showed that some rhinovirus isolates in group C (which do not replicate in traditional monolayer cell culture) may not be inhibited by capsid binders. This information will need to be taken into account in the design of new agents.

5.20.3.2.2 Protease inhibitors

Picornaviruses encode a protease encoded by the 3C gene. The 3C protease is essential for replication and is responsible for cleavage of the viral polyprotein into the active enzymes and structural components. Viral encoded proteases have been extensively explored as targets for chronic viral infections. These efforts inspired pioneering work on the equivalent rhinovirus enzyme by the Agouron group (later acquired by Pfizer). This team used a structure-based approach to optimize 3C protease inhibitors, culminating in ruprintivir (8) (formerly AG-7088), a potent agent active against all the rhinovirus isolates tested and some other picornaviruses.[15] The compound is a peptidomimetic whose design is based upon the picornaviral cleavage-site recognition characteristics. In these proteases, most cleavages occur between glutamine and glycine residues. In addition, the rhinovirus 3C protease catalytic triad of cysteine, histidine, and glutamic acid with a geometry similar to those observed in trypsin-like serine proteases suggested the incorporation of a covalent modifier warhead, specifically the α,β-unsaturated ester present in AG-7088. Incorporation of a cyclic butyramide at P1 provided the optimal structure shown in Fig. 3. A detailed description of the optimization of the structural elements P2, P3, and P4 has been published.[16]

The poor aqueous solubility of ruprintivir rendered formulation challenging, but adopting a nasal spray formulation enabled a clinical challenge study to explore the effectiveness of the drug against experimentally acquired infection.[17] While significant effects on some viral parameters were seen (especially with five times a day prophylactic dosing), there was little effect on the development of rhinovirus colds. As high concentrations of drug were reached in the nasal epithelium, this raises questions concerning the bioavailability of such drugs in the upper respiratory tract (URT) on one hand and the relevance of the experimental challenge model on the other.

5.20.3.2.3 Polymerase inhibitors

All picornaviruses encode an RNA polymerase (3D gene product) that in principle appears an ideal target for broad-spectrum inhibitors, as all share a somewhat invariant RNA sequence (reviewed in Ref. 18). An enormous amount of academic work has explored the structure of RNA polymerases from many picornaviruses and in many states (for review, see Ref. 19). A variety of picornavirus polymerase inhibitors have been discovered though screening programs or testing of nucleoside libraries, encompassing both purine and pyrimidine nucleosides[14,20] as well as potential nonnucleoside inhibitors.[18] The clinical impact of inhibitors of polymerases for chronic viral infections suggests that optimized versions of these leads might have high utility.

5.20.3.3 Opportunities for Combination Therapies

Given the extreme plasticity of the picornavirus genome due to its error-prone RNA polymerase, combination therapy will undoubtedly be important in the development of effective broad-spectrum treatments. These may include not only improved small-molecule inhibitors of the types discussed earlier but also biological agents like interferons and soluble viral receptors.

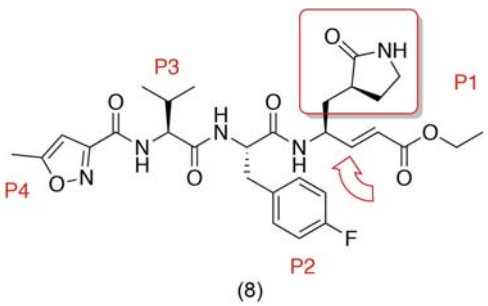

Fig. 3 Ruprintivir (8), showing the position of cysteine attack (*red arrow*) and key butyramide modification (*red box*) in P1. P2–4 indicate other optimization pockets.

5.20.4 Influenza Viruses

5.20.4.1 Reasons to Develop Antiviral Drugs for Influenza Virus Infections

There has been considerable success in the development of both vaccines and antiviral drugs to treat influenza infections, but the unmet medical need is still high. This is largely due to the plasticity of the viral genome that both mandates the manufacture of new vaccines for each virus "season" and allows for the rapid development of resistant virus. The impetus to develop new approaches to influenza comes largely from the potential emergence of a new "pandemic" virus to which the population has little resistance.

As with other respiratory viruses, influenza is already a significant problem in the elderly, the immunocompromised, and the asthmatic population. According to the WHO, influenza occurs globally with an annual attack rate estimated at 5–10% in adults and 20–30% in children. Worldwide, annual epidemics are estimated to result in about 3–5 million cases of severe illness and about 250,000–500,000 deaths.

5.20.4.2 Classes of Influenza Agents

5.20.4.2.1 Ion channel blockers

From early discovery efforts using phenotypic cellular screens for antiinfluenza activity, amantadine was discovered to have potent inhibitory effects. At the time of this discovery, little was known about virus genes and the proteins they encode. In the clinic, the drug was shown to have modest efficacy. Analogs of amantadine were synthesized and found to have a slightly improved profile. The most widely studied was rimantidine, which was extensively used in the former Soviet Union (reviewed by Zlydnikov et al.[21]).

Resistant mutants were easily isolated and mapped to the viral M2 protein. We now know that this protein is an ion channel encoded within the viral genome. With the discovery of the more active neuraminidase (NA) inhibitors and the development of widespread resistance to both amantadine and rimantadine in the clinic, the interest in this target has reduced. Molecular studies of resistant mutants have identified the mechanism of resistance within the structure of the M2 protein, and the area is deserving of more attention as the interest in combination therapies for this virus family grows. Recently, work has been reported on novel scaffolds working on the same target[22] and on novel adamantine analogs.[23]

5.20.4.2.2 Fusion inhibitors

The fusion activity of the influenza hemagglutinin has been shown to be essential for the release of the viral particle from endosomes, allowing replication to begin. Arbidol (**Fig. 4** (9)) is a small indole derivative that was discovered and developed in Russia and is approved and used there and in China,[24] which acts (at least in part) through this mechanism. The clinical trial data reported from the Russian and Chinese studies are not dissimilar to those obtained with the NA inhibitors, but only one clinical study is reported on https://clinicaltrials.gov (NCT01651663). Unfortunately, the compound is clearly suboptimal with relatively poor activity and off-target effects. There have been some attempts to improve on Arbidol's selectivity and activity using its indole scaffold, but as yet, no candidate compounds have emerged.[25,26] The target remains to be exploited but probably through a new lead discovery exercise.

5.20.4.2.3 Neuraminidase inhibitors

By far, the most widely used antivirals for influenza are the NA inhibitors. The NA enzyme is encoded by the viral genome and is present in the external surface of the virus particle. NA has roles in both entry and exit of the virus from the host cell and in the passage of virus through mucus-rich surfaces. Inhibitors of the enzyme are natural substrate analogs based around the structure

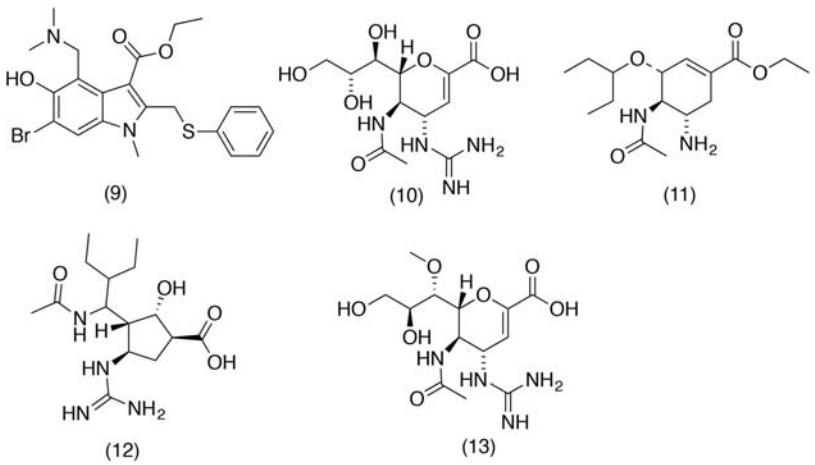

Fig. 4 Arbidol (9), zanamivir (10), oseltamivir (11), peramivir (12), and laninamivir octanoate (13).

of the viral receptor, sialic acid. The approved NA inhibitors zanamivir (Fig. 4 (10)) (Relenza) and oseltamivir (Fig. 4 (11)) (Tamiflu) are potent inhibitors of the enzyme[27,28] and of virus replication in tissue culture. Zanamivir has poor physicochemical characteristics and was formulated for intranasal dosing, while oseltamivir is an oral prodrug that has seen more widespread use. Both drugs showed clear effects in well-controlled experimental challenge models of influenza infection in volunteers.[29,30] It has been far more difficult to prove that the compounds have a significant effect on naturally acquired influenza infections. Indeed, the controversy is still active; while the drugs clearly have an effect on viral load, their effects on URT symptoms do not seem to relate to virus infection as they are seen in patients without proven infection.[31]

At the time of the discovery and development of these drugs, attention was focused on the treatment of seasonal influenza, but anxiety about potential pandemics of newly emerging influenza strains led to extensive stockpiling by government agencies of both agents. This stockpiling activity has had a significant effect on the return on investment on the development of the drugs and illustrates well how the commercial environment can vary for different viruses causing URT infections.

Another significant factor in the use of NA inhibitors has been concern with the development of significant levels of resistance to the drugs. This was enhanced by the emergence of an H1N1 influenza during the 2007–08 influenza season that carried a mutation for oseltamivir resistance and that spread rapidly.[32] Together with the mutation for oseltamivir resistance, this virus carried compensatory mutations that allowed it to replicate normally. The virus spread around the world even in the absence of selective pressure with the drug, but subsequent seasons have not seen a rise in oseltamivir resistance rates above the background level of about 3% of all isolates. The level of resistance to other NA inhibitors is even lower (<1%), but it is not clear if this is due to a real difference in the ease of mutant generation or to the much lower use of the other drugs.[33]

Efforts have continued to develop improved NA inhibitors with enhanced activity, physicochemical properties, and ability to inhibit virus isolates resistant to other NA inhibitors. Peramivir (Fig. 4 (12)), developed by BioCryst, is a more costly NA inhibitor that can be given by infusion and is recommended in cases where oral or IV administration is difficult.[34] Laninamivir octanoate (Fig. 4 (13)) is a long-acting NA inhibitor developed by Biota in collaboration with Daiichi Sankyo. This drug is approved for use in Japan but remains in phase II trials in the rest of the world. The compound is given by the inhaled route as a single administration, and drug levels are maintained over a 5-day period.[35]

5.20.4.2.4 Polymerase inhibitors

As with all other viruses, the RNA polymerase of influenza makes an attractive target for new drugs. Polymerase inhibitors for the influenza virus have been identified either by screening programs, through nucleoside chemistry or more recently through target-driven approaches to the subunits of the enzyme.

Favipiravir (T-705) (Fig. 5 (14)) is the polymerase inhibitor in most advanced development for influenza infections. This compound was discovered at Toyama Chemical in Japan through lead optimization of a screening program hit. The compound is activated by cellular enzymes to a triphosphate form, which then inhibits the viral polymerase.[36] Its activity against influenza is in the range of 0.2–10 μM in in vitro assays. Favipiravir has shown activity in two Japanese phase III trials and is licensed in Japan for stockpiling against pandemic influenza. Currently, the drug is in phase III trials in the United States to treat influenza in adults, using a much higher dose (Japanese dose is a 1.6 g loading dose followed by 400 mg twice a day, while the US dose is a loading dose of 3.6 g plus 400 mg four times a day). Favipiravir has weak activity against a wide variety of RNA viruses, including Ebola virus. Clinical trial data are awaited on the efficacy of the drug against the latter.

A wide variety of pyrimidine and purine nucleosides have been claimed to have activity against influenza viruses. Unfortunately, to date, none of these have been found to be sufficiently selective for the virus over host cell enzymes to develop further.

A nonnucleoside polymerase inhibitor VX-787 was developed by Vertex and licensed to Johnson & Johnson in 2014 and renamed JNJ-872. This compound was discovered as an inhibitor of the "cap-snatching" activity of the PB2 subunit of the viral

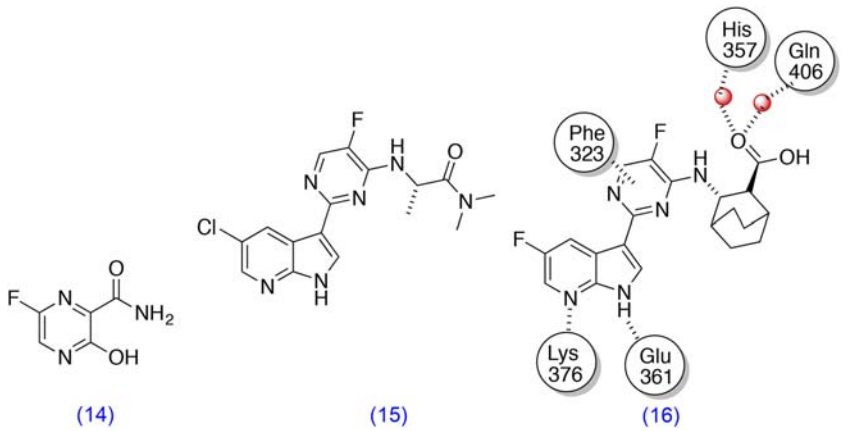

Fig. 5 Favipiravir (14). A representative hit (15) from the phenotypic screening program undertaken at Vertex and its optimization, showing the key interactions of VX-787 (16) with residues within the cap-binding domain.

RNA polymerase and indeed occupies the 7-methyl GTP cap-binding site.[37] In preclinical studies, the compound showed excellent activity against influenza in animal models of the disease. Unfortunately, the compound has no activity against influenza B strains. Interesting activity over a longer window of activity than that seen with NA inhibitors stimulated investment by BARDA in the phase III program on this compound for treatment of patients hospitalized with influenza infection.

As with many influenza programs, VX-787 was discovered utilizing a phenotypic cellular assay.[38] The initial screen was limited to 1000 compounds but identified several with measurable antiviral activity. The identification of a kinase inhibitor template as a hit was perhaps not only a reflection of the focused source of compounds but also an example of the successful reuse of drug-like compound types provided by kinase-based screening sets. Specifically, a series of pyrimidine azaindoles emerged from the screen with significant activity and are represented by compound 15 (**Fig. 5**). The project was supported by crystallography, with several structures generated of compounds bound to the GTP cap-binding domain revealing key hydrogen-bonding interactions between the azaindole and lysine and glutamic acid side chains in the binding site. Further interactions were delineated in the clinical compound for the carboxylic acid, introduced as part of the optimization process and resulting in VX-787 (**Fig. 5** (16)).

The endonuclease activity of the PA subunit of the polymerase was targeted by the Merck group in the 1990s.[39] Although this project did not lead to clinical candidates, the leads became an excellent starting point for the very successful program that led to HIV integrase inhibitors (the enzyme shares a similar active site). Two companies have PA inhibitors in clinical trials: S-0033188, from Shionogi, is in phase 1 in Japan, and Alios (J&J) has AL794 in a challenge study in the United States (https://clinicaltrials.gov, NCT02588521).

5.20.4.3 Combination Therapy for Influenza

Clear clinical needs and interesting opportunities exist for further antiinfluenza research. For a truly effective approach to pandemic management, a combination regimen using different inhibitor classes would be appropriate, and in this context, the concept of combining polymerase PA and PB2 inhibitors to provide a broad-spectrum therapeutic is appealing.

5.20.5 Adenoviruses

5.20.5.1 Reasons to Develop Antiviral Drugs for Adenovirus Infections

Adenoviruses are the cause of a variety of important human and animal infections, and yet, there has been little progress in the development of antiviral drugs to treat these diseases. Given the size of the adenovirus genome, the number of attractive targets encoded therein, and the stability of a double-stranded DNA viral genome, antiviral drugs could clearly be developed were sufficient commercial incentive to exist. The three major opportunities are infectious viral conjunctivitis, lung infections in the immunocompromised (especially in transplant patients), and epidemics of adenovirus pneumonia in young adults (especially military recruits or students brought into close proximity due to enlistment or starting college).

Conjunctivitis is an ocular inflammation that can be caused by a virus, a bacterium, or an allergen. Adenovirus infections account for up to 90% of all viral conjunctivitis. Rapid diagnostic tests at point of care are now available and would aid rapid treatment. There are signs of interest in this area from specialist ophthalmic companies. It is difficult to get accurate estimates of the numbers of patients, as in most countries infection is not notifiable.

Adenovirus infection in the immunocompromised patient is a major threat. Infection is especially common in young recipients of stem cell transplants. Given the otherwise excellent prognosis for these patients, their significant numbers, and the complete lack of treatment options, this indication may represent an "orphan drug" designation with an attractive price to support development.

Military support has enabled the development of a vaccine against adenovirus types 4 and 7 that is used extensively by the US army. The complex nature of the adenovirus family mitigates against the development of a pan-family vaccine.

5.20.5.2 Classes of Adenovirus Agents

5.20.5.2.1 Polymerase inhibitors

Cidofovir is a nucleotide analog that was discovered in Prague by Holy's group[40] and developed by Gilead as a treatment for cytomegalovirus (CMV) retinitis in AIDS patients (a major problem before the development of effective combination regimens). It was the first nucleotide analog to be approved for human use. The compound was active against a range of DNA viruses, including adenovirus, but its use was limited by its nephrotoxicity and lack of oral availability.

Chimerix used a proprietary lipid conjugate technology to produce an orally available prodrug of cidofovir, brincidofovir (CMX001), with the primary aim of reducing the impact of CMV in the immunocompromised. Brincidofovir is orally available and avoids some of the issues with cidofovir therapy. During its development, the compound became the target of a social media campaign for its compassionate use in a young patient with adenovirus infection, as no other therapy was available. Data from an ongoing open label phase III trial in 20 stem cell transplant patients with adenovirus infection that completed enrollment in Aug. 2015 are awaited (https://clinicaltrials.gov, NCT02087306). Unfortunately, this trial appears not to have shown a therapeutic benefit, although viral load was reduced (http://www.chimerix.com, May 9, 2016).

5.20.5.2.2 Other targets

Nicox is developing NCX 4240 for viral conjunctivitis. NCX 4240 is Carragelose (iota-carrageenan), a sulfated galactose polymer derived from red seaweed with antiviral properties. Carragelose inhibits viruses from binding to and entering human cells, reducing viral replication and associated symptoms. Carragelose is already available without prescription for the treatment of respiratory viral infections. Antiviral activity has been demonstrated in preclinical studies, including three of the most important adenoviruses causing conjunctivitis. Nicox plans to conduct clinical investigation of NCX 4240 as a medical device (http://www.nicox.com, 2016).

5.20.6 Paramyxoviruses

5.20.6.1 Reasons to Develop Antiviral Drugs for Paramyxovirus Infections

The paramyxoviruses are quite distinct from the orthomyxoviruses (Influenza viruses) and have a completely different genomic structure and epidemiology, despite both groups causing infections of the respiratory tract. RSV is clinically the most important member of the Paramyxoviridae family and was first isolated in 1956. There are two major serotypes of RSV, A & B, which alternate with each other and which cause similar disease. RSV is highly infectious and is transmitted through respiratory secretions via close contact with infected individuals, through droplets or through contaminated surfaces. In healthy adults, RSV is one of the causes of "winter colds," but in infants, the virus causes 1–2 weeks of respiratory tract disease. Infants can continue to excrete virus for several weeks. By age 2, virtually all children have been infected by the virus. Infection by RSV induces only partial protection, and subsequent infection can occur even in the same winter season. RSV is a significant pathogen of the very young, the immunocompromised, and the elderly:

- *RSV in new born infants*: In the United States, between 100,000 and 126,000 infants under 1 year have been hospitalized in each of the last 5 years. There are about 2.1 million outpatient consultations for the under 5 s with RSV each and every year. Each of these infants is a prime candidate for a safe and effective oral therapy. The mortality rate in the very young at risk infants is between 2% and 3% in most developed countries including the United States. Care of babies with RSV infection imposes a major burden on the hospital sector and limits capacity to undertake routine surgery.
- *RSV in the immunocompromised or other medically compromised patients*: RSV is a major issue in those who are immunocompromised through natural causes, by cancer or chemotherapy, or deliberately for transplantation. Although numerically less significant, the considerable investment in such patients mandates their treatment.
- *RSV in the elderly*: There is increasing awareness of the burden caused by RSV in the elderly. In years without a major influenza epidemic (i.e., most years; see **Fig. 1**), RSV is a more significant cause of morbidity and mortality in the over 60s. There are more than 2 million consultations with physicians in the United States each year due to RSV infection. The virus is also a significant problem in adults with COPD, where it is a major cause of exacerbations. In care homes, RSV causes annual epidemics during the winter season.

5.20.6.1.1 Intervention opportunities

As for influenza infections, otherwise healthy adults will develop a severe cold but will normally recover unaided. Consequently, therapies are being developed to treat firstly infants and those children where the disease is more severe both in terms of duration and the severity of the possible outcomes. Studies have shown that such children see up to three physicians prior to hospital admission, presenting multiple prescribing opportunities.[41] Secondly, in the "compromised" adult patients, the treating physician would generally be well aware of the need to survey his or her patients for RSV infection and to use effective remedies quickly and efficiently. Finally, in the adult population, treatment during a local epidemic would be of use to prevent the spread of this life-threatening infection. The concept that there is insufficient time for therapeutic intervention during respiratory virus infections, derived from the influenza field, is now regarded as outmoded.[42] Due to the longer duration of RSV disease in both infants and adults, it is now widely accepted by the experts in the field that a small-molecule drug could be effective either for treatment or for prophylaxis.[43]

5.20.6.2 Antiviral Agents for RSV

Two agents are approved for the treatment of RSV infections. The first, ribavirin, is a nucleoside analog that was discovered to have anti-RSV activity in a screening program. Its clinical use is restricted due to limited antiviral potency, inherent toxicity, and teratogenic potential. The other approved agent is the prophylactic monoclonal antibody Synagis (paluvizimab), marketed by AstraZeneca. This antibody, which interacts with the F glycoprotein of the virus (see in the succeeding text), has been shown to provide protection in infants and has gained widespread use to protect premature babies. The cost of therapy (about $5000 per infant for the winter season) limits wider uptake.[43–45] There is thus an obvious clinical need for new small-molecule inhibitors of the virus.

5.20.6.2.1 Fusion protein inhibitors

RSV encodes two surface glycoproteins, the F and G proteins. G is dispensable in tissue culture, but its deletion attenuates virus infectivity. The F protein is essential for the entry of the virus into the host cell. Expression of the protein at the cell membrane causes

cell-to-cell fusion, leading to the giant syncytia characteristic of RSV infection. Since the early discovery that inhibitors of the fusion of RSV virus particles and host cells could be readily identified by high-throughput screening, a great deal of work has been done to refine the potency and selectivity of a variety of structural types of inhibitor. Early work in the field has been surveyed in previous reviews.[46,47] More contemporary research has led to a high-resolution, three-dimensional understanding of the fusion process and its inhibition.

For an excellent detailed overview of F protein structure and function, see Battles et al.,[48] who described a structural analysis of inhibitor interaction with the prehairpin structure of the RSV fusion protein. In that work, a number of inhibitor structures were docked into a trimeric model of the fusion complex based upon the crystal structure of JNJ-250685 bound to a prefusion construct. Although not all-encompassing, a rational description of the binding of these drug-like and structurally diverse inhibitors is evident from these studies. **Fig. 6** provides an annotated version of the binding modes of JNJ-2408068 (17), Biota-9881 (substituting in this analysis for the structurally related BTA-C585 (18) and GS-5806 (19)). Most evident is the hydrophobic π/π nature of the binding of the Biota compound (18), with JNJ-258606 and presumably GS-5806 taking advantage in addition of further energetically beneficial polar interactions by virtue of the amines they incorporate.

All of these inhibitors exhibit potency against laboratory strains of RSV and are orally bioavailable. The discovery and progress toward clinical evaluation of presatovir (GS-5806) have been described recently.[49] A moderately active screening hit (20, **Fig. 7**) with a poor oral pharmacokinetic profile was transformed in an efficient manner into the clinical compound. Of note is the role of the pendant amine in presatovir, perhaps incorporated to target potential salt-bridge binding interactions as described earlier. A further recent disclosure[50] draws a comparison between the improved lung distribution properties of presatovir and its alcohol analog (21, **Fig. 7**). This advantage of the basic amine-containing compound is rationalized as product of the interaction at lung epithelial cells with phospholipids, phosphatidyl choline, or fatty acids in the pulmonary surfactant.

To date, less information is available regarding the Biota compound BTA-C585. In 2014, Draffan et al.[51] disclosed a generic structure for a compound that is potent in the human epithelial airway model (EC_{50} 8.4 nM), but with some variability in clinical isolate data (most EC_{50}s appear around 100 nM), and exhibits oral bioavailability (59% is quoted in rat and 107% in dog at a dose of 20 mg kg^{-1}). Efficacy in the cotton rat model is described, with a 99% reduction in viral titer observed at 100 mg kg^{-1}. A 2011 patent supporting this generic structure describes example 22 (**Fig. 8**) as one of the more potent examples (2.2 nM in an RSVA2 cytopathic effect assay).[52]

The failure of a single fusion inhibitor to reach the market may reflect an attrition rate typical of pharmaceutical development in general but leaves open the question of clinical validation. In that context, the first successful clinical study with a fusion inhibitor was recently reported by Gilead with GS-5806.[53] This compound given rapidly reduced viral load and symptoms of RSV disease in volunteers with confirmed RSV infection. The compound is leading a group of fusion programs from J&J, Biota Holdings, Teva, ARK Therapeutics, and ReViral. **Table 2** gives an overview of the stage of development of these efforts, all of which are or will be in clinical studies in 2016.

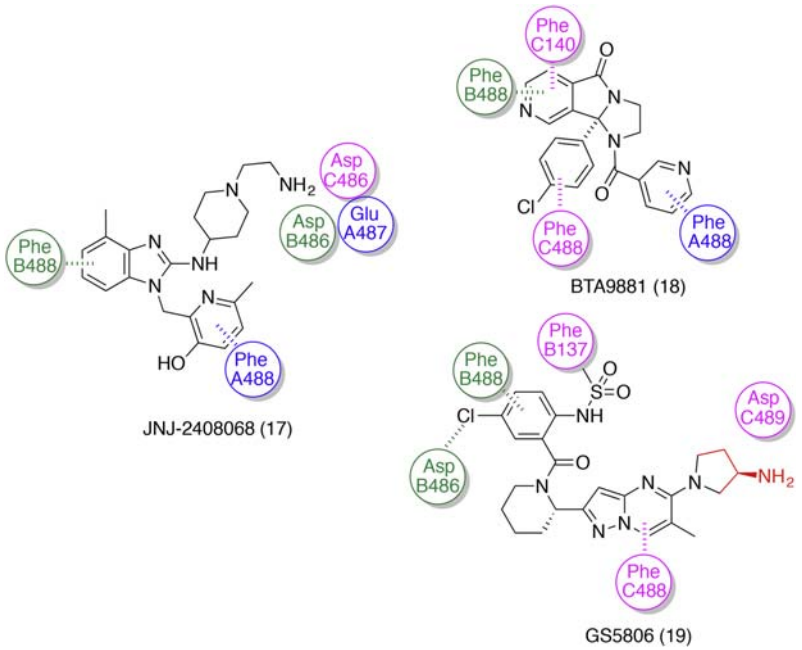

Fig. 6 An annotated schematic of the proposed binding modes of JNJ-2408068 (17), BTA-9881 (18), and GS-5806 (19).[48] Key binding interactions are shown for each inhibitor with colors indicating an individual component of the trimeric fusion protein complex.

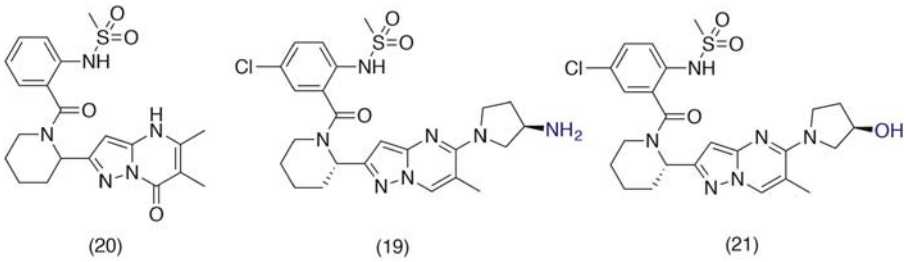

Compound	EC_{50} (RSVA2)	PPB (Human, %)	EC_{50} Fold shift in plasma	F (%, rat)
20	65	93.5	13	2
19	1.5	94.4	13	67
21	1.5	94.5	10	42

Fig. 7 Selected pharmacokinetic and potency data for hit compound (20), presatovir (19), and the hydroxyl analog (21).

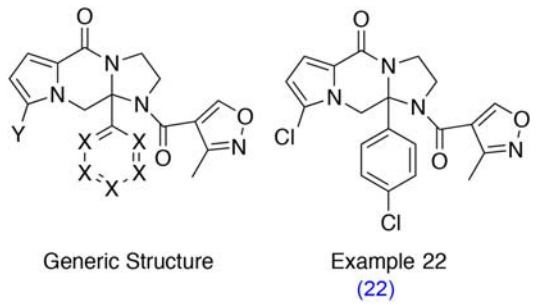

Fig. 8 Generic structure and potent example from Biota.

Table 2 Fusion inhibitors under pharmaceutical development

Compound	*Company*	*Status*
GS-5806 Presatovir	Gilead	Completed a challenge study and now in phase II study in stem cell transplant patients
JNJ-2408068	Johnson & Johnson	Extensively studied preclinical candidate with suboptimal PK characteristics. Superseded by TMC-353121 and a new fusion inhibitor JNJ-53718678 for which little data are in the public domain. A phase I study in hospitalized infants is underway
VP-14637/MDT-637	Teva—MicroDose Therapeutx (MDT)	Difficult to formulate compound discovered by ViroPharma and licensed to MDT. Reformulated and partnered with Gilead but returned. MDT acquired by Teva. A challenge study was undertaken but no data yet released
BTA-C585	Biota	Completed phase I in 2015. Challenge study underway in Apr. 2016 at relatively high doses. Clinical hold reported on Aviragen (Biota) website (http://www.aviragen.com, May 2016) due to a cardiovascular issue
AK0529	Ark Biosciences Inc.	Out-licensed by Roche, no challenge study was undertaken but a phase Ib study in hospitalized infants underway in Australia
RV521	ReViral	Entering phase I in 2016

There is an active debate about the ultimate clinical utility of fusion inhibitors given the relatively rapid emergence of resistance mutants during in vitro studies. This was first observed in the pioneering work of the BMS group.[54] Subsequently, Yan et al.[55] showed that mutants obtained to a novel fusion inhibitor structure mapped to the same region of the protein as other fusion inhibitor mutants. This group claimed that one of their mutants was equally pathogenic to the wild-type virus in a murine model of RSV.

Extensive use has been made of the differentiated human airway epithelium model of RSV replication to measure the "fitness" of resistant mutants[48] where mutants that had become less sensitive to fusion inhibitors paid a cost in replication efficiency. Clinical

data further showed that although resistant mutants do occur when humans are treated with fusion inhibitors, Gilead's GS-5806 was very effective in reducing both virus load and the signs and symptoms of disease.[53]

5.20.6.2.2 RSV RNA replication

To replicate its RNA, RSV requires four viral proteins—the M2-1 protein (only required for transcription), the nucleocapsid (N), phosphoprotein (P), and large (L) proteins. This complex provides a variety of potential targets for viral inhibition. In vitro replicon systems are now available, which measure the role of N, P, and L in RNA duplication. The role of the three proteins is gradually becoming clearer, and we are starting to see the fruit of research in emerging development programs aimed at these targets. A recent publication, for example, examines a druggable pocket at the N–P interface using high-resolution 3D structures.[56] This group identified compounds based on docking studies using this structure, which confirm that the site is a viable target.

Several compounds targeting different aspects of RSV replication are in various stages of preclinical and clinical development (see **Table 3**).

The Alios research program[58] was directed toward the identification of nucleosides that could inhibit RSV polymerase by chain termination. A large number (>100) of structurally diverse nucleosides were designed and screened in a cell-based RSV assay. The nucleoside analogs were also converted to their 5′-triphosphates and screened for inhibition of RSV RNA-dependent RNA polymerase activity. One compound, 4′-azido-2′-deoxy-2′,2′-difluorocytidine (23, **Fig. 9**), exhibited potent inhibition of the cytopathic effect of long-strain RSV, with an EC_{50} of 1 μM. Furthermore, the corresponding triphosphate was identified as a potent RSV polymerase inhibitor with an IC_{50} of 0.3 μM.

An intensive, primarily safety-guided optimization process furnished a selective inhibitor of RSV. The isobutyryl prodrug of this inhibitor, termed ALS008176 (24, **Fig. 9**), showed acceptable oral bioavailability in hamsters, rats, and monkeys and has progressed into clinical trials.

PC786, most likely the subject of a recent patent filing by Pulmocide Ltd.,[59] appears to be a derivative of a series of RSV inhibitors exemplified by YM-53403 (25), originally described by Yamanouchi[60] and further elaborated by Gilead[61] and AstraZeneca.[62] They are high-molecular-weight, low-solubility compounds that in their AstraZeneca and Gilead guises can be characterized as weak bases. The structural modifications in this evolution are shown in **Fig. 10**.

PC786 is intended for inhaled dosing, presumably through increasing molecular weight and clogP, and in this context, the addition of a fluoro toluidine fragment into the molecule is noteworthy; an earlier representative of this chemotype, however, was retained poorly in lung tissue.[59]

5.20.6.3 Combination Therapy for RSV Infection

Although treatment of RSV infections will likely be short term, longer-term regimens will be optimal for the elderly where prophylaxis may be required. Combination therapies targeting multiple different viral targets would optimize antiviral effect and reduce the risk of significant resistance emerging.

Table 3 Other small-molecule inhibitors of RSV replication in development

Compound	*Company*	*Status*
ALS-008176	Alios (now part of J&J)	Nucleoside analog that inhibits RNA polymerase activity. Potent activity in viral challenge studies. Currently in early phase II trials in infants
PC786	Pulmocide	A nonnucleoside RNA polymerase inhibitor with physical characteristics suitable for inhaled administration. Currently in formal preclinical studies
Ribavirin	M,S&D and multiple generics	Licensed medicine whose limited activity against RSV is still a matter of controversy. Major mechanism against RSV is probably hypermutation via the RNA replication complex[57]
RSV604	Novartis	RSV 604 interacts with the N protein and proved to be effective in early clinical studies

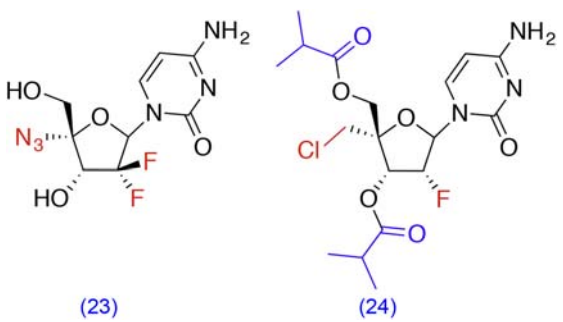

Fig. 9 The initial hit nucleoside (23) discovered by Alios and its optimized prodrug ALS-008176 (24). The isobutyryl prodrug functionality is shown in blue. Key optimization modifications are highlighted in red.

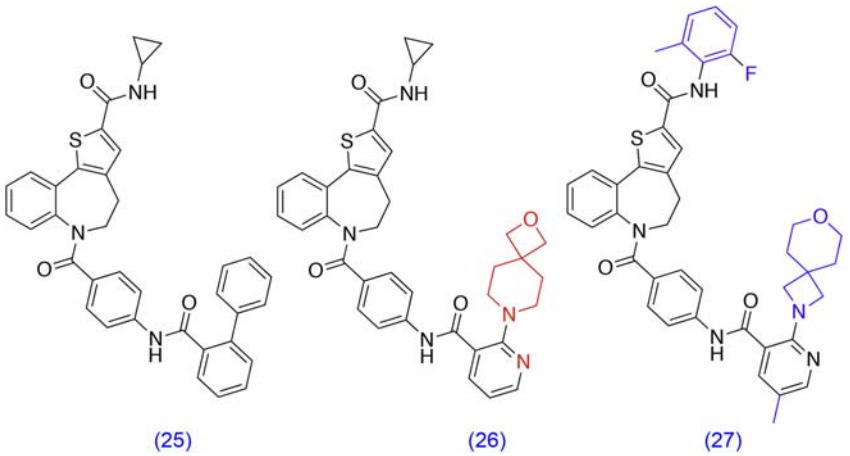

Fig. 10 The optimization of the original Yamanouchi series (25) to the Pulmocide compound (27) via AZ (26).

5.20.7 Emerging Virus Infections

As the impact of climate change on the spread of insect vectors grows, viruses are emerging, which are well-documented human pathogens but whose geographic range has been limited. The large increase in global travel for business and leisure has also created the opportunity for any virus to be transported around the world in hours and days.[63]

When any new virus emerges, a clamor arises for a new vaccine or drug to control the infection and hurried clinical trials using agents with limited preclinical validation result. Rarely do such repurposing efforts prove useful; genomic and functional diversity across viral pathogens mandates specific drug optimization efforts, despite the precedent from broad-spectrum antibacterial agents. An alternative approach is to identify antiviral agents working through host targets, but this field remains in its infancy. Here, we present a brief overview of recent viral epidemics to illustrate these points and end with an alternative scenario for pandemic preparedness.

5.20.7.1 Coronaviruses

SARS-CoV appeared in 2003. It appears to have spread from small mammals in China to humans and then to have passed from human to human via close contact with respiratory secretions either directly or through fomites.[64] The virus is a member of the corona virus family some members of which were known to cause mild symptoms like those of the common cold. The SARS epidemic spread rapidly by air travel of infected patients and caused about 8000 infections, with a mortality rate of about 10% (http://www.WHO.int). The epidemic was controlled by strict public health measures—isolating patients and providing high-quality support. The virus has caused no new case since 2004.

Coronaviruses are small RNA viruses that encode a replicase and a protease most similar to the rhinoviruses (see in the preceding text) and other targets. Attempts have been made to utilize the knowledge gained from the latter to accelerate drug development,[65] but more than a decade later, no strong candidate molecule has emerged. The coronavirus replicase complex has been studied extensively since 2003 and is quite different from other small RNA viruses.

The failure to go from promising ideas to candidate drugs probably resulted from a lack of commercial market for a SARS drug, but then, in 2012 another Coronavirus, MERS-CoV, emerged. This virus is thought to have transferred to humans from bats (bats are a natural reservoir for many coronaviruses) with camels as a major intermediate host. MERS-CoV does not spread readily from human to human. Nevertheless, the virus has caused small epidemics, mainly in Saudi Arabia. In total, there have been about 1644 cases and 590 related deaths. Cases have been exported to several countries including South Korea, where more than 100 cases resulted though infection in a healthcare setting. Good infection control measures are very effective. The arrival of a second coronavirus with significant healthcare impact has reawakened interest in both vaccine and drug research.

5.20.7.2 Ebola

Ebola is caused by a filovirus and was first recognized in 1976 in Sudan and the Congo. The most recent outbreak began in 2014 and is the largest to date (>28,657 cases and 11,325 deaths). The infection has about a 50% mortality rate and has been transported via air travel. The natural hosts of Ebola virus are thought to be fruit bats. Infection of humans occurs through contact with dead animal tissue or body fluids; human-to-human transmission occurs by similar routes. Ebola virus belongs to the Filoviridae family of the Mononegavirales, in the same order as the Paramyxoviridae family. Given clinical precedent with these related viruses, the viral RNA polymerase is a logical target for drug discovery. Several groups have screened nucleoside libraries to identify leads. Of existing nucleoside antivirals, favipiravir (see section "**Influenza Viruses**"), brincidofovir (see section "**Adenovirus**"), and BCX4430

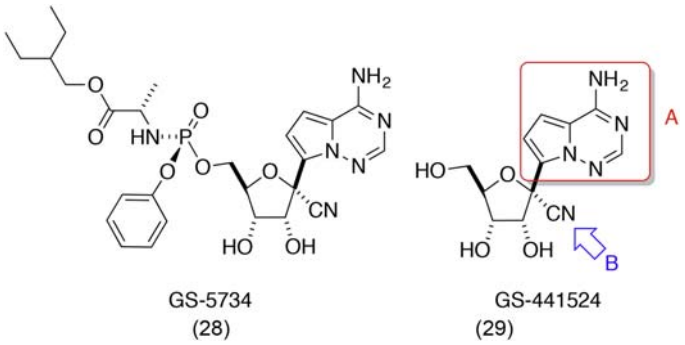

Fig. 11 The phosphoramidate prodrug GS-5734 (28) and its parent nucleoside GS-441524 (29).

(BioCryst)[66] have all shown some activity in animal models. Unfortunately, none were used early enough in the epidemic to obtain indications of clinical efficacy. Further work is underway to look for selective Ebola virus nucleoside inhibitors.

GS-441524 was identified as a novel inhibitor of the West African Ebola strain and other Ebola species. The 1′-cyano group (29, Fig. 11) provided potency and selectivity for viral polymerases, while the C-linked pyrrolo[2,1-f][1,2,4]-triazin-4-amine base fragment (28, Fig. 10) is stable to deglycosylation. A program to identify a suitable prodrug of GS-441524 provided GS-5734, a monophosphoramidate, which has potent in vitro activity against multiple filoviruses, with EC_{50} values in the 0.1–0.2 μM range (Ref. 67; http://www.usamriid.army.mil, Oct. 9, 2015). In a rhesus monkey model of Ebola infection, the compound was effective in a therapeutic mode.[68] GS-5734 has activity against not only filoviruses but also arenaviruses and coronaviruses. The compound's clinical potential mandated its use in a Scottish nurse who had contracted the Ebola infection while working with patients in Sierra Leone. She was treated at the Royal Free Hospital in London and discharged Jan. 2015 but was readmitted to the same hospital in Oct. 2015, when her Ebola virus infection relapsed in the form of acute meningitis.

As a consequence of the successful in vivo testing, Gilead filed an IND July for the use of GS-5734 to treat Ebola virus disease, and phase I testing in healthy human volunteers began in August. When the Scottish nurse was hospitalized in early October, sufficient data had been obtained to support compassionate use of the drug.

5.20.7.3 Nipah and Hendra Viruses

These viruses belong to the Paramyxoviridae family in the order Mononegavirales, and as such are quite closely related to RSV. Both viruses' natural hosts are fruit bats. Hendra virus was first described in 1994 as the causative agent of an equine epidemic in Hendra, a town in Queensland, Australia. The fatality rate is high—74% in horses and 60% in humans, infected by contact with diseased horses. More than 50 outbreaks of Hendra have occurred since the virus emerged. A vaccine is available for horses, but there are little data on efficacy. Nipah virus emerged in 1998 on pig farms in Malaysia with 257 human infections and 105 deaths. The virus may have the ability for transfer between humans as it causes respiratory infections. Again, the virus's natural host is thought to be a fruit bat. Fruit bats excrete the virus in urine, which probably contaminates pig feed. Since 1998, eight further outbreaks have occurred in Bangladesh and the neighboring areas of India.

The emergence of both viruses probably relates to the loss and change of habitat due to human encroachment. Both viruses would appear to have the potential for widespread dissemination, and further discovery work is justified. Ribavirin has been used in experimental animal models and patients with equivocal results.[69] The discovery efforts described earlier for the related RSV provide a rationale for exploration of fusion inhibitors and nucleosides.

5.20.7.4 Zika Virus

Although Zika virus was discovered in the 1940s during surveys of arthropod-borne viruses in Uganda, it received very little attention until the recent outbreak in South America. The virus moved across the Pacific from about 2007 and arrived in South America in 2014 and Brazil in 2015. It is thought that between 0.4 and 1.3 million cases were infected in 2015 in Brazil. The virus appears to be spreading much more rapidly in the Americas than was seen in Africa, giving little opportunity for the development of countermeasures.

Zika is a member of the Flavivirus genera of the Flaviviridae family, other members of which include yellow fever virus (YFV), West Nile virus, and dengue virus. As such, there are good reasons to think that effective vaccines and antiviral medications will be developed for the infection. In the most recent outbreak, manifestations of Guillain–Barre syndrome and fetal abnormalities have been associated with Zika infection, and it is unclear whether these result from the larger patient population or whether the virus evolved CNS tropism during its spread. The rapid spread of Zika is probably due to increased human travel and the northerly spread of the viral vectors *Aedes aegypti* and *Aedes albopictus*.[70–72]

The very successful antiviral discovery programs for the related flavivirus hepatitis C provide a solid platform for the discovery of anti-Zika compounds.

5.20.7.5 Yellow Fever

A recent resurgence of YFV in Angola has already spread to China, Kenya, and the Congo and has reawakened awareness of the infection. YFV is a flavivirus (the name derives from yellow fever) that causes between 81,000 and 170,000 cases per year and about 60,000 deaths, despite the availability of an effective and affordable vaccine. A current shortage of vaccine stocks has precipitated a lively debate about increasing the number of people protected by diluting the vaccine (an untested measure). This outbreak illustrates the dangers of complacency in infectious disease; an antiviral treatment for YFV would be very useful in such a rapid-response context.

5.20.7.6 Alternative Approach to Emerging Infections

The previous section illustrates the growing threat from viruses emerging or reemerging from reservoirs in the changing environment. Each new emergence stimulates fresh research efforts, but these frequently lack the sustained commitment and investment to provide clinically effective agents and the episodic threat abates. Greater coordination between international agencies might provide for discovery programs at relatively nominal cost to produce credible lead molecules for the identifiable viruses that threaten us. Such a small investment could save thousands of lives in future emerging viral epidemics.

5.20.8 Conclusions

The aim of this article was to survey the progress in the discovery of new antiviral drugs to treat acute viral infections. The antiviral therapeutic area is one of the great success stories of the pharmaceutical industry. In the case of HIV infections, we have seen the introduction of more than 20 new drugs used in ever more sophisticated combinations and formulations to extend the life span of infected individuals to near normal, with a good quality of life. In hepatitis C, we have seen effective cures for patients, reducing treatment times from a year to a few weeks. This success can now be applied to acute viral infections. Using four examples of respiratory tract infection, we have sought to illustrate the different challenges that need to be overcome to bring a new medicine to patients. Although the scientific challenge is far from trivial, the greater problem is to make the investment case support the discovery effort.

5.21.1 New Drugs and Economic Incentives

5.21.1.1 New Drug Approvals

Between 2007 and 2014, only eight new drugs or new drug combinations were approved by the Food and Drug Administration (FDA) for treatment of bacterial infections (Table 1 and Figs. 1 and 2).[1] With four of these eight approvals occurring in 2014, an upward trend appears to be emerging in antibacterial drug discovery, perhaps signaling a welcome resurgence in productive research. However, most of the recent approvals are indicated for infections caused by Gram-positive pathogens, with only two new drugs approved for the treatment of Gram-negative infections (ceftaroline in 2010 and ceftolozane + tazobactam in 2014). A recent report by the World Health Organization cited an alarming rise in resistance against certain infections caused by Gram-negative pathogens, with few treatment options remaining.[2] The paucity of new drugs coming to the market for infections caused by Gram-negative pathogens is likely due to economic disincentives for their development (e.g., low predicted return on investment if physicians are reluctant to prescribe new and expensive medications), combined with the high discovery and development hurdles in identifying novel treatments for these infections.[3] Further to this, such expensive medications will not be affordable in resource-limited nations, where resistance to common antibiotics is already approaching critical levels.[2] Ultimately, these factors have resulted in a lack of new Gram-negative drugs emerging from pharmaceutical R&D.[3]

From a structural point of view, most of the new drug approvals stem from legacy antibacterial scaffolds. Fig. 1 depicts the three vancomycin analogs **1**, **2**, and **3** that have been approved to treat specific Gram-positive infections. Fig. 2 includes two recently approved cephalosporins (ceftolozane **8** and ceftaroline **9**), the latest in a long line of such antibiotics. Tedizolid **4** is member of the oxazolidinones, originating from linezolid (approved in 1988). Only fidaxomicin **5** and bedaquiline **6** represent new chemical classes to enter the market. These examples serve to highlight the difficulty across the industry in identifying truly novel antibacterial mechanisms or new chemical classes acting via previously established targets. The remainder of this article will discuss new initiatives that are helping to promote innovation in this area as well as some examples of important new scaffolds that are emerging in the field.

5.21.1.2 Economic Incentives: The Generating Antibiotic Incentives Now Act and Innovative Medicines Initiative

A significant legislative change in the United States that provides economic incentives to develop new antibacterials is the Generating Antibiotic Incentives Now (GAIN) Act passed in 2011.[4] This legislation provides for 5 years of exclusivity and fast-track approval for antibiotics termed "qualified infectious disease products (QIDP)."[4] The QIDP designation is applicable to exploratory agents for the treatment of serious or life-threatening infections from pathogens such as vancomycin-resistant *Enterococcus* spp., methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *S. aureus*, *Acinetobacter baumannii*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *E. coli*. Collectively, these have been given the acronym the ESKAPE pathogens, and they now form the core of most new drug discovery antibacterial research programs and government-funded initiatives.[5] The first drug approved under this act was dalbavancin for treatment of acute bacterial skin and skin structure infections in May 2014.[6,7] Beyond the United States, European initiatives such as the Innovative Medicines Initiative New Drugs for Bad Bugs (IMI ND4BB) have allocated over €600 M toward structured partnerships between academia and industry[8] addressing basic research into some of the most fundamental problems of new antibiotic drug discovery, such as bacterial resistance (COMBACTE) and drug translocation across bacterial membranes (TRANSLOCATION).

5.21.2 Current Technical Challenges for New Antibacterial Lead Discovery

5.21.2.1 Understanding the Physical Property Determinants of Antibacterial Chemical Space

The structures in Fig. 1 reveal that of the eight new compounds approved by the FDA since 2007, five are natural products in origin (dalbavancin, fidaxomicin, telavancin, and the β-lactams ceftaroline and ceftolozane). Only two were truly synthetic in origin

Table 1 Approved antibacterial drugs 2007–2014

Year	*Name*	*Indication, spectrum*
2014	Dalbavancin	ABSSSI, Gram-positive-related infections
	Tedizolid	ABSSSI, Gram-positive-related infections
	Ceftolozane + tazobactam	cUTI and cIAI-, Gram-positive- and Gram-negative-related infections
	Oritavancin	ABSSSI-, Gram-positive-related infections
2012	Bedaquiline	MDR TB
2011	Fidaxomicin	*C. difficile*-associated diarrhea
2010	Ceftaroline	cSSSI, CAP, Gram-positive- and Gram-negative-related infections
2009	Telavancin	cSSSI and HAP, VAP by *S. aureus*
2007 and 2008	No FDA approvals	

ABSSSI, acute bacterial skin and skin structure infections; *cSSSI*, complicated skin and skin structure infections; *cUTI*, complicated urinary tract infection; *cIAI*, complicated intra-abdominal infections; *MDR TB*, multidrug-resistant tuberculosis; *CAP*, community-acquired pneumonia; *HAP*, hospital-acquired pneumonia; and *VAP*, ventilator-associated pneumonia.

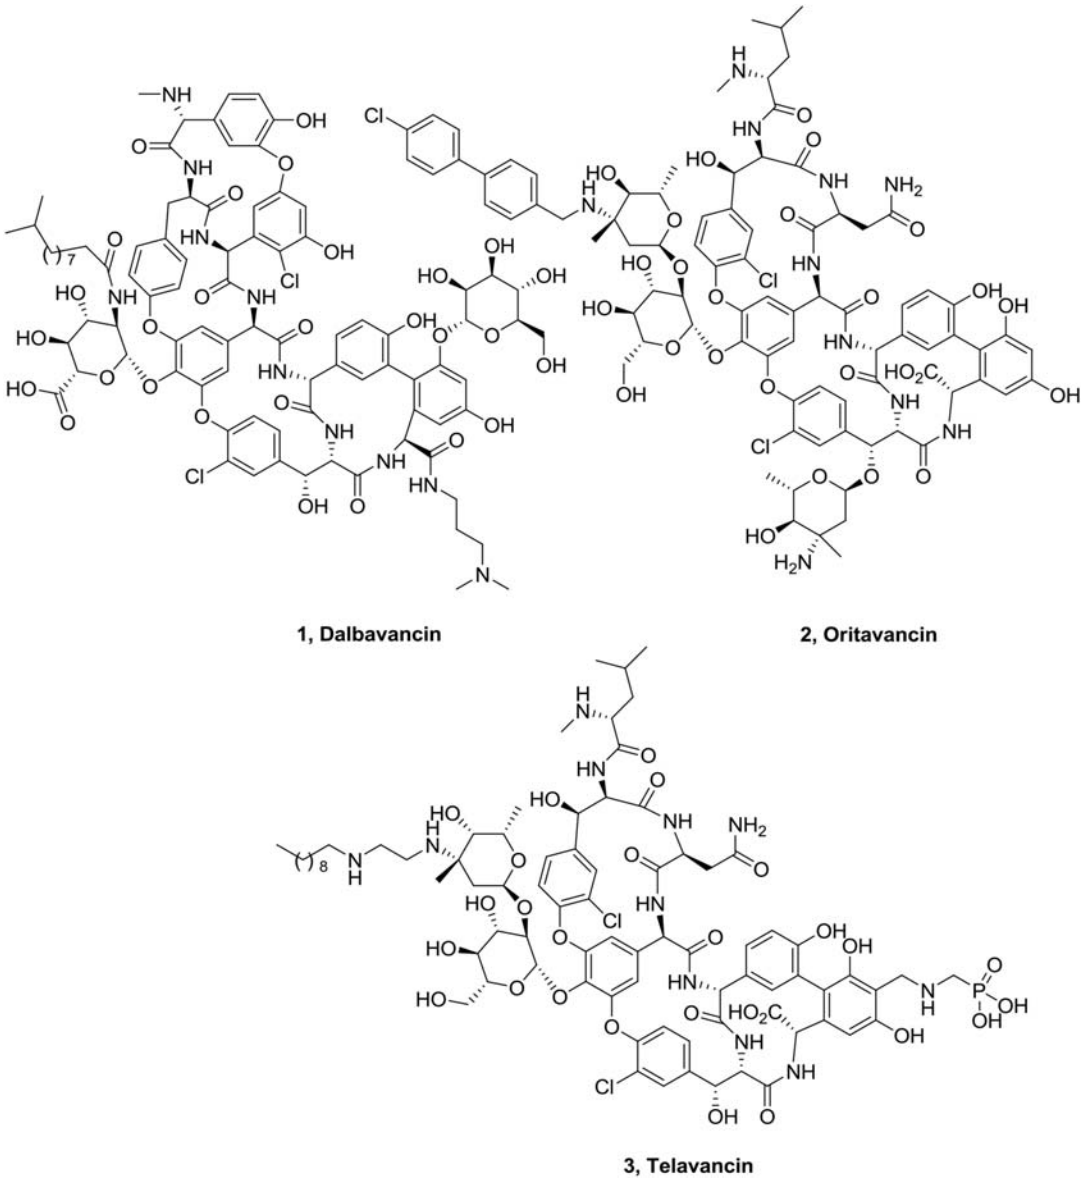

Fig. 1 FDA-approved vancomycin analogs 2007–2014.

(tedizolid and bedaquiline). It is widely recognized that many of the established antibacterial drug classes were discovered through natural product screening.[9] However, with the explosive recent growth of biochemical tools and the complete sequencing of the bacterial genome in 1995, discovery strategies shifted away from traditional phenotypic cell-based natural product screens. A significant investment was made instead in target-based approaches, coupled with high-throughput screening (HTS), in an effort to find new antibacterial leads. At the outset, this approach offered the prospect of efficient and productive discovery of many new antibacterial drugs. However, this turned out not to be the case. Researchers at GSK in 2007 were the first to report that the new strategy had failed to meet its high expectations.[10] They concluded that the major reasons for failure were the inability to find antibacterial-like leads from within the corporate screening collection, coupled with the challenges of requiring broad-spectrum (i.e., both Gram-positive and Gram-negative) activity. These themes were further reinforced by Moser et al., who analyzed antibacterial drug-like space as being much more polar than oral drug-like space for human targets.[9] In further exploration of this topic, the profiles of antibacterial actives across species were compared by authors at AstraZeneca to those emerging from HTS (Fig. 3A and B).[11] The authors concluded that antibacterial HTS screening hits were typically very lipophilic compounds (in fact, often more so than the screening collection average), inconsistent with antibacterial drug-like space. The difficulty in achieving optimal physical properties (e.g., often logD <0) for antibacterial cellular activity while maintaining biochemical potency is enormous and is perhaps a unique challenge for antibacterial drug discovery. Furthermore, simply optimizing to a low logD range does not guarantee

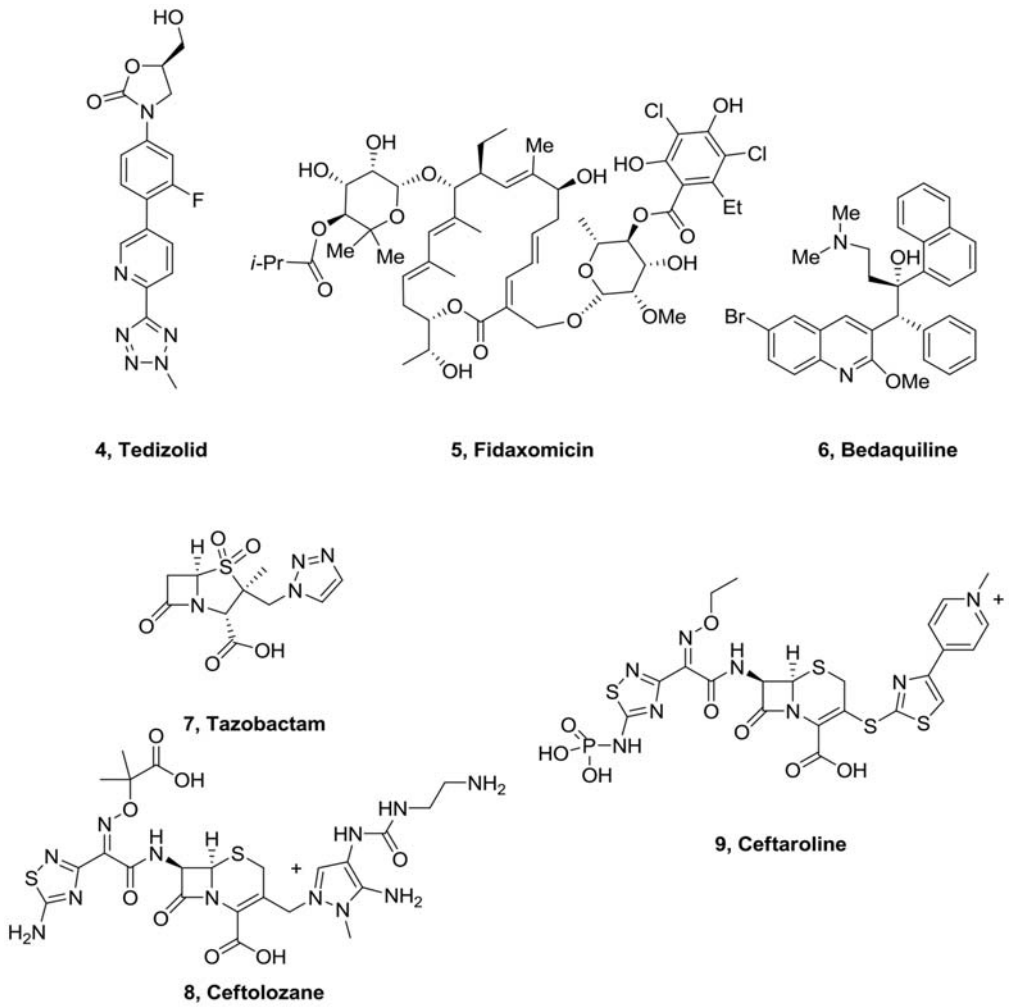

Fig. 2 Other FDA-approved antibacterial drugs 2007–2014. (Note that tazobactam **7** was already an approved β-lactamase inhibitor prior to 2014. It is included here for completeness since it was approved in combination with ceftolozane.)

antibacterial activity. The nature of the outer membrane in Gram-negative organisms and the wide variety of efflux pumps expressed present a complex barrier whose penetration is not assured merely by addressing one simple chemical descriptor such as logD. Tomassi and coauthors at AstraZeneca published a further review on their experiences with HTS screening and antibacterial drug discovery.[12] Their experience contrasted with GSK[10] in that many hits and leads were found by HTS screening, but the lack of viable medicinal chemistry tactics to engineer penetration of Gram-negative outer membranes proved to be the key limitation.[12] The importance of understanding translocation phenomena at a molecular level and the development of potential Structure activity relationships (SAR) rules would provide life to many of these abandoned hits and open up new frontiers in antibacterial drug discovery.

5.21.2.2 Understanding Translocation and Efflux at a Molecular Level

In order to develop a fundamental understanding of medicinal chemistry tactics to enable penetration of bacterial cell membranes, it is critical to understand the various barriers and entry mechanisms and in particular those in Gram-negative bacteria. The barriers for compounds to penetrate the outer membrane of Gram-negative bacteria are the following: (a) a highly polar outer membrane, (b) small narrow openings for nutrient transport (porins), and (c) promiscuous efflux pumps.[13,14] One strategy to overcome these barriers has been to develop compounds that are amphiphilic and highly cationic and can thereby disrupt the membrane, but these may also be cytotoxic if they exhibit similar properties in mammalian cells. An example of this approach can be found in the field of amphiphilic cationic homopolymers, which work through bacterial membrane disruption but can also give rise to hemolysis in mammalian cells.[15] Other strategies include translocation through porins, but the structure of these channels places severe constraints on molecular characteristics for efficient passage to take place. The crystal structure of the *P. aeruginosa* porin OccD1 is shown in the succeeding text to illustrate the β-barrel type topography and specific arrangement of charged amino acids, with

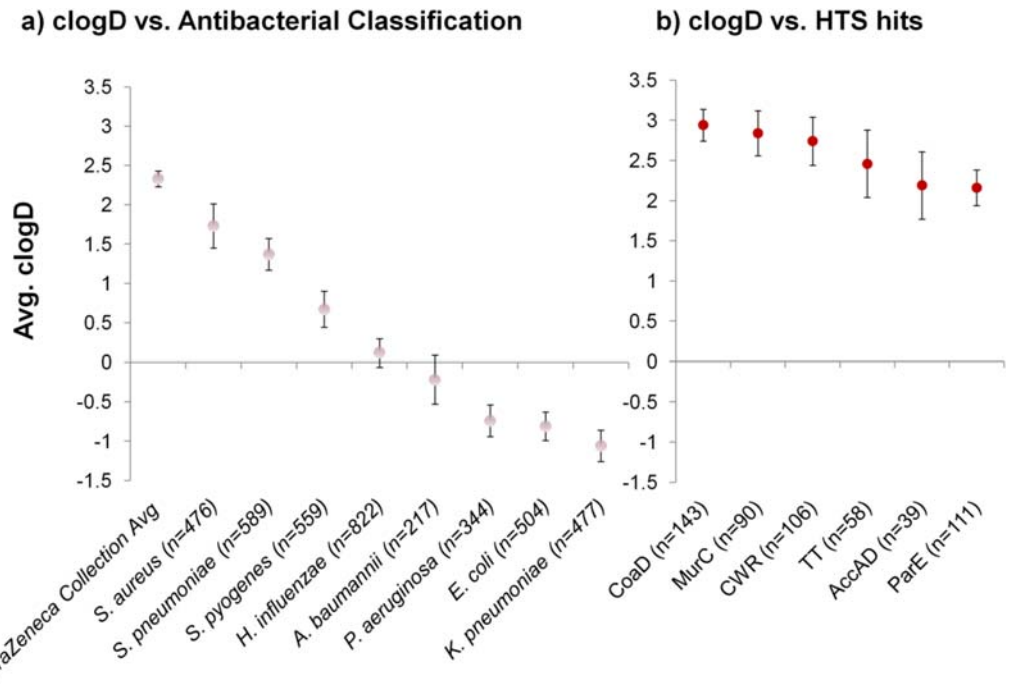

Fig. 3 Physical property analysis of antibacterial actives compared with HTS actives. Panel (A) is the average calculated logD (clogD) of antibacterial actives from AstraZeneca projects for specific pathogens (active defined as minimum inhibitory concentration (MIC) $\leq 8\ \mu g\ mL^{-1}$). Vertical bars represent the $\pm 99\%$ confidence interval of the mean. Numbers in parentheses indicate the number of actives included in the analysis. The "AstraZeneca Collection Avg" is the average of a random sample of 45 K compounds from the corporate screening collection. Panel (B) illustrates actives identified by HTS screening of a representative sample of HTS campaigns. *CoaD*, pantetheine-phosphate adenylyltransferase; *MurC*, UDP-*N*-acetylmuramic acid: L-alanine ligase; CWR, cell wall reporter gene assay in *E. coli*; TT, transcription and translation phenotypic screen; AccAD, carboxytransferase activity of acetyl-CoA carboxylase; ParE, topoisomerase IV ATP-hydrolyzing subunit.

consequent narrow openings (Fig. 4).[16] Passive diffusion is thought to be severely diminished for compounds with MW > 600 Da, since porin channels in the bacterial outer membrane are quite narrow.[17] However, a recent example by van den Berg and coauthors identified the passive diffusion of very large cyclodextrins in *K. oxytoca* via a monomeric 14-stranded β-barrel large pore, which appears to be gated on the periplasmic side by the N-terminal domain of the protein.[17] In other recent studies in outer membrane transport, Tommasi and Isabella et al. used an integrated genetics and computational approach to characterize the translocation of meropenem through the *P. aeruginosa* porins OccD1 and OccD3.[18] Meropenem analogs were then designed to retain critical binding features to the intended penicillin-binding protein target and also test SAR around the molecular dynamic simulation models. This is the first reported example of a rational approach to enhance permeation through a bacterial porin channel and offers a glimpse into the next generation of antibacterial drug design.

A much needed tool in the arsenal of antibacterial medicinal chemists is a biophysical method to understand bacterial cell penetration across a range of similar compounds, thus establishing permeation–structure relationships, which can be applied across programs. A review of electrophysiology and molecular modeling methods by Winterhalter and Ceccarelli suggested that advances in nanotechnology and electrophysiology coupled with molecular modeling might prove of benefit in optimizing translocation of hits.[19] This work is also significant in that it highlights the emerging impact of the innovative medicines initiative (IMI)-funded initiatives described earlier.

5.21.2.3 Siderophore-Mediated Bacterial Cell-Wall Translocation

Another strategy for bacterial translocation is to incorporate a structural motif into the drug molecule that is recognized by a transporter that is essential for bacterial nutrition, thereby facilitating uptake. One of the most well-studied such approaches exploits siderophores, which transport Fe^{3+} (required for bacterial survival and replication) from the host to the pathogen.[20] Although this approach has been studied on many antibacterial scaffolds, the tactic has been most widely applied with β-lactams. This combination confers the advantage that the putative drugs need to only penetrate the bacterial outer membrane, given that the targets (penicillin-binding proteins) are located within the periplasmic space. (Bacterial targets such as the ribosome that reside in the cytoplasm would require that these highly polar molecules, which would also be coordinated to Fe^{3+}, must penetrate the hydrophobic inner cytosolic membrane and the polar outer membrane.) Some of the more advanced programs were published by a Pfizer-led team (Fig. 5), where three scaffolds incorporating siderophore motifs were studied – the lactivicins (**10** → **11**),[21] monocarbams

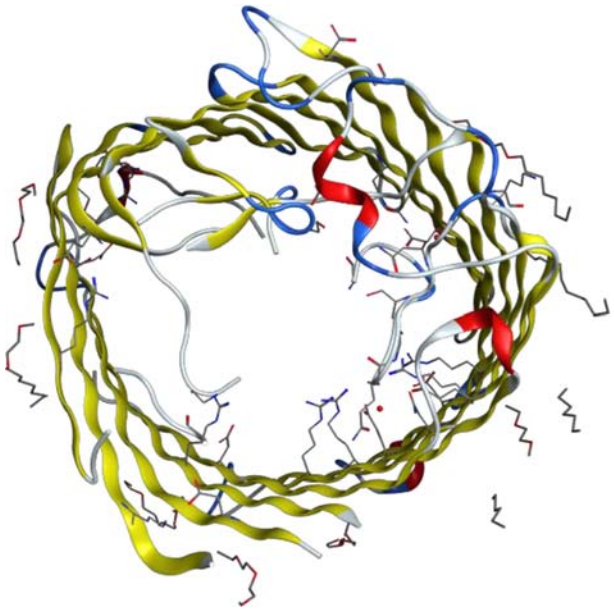

Fig. 4 X-ray crystal structure of *P. aeruginosa* OccD1 (PDB code, 4FOZ).

(**12**),[22a] and monobactams (**13**).[22b] Dramatic improvements in antibacterial activities were illustrated with the lactivicins (**10** → **11**), where a 64-fold shift in minimum inhibitory concentration was engineered through incorporation of the siderophore with no change in the biochemical activity. Despite these promising in vitro results, the tactic failed to translate in preclinical in vivo models. Despite adequate free systemic drug levels, the monobactam **12** (MB-1) did not generate the antibacterial effect predicted by in vitro assays. The drop-off in activity was attributed to adaptation-based resistance within these animal models of infection. These discouraging results have left serious concerns about the potential of siderophore-based approaches for circumventing the Gram-negative outer membrane. A study revealed that combination dosing with an efflux pump inhibitor (reserpine) could potentiate and circumvent the proposed adaptive in vivo resistance mechanism and perhaps rescue this type of approach.[23]

Another noteworthy example of the siderophore approach is the clinical development candidate BAL30072 from Basilea (**14**). This compound has reached Ph1 human clinical trials, but little has been published since that disclosure.[24] When this agent demonstrates clinical activity, it would validate not only Gram-negative penetration through siderophore-mediated uptake but also the avoidance of monobactam cleavage by class B metallo-β-lactamases (MBLs) (discussed further in the succeeding text).

5.21.3 β-Lactamase Inhibitors

Since the introduction of penicillin, resistant strains of bacteria have emerged with an enormous number of enzymes capable of hydrolyzing β-lactams. These enzymes are termed β-lactamases, and they are divided into four major classes (A, B, C, and D). The currently marketed β-lactamase inhibitors clavulanic acid, tazobactam, and sulbactam are all derived from a β-lactam core (Fig. 6)[25,26] and are becoming less effective against a rising tide of extended-spectrum β-lactamase-producing organisms. Class A, C, and D β-lactamases are serine-based proteases and as such hydrolyze the β-lactam rings in these molecules in a suicide-based mechanism. Furthermore, established β-lactamase inhibitors offer no protection against class B (metallo-) β-lactamases, because the metalloprotease mechanism and active site are very different from class A, C, and D enzymes.

5.21.3.1 MBL Inhibition Strategies

The rise of bacteria-producing class B MBLs has triggered significant alarm within the health community, with very few treatment options available to the physician should an outbreak occur.[27] MBLs are promiscuous enzymes that rapidly hydrolyze most β-lactam antibiotics and thus render them useless before they can bind to penicillin-binding proteins within bacteria.[28,29] Among the β-lactam classes, only the monobactams such as aztreonam are not hydrolyzed and thus are resistant to these enzymes. However, the relatively weak intrinsic antibacterial efficacy and the susceptibility of most monobactams to serine β-lactamases limit the general utility of the class.[30] Worse, MBLs are typically coexpressed with serine β-lactamases, such that any clinically effective regimen must address the impact of both simultaneously.[26] Over the past few years, two different approaches have been taken to try and develop new drugs against MBL-expressing bacteria: (a) direct inhibition of the MBL and (b) potentiation of monobactam potency with new-generation β-lactamase inhibitors.

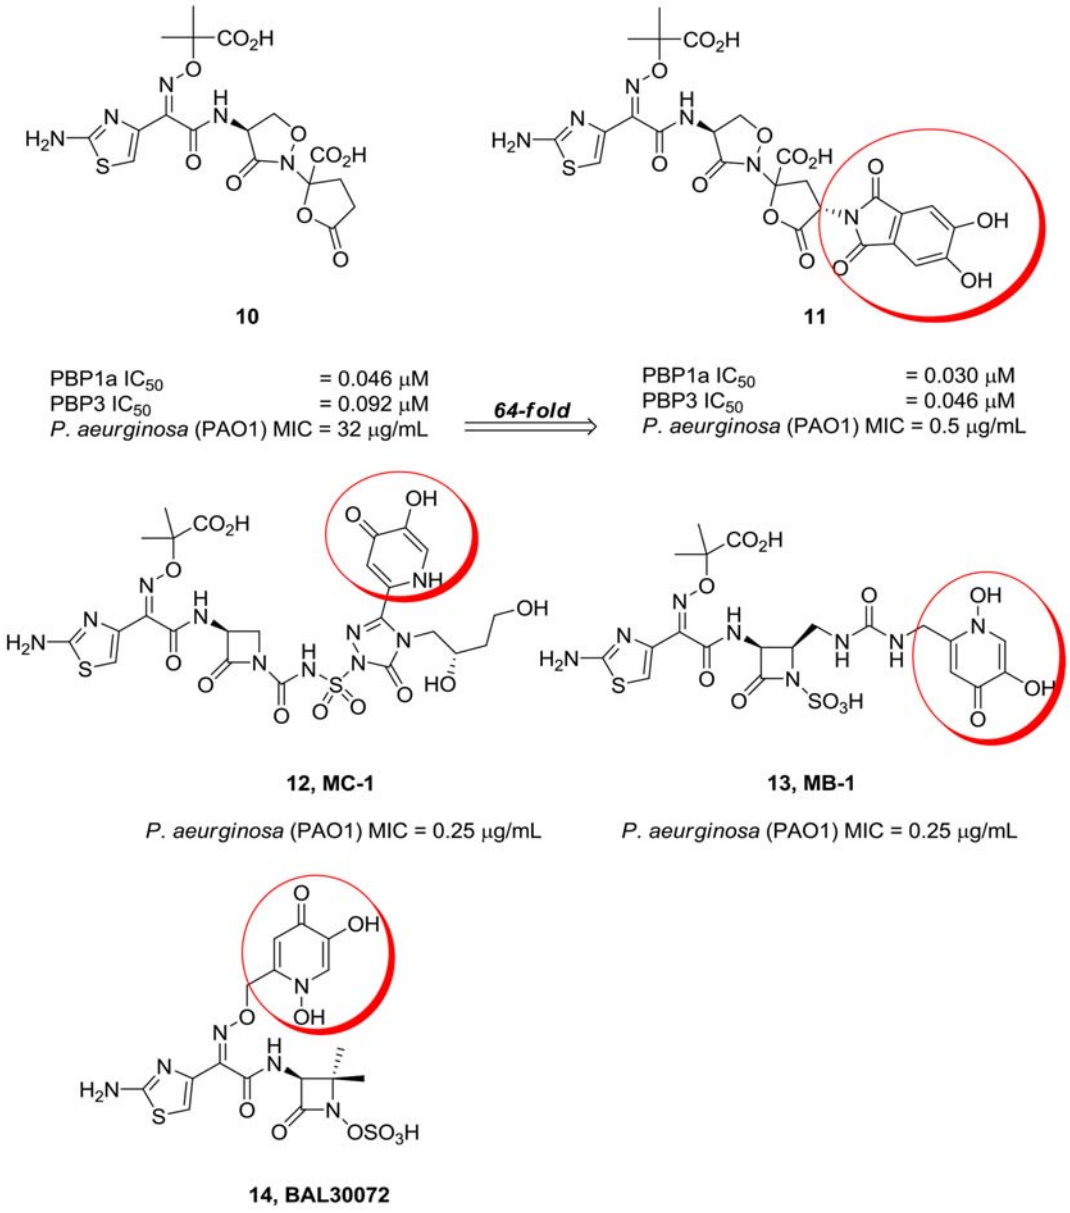

Fig. 5 Representative examples of siderophore-containing antibacterial compounds. The siderophores are highlighted in red circles.

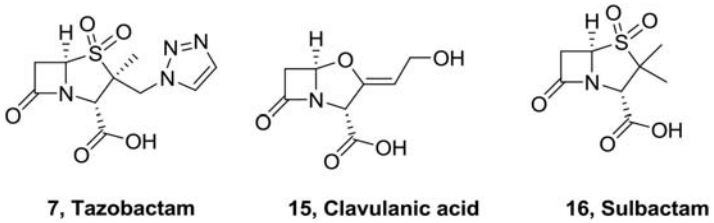

Fig. 6 Marketed β-lactamase inhibitors.

5.21.3.1.1 Direct MBL inhibitors

Direct, specific inhibition of an MBL is an attractive option since it can be enabled by structure-based discovery, and inhibition of metalloenzymes is precedented in other therapeutic contexts. However, such an approach would necessitate triple combination therapy, since a serine β-lactamase inhibitor and the intrinsic antibacterial β-lactam would also be required for clinical effectiveness. There would almost certainly be the need for rapid diagnostics in such an approach, since such a regimen would not be used unless a physician could confirm the presence of an MBL drug-resistant strain. This is further complicated in that most of the concern with MBLs is found in developing nations, where implementing such a diagnostic and treatment protocol would be particularly problematic. Furthermore, the MBL inhibitor would likely need to cover all genetic variants of MBLs. In spite of these hurdles, investments in this area continue, and the field continues to grow. As an example of the types of scaffolds being explored, a group at Goethe University has explored the potential of current marketed thiol-containing drugs (which might interact with the active-site Zn^{2+}) to prevent hydrolysis of β-lactams such as imipenem (Fig. 7).[31] Several MBL inhibitors were identified (exemplified by **17** and **18**) that demonstrated potentiation against imipenem-resistant Gram-negative clinical isolates and genetically altered *E. coli* strains (Fig. 7). The authors point out that one component in further optimization of molecules of this type may be to assess limitations in bacterial translocation.

A novel discovery strategy was adopted by Hu and coworkers at AstraZeneca using a cell-based NMR screen for MBL inhibitors.[32] In this assay, the hydrolysis product of meropenem is expelled into the supernatant by New Delhi metallo-β-lactamase (NDM-1)-expressing bacteria and can be monitored in real time using 1-D NMR methods. The method also allowed the opportunity to screen small libraries in 96-well format for potential inhibitors. From this approach, novel inhibitors of NDM-1 were identified (e.g., **19**) that like **17** and **18** contain thiols. Other classes of molecules that have been identified as MBL inhibitors are EDTA-like moieties, which function to sequester the Zn^{2+} from the active site. One interesting example is the natural product AMA (**20**), which has been shown to remove both Zn^{2+} atoms in NDM-1.[33] The diversity of potential MBL inhibitors is highlighted by an unusual selenium-containing class of inhibitors (**21,** ebselen) discovered by a cell-based screening approach. The lead compound was found to be a potent irreversible inhibitor with limited cytotoxicity.[34]

The first report of potent dual serine and MBL inhibition has been disclosed by The Medicines Company with the oxaborole-based inhibitors exemplified by **22** (KPC2 $IC_{50} = 0.01$ μM and OXA-48 $IC_{50} = 0.01$ μM).[35] As revealed by crystal structures, the boronate oxygen and the carboxylate both bind to the MBI Zn^{2+} ion. As mentioned previously, the potential clinical advantage of such a compound is considerable. The two-drug antibacterial combinations are well established, whereas three-drug regimens are likely to be significantly more problematic.

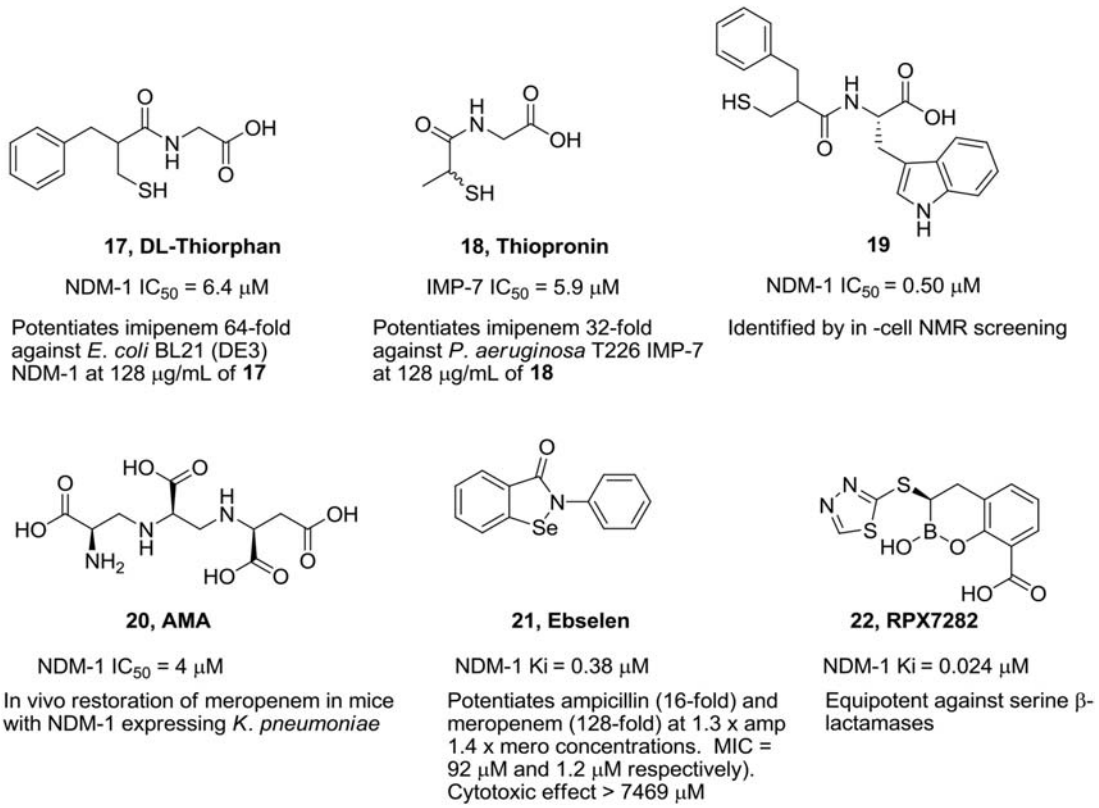

Fig. 7 Representative examples of metallo-β-lactamase inhibitors.

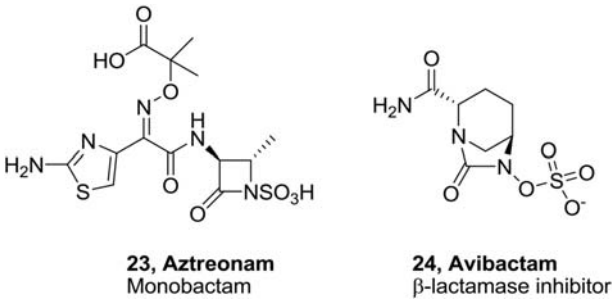

Fig. 8 Current combination in development for treatment of MBLs.

5.21.3.1.2 Exploiting monobactam insensitivity to MBLs

Aztreonam is now a generic drug, but its clinical use has been limited due to its narrow spectrum of activity as a single agent and its susceptibility to serine-based β-lactamases.[30] However, its lack of susceptibility to MBL-mediated hydrolysis has stimulated a search for more effective serine-based β-lactamase inhibitors for combination therapy. A combination currently in clinical development is aztreonam–avibactam (Fig. 8).[36] The aforementioned BAL30072 also belongs in this category in that it is a monocyclic β-lactam that is not susceptible to class B β-lactamases.[24]

5.21.3.2 Serine β-Lactamase Inhibitors

Not only will the world need to address the emergence of MBLs, but also the serine β-lactamases are also becoming more and more resistant to the inhibitors currently used in clinical practice. As a result, substantial effort has been invested in novel chemotypes, a subset of which is discussed in the succeeding text.

5.21.3.2.1 Oxaboroles as β-lactamase inhibitors

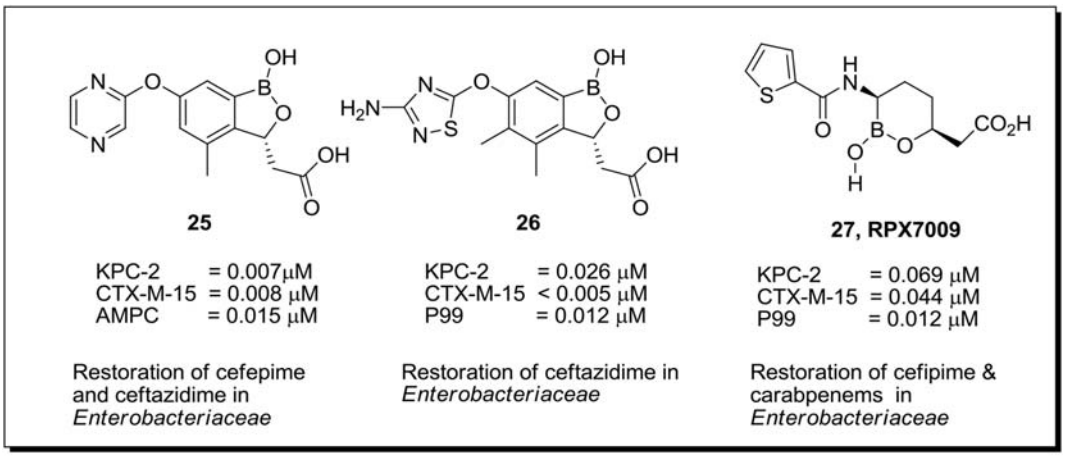
Oxaboroles have a dual role in antibacterial research, as they can function as both β-lactamase inhibitors and intrinsic antibacterial agents. Their mechanism of action as serine β-lactamase inhibitors involves reversible covalent complexation with the active-site nucleophile, which is distinct from their mechanism of intrinsic antibacterial activity (inhibition of leucine-tRNA synthetase, discussed in section "Leucine-tRNA synthetase inhibitors and oxaboroles"). Two classes of oxaborole-based β-lactamase inhibitors are shown in Fig. 9. Compounds **25** and **26** represent fused aromatic oxaboroles, which demonstrate potent activity in biochemical assays (e.g., inhibition of nitrocefin degradation by β-lactamases) and potentiation of β-lactams in *E. coli*- and *K. pneumoniae*-resistant strains.[37,38] A cocrystal structure revealed **26** anchored as a stable borate species in the active site of the enzyme by virtue of an interaction of the nucleophilic serine with the boron atom. The second class of oxaborole inhibitors is the aliphatic type as exemplified by **27** (RXP7009, The Medicines Company). RPX7009 demonstrates high selectivity over mammalian serine proteases (>100 μM against 11 representative enzymes) with potent activities at bacterial β-lactamases such as *K. pneumoniae* carbapenemases (KPC $IC_{50}=0.069$ μM), CTX-M ($IC_{50}=0.044$ μM), SHV ($IC_{50}=0.029$ μM), and CMY ($IC_{50}=0.099$ μM).[39] The compound also restores the MIC for *Enterobacteriaceae* expressing class A carbapenemases for carbapenems (e.g., in *E. coli* 1007 KPC-3, the MIC of meropenem was improved from 4 to <0.06 μg mL^{-1} in combination with 4 μg mL^{-1} of RPX7009). RPX7009 also restored imipenem activity in a carbapenem-resistant *K. pneumoniae* mouse lung infection model strain (two-log reduction in CFU at 50 mg kg^{-1} RPX7009 and 100 mg kg^{-1} meropenem). The potential for general electrophilicity of the oxaborole has not translated into demonstrable toxicity: The compound was tolerated at doses up to 1000 mg kg^{-1} in preclinical rodent studies,[40] and in phase 1 studies, the compound was well tolerated at 1500 mg kg^{-1} infused over 3 h.[39] RPX7009 is currently under investigation in a phase III trial in combination with meropenem for treatment of carbapenem-resistant *Enterobacteriaceae*.[41]

5.21.3.2.2 Diazabicyclooctanes

Another class of novel β-lactamase inhibitors is the diazabicyclooctanes (DABCOs), as shown in Fig. 10. The discovery that highly strained five-membered ring ureas could mimic the reactivity of a β-lactam has delivered a brand new weapon in the arsenal against drug-resistant bacteria.[42] The urea in these compounds is stable under physiological conditions but behaves in a similar manner to β-lactams in that it is hydrolyzed by the active-site serine of the class A, C, and D β-lactamases. The leading examples in the field are avibactam (**24**),[43] which was the first in class to be approved (in combination with ceftazidime), and relebactam **28**, which is currently in phase III trials in triple combination with imipenem/cilastatin.[44] Relebactam was designated fast-track QIDP approval by the FDA for the study of complicated urinary tract infections (cUTIs).

Another member of the DABCO class of β-lactamase inhibitors has been disclosed by Fedora as FPI-1465.[45] This compound, like other members of the class, also inhibits penicillin-binding protein 2, which provides intrinsic antibacterial activity and β-lactamase inhibition.[45]

A unique feature of at least one member of the chemical class of the DABCOs is the reversibility of covalent binding of the strained urea, a phenomenon that has not been reported for the β-lactams (Fig. 11). Ehmann et al. demonstrated that avibactam



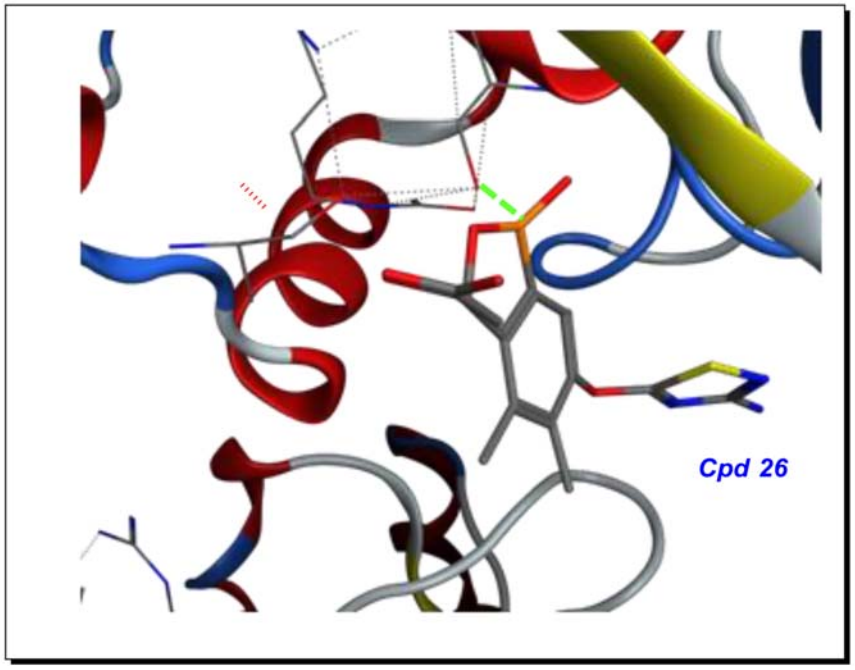


Fig. 9 Oxaborole β-lactamase inhibitor **26** bound to active site of a β-lactamase.[37] The dashed green line indicates the serine OH covalent bond with the boron atom of the oxaborole.

binds in covalent fashion to the active-site serine residues of TEM-1 and AmpC, but, that surprisingly, the urea could be regenerated and subsequently binds to another β-lactamase in the vicinity.[46] It is not yet known to what extent this feature contributes to the efficacy and resistance mechanisms of avibactam, but the discovery has opened up significant new ideas on β-lactamase inhibitor design.

5.21.4 Beyond β-Lactams and β-Lactamase Inhibitors

This section will review some of the most important examples of new approaches to antibacterial agents outside of the β-lactam class and will highlight some of the unique developments that are changing the field.

5.21.4.1 Protein Synthesis Inhibitors

5.21.4.1.1 Ribosome binders

Disruption of bacterial protein synthesis through binding to the ribosome is the basis of action for many successful drug classes, including aminoglycosides, tetracyclines, oxadiazoles, and macrolides.[47] New representatives in these classes continue to advance

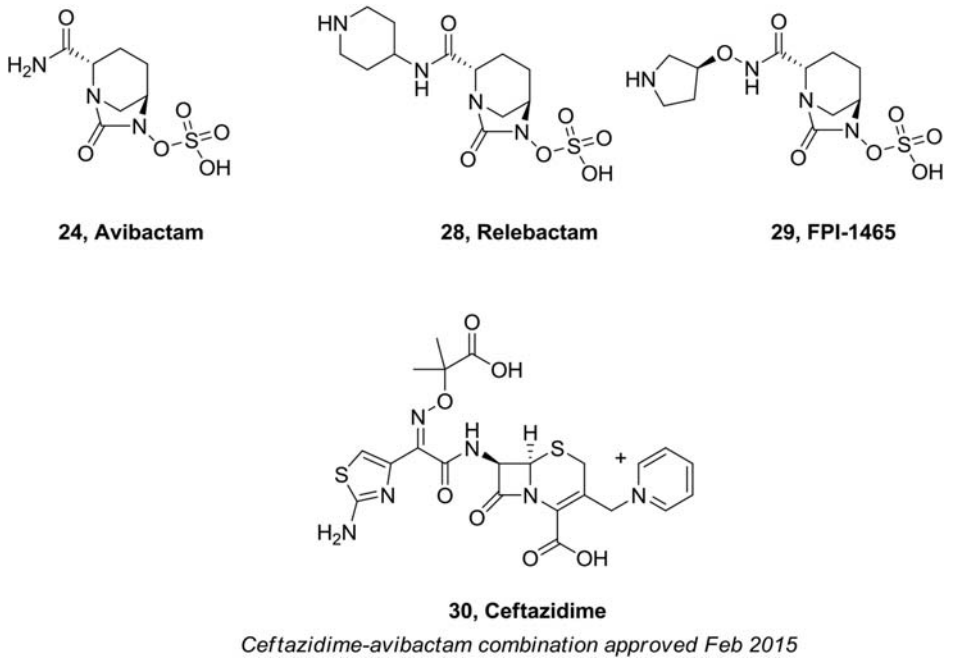

Fig. 10 Examples of diazabicyclooctane-based β-lactamase inhibitors (**24**, **28**, and **29**).

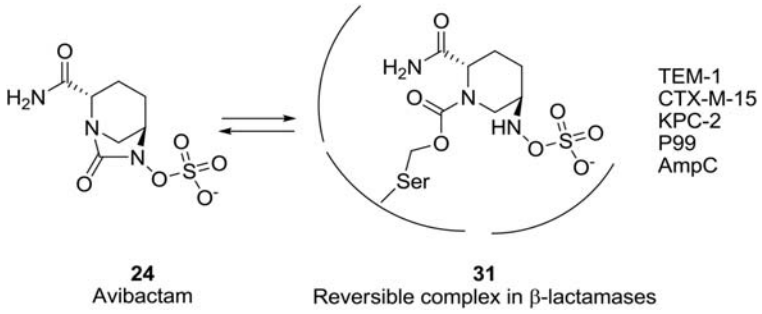

Fig. 11 Reversibility of avibactam.

into clinical development (e.g., the next-generation aminoglycoside plazomicin, currently in phase III trials).[48] This section will not review these legacy classes, but rather examine some of the new technology and chemical series that have emerged recently.

One major breakthrough in the past decade for ribosome-based targets has been the incorporation of high-resolution X-ray crystallography in drug discovery programs. For many years, the size and complexity of the ribosome prevented routine deployment of the technology, and challenges still remain.[49] However, several recent examples illustrate the power of this technique to identify novel binding modes and chemical starting points. A group at Rib-X Pharmaceuticals has made use of the 50S subunit of the ribosome from *Haloarcula marismortui*.[50] This archaeon, isolated from the Dead Sea in Israel, grows in high salt conditions and generates ribosomes that are structurally robust enough to be amenable for crystallography.[51] Using the structural information gained in this way, scaffolds such as **32** (Fig. 12) were optimized to deliver very potent broad-spectrum anti-Gram-negative activity, in particular against *P. aeruginosa*. This is significant, since compounds working at this site have to penetrate not only the highly polar outer membrane (while also avoiding efflux mechanisms) but also the inner cytosolic membrane (thus requiring sufficient hydrophobicity). The mechanism by which these molecules reach the cytosol has not been reported, but further analysis would certainly be of interest.

Another chemical class known to bind to the ribosome is derived from the natural product negamycin (**33**). Originally discovered in 1970, the antibacterial activity of this compound was subsequently attributed to inhibition of bacterial protein synthesis.[52–54] Crystal structures have been reported wherein negamycin binds to the nascent chain exit tunnel of the *H. marismortui* 50S ribosome subunit, but analogous binding in the more relevant pathogen *E. coli* has not been established.[55] Instead, the application of ribosome crystallography in *E. coli* and small molecule FRET techniques has revealed that in this species, negamycin acts by causing translational stalling and miscoding.[56] The crystal structure was different from that reported in *H. marismortui* and was found to

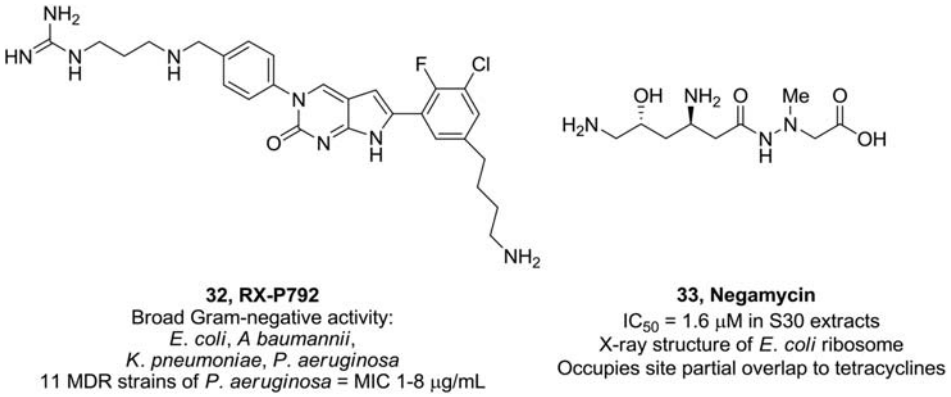

Fig. 12 Inhibitors of bacterial ribosomes.

partially overlap with the tetracycline-binding site, thus highlighting the critical relevance of high-resolution *E. coli* ribosome crystallography. Furthermore, two potential mechanisms of negamycin transport across the hydrophobic inner membrane of *E. coli* were characterized (a high-affinity route facilitated by the Dpp dipeptide transporter and a low-affinity energetically driven change in membrane potential).[57] This study nicely illustrates the benefit of understanding the mode of bacterial translocation, which may in principle be applicable across multiple drug classes.

5.21.4.1.2 Leucine-tRNA synthetase inhibitors and oxaboroles

The oxaboroles represent a novel and versatile chemical motif in the fight against drug-resistant bacteria. Not only are they potential inhibitors of β-lactamases, as discussed previously, but also they can be optimized for intrinsic antibacterial activity, especially through inhibition of leucine-tRNA synthetase.[58] This enzyme is responsible for transferring leucine to growing peptide chains, and, as such, inhibition results in a disruption of normal protein synthesis and bacterial cell death. Oxaboroles function by formation of a covalent borate complex with the ribose alcohols on the adenine moiety within the active site, and, uniquely, they exhibit relatively weak biochemical activity that nonetheless translates to potent antibacterial activity in vitro (Fig. 13).[59] This phenomenon may be related to slow but tight binding kinetics on the enzyme. For example, tavaborole (**35**) has a half-life of ~424 min on yeast cytoplasmic leucyl-tRNA synthetase, despite modest potency in conventional inhibitory assays (IC_{50} = 2.1 μM).[60] However, one of the leading oxaboroles in development for bacterial infections, AN3365, was halted in phase II cUTI clinical trials due to the development of resistance.[61] Although this was a setback for this target class, it should be noted that tavaborole has reached the market as a topical antifungal for treatment of onychomycosis of the toenail.[60]

5.21.4.2 DNA Synthesis: Novel Topoisomerase Inhibitors

Similar to the ribosome, inhibition of bacterial topoisomerase function has provided a rich legacy of antibacterial drugs, including the fluoroquinolones (e.g., ciprofloxacin) and novobiocin.[62] The search for potent topoisomerase inhibitors that are safe and do not show cross-resistance to fluoroquinolones has been at the center of many recent research efforts. The identification of several unique binding modes distinct from fluoroquinolones has enabled the discovery of several novel chemical classes and advanced clinical compounds, leading examples of which are shown in Fig. 14. The spiropyrimidinetrione EXT0914 (formerly AZD0914) **36** exploits a binding site that was first reported in 2007 with PNU-286607.[63] The mechanism of action is attributed to inhibition of DNA synthesis via accumulation of double-strand cleavages by stabilization of the cleaved DNA complex, thus preventing religation to circular DNA. EXT0914 was optimized for potency against Gram-positive bacteria and also *N. gonorrhoeae*.[64] The recent

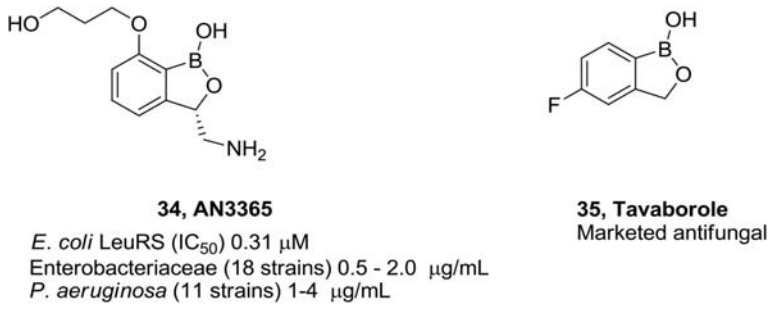

Fig. 13 Examples of oxaborole leucyl-tRNA synthetase inhibitors.

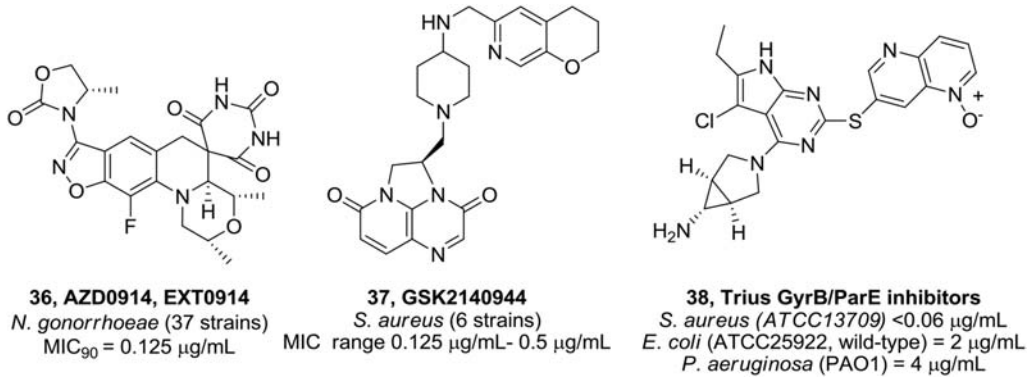

Fig. 14 Topoisomerase inhibitors.

emergence of drug-resistant *N. gonorrhoeae* infections has prompted the Centers for Disease Control and Prevention to call attention to this crisis.[65] EXT0914 lacks cross-resistance to clinical isolates resistant to fluoroquinolones[63,64] and is currently under investigation in patients in a phase II trial.

Another unique mode of interaction for type II topoisomerase inhibition is exemplified by GSK2140944 (**37**).[66,67] Compounds of this type work by stabilization of the precleavage DNA topoisomerase-DNA complex, thus leading to single-strand DNA breaks. GSK2140944 is also currently in phase II clinical trials.

A third mechanistic approach involves the dual inhibition of DNA gyrase (GyrB) and topoisomerase IV (ParE). Compounds that are known to inhibit these targets do so by binding to the ATPase subunits of the complex and interfere with supercoiling processes of bacterial DNA. Trius reported on a series of pyrrolopyrimidines, exemplified by **38**, which demonstrate potent broad-spectrum Gram-negative activity by virtue of this dual-inhibition mechanism.[68]

Collectively, these three mechanisms offer an opportunity to further exploit DNA synthesis as a target for antibacterial drugs while circumventing the increasingly widespread resistance to fluoroquinolones.

5.21.4.3 Cell-Wall Biosynthesis Inhibitors

Inhibition of cell-wall biosynthesis is the mechanism of action of many marketed drugs, divided into two major classes: (a) β-lactams, which target penicillin-binding proteins and (b) glycopeptides of the vancomycin family, which bind to D-Ala-Ala precursors.[69] This section will cover some of the emerging cell-wall biosynthesis targets that are distinct from those exploited by established agents.

5.21.4.4 LptD Inhibitors

A group at Polyphor AG has recently described their work originating from protegrin-1 (**39**, Fig. 15).[70] Naturally occurring protegrins were identified as antimicrobials but were limited by hemolytic activity. Through the use of a D-proline–L-proline template for stabilization of β-turns, potent *P. aeruginosa*-specific compounds were identified as exemplified by POL7001 (**40**). These compounds bind to the β-barrel protein LptD and thereby disrupt the translocation of lipopolysaccharide from the periplasm to the outer membrane. From this effort, a clinical candidate was identified (POL7080, structure not disclosed; *P. aeruginosa* (ATCC 27853) MIC = 0.008 μg mL^{-1}; and hemolytic activity > 100 μg mL^{-1}). This compound acts exclusively on *P. aeruginosa* and is inactive against other Gram-negative and Gram-positive bacteria. In a phase 1 trial, no adverse events were seen upon 6-day dosing of POL7080 (2–3 h infusion up to three times daily at up to 10 mg kg^{-1} day^{-1}).[71]

5.21.4.5 LpxC Inhibitors

A promising class of agents that demonstrate activity in wild-type strains of *P. aeruginosa* is those that target UDP-3-*O*-(*R*-3-hydroxymyristoyl)-*N*-acetylglucosamine deacetylase, encoded by *LpxC*.[72] This is the first committed step in the lipid A biosynthetic pathway, which has been shown to be essential in Gram-negative bacteria. All of the known LpxC inhibitors are characterized by a hydroxamic acid, which coordinates the active-site Zn^{2+}, and by a lipophilic tail, which mimics the natural lipid A precursor substrates. As mentioned earlier, lipophilic molecules are not typically found to be active against Gram-negative pathogens, even when they have very potent biochemical activity at their intended target. However, despite a wide logD range, many LpxC inhibitors provide potent wild-type activity in *P. aeruginosa*[11,12] with a yet unknown mechanism of cellular penetration. Potent examples are **41**, **42**, **43**, and **44** (Fig. 16).[73–75] These compounds have also been used to demonstrate the different resistance phenotypes, which can be manifested across species: for example, efflux is the primary first-step mechanism of resistance in *P. aeruginosa* but not in *K. pneumoniae* (where it is mutation in *fabZ*). Further to the mechanism of action, a collaborative study by

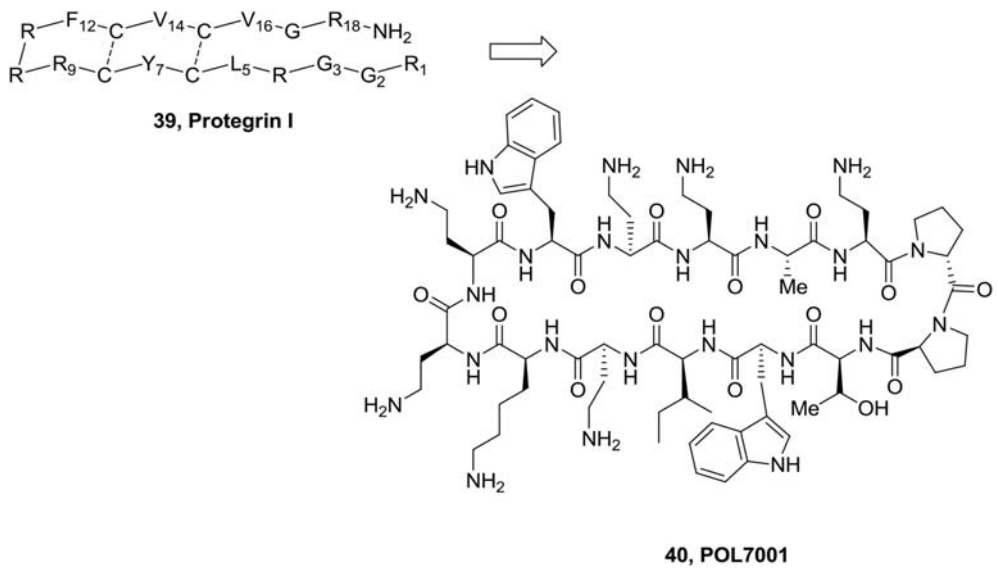

Fig. 15 Protegrin LptD inhibitors.

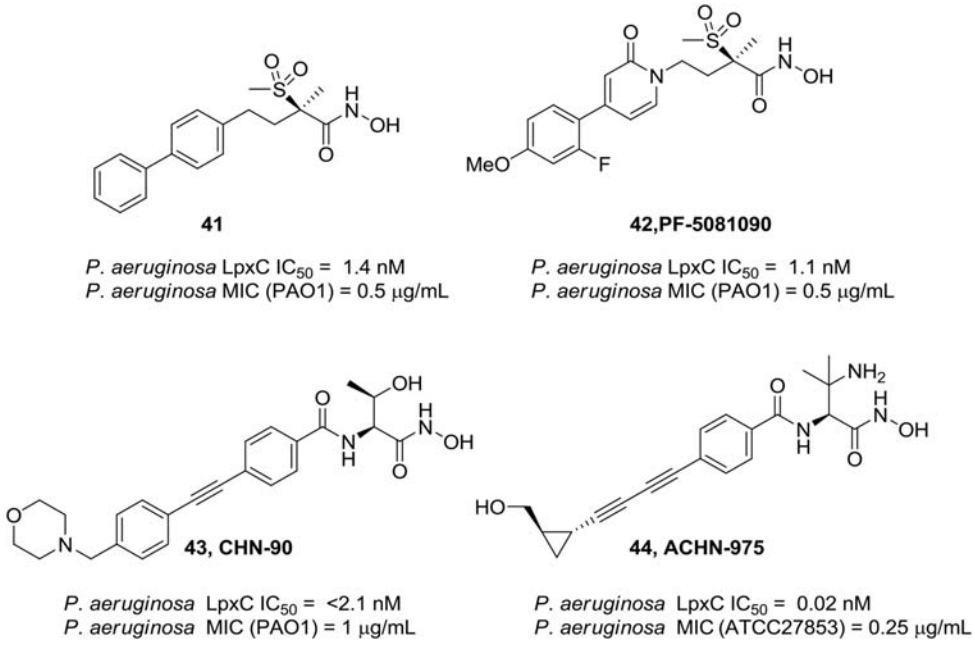

Fig. 16 LpxC inhibitors.

AstraZeneca and Stony Brook University has demonstrated that some LpxC inhibitors demonstrate slow-binding kinetics and a prolonged postantibiotic effect (PAE).[76] The off rate was correlated with the PAE, which in turn was incorporated into a model to predict efficacy in a mouse thigh model of infection. The first compound in the class to enter clinical trials was ACHN-975.[77] This compound was withdrawn due to inflammation at the infusion site in some phase 1 subjects.[78] It is hoped that this promising target can eventually lead to new antibacterial drugs, but no examples have yet reached late-stage clinical trials.

5.21.5 *Clostridium difficile* Infections

Over recent years, *Clostridium difficile* has emerged as an important gut pathogen that causes colitis due to the toxins it secretes. The treatment presents unique technical challenges: the therapy not only needs to target the intestinal tract but also should be pathogen

specific to avoid perturbing the normal enteric bacterial population.[79] The current oral use of vancomycin fulfills the first criterion (by virtue of its low oral bioavailability) but is suboptimal due to its lack of bacterial selectivity.[80]

5.21.5.1 Surotomycin From Daptomycin

Surotomycin **46** is a new clinical candidate that is currently in a phase III trial for the treatment of *C. difficile*-associated disease (CDAD).[81] Surotomycin **46** is a semisynthetic analog of daptomycin **45**, a natural product antibiotic (Fig. 17).[82] Granted fast-track QIDP designation in 2012, surotomycin represents a further example of the influence of the GAIN Act in support of the development of new antibacterial agents. Like daptomycin, surotomycin acts to depolarize (but not to permeabilize) bacterial membranes.[81] However, surotomycin also demonstrated less disruption of gastrointestinal microbiota and improved antibacterial activity against daptomycin-resistant strains of *E. faecium* and *E. faecalis*, as well as nonsusceptible strains of *S. aureus*.

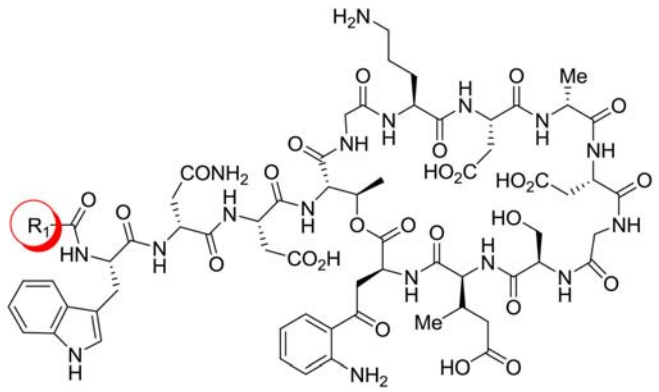
5.21.5.1.1 Cadazolid

Another approach to the treatment of CDAD is the "chimeric" molecule cadazolid **47** (Fig. 18), which bears the features of an oxazolidinone ribosome inhibitor and those of a fluoroquinolone topoisomerase-type inhibitor and has recently completed a phase 1 clinical trial.[83] Cadazolid demonstrates potent in vitro activity against linezolid (oxazolidinone)- and fluoroquinoline-resistant or nonsusceptible strains of *C. difficile*.[84,85] Mechanistically, it has been established that it acts predominantly via inhibition of protein synthesis (attributable to the oxazolidinone moiety) and to a lesser extent by interfering with DNA synthesis.

5.21.5.1.2 LFF571

LFF571 (**48**) is derived from a series of thiopeptide-based secondary metabolites that interfere with bacterial protein synthesis by inhibition of elongation factor EF-Tu (Fig. 18).[86] Through semisynthesis, the poor solubility of the lead natural product structures was dramatically improved (original lead <0.001 mg mL^{-1}) while maintaining activity against *C. difficile*.[87,88] In a phase II trial, LFF571 was generally safe and well tolerated and demonstrated noninferiority to vancomycin (clinical cure 90.6% vs. 78.3%).[88]

Overall, several new approaches to treating CDAD are moving through advanced clinical studies. It is expected that these will serve to alleviate patient suffering and decrease the hospitalization stays caused by these troublesome infections.



Cpd	R1	Name	*C. difficile* MIC_{90} (30 isolates)

5.21.6 Finding New Drug Leads

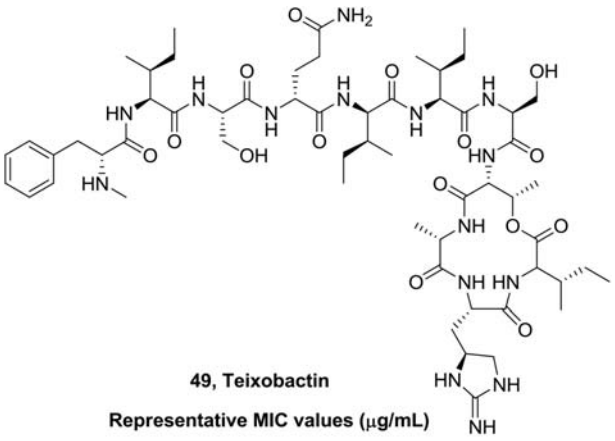
5.21.6.1 Natural Products

5.21.6.1.1 Novel screening approaches

It is estimated that 99% of microbes are "unculturable."[89] A team from NovoBiotic, Northeastern University, and the University of Bonn has developed methods to culture some of these organisms and, by doing so, isolated the novel antibacterial agent teixobactin (Fig. 19) from *Eleftheria terrae*.[90] Teixobactin has potent broad-spectrum Gram-positive activity, with MICs for most strains well below 1 μg mL^{-1}. Remarkably, no resistant strains emerged in either *S. aureus* or *M. tuberculosis* in the presence of the compound over a period of 27 days. The compound was not toxic to mammalian cells even at high concentrations (100 μg mL^{-1}) and was active in murine septicemia (*S. aureus*, PD_{50} 0.2 mg kg^{-1}), thigh (*S. aureus*), and lung (*S. pneumoniae*) models of infection. Mechanistically, the activity was attributed to binding of lipid II and lipid III, precursors of cell-wall synthesis.

5.21.6.1.2 New natural products from legacy screening approaches

Promysalin **50** (Fig. 20) is an amphipathic salicylate produced by *P. putida*.[91] Notably, it is one of the few natural products with activity reported against *Pseudomonas*: among 16 species tested, sensitive strains were found in 12. The initial report of promysalin did not identify the active stereoisomer from among the eight possible stereoisomers. A total synthesis was completed by Wuest in order to establish the stereochemistry and provide pure material for further mechanistic investigation.[92] It was assumed that the (*S*) configuration at C-16 was likely since no epimerase or thioesterase was found in the biosynthetic gene cluster. Thus, the synthetic investigation was narrowed to four stereoisomers, and all were synthesized to ultimately identify the bioactive ones (2*R*, 8*R*, and 16*S*). Further investigation identified two antivirulence phenotypes: mature biofilm dispersion and inhibition of pyoverdine production.



49, Teixobactin

Fig. 20 Promysalin, a unique natural product targeting *P. aeruginosa*.

5.21.6.2.3 New natural products with new chemistry applied

An example of an emerging class of natural products with potent Gram-positive activity is the cyclic acyldepsipeptides called enopeptins (Fig. 21).[93] Simplification of the acyl side chain present in the natural products served to improve solubility and metabolic stability, leading to ADEP4 (**53**).[94] The scaffold was further modified by a group at Brown University, incorporating methyl substituents as illustrated in **54** in order to further stabilize the hypothetical, transannular H-bond-dependent bioactive conformation.[95] These structural modifications led to a 1200-fold improvement in potency.

5.21.6.2 Screening Libraries

Being mindful of the challenges in identifying high-quality antibacterial leads from existing screening libraries,[10] Houghten and Shaw recently demonstrated that large libraries can be designed incorporating some of the key molecular properties required for cellular penetration in Gram-negative bacteria (e.g., amphiphilic and highly basic).[96] In this work (Fig. 22), the authors generated mixtures (exploiting 37 unique cores) totaling six million compounds. Using a scanning positional approach, they identified a library of 45864 individual compounds, constituted in 110 mixtures, with activity against the ESKAPE pathogens. The systematic library structure enabled efficient deconvolution, leading to a preferred series illustrated by **56**. Despite the high clogD, this compound still displays Gram-negative activity. The authors note that the potency of these molecules is limited by bacterial efflux mechanisms, and the use of an efflux pump inhibitor would improve their intrinsic activity.

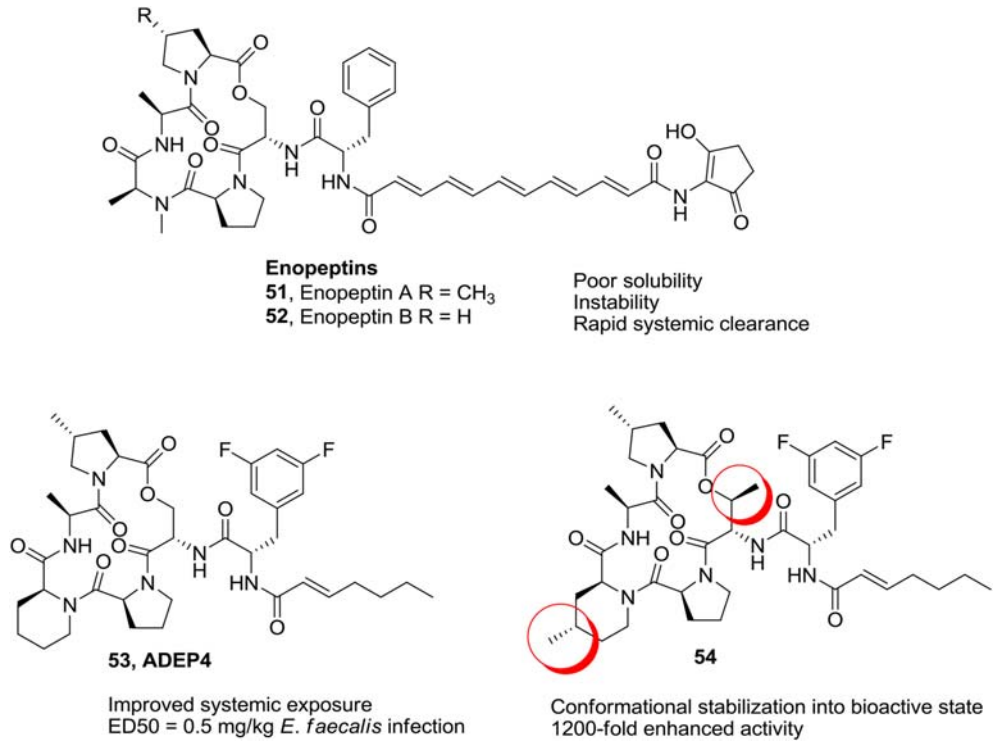

Fig. 21 Progression of enopeptins to stable and potent antibacterial lead structures.

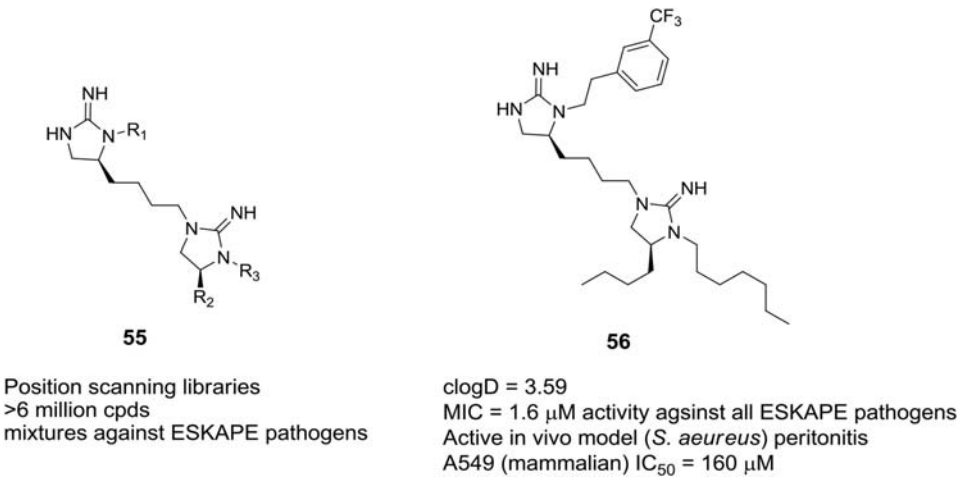

Fig. 22 Synthetic libraries leading to new Gram-negative scaffolds.

5.21.7 Nontraditional Approaches: Host Factors and Virulence Targets

The topics reviewed earlier can be considered classical antibacterial approaches in that their discovery and clinical development are based upon MICs in relevant strains as an indicator of antibacterial potential. Although the challenges in identifying new leads and drugs in this way are substantial, their path to regulatory approval is well precedented. However, diseases resulting from bacterial infections are complex and multifactorial, and modulation of host factors and bacterial gene products that affect virulence might well prove to be of clinical benefit. Unfortunately, it is the lack of clinical precedence of such approaches that makes the discovery, development, and regulatory path unclear. The reader is directed to a recent review in this area,[97] which is not addressed further here. Success against any of these types of targets might unlock significant new potential for sustained management of antibacterial diseases.

5.21.8 Conclusions

Over the past decade, clinical trends in antibacterial therapy have changed in several significant ways, and these have influenced the direction of antibacterial research as outlined earlier. Economic and regulatory incentives have helped to push new drugs forward into the clinic, which might never otherwise would have found traction. A focus on narrow spectrum agents, illustrated in particular by those directed toward infections caused by *C. difficile*, *P. aeruginosa* (POL70082), and *N. gonorrhoeae* (EXT0914), may point toward the future of the industry. The increasing rise of β-lactamases and especially MBLs requires new tools to combat these emerging outbreaks, and the discovery of DABCOs and boron-based β-lactamase inhibitors offers hope for their clinical management. It is also likely that these approaches will benefit greatly from a companion diagnostic method to enable the physician to rapidly determine the most appropriate antibiotic agent to prescribe. These new and emerging trends provide evidence of a path forward in the search for lifesaving treatments for serious drug-resistant bacterial infections.

5.22.1 Introduction to Fungal Disease

Over the last decade infectious diseases have been consistently making headlines in the world news. Whether it be the global rise of methicillin resistant Staphylococcus aureus (MRSA) and antibiotic resistance, epidemics due to SARS, Ebola, and hepatitis C or the threat of malaria and tuberculosis to the health of the world's poorest people, infectious diseases have been constantly in the global consciousness.

One group of microorganisms have had little of the global infectious disease limelight—the fungi.

This is perhaps surprising because it is estimated that 300 million people suffer from a fungal infection with up to 1.5 million deaths annually.[1] Indeed cryptococcal infections are estimated to kill over 500,000 people in sub Saharan Africa and this is as high a death toll as that due to tuberculosis, a disease which is widely recognized.

Fungal diseases can be divided into two broad categories: superficial and invasive.

Superficial fungal infections are by far the most common mycoses, with dermatophytes representing the most common fungi isolated from immunocompetent people. Dermatophyte infections occur within the stratum corneum of the skin and other keratin-containing structures such as hair and nails. Dermatophyte infections are ubiquitous and it is estimated that 20–25% of the world's population suffers from some form of dermatophyte infections, making it one of the commonest infections in humans.[2] Whilst considered trivial, dermatophyte infections can cause significant stress and psychological impact. Superficial fungal infections may require extended periods of dosing for effective treatment: for onychomycosis, treatment periods of up to 12 months are common.

Fungal infections by *Candida* species are also common, with mucocutaneous candidiasis a typical presentation.

Oesophageal candidiasis or oral thrush, is a common infection in immunocompromised patients, particularly HIV patients not receiving Highly Active antiretroviral therapy (HAART) therapy, whilst vulvovaginal candidiasis (VVC) occurs in up to 70% of premenopausal women, with 5–9% having recurrent infection.[1,3]

Serious systemic fungal infections are predominantly infections of the immunocompromised host, and increased globally in the latter half of the 20th century as a result of the enhanced use of immunosuppressive therapies in transplant and for the treatment of cancers in an aging population. Major advances in diagnostic tests for invasive fungal disease have also contributed to the increase in recording of disease.

Three genera of fungi, *Candida*, *Aspergillus*, and *Cryptococcus*, are responsible for the vast majority of invasive fungal infections.

Candida are commensal dimorphic fungi that reside on mucosa and in the gastrointestinal tract of healthy individuals. Along with superficial skin infections, *Candida* spp. can also cause life threatening invasive disease. Invasive *Candida* infections are the most prevalent systemic fungal infections worldwide, with *Candida* the fifth most common cause of blood stream infection in the United States. Mortality for candidemia approaches 40% but can be higher depending on the underlying disease.[4]

Aspergillus species are ubiquitous environmental saprophytic molds whose ecological niche is the soil, where they are important in the decay of biological matter. Aspergilli are spore-forming organisms that produce aerial reproductive structures called conidiophores, which in turn produce many smaller spores or conidia. These hydrophobic conidia are released into the air in vast numbers in order to propagate the organism, and infection occurs when they are inhaled by a susceptible host. A spectrum of disease associated with *Aspergillus* infections exists, ranging from noninvasive colonization of the upper airways, localized growth within the lung, allergic disease exacerbating preexisting respiratory disease, to full disseminated invasive infection. The extent of disease is related to the immune status of the host. Invasive aspergillosis is predominantly a disease of the neutropenic host, and people with hematological malignancies are at the greatest risk. Additionally, solid organ transplant and hematopoietic stem cell transplant recipients and patients on prolonged corticosteroid therapy are also at considerable risk.[5] Mortality of invasive aspergillosis at one time ranged from 40% to 90% dependent on the underlying medical condition responsible for the immunosuppressed state, but with the advent of modern antifungal therapy this has been reduced to 20–30%.[6]

Of the 200 species of aspergilli known, only around 20 cause infections in man and of these, four are isolated more frequently than the rest. *A. fumigatus* is by far the most common species infecting man and resistance to first line antifungal therapy is now emerging. Resistance to the azole class of antifungals is now recognized globally and carries very high mortality of over 80%.[7]

Cryptococcosis is a severe fungal infection that is primarily caused by two species of capsulated yeast, *Cryptococcus gattii* and *Cryptococcus neoformans*. The disease has been recognized for over a 100 years but the incidence has increased dramatically as a result of the Acquired immune deficiency syndrome (AIDS) pandemic with over 600,000 deaths in the Human Immunodeficiency virus (HIV) population in Africa annually.[8] *Cryptococcus* is also a disease of the immunocompromised patient, with mortalities of up to 30% in organ transplant and cancer patients.[9] Recently an outbreak of hypervirulent *C. gattii* infections occurred in north western United States in an immunocompetent patient population.[10]

At the turn of the 21st century there was a significant global decline in antiinfective drug research and development. Antifungal drug discovery was one of the most affected areas, with almost no new discovery undertaken at this time, particularly by large pharmaceutical companies. Instead discovery research became the almost exclusive remit of biotechnology companies supported in part by academia. In this period the only antifungal products to make significant progress were those already established in clinical development. A few new antifungal drug registrations did result, most notably voriconazole in 2002. At this time the echinocandins became the first new class of systemic antifungal agents to be marketed for over a decade (**Fig. 1**).

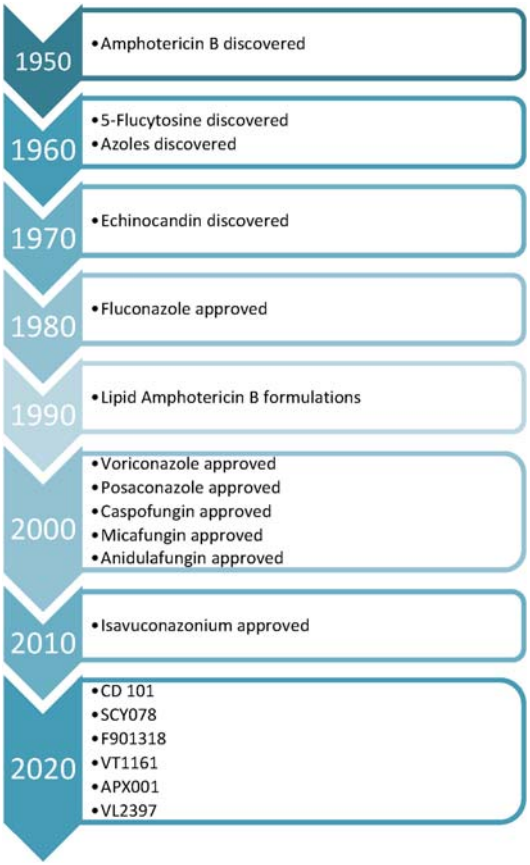

Fig. 1 Timeline of systemic antifungal drug discovery.

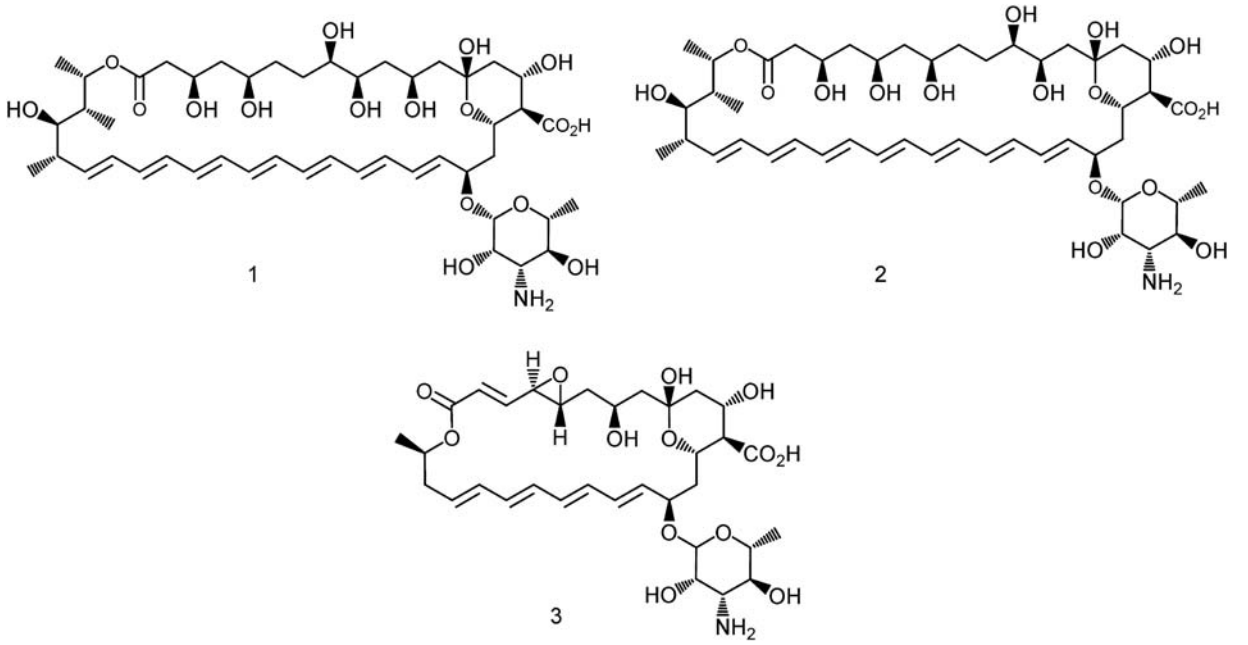

Fig. 2 **1**, Amphotericin B; **2**, nystatin; and **3**, natamycin.

5.22.2 Current Systemic Antifungal Agents

5.22.2.1 Polyenes

Polyenes are a class of broad spectrum antifungal compounds with a cyclic amphiphilic macrolide substructure which are derived from a species of *Streptomyces* bacteria.[11] The polyenes are antifungal by virtue of binding to ergosterol, which is a prevalent steroid in the fungal cell wall, resulting in depolarization of the membrane leading to increased K^+ and Na^+ permeability and ultimately cell death.[12]

The main polyene drug used in the treatment of fungal infections is amphotericin B (AmB, **1**) (Fig. 2), with other compounds within the class being nystatin (**2**) and natamycin (**3**). The polyene class possess a slight affinity for binding to human cholesterol which in turn leads to toxic effects mainly associated with the kidneys and liver.[13] The polyenes are not orally bioavailable, and nystatin (**2**) and natamycin (**3**) use is limited to treatment of fungal infections of the oral cavity. AmB is the only polyene that is dosed systemically, via intravenous (IV) infusion, with infusion-related adverse effects and dose limiting nephrotoxicity being problematic. An improved toxicity profile has been achieved through lipid and nanoparticulate formulations, which allow the administration of larger doses with a reduction in renal toxicity.[14]

Its broad spectrum of activity, encompassing both most yeasts and filamentous fungi,[15] and inherent low propensity for the development of resistance has led to AmB being widely regarded as the gold standard for the treatment of systemic fungal infections for many years.

5.22.2.2 Flucytosine

Flucytosine or 5-fluorocytosine (5-FC, **4**) (Fig. 3) was initially intended as an antitumor agent[16] but was later found to be an effective antimycotic.[17] 5-FC is transported into fungal cells by cytosine permease and the active form is only formed upon conversion into 5-fluorouracil (5-FU, **5**) by cytosine deaminase in susceptible fungal cells. 5-FU is in turn converted to active metabolites by uracil phosphoribosyltransferase, giving 5-fluorouridine monophosphate (5-fluoro-UMP) which inhibits the synthesis of fungal DNA by targeting thymidylate synthetase.[18] Further conversion of 5-fluoro-UMP to 5-fluorouridine triphosphate also perturbs protein synthesis by incorporation into fungal RNA, leading to cell death. Mammalian cells are not subjected to the toxic effects of 5-FC as they lack the requisite cytosine deaminase.[19,20]

5-FC displays good activity against *Candida* and *Cryptococcus* species, but activity against *Aspergillus* species is far more limited.[19]

5-FC is usually only dosed in combination with other antifungal agents such as AmB or an azole, as the development of resistance is a common problem when used as monotherapy.[21] 5-FC is orally bioavailable but elicits some problematic side effects such as bone marrow suppression, GI disturbances, and hepatotoxicity. It continues to be used for the initial management of severe cryptococcal pneumonia and meningoencephalitis infections[22] and (less frequently) in select invasive candidal infections.

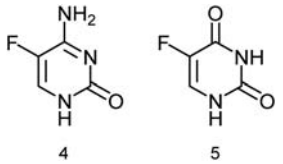

Fig. 3 **4**, Flucytosine and **5**, fluorouracil.

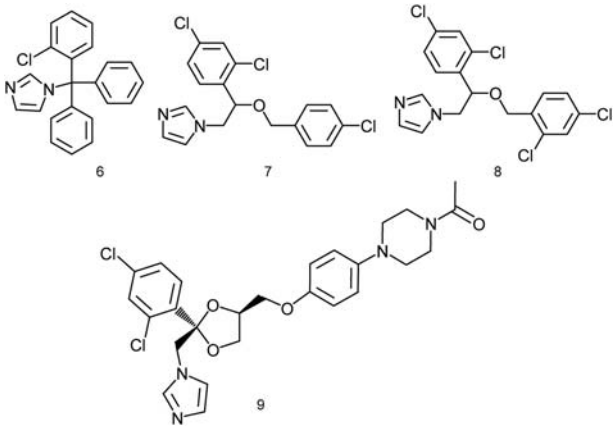

Fig. 4 **6**, Clotrimazole; **7**, econazole; **8**, miconazole; and **9**, ketoconazole.

5.22.2.3 Azoles

In recent years the azole class of antifungal compounds has been the richest source of antifungal discovery leading to new therapies for clinical use.[23] They are typified by the presence of an imidazole or triazole ring.

The azoles elicit an antifungal effect by inhibition of lanosterol 14α-demethylase, the cytochrome P450 3A enzyme that is responsible for the conversion of lanosterol to ergosterol. This has the effect of disrupting the fungal cell membrane integrity and ultimately cell death.[24,25]

The initial imidazole azole antifungals clotrimazole (**6**), econazole (**7**), and miconazole (**8**) (Fig. 4) became available in the late 1960s. However, due to their toxicity profiles their use was primarily in topical administration as an alternative to nystatin for the treatment of cutaneous and mucocutaneous dermatophyte and *Candida* infections. At the time only miconazole found an application for IV therapy for the treatment of cryptococcal meningitis and disseminated candidiasis. However significant adverse effects now limit its use to the nonsystemic treatment of oropharyngeal candidiasis, VVC and tinea corporis, and pedis and cruris infections, administered in gels, creams, and buccal patches.

In the 1980s a new imidazole azole called ketoconazole (**9**) was developed which displayed a spectrum of activity similar to miconazole but showed improved tolerability over both miconazole and AmB and therefore became the preferred treatment. However it was only available for oral administration and displayed variable absorption. Ketoconazole also displayed significant toxicity, such as a dose-dependent reduction in testosterone and cortisol levels due to inhibition of the human CYP450 enzymes required for hormone synthesis.[26,27] This and other adverse effects resulted in the Food and Drug Administration (FDA) recommending that ketoconazole be restricted to instances where alternative therapies have failed.[28]

The imidazole azoles demonstrate good activity against a number, but not all, yeast infections and no activity against mold species such as *A. fumigatus*. Currently the use of imidazole azole antifungals is limited almost exclusively to the treatment of nonsystemic infections.[29]

During the 1990s a new class of azole antifungals, the triazoles, emerged in the form of the first-generation agents itraconazole (**10**) and fluconazole (**11**) (Fig. 5). Fluconazole was the first approved for clinical use, in 1990, and represented a huge advance for the treatment of mucosal and invasive candidiasis, via IV and oral dosage forms, with an improved pharmacokinetic and safety profiles over ketoconazole. Nonetheless, the treatment of clinically important fungal infections such as aspergillosis remained a problem, as although fluconazole had good activity against many *Candida* and *Cryptococcus* spp., *C. krusei*, and *C. glabrata* are less susceptible and activity is completely lacking against molds such as *A. fumigatus*.

Itraconazole was approved for clinical use in 1992 and displayed an expanded antifungal spectrum that included the problematic molds such as *Aspergillus* species. However, the drug presented extreme challenges in formulation; oral dosage forms proved unreliable due to highly variable adsorption and the IV preparation was eventually withdrawn from use.

Despite their improved antifungal effects the triazoles, like the imidazoles, are associated with potential safety and tolerability issues. These include nausea, vomiting, diarrhea, hepatic toxicity, and QTc prolongation.[30] Drug–drug interactions are also a significant problem due to cross inhibition of a variety of the human CYP450-dependent enzymes.[31]

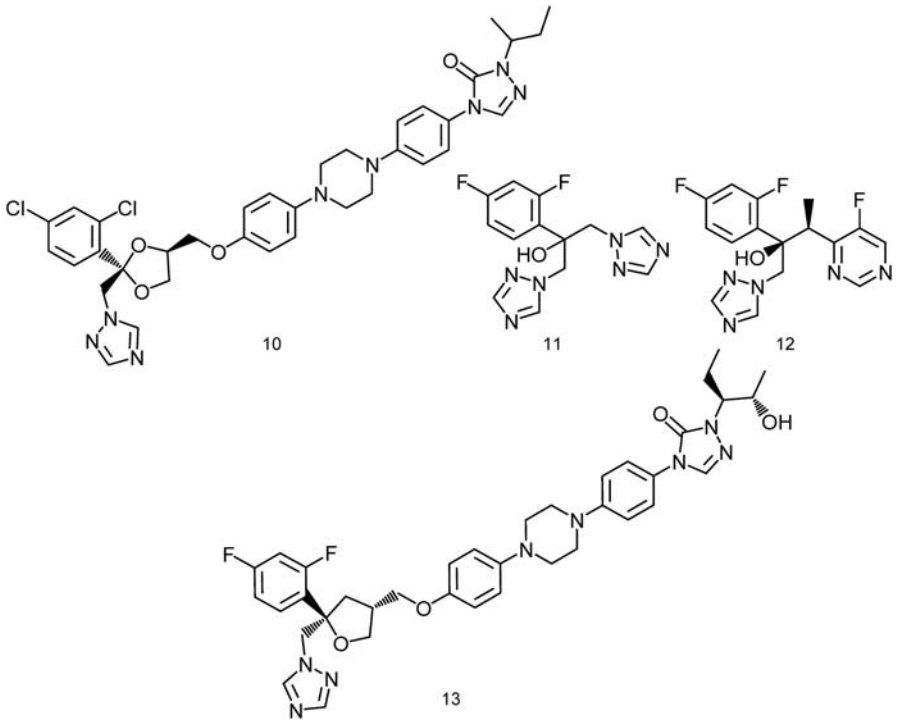

Fig. 5 **10**, Itraconazole; **11**, fluconazole; **12**, voriconazole; and **13**, posaconazole.

The second-generation triazoles, voriconazole (**12**) and posaconazole (**13**) were approved for clinical use in 2002 and 2006, respectively. These demonstrated improved antifungal spectrum, potency, and toxicity profiles over the first-generation azoles. With a 70% 12 week survival rate compared to 57% for the AmB control population,[32] voriconazole rapidly became the gold standard therapy for invasive aspergillosis but its use is associated with significant drug–drug interactions, hypervariable pharmacokinetics, and visual disturbances. Posaconazole has been shown to be effective against *Candida* spp., *Aspergillus* spp., *Cryptococcus* spp., *Zygomycetes* spp., and *Fusarium* spp. infections, with reduced inhibition of cytochrome *c*-dependent enzymes resulting in less pronounced drug–drug interactions.

The most recent triazole azole compounds to be developed are ravuconazole (**14**), albaconazole (**16**), isavuconazole (**17**), and its prodrug isavuconazonium (**18**) (Fig. 6).

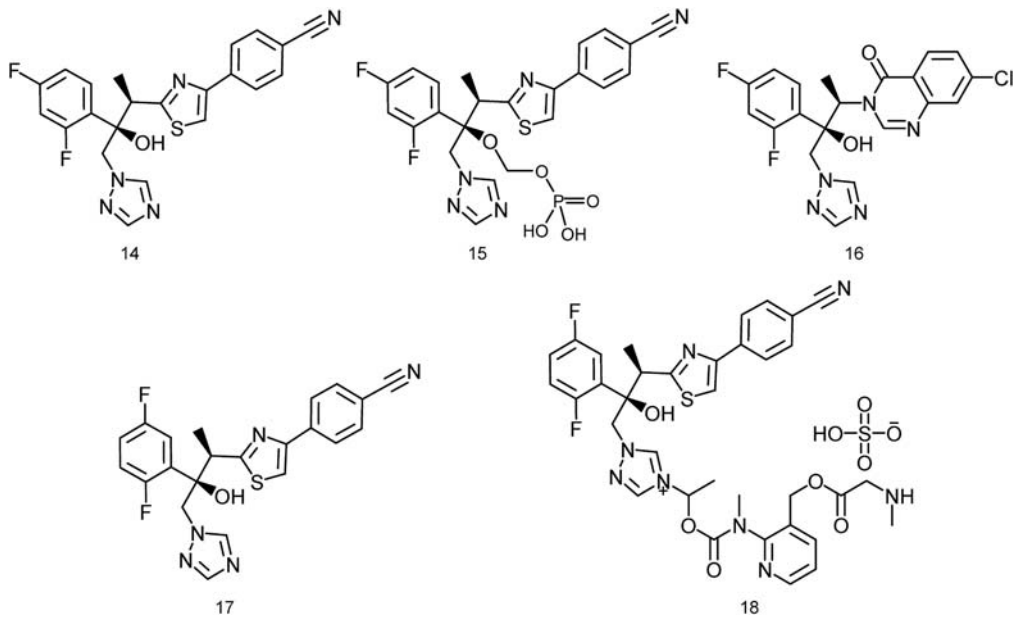

Fig. 6 **14**, Ravuconazole; **15**, BMS-379224; **16**, albaconazole; **17**, isavuconazole; and **18**, isavuconazonium.

Isavuconazonium was granted approval by the US FDA in 2015 for the treatment of invasive aspergillosis and mucormycosis. Isavuconazonium sulfate is a water-soluble prodrug of isavuconazole that is rapidly cleaved by plasma esterases upon either IV or oral administration. This is advantageous because the IV formulations for both voriconazole and posaconazole contain sulfobutyl cyclodextrins, which are implicated in nephrotoxicity. In comparison to voriconazole, isavuconazole displays a significantly lower rate of drug-related adverse events, but while drug–drug interactions are also reduced, they remain significant. Other side effects such as nausea, vomiting, and diarrhea are also common, but the visual disturbances, hallucinations, and photosensitivity witnessed with voriconazole have not been observed. The antifungal activity of isavuconazole against *Candida* spp. and some of the most common *Aspergillus* spp. is generally comparable with voriconazole and posaconazole.[33] As is common with other azoles,[34] isavuconazole suffers from a similar increase in minimum inhibitory concentration (MIC) with azole-resistant organisms through a variety of resistance mechanisms.[35]

Ravuconazole (**14**) is currently in clinical trials and is an isomer of isavuconazole. Ravuconazole is an oral agent while the phosphonooxymethyl ether derivative BMS-379224 (**15**), a much more soluble prodrug,[36] is in development for IV use. Ravuconazole displays an antifungal spectrum similar to voriconazole but with limited activity against *Fusarium* spp., *Scedosporium* spp., and *Zygomycetes* spp.[37–39]

Albaconazole (**16B**) is also in clinical trials and displays >80% bioavailability, good oral pharmacokinetics, and an antifungal spectrum that includes *Scedosporium prolificans*,[40] which is otherwise difficult to treat. Interestingly albaconazole also displays an encouraging safety profile relative to other members of the class. Albaconazole is currently in trials for onychomycosis and *Candida vulvovaginitis* and displays promising results, although natural resistance has been observed.[37,38]

5.22.2.4 Allylamines

The allylamines naftifine (**19**) and terbinafine (**20**) (Fig. 7) form a class of antifungal agents that act via inhibition of ergosterol synthesis at the level of squalene epoxidase, with minimal effects on mammalian cholesterol synthesis. The subsequent accumulation of squalene within the fungal cell leads to an increase in cell permeability, with disruption of intracellular organization and eventually cell death. The allylamines are fungicidal against dermatophytes and have fungistatic activity against *Candida* spp. Naftifine is the original member of the class and is efficacious when administered topically against superficial dermatomycoses.[41] Terbinafine can be utilized both topically and orally to treat fungal infections of skin, nails, and hair and is the drug of choice for dermatophyte onchomycosis.[42]

5.22.2.5 Echinocandins

The echinocandins are semisynthetic lipopeptides derived from the fermentation broths of fungi that are cyclic hexapeptides with N-linked acyl lipid side chains. Caspofungin (**21**), micafungin (**22**), and anidulafungin (**23**) are derivatives of lipopeptides from *Glarea lozoyensis*, *Coleophoma empedra*, and *A. nidulans*, respectively (Fig. 8).

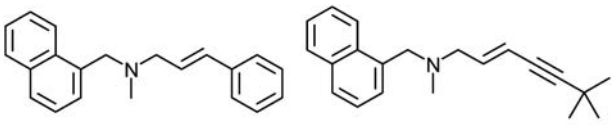
The echinocandins elicit an antifungal effect by inhibition of the synthesis of 1,3-β-D-glucan, an essential component of the fungal cell wall. 1,3-β-D-glucan is particularly prominent in the cell wall of *Candida* and *Aspergillus* species but is not present in mammalian cells, and therefore the echinocandins avoid direct human cell toxicity. They are fungicidal against *Candida* species, including those known to be intrinsically resistant to azoles and AmB, but are fungistatic against *Aspergillus* species.[43,44] Lacking oral bioavailability, all three echinocandins are administered by IV infusion. Central nervous system tissue penetration is minimal, but the echinocandins distribute extensively into other major tissues such as lung, liver, and spleen. The class is generally well tolerated, with mild adverse effects that include local phlebitis, fever, abnormal liver function tests, and haemolysis.[45] The echinocandins demonstrate an additive to synergistic effect with triazoles when used in combination therapy for the treatment of *A. fumigatus*.[46]

The development of resistance to echinocandins has been reported to arise due to the selection of either stable mutational or reversible physiological alterations.[47]

5.22.3 Notable Others

5.22.3.1 Nikkomycin Z

Nikkomycin Z (**24**) is a uridine-based secondary metabolite of *Streptomyces tendae* initially isolated in the mid-1970s and subsequently shown to inhibit the activity of fungal chitin synthase (Fig. 9). The polysaccharide chitin is an important structural



19 20

Fig. 7 **19**, Naftifine and **20**, terbinafine.

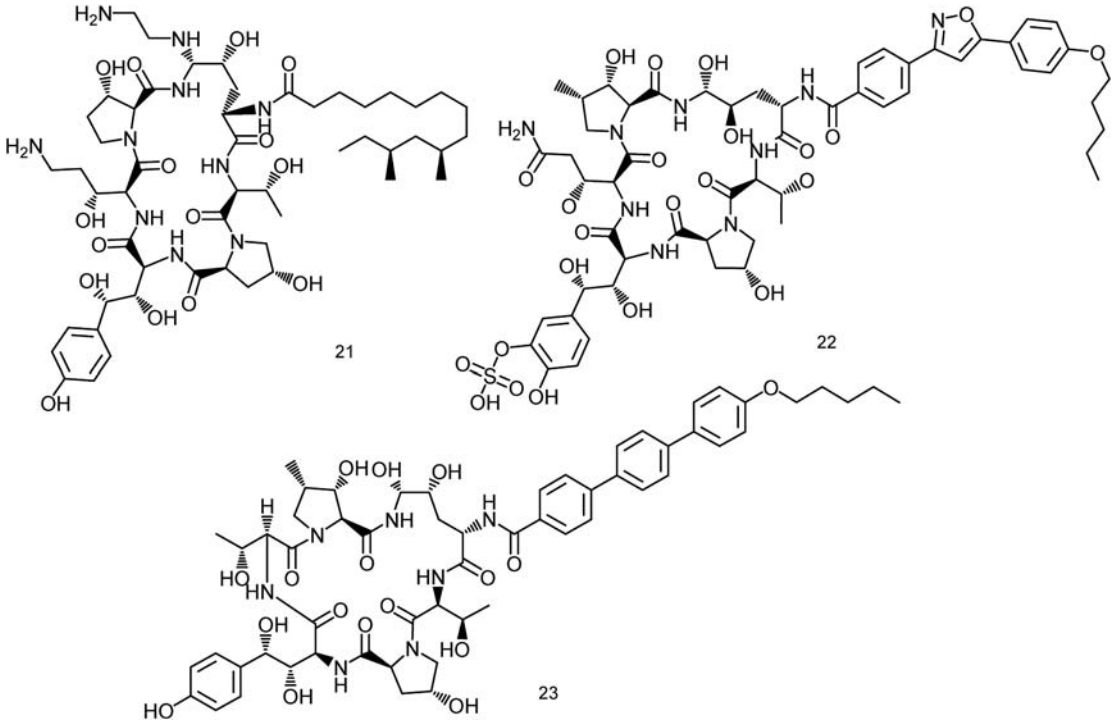


Fig. 8 **21**, Caspofungin; **22**, micafungin; and **23**, anidulafungin.

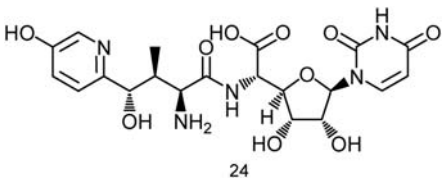

Fig. 9 **24**, Nikkomycin Z.

component of the cell wall of many fungi. Originally identified in an agrochemical fungicide program, no commercial products were developed and Nikkomycin Z became a research tool. In the late 1990s it was discovered that Nikkomycin Z had good in vivo activity against *Coccidiodes immitis*, the causative agent of Valley Fever, an endemic fungal infection occurring in Arizona. Nikkomycin Z is now under clinical development for the treatment of coccidioidomycosis[48] and has entered Phase II clinical trials. The agent is also active against other endemic fungal pathogens such as *Histoplasma capsulatum* and *Blastomyces dermatidis*. Nikkomycin displays acceptable oral bioavailability and is well tolerated with no adverse effects with doses up to 2000 mg.

5.22.3.2 Tavaborole

Tavaborole (**25**, Fig. 10) is a low molecular weight benzoxaborole derivative that is the first of its class and exploits a novel mode of action: inhibition of aminoacyl-transfer ribonucleic acid synthetase prevents fungal protein synthesis, leading to inhibition of cell growth and ultimately to cell death. Tavaborole was approved for the topical treatment of onychomycosis of the toe nail in July 2014 and has shown a favorable safety and efficacy profile.[49]

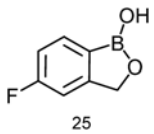

Fig. 10 **25**, Tavaborole.

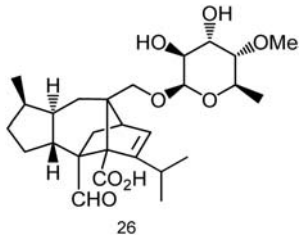
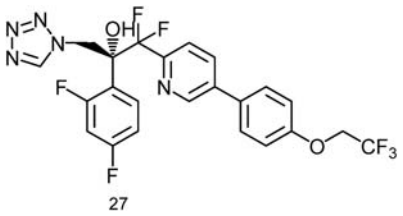


26

Fig. 11 **26**, Sordarin.



27

Fig. 12 **27**, VT-1161.

5.22.3.3 Sordarins

The sordarins are a family of compounds that have a tetracyclic diterpene glycoside substructure (Fig. 11). Unlike other antifungals that target the integrity of the fungal cell wall, the sordarins act by the inhibition of fungal protein synthesis through the inhibition of elongation factor 2.[50] With good activity against *Candida albicans* and a number of other prevalent pathogenic fungi, sordarin (**26**) and its derivatives are interesting class for future antifungal development.

5.22.4 New Antifungals in Clinical Development

5.22.4.1 VT-1161

VT-1161 (**27**, Fig. 12) is an example of a metalloenzyme inhibitor consisting of a core scaffold coupled to a metal binding group (MBG) designed to interact with the metal ion intrinsic to the target enzyme. The potency of metalloenzyme inhibitors relates to the affinity of the MBG for the metal and is a function of the electronic forces in the immediate environment. While the potency can therefore be tuned by altering the affinity of the MBG for the metal, overly strong interactions can lead to nonspecific inhibition.

Previously this principle has been well exemplified with the azoles, discussed earlier.[51] In the first-generation azoles the 1-imidazole moiety served as a high affinity MBG that was often associated with off-target side effects. In the triazole-containing second-generation azoles, the affinity of the MBG was reduced and the drugs were better tolerated, although drug–drug interactions and liver toxicity remained significant clinical issues.[52]

VT-1161 was derived from a structure-guided effort specifically targeting MBGs with lower affinity for the CYP51 iron complex. Viamet Pharmaceuticals hypothesized that the off-target effects of both imidazole and triazole antifungals were due to high affinity MBG interactions. An antifungal drug discovery program was devised to identify MBGs with reduced or differential metal affinity between human and fungal CYP51. A series of MBGs were selected in silico and ranked for their predicted affinity to the CYP51 heme–iron complex. Initially a 1-tetrazole MBG was identified as of high interest and from this a number of additional targets were modeled and tested using in vitro activity against *C. albicans* and CYP3A4 assays as primary screens.

Docking studies of the 1-tetrazole MBGs in CYP51 suggested that conserved tyrosine 118 residue could be exploited through π-stacking interactions. A series of electron-deficient 2,5-disubstituted pyridines were designed to exploit this possibility. Through these modifications, analogs were discovered with significant improvements in in vitro potency and good oral efficacy in murine models of invasive candidiasis.[52] Following further rounds of modeling and synthesis, further improvements in potency were achieved by incorporating H-bond interactions with Ser378, ultimately leading to the identification of the trifluoroethyl ether-containing analog VT-1161.

VT-1161 has high affinity for the *C. albicans* CYP51 (ERG11) with a dissociation constant K_d of $\leq$39 nm. Conversely, it did not inhibit the human CYP51 at concentrations up to 50 μM, demonstrating a 2000-fold selectivity index.[53]

VT-1161 has activity against *Candida* spp. (including azole-resistant *C. albicans* and *C. glabrata*), *Coccidiodes* spp. and dermatophytes.[54–56]

IC_{50} values against the common CYP enzymes CYP2C9, CYP2C19, and CYP3A4 are up to 10-fold higher for VT-1161 than for voriconazole, highlighting the reduced affinity for human enzymes.[53]

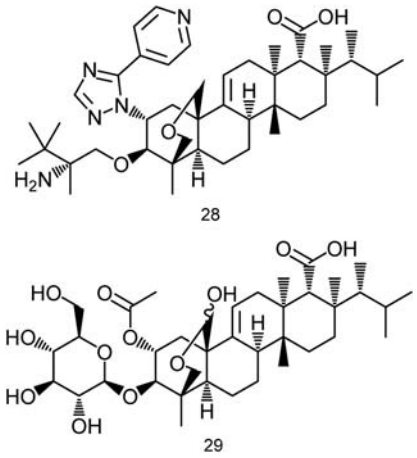


Fig. 13 **28**, SCY-078 and **29**, enfumafungin.

Recently VT-1161 has been reported to be active against the protozoan pathogen *Trypanosoma cruzi* with CYP51 dissociation constants in the region of 24 nM, and reductions in parasitemia in a mouse model of infection with a drug-resistant strain have been demonstrated.[57]

5.22.4.2 SCY-078

SCY-078 (**28**, Fig. 13) was discovered from a multiyear collaboration between Merck & Co and Scynexis. The project was focussed on the discovery and development of orally bioavailable glucan synthase inhibitors, following Merck's earlier success with the approval of the parenteral echinocandin caspofungin.

Initial chemistry was based around the work of Onishi et al.[58] who had previously identified a group of acidic triterpene compounds from a natural product antifungal screen. One of these hits, a triterpenoid glycoside named enfumafungin (**29**) had improved pharmacokinetic properties and comparable in vitro antifungal activity to caspofungin.

The semisynthetic derivatization of enfumafungin targeted improving in vivo activity and bioavailability. Considerable synthetic effort established the key structural features associated with antifungal activity, with the glycosidic ether moiety playing an essential role.[59] Replacement with an amino ether moiety and installation of the 1,2,4-triazole heterocycle at the C2 position provided significant improvement in oral bioavailability without loss of antifungal activity.[60]The resulting optimized compound was MK3118, which was renamed SCY-078 after the compound was in-licensed by Scynexis.

The spectrum of activity of SCY-078 is similar to that of the echinocandins, with potent in vitro activity across a broad range of clinical *Aspergillus* and *Candida* spp. MIC_{90} values are reported to be lower than caspofungin for SCY-078 against *C. albicans*, *C. glabrata*, and *C. parapsilosis* but higher for *C. krusei*.[61–63] Potency against a range of clinical *Aspergillus* species is significantly lower for SCY-078 than for the echinocandins with MIC_{90} values in the range 0.12–0.25 $\mu g\,mL^{-1}$ versus 0.03–0.06 $\mu g\,mL^{-1}$ for caspofungin.[61]

Mutations in the fungal glucan synthase gene (FKS) are known to cause reduced susceptibility to the echinocandins, with a corresponding reduction in clinical effectiveness.[64] SCY-078 shows enhanced activity against *C. albicans* and *C. glabrata* isolates with known FKS mutations and so represents an alternative clinical option when FKS-resistant species are identified.[65]

5.22.4.3 CD101

CD101 (**30**, Fig. 14) is a derivative of the echinocandin anidulafungin with an improved stability profile, allowing its use as a topical agent. Trials for VVC and invasive *C. albicans* are ongoing.

CD101 represents the first echinocandin candidate identified from a program aimed at developing molecules with alternate dosing routes and more flexible administration. The research was undertaken at Seachaid Pharmaceuticals, which focussed specifically on modifications of pneumocandin B, caspofungin, and anidulafungin. CD101 incorporates a modified cyclic peptide bearing a quaternized choline ether derivative. The result is an echinocandin with unique chemical and biological properties that include physical and chemical stability, high solubility, enhanced spectrum of activity and potency, extended plasma half-life, and improved safety margins.[66]

CD 101 has very favorable preclinical characteristics with minimal interaction with recombinant CYP enzymes, and no notable effects on liver enzymes. No macroscopic effects were seen in the liver following 14 day IV administration, nor were there any effects on hematology, coagulation, or urinalysis.[67,68] A notable feature is the prolonged plasma half-life, which was increased 5–10-fold in representative toxicological species over the other marketed echinocandins (Table 1). In humans, the half-life is in excess of 80 h, leading to the possibility of once weekly IV dosing.[66–68]

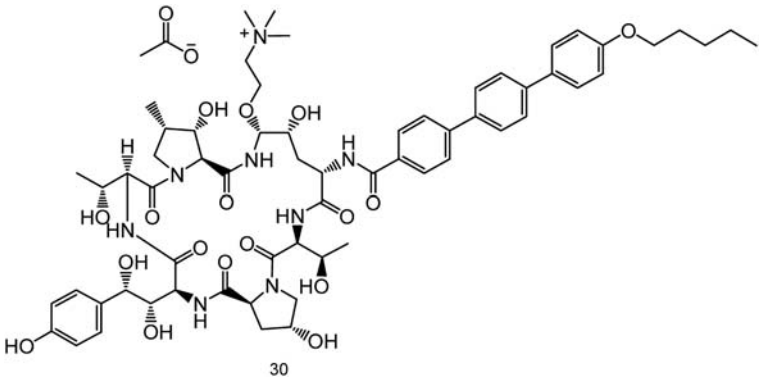

Fig. 14 **30**, CD101.

Table 1 Half-life of prior echinocandins and CD101 **30** in various species

	Half life (h)			
Species	*Caspofungin*	*Micafungin*	*Anidulafungin*	*CD101*
Rat	6–7	5	18–22	30
Dog	NA	NA	12–16	53
Monkey	5–6	NA	8	40
Chimpanzee	5–8	NA	30	81
Man	9–11	10–17	24–26	>80

CD0101 retains an antifungal spectrum similar to the existing echinocandins, with potent activity across *Candida* species comparable to anidulafungin and superior to micafungin and caspofungin.[69–71]

Phase II trials exploring the utility of CD101 (**30**), dosed IV, for the treatment of candidemia are currently being initiated, following the successful completion of Phase I studies in which no adverse effects or clinical signs were observed. CD101 is also being developed as a topical treatment for VVC.

5.22.4.4 F901318

F901318 (**31**, Fig. 15) is a pyrrole glyoxylamide derivative that is the first member of the novel orotomide class of antifungals. Discovered by classical whole cell phenotypic screening, the series was optimized iteratively with antifungal activity and pharmacokinetics driving further improvements. F901318 acts by inhibition of the fungal dihydroorotate dehydrogenase (PyrE), which catalyzes the oxidation of dihydroorotate to orotate in the de novo synthesis of pyrimidines and as such is essential for cell growth.[72] F901318 displays potent activity against clinically relevant *Aspergillus* spp. and an extended spectrum against other intrinsically resistant molds[73,74] including azole-resistant aspergilli.[74] No activity is seen against *Candida* spp., *Cryptococcus*, or the *Mucorales*.

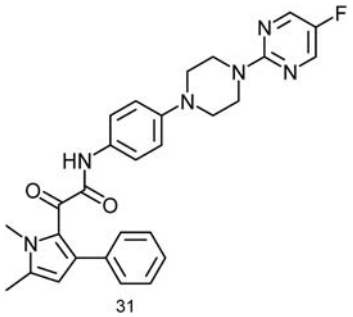

Fig. 15 **31**, F901318.

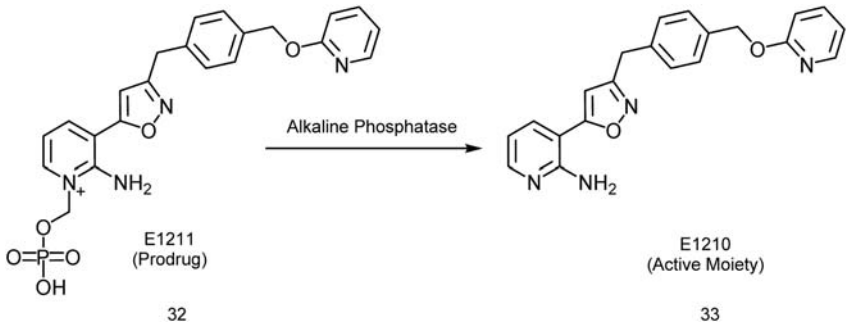

Fig. 16 **32**, E1211 and **33**, E1210.

F901318 demonstrated excellent survival rates in lethal immunosuppressed murine models of invasive aspergillosis with 100% survival at doses of 10 mg kg^{-1} dosed three times daily,[75] administered either IV or orally. The drug was well tolerated in Phase I IV studies and is currently progressing to Phase II.

5.22.4.5 E1210

E1210 (**33**, Fig. 16) was developed from an initial screening hit, 1-(4-butylbenzyl)isoquinoline, that was shown to act by the inhibition of glycosylphosphatidylinositol (GPI) anchored proteins. Further chemical optimization led to the development of the isoxazole E1210 and its corresponding phosphate prodrug E1211 (**32**).[76]

GPI anchored proteins are significant components of the cell walls of eukaryotic microorganisms, including fungi. GPI anchored cell wall proteins play a vital role in cell wall structural architecture and regeneration and are implicated in host cell adhesion.[77] E1210 specifically prevents GPI protein maturation through the inhibition of inositol acyltransferase (GWT1). The reduction in acylated inositol produces defects in the fungal cell leading to the inhibition of hyphal elongation and reduced adherence to biological substrates. The inhibition of GWT1 appears to be specific to fungi, and E1210 exhibits broad spectrum activity against yeast and filamentous fungal pathogens.

In vitro activity has been demonstrated against a range of clinically significant *Candida* species including both azole-resistant and echinocandin-resistant strains. For the majority of *Candida* species tested ($n = 154$) the MIC ranges were tightly clustered in the range 0.008–0.06 μg mL^{-1}. One species, *C. krusei*, had significantly raised MIC levels (2 to >32 μg mL^{-1}) compared to other isolates tested.[78] A lesser level of activity against aspergilli was also demonstrated. The MICs for the key species *A. fumigatus*, *A. flavus*, *A. terreus*, and *A. niger* ranged from 0.016 to 0.13 μg mL^{-1}. *Fusarium* and *Scedosporium* are genera of fungi against which current antifungals are commonly ineffective, but E1210 is highly active against the dominant pathogens in these genera including *Fusarium solani* (0.015–0.12 μg mL^{-1}) and *Scedosporium prolificans* (0.03–0.25 μg mL^{-1}).

In vivo, E1210 proved effective in treating invasive fungal infections in immunocompromised murine models infected with *Candida*, *Aspergillus*, and *Fusarium*.[76] Oral administration of E1210 twice daily at 12.5 mg kg^{-1} resulted in 89% survival in a model of disseminated candidiasis. In a lethal murine model of pulmonary aspergillosis, E1210 (**33**) at 25 mg kg^{-1} was shown to result in 100% protection. The oral bioavailability of E1210 (**33**) in these models was calculated at 57.5% and the drug was well tolerated at doses up to 300 mg kg^{-1}, with adaptive hepatocellular hypertrophy cited as the main toxicity signal.

Following out-licensing, E1210 is being developed by Amplyx Pharmaceuticals in the form of the prodrug E1211, named APX1211, presumably to increase solubility for the purposes of enhancing oral bioavailability.

5.22.4.6 VL-2397

VL-2397 (**35**, Fig. 17) (formerly ASP2397) is a novel IV antifungal agent currently in Phase I development. The compound was initially identified from a natural product library using whole cell screening aimed at finding novel molecules with antiaspergillus activity. The compound is structurally related to the cyclic hexapeptide siderophore ferrichrome (**34**) and was isolated from an environmental isolate of the fungus *Acremonium*.

The antifungal spectrum of VL-2397 includes both filamentous fungi and yeasts but the agent cannot be considered truly broad spectrum due to significant species gaps. For example, in vitro activity has been demonstrated against clinical aspergilli including *A. fumigatus*, *A. terreus*, and *A. flavus* with MIC values in the range 0.06–16 μg mL^{-1}, but the MIC against *A. niger* is >16 μg mL^{-1}. Similarly activity is reported against *C. glabrata* (MIC < 2 μg mL^{-1}) but other clinically significant *Candida* spp. including *C. albicans* have considerably reduced susceptibility (MIC > 16 μg mL^{-1}). *A. fumigatus* strains with the G54E and M220K CYP51A mutations were resistant to VL-2397 (**35**).[79,80] The limited breadth of activity across *Aspergillus* species may prove to be a limitation clinically, as precise species diagnosis is rarely available at the start of antifungal therapy. Interestingly in the presence of human serum the MIC activity range for *Aspergillus* spp. is increased for some species.

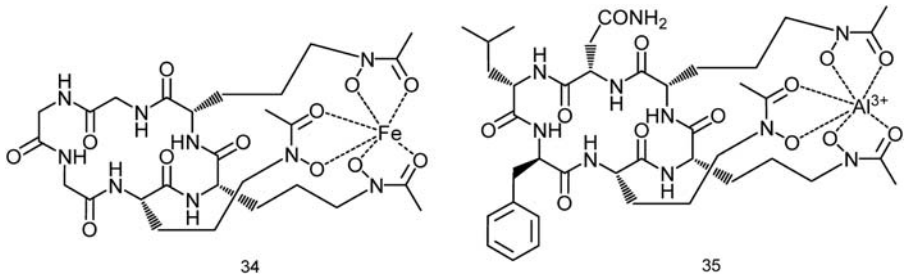

Fig. 17 **34**, Ferrichrome and **35**, VL-2397.

The antifungal activity of VL-2397 is rapid and results in the arrest of hyphal elongation in germinated conidia. VL-2397 is fungicidal with a two Log_{10} reduction in fungal organ burden observed in murine infection model werethe exposure was four times the MIC after 48 h. Uptake studies have shown that VL-2397 is actively transported by the aspergillus siderophore transporter SIT1 and that it accumulates within hyphae. UV mutant strains that are resistant to VL-2397 can be restored to sensitivity by the addition of extra chromosomal copies of SIT1. Conversely, mutation in the SIT1 transporter confers resistance. Thus uptake phenomenon alone is insufficient for an antifungal effect, suggesting an alternate intracellular target exists.

VL-2397 showed excellent survival benefit at doses of 4 and 8 mg kg^{-1} twice daily in both azole susceptible and azole refractory murine models of invasive aspergillosis. Survival correlated with lung tissue burden reductions of 1–2 log_{10} and reductions in lung inflammation and necrosis. At a dose of 8 mg kg^{-1} BID, VL-2397 demonstrated superior survival over other existing antifungals in a delayed treatment mode. The compound also showed no antagonistic effect when dosed with posaconazole in combination therapy studies.[79,80]

5.22.5 Summary

Systemic antifungal drug discovery and development has historically lagged behind that of antibacterials. Numerically, the number of systemic antifungal infections is low and would rank as an orphan disease indication for all species causing disease, and in the last century mortality rates from invasive candidiasis and invasive aspergillosis infections approached 80%.

The turn of the 21st century saw the introduction of third-generation azoles such as voriconazole and posaconazole which transformed treatment for invasive aspergillosis, reducing mortality rates considerably. Similarly, the introduction of the echinocandins provided an effective alternative treatment for invasive candidiasis, again reducing mortality. These two classes of agents along with AmB remain the totality of the antifungal armamentarium for systemic fungal infections. The emergence of global resistance within the aspergilli, increasing year on year, has cast doubt on the future of the azoles as a frontline therapy. Similarly changes in the epidemiology and the emergence of echinocandin resistance have led to reduced effectiveness of current agents for the treatment of candidiasis. Given that only three classes of antifungals are used to treat these diseases, new agents with alternate mechanisms are desperately needed.

Antifungal drug research and development has entered a new era with multiple new compounds in clinical development. Several target known mechanisms, for example, VT-1161, SCY-078, and CD101, and these agents may overcome the resistance issues seen with current agents. Other compounds in development are new chemical classes and act via completely new mechanisms. By inhibiting new cellular targets, F901318, APX001, and VL-2397 have the potential to make a bigger therapeutic impact, particularly against infections where current agents are of little use.

5.23.1 Introduction

Parasitic infections are estimated to lead to over 2 million deaths per year and account for close to 200 million disability-adjusted life years.[1] Though endemic in all countries and regions of the world, parasitic infections are disproportionately problematic in regions of poverty, where they have been associated with limiting rates of economic development. While a great diversity of organisms are known to be responsible for parasitic infections, it is generally appreciated that monocellular protozoans and multicellular helminths compose the majority of species of interest. In the protozoan class, several classes dominate the landscape of public attention—apicomplexans such as *Plasmodium falciparum* and *Cryptosporidium parvum* as causative agents of malaria and diarrhea, respectively; kinetoplastids such as *Trypanosoma cruzi* and *Leishmania donovani* as causative agents of Chagas disease and visceral leishmaniasis, respectively; and amoebas such as *Giardia lamblia*, also a causative agent of diarrhea. A great diversity of helminth infections have been documented and can be grouped into those caused by roundworms (nematodes)—flatworms (trematodes) or tapeworms (cestodes). Given the diversity of helminths that are known to infect humans, it is not surprising that the organs targeted by and consequences of such infections are also quite diverse, ranging from gastrointestinal infections leading to discomfort and diarrhea to infections of the central nervous system (CNS) leading to neurological damage and death.

Routes of infection by parasites, whether protozoan or helminth, are also quite varied, ranging from transmission by insect vectors, to ingestion from contaminated food or water supplies, to infection through mucosal surfaces or open wounds. In addition, some parasitic infections can be passed from mothers to their unborn children through placental blood transfer or from individual to individual via transfusion of infected blood.

Medicinal chemistry strategies to discover new treatments for parasitic infections are similarly diverse, with several recent developments in both societal perspective and science impacting the nature of work in this area. From the social perspective, increased public awareness of the plight of people in underdeveloped parts of the world to be disproportionately affected by parasitic infections has prompted the establishment of a geographically and financially broad range of philanthropic organizations that provide funds for drug discovery projects to address these classically "neglected" diseases.[2] Similarly, governments across North America, Europe, and Asia have expanded funding of work in support of drug discovery for diseases of the developing world, and product development partnerships (PDPs) such as Medicines for Malaria Venture (MMV), the Drugs for Neglected Diseases Initiative (DNDI) and the Global Alliance for TB Drug Development have emerged as mechanisms for coordination of efforts across the globe to ensure efficient utilization of the limited funds available for these diseases.

Scientifically, advances in the ability to determine the sequence of the entire complement of genetic information in a rapid and cost-effective manner have allowed for identification of biochemical targets for a number of parasitic organisms. Increases in speed of sequencing, coupled with advanced bioinformatic approaches for comparison of drug-resistant mutant parasites, for example, have increased the ability of drug discovery teams to deconvolute results from phenotypic screening of compound libraries to identify the molecular target of known and potential drugs, thus providing new approaches to design of selective antiparasitics. These

advances, in conjunction with renewed interest in utilization of natural products and biodiversity, have provided drug discovery teams with previously unexplored classes of molecules for optimization. Another trend in the discovery of new antiparasitic drugs is the growing emphasis on repurposing existing drugs from other human disease targets for these infections. This interest is, in part, due to the increased understanding of potential biochemical targets for antiparasitics as a consequence of the genetic sequencing efforts described in the preceding text, but is also a consequence of the perception that progression of these drugs to clinical trials may be quicker and less costly than *de novo* design of new chemical entities.

Taken together, these changes in public perception and scientific capacity bode well for the future discovery and development of new antiparasitics. The future does indeed look bright for addressing the significant unmet medical need in this area. This article will highlight some of the more recent approaches and advances for both protozoan and helminth infections.

5.23.2 Protozoans

5.23.2.1 Apicomplexans

The apicomplexan phylum of protozoa is characterized by the presence of an organelle (the apicoplast) that is likely derived from an endosymbiotic relationship between the parasite and a bacterium and/or algae in the ancient past.[3] As the apicoplast is unique to the parasite, it has been considered to be a potential target for drugs that could have potent antiparasitic activity while exhibiting minimal effects on the mammalian host.[4] Of the apicomplexans, *Plasmodium* species are the most extensively characterized and addressed by drug discovery efforts, as they are the causative agents of malaria, which is responsible for approximately 500,000 deaths per year.[5]

Toxoplasma gondii is also a widely distributed apicomplexan parasite with significant impact on both humans and animals. In the United States alone, it has been estimated that over 1 million people are infected with this parasite each year.[6] While otherwise healthy people exhibit minimal symptoms when infected with *T. gondii*, immunocompromised individuals can suffer from significant neurological impairment[7] and ocular disease.[6,8] In addition, pregnant women infected with *T. gondii* are at risk for miscarriage and can pass the infection to their unborn child.[9]

Like *Toxoplasma*, the apicomplexan parasite *Cryptosporidium parvum* is widely prevalent across the globe and results in persistent diarrhea in children and immunocompromised patients[10] and is the second leading cause of death due to diarrhea in children.[11] In addition to the acute consequences of diarrhea, infection with *Cryptosporidium* in children has been associated with impaired cognitive function and reduced growth rates.[12]

Treatment options for individuals infected with these parasites are often limited, and most treatments suffer from suboptimal efficacy and toxicity profiles. In the case of malaria, resistance to existing treatments has become a major challenge in many parts of the world.[13] For toxoplasmosis and cryptosporidiosis, very few new drugs have been discovered or developed due to the lack of financial incentives and commercial market potential. Therefore, treatment of these diseases is addressed through the use of older agents.[14]

5.23.2.1.1 Plasmodium

Significant advances in the treatment of malaria have occurred over the past decade, though emergence of resistance to even the newest treatment options continues to be a significant and emerging problem.[13,15] For example, the development and use of artemisinins (**Fig. 1**), semisynthetic drugs derived from a natural product from the plant *Artemisia annua*,[16] were widely viewed as a large step forward in the early 2000s, but by 2006, it was clear that monotherapy with these drugs was resulting in emergence of resistance, and the WHO actively promoted development of combination therapy approaches.[17]

In response to this need, several artemisinin combination therapies have been developed and are currently available to patients as summarized in **Table 1** and **Figs. 1** and **2**.

Even with these combination therapies, resistance continues to develop, and additional new chemical entities are required to provide long-term treatment options.[23] Fortunately, several new strategies, through both exploration of novel mechanisms of action and repurposing of existing drugs, provide promise for continued expansion of the armamentarium of antimalarials.

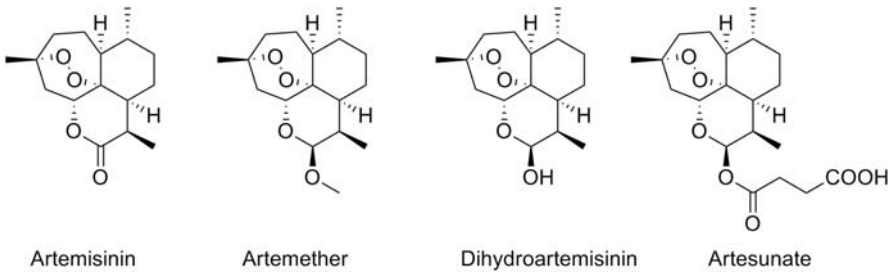

Fig. 1 Artemisinins used to treat malaria.

Table 1 Artemisinin combination therapies approved for treatment of malaria

Product	*Artemisinin component*	*Partner drug*	*Approval date*	*Partners*	*References*
Coartem	Artemether	Lumefantrine	2001/2009	Novartis, MMV	18

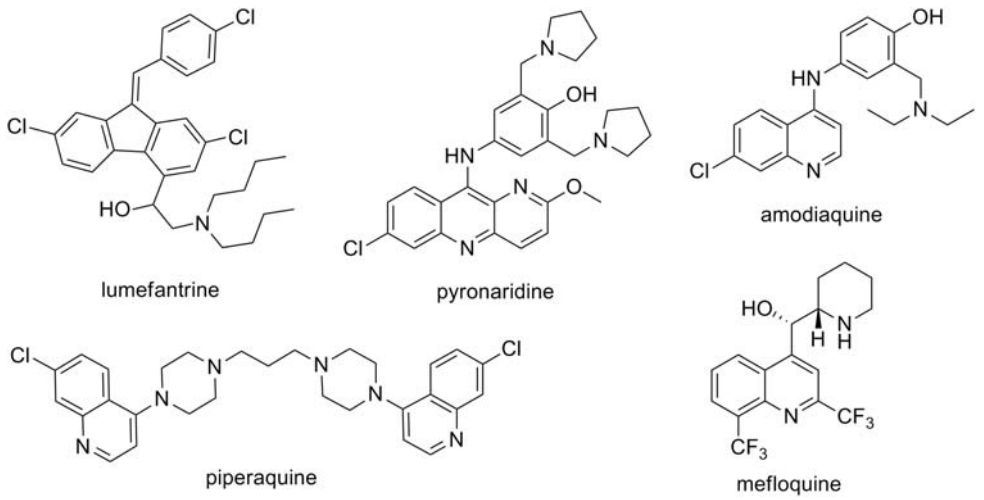

Fig. 2 Molecules used in combination with artemisinins for treatment of malaria.

5.23.2.1.1.1 Synthetic peroxides

Building on the success of artemisinins, which are semisynthetic molecules based on a natural product core containing an endoperoxide, a multinational drug discovery team—including medicinal chemists at the University of Nebraska—began exploration of fully synthetic endoperoxides as potential antimalarials. Early work in the dispirotrioxolanes focused on very lipophilic analogs that contained a sterically demanding adamantane core to provide highly potent compounds with modest pharmacokinetic properties (Fig. 3).[24] Attempts to reduce lipophilicity and increase oral bioavailability while maintaining good antimalarial potency were generally successful, with piperidines,[25] aminomethylcyclohexanes,[26] and aminoalkylcarboxamides[27] all demonstrating improved "drug-like" properties relative to the original leads. The first compound from this class that was progressed to clinical trials was

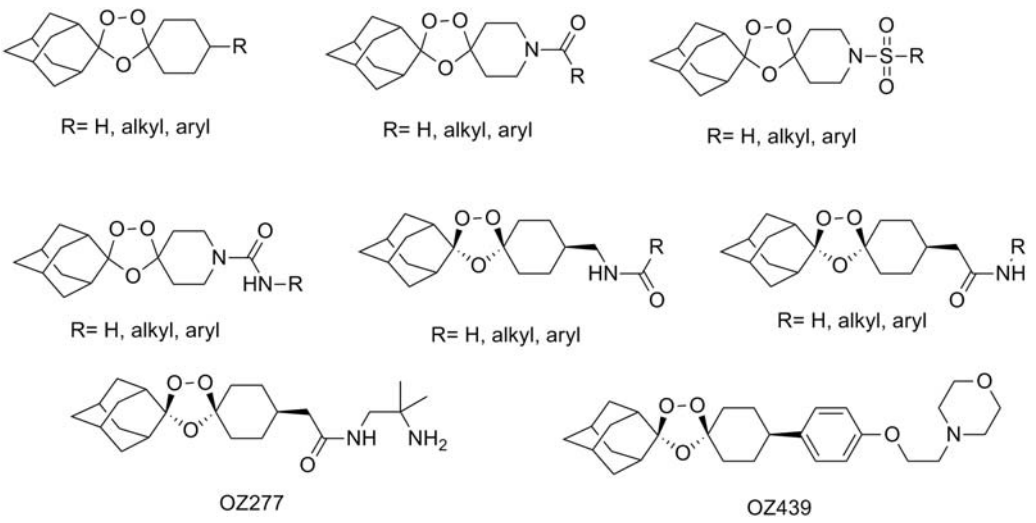

Fig. 3 Synthetic trioxolane peroxides for malaria.

OZ277, which exhibited excellent potency, bioavailability, and safety in preclinical models.[28] After successful completion of phase I trials, OZ277 was evaluated in patients, where it was found to have a threefold lower exposure compared with that seen in healthy volunteers, a difference that was attributed to instability of OZ277 due to high levels of free iron in the blood of infected patients.[29] Consequently, efficacy as a monotherapy was not as high as anticipated, which prompted further evaluation of OZ277 as a combination therapy with the known antimalarial piperaquine.[30] In parallel, further exploration of the dispirotrioxolanes identified the morpholine analog OZ439, which demonstrated improved pharmacokinetics in both animal models and human volunteers.[31] With this improved exposure, OZ439 has been evaluated in an open label phase IIa trial in patients infected with uncomplicated *P. falciparum* or *P. vivax* malaria, where it demonstrated significant parasite reduction rates and a favorable safety profile.[32] Further human clinical trials are under way to establish its potential as a single-dose cure for malaria.[33]

5.23.2.1.1.2 Spiroindolones

Through whole-cell phenotypic screening, a series of spiroindolones was discovered by a team at the Novartis Institute for Tropical Diseases as having activity against cultured intraerythrocytic *P. falciparum*. Initially synthesized as a mixture of isomers, it was quickly determined that the antimalarial activity was found in only the 1*R*,3*S* diastereomer (**Fig. 4**).[34] The result of the initial SAR exploration of this series, which focused on improvements in physicochemical and pharmacokinetic properties, was the identification of NITD609.[35] Subsequently renamed KAE609 (or cipargamin), this compound was progressed to clinical trials in human volunteers, where it was shown to exhibit approximately dose-proportional pharmacokinetics following single or multiple doses.[36] In a phase IIa study in patients infected with either *P. falciparum* or *P. vivax*, KAE609 was found to rapidly clear parasitemia following administration of 30 mg kg^{-1} for 3 days.[37] Evidence has been presented for the cation ATPase PfATP4 as the likely biochemical target for KAE609, offering the potential for discovery of additional chemical scaffolds as antimalarials.[38]

5.23.2.1.1.3 Imidazolopiperazines and imidazolopyrazines

A second series of compounds to emerge from large-scale screening efforts at Novartis were the imdazolopiperazines (**Fig. 5**). The initial leads from the HTS,[39] which contained metabolically sensitive functionality on the imidazolopiperazine core including a 3,4-methylenedioxoaniline, exhibited good *in vitro* potency but poor oral bioavailability.[40] Modification of the substituents at C(2), N(3), and N(7) of the imidazolopiperazine core afforded analogs with improved metabolic stability, good oral exposure, and *in vivo* efficacy in a *P. berghei* mouse model, but micromolar affinity for the hERG channel was perceived as a liability. This liability

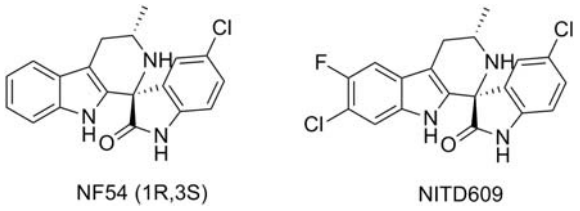

Fig. 4 Spiroindolones for treatment of malaria.

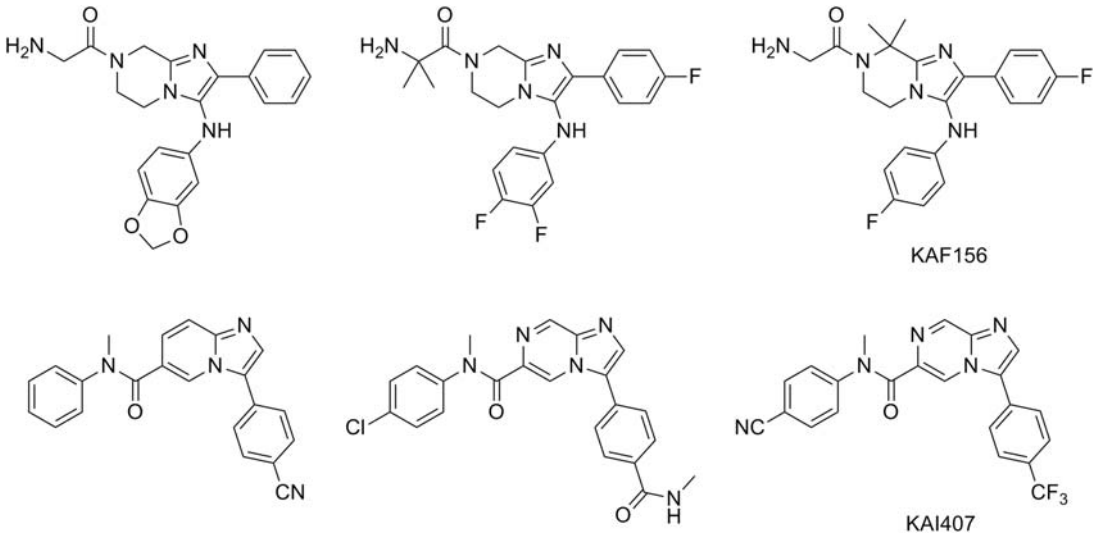

Fig. 5 Imidazolopiperazines and imidazolopyrazines identified by Novartis HTS.

was overcome through introduction of methyl groups at C(8) of the core, which also improved potency and oral exposure.[41] From these efforts, the clinical candidate KAF156 has been identified; this compound has demonstrated potent *in vivo* efficacy as well as activity against multiple stages of the *P. falciparum* life cycle.[42] Initial studies on parasites selected for resistance to KAF156 have suggested a novel protein target for this compound, designated PfCARL, though further work remains to confirm the exact role of this protein in the mechanism of action of KAF156.[42]

From the same HTS effort, a structurally similar series of imidazopyridines was identified (Fig. 5) that were of modest potency against blood stage parasites but were found to have activity against liver stage parasites.[43] Optimization of this class through variation of the C(3) aryl and C(5) amide substituents, accompanied by "scaffold hopping" to the imidazolopyrazine core, provided compounds with good physicochemical and pharmacokinetic properties and *in vivo* activity against the liver stage of the malaria parasite.[44] Selection of parasites resistant to one of the leads in this series, KAI407, has resulted in the identification of phosphatidylinositol-4-OH kinase (PI(4)K), a lipid kinase, as a likely target of this class of compounds.[45]

5.23.2.1.1.4 Benzoxaboroles

A new class of boron-containing agents, the benzoxaboroles, has demonstrated considerable utility as antiparasitics (vide infra), including activity against malaria. From a phenotypic whole-cell screen, a series of 7-carboxyethylbenzoxaboroles was identified as having submicromolar activity against *P. falciparum*.[46] Early SAR suggested that a carboxylic acid or acid isostere was required for activity, as amides, ketones, and esters were essentially inactive. Continued exploration of the series demonstrated that the boron-containing heterocycle was essential for activity, and minor modification of the substituents improved potency.[47] In addition to this series, the Anacor group has recently reported exploration of a series of 6-(hetero)aryloxybenzoxaboroles (Fig. 6) as antimalarials.[48] In the latter series, the parent carboxylic acids as well as esters and amides were found to be potent *in vitro*, with several compounds demonstrating good pharmacokinetic profiles and *in vivo* efficacy following oral administration.[48] To date, no definitive data on the biochemical target(s) of these boron-containing compounds have been reported.

5.23.2.1.1.5 Quinoline carboxamides

Screening of a kinase scaffold library against *P. falciparum* by scientists at the University of Dundee identified a 2,6-disubstituted quinolone carboxamide (Fig. 7) as a lead antimalarial. Optimization of this lead through modification of the amide substituent and incorporation of a solubilizing group on the C(2) aryl group led to the identification of DDD107498, which has been progressed to preclinical status.[49] Generation of drug-resistant parasites, followed by genomic sequencing studies identified *P. falciparum* translation elongation factor 2, which is essential for protein synthesis in the parasite as a potential target of this class.

Taken together, these efforts from a broad range of academic and industrial laboratories demonstrate the value of phenotypic screening coupled with genetics-based target identification to discover new scaffolds and mechanisms of action for treatment of malaria. Extension of these strategies to other parasitic diseases is ongoing.

5.23.2.1.1.6 Dihydroorotate dehydrogenase inhibitors

In contrast to the structural classes described in the preceding text that were initially identified from phenotypic screens, another strategy that has also been successful in identification of antimalarial leads has been to target specific essential enzymes in the *P. falciparum* life cycle. One such example is dihydroorotate dehydrogenase (DHODH), the rate-limiting enzyme in the pyrimidine biosynthesis pathway.[50] As the malaria parasite cannot salvage pyrimidine bases or nucleosides from the environment, *de novo*

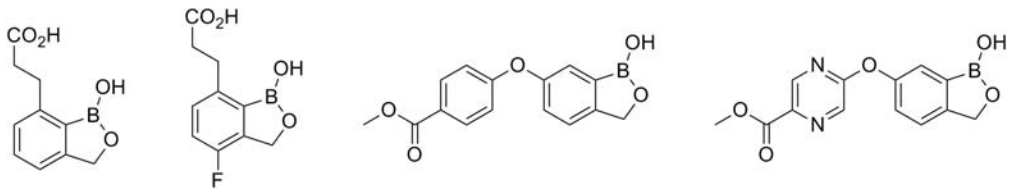

Fig. 6 Benzoxaboroles for malaria.

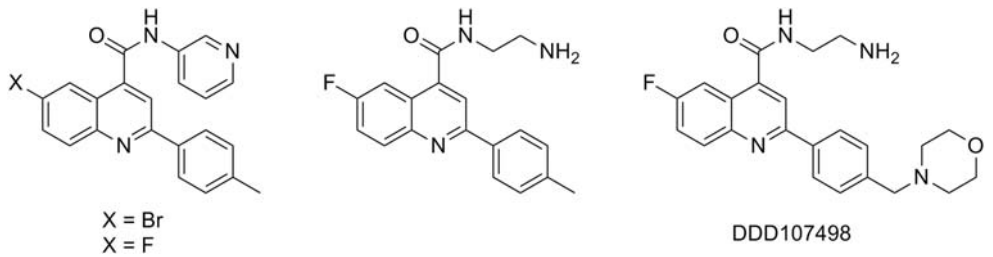

Fig. 7 Dundee quinolone carboxamide antimalarials.

biosynthesis is essential, and inhibition of DHODH has been shown to be an effective approach to killing the parasite. Following cloning and expression of *P. falciparum* DHODH, high-throughput screening of a chemical library identified hundreds of starting points for lead optimization.[51] Early hits from this screen were compromised by poor activity in whole-cell assays, but a series of triazolopyrimidines was found to address this limitation.[52] Initial optimization focused on improvement of metabolic stability and identified the 4-trifluoromethylphenyl analog DSM74 (**Fig. 8**) as an attractive lead that exhibited good pharmacokinetics and *in vivo* efficacy in a mouse model of malaria.[53] Further optimization of this lead resulted in the identification of DSM265, which has been found to have low plasma clearance and a long half-life in preclinical species, as well as an attractive profile in preclinical safety studies.[54] DSM265 has progressed to phase I clinical trials.

5.23.2.1.2 Toxoplasma

5.23.2.1.2.1 Repurposing of antimalarial and anticancer drug candidates

Among foodborne parasitic pathogens, *T. gondii* is estimated to affect the largest number of patients and cause the largest number of hospitalizations and deaths annually in the United States.[55] Given the taxonomic similarity to *Plasmodium*, it is not surprising that compounds demonstrated to have antimalarial activity have been explored for toxoplasmosis. For example, workers in Cameroon have recently reported screening of the MMV Malaria Box[56] in an *in vitro* phenotypic assay and identified a number of hits including the piperidine acetamide shown in **Fig. 9**.[57] In another example of repurposing of a *P. falciparum*-active compound for use against *Toxoplasma* infections, the spiroindolone NITD609 was found to be a cidal inhibitor of *T. gondii* in both *in vitro* and *in vivo* models.[58]

Quinolines, and in particular aminoquinolines, have been well described as antimalarials. Screening of a number of aminoquinolines originally prepared as potential anticancer agents has identified a number of analogs as potential starting points with nanomolar activity against *T. gondii*.[59] Another anticancer agent, gefitinib, has also shown weak activity against *T. gondii* and has been suggested as a repurposing candidate.[60]

A final repurposing approach for *T. gondii* activity has focused on the FDA-approved rheumatoid arthritis drug auranofin.[61] This compound, a complex of gold, has been demonstrated to reduce growth of the parasite both *in vitro* and *in vivo*. While the biochemical target of auranofin in *T. gondii* has not been rigorously established, it is likely that it acts through inhibition of thioredoxin reductase, as this has been shown in a leukemia cell line[62] and *Schistosoma mansoni*,[63] as has inhibition of the related glutathione reductase in *Leishmania infantum*.[64]

5.23.2.1.2.2 Kinase inhibitors

With the availability of genome sequences for a variety of apicomplexan parasites, including *T. gondii*, classes of protein targets with utility for drug discovery across other areas have been a popular focus of efforts in this field. One such class is kinases, which have shown great promise in diverse therapeutic areas and provide opportunities for treatment of toxoplasmosis.[65] A particular kinase

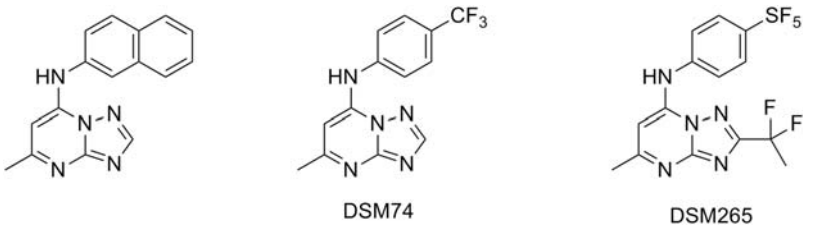

Fig. 8 Triazolopyrimidine DHODH inhibitors.

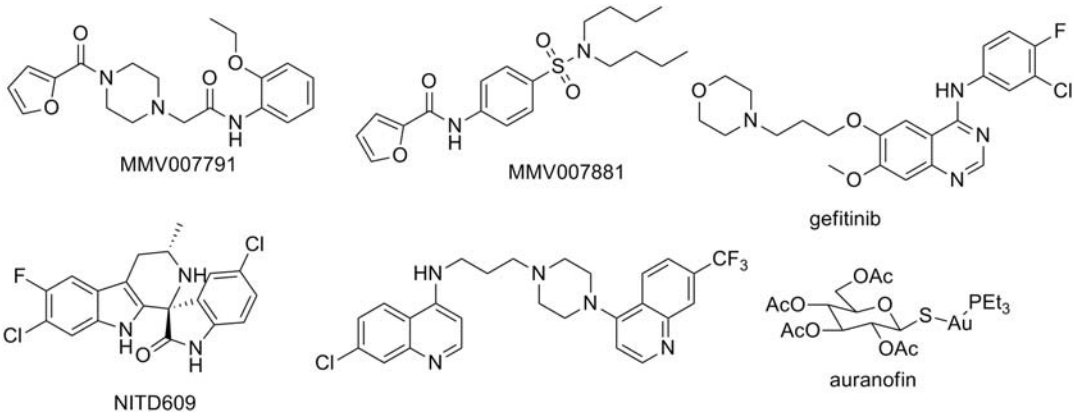

Fig. 9 Lead compounds active against *T. gondii*.

that has yielded promising leads for the latter is the *T. gondii* calcium-dependent protein kinase 1 (TgCDPK1).[66] Careful analysis of the crystal structure of TgCDPK1 revealed that a small but significant difference between this kinase and representative mammalian kinases of the same class provided an opportunity for design of parasite-specific inhibitors.[67] Based in part on early work on pyrazolopyrimidine scaffolds identified as inhibitors of Src-family kinases,[68] a series of potent and selective inhibitors of TgCDPK1 (and the related enzyme from *C. parvum*; see section "Kinase inhibitors"), depicted in **Fig. 10**, were identified and termed "bumped-kinase inhibitors."[69] Optimization of this series of pyrazolopyrimidines has led to the advanced lead BKI1294, which has efficacy following oral administration in a murine model of toxoplasmosis.[70] A second series of benzoylbenzimidazoles has also been described as inhibitors of TgCDPK1 (**Fig. 10**).[71]

5.23.2.1.3 Cryptosporidia

In comparison with the aforementioned apicomplexan parasites, drug discovery efforts for cryptosporidiosis have been less well developed, with only a small number of advanced leads and repurposing candidates having been identified. Recently, a cell-based HTS assay for *C. parvum* has been developed and used to screen both a library of FDA-approved drugs[72] and the open-access Malaria Box.[73] From the FDA-approved drug library, a particularly interesting outcome was identification of a number of approved HMG-CoA reductase (HMGR) inhibitors (**Fig. 11**) that exhibited low micromolar activity against *C. parvum*.[72] Bioinformatic analysis of the *C. parvum* genome suggested that it was unlikely that the HMGR inhibitors were directly inhibiting parasite growth, but were inhibiting production of isopentenyl pyrophosphate (IPP) in the mammalian host cell, which is an essential nutrient for the parasite. This hypothesis was supported by biochemical studies that showed that the parasites could be protected by addition of IPP to the growth medium.[72] Screening of the malaria box library identified several potential starting points for lead optimization, the most explored of which was a series of quinolinols (**Fig. 11**) that exhibited submicromolar potency.[73]

5.23.2.1.3.1 Kinase inhibitors

As *C. parvum* and *T. gondii* are phylogenetically closely related, it should not be surprising that targets identified in one parasite would be attractive in the other. Such is the case with the calcium-dependent protein kinase inhibitors such as BKI1294 discussed

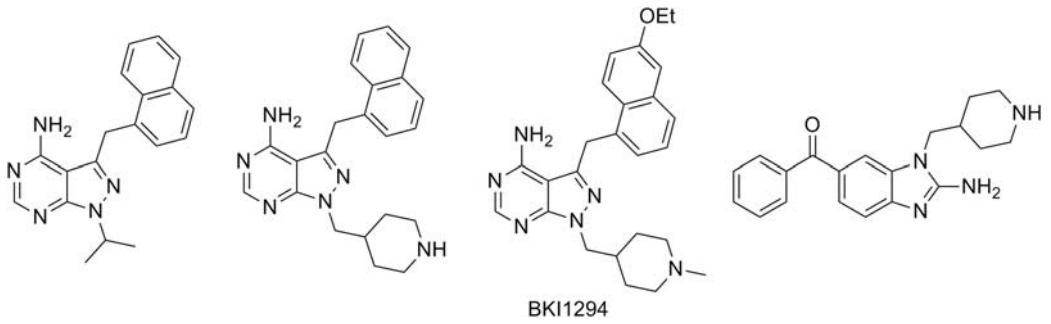

Fig. 10 Inhibitors of TgCDPK1 for treatment of toxoplasmosis.

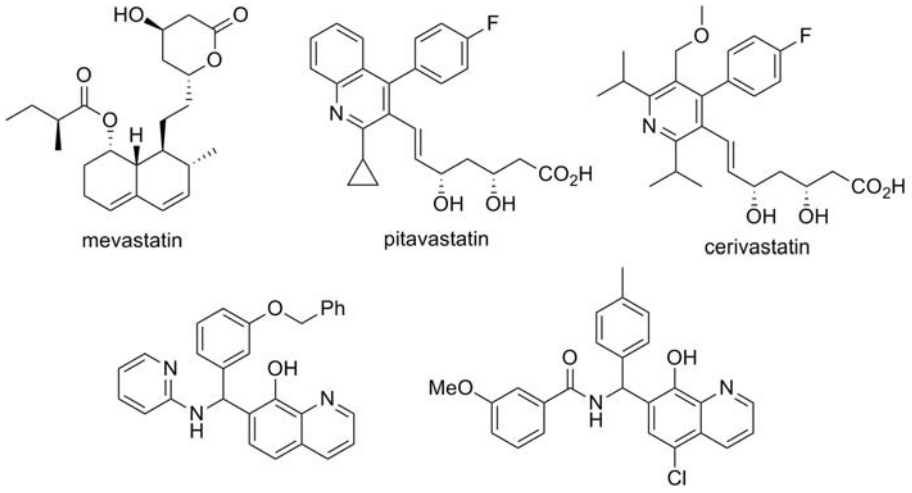

Fig. 11 Leads identified from repurposing screening for *Cryptosporidium*.

in section "Kinase inhibitors" for *Toxoplasma*, which have also been shown to be efficacious in a mouse model of cryptosporidiosis.[74]

5.23.2.1.3.2 Inosine-5′-monophosphate dehydrogenase inhibitors

One biochemical target that has provided multiple starting points for development of drug candidates for cryptosporidiosis is inosine-5′-monophosphate dehydrogenase.[75] This enzyme, which is important to the parasite's ability to generate guanine nucleotides, was identified as a potential target, cloned, expressed, and used in high-throughput screens of over 100,000 compounds to identify several hundred hits.[76] Based on this outcome, hit-to-lead and lead optimization projects focused on ureas,[77] benzimidazoles,[78] benzoxazoles,[79] phthalazinones,[80] and benzopyranopyrazoles[81] have been reported (**Fig. 12**). These efforts have been aided by X-ray crystallography of several compounds complexed in the active site of *Cp*IMPDH,[81,82] and several compounds from these series have demonstrated oral activity in a mouse model of cryptosporidiosis, validating IMPDH as a target for this disease.[83]

5.23.2.2 Kinetoplastids

The kinetoplastids are a diverse class of flagellated unicellular parasites characterized by the presence of several unique and conserved structural organelles including the kinetoplast and glycosome.[84] The kinetoplast is a network of mitochondrial DNA; transcription of kinetoplast genes, RNA editing, and maintenance of the catenated DNA network are unique to this class of parasites.[85] The glycosome is an unusual peroxisome-like organelle that localizes the seven enzymes of the glycolytic pathway, the sole source of ATP and energy in kinetoplastids.[86] As a consequence of the presence of these unique organelles and pathways, drugs targeting biochemical targets associated with them have become attractive targets for drug discovery.[84]

The most widely distributed kinetoplastid order is *Leishmania*, which infect individuals in subtropical climates around the globe, including Asia, the Middle East, Africa, southern Europe, and Central and South America.[87] Diseases caused by *Leishmania* species range from relatively mild and ultimately self-resolving cutaneous leishmaniasis, to disfiguring mucocutaneous leishmaniasis, to the potentially fatal visceral leishmaniasis. Since 2005, cutaneous leishmaniasis has been identified as a problem for military forces participating in conflicts in Afghanistan and Iraq.[88] Mucocutaneous leishmaniasis is widely distributed in both southern Europe and the Americas and represents a significant health problem, particularly in children.[89] The most serious disease caused by *Leishmania* parasites, visceral leishmaniasis, is most prevalent in India and Eastern Africa, and significant mortality continues to be an issue in these areas.[90]

Chagas disease, caused by the parasite *T. cruzi*, is widely distributed across Central and South America and is considered the leading infectious cause of cardiomyopathy and death due to parasitic infection in the Western Hemisphere.[91] It is estimated that over 7 million individuals are infected with *T. cruzi* parasites, and over 100 million are at risk.[92] With continued global warming, northward expansion of *T. cruzi* infections into the United States has been observed.[93] A particular challenge of Chagas disease is that the acute symptoms are relatively minor, such that the majority of patients are undiagnosed for decades; only 30% of chronically infected individuals will develop cardiovascular disease.[94]

The final major genus of kinetoplastid parasites important in human disease is the multiple *Trypanosoma brucei* subspecies responsible for human African trypanosomiasis (HAT) or African sleeping sickness. Although epidemiologically the least widespread of the kinetoplastids, infections by *T. brucei* are particularly problematic as they are inevitably fatal if untreated. Distributed across sub-Saharan Africa, it is estimated that only 50,000–70,000 individuals are infected with *T. brucei*, though it is likely that actual incidence is somewhat higher due to the difficulty in reaching disease-endemic areas and reluctance of individuals to be screened.[92] Like Chagas disease, individuals acutely infected with *T. brucei* (stage 1 disease) experience only mild, nonspecific symptoms (e.g., fever, headache, and muscle aches), which makes diagnosis difficult.[95] It is only upon migration of the parasites across the blood–brain barrier and progression to stage 2 disease that the hallmark symptoms of HAT such as sleep disturbances,

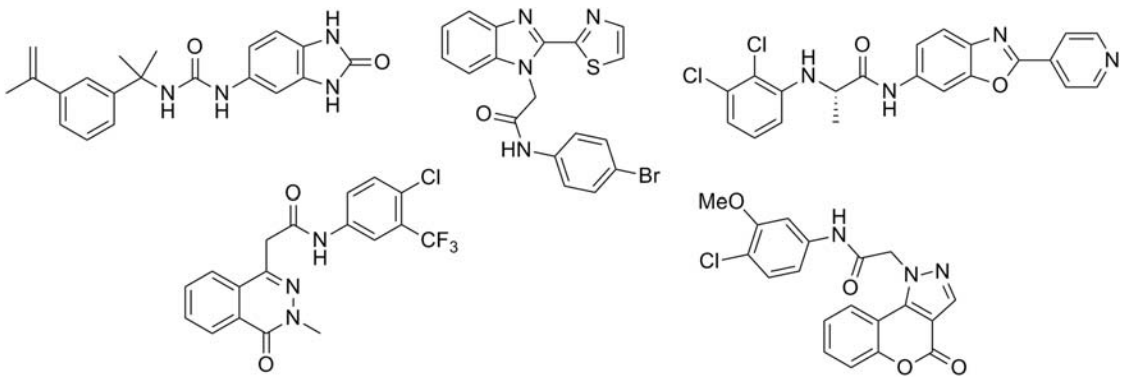

Fig. 12 Inhibitors of IMPDH for *Cryptosporidium*.

hallucinations, and sensory disorders emerge. Confirmation of stage 2 HAT requires collection of cerebrospinal fluid by way of a lumbar puncture, a procedure that is challenging to perform in the field.[96]

Drugs available to treat the kinetoplastid diseases are relatively old and are summarized in Table 2 and Fig. 13. Significant toxicities are known for most of these drugs, and emergence of resistance has been reported for many.[97]

As with other parasitic diseases, drug discovery efforts for the kinetoplastid diseases have benefited over the past decade from increased funding from philanthropic organizations such as the Bill & Melinda Gates Foundation and the Wellcome Trust[2] and have focused on either unique biochemical targets in the parasites or repurposing of approved or clinically relevant therapeutics.

5.23.2.2.1 Leishmania

Although the *Leishmania* parasites are closely related from a taxonomic perspective, the range of disease caused by individual species of *Leishmania* is quite varied, ranging from relatively mild and self-curing cutaneous leishmaniases to more severe disfiguring mucocutaneous leishmaniases and potentially fatal visceral leishmaniases.[98] It is beyond the scope of this article to discuss the similarities and differences between the various manifestations of leishmaniasis, but these differences have substantial impact on the drug discovery strategies employed for each disease. Depending on the specific parasite targeted, programs may need to focus on physicochemical properties to enable development of specific formulations or routes of administration or on identification of compounds that balance efficacy across a wide range of *Leishmania* strains.[87a]

5.23.2.2.1.1 Diamidines and arylimidamides

Based on the well-known antileishmanial agent pentamidine, efforts to discover improved diamidines have been a key area of exploration in the past decade.[99] In a series of papers in the early 2000s, Boykin and coworkers described numerous variations of the diamidines, with modifications of the linker between the two amidine moieties providing a central theme for modulation of both DNA binding affinity and physicochemical properties, as summarized in Fig. 14.[100]

One of the key limitations of the diamidines, which were examined for not only their activity against *Leishmania* spp. but also *T. cruzi* and *T. brucei*, centered on their poor pharmacokinetic profiles, attributable to the dicationic nature of the molecules. This limitation prompted several avenues of exploration, including preparation and evaluation of prodrugs[101] and less basic reversed diamidines designated arylimidamides.[102] Emerging from the arylimidamide effort were the advanced leads DB745 and DB766 (Fig. 15), which demonstrated potent antileishmanial activity, moderate oral bioavailability, and efficacy in animal models of leishmaniasis.[103] Further optimization of the arylimidamide class to improve pharmacokinetic properties afforded additional advanced leads such as DB1852 and DB1960. Unfortunately, repeat-dose toxicology studies have suggested that adverse effects on the host will limit the utility of these compounds.[104]

Table 2 Available drugs for treatment of kinetoplastid diseases[97]

	Decade introduced	*Route of administration*	*Uses and limitations*
Leishmaniasis (visceral and cutaneous)			
Sodium stibogluconate	1950s	Intramuscular, intravenous	Variable efficacy and emergence of resistance
Meglumine antimoniate	1950s	Intramuscular, intravenous	Variable efficacy and emergence of resistance
Amphotericin B	1980s	Intravenous	Effective in areas where resistance has emerged. Expense of lipid formulations limits use
Miltefosine	1980s	Oral	Effective in areas where resistance has emerged. Potentially teratogenic
Paromomycin	2000s	Intramuscular	Variable efficacy
Chagas disease			
Nifurtimox	1960s	Oral	Requires 60–120 days treatment. GI, dermatologic, and neurological toxicity
Benznidazole	1970s	Oral	Requires 40–80 days treatment. GI, dermatologic, and neurological toxicity
Human African trypanosomiasis			
Suramin	1910s	Intramuscular	First-line therapy for stage 1 *T. rhodesiense*, not effective in stage 2. Emergence of resistance
Pentamidine	1930s	Intramuscular	First-line therapy for stage 1 *T. gambiense*, not effective in stage 2. Emergence of resistance
Melarsoprol	1940s	Intravenous	First-line therapy for stage 2 HAT. Significant toxicity. Painful injection
Eflornithine	1970s	Intravenous	Emerging first-line therapy for stage 2 HAT. Requires 14 days of infusions (4 day^{-1}). Can be combined with nifurtimox (oral) to reduce course of treatment to 10 days

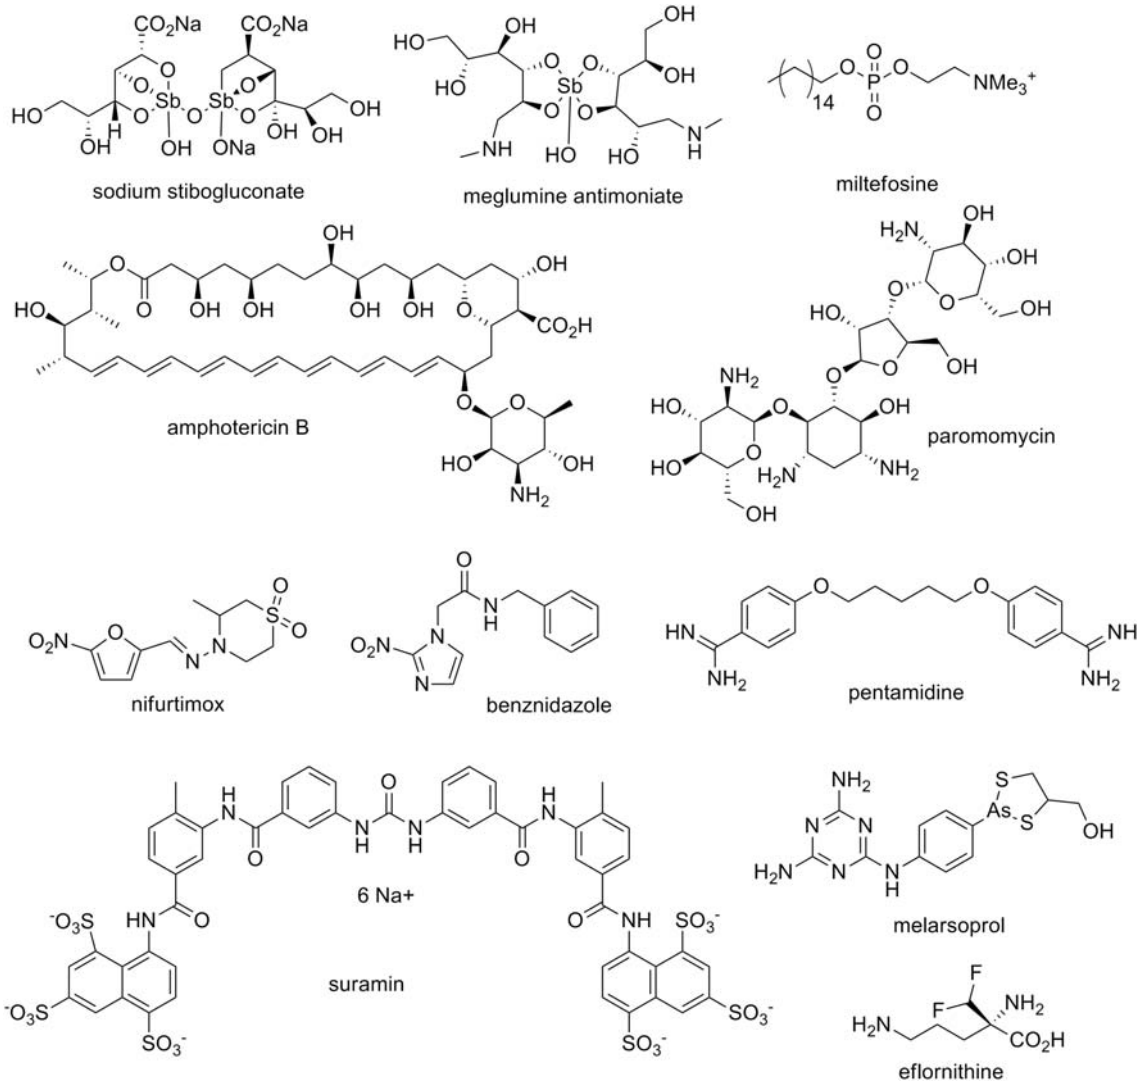

Fig. 13 Current treatments for kinetoplastid infections.

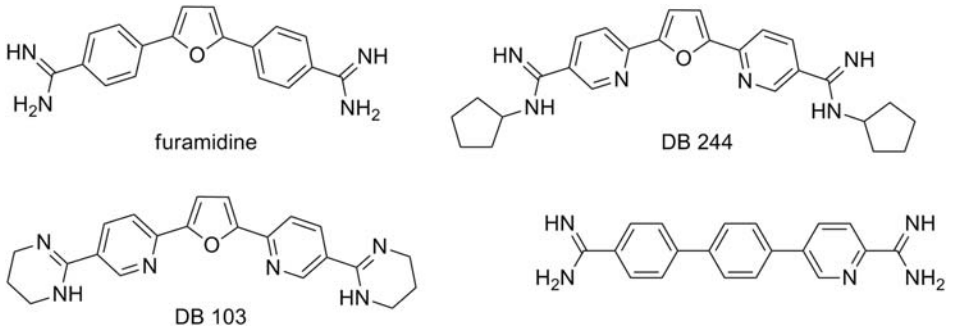

Fig. 14 Diamidines evaluated for antileishmanial activity.

5.23.2.2.1.2 Cdc2-related kinase 3 inhibitors

As in other parasites, inhibition of cell cycle kinase targets provides an attractive approach to development of antileishmanial drugs, provided one can obtain sufficient selectivity for disruption of the parasite life cycle relative to effects on the mammalian host. One such target is the Cdc2-related kinase 3 (CRK3), originally identified as a potential target in the late 1990s[105] and demonstrated to

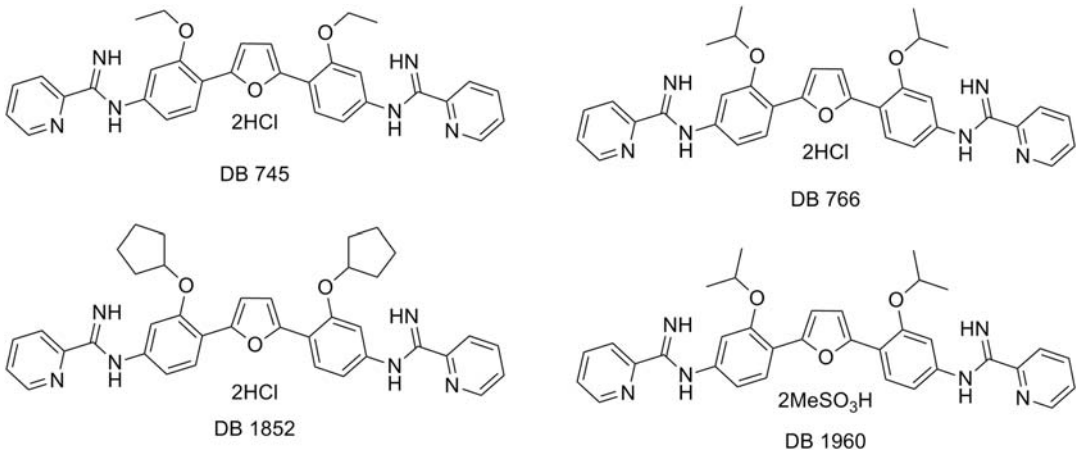

Fig. 15 Arylimidamides for visceral leishmaniasis.

be essential to growth of *Leishmania* spp. in the early 2000s.[106] More recently, screening of several kinase inhibitor libraries afforded a number of hits for initiation of medicinal chemistry programs, as summarized in Fig. 16.[107]

To date, none of these series have progressed to delivery of a preclinical candidate, despite some optimization to provide very potent and selective inhibitors of CRK3. It has been suggested that this failure indicates that CRK3 is not essential for parasite proliferation, despite the early genetic data that suggested this to be the case.[107c] This outcome highlights one of the major challenges for antiparasitic drug discovery—the all-too-frequent disconnect between biochemical potency and lack of cellular activity, which has caused many in the field to discount the value of target-based screening approaches in favor of phenotypic cell-based screening.

5.23.2.2.1.3 Inhibitors of dihydrofolate reductase–thymidylate synthase

Inhibition of inhibitors of dihydrofolate reductase–thymidylate synthase (DHFR–TS) has long been a potentially attractive target for design of antileishmanial drug candidates.[108] Early studies of 2,4-diaminopyrimidines and 2,4-diaminoquinazolines (Fig. 17) as inhibitors of leishmanial DHFR–TS identified a number of potent enzyme inhibitors, but activity in parasite proliferation assays

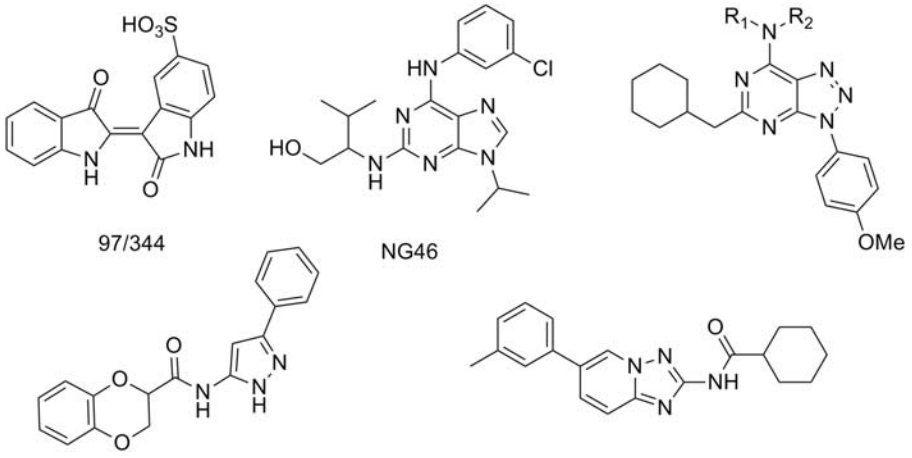

Fig. 16 CRK3 inhibitors as antileishmanials.

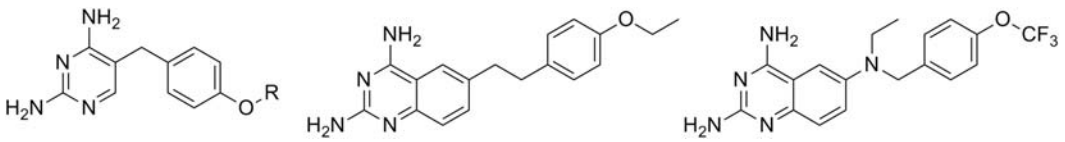

Fig. 17 Dihydrofolate reductase–thymidylate synthase inhibitors as antileishmanials.

was suboptimal, presumably due to poor physicochemical properties.[109] More recently, a related series of quinazolines with an aminoethyl linker has been shown to inhibit growth of *L. mexicana* promastigotes at low micromolar concentrations.[110]

5.23.2.2.1.4 Hits from phenotypic screening

As described in the preceding text, the difficulty of obtaining compounds that are active in whole-cell assays starting from biochemical targets has prompted greater dependence on use of phenotypic assays as primary screens for identification of lead series. Several classes of molecules have been identified in the past several years utilizing *L. donovani* and *L. infantum* parasites hosted in macrophages. Among these are series of aminothiazoles,[111] *N*(2),*N*(4) disubstituted quinazolines,[112] substituted quinolines,[113] and aminopyrazole carboxamides[114] (**Fig. 18**). The aminothiazoles exhibited very good *in vitro* potency, but were challenged by poor metabolic stability and pharmacokinetics.[111] In the quinazoline series, optimized analogs demonstrated good physicochemical and pharmacokinetic properties, but demonstrated only modest efficacy in a mouse model of visceral leishmaniasis due to toxicity at higher doses.[112b] In the quinoline series, an optimized analog was identified, which was efficacious in a hamster model following oral dosing.[113b] Further exploration of this series focused on minimizing the CYP1A2 inhibition of the lead candidate, but did not provide additional compounds with sufficient *in vivo* efficacy to be considered further.[113a] The most successful lead series identified from these screening efforts was the aminopyrazole series, which achieved good exposure following oral dosing, resulting in over 90% reduction of parasite load in hamsters following 5 days of dosing at 40 mg $kg^{-1}day^{-1}$.[114]

Taken together, these observations provide support for the continued use of phenotypic assays for identification of leads, as this approach overcomes the translation of activity in a biochemical assay to activity in a whole-cell assay.

5.23.2.2.1.5 Repurposing of approved and clinically evaluated drugs

Repurposing of approved drugs for use in treatment of leishmaniasis has been a popular approach over the last several years. As described earlier, the attractiveness of this approach is the perception that approval of these drugs for a new indication will be faster and less costly than for new chemical entities.

The rheumatoid arthritis drug auranofin (see **Fig. 7**), a gold (I) complex, was shown to inhibit trypanothione reductase derived from *L. infantum*, as well as to have antiproliferative effects on the promastigote stage of this strain.[64] In a more recent study, auranofin has been demonstrated to have significant *in vitro* and *in vivo* activity against several *Leishmania* strains, most notably *L. major* and *L. amazonensis*, which are important causative strains for cutaneous disease.[115] In addition to auranofin itself, an additional 39 gold(I) complexes were evaluated, with several demonstrating improved potency and selectivity relative to host cells. Cell biology studies suggested that auranofin caused apoptosis in *Leishmania* parasites via an undefined mechanism that induced caspase 3/7-like activity and DNA fragmentation.

Screening of a number of commercially available protein kinase inhibitors in several *Leishmania* strains identified sorafenib, sunitinib, and lapatinib (**Fig. 19**) as having micromolar-level activity *in vitro*.[116] Subsequent evaluation of these compounds in an *in vivo* model of visceral leishmaniasis revealed only modest efficacy. Independently, Pollastri and coworkers also identified lapatinib as having potent activity against *T. brucei* and pursued a lead optimization program on this class (vide infra).[117] The same group also identified the Aurora kinase inhibitor hesperadin as a potential repurposing candidate for leishmaniasis and other kinetoplastid diseases.[118]

The serotonin receptor antagonist ketanserin (**Fig. 19**) was also found to have modest activity against *L. donovani* promastigotes and amastigotes (in THP-1 cells) while exhibiting little cytotoxicity to the THP-1 cells.[119] The antileishmanial activity of ketanserin was attributed to its interaction with HMGR in the parasite, supported by enzyme inhibition studies and weaker activity in HMGR-overexpressing parasites. The tricyclic antidepressant mianserin was also evaluated and shown to be antileishmanial via the same mechanism.[120] Work from the same group has also demonstrated activity for the HMGR inhibitors atorvastatin, simvastatin, and mevastatin (**Fig. 11**).[121] Further characterization of the effect of mevastatin on sterol metabolism in *L. donovani* revealed significant and dose-dependent reduction of ergosterol levels and accumulation of lipid bodies in the parasites that impacted parasite viability.[121b]

Though not a primary focus for leishmaniasis applications, nitroheterocyclic compounds have been found to be efficacious against the other kinetoplastids (vide infra). Consequently, evaluation of nitroheterocycles as potential antileishmanials has been reported. For example, the advanced clinical candidate fexinidazole has been evaluated in preclinical studies, where it

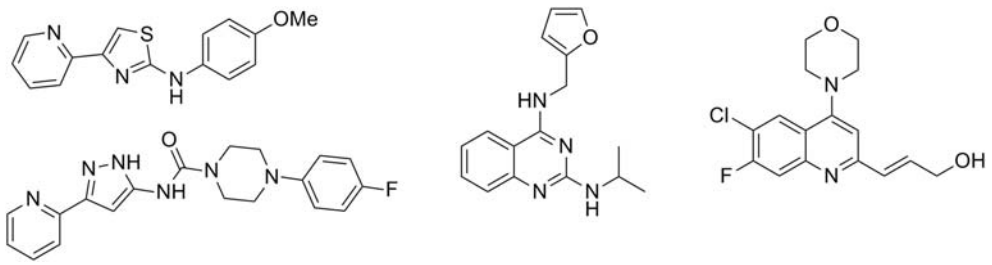

Fig. 18 Antileishmanial leads from phenotypic screening.

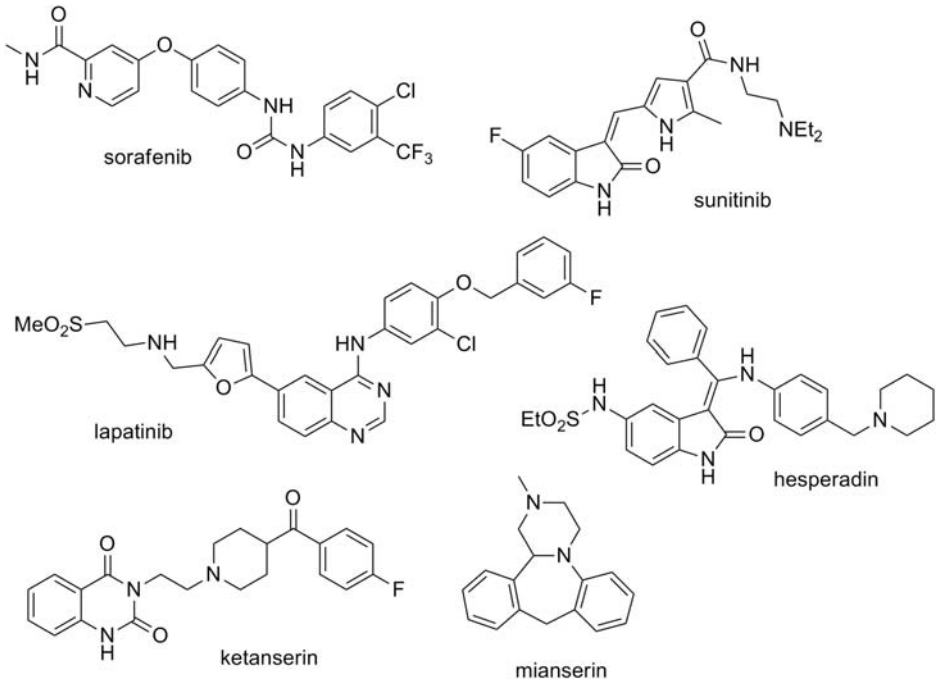

Fig. 19 Repurposed approved drugs identified as potential starting points for antileishmanials.

demonstrated efficacy equivalent to miltefosine in a mouse model of visceral leishmaniasis.[122] In a similar repurposing strategy, it has been reported that a single enantiomer of the antitubercular clinical candidate PA-824 has an attractive *in vitro* and *in vivo* profile with potential for oral administration.[123]

5.23.2.2.2 Trypanosoma cruzi

As described in section "Kinetoplastids," infection of individuals with *T. cruzi* results in development of Chagas disease, a chronic condition that ultimately leads to gastrointestinal and cardiac problems decades after initial infection.[124] Though described as a single disease, the genetic diversity of *T. cruzi* complicates treatment of Chagas patients, resulting in highly variable efficacy for existing drugs and facile development of resistance in the infected population.[125] The importance of identifying drug candidates and biochemical targets that will provide broad efficacy across the diversity of *T. cruzi* strains encountered in the field has been highlighted in the past several years through the failure of several clinical candidates from the azole class of ergosterol biosynthesis inhibitors.[126] In addition to the view that exposure to these clinical candidates was insufficient to effect cure in all individuals, the variability in strain susceptibility has been put forth as contributory to the negative outcome.[127] These failures are in sharp contrast to clinical experience with the nitroimidazoles benznidazole and nifurtimox, which have been the standard of care for Chagas disease for decades, though a recent trial of benznidazole has suggested that, while parasitemia is significantly reduced in patients treated with this drug, beneficial effects on cardiac function are not significant.[128] As a consequence of these observations, drug discovery efforts in the past several years have moved away from identification of additional candidates that act on the CYP51 enzyme to more diverse and novel mechanisms of action, with phenotypic screening of compound libraries in newly developed and validated *in vitro* and *in vivo* assays taking a prominent role.[129]

5.23.2.2.2.1 Ergosterol biosynthesis (CYP51) inhibitors

In spite of the recent failure of both posaconazole and ravuconazole to demonstrate meaningful efficacy in clinical trials,[126] several new inhibitors of CYP51 (VFV and VNI) have been reported (**Fig. 20**).[130] The strategies supporting the proposals for progression of these newer compounds to preclinical studies are centered on (a) utilization of crystallographic data to optimize both potency and selectivity for the *T. cruzi* enzyme[130a,c] and (b) modulation of physicochemical and pharmacokinetic properties to improve exposure and tissue distribution.[130b–d]

5.23.2.2.2.2 Nitroheterocycles

The clinical utility of benznidazole and nifurtimox for treatment of Chagas disease continues to provide enthusiasm for exploration of new nitro-substituted heterocycles, despite the potential genotoxicity exhibited by many members of this broad structural motif.[131] One of the most advanced clinical candidates from this class that is being explored for utility in both Chagas disease and HAT, fexinidazole, has been thoroughly profiled in a range of assays predictive of genotoxicity potential, and it has been concluded that it presents minimal risk to patients.[132] Several groups have reported a range of five-membered nitro-substituted

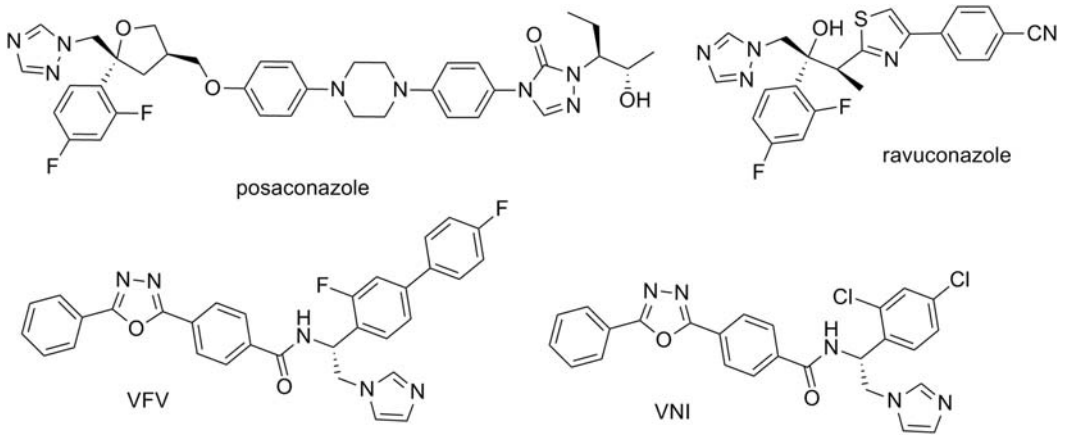

Fig. 20 CYP51 inhibitors evaluated for Chagas disease.

heterocycles (Fig. 21) over the past several years with variable potency against *T. cruzi* and focused on improvement of physicochemical and pharmacokinetic properties to achieve better *in vivo* efficacy.[133] Based in part on the observation that the combination of benznidazole and posaconazole in an acute murine infection model of Chagas disease provided superior efficacy to either agent alone,[134] Papadopoulou and coworkers synthesized and evaluated a series of 3-nitrotriazoles structurally related to fluconazole in an effort to generate bifunctional drug candidates.[135] While several analogs demonstrated good *in vitro* potency against *T. cruzi* and inhibition of the TcCYP51 enzyme, little evidence for synergism was observed in an *in vivo* efficacy experiment.

5.23.2.2.2.3 Lipophilic amines: Inhibitors of squalene synthase

In another example of repurposing an antibacterial clinical candidate for use as an antiparasitic, it has recently been reported that the antitubercular drug SQ109 (Fig. 22) holds promise for treatment of Chagas disease.[136] Originally discovered from screening of a combinatorial library of lipophilic 1,2-ethylenediamine analogs[137] and shown to have acceptable pharmacokinetics in mice,[138] SQ109 was progressed to clinical trials for tuberculosis.[139] The antitubercular mechanism of action of SQ109 was proposed to involve inhibition of a transporter important for cell wall biosynthesis,[140] with subsequent studies supporting multiple modes of action, including uncoupling of pH gradients and membrane potentials[141] and inhibition of dehydrosqualene synthase.[142] Earlier work from several laboratories had shown that lipophilic amines, such as quinuclidines, inhibit *T. cruzi* squalene synthase, though none have progressed to preclinical status.[143]

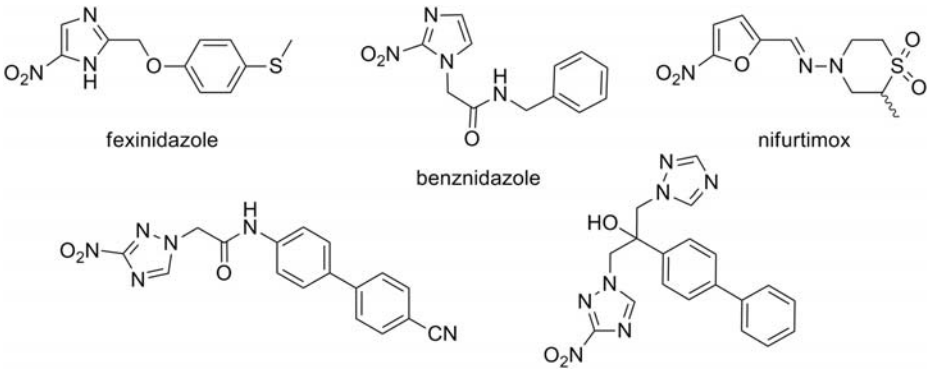

Fig. 21 Nitro-substituted heterocycles for Chagas disease.

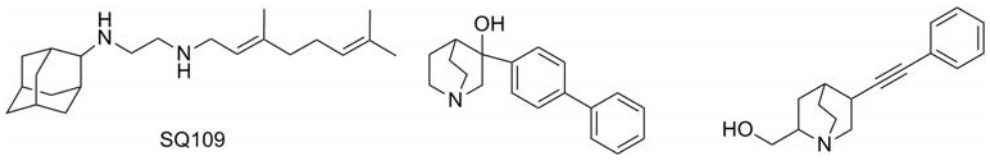

Fig. 22 Lipophilic amines explored as treatments for Chagas disease.

5.23.2.2.3 Trypanosoma brucei

The final kinetoplastid parasite to be considered is *T. brucei*, the causative agent of human African sleeping sickness. Though similar to the *Leishmania* spp. and *T. cruzi* parasites discussed in the preceding text, the site of *T. brucei* infection poses the added challenge to drug discovery of requiring molecules with the ability to cross the blood–brain barrier for robust and durable *in vivo* efficacy. This challenge has proved to be significant, as several of the biochemical targets pursued for other kinetoplastids (e.g., kinases) require structural features such as multiple hydrogen bond donor/acceptor pairs in drug candidates to achieve high potency and selectivity, and these limit CNS penetration. For example, while a subset of *T. brucei* mitogen-activated protein kinases was found to be the target(s) of a series of diaminopyrimidines, their utility as candidates for treatment of HAT was limited due to poor CNS permeability.[144] Similar limitations have been observed for other targets and series as highlighted in the following sections. In some cases, this has resulted in "repurposing" of lead series to either *Leishmania* or *T. cruzi*. A strong trend in HAT discovery over the past several years has been an increasing appreciation of the interplay between pharmacokinetics and pharmacodynamics. As with other protozoan parasites, many hit series have been identified by phenotypic screening from a variety of compound library sources.[145] This approach has been particularly attractive for *T. brucei*, as the parasite is free-living and not dependent on maintenance in a host mammalian cell, rendering it the most easily cultured of the kinetoplastids. Consequently, it is anticipated that repurposing of *T. brucei* hits to the other kinetoplastids and apicomplexans will be a feature of future work, highlighting the importance of cross collaboration between research groups in these areas.

5.23.2.2.3.1 Diamidines

Described earlier as potential candidates for treatment of leishmaniasis, the diamidines related to the clinically effective stage 1 sleeping sickness drug pentamidine have continued to receive attention from the drug discovery community. Most notably, DB289, a methoxyamidine prodrug of the diamidine DB75 (**Fig. 23**), was progressed to clinical trials for stage 1 sleeping sickness following an extensive lead optimization and preclinical development program.[146] Though early clinical experience with DB289 was quite encouraging, longer duration treatment of patients resulted in liver and kidney toxicities that ultimately led to discontinuation of its development.[147]

Continued optimization of the diamidine series, with a focus on identification of analogs with superior pharmacokinetics, CNS penetration, and safety, has resulted in the progression of several aza analogs of DB289, including DB829,[148] DB844,[149] and 28DAP10[150] to preclinical evaluation for both stage 1 and stage 2 sleeping sickness.

While these compounds have been extensively characterized in a variety of *in vitro* and *in vivo* models, there is no evidence that any have progressed to clinical trials.

5.23.2.2.3.2 Trypanosomal phosphodiesterase inhibitors

Another class of targets that have garnered attention for treatment of HAT are the phosphodiesterases (PDEs), in particular TbrPDEB1 and TbrPDEB2.[151] These enzymes have been shown to be essential for control of cyclic adenosine monophosphate levels in the parasite, and disruption of their function by RNAi results in parasite death.[151a,b] Early efforts in the discovery of TbrPDEB1 inhibitors looked to repurpose inhibitors of the human PDE4 enzyme, resulting in the exploration of a number of potential leads (**Fig. 24**). In particular, two series of compounds, the first based on a phthalazinone[151b] and the second on a pyrazolinone core,[152] were identified from a proprietary PDE-focused screening library. Unfortunately, elaboration of these leads to provide parasite-selective inhibitors has proved difficult. In order to address this limitation, a virtual screening approach using a crystal structure of TbrPDEB1 has been pursued, resulting in the identification of additional scaffolds for optimization.[153]

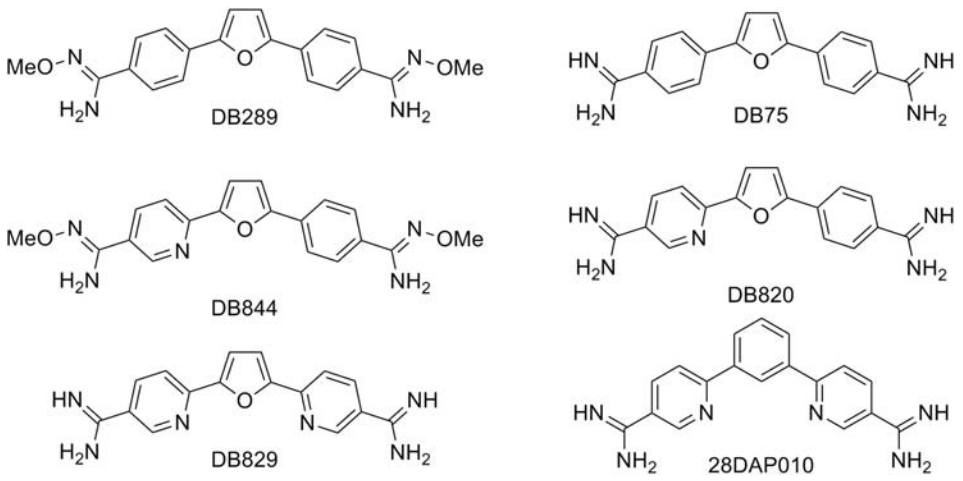

Fig. 23 Diamidines for human African trypanosomiasis.

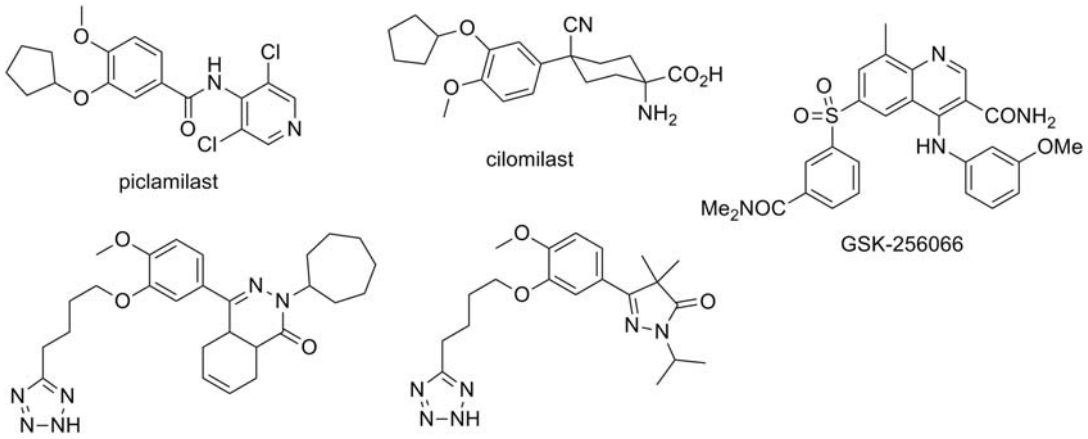

Fig. 24 Inhibitors of TbPDE4B1.

Concurrent with these efforts, consideration of additional human PDE4 inhibitors prompted exploration of a series of catechol diethers based on piclamilast.[154] Work focused on modification of the dichloropyridine region of this molecule proved unsuccessful, with only weak activity for TbPDEB1 observed.[155] Somewhat more success has been reported for modification of the hPDE4 inhibitor cilomilast, with identification of an analog with submicromolar activity against TbPDEB1 and modest activity in a whole-cell assay.[156] Most recently, an effort focused on the 4-aminoquinoline class represented by GSK-256066 has been reported with similar outcomes.[157] Synthesis and characterization of over 40 analogs of this lead identified a number of compounds with single-digit micromolar activity for both the TbPDEB1 and TbPDEB2 enzymes, but these compounds retained nanomolar affinity for the hPDE4 enzyme, limiting their utility.[157] These studies highlight the challenge of repurposing existing human therapeutics for neglected diseases, suggesting that the initial enthusiasm exhibited by the industry for "quick wins" using this approach may need to be reevaluated.

5.23.2.2.3.3 Benzoxaboroles

From a phenotypic whole-cell screen of compounds against *T. brucei*, a series of 6-substituted benzoxaboroles were identified as leads for treatment of HAT as outlined in **Fig. 25**.[158] From this initial work, it was demonstrated that thioethers, sulfoxides, sulfones, and amides were all submicromolar actives *in vitro*, and the 4-chlorophenylsulfoxide was shown to be active in an *in vivo* model.[159] Initial optimization of the series focused on 6-carboxamides and identified SCYX-6759 as an advanced lead with good *in vitro* potency, acceptable pharmacokinetics, and oral activity in models of HAT.[160] While SCYX-6759 was robustly active in a stage 1 HAT model, the pharmacokinetics of this compound in the brain were insufficient to warrant progression to preclinical status, which prompted further optimization focused on increasing brain exposure. These efforts led to the discovery of the clinical candidate SCYX-7158,[161] which has recently completed a phase I clinical trial where it demonstrated very good pharmacokinetics and safety in human volunteers.[162]

5.23.2.2.3.4 Aminoacyl tRNA synthetase inhibitors

Aminoacyl tRNA synthetases (aaRSs) are essential to *T. brucei* (and other parasites) for protein synthesis; hence, inhibition of individual enzymes in this class has been postulated to provide attractive targets for drugs, especially if one were to design compounds selective for the parasite enzyme(s). Of the 24 aaRSs encoded by the *T. brucei* genome, 16 have been shown to be essential for parasite survival by either RNAi or chemical methods.[163] While some enzymes such as isoleucyl-RS and histidyl-RS have been explored

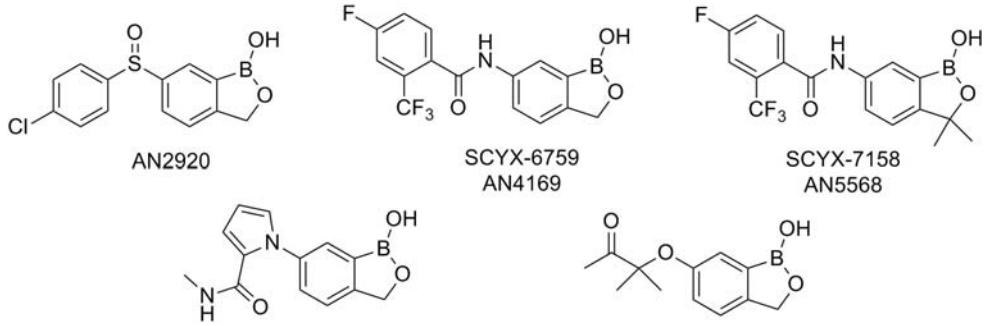

Fig. 25 Benzoxaboroles for HAT.

only for substrate-based inhibitors,[164] others such as methionyl-RS and leucyl-RS have yielded more diverse scaffolds as leads for drug discovery (Fig. 26).[165]

In the case of the methionyl-RS, a series of diaryl diamines have been explored, with numerous examples exhibiting nanomolar potency in whole-cell *T. brucei* assays and no effect on mammalian cells.[165a] The most potent compound from this series was found to be efficacious in a murine model, but poor pharmacokinetics and permeability into the CNS precluded further development. To address these issues, the 4-quinolone moiety in early compounds was replaced by a urea, affording compounds with good oral pharmacokinetics, including CNS exposure.[165b] Further understanding of the structural features in both the quinolone and urea series has been gleaned through extensive cocrystallization of inhibitors from both classes with *T. brucei* methionyl-RS.[165c] Most recently, screening of a large library of compounds, coupled with counterscreening in a human methionyl-RS functional assay to reject nonselective compounds, has identified additional chemical scaffolds for optimization including a series of indoles.[165d]

For leucyl-RS, attempts to capitalize on the known benzoxaborole scaffold known to interact with the editing domain of fungal[166] and bacterial[167] enzymes afforded a series of weakly active analogs (Fig. 25).[165e] Screening of a small library of compounds in a *T. brucei* leucyl-RS aminoacylation assay identified a series *N*-sulfamoylthioureas.[165f] Lastly, virtual screening of a database of commercially available compounds led to exploration of a series of pyrrolinones, also providing weakly active leads for further optimization.[168] These efforts suggest that identification of high-potency compounds for this enzyme may be challenging.

5.23.2.2.3.5 *N*-Myristoyltransferase inhibitors

Posttranslational modification of proteins is an essential cellular function for modulation of biochemical pathways, directing proteins to specific subcellular organelles and identifying proteins to be degraded. One modification, effected by the enzyme *N*-myristoyltransferase (NMT), is myristoylation—a process that has been shown to be essential in kinetoplastids through RNA interference studies[169] and that has been postulated to play an important role in the life cycle of protozoan parasites including *T. brucei*, *Leishmania* spp., and *P. falciparum*. Early explorations repurposing fungal NMT inhibitors further validated this target for both *T. brucei* and *L. major*, but these compounds were insufficiently potent to progress to *in vivo* studies.[170]

In 2010, workers at the Dundee Drug Discovery Unit reported the identification of a potent TbNMT inhibitor, DDD64558 (Fig. 27), from screening of a diversity-based library and conducted early hit-to-lead work to identify DDD85646 as a lead compound with modest oral pharmacokinetics and efficacy in a murine model of HAT.[171] Further optimization of this lead focused on reduction of polar surface area improved the CNS permeability of the series to afford the brain-penetrant compound DDD100097 with some efficacy in a stage 2 HAT model.[172] Additional lead series based on thiazolidinone and benzomorpholinone scaffolds from the initial screen and optimization of these series to further improve potential for CNS permeability and full efficacy in HAT have also been reported.[173]

In part, based on these observations, renewed interest in NMT inhibitors as leads for treatment of both malaria and leishmaniasis has been observed, as these diseases do not require CNS penetration for efficacy. As in the *T. brucei* program, hits for *L. donovani*, *P. falciparum*, and *P. vivax* NMT were identified from screening of diversity libraries (Fig. 28).[174] Concurrently, optimization of known fungal and *T. brucei* NMT inhibitors was undertaken in conjunction with X-ray crystallography to identify a series of benzofuran-based *P. falciparum* NMT inhibitors.[175]

Taken together, these efforts highlight the potential for application of leads and biochemical targets across parasites, with medicinal chemical optimization specific to each to efficiently target the relevant specific compartment or tissue.

5.23.2.2.3.6 Hit identification from phenotypic screening

As with the other kinetoplastids, the ability to screen large compound libraries against cultured *T. brucei* has been used to advantage to identify numerous classes of hits for optimization. Both diversity-oriented and biochemically targeted libraries have been evaluated, and numerous hit series have been identified (**Fig. 29**). One class of molecules, a series of 2-phenyloxazolopyridine amides, was identified and pursued independently by two groups, one from the Monash University and the second from the University of Washington.[176] Both screening efforts used diversity libraries assembled from commercial sources and identified the same hit, mining their databases for similar compounds to establish early SAR trends. Based on these, both groups initiated hit-to-lead synthetic chemistry campaigns focused on modification of three regions—the amide moiety, the aryl spacer, and the heterocyclic core. The most advanced lead from these studies is a pyrrolidine amide of an imidazopyridine core, which demonstrated an attractive *in vitro* and *in vivo* pharmacokinetic profile and was efficacious in a murine model of HAT.[176b]

Additional hits from the Monash University team have also been reported, including *N*-sulfonyl-tetrahydroquinolines,[177] pyridyl benzamides,[178] and arylpyrazine carboxamides.[179] The latter is the most advanced of these series affording a lead compound with low nanomolar activity against *T. brucei* and good physicochemical and modest *in vitro* pharmacokinetic properties.[179] One feature of this series that has been highlighted is its similarity to known kinase inhibitors, suggesting the potential for scaffold hopping.

The potential attractiveness of known kinase inhibitors and scaffolds as starting points for drug discovery projects for *T. brucei* has also been highlighted by the outcome of high-throughput phenotypic screens of kinase-focused libraries at GSK/Northeastern University, the University of Dundee, and Institut Pasteur Korea.[145,180] In the GSK/NEU screen, over one hundred hits representing over fifty structural classes were identified with submicromolar potency and evidence for cidality.[180a] The pharmacokinetic profiles of several representative compounds were evaluated, and one (NEU-1053) was progressed to an *in vivo* efficacy study. From the Dundee effort, a series of imidazopyrazinones was identified; preliminary hit-to-lead work, including scaffold hopping to a pyrazolopyridine core, was reported. Taken together, these studies suggest that a considerable diversity of kinase-directed scaffolds offer opportunities for continued exploration of novel chemical space and mechanistic approaches.

Screening of a protease-focused library at Dundee afforded a series of indoline carboxamides, which were progressed to hit-to-lead studies, resulting in the identification of several analogs that exhibited cures in a murine stage 1 HAT model and partial cures in a stage 2 model.[181] Lastly, groups at St. Jude Children's Research Hospital and the Eskitis Institute have independently reported screening and evaluation of small libraries of histone deacetylase inhibitors (HDACs).[182]

As can be seen from the preceding paragraphs, numerous opportunities exist for development of new drug candidates to treat HAT should more advanced clinical candidates fail to deliver the promise held in current trials. Finally, the potential to repurpose hits from *T. brucei* screens to other kinetoplastid and apicomplexan parasites exists, and will likely be the focus of future work in this area.

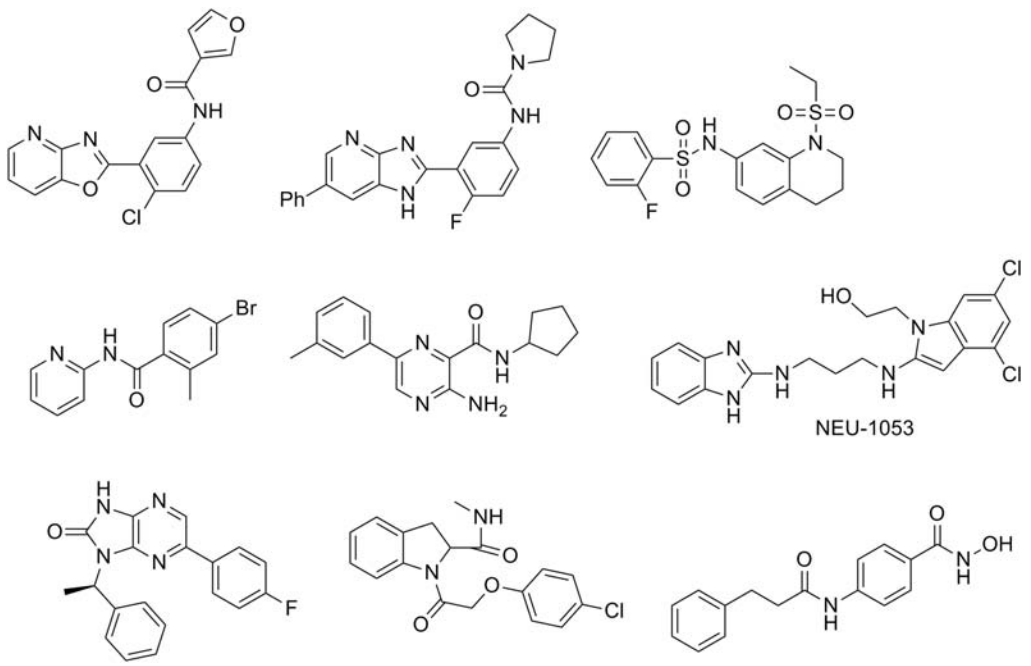

Fig. 29 Phenotypic screening hits for *T. brucei*.

5.23.2.3 Amoebas: *Entamoeba* and *Giardia* Species

Amoebiasis caused by the parasite *Entamoeba histolytica* is estimated to cause over 100,000 deaths per year, making it the second most deadly parasitic infection behind malaria.[183] Most infections with *E. histolytica* are confined to the intestine, resulting in diarrhea, but a proportion migrate to the liver, where abscesses can develop and lead to death.[183a] The current standard of care for *E. histolytica* infections is metronidazole, a nitroheterocyclic drug that is compromised by significant side effects including neurotoxicity[184] and carcinogenicity.[185] Despite these limitations, relatively little drug discovery has been conducted on this disease. This paucity of research is in part due to the difficulty of developing a high-throughput screen for this anaerobic parasite. The challenge is evident in efforts from the Castillo lab repurposing of benzimidazoles, benzotriazoles, and related heterocycles (**Fig. 30**) known to be active against nematodes and protozoa.[186] In these studies, a small number of compounds were selected based on comparison with known antiparasitics and by computational screening of large databases. A similar strategy for identification of inhibitors of heat shock protein 90 for *E. histolytica* activity[187] based on a high-throughput screen in *P. falciparum*[188] has also been reported. Additional efforts to identify starting points via *in silico* methods (e.g., docking to homology models of key protein targets) have been reported for inhibition of *E. histolytica* hexokinase 1.[189] Several series of compounds with antiamoebic properties have been reported as leads including pyrazolo[3,4-d]pyrimidines, pyrazolines, and bis-pyrimidines.[190]

Despite the challenges posed by screening an anaerobic pathogen, the outcome of two screens has been reported. In the first, screening of a library of FDA-approved and commercially available compounds identified the gold complex auranofin (vide supra; **Fig. 9**) as a potential lead for *E. histolytica*.[191] More recently, repurposing of the 400-member open-access Malaria Box identified two leads (**Fig. 30**) for *E. histolytica*.[57] Further optimization and development of these newly identified leads offer promise for future treatment of this amoebiasis.

Like *E. histolytica*, infection of individuals with *Giardia* parasites results in acute life-threatening diarrheal disease, particularly in children.[192] Repeated infection with *Giardia* has been associated with reduced growth rates of children and "failure to thrive" in many parts of the developing world. Treatments for giardiasis include metronidazole and related nitroheterocycles, and emergence of resistance to these drugs has been reported.[193] Unfortunately, very little new medicinal chemistry projects have been initiated against *Giardia*, with most leads arising from cross screening of compounds designed for other parasites such as *E. histolytica* and *L. donovani*. Similar repurposing screens to those described in the preceding text have identified a small number of compounds that inhibited growth of *G. lamblia* including the gold complex auranofin (**Fig. 9**).[191] It was shown that auranofin was active against metronidazole-resistant strains, inhibited the giardial thioredoxin oxidoreductase, and was active in several rodent models of giardiasis.[194]

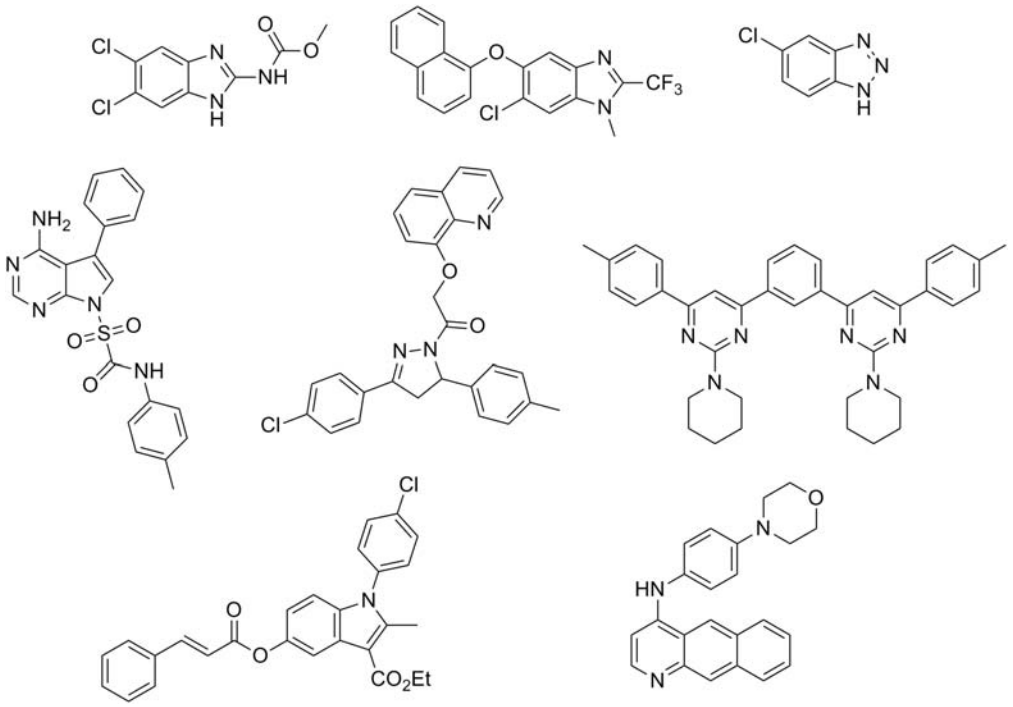

Fig. 30 Leads for treatment of amoebiasis caused by *E. histolytica*.

5.23.3 Helminths

In comparison with protozoans, drug discovery efforts aimed at elimination of helminth infections have been markedly less well developed. Multiple reasons account for this difference, including the existence of relatively effective broad-spectrum anthelmintics such as ivermectin and albendazole, the absence of robust high-throughput screening methodologies, and the much greater complexity and diversity of helminth biology.

5.23.3.1 Nematodes

5.23.3.1.1 Soil-transmitted helminths

Intestinal infections caused by helminths that spend a portion of their life cycle in the soil are widespread across the world and cause significant morbidity and mortality.[195] In fact, it is generally accepted that soil-transmitted helminth infections carry the highest burden of all neglected tropical diseases excluding malaria.[1] While some infections are relatively benign (i.e., *E. vermicularis* (pinworm)), others such as those caused by *A. duodenale* and *N. americanus* (hookworm) can result in significant anemia,[196] stunted growth,[197] and impaired cognitive ability[198] in children.

Despite these impacts, very little drug discovery and development have occurred over the past 10 years, indicative of the effectiveness of existing treatments. The well-known drugs albendazole, mebendazole, pyrantel pamoate, and levamisole (**Fig. 31**) continue to be the mainstay treatments for these diseases, with mass drug administration (MDA) programs having been very effective across the globe.[199]

5.23.3.1.2 Filarial worms

Infections by tissue-dwelling filarial worms such as *Wuchereria bancrofti*, *Brugia malayi*, *Onchocerca volvulus*, and *Dracunculus medinensis* are common across South America, Africa, and Asia. Diseases caused these infections (lymphatic filariasis, river blindness, and Guinea worm, respectively) are of substantial concern, particularly in sub-Saharan Africa.[200] Considerable effort has been expended on elimination of these parasites through a variety of means, including transmission blocking through improved sanitation[201] and MDA.[202]

Individuals who are bitten by mosquitoes carrying the larval stages of *W. bancrofti* or *B. malayi* will develop lymphatic filariasis (LF), where the larvae develop into adult worms in the lymphatic tissues. Long-term infection results in development of lymphedema, predominantly in the legs, ankles, and feet, commonly referred to as elephantiasis. This results in significant loss of mobility due to the swelling, rendering the individual unable to lead a normal productive life. Similarly, onchocerciasis develops in patients bitten by the black fly of the genus *Similium*, which host the larval stages of *O. volvulus*. This parasitic worm develops in subcutaneous nodules, with microfilaria migrating to the eyes of the patient, where they die and cause inflammation. Chronic inflammation caused by *O. volvulus* microfilaria in the eye ultimately leads to blindness.[200]

Current treatment of LF is accomplished through MDA programs utilizing albendazole, ivermectin, and diethylcarbamazine (**Fig. 32**).[203] These programs are targeted at reducing transmission by killing microfilaria in infected people, as the drugs do not kill the adult worm. Similarly, MDA programs with ivermectin have been employed for treatment of onchocerciasis. While this approach has been very successful in many countries and regions, several limitations have prompted continued exploration of new drug candidates to treat this disease. More specifically, the fact that the current drugs only kill the microfilaria and not the adult worms requires yearly retreatment for 4–6 years, and coinfection of patients with related filarial worm species, most significantly *Loa loa*, precludes use of ivermectin due to risk of serious side effects caused by rapid concomitant death of the *L. loa* worms.[204] Consequently, current drug discovery programs are focused on discovery of macrofilaricidal compounds that do not quickly kill microfilaria.

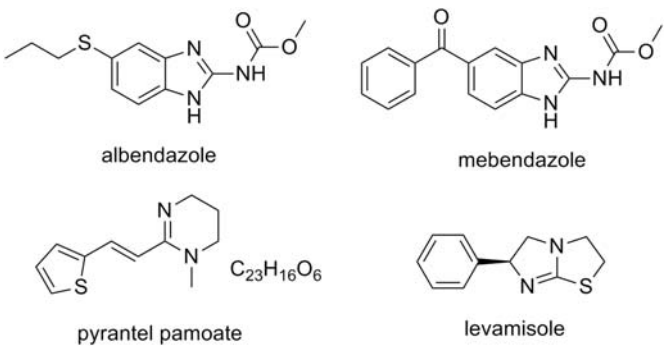

Fig. 31 Current drugs for treatment of soil-transmitted helminth infections.

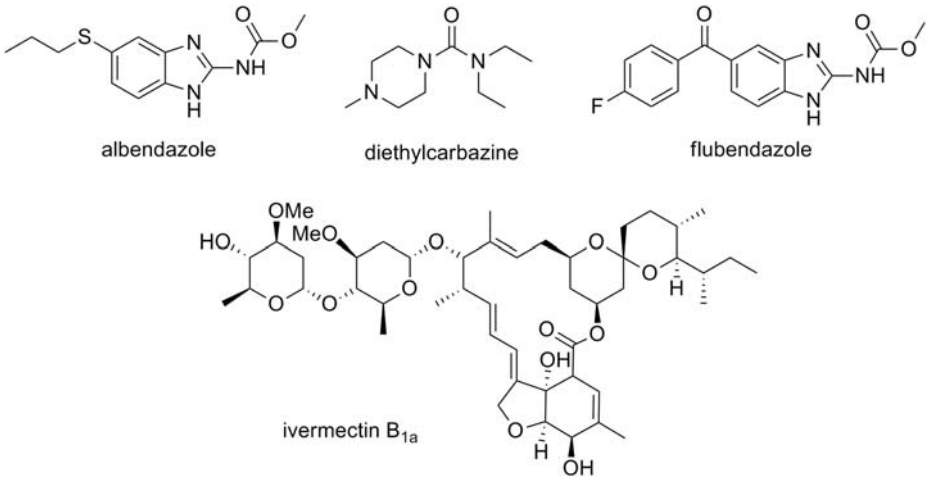

Fig. 32 Current treatments for lymphatic filariasis and onchocerciasis.

5.23.3.1.2.1 *Direct-acting macrofilaricides*

Consequently, the focus of drug discovery efforts for LF and onchocerciasis has been on discovery of macrofilaricidal agents that can cure patients with short courses of treatment (e.g., $<$14–28 days) and can be used in regions where coinfection with *L. loa* is possible. Described earlier in this article, a repurposed drug that has shown promising efficacy in animal models of LF is the gold complex auranofin (**Fig. 9**).[205] Auranofin was found to kill *B. malayi* worms at micromolar concentrations *in vitro* and affected up to 91% reduction of worm burden in an *in vivo* study in gerbils.[205] Mechanism of action studies supported the premise that auranofin inhibits the thioredoxin reductase enzyme, analogous to its mechanism in other parasites.[205]

In another repurposing project, the potential for the tubulin polymerization inhibitor flubendazole (**Fig. 32**) to be reformulated to improve oral bioavailability has been explored as a means to treat LF and onchocerciasis in Africa.[206] Of some concern to this approach, however, is the known embryotoxicity of flubendazole, which may preclude use in children and women of childbearing potential.[207] In addition, flubendazole and one of its metabolites have been shown to be aneugenic in an *in vivo* micronucleus test, although it has been argued that the risk posed to patients treated for a short period of time as required for anthelmintic efficacy is low.[208]

A third example of repurposing applied to discovery of anthelmintic drugs for LF and onchocerciasis is work reported on the development of NMT inhibitors.[209] The sequences of NMT enzymes of *B. malayi*, *O. volvulus*, and other filarial worms were compared with the homologous enzymes in other parasites and humans. The *B. malayi* enzyme was expressed in *E. coli* and used to screen several leads identified in a kinetoplastid NMT project (**Fig. 27**), where nanomolar activity was demonstrated. Finally, two lead compounds DDD85646 and DDD100870 were found to reduce motility of male and female *B. malayi* adults in culture.[209]

5.23.3.1.2.2 *Anti-*Wolbachia *compounds*

One of the unique features of the filarial worms that cause LF and onchocerciasis is the presence of an endosymbiotic bacterium, *Wolbachia*.[210] It has been known for quite some time that antibacterial drugs such as doxycycline that kill the *Wolbachia* present in worms are effective as antifilarials, as the growth of *Wolbachia*-depleted worms is inhibited, embryogenesis in female worms is interrupted, and the overall life span of the worms is significantly reduced.[211] One of the particularly attractive features of an anti-*Wolbachia* approach is that the eyeworm *L. loa* does not harbor the endosymbiont and, as such, is not affected by antibacterials.[210c] This "selectivity" is particularly important, as concurrent killing of both *O. volvulus* and *L. loa* has been associated with serious adverse events in the field.[212] Although effective, use of doxycycline (or minocycline) in disease-endemic areas is complicated by the need to treat patients for long periods (4–6 weeks).

As with direct-acting macrofilaricides, a significant effort has been applied to repurposing of approved drugs as anti-*Wolbachia* agents.[213] This effort has been facilitated by the development of high-throughput screens utilizing either *A. albopictus*[214]- or *D. melanogaster*[215]-derived cell lines infected with *Wolbachia*, which have allowed screening of thousands of known drugs as well as novel compound libraries.[216] Perhaps not surprisingly, a large percentage of the hits from screening known drugs were antibiotics, including representatives from the tetracycline, fluoroquinolone, and rifamycin classes (**Fig. 33**).[213] Very recently, a number of macrolides derived from tylosin have been reported as having significant anti-*Wolbachia* activity and have been evaluated in preclinical models of LF and onchocerciasis.[217]

5.23.3.2 Trematodes: *Schistosoma* and *Fasciola*

The trematodes are parasitic flatworms that are widely distributed geographically and infect both animals and humans. The two most important trematodes of relevance to human health are *Schistosoma* spp. and *Fasciola* spp., which infect the gastrointestinal

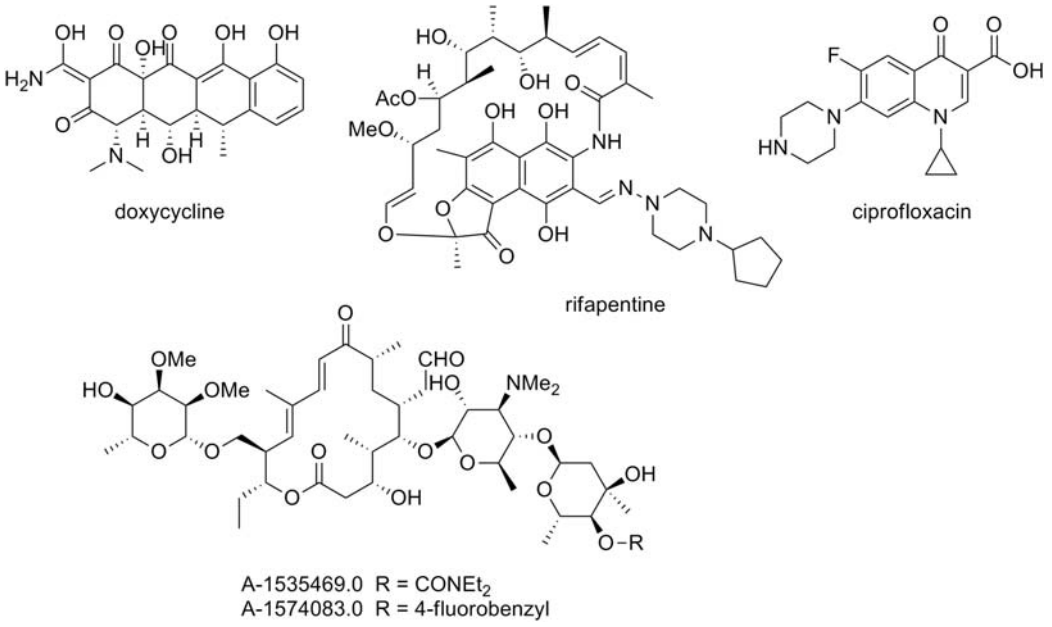

Fig. 33 Compounds active against *Wolbachia* spp. with potential as anthelmintics.

tract and liver, respectively. Infections are propagated by consumption of untreated drinking water, as these parasites are hosted in snails that are present in lakes and rivers around the globe. It has been estimated that over 265 million individuals are infected with *Schistosoma*, with over 280,000 deaths annually.[218] Epidemiological data for *Fasciola* infection in humans are less readily available, but a 2005 estimate suggested that over 90 million individuals are at risk.[219]

Despite the significant impact of *Schistosoma* infections on human health, the only drug used to treat schistosomiasis is praziquantel.[220] While generally effective, concerns over emergence of resistance continue to grow due to the reliance on a single drug. Numerous efforts have emerged to discover new drugs to treat schistosomiasis, primarily focused on development and application of high-throughput screens against the larval stage of *Schistosoma*, the schistosomula, which can be isolated from snails in culture.[221] Using these screening methods, a number of chemotypes have been identified from both commercial and proprietary compound libraries, representatives of which are depicted in **Fig. 34**.[221a,222]

Based on these hits, several early hit-to-lead or lead optimization projects have emerged and focused on a diaryl urea from the MMV Malaria Box[223] and synthetic peroxides previously studied as antimalarials (**Fig. 3**).[224] The synthetic peroxides have also been found to be effective against *F. hepatica*.[225]

In addition to phenotypic screening, a limited number of biochemical targets have been evaluated as sources of new chemotypes for treatment of schistosomiasis. One such example is the class I *S. mansoni* histone deacetylase 8.[226] This work has been facilitated by the availability of recombinant enzyme and X-ray crystallography of lead compounds bound to the enzyme active site.[227] Preliminary optimization of a series of hydroxamic acids afforded a lead with nanomolar affinity for the enzyme and activity against the schistosomula (**Fig. 35**).[228] More recently, the same researchers have characterized and developed a screening assay to identify leads from the class III HDAC, *S. mansoni* sirtuin 1.[229]

A third biochemical target that has been examined as a source for antischistosomal leads is polo-like kinase 1 (PLK1). Following validation of the target for development of schistosomula by RNAi, screening of known human PLK1 inhibitors identified a series of benzimidazole thiophenes (**Fig. 35**) as leads for this enzyme.[230]

5.23.4 Summary and Conclusions

In the past decade, considerable effort has been expended on the discovery and development of new drug candidates for the treatment of a wide range of parasitic infections. Much of this work has been facilitated by collaborative efforts between governments, philanthropic organizations, and PDPs that aim to close the gap that exists between economic incentive and unmet medical need. In particular, the Bill and Melinda Gates Foundation has committed to eradication of the top 10 parasitic diseases by 2020 and has provided considerable resources, both financial and organizational, to achieve this goal. Clinical candidates for both protozoan (malaria, HAT, and Chagas disease) and helminth (onchocerciasis) have recently been identified, with lead optimization programs focused on leishmaniasis, amoebiasis, and schistosomiasis progressing toward preclinical candidates. Continued engagement of the partners identified in the preceding text is critical to the long-term success of discovery and development efforts in this area. One of the main areas of focus in the past few years has been to repurpose approved drugs and clinical

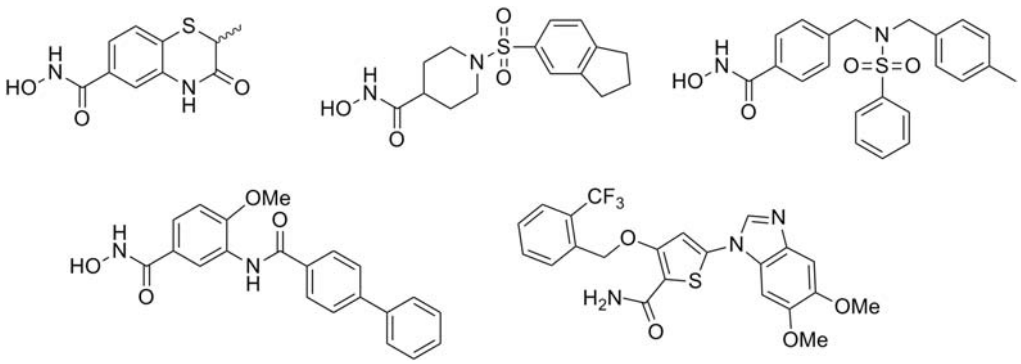

Fig. 35 Leads from target-based screening for antischistosomal compounds.

candidates from other diseases for use in parasitic infections, an approach that has been facilitated by a significantly increased understanding of the biochemistry of the target organisms. While this approach has offered some quick wins (e.g., ivermectin and fexinidazole) in providing useful treatments for some diseases, there remains a need for new chemical entities that are designed to kill parasites by those biochemistries that are unique to the parasite. These scientific strategies, coupled with creative approaches for funding of discovery and development projects for what are often diseases of the developing world, offer hope for continued progress in this field.

PREFACE

Previous editions of *Comprehensive Medicinal Chemistry*, published in 1990 and 2006, provided an integrated reference source that encompassed all major aspects of drug discovery research. The third edition follows this tradition and considerably expands its scope and content.

The trailblazing scientific discoveries of the 21st century have brought new opportunities for drug discovery research. The discipline of medicinal chemistry continues to evolve as it adapts to these new opportunities and strives to solve new challenges. Covered in the new edition are not only the breakthrough therapies of the past decade in cancer, hepatitis C, heart failure, dyslipidemia, cystic fibrosis, multiple sclerosis, HIV, etc., but also extensive discussion of new business models in drug discovery research, shifting industry demographics, emerging technologies, *in silico* drug discovery tools, experimental ADME and toxicology, and biologics medicine. The tone of this edition is prospective in which contributors identify outstanding issues and paths forward in their area of expertise. The aim is to provide drug discovery scientists in industry, government, academia, and research organizations with a contemporary global perspective on the field that includes a look ahead in selected areas.

The eight individual volumes fulfill these objectives and include extensive discussion of biomolecular therapeutics, drug targeting and delivery, development of chemical biology tools, data collection and analysis, *in silico* models as predictors for biological properties, identification/validation of new targets, approaches to quantify target engagement, new methods for synthesis of drug candidates such as green chemistry, development of novel scaffolds for drug discovery, and the role of regulatory agencies in drug discovery.

The individual volume editors have done an outstanding job to identify topics and contributors to meet these goals and we thank them for their hardwork and diligence. In volume 1, Ana Martinez and Carmen Gil recruited an international group of contributors who provide chapters on the emerging role of organizations other than traditional pharmaceutical companies in drug discovery, the evolving science of chemical biology, and new organic chemistry contributions to the discipline. In volume 2, Helmut Buschmann, Norbert Handler, and Andrea Wolkerstorfer have accomplished a seemingly impossible task and attracted world-leading experts across the wide field of drug discovery enabling technologies, covering contemporary thinking in a wide range of key disciplines that enable modern medicinal chemistry and drug discovery and development. The computational enabling technologies are the focus of volume 3, in which Andy Davis and Colin Edge have assembled chapters covering both ligand-based and protein structure–based advances as well as exciting new methodologies and case studies exploiting these. Alan Wilson identified experts in the fields of pharmacokinetics and toxicology who describe a wide range of contemporary advances in prediction and analysis of pharmaceutical properties and drug safety in volume 4. In volume 5, Ian Collins, Louis Lombardo, and Will Watkins have assembled leading experts to discuss high impact drug discovery accomplishments over the past decade in cancer chemotherapeutics, immunology and inflammation, and infectious diseases therapeutic areas. Ved Srivastava edited volume 6 on biologic medicines, a significant and rapidly evolving area where medicinal chemistry plays an important role. The chapters in this volume provide timely information on not only protein-based drugs, such as monoclonal antibodies and therapeutic proteins, but also peptides and nucleic acid–based therapeutics. Volume 7, edited by Adrian Hall, Santhosh Neelamkavil, and Rob Jones, presents a detailed account of the major advances in CNS, metabolic, and cardiovascular fields over the past decade and the promising new opportunities. Joerg Holenz edited volume 8 that presents case histories of successful drug discovery and strategic differentiation that have resulted in commercialized drugs and candidates in advanced clinical trials.

We are truly grateful to the publishing team at Elsevier that includes Gemma Tomalin, Rachel Gerlis, Marise Willis, and Sean Simms for their assistance and support throughout the process. With their expertise, this project became what we believe is a noteworthy and valuable resource for the discipline of medicinal chemistry. We look forward to the response and feedback of our colleagues who will use this information in their own work.

Samuel Chackalamannil, David P. Rotella, and Simon E. Ward

EDITORS-IN-CHIEF: BIOGRAPHIES

Dr. Samuel Chackalamannil

Dr. Chackalamannil obtained his PhD in chemistry from Yale University in 1984 and subsequently worked in drug discovery research at Schering-Plough Corporation and Merck Research Laboratories, where he was a distinguished fellow when he left in 2011. Since then, he has been teaching at Ernest Mario School of Pharmacy, Rutgers University, New Jersey.

Dr. Chackalamannil has significant accomplishments in the discovery of new medicines. He led the discovery of vorapaxar (Zontivity®), an FDA-approved antiplatelet drug for the prevention of heart attack and stroke. His group also discovered a PDE-5 inhibitor clinical candidate dasantafil and an adenosine A2a antagonist clinical candidate for the treatment of Parkinson's disease. Altogether, he was responsible for the discovery of nine development candidates in cardiovascular, central nervous system, and metabolic disease areas.

Dr. Chackalamannil is a coinventor of 62 allowed US patents and numerous patent applications worldwide. He has published 81 peer-reviewed articles and has coauthored a book. He has also given numerous lectures at international meetings and academic institutions.

Dr. Chackalamannil is a two-time recipient of the Thomas Alva Edison Award for Emerging Technology Patent and a two-time recipient of the Presidential Award for Discovery at Schering-Plough Research Institute. He has chaired several sessions at American Chemical Society national meetings and Gordon Research Conference on Medicinal Chemistry and was an organizer for Chemistry as a Life Science Symposium.

Dr. David Rotella

Dr. Rotella earned a PhD in medicinal chemistry from The Ohio State University and carried out postdoctoral research in organic chemistry at Penn State University. He joined the faculty at Montclair State University in July 2011 as the Margaret and Herman Sokol Professor of medicinal chemistry after a successful career in the pharmaceutical industry. He is an expert in the discovery and optimization of small molecule drug candidates for use in metabolic, cardiovascular, cancer, and central nervous system diseases. His current research is focused on discovering new lead compounds for use in parasitic and central nervous system diseases. He has coedited the seventh edition of *Burger's Medicinal Chemistry* and is a senior editor for the Royal Society of Chemistry's Drug Discovery book series. He has authored over 40 peer-reviewed articles, is an inventor on 8 issued US patents, and has contributed 10 book chapters.

Simon E. Ward

Simon Ward has an MA in natural sciences and PhD in synthetic organic chemistry from Cambridge University, UK. He has a wide-ranging experience of drug discovery in both large and small companies (GlaxoSmithKline, Knoll Pharmaceuticals, Vernalis, Chiroscience, BioCrea) and specialist experience of discovering and developing drugs for central nervous system indications. He has led multidisciplinary project teams and medicinal chemistry groups from target identification through to early clinical studies, delivering multiple clinical development candidates across indications. He is a fellow of the Royal Society of Chemistry. He is currently a professor of medicinal chemistry at the University of Sussex, UK, and the director of the Sussex Drug Discovery Centre, which he established within the University of Sussex in 2010.

INTRODUCTION

Biopharmaceuticals are now becoming an innovative strategy for developing new therapeutic agents. The field of biologics medicine is expanding into new areas of molecular diversity, which comprises polypeptides, oligonucleotides (DNA, siRNA, microRNA), antibodies (monoclonal and conjugated antibodies), and PNA (peptide nucleic acid) structures. The aim of introducing biologics medicine to the *Comprehensive Medicinal Chemistry* series is to present an overview of different large molecule drug modalities and the innovative science and challenges involved in developing biologics-based medicine. Biopharmaceuticals are in an earlier stage of development relative to small molecules, but the field is progressing exponentially. Advances in the basic science and application of technologies related to DNA/RNA heteroduplex oligonucleotide, antisense oligonucleotide (ASO) mRNA/protein, and transformative heterodimeric IgG bispecific antibodies including clinical evaluation of drug candidates in the field are accelerating.

During the last four decades, peptide therapeutics progress has grown exponentially. There are more than a thousand peptide molecules currently being studied for therapeutic indications in a variety of disease areas such as cancer, infectious disease, metabolic diseases, CNS, and numerous others. Several molecule types including linear and cyclic peptides, peptide mimetics, peptide conjugates are currently being developed in different dosage forms including parental, buccal, inhalation, or oral. There are some challenges that still need to be overcome such as target validation, understanding the intracellular targets, cost-effectiveness, and patient-friendly noninvasive delivery. Recently approved peptide-based drugs such as GLP-1 agonists (Trulicity™ and Tanzeum™) for diabetes are great examples of clinical successes of peptide−protein/antibody hybrid technologies.

Protein-based biologics are advancing rapidly as exemplified by the progress of a number of candidates in clinical trials and with the approval of several first-in-class therapies such as a CD38 monoclonal antibody (Darzalex™) for multiple myeloma, an IL-5 antagonist monoclonal antibody (Nucala™) for asthma, a bispecific mab-CD19-CD3 (Blincyto™) for leukemia, and a vaccine for meningitis B (Trumenba™). However, the challenges and risk mitigation strategies with large biomolecules such as immunogenicity, multidomain binding protein interactions, formulation, and manufacturing and assessing appropriate drug delivery alternatives need to be clearly understood.

In this volume, we have focused on four themes—vaccine therapies, peptide therapeutics, antibody/protein-based therapeutics, and oligonucleotides (RNA-based medicine). The first two chapters describe contributions on the current status and future direction of peptide vaccines and cancer immunotherapy, followed by chapters on peptide therapeutics covering the general strategy and tactics for designing peptide analogs with specific examples of peptide drug candidates including clinical studies for neuroendocrine diseases. This is followed by describing basic formulation principles and various approaches for alternatives to parental biologic drug delivery, which include an example of an orally active peptide for the treatment of gastric disorders.

Subsequent chapters cover the cutting-edge science for recombinant antibody development and manufacturing processes, current- and next-generation platforms, emerging novel bioanalytical methods for biological molecule characterization, and a formulation development roadmap for protein therapeutics.

The final section covers the medicinal chemistry and the downstream process of oligonucleotide-based medicine, drug discovery of ASO mRNA/protein, the current and future prospects of RNA-based therapeutics, and an extensive description of the process for manufacturing oligonucleotide-based molecules.

I would like to thank all the authors who contributed to this volume of comprehensive medicinal chemistry. I highly appreciate all their hardwork in writing the chapter and sharing their expertise with a broad spectrum of readers. Thanks to Elsevier project team members especially Gemma Tomalin and Editors-in-Chief Prof. David P. Rotella and Prof. Samuel Chackalamannil for continued support and advice in editing this volume.

6.01.1 Introduction

Traditional chemotherapy and radiotherapy regimens are often associated *with significant toxicities and severe debilitating side effects, limited by a narrow therapeutic* index and frequently acquired resistance toxicity.[1,2] Over the past two decades, the paradigm for cancer treatment has evolved to selective, mechanism-based targeted therapies (monoclonal antibodies, mAbs) and tyrosine kinase inhibitors (TKIs) that block the growth and spread of cancer with fewer side effects than nonspecific chemotherapies (reviewed in Kaumaya[3]). The market for mAb therapeutics currently stands at more than $60B annually. Receptor tyrosine kinases (RTKs) transduce growth-promoting signals that drive the development and progression of many types of cancer.[4] The most aggressive RTKs are the epidermal growth factor receptors (ErbB), which include EGFR (HER-1), HER-2, HER-3, and HER-4; vascular endothelial growth factor receptor (VEGFR)[5]; and insulin growth factor receptor (IGFR)[6] have been prime targets for developing a plethora of FDA-approved RTK inhibitors.[7] Targeted therapies with HER-2 (trastuzumab, pertuzumab, lapatinib) and EGFR (cetuximab, gefitinib, erlotinib) have markedly improved survival in the adjuvant setting but still demonstrate significant toxicities, intrinsic or acquired resistance, and the majority of patients finally succumb to their disease. Thus, novel approaches and other treatment options are urgently needed (reviewed by Kaumaya[3]) to overcome these difficulties.

The greatest potential significance of our peptide strategy is twofold: (1) It combines multiple mechanisms of action by activating both B- and T-cell functions and promoting immunological clearance; (2) it is also a targeted approach aimed at inhibiting molecular signaling pathways that are crucial for tumor growth and maintenance. The major attraction of the peptide vaccine approach is the potential for a sustained antitumor effect related to immunological memory that protects against relapsing tumors, obviating the requirement for multiple infusions of humanized mAbs or small-molecule inhibitors and overcoming escape mechanisms.

Our studies have made major contributions to the existing fields of cancer immunology, drug development, and mechanisms of cancer pharmacology by (1) developing new immune-based approaches to combat receptor kinase-driven cancers and (2) understanding and overcoming clinically relevant mechanisms of resistance to currently used HER-2-directed agents. To promote a rational, systematic development of combination therapies in multivariate ways, next-generation combination therapies can be constructed with a clear understanding of how mechanisms of resistance to multidrug regimens differ from single agent resistance. Active immunotherapy with conformational B-cell epitopes affords the possibility of generating an enduring immune response, eliciting protein-reactive high-affinity antipeptide antibodies. In addition, immunologic memory is elicited with an active approach; the longevity of the immune response could prevent the reemergence of the tumor. Additional benefits of the peptide vaccine approach include the ease and rapid synthesis, safety, lack of toxicity, and cost-effectiveness.

6.01.1.1 Immunotherapy

Recent advances in immunology and tumor biology have opened new avenues for the clinical testing of rationally designed vaccination strategies against cancer. Innovative and rationale strategies are needed to enhance the immunogenicity of inherently weak immunogenic self-antigens such as HER-2. Active, specific immunotherapy for cancer holds great potential of providing an approach for treating cancers, which have not been controlled by conventional therapy, with very little or no associated toxicity. Active immunotherapy offers many advantages, including tumor specificity and the activation of immune responses against antigens that are selectively expressed by tumor cells. As a result, nonspecific toxicity to normal tissues is reduced and antitumor responses are more durable and adaptable to cancer control at different stages of disease, including early-stage disease and disease with low tumor burdens.

6.01.1.1.1 Active immunotherapy

Vaccines have been used in both preclinical and clinical studies including peptide, DNA, whole-cell, dendritic cell, and adoptive therapy. HER-2 vaccines have been designed that use whole-cell expressing tumor antigens,[8] proteins,[9] DNA,[10] and B-cell epitope peptides[11] as sources of antigen. Many cancer immunotherapeutic strategies are designed to activate specific cytotoxic T-cells (CTLs) which play a major role in tumor rejection, and there are numerous reviews on this subject.[12] Preexisting CD4 T-cell and antibody-mediated immunity against HER-2 have been described in patients with HER-2+ breast cancer providing further rationale for

active-specific immunotherapy strategies to augment the anti-HER-2 immune response.[13] Most of the immunotherapies targeting the HER-2 oncoprotein have focused on T-cell epitopes, and several studies have produced notable results indicating that vaccinated patients can develop immunity to HER-2 peptides and native protein.[14] Recent clinical trial results using a HER-2 CTL epitope showed an increase in disease-free survival in vaccinated HER-2/neu-expressing breast cancer patients (85.7%) compared to the control group (59.8%).[15] However, the effectiveness of a CTL vaccine for clinical use is limited to patients who express the appropriate HLA haplotype.

6.01.1.1.2 mAb therapies

mAb therapies have been successful and generated new interest in the contribution of humoral effector molecules. There has been a number of mAbs developed that target solid tumors. These targets include cell-surface proteins and antigens involved in tumor-associated vasculature that support tumor growth. Trastuzumab, a humanized mAb specific for HER-2, is active in combination with chemotherapy in patients with breast cancer overexpressing HER-2. A mAb targeting CD20 (IDEC-C2B8, Rituximab/Rituxan) is approved for use in B cell non-Hodgkin's lymphoma and is among the most effective mAb therapies.[16] Cetuximab (Erbitux) and panitumumab (Vectibix) both target EGFR and are approved for treatment by the FDA to treat colorectal cancer. Both these anti-EGFR mAbs block ligand–receptor interactions. VEGF (vascular endothelial growth factor) and its receptors (Flt-1 and KDR) have been implicated in promoting solid tumor growth and metastasis by stimulating tumor-associated angiogenesis. Bevacizumab (Avastin) is a recombinant humanized IgG1 mAb that is approved for treatment of the lung and colorectal cancers. Bevacizumab binds VEGF and prevents the interaction of VEGF with its receptors on the surface of endothelial cells.

6.01.1.1.3 Disadvantages of antibody immunotherapy

Humanized mAb's approved for treatment of several cancers is fraught with a number of concerns exist. Treatment is expensive and has a limited duration of action, necessitating repeated administrations of the mAb.[17] The half-life of IgG administered intravenously can range from 5 to 21 days. Thus, repeated treatments with trastuzumab are necessary; patients typically receive the mAb every week to 3 weeks. The repeated treatment with trastuzumab raises the cost of passive immunotherapy with this mAb to ~$150,000 USD a year. Additionally, patients are constantly infused with a large quantity of trastuzumab, which contributes to the cardiotoxicity associated with trastuzumab treatment.

6.01.1.1.4 Small-molecule TKIs

Another therapeutic approach is the use of small-molecule TKIs that inhibit the specific catalytic activity of HER kinases by interfering with the binding of ATP. This area of study was revolutionized by the discovery of modified quinazoline compounds as highly specific and potent inhibitors of EGFR.[18,19] The clinical success of the ABL-kinase inhibitor imatinib mesylate (Gleevec; Novartis) in the treatment of ABL-driven leukemia[20] raised hopes that drugs targeting HER kinases implicated in other types of cancers would be similarly efficacious. However, TKIs lack the singular target specificity of antibodies.

Various strategies involving TKIs have been developed to target EGFR and/or its family members, and these are in a range of stages for clinical testing. Nearly all of these agents are ATP analogs and inhibit kinase activity by binding the ATP pocket of the catalytic domain.[21] Gefitinib (Iressa; AstraZeneca) and erlotinib (Tarceva; OSI Pharmaceuticals, Genentech), which bind to the ATP binding site of the intrinsic tyrosine kinase domain of EGFR, received fast-track approval by the US FDA in 2003 and 2004, respectively, for patients with advanced NSCLC who had failed to respond to conventional chemotherapy. In addition, lapatinib (Tykerb; GlaxoSmithKline), a dual inhibitor of EGFR and HER-2 kinases, is being investigated in phase II and III trials in combination with chemotherapy and/or hormonotherapy. In cell-based assays these orally bioavailable ErbB family TKIs are effective at inhibiting both EGFR and HER-2, and EGFR and HER-2 phosphorylation. Despite this success, TKIs have shown very limited clinical activity, marked by modest delays in tumor progression. Although gefitinib received fast-track approval in 2003, the conditions of the approval were restricted in 2004 because of negative results of the phase III Iressa Survival Evaluation in Lung Cancer (ISEL) trial.[22] Gefitinib is not presently clinically available in the United States.

6.01.1.1.5 Peptide-based cancer vaccines

Vaccination has been one of the most successful clinical interventions for the prevention of human diseases. Vaccines have contributed to the eradication of smallpox, an extremely contagious and deadly disease. The occurrence of other diseases such as polio, measles, mumps, rubella, chickenpox, and typhoid has decreased significantly as a result of vaccination. Despite a large body of work, there is still no effective cancer vaccine. This, in large part, is due to the immune system's weak and ineffective response to cancer, whereas the immune system responds efficiently to bacteria, viruses, and other agents. It has long been thought because of tolerance to self, tumor-associated antigens are not antigenic because they are self-antigens. This is an argument against active immunotherapy. However, it has been proposed that this issue can be circumvented using subdominant epitopes with a synthetic peptide vaccine.[14a] Peptide vaccines can be broadly characterized into two groups: cellular (T cell) and humoral (B cell) vaccines.

6.01.1.1.6 Vaccine studies are focused on a cellular immune response

T-cell epitopes are used exclusively due to the fact that when presented in the context of MHC Class I, the resulting activated CTLs can become activated and lyse transformed tumor or infected cells. This response is thought to be the most prominent mechanism utilized by the immune system to control viral replication and kill transformed tumor cells. However, the humoral arm could play a critical role in the generation of an antitumor response. The successful clinical usage of passively infused mAbs points to the

effectiveness of the humoral arm of the immune system. B-cell epitope vaccines are designed to induce a protective humoral response. This response includes creation of antibody-producing plasma cells as well as immunologic memory. B-cell epitopes have been used in a variety of vaccines. Peptides have the potential to be safe, noninfective, well-defined, and stable vaccines. Several factors need to be considered in formulating an effective peptide vaccine; these factors include inclusion of a universal T-helper epitope and the necessity to mimic the structure of the parent antigen to generate high-affinity Abs.

6.01.1.1.7 Rational design of B-cell peptide vaccines

In the design of a synthetic peptide vaccine, it is necessary that the B-cell epitope be presented along with an appropriate helper T-cell epitope. The interaction between B cells and T cells recognizing the same antigen is essential for B-cell proliferation and differentiation and the generation of high-affinity antibodies that are of the IgG isotype. For sequences shorter than 15 residues, peptides are traditionally coupled to a larger carrier protein such as keyhole limpet hemocyanin (KLH) or bovine serum albumin (BSA). This approach can be problematic for several reasons including epitope suppression by the carrier protein and poorly defined constructs due to lack of control during the chemical coupling reaction. Several alternatives have been described to produce conformationally stable peptides.

6.01.1.1.8 Chimeric peptides incorporating "promiscuous" T-cell epitopes

The ideal vaccine should be composed of appropriate tumor antigen B-cell epitopes or CTL epitopes, and a universally immunogenic T-helper epitope. Another alternative involves B- and T-cell epitopes constructed in a colinear fashion. This has limited usage when the T-helper epitope is recognized by one or a few MHC class II alleles. Thus the identification of "universal" or "promiscuous" T-helper epitopes that bind multiple MHC haplotypes is necessary in the design of an optimum vaccine. Universal T-helper epitopes from tetanus toxoid (TT) and measles virus fusion (MVF) protein have been identified.[23] B-cell epitopes are synthesized as chimeric constructs with MVF promiscuous T_H epitope,[11a,c] thus proving the utility of a chimeric vaccine construct incorporating B and T_H epitopes in a collinear fashion. The most important consideration in the successful design of a peptide vaccine is that the B-cell epitope must be covalently linked to the "helper" T-cell epitope at either the N- or C-terminus (**Fig. 1**). The size of the B-cell epitope should minimally be ~18 amino acid residues (~900 Å^2) the size of antigen:antibody binding region to ensure the peptide propensity to adopt a defined structure, The helper T-cell should ideally be a "promiscuous" epitope (~18 residues) and the linker (~4 residues), and the final construct should consist between 40 and 60 amino acid residues. Traditionally, peptide sequences are coupled to a larger carrier protein such as BSA, TT, or KLH to induce immunogenicity. This approach is fraught with difficulties as the resulting conjugate is subject to processing by the immune cells and the resulting B-cell epitope may not represent the exact epitope identity or configuration resulting in low-affinity antibodies.

6.01.1.1.9 Enhancing immunogenicity of peptide vaccines

In addition the peptide vaccine must be formulated with an adjuvant or cytokines. Adjuvants are usually defined as compounds that increase and/or moderate the intrinsic immunogenicity of an antigen.[16] Different types of receptors on antigen-presenting cells (APCs) can be targeted by adjuvants. Oil-in-water emulsion adjuvants are thought to be linked to the depot for the antigen at the site of vaccination recruiting APC's such as macrophages and B cells. Muramyl dipeptides are a ubiquitous constituent of bacterial cell walls and are recognized by APCs such as macrophages. The muramyl dipeptide synthetic compound *N*-acetyl-glucosamine-3 yl-acetyl L-alanyl-D-isoglutamine when emulsified in ISA720 (SEPPIC) can be used as an adjuvant to activate APCs and has been used extensively in our laboratory with success. Oil-in-water emulsion adjuvants are thought to be linked to the depot effect as well. Tiny drops of antigen are surrounded by oil, trapping the antigen. As a result the antigen is released slowly over a prolonged period, destruction of the antigen is delayed, and an individual's exposure to the antigen is lengthened. Montanide ISA 720 is one such emulsion approved for human usage and is used in the Phase I Clinical Trial.

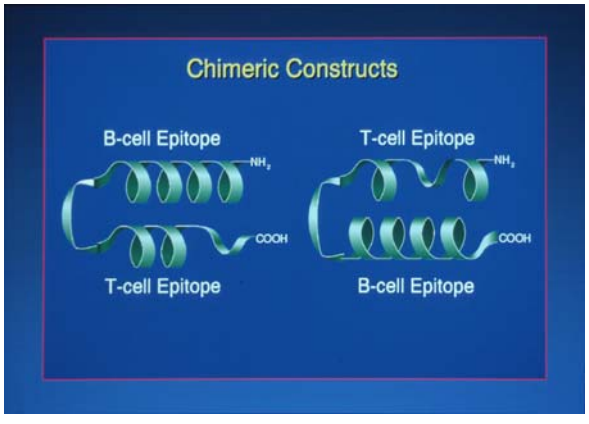

Fig. 1 Chimeric peptides incorporating B- and T-cell epitopes.

6.01.1.1.10 Peptide therapeutics

A relatively newer class of targeted therapeutic drugs is emerging in cancer drug development, and these drugs are called peptide therapeutics. Peptides are short sequences of amino acids that can be produced biosynthetically, via natural or recombinant microbial fermentations, or chemically, through mechanisms such as solution-based or solid-phase peptide synthesis. The concept of using peptides as therapeutics has been historically disregarded, mainly due to peptide stability, susceptibility to degradation, size (>5000 Da), and consequent limitations in methods of delivery (low oral bioavailability). In recent years, however, the development of peptides as drugs is attracting increasing attention from the pharmaceutical industry, especially as the technologies for peptide development and manufacturing continue to mature. New synthetic strategies to improve productivity and reduce metabolism of peptides, along with alternative routes of administration, have been developed in recent years, and a large number of peptide-based drugs are now being marketed.[17] As of 2010, there were ~60 therapeutic peptides on the market, 150 in clinical phases and 400 in advance preclinical stages. Peptide drugs are now being universally marketed, and more than 100 pharmaceutical and biotech companies are now active in the peptide field. Of the products now approved, about 30 peptide drugs are currently marketed in the United States, and 17% are used in the cancer clinical setting.[24] The peptide therapeutics foundation anticipates that pharmaceutical and biotechnology industries will continue to focus on these versatile molecules because of the increased acceptance of injected drugs on the market, the availability of new formulation and delivery technologies, and the relatively high approval success rates.

Development of peptide therapeutics has the potential of overcoming some of the obstacles observed with mAbs and TKIs. Currently, one of the greatest strengths of peptides as potential therapies lies in the powerful new approaches for discovering and screening new drug candidates. In theory, peptide-based drugs have given oncologists an opportunity to expand the repertoire of "druggable proteins." As mentioned before, mAbs and TKIs are limited to the number of candidates they can effectively target; mAbs are too large and complex for entry into the cell, while small-molecule inhibitors are limited to proteins with well-defined small binding pockets. Peptides are also small enough to penetrate the cell membrane, and they can be rationally designed to target almost any protein of interest.[25] Peptides now have a broad range of potential clinical benefits against numerous protein targets, with applications in some of the most prevalent disease categories.[26] These molecules are rationally designed to mimic the binding region between two or more proteins involved in various disease states. A perfect peptide agent is designed rationally and has the ability to reach, bind, and antagonize the function of a target protein with high selectivity and affinity.[27] Their small size and specific binding properties make peptides ideal candidates for physiologically disrupting on-target functional protein–protein complexes. Peptide-therapeutics may consequently aide in the reduction of current therapeutic problems, such as off-target side effects and the requirement of high-dosage treatment.

6.01.2 High-Value Cancer Targets Overexpressing RTK'S

The crucial tenet of our research program requires the identification of important therapeutic targets that drives cancer metastasis though mechanisms of resistance, the rapid development of effective peptide antagonists directed against these RTK targets, and the efficient testing of these agents in relevant animal models of human cancer. We have focused on Breast and GI cancers: (1) metastatic gastric or gastroesophageal (GE) junction adenocarcinoma, (2) colorectal, and (3) pancreatic cancers.

6.01.2.1 Breast Cancer

Breast cancer is a heterogeneous group of diseases consisting of multiple subtypes.[28] In 2016, it is estimated by the American Cancer Society that 249,260 people will be diagnosed with breast cancer and 40,890 people will die as the consequence of this disease. HER-2 overexpressing breast cancer represents about 20–30% of all breast cancer cases.[29] Breast cancers that show amplification and overexpression of the *HER-2* gene represent about 20% of metastatic cases.[29a] HER-2 overexpression is associated with aggressive growth and poor clinical outcomes.[30] Despite the success of trastuzumab, ~70% of patients develop resistance to monotherapy within 1 year (acquired resistance),[31] and ~35% do not respond at all (de novo resistance).[32] Since 2007, three new HER-2-targeted therapies (lapatinib, pertuzumab, and T-DM1) have been approved, but even the latest iteration, kadcyla (T-DM1), demonstrates resistance *suggesting that the current approved drugs remain ineffective in the long term*. Cross talk and compensatory signaling networks limit the activity of most targeted therapies, including HER-2-targeted agents. Multiple mechanisms of trastuzumab resistance have been proposed. The mechanisms through which trastuzumab blocks tumor growth include reduced downstream signaling, inhibition of angiogenesis, and increased immune activity, primarily antibody-dependent cellular cytotoxicity (ADCC).[31]

Increased expression of the insulin-like growth factor-1 receptor (IGF-1R) also reduces the growth inhibitory activity of trastuzumab.[33] Among patients with HER-2-overexpressing breast cancer, high IGF-1R expression and activation correlate with worse response to preoperative trastuzumab and chemotherapy[34] and reduced progression-free survival.[35] Others and we have reported the formation of a unique receptor complex containing IGF-1R and HER-2 in resistant cells. This complex facilitates cross talk from IGF-1R to HER-2, resulting in sustained HER-2 phosphorylation in resistant cells.[36] HER-3 has also been shown to be involved in acquired resistance to HER2-targeted therapies and other inhibitors that directly or indirectly antagonize PI3K signaling.[37] HER-2 antibody trastuzumab has been shown to be mediated by increased HER-3 signaling in part due to heterodimerization of HER-2 and HER-3 which is critical for the growth and progression of HER-2 positive breast cancers,[3,38] or HER-2 and IG-1R and in part through the formation of heterotrimers involving HER-2, HER-3, and IGF-1R.[36b]

6.01.2.2 Gastric Carcinoma

Gastric carcinoma is a substantial health care problem worldwide, with over 900,000 new diagnoses and 700,000 deaths worldwide annually, making it the second leading cause of cancer mortality in the world.[39] In 2016, it is estimated that 16,910 men and women will be diagnosed with esophageal cancer and 15,690 people (92%) will die as the consequence of this disease.[40] (http://www.cancer.org). Esophageal adenocarcinoma (EAC) has a very high fatality rate and is one of the fastest rising cancers worldwide. In the past, patients with advanced or metastatic gastric or gastroesophageal junction cancer have had few treatment options and generally poor survival rates. HER-2 is overexpressed in gastric (21%) or gastroesophageal junction cancers (33%), in association with an increased risk of metastasis, decreased survival,[21] and increased tumor invasion[41]; this correlation between HER-2 overexpression and poor prognostic markers established HER-2 as a potential therapeutic target. Trastuzumab has been approved for patients with HER-2-positive metastatic gastric adenocarcinoma in combination with chemotherapy.[42] Trastuzumab (Herceptin Genentech/Roche) has been shown to improve the survival of patients with advanced gastric cancer.[43] Trastuzumab resistance is a major clinical problem to be resolved in patients with HER-2-positive gastric cancers. Using HER-2-amplified cell lines, Kim et al.[44] demonstrated that secondary oncogenic events could confer resistance to HER-2-directed therapies. Several studies have reported the overexpression of HER-1 (EGFR) and HER-2 in esophageal cancers with extremely high rates in esophageal adenocarcinoma when compared to squamous cell carcinomas of the esophagus[45]; inhibition of these receptor kinases is now widely considered as a therapeutic strategy in the treatment of these cancers.[46] HER-1 overexpression is correlated with poor prognosis in EAC[47] makes it an attractive target for drug therapy. Several studies have reported the dual overexpression of HER-1 and HER-2 in EAC[45]; thus, there is a potential clinical benefit in cotargeting HER-1 and HER-2 in EAC.[48] HER-1 and HER-2 targeted inhibitors are widely considered a potential therapeutic strategy in the treatment of EAC.[46] Novel therapeutic targets are urgently needed because the inadequate improvement in the cure rate of about 10% realized by adjunctive treatments to surgery is unacceptable as >50% patients with localized gastric cancer succumb to their disease.[49] Additionally, the HER-2-targeted hmAb pertuzumab (Perjeta) has had significant clinical success in the treatment of breast cancer when combined with trastuzumab[50]; similar dual-targeting clinical trials are under way for esophageal cancer (NCT02120911).

6.01.2.3 Human Colorectal Cancer

Human colorectal cancer (CRC) is one of the most common malignancies and remains largely incurable. Colorectal cancer is the third most common malignancy in men and the second most common in women worldwide accounting for 8% of global cancer deaths. In 2016, it is estimated that 95,270 men and women will be diagnosed with colon cancer, and 49,190 people will die as the consequence of this disease. HER-1 and HER-2 are highly implicated in colorectal cancers,[51] and cetuximab, a blocking anti-EGFR mAb, is effective in combination with chemotherapy or as single agent for the treatment of patients with KRAS wild-type metastatic colorectal cancer.[52,53] After an initial response, secondary resistance invariably ensues, thereby limiting the clinical benefit of this drug[54] leading to treatment failure. An extensive effort has been made to understand cancer cell resistance mechanism(s) to EGFR inhibitors.[1] A rationally designed combination of trastuzumab and lapatinib was effective in HER-2+ mCRC (ORR 34%, Control of Disease 78%, TTP 5.5 months). HER-2+ mCRC patients were primarily resistant to cetuximab or panitumumab, supporting the use of HERACLES dual therapy in anti-EGFR-naive patients (presented as ASCO, Annual 2015). In developed countries, colorectal cancer (CRC) is the third most common malignancy, but it is the second most frequent cause of cancer-related death. Clinicians are still faced with numerous challenges in the treatment of this disease, and future approaches which target the molecular features of the disorder will be critical for success in this disease setting. HER-1 and HER-2 are highly implicated in colorectal cancers,[51] and cetuximab, a blocking anti-EGFR mAb, is effective in combination with chemotherapy or as single agent for the treatment of patients with KRAS wild-type metastatic colorectal cancer.[53,55] After an initial response, secondary resistance invariably ensues, thereby limiting the clinical benefit of this drug[38d] leading to treatment failure. An extensive effort has been made to understand cancer cell resistance mechanism(s) to EGFR inhibitors.[5f] A rationally designed combination of trastuzumab and lapatinib was effective in HER-2+ mCRC (ORR 34%, Control of Disease 78%, TTP 5.5 months). HER2+ mCRC patients were primarily resistant to cetuximab or panitumumab, supporting the use of HERACLES dual therapy in anti-EGFR-naive patients (presented at ASCO, Annual 2015).

6.01.2.4 Pancreatic Cancer

An estimated 46,420 new cases of pancreatic cancer (PC) are expected to occur in the United States during 2016 with an estimated 39,590 deaths. Several studies demonstrate that HER-1 overexpression correlates with poor prognosis and increased metastasis of PCs.[56] Several recent studies also show that HER-3 is frequently upregulated in cancers with HER-1 (EGFR) overexpression. HER-3 signaling has been shown to be a major driver of resistance to IGF-1R-targeted agents. It is clear that innovative approaches are needed for the prevention and treatment of PC.[57] IGF-1R has also been implicated in the growth and development of multiple tumor types[58] and is expressed in 50–60% of pancreatic cancers.[59] The IGF-1R:IGF-1 pathway is implicated in the development of resistance to anticancer drugs[6a,60] in pancreatic cancer.[61] HER-1 is implicated in aggressive pancreatic cancers with poor patient outcome[62] and decreases overall survival.[63] Increased expression of IGF-1R increases the expression of HER-1 and results in the formation of IGF-1R/HER-1 dimers.[64] There is considerable evidence of cross talk between HER-1 and IGF-1R in pancreatic cancer cells.[65]

6.01.3 Targeted Therapies With RTK'S

6.01.3.1 Human Epidermal Growth Factor Receptors and Cancer

The human epidermal growth factor receptor (HER) family consists of four homologous members: HER-1 (EGFR), HER-2, HER-3, and HER-4.[66] In response to a ligand, these RTKs can form homodimers or heterodimers and initiate intracellular signaling. The HER family of proteins form part of a complex signaling cascade that modulate cell proliferation, survival, and adhesion.[67] These HER receptors are also involved in tumorigenesis when their signaling functions are inefficiently regulated.[66,67]

The signaling pathways of HER family members, VEGF and IGF-1R and the current drugs that target these oncoproteins in cancer, are shown in Fig. 2. HER-2 can heterodimerize with any of the ligand-activated HER receptors (HER-1, HER-3, or HER-4), and this association leads to intracellular signaling via two major pathways, the MAPK pathway and the PI3K pathway, leading to proliferation, cell survival, metastasis, and angiogenesis. On the other hand, VEGF can bind to its main receptor, VEGFR-2 (KDR), and this binding causes intracellular phosphorylation of the receptor, thereby stimulating the PI3K pathway and stimulating angiogenesis. The signaling pathways can be targeted extracellularly using humanized mAbs, such as trastuzumab and pertuzumab (HER-2), cetuximab (EGF receptor), bevacizumab (Avastin) (VEGF), and cixutumumab (IGF-1R) which can prevent ligand binding and activation of the receptors or can directly block binding of an activated receptor to another. At the intracellular level, small-molecule inhibitors, such as sunitinib (VEGF), lapatinib (HER-1 and HER-2), and erlotinib (HER-2), can disrupt the phosphorylation sites and directly prevent activation of the PI3K or MAPK pathways. P, phosphate; VEGFR, VEGF receptor.

6.01.3.1.1 Structure and signaling of HER proteins

All four HER receptors (EGFR, HER-2, HER-3, and HER-4) share extracellular domains (composed of four subdomains, two of which are disulfide-rich) with high structural homology, a single transmembrane spanning helix, and a cytoplasmic portion that contains a conserved but not equally functional tyrosine kinase domain flanked by a carboxy-terminal tail with autophosphorylation sites. The extracellular region consists of ~620 amino acids arranged into four subdomains, called L1 (I), S1 (II), L2 (III), and (IV).[68] Despite their structural homology, the HER family members differ with respect to preferred ligands, affinity for ligands, tyrosine kinase activity, and rate of cellular downregulation.[69] All HER ligands have in common an EGF-like domain of ~60 amino acids including six cysteine residues that interact covalently to form three loops.[70] HER ligands can be divided into three groups.[71]

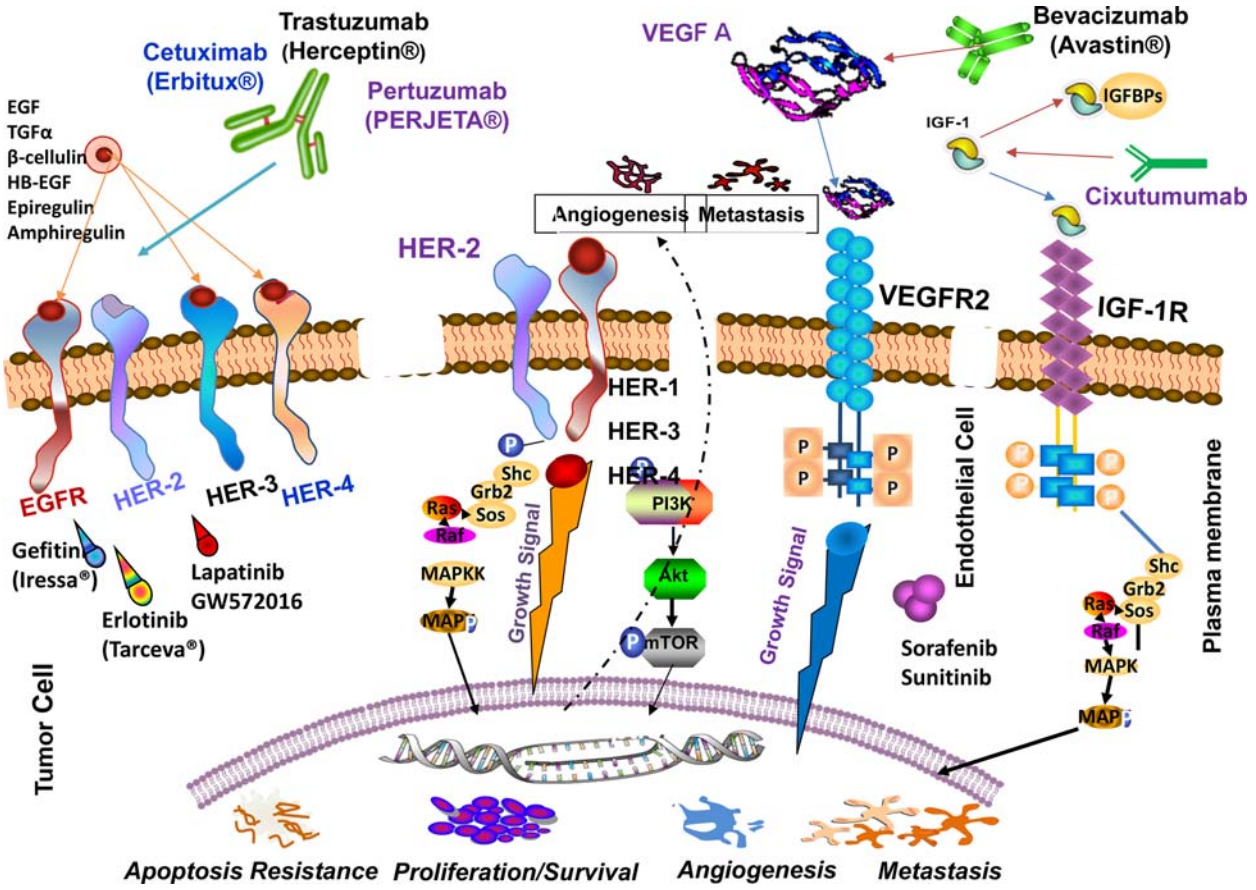

Fig. 2 Signal transduction pathways drive cancer metastasis.

The first group specifically binds EGFR, including EGF, amphiregulin (AR), and TGF-α. The second group exhibits dual specificity for EGFR and HER-4 including betacellulin, heparin-binding EGF, and epiregulin.[4a] The third group is composed of the neuregulins (NRG, also called heregulins, HRG) and includes two subgroups based on their ability to bind HER-3 and HER-4 or only HER-4. In particular, HER-2 has no known ligand-binding activity, while HER-3 lacks intrinsic kinase activity.[66b,c,67,72] Ligand binding to the extracellular domain initiates a conformational rearrangement that allows for dimerization (pairing). Specifically, ligands bind to domains I and III and cause a conformational change. Domain II becomes exposed, and the receptor can then undergo dimerization.[73] Receptor dimerization is an essential requirement for HER function and for the signaling activity of these receptors.[68a] Only EGFR and HER-4 are completely functional in terms of ligand binding and kinase activity. HER-2 appears to lack a high-affinity ligand,[74] and HER-3 has impaired kinase activity,[75] relying on the kinase activation of its heterodimerization partners for activation.

HER-2 plays a major coordinating role in this network, since each receptor with a specific ligand seems to prefer HER-2 as its heterodimeric partner.[76] HER-2-containing heterodimers potently amplify signaling because HER-2 reduces the rate of ligand dissociation, allowing strong and prolonged activation of downstream signaling pathways.[77] The most significant intracellular pathways activated by the HER receptors are those involving the phosphatidylinositol-3-kinase (PI3K) and mitogen-activated protein kinase (MAPK).[78] In normal cells activation of the HER family initiates a rich network of signaling pathways that control normal cell growth, differentiation, motility, and adhesion in several cell lineages.[79] The formation of heterodimers and the resulting activation are temporally and spatially controlled in normal cells and tissues.[80]

6.01.3.1.2 HER-2 and cancer

HER-2 is an attractive therapeutic target in cancers for several reasons. The amount of HER-2 expressed on cancer cells is much higher than in normal adult tissues,[81] potentially reducing the toxicity of HER-2 targeting drugs. Tumors with a high expression of HER-2 often show homogenous, intense IHC staining,[82] signifying that HER-2 targeted therapy would target most cancer cells in a given patient. Additionally, HER-2 overexpression is found in both the primary and metastatic sites,[83] suggesting that HER-2-targeted therapy may be effective in all disease sites. Increased wild-type HER-2 expression levels causes dysregulation of the HER network in tumor cells, providing both growth and survival advantages for the tumor.[84] Slamon et al. demonstrated that HER-2 amplification is a significant predictor of both overall survivor and time to relapse in the breast cancer patients and overexpression of HER-2 occurs in 20–30% of invasive breast cancers.[29]

Breast cancers can have up to 25–50 copies of the HER-2 gene and up to 100-fold increase in HER-2 protein expression resulting in up to 2 million receptors expressed at the tumor cell surface.[85] FDA-approved tests for determining HER-2 status include immunohistochemistry (IHC) for protein overexpression using the Herceptest KIT (Dako) or gene amplification by fluorescent in situ hybridization (FISH). HER-2 overexpression has been defined by IHC as being highest (reported as 3+) when receptor levels near 2 million, or medium intensity (2+) when receptor levels are around 500,000. Normal levels of membrane-bound HER-2 are ~20,000–50,000 per cell.[31] Breast cancers overexpressing HER-2 have biological characteristics that differentiate them from other types of breast cancers including resistance to certain hormonal agents, increased sensitivity to certain cytotoxic chemotherapeutic agents, and increased propensity to metastasize to the brain.[86] Additionally, HER-2 overexpression and amplification are seen in subsets of gastric, esophageal, endometrial, uterine, ovarian, and lung cancers.[45d,87]

6.01.3.1.3 HER-1 (EGFR) and cancer

HER-1 (EGFR) is central to human tumorigenesis, and deregulation of this receptor is mainly due to increased expression[88] and mutations in different domains of the receptor.[89] EGFR is overexpressed in most epithelial cancers including breast/triple negative breast cancer (TNBC (14–90%),[90] nonsmall cell lung (NSCLC) lung (40–80%),[91] head and neck (80–100%), colorectal (25–77%), and other cancers). HER-1 overexpression in tumors is responsible for aggressiveness, poor prognosis, decreased survival, poor response to therapy, and development of resistance.[92] HER-1 forms heterodimers with other HER family members like HER-2, HER-3, and HER-4 resulting in aggressive forms of cancer with lower survival rates.[93] The development of antibodies targeting HER-1 is mainly dependent on structural studies that help outline the details of the receptors and other conformational changes affecting its activation and downstream signaling. HER-1 signaling is highly dependent on ligand binding which is a key factor in releasing the dimerization arm of the receptors,[94] and this explains why many of the anti-HER-1 antibodies are directed toward the ligand-binding region. Cetuximab, a humanized mAb, binds HER-1 and prevents ligand binding and is FDA approved for the treatment of metastatic colorectal cancers with high EGFR expression.[95] However, the emergence of resistance to cetuximab has led to the proposal that other mechanisms exist that are independent of ligand binding, and this has led to the development of other antibodies with key epitopes that are different from cetuximab. For instance, activation of other HER family receptors may help in the stabilization of HER-1 even in the absence of ligand binding.[96] These studies simply illustrate that multiple HER-1 targeting strategies can be employed in targeting EGFR signaling mechanisms in cancer, and this may avoid resistance and additively or synergistically inhibit tumor growth.

6.01.3.1.4 HER-3 and cancer

HER-3, the third member of the HER family, is a single membrane-spanning receptor that exerts its function through heterodimerization with other HER family receptors. HER-3, like the other members of the HER family, consists of an extracellular domain, a transmembrane domain, and an intracellular domain. HER-3 overexpression is commonly seen in various malignancies such as breast cancer; colorectal carcinoma; squamous cell carcinoma of the head and neck; and gastric, ovarian, prostate, and bladder

cancers. Subdomain II also contains the dimerization loop required for dimer formation. Unlike HER-1 and HER-2, it cannot form a homodimer and lacks the intracellular kinase activity. Unliganded receptor adopts a confirmation that inhibits dimerization. Binding of neuregulin to the ligand-binding subdomains (I and III) induces a conformational change in ErbB3 that causes the protrusion of the dimerization loop in subdomain II, activating the protein for dimerization. Activation of HER3-containing heterodimers leads to HER-3 phosphorylation and subsequent activation of signaling pathways. It was previously considered not to contain tyrosine kinase activity and catalytic activity, and the intracellular region of HER-3 could not bind ATP and be autophosphorylated. Thus, the clinical value of HER-3 was ignored. Currently, biochemical analysis has confirmed that the kinase domain of HER-3 is a specific allosteric activator; it acts as a functional activator to activate the recipient kinase (HER-1, HER-2, HER-4). With the in-depth knowledge of its structure and function, studies on the relationship of HER-3 and human tumors are rapidly increasing. HER-3 is closely related to tumorigenesis, progression, and metastasis. HER-3 also has the highest binding affinity for phosphoinositol 3-kinase (PI3K) when compared to all other HER proteins. As a result, HER3 serves as a key activator in downstream signaling of PI3K, which ultimately leads to apoptosis resistance in a wide range of cancers.[97] HER-3 is involved in resistance to targeted therapy and may serve as a new therapeutic target. The expression of HER-3 helps predict prognosis and treatment efficacy. HER-3 has become a focus of concern in the HER family and has gained significant attention in the search for cancer treatment.

6.01.3.1.5 IGF-1R and cancer

The insulin-like growth factor receptor (IGFR) has been implicated in the growth and development of several malignancies.[58] IGF-1R belongs to the insulin receptor (IR) family that includes the IR (a homodimer), IGF-1R (a homodimer), IGF-1R/IR (hybrid, heterodimeric receptors), and the mannose-6-phosphate receptor (also known as IGF-2R). The main signaling pathway implicated in cancer is the IGF-1R:IGF-1 pathway which supports the growth of many different types. This pathway does not only contribute to tumorigenesis but is highly implicated in the development of resistance to other anticancer drugs that are available in the clinic.[6a,60] The IGF-1:IGF-1R pathway has been shown to play critical roles in many cancers including lung,[98] breast,[99] pancreas,[61] colorectal,[100] prostate,[101] and head and neck[102] cancers. Apart from the HER family receptors, the insulin-like growth factor has emerged as a key regulator of tumorigenesis in colorectal cancer.[103] Expression of IGF-IR and its ligands are therefore considered as potential prognostic and predictive markers in colorectal cancer.[104] Downregulation of IGF-1R dependent pathways have also been shown to sensitize colorectal cancer cells to apoptosis mediating agents indicating that IGF-1R may play a role in resistance development in colorectal cancer cells signaling.[105] Recent studies have even implicated IGF-1R-dependent pathways as a cause of resistance to cetuximab-based therapies in colorectal cancer,[18] and this indicates that a combined approach targeting the HER family receptor and IGF-IR will effectively target colorectal cancer cells and shutdown alternative signaling pathways.

6.01.3.1.6 Angiogenesis and cancer: VEGF

Angiogenesis, or formation of new blood vessels, is crucial to cancer tumor growth. Tumor growth, progression, and metastasis are critically influenced by the production of the proangiogenic factor vascular endothelial factor (VEGF). Virtually all solid tumors are neovascularized by the time they are detected. However, there is a prevascular phase during early tumor development where few or no tumor cells are angiogenic, and expansion of the tumor is restricted to a few millimeters. When enough tumor cells become angiogenic, the tumor can expand progressively and shed metastatic cells. This "angiogenic switch" has recently been documented in several forms of cancer.[19] One of the most proangiogenic factors known today is vascular endothelial growth factor, or VEGF.[5g] VEGF expression is increased in many different types of cancer, and most tumor cells secrete VEGF.[20] It is also thought that VEGF is a key promoter of metastasis.[22] VEGF is a 34–42 kDa, homodimeric, heparin binding, disulfide-bonded glycoprotein that has several isoforms arising from splice variants.[5d,g,20,106] VEGF has three known tyrosine kinase receptors: Flt-1 (VEGF-R1), KDR (VEGF-R2, Flk-1), and Flt-4 (VEGF-R3). VEGF-R1 has a higher affinity for VEGF, but it has been shown that VEGF-R2 is the biologically relevant receptor. Therefore, VEGF and its receptors VEGFR-1 and VEGFR-2 are prime targets for antiangiogenic intervention which is thought to be one of the most promising approaches in cancer therapy. Overexpression of VEGF also occurs in many different types of cancer, and thus VEGF and its receptors VEGFR1 and VEGFR2 are considered as prime targets for antiangiogenic intervention.[5h–j] Most importantly, overexpression of HER-2 is associated with increased expression of VEGF at both the RNA and protein level in breast cancer cells, and a positive association between HER-2 and VEGF expression in breast cancer patients has been identified.[5i] Specialized cancer treatments with antiangiogenic agents approved by the FDA include mAb, bevacizumab (Avastin) or small TKIs, SU11248 (sunitinib), and BAY 43-9006 (sorafenib).[107] Although the clinical application of these drugs in cancer therapy is promising, drug resistance development and long-term side effects like hypertension and endothelium dysfunction remain a concern.[108]

6.01.4 Peptide Immunotherapeutic Approaches

6.01.4.1 Peptide Vaccine Versus Peptide Therapeutics

These are two fundamentally different approaches that also exhibit different mechanisms of action. The only commonality is that both approaches utilize the same functional B-cell epitope as the main ingredient in the vaccine or in the therapeutic peptide. Fig. 3 depicts the difference between the two approaches.

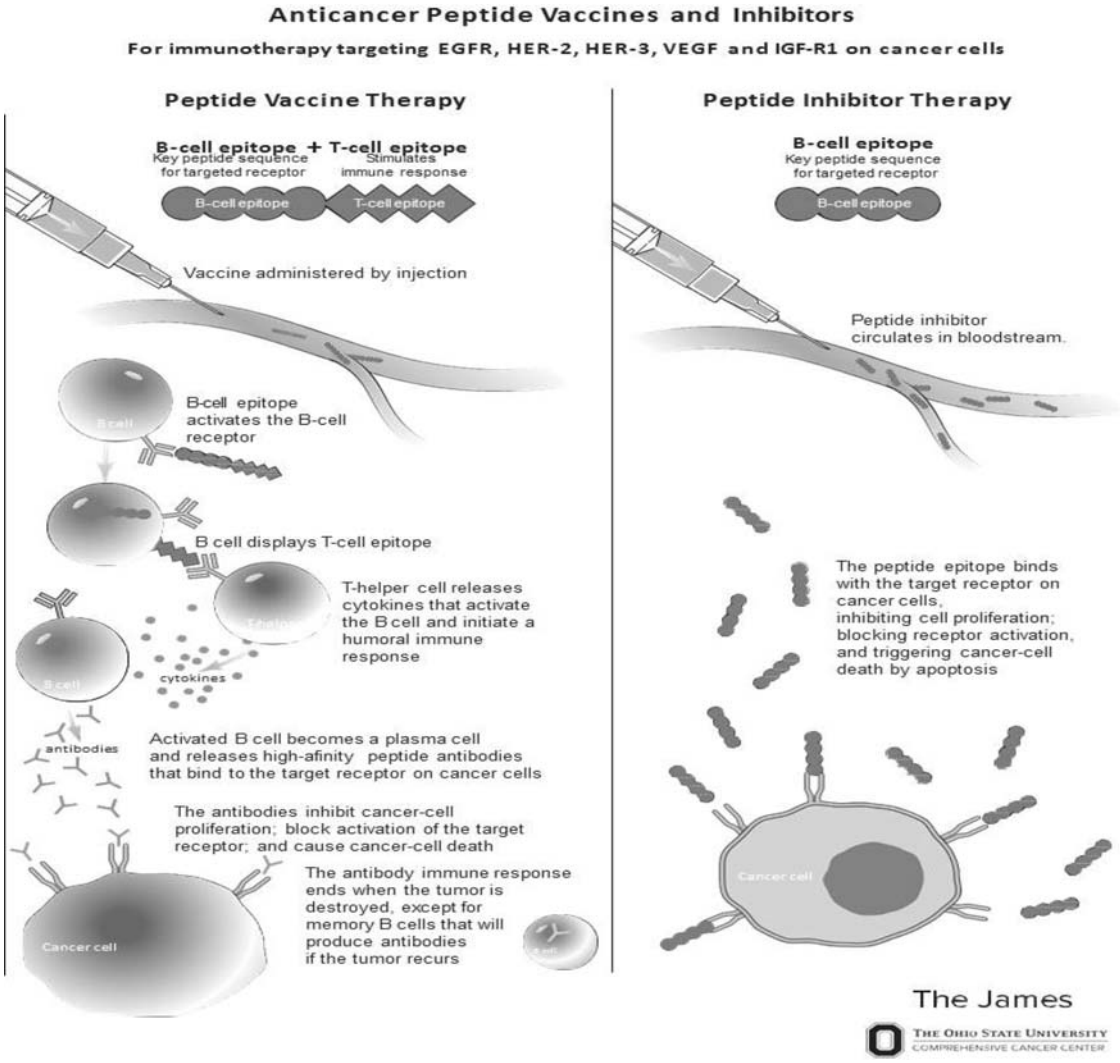

Fig. 3 Peptide vaccine versus peptide therapeutics.

6.01.4.1.1 Significance of peptide vaccine approaches

The greatest potential significance of our proposed strategy is twofold. (1) It combines multiple mechanisms of action by activating both B- and T-cell functions and promoting immunological clearance. (2) It is also a targeted approach aimed at inhibiting molecular signaling pathways that are crucial for tumor growth and maintenance. The major attraction of the peptide vaccine approach is the potential for a sustained antitumor effect related to immunological memory that protects against relapsing tumors, obviating the requirement for multiple infusions of humanized mAbs and overcoming escape mechanisms. Active immunotherapy offers many advantages, including tumor specificity and the activation of immune responses against antigens that are selectively expressed by tumor cells. As a result, nonspecific toxicity to normal tissues is reduced and antitumor responses are more durable and adaptable to cancer control at different stages of disease, including early-stage disease and disease with low tumor burdens. Additional benefits of the peptide vaccine approach include the ease and rapid synthesis, safety, lack of toxicity, and cost-effectiveness.

6.01.4.1.2 Significance of peptide mimic approaches

The significance of the peptide approach versus receptor-targeted mAbs and small molecules is that rationally designed peptide mimics represent a viable therapeutic strategy for blocking aberrant molecular signaling pathways with high affinity, high specificity, strong potency, and improved safety profiles.[27] There are several advantages of peptide therapeutics over mAbs and small molecules: (1) peptides will not accumulate in specific organs such as the kidney and liver, minimizing potential toxic side effects; (2) the tight structural relationship between the constructed peptide and the physiologically active parent molecules from which it is derived minimizes side effects; and (3) peptides help reduce current therapeutic problems, such as off-target side effects, requirements for high-dose regimens, and minimal drug–drug interactions. Generally, peptides are not directly linked to severe side effects since

they are composed of naturally occurring amino acids that are metabolically tolerable. In contrast, small molecules can build up in various organs, ultimately leading to severe toxic side effects.

Peptides are small protein-like chains of amino acids, and a peptide mimic is a peptide or a peptide-like molecule that intends to mimic one portion of the entire protein which is usually a binding or active site of an enzyme.[109] Peptides are easily synthesized, optimized, chemically stable, easily deliverable, and amenable to site-specific modification to target and kill cancer cells[110] with minimal toxicity. Peptide mimics offer the benefits of being water soluble, nonimmunogenic, and the ability to easily cross tissue barriers.[111] The main goal is to maintain the conformational space and orientation of the bioactive surface while retaining sufficient flexibility to bind cooperatively with a given receptor.[112]

Importantly, the simplicity of producing clinical grade peptides allows for rapid translation into phase I/II trials in humans patients. The disadvantages of peptide drugs are mainly related to their in vivo instability including short half-life and low bioavailability, susceptibility to proteases, formulation, and manufacturing challenges. New synthetic strategies to improve productivity and reduce metabolism of peptides, along with alternative routes of administration, have been developed in recent years, and a large number of peptide-based drugs are now being marketed.[17] There are ~60 therapeutic peptides on the market, 150 in clinical phases, and 400 in advance preclinical stages. Among the products that are approved, about 30 peptide drugs are currently marketed in the United States, and 17% are used to treat cancer.[24] One of the major drawbacks of using peptides as therapy is their high susceptibility to proteosomal degradation.[113] This obstacle can be overcome with the use of pseudo and modified peptides. The retro-inverso modification is the reversal of the peptide backbone by inverting the amino acid sequence, as well as reversal of the amino acid chirality by utilizing D-amino acids (**Fig. 4**). The resulting product is a topographical equivalent of the parent peptide with the amino side chain in similar orientation. Because retro-inverso peptides are synthesized with D-amino acids and proteases usually recognize L-amino acids, they should be resistant to proteosomal degradation and therefore will increase the bioavailability of the peptidomimetic therapeutic in vivo.[113,114]

6.01.4.1.3 Overall strategy

Innovative immune-based therapies that target receptor kinases have the potential to achieve long-term control in several tumor types without causing the numerous toxicities associated with most FDA-approved anticancer combination regimens. We have tested our model outlined in **Fig. 5** in multiple disease types. We have addressed several crucial issues in developing epitope-driven peptide vaccines over the past two decades by developing innovative anticancer strategies.[66b,115] Our strategy as outlined in **Fig. 1** consists of several steps: (1) initial prediction of B-cell epitopes is based on multiple computerized antigenicity/immunogenicity algorithms.[116] This represents a critical component in the overall process. (2) B-cell linear epitopes are refined through mutagenesis studies, and epitopes are modeled based on the three-dimensional native antigen structure and antigen:antibody complex if available. The unique B-cell epitope peptides are engineered to recapitulate the exquisite native structure of the tumor antigen.[117] This is a crucial prerequisite to developing high-affinity antibodies given that B-cell epitopes can be both linear (contiguous amino acid sequence) and conformational (discontinuous in the primary sequence but close in proximity of the folded 3D structure). (3) The chimeric vaccine is designed to include a "promiscuous" T-cell epitope[118] for a universal vaccine for an outbred population that can bypass haplotype-restricted immune responses; (4) highly efficacious native-like antipeptide–antibodies are then elicited in animals[11a,b,119] from the immunogen emulsified with an adjuvant in a squalene–arlacel oil–water ISA720 vehicle; (5) stable peptide mimics are designed as retro-inverso analogs that can block receptor:ligand interactions;[114b,120] (6) both antibodies and peptide mimics are used in a series of in vitro assays in different human cell lines to evaluate their efficacy. By corroborating the data, we are able to reduce the numbers of lead candidates to a minimum. (7) Combinations of the best performing epitopes are assessed in combination with human cell lines to determine synergy/additivity; (8) in vitro testing of potential combinations is then performed in different tumor cell lines using NOD/SCID mice as a surrogate animal model to simulate human cancers and evaluate the effects of peptide antibodies elicited in response to the vaccine epitopes. We can then finalize the potential candidates; (9) evaluate the effects of peptide mimics/antibodies elicited in response to finalize the potential candidates; (10) test efficacy in transgenics or appropriate animal model; (11) finally, conduct human clinical trials[121] to assess safety and toxicity.

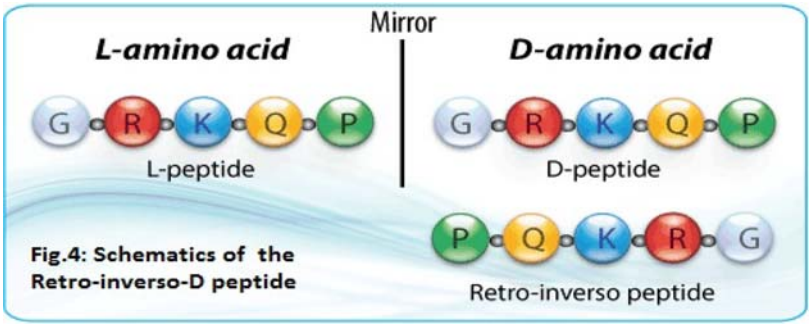

Fig. 4 Schematics of the retro-inverso-D peptide.

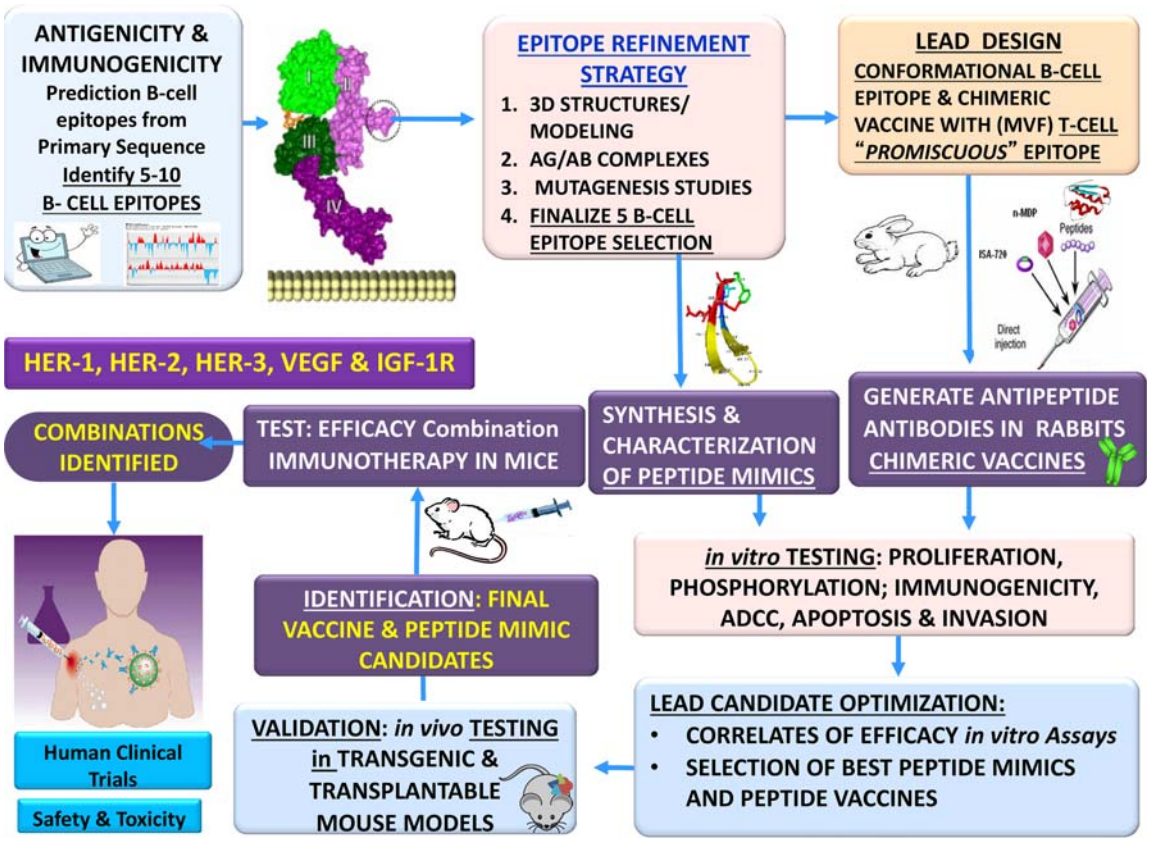

Fig. 5 Overall strategy of peptide approaches.

6.01.4.1.4 Road map for the design of an effective peptide vaccine versus a peptide mimic strategy

Our oncoimmunology approach is based on targeting signaling networks that are potential drivers of resistance and tumor progression while eliciting durable immune responses. Given the lack of preclinical models (transgenic or syngeneic animal model) to reliably predict clinical activity of vaccine constructs (active immunization) that target multiple tumor types concurrently, we have instead utilized a *surrogate and indirect model* in which rabbit antibodies elicited by the vaccine are used to test the efficacy of the vaccine *in transplantable mouse models challenged with human tumor cell lines*. Our peptide mimics serve a similar purpose, to corroborate the effects of the antibodies in transplantable mouse models as their mode of action is similar by preventing the heterodimerization of RTK. This allows us to have increased confidence in validating the vaccine epitopes. The peptide mimics could be a therapeutic approach by itself.

Fig. 6 outlines our road map of designing peptide vaccines and peptide mimics and their mode of action toward the same goal of tumor destruction by several mechanisms. *Pathway A* involves the *design of chimeric peptides*[117a,c] *comprising the conformational B-cell epitope and incorporating a "promiscuous" T-cell epitope*.[118] The vaccine is emulsified with an adjuvant (nor-MDP) in a vehicle (ISA 720; squalene/arlacel) (**C**) and used for vaccination. When relevant transgenic mice (MMTV/neu) or a syngeneic model (**D1**) is available for assessing vaccine efficacy, these mice are immunized sc with the chimeric peptide vaccine and tumor growth/reduction is monitored over time.[11a,c,119] Rabbits are used as a surrogate model (**D2**) to develop high-affinity antipeptide antibodies which can be used to treat transplantable mouse models (NOD/SCID) (**E1**) after tumor challenge. Tumor growth is then monitored over time as we have described.[122] *Pathway B* involves *the design of conformational B-cell-peptide mimics* with enhanced proteolytic stability.[4-b,120a,122b] Because a T-cell epitope is not included, the peptide lacks immunogenicity, thus the peptide mimic treatment does not elicit antibody production. The peptide mimics are dissolved in PBS and are injected in mice by *iv* treatment (**E2**) at the time of tumor challenge with repeated weakly treatment until control mice develop large tumors. This strategy allows us to corroborate effectiveness of antibody treatment versus peptide treatment,[123] allowing us to prioritize peptide constructs for testing in (1) transgenic mouse models (**F**) and (2) human clinical trials (**G**).[121] Both the vaccine and peptide mimic approach can induce tumor cell death by a variety of antitumor cellular mechanisms (e.g., ADCC (only Ab)), inhibition of proliferation or phosphorylation, and apoptosis. The mode of action for active immunization: The conformational peptide epitope binds the B-cell receptor, and the measles virus MVF "promiscuous" T-cell epitope binds MHC class II and does not require antigen processing,[118,124] preserving the native structure of the vaccine construct. On the other hand, the mechanism of action for the peptide mimic is direct binding of the B-cell peptide mimic to the receptor, preventing heterodimerization.

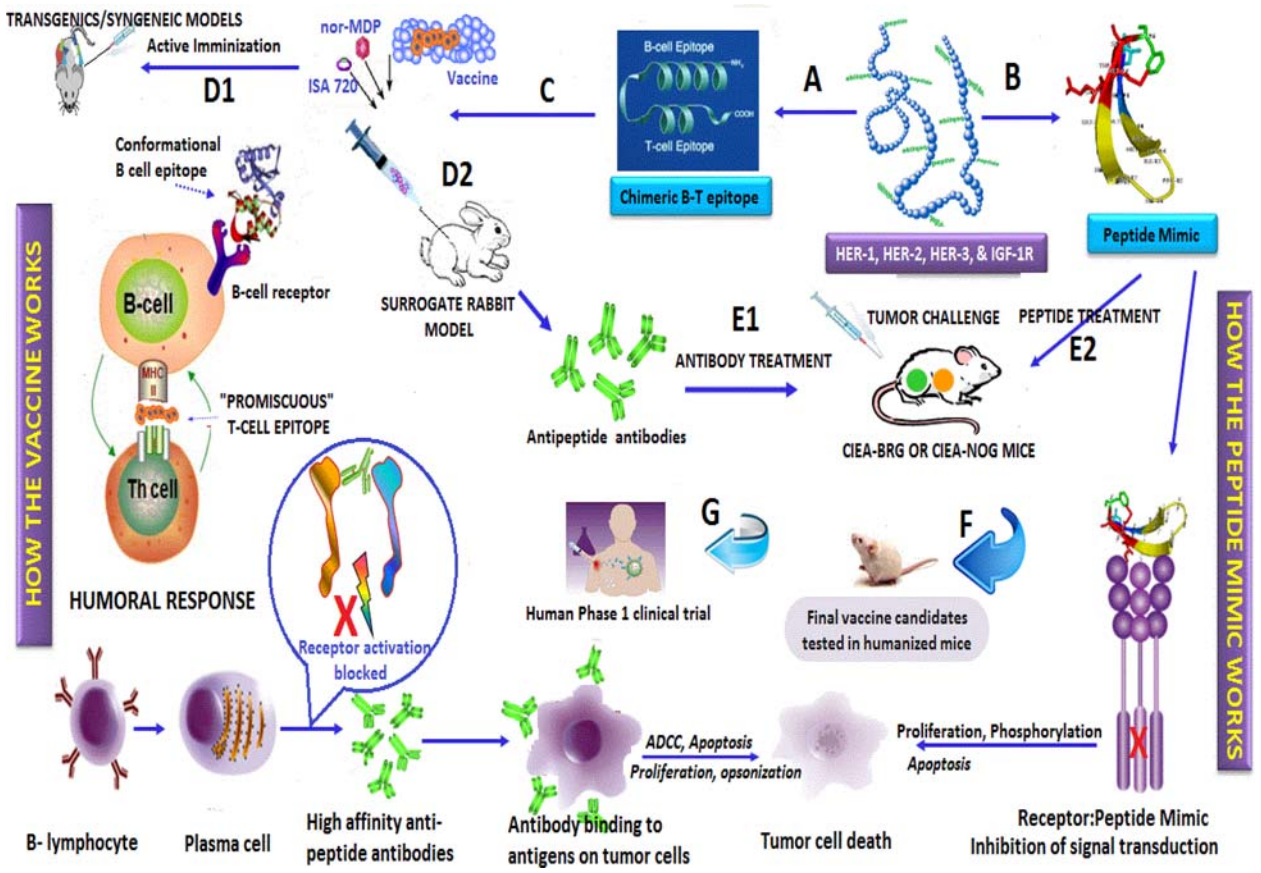

Fig. 6 Road map for combined peptide strategies.

6.01.5 Targeted Therapies Against HER-2

6.01.5.1 Humanized mAbs and Small-Molecule Inhibitors

Over the last decade, many drugs have been developed to target the HER family members especially HER-1 and HER-2, and some of these drugs have gained FDA approval, while others are still being evaluated in clinical trials.[125] Most of the FDA-approved targeting HER-1 (cetuximab, erlotinib, and gefitinib) and HER-2 (trastuzumab, pertuzumab, and lapatinib) have significant toxicities with unacceptable safety profiles in most patients.[126]

6.01.5.1.1 Development of trastuzumab and treatment

Since HER-2 is a membrane-bound receptor, exposed to the extracellular matrix, development of mAb's could bind the ECD of HER-2 and interfere with signal transduction and thus inhibit tumorigenic HER-2 function.[127] Over 100 mAbs directed against the ECD of HER-2 have been generated. Dependent upon epitope specificity, the interaction of HER-2 and anti-HER-2 antibodies (Abs) resulted in no effect, inhibition, or stimulation of tumor growth.[128] One of these anti-HER-2 mAb was developed for clinical testing, initially identified as mouse mAb 4D5. 4D5 was created by the fusion of a mouse myeloma cell line with splenocytes from BALB/c mice immunized NIH 3T3 cells stably transfected with HER-2.[7a,129] 4D5 was selected from a panel of mouse anti-HER-2 Abs at Genentech Inc. because it inhibited the growth of breast tumor cell lines overexpressing HER-2 in both anchorage-dependent and independent assays in vitro and inhibited tumor growth in mouse models.[7a,130] To avoid human antimouse antibody responses, mouse mAb 4D5 was humanized.[131] The IgG1 isotype is favored due to its ability to support effector functions such as ADCC and CDC.[132] Trastuzumab proved to be more efficient than its murine counterpart 4D5 in mediating ADCC.[131,133] Additional preclinical studies demonstrated trastuzumab's ability to reduce cell culture antiproliferative activity and antitumor efficacy in mouse xenograft studies.[133b,134]

6.01.5.1.2 Clinical trials of trastuzumab

Trastuzumab tested as a single agent in HER-2 overexpressing metastatic breast cancer demonstrated response rates of 12–34% for a median duration of 9 months.[135] The most beneficial clinical use of trastuzumab has been in combination with a variety of cytotoxic chemotherapies.[127] Trastuzumab added to multiple chemotherapy treatments significantly increases their antitumor

efficacy.[136] Trastuzumab's largest impact has been in the treatment of patients with potentially curable early-stage breast cancer.[127] The addition of trastuzumab to chemotherapy regimens to early-stage HER-2 overexpressing breast cancer patients, who receive chemotherapy after surgical resection, significantly prolongs disease-free survival and reduces the chance of recurrence.[137] As a result of these studies, trastuzumab has recently been approved in combination with doxorubicin, cyclophosphamide, and paclitaxel in adjuvant treatment for early-stage breast cancer after primary therapy.[138] The clinical activity of trastuzumab is limited to HER-2 overexpressing tumors, and trastuzumab has no significant activity against breast cancers without HER-2 overexpression.[135c,139]

6.01.5.1.3 Side effects of trastuzumab treatments

Despite the impressive clinical results with trastuzumab, there are side effects associated with this mAb including cardiotoxicity. Initial clinical trials revealed trastuzumab had significant cardiotoxicity, with the incidence of cardiac dysfunction ranging from 4% to 7%.[140] Subsequent randomized clinical trials demonstrated significant trastuzumab-associated cardiotoxicity, with 5–17% increase in left ventricular ejection fraction, a measure of the pumping ability of the heart, and 1–3% increase in congestive heart failure.[141] The mechanism of trastuzumab-induced cardiac dysfunction is not fully understood.[142] HER-2 may aid in the repair of cardiac myocyte injury. Thus, the use of trastuzumab and the loss of HER-2-dependent cardiac myocyte survival pathways could make patients more vulnerable to cardiac damage.[143]

Fevers and chills are the most common side effects that patients experience after receiving trastuzumab. The fever and chills are sometimes accompanied by rigors (uncontrollable shaking). Fevers, chills, and rigors respond well to simple medical treatments. Other side effects experienced by patients receiving trastuzumab include rash, shortness of breath, low blood pressure, nausea/vomiting, pain, headache, dizziness, and asthenia (weakness). All of these side effects occurred most commonly either during the first dose of trastuzumab and not very frequently thereafter. The use of Herceptin may be associated with damage to the heart muscle and an associated decrease in heart function and symptoms of congestive heart failure. These symptoms include fatigue and difficulty breathing. Heart failure has occurred in about 4% of patients who have received trastuzumab alone. Most patients treated with trastuzumab have been treated previously with a class of drugs called anthracyclines that can sometimes injure the heart. The chance of heart failure may be lower in patients who have not received anthracyclines. The risk of heart problems with trastuzumab may be greater in patients receiving higher total amounts of trastuzumab, in patients with a previous history of heart disease, and in patients who have received X-ray therapy to the chest. This condition may be reversible with medication, but persistent severe heart failure may be possible. Some patients have a very slight decrease in heart function, while others have actually died of heart failure. Heart failure may only show up many months after trastuzumab treatments have been stopped. Allergic reactions (rash, itching, difficulty breathing, or even shock) may be seen following treatment with Herceptin as with any foreign protein, but these are uncommon. Lowered numbers of red blood cells and/or white blood cells may occur following treatment with trastuzumab (about 1% of the time). Diarrhea was seen in about 25% of patients receiving Trastuzumab alone. Because one of these epitopes correspond to trastuzumab, it is possible that similar reactions may occur in the patients. Therefore, cardiac status will be determined using history and physical, vital signs, troponin levels, EKG, and MUGA scan results. Our experience with similar epitopes in our previous trial showed none of the signs described earlier.

6.01.5.1.4 Possible mechanisms of action and resistance to trastuzumab

Many studies have attempted to decipher the molecular mechanisms underlying the clinical activity of trastuzumab. Early studies supported trastuzumab-mediated endocytosis and degradation of the HER-2 receptor,[144] with consequent inhibition of the downstream PI3K and MAPK signaling pathways. However, other studies have shown trastuzumab does not downregulate HER-2.[145] Austin et al., using immunofluorescence and quantitative immunoelectron microscopy, demonstrated that trastuzumab binds and internalizes with surface HER-2 but reappears with HER-2 at the cell surface, only accompanying HER-2 passively along its normal endocytic recycling route.[145a] Trastuzumab binding to HER-2 inhibits the proteolytic cleavage and shedding of HER-2 by matrix metalloproteases.[146] This could be a part of the antitumor properties of trastuzumab since truncated HER-2 is associated with increased kinase activity and increased transforming efficiency,[147] although many HER-2 overexpressing breast cancers do not have significant truncation of HER-2.[127] Trastuzumab is unable to inhibit HER-2 from dimerizing with other members of the HER family including EGFR and HER-3.[148]

While the effect of trastuzumab on the function of its direct target HER-2 remains to be identified, numerous studies have described the effects of trastuzumab on downstream signaling pathways. Cells treated with trastuzumab undergo arrest during the G1 phase of the cell cycle modulated by the induction of p27, with a concurrent reduction in proliferation.[149] Overexpression of HER-2 in tumors is associated with increased angiogenesis and expression of vascular endothelial growth factor (VEGF).[150] Trastuzumab exhibits certain antiangiogenic properties. Trastuzumab treatment on HER-2 overexpressing breast cancers reduces tumor volume and decreases microvessel density in vivo.[151] Trastuzumab may block PI3K signaling via disrupting the interaction between HER-2 and Src tyrosine kinase, leading to the inactivation of Src with subsequent activation of the PI3K inhibitor PTEN.[152]

In light of recent data indicating that trastuzumab does not downregulate cell-surface HER-2, there is a renewed interest in another possible mechanism of action of trastuzumab, its ability to induce an immune response via its Fc domain. Trastuzumab is highly efficient at activating ADCC in vitro.[131,153] Natural killer (NK) cells, a major immune cell type involved in ADCC, express the Fc-γ receptor III, to which the Fc domain of trastuzumab binds, activating NK-mediated cell lysis. Xenograft studies with mice bearing HER-2 overexpressing tumors displayed a tumor regression rate of 96% when treated with trastuzumab. Mice lacking the Fc receptor showed only 29% tumor growth inhibition when treated with trastuzumab.[134b] This model provides convincing evidence that the antitumor activity of trastuzumab is mediated through immunological targeting mechanisms.[127]

6.01.5.1.5 Trastuzumab-DM1

Trastuzumab-DM1 (T-DM1; Genentech/Roche, South San Francisco, California) is a novel chemistry-driven conjugated HER-2 mAb in which the trastuzumab is conjugated with a fungal toxin DM1 (maytansine).[154] The purpose of developing this compound is to overcome trastuzumab resistance and boost the efficacy of this targeted strategy. Maytansine is an antimicrotubule agent that inhibits the assembly of cellular microtubules. In vitro studies showed that the cytotoxicity of maytansine is over 1000 times that of any other chemotherapeutic agent.[155] In trastuzumab-DM1, trastuzumab mainly works as a carrier that delivers DM1 to the tumor cells labeled with HER-2. Trastuzumab-DM1's mechanism of action is independent of functional HER-2 signaling but only requires a high expression level of HER-2 on the cellular surface. Therefore, trastuzumab-DM1 can successfully overcome several trastuzumab resistance mechanisms related to HER-2 downstream signaling, such as PI3K mutation and PTEN downregulation.

6.01.5.1.6 Pertuzumab: HER-2 dimerization inhibitor

Pertuzumab (Omnitarg; Genentech/Roche, South San Francisco, California) is a humanized mAb that targets the extracellular domain of HER-2. From the panel of anti-HER-2 mAbs developed at Genentech Inc., the mAb 2C4 was also selected for further characterization. Compared with mAb 4D5, 2C4 has diminished antiproliferative activity in vitro with the HER-2 overexpressing cell line SKBR3.[7a] Agus et al. showed that 2C4 but not trastuzumab is able to block the association of HER-2 and HER-3 in breast cancer cell lines,[148a] indicating 2C4 has properties distinct from trastuzumab. Additionally it was reported that 2C4 inhibited heregulin-mediated HER-2 phosphorylation and MAPK and Akt activation in breast cancer cells not overexpressing HER-2.[148a] In vivo preclinical xenograft studies have demonstrated 2C4 has activity on breast, ovarian, and prostate tumors including tumors without HER-2 overexpression.[148a,156] 2C4 has been humanized to be used for human clinical usage,[157] and the resulting humanized mAb is called pertuzumab (Omnitarg). Limited data have been presented on 2C4 or pertuzumab's ability to inhibit cell signaling pathways since these mAbs are not yet accessible to the wider scientific community.[127] Phase I studies of pertuzumab revealed the agent was well tolerated with side effects of fatigue, nausea, and vomiting.[158] A number of phase II trials have been conducted in breast, nonsmall cell lung cancer (NSCLC),[159] ovarian,[160] and prostate[161] cancers. Clinical responses were seen in a Phase II trial of ovarian cancer patients, with an overall response rate of 4.3%.[160] Pertuzumab has shown synergy with trastuzumab in vitro,[162] and a phase II trial is investigating the effect of a combination of pertuzumab and trastuzumab in HER-2 overexpressing breast cancer.[163] The effects of pertuzumab on HER-2 expressing cancers await additional preclinical and clinical studies.

6.01.6 Rationale for Developing HER-2 Vaccines

6.01.6.1 Numerous X-Ray Crystallographic Structural Studies Reveal How the HER Family Initiates Signal Transduction

There are many crystal structure determination of the HER receptors alone or in combination with either antibodies or their ligand. These studies have provided us with accurate identification of the binding regions for rational design.

6.01.6.1.1 Structural studies with HER-2 and trastuzumab

Two independent groups published crystal structures of the extracellular region of HER-2.[164] HER-2 adopts an open conformation that resembles the ligand-activated state of EGFR. The contact between domains II and IV, observed in ligand-less EGFR and HER-3, is absent in HER-2, instead an interaction between domains I and III is seen. This structure of HER-2 is similar to a ligand-activated state, showing HER-2 poised to dimerize with other HER receptors in the absence of direct ligand binding and explains the inability of HER-2 to bind any known ligands.

The structure of soluble HER-2-trastuzumab Fab complex reveals that trastuzumab binds on the C-terminal side of domain IV of the HER-2 ECD (Fig. 7). The trastuzumab-HER-2 interaction buries 1350 Å^2 of the HER-2 surface. Three loops are observed to make contact with trastuzumab. Loop 1 contains residues 579–583 and loop 3 contains residues 615–625, and these loops are composed

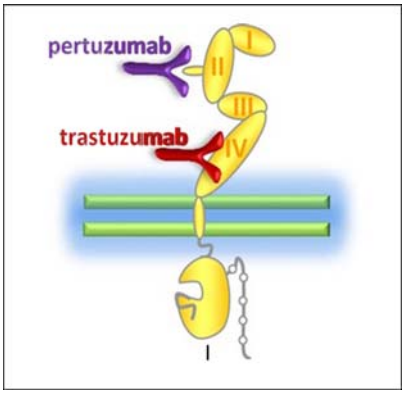

Fig. 7 HER-2-binding sites.

of primarily electrostatic interactions with trastuzumab. Loop 2 comprises residues 592–595, and this loop makes primarily hydrophobic contacts with trastuzumab. The specific details of the contact region between HER-2 and trastuzumab may allow for the design of possible small peptides or peptide analogues.

6.01.6.1.2 Structural studies with HER-2 and pertuzumab

The crystal structure of the HER-2 ECD bound to pertuzumab reveals this mAb binds a different epitope than trastuzumab, found at the center of domain II, near the junction of domains I, II, and II[165] (Fig. 7). The contact buries 1210 Å^2 on the HER-2 side of the interface. The interface between HER-2 and pertuzumab is mostly polar, with few hydrophobic or charged residues in the interface. Domain II in HER-2 and EGFR is highly conserved, and this is the same region involved in EGFR dimerization. This region overlaps with pertuzumab binding, indicating that pertuzumab binds at the HER-2 dimerization interface. This structure provides a model in which pertuzumab sterically interferes with HER-2 dimerizing with other members of the HER family and thereby interrupts the growth signals mediated by HER-2 ligand-activated heterodimers. However, the structure and function analysis demonstrated that pertuzumab binds to a quite distinct site of the HER-2 extracellular part from that of trastuzumab and is considered to serve as a HERs dimerization inhibitor. Receptor dimerization can occur between two different EGFR family members (heterodimerization) or between two symmetric EGFR receptors (homodimerization).

6.01.6.1.3 Rationale for conformational HER-2 epitopes

To induce functional cross-reactive immune responses, it appears essential that peptide design takes into account conformational correctness.[166] One approach to achieve molecular mimicry to the parent protein is through constricting the peptide by cyclization. Linear peptides are very flexible and can adopt an assortment of conformations in solution, but only a few of these conformations are responsible for their immunoreactivity. Cyclic peptides can cause favored spatial arrangements that reproduce the bioactive conformation resulting in superior binding and immunological properties. There are several extensive reviews on the cyclization of peptides.[167] Disulfide bridges are important evolutionarily conserved structural motifs found in many biologically important peptides and proteins including hormones, growth factors, and immunogloblins. Artificial introduction of disulfide bonds into designed peptide vaccines is performed with the goal to improve the cross-reactivity of the elicited antibodies to the native protein and thus enhanced activity of the vaccine. Regioselective pairing of disulfides can occur by controlled chemistries involving orthogonally removable Cys protecting groups. The utility of peptide cyclization with the incorporation of the two native disulfide bonds of the 626–649 sequence of HER-2 has been shown by our group previously.[11b]

The structures of the HER-2-trastuzumab complex and the HER-2-pertuzumab complex (Figs. 8A and 9A) have led to new insights into the mechanistic and biological activities of HER-2 antibodies as well as the process of ligand-induced receptor dimerization which in turn has empowered us to rationally design more effective HER-2 conformational epitopes with potentially increased efficacy for preventing and inhibiting tumor growth. To date no conformational peptides have been designed and tested based on the crystal structure of the HER-2 ECD in complex with the trastuzumab or the pertuzumab Fab fragments, hence these studies are novel.

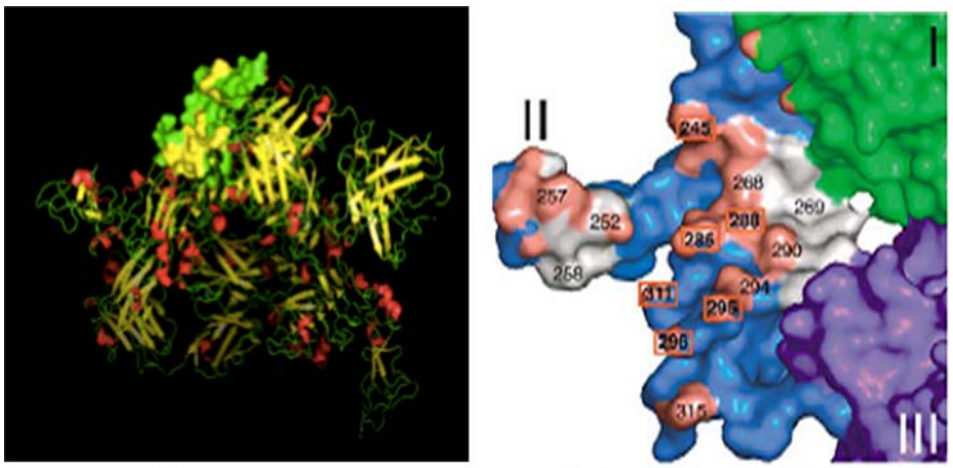

Fig. 8 Crystal structure of HER-2 pertuzumab-binding site. (A) X-ray structure pertuzumab and HER-2 complex and (B) engineered pertuzumab epitope 266–297.

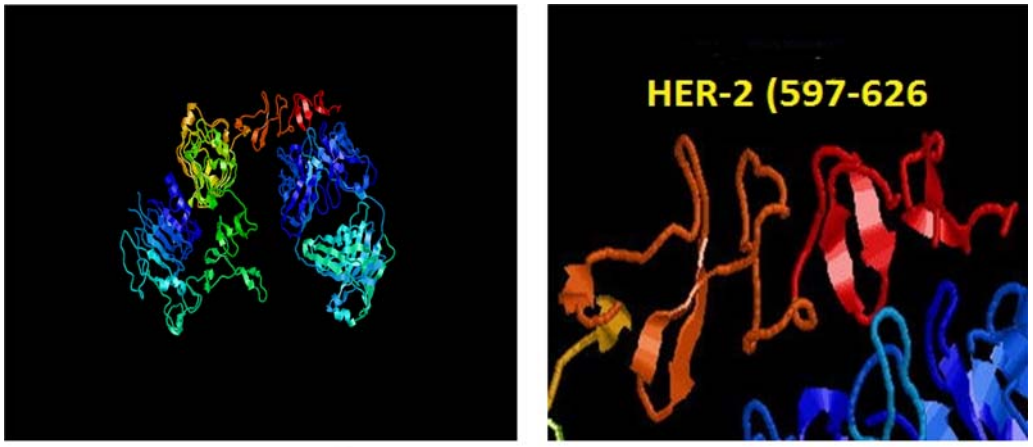

Fig. 9 (A) X-ray structure Herceptin/trastuzumab and HER-2 complex and (B) engineered trastuzumab epitope 597–626.

6.01.6.1.4 Design and evaluation of novel pertuzumab-binding conformational B-cell epitopes

The crystal structure of pertuzumab bound to the ECD of HER-2/neu[91] elucidated the details of interacting region of residues 266–333 (Fig. 8B). We examined three different sequences, 266–296, 298–333, and 315–333, to determine the best minimal conformational epitope for effective B-cell immunization. We report on the activity of several constructs containing complex, differential disulfide pairings as well as their linear counterparts in order to mimic the pertuzumab-binding conformational region.

The immunogenicity of each cyclized (Cyc) and noncyclized (NC) constructs were determined in both mice and rabbits, eliciting a high affinity, high titer antibody responses. The antibodies recognized the native HER-2/neu receptor. Additionally, only three of the six putative constructs 266–296(CYC), 266–296(NC), and 315–333(CYC) were able to mediate ADCC and reduce phosphorylation of the HER-2/neu tyrosine kinase domain. Epitope 266–296 was able to suppress cellular proliferation in heregulin (HRG)-stimulated MCF-7 cells. Our results show that these pertuzumab-like epitope constructs had statistically reduced tumor onset in both transplantable tumor models (FVB/n and Balb/c) and significant reduction in tumor development in two transgenic mouse tumor models (Balb-neuT and VEGF$^{+/-}$Neu2-5$^{+/-}$). These studies demonstrate that both the linear (NC) and conformational (CYC) peptide vaccines corresponding to residues 266–296 of the dimerization region of HER-2/neu are able to elicit an immune response with antitumor capabilities, resulting in a peptide vaccine that will be able to mimic the effects of pertuzumab in vivo without the harmful side effects associated with mAb therapy.

6.01.6.1.5 Design and evaluation of novel trastuzumab/Herceptin-binding conformational B-cell epitopes

The three-dimensional structure of human HER-2 in complex with Herceptin (Fig. 9A) revealed that the antigen-binding region of HER-2 spans residues 563–626 that comprises an extensive disulfide bonding pattern.[89,90] In order to minimally dissect the interacting-binding region of HER-2, we have designed four synthetic peptides with different levels of conformational flexibility. The interacting loops in subdomain IV comprise residues in loop 1: 579–583 (two disulfide pairings between C563 and C576, and between C567 and C584), loop 2: 592–595 (cysteine disulfide pairing between C587 and C596), and loop 3: 615–625 (cysteine disulfide between C600 and C623). Chimeric peptides incorporating the MVF "promiscuous" T-cell epitope via a four-residue linker sequence were successfully synthesized, purified, and characterized. All conformationally restricted peptides were recognized by trastuzumab, with 563–598 and 597–626 showing higher reactivity. All peptide sequences prevented the function of trastuzumab inhibiting tumor cell proliferation. All epitopes were immunogenic in FVB/N mice with antibodies against 597–626 and 613–626 recognizing HER-2. The 597–626 epitope was immunogenic in outbred rabbits eliciting antibodies which recognized HER-2 at the HER-2/trastuzumab interface, inhibited proliferation of HER-2-expressing breast cancer cells in vitro, and caused their ADCC. Moreover, immunization with the 597–626 epitope significantly reduced tumor burden in transgenic BALB-*neu*T mice. These results suggest that the peptide B-cell immunogen is appropriate as a vaccine for HER-2-overexpressing cancers since the resulting antibodies show analogous biological properties to trastuzumab. We conclude the HER-2 597–626 sequence is a potential vaccine candidate that could be translated to the clinic. One epitope, 597–626, was pursued for additional studies based on its ability to be recognized by trastuzumab and the ability of antibodies elicited against the peptide to bind HER-2 at the same site as trastuzumab. Antibodies against the 597–626 construct were able to mediate both direct and indirect mechanisms of antitumor activity against HER-2 in vitro. Additionally, the 597–626 peptide vaccine was able to impede the autochthonous tumor formation in BALB-*neu*T transgenic mice.

6.01.7 VEGF Peptide Strategies

Most solid tumors cannot grow beyond a few millimeters without the angiogenic switch being turned on[168] making angiogenesis inhibition a attractive therapeutic strategy for targeting tumors. The most well-known proangiogenic factor today is VEGF,[5g] and its overexpression is reported in many different types of cancers.[19,169]

There are many potentially beneficial combinations applicable in cancer immunotherapy ranging from antibodies to growth factors with small TKI molecules to CTL vaccines with inhibition of regulatory T cells with or without radiation and/or chemotherapy. HER-2 and VEGF represent validated targets for several tumor types, and inhibitors of these growth factors have become key therapies to improve antitumor efficacy. Because of the interdependence between these growth factors, concurrent inhibition of these multiple pathways might result in significantly better therapeutic outcomes.

6.01.7.1 VEGF Peptide Mimics

Unlike other growth receptors that only trigger mitogen pathways, VEGF signaling via VEGFR-2 activates pathways leading to survival, three-dimensional tube organization and vascular permeability.[170] VEGF:VEGFR-2 interaction is therefore very important for angiogenesis, and blocking this interaction is the most attractive model in the development of antiangiogenic drugs.[171]

Our strategy to develop angiogenic inhibitors involves the synthesis of conformational peptides that can mimic the VEGF-binding region to VEGFR-2 which will inhibit angiogenesis by competing with VEGF for binding to its receptor.

6.01.7.1.1 Design and synthesis of VEGF peptide mimics

The interface between VEGF and VEGFR-2 has been mapped by alanine scanning, which showed that the binding site is localized at the loop between β5 and β6.[172] This loop is within the region containing the biologically activity site (also called "hot spot") in the VEGF protein, which includes monoclonal epitope binding (Avastin, G-6, and B20-4) and VEGF receptor binding. Both Muller et al.,[173] who analyzed the contact residues on both sides of the interface of the complex between VEGF and the Fab fragment of a humanized antibody, and Zilberberg et al.[174] analysis of the VEGF sequence interacting with VEGF receptor-2 have concluded that residues spanning sequence 79–93 are important. Thus, we selected the VEGF sequence 102–122 (detailed in Fig. 10) to design our VEGF peptide mimic; this region corresponds to sequence 76–96 in the VEGF crystal structure and includes the entire loop region between β5 and β6.[175]

Our strategy for creating the conformational cyclic peptide VEGF-P3 (CYC) which displays an antiparallel β-sheet (Fig. 10) was to introduce two artificial cysteine residues between residues Gln79 and Gly92, and also between residues Ile80 and Glu93. The

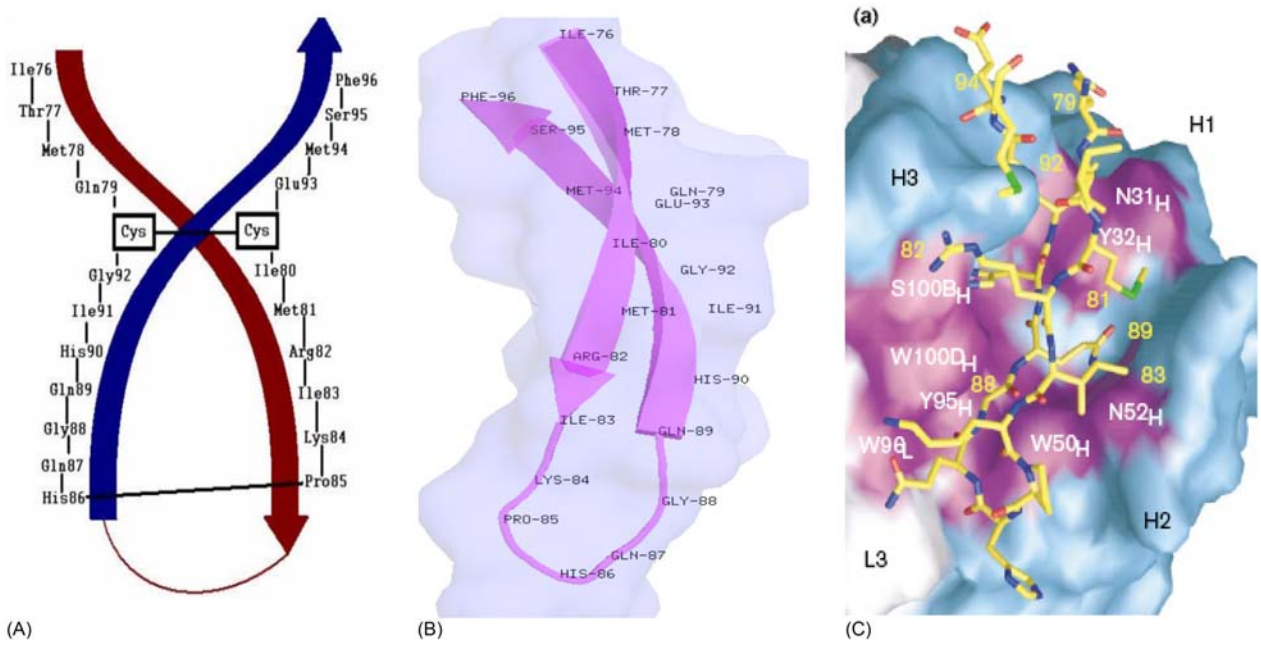

Fig. 10 Schematics of VEGF Peptide mimics. (A) Illustrates the engineered VEGF peptide mimic with two artificial cysteine residues inserted to form a cyclized antiparallel β-structure. The complex peptide is synthesized from Phe96 to Glu93 followed by CYS, and the synthesis continues with Ile80 through Gly92. The other CYS is placed between Gly92 and Gly79 and ends with Ile76. (B) The antiparallel β-sheet structure of VEGF 76–96 connected by loop residues 83–89. (C) The structure of VEGF shows the critical amino acid residues that are involved in binding of VEGF to its receptor VEGFR2.

VEGF-P3 (CYC) was synthesized with cysteines at position 80 and 92 to allow cyclization to yield a peptide mimicking its native conformation that of an antiparallel β-sheet contained within a loop structure. The VEGF-P3 noncyclized peptide after synthesis, cleavage, and HPLC purification was oxidized using iodine and characterized by mass spectrometer. The VEGF-RI-P4 peptide mimic required the use of D-amino acids to yield the retro-inverso (RI) peptidomimetic[176] resulting in a more stable peptide than its L-amino-acid counterpart that would exhibit similar activity and with higher bioavailability. The VEGF mimic peptides were evaluated as inhibitors in several assays where VEGF-dependent signaling pathways are observed. The engineered cyclic VEGF mimic peptide (VEGF-P3(CYC)) shows the highest inhibitory effects in several angiogenic in vitro assays compared to unstructured peptides. We also demonstrate that this VEGF mimic peptide significantly delays tumor growth in a transgenic mouse model ($VEGF^{-/+}$/$Neu2\text{-}5^{-/+}$), in which the acceleration of spontaneous tumor burden is due to overexpression of VEGF. These results indicate that the structure-based design is important to the development of this peptidomimetic and to its antiangiogenic effects. The VEGF-P3(CYC) is the best peptide candidate for the development of a peptidomimetic angiogenic inhibitor.

6.01.7.1.2 Combination therapy targeting both HER-2 and VEGF in cancer

The overexpression of HER-2 is associated with increased expression of VEGF at both the RNA and protein level in human breast cancer cells.[150] In addition, exposure of HER-2 overexpressing cells to trastuzumab significantly decreases VEGF expression.[151a] Taken together these data suggest that VEGF is a downstream target of the HER-2 signaling pathway. A positive association between HER-2 and VEGF expression in breast cancer patients has been identified.[177] A two-pronged approach to target cancer cells by coimmunizing with defined tumor-associated antigens and angiogenesis-associated antigens has been shown to have synergistic effects.[178] Combination treatment with defined tumor- and angiogenesis-associated antigens is well known to produce synergistic effects.[179] Combining antiangiogenic therapies with other direct anticancer agents has been shown to be beneficial in various malignancies.[180] Because of the potential synergy between therapy with HER-2 inhibitors and antiangiogenic therapy with VEGF inhibitors in vitro and in vivo, we evaluated the effects of combination treatment.

From our previous studies, the peptide epitope HER-2-266–296 was shown to produce the best antitumor effects both in vitro and in vivo. We therefore decided to combine this novel HER-2 peptide mimic with our antiangiogenic VEGF peptide mimic with these two peptides.

As shown in Fig. 11, antibodies elicited by immunization with MVF-HER-2 (266–296) vaccine bind to domain II of HER-2 and similarly anti-MVF-HER-2 (597–626) binds domain IV of HER-2 providing dual inhibition of homo/heterodimerization and consequently downstream signaling shutting down the PI3K and MAK kinase pathways, thereby preventing cancer growth and metastasis. On the other hand VEGF peptide mimics P3 and P4 are designed to directly block VEGF binding to VEGFR2 and inhibit intracellular phosphorylation of the tyrosine kinase domain which reduces angiogenesis.

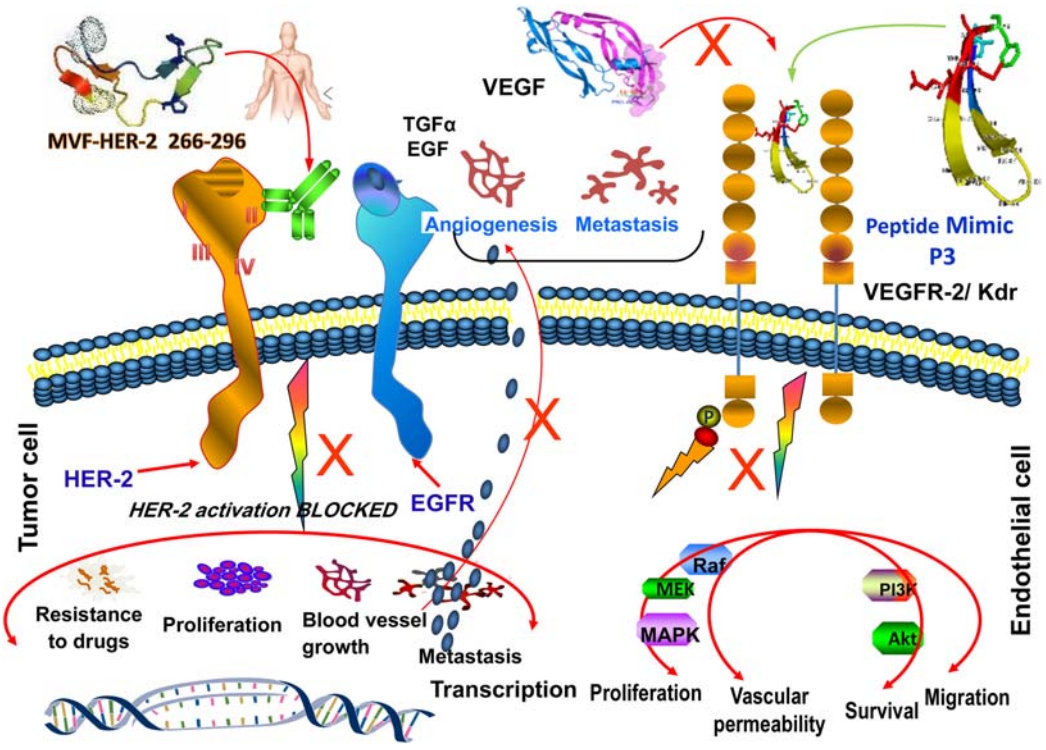

Fig. 11 Combination of HER-2 vaccines and VEGF peptide mimics.

6.01.8 Crucial Peptides Targeting HER-1, HER-3, and IGF-1R Have Been Identified and Fully Characterized Biochemically and Immunologically

6.01.8.1 Extensive Cross talk Among ErbB/HER Receptors

Extensive cross talk among ErbB/HER receptors suggests that blocking signaling from more than one family member may be essential to effectively treat cancer and limit drug resistance. Recently, we have extended our portfolio of RTK inhibitors by identifying crucial and novel peptides targeting HER-1(HER-1),[52] HER-3,[181] and IGF-1R.[38d,182]

6.01.8.1.1 HER-1

The crystal structure of the complex between EGF and EGFR and analysis of the contact residues on both sides of the interface have been well analyzed,[183] while the structural basis for the inhibition of EGFR by cetuximab has also been studied.[95] Results from these two separate studies showed residues critical for cetuximab binding are also important for EGF binding, which indicates that the neutralizing effect of cetuximab binding results from disrupting EGF:EGF receptor interaction. Several residues are important for EGF binding and with the aid of these crystallographic studies and computer-aided analysis; we have selected peptide epitopes that include these key residues for ligand binding as potential candidates for our vaccine and therapeutic approach. Several residues are important for EGF binding and with the aid of these crystallographic studies and computer-aided analysis; we have selected peptide epitopes that include these key residues for ligand binding as potential candidates for our vaccine and therapeutic approach (see **Table 1** and **Fig. 12**).

In this study, we selected three critical epitopes of EGFR (347–374, 382–410, and 418–435) that are all involved in ligand binding and by active immunization in rabbits; we have generated sequence-specific antipeptide antibodies to the EGFR ligand-binding domain. We then evaluated the in vitro antitumor effects of the antibodies and the peptide mimics (B-cell epitope alone) in different signaling assays like cellular proliferation, apoptosis induction, EGFR dephosphorylation, inhibition of signaling pathways, and ADCC. The peptide vaccines were highly immunogenic in both mice and rabbits, and the antibodies elicited were able to specifically recognize the native EGFR receptor as shown by their reactivity in MDA-MB-468 TNBC cells and A549 lung cancer cells in flow cytometry and their binding to recombinant human EGFR in ELISA. The peptide mimics and antipeptide antibodies to all three epitopes inhibited cancer cell growth, prevented EGFR-specific phosphorylation, downregulated EGFR-signaling pathways, caused increased apoptosis, and ADCC in EGFR expressing cells. In mouse model studies, two of the vaccine epitope were able to delay tumor growth in a met-1 transplantable breast cancer model. The antipeptide antibodies also prevented tumor growth in SCID mice that were inoculated with A549 lung cancer cells. Immunohistochemical analysis also showed significant reductions in microvascular density and actively dividing cells in the tumor sections after treatment in the FVB/n breast cancer model. The 382–410 and 418–435 B-cell epitopes were the best candidate both as a vaccine and peptide mimic because it caused significant inhibition in the two mouse models. Our results show that this novel EGFR B-cell epitopes has great potentials to be used as a vaccine or treatment option for EGFR-expressing cancers.

6.01.8.1.2 HER-3

HER-3 is frequently upmodulated in cancers with EGFR or HER-2 overexpression, and HER-3 may provide a route for resistance to agents that target EGFR or HER-2. Currently, therapeutic mAbs such as AMG 888 and MM-121 specifically target HER-3 and are currently being evaluated in clinical trials. Unlike HER-2, HER-3 lacks the ability to form homodimers. As a result, HER-3 signaling is entirely dependent on heterodimerization.[184] Interestingly, the heterodimer of HER-2/HER-3 constitutes the most potent receptor with respect to strength of interaction, ligand-induced tyrosine phosphorylation, and downstream signaling.[5k,120a] It forms a high-affinity heregulin receptor with kinase activity.[185] In addition, the HER-2/HER-3 heterodimer was found to mediate the most mitogenic signal in vitro.[184b,186] It also induced cellular transformation of a mouse fibroblast cell line that expressed nontransforming levels of HER.[184b,186c] The combination of HER-2 and HER-3 receptors may be critical in breast cancer growth and progression, and HER-3 may be a necessary partner for the oncogenic activity of HER-2.[67] HER3 may also provide a route for resistance to agents that target EGFR or HER.[187] Recent evidence suggests that HER-3 contributes to escape from therapeutic suppression by several TKIs in breast cancer.[187a,d,e] In fact, HER-3 expression or signaling is associated with resistance to: HER2 inhibitors in HER2-amplified breast cancers,[187e] EGFR inhibitors in lung cancers,[188] pertuzumab resistance in ovarian cancers,[189] antiestrogen therapies in ER-

positive breast cancers,[189,190] EGFR inhibitors in head and neck cancer,[191] and hormone resistance in prostate cancers.[192] As a result, treatments using HER-3 peptide mimics and antipeptide antibodies can provide maximal benefit.

We have used several computer-generated algorithms to predict potential immunogenic amino acid sequences in domains II and III (involved in dimerization and ligand binding, respectively) of the HER-3 extracellular domain (Fig. 13). The methods used predict antigenic determinants in a protein that have a high chance of producing protein-reactive antipeptide antibodies (B-cell epitopes). Ten profiles were essentially used to predict HER-3 sequences that are hydrophilic or exposed on the surface of a protein. Hydropathy profiles were calculated using the scale of Kyte and Doolittle.[205] Hydrophilicity profiles were generated using the programs Hopp and Woods,[206] Parker,[207] and Fraga.[208] The Janin[209] and Novotny[210] scales were used to predict regions of HER-3 accessibility. Protruding portions of a protein were calculated by Hopp Acrophilicity and Bulk scales.[211] The Welling et al.,[212] Antigenicity profile was used to predict amino acids in antigenic regions. The crystal structure of the complex between D11 and HER3, with analysis of the contact residues of the HER3:D11 interface, was published by Schaefer et al. The residues critical for D11 binding are also important for HRG binding; therefore D11 has the ability to block the HRG:HER3 interaction. Several residues are important for D11 binding, and we have selected a peptide that includes these key residues, HER-3 461–479. We identified and evaluated novel HER-3 peptide epitopes (Table 2) encompassing residues 99–122, 140–162, 237–269, and 461–479 of the HER-3 extracellular domain as putative B-cell epitopes for active immunotherapy against HER-3 positive cancers. The HER-3

237–269 epitope overlapped with sequences found in all 10 of the prediction algorithms, and the second epitope HER-3 461–479 was found in 9/10 of the hydrophilic profiles. We showed that the HER-3 vaccine antibodies and HER-3 peptide mimics induced antitumor responses: inhibition of cancer cell proliferation, inhibition of receptor phosphorylation, induction of apoptosis, and ADCC. Two of the HER-3 epitopes 237–269 (domain II) and 461–479 (domain III) significantly inhibited growth of xenografts originating from both pancreatic (BxPC3) and breast (JIMT-1) cancers.

6.01.8.1.3 IGF-1R

IGF-1R has evolved as a particularly important target in cancers that have developed resistance to EGFR/HER-1- and HER-2-targeted therapies. IGF-1R overexpression[33] and/or cross talk to HER-2 contribute to the development of trastuzumab resistance.[36c,193] In fact, IGF-1R overexpression and increased signaling have been reported in cell lines and clinical samples derived from trastuzumab-resistant breast cancers.[194] Similarly, cross talk between IGF-1R and EGFR/HER-1[195,196] is associated with the development of resistance to EGFR/HER-1 inhibition.[197] Targeting the IGF:IGF-1R axis with innovative peptide inhibitors and vaccine antibodies represents a promising therapeutic strategy to overcome drug resistance and to provide new avenues for individualized and combination strategies.

We have identified four sequences that are derived from the IGF-IR ligand-binding domain. The four peptide mimics (**Fig. 14**) are IGF-IR-6–33, IGF-IR-56–81, IGF-IR-234–252, and IGF-IR-306–341, and the sequences of the peptides are shown in **Table 3**. These epitopes were designed based on the ligand-binding site of the receptor using crystallographic structures, mutagenesis studies, and models of the complex between the receptor–ligand interactions.[198]

In this study, we designed, synthesized, and characterized several B-cell epitopes from the IGF-1:IGF-1R axis. The chimeric peptide epitopes were highly immunogenic in outbred rabbits, eliciting high levels of peptide vaccine antibodies. The IGF-1R peptide antibodies and peptide mimics inhibited cell proliferation, receptor phosphorylation, induced apoptosis, and ADCC

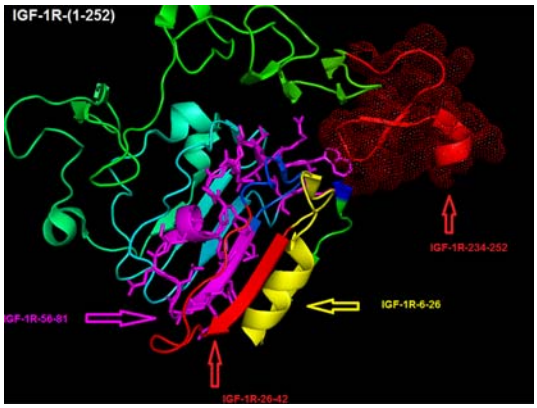

Fig. 14 The three-dimensional crystal structure of IGF-1R extracellular domains 1 and 2. The four predicted IGF-1R peptide epitopes are clearly shown. IGF-1R 6–26 is an α-helix shown in yellow stabilized by the 26–42 sequence is a β-sheet shown in red, and sequence 56–81 is shown in pink with the side chains shown and includes a β-sheet and a turn. The IGF-1R 234–252 includes two antiparallel beta β-strands and a turn and is also shown in red.

and significantly inhibited tumor growth in the BxPC-3 pancreatic and JIMT-1 breast transplantable models of cancer. Our results showed that the 56–81 and 233–251 peptides and antibodies are potential therapeutic and vaccine candidates for the treatment of IGF-1R-expressing cancers, including those that are resistant to the HER-2-targeted antibody, trastuzumab.

6.01.9 Conclusions and Future Outlook

Extensive cross talk among ErbB/HER receptors suggests that blocking signaling from more than one family member may be essential to effectively treat cancer and limit drug resistance. There is a desperate need for new anticancer agents that are less toxic and more effective. Therapies that block the extensive cross talk between RTKs are more likely to overcome drug resistance, including in particular, the signaling networks consisting of IGF-1R, EGFR/HER-1, HER-2, VEGF, and HER-3 play major roles in trastuzumab resistance.[33,36b,c,199] Our studies have made major contributions to the existing fields of cancer immunology, drug development, and mechanisms of cancer pharmacology by (1) developing new immune-based approaches to combat receptor kinase-driven cancers and (2) understanding and overcoming clinically relevant mechanisms of resistance to currently used HER-2-directed agents. To promote a rational, systematic development of combination therapies in multivariate ways, next-generation combination therapies can be constructed with a clear understanding of how mechanisms of resistance to multidrug regimens differ from single agent resistance. We have established the underlying mechanisms that drive the advantages of combination therapies with independent mechanisms of action, and design methods to determine drug targets for combination regimen that effectuates long-term tumor control and destruction.

Due to our prior successes, our next step is to create innovative combinations of B-cell vaccines against multiple RTKs (reviewed in Kaumaya et al.[3]). We hypothesized that this new strategy will synergistically activate host immunity, achieve durable responses with little toxicity, and overcome drug resistance. In order to solve the existing toxicity and resistance problems in immunotherapy, we have expanded our portfolio of already established vaccines to RTK-directed agents (HER-1, HER-2, and VEGF) by identifying novel HER-3 and IGF-1R peptide vaccines and peptide mimics.[38d,200] We have targeted cross talk from insulin-like growth factor-1 receptor (IGF-1R)[6] and HER-3[3,201] to HER-2 to overcome sustained HER-2 signaling and resistance from HER-2-targeted therapies. Ultimately, our goal is to identify the most biologically effective combinations of HER-1, HER-2, HER-3, and/or IGF-1R peptide vaccines to selectively inhibit multiple receptors and signaling pathways to block the extensive receptor cross talk that drives the biology and resistance of HER-2-overexpressing cancers. This strategy holds the promise of achieving durable cures for multiple types of cancers (breast, TNBC, pancreatic, colon, and esophageal cancers) and can be translated to human clinical trials. We have demonstrated efficacy in reducing tumor growth in different xenograft models in multiple cancer indications. We have shown superior synergistic antitumor effects in vitro and in vivo by combining HER-2 and VEGF peptide vaccines/mimics.[202,203] Additionally, we have characterized potential combinations of therapies targeted against HER-3 or IGF-1R with those against HER-2 and HER-1 resulting in highly synergistic in vitro antitumor responses in several tumor types. Rationally designed peptide therapeutics[204] could also represent a novel class of anticancer agents that specifically target cancer cells with lower toxicity to normal tissues, high specificity, and significant biological activity. The combination of different vaccine and therapeutic strategies to target specific molecular pathways that are dysregulated in tumors may create clinical breakthroughs for safe and efficacious cancer cures.

6.02.1 Cancer and the Immune System

Since President Richard Nixon declared war on cancer in 1971, real progress has been made to improve cancer prevention, early detection, and treatment.[1,2] This effort has led to a decrease in the mortality rates for most cancers, including lung, breast, colon, and prostate.[3] Nevertheless, the war on cancer has not been won, and much work remains to be done.[1] In the United States, cancer is the second most common cause of death, exceeded only by heart disease.[4] It is estimated that ~1.6 million cases are diagnosed and about 585,720 cancer patients die from this disease yearly, in the United States.[5] It is expected that over the next 14 years, cancer will surpass heart disease and become the leading cause of death.[6]

Typically, host immunity can detect and destroy cancer cells through an immune surveillance mechanism.[7] However, some malignant cells have the capacity to adapt to immune selection pressures, thereby avoiding immune-mediated destruction.[8] To restore and enhance the immune system's ability to fight cancer, it is important to first understand the link between cancer and immunity.

6.02.1.1 The Immune System Is Crucial for Survival

The immune system is composed of diverse organs, tissues, cells, and soluble molecules. All these components work together, in a highly organized manner, to protect individuals from external and internal dangers.[9] In fact, humans are exposed to millions of

potential pathogens every day.[10] To protect the body from these dangerous invaders, the immune system identifies the pathogens, eliminates them, and creates a memory response to prevent future infection.[9] Moreover, although the human body is home to billions of microbiota,[11] this system can differentiate between harmful and beneficial microorganisms. Additionally, in a human body with 37.2 trillion cells,[12] billions of cells experience mutations every day.[10] Some of these mutations can transform normal cells into cancerous cells.[13] Fortunately, the human body has efficient anticancer defense mechanisms, including tumor immune surveillance.[14] This process allows the immune system to recognize and destroy cancerous and/or precancerous cells leaving normal cells intact.[7]

6.02.1.2 Components of the Immune System

6.02.1.2.1 Innate immunity

The immune system is typically divided into two main categories: innate and adaptive. The innate immune system is so named because it is present at birth. It involves physical and chemical barriers and cellular and humoral components. Innate immunity has readily available recognition properties that are not specifically directed against a particular organism or target. For example, skin prevents the entry of pathogens, mucus in the respiratory tract traps dirt and dangerous molecules, and tears and saliva have antibacterial enzymes that work like antibiotics. When these barriers fail, humoral and cellular components orchestrate an effective response against the invader. An invading pathogen then activates the complement system and stimulates cytokine production, which can recruit innate killer cells. These cells include granulocytes (basophils, eosinophils, and neutrophils), mast cells, macrophages, dendritic cells (DCs), and natural killer (NK) cells (Fig. 1).[9] Whether or not the innate immune response eliminates the danger, it may trigger an adaptive immune response through now well-understood mechanisms.[15]

6.02.1.2.2 Adaptive immunity

The adaptive immune response is also called the acquired immune response because it is acquired after the exposure to foreign antigens. It involves T and B lymphocytes and their secretory molecules (Fig. 1). B cells and T cells can recognize specific structures, called epitopes, on antigens that elicit immune responses. Primary lymphoid organs, including bone marrow and the thymus, produce the primary repertoire of B and T lymphocytes. These cells remain naive and inactive, until they interact with antigens

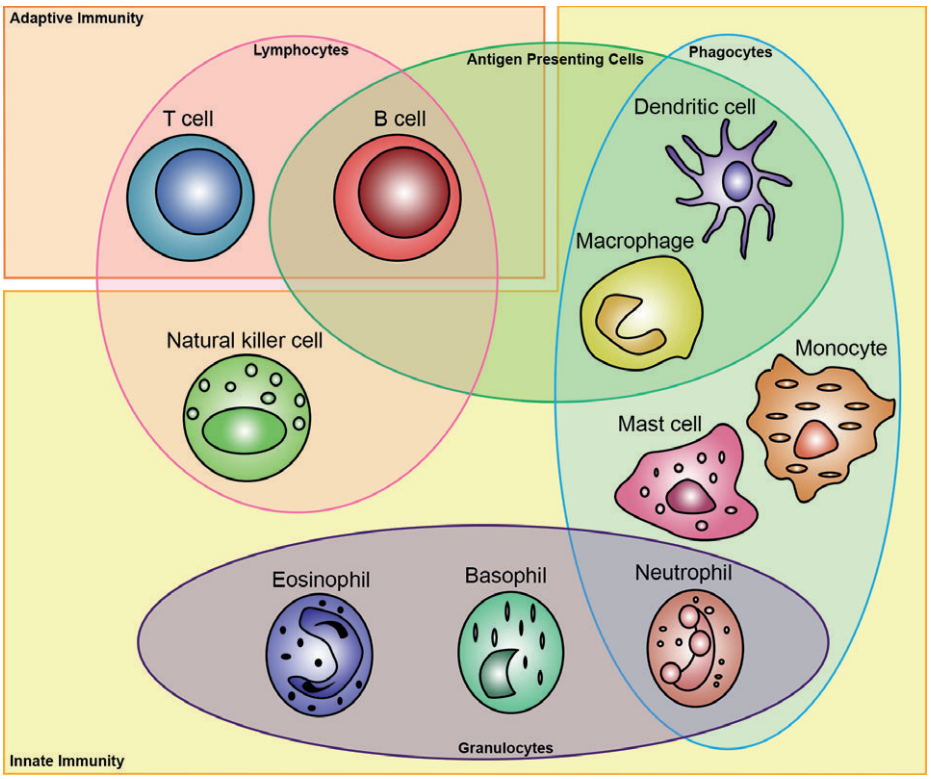

Fig. 1 Cells of the immune system. The immune system has two major functional components: innate and adaptive. Cellular components involved in the innate immune response include natural killer cells, granulocytes (neutrophils, basophils, and eosinophils), macrophages, and dendritic cells. Some of these cell populations function as professional antigen-presenting cells, as do B lymphocytes. Innate immunity thus has direct antiinfection and antitumor properties and also presents antigens to cells of the adaptive immune system, which is composed of B lymphocytes and T lymphocytes.

in secondary lymphoid tissues, such as lymph nodes, tonsils, spleen, Peyer's patches, and mucosa-associated lymphoid tissue. Following activation of naive T cells and B cells, they differentiate into effector cells and memory cells. Although B and T lymphocytes have some similarities, they differ in many aspects. First, B cells are produced by the bone marrow, whereas T cells originate in the bone marrow, but then they move to the thymus to complete their maturation. Second, the B-cell receptor (BCR) is composed of a membrane-bound immunoglobulin molecule bound to a signal transduction moiety (CD79). Immunoglobulins can also be synthesized in secreted forms by activated B cells or plasma cells. Thus, B lymphocytes can interact with free and membrane-bound antigens. Also, they recognize both linear (i.e., peptide sequences) and conformational epitopes with exquisite specificity and high affinity. In contrast, the T-cell receptors (TCR) are located on the surface of T lymphocytes. They can only recognize short peptide fragments bound to major histocompatibility complex proteins (MHCs) on antigen-presenting cells (APCs).[9] Of note, although it has been known for decades that only adaptive immune cells have immunologic memory, recent studies have shown that innate immune cells can also remember previously encountered antigens.[16]

6.02.1.2.3 Phagocytosis

Phagocytosis is a process mediated by a specialized group of innate immune cells called phagocytes, including neutrophils, monocytes, macrophages, DC, and mast cells. During phagocytosis, phagocytes engulf solid particles, larger than 0.5 μm in diameter, such as bacteria and dead tissue cells. After internalization, these particles are confined to intracellular vesicles called phagosomes, which then fuse with endosomes or lysosomes forming phagolysosomes. These vesicles contain enzymes and toxic peroxides that are able to break down the engulfed particles. Besides clearance and neutralization, macrophages and dendritic cells, which function also as APCs, are important in processing and presenting the phagocytosed antigens to T cells. Additionally, phagocytosis is typically accompanied by the production of inflammatory cytokines, which can recruit innate immune cells to the site of infection and, ultimately, determine the nature of the adaptive immune response.[17]

6.02.1.2.4 Antigen presentation

All nucleated cells have the ability to process and present antigens via MHC class I (MHC I), which can activate cytotoxic $CD8^+$ T cells. Therefore, all mammalian cells, except red blood cells (RBCs), are considered as nonprofessional APCs. By contrast, professional APCs, including DCs, macrophages, and B lymphocytes, are highly specialized cells. They can process and present an antigen together with MHC I or MHC class II (MHC II) on their surfaces. Thereby, this Ag–MHC complex can stimulate helper $CD4^+$ T cells or cytotoxic $CD8^+$ T cells, respectively.[9] It should be noted that although antigen presentation is required for T-cell activation, this process does not initiate an immune response in and of itself.[1]

6.02.1.2.5 T-cell activation

There are two signals required for the activation of naive T cells. The first signal is called "signal 1" or "recognition signal." It involves the specific recognition of an Ag–MHC complex by TCR in the context with CD4 or CD8 coreceptors. The second signal is called "signal 2" or "costimulatory signal." It is provided through the binding of APC-based B7.1 or B7.2 molecules to CD28 on T cells. By delivering only signal 1, the antigen would not be recognized by TCR, leading to T-cell deletion or rendering them unresponsive (anergic). In contrast, T cells that receive the second signal only cannot recognize the specific peptide and thereby may remain naive. In other words, to activate a T cell, it has to get stimulated by an APC through both signal 1 and signal 2, and receiving one of the signals only is not sufficient. Once they are activated, T lymphocytes can proliferate and differentiate into effector cells, such as cytotoxic and helper T cells, or memory T cells.[9]

On the other hand, because there are severe adverse effects of immune system overstimulation, this process has to be tightly regulated. Hence, activated T cells are typically turned off once they have done their jobs and before they develop chronic inflammation and tissue damage. In fact, deactivating T cells is very important to maintain self-tolerance and prevent autoimmunity. There are many strategies employed by the immune system to reduce the activity of effector T cells. This includes (1) induction of immunomodulatory cytokines, such as interleukin 10 (IL-10) and transforming growth factor beta (TGF-β); (2) stimulation of immunosuppressive cells, such as regulatory T (T-reg) cells; and (3) upregulation of immune checkpoints, including anticytotoxic T lymphocyte-associated antigen 4 (CTLA-4), and antiprogrammed death 1 (PD-1).[1,18]

6.02.1.2.6 B-cell activation

Mature B cells released from the bone marrow remain inactive in peripheral tissues until they interact with an antigen. As mentioned earlier, the B cell is one of the three professional APCs.[9] Thus, engagement of a BCR with an antigen initiates a cascade of intracellular signaling, leading to the internalization of the antigen, processing, and presentation on an MHC II molecule to $CD4^+$ T cells.[19] The activated T cells can then provide a second activation signal to the B cell, resulting in B-cell proliferation and differentiation into a plasma cell, the antibody-producing cell, or memory B cell.[20]

6.02.1.2.7 Antibodies

Antibodies are the major components of the humoral immune response. Each antibody interacts with the specific antigen that induced B-cell activation and immunoglobulin production.[20] Antibodies can eliminate immunogenic molecules and manipulate cell biology through several mechanisms, for example, antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC), cell signaling disruption, antibody-dependent cellular phagocytosis (ADCP), agglutination, and

neutralization.[21] Nowadays, antibody-based drugs have become one of the most important therapeutics for cancer.[22,23] Further details will be discussed later in this article.

6.02.1.2.8 Cytokines

The term cytokine encompasses a large and diverse family of regulatory molecules.[24] They are low-molecular-weight bioactive proteins[25] that are used as a common chemical language for communication within and between cells.[26] They play a major role in regulating cellular proliferation, survival, differentiation, activation, migration, and death. Depending on many factors, such as cytokine concentrations, cytokine receptor expression, type of secretory cells, and the activation state of surrounding cells, they can mediate either local or systemic effects. Also, they can induce antitumor or protumor immune responses.[27]

6.02.1.2.9 Complement

The complement system is a proteolytic cascade made up of a large number of distinct proteins that interact with one another. Besides recruiting immune cells to the problem area, the complement proteins can promote the destruction of free pathogens in the circulation via agglutination reaction. They tag their targets in a process called opsonization, allowing the immune system to recognize and eliminate the danger. Also, they can cause target cell lysis through the formation of a membrane attack complex (MAC).[20]

6.02.1.3 Cancer Immunity

There are many escape routes that cancer cells can employ to overcome an antitumor immune response, for example, overwhelming, hiding from, subverting, shielding from, outlasting, and defending against the host immune response. However, these cells only do what is advantageous for their growth and survival. They do not use all the immune escape strategies, and they do not use any one arbitrarily.[1] Also, the selected strategies are not fixed, but are constantly changing.[28,29] Accordingly, to restore the immune system's ability to eliminate the cancer, we need to understand the immune escape mechanisms and determine which ones are dominantly employed in a particular patient.

6.02.1.3.1 Cancer cells can overwhelm the host immune system

Lymphoma and leukemia are cancers that start in leukocytes located in the lymph nodes and in the blood, respectively. Transformation of immune cells, such as T and B lymphocytes, into malignant cells promotes ineffective regulation of immunologic recognition and function, leading to ineffective anticancer immune responses.[30] Moreover, some rapidly proliferating malignancies might create a rapidly expanding tumor burden that overwhelms the kinetics and amplitude of available immune defense mechanisms.[1] To restore host immunity against cancer cells, autologous or allogeneic T cells can be infused into patients. In some situations, T cells genetically modified to react against an accessible tumor-related antigen, that is, chimeric antigen receptor (CAR) T cells, have shown remarkable antitumor properties.[31] T-cell immunotherapy involves the use of T cells that replace ineffective host immunity with cells bearing potent effector functions against tumor antigens.[32] However, if a cancer cell population employs other escape mechanisms that suppress T-cell activation, homing, or function, T-cell therapy alone would not be sufficient to restore a patient's immunity and to eradicate malignant cells. Thus, immunotherapy combinations might be needed.[33]

6.02.1.3.2 Cancers can hide from the host immune system

Malignant cells can avoid immune detection by either hiding their antigens or hiding themselves physically. For example, cancer cells might reduce antigen presentation so that T cells are blind to their presence.[33] In support of this hypothesis is the fact that many types of malignancies can lose up to 90% of normal MHC I expression.[34] Also, loss of members of the antigen-processing machinery (APM), such as the transporter associated with antigen processing (TAP), the endoplasmic reticulum aminopeptidase associated with antigen processing (eraap in mice and erap1 and erap2 in humans), and tapasin, was shown to correlate with poor cancer prognosis. These molecules are responsible for antigen translocation into the endoplasmic reticulum (ER), final trimming, and editing of the peptide before loading on MHC I.[35] Many oncogenes that are highly expressed in aggressive malignancies can interfere with antigen presentation and promote the outgrowth of MHC I-deficient tumor types. For example, it has been suggested that HER2 oncogene expression is inversely correlated with MHC I and TAP. To emphasize this, the level of surface MHC I on HER2+ breast carcinoma cell lines was evaluated after HER2 silencing by siRNA. This experiment showed significant increase in MHC I expression after HER2 knockdown. Moreover, it was reported that HER2 overexpression may induce defects in APM components. Consequently, it is suggested that HER2 has an important role in protecting cancer cells from immune system-mediated destruction.[36] Another strategy that tumors employ to reduce antigen presentation is by downregulating target antigen expression.[37] Poor tumor antigenicity stimulates a weak, slow, and nondestructive anticancer immune response. This phenotype, which is also called immunoediting, allows tumor cells to escape from immune-mediated rejection and promote cancer progression.[38]

The most important immune cells that can kill cancers directly are cytotoxic T lymphocytes (CTLs) and NK cells.[39] Interestingly, these cells perform complementary roles; CTLs lyse tumors expressing antigens on MHC I, and NK cells lyse cells lacking MHC I on their surface.[40] This shows how the immune system carefully orchestrates the elimination of abnormal cells. The question of how cancer cells elude these seemingly complementary lines of defense has not yet been fully elucidated. One possible explanation is that NK cell-mediated immunosurveillance is not sufficient to eliminate cancer cells. It is argued that in most cases immune cell infiltrates contain many more T cells than NK cells.[35] Another explanation is that MHC I can act as tumor suppressor molecule.

Thus, its downregulation promotes tumor progression that outweighs the antitumor effects of NK cells. In fact, it has been reported that in human melanoma cells, MHC I regulates cell cycle gene expression, invasion, cellular proliferation, and intrinsic oncogenic capacity.[41] Another possible interpretation is that tumor cells can overcome the absence of MHC I molecules by expressing inhibitory ligands, such as the nonclassical MHC I human leukocyte antigens G (HLA-G) and E (HLA-E). Nevertheless, the evidence supporting this hypothesis of the "replacement model" is not very strong. Indeed, HLA-E can stimulate both inhibition and activation of antigen presentation, and its presence can be associated with good and bad prognosis. Also, HLA-E expression may not be restricted to MHC I-deficient tumors.[35]

In addition, malignant cells can be physically sequestered from immune recognition and destruction through three different mechanisms. For example, some malignancies such as pancreatic adenocarcinoma may develop within dense collagenous stroma in the tumor microenvironment (TME).[42,43] The fibrotic TME in pancreatic cancers, which are generally associated with poor prognosis and high mortality rates, serves as a physical and functional barrier between the pancreatic tumor and immune cells, potentially allowing cancer cells to avoid immune surveillance.[44] Second, malignant cells growing in immune-privileged sites, such as the brain or the eye, cannot be detected by host immunity. Finally, cancer cells that fail to migrate to lymph nodes, where antigens can be presented to adaptive immune cells, might escape from immune recognition.[42]

6.02.1.3.3 Cancers can subvert the immune system

Under the influence of cellular transformation, cancer cells, immune cells, and stromal cells secrete immune-inhibitory cytokines, such as IL-10, IL-6, and TGF-β.[26] Simultaneously, cancer cells stimulate the local induction of immunosuppressive cells, including T-reg cells, myeloid-derived suppressor cells (MDSCs), tumor-associated fibroblasts (TAFs), "type 2" macrophages, and DCs. As a consequence, malignant cells become able to escape from cancer immune surveillance.[1] Not surprisingly, many clinical trials have aimed to restore the immune-activating microenvironment by neutralizing the suppressive cytokines[26] and/or targeting the cellular components of the immunosuppressive TME.[45–47]

Furthermore, cancer cells can subvert antitumor host immunity by promoting hypoxia and manipulating cellular metabolism.[48] An example of metabolism-mediated immune escape strategy used by cancer cells is the modulation of the tryptophan (TRP) to kynurenine (KYN) metabolic pathway. In this pathway, tumor cells or myeloid cells express high levels of indoleamine 2,3-dioxygenase 1 (IDO1), which is the first and rate-limiting enzyme in the degradation of TRP. Subsequently, when T cells are starved for TRP, they cannot divide and thus cannot respond to the activation signals. Therefore, it is suggested that targeting IDO1 or the other key components of this pathway, such as general control nondepressible 2 (GCN2) and TRP-2,3-dioxygenase 2 (TDO), may reverse cancer-associated immunosuppression.[49] To test this hypothesis, many clinical trials have been launched to evaluate the safety and efficacy of IDO1-targeting interventions in cancer patients.[50] In line with that, it is hypothesized that adding IDO1 inhibitors to immune checkpoint inhibitors may improve patients' outcomes.[51] To examine this idea, mouse syngeneic tumor models were utilized to demonstrate that treatment with the combination of an IDO1 inhibitor and anti-PD-L1 antibody improved antitumor immunity and efficacy compared with the mice treated with anti-PD-L1 alone.[52]

Another mechanism of metabolism-mediated immune escape in cancer is hypoxia-driven immunosuppression. Under conditions of low oxygen supply, cancer cells tend to change their metabolic phenotypes to enhance their survival and progression. Also, hypoxia can modulate the function of the surrounding immune cells and vascular cells to further promote tumorigenesis and cancer immune evasion.[53] The master regulators of hypoxia are the transcription factors hypoxia-inducible factors (HIFs).[54] They are stimulated in response to limited O_2 supply[55] and can be stabilized via upregulation of glycolysis. Interestingly, it has been shown that HIF transcription factors can mediate immunosuppression through multiple mechanisms. For example, HIF-1a can stimulate expansion of MDSCs and promote their differentiation toward tumor-associated macrophages (TAMs). Also, hypoxia can enhance T-cell differentiation toward the tumor-promoting T-helper 2 (T_H2) phenotype and away from the antitumor T_H1 phenotype.[53] This concept was supported by various preclinical studies in animal models with HIF-1a deletions or knockdown. These studies revealed that the HIF-1a-deficient CTLs and helper T cells can produce more pro-inflammatory cytokines, such as IFN-γ, compared with HIF-1a-expressing control T cells, confirming the role of HIF-1a in T-cell suppression.[56] Based on this observation, it was hypothesized that because innate and adaptive immune cells are modified under poor oxygen supply, targeting tumor hypoxia in combination with immunotherapies might improve cancer treatments.[57]

6.02.1.3.4 Cancers can erect shields to deflect the immune system

Another mechanism that cancers employ to elude the immune system is shedding cancer-related antigens into the circulation and/or surrounding microenvironment, and thus, T cells may be accordingly diverted.[1] In fact, circulating tumor-associated antigens can be ingested and presented by a specific type of APC, liver sinusoidal endothelial cells (LSECs). The recognition of the peptide–MHC complex on LSEC by antigen-specific $CD8^+$ T cells can lead to the production of functionally incapacitated cytotoxic T cells. These cells are neither able to produce cytokines nor able to directly kill antigen-expressing tumor cells.[58,59] Interestingly, this feature has been reported in various cancer types, including carcinoembryonic antigen (CEA) in colorectal carcinoma (CRC),[60] cancer antigen-125 (CA125) in ovarian cancer,[61] HER2/neu in breast cancer,[62] and prostate-specific antigen (PSA) in prostate cancer.[63] Nevertheless, although antigen shedding might contribute to tumor immune escape, it can improve the efficiency for the delivery of cancer antibody-based therapeutics.[64]

6.02.1.3.5 Cancer cells can acquire resistance to immune cell killing

CTLs and NK cells mediate their cytotoxic functions by activating either the death receptor pathway or the granule exocytosis pathway. In the death receptor pathway, death ligands on tumor-specific CTLs or NK cells engage their receptors, such as Fas ligand (FasL/CD95L/APO1L), or the TNF-related apoptosis-inducing ligand (TRAIL/Apo2L) on the target cell surface.[42] Then, the receptor–ligand interaction induces the extrinsic cascades to initiate apoptosis, which causes target cell death.[53] It has been shown that cancer cells can develop resistance to immune cell killing by modulating the death receptor pathway.[42] In fact, in human CRC patients, loss of Fas expression and/or function is associated with enhanced metastatic potential of colon carcinoma cells. It is suggested that Fas-deficient tumor cells preexist in the primary colon cancers. Then, under immune-selective pressure, these Fas-resistant cell populations emerge and influence cancer metastatic capability. Supporting evidence comes from the observation that, in FasL knockout mice, the increase in spontaneous tumor metastasis is associated with a deficiency of the Fas-mediated apoptosis.[65]

However, it must be stressed that within the context of cancer development, the decrease in Fas expression and function acts only as an "enhancer" and not as an "initiator."[65] Moreover, although directly targeting FasL and using Fas receptor agonists were hoped to be useful for cancer therapy, these treatments resulted in severe toxicities that have precluded their systemic use.[66] TRAIL-R1 and TRAIL-R2, deletions, mutations, and downregulation of these receptors have been reported in many types of cancer, including head and neck cancer and nonsmall cell lung cancers. As expected, these alterations can impair tumor immunosurveillance by NK and T cells, promoting cancer immune evasion and progression.[42] To elucidate the role of TRAIL ligand–receptor signaling in tumor development, different mouse models were utilized. Preclinical studies showed that neutralization of TRAIL in tumor mouse models promotes tumor development and may also enhance tumor metastasis in perforin-deficient mice.[67] Unlike Fas/FasL targeting therapies, TRAIL receptor agonists (TRAs) should more selectively trigger apoptosis in cancer cells. This strategy has demonstrated robust antitumor activity in many preclinical studies.[68]

Furthermore, NK cell and CTL-mediated lysis by cytotoxic granules plays a critical role in adaptive immunity against cancer cells.[69] In the granule exocytosis pathway, the pore-forming protein, perforin, secreted by activated immune cells, promotes granzyme delivery to the target cell cytosol. After entry, the granzymes cleave their intracellular substrates, inducing membrane damage and target cell swelling and lysis.[51,53] Interestingly, it has been reported by many groups that perforin-deficient mice and humans are more susceptible to cancer.[70]

6.02.1.3.6 Cancer cells can defend against T-cell frontal assaults

Besides the suppression effects of immune-modulatory cytokines and immunosuppressive cells, cancer cells can upregulate immune checkpoints to further defend against effector T cells.[18,71] As mentioned earlier, immune checkpoint pathways are critical to avoiding autoimmunity and immune system overstimulation. However, during malignancy, these pathways are commonly co-opted by cancer cells, leading to suppression of antitumor immunity.[18,1] Targeting immune checkpoints, such as CD28/CTLA4 and PD-1/PD-L1 pathways, has been shown to have significant clinical efficacy in many types of cancer.[72–75] Indeed, these immunotherapies are able to restore antitumor immunity and mediate very prolonged tumor regressions, allowing them to receive great attention.[76]

In addition, tumor cells may defend against T cells by utilizing the FasL/Fas pathway. Activated lymphocytes typically express Fas receptors. Therefore, it is hypothesized that high expression of Fas on the surface of cancer cells enables them to kill tumor-infiltrating lymphocytes (TILs). Although it is still controversial, it was reported that malignant cells can induce apoptosis of Fas-sensitive lymphocytes in vitro. Also, FasL expression has shown to be associated with increased apoptosis of tumor-infiltrating effector cells in vivo. These results suggest that increased expression of FasL on the cancer cell surface might be considered as a tumor escape mechanism.[77] Notably, besides immune checkpoints and FasL, cancer cells can overexpress many other ligands for negative regulatory receptors on T cells, such as CD200 and receptor-binding cancer antigen expressed on SiSo cells-1 (RCAS1).[78]

6.02.2 Cancer Immunotherapy

6.02.2.1 The Principle of Cancer Immunotherapy

It is well established that the immune system can identify cancer cells and destroy them in a process called immunosurveillance.[7] However, it also has the ability to edit cancer cells and induce their immune evasion.[8] Therefore, cancer immunotherapies are designed to cure cancer by enhancing the cancer immunosurveillance activity and/or restoring antitumor host immunity.

6.02.2.2 Limitations of Conventional Cancer Treatments

The traditional types of cancer treatments are surgery, chemotherapy, radiation therapy, and targeted therapy. Surgery is the oldest discipline among these oncological treatments. It has been thought that Leonidas of Alexandria was the first to describe an oncologically adequate surgical procedure.[79] In the 1st century AD, he removed breast cancerous cells with adjacent healthy cells by alternately cutting and cauterizing the tissue with hot irons.[80] Nowadays, surgery remains the most effective single modality in cancer treatment.[79] Nonetheless, curative surgery is limited to localized tumors.[81,82] Moreover, in many cases, surgery alone may not be sufficient to decrease the chance of metastasis[83] or tumor recurrence.[84–86]

After the use of surgery in cancer treatment, radiation therapy was implemented to treat localized malignant tumors that were not surgically removed. The field of radiation oncology was born a few years after the discovery of X-rays in 1895 by Wilhelm

Conrad Röntgen.[87] The principle of radiation therapy is to use a very high dosage of radiation to damage cancer cells. Then, DNA damage can lead to the death of cancer cells and tumor shrinkage.[88] Despite the fact that radiation therapy is used to treat about half of all solid tumors, it has limitations. For example, it can cause early and late toxicity and have a negative impact on quality of life in patients.[89] Also, radiation therapy is primarily a local modality.[90]

Later, it was found that chemotherapy could be used to treat cancers that could not be removed by surgery or destroyed by radiation. During the Second World War, the US military sent pathologists to conduct autopsies from soldiers affected by mustard gas, a chemical agent that was used in the war, to uncover the mechanism of its toxicity. Unexpectedly, pathologists found that affected individuals had profoundly low levels of white blood cells with shrinkage of lymph nodes. This finding encouraged the US Department of Defense (DOD) to study the potential therapeutic applications of mustard gas. DOD recruited two pharmacologists from the Yale School of Medicine, Louis Goodman and Alfred Gilman. The hypothesis was that if mustard gas could destroy normal white blood cells, it might be able to destroy cancer cells, too. When the preclinical animal experiments supported the hypothesis, a patient with non-Hodgkin's lymphoma was treated with nitrogen mustard. This chemotherapy showed great impact on the patient's health; however, the effect only lasted for a few weeks.[91] Mechanistic studies showed that the chemotherapy disrupted the DNA of replicating malignant cells. In addition, chemotherapy can damage the DNA of normal, actively replicating cells, such as cells in the bone marrow and in the digestive system, and hair follicles. Therefore, chemotherapy not only can be effective but also has significant toxicities.[92]

In the late 1990s, with the advance in molecular biology techniques, scientists identified many molecules in/on cancer cells that can enhance malignant cell proliferation and survival.[93] Thus, new therapies have been developed to more selectivity target malignant cells. As a result, targeted therapies are predicted to kill cancer cells with less toxicity[94] and fewer or different off-target effects compared with chemotherapy and radiation therapy.[95] Nevertheless, cancer cells have shown to be highly resilient drug targets, since resistance frequently emerges to all[96] but a handful of targeted therapies, such as BCR-ABL inhibitors in chronic myelogenous leukemia (CML).[1]

Today, immunotherapy has been added as an important modality of cancer therapy, supplementing and in some cases replacing the need for traditional modalities such as chemotherapy.[97,98]

6.02.2.3 History of Cancer Immunotherapy

In the early 1890s, Dr. William B. Coley noticed that some cancer patients with acute bacterial infections had spontaneous tumor regressions. Based on this observation, he injected a patient with an inoperable soft tissue sarcoma with Coley's toxins,[99] which was composed of a mixture of live *Streptococcus*, *Serratia marcescens*, *Staphylococcus*, and *Escherichia coli* bacteria.[100] Interestingly, the tumor in that patient underwent extensive necrosis, and the patient remained disease-free until he died of heart disease 33 years later.[101] Nevertheless, at that time, there was an increasing emphasis on X-ray and radium treatment and, subsequently, chemotherapy.[100] By contrast, Coley's work was not reproducible and most cases treated with his method ended in failure and death.[102,103] Therefore, the field of cancer immunology was neglected for many years.

In 1909, Paul Ehrlich, a Nobel Prize winner, also predicted a role for immunity in protecting against tumors.[104] He suggested that cancer would occur if the immune system did not suppress the growth of continuously arising cancer.[105] Although the idea of host-protective role of immunity against cancer was compelling, it had to wait for the maturation of the developing field of immunology.[37] In the late 1950s, Macfarlane Burnet from Australia and Lewis Thomas proposed the concept of immunologic surveillance of cancer. They speculated that lymphocytes play a major role in protecting against tumor development.[106] The concept was difficult to validate due to the lack of appropriate animal models and good experimental designs.[37]

Although Coley's toxins did not have significant antitumor efficacy, many groups of cancer immunologists still believed in the concept of antitumor immunity. Therefore, to understand the interaction between immunity and cancer, they used Bacillus Calmette–Guérin (BCG) vaccine. This vaccine was made of a live attenuated strain of *Mycobacterium bovis*, which was expected to stimulate a local inflammatory response with the infiltration of granulocytes, macrophages, and lymphocytes that collectively can kill cancer cells.[107] In the 1950s, BCG was shown to have antineoplastic qualities in mice.[108] However, in the 1970s, this therapy was shown to be ineffective in treating human cancers, and thus, it was discarded.[107]

The effort was continued until 1974 when Osias Stutman published his report in *Science*. Stutman used athymic CBA/H strain nude mice, which lack an adaptive immune system, as a model to test the hypothesis. He argued that if this hypothesis was correct, these immunodeficient mice would have an increased incidence of tumors induced by 3-methylcholanthrene (MCA), a chemical carcinogen, compared with wild-type (WT) mice. The results suggested otherwise.[37] Two years later, in 1976, Alvaro Morales reported that the BCG treatment could reduce bladder tumor recurrence remarkably.[109] However, Stutman's conclusion was very convincing, and controlled trials in advanced bladder cancer failed to support Morales' results. Consequently, the claim that host immunity was capable of detecting and destroying cancer cells could not be supported.

About two decades after the apparent death of the immune surveillance hypothesis, a major shift occurred in the field of cancer immunology. Scientists realized that there are caveats to Stutman's conclusions: (1) The CBA/H nude mouse model that he used in his experiments may have been highly sensitive to MCA-induced tumor formation; (2) these nude mice have detectable levels of functional T cells, NK cells, and other innate effector lymphocytes. Thus, they are not completely immunodeficient and so they could possess some degree of immunosurveillance capacity; (3) another supporting piece of evidence came when scientists used a different titer of MCA to induce tumors in nude and SCID mice on a BALB/c background.[37] It was clear that nude and SCID mice were more susceptible to tumor formation than WT mice; and (4) additional studies showed that perforin −/− mice and

recombination-activating gene 2 (RAG2 −/−) mice have a greater sensitivity to MCA-induced tumors compared with their WT counterparts.[37,110] Furthermore, it proved possible to improve the BCG therapeutic response. Morales reported that a minimum of 3 weeks of treatment was necessary, and the vaccine had to be given intradermally.[109] Subsequent studies showed that BCG vaccination can lead to statistically significant reduction in tumor growth and risk of bladder cancer recurrence. As a consequence of these encouraging findings, in 1990, BCG was the first FDA-approved immunotherapy to treat certain types of bladder cancer.[107] A few years later, in 1995 and 1998, interferon alpha-2 (IFN-α 2) and interleukin 2 (IL-2), respectively, received FDA approval, as well.[111]

6.02.2.4 Cancer Immunoediting

As a result of these discoveries, resistance to the immunosurveillance theory weakened.[110] Nevertheless, scientists did not have answers for many important questions. For example, why do cancers occur in immunocompetent individuals[37]? Do cancers result from a failure of "immunosurveillance"? These questions remained unanswered until the cancer immunoediting concept was evolved. In late 1990s, Robert Schreiber proposed that the immune system not only is capable of identifying and destroying developing cancer but also can manipulate cancer cells and enhance their malignancy. His proposal was based on a series of seminal experiments demonstrating this phenomenon. To do these experiments, a cohort of sex-, stage-, and strain-matched WT mice and immune-deficient RAG2 −/− mice on a pure 129/SvEv background were used.[8] RAG2 −/− mice carry a germ-line mutation in which a large portion of the RAG-2 coding region is deleted. This gene encodes a protein that is important for V(D)J recombination during B- and T-cell maturation. Hence, homozygous mutants are viable, but have very immature lymphoid cells, and thus, they are considered as completely immune-deficient.[112] In these experiments, both WT and RAG2 −/− mice developed malignant sarcomas after treatment with MCA, the same powerful carcinogen that Stutman used. Not surprisingly, RAG2 −/− mice that did not have adaptive immunity exposed to MCA developed tumors more rapidly and in a higher number than the WT mice. Thereafter, cells were inoculated into naive WT and Rag2 −/− mice. This experiment showed that regardless of the immune status of the recipient mice, if the tumor originally grew in WT mice, in the presence of an intact immune system, it could always form progressively growing tumors. Similarly, if the tumor was originally generated in and explanted into immune-deficient mice, it could rapidly grow and form cancers. However, when the tumors were originally generated in immune-deficient mice and explanted into WT mice, 50% of tumors were rejected spontaneously. The suggested explanation of this phenomenon was that the tumors that originally grew in WT mice had already undergone attack and "editing" by the intact host immune system. They found that these cancer cells displayed a reduced level of immunogenicity, making them less recognizable by the immune system. In contrast, tumors that grew first in the absence of immune selection pressure were unedited. Hence, they were highly immunogenic and still could be recognized and killed by the mice with intact immune systems.[8]

Finally, it must be stressed that when tumors were isolated from WT or RAG-2 −/− mice and transplanted into RAG-2 −/− recipients, they all grew at the same rate. This observation confirmed that these tumors consisted of transformed cancer cells, and there were no inherent growth differences between tumors. As a result, the rejection only happened because there was no immune editing, suggesting that the immune system exerts both host-protective and tumor-sculpting effects on developing tumors.[8] Later studies revealed that the effect of the immune system on cancer cells depends on many factors, including the stage and nature of transforming events and the type and activity of immune-infiltrating cells.[113]

Subsequent work has provided a mechanistic framework for the concept of immune editing. Schreiber and colleagues characterized this process as consisting of three phases: *elimination*, *equilibrium*, and *escape*. First, the immune system is usually successful in eliminating developing tumors bearing strong antigens (*elimination*), though resistant cells may remain. Then, in the *equilibrium* phase, cancer cells display low levels of immunogenicity or develop immune defense mechanisms, creating in effect a smoldering truce with the immune system. Also, during this phase, the natural selection of tumor variants may occur over a period of many years, allowing cancer cells to move into the *escape* phase. In that process, these resistant cells change their antigen profile and acquire additional mutations. Therefore, they gain the ability to escape from immune attack, proliferate, and metastasize.[114]

6.02.2.5 Types of Cancer Immunotherapy

Cancer immunotherapy encompasses many treatment modalities, including monoclonal antibodies, cellular therapies, cancer vaccines, and cytokines. Although these treatments have different mechanisms of action, they all aim to enhance the body's immune system to fight the enemy cancer within.

6.02.2.5.1 Monoclonal antibodies

Monoclonal antibody-based treatments have emerged as important therapeutics for both hematologic malignancies and solid tumors[22] (**Table 1**). Before discussing monoclonal antibody-based cancer therapeutics in detail, we provide an overview of the antibody types, structures, biological effector functions, and mechanisms of action.

6.02.2.5.1.1 Definitions

Antibodies are glycoproteins belonging to the immunoglobulin (Ig) superfamily. They bind to native (unaltered and unprocessed) membrane-bound or soluble antigens. Under appropriate conditions, antigen–antibody interaction can induce immune response to eliminate the target. The antigen sequence that is recognized by antibodies is called the *epitope*, which consists of hydrophilic sequences of 6–7 amino acids. On the other hand, the antigen-binding site of an antibody, which can recognize and bind

Table 1 FDA-approved antibodies for the treatment of cancer

Target		*Generic name (trade name)*	*Conjugation*	*Origin*	*Isotype (conjugate)*	*Cancer(s) treated*	*Initial approval*
Cancer cells	CD20	Rituximab (Rituxan)[115,116]	Unconjugated	Chimeric	IgG1	Chronic lymphocytic leukemia, non-Hodgkin's lymphoma	1997
		Ibritumomab tiuxetan (Zevalin)[117]	RIT	Murine	IgG1 (^{90}Y)	Non-Hodgkin's lymphoma	2002
		Ofatumumab (Arzerra)[118,119]	Unconjugated	Human (XenoMouse)	IgG1	Chronic lymphocytic leukemia	2009
		Obinutuzumab (Gazyva)[120,121]	Unconjugated	Humanized	IgG1	Chronic lymphocytic leukemia, non-Hodgkin's lymphoma	2013
	CD19	Blinatumomab (Blincyto)[122]		BiTE		Acute lymphocytic leukemia	2014
	CD30	Brentuximab vedotin (Adcetris)[123]	ADC	Chimeric	IgG1 (MMAE)	Hodgkin's lymphoma, systemic anaplastic large cell lymphoma	2011
	CD38	Daratumumab (Darzalex)[124]	Unconjugated	Human	IgG1	Multiple myeloma	2015
	HER2 (ErbB2)	Trastuzumab (Herceptin)[125,126]	Unconjugated	Humanized	IgG1	Breast, gastric cancers	1998
		Pertuzumab (Perjeta)[127]	Unconjugated	Humanized	IgG1	Breast cancer	2012
		Ado-trastuzumab emtansine (Kadcyla)[128]	ADC	Humanized	IgG1 (DM1)	Breast cancer	2013
	EGFR (ErbB1)	Cetuximab (Erbitux)[129–132]	Unconjugated	Chimeric	IgG1	Colorectal, squamous head/neck, lung cancers	2004
		Panitumumab (Vectibix)[133]	Unconjugated	Human	IgG2	Colorectal cancer	2006
		Necitumumab (Portrazza)[132,134]	Unconjugated	Humanized	IgG1	Squamous nonsmall cell lung cancer	2015
	SLAMF7	Elotuzumab (EMPLICITI)[135]	Unconjugated	Humanized	IgG1	Multiple myeloma	2015
	GD2	Dinutuximab (Unituxin)[136,137]	Unconjugated	Chimeric	IgG1	Neuroblastoma	2015
Microenvironment	VEGF	Bevacizumab (Avastin)[138–141]	Unconjugated	Humanized	IgG1	Colorectal, nonsmall cell lung, ovarian, fallopian tube, peritoneal, cervical cancers, glioblastoma, renal carcinoma	2004
		Ziv-aflibercept (Zaltrap)[142]	Unconjugated	Humanized	IgG1	Colorectal cancer	2012
	VEGFR2	Ramucirumab (Cyramza)[143–145]	Unconjugated	Humanized	IgG1	Gastric, gastroesophageal junction adenocarcinoma, colorectal, nonsmall cell lung cancers	2014
	RANKL	Denosumab (Xgeva)[146]	Unconjugated	Human	IgG2	Breast cancer	2013
Immune cells	CTLA-4 (CD152)	Ipilimumab (Yervoy)[72]	Unconjugated	Humanized	IgG1	Melanoma	2011
		Tremelimumab[147]	Unconjugated	Humanized	IgG2	Malignant mesothelioma	2015
	PD-1	Nivolumab (Opdivo)[73,148–150]	Unconjugated	Human	IgG4	Melanoma, squamous nonsmall cell lung cancer, renal cell carcinoma	2014
		Pembrolizumab (Keytruda)[151,152]	Unconjugated	Humanized	IgG4	Melanoma, nonsmall cell lung cancer	2015

specifically to a single epitope, is called the *paratope*. Typically, each immunogenic molecule is heterogeneous, meaning that it has multiple different epitopes.[9] Each of these epitopes can stimulate one plasma cell clone to produce specifically binding antibodies. That said, antibodies secreted from a single B clone are referred to as *monoclonal antibodies*, whereas the ones produced from multiple B-cell clones within the body are referred to as *polyclonal antibodies*.[153]

6.02.2.5.1.2 Antibody types

Based on the structural differences in the constant region of the heavy chain, antibodies are divided into five classes: IgM, IgD, IgG, IgE, and IgA.[9] Immunoglobulin M (IgM) antibodies present as either a membrane-bound form expressed on B cells or a secreted

form (sIgM) found in the blood. sIgM has a pentavalent structure; it has ten antigen-binding sites. Hence, it can form strong interactions with its binding partners. Also, IgM is typically synthesized early during an immune response.[154] Immunoglobulin G (IgG) antibodies emerge subsequently.[9] IgG is the most abundant immunoglobulin type, accounting for ~75% of the total serum Ig proteins in a healthy individual.[155] There are four IgG isotypes (IgG1, IgG2, IgG3, and IgG4), which are named in order of decreasing abundance.[156] Each of these subclasses has structurally and/or functionally distinct constant domains.[155] Membrane-bound immunoglobulin D (IgD) antibodies are coexpressed with IgM on the surface of naive B cells. However, the biological significance of IgD has remained obscure since its discovery in 1965. Recent studies suggested that this class of Ig is important in enhancing mucosal immunity of the upper respiratory tract.[157] However, immunoglobulin A (IgA) antibodies have the most critical roles in mucosal immunity. Finally, immunoglobulin E (IgE) antibodies play a fundamental role in mediating allergic reactions.[1] The most typical antibody type used for cancer therapeutics is typically of the IgG class[22]; therefore, this section focuses mainly on IgG immunoglobulins.

6.02.2.5.1.3 Antibody structure

Although IgG antibodies are the smallest antibodies, they are still considered large molecules, having a molecular weight of ~150 kDa. As indicated in Fig. 2, each IgG molecule has a dimeric structure; it is composed of two identical heavy and light chains arranged in a Y shape. Also, IgG antibodies have two antigen-binding fragments (Fabs) and one constant fragment (Fc). The former, which is represented by the two arms of the Y, includes two heavy- and light-chain heterodimers.[20] Fab also is subdivided into hypervariable (HV) and framework (FR) regions. The HV regions of each heavy and light chain combine to form the antigen-binding sites, which are called complementarity-determining regions (CDRs).[158] Whereas the Fc part, which is represented by the tail of the Y, includes the heavy-chain dimers derived from the second and third constant domains.[9] Through the Fc region, antibodies interact with other molecules and cells to exhibit antibody effector functions.[159]

6.02.2.5.1.4 History of monoclonal antibody-based cancer therapeutics

In 1975, César Milstein and Georges J.F. Köhler developed the hybridoma technology, which involved the fusion of a plasma cell with a myeloma cancer cell.[160] Under specific conditions, using these hybrid cells, which were then called hybridomas, they were able to produce monoclonal antibodies against tumor cell surface antigens.[161] Because this technology had a great impact on modern biological and clinical research, in 1984, Kohler and Milstein received the Nobel Prize for Medicine and Physiology.[162]

6.02.2.5.1.5 Types of monoclonal antibody-based cancer therapeutics

6.02.2.5.1.5.1 Murine monoclonal antibodies

Monoclonal antibodies were initially developed from mice and thus had significant drawbacks: (1) They were immunogenic in humans,[22] (2) mouse monoclonal antibodies have relatively weak binding affinity for the human Fc receptors (therefore, they have shorter half-life compared with human IgG), and (3) they mediate weak antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC), resulting in minimum biological effects.[163] Not surprisingly, only two murine monoclonal antibodies have been approved for clinical use: ibritumomab tiuxetan (Zevalin)[117] and tositumomab (Bexxar)[164]; both of these agents consist of anti-CD20 antibodies that deliver radioactive particles to CD20-expressing lymphomas. Neither agent has emerged as a major treatment option for the management of these types of neoplasms.

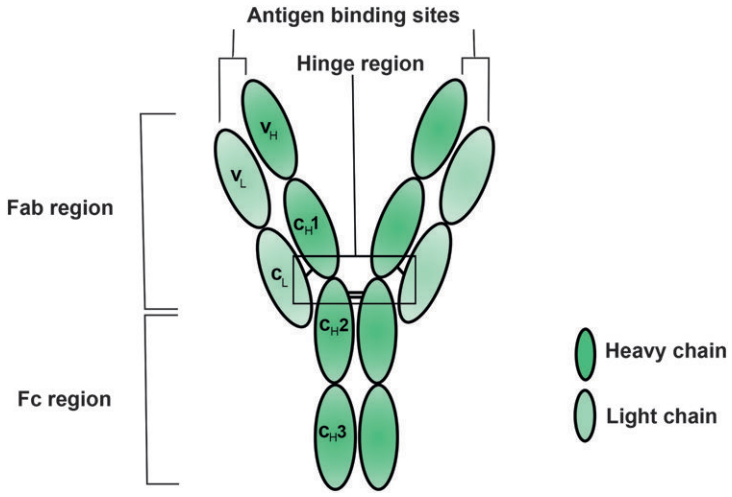

Fig. 2 Structure of an immunoglobulin G (IgG) molecule. The IgG molecule is a dimer composed of two heavy chains and two light chains. The heavy chains dimerize to form the Fc domain, which serves as an immune recruiting signal, whereas heavy-chain to light-chain dimers form the Fab domain that is responsible for the antibody binding to its target antigen.

6.02.2.5.1.5.2 Chimeric murine–human monoclonal antibodies

In an attempt to overcome the drawbacks of mouse monoclonal antibodies and still retain antigen specificity, genetic engineering was applied to generate chimeric mouse–human antibodies. This technique allowed for the production of monoclonal antibodies that are ~65% human. The entire antigen-specific variable domains are usually encoded by mouse genes, whereas the constant regions are from human genes (Fig. 3).[163] Currently, at least three FDA-approved chimeric antibodies are used as cancer immunotherapies: rituximab (Rituxan),[115,116] brentuximab vedotin (Adcetris),[123] and cetuximab (Erbitux).[129–132] Although chimeric monoclonal antibodies have shown highly encouraging results in these and other diseases, they may induce hypersensitivity and serum sickness, and altered pharmacokinetic profiles (i.e., rapid systemic clearance) may reduce the efficacy of the antibody project.[163] As a result, there remained an urgent need to improve monoclonal antibody technology.

6.02.2.5.1.5.3 Humanized monoclonal antibodies

Later advances in antibody engineering allowed for the synthesis of humanized monoclonal antibodies. To humanize an antibody, only the hypervariable regions from murine origin are grafted onto the human antibody framework and constant regions (Fig. 3). These molecules have high similarity to human antibodies; they are ~95% human.[165] The majority of FDA-approved monoclonal antibodies for the treatment of cancer belong to this category, for example, the HER2-targeting antibody trastuzumab (Herceptin), which is the first humanized monoclonal antibody to be approved for therapeutic use,[125,126] and elotuzumab (EMPLICITI), which is the most recently approved cancer monoclonal antibody drug.[135]

6.02.2.5.1.5.4 Fully human monoclonal antibodies

To further reduce antibody immunogenicity, fully human monoclonal antibodies have been generated (Fig. 3). Today, three human monoclonal antibodies are licensed to treat malignancies: ofatumumab (Arzerra),[118] panitumumab (Vectibix),[133] and denosumab (Xgeva).[146] Antibodies that belong to this category have been synthesized by phage display libraries or transgenic mouse technologies over the last 25 years.[166] However, their production still involves a labor- and cost-intensive multistep process.[167] For instance, the transgenic mouse methodology requires the creation of a specific mouse strain.[168] The phage display technique requires counting of transducing units and sequencing the phage DNA from each individual colony or plaque.[167]

6.02.2.5.1.5.5 Conjugated monoclonal antibodies (immunoconjugates)

Immunoconjugates are antibodies conjugated to a therapeutic agent, via a linker. The antibody, through its Fab region, binds specifically to its target on the surface of malignant cells. The linker attaches the effector molecule to the antibody and releases it at the target site to kill cancer cells or the surrounding TME.[169] According to the type of the cytotoxic agent, conjugated monoclonal antibodies can be divided into four groups.

6.02.2.5.1.5.5.1 Antibody–drug conjugates. To overcome some limitations of conventional chemotherapies, which usually damage healthy tissues and may cause multiple severe adverse reactions, antibody–drug conjugates (ADCs) have been developed. This type of immunotherapy utilizes monoclonal antibodies that bind to cancer antigens with high specificity. Therefore, they can deliver a highly potent cytotoxic agent to the target site, leaving normal cells intact.[170] Brentuximab vedotin[123] and trastuzumab emtansine[128] are the only two licensed ADCs by the FDA. They are approved for the treatment of certain lymphomas and certain breast cancers, respectively.

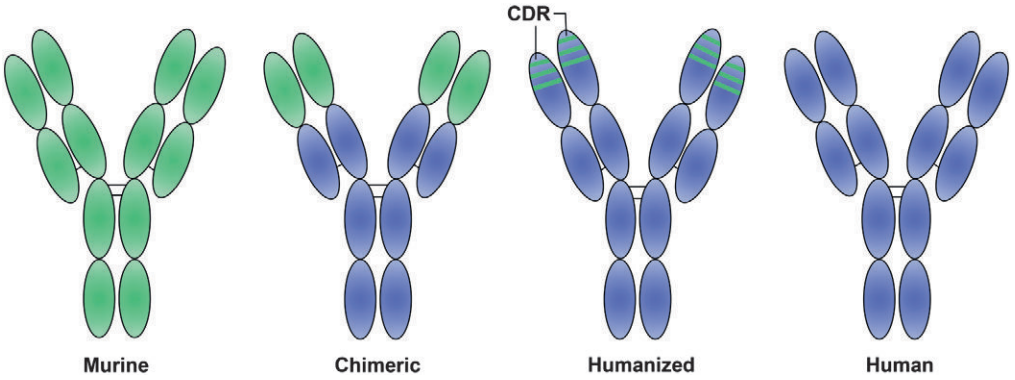

Fig. 3 Types of monoclonal antibodies. Hybridoma technology initially was employed to generate murine monoclonal antibodies. Cloning of mouse variable genes into human constant-region genes by genetic engineering generates chimeric antibodies. The insertion of mouse complementarity-determining regions (CDRs) onto human constant and variable domain frameworks generates humanized antibodies. Fully human antibodies can be generated by the use of purely in vitro antibody engineering techniques, by immunizing human IgG transgenic mice or by employing human hybridomas.

6.02.2.5.1.5.5.2 Radioimmunoconjugates. Radioimmunoconjugates (RICs) are generated by linking an antibody to a radioactive isotope, allowing the delivery of higher doses of radiation therapy to the target site. Therefore, while RIC treatments are expected to increase the therapeutic efficacy of radiation therapy, they can decrease the potential risk of radiation off-target effects.[171] Ibritumomab tiuxetan (Zevalin)[117] and tositumomab (Bexxar)[164] have been the only FDA-approved radioimmunoconjugates. Tositumomab has been discontinued by the manufacturer due to infrequent practitioner use, attributed in part to the complicated nature of its administration.[165]

6.02.2.5.1.5.5.3 Immunocytokine conjugates. It is well accepted that cytokine treatments for cancer can result in durable responses. However, some cancer patients treated with cytokines experienced severe side effects.[26] Therefore, it was hypothesized that delivering the cytokines directly to the target site at high doses will cause less toxicity and exert powerful antitumor effects.[172] To test this hypothesis, some cytokines that stimulate antitumor responses, such as IL-2, interleukin 12 (IL-12), and tumor necrosis factor-α (TNF-α), were conjugated to immunoglobulin antibodies.[173] These immunocytokine conjugates (ICs) are still under clinical investigation.[174]

6.02.2.5.1.5.5.4 Immunotoxins. Immunotoxins are obtained by conjugating catalytic toxins with monoclonal antibodies. Catalytic toxins are typically derived from bacteria (e.g., *Pseudomonas* exotoxin) or plants (e.g., ricin).[175] Although there is no FDA-approved immunotoxin yet, several drugs have been evaluated in clinical trials and demonstrate promising properties.[176]

6.02.2.5.1.5.6 Fab-engineered monoclonal antibodies and antibody-like molecules

As mentioned earlier, the Fab domain is the portion of the antibody responsible for antigen recognition and binding. Indeed, in mouse xenograft models, only between 10% and 30% of injected dose of targeting IgG antibodies can be retained by the tumors. More importantly, in humans, due to the larger vascular and extravascular volume of distribution, this portion can reduce to $<0.1\%$.[177–179] To overcome this challenge, it was first hypothesized that generating antibody variants with very high affinity may improve selective tumor delivery and prolong tumor retention,[180] overcoming a "binding site barrier."[181] However, surprisingly, these modified antibodies had modest therapeutic effects.[169] These findings allowed for the generation of another hypothesis, namely, that very high-affinity interactions between antibodies and tumor antigens may impair the penetration of monoclonal antibodies from the vasculature to the tumors; this proved to be true.[182] Moreover, it was found that antibodies with high binding affinity can be rapidly internalized and degraded.[183] Also, they can bind to shed tumor antigens in the circulation, resulting in their diversion from the tumors.[184] Collectively, these observations suggest that modifying the affinity between antibodies and their target antigens requires careful consideration of consequences for selective tumor targeting.[169]

Another strategy employed to improve antibody therapeutic benefit was to generate smaller fragments, such as Fab and their recombinantly engineered counterparts.[169] The hypothesis was that the large size of IgG antibodies impedes their extravasation and thus impairs their tumor penetration properties. Accordingly, generating smaller fragments might help overcome this problem.[179] Also, these fragments can be cleared more rapidly from the body, improving their selectivity against their targets.[185] However, subsequent studies showed that quantitative delivery of these smaller molecules may be required for high efficacy.[169]

Recombinant protein engineering has allowed the design of monovalent single-chain Fv (scFv) fragments, which are composed of the variable domains (V_H and V_L) or even intact IgG molecules to bind to multiple targets, for example, bispecific monoclonal antibodies engineered to recognize two targets and trispecific antibodies engineered to recognize three targets. The typical goal of dual engagement is to bring the target, mainly tumor antigen such as EGFR, EpCAM, or CD19, in a close proximity to activated effector cells such as T lymphocytes, to elicit immune-mediated killing.[165] Other bispecific formats can simultaneously engage distinct tumor antigens or epitopes on the same antigen. Examples of bispecific antibody-based molecules include the BiTE (bispecific T-cell engager),[122] DART (dual-affinity retargeting),[186] and TandAb (tetravalent tandem antibody) structures.[187] BLINCYTO (blinatumomab) is the first BiTE immunotherapy to be approved by the FDA. It engages CD3 and CD19 and was approved in 2014 for the treatment of patients with Philadelphia chromosome-negative (Ph−) relapsed or refractory B-cell precursor acute lymphoblastic leukemia (ALL).[122]

6.02.2.5.1.5.7 Fc-engineered monoclonal antibodies

When an antibody interacts with an antigen through the Fab domain, the Fc region of the same antibody stimulates immune cells to attack the bound antigen. The Fc domain mediates effector activities by binding to Fc gamma receptors (FcγRs) expressed on effector cells. There are several known types of FcγRs that are divided into two main groups: activating receptors, including FcγRI (CD64), FcγRIIA (CD32A), FcγRIIC (CD32C), FcγRIIIA (CD16A), FcγRIIIB (CD16B), and FcγRIV (in mice), and an inhibitory receptor FcγRIIB (CD32B).[165,188]

In most cases, the therapeutic significance of the Fc domain relies on its ability to induce antitumor responses and to remain stable over a long period of time.[165] In fact, one of the main antitumor mechanisms of action mediated by IgG is ADCC. This process is frequently mediated by NK cells, which rely on FcγRIIIa. Thus, the binding affinity between the antibody's Fc domain and FcγRIIIa is very critical. Nevertheless, it was reported that 80% of the White population has a phenylalanine, instead of valine, in position 158 of FcγRIIIa, which represents a low-affinity variant of the receptor. Also, IgG affinity for FcγRIIIa can be highly influenced by posttranslational modifications of the Fc domain. The glycosylation of the two conserved asparagine (Asn) residues in each of the Ch2 domains of the Fc region can change antibody structure and function dramatically. For example, the presence of fucose residues on Asn297 was shown to reduce the affinity of IgG to FcγRIIIa, leading to a reduction in ADCC efficiency. While

it is currently infeasible to modify human genes in vivo, it is relatively easy to produce therapeutic antibodies with defucosylated Fc regions. Interestingly enough, it is assumed that defucosylated antibodies have higher affinity for FcγRIIIa/b, making them more efficient anticancer drugs. To generate these antibodies, new cell lines were developed by deleting the *FUT8* gene coding for the enzyme α-1,6-fucosyltransferase or overexpressing a recombinant β-1,4-N-acetylglucosaminyltransferase III in CHO cells.[189] An example of an anticancer therapeutic that utilizes the principle of Fc region defucosylation is obinutuzumab (GAZYVA).[190]

IgG antibodies also bind to the neonatal Fc receptor (FcRn). FcRns are structurally distinct from FcγRs; each receptor is a heterodimer composed of an MHC class I-like heavy chain and a b_2 microglobulin (b_2m) light chain. FcRns bind to IgG antibodies and albumin in a pH-dependent manner in which the affinity between FcRn and IgG is inversely related to the pH level. FcRns are found in an acidic endosomal compartment within endothelial cells and circulating monocytes. These cells can internalize IgG antibodies by endocytosis, allowing for IgG–FcRn interaction with high affinity at low pH (<6.5). Then, this complex is carried back to the cell surface where it is exposed to the physiological pH (7.4). This process decreases the affinity between the two molecules, leading to the dissociation of the IgG antibodies from the FcRns. Therefore, FcRn is able to recycle IgG back into circulation, protect it from transcytotic lysosomal catabolism, and thus extend its serum half-life from 1 day to several weeks.[191] To demonstrate this property, FcRn knockout mice were utilized. It was reported that, in these mice, the catabolism rate for IgG accelerated up to 10 times compared with WT control animals.[192] Moreover, several studies demonstrated that FcRn can contribute to antibody-mediated antigen presentation.[191] Accordingly, to determine if this is clinically relevant, scientists have manipulated IgG Fc domains by mutagenesis to increase their affinity for FcRn at acidic pH. To date, a noncancer treatment, motavizumab-YTE, which is an Fc-modified monoclonal antibody that targets respiratory syncytial virus (RSV), has finished a phase I clinical trial.[193] However, there is no approved cancer therapy that utilizes this principle.

6.02.2.5.1.6 Antibody mechanisms of action

The mechanisms of tumor cell killing by IgG antibody can be summarized as follows (**Fig. 4**).

6.02.2.5.1.6.1 Perturbation of signaling pathways

In order for cells to function and survive, they must communicate with each other and with their external environment through signaling molecules. Cells need to communicate to maintain protein synthesis, proliferation, differentiation, maturation, motility, and polarity under tight control. During tumor initiation and progression, malignant cells acquire a number of genetic and epigenetic alterations that favor their uncontrolled growth and immortalization.[194] One of the main antitumor activities of antibodies is the disruption of key components in cancer signaling pathways that are involved in the maintenance of the malignant phenotype.[22] Blocking of relevant ligand–receptor binding can be accomplished by using either neutralizing antibodies directed against the receptor or the ligand. Other antibodies might therapeutically function as signaling agonists.

6.02.2.5.1.6.2 Delivery of cytotoxic agents

As mentioned earlier in this section, monoclonal antibodies can be used for cancer therapy to deliver therapeutic agents to the site of tumor. Conjugated cytotoxic drugs, radiolabeled isotopes, toxins, and cytokines can kill target cells with higher specificity, improved efficiency, and less toxicity.[169]

6.02.2.5.1.6.3 Stimulation of tumor-specific immune responses

Antibodies can trigger innate immunity using three different mechanisms: ADCC, CDC, and ADCP. Also, following the induction of innate immunity, antibodies can stimulate adaptive immune responses.

6.02.2.5.1.6.3.1 Antibody-dependent cellular cytotoxicity. ADCC is an important mechanism by which monoclonal antibodies are able to elicit killing of antibody-coated target cells. Through Fab antigen-specific binding, the Fc portion serves as an immune recruiting signal. It binds to its receptors (FcRs) on the surface of effector cells such as NK cells, neutrophils, γδ T cells, DCs, and macrophages. Then, the Fc–FcR cross-linking results in the formation of an immune synapse leading to direct tumor cell lysis through the release of perforins and granzymes.[22,195] The interaction between Fc and its receptor is not always stimulatory to the effector cell, but it can also be inhibitory, depending on which FcR is engaged.[165] A positive killing signal in macrophages, neutrophils, NK cells, and DCs is facilitated by both FcγRI and FcγRIIIa.[195] This concept has been supported and mechanistically dissected through the use of FcγRI, FcγRIIIa, and FcγRIIB knockout mice.[196] While NK cells are considered to be important ADCC effector cells, macrophages and dendritic cells can mediate ADCC, as well.[197] More importantly, the significance of FcγR interactions has been observed in the clinic, where a correlation was found between FcγR polymorphism and the efficacy of therapeutic antibodies, including rituximab in lymphoma, cetuximab in metastatic colorectal cancer, and trastuzumab in HER2/neu-positive metastatic breast cancer.[198–201]

6.02.2.5.1.6.3.2 Complement-dependent cytotoxicity. Complement can trigger activation of immune responses against cancer cells in different ways. Therapeutic and natural antibodies are generated to target specific antigens expressed on the surface of cancer cells. Upon the engagement of multiple antibodies to their targets on a cancer cell, the C1 complex can attach to the antibody Fc domain and thereby activate the classical complement pathway. The serine protease C1 complex can cleave other complement components C4 and C2, leading to the formation of C3 convertase (C4b2a). This enzyme can then convert C3 into C3a and C3b. The former is an anaphylatoxin that recruits immune effector cells to the site of complement activation, whereas C3b incorporates into C3

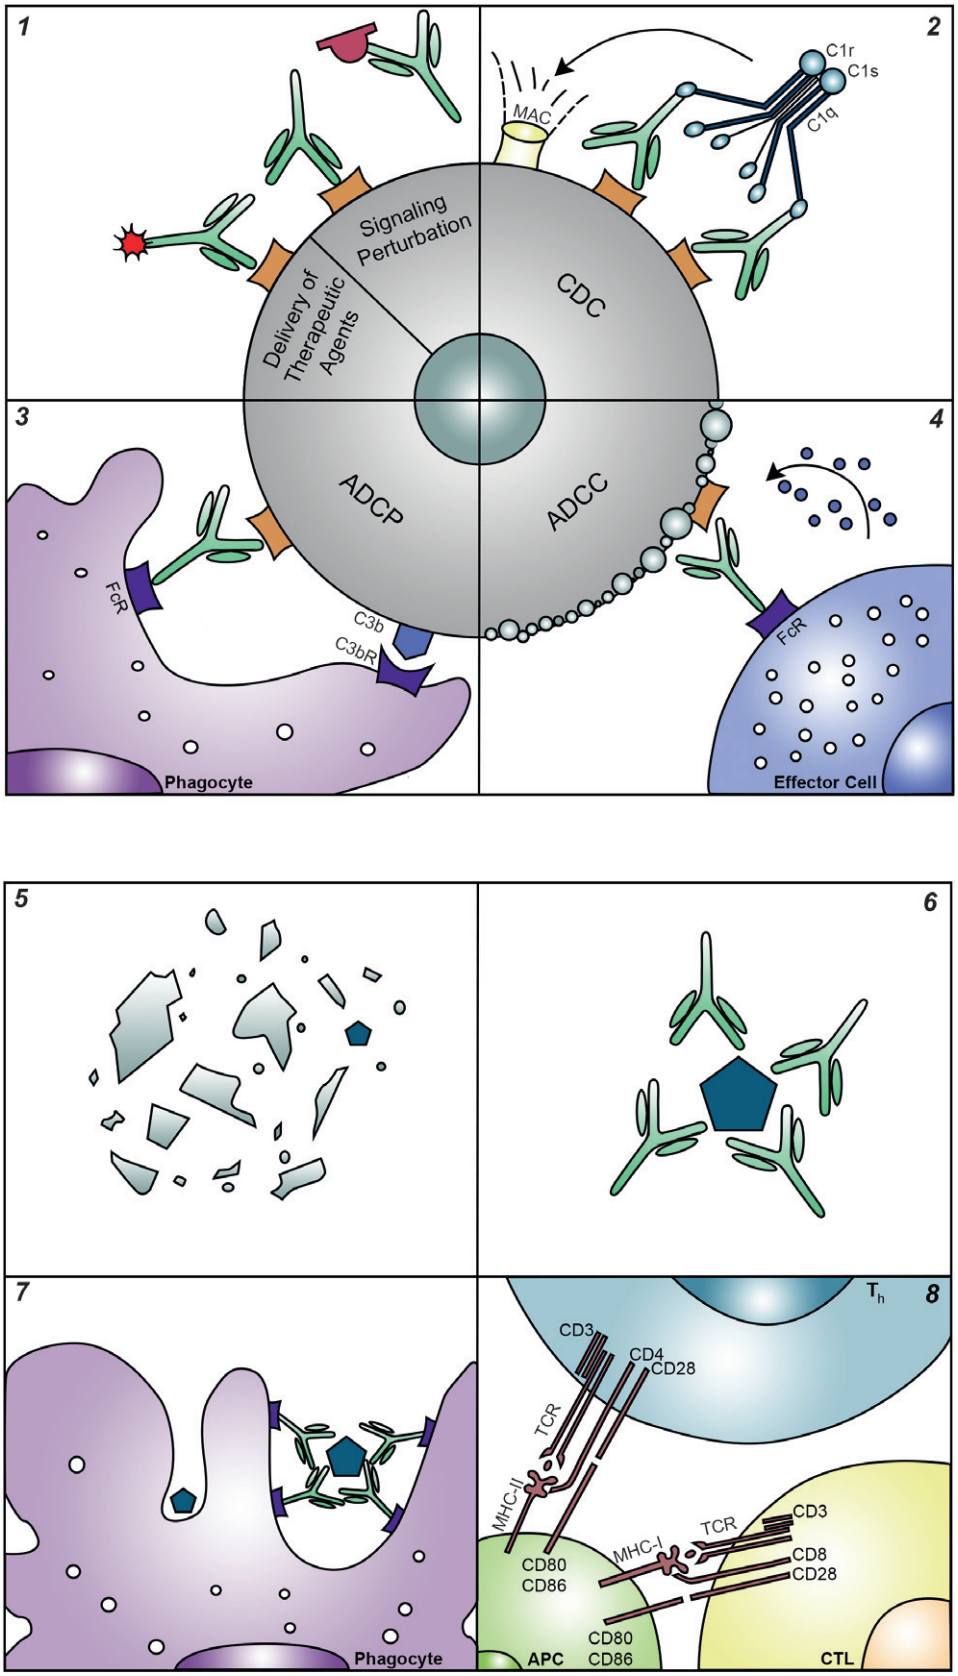

Fig. 4 Mechanisms of action of antibody-based immunotherapy in cancer. Mechanisms of action of antibodies in cancer therapy are diverse and represent the versatility of antibody-based approaches. Here, different strategies of antibody-mediated antitumor immunity are depicted. (1) Perturbation of signaling pathways: monoclonal antibodies can block ligand–receptor binding by targeting either the receptor or the ligand. Delivery of cytotoxic agents: also, monoclonal antibodies can deliver cytotoxic agents to targeted cells. (2) Stimulation of complement-dependent cytotoxicity (CDC): antibodies can cause target cell lysis through the formation of the membrane attack complex (MAC). (3) Stimulation of antibody-dependent cellular cytotoxicity (ADCC): the Fc portion of monoclonal antibodies can engage immune effector cells including NK cells, macrophages, and dendritic cells through FcRs, which can lead to target cell fragmentation. (4) Stimulation of antibody-dependent cellular phagocytosis (ADCP): opsonized cancer cells can engage to phagocytes, which can lead to target cell phagocytosis. (5) CDC, ADCC, and ADCP can lead to target cell fragmentation and release of tumor antigens. (6) Opsonization of released tumor antigens. (7) Phagocytosis of opsonized tumor antigens. (8) Induction of adaptive immunity: internalized tumor particles and phagocytized antigens can be processed and presented via MHC class I and MHC class II, which can activate $CD8^+$ and $CD4^+$ T cells, respectively.

convertase, activating other proteins in the pathway. Finally, this can lead to the formation of the membrane attack complex (MAC) and the production of a stronger anaphylatoxin, C5a. MAC, a transmembrane channel that works as a pore in the target cell surface, can disrupt cellular homeostasis, leading to cancer cell death and fragmentation. As a result, this process is called complement-dependent cytotoxicity (CDC). Moreover, C3b can trigger the formation of additional MAC channels by activating the alternative complement pathway. Accordingly, the complement system can influence the efficacy of some cancer therapeutic monoclonal antibodies.[202]

There is a large amount of evidence supporting CDC as a major mechanism of rituximab antitumor activity.[202] For example, lymphoma syngeneic knockout animals completely lacking C1q ($C1qa^{-/-}$) are capable of mediating ADCC. However, in these mice, the antitumor effect of rituximab therapy was abrogated. Therefore, it was concluded that C1q is required for rituximab to exert therapeutic benefit.[203] Further evidence has emerged for the relationship between CDC and rituximab therapeutic effects. It was reported that in follicular lymphoma patients, polymorphisms in the *C1qA* gene influence the efficacy of rituximab.[204] However, it must be stressed that the precise antitumor mechanism of action for rituximab is multifactorial. Further, although many chronic lymphocytic leukemia (CLL) patients have been successfully treated with this antibody, CLL cells express low levels of CD20, making them less susceptible to CDC.[205] Therefore, while the complement cascade is required for optimal rituximab treatment effect, there are other mechanisms of action that can be important. Additionally, ofatumumab is a human monoclonal antibody that targets a distinct epitope of CD20.[206] It binds to C1q with higher avidity and thus induces greater CDC compared with rituximab, which may explain why ofatumumab is able to destroy rituximab-resistant large B-cell lymphoma cell lines and demonstrates clinical efficacy.[207]

6.02.2.5.1.6.3.3 Antibody-dependent cellular phagocytosis. Another important function of C3b is the opsonization of target cells and molecules. C3b deposition on cancer cells allows their engagement to phagocytes that express C3b receptors (C3bR) on their surface.[202] Because phagocytes express FcyRs on their surface, too, they can also bind to cancer cells that are tagged by antibodies. Both mechanisms of opsonization allow phagocytes to recognize, engulf, and destroy cancer cells.[208]

6.02.2.5.1.6.3.4 Induction of adaptive immunity. Antibody-targeted cytotoxicity initiated by CDC, ADCC, and ADCP can generate tumor cell fragments and release tumor antigens. Therefore, the cell lysis products can be taken up by professional APCs, such as DCs, either directly by phagocytosis or after opsonization and internalization via specific receptor-mediated processes.[209] Then, these antigens can be processed and presented via MHC I and MHC II. Antigen–MHC II complexes can prime $CD4^+$ T-cell responses that are important in stimulating humoral immunity and activating cell-mediated immune activity.[210] While extracellular antigen presentation by MHC II is relatively simple, subsequent antigen cross-presentation via MHC I is very complex and incompletely understood.[209] After the internalization of exogenous antigens by professional APCs, they transfer from the lumen of endocytic compartments to the cytosol. Therefore, the antigens get degraded and loaded onto MHC I molecules by peptide exchange.[211] This process is called antigen cross-presentation, and it has many potentially advantageous features. First, it allows therapeutic antibodies, which are generated against a specific antigen on cancer cells, to induce adaptive immunity that may extend beyond the targeted antigen. Secondly, typically, antibodies can only interact with extracellular antigens. However, cross-presentation allows them to induce immune responses against intracellular antigens, which are thought to be inaccessible to antibody therapies. Thirdly, antigen cross-presentation activates helper $CD4^+$ and CTL $CD8^+$ T cells, enabling immunologic memory directed against the presented antigens. Thus, this process may provide long-term immunity and prevent tumor recurrence.[210] In fact, many lines of evidence support this hypothesis. For instance, clinical response to rituximab usually needs about 6 weeks after initiation of treatment. This lag time is consistent with an adaptive immune mechanism of action.[156,159,212]

6.02.2.5.2 Cellular cancer immunotherapy

6.02.2.5.2.1 T cell-based cancer immunotherapy

The crucial role of tumor-infiltrating lymphocytes (TILs) in cancer treatment was first emphasized in the 1960s. Using murine tumor models, it was shown that the transfer of syngeneic lymphocytes that had been previously sensitized to tumor antigens can result in modest growth inhibition of small established tumors.[213] Another interesting study was published about a decade later, in 1979. It was reported that the relative relapse rate in leukemia patients who underwent allogeneic bone marrow transplantation and developed graft-versus-host disease was 2.5 times less than in patients without this complication. This result suggested that donor-derived T cells can target and eliminate leukemic cells, emphasizing that T-cell transfer may elicit antitumor immunity.[214,215] Meanwhile, in 1976, IL-2 was first identified by Morgan et al.[216] Experiments showed that IL-2 induces in vitro growth of antigen-stimulated T cells, leaving their effector functions intact,[213] and thus, it was described as "T-cell growth factor."[216] In 1982, studies demonstrated that the adoptive transfer of syngeneic murine lymphocytes isolated from the spleen and expanded with IL-2, also called lymphokine-activated killer (LAK) cells, can cure mice with disseminated FBL-3 lymphoma.[213] A few years later, in 1986, it was shown that lymphocytes found within neoplastic lesions (TILs) expanded with IL-2 were 50–100 times more effective in their therapeutic potency than LAK cells, when transferred to mice bearing micrometastases. More importantly, these cells could mediate regression of established lung and liver tumors in murine models.[217] In addition, a subsequent study determined that TILs isolated from resected melanomas can be expanded in vitro, generating a sufficient number of cells that are capable of selectively recognizing autologous tumors. This new approach allowed the induction of clinical trials to evaluate the antitumor therapeutic efficacy of expanded TILs in treating patients with metastatic melanoma.[213] However, although some patients with metastatic melanoma and renal cell carcinoma experienced remarkable, curative clinical responses following high-dose IL-2 therapy, with or without

infusions of autologous LAK cells or TIL, the results for most patients treated on these clinical trials were disappointing. The infused lymphocytes were unable to persist in the circulation and they disappeared within days after transfusion. This short-term response to the adoptive transfer approach limited the applicability of this treatment for more than a decade.[213,218] In 2002, a new discovery was made that dramatically changed the effectiveness of tumor-infiltrating lymphocyte (TIL) therapy.[213] It was shown that lymphodepletion produced by chemotherapy with or without radiation immediately before TIL transfusion increased rates of cancer regression.[213,218] Indeed, the transferred antitumor lymphocytes accounted for up to 80% of $CD8^+$ T cells in patients' circulation a month after transfer. The exact mechanism as to how lymphodepletion improves the effectiveness of TIL therapy is complex and remains to be determined.[213]

Tumor-reactive TILs are usually generated by first resecting the tumor specimen and digesting it into a single-cell suspension or multiple tumor fragments. Then, individual cells are grown in the presence of IL-2, resulting in pure cultures of tumor-specific lymphocytes within 2–3 weeks. Following the confirmation of their reactivity against tumors, they can be rapidly expanded for about 5–6 weeks, generating 10^{11} lymphocytes that can be infused back into patients who have received a lymphodepleting preparative regimen.[213,218] Interestingly, in patients with metastatic melanoma, adoptive cell therapy using autologous TILs can induce complete durable regression beyond 5 years, suggesting that these patients are cured. The overall response rates and complete response rates for this disease were around 50% and 20%, respectively. Notably, responses were seen in all visceral sites including the brain.[218]

Despite the fact that adoptive transfer of autologous TILs could show improved patient outcomes in melanoma, this therapeutic strategy has some limitations. First, it seems that this treatment approach may not be applicable to malignancies other than melanoma. In fact, the reasons behind this phenomenon are not fully understood. A possible explanation is that melanoma tumors have high frequency of immunogenic mutations, which can enhance antitumor T-cell responses. However, it should be noted that other highly mutated tumors, such as lung cancer, have not consistently shown significant therapeutic response rates to autologous TIL therapy.[213,218] Secondly, the antigens recognized by transferred lymphocytes have to be cancer-specific and not expressed on essential normal cells. Thirdly, to isolate infiltrating lymphocytes within the neoplastic lesions, the patient has to provide a surgical resection. Also, this patient has to be able to tolerate the lymphodepletion and IL-2-based treatments. Further, generated TILs have to be expanded ex vivo without loss of their antitumor cytotoxicity. This has to be done in specialized laboratories that have highly trained personnel. While these laboratory procedures may require several weeks, the patient may not be able to wait for this long because of rapid disease progression. Finally, cancer cells can suppress the function of transferred TILs by employing various escape mechanisms, such as upregulating immune checkpoints.[218]

New approaches have been developed in order to broaden the application of T cell-based therapy to treat other types of malignancy. These strategies involve the generation of genetically modified peripheral blood T cells to express either conventional alpha–beta TCRs or CARs. The genetic modifications can be achieved by using virus vectors (retroviruses or lentiviruses) or a transposon system (Sleeping Beauty). Then, transfected cells can be expanded and transferred into patients following their treatment with lymphodepleting agents.[213]

TCR T cells are peripheral blood T lymphocytes redirected by the integration of genes encoding TCRs targeting specific tumor-associated antigens. There are at least two main advantages of TCR T-cell therapy. First, surgical resection of the tumor is not needed to obtain the cells, improving the feasibility of this treatment. Also, TCR can recognize intracellular tumor antigens displaying target peptides in the context of self-MHC, overcoming a limitation of CAR T-cell therapy. On the other hand, a major limitation of TCR therapy is the difficulty in identifying tumor antigens that are not expressed by normal cells.[213] In fact, since 2006, TCR T cells have been used in clinical trials to target antigens expressed by normal tissues. Therefore, as expected, these trials were accompanied by on- or off-target toxicity, limiting the therapeutic efficacy of TCR therapy. For example, melanoma differentiation antigens (MDAs), such as melanoma antigen recognized by T cells 1 (MART1) and glycoprotein 100 (gp100), are normally expressed by melanocytes found in the skin, retina, and inner ear. Thus, patients treated with MART1 and gp100 TCR cells experienced skin rash, uveitis, and hearing loss. Another example is CEA antigen, which is expressed on normal epithelial cells throughout the gastrointestinal tract. TCR cells targeting CEA resulted in dose-limiting severe colitis. Similarly, targeting melanoma-associated antigen 3 (MAGE-A3), which is expressed in the central nervous system, by TCR was associated with neurological toxicity. Moreover, MAGE-A3-specific TCRs unexpectedly recognized a cardiac peptide antigen called titin, leading to off-target interaction and fatal cardiac toxicity. By contrast, NY-ESO-1 is an antigen that is usually detected in tumors but not in normal tissues. Hence, NY-ESO-1-specific TCR cells have appeared to be relatively safe.[218] Another limitation of this therapy is that transferred T cells only recognize the relevant Ag-derived peptide–MHC complex. Because MHC I molecules are commonly downregulated upon cellular transformation, these tumors may escape T cell-induced antitumor immune responses. Finally, TCR therapy can only be administered to MHC-compatible patients.[213]

To overcome some of these obstacles, CAR therapy has been developed. First-generation CAR T cells were constructed by fusing an scFv fragment to T-cell intracellular signaling domains, targeting tumor antigens displayed on the tumor cell surface. Second- and third-generation CARs include intracellular domains of one or multiple costimulatory molecules, such as CD28, OX40, and 4-1BB.[218] One major advantage of this treatment approach is that CARs on genetically modified T cells are similar to cell surface immunoglobulin antibodies on B cells. So, they do not depend on antigen processing and presentation. As a result, they can target tumors that have impaired antigen presentation capacity or downregulated HLA class I molecules. Finally, similar to TCRs, peripheral blood T lymphocytes are used to generate the CAR T cells, and thus, surgical tumor resection is unnecessary.[213] In 2010, T lymphocytes genetically engineered to express CARs were tested in a clinical trial for the first time. CAR T cells against CD19 mediated regression in advanced B-cell lymphoma.[219] Many trials have been conducted subsequently, evaluating the clinical utility of

CAR T cells targeting different tumor-associated antigens, including HER2 for colorectal cancer, folate receptor-a (FRA) for ovarian cancer, and carbonic anhydrase IX (CAIX) for renal cell carcinoma. Unfortunately, to date, the clinical results have demonstrated that CARs have low efficacy in solid tumor and significant toxicities, though it is hoped that continued development of this approach will overcome obstacles to widening the scope of therapeutic indications for this exciting new treatment modality. One promising example is the use of GD2-targeting CAR T cells to treat neuroblastoma.[218]

In conclusion, T cell-based therapy requires continued intensive study to lay the groundwork for major improvements in toxicity, applicability, and clinical efficacy. Also, compared with off-the-shelf monoclonal antibodies that can be applied across tumor types, adoptive T-cell therapy is personalized for each patient. Therefore, it is more expensive, labor-intensive, and time-consuming. However, it has some unique features that allow this treatment to be clinically useful. For example, administered T cells have high-avidity recognition against tumor antigens. Secondly, T cells can proliferate in the circulation and maintain their antitumor effector functions after transfer. Hence, they can be considered as "living drugs." Finally, while immunodepletion before transfusion is important to achieve a desirable number of circulating antitumor T cells for at least 1 month, it may also eliminate suppressor cells, such as T-reg and MDSCs, providing a favorable microenvironment tumor-directed T-cell function.[213]

6.02.2.5.2.2 NK cell-based cancer immunotherapy

NK cells are a type of lymphocytes that are distinct from T and B lymphocytes and are characterized by the following properties: (1) NK cells are components of the innate immunity. Therefore, they kill their target cells without prior immunization and they lack antigen specificity, (2) they are larger in size, and (3) they contain cytotoxic cytoplasmic granules, such as perforins and granzymes.[220]

NK cells express activating receptors, including the natural cytotoxicity receptors (NCRs), and inhibitory receptors, including killer cell immunoglobulin-like receptors (KIRs). The inhibitory receptors bind to MHC I molecules and thereby inhibit NK cell activation. Because MHC I is expressed on almost all cell types, the interaction between these two surface molecules prevents NK cell killing of normal cells. However, under stress conditions, target cells, such as transformed cells or virus-infected cells, downregulate MHC I molecules, leaving the inhibitory receptor inactive and thus activating NK cells (missing-self-recognition). On the other hand, activating receptors can activate NK cell-mediated killing once they bind to pathogen-encoded molecules (nonself-recognition) or self-expressed proteins that are upregulated by transformed or infected cells (stress-induced self-recognition). Typically, there are multiple NK cell activation and inhibitory receptors on a given NK cell. Therefore, whether NK cells will kill the target cell or not depends on the balance between the inhibitory and activating signals.[220]

NK cells can induce killing of malignant cells directly and indirectly. As mentioned previously, direct tumor elimination by NK cells can be achieved by activating either the death receptor pathway or the granule exocytosis pathway. Another mechanism of direct NK-mediated cytotoxicity includes the release of effector molecules, such as IFN-γ and nitric oxide (NO), and ADCC. Additionally, NK cells can induce tumor cell lysis indirectly by releasing various cytokines, chemokines, and growth factors. Accumulating evidence in both mice and humans emphasizes the role of NK cells in tumor clearance. For example, an 11-year follow-up study of cancer patients indicated that the cancer risk was associated with low NK-like cytotoxicity. Moreover, it was shown that in patients with colorectal carcinoma, gastric carcinoma, and squamous cell lung cancer, NK cell infiltration into the tumor is considered as a positive prognostic marker.[220]

Cancer cells can employ many strategies to evade NK cell attack and diminish their cytotoxic activity. One mechanism is by upregulating MHC I expression, which results in a stronger inhibitory signal to NK cells. Another escape mechanism is decreasing the number and activity of NK cells. A supporting observation is that in AML, NCR expression is often impaired.[221] Also, impaired ADCC activity has been reported in various malignancies, including head and neck, breast, gastric, esophageal, cervical, and urological cancers, as well as leukemia and myeloma.[222,223]

Consequently, NK cells may become good therapeutic targets for cancer treatment.[220] Besides their role in mediating ADCC in therapeutic antibody treatments against malignant cells, cellular-based strategies have shown good therapeutic impact on cancer treatment. The first attempt was to test the antitumor effect of autologous NK cell adoptive transfer. Strikingly, although this treatment approach can result in high levels of circulating NK cells, it failed to mediate tumor regression.[224] Then, an alternative strategy was to use allogeneic NK cell adoptive transfer. This strategy, which is based on selecting mismatched donors with specific criteria, has been more successful for treatment of leukemia and solid cancers and has been considered as a safe therapy with minimal toxicity. To further improve NK cell-based immunotherapy, strategies using adoptively transferred genetically modified NK cells have been tested. For example, NK cells with altered cytokine expression, activating receptor overexpression, and inhibitory receptor downregulation have been used. This therapeutic approach has been shown to increase the cytotoxic capacity, proliferative rate, survival ability, and in vivo antitumor activity of transferred NK cells. NK cells with chimeric tumor antigen-specific receptors have been generated and examined for adoptive transfer. Chimeric receptors against HER2/neu, CEA, CD33, CD20, and CD19 showed increased specific cytotoxicity both in vitro and in vivo. However, these immunotherapies are still under development.[220]

6.02.2.5.3 Cancer vaccines

Cancer vaccines fall into two main categories: prophylactic vaccines and therapeutic vaccines.[225]

6.02.2.5.3.1 Prophylactic cancer vaccines

The principle of preventive cancer vaccination is to prime the immune system and create an antigen-specific memory to prevent future infections. Thereby, when exposure occurs, the immune system would be ready to eliminate the antigen quickly and

effectively and thus precludes disease occurrence. Currently, there are two prophylactic infectious targets for which there are FDA-approved vaccines: hepatitis B virus (HBV) and human papilloma virus (HPV).[226] Hepatocellular carcinoma is the second most common cause of death from cancer worldwide,[227] and chronic HBV infection is associated with 50–75% of all cases.[226] Likewise, cervical cancer is the most common cause of cancer-related deaths in women,[228] and high-risk HPV serotypes directly cause most cervical cancers and are also associated with other genital, oropharyngeal, and anal cancers. HBV and HPV vaccines that prevent infection have reduced the risk of liver and cervical cancers, respectively, making them clinically very useful. Nevertheless, it must be noted that once a person gets infected, prophylactic vaccines cannot prevent cancer from developing.[226]

6.02.2.5.3.2 Therapeutic cancer vaccines

These vaccines aim to treat established tumors by stimulating the host anticancer immune response.[225] Various approaches for therapeutic cancer vaccination have been studied in preclinical and clinical settings, including vaccination with tumor cells, cancer-related peptides, proteins, and DNA molecules, as well as DC vaccination.[229] However, except for sipuleucel-T (Provenge), all therapeutic vaccines tested for cancer treatment have been unsuccessful in inducing tumor regression and improving survival to the extent that they can be approved for use by regulatory authorities. It is believed that the major reasons behind this failure are the potent immunosuppressive effect of the TME,[226] the downregulation of MHC molecules on the surfaces of malignant cells, and the low immunogenicity of tumor antigens that have been selected as vaccine targets.[230] Moreover, many therapeutic vaccines have limited efficacy because they promote immune destruction of normal cells bearing the antigen of interest. However, this is not a problem with the prophylactic vaccines because they induce immune responses against antigens of the oncogenic viruses, which are not expressed by normal human cells.[226]

6.02.2.5.4 Cytokines

Cytokines mediate their biological effects by first binding to common and shared receptors. These receptors can be grouped into seven families: type I and type II cytokine receptors, immunoglobulin superfamily receptors, tumor necrosis factor (TNF) receptors, G protein-coupled receptors, TGF-β receptors, and IL-17 receptors. The major cytokines involved in cancer immunotherapy are the interferons, IL-2 and its related cytokines (IL-7, IL-15, and IL-21), IL-6, granulocyte macrophage colony-stimulating factor (GM-CSF), IL-10, and TGF-β. All these cytokines, except TGF-β, bind to either type I or type II receptors. The engagement of the cytokines to these receptors activates the Janus kinase–signal transducer and activator of transcription (JAK–STAT) signaling pathway,[26] which regulates the transcription of a wide range of genes that are involved in many physiological processes.[231]

6.02.2.5.4.1 The roles of cytokines in cancer treatment

IFN-α was the first approved immunotherapy for adjuvant therapy of high-risk melanoma.[232] IL-2 was the first immunotherapy used for the effective treatment of metastatic cancer. In the 1980s, it was shown that the intravenous administration of high doses of recombinant human IL-2 can cause tumor regression in mice, and it was shown subsequently to have curative potential in some patients with metastatic melanoma and renal cell carcinoma.[233,234] The cytokine-based approaches for cancer treatment can be divided as the following:

6.02.2.5.4.1.1 Administration of cytokines that exhibit antitumor activity

To date, two cytokines have received FDA approval for cancer treatment: (1) IL-2, which was approved for treating renal cell carcinoma and metastatic melanoma in 1992 and 1998, respectively,[235] and (2) IFN-α, which achieved FDA approval in 1995 for the adjuvant treatment of patients with advanced melanoma.[236] IFN-α was also approved for use in hairy cell leukemia (HCL) in 1986; however, because of its low therapeutic efficacy in HCL, it has been superseded by more effective therapies.[237] Notably, although IL-2 and IFN-α have been used in the clinic for more than two decades, significant challenges still exist. It is very difficult to achieve meaningful antitumor responses using these cytokines without also causing treatment-limiting toxicities.[26]

6.02.2.5.4.1.2 Neutralization of immunosuppressive cytokines

Besides the cytokines that exhibit immunostimulatory properties, there is another group of cytokines that have immune-suppressive activity, such as TGF-β, IL-10, IL-4, and IL-13. Although many treatments targeting the immunosuppressive cytokines have been considered and developed, none of them have demonstrated sufficient anticancer activity to warrant FDA approval. It is likely that the underlying barrier to the utility of these approaches is their pleiotropism, meaning that some cytokines act on many different cell types and have diverse and/or opposing effects. This is further complicated by the redundancy of cytokine signaling, meaning that multiple cytokines can mediate the same functional effects. Another challenge is that TGF-β and few other cytokines have dual functions, as they may induce both immune activation and immune suppression, depending on the stage of the disease and the context of their use.[26]

6.02.2.5.4.1.3 Improving the efficacy of adoptive T-cell therapy

As mentioned in the preceding text, adoptive T-cell therapy involves isolating a patient's T lymphocytes, expanding them ex vivo, followed by reinfusion of these cells into the patient. During the ex vivo generation of antitumor T cells, IL-2 and IL-2-related growth factors can be used to stimulate the growth of T cells and maintain their cytotoxic activity. Besides the addition of cytokines ex vivo, the administration of low-dose IL-2 to the patient following T-cell infusions has become a standard component of adoptive cellular

therapy. IL-2 can prolong the survival of the adoptively transferred cells and thus can improve the chances of a favorable clinical outcome.[26]

6.02.2.5.4.1.4 Improving the efficacy of cancer vaccination

In an attempt to improve DC vaccination, different mixtures of cytokines can be used during various steps of this procedure. For example, IL-4 and GM-CSF can be used to elicit DC from peripheral blood monocytes obtained by leukapheresis. Also, TNF-α and IL-1β can be used to enhance the maturation of isolated DCs to potent APCs. In addition to the ex vivo cytokine treatment, GM-CSF can also be used to activate DCs by infusing this molecule within the vaccine. The "built-in" GM-CSF strategy was employed in the development of sipuleucel-T prostate cancer vaccine, improving its efficacy and allowing for its FDA approval.[26]

6.02.2.5.4.2 Strategies for cytokine delivery

In the 1980s, when cytokines first were tested in clinical trials, they were administered directly into the patients. However, due to the treatment-limiting toxicities and severe adverse effects of systemic cytokine administration, many alternative strategies have been developed. This includes (1) immunocytokine conjugates, also called cytokine–antibody fusion molecules; (2) recombinant viruses, for example, attenuated oncolytic herpes simplex virus type 1 encoding GM-CSF, which can selectively replicate in tumor cells; (3) cell engineering approaches, which involve the infusion of GM-CSF into allogeneic irradiated whole-cell tumor vaccines; and (4) cytokine PEGylation. Conjugation of the polymer polyethylene glycol (PEG) to the cytokine has been shown to decrease its clearance from plasma and increase its in vivo half-life significantly.[26]

6.02.2.6 Targets for Cancer Immunotherapy

Immunotherapies can be developed to target cancer cells, to manipulate the TME, or to enhance antitumor host immunity.

6.02.2.6.1 Targeting cancer cells

Tumor antigens may serve as good targets for cancer immunotherapy. They can be divided into two main categories: tumor-specific antigens (TSAs; neoantigens) and tumor-associated antigens (TAAs), which include overexpressed self-proteins, tissue-specific differentiation antigens, and cancer testis (oncofetal) antigens.

6.02.2.6.1.1 Targeting tissue-specific differentiation antigens

These antigens are shared between tumors and the normal tissue of origin, such as CD20 and CD19, which are expressed by both normal and cancer B cells.[238]

6.02.2.6.1.1.1 CD20

CD20 is a transmembrane protein expressed on B cells. Early experiments suggested that it was important in the regulation of human B-cell activation, proliferation, and Ca^{2+} transport. However, CD20-deficient ($CD20^{-/-}$) mice appeared normal.[239] Hence, the exact biological function of CD20 and its physiological ligand remain to be fully defined.[240] Regardless of the uncertainty in the biological role of this antigen, it is a good target for cancer immunotherapy. This is because (1) it is expressed specifically on B cells, but not found on other normal cells; (2) it is not expressed on the first stage of B-cell development, but only on pre-B cells and mature B lymphocytes[241]; and (3) it can be detected in more than 95% of malignant B cells.[242]

Today, there are four clinically available anti-CD20 monoclonal antibodies, and several more are being investigated. Rituximab was the first monoclonal antibody licensed for therapeutic use.[243] It was discovered in 1991, entered human phase I trials in 1993, and was approved for use in adults with CD20-positive B-cell lymphoma in 1997.[244] It is a mouse–human chimeric monoclonal antibody against CD20, consisting of human IgG1 constant region with mouse variable regions.[245] Therefore, it can selectively bind to CD20 on B cells while inducing cell-mediated effector functions to destroy the target cells.

A few years later, in 2002, ibritumomab tiuxetan was licensed for the treatment of non-Hodgkin's lymphoma.[117] Also, it was the first radioimmunotherapy approved for the treatment of cancer. It consists of an anti-CD20 murine IgG1 monoclonal antibody ibritumomab, linked to the radiolabeled isotope yttrium-90.[244] The monoclonal antibody portion of ibritumomab tiuxetan binds to CD20 specifically on the surface of malignant cells. When such cells are exposed to radiation, it destroys all the CD20-positive B cells and the immediately surrounding CD20-negative malignant cells. However, due to the "cross fire" effect, normal cells that are not targeted by the antibody also can be damaged by the radiation. Notably, radioimmunotherapies are predicted to be more successful in treating B-cell lymphomas, but may have limited translational success in solid tumors. In contrast to solid tumor targets, CD20 is a good radioimmunotherapy target because malignant B cells have high inherent radiation sensitivity and vascularity.[246] By contrast, solid tumor cells are typically less radiosensitive, and radioimmunoconjugates have comparatively limited initial penetration into solid tumors.[169]

Since the approval of rituximab in 1997, many efforts have aimed to improve its efficacy. This has involved the exploration of resistance mechanisms, pharmacokinetic parameters, and the evaluation of subcutaneous route.[247] While rituximab has proved to be an important and effective therapy for many patients, there remains room to improve response rates and the duration of clinical benefit. Therefore, a new-generation anti-CD20 monoclonal antibody has been generated that may provide advantages over rituximab. One of the potential limitations of rituximab was that it is a chimeric monoclonal antibody that might be immunogenic in some cases. Accordingly, humanized and fully human antibodies have been developed. These second-generation drugs include

ocrelizumab, veltuzumab, and ofatumumab.[245] Ofatumumab is the only approved fully human anti-CD20 monoclonal antibody, binds to CD20 with higher avidity, possesses higher ADCC activity, and binds to C1q complement protein with higher avidity and thus stimulates greater CDC.[159,248] Clinical trials have supported the potential relevance of these preclinical data. Ofatumumab is useful for the therapy of refractory CLL patients, leading to its approval in 2009. Ocrelizumab and veltuzumab are humanized antibodies and are still under investigation.[119]

Furthermore, to improve the affinity of anti-CD20 antibodies, especially in patients who have a low-affinity version of the Fc receptor, third-generation antibodies were synthesized. These are humanized monoclonal antibodies that are modified in the Fc region. Obinutuzumab (GAZYVA) is the first FDA-approved glycoengineered antibody-based therapy.[120,121,249] In vitro experiments indicated that the Fc alterations enhanced immune effector cell activities including ADCC, ADCP, and direct nonapoptotic cell death, whereas it reduced CDC,[190] which may not be an obligatory requirement for improved clinical efficacy.[250] This drug has led to significant clinical improvement over first-generation anti-CD20 immunotherapy with rituximab in a phase III trial in CLL, leading to its approval in 2013.[190]

Besides targeting CD20 antigen by monoclonal antibodies, CD20-specific CARs have been tested in a pilot clinical trial. T cells containing CARs with CD28 and 4-1BB costimulatory domains were transferred to three patients after cyclophosphamide lymphodepletion. Two patients, who participated in this trial without evaluable disease, remained progression-free for 12 and 24 months. The third patient had an objective partial remission and relapsed at 12 months.[251]

6.02.2.6.1.1.2 CD19

CD19 is a transmembrane protein that is specifically expressed in normal and neoplastic B cells. It serves as an attractive target for immunotherapy for many reasons: (1) It is expressed on most B-cell malignancies; (2) it is expressed in the B-cell lineage at an early stage, even before the expression of CD20; (3) it internalizes efficiently in lymphoma tumor models[252]; and (4) it is possibly involved in the development of B-cell cancers. For example, several studies reported that CD19 can upregulate the expression and phosphorylation of c-Myc,[253] which is a proto-oncogene that is found mutated and/or overexpressed in many malignancies.[254] Accordingly, CD19 may be considered as a poor prognostic factor in human lymphomas.[253]

These facts, therefore, provided a stimulus to target CD19 for the treatment of B-cell leukemia and lymphoma. Many methods have been tested in preclinical experiments and clinical trials. Early attempts, in the 1990s, focused on utilizing conjugates of anti-CD19 antibodies and cytotoxic agents, such as ricin A chain, pokeweed antiviral protein, and the plant-derived ribosome-inactivating protein saporin. The aim of these drugs was to eliminate cells expressing CD19 directly. However, because of design limitations of the conjugated molecules, and low efficacies of antimurine antibodies, these treatments were not successful.[253]

An example of approved next-generation anti-CD19 therapies is the bispecific T-cell engager (BiTE) antibodies, blinatumomab (BLINCYTO). This agent has demonstrated striking activity in patients with advanced, CD19-expressing leukemias.[255] Additional antibody-based therapeutics targeting CD19 include the fucosylated, humanized antibodies Medi-551 and MDX-1342. These drugs exhibit high affinity to FcγRIIIA. Further, CAR–CD19-specific T-cell therapy is currently being studied in many clinical trials and with very promising results. These CARs are genetically modified T cells that are composed of extracellular recognition sequences, CARs, designed to engage CD19 on target cells, with T-cell intracellular signaling components, resulting in enhanced T-cell responses against CD19-positive cells.[253]

6.02.2.6.1.1.3 CD30

CD30 is a transmembrane protein that is expressed in normal activated T cells, B cells, NK cells, and malignant cells. Currently, the molecular function of CD30 in human physiology is still unclear. However, it has been suggested that CD30-mediated signaling plays an important role in regulating the development of both effector and memory $CD4^+$ cells. In 2011, the FDA granted accelerated approval to brentuximab vedotin for the treatment of certain patients with Hodgkin's lymphoma or systemic anaplastic large cell lymphoma (ALCL). Brentuximab vedotin is an antibody–drug conjugate (ADC). It is composed of anti-CD30 mouse–human chimeric IgG1 monoclonal antibody. Each antibody carries an average of four monomethyl auristatin E (MMAE) groups, via a protease-sensitive dipeptide linker. Upon the ligation of the monoclonal antibody portion of brentuximab vedotin with CD30 on the surface of cancer cells, the molecule is internalized via endocytosis. Then, the dipeptide linker gets cleaved, allowing for the release of the MMAE, a potent antimicrotubule drug that binds to tubulin and disrupts the microtubule network within the cell, leading to induction of cell cycle arrest and apoptosis. Consequently, this ADC has three advantages. It can discriminate between normal and cancer cells and thus has lower in vivo toxicity. MMAE conjugated with the monoclonal antibody remains relatively stable in the circulation; therefore, it has a higher cytotoxicity. Finally, if a small fraction of MMAE is released into the TME, it might kill surrounding untargeted CD30-expressing malignant cells as well as nonmalignant cells that have protumor effects. These observations were supported by clinical trials that have demonstrated brentuximab vedotin's durable antitumor activity with a manageable safety profile in patients with Hodgkin's lymphoma and ALCL.[256]

6.02.2.6.1.2 Targeting overexpressed self-proteins

During the course of tumor progression, malignant cells may increase the expression of normal proteins that possess proliferation- or survival-promoting function.[257] Examples of self-proteins that are commonly overexpressed in various types of malignancies are two members of the ErbB family receptors: epidermal growth factor receptor (EGFR/HER1/ErbB1) and human epidermal growth factor receptor 2 (HER2/ErbB2).

6.02.2.6.1.2.1 Epidermal growth factor receptor

Overexpression of EGFR has been reported in many patients with early-stage epithelial tumors, including lung, HNSCC, colon, pancreatic, brain, and breast. Therefore, it was hypothesized that this receptor plays a critical role in cancer initiation and progression. Intensive research over the past three decades has shown that EGFR engages a very complex signaling network. The receptor consists of an extracellular ligand-binding domain, transmembrane domain, juxtamembrane nuclear localization signal (NLS), tyrosine kinase domain, and tyrosine-rich C-terminal tail. EGFR receptor–ligand interaction induces conformational changes in the receptor that stimulates its dimerization with another EGFR molecule (homodimerization) or with other activated HER family members (heterodimerization). Upon dimerization, receptors' intrinsic tyrosine kinase domains get activated, inducing phosphorylation of tyrosine residues on C-terminal tails. Then, activated EGFR activates several signaling pathways, such as RAS/MAPK, PI(3)K-Akt, PLC-PKC, and Jak-STAT.[258] These EGFR-mediated downstream signaling cascades have been strongly implicated in tumor growth and progression.[259] Accordingly, EGFR has been one of the most targeted receptors in the field of oncology.[258]

In 2004, the FDA allowed for accelerated approval of cetuximab (Erbitux) for the treatment of metastatic colorectal cancer. This accelerated approval was based on the tumor response rates in phase II trials. Cetuximab is a mouse–human chimeric monoclonal antibody that binds specifically to the extracellular domain of EGFR. It blocks binding of ligands to this receptor and thus inhibits downstream signaling.[259] Also, it has been shown that cetuximab may establish antitumor response via ADCC and CDC.[134] Seven years after the initial approval of cetuximab, FDA expanded its approval for patients with head and neck squamous cell carcinoma (HNSCC).[260] Because this antibody mediates its function through its binding to EGFR, the association between EGFR expression levels and cetuximab clinical outcome has been widely studied. For example, the FLEX trial reported that advanced nonsmall cell lung cancer (NSCLC) patients who have tumors with elevated levels of EGFR expression would have survival benefit from the addition of cetuximab to first-line chemotherapy. Thus, in some groups of patients, EGFR expression is considered a tumor-predictive biomarker.[261]

Panitumumab is another anti-EGFR monoclonal antibody that was approved by the FDA in 2006.[133] Like cetuximab, it blocks ligand–receptor interactions, but differs from cetuximab in several ways. For example, it is a fully human antibody and so induces allergic reactions in fewer than 1% of treated patients. Second, it belongs to the class of IgG2 immunoglobulin antibodies, meaning that it has no or limited ability to induce ADCC. Finally, while the half-life of cetuximab in the plasma is up to 1 week, it reaches 2 weeks for panitumumab, presumably because it is a fully human antibody. Thus, it can be administered less frequently, adding to patient convenience.[262] To directly compare the efficacy and toxicity of both agents, the phase III ASPECCT (A Study of Panitumumab Efficacy and Safety Compared to Cetuximab) study was conducted. In this study, 999 chemotherapy-refractory metastatic colorectal cancer patients with *KRAS* exon 2 wild-type tumors were recruited. This trial showed that panitumumab is noninferior to cetuximab. Also, they reported that these agents provide similar overall survival benefit and toxicity profiles in this population.[263]

Recently, in 2015, necitumumab (PORTRAZZA), a new anti-EGFR monoclonal antibody, received FDA approval for the treatment of metastatic NSCLC. It is mechanistically similar to cetuximab as both of them belong to the IgG1 subclass. However, because necitumumab is a fully human antibody, fewer adverse immune reactions are expected to occur.[264] Additionally, matuzumab, a humanized anti-EGFR monoclonal IgG1 antibody, is currently being tested in clinical trials.[265] Finally, it is worthy to note that there are many approved small-molecule inhibitors that can also target EGFR, such as gefitinib, erlotinib, lapatinib, icotinib hydrochloride, and afatinib. This category of cancer drugs is beyond the scope of this review and it has been comprehensively covered elsewhere.[266–269]

6.02.2.6.1.2.2 Human epidermal growth factor receptor 2

Similar to EGFR, HER2 receptor can be activated through homodimerization or heterodimerization with members of the ErbB family, leading to phosphorylation of tyrosine residues on C-terminal tails and activation. Thereby, receptor phosphorylation activates downstream signaling molecules, which promote oncogenic transformation and tumorigenesis. However, HER2 is different than the other receptors of the ErbB family in that it has no known high-affinity ligand.[270] Notably, overexpression of HER2 has been reported in a variety of cancer types, including carcinomas of the breast, bladder, and pancreas; nonsmall cell lung cancer (NSCLC); and ovary, endometrium, colon, kidney, head and neck, stomach, esophagus, and prostate cancers.[271] In some cases, most notably in breast and gastric cancers, this overexpression is caused by gene amplification.[272] Based on this observation, HER2 has become an attractive and important target for cancer therapy. In fact, several antibody-based therapeutics and small-molecule inhibitors targeting HER2 have received FDA approval, and many others are currently being tested in clinical studies or preclinical experiments.[125–128]

Trastuzumab (Herceptin) is a humanized monoclonal antibody that targets the HER2 extracellular domain. This drug is approved by the FDA for the treatment of HER2-overexpressing early-stage and metastatic breast cancer and HER2-overexpressing metastatic gastric cancer.[273] The precise mechanism of action for trastuzumab is not fully elucidated. However, several mechanisms have been proposed, including blocking the downstream signaling pathways involved in cancer initiation and progression, enhancing HER2 internalization and degradation, inhibiting extracellular domain proteolysis, promoting cell cycle arrest and apoptosis, stimulating immune destruction by mediating ADCC, and inhibiting DNA repair and angiogenesis.[274]

Not surprisingly, trastuzumab, in combination with chemotherapy, improves response rates, disease-free survival, and overall survival in HER2-positive breast cancer and gastric cancer patients. However, in the case of metastatic breast cancers, most patients develop disease progression within 12 months, and about 15% of early-stage HER2-positive breast cancer patients relapse after trastuzumab-based adjuvant chemotherapy.[274] Therefore, several attempts have been made to improve HER2-targeted therapies. In 2012, the second anti-HER2 antibody, pertuzumab (Perjeta), was licensed to treat metastatic HER2-positive breast cancer in

combination with trastuzumab and a taxane in the first-line setting.[275–277] Pertuzumab is a humanized IgG1 monoclonal antibody that targets an epitope of the extracellular domain of HER2 that is distinct from that that binds to trastuzumab. Similar to trastuzumab, pertuzumab blocks receptor dimerization and prevents activation of downstream signaling pathways.[274]

To further improve the therapeutic efficacy of HER2-targeted treatments, an anti-HER2 monoclonal antibody was conjugated to a cytotoxic antimicrotubule agent (DM1) to create trastuzumab emtansine (T-DM1; Kadcyla). While trastuzumab can mediate its antitumor effect, DM1 acts as a highly potent cytotoxic agent.[274] Interestingly, further studies supported the hypothesis that T-DM1 has greater activity than trastuzumab with high selectivity for HER2-positive cells.[278,279] As a result, T-DM1 achieved FDA approval for the treatment of patients with breast cancer in 2013.[128]

6.02.2.6.1.3 Targeting cancer testis antigens

This group of antigens is normally only expressed in germ cells; however, because they have oncogenic functions, including support of growth, survival, and metastasis, they are frequently activated in malignancies. Cancer testis antigens (CTs) frequently are cancer-specific, immunogenic, and commonly expressed in various types of cancer, making them promising candidate targets for cancer treatment.[280]

In general, the two approaches that have been applied to target CTs are cancer vaccination and adoptive T-cell therapy. To date, many CTs that have been targeted by immunotherapies, such as MAGE, GAGE, SSX, CT45, and NY-ESO-1, and many clinical trials have been conducted to test the therapeutic benefit of this approach. Indeed, at least 35 clinical studies have been performed that solely target NY-ESO-1. Although there is no CT antigen-based immunotherapy that has received FDA approval, some DNA methyltransferase (DNMT) inhibitors, which have been licensed for the treatment of hematologic malignancies, have shown to upregulate the expression of CT antigens on the surface of cancer cells. Hence, it has been hypothesized that DNMT inhibitors may trigger immune responses against tumor-expressed CTs.[280] Support for this hypothesis comes from the observation that combined treatment with azacitidine, a DNMT inhibitor, and sodium valproate has been associated with induction of MAGE-specific T-cell responses in AML and myeloid dysplastic syndrome patients. These findings suggest that combining DNMT inhibitors with CT antigen-based immunotherapy may induce CT antigen expression, allowing for the induction of potent antitumor immunity.[281]

6.02.2.6.1.4 Targeting tumor-specific antigens

This type of antigen is specifically expressed by tumors and not present in normal cells. They represent either oncogenic viral proteins or mutant antigens. During tumorigenesis, cancer cells acquire mutations that are important for their transformation (driver mutations). Also, as a result of genetic instability, these cells can acquire random mutations that may not provide a growth advantage (passenger mutations). Virtually, all cancers contain somatic mutations, and many of these mutations encode for TSAs that can be recognized by $CD8^+$ T cells, resulting in antitumor immune responses. Since these mutant antigens are new to the immune system, they are named neoantigens. It has been claimed that targeting neoantigens has certain advantages over targeting TAAs. For example, TSAs are nonself-proteins and thus are unlikely to induce immunologic tolerance. TAAs are frequently poorly immunogenic and may exhibit lower affinity to TCRs compared with TSAs. Accordingly, there is increasing interest in TSAs as potential targets for immune recognition and destruction.[257]

Early experiments indicated that it is possible to find TSAs and utilize them clinically to treat cancer. However, using conventional antigen-cloning approaches, this process is time-consuming and poorly adaptable to patient care. In 2012, two groups proposed distinct strategies that utilize genomics and bioinformatics approaches to identify tumor-specific mutant proteins. Both approaches employed a combination of next-generation sequencing, *in silico* epitope prediction, and immunologic approaches to identify and validate neoantigens in murine models (B16-F10 melanoma and MCA-induced sarcoma). Interestingly, the two independent studies determined that the proposed strategies could shorten the time frame needed to identify TSAs to only a few weeks. In the following year, this work was extended to human cancers.

The framework of personalized TSA-based cancer immunotherapy is first to compare the genome of tumor and normal tissues by whole-exome sequencing and RNA-Seq, allowing for the identification of nonsynonymous somatic mutations that are specifically expressed in the tumor but not in the normal cells. The next step is to predict the MHC epitopes that the T cells can recognize. The list of candidate antigens can then be used to treat cancer patients either by generating neoantigen vaccines or by transfusing mutant neoantigen-specific autologous T cells.[257]

Meanwhile, studies showed that checkpoint inhibitors may facilitate the expansion of preexisting T cells specific for tumor neoantigens in human melanoma patients. Therefore, it was suggested that the combination of checkpoint blockade immunotherapy with personalized cancer vaccines, or individualized adoptive cell therapies, may show increased therapeutic impact. It is argued that they would at least enhance many aspects of antitumor immunity.[257] Such concepts merit further investigation.

6.02.2.6.2 Targeting the tumor microenvironment

Tumors are complex tissues composed of cancer cells; various types of stromal cells, including endothelial cells; fibroblasts and immune cells; and extracellular matrix. Recent studies have shown that the TME plays an important role in both malignant tumor progression and treatment response.[282]

6.02.2.6.2.1 Targeting the tumor vasculature

Angiogenesis is defined as the formation of new blood vessels from preexisting vessels and circulating endothelial precursors.[283] The link between tumor growth and angiogenesis was first proposed more than a century ago. Thereafter, in 1927, a study showed that

the vascular architecture varied in several murine tumors, suggesting that the tumor environment can highly influence the growth and morphology of surrounding blood vessels.[284] About a decade later, in 1939, it was hypothesized that cancer cells can promote angiogenesis by the secretion of blood vessel growth-stimulating factor, which was then associated with rapid growth of transplanted tumors.[285] Today, it is well established that while proliferating cancer cells stimulate angiogenesis, new blood vessels supply tumors with oxygen and nutrients, allowing tumors not only to survive but also to progress and metastasize.[284]

Vascular endothelial growth factor A (VEGF-A) is a major regulator of normal and abnormal angiogenesis.[285] When tumors and surrounding stromal cells secrete VEGF-A, it binds to its receptors, VEGFR-1 and VEGFR-2, or its coreceptors, neuropilin 1 (NRP1) and NRP2. This ligand binding leads to receptor dimerization and phosphorylation, activating multiple downstream signaling pathways, which can promote the survival and proliferation of endothelial cells and enhance filopodial extension, chemotaxis, and ECM degradation, leading to increased angiogenesis and vascular permeability.[284]

In addition, accumulating evidence suggests that VEGF not only has an important role in tumor angiogenesis but also may induce immune suppression via different mechanisms.[286] For example, VEGF secreted in the TME may act as a strong negative modulator of DC function.[287] In fact, tumor-bearing mice treated with anti-VEGF antibody showed significant increases in the number and function of DCs in draining lymph nodes and spleens.[288,289] More importantly, treating lung, breast, and colorectal carcinoma patients with anti-VEGF antibody led to improved DC development and increased DC populations in the peripheral blood.[290,291] Also, VEGF can induce immune suppression by inhibiting T-cell development and promoting the expression of PD-1 and other inhibitory checkpoints, which can lead to T-cell exhaustion.[292] Supportive evidence came from studies that have shown that blocking VEGF or its receptors can enhance T-cell antitumor immunity.[293] Moreover, VEGF may promote the expansion of immunosuppressive cells, such as MDSCs and T-regs.[291,294] In line with these findings, blocking the VEGF signaling pathway in breast cancer animal models resulted in increased maturation of DCs and inhibited infiltration of immune-suppressive cells.[295]

Not surprisingly, VEGF-A–VEGFR signaling pathway has become an attractive target for cancer therapy. In fact, different strategies have been employed to target VEGF-A and its receptors directly, using antibody-based therapies, tyrosine kinase inhibitors (TKIs), and soluble VEGFR/VEGFR hybrids. Also, many other approaches have been developed to target the components of this signaling pathway indirectly, such as chemotherapy and targeted therapies against tumor antigens or against other components of the TMEs.[296] In this section, we will focus on bevacizumab (Avastin), ziv-aflibercept (Zaltrap), and ramucirumab (Cyramza) as they are relevant to cancer immunotherapies.

Bevacizumab (Avastin) was the first antiangiogenic drug approved for cancer therapy.[36,138,139,141] It is a humanized IgG1 monoclonal antibody against human VEGF-A. It neutralizes VEGF after its secretion from tumor cells and thus inhibits VEGF-A binding to its receptors. Hence, this treatment is expected to cause a regression of existing tumor blood vessels, reduction in the formation of new blood vessels, and normalization of surviving vessels. Thereby, it can limit the blood supply to tumor tissues and enhance the delivery of anticancer treatments.[297] Additionally, a recent study indicated that although bevacizumab is a human antibody and it does not recognize mouse VEGF-A, it could suppress angiogenesis in three different animal models through its binding to FcγRI (CD64) and c-Cbl, impairing macrophage migration.[298]

In addition, because the new tumor vessels within or surrounding the neoplastic lesions are usually structurally abnormal and leaky, they can increase interstitial pressure and hence restrict the delivery of cytotoxic agents. Therefore, it was hypothesized that bevacizumab may have a synergistic therapeutic effect when combined with chemotherapy. Thereafter, many clinical trials supported these hypotheses, leading to the first FDA approval of bevacizumab in 2004 for the treatment of patients with colorectal cancer. Then, over the following years, this approval was expanded to other cancers, including NSCLC, renal cell carcinomas, and glioblastoma. However, the significant benefit from the addition of bevacizumab was not seen in all malignancies, such as in metastatic HER2-negative breast cancer and prostatic and pancreatic cancers.[297] Moreover, ziv-aflibercept (Zaltrap) was also generated to target VEGF-A besides other members of the VEGF family, including VEGF-B and PlGF. It is a soluble recombinant fusion protein composed of the second Ig domain to VEGFR-1 and the third Ig domain of VEGFR-2 to the Fc section of human IgG1.[299] It binds to VEGF ligands with high affinity, preventing them from engaging to their receptors, and it was approved to treat colorectal cancer in 2012.[142]

Furthermore, given the fact that VEGFR2 is the main mediator of VEGF-A biological effects, many drugs have been developed to target this molecule, including ramucirumab (IMC-1121B). This concept is supported by the observation that VEGFR-2 −/− knockout mice cannot survive due to defective development of blood islands, endothelial cells, and hematopoietic cells. Ramucirumab is a fully humanized monoclonal IgG1 antibody that prevents VEGF ligand binding to the receptor through neutralizing VEGFR-2. It received its initial FDA approval in 2014 for the treatment of patients with advanced or metastatic gastric cancer or gastroesophageal junction (GEJ) carcinoma who had previously failed first-line chemotherapy.[297] Today, it is also approved for colorectal and nonsmall cell lung cancers[143–145].

6.02.2.6.2.2 Targeting the extracellular matrix

An example of a cancer therapeutic antibody that targets a specific soluble ligand is denosumab (Xgeva). It is an anti-RANKL human monoclonal antibody that was approved in 2013 by the FDA for the treatment of bone metastases in breast cancer patients,[300] the most frequent site of metastasis among these patients.[301] Interestingly, it was discovered that bone-disseminated breast cancer cells can modulate bone environments. These malignant cells were shown to stimulate osteoblasts to overexpress the receptor activator of nuclear factor-kB ligand (RANKL). The ligation of RANKL molecules to their receptors on the surface of osteoclast precursors can increase maturation, activity, and life span of osteoclasts. Then, osteoclasts, through the secretion of growth factors and cytokines, can promote tumor progression and metastasis, suggesting that RANKL pathway plays a major role in tumorigenesis and

metastasis.[300] Also, RANK ligand–receptor interaction can increase the risk of cancer-related bone diseases.[302] Therefore, denosumab and other RANKL antagonists, such as bisphosphonates, may exert potent antitumor effects. Interestingly, studies have shown that fibroblasts, T and B lymphocytes, and DCs within the TME can express high levels of RANKL. Indeed, the role of RANKL/RANK signaling in immunity is very important. It regulates lymph node development, lymphocyte differentiation, dendritic cell survival, T-cell activation, and immune tolerance. Not surprisingly, in addition to the osteoclast-dependent effects of RANKL/RANK signaling on tumorigenesis, some studies have suggested that this pathway can manipulate antitumor host immunity. For example, it may have direct effects on DC survival and T-cell proliferation and function. However, DC and monocytes in RANKL and RANK knockout (KO) mice develop normally and exhibit intact function. Therefore, further investigation is needed.[303–305]

6.02.2.6.3 Targeting immune cells

6.02.2.6.3.1 Targeting T lymphocytes

During tumorigenesis, T lymphocytes may migrate toward the TME, where they exhibit a significant effect on cancer development. Although this effect can range from protumor to antitumor responses, for many malignancies, including melanoma, renal cell cancer, colon cancer, ovarian cancer, and some subtypes of breast cancer, the presence of cytotoxic $CD8^+$ lymphocytes is associated with favorable outcomes.[32,306] Infiltrated T lymphocytes within the tumor are mainly of $CD8^+$ and $CD4^+$ subtypes. While $CD8^+$ can induce tumor cell lysis directly,[42] $CD4^+$ can promote tumor rejection by activating other immune cells, such as $CD8^+$ T cells and B cells, and secreting various types of cytokines and chemokines. However, upon cellular transformation, malignant cells can manipulate the function of immune cells, including T lymphocytes, to evade immune destruction. Therefore, to restore or enhance the immune system's ability to fight cancer, different immunotherapies have been developed to generate, educate, and/or enhance T-cell activity directed against tumor antigens.

Tumor-infiltrating T cells have distinctive properties. They can kill cancer cells directly and indirectly. They can mediate tumor rejection through various mechanisms. Also, as they are components of the adaptive immunity, they are able recognize tumor antigens specifically, and then later, they may create immunologic memory against these antigens.[257] As a result, T cells have been receiving increasing attention as a therapeutic target for cancer treatment. Cancer immunotherapies that target T cells can induce either antigen-specific or nonantigen-specific T-cell responses. Indeed, immune checkpoint inhibitors, such as anti-CTLA-4 and anti-PD1/PDL1, and cytokines, such as IL-2, have emerged as the most effective immunotherapies that can broadly activate the immune system to focus T cell-mediated antigen-specific, antitumor immune responses.

CTLA-4 (CD152) is a molecule expressed on activated T cells. It binds B7 molecules with a high avidity, outcompeting the activating effects of CD28 binding to B7 and thus attenuating T-cell proliferation and activation. Therefore, CTLA-4 defines a class of inhibitory or immune checkpoint molecules on T cells.[307] Several CTLA-4 antagonistic antibodies have been developed and evaluated in clinical trials. Currently, two of them have received FDA approval, ipilimumab (Yervoy) and tremelimumab.[72,147] After decades of intensive research and development, ipilimumab was shown to improve treatment outcomes in advanced melanoma. Treatment improved overall survival (OS), induced some durable responses, and may be curative in some patients. This IgG1 fully human monoclonal antibody targets CTLA-4 on T cells to reverse the inhibitory signal and allow B7 molecules to stimulate T cells through CD28.[308] However, additional mechanisms of action have been identified. For example, CTLA-4 is expressed within tumors to a higher extent on T-reg cells than on effector T cells. Therefore, similar to many other monoclonal antibodies, the FcγR of anti-CTLA-4 can result in elimination of T-reg cells by mediating ADCC, leaving effector T cells intact.[309] Moreover, it was identified that CTLA-4 signaling can induce IDO production in APCs and subsequently inhibit T-cell proliferation.[310] Also, CTLA-4 interaction with B7 molecules on APCs stimulates their internalization and thus prevents their binding to CD28.[311]

PD1 is another inhibitory molecule on T cells. While PD1 is expressed on the surfaces of activated T cells, its ligand (PD-L1) is expressed by malignant cells and APCs. When PD-L1 engages PD-1, it interrupts the signaling of CD28 in the cytoplasm of T cells, resulting in "exhausted" and ineffective T cells.[73,312] The expression level and kinetics of PD-1 depend on the strength and kinetics of T-cell activation, which also depend on the amount and source of the target antigen.[313] To date, two anti-PD-1-targeting antibodies are approved by the FDA: nivolumab (Opdivo) in 2014[73,312] and pembrolizumab (Keytruda) in 2015.[151,152] Both of these immunotherapies are approved for the treatment of patients with melanoma and squamous nonsmall cell lung cancer; moreover, nivolumab (Opdivo) is also approved for renal cell carcinoma.

Many other immune checkpoints are utilized by cancer cells to modulate antitumor immune responses. These ligand–receptor interactions can deliver either costimulatory signals or inhibitory signals. In fact, the favorable treatment outcomes of CTLA-4 and PD1/PDL1 antagonists have provided a stimulus for many groups to intensely search for new targets. Today, many new agents are under clinical evaluation, targeting immune checkpoints such as OX40, GITR, TIM-3, and LAG-3.[18]

Another strategy that has been employed to promote T-cell activity without targeting a specific tumor antigen is through the use of IL-2. In 1986, it was reported that the direct administration of high doses of recombinant human IL-2, even without adoptive transfusion of autologous TIL, can cause tumor regression in mice.[217] Driven by these encouraging results, clinical trials of recombinant IL-2 in patients with metastatic cancer were initiated. Interestingly, this treatment approach could result in complete durable tumor regressions in some patients with metastatic melanoma,[314] allowing for its approval in the 1990s.[315] IL-2 mediates its physiological functions by promoting the proliferation and activation of T cells, B cells, and NK cells, resulting in improved antitumor immunity. Nevertheless, since IL-2 can also promote T-reg cell activity, it may act as regulatory cytokine, rather than a purely stimulatory T-cell growth factor.[26]

In addition to the induction of nonspecific T-cell activation, novel treatments that stimulate antigen-specific T-cell responses have also received considerable attention. This includes T cell-based therapies, bispecific/trispecific antibodies, and immunotherapies that can enhance DC-mediated T-cell activation.

6.02.2.6.3.2 Targeting dendritic cells

DCs are bone marrow-derived cells that are found in all tissues in the body. Typically, inactive DCs exhibit high antigen-capture activity and binding capacity, allowing them to sense for a wide range of danger signals efficiently.[316] The main types of antigen receptors expressed on DCs are mannose receptor (MR), DC-SIGN, scavenger receptor (SR), DEC-205, and Toll-like receptors (TLRs).[317] Each of these receptors can bind to specific types of antigens. Also, each antigen receptor interaction can activate DCs through distinct molecular pathways and thus induce various types of immune cell responses.[316] DCs play a central role in the priming of $CD4^+$ and $CD8^+$ T cells.[318] Detection of an antigen by DCs triggers its internalization, processing, and presentation on MHC molecules. When lymph node-resident DCs detect an antigen directly in the lymph node, they present the antigen to naive T cells. This interaction may result in T-cell priming, proliferation, and clonal expansion. Subsequently, when inactive DCs in peripheral tissues capture the same antigen, they migrate to the lymph node, where they meet with the already activated antigen-specific T cells, promoting the generation of effector T cells. Hence, DCs act as a bridge between innate and adaptive immunity. Additionally, DCs can regulate humoral immunity through the interaction with B cells directly or indirectly, by stimulating the expansion and differentiation of $CD4^+$ helper T cells. Besides the regulation of adaptive immune cells, DCs can also regulate the cells of the innate immune system, such as NK cells and mast cells.[316]

In the context of cancer, DCs play a major role in initiating antitumor responses. For instance, the interaction between DCs and dying tumor cells triggers at least three different signals, including "find me," "eat me," and "do not eat me" signals. First, apoptotic cancer cells secrete soluble mediators, such as lipid lysophosphatidylcholine (LPC), sphingosine-1-phosphate (S1P), chemokine (C-X3-C motif) ligand 1 (CX3CL1), and the nucleotides ATP and UTP, that recruit DCs and other phagocytes to the site of tumor ("find me" signals). The second step is the exposure of several membrane-bound molecules on the surface of dying tumor cells, including phosphatidylserine, $\alpha v\beta 5$ integrin, and CD36. These molecules tag the target cells and thus promote their recognition and engulfment by phagocytes ("eat me" signals). Additional "eat me" signals are opsonizing antibodies, including therapeutic antibodies and antibody-like molecules, and complement components. Upon the binding of these molecules to tumor antigens, DCs can recognize cancer cells, through the FcyRs and complement receptors, respectively, leading to tumor cell eradication (ADCP).[316,319]

Malignant cells can employ a variety of strategies to impair the anticancer properties of DCs and thus enhance tumor growth and progression. This includes upregulating the "do not eat me" signals, switching the differentiation of monocytes to macrophages rather than DCs, inhibiting DC maturation through the secretion of IL-10 and other immunosuppressive cytokines, preventing efficient antigen processing and presentation to T cells, and stimulating the production of protumor DCs, which indirectly favor tumor growth.[316] Accordingly, research efforts have targeted DCs in order to restore and enhance host immunity against cancer.

One approach is to inhibit the "do not eat me" signals or inhibit the inhibitors of phagocytosis, such as CD47. These molecules can downregulate the phagocytosis of cancer cells, allowing them to escape from immune destruction. CD47 on target cells can bind to SIRPα on macrophages, DCs, and other myeloid cells. This ligand–receptor interaction triggers prophagocytic inhibitory signals and prevents proper cytoskeleton rearrangements that are necessary for phagocytosis.[320] Interestingly, various types of solid tumors, such as ovarian cancer, bladder cancer, breast cancer, and leiomyosarcoma, as well as hematopoietic malignancies, including AML, tend to induce high levels of CD47 expression on their cell surfaces.[208] These observations provided the rationale to target the CD47-SIRPa axis for cancer therapy. Several in vivo studies have supported this hypothesis.[321,322] For example, human B-cell non-Hodgkin's lymphoma-engrafted mice treated with anti-CD47 antibodies showed reduced lymphoma burden and improved survival. Also, using the same model, it was reported that the addition of CD47 blockade to rituximab treatment led to elimination of lymphoma and cure. Driven by the encouraging results, a humanized anti-CD47 antibody (Hu5F9-G4) was developed and is in clinical development for patients with AML and solid tumors.[322]

Another strategy is to induce DC antitumor activity by autologous DC vaccination. To deliver this vaccine, DCs are first isolated from cancer patients and cultured ex vivo with tumor antigens, resulting in DC activation. Then, activated DCs are reinfused back into the patients. This therapy was proposed to increase tumor antigen presentation to T cells, thereby enhancing host immunity against the tumor and inducing immunologic memory to reduce the chance of cancer recurrence.[316] However, this approach has not yet routinely induced strong T-cell responses that can completely eliminate established tumors.[323] To enhance the efficacy of DC vaccination, key regulators have been modified in DCs. These strategies include overexpression of costimulatory molecules, such as CD80, CD54, and CD58, and tumor-associated antigens, such as CEA.[324] To date, sipuleucel-T is the only DC vaccine that has achieved FDA approval. It was shown to modestly improve overall survival in prostate cancer, without meaningful decreases in symptoms or tumor measures, leading to its approval in 2010.[325,326]

Another strategy to enhance the interaction between DCs and T cells is by using agonistic monoclonal antibodies that target cell surface molecules, such as CD40. The rationale for the use of this immunotherapy for cancer treatment is that the engagement of CD40 on APCs with its ligand CD154 (CD40L) on activated CD4 + T cells can enhance the expression of MHC and costimulatory molecules, leading to improved T-cell priming and differentiation. Also, this receptor–ligand binding can promote the secretion of pro-inflammatory cytokines, which may indirectly activate NK cells. Moreover, CD40 ligation can promote apoptosis and reduce

proliferation, causing tumor regression. Based on these findings, anti-CD40 agonistic antibodies that mimic the function of CD40L were developed and are currently being tested in clinical trials.[327,328] Importantly, monoclonal antibody-based immunotherapies are expected to overcome some challenges of the autologous DC vaccination, including time and money efficiency, and the risk of ex vivo cellular activation and expansion.[329]

6.02.2.7 Future Directions

Immunotherapeutics have been shown to be successful in making cancer a controllable and curable disease in an increasing number of malignancies, but many challenges remain. Resistance is a major obstacle to successful cancer immunotherapy, and it can be divided into three main types: intrinsic resistance, naturally acquired resistance, and treatment-induced acquired resistance. In general, the effectiveness of the immunotherapeutic approach relies on the competence of the host's immune system and the level of tumor immunogenicity. Therefore, it is difficult to treat patients who have systemic immune failure, such as HIV and transplantation patients, and elderly people. A possible solution for these individuals is to transfer activated tumor-specific T cells that can restore the antitumor host immunity using autologous or allogeneic adoptive T-cell therapy. Moreover, even when there are a sufficient number of competent T lymphocytes, tumors that do not contain potent immunogens may not be recognized by the T cells. To overcome this challenge, DNA-damaging agents, such as chemotherapy and radiation therapy, can be used in combination with immunotherapies. This therapeutic strategy is hoped to increase the number of mutations, leading ultimately to more immunogenic tumors and improved patient outcomes.[330]

In addition to systemic immune failure, local immune dysfunction can also be seen in many cancer patients. A noninflammatory TME may result in impaired immune cell recruitment to the site of neoplastic lesions. Also, an immunosuppressive TME can influence the activity of TILs, rendering them unable to induce antitumor immune responses. For these cases, targeting components of the TME might help to restore the immune system's ability to eradicate the cancer.[330]

Besides intrinsic resistance, naturally acquired resistance frequently occurs in cancer. For example, under immune selection pressure, cancer cells can evade immune destruction by continuously selecting cancer cell populations that are less immunogenic, have impaired antigen processing and presentation capacity,[330] or have mutations that may give the cells a growth advantage. For example, primary resistance to the anti-EGFR antibodies cetuximab and panitumumab has been reported in colorectal cancer patients with activating KRAS mutations.[159] Another escape strategy commonly employed by malignant cells is the upregulation of immune checkpoint proteins. These escape mechanisms may result in failure of many immunotherapies. To reverse this acquired resistance, combination therapy of immune checkpoint inhibitors with standard cancer treatments or cell-based immunotherapies may be necessary.[330]

There is an urgent need to identify biomarkers that can assist in selecting the patients who are likely to respond, as well as biomarkers that can help to select the right treatment with the right dosing schedule. These findings will not only make the therapy more effective, and safer, but also decrease the cost and allow the treatments to be more easily available for more cancer patients.[331–333]

With regard to personalized cancer immunotherapies, although it is predicted that therapeutically targeting TSAs can make cancer treatment more specific, more effective, and safer, this approach may have limited translational success. One issue is that it is not very clear if personalized immunotherapy might lead to any autoimmune consequences. Also, it may not be possible to complete the development of the treatment within a clinically relevant time frame. Moreover, it involves the use of sequencing technologies, and thus, it may create many logistical challenges, for example, how to prioritize potential tumor-specific antigens for selection as therapy targets and how to achieve highly accurate sequencing results. Because of the complexity of these issues, many cancer patients may have limited or no access to personalized immunotherapy until these issues have been successfully addressed.[334]

Therapeutic cancer vaccines may have improved efficacy when administered earlier during the disease course, perhaps because cancer patients have lower tumor burdens and more intact immune systems capable of eliciting stronger immune responses against tumors.[335]

Cancer immunotherapy-related toxicities are different depending on the type of administered treatment.[336] The associated symptoms can range from very mild, such as itching and inflammation, to severe disease and even death.[337] Cytokine therapy, including high-dose IL-2 treatment, is typically associated with nonspecific T-cell reactivity.[336] The most common side effect of IL-2 therapy is capillary leak syndrome, which is potentially life-threatening.[338] However, a recent study reported a retrospective analysis of the outcomes of 500 patients with metastatic renal cell carcinoma or melanoma treated with high-dose IL-2. In this analysis, IL-2-mediated toxicities were reversible and the incidence of fatal toxicity was $<1\%$.[339] In contrast, other immunotherapies, including vaccines, CAR and TCR cellular therapies, and checkpoint inhibitors, may activate T cells more specifically, causing specific organ damage.[336] Some cancer therapeutic antibodies such as rituximab and alemtuzumab have significant risks for infusion reactions (over 50% each). However, these reactions are mostly mild. Only $\sim 0.3\%$ of treated patients can have serious reactions.[337]

Immunotherapy is changing the paradigm for cancer treatment. Indeed, its ability to prolong tumor regression and cure cancer with mostly manageable side effects challenges prior dogmas and creates new directions for cancer therapy. Moreover, many novel, promising immunotherapeutics are being currently evaluated in clinical trials. Future prospects for this exciting field have never been brighter.

6.03.1 Minimum Active Sequence

A minimum active sequence (MAS) is defined as the shortest amino acid sequence that can be derived from an endogenous peptide without compromise of potency or binding affinity to its native target. Conventionally, after discovery of a biologically active peptide or protein, key amino acid residues that contribute to bioactivity must first be identified. Alanine scanning and D-amino acid substitution are often carried out to identify any such residues of significance. Once essential amino acids are located, the truncation process can begin while maintaining important residues (i.e., pharmacophores) within the sequence of truncated peptides. This process removes "biologically redundant" amino acid residues that contribute little to the molecular recognition of the full-length peptide or protein.[1] The identification of an MAS via truncation is typically carried out by stepwise deletion of amino acids at either terminus or both termini.

Endogenous peptides in initial stages are often too lengthy to be effectively synthesized in a high yield, and truncation is a logical step for transformation of peptides to a manageable size. This not only facilitates efficient synthesis but also subsequently enables comprehensive structure–activity studies, both of which may accelerate drug development processes. There are a plethora of truncation studies reported to date, and **Table 1** highlights several peptide therapeutics that are already approved by the Food and Drug Administration (FDA).

6.03.1.1 Cholecystokinin

Cholecystokinin (CCK) is a peptide hormone primarily responsible for stimulating the digestion of fat and protein and inducing satiety. Several biologically active forms of CCK have been identified, such as CCK58, CCK33, CCK22, and CCK8. The most prevalent is the C-terminal octapeptide CCK8 [CCK(26–33)] that is widely distributed throughout both the peripheral and central nervous systems (CNS). The truncated octapeptide was previously thought to be the MAS of CCK, showing nanomolar affinity and efficacy on the two CCK receptor subtypes (CCK-A and CCK-B/gastrin receptor). However, the C-terminal tetrapeptide CCK(30–33) was found to have comparable activity,[2] and it has since been established as the MAS required for nanomolar affinity in the brain, while the sulfated octapeptide [sulfated CCK(26–33)] is the MAS for nanomolar affinity on the pancreatic tissue.

6.03.1.2 Melanin-Concentrating Hormone

Truncation studies of the heptadecapeptide melanin-concentrating hormone (MCH) have determined an MAS comprising only eleven residues.[3] Systematic deletion from the C-terminus was found to be acceptable up to the residue at position 16, resulting in MCH(5–15) that is equipotent to the full-length peptide. However, another deletion of Trp at position 15 significantly provoked the potency (>10-fold decrease).

6.03.1.3 P-Selectin

P-selectin is a 140-kDa integral membrane glycoprotein. In order to identify the active core region in the lectin domain, deletions from both the N- and C-termini were carried out. Two sequences, residues 36–49 and 41–50, were found to be the MAS and showed substantial inhibitory activity of selectin-dependent leukocyte adhesion.[4]

Table 1 Selected examples of truncated peptide therapeutics approved by the FDA

Peptide/protein	*Trade name*	*Manufacturer*	*Parent peptide/protein*	*Original size*	*MAS size*
Enfuvirtide	Fuzeon	Roche	HIV-1 envelope protein gp41	345-mer	36-mer
Eptifibatide	Integrilin	Millennium	Disintegrin protein	73-mer	7-mer
Octreotide	Sandostatin	Novartis	Somatostatin	14/28-mer	8-mer
Teriparatide	Forteo	Eli Lilly	Human parathyroid hormone	84-mer	34-mer
Sermorelin	Geref	Serono	Human growth hormone-releasing hormone	44-mer	29-mer

6.03.1.4 Annexin A1

Derived from the N-terminal region of a 37 kDa glucocorticoid-regulated protein and previously referred to as lipocortin 1, annexin A1 (acetyl 2–26) was identified as the MAS for anti-inflammatory activity.[5] The truncated N-acetylated peptide that contains 25 amino acids (residues 2–26) showed a similar efficacy to that of the native protein.[6]

6.03.1.5 Eptifibatide

Eptifibatide (Integrilin, Millennium Pharmaceuticals) is an FDA-approved glycoprotein IIb/IIIa antagonist for anticoagulant activity. It is a platelet aggregation inhibitor indicated for patients with acute coronary syndrome and those undergoing percutaneous coronary intervention. This antagonist is a cyclic heptapeptide derived from Cys-rich snake venom that is a 73-amino acid-containing disintegrin protein. Truncation of the long peptide to a short loop, in addition to other modifications like guanylation at Lys side chain and deamination at the N-terminus, resulted in a highly potent therapeutic peptide.[7]

6.03.1.6 Enfuvirtide

A milestone achievement of truncation is the enfuvirtide (DP-178) peptide, formally known as T-20. It is marketed by Roche under the trade name Fuzeon and was approved by the FDA in 2003 as the first human immunodeficiency virus (HIV) fusion inhibitor, forming a new class of antiretroviral drugs. Enfuvirtide is a 36-amino acid-containing peptide of which sequence corresponds to the residues 638–673 of HIV-1_{LAI} isolate.[8] This peptide binds to glycoprotein 41 (gp41) of HIV type 1 (HIV-1) that is involved in the fusion of the virus with the membrane of the CD4+ host cell.[9] It prevents the viral entry by closing the entry pore for the viral capsid.

6.03.1.7 Octreotide

Octreotide is an FDA-approved peptide drug marketed under the brand name Sandostatin by Novartis Pharmaceuticals. It is an octapeptide somatostatin analog and is primarily employed for treating growth hormone-producing tumors and pituitary tumors.[10] It is also used as a radiopharmaceutical. An indium-111-labeled octreotide (octreoscan) is used to noninvasively image tumors expressing the somatostatin receptor.

Octreotide differs from examples described in the preceding text because truncation has not only achieved the MAS but also improved the half-life. Somatostatin inhibits the release of numerous hormones that include glucagon, insulin, secretin, and growth hormone. However, its therapeutic use is highly compromised due to its short half-life of about 2 min.[11] Search for a long-acting somatostatin analog led to the octapeptide that contains the essential pharmacophore Phe^7-Trp^8-Lys^9-Thr^{10} with substitution of D-Trp at position 8 and is constrained by a disulfide linkage.[12]

6.03.1.8 Teriparatide

Teriparatide is a recombinant form of N-terminally truncated and 34-amino acid-containing human parathyroid hormone (1–34). It is marketed by Eli Lilly under the brand name Forteo. It is prescribed as an anabolic agent indicated for use in postmenopausal women with osteoporosis.[13] The parent human parathyroid hormone is an 84-amino acid-containing peptide synthesized and secreted by the parathyroid glands. The truncated N-terminal fragment (residues 1–34) exhibits comparable biological activity and pharmacological profile with its parent peptide in stimulating bone formation.[14] It acts on the kidneys, intestine, and bone to regulate plasma calcium homeostasis by increasing intracellular calcium.

6.03.1.9 Sermorelin

Sermorelin is an analog of growth hormone-releasing hormone (GHRH) primarily used for diagnostic purposes. It is a 29-amino acid-containing fragment of endogenous human GHRH, also represented as GHRH (1–29). Sermorelin is the shortest fully functional synthetic fragment of GHRH.[15] It was marketed under the trade name of Geref by Serono Laboratories, but the FDA recently listed it as a "discontinued drug product."

6.03.1.10 Glucagon-Like Peptide-1

Glucagon-like peptide-1 (GLP-1) is a 30-amino acid incretin produced by the intestinal L cells. It plays an important physiological role in glucose homeostasis primarily by stimulating insulin secretion from pancreatic β cells as a response to food intake.[16] While many truncated peptides of GLP-1 failed to offer biological activity, Mapelli and coworkers reported on the discovery of an 11-mer GLP-1 analog that comprises an N-terminal nonapeptide connected to a substituted C-terminal biphenylalanine dipeptide.[17] It was found to be a full agonist to the GLP-1 receptor and also showed improved half-life over that of the full-length peptide.

6.03.2 Modifications at the Termini and Side Chains

Peptides carry a number of polar functional groups, such as ammonium groups at the N-terminus and Lys side chain; carboxylate groups at the C-terminus and the side chains of Asp and Glu; thiol groups of Cys; hydroxyl groups from Ser, Thr, and Tyr; and guanidine groups from Arg. These hydrophilic functional groups in peptides are often modified to improve affinity to their targets, to enhance metabolic stability, and to gain new physicochemical and biological properties.

6.03.2.1 N-Acetylation

N-terminal acetylation is the most common form of N-terminal modification and places an acetyl group at the amino end of a peptide. It is one of the most common posttranslational covalent modifications of proteins and is catalyzed by a set of N-terminal acetyltransferases that transfer an acetyl group from acetyl coenzyme A to the α-amino group of the first amino acid residue.[18] The α-melanocyte-stimulating hormone (α-MSH) is an example of a naturally acetylated peptide. Synthetically, acetylation can be made by using acetic anhydride at the end of peptide synthesis.

Acetylation removes a positive charge from the N-terminus and decreases the net charge of a peptide, which may change the solubility profile. It can enhance proteolytic stability of peptides in addition to improving biological activity.[19] The removal of the positive charge at the N-terminus may help synthetic peptides mimic endogenous proteins more closely, in particular when the sequence of a peptide is derived from the segments in a protein. Acetylation has also been found to enhance cell permeability and intestinal absorption of peptides. In addition, acetylation has been used as an important tool for MS/MS sequencing of peptides and proteins.[20]

This N-terminal capping strategy has been widely used in peptide drug development. N-acetylation of a somatostatin analog was found to improve the half-life significantly from 3 min of the natural peptide to approximately 400 min.[21] An N-acetylated pentapeptide thymopoietin analog demonstrated similar metabolic protection, showing no detectable degradation, whereas the native peptide had a half-life of approximately 1 min.[22] Enfuvirtide and gonadotropin-releasing hormone (GnRH) analogs including abarelix acetate, cetrorelix acetate, degarelix acetate, and ganirelix acetate are FDA-approved N-acetylated peptide therapeutics (Table 2). N-Acetylated cyclic pentapeptide ADH-1 (Exherin), developed by Adherex Technologies for inhibiting N-cadherin to disrupt tumor vasculature, is currently undergoing phase II clinical trials.[24]

6.03.2.2 *N*-Pyroglutamate Formation

Discovered in the late 1880s, pyroglutamate (pE), also known as pyrrolidone carboxylate or 5-oxoproline, is a cyclic amino acid formed as a result of dehydration of glutamate.[25] Catalyzed by glutaminyl cyclases (QCs), the N-terminal α-amino group of either Glu or Gln cyclizes to form a lactam bond during posttranslational modification (Fig. 1).[26] There are numerous examples of N-terminal pE-containing peptides and proteins originated from plants and animals (Table 3).[23]

In addition to Gln, Glu at the N-terminus can undergo spontaneous cyclization for irreversible formation of a pE at elevated temperature or under an acidic condition.[27] Whereas the conversion of Glu to a pE occurs more slowly than Gln, it has been observed to take place near a physiological condition.[27a] On the other hand, an *N*-pyroglutamate can be chemically synthesized by condensing the carboxylic acid side chain of an N-terminal Glu with its N^{α}-amine by using a coupling reagent, which results in the formation of a lactam bond.

Gastrin-17, neurotensin, thyrotropin-releasing hormone (TRH), GnRH, and fibronectin are examples of pE-containing peptides of human origin.[26] The pE moiety is often found to be important for exerting biological functions of the peptides. The pE of thyrotropin-releasing factor is involved in receptor recognition.[28] On the other hand, pE-containing peptides have been found to cause an altered effect over their non-pE-containing counterparts. For example, a pE helix B surface peptide derived from erythropoietin (EPO) was found to have a cardioprotective action against ischemic myocardial damage similar to EPO, but lacked the undesirable parallel activation of erythropoiesis and thrombogenesis that occurs with EPO.[29] pE is also found to provide stability

against N-terminal degradation by aminopeptidases as demonstrated with GnRH[30] and monocyte chemotactic protein-2.[31] It is interesting to note that N-pE analogs of GnRH act as agonists in combination with other modifications, while N-acetylated analogs are found to be antagonists.

6.03.2.3 C-Amidation

The formation of a carboxamide at the last amino acid in the sequence of a peptide is one of the most common and important posttranslational modifications. More than the half of all biologically active peptides and proteins are α-amidated at the C-terminus, and the C-amidation appears to be essential for their full biological activity.[32] It is catalyzed by a bifunctional enzyme, peptidylglycine α-amidating monooxygenase (PAM). Calcitonin, oxytocin, and vasopressin are examples of C-amidated endogenous peptides.

C-terminal amidation of a peptide produces effects similar to those of N-acetylation. These include a change in net charge, which alters the solubility profile. It can also improve proteolytic stability by evasion from carboxypeptidases, as observed in peptides like endomorphon-1. While a carboxylate group may be converted to an ester to prevent degradation by carboxypeptidases, esters are susceptible to numerous esterases, and C-amidation therefore offers a more effective alternative. C-terminal amidation increased the in vivo half-life of Met-enkephalin from seconds to nearly an hour, along with other modifications.[33]

6.03.2.4 PEGylation

Covalent attachment of one or more polyethylene glycol (PEG) chains to a peptide or protein is called PEGylation. Compared with other N- and C-terminal modifications that may naturally occur (e.g., N-acetylation, N-pyroglutamylation, and C-amidation), PEGylation is strictly a synthetic modification. As it is nontoxic, nonimmunogenic, nonantigenic, and highly soluble in aqueous media, PEG appears to be the most biologically compatible polymer and is approved by the FDA for internal use.

PEGylation is primarily used to overcome disadvantageous physicochemical properties of biomolecules like peptides and proteins. It prolongs circulation half-life in the body, which requires less frequent administration and ultimately leads to better patient compliance. PEGylation also increases the aqueous solubility of peptides and enhances resistance to proteases and metabolic enzymes. Reduction of immunogenicity of conjugated biomolecules is another attribute of PEGylation, which may be significant for using peptides of nonhuman origin. PEG also frequently serves as a spacer or linker. A bifunctional PEG spacer can connect a peptide to another molecule. Since the first instance of PEGylation of albumin and catalase in the late 1970s by Davis and

Abuchowski,[34] a number of chemical and enzymatic methods have been developed for conjugating PEG, including site-specific modification.

Pegademase bovine was the first PEGylated protein drug approved by the FDA in 1990. It is marketed by Enzon Pharmaceuticals under the brand name Adagen for the treatment of X-linked severe combined immunodeficiency syndrome as an alternative to bone marrow transplantation and enzyme replacement by gene therapy. Since then, a number of PEGylated peptide and protein drugs have entered the market (**Table 4**).

One of the unfortunate consequences of PEGylation may be a loss of biological activity. However, this loss can be compensated by a prolonged circulation time resulting from increased stability, which gives a higher hydrodynamic volume.[36] For example, 40 kDa branched PEG-conjugated antiviral protein PEG-interferon-α-2a has only 7% of the antiviral activity of the unmodified protein[37]; however, the PEGylated conjugate showed higher in vivo efficacy for the treatment of hepatitis C compared with the unmodified form by virtue of its improved pharmacokinetics.

The most important properties to consider for PEGylation are the size and structure of the PEG chain and the site of attachment on a peptide. Since PEG is a synthetic polymer, it is polydisperse, and a batchwise variation in the number of monomers is inevitable, which in turn yields a Gaussian distribution of the molecular weight.[36] Thus, conjugation of such a polydisperse polymer may lead to a population of drug conjugates that have slightly different physicochemical and pharmacokinetic properties dependent on the size of the PEG chain. The size of PEG is important since proper clearance from the body depends largely on this factor. It is usually excreted in urine and feces. However, if the molecular weight is too large, it may accumulate in the liver.

Peptides and proteins are typically sensitive to modification. In addition, chemical reactions used to make a modification should be mild enough not to denature or inactivate such delicate biomolecules. The site of modification and the type of chemical reactions for the conjugation should be carefully considered for PEGylation of peptides and proteins. While the imidazole group of His, carboxylic group of Glu/Asp, hydroxyl group of Ser/Tyr, and even the carboxamide side chain of Gln have been reported for the conjugation,[35] PEGylation is typically carried out at the side chains of either Lys or Cys (**Fig. 2**).

The amino groups of the Lys side chain and the N-terminus are the most exploited sites for PEGylation. The conjugation is carried out by either alkylation or acylation. While alkylation does not alter the total charge of a protein, acylation forms a neutral amide bond that removes a positive charge. The change in the surface charge may play a role in target interaction. Examples of reactive functional groups to amines for PEGylation are shown in **Fig. 2A**. Trichlorotriazine and aldehyde yield a conjugated product that maintains the positive charge after PEGylation.[34b,38] Attachment of PEG to an amine via an activated carboxylic acid like *N*-hydroxysuccinimide ester forms an amide bond.[39] Similarly, carbonate-activated PEGs like *p*-nitrophenyl chloroformate, succinimidyl carbonate, and benzotriazole create a stable urethane linkage.[40]

The thiol group of Cys is an outstanding nucleophile for site-specific modifications. PEG conjugation via a stable thioether linkage can be conveniently produced with PEG-derivatized maleimide, vinyl sulfone, or iodoacetyl groups.[41] Since the prevalence of Cys is lower than that of Lys, the thiol-mediated conjugation can be more site-specific. An ortho-pyridyl disulfide-derivatized PEG can make a reversible disulfide bond with Cys of peptides, which can be reduced to release the native proteins under a mild condition.[42] A thiol-ene reaction has also been attempted to conjugate a copolymer of di(ethylene glycol) methyl ether methacrylate and allyl methacrylate to α-keratin via hetero-Michael addition.[43]

In addition to amino and mercapto groups, the hydroxyl groups of Ser, Thr, and Tyr have been employed for PEGylation. While modification at Ser and Thr usually requires reaction conditions that are too harsh for proteins, an enzymatic approach has been successfully applied for site-directed PEGylation by using glycosyltransferases to attach PEG to O-glycans.[44] Tyr of Leu-enkephalin and salmon calcitonin were conjugated with diazonium salt-terminated linear monomethoxy poly(ethylene glycol)s (mPEGs) and poly(mPEG) methacrylate.[45] While the acyl-His bond is not stable, PEG conjugation to the imidazole group of His in interferon-α-2b has been reported to produce a prodrug that slowly releases the protein.[46] In addition, azide–alkyne cycloaddition (also known as "click chemistry") has also been used to make PEGylated peptides.[47]

6.03.2.5 Lipidation

Conjugation of a fatty acid is referred to as lipidation, and it increases lipophilicity of conjugated peptides and proteins. Lipidation is one of the most commonly encountered posttranslational modifications that modulates hydrophobicity, secondary structures,

Table 4 Selected examples of FDA-approved PEGylated peptide/protein therapeutics[35]

and self-assembling propensities. Lipidated peptides can also offer enhanced metabolic stability, membrane permeability, bioavailability, and pharmacokinetic and pharmacodynamic properties.[48] Moreover, it increases plasma stability and decreases renal clearance of peptides, which leads to a long circulation half-life. GLP-1 analog liraglutide (Victoza), insulin detemir (Levemir), and antibiotics like daptomycin and polymyxin B are examples of lipidated peptide therapeutics approved by the FDA (Table 5).

Marketed as Victoza by Novo Nordisk, liraglutide is a GLP-1 analog prepared by attaching a C16 fatty acid to an amino side chain of Lys via a γ-glutamyl spacer. The conjugation of the fatty acid increased the plasma half-life from 1.2 to 13 h after subcutaneous injection.[49] Similarly, tesamorelin, an analog of human growth-releasing factor hGRF(1–44)NH_2, has a *trans*-3-hexenoyl moiety conjugated to Tyr that resulted in resistance against dipeptidyl peptidase-IV (DPP-IV) degradation.[50]

Besides increasing plasma stability, lipidation has also been utilized as a strategy to improve absorption by passive diffusion. Peptide drugs, in particular hydrophilic ones, are lipidated to enhance membrane permeability. For example, a naturally occurring dipeptide thymic immunomodulator that has high hydrophilic character and low permeability was conjugated to 2-aminododecanoic acid to improve oral absorption.[51]

The chain length of a lipid moiety is an important parameter that needs to be considered for lipidation since the length may have a strong impact on the bioactivity of lipidated peptides.[48] However, an increase in the chain length most likely leads to a decrease in aqueous solubility. A longer chain fatty acid conjugate of Phe-Asp-Cys-amide was found to be more effective than its shorter chain counterpart in inhibition of melittin-induced hemolysis.[52] On the other hand, a longer lipid chain connected to an enkephalin analog unfortunately led to a decrease in biological activity despite improved cell permeability from its increase in length.[53]

The site and chemical reaction for lipidation also need to be carefully considered. Modification of peptides and proteins with lipids can be carried out by similar reactions used for PEGylation. Amines of the N-terminus and the lysine side chain are the most exploited lipid modification sites. N-terminal myristoylation and palmitoylation are common peptide lipidation strategies. For example, palmitoyl lipidation at the N-terminus of the α-helix 2 fragment of STAT3 showed an enhanced inhibition of breast cancer cell growth.[54] The significance of the site of lipidation is made clear with the example of the lipidated analog of cecropin A–melittin hybrid peptide, CA(1–7)M(2–9). Acylation with saturated linear fatty acids at Lys^7 showed drastically decreased leishmanicidal activities, whereas acylation at Lys^1 to either the α- or ε-amino group increased the activity up to 3 times against promastigotes and up to 15 times against amastigotes.[55]

Among many lysine lipidations, insulin detemir (Levemir), a long-acting human insulin analog, is probably one of the most well-demonstrated examples (Fig. 3).[56] Marketed by Novo Nordisk, Levemir is an insulin analog with a myristic acid conjugated

Table 5 Selected examples of FDA-approved lipidated peptide/protein therapeutics

Tesamorelin	Egrifta	Theratechnologies	Fatty acid (C6)
Teicoplanin	Targocid	Sanofi-Aventis	Fatty acid (mixture)
Insulin degludec	Tresiba	Novo Nordisk	Acidic fatty acid (C16)

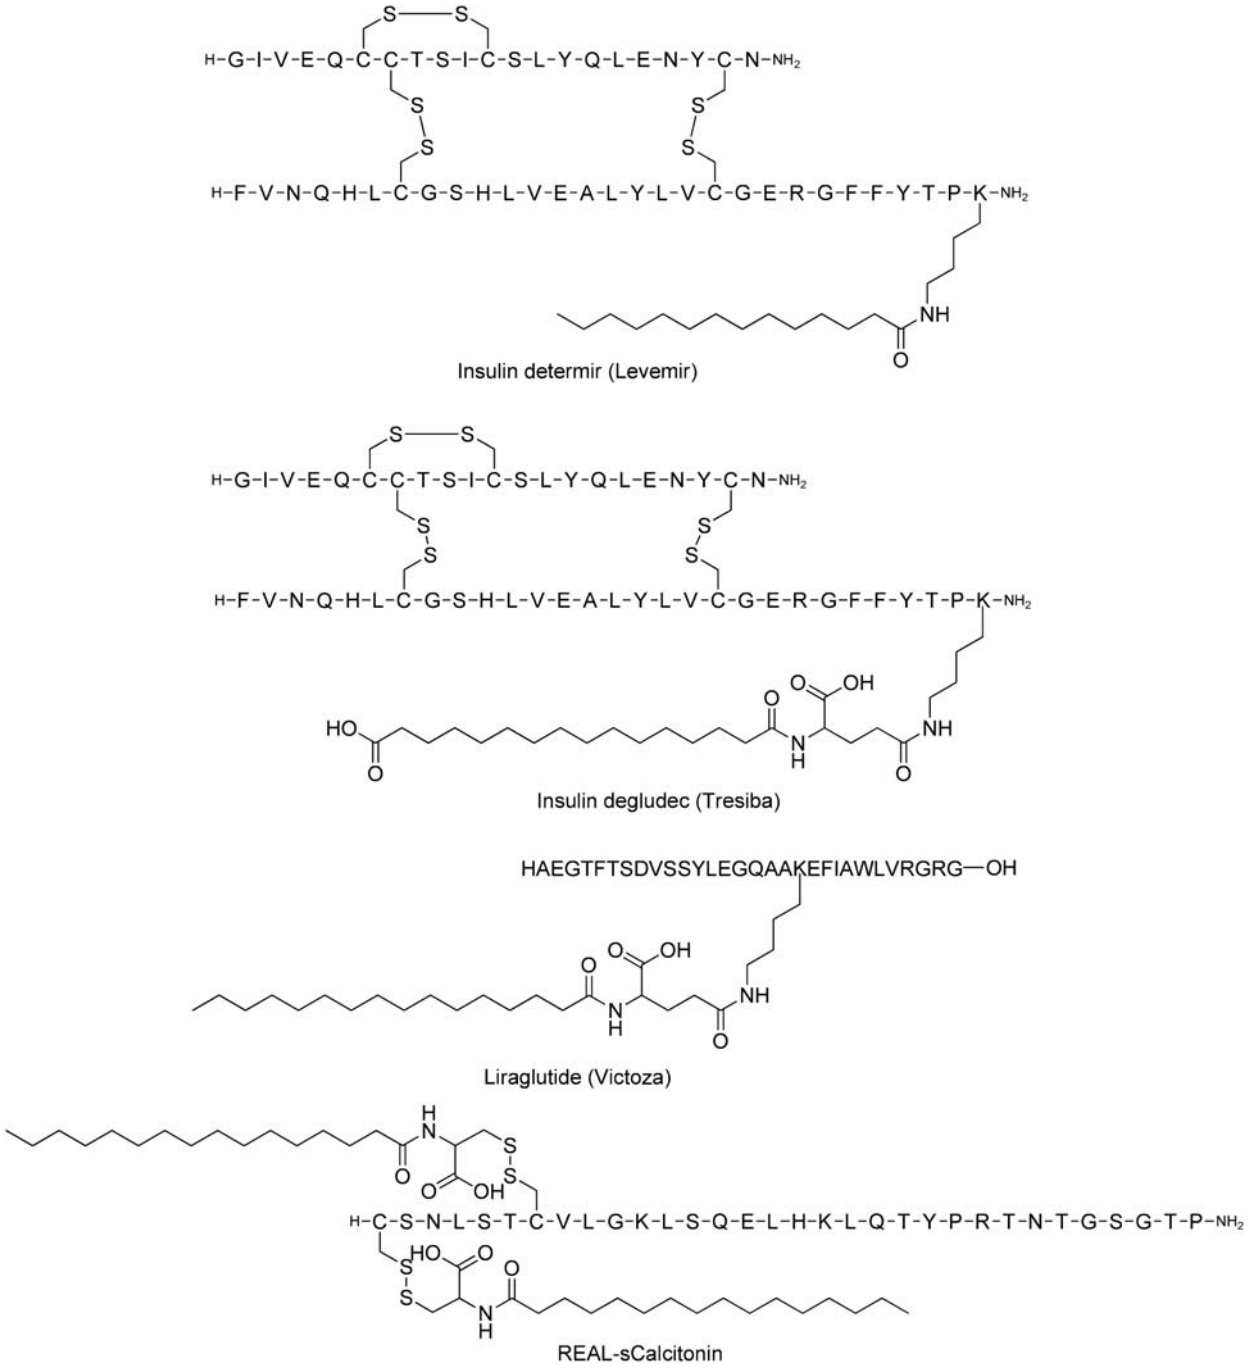

Fig. 3 Structures of lipidated peptides.

to the ε-amino group of Lys[29] of the B chain without Thr[30]. It showed outstanding serum binding affinity and a blood glucose-lowering effect for longer duration, up to 24 h.[56,57] An additional milestone example is liraglutide, another FDA-approved peptide drug lipidated at the ε-amino group of Lys of GLP-1.

The thiol group of Cys, if present, is an easily accessible site for lipidation of peptides and proteins. One of the widely used methods for Cys lipidation is called reversible aqueous lipidation (REAL) technology that involves the lipidation of peptides via a disulfide bond formation reaction between (*N*-palmitoyl cysteinyl)-2-pyridyl disulfide and the thiol group of Cys.[58] DiC_{16}-desmopressin lipidated with the REAL technology showed fourfold longer antidiuretic activity compared with the unmodified desmopressin.[59] Similarly, salmon calcitonin was also successfully lipidated with *N*-palmitoyl cysteinyl 2-pyridyl disulfide.[60] The reversibly lipidized peptides exhibited not only improved pharmacokinetic and pharmacodynamic behaviors but also

enhanced oral bioavailability. Lipids conjugated via labile linkages can be cleaved to release native biomolecules under a suitable condition.[61] Such a prodrug strategy has the advantage of enhancing the pharmacological characteristics of a parent peptide without decreasing its activity and selectivity.[62]

Lipidation can also be accomplished by introduction of unnatural lipoamino acids (LAAs).[63] Toth's group reported an amino acid-based oligopeptide system that combines the structural features of lipids and amino acids. Lipidation of ryanodine receptor agonist with LAA improved Ca^{2+} release activity and permeability across caco-2 cells without disrupting the α-helical structure-bearing critical residues.[64] In addition, a carboxylic fatty acid has been used for lipidation. Acylation with a dicarboxylic acid changes the positively charged amine into a negatively charged carboxylate. Insulin degludec, marketed by Novo Nordisk under the brand name Tresiba, is one of the successful examples of lipidation, and it was recently approved by the FDA in 2015.[65] It is an extremely long-acting insulin, and the hexadecandioyl fatty diacid is conjugated via a γ-glutamic acid spacer to the ε-amino group of Lys^{B29} of the B chain lacking Thr^{B30}.

6.03.2.6 Glycosylation

Glycosylation is the covalent attachment of oligosaccharide moieties to peptides or proteins and is considered the most complex posttranslational modification.[66] Glycopeptides and glycoproteins are important components of biochemical processes, and they play significant roles in cell growth regulation, immune response, binding of pathogens, cancer cell metastasis, and inflammation. Glycans on proteins may also play a role in protein folding and stabilization of tertiary structure.[67] Since the conjugated sugar moieties can be very large and bulky, it can either facilitate or inhibit protein–protein interactions (PPIs). In addition, glycosylation increases the aqueous solubility of biomolecules.

There are a number of natural and synthetic glycopeptides and glycoproteins used as therapeutics. For example, glycopeptide antibiotics have been instrumental in the fight against infectious diseases.[68] Vancomycin was approved in 1958 by the FDA to treat penicillin-resistant staphylococci, and lipoglycopeptide analogs of vancomycin, such as telavancin and dalbavancin, have been developed to tackle increasing cases of resistance.[68] In addition, glycoconjugate vaccines comprising a fully synthetic capsular polysaccharide antigen of *Haemophilus influenzae* type b (Hib) have been developed.[69]

A variety of functional groups can be used to form a glycosidic bond, and different types of linkages are often found within a single molecule. In 1961, Johansen and coworkers first reported on glycosylation in ovalbumin via a GlcNAc-β-Asn linkage.[70] For glycosylation, several factors must be considered, such as the site of glycosylation, the type of glycan composition, and the length, size, and structure of the glycan. There are mainly five different types of glycosidic linkages found in nature (**Fig. 4**): N-linked (bound to the amino group of an amino acid, usually Asn), O-linked (bound to the hydroxyl group of Ser, Thr, or Tyr), glypiation (linked to a phospholipid), C-linked (linked to the indole ring of Trp), and phosphoglycosylation (bound to Ser via a phosphodiester bond).[71] Thirteen monosaccharides and 8 amino acids have been identified that participate in glycosidic bond formation to date.[71]

Glycosylation still remains a less explored field for peptide therapeutic development. In recent years, however, there has been a growing interest in the development of new methods for linking sugars to peptides. Synthesis of a glycopeptide/glycoprotein requires robust chemical methods from both carbohydrate and peptide fields since it involves the formation of the integral glycan–amino acid bond.[72] Glycopeptides are chemically synthesized mainly by two different strategies: linear assembly and convergent assembly. Linear assembly uses glycoamino acid building blocks. Glycoamino acids are synthesized separately and later assembled together by using solid-phase peptide synthesis (SPPS) protocol.[73] Protected glycoamino acids are now commercially available, ready for coupling onto a growing peptide on polymer support. However, extensive protection and deprotection steps

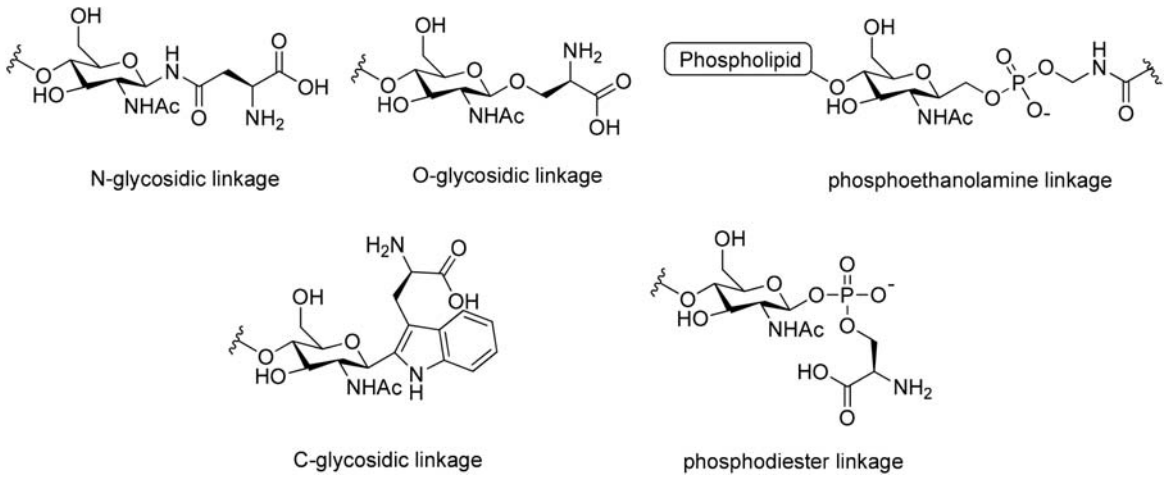

Fig. 4 Structures of glycosidic linkages.

of both the carbohydrate moieties and amino acids, along with the limitation on the length of peptides that can be synthesized with acceptable purity, may compromise effective production of glycosylated biomolecules, especially glycoproteins. In convergent assembly, a peptide chain and glycan residues are synthesized separately, and glycosylation can be carried out later on a specific side-chain residue of the peptide.[72] Direct convergent peptide glycosylation often produces a lower yield, but has been used to couple glucosamine to carboxylates of peptides.[74]

A number of chemical strategies have been developed for the synthesis of natural glycosidic linkages (Fig. 5). A reaction of either protected or deprotected glucosamine with protected Asp is the most commonly used route for N-linked glycosylation.[75] Staudinger ligation strategy was also developed to conjugate glycosyl azides to carboxylates or their derivatives of peptides in the presence of PPh_3.[76] On the other hand, O-linked glycosidic linkages are formed most commonly on the hydroxyl group of Ser or Thr by using standard glycosyl donors. Field and coworkers reported the synthesis of 1,2-trans disaccharides in high yields by activating

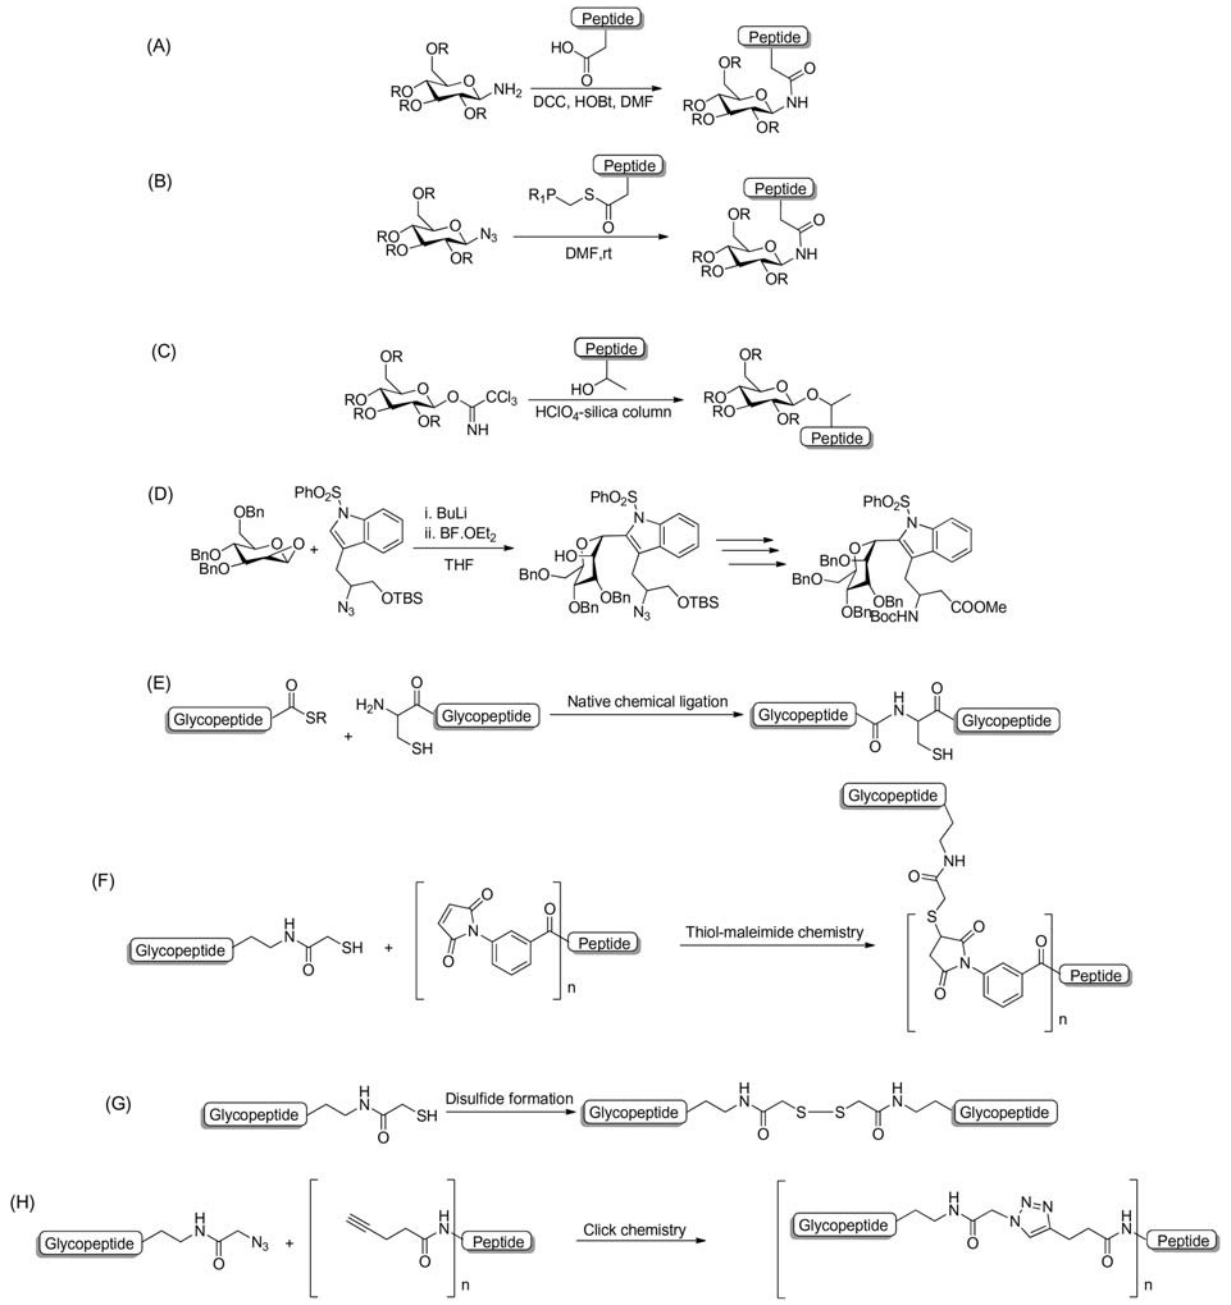

Fig. 5 Synthetic strategies for the preparation of glycopeptides. (A) N-linked, (B) N-linked via Staudinger reaction, (C) O-linked, (D) C-linked, (E) via native chemical ligation, (F) via thiol–maleimide chemistry, (G) via disulfide formation, and (H) via azide–alkyne cycloaddition reaction ("click chemistry").

ester-protected glycosyl trichloroacetimidate donors with perchloric acid immobilized on silica.[77] For C-linked glycosidic bond formation between Trp and mannose moieties, Ito and coworkers carried out ring opening of a benzyl-protected 1,2-anhydro-mannose with a lithiated indole derivative. After a series of functional group conversion and deprotection steps, glycoamino acids were synthesized as building blocks for peptide elongation.

Chemical glycosylation methods are not limited to the production of natural glycoproteins. Neoglycoproteins that bear unnatural glycosidic linkages can be synthesized by using reactive side-chain functional groups like the amine and thiol of Lys and Cys, respectively.[78] One of the most widely used and robust convergent synthetic strategies is native chemical ligation (NCL). Diptericin is an antibacterial glycopeptide that contains 82 amino acids and 2 O-linked glycosylation sites, and its total synthesis was accomplished by NCL.[79] Glycosylation has also been carried out with site-selective Cys ligation utilizing thiol–maleimide chemistry.[80] Cu-catalyzed azide–alkyne cycloaddition (often referred as "click chemistry") is another robust bioconjugation method, making triazole-linked glycopeptides. This method has been used to synthesize simple glycoconjugates,[81] multiglycan peptides,[80] and carbohydrate-conjugated peptide libraries.[82]

6.03.3 Amino Acid Modification

Peptides are easily degradable biomolecules, and this becomes one of the major hurdles for developing peptide therapeutics.[83] Proteases and metabolic enzymes lower half-life and bioavailability, which returns suboptimal pharmacokinetic profiles. In order to tackle these issues, numerous strategies have been devised, and this section summarizes amino acid modifications, such as D-amino acid substitution, N-methylation, C^{α}-tetrasubstitution, and β-amino acid substitution.

6.03.3.1 D-Amino Acids

Peptides and proteins are primarily composed of natural amino acids that have L-configuration. Natural peptides containing D-amino acids, however rare, do exist and are the results of posttranslational modification of L-amino acids. More than 30 examples of such D-amino acid-containing peptides have been isolated from a variety of species including frogs, snails, crustaceans, spiders, and mammals.[84] Since the unnatural configuration of D-amino acids is not recognized by proteases, substitution with D-amino acids can increase metabolic stability significantly. In addition, the D-configuration allows peptides to access different conformational spaces over their natural L-amino acid counterparts, which may impose local conformational constraints and lead to stabilization of unique structures.

The most common purpose for the incorporation of D-amino acids in synthetic peptides is to provide enhanced proteolytic stability. This is well demonstrated by the works of Tugyi and coworkers on an MUC2 peptide that contains the PTGTQ epitope of an MUC2 protein backbone-specific monoclonal antibody.[85] The N- and C-terminal flanking regions were replaced by up to three D-amino acids. The epitope function of the resulting peptides was found to be uncompromised by these D-amino acid substitutions (e.g., tpTPTGTQtpt). Extending the peptide chain with D-amino acids only to the N-terminus (tPTPTGTQTPT and tptPTGTQTPT) increased the stability, but failed to protect completely from degradation. On the other hand, adding both flanks with D-amino acids successfully offered complete protection.

[GLP-1(7–36)-NH_2] is a 30-amino acid-containing incretin and highly susceptible to degradation by DPP-IV at the penultimate peptide bond between Ala^8 and Glu^9. The resulting metabolite, GLP-1(9–36)-NH_2, is found to have 100-fold lower binding affinity to its receptor (GLP-1R) and negligible agonist activity (>10,000-fold decrease) compared with the intact peptide.[86] The cleavage of the dipeptide by DPP-IV was successfully inhibited by the substitution of Ala^8 with D-Ala with nearly no loss of biological activity.[87]

Although incorporation of D-amino acids is mostly linked to proteolytic stability, this modification has also proved valuable for enhancement of biological activity by the stabilization of a β-turn conformation as demonstrated in many peptides including α-MSH. Substitution of Phe^7 with D-Phe in α-MSH produced a potent analog by stabilizing a β-turn structure required for receptor interaction.[88] It has been found that cyclic pentapeptides with one D-amino acid placed at the $i+1$ position prefer to adopt a β-turn conformation (type II′).[89] This preference was exampled by cyclic pentapeptides of thymopoietin.[90] In addition, the cyclic RGD pentapeptide cilengitide, c[RGDf(N-Me)V], demonstrated substantially increased potency as compared with its linear peptide after introduction of D-Phe, in combination with N-methylation of Val. It is currently in phase III clinical trial for the treatment of glioblastomas.[89] Similarly, substitution of L-Pro^4 with D-Pro in β-casomorphin-(5) and β-casomorphin-(4) amide resulted in high binding affinity and selectivity to μ-opioid receptor.[91] Conversely, some naturally occurring peptides with D-amino acids have been found to lose their biological activity when substituted with L-amino acids.[92]

6.03.3.1.1 Desmopressin

One of the first examples of peptide therapeutics is desmopressin. It is an analog of vasopressin containing a desaminocysteine residue at position 1 along with D-Arg substitution for Arg at position 8.[93] The resulting vasopressin analog is orally active even at a dose 1/75th of natural lysine vasopressin, mainly due to its enhanced permeability across intestinal epithelia and proteolytic stability.[94]

6.03.3.1.2 Octreotide

Octreotide is a somatostatin analog and marketed under the brand name Sandostatin by Novartis. Before the cyclic octapeptide octreotide was developed, a potent somatostatin analog was designed with D-Trp at position 8, which increased its potency by eight-fold.[21] Conformational and structure–activity studies showed a β-turn (type II′) stabilized by the introduction of the D-Trp residue that accounts for the improvement in potency. This substitution with D-Trp was carried forward to the design of octreotide.

6.03.3.1.3 Bivalirudin

Bivalirudin, marketed as Angiomax by the Medicines Company, is a 20-amino acid-containing peptide derived from an anticoagulant protein found in the saliva of the medicinal leech, *Hirudo medicinalis*. It is a potent, highly specific, and reversible inhibitor of thrombin. D-Phe is placed at the N-terminus to provide resistance to proteolytic cleavage, resulting in an increased circulation half-life.

6.03.3.1.4 Icatibant

Icatibant is a potent, specific, and reversible antagonist to the bradykinin B2 receptor. It was approved by the FDA in 2011 for the treatment of hereditary angioedema and is marketed by Jerini under the trade name Firazyr. Icatibant is a synthetic decapeptide with structural similarity to native 9-mer bradykinin, but bearing heavy modifications with five unnatural amino acids including two D-amino acids, D-Arg^{1} and D-Tic^{8}.[95]

6.03.3.1.5 GnRH analogs

Analogs of GnRH are additional examples of D-amino acid substitution for modulating peptide conformation.[23b] Native GnRH is a 10-amino acid-containing peptide with N-terminal pyroglutamation and C-terminal amidation. As GnRH binds to its pituitary receptor with a β-turn conformation formed at Gly^{6}, a series of GnRH analogs with substitution at position 6 with various D-amino acids was synthesized (Table 6).[23b]

6.03.3.2 N-Methylation

Methylation is one of the most prevalent and simplest posttranslational modifications found in peptides and proteins. Methyltransferases are responsible for the modifications at various functional groups, including carboxylates; the sulfhydryl and thioether side chain of Cys and Met, respectively; and the nitrogen of the N$^{\alpha}$-amine group of amino acids and the side chains of Lys, Arg, His, Asn, and Gln. Among these, N-methylation is the most common and has a great impact on overall physical and chemical properties of peptides and proteins. Nature has several fine examples of N-methylated cyclic peptides (e.g., cyclosporine and omphalotin, a powerful immunosuppressant[96] and a nematicide,[97] respectively) and linear peptides (e.g., hemiasterlin, a cytotoxic peptide[98]), shown in Fig. 6.

N-Methylation is a useful tool for restricting phi and psi angles in the peptide backbone.[99] This structure-constraining strategy has been widely used to understand backbone conformations and ultimately applied to modulate the biological activity and selectivity of peptides. Proline is frequently found to induce β-turn structures and well known to have *cis*-peptide bonds.[100] Since N-methylation influences the *cis*–*trans* equilibrium of the peptide bond by inducing steric hindrance, it has been studied as a replacement for Pro.[100] One advantage of this substitution is the capability to place a side-chain functional group that is not present in Pro.

Table 6 Selected examples of D-amino acid-containing peptide therapeutics approved by the FDA[23]

Peptide	*Trade name (manufacturer)*	*Modification*	*FDA approval*
Desmopressin	DDAV (Sanofi-Aventis), Stimate (CSL Behring), Minirin (Ferring)	D-Arg^{8}	1984, 1994, 2002
Octreotide	Sandostatin (Novartis)	D-Trp^{8}	1988
Bivalirudin	Angiomax (Medicines Co.)	D-Phe^{1}	2000
Icatibant	Firazyr (Jerini)	D-Arg^{1}, D-Tic^{8}	2011
GnRH analogs			
Abarelix	Plenaxis (Praecis)	D-Asp^{6}	2003
Buserelin	Suprefact (Sanofi-Aventis)	D-Ser(tBu)^{6}	
Cetrorelix	Cetrotide (EMD Serono/Asta Medica)	D-Citrulline^{6}	1997
Deslorelin	Suprelorin (Peptech)	D-Trp^{6}	
Ganirelix	Antagon (Organon)	D-Diethylhomo-Arg^{6}	1999
Goserelin	Zoladex (AstraZeneca)	D-Ser(tBu)^{6}	1989
Leuprolide	Lupron (Takeda/Abbott), Viadur (Johnson & Johnson), Eligard (Sanofi-Aventis)	D-Leu^{6}	1985, 2000, 2002
Nafarelin	Synarel (Pfizer)	D-Napthyl-Ala^{6}	1990
Triptorelin	Decapeptyl, Trelstar (Watson Laboratories)	D-Trp^{6}	2001

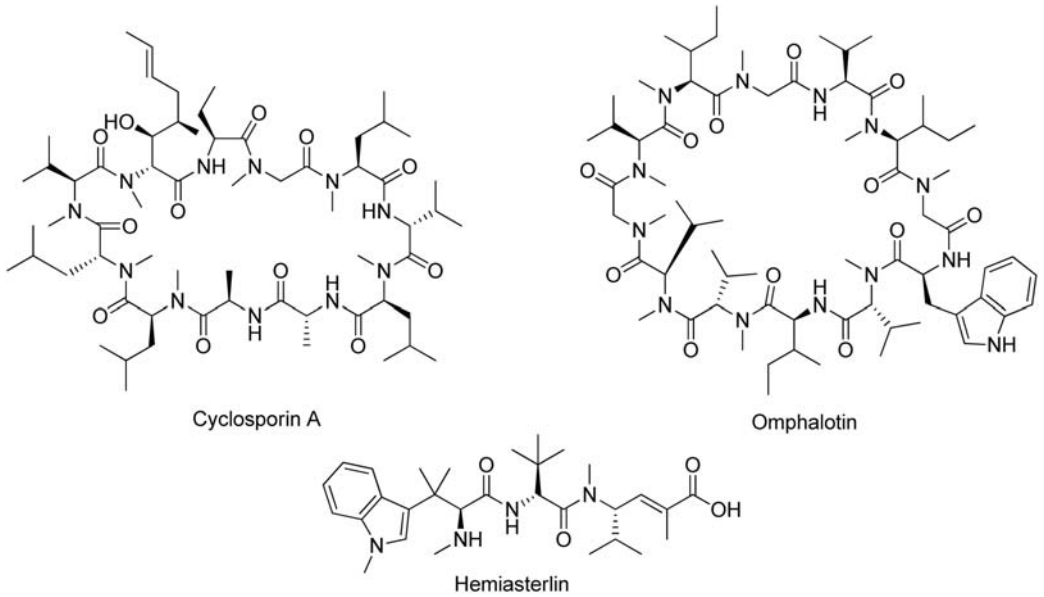

Fig. 6 Naturally occurring N-methylated cyclic and linear peptides.

Increased selectivity resulting from N-methylation is well demonstrated by cyclic RGD peptide integrin ligands.[101] N-Methylation of solvent-exposed amide bonds resulted in significant enhancement of selectivity to integrin receptor subtypes due to reduced backbone flexibility. N-Methylation also modulates the properties of a peptide by reducing the number of amide protons that play a role in forming hydrogen bonds. This property has been exploited to avoid aggregation of peptides into β sheets. For example, N-methylation of islet amyloid polypeptide at two sites resulted in a nonamyloidogenic analog.[102] It also raises hydrophobicity of peptides, which may promote membrane permeability, although the exact mechanism of enhanced permeability is not fully elucidated.[103]

N-Methylation also promotes resistance to proteolytic cleavage. For example, DhHP-6, a microperoxidase mimetic peptide that scavenges reactive oxygen species, was subjected to site-specific multiple N-methylation.[104] It was found that tri-N-methylation of DhHP-6 could significantly increase intestinal flux, which resulted in up to threefold enhanced intestinal permeability. In addition, N-methylation at a particular residue like Glu led to prolonged resistance against proteolytic degradation, resulting in up to a 140-fold longer half-life. All these features of N-methylation summate to ultimately improve bioavailability, and N-methylation has been reported in many peptides. Examples include TRH, opioid peptides, somatostatin, luteinizing hormone-releasing hormone (LHRH), bombesin, bradykinin, CCK, angiotensin II, endothelin, insulin, neurotensin, tachykinin, RGD peptides, C5a anaphylatoxin, pseudopeptides for MHC-II, β-amyloid, corticotropin-releasing factor, and growth hormone-releasing factor. Some of these peptides are currently under various stages of clinical trials, while others are already on the market (**Table 7**).[99]

N-Methylation, in particular mono-N-methylation, has been utilized in numerous peptides.[105] There are two main synthetic routes for preparing N-methylated peptides, and one involves the use of presynthesized N-methylated amino acids as building blocks for peptide synthesis. A variety of N-methylated amino acids, although expensive, are now commercially available. On the other hand, synthesis of N-methylated amino acids and derivatives is well established, including direct N^{α}-methylation of N^{α}-protected amino acids or amino acid esters and 5-oxazolidinone formation and reduction (**Fig. 7**).[106] Several other methods have been also reported, such as reductive amination, Mitsunobu reaction, and Diels–Alder and subsequent retro-Diels–Alder reactions.[99,106] Biron and coworkers reported an efficient synthetic procedure of N-methylated amino acids that does not require laborious purification steps.[106] N^{α}-Methyl-N^{α}-(*o*-nitrobenzenesulfonyl)-α-amino acids (N-Me-oNBS amino acids) are compatible with Fmoc SPPS protocols and can be prepared by N-alkylation of an N^{α}-arylsulfonylamino ester. The oNBS protecting group can be selectively removed with mercaptoethanol and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) during SPPS.

Table 7 Selected examples of N-methylated peptide therapeutics

Peptide/protein	*Trade name*	*Manufacturer*	*N-Methylation*
Cyclosporine	Sandimmune, Neoral, Restasis, Gengraf	Novartis, Allegran, Abbott	Multiple N-Me
Abarelix	Plenaxis	Praecis	N-Me-Tyr
Plitidepsin	Aplidin	PharmaMar	Di-N-Me
Cilengitide	Cilengitide (phase III)	Merck KGaA	N-Me-Val

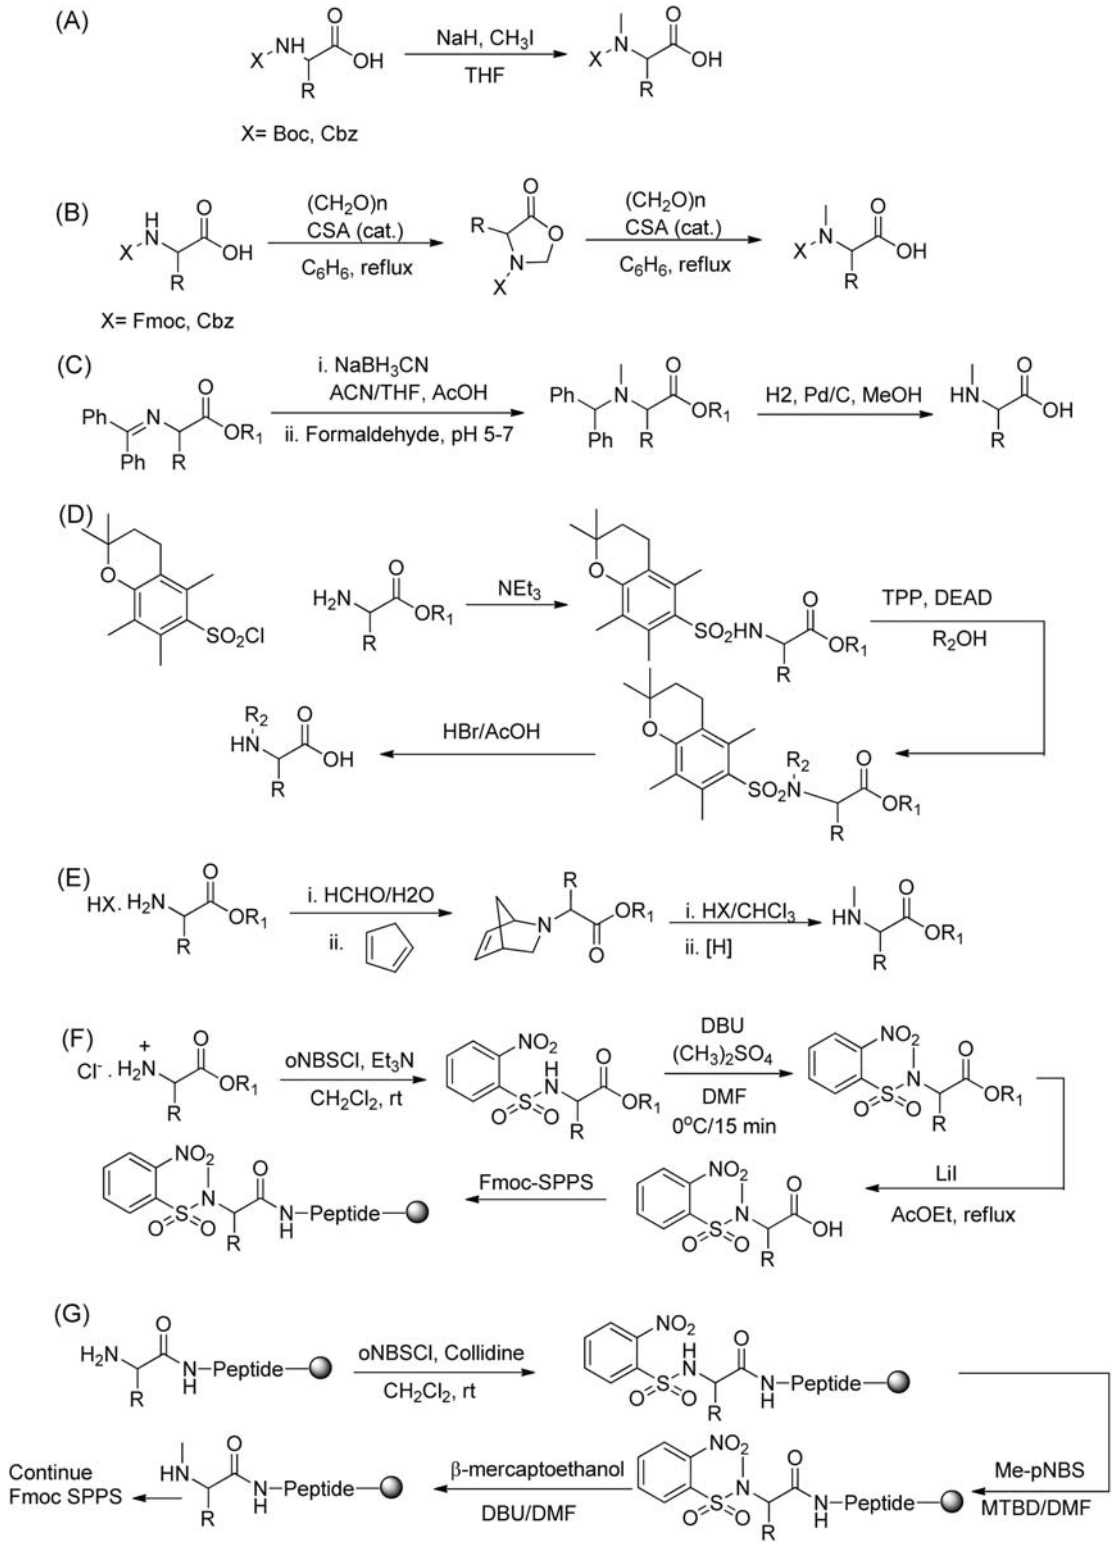

Fig. 7 N-Methylation reactions of amino acids and peptides.[106–108] (A) Direct N-methylation, (B) 5-oxazolidinone method, (C) reductive amination, (D) Mitsunobu reaction, (E) Diels–Alder and subsequent retro-Diels–Alder reactions, (F) oNBS protecting group strategy, (G) oNBS strategy on solid phase.

The second route for N-methylation involves site-specific N-methylation on a resin-bound peptide after the peptide is fully assembled in solid phase.[107] This method also involves an oNBS protecting group for site-specific methylation reactions. An activated amino group of a peptide bound on resin is methylated either via a nucleophilic substitution reaction with dimethyl sulfate and DBU[109] or via a Mitsunobu reaction.[110]

6.03.3.3 C^{α}-Tetrasubstitution

Noncoded and unnatural amino acids are frequently used in structure–activity studies of peptides to investigate and optimize their conformation and interaction with biological targets. In particular, α,α-disubstituted α-amino acids, also known as C^{α}-tetrasubstituted amino acids or quaternary amino acids, have gained tremendous attention lately.[111] While natural α-amino acids have only one side chain stemming from the α-carbon, α,α-disubstituted α-amino acids have two side chains attached to it (Fig. 8). Aminoisobutyric acid (Aib) is an example of a simple quaternary amino acid, and it is a strong helix inducer that forms 3_{10}-helices on oligomerization.

Quaternary amino acids are found in the structures of many drugs. For example, α-difluoromethylornithine,[112] eflornithine as common name, is on the WHO model list of essential medicines for the treatment of facial hirsutism and African trypanosomiasis (sleeping sickness). It is marketed by Sanofi-Aventis under the brand name Ornidyl. Similarly, methyldopa (L-α-methyl-3,4-dihydroxyphenylalanine) is an indirect-acting α-adrenergic antagonist psychoactive agent.[113] It is marketed under the brand names of Aldomet, Aldoril, and Dopamet by Aspen Pharmacare, Merck, and Novartis, respectively, for the treatment of hypertension and gestational hypertension. There are also naturally occurring peptaibol peptides that contain Aib. Alamethicin is a peptide antibiotic containing 8 Aib residues distributed throughout the sequence of 20 natural and unnatural amino acids.[114] Lantibiotics, a class of antibiotics often used as veterinary antibiotics and food preservatives, also possess Aib.[115]

Like D-amino acid substitution and N-methylation, one of the main advantages of quaternary amino acids is introduction of local conformational constraints that may induce more global structural changes. Incorporation of Aib or other related C^{α}-tetrasubstituted amino acids can create a folding nucleus for helix formation. The type of helix formed by Aib has been found to depend on the prevalence of Aib in the peptide sequence.[116] It was observed that 3_{10}-helices are favored when more than 40% of the sequence are Aib, while α-helices are preferred when the Aib content in the sequence is less than 40%. As unnatural amino acids, they offer proteolytic resistance and may increase selectivity and affinity to target proteins. For instance, mono- or di-Aib substitution of D-Ala^2 and/or Phe^3, critical N-terminal residues of amphibian skin opioid deltorpin C, exhibited high δ-opioid receptor affinity and up to ninefold greater selectivity than the parent peptide.[117] Substitution with Aib also resulted in inhibition of human islet amyloid polypeptide amyloid fibril formation.[118]

6.03.3.4 β-Amino Acids

While naturally occurring α-amino acids have both amino and carboxylic acid groups bonded to the same α-carbon center (C^{α}), β-amino acids have the amino group connected to the β-carbon (C^{β}). The major difference between β-peptides and their natural α-counterparts is the addition of a methylene group to the peptide backbone. There are two types of β-amino acids, β^2-amino acids and β^3-amino acids (Fig. 9A). A β-amino acid with its side chain attached to the α-carbon is called a β^2-amino acid. If the side chain is bonded to the β-carbon, it is called a β^3-amino acid. Peptides made up of β^2-amino acids are referred as β^2-peptides, and β^3-peptides consist of β^3-amino acids.

β-Peptides are similar to α-peptides in many ways. Both contain amide bonds capable of forming and stabilizing intra- and intermolecular hydrogen bonds.[119] β-Peptides adopt diverse secondary structures, such as helices, sheets, and turns, contradictory to earlier speculation that the additional carbon–carbon bond in the backbone may cause chaotic increase in their structures.[120] More diverse structures like 10/12-, 12-, and 14-helices are indeed observed.[121] This suggests that β-amino acids can offer structural diversity and exert unique and significant biological functions unsatisfied by α-amino acids alone.[122]

Among many β-amino acids occurring in natural products, β-alanine is the most prevalent. It is an essential amino acid component of pantothenic acid in coenzyme A and carnosine in muscle tissue. β-Amino acids are found in cyclic nonribosomal peptides and their polyketide hybrids that include microcystin-LR, iturin A, guineamide A, and dolastin D.[122] Some of the most common biologically active natural products that contain β-amino acids are the anticancer agent taxol, the infamously addictive drug cocaine, and the antibiotics, penicillin V and nocardicin A. While β-amino acid building blocks are commercially available for the synthesis of β-peptides, a number of synthetic methods have been developed, including Arndt–Eistert homologation of N-protected α-amino acids.[123]

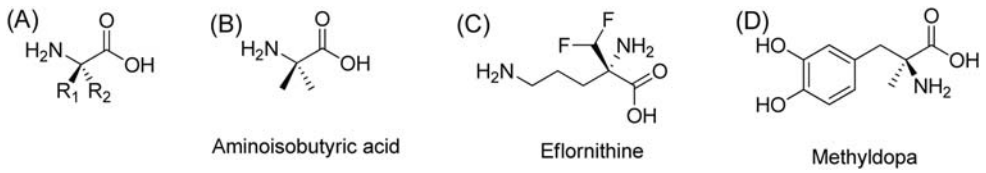

Fig. 8 Structures of (A) C^{α}-tetrasubstituted amino acid, (B) aminoisobutyric acid (Aib), (C) eflornithine, and (D) methyldopa.

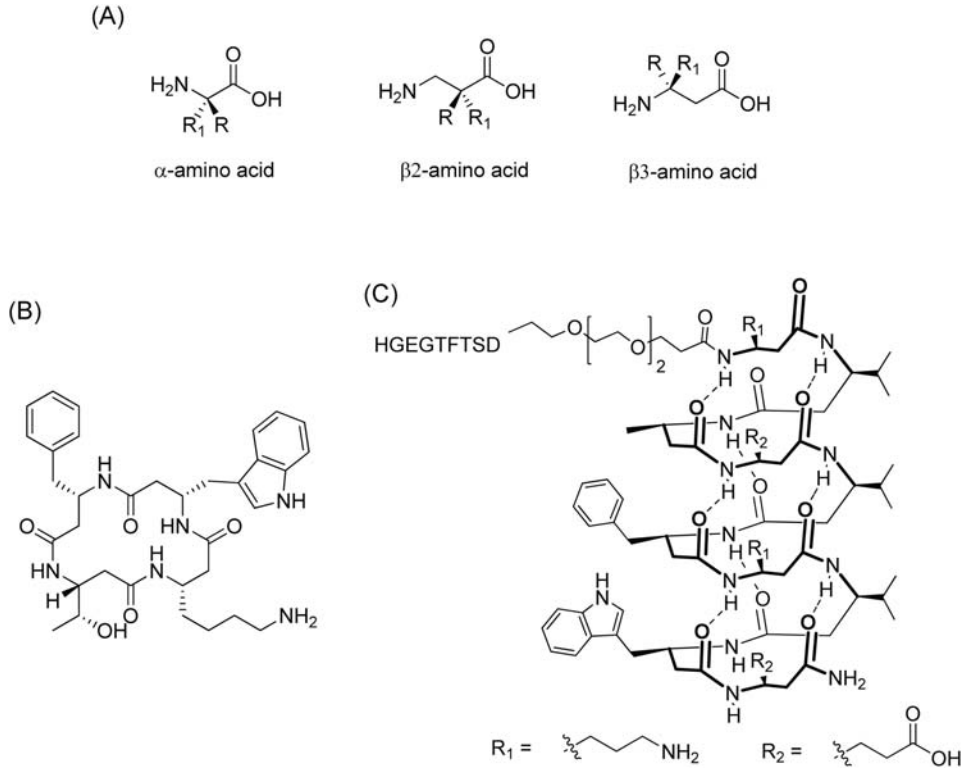

Fig. 9 Structures of (A) α-, β^2-, and β^3-amino acids, (B), β-peptide analog of octreotide, and (C) β^3-peptide analog of GLP-1.

Although biologically active peptides are dominated by α-peptides, β-peptides have been of interest since as early as the 1920s.[120] The major advantage of β-peptides over the α-form is that β-peptides are stable to proteolytic degradation in vitro and in vivo. This has encouraged the incorporation of β-amino acids to achieve increased resistance to enzymatic degradation, while maintaining the structure and function of natural peptides. Seebach and coworkers conducted one of the simplest yet most successful comparisons of their structural and enzymatic stability by using a β-hexapeptide [H-(β-HVal-β-HAla-β-HLeu)$_2$-OH] and its natural α-counterpart [H-(Val-Ala-Leu)$_2$-OH].[123] Surprisingly, β-peptide helices are more stable than those present in α-peptides. In addition, the β-peptide was resistant to cleavage by pepsin at pH 2 for at least 60 h, whereas the corresponding α-hexapeptide was degraded almost instantaneously.

Besides the structural and metabolic stability, β-peptides have been examined on their capability of interacting with proteins. For example, a β^3-decapeptide was designed based on the HIV gp41 C-terminal WWI epitope and it was found to inhibit gp41 six-helix bundle formation.[124] It was also demonstrated that short β-peptide 14-helices can inhibit an intramolecular PPI in vivo. β-Peptide analogs of the cyclic α-octapeptide octreotide have been investigated to improve the biological properties (**Fig. 9B**), and it is interesting that a β-peptide analog, although in a micromolar range, showed affinity to five human somatostatin receptors.[125] Likewise, a β^3-peptide analog of GLP-1 was developed by Schepartz and coworkers.[126] The analog is made of nine α-amino acids at the N-terminus of exendin-4 and a 14-helix β^3-peptide at the C-terminus, connected together with a short PEG chain (**Fig. 9C**). Despite a weak potency, this analog can interact with and activate the GLP-1 receptor. While the natural GLP-1 is highly susceptible to proteolytic degradation, the β^3-peptide analog showed significantly enhanced in vivo stability.

In addition to homogenous β-peptides, mixed α/β-peptides have also been investigated. A cyclic tetrapeptide c[Ser(OtBu)-β-Ala-Gly-β-Asp(OMe)] forms a 14-membered ring with alternating α- and β-amino acids, and it was found to make a tubelike assembly by virtue of stacks of intermolecular hydrogen bonds.[127] Similarly, Clark and coworkers developed a new class of self-assembling transmembrane ion channels in phospholipid bilayers based on cyclic β^3-peptides.[128] It is interesting that the conformation adopted by an α/β-peptide can be controlled by the pattern of β-amino acids in the backbone and other molecular parameters like the side-chain topology and solvent.[129] Alternating α- and β-amino acids in the sequence prevents the resulting α/β-peptides from being recognized by proteolytic enzymes, enhancing enzyme stability.[130]

6.03.4 Peptide Bond Replacements and Pseudopeptides

All the peptide modifications described earlier (e.g., peptide truncation; N-acetylation and pyroglutamylation; conjugation of PEG, oligosaccharide, and lipid; and substitution with D-, *N*-methyl, and β-amino acids) have one thing in common: the native amide

bond. The outcome of these modifications is still a peptide. On the other hand, a new class of molecules known as pseudopeptides, also referred to as amide bond surrogates, arises when the amide bond is replaced by other functional groups, altering the backbone structure of peptides (Fig. 10). The nomenclature used for such a replacement is known as a "psi bracket," indicating the type of chemical structure incorporated.[131] For example, an Ala-Gly pseudopeptide with a CH_2CH_2 backbone is denoted as Alaψ[CH_2CH_2]Gly. The advantage of pseudopeptides is complete resistance to proteolytic degradation of the amide bond. This advantage, however, comes with a heavy toll for conformation, flexibility, and hydrophobicity.

6.03.4.1 Reduced Bond (CH_2NH)

Reduced peptide bond ψ[CH_2NH] is one of the simplest peptide bond replacement strategies, and it offers free rotation around the C═N bond (ω angle).[132] This change helps to determine the significance of a carbonyl group or specific amide bond in peptides. It introduces a basic functional group (i.e., amino group) that can be protonated and increase the hydrophilicity.[131] It has been widely used in the design of metabolically stable analogs of natural peptides.[132] For example, an amide bond surrogate ψ[CH_2NH] between Tyr^1 and Gly^2 of Met-enkephalin improved the potency by twofold compared with the unmodified peptide, in combination with a methioninol replacing Met at the C-terminus.[133] On the other hand, replacement of the same amide bond with a hydrocarbon analog (CH_2CH_2) led to a significant decrease in activity compared with its reduced bonded analog. Similarly, replacement of the natural amide bond between Leu^{10} and Leu^{11} of an octapeptide analog (residues 6–13) of equine angiotensinogen with the reduced bond surrogate CH_2NH significantly increased binding affinity and resistance to the cleavage by renin.[134]

6.03.4.2 Methylene Thioether (CH_2S)

Methylene thioether ψ[CH_2S] replacement is another reduced bond surrogate. It increases the lipophilicity and may be advantageous for membrane permeability; however, it may lead to a loss of potency by virtue of its high flexibility.[131] For example, ψ[CH_2S] replacement between Gly^6 and Leu^7 in an LHRH agonist resulted in a loss of activity, while the same replacement between

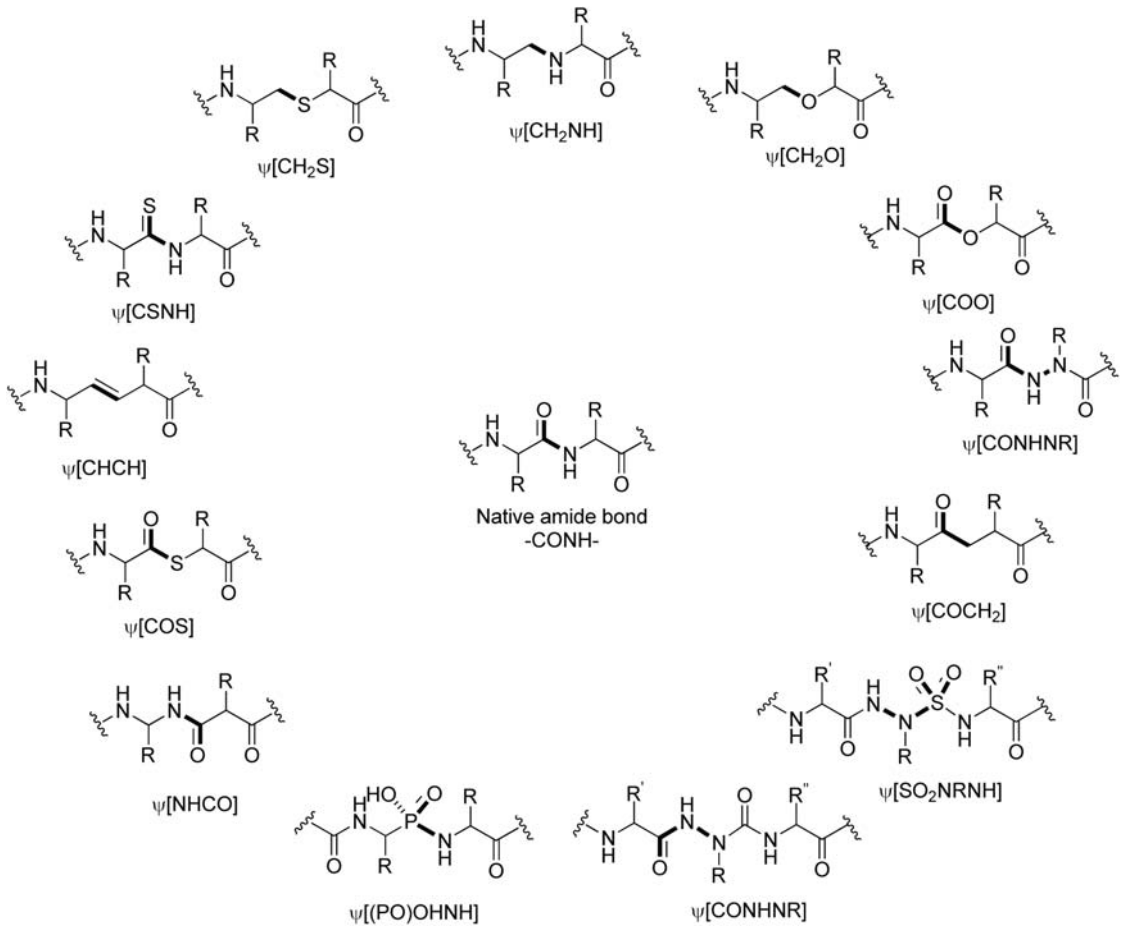

Fig. 10 Structures of amide bond surrogates.

Tyr^5-Gly^6 and Pro^9-Gly^{10} retained about 2% and 10% of the original activity, respectively.[135] In the case of antagonist analogs, the N- and C-terminal modification retained substantial LHRH and FSH inhibitory activity, while the modification at the amide bond between positions 6–7 was not tolerated.

6.03.4.3 Methylene Ether (CH_2O)

Methylene ether ψ[CH_2O] pseudopeptides are very similar to methylene thioester analogs with respect to their conformation and lipophilicity. This reduced backbone consists of an oxygen atom instead of the amino group that participates in the amide bond formation in natural peptide linkage.

6.03.4.4 Alkylidene (CH═CH)

Preservation of the stereochemistry imparted by the natural amide bond may be of importance when choosing a suitable surrogate. An alkylidene ψ[CH═CH] surrogate can be the best replacement for mimicking the planarity and rigidity of an amide bond.[131] In addition, the distance between the two α-carbons (C^{α}═C^{α}) is also found to be equal to that of natural dipeptides. An example of such a modification is the N-terminal amide bond replacement of Leu^5-enkephalin analogs by a *trans*-double bond.[136] The ψ[CH═CH] pseudopeptide replaced at Tyr^1-Gly^2 retained comparable activity with that of its parent peptide.

6.03.4.5 Endothiopeptide (CSNH)

A thioamide group is isosteric to the amide bond. Instead of a carbonyl, a thioamide has a thiocarbonyl group. Replacement with a thioamide bond ψ[CSNH] retains the bond length and angle within 0.01 Å and 0.5° compared with the natural amide bond.[137] Conversion of an amide carbonyl to a thiocarbonyl has become relatively easy with the development of a thionation reagent called Lawesson's reagent.[138] Endothiopeptides containing a thioamide in their backbones cannot form a strong hydrogen bond with it, and this may reveal critical information on the importance of a particular amide bond.[139]

6.03.4.6 Depsipeptide (CO_2)

In depsipeptides, one or more of the amide bonds are replaced with an ester bond ψ[CO_2]. There are a number of depsipeptides in nature, especially cyclic depsipeptides such as anticancer agent romidepsin, antibiotic agent etamycin, and anti-HIV agents papuamides A and B. Synthesis of depsipeptides is relatively easier compared with other pseudopeptides. Depsipeptides are synthesized with α-hydroxy acids as building blocks that can be prepared from α-amino acids.[140] Modification of the amide bond to an ester increases the lipophilicity that may subsequently increase cell permeability. Depsipeptides have been also used to determine the importance of hydrogen bonds that are formed by amide bonds in natural peptides.

6.03.4.7 Thioester (COS)

Thioester ψ[COS] modification on the peptide backbone is not widely used, because enzymes that hydrolyze the native amide bond can also cleave thioester bonds at an approximately equal rate of proteolytic degradation. Like depsipeptides, thioester backbones are relatively easy to be synthesized compared with other pseudopeptides, by condensation between an α-amino acid and an α-mercapto acid.

6.03.4.8 Ketomethylene ($COCH_2$)

A ketomethylene ψ[$COCH_2$] surrogate consists of a ketone functional group and a methylene moiety substituting for the amino group of an amide bond. It is highly resistant to degradation by proteases, but lacks the rigidity of the native amide bond. Since the ketomethylene group cannot serve as a hydrogen bond donor, its exchange of an amide bond may cause a substantial impact on the overall structure of peptides. Two ketomethylene analogs of substance P were synthesized by incorporating the ketomethylene surrogate ψ[$COCH_2$] between Phe^8 and Gly^9, and a hexameric pseudopeptide was found to be a full agonist and contracted isolated guinea pig ileum with 70% potency of the parent peptide.[141] It also acts as a potent inhibitor of substance P-degrading peptidase.

6.03.4.9 Phosphonamide (PO_2RN)

Enzyme inhibitors have been designed by replacing a scissile amide bond with an isostere that mimics the tetrahedral transition state of enzyme-catalyzed amide bond hydrolysis. The tetrahedral phosphorus atom in an α-aminophosphonamide or α-aminophosphonamidate ψ[PO_2RN] offers this geometry and leads to strong inhibition of proteases.[142] Cyclophilins are peptidylprolyl isomerases (PPIases) that catalyze the *cis–trans* interconversion of the aminoacyl-prolyl amide bond.[143] PPIases play a critical role in protein folding, replication of HIV-1 virions in host CD4 + T-cells, and other biological processes like cellular multiplication and communication.[144] As a cytosolic member of the human cyclophilin subfamily, hCyp-18 is also the main receptor of the

undecapeptide cyclosporine, implicated in immunosuppression.[145] Damage and coworkers made a phosphonamide analog containing a Glyψ(PO_2RN)Pro surrogate (R═H or alkyl group) as a selective transition-state analog inhibitor of cyclophilin, and this pseudopeptide was found to be a micromolar inhibitor of hCyp-18 (Fig. 11B).[147]

6.03.4.10 Azapeptide (CONHNR)

Bearing semicarbazides, azapeptides are created by substituting the α-carbon atom of an α-amino acid with a nitrogen atom. This connects the side chain of an α-amino acid to the achiral nitrogen center instead of the chiral α-carbon. Experimental and theoretical studies have demonstrated that aza-amino acids in peptides have characteristic structural preferences.[148] The dihedral angles (ϕ and ψ) of aza-amino acids favor 90° ± 30° and 0° ± 30° and 90° ± 30° and 180° ± 30°, which promote and stabilize β-turn and polyproline II structures, respectively, when placed at the $i+2$ position.[148]

As β-turn conformations are recognized by numerous proteins, such as the cluster of differentiation 36 (CD36) class B scavenger receptor, integrins, and the prostaglandin $F_{2\alpha}$ receptor (FP), azapeptides have been designed to target such proteins. Hexarelin is a β-turn adopting hexapeptide ligand to the CD36 receptor, and two azapeptides were developed to stabilize the β-turn structure (Fig. 12A).[149] They exhibited comparable affinities (2.4 and 1.3 μM) with that of hexarelin (2.3 μM). Cyclic RGD pentapeptides, such as peptide 1 and cilengitide (Fig. 12B), adopt a β-turn conformation and exhibit subnanomolar activity with high selectivity for the $\alpha_v\beta_3$ integrin receptor.[150] Aza-scanning is substitution of an aza-amino acid for each α-amino acid residue in the sequence of a peptide,[151] and aza-scanning of cyclic RGD pentapeptide antagonists discovered an aza-Gly-containing analog that retained nanomolar activity to the $\alpha_v\beta_3$ integrin receptor.[151]

The prostaglandin FP plays a crucial role in regulating uterine activity for human labor and parturition. In search of novel tocolytic agents, azapeptides have been developed and showed strong potency in lowering the strength and duration of both PGF2α-induced and spontaneous myometrium contractions.[152] Azapeptides were designed to mimic a potent ligand to FP, PDC113.824, and were found to adopt a β-turn structure (type I and II′)[152b] and showed significant tocolytic activity in delaying preterm labor in a mouse model (Fig. 12C).[152a]

6.03.4.11 Azasulfurylpeptide (AsF, CONHNRSO$_2$)

AsFs are peptidomimetics possessing an amino acid residue of which the α-carbon and the carbonyl have been replaced with a nitrogen atom and a sulfonyl group, respectively, to form an *N*-aminosulfamide group. The tetrahedral sulfur in the *N*-aminosulfamide moiety favors an ω-torsional angle of ±90° and ϕ-torsional angle of ±60° and ±100°, instead of *cis*- and *trans*-amide configurations at 0° and ±180°, respectively. Because of these preferred dihedral angles, AsFs are found to adopt a γ-turn conformation and show higher stability to enzyme degradation.[153] An AsF was designed with an azasulfurylphenylalanine moiety to mimic the tetrahedral transition-state geometry and was found to be a micromolar inhibitor of HIV-1 proteinase (Fig. 13). Human urotensin $II^{(4-11)}$ (*h*UII) is a vasoconstrictor peptide and has been suggested to adopt a γ-turn conformation that is stabilized by a disulfide bridge and intramolecular hydrogen bonds between Trp^7 and Tyr^9.[154] Cyclic AsFs of *h*UII were synthesized to investigate the role of backbone structure on their biological activity.[154]

6.03.4.12 Retro-Inverso (RI, NHCO)

RI peptides are linear peptides of which the amino acid sequence is reversed and the α-carbon chirality of the amino acid residues is inverted from L to D (Fig. 14). This isosteric modification maintains the side-chain topology identical to the parent peptide in an

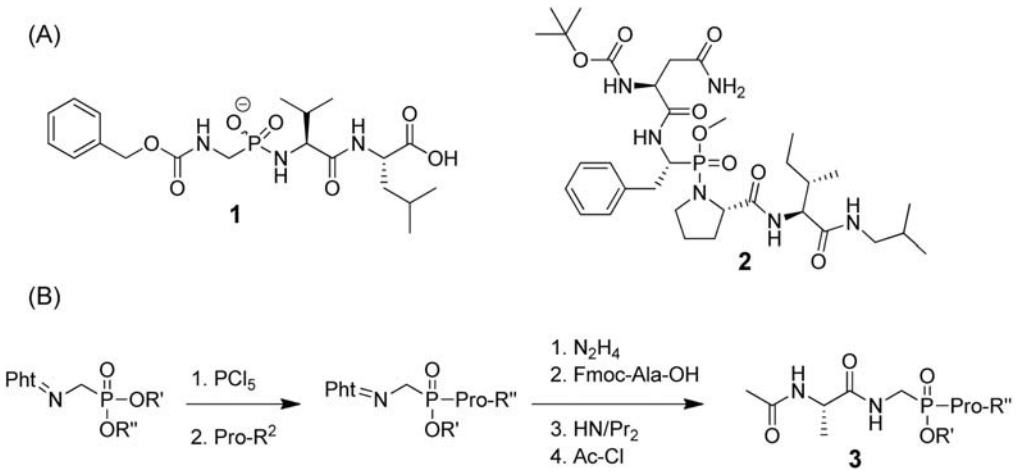

Fig. 11 (A) Structures of a phosphonamide inhibitor of thermolysin (1)[146] and a phosphonamidate inhibitor of HIV-1 proteinase (2)[142] and (B) synthesis of a phosphonamide inhibitor of hCyp-18 (3).[147]

extended conformation.[155] RI peptides are an attractive alternative to natural peptides as pharmaceuticals due to their high metabolic stability with retention of the majority of pharmacophores and potentially comparable biological activity. Thus, RI peptides have been widely employed for the study of PPIs through the design of peptidomimetics that emulate the shape of peptide epitopes and interfaces of PPIs.[156]

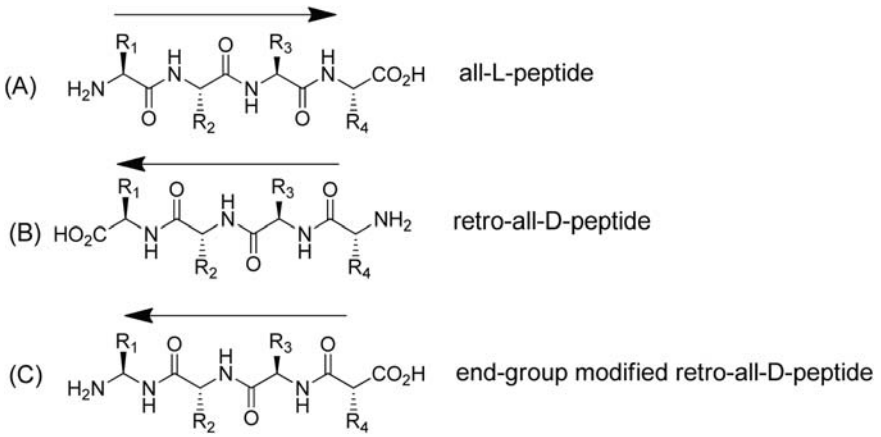

Fig. 14 Structures of retro-inverso peptides: (A) L-peptide, (B) retro-inverso peptide, (C) end group-modified retro-inverso peptide containing a gem-diaminoalkyl residue at R_1 and a malonyl residue at R_4.

Chorev[155] and coworkers synthesized partially modified RI analogs of enkephalin (Fig. 15A and B), in which two consecutive peptide bonds were reversed by introduction of gem-diamino and D-amino acids.[157] The formyl group at the C-terminus reproduces the electronic and steric characteristics of a carboxamide. The RI peptides 15A and 15B are three times as potent as their corresponding natural enkephalins 15C and 15D, respectively. Notably, the RI peptides 15A and 15B also displayed an activity profile similar to that of β-endorphin inducing catatonia in rats that lasted 3 h following intracisternal injection, indicating that the RI linkage can protect the peptides from enzymatic degradation.[157]

Schorderet and coworkers developed a cell-permeable and protease-resistant peptide inhibitor to selectively block the access of c-Jun NH_2-terminal kinase (JNK) to c-Jun.[158] The RI peptide D-JNKI-1, also known as XG-102, comprises a 10-amino acid-containing HIV transcriptional activator (Tat) (48–57) delivery sequence and a 20-residue long JNK-binding motif (JBD20) of JNK-interacting protein-1/islet-brain 1 with two Pro residues inserted as a spacer between the Tat and JBD20 peptides to allow maximal flexibility (Fig. 16). The use of all-D-retro-inverso form (D-JNKI-1) brought in remarkable stability against proteolytic degradation and extended its half-life in vivo. D-JNKI-1 showed inhibitory activity against JNK (IC_{50} ~20 μM), whereas 1 μM of D-JNKI-1 is

sufficient for preventing pancreatic β cells from interleukin-1β-induced apoptosis by 50%.[158] D-JNKI-1 was examined for its neuroprotective effect in an ischemic stroke model in rodents.[159] D-JNKI-1 was expected to block neuronal apoptosis induced by excitotoxicity during cerebral ischemia. This cell-penetrating RI peptide showed powerful protection (>90%), even when D-JNKI-1 was administered 6–12 h after the onset of ischemia. This study indicates that neuronal death can be blocked even 6–12 h after the onset of stroke and established a proof of principle for the JNK pathway as a target for therapeutic intervention.[159]

To overcome enzymatic barriers in the blood–brain barrier (BBB) as well as in circulating blood, Lu and coworkers developed an RI peptide ligand to nicotine acetylcholine receptors (nAChRs)[160] based on a 16-amino acid-containing peptide ^{L}CDX that was derived from the loop II region of the snake neurotoxin candoxin (Fig. 16).[161] BBB mainly consists of brain endothelial cells connected by tight junctions and protects the brain from toxic molecules in the bloodstream while supplying essential nutrients to the brain. However, BBB becomes a hurdle to drugs and drug delivery systems for the treatment of CNS diseases.[162] nAChRs are highly expressed in brain capillary endothelial cells, and they have been known to promote BBB crossing to deliver various therapeutic agents to the brain.[161]

^{D}CDX, an RI analog of ^{L}CDX, showed fivefold higher binding affinity ($IC_{50}=84.5$ nM) as compared with the parent L-peptide ^{L}CDX ($IC_{50}=441.6$ nM). In addition, ^{D}CDX was found to be exceptionally stable in lysosomal homogenate and serum after 4 h incubation, while ^{L}CDX underwent fast degradation. ^{D}CDX demonstrated significantly higher transcytosis efficiency in an in vitro BBB monolayer as compared with ^{L}CDX. In vivo studies showed that ^{D}CDX mediates brain-targeted drug delivery of doxorubicin-loaded liposomes when conjugated to the surface of PEGylated liposomes and significantly prolongs the survival time of intracranial human glioblastoma multiforme-bearing nude mice.

6.03.5 Macrocyclic Peptides

Functions of proteins depend on properly formed three-dimensional structures that are organized by highly ordered folding of polypeptide backbones.[163] Small yet structurally defined regions are frequently responsible for biological activity of proteins; thus, they are of high interest for development of new therapeutic candidates. However, such short peptide segments, typically containing less

than 15 amino acid residues, have several limitations for therapeutic application. Short peptides often lose their well-defined structures or adopt less organized conformations in solution when taken out of proteins, which results in loss of binding affinity to their targets. In addition, short peptides are prone to proteolytic degradation, especially in an extended conformation,[164] and have difficulty in penetrating cellular membranes.[165] These drawbacks severely compromise the use of short peptides as therapeutics. Cyclization has been recognized as an efficient means to restrict peptide conformational flexibility and promote protein-like bioactive conformations.[166] Cyclic peptides often exhibit enhanced potency, proteolytic stability, membrane permeability, and bioavailability, all of which strongly improve drug-like properties.[131,167]

6.03.5.1 Tyrocidine A

Tyrocidine A is a cyclic decapeptide isolated from *Bacillus brevis*, showing bactericidal activity against a broad spectrum of Gram-positive organisms.[168] It forms an amphipathic β-sheet structure in which the hydrophobic face is oriented toward the membrane interior, while the hydrophilic surface is presented to the aqueous phase.[169] The cyclic peptide binds to bacterial membranes and disrupts structural integrity, resulting in bacterial cell death.[170] Walsh and coworkers employed a chemoenzymatic approach to achieve macrocyclization of tyrocidine A in which isolated thioesterase domains catalyzed the cyclization of linear peptides that were immobilized on a solid-phase support with a biomimetic linker (**Fig. 17**). They constructed a library of cyclic peptides containing natural and unnatural amino acids at the D-Phe^4 position. Two analogs, A02 and F10, displayed broad-spectrum activity against Gram-positive and Gram-negative microorganisms and reduced hemolytic effects related to the tyrocidine A.[171]

6.03.5.2 Cyclosporine A

Cyclosporine A is an immunosuppressant indicated for preventing organ rejection in transplantation surgery. It is a highly N-methylated, macrocyclic, 11-amino acid-containing peptide isolated from the fungus *Tolypocladium inflatum* (*Beauveria nivea*).[172] This macrocyclic peptide consists of seven N-methylated amino acids and four hydrogen-bonded amide protons, and it displays drug-like properties, such as cell membrane permeability, proteolytic stability, and oral bioavailability.[173] Wenger synthesized cyclosporine A by first coupling two short peptides (tetra- and heptapeptides shown in **Fig. 18A**), which contained the unusual amino acid (2S,3R,4R,6E)-3-hydroxy-4-methyl-2-methylamino-6-octenoic acid, followed by cyclizing the linear undecapeptide with (benzotriazol-1-yloxy)tris(dimethylamino)phosphonium hexafluorophosphate (BOP).[174]

Danishefsky and coworkers utilized an isonitrile coupling reaction to synthesize cyclosporine A (**Fig. 18B**). In the isonitrile-mediated amide bond formation, a thioacid was treated with an isonitrile to provide a putative formimidate (thio)carboxylate mixed anhydride that was intercepted by an amine, generating a dipeptide. The isonitrile coupling method was used to elongate the peptide and cyclize the linear undecapeptide.[175]

6.03.5.3 Colistin A

Colistin (polymyxin E) is a polymyxin antibiotic produced by the soil bacterium *Bacillus polymyxa*.[176] It was approved in the late 1950s for the treatment of acute and chronic infections caused by certain sensitive strains of Gram-negative bacteria. After

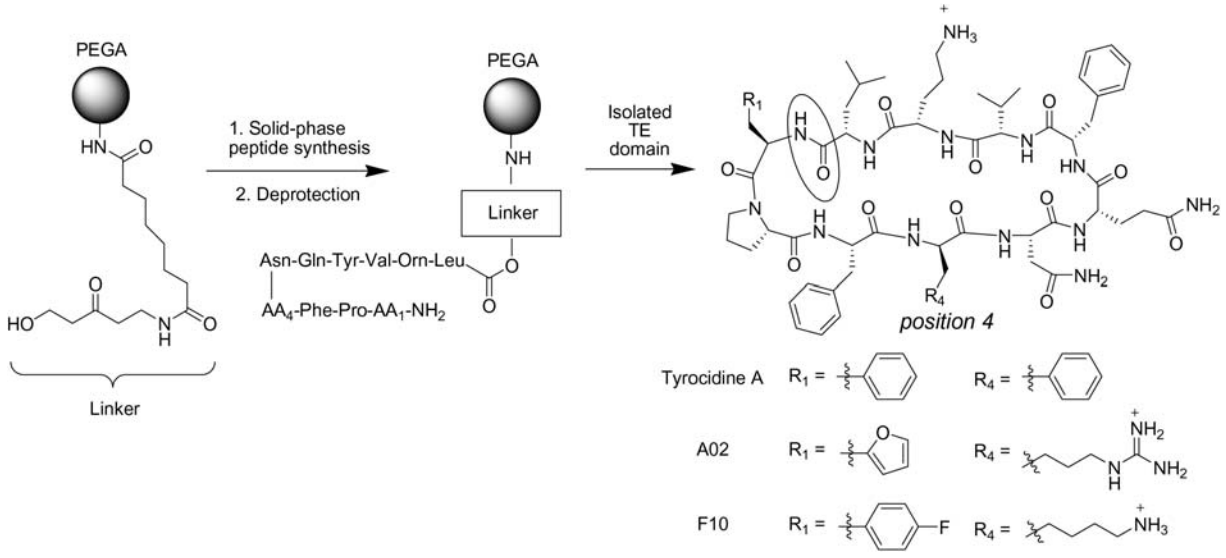

Fig. 17 Biomimetic macrocycle synthesis of tyrocidine A and its analogs.

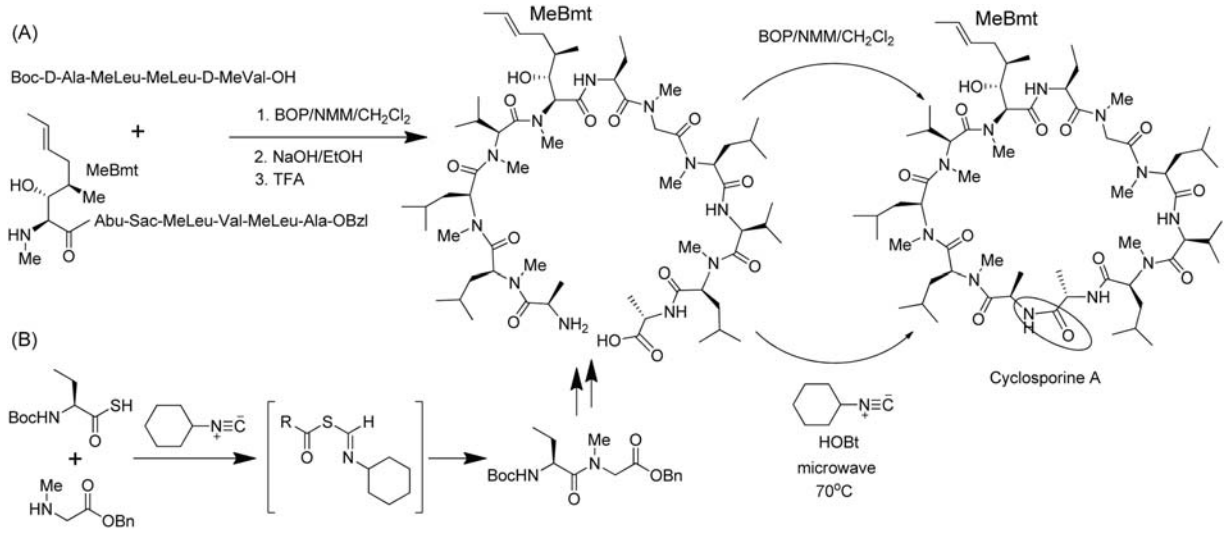

Fig. 18 Synthesis of cyclosporine A.

introduction in clinical practice, the use of colistin gradually declined because of its nephrotoxicity. However, with antibacterial resistance on the rise, colistin was recently reintroduced to treat severe, multidrug-resistant Gram-negative bacterial infections.[177]

Colistin is a mixture of cyclic polypeptides colistin A and B that are acylated by (*S*)-6-methyloctanoic acid and (*S*)-6-methylheptanoic acid, respectively. The hydrophobic (N-terminal fatty acyl chain and a D-Leu-Leu) and hydrophilic (three or four cationic amino acids) regions of colistins create amphiphilic surfaces that enable detergent-like interactions with bacterial membranes and bactericidal action. Colistin interacts with the lipid A of lipopolysaccharides (LPSs) on the outer membrane of Gram-negative bacteria and displaces the calcium and magnesium bridges that stabilize the LPS. Subsequently, colistin permeabilizes the bacterial outer membrane and disrupts the integrity of the inner membrane, ultimately causing cell death.[178] Kline and coworkers reported a synthetic procedure using Fmoc/tBu SPPS protocols and Alloc protection for Dab[4] (Fig. 19). The partially protected peptide, prepared on 2-chlorotrityl resin, underwent a cyclization reaction, followed by full deprotection to afford colistin.[179]

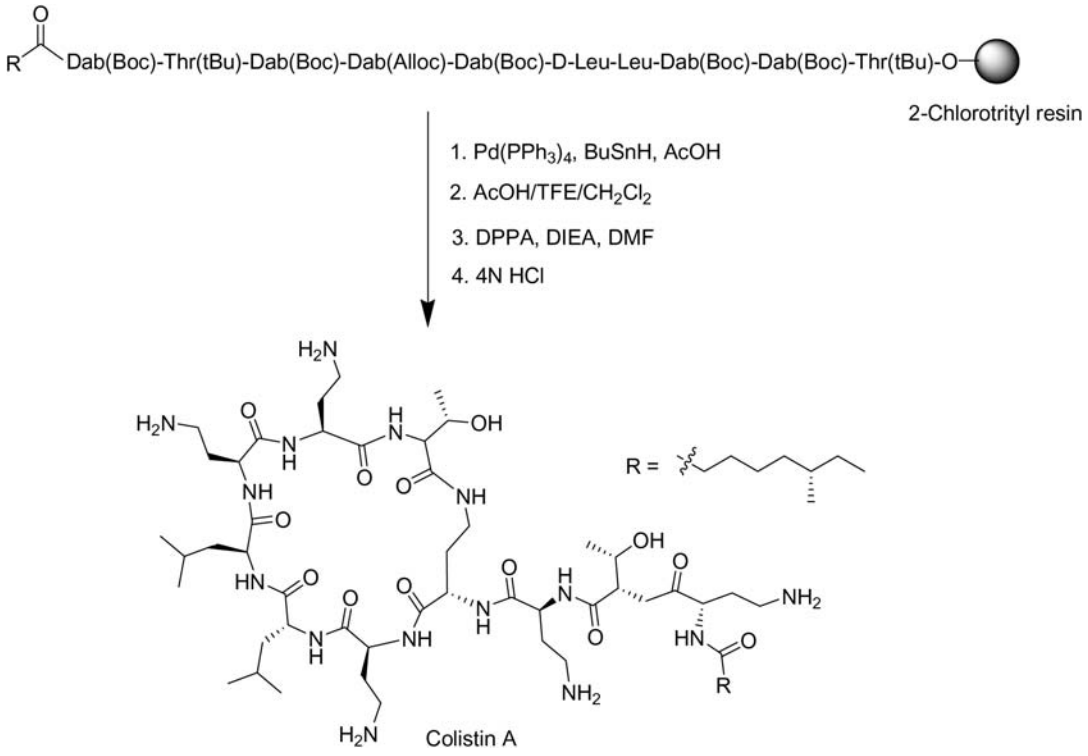

Fig. 19 Solid-phase synthesis of colistin A.

6.03.5.4 PMX53 (3D53)

Complement fragment (C)5a is a 74-amino acid-containing pro-inflammatory polypeptide produced during activation of the complement cascade of serum proteins in response to stimuli, such as infectious organisms (e.g., bacteria, viruses, and parasites) and tissue damaged by physical, chemical, or neoplastic insults.[180] C5a regulates many types of cells, including human immune cells, by binding to a specific receptor on the cell surface, triggering cellular immune responses, and releasing numerous inflammatory mediators.[181] However, overexpression or underregulation of C5a is implicated in several diseases like rheumatoid arthritis, adult respiratory distress syndrome, ischemia/reperfusion injury, and sepsis.[182]

In an effort to combat the effects of C5a in disease development, Fairlie and coworkers developed a C5a antagonist by mimicking the C-terminus of C5a responsible for binding to and activating the C5a receptor. Based on the structure of a truncated hexapeptide,[183] PMX53 was derived to stabilize a putative turn structure. PMX53 features a pentapeptide macrocycle formed by a lactam linkage between Orn^2 and Arg^6.[184] It showed potent full antagonism ($IC_{50} = 20$ nM) and oral activity at 0.3–10 mg kg^{-1} doses in rodent models of inflammatory and other diseases and is currently under clinical trials.[182]

PMX53 was prepared by cyclizing the linear peptide in solution that was synthesized on PAM resin using Boc chemistry (Fig. 20A).[184] In a convergent approach, two tripeptide fragments, Ac-Phe-Orn-(Boc)-Pro-OH and H-D-Cha-Trp(For)-Arg-OEt, were coupled to form a linear hexapeptide that, after deprotection, was cyclized in solution with BOP, affording PMX53 (Fig. 20B).[185]

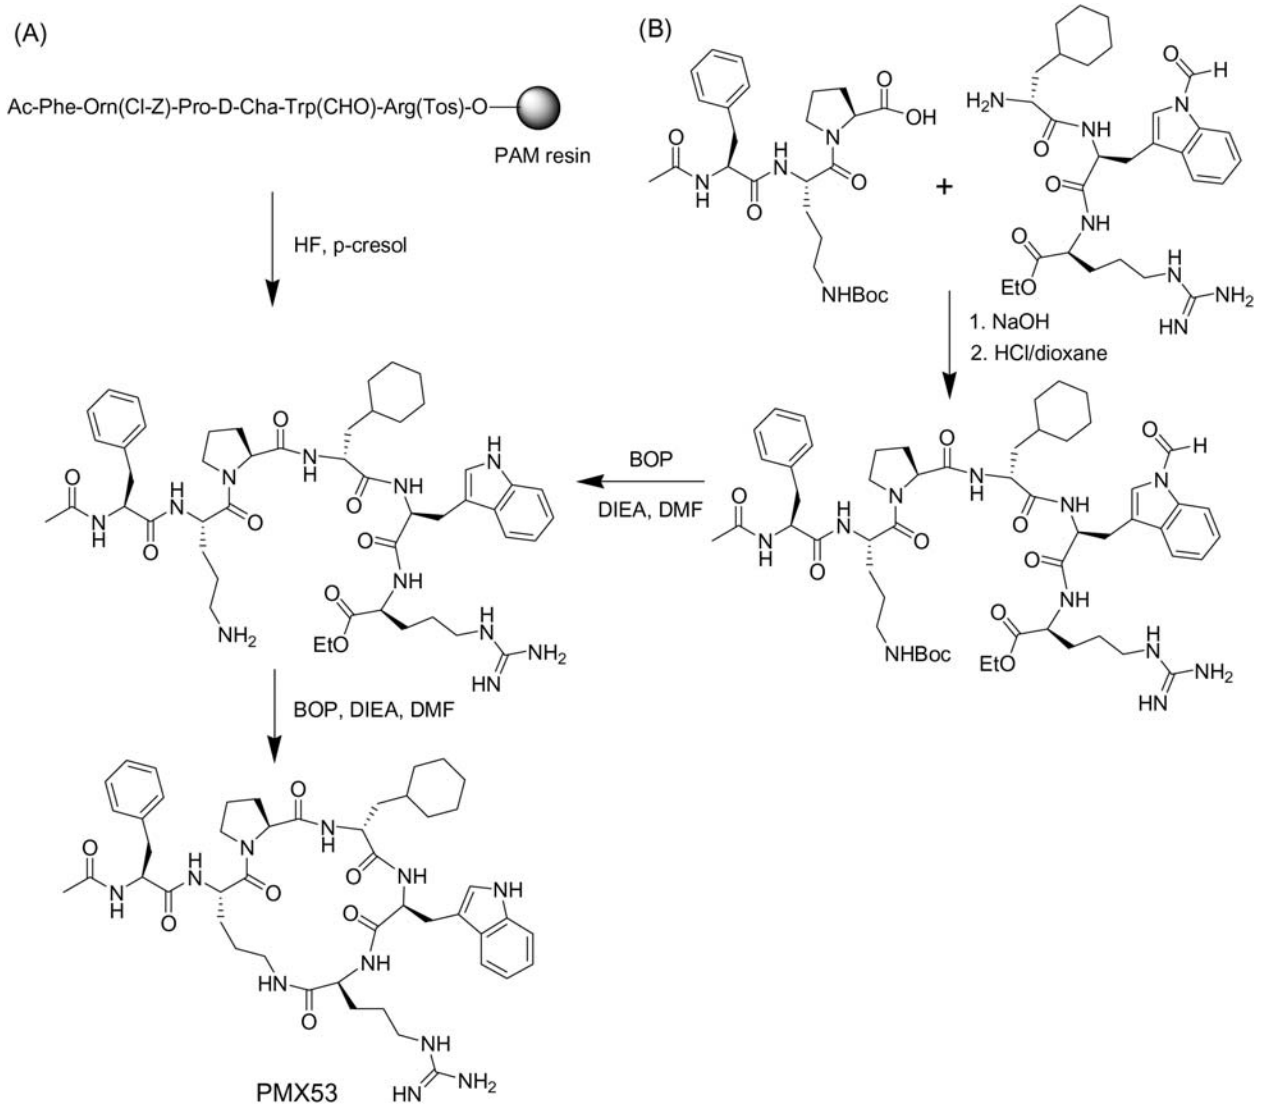

Fig. 20 Synthesis of PMX53. (A) Solid-phase synthesis of a linear peptide intermediate and subsequent solution-phase cyclization. (B) A convergent approach to prepare the linear peptide precursor.

6.03.5.5 Octreotide (Sandostatin)

Somatostatin (Fig. 21), a cyclic tetradecapeptide, has been isolated from ovine hypothalamus. It inhibits the release of numerous peptide hormones including glucagon, insulin, secretin, and growth hormone. Somatostatin has been employed in the treatment of acute gastrointestinal disorders, but its therapeutic use is limited by the short in vivo half-life of 1–2 min.[186]

Octreotide, a synthetic octapeptide analog of somatostatin, was developed to mimic the pharmacology of somatostatin (Fig. 21). The pharmacophore of somatostatin, Phe^7-Trp^8-Lys^9-Thr^{10}, was conformationally restricted by a disulfide linkage between two Cys residues, and D-Phe and D-Trp at positions 1 and 4, respectively, were introduced to improve druggability by enhancing proteolytic stability and potency. Together with the disulfide cross-link, D-Trp^4 was found to stabilize a β-turn structure (type II′) in the pharmacophore.[187] The carboxylic acid at the C-terminus was reduced to an alcohol to further increase stability against enzymatic degradation. Octreotide was found to be more potent than the native hormone in inhibiting the secretion of growth hormone both in vitro and in vivo.[188] It is successfully used in the treatment of neuroendocrine disorders, such as acromegaly and gastroenteropancreatic neuroendocrine tumors.[189] It was prepared in solution on the semi-industrial scale by using the 4 + 2 + 2 strategy, followed by deprotection and oxidative cyclization (Fig. 22).[190]

6.03.5.6 Conopeptides

Conopeptides are a group of neurotoxic peptides expressed in the venom duct of cone snails (Conoidea, *Conus*). These are highly structured peptides of which sequences comprise 10–30 amino acids with one or more disulfide bonds. Conotoxins have been the subject of pharmacological interest because of their high potency and selectivity for a broad range of cellular targets.[191] For example,

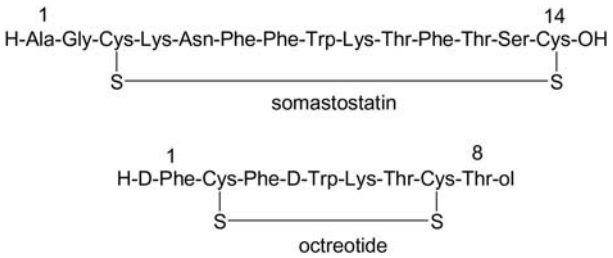

Fig. 21 Structures of somatostatin and octreotide.

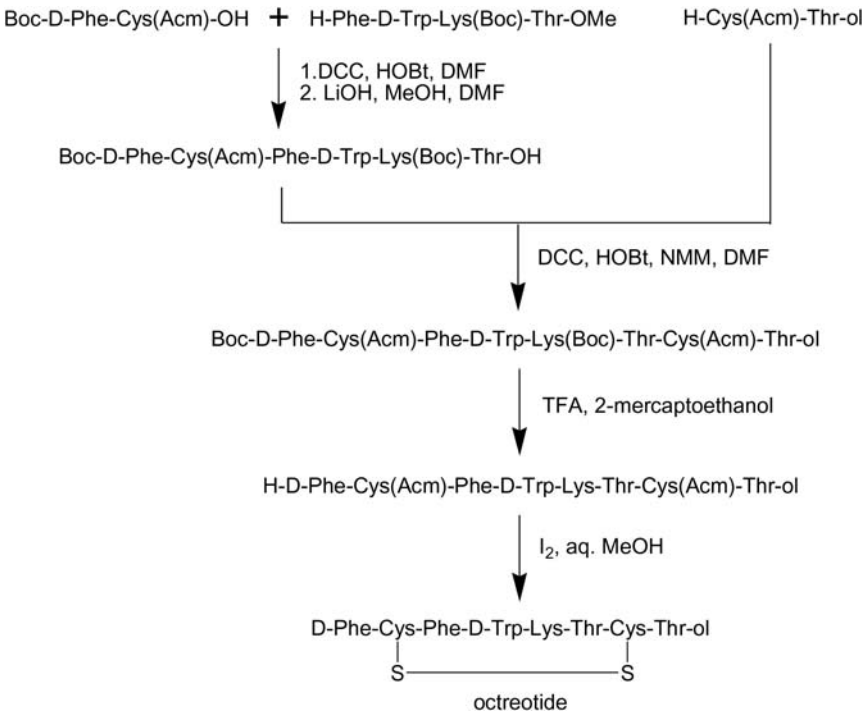

Fig. 22 Synthesis of octreotide.

conopeptide MVIIA, marketed as ziconotide by Prialt, is a synthetic equivalent of a conopeptide form *Conus magus*, and it selectively blocks Cav2.2 N-type voltage-gated calcium channels[192] It is approved by the FDA for treating severe chronic pain.

Conopeptides can be synthesized by following standard SPPS protocols; however, forming the correct disulfide linkages is a challenging task. Several methods have been developed for regioselective formation of multiple disulfide bonds after the construction of a linear peptide on solid support, and these methods include oxidation (S–S formation), reduction (S–S breakage), and isomerization (S–S rearrangement) reactions.[193] A common regioselective in-solution disulfide bond formation utilizes a variety of thiol-protecting groups, such as triphenylmethyl (S-Trt), acetamidomethyl (S-Acm), *t*-butyl (S-tBu), and *p*-methylbenzyl (S-Meb) groups. Typically, a peptide is cleaved from solid support with all S-protecting groups intact except for S-Trt (**Fig. 23**). The first disulfide bond is formed by air oxidation between the free Cys residues.[194] The second disulfide bond is generally formed by treatment with iodine. The S-Meb protecting group appears to be more stable than the S-tBu group at room temperature under trifluoroacetic acid,[195] which allows selective formation of the third disulfide bridge. The fourth disulfide bond is finally formed by increasing the reaction temperature from 25°C to 65°C.

6.03.5.7 Linaclotide

Linaclotide was approved by the FDA for the treatment of chronic idiopathic constipation and irritable bowel syndrome with constipation in adults.[196] It is a synthetic peptide analog of diarrheagenic bacterial enterotoxins and endogenous hormones guanylin

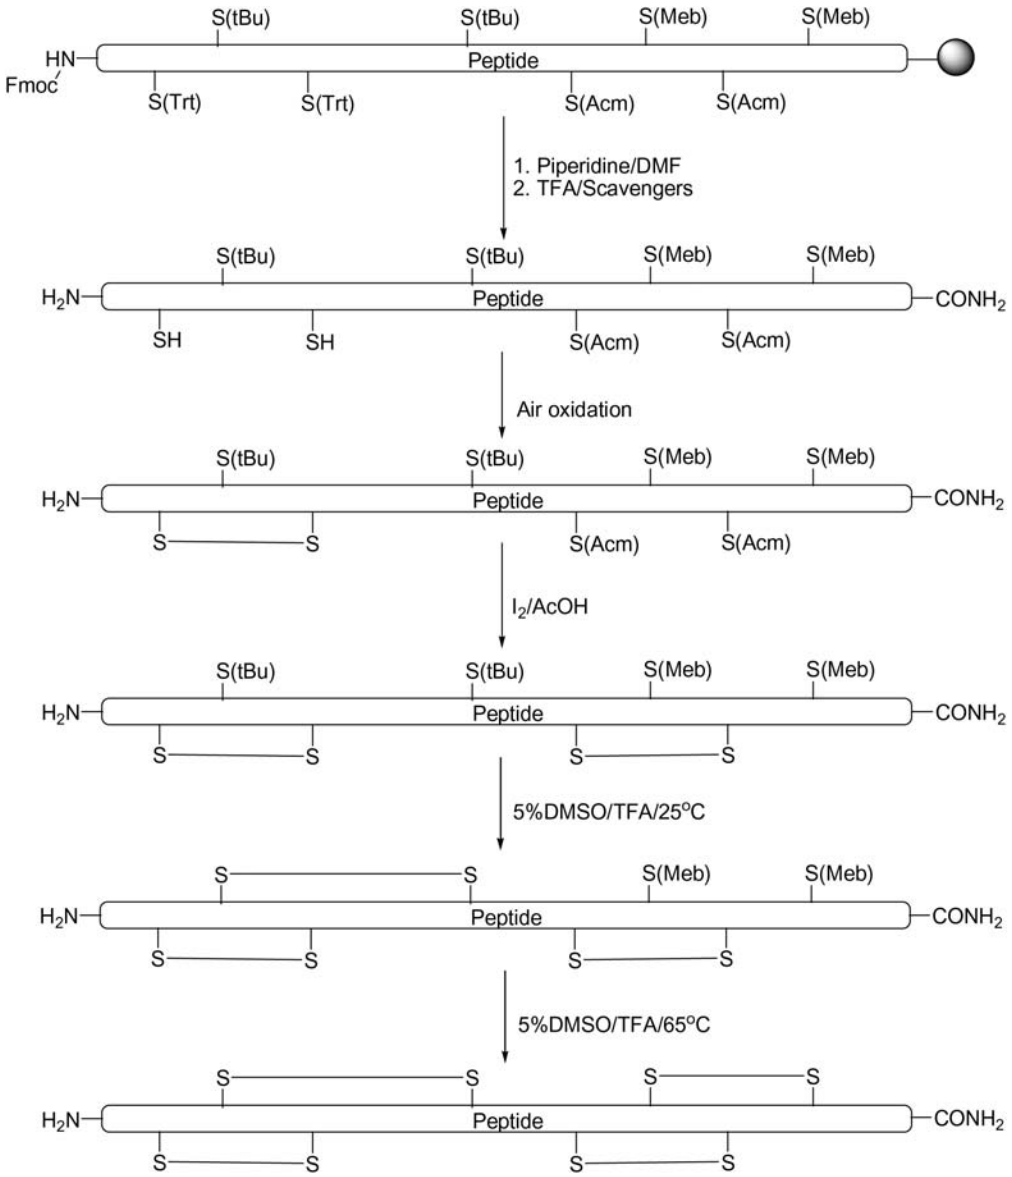

Fig. 23 Synthesis of conopeptides with multiple disulfide bridges.

and uroguanylin, which act as a potent guanylate cyclase C (GCC) receptor agonist. On intestinal epithelial surfaces, linaclotide binds to and activates the GCC receptor, which subsequently stimulates the production of cyclic guanosine monophosphate. This in turn increases intestinal motility and fluid secretion and ultimately reduces abdominal pain.[197] Linaclotide is an orally available 14-residue long peptide that features three intramolecular disulfide bonds between C1–C6, C2–C10, and C5–C13. These structures improve resistance to proteolytic degradation in the gastrointestinal tract.[198]

Albericio and coworkers synthesized linaclotide by using a random disulfide bond formation strategy.[199] A linear peptide containing six Cys residues was prepared in solid phase and cyclized in solution. A disulfide bond analysis by using a modified method developed by Wu and Watson[200] confirmed that the correct pairing of Cys residues was achieved, indicating that the linear peptide can fold naturally to the right conformation (Fig. 24).

6.03.5.8 Cyclic Melanocortin Analogs

Melanocortin receptors are seven transmembrane-spanning G protein-coupled receptors that increase the intracellular cAMP level upon ligand binding, and five receptor subtypes (MC1R–MC5R) have been identified to date.[193,201] The endogenous melanocortin peptides are α-, β-, and γ-melanocyte-stimulating hormones and adrenocorticotropic hormone and have a conserved tetrapeptide sequence (His-Phe-Arg-Trp) that is found to be essential for receptor interaction.[202] Extensive structure–activity relationship studies have been carried out for the tetrapeptide pharmacophore and flanking regions of α-MSH. Phe^7, after examination by gas chromatography, was identified as a predominantly racemized residue, and this discovery led to the design of a highly potent and prolonged acting α-MSH analog, NDP-MSH, with D-Phe at position 7 (Table 8).[203]

Both α-MSH and NDP-MSH adopt a folded conformation that places the aromatic residues [i.e., His^6, Phe^7 (or D-Phe^7), and Trp^9] on the same side in a β-turn structure. This places the hydrophilic residues (Glu^5, Arg^8, and Lys^{11}) on the opposite face and brings Glu^5 and Lys^{11} in close proximity. To stabilize the turn conformation around the pharmacophore, a lactam bridge between Asp^5 and Lys^{11} was created, resulting in a small cyclic analog, melanotan II (MTII in Table 8).[204] Interestingly, substitution

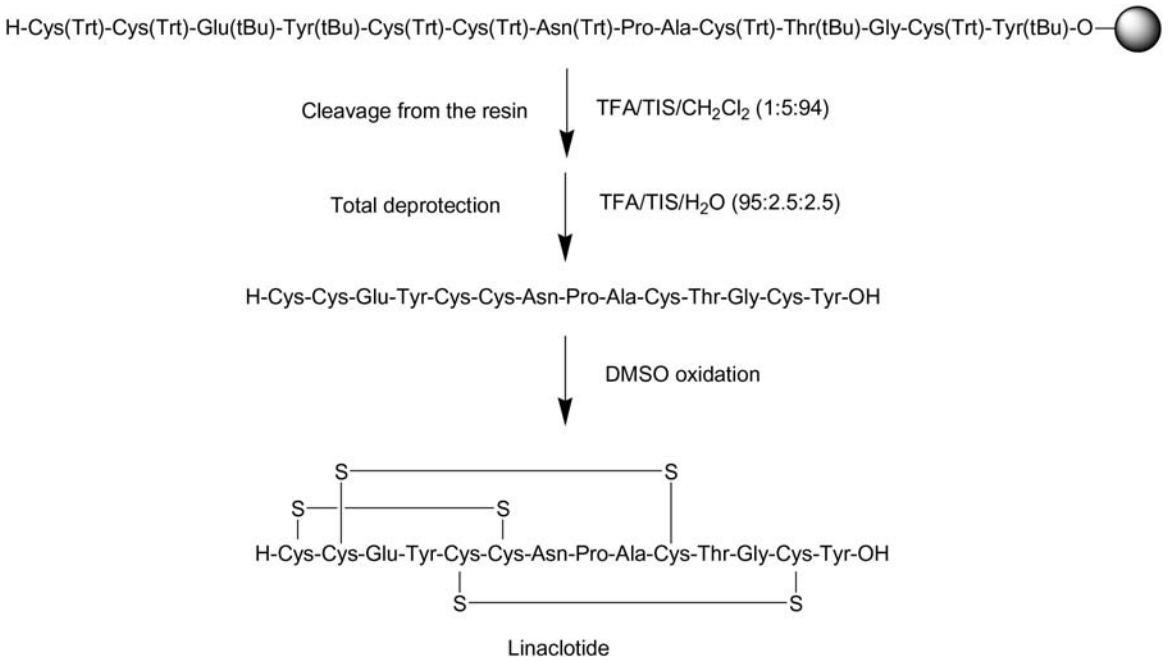

Fig. 24 Synthesis of linaclotide.

Table 8 Sequences of melanocortin peptides

Ligand	*Sequence*
α-MSH	Ac-Ser-Tyr-Ser-**Met**-Glu-His-**Phe**-Arg-Trp-Gly-Lys-Pro-Val-NH_2

of D-Phe at position 7 with a bulky aromatic amino acid like D-Nal(2′) converted the potent agonist into a strong antagonist SHU9119 to MC3R and MC4R.[205]

6.03.5.9 Cyclic Opioid Peptides

Endogenous opioid pentapeptides (i.e., [Met^5]- and [Leu^5]-enkephalin) bind to several subtypes of opioid receptors, such as μ-, δ-, and k-opioid receptors.[206] To achieve selectivity to a receptor subtype, conformationally constrained analogs were synthesized utilizing a disulfide linkage between D-Cys^2 and D/L-Cys^5.[207] A cyclized peptide, c[D-Cys^2,D-Cys^5]enkephalin, was found to be twice as potent as c[D-Cys^2,L-Cys^5]enkephalin and 73 times as potent as [Met^5]enkephalin. The cyclic peptide c[D-Cys^2,D-Cys^5]enkephalin showed a moderate preference for the μ-opioid receptor over the δ-subtype and was found to be more resistant to enzymatic degradation than [Met^5]enkephalin.[207]

Mosberg and coworkers continued the search for selective enkephalin analogs and introduced a germinal disubstituted penicillamine (Pen) at position 2 along with the disulfide bridge between residues 2 and 5.[208] The resulting peptides, c[D-Pen^2,L-Cys^5]- and c[D-Pen^2,D-Cys^5]-enkephalinamide, showed a high δ-opioid receptor specificity. In addition, a carboxylate at the C-terminus was found to increase the selectivity to the δ-subtype.[209] A more constrained analog was further designed by the introduction of two Pen residues at positions 2 and 5, and the resulting peptide c[D-Pen^2,D-Pen^5]-enkephalin (DPDPE) showed an order of magnitude improvement for selectivity to the δ-opioid receptor (**Fig. 25**).[210] Conformational analysis by nuclear magnetic resonance (NMR) and molecular modeling suggested a type IV β-turn and transannular interactions of the aromatic side chains of Tyr^1 and Phe^4 with the β,β-dimethyl groups of D-Pen^2.[211]

6.03.6 Stabilization of Secondary Structures

Peptides can be folded to a variety of conformations, and several key structures have been commonly observed, such as α-helix, β-sheet, and reverse turns. These secondary structures are important for the topography of peptides and proteins, playing a role in target recognition. However, due to the entropy effect, short peptides have difficulty in retaining such organized conformations by themselves, resulting in a loss of biological activity. Thus, stabilization of protein secondary structures has been practiced to improve peptide leads.

6.03.6.1 Stabilized β-Turns

β-Turns are one of the most common structural motifs in proteins and change the direction of the peptide backbone by nearly 180°, allowing the peptide chain to fold back onto itself.[212] A β-turn is defined by four consecutive amino acids and has a characteristic of the distance between two α-carbons of residues i and $i+3$ being less than 7.0 Å (**Fig. 26**). β-Turn structures can be further classified to various types according to the backbone torsional angles (ϕ_{i+1}, ψ_{i+1}, ϕ_{i+2}, and ψ_{i+2}) in residues $i+1$ and $i+2$. Type I and II β-turns are the most common, and they are stabilized by a backbone hydrogen bond between the CO of residue i and the NH of residue $i+3$.[212c,213] Type I and II β-turns are different mainly in the orientation of the amide bond between the residues $i+1$ and $i+2$ on the plane of the β-turn. Type I′ and II′ β-turns are mirror images of the backbone conformations of type I and type II, respectively.

Statistical analysis revealed that Pro and Gly residues are favored in β-turns presumably due to the cyclic structure of Pro and the flexibility of Gly.[214] Hydrophilic amino acids, such as Asn and Asp, also have a high propensity for a β-turn formation mainly owing to their placement on solvent-exposed surfaces of globular proteins. In addition to their role in protein folding,[215] β-turns can also serve as recognition motifs of PPIs.[216]

One method for stabilizing a β-turn structure is to create a disulfide bridge between side chains. By employing this strategy, Hruby and coworkers designed conformationally restricted μ-opioid receptor antagonists based on a somatostatin template.[217] Although somatostatin binds weakly to opioid receptors, its analog octreotide was found to bind to the μ-opioid receptor with

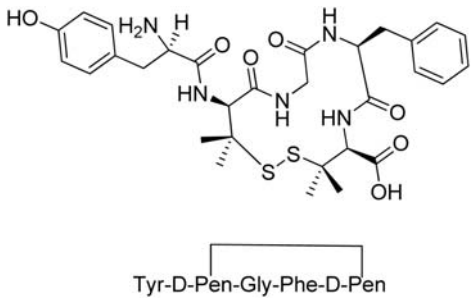

Fig. 25 Structure of c[D-Pen^2,D-Pen^5]-enkephalin (DPDPE).

Fig. 26 The structure and classification of β-turns.

an IC_{50} value of 38 nM.[218] This observation led them to convert somatostatin to an opioid ligand.[217] To develop a selective μ-opioid receptor antagonist with little or no somatostatin-like biological activity, they used the tetrapeptide somatostatin sequence (Phe-D-Trp-Lys-Thr) as a β-turn adopting template. A series of conformationally restricted somatostatin analogs were synthesized with disulfide bridges, and a leading compound CTP exhibited a high affinity to the μ-opioid receptor (IC_{50} = 3.7 nM), 7000 times more potent than somatostatin (**Table 9** and **Fig. 27**). CTP showed approximately 200-fold increased selectivity to the μ-opioid receptor over the δ-subtype. Conformational analysis by NMR showed that CTP possesses a well-defined type II′ β-turn at the core tetrapeptide motif with a hydrogen bond between Tyr^3 and Thr^6.[220]

To lower affinity to the somatostatin receptor, Lys^5 of CTP was replaced with Orn, and the resulting peptide CTOP showed significantly improved specificity to the μ-opioid receptor over the somatostatin receptor (**Table 9** and **Fig. 27**).[221] In addition to the cyclization via the disulfide bridge, D-Phe^1 was substituted with D-Tic to offer a topographical constraint in a χ conformational space on the side chain of residue 1, and the resulting peptide TCTOP showed further enhanced receptor selectivity.[222]

Another approach to induce and stabilize a β-turn structure is the dipeptide D-Pro-L-Pro that was found to adopt a stable type II′ β-turn[223] and facilitate the nucleation of β-hairpins.[224] A β-hairpin structure is composed of two consecutive hydrogen-bonded antiparallel β-strands connected by a loop region that typically comprises 1–5 amino acid residues.[225] β-Turns are the most abundant structures in the loop segment with a preference of types I′ and II′.[226] β-Hairpins are a key motif in antiparallel β-sheets,[227] and they are widely found in a variety of proteins including IgG antibodies,[228] cytokine receptors,[229] growth factors,[230] integrins,[231] and viral proteins.[232] In addition, naturally occurring bioactive cyclic antimicrobial peptides (e.g., protegrins, polyphemusins, and tachyplesin), gramicidin S, and tyrocidine are known to adopt β-hairpin structures.[233]

The β-hairpin-stabilizing template D-Pro-L-Pro was designed to stabilize β-hairpin structures of the L3 loop region of the anti-hemagglutinin antibody HC19. The loop mimetic 1 was created by transplanting the loop from the immunoglobulin framework onto a D-Pro-L-Pro template (**Fig. 28**). NMR studies showed that the mimetic adopts a β-hairpin conformation and aromatic stacking between the side chains of Trp residues located on opposite sides of the hairpin, which are essentially identical to those in the antibody crystal structure.[234]

Robinson and coworkers utilized the D-Pro-L-Pro template to design inhibitors of the Tat protein–transactivation response element (TAR) interaction in bovine immunodeficiency virus (BIV). They prepared mimetics containing 12 amino acid loops by transplanting the key residues of Tat for binding to TAR (Thr^{72}-Ile^{79}) onto the D-Pro-L-Pro template.[235] One of these mimetics,

BIV-2, was found to bind to TAR RNA with a K_d value of 150 nM, comparable with that of the wild-type BIV Tat (65–81) peptide ($K_d = 50$ nM).[235] An NMR study showed that BIV-2 adopts a β-hairpin conformation and binds to TAR RNA with an orientation opposite to what is observed in the Tat protein.[236] Based on the structure of the mimetic–TAR RNA complex, they modified the sequence and found that L-22 binds to TAR RNA with a 10-fold increase in activity, compared with BIV-2 (Fig. 29).[237]

β-Hairpin mimetics were employed as a scaffold to preorganize the side chains of the i, $i+4$, and $i+7$ positions of an α-helical peptide, representing one helical face.[238] Inhibitors were developed to disrupt p53–HDM2 interaction by mounting the critical residues, such as Phe^{19}, Trp^{23}, and Leu^{26} in an amphipathic α-helical p53 peptide onto the D-Pro-L-Pro dipeptide template. Based on molecular modeling, Phe^{19}, Trp^{23}, and Leu^{26} of the p53 peptide were incorporated into the positions 1, 3, and 4 of the mimetics, respectively. Although mimetic 2 showed a weak binding affinity ($IC_{50} = 125$ μM), further optimization led to mimetic 8 that contains a 6-chlorotryptophan[239] at position 3, showing a 900-fold increase in affinity for human double minute 2 (HDM2) ($IC_{50} = 140$ nM) (Fig. 29). A crystal structure of the mimetic 8 in complex with HDM2 confirmed that it adopts a β-hairpin conformation, and the side chains of Phe, 6-ClTrp, and Leu occupy the hydrophobic pocket on the surface of HDM2.[240]

6.03.6.2 Stabilized β-Sheets

Amyloid fibrils are insoluble protein aggregates, and their formation may cause a variety of human degenerative disorders including Alzheimer's disease, Parkinson's disease, Huntington's disease, prion disease, and type II diabetes, each of which is associated with

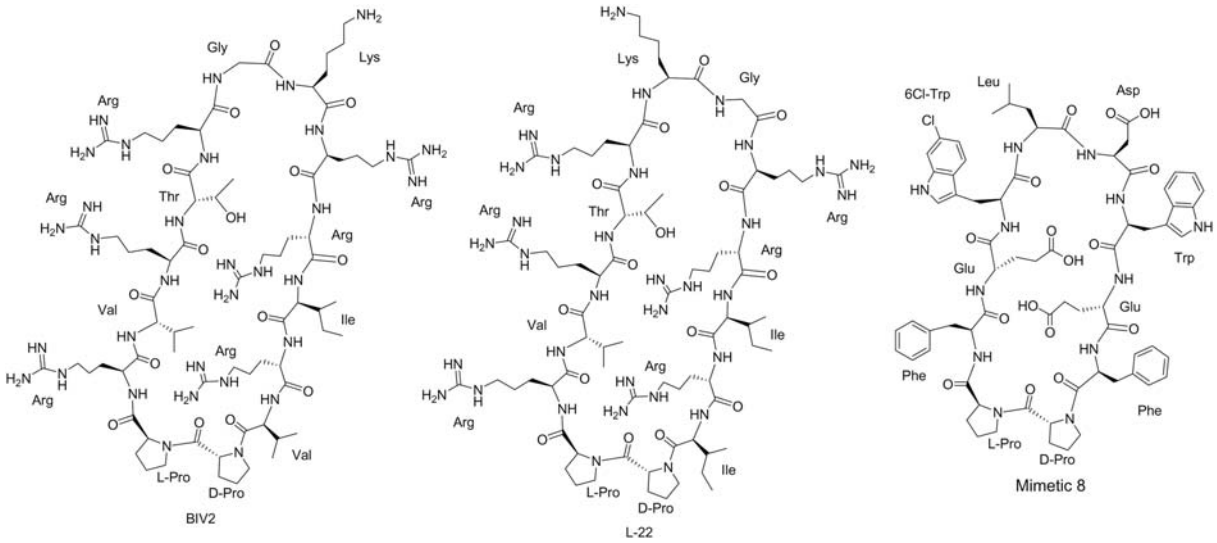

Fig. 29 Structures of β-hairpin peptidomimetics: BIV2, L-22, and mimetic 8.

a specific peptide or protein.[241] For example, β-amyloid protein, α-synuclein, and islet amyloid peptide are related to Alzheimer's disease, Parkinson's disease, and type II diabetes, respectively.[242] Despite the differences in amino acid sequences, native structures, and physiological activities, amyloidogenic peptides and proteins share a characteristic cross-β-sheet structure in which adjacent β-sheets are held together tightly by zipper-like side-chain interactions with a network of hydrogen bonds running parallel to the fibril axis.[243]

Nowick and coworkers have developed macrocyclic β-sheet mimics as a platform to display amyloidogenic peptides from various amyloid proteins.[244] The β-sheet mimics comprise a heptapeptide β-strand (the upper strand, R_1–R_7), one Hao template (hydrazine, 5-amino-2-methoxybenzoic acid, and oxalic acid), and four additional amino acids (the lower strand, R_8–R_{11}) and two δ-linked Orn turns (**Fig. 30**). The Hao template was designed to facilitate β-sheet dimer formation with the upper strand and to prevent the opposite side of the lower strand from making higher oligomers, as demonstrated by X-ray crystallography.[245]

The mimics 1a, 1m, and 1o (**Fig. 30**) possess amyloidogenic heptapeptide sequences derived from amyloid-β peptide (Aβ), human β_2-microglobulin, and human α-synuclein, respectively, and delayed aggregation of their parent proteins.[246] In particular, the mimic 1a blocked $A\beta_{40}$ and $A\beta_{42}$ aggregation by 430% and 600%, respectively, up to 20 μM Aβ peptides, and reduced the toxicity of $A\beta_{40}$ and $A\beta_{42}$ in PC-12 pheochromocytoma cells.

6.03.6.3 Stabilized α-Helices

PPIs are frequently controlled by well-ordered secondary structures like α-helices, regulating essential biological processes including enzyme activity, protein synthesis, transcription, DNA binding, immune response, and signal transduction.[247] Thus, α-helices found

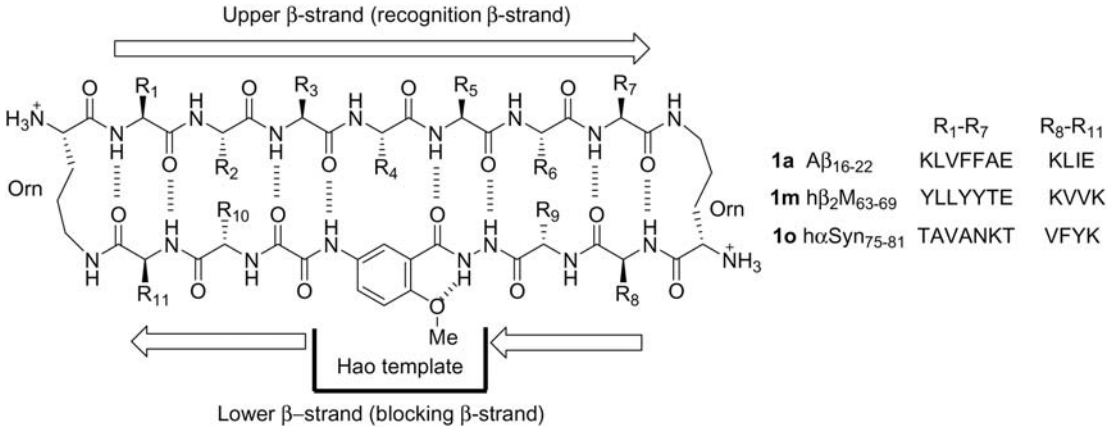

Fig. 30 Structure of β-sheet mimic Hao and its stabilization of β-strands.

at the interfaces of PPIs have been recognized as attractive targets to intervene for treating diverse human diseases including cancer, neurological disorder, and viral infection.[247a,248] However, short peptides (typically <15-mer in size) derived from such helical segments in proteins have several limitations. Short peptides often lose their well-defined structures or fail to adopt organized conformations like α-helices in solution when taken out of the proteins, resulting in decreased binding affinity to their targets.[249] In addition, short peptides are susceptible to proteolytic degradation, especially when they are in an extended conformation, and have difficulty in penetrating cellular membranes.[164,250] These drawbacks severely compromise effective use of short peptides as PPI modulators. To overcome these limitations, a variety of methods have been developed for stabilizing helical structures that not only retain high binding affinity but also provide resistance to proteolysis and even cell permeability.

Cross-linking the side chains of appropriately spaced residues is well known to stabilize α-helices, and a variety of cross-linking methods have been developed (**Fig. 31**).[251] Among them, formation of a lactam bridge offers a convenient means for introducing conformational constraints into a peptide structure.[252] An amide linkage can be created between amine- and carboxylic acid-bearing amino acid residues that are located at the i and $i+3$, i and $i+4$, or i and $i+7$ positions in the peptide sequence and has demonstrated its capability of stabilizing α-helices (**Fig. 31A**).[253] To investigate the effect of the length and orientation of a lactam bridge on helicity, Lys or Orn and Asp or Glu were placed at the positions i and $i+4$ (i.e., positions 1 and 5), respectively, in a cyclic pentapeptide. This study showed that a lactam bridge between Lys at the position i and Asp at the position $i+4$ was superior to others for stabilizing α-helicity, independent of concentration, TFE, denaturants, and proteases.[253] A variety of orthogonal protecting groups for amines and carboxylic acids have been developed, allowing facile synthesis of mono- and bis-lactam-bridged peptides in solid phase.[254]

Schultz and coworkers reported that an intramolecular disulfide bond between D- and L-2-amino-6-mercaptohexanoic acid placed at the i and $i+7$ positions stabilized a short α-helical peptide.[255] The resulting disulfide-containing cyclic peptides displayed an enhanced helicity compared with the linear counterpart. In addition, the disulfide linkage between D-Cys at the i position and Cys at the $i+3$ position also increased the helicity (**Fig. 31B**).[256]

Another cross-linking method is making a nonnative carbon–carbon bond (often referred as "hydrocarbon stapling") that may increase resistance to proteolysis over that observed with lactam and disulfide bridges. The Grubbs group reported the hydrocarbon stapling via a ring-closing metathesis reaction with O-allyl-protected Ser residues located on adjacent helical turns.[257] As an alternative hydrocarbon stapling approach, Verdine and coworkers devised an all-hydrocarbon cross-linking system in which the cross-link is created between two amino acids bearing olefinic side chains placed at the i and $i+4/i+7$ positions, followed by an olefin metathesis reaction (**Fig. 31C**). Hydrocarbon-stapled peptides show not only enhanced and stabilized helical structures but also increased membrane permeability, presumably resulting from the lipophilic nature of the cross-link.[258]

The Ghadiri and Hopkins groups exploited the affinity of a transition metal ion to ligands for the stabilization of α-helical peptides. Peptides carrying His and Cys residues at the i and $i+4$ positions interact with a transition metal ion like Ca^{2+} and Ni^{2+} and form a bidentate metal complex, which fixes the peptide in an α-helical conformation (**Fig. 31D**).[259] Oppositely charged residues on the same side of an α-helical peptide can also stabilize a helical conformation by making a salt bridge. This ion pair system of Glu at the i position and Lys at the $i+4$ position has been employed to increase the helicity of peptides (**Fig. 31E**).[260]

Alleman and coworkers developed a photocontrollable system that manipulates peptide conformations by irradiation of light.[261] An azobenzene cross-link placed between two Cys residues undergoes *cis–trans* isomerization upon irradiation in a reversible manner, switching the structure of a peptide between α-helix and random coil (**Fig. 31F**).

Glucagon is a 29-amino acid-containing peptide hormone secreted by the α cells of pancreatic islets. It plays a critical role in glucose homeostasis by stimulating gluconeogenesis and glycogenolysis in hepatocytes and lipolysis in adipocytes during the hypoglycemic state. Thus, glucagon receptor antagonists may be of interest in the treatment of diabetes mellitus.[262] Hruby and coworkers utilized a salt bridge to increase the α-helicity of glucagon.[263] Two Lys and a Glu were introduced in the sequence of glucagon to create a salt bridge for the stabilization of the α-helical structure at the C-terminal region of the peptide (**Fig. 32**). The resulting [$Lys^{17,18}$, Glu^{21}]glucagon displayed an increased binding affinity and receptor activation potency (five- to sevenfold increase).

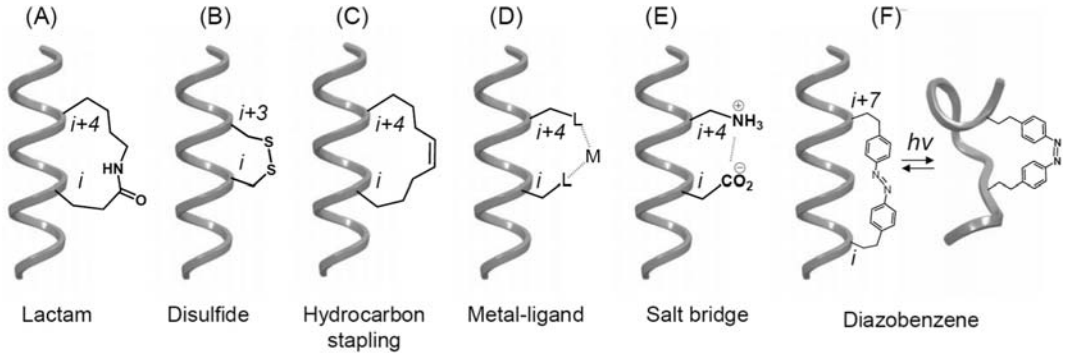

Fig. 31 Selected examples of side chain-cross-linked α-helical peptides.

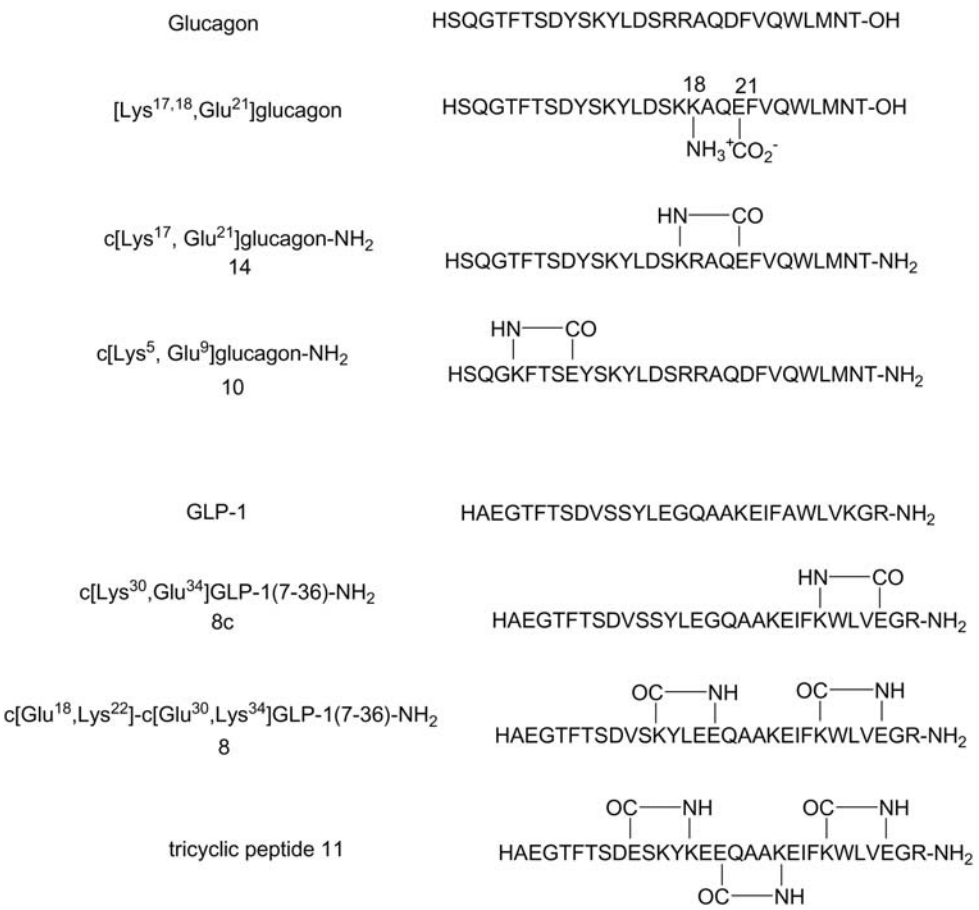

Fig. 32 Structures of glucagon and GLP-1 analogs.

The increased potency appears to be caused by a significantly increased α-helical content as determined by circular dichroism (CD) spectroscopy and X-ray crystallography.

Ahn and coworkers developed a positional cyclization scanning approach to determine the presence and location of secondary structures in the bioactive conformation of glucagon.[264] Positional cyclization scanning consists of a series of structure–activity relationship studies with conformationally restricted peptides to interrogate the structural requirement for optimal receptor recognition. Conformational restrictions were surveyed in the sequence of glucagon with a disulfide bridge between two Cys at the i and $i+5$ positions for stabilization of a turn conformation and a lactam bridge between Lys at the i position and Glu at the $i+4$ position for fixation of a helical structure. Based on the binding affinity changes and the locations of the conformational restrictions, they reached a model of two helical segments in the N- and C-terminal regions, connected by a short and nonhelical segment. Some of the lactam-bridged glucagon analogs were found to have an enormous increase in binding affinity (six- to eightfold increase) and receptor-stimulating potency (up to 21-fold increase).

GLP-1 is a 30-amino acid-containing incretin, and its primary role is regulating postprandial insulin release. It also induces pancreatic β-cell differentiation and proliferation, inhibits apoptosis of the β cells, blocks glucagon secretion, decelerates gastric emptying, reduces appetite, and induces satiety. All of these regulatory functions have made this peptide an attractive therapeutic for treating diabetes.[265] To elucidate the receptor-bound conformation of GLP-1, Ahn and coworkers prepared a series of conformationally constrained GLP-1 analogs by introducing a lactam bridge between Lys at the i position and Glu at the $i+4$ position at various locations in the GLP-1 sequence (**Fig. 32**).[266]

This study identified two lactam bridges that significantly stabilize two helical segments at the N- and C-terminal regions of the peptide. Based on those results, they designed and synthesized bicyclic and tricyclic GLP-1 analogs by placing multiple lactam bridges together to simultaneously stabilize both α-helical segments in the N- and C-terminal regions of the peptide.[267] These highly constrained GLP-1 analogs showed not only outstanding conformational stability, which increased binding affinity and receptor activating potency (two- to fourfold increase), but also remarkable metabolic stability against enzymatic degradation. The most potent bicyclic GLP-1 analog, [D-Ala^8]-c[Glu^{18},Lys^{22}]-c[Glu^{30},Lys^{34}]GLP-1(7–36)-NH_2, has been under evaluation for its utility in pancreatic β-cell imaging with PET modality.[16,268]

A 13-residue-containing peptide 2, derived from respiratory syncytial virus (RSV) fusion protein, was constrained with two back-to-back lactam bridges to fix it in an α-helical conformation (**Fig. 33**).[269] The resulting bicyclic peptide 1 was found to be highly

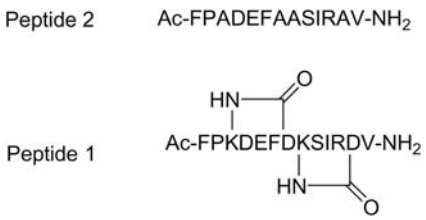

Fig. 33 RSV fusion inhibitor stabilized by two lactam bridges.

α-helical in water, determined by CD and NMR spectroscopy, correctly positioning crucial binding residues (F488, I491, and V493) on the same helical face and the lactam bridges on a noninteracting face of the helix. This compound showed potent activity in both a recombinant fusion assay and an RSV antiviral assay (IC_{50} value of 25 and 36 nM, respectively). In contrast, the linear peptide 2 had no α-helical structure in water and showed no antiviral activity up to 10 μM. The potency of the bicyclic peptide 1 for inhibiting RSV fusion ($IC_{50}=25$ nM) also contrasts starkly with the potency for the full-length heptad repeat C peptide ($IC_{50}=2900$ nM) in a cell fusion assay.[270]

HDM2 and human double minute X (HDMX) induce tumorigenesis by inhibiting the tumor suppressor p53.[271] HDM2 acts as a ubiquitin ligase that directly binds to p53, leading to proteasomal degradation of p53.[272] Although HDMX binds to p53 at the same site as HDM2, HDMX inhibits p53 transactivation by sequestering it into inactive complexes due to its lack of ubiquitin ligase activity.[273] Thus, inhibition of HDM2 can be compromised by overexpression of HDMX, and blocking both proteins appears to be key for restoring p53 activity in a number of cancers.[274]

Verdine and coworkers applied the hydrocarbon stapling strategy for creating peptide-based HDM2 inhibitors that exhibit high affinity for HDM2 and readily enter cells.[275] A panel of stapled peptides was designed based on the p53-derived 15-mer peptide by installing an all-hydrocarbon staple between the residues at the *i* and *i*+7 positions (**Fig. 34**). Fluorescence polarization (FP) assays with HDM2 identified a stapled p53 peptide (SAH-p53-4) as a potent inhibitor with a K_d value of 0.92 nM, which is nearly three orders of magnitude greater than that of the wild-type p53(14–29) peptide ($K_d=410$ nM). However, SAH-p53-4 was unable to penetrate the cell membrane.

To adjust the ionized state of the peptide, SAH-p53-4 was modified by replacing Asp and Glu with Asn and Gln, respectively, and by substituting Leu and Lys to Gln and Arg, respectively, as previously reported to participate in p53 nuclear export (L14Q)[276] and ubiquitylation (K24R).[277] The resulting stapled peptide (SAH-p53-8) efficiently penetrated cells and showed high binding affinity to HDM2 with a K_d value of 55 nM (**Fig. 34**). Furthermore, SAH-p53-8 exhibited dose-dependent inhibition of SJSA-1 cells with an EC_{50} value of 8.8 μM and triggered caspase-3 activation with an EC_{50} value of 5.8 μM, demonstrating that SAH-p53-8 inhibited cell

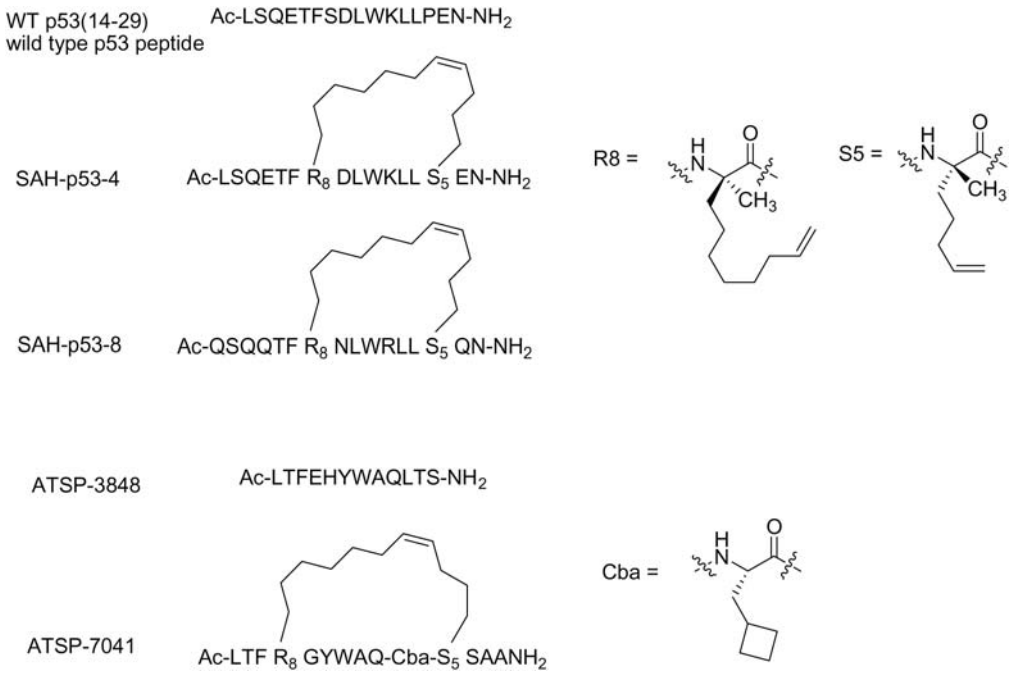

Fig. 34 Hydrocarbon-stapled p53 peptides.

viability by activating apoptosis in HDM2-overexpressing SJSA-1 cells.[275] The crystal structure of the SAH-p53-8/MDM2 complex revealed that the interaction of the stapled peptide to the protein is similar to that of the native p53 peptide. In addition, the staple appears to make hydrophobic contacts with the rim of the MDM2 binding site, enhancing the binding affinity.[278]

Sawyer and coworkers developed a potent and selective dual inhibitor of MDM2 and MDMX, ATSP-7041 (Fig. 34), which effectively activates the p53 pathway in tumors both in vitro and in vivo.[279] A series of stapled peptides was synthesized by placing a hydrocarbon staple between Glu^{20} and Thr^{27} of a phage display-derived peptide, ATSP-3848. In addition to the conventional molecular recognition elements (e.g., Phe^{19}, Trp^{23}, and Leu^{26}), the stapled peptides in the study feature Tyr^{22}, which was identified as another key amino acid. The stapled peptides were further modified to enhance solubility and target binding. Substitution of His^{21} and Leu^{26} with Glu and 3-cyclobutylalanine, respectively, and C-terminal extension with Ala-Ala created a potent dual inhibitor of MDM2 and MDMX, ATSP-7041. FP assays showed that ATSP-7041 has strong binding affinity to both MDM2 ($K_i = 0.9$ nM) and MDMX ($K_i = 7$ nM). A crystal structure of MDMX complexed with ATSP-7041 revealed that the stapled peptide binds to the p53 binding site of MDMX in an identical manner to that of the wild-type p53 peptide. In addition, the staple moiety also associates with MDMX, highlighting the potential of the hydrocarbon staple to further enhance molecular recognition. ATSP-7041 induced reactivation of the main p53 cellular functions, such as cell-cycle arrest and apoptosis, and also suppressed growth of cancer cells that overexpress MDM2 (SJSA-1 cells) or MDMX (MCF-7 cells). Furthermore, ATSP-7041 suppressed tumor growth in human xenograft models and possesses favorable pharmacokinetic and tissue distribution properties.[279]

The α-helix is structurally stabilized by a network of hydrogen bonds formed between the carbonyl of the residue at the *i* position and the amide proton of the residue at the $i+4$ position. To initiate the folding process for a helix, three consecutive amino acid residues need to adopt a helical orientation, which is an entropically unfavorable step.[280] Thus, helix-inducing templates can promote helix formation and prevent fraying of the ends by fixing the orientation of the first three residues of a peptide in an α-helical conformation. Kemp and coworkers developed an N-terminal template 3 that is capable of enforcing α-helix formation (Fig. 35). The pyrrolidine ring and thiamethylene bridge of template 3 constrain its pi and psi angles to the ideal helix value, which makes template 3 assume a helix nucleating conformation.[281]

Another approach for constraining to induce an α-helical structure is introduction of a cross-link that mimics the hydrogen bond between the carbonyl and amide proton of two residues at the *i* and $i+4$ positions, respectively. The Satterthwait group designed a hydrazone link to replace a hydrogen bond in an α-helix (Fig. 35).[282] Arora and coworkers further elaborated the covalent mimic and utilized a chemically stable carbon–carbon bond that can be prepared by a ring-closing metathesis reaction between olefin-bearing residues at the *i* and $i+4$ positions (Fig. 35).[283] The resulting hydrogen bond surrogate (HBS) approach stabilizes α-helical conformation in short peptide sequences (e.g., 7–12-residue long peptides).

Hypoxia-inducible factor-1 (HIF-1) is a transcriptional factor that plays a crucial role in adaptive responses of tumor cells to changes in oxygen level. Under hypoxic conditions, HIF-1 activates transcription of HIF-1 target genes (e.g., vascular endothelial growth factor) that regulate a variety of biological processes including angiogenesis, cell proliferation and survival, glucose metabolism, and migration. The elevated level of HIF-1 has been correlated to tumor progression and angiogenesis, making the HIF-1 pathway an attractive target for cancer therapeutics.[284] The HIF-1α subunit forms a heterodimer with its β-subunit and binds to the hypoxia response element. HIF-1α triggers transcription of target genes by recruiting transcriptional coactivator proteins including CBP/p300. The C-terminal transactivation domain (C-TAD) of HIF-1α forms three short helices (helix 1, G784-D788; helix2, D799-A804; and helix 3, E817-Q824) and wraps around the cysteine/histidine-rich domain-1 (CH1) of p300.[285]

Arora and coworkers developed HBS1 peptide based on the helix 3. For synthetic efficiency, Leu^{819} was replaced with Ala in HBS1 (Fig. 36). Tryptophan fluorescence binding assay showed that HBS1 binds to p300 CH1 with a K_d of 690 nM. Peptide 3, an unconstrained analog of HBS1, binds to the CH1 domain with a K_d of 6060 nM, indicating that stabilization of the α-helical conformation in such a short peptide can offer a significant increase (ninefold) in binding affinity. FP assay with the p300 CH1 domain and fluorescein-labeled HIF-1α C-TAD peptide (residues 786–826) demonstrated that HBS1 disrupted the complex

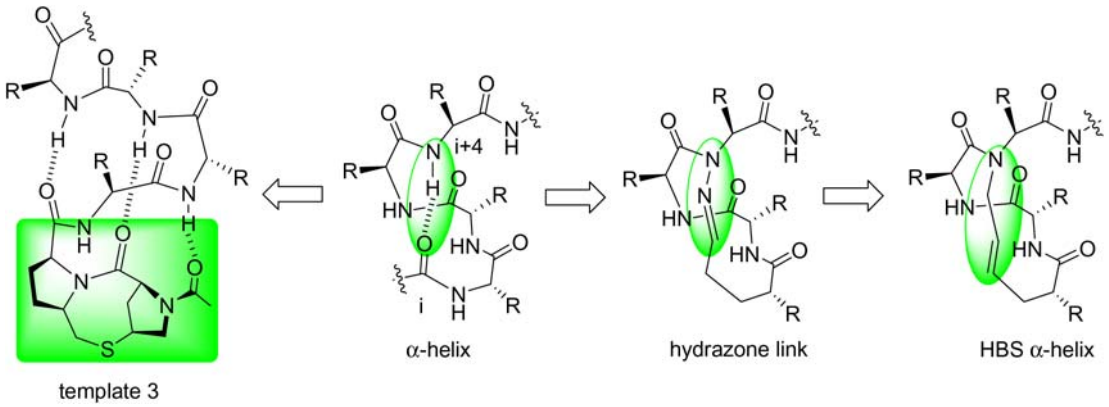

Fig. 35 Structure of helix-inducing templates.

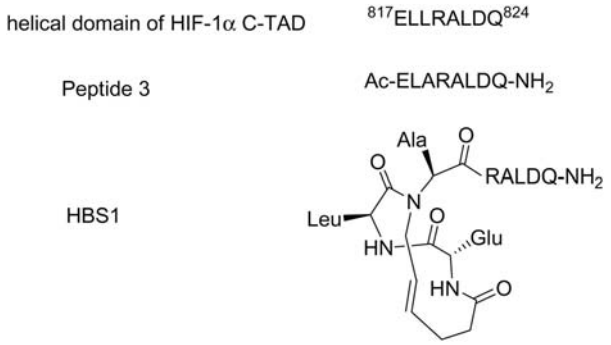

Fig. 36 Structures of HBS-HIF-1α peptide.

with a K_i value of 3.5 μM, while the linear peptide 3 did not inhibit the complex formation. Gene expression profiling with oligonucleotide microarrays revealed that HBS1 effectively inhibited the transcription of hypoxia-inducible genes with relatively minimal perturbation of nontargeted signaling pathways. Furthermore, HBS1 successfully suppressed tumor growth in a mouse tumor xenograft model.[286]

β-Amino acids differ from α-amino acids in that they have an additional carbon atom in the backbone, and β-peptides can form well-defined three-dimensional structures. β^3-Peptides generally have a high propensity to form a 14-helix that is stabilized by 14-membered rings resulting from a hydrogen bond between an amide proton on the residue *i* and a carbonyl on the residue $i+2$. While the α-helix has 3.6 residues in a single turn, the 14-helix makes a turn with approximately every 3 residues (**Fig. 37**).[287] β-Peptides have advantages over their α-amino acid counterparts, such as enhanced conformational and proteolytic stability. In addition to homogeneous β-peptides containing exclusively β-amino acids, heterogeneous α/β-peptides have both α- and β-amino acids and are also capable of adopting diverse helical conformations.[288]

Schepartz and coworkers used the β-peptide 14-helix as a scaffold for mimicking the projection of the three hydrophobic side chains (i.e., Phe^{19}, Trp^{23}, and Leu^{26}) from the α-helical segment of p53 (**Fig. 38**).[289] For these three key residues, β^3-homoleucine, β^3-homotryptophan, and β^3-homophenylalanine were incorporated at positions 3, 6, and 9, respectively, of deca-β-peptides and were expected to form one face of a 14-helix. The 14-helix was also stabilized with a salt bridge between the side chains of β^3-homoornithine and β^3-homoglutamic acid placed on a solvent-exposed surface of the helix. The 14-helix structure in β53-1 was confirmed by CD and NMR spectroscopy. A fluorescein conjugate of β53-1 was found to bind HDM2 with a K_d value of 292 nM, while p53 peptide showed a K_d value of 72.5 nM.[289] Substitution of a 3-trifluoromethylphenylalanine for Trp^{23} increased binding affinity to HDM2 ($K_d = 28.2$ nM).[290]

In spite of their strong affinity to HDM2, β-peptides are typically not cell-permeable, which limits their utility as potential therapeutics. Thus, Schepartz and coworkers introduced either a diether or hydrocarbon bridge between the residues at the *i* and $i+3$ positions in order to increase cellular uptake (**Fig. 38**). β-Peptides containing a diether (47OS) or hydrocarbon linkage (47CS)

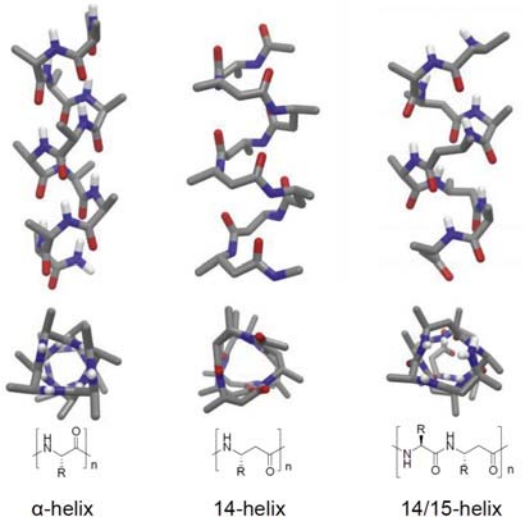

Fig. 37 Structures of α-helix, 14-helix, and 14/15-helix formed by α-peptide, β-peptide, and mixed α/β-peptide, respectively.

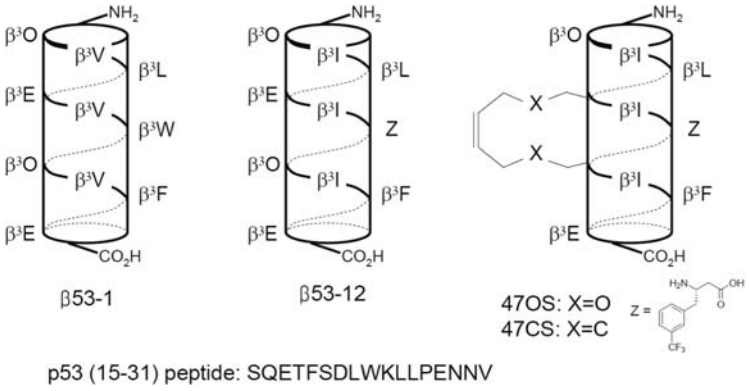

Fig. 38 Structures of p53 β-peptides.

between positions 4 and 7 bind to HDM2 with K_d values of 53.9 and 94.1 nM, respectively, comparable with the native p53 peptide, and these stapled β-peptides showed significant cell uptake.[291]

Although β-peptides have the capability to form 12- or 14-helices, their binding affinity to Bcl-xL proteins was found to be very weak ($IC_{50} > 500$ μM), presumably because the backbone of β-peptides does not precisely reproduce the side-chain projection pattern of an α-helix. Gellman and coworkers developed an alternative approach of partial replacement of the α-amino acid residues in a helical peptide sequence with analogous β-amino acids to retain the recognition properties of the original α-helix.[292] A variety of α/β-peptide homologues in ααβααβ, ααβ, and αααβ repeat patterns were evaluated on their ability to inhibit antiapoptotic Bcl-2 proteins. They synthesized a series of α/β-peptides in the ααβααβ pattern to represent the BH3 domain of Puma that binds promiscuously to antiapoptotic Bcl-2 family members (Fig. 39). Among them, α/β-peptide 4 showed the highest binding affinity with a K_i value of less than 1 nM to Bcl-xL and a K_i value of 150 nM to Mcl-1 in FP assays. In addition, α/β-peptide 4 showed significantly improved resistance against degradation by proteinase K and pronase, compared with the Puma BH3 α-peptide.[293] The crystal structure of the α/β-peptide bound to Bcl-xL showed that the α/β-peptide accurately mimics the four key side chains, organizing the same hydrophobic surface as the native BH3 domain does. It also forms an ion pair between Asp^{14} of the peptide and Arg of Bcl-xL that is conserved in all of the anti- and proapoptotic Bcl-2 protein complexes.[294]

In addition, ααβααβ, ααβ, and αααβ repeat patterns were examined in the context of mimicking the helical BH3 domain of Bim (Fig. 39). Surface plasmon resonance experiments suggested that αααβ-peptide 7 is superior to the other α/β-peptides (e.g., ααβααβ- and ααβ-peptide) in reproducing the binding profile of the Bim BH3 domain. α/β-Peptide 7 showed comparable affinity on Bcl-2, Bcl-w, Bcl-xL, and Mcl-1 with those of the Bim BH3 peptide with IC_{50} values of 5.2, 7.5, 7.5, and 2.4 nM, respectively. The crystal structure of α/β-peptide 4c complexed with Bcl-xL revealed that four hydrophobic side chains of α/β-peptide 4c (Ile^3, Leu^7, β^3-$hIle^{10}$, and β^3-$hPhe^{14}$) dock into the BH3-binding pockets of Bcl-xL. α/β-Peptide 7 was examined on wild-type mouse embryonic fibroblast (MEF) that is protected from apoptosis because of overexpressed Mcl-1 and Bcl-xL, to determine the peptide's capability to initiate apoptosis signaling, and it was observed to induce cytochrome *c* release in wild-type MEF extracts.[295]

6.03.7 Combinatorial Peptide Libraries

Peptide libraries are a valuable research tool to identify biologically active compounds for chemical biology and drug discovery, and these libraries can be generated by either chemical or biological approaches. A number of combinatorial methods have been

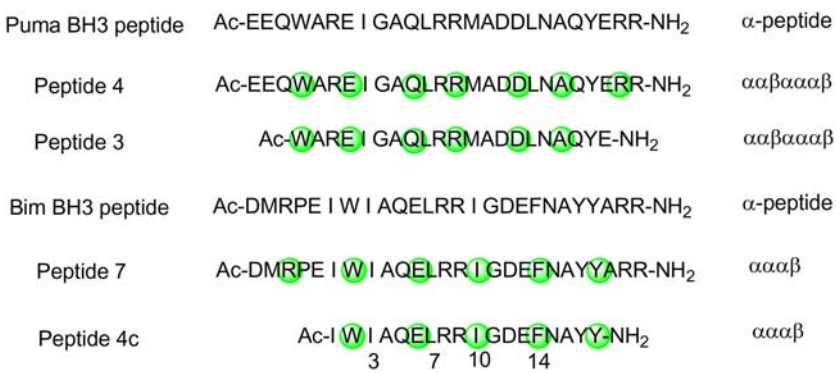

Fig. 39 Primary sequences of BH3 peptides derived from Puma and Bim and their α/β-peptide analogs. β^3-Amino acids are highlighted in *green*.

developed for the production of peptide libraries, allowing high-throughput synthesis and screening to facilitate rapid drug discovery. These synthetic methods include parallel synthesis, split–mix synthesis, and peptide microarray.[296]

6.03.7.1 Spatially Addressable Parallel Synthesis

In a parallel synthesis method, individual peptides are synthesized in separate reaction vessels, and this defines the sequence of a peptide based on the location of a particular reaction vessel. Geysen and coworkers reported the first combinatorial peptide library prepared with a multipin technology (Fig. 40A).[297] In this method, individual peptides were chemically synthesized on polyacrylic acid-grafted polyethylene pins that were arrayed in a 96-well microtiter plate. Each well in the plate served as a distinct reaction vessel. Pin loading levels are relatively low (approximately 50 nmol pin^{-1}) compared with standard solid supports.

Houghten and coworkers introduced a tea-bag method for multiple peptide synthesis (Fig. 40B).[298] In this method, peptide synthesis occurs on polymer beads that are sealed inside labeled and porous polypropylene packets. Amino acid couplings are carried out by immersing each packet in a solution of an activated amino acid. By using this method, a 248-membered peptide library of 13-residue long peptides was constructed in the quantity of 10–20 mg for each peptide.

With SPOT synthesis protocol, a peptide library can be produced in a stepwise manner on a flat surface like functionalized cellulose membrane by following standard SPPS procedures (Fig. 41).[299] A solution containing an activated amino acid is dispensed on the membrane, and the resulting circular spots serve as independent microreactors. The dispensed volume determines the spot size that defines the number and quantity of peptides that can be assembled on the membrane. A completed peptide library can be either screened directly while bound to the membrane or released from the membrane for subsequent solution-phase bioassays. Although the density of peptide libraries from SPOT synthesis is relatively low (approximately 20 spots cm^{-2}) compared with photolithographic methods (vide infra), SPOT synthesis offers several advantages for building peptide libraries, such as ease of experimental procedures, inexpensive equipment, and highly flexible library formats.

Fodor and coworkers first described light-directed, spatially addressable peptide array synthesis by combining solid-phase chemistry with lithography techniques (Fig. 42).[300] In this method, a photolabile group [e.g., 6-nitroveratryloxycarbonyl (NVOC)] is used for protecting the α-amino groups of amino acids. The photolabile group on a glass substrate is removed in a spatially defined manner by illuminating specific regions through a lithographic mask. Subsequently, the released amino groups in the exposed

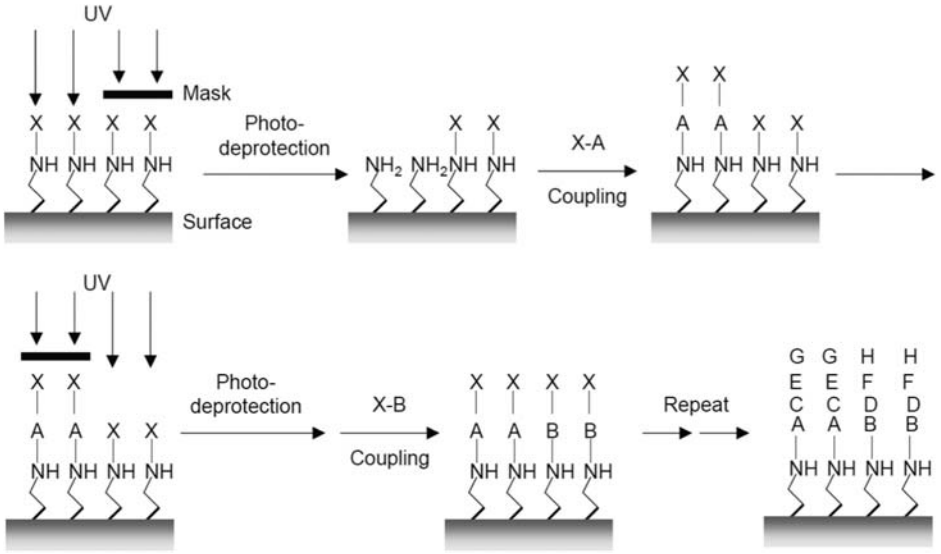

Fig. 42 Light-directed, spatially addressable peptide array synthesis.

sectors are coupled to an NVOC-protected amino acid. By repeating the selective photodeprotection and coupling cycles, they prepared a peptide array consisting of 40,000 compounds cm^{-2} with a $50 \times 50\ \mu m^2$ mask.

6.03.7.2 Split and Mix Synthesis

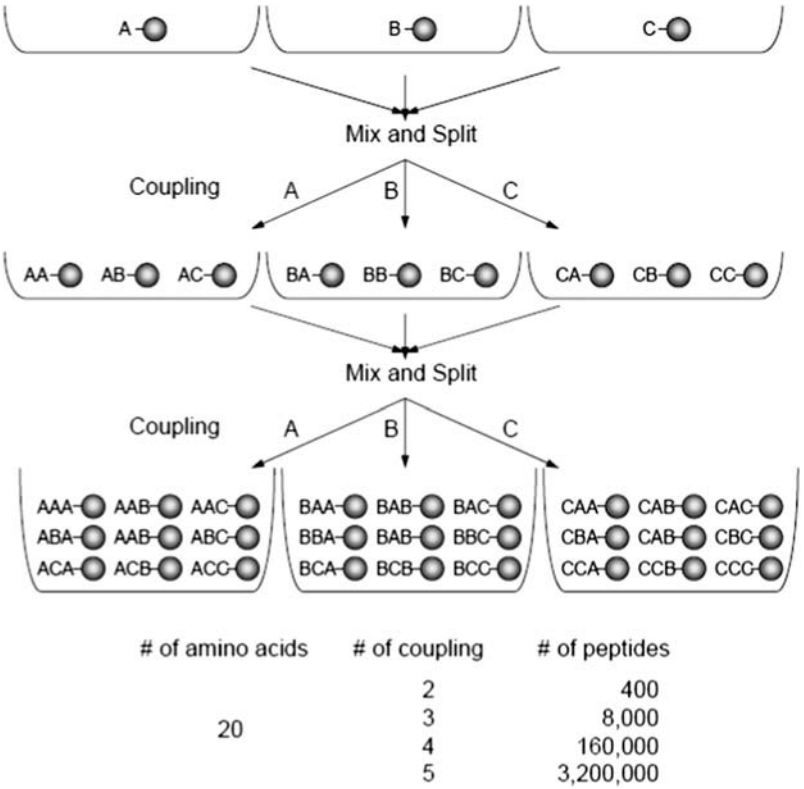
Hruby and coworkers reported a split and mix synthesis strategy for the construction of libraries with equimolar mixtures of peptides.[301] In this method, resin beads are split into multiple, equally sized portions in separate reaction vessels for coupling individual amino acids separately. All resin portions are then combined and mixed thoroughly. By repeating the procedure for 3 coupling steps with 3 amino acids, a combinatorial library of 27 peptides, for instance, can be readily prepared (**Fig. 43**). The library size increases with the number of coupling steps and amino acids. A pentapeptide library with 20 natural amino acids would contain 3,200,000 different peptides. Alternatively, a large peptide library can be prepared by coupling mixtures of all amino acids in one reaction vessel. To compensate for the difference in coupling rates of each amino acid, the ratio of amino acids in the coupling mixture can be corrected by adjusting their relative concentrations.[302]

Since this split and mix method produces mixture-based libraries, a deconvolution process is required to identify active molecules in the mixture of peptides. There are two main deconvolution approaches, an iterative process[303] and positional scanning.[304] Using the iterative deconvolution approach, a set of sublibraries are prepared in a manner such that each separate sublibrary has a defined amino acid at position 1 with a combination of all amino acids at the remaining positions 2–6 (**Fig. 44A**). Screening the sublibrary determines the most effective amino acid at the defined position (e.g., Asp in **Fig. 44A**). With the best amino acid fixed at position 1, another sublibrary containing a defined amino acid at the next position is prepared and screened to determine the best amino acid residue at position 2. Repeating this procedure for all of the positions, a complete sequence of the final peptide can be identified.

In the positional scanning approach, separate positional libraries are produced, each of which contains a defined amino acid at one position and a combination of all amino acids at the others (**Fig. 44B**). All sublibraries are then examined to determine the most effective amino acid at each position. Final peptide sequences are reconstructed by placing the amino acid that shows the best results at each position.

6.03.7.3 Phage Display Library

In the phage display technique, foreign DNA fragments are inserted into the encoding gene for a bacteriophage (phage) coat protein for inducing the phage to express peptides on its surface without affecting virus infectivity.[305] Filamentous phage M13 is the most widely used for peptide display due to its high capacity for replication and ability to accommodate large pieces of foreign DNA. Peptides are expressed as fusions to the N-terminus of pIII proteins of M13 phage (**Fig. 45**). The phage display is easy to grow and amplify through infection to the bacteria host *E. coli*, which generates a diversity of 10^8–10^{10} different peptide sequences. The sequences of biologically active peptides identified from phage display libraries can be easily determined by DNA sequencing.



# of amino acids	# of coupling	# of peptides
20	2	400
	3	8,000
	4	160,000
	5	3,200,000

6.04.1 Introduction

The development of somatostatin–dopamine chimeric compounds began with the search for more effective therapies for acromegaly. Acromegaly, which is caused by chronic, excess growth hormone (GH) secretion, is nearly always due to a benign tumor of the somatotroph cells of the pituitary gland. GH is one of the main factors responsible for regulation of growth and metabolism. Its production and release are normally tightly regulated through the dual action of two factors originating in the hypothalamic region of the brain: which stimulates the release of GH, and somatostatin (SST), which inhibits GH secretion. GH acts by binding to and activating specific receptors in the liver which results in the production and release of insulin-like growth factor 1 (IGF1), which is the primary effector of GH action. In addition to inducing growth and metabolic actions, circulating levels of IGF1 feedback to act on both the hypothalamus and the pituitary, to suppress GH secretion. When a somatotroph tumor (somatotropinoma) develops, GH secretion escapes the normal regulatory mechanisms and is secreted in excess, resulting in excess production of IGF1. When a somatotroph tumor occurs prior to the closure of the epiphyseal plates at the time of puberty, the excess GH and IGF1 production induces excess growth that can result in gigantism. Following puberty, and closure of the epiphyseal plates, excess GH and IGF1 induce growth of the soft tissues with resulting in physical changes in appearance, significant morbidity, and potentially, mortality.

6.04.2 Somatostatin

SST was first isolated from hypothalamic extracts in 1973, based on the suppression of GH secretion from cultured rat anterior pituitary cells.[1] The ability of SST to suppress GH is the basis for the development of several therapeutic SST analogs that retain the GH-suppressing property of natural SST, but have greatly enhanced metabolic stability and circulating half-lives. SST analogs are the most widely used medical therapy for controlling GH secretion in acromegaly; however, they are only fully effective in normalizing GH and IGF1 in approximately 35% of patients,[2] as illustrated in Fig. 1.

6.04.2.1 Lanreotide (Somatuline®) and Octreotide (Sandostatin®)

Part of the explanation as to why the current SST analogs are not more effective is due to the lack of information available for SST receptors (SSTRs) at the time of their development. The currently used analogs, lanreotide (Somatuline®) and octreotide (Sandostatin®) (Fig. 2), were developed prior to the elucidation of the SSTRs, and were optimized on the basis of minimizing the recognized ability of SST to suppress insulin, while maximizing the suppression of GH in rat models.[3–6] With the discovery of five distinct SSTRs, it was found that the type 2 SSTR (SSTR2) is the primary receptor responsible for suppressing GH secretion in the rat.[7] Consequently, both lanreotide and octreotide are highly potent at SSTR2 (Table 1).

6.04.2.2 Mechanism of Action

Later studies, utilizing human pituitary cells, revealed that in humans, unlike rats, both SSTR2 and SSTR5 suppress GH secretion,[7] and that activation of both receptors results in significantly greater suppression of GH than either alone.[10] Recognizing that natural SST has the ability to activate all five of the SSTRs, the combined activation of SSTR2 and SSTR5 is likely the mechanism by which GH secretion is normally suppressed in humans. This finding further suggests that one of the key factors responsible for the rather low percentage of acromegalic patients that are fully normalized by the currently available SST analogs is the need for greater activation of SSTR5, in combination with the ability to effectively activate SSTR2.

The concept that potent activation of both SSTR2 and 5 induces greater efficacy in suppressing GH than activation of SSTR2 alone is further substantiated by studies in cultured, human GH-secreting tumor cells using a potent, bi-selective activator of both the SSTR2 and 5 receptors, BIM-23244. Tumor cells were collected from acromegalic patients classified as either fully or only partially controlled clinically by the current SST analog, octreotide, and placed into culture. When tested in the cell cultures, octreotide induced a dose-related suppression of GH from the cells collected from fully responsive patients, but was only partially effective in suppressing GH from cells collected from partially responsive patients. In contrast, the SSTR2 and 5 bi-selective analog, BIM-23244, induced a full dose-related suppression of GH secretion in the cells from both populations, confirming greater efficacy from combined activation of both SSTR2 and 5.[11]

Unfortunately, additional studies into the pancreatic actions of the SSTRs revealed that, while activation of the SSTR2 indirectly suppresses insulin by suppressing glucagon secretion from the alpha cells, which still allows a normal insulin response to glucose, the activation of SSTR5 directly suppresses insulin secretion from the beta cells and does not allow the pancreas to respond to normal stimuli, resulting in the development of hyperglycemia.[12,13] Thus, therapeutic analogs with potent SSTR5 activity are

potentially problematic for chronic use. Understanding that the currently used clinical analogs of SST were optimized on the basis of separating GH- and insulin-suppressing activity, explains the greater potency at SSTR2 versus SSTR5, and, consequently, at least in part explains the reason for their inability to normalize GH and IGF1 in a greater percentage of acromegalic patients. While combined, potent activation of both SSTR2 and 5 proved to be problematic, it did establish the concept that activation of multiple receptors could offer enhanced therapeutic options for acromegaly, as well as other target diseases.

Building on the concept of targeting multiple receptors to achieve greater efficacy, observations reported in the clinical literature indicated that treatment of acromegalic patients with a combination of SST and dopamine (DA) agonists results in greater control of GH than the use of either agent alone.[14–17] DA, which is the natural suppressor of prolactin (PRL) secretion, stimulates GH secretion in normal individuals; however, in acromegalic subjects, DA suppresses GH.[18] These clinical observations lead to the idea of combining structural elements of both SST and DA into a single, chimeric compound that would retain the ability to interact with both receptors. Once prototype chimeric compounds had been obtained, studies in cultured primary human GH-secreting adenoma cells were used to compare the GH-suppressing activity of the chimera versus individual SST and DA analogs, both alone and in combination. In this system, both the individual SST and DA analogs produced dose-related suppression of GH secretion; however, in contrast to the clinical literature, when tested at the cellular level, the combination of SST and DA agonists produced no greater suppression of GH than the SST agonist. In sharp contrast to the results with combined individual SST and DA analogs, the addition of the dual SST and DA chimeric compound induced significantly superior potency and efficacy in suppressing GH.[19,20] In addition, the chimeric compounds were significantly more potent than individual DA analogs in suppressing PRL secretion from culture-mixed GH- and PRL-secreting adenomas.[19,20]

While the actual mechanism for the superior activity of the chimeric compound versus combined individual agonists remains unknown, an intriguing possibility has presented itself with the observation that SST and DA receptors interact to form heterodimers that, once activated, induce greater effect than the monomeric receptors.[21,22] While it is unlikely that the chimeric SST–DA

compounds physically induce heterodimer formation, it is possible that they stabilize the receptor interactions that occur spontaneously, and, in doing so, produce greater activation of transduction mechanisms and, consequently, greater efficacy in suppressing GH. This possibility remains to be fully elucidated.

Finally, acromegalic tumors are not alone in being affected by both SST and DA. Other potential indications include ACTH-secreting corticotroph tumors that cause Cushing's disease; prolactinomas, that in most cases are highly sensitive to the suppressive actions of DA, but in a portion of cases are resistant; nonfunctioning-pituitary adenomas that are largely derived from the gonadotroph cells, and are so-called because they secrete nothing of biological consequence but pose a threat from unabated growth; and the gastroenteropancreatic neuroendocrine tumors (GEP-NETs) of the GI tract. Additional study will be required to determine if the enhanced interactions observed between SST and DA receptors in acromegalic tumors, and induced by the chimeric SST–DA compounds, also occurs in other cell types, and offers the potential for treatment by this novel class of compounds.

6.04.2.3 Initial Design: Selection of the SST Agonist Peptide Fragment

We initiated our designs for the chimeric molecules by selecting peptide fragments targeting SSTR2 from our extensive library of somatostatin-like peptides. These peptide analogs were produced at IPSEN during the development of lanreotide primarily as selective dual SSTR2 and SSTR5 agonists. All peptides with potent, selective SSTR2 agonist activity that were structurally similar to octreotide and lanreotide were selected for initial evaluation. Binding activity across all five of the human SSTR subtypes was then assessed relative to somatostatin, lanreotide and octreotide (Table 1). In general, these compounds had excellent activity for SSTR2 with approximately 10-fold less activity on SSTR5, poor activity on SSTR3, and little to no activity on SSTR1 and 4.

We focused our attention on the peptides BIM-23190 and BIM-23197 (Fig. 3), which besides having a desirable selectivity profile against the SSTRs, had also been evaluated for their pharmacokinetic properties in rats.[9] BIM-23190 and BIM-23197 demonstrated improved plasma stability with terminal half-lives of 3.76 and 3.26 h, respectively, when compared with lanreotide, which is

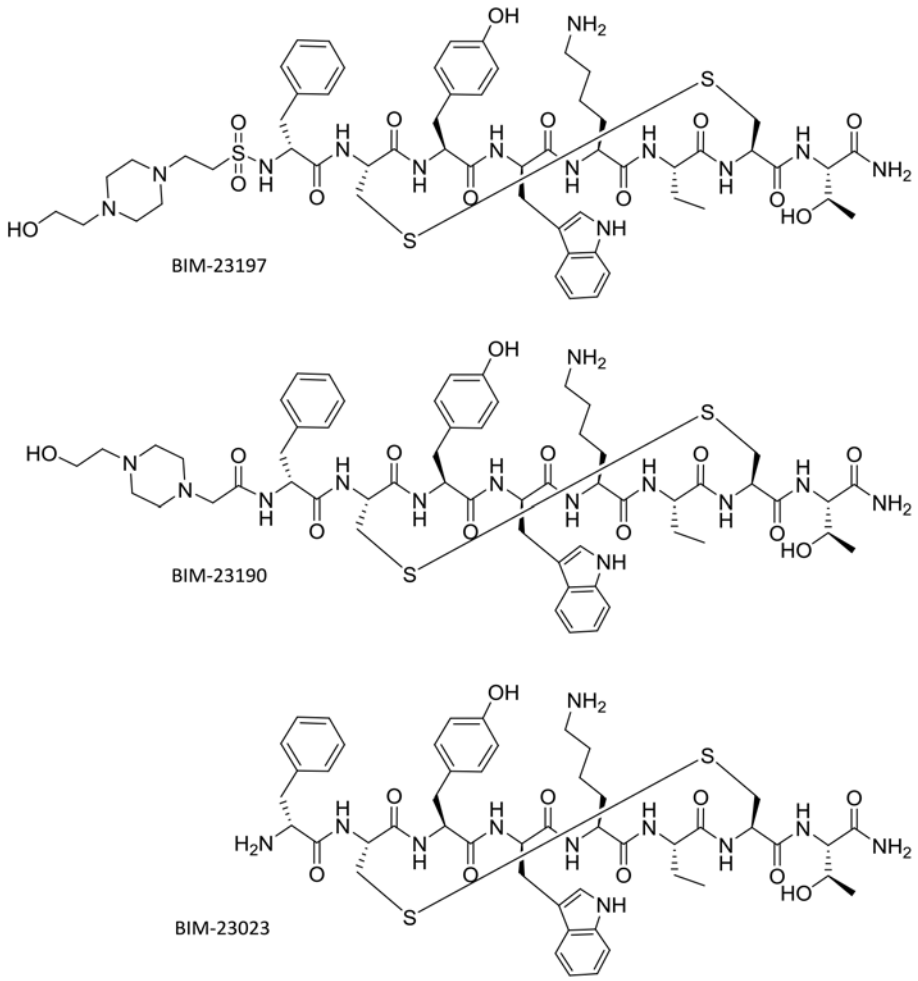

Fig. 3 Chemical structures of selected SST peptide analogs.

rapidly metabolized within 1 h. They also had desirable tissue distribution profiles, with a preference for adrenal, pituitary, and pancreatic tissues that closely correlates with the abundance of SSTR2 mRNA seen in these tissues.[9]

Peptides BIM-23190 and BIM-23197 were also interesting from a structural point of view as they differ from lanreotide primarily in the groups attached at the N-terminal amino acid. The addition of these groups did not seem to have an effect on the overall selectivity or the level of binding to the SSTRs, but did significantly increase the in vivo terminal half-lives. These data suggested that using the N-terminal region of these peptides as an attachment point for different groups, like a DA agonist, would be a good place to start. Potentially with these type of modifications, it might be possible to maintain the good receptor binding profile and beneficial effects on PK and tissue distribution seen with molecules like BIM-23190 and 23197. The parent peptide of both BIM-23190 and 23197 analogs was the same peptide BIM-23023, which then became our scaffold of choice for the preparation of the first chimeric dual agonists or dopastatins.

6.04.2.4 Initial Design: Selection of the DA Receptor Agonist Fragments

At the beginning of the dopastatin project, IPSEN did not have any molecules in its compound repository that were specifically designed to target DA receptors. Therefore, we conducted a comprehensive search of the literature for existing DA receptor subtype 2 (D2R) agonists. The search focused on small molecules in order to keep the molecular weight of the final compound as low as possible and not counteract the desirable physical properties associated with the peptide. Four potential candidates seemed reasonable: pergolide, cabergoline, terguride, and bromocriptine (**Fig. 4**). From this list, bromocriptine, a semisynthetic analog of ergocryptine,[23] was eliminated because of its complicated structure (polycyclic tripeptide group) and instability in vivo.[24] This left only three compounds as potential starting points for the DA fragment that would be attached to the peptide.

Examination of the three remaining structures showed that they only differ in the substitutions at the N-6 and C-8 positions. None of them, unfortunately, had obvious attachment points for coupling to a peptide, or were available in large enough quantities to allow for easy chemical modification. Therefore, development of a synthetic route to these fragments that was both flexible and scalable became a high priority for the project. Fortunately, starting from the readily available lysergol, a synthetic route (**Scheme 1**) which was suitable for producing analogs of all three parent molecules, was able to be developed.[25] Selective reduction of the protected lysergol ring junction double bond produced the desired "core scaffold" with the correct stereochemistry. Subsequent removal of the N-6 methyl group with ACE-Cl then allowed easy substitution with other groups, such as the propyl chain found in pergolide. One of the key features needed in the DA fragments was a good attachment point to link to the peptide. In that regard, further modification at the C-8 position of the "core scaffold" via displacement of the mesylate from intermediate 2 with 2-thioacetate and hydrolysis, yielded an acid group suitable for coupling to the N-terminal amine of the peptide (**Scheme 1**). In particular, the DA fragments with the N-6 methyl or propyl groups shown in **Scheme 1**, named "Dop1" and "Dop2," respectively, were used extensively throughout the program. By using similar chemistry, we were able to make a variety of DA fragments suitable for coupling to the peptide. To be sure that the modifications we had made to the fragments were not going to adversely affect their ability to bind the D2R receptor, we tested most of the fragments for their D2R affinity prior to coupling (**Table 2**). Those fragments that retained activity were then coupled to the peptide fragments to make the first dopastatins.[25]

6.04.2.5 Dopastatin Synthesis and Structure–Activity Relationship

The synthesis of the chimeric compounds began with the solid-phase peptide synthesis on Rink® resin of the peptide fragment using standard Fmoc chemistry. Cyclization to form the disulfide bridge, followed by coupling to the DA fragment, deprotection, and purification by reverse-phase HPLC, produced the desired chimeric dopastatin molecules. For example, BIM-53097 (Dop2) was coupled to Boc-BIM-23023 to create dopastatin analog BIM-23A387 (Scheme 2).

A library of dopastatin analogs was produced in this manner by coupling a variety of DA fragments to the terminal amino group of the peptides. The DA and SSTR binding affinities were then evaluated using radioligand binding assays with membranes from transfected CHO-K1 cells expressing the appropriate receptor subtype. From the library of dopastatin molecules, several structure–activity relationship trends became apparent. As exemplified by the compounds derived from the BIM-23023 peptide (Table 3), the pergolide-based DA fragments, such as those used for BIM-23A370 and BIM23A387, gave the best overall affinity at both the D2R and SSTR2 receptors. Additionally, compounds with propyl groups at N-6 had higher D2R affinity than their methyl counterparts. Following these observations, most of the subsequent optimization focused on compounds which retained these modifications.

The type and length of the linkers used for the coupling of the DA fragment to the peptide were also extensively studied. Various Aepa and/or Doc linkers (Table 4) were used to test the effects of length, rigidity, and polarity with both Dop1- and Dop2-type fragments. The reason for choosing Aepa as the linker was the following. First, the N-termini of both lanreotide and octreotide are positively charged (free amines), and Aepa, which has two free amines, would maintain or increase this positive charge. Second, both peptides BIM-23190 and BIM-23197 with excellent SSTR2 binding affinity and in vivo PK properties contain similar groups to Aepa at their N-termini (Fig. 3), which we would like to mimic. The Doc linker was selected because of its good hydrophilic properties and structural flexibility that would allow the DA fragment to find its best binding conformation. Having a linear ethylene oxide unit, Doc also allows the distance between the peptide and DA moieties to be extended slightly further than with Aepa, which might help facilitate the simultaneous interaction with both the D2R and SSTR2 binding sites. To further explore if the length of the linker would have a positive impact on binding, we also used the double linkers Doc–Doc or Aepa–Aepa. In general, the binding affinity data showed that the Doc linker consistently outperformed the positively charged Aepa (see BIM-23A732 vs. BIM-23A730 and BIM-23A756 vs. BIM-23A745) (Table 4). Interestingly, the length of the linker turned out to be the more critical parameter. Compounds with double spacers had lower affinity than those with only a single spacer, and the no linker or directly attached DA compounds like BIM-23A370 and BIM-23A387 had significantly higher affinity. Again, the N-6 propyl Dop2 compounds consistently outperformed the N-6 methyl Dop1 analogs.

From the binding data, the best compound, BIM-23A387, was chosen as a lead candidate for further biological evaluation. The ability of BIM-23A387 to suppress GH and PRL secretion was assessed in cell cultures prepared from human GH-secreting pituitary adenomas collected at surgery from acromegalic patients. BIM-23A387 was compared to its parent SST peptide analog, BIM-23023, and the D2R agonist, BIM-53097 (Dop2), both of which had comparable activities as BIM-23A387 at their respective receptors.[19]

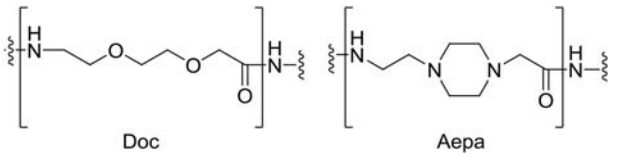

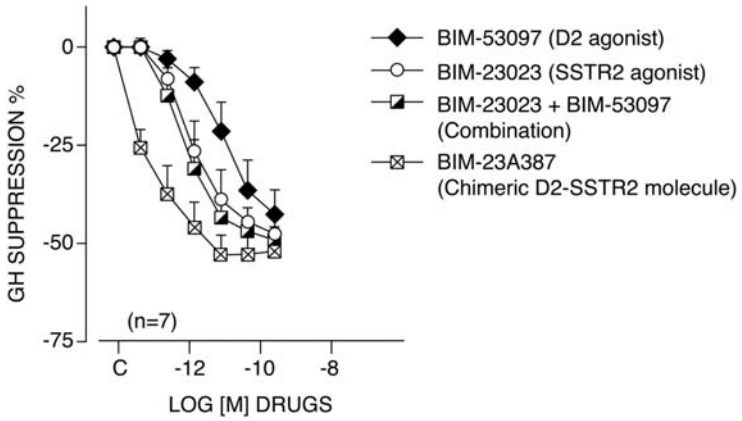

Fig. 5 Dose responses of GH suppression by D2R agonist BIM-53097, SSTR2 agonist BIM-23023, the combination of both compounds, and BIM-23A387 in seven octreotide-sensitive adenomas.[19]

While BIM-23A387 showed similar maximal inhibition of GH release as the combination of the two individual SST and DA analogs, the mean EC_{50} for suppressing GH secretion was 50-fold lower than for the individual agonists, either tested individually or combined (Fig. 5).

Similar data for BIM-23A387 was obtained with tumors collected from individuals that, clinically, were only partially responsive to octreotide; however, significantly greater maximal suppression of GH was obtained with the dopastatin analog versus the combination of the two individual agents. In addition, a mean 73% ± 6% inhibition of PRL secretion from mixed GH- and PRL-secreting tumors further demonstrated the superior activity of BIM-23A387. For all the samples, real-time PCR quantitative analysis was performed on the tumor fragments to confirm the expression of D2R and SSTR2 receptors.

Following the success of BIM-23A387, we decided to investigate the optimal ratio of DA fragments relative to the peptide to try and further increase D2R activity. In order to increase the number of DA fragments in the final molecule, it was necessary to increase the number of linker sites on the peptide. This was done by using lysine as a terminal amino acid, in addition to, or as a replacement for, the terminal D-phenylalanine.

Table 5 Binding affinity of dopastatins with varying dopamine fragments (nM)

BIM-23A760	843	0.03	160	>1000	42	15

Addition of a lysine bearing two Dop2 fragments to the peptide resulted in the compound BIM-23A766 with minor improvement in DR2 binding (Table 5). When the terminal phenylalanine was replaced with lysine, as in BIM-23A757, the affinity at the D2R did increase but at the expense of affinity at the SSTR2 receptor. In order to more closely mimic the D-phenylalanine present in the parent peptide and enhance the enzymatic stability of the linker, the lysine was replaced by its D-isomer resulting in compound BIM-23A760. Impressively, a dramatic improvement was seen on the SSTR2 binding without any loss to the DR2 affinity. Compound BIM-23A760 turned out to be the best SSTR2 binder we had achieved to date and became the lead molecule for the program selected for preclinical development.

BIM-23A760 (Fig. 6) was fully profiled against all of the SSTRs (Table 6) and demonstrated excellent selectivity for the SSTR2. With good primary affinity, we were particularly keen to see if this would translate into improved cellular and in vivo activity.

BIM-23A760 was studied in a comprehensive set of experiments focused on the suppression of GH and PRL in 18 human GH adenomas that were only partially responsive to octreotide or lanreotide. It was compared with octreotide, BIM-23A387, and a number of other dopastatin analogs.[20] BIM-23A760 demonstrated significantly superior suppression of GH, both in terms of potency and maximal suppression, as compared with the individual SST and DA analogs, both alone and in combination, as well as compared with the original dopastatin prototype, BIM-23A387. With these in vitro results in hand we began to profile BIM-23A760 in vivo.

6.04.3 Profiling of BIM-23A760

After initial in vitro evaluation, BIM-23A760 was tested in several animal models, including normal cynomolgus monkeys.[26] A single, subcutaneous (SC) injection of 1 nM to 1 μM kg^{-1} produced a significant, dose-related suppression of GH from 15 min to 48 h postinjection. There was a similar dose-related effect on PRL and dose-related suppression of IGF-1 at 24 h postinjection.

Significantly, no effect was observed on insulin secretion or circulating glucose at any time or dose of BIM-23A760 during the study.[27] These results suggested that BIM-23A760, may be an effective therapy for a larger percentage of acromegalic patients than currently available with pure SST and dopmaine agonists, with no untoward effects on either insulin secretion or glycemic control.

BIM-23A760 was subsequently advanced into clinical development primarily based on the following criteria:

- High affinity and selectivity for the DA and SSTRs.
- Greatly enhanced potency and efficacy in suppressing GH secretion from cultured human acromegalic tumors, as compared with SST and DA analogs, both alone and in combination.
- Efficacy in multiple in vivo animal models.
- Excellent safety results, no clinical toxicity signs seen in animal studies and no effect on insulin secretion or glycemic control.

6.04.3.1 BIM-23A760 Phase 1 Clinical Studies

Phase 1 PK studies with single SC bolus injections of BIM-23A760 in healthy subjects demonstrated dose proportionality (Fig. 7) and an extended half-life. Pharmacodynamic effects on PRL levels showed significant suppression for prolonged periods of time >8 days with doses >1 mg with no significant side effects[28] (Fig. 8). Doses of 1 and 4 mg were subsequently selected for further evaluation during Phase 2 studies.

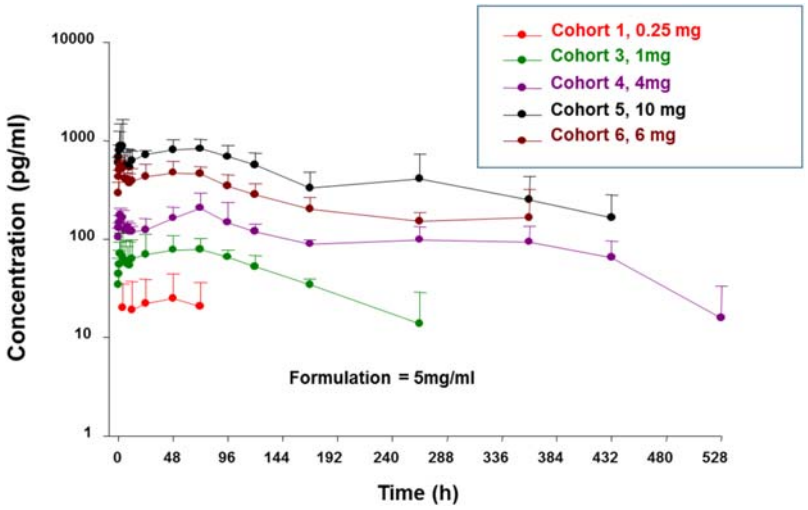

Fig. 7 Phase 1 pharmacokinetics of BIM-23A760 from single subcutaneous bolus injections in healthy subjects.

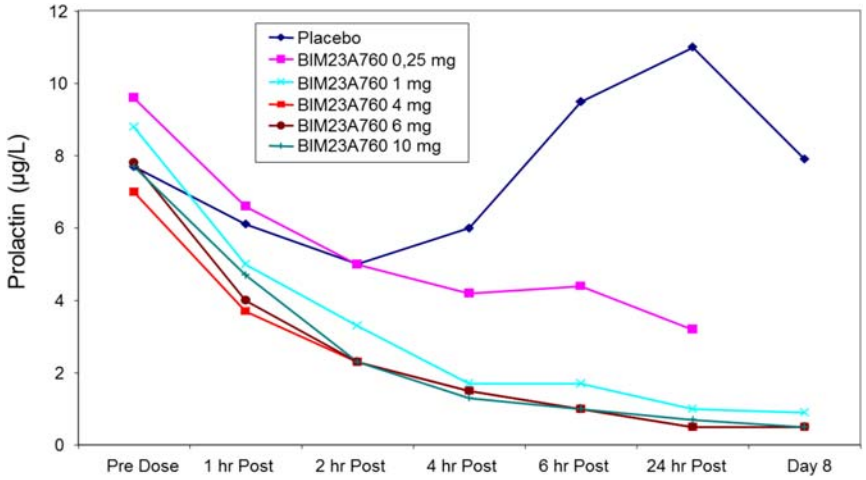

Fig. 8 Phase 1 PRL pharmacodynamic effects of BIM-23A760 from single SC bolus injections in healthy subjects.

6.04.3.2 BIM-23A760 Phase 2a and b Clinical Studies

The initial Phase 2a study on BIM-23A760 in acromegalic patients demonstrated that a single SC dose resulted in a significant and prolonged, dose-related suppression of circulating GH levels[29] (Fig. 9).

Unexpectedly, however, during the Phase 2b Tulipia study, NCT00994214, examining chronic, repeat dosing of BIM-23A760 in acromegalic patients, the suppressive effect on circulating GH levels diminished over time, while PRL levels remained profoundly suppressed. Without the ability to be effective when dosed over an extended period of time, BIM-23A760 was withdrawn from further clinical studies.

In order to determine the cause for the lack of sustained effect upon GH levels, the clinical blood samples were examined to determine the concentration of BIM-23A760, and were analyzed for major metabolites.

6.04.3.3 BIM-23A760 Metabolite Analysis

The follow-up study of the clinical blood samples revealed that BIM-23A760 produced a metabolite that was present in high concentrations and that accumulated rapidly with continued administration (Fig. 10). The metabolite consisted of the terminal lysine amino acid coupled to both of the DA fragments (Fig. 11). The affinity of the BIM-23A760 metabolite at the D2R receptor was compared to that of BIM-23A760 and found to be similar (Table 7). Strikingly, however, the metabolite turned out to be >200-fold more potent at activating the D2R receptor than its parent BIM-23A760, with an EC_{50} of 0.005 nM. The metabolite also demonstrated significantly lower plasma protein binding than BIM-23A760, indicating that it might be more readily available for binding

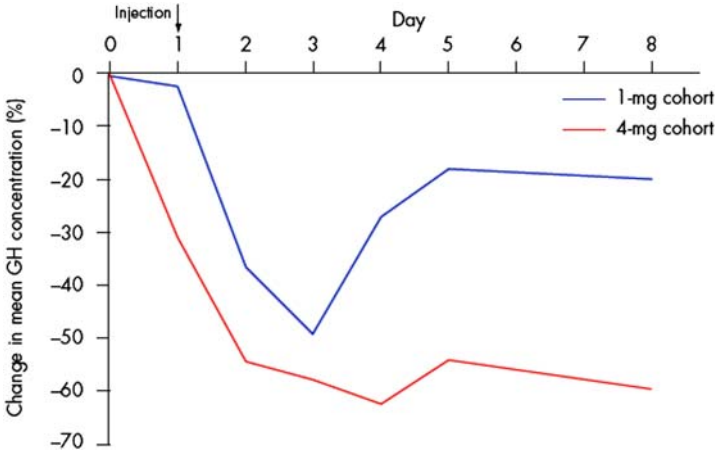

Fig. 9 Phase 2a study of GH levels in acromegalic patients from single SC bolus injection of BIM-23A760.

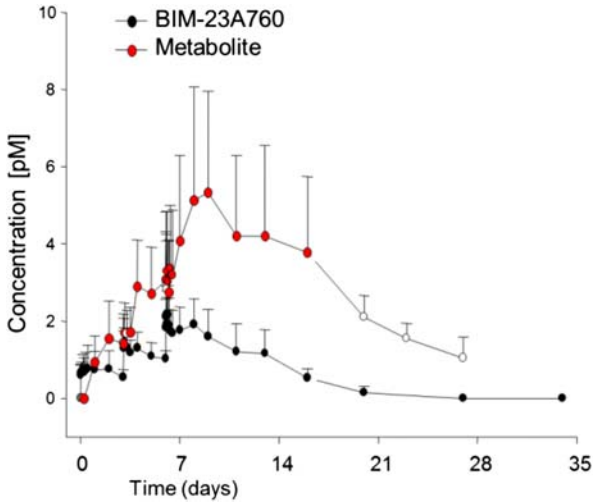

Fig. 10 PK of BIM23A760 and its major metabolite in human subjects.

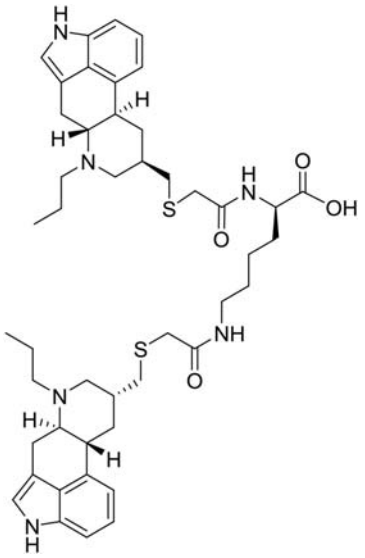

Fig. 11 Structure of the major metabolite of BIM-23A760.

Table 7 Comparison of the receptor activity of BIM-23A760 and its major metabolite (nM)

	D2R	
Compound	*Binding (K_i)*	*cAMP (EC_{50})*
BIM-23A760	4.5	1.1
Metabolite	7.8	0.005

to the receptor than BIM-23A760. With increased availability and superior potency at the D2R receptor, the metabolite may effectively outcompete BIM-23A760, reducing its ability to act as a dual-receptor agonist, and its synergistic effect. The observed accumulation of the metabolite over time would likely exacerbate this problem. Based on these findings, a theory was proposed that the observed loss of BIM-23A760 clinical efficacy with chronic administration might be due to the accumulating metabolite competing with BIM-23A760 for the DA receptor.

6.04.4 Second-Generation Dopastatin Design Concepts

Although BIM-23A760 was stopped in Phase 2 clinical development for lack of continued efficacy, the concept of a chimeric dual SST-DA agonist as a treatment for acromegaly still remained valid. We, therefore, chose to redesign the dopastatin molecules and create a second-generation compound to overcome the limitations associated with BIM-23A760.

Coincidentally, as the clinical development of BIM-23A760 was being stopped, pergolide, the marketed DA analog that formed the basis of the DA fragment for most of the dopastatins, was also withdrawn from the US market for human use (FDA advisory). Published studies earlier in 2003 and 2004 had revealed a link between the drug and increased rates of heart disease and cardiac fibrosis.[30] The cause of these effects seemed to be associated with significant agonist activity at the serotonin 2B receptor (5HT2B). Similar effects were observed with several other ergoline compounds such as cabergoline.[31] Interestingly, while pergolide acts as a full 5HT2B agonist, lisuride, a structurally similar compound exhibits no agonist activity at the 5HT2B receptor, and had not been linked to any adverse cardiac side effects.[31] In 2008, scientists from the University of Berlin characterized a number of pergolide derivatives in order to identify the molecular fingerprint that might be responsible for its adverse cardiac effects. Specifically, eight derivatives were tested with varying substitutions at positions N-6 and C-8 (Fig. 12). The data showed that the 5HT2B activity was almost completely attenuated when the N-6 propyl group was switched to a methyl group, while changes at the C-8 position showed little effect. Following this information, we chose to focus only on the N-6 methylated compounds for incorporation into our second-generation compound designs to minimize the chance for 5HT2B activity.

Another critical factor for the second-generation compound design centered around metabolism. With a major interfering metabolite possibly leading to the failure of BIM-23A760 in the clinic, producing compounds that minimized metabolite

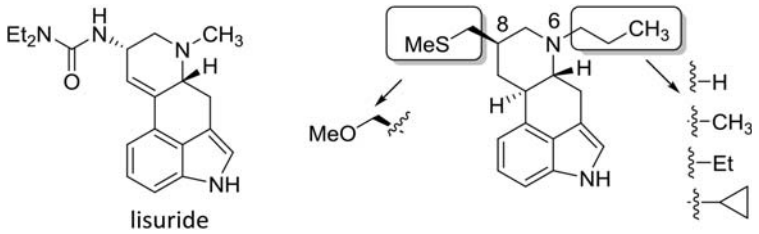

Fig. 12 Lisuride and pergolide analogs studied for 5HT2B receptor activity.

formation, or that produced metabolites with minimal capacity to interfere at the receptors, was a high priority. To assess our second-generation compounds, we also developed a new screening paradigm incorporating the following criteria:

- Increasing metabolic stability by fivefold relative to BIM-23A760, with no active metabolite that can interfere with the parent compound.
- Maintain efficacy at suppressing GH activity ≥ BIM-23A760.
- Decrease protein binding fivefold compared to BIM-23A760.
- Improve selectivity for DA receptors by reducing activity on 5HT2B receptor threefold compared to BIM-23A760.

With specific criteria established for the development of a second-generation compound, the program was taken back into research focused on delivering compounds against these parameters.

6.04.5 Second-Generation Design and Discovery of Lead Compound BIM-065

In order to minimize the formation of metabolites containing DA fragments, the peptide scaffold and the linker of the first-generation compounds were completely redesigned. Unlike the first-generation compounds, such as BIM-23A760, the linker was designed without a readily cleavable amide bond. The cyclic disulfide was also removed and replaced by cyclizing the peptide from its C-terminus to a sidechain residue. We also chose to eliminate any amino acid residues that would extend beyond the cyclic system to avoid additional enzymatic degradation. Incorporation of nonnatural amino acids also allowed for fine-tuning of the physical properties, particularly solubility. A series of high-affinity selective compounds were made, resulting with the selection of BIM-065 as a lead candidate. BIM-065 was directly compared to the first-generation lead compound BIM-23A760 for activity at the SST and DA receptors (Table 8).

BIM-065 demonstrated up to 16-fold greater SSTR2 agonist activity and similar selectivity versus SSTR5, compared to BIM-23A760. The excellent selectivity of BIM-065 for SSTR2 over SSTR5 continued to minimize adverse effects due to changing insulin levels. BIM-065 is threefold less active at the 5-HT2b receptor than BIM-23A760, and it is only a partial agonist, which greatly reduces the chance for any associated cardiovascular effects. In primary human tissue cultures of GH-secreting adenoma cells, BIM-065 demonstrates a clear dose-dependent suppression of GH secretion with an EC_{50} of 0.5 pM, and a maximal inhibition of GH release of 61%, demonstrating that the potency and efficacy of BIM-065 in suppressing GH secretion is superior to that of BIM-23A760 (Table 9).

0.5	2.5	61	41

Table 10 Comparison of the first- and second-generation dopastatins and their primary metabolites

	D2R			5HT2B		
	Binding	Ca^{2+}	cAMP	Binding	Ca^{2+}	
Compound	K_i (nM)	EC_{50} (nM)	EC_{50} (nM)	K_i (nM)	EC_{50} (nM)	$\%E_{max}$
BIM-23A760	4.4	16.7	1.1	1.4	31.2	92.1
760 metabolite	7.8	4.4	0.005	13.6	36.2	103.4
BIM-065	27.2	5.0	2.1	74.9	104.1	55.0
065 metabolite	490.8	836.8	21.8	>1000	>1000	68.4

In addition to improved potency and efficacy, BIM-065 has much better physicochemical properties than BIM-23A760. It is freely soluble at pH 5.5 ($\geq$113 mg mL^{-1}), with lower plasma protein binding, and an unbound fraction of ~7–12% as compared with ~0.5–0.7% for BIM-23A760. More importantly, its overall metabolic stability is greatly improved. In S9 fractions, BIM-065 has a half-life of greater than 180 min versus only 10 min for BIM-23A760. Despite these significant improvements, when BIM-065 was tested in vivo it still produced a significant metabolite. Because of the issues seen with the first-generation metabolite, we were extremely concerned about profiling the activity of the metabolite on the D2R and 5HT2B receptors, as well as its effects on GH secretion. We were pleased to find that the profile of the BIM-065 metabolite was significantly different than both BIM-065 and the metabolite of BIM-23A760 (Table 10).

The D2R and 5HT2B binding and activity of the BIM-056 metabolite are significantly less than the parent compound, BIM-065. The metabolite was also tested in rats with multiple doses up to 10,000 times greater than BIM-065 with no significant adverse events or accumulation after 5 days dosing. Most importantly, the ability of the metabolite to interfere with the effect of BIM-065 on GH secretion was tested in cultured pituitary adenomas that were partially responsive to octreotide. Increasing concentrations of the metabolite up to 10,000-fold excess were unable to alter the effect of BIM-065 on GH release tested at both the EC_{50} and EC_{80} effective concentrations.

6.04.6 Second-Generation Dopastatin: Current Status

With an improved biochemical and physicochemical profile, BIM-065 is able to overcome the major obstacle of producing an interfering metabolite that is believed to have resulted in the failure of the first-generation compound, BIM-23A760. BIM-065 has subsequently advanced through its preclinical evaluation and is currently completing Phase 1 clinical studies. Subsequent trials will help to validate BIM-065, as well as the overall dopastatin approach of a chimeric dual D2R and SSTR2 agonist, for the treatment of acromegaly, and indeed other potential indications that may be amenable to treatment through combined activation of SST and DA receptors.

6.05.1 Introduction

Biologic-based drugs are difficult to administer to patients in their native form. Proper formulation ensures the safety and efficacy of the active pharmaceutical ingredient (API) at the time of dosing and for extended periods of time in storage. The easiest storage of orally available drugs is in the tablet or capsule forms they are administered to patients. However, most biological drugs, such as peptides, proteins, and nucleic acids, are unstable and/or fail to be absorbed during enteric administration. The Lipinski's rule of five placed biological drug APIs into the unwanted second-grade pharmaceutical category.[1] The requirements for less than 500 Da molecular weight (MW), low hydrophilicity, less than five hydrogen-bond donors, and 10 acceptors all precluded biologics from being considered as desirable drugs for medicinal chemists. It was just very recently when it became clear that peptides/proteins outperform small molecules at the phase II → phase III transition stage (except for oncology applications) with 29% for small molecules and 42% for the biological drug candidates.[2] Although new delivery technologies widen the way peptide/protein APIs are stored, still, the most common forms are lyophilized powders or aqueous solutions in vials or other closed containers. Thus, the first tier of biological drug formulation is to make sure the solution structures are stable and deliverable, and their administration poses no danger to the patients.

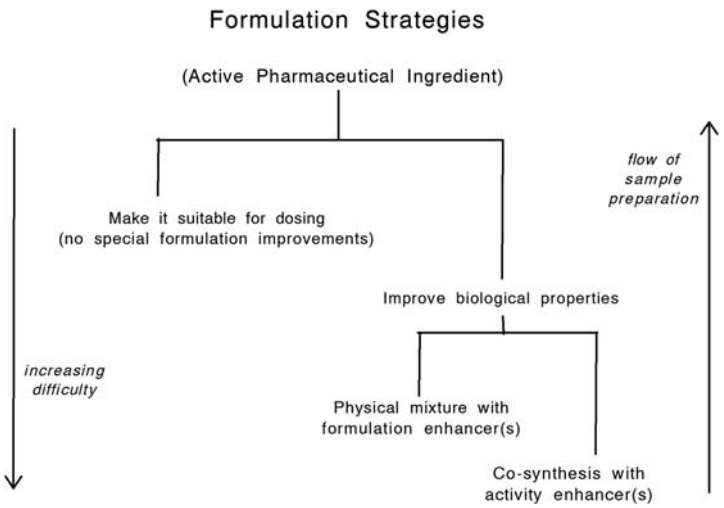

Fig. 1 Levels of formulation complexity for peptide and protein drugs.

The second tier of formulation returns to the drawbacks of peptide and protein drugs frequently cited, that is, proteolytic instability, low levels of oral activity and poor blood–brain barrier (BBB) penetration, disconnect between pharmacokinetic and pharmacodynamics parameters, and rapid renal and sometimes hepatic clearance.[3] To overcome these potentially troubling properties, biological dugs are either physically mixed or covalently linked to absorption enhancers, sequence and structure stabilizers, or agents aiming to delay the elimination time (Fig. 1).

Either with or without activity enhancers, various devices used for quick and efficient mucosal, subcutaneous, or intramuscular administration of any drug are optimized for peptide and protein API delivery.

6.05.2 Basic Formulation Principles

6.05.2.1 Solution Behavior of Nucleic Acids

The focus of this article is peptide and protein drugs that not only have proved clear therapeutical value by now but also for which significant medicinal chemistry efforts are devoted. Nevertheless, nucleic acids as drugs cannot be ignored, although gene therapy is still in its infancy in terms of clinical significance and treatment preference among all drug classes.[4] DNA-based drugs include plasmids and aptamers, and oligonucleotides are used as antisense and antigene applications. RNAs are also applied as aptamers and antisense treatment options, in addition to more contemporary variations such as small interfering and microRNAs.

Upon direct injection into skeletal and heart muscle, purified plasmid DNA is able to express recombinant genes.[5,6] The injection cocktails contain circular or linear nucleic acids dissolved in phosphate-buffered saline alone or in aqueous buffers supplemented with hypoxanthine, thymidine, sodium pyruvate, L-glutamine, trace elements, and growth factors. Alternatively, the DNA is dissolved in 5–20% sucrose prior injection by using a narrow needle.[7] Interestingly, naked plasmid DNA provides better gene transduction results than DNA complexes. Inflammation-inducing chemicals introduced during sample purification, including EDTA, endotoxins, and ethidium bromide, have to be removed from the solution to be administered. The efficacy of naked DNA delivery to tissues can be increased if physical force is applied, most notably pressure or high-frequency, low-voltage electric pulses.[8,9] Purely synthetic vectors seem to be safer than nucleic acids produced by viruses although at the same time they are also less efficacious.[10]

DNA is sensitive to hydrolytic degradation with significantly lower half-lives in room temperature than at colder environments.[11] This argues for storage as a lyophilized form especially as freezing, the first step of the lyophilization protocol, is the second safest storage form of synthetically made DNA therapeutics.

6.05.2.2 Solution Behavior of Proteins and Peptides

The basic formulation strategies of biopolyamides are regulated by the solution behavior of proteins and peptides. The regularly used distinction between peptides and proteins is still unclear and does not really apply to here. If we consider peptides as any native or backbone-modified polyamide that can be made on a contemporary peptide synthesizer, then the limit in size (approximately 100 residues) exceeds the arbitrary cutoff of 50 amino acids originally setup by the US Food and Drug Administration (FDA).[12] New FDA definition of peptides places the limit of amino acids to 40 residues although retains the 100 residue limit for entirely synthetic polyamides. More important, however, is how these molecules change some of their properties upon storage.

Proteins in solution can undergo a series of physical and biochemical alterations. For the sake of this discussion, we have to disregard enzymatic degradation or isomerization induced by catalysts included in the formulation. While this requirement seems

plausible for pharmaceutical grade preparations, other protein[13] or enzyme[14] contaminants are not unheard of in protein batches undergoing less thorough cleaning steps. The two main chemical modifications of protein formulations are deamidation and oxidation[15] in addition to biochemical alterations such as aggregation and denaturation or more generally conformational changes.[16] Other factors that may modify the physical characteristics of proteins in solution are pH, osmolality (ionic strength), temperature, and buffer composition.[17]

The main source of deamidation is the hydrolysis of asparagine and glutamine residues into aspartic acids and glutamic acids, respectively.[18] The reaction mechanism proceeds through cyclic imide intermediates without influence of time or temperature, suggesting a pathway without any direct side-chain hydrolysis.[19] One of the best known examples is insulin in which AsnB3 is deamidated in neutral and AsnA21 in acidic conditions. Similar reaction can also be observed for peptides such as exenatide. Conjugative degradation of model short aspartyl peptides was observed in aqueous solutions, and the reaction mechanism was suggested to be an alternative route to irreversible denaturation of proteins.[20] Similarly, isomerization of aspartic acid bonds at positions 1 and 7 into isoaspartates at the amyloid Aβ peptide results in the formation of extended structure, which can lead to aggregation in Alzheimer's disease.[21] As shown by using smaller peptides, a diisomerized Aβ fragment exhibits increased stability toward serum peptidases compared with the unmodified or single isoaspartic acid-containing peptides, suggesting yet another possible mechanism of enrichment of isomerized Aβ in the affected brains. Finally, isomerized Aβ fragments are more immunogenic than those having regular aspartic acid side-chain structures. While peptides are in general unable to induce antibody production in animals, if it does happen, immunogenicity of modified peptides and especially proteins is detrimental for potential therapeutic use. Other nonenzymatic chemical modifications of proteins include the loss of carbohydrate side chains or reduction of disulfide bonds together with formation of nonnative Cys–Cys bridges.

Aggregation is the assembly of protein chains to higher MW, even sometimes visible or subvisible particles.[16] For most cases, conformational changes leading to extended structures precede macromolecular aggregation, and thus, it is important to maintain the thermodynamic and structural stability of proteins in liquid environment. Some of the aggregates formed upon storage are/can be reversed before administration to patients, although, in these cases, emerged toxicity issues should be studied very diligently. When aggregation is not reversible, visible precipitates form that are similar to a priori insoluble protein deposits. In our experience, addition of various adiponectin protein preparations to cells induces a wide range of biological responses (or lack thereof),[22] and this phenomenon was explained as the varying aggregation state of commercial adiponectin preparations from monomers through trimers to hexamers.[23] In addition to the β-pleated sheet-forming potential (or related to that), the extreme hydrophobicity of adiponectin protein and its C-terminal, active domain, prevents pharmaceutical development at the research scale and is expected to raise even larger problems when the larger polyamide preparations are ready for vialing and clinical development.[24] In this regard, active site peptides are significantly easier to handle and optimize for maximal therapeutic effects.[25]

In addition to aggregation initiated by thermodynamic instability of monomers, physical stress can also induce aggregation of protein therapeutics. From these, the most studied processes are thermally induced and mechanically induced aggregation, where the former category can be expanded with aggregation taking place during freeze-drying cycles.

Exposure to hydroxyl radicals leads aggregation to the last most studied protein modification, that is, oxidation. Hydroxyl radicals in solution, but not exposure to superoxides, can produce covalently bound protein aggregates together with extensive changes in net electric charge.[26] Tryptophan is lost, and bityrosine biphenol appears during hydroxyl radical exposure. Residual metals can initiate oxidative degradation in proteins, even when tight controls with stringent specification on the amount of metal impurities are implemented.[27] Redox-active transition metals influence the processing and/or storage of biological pharmaceuticals and are capable of generating radicals by redox reactions with organic and inorganic substrates and molecular oxygen.[28] The major mechanisms of oxygen activation by metal ions are Fenton/Haber–Weiss reaction and autoxidation.[27] The substrates are molecular oxygen, superoxide, and hydrogen peroxide. Organic solvents or photochemical reactions involving some excipients can also induce oxidative damage in protein therapeutics.

6.05.2.3 Freezing and Lyophilization

To avoid the problems related to physical and biochemical changes of proteins and peptides in aqueous solutions, freezing and lyophilization are the preferred method for long-term storage of these polyamides. Freezing of peptides and proteins is certainly a useful procedure to avoid deterioration of the products by significantly slowing down or completely stopping of kinetically controlled processes. However, repeated freeze–thaw cycles have their own dangers for protein quality and biological activity. While slow freezing (at a freezing rate about $1^{\circ}C\ min^{-1}$) and fast thawing (at a thawing rate $> 10^{\circ}C\ min^{-1}$) protocols yield higher activity recovery, fast freezing with slow thawing results in more severe damage to proteins.[29] This phenomenon is probably due to surface-induced denaturation during the freezing and thawing process. The freezing damage of proteins and aqueous solutions can be reduced by optimally selecting the type of storage buffer type and its composition.

Protein chemistry laboratories recommend adding 5% glycerol or sucrose or various salts to sufficiently stabilize a protein to freezing in liquid nitrogen. Many enzymes that are stable at high concentrations appear to be unstable when used or stored after dilution. The reason of this observation is likely adsorption to the wall of the containers used for storage. In this case, siliconizing the containers or adding low concentrations of surfactants or auxiliary proteins can eliminate the loss of protein activity. If the right solution is found for freezing, the main difficulty is securing stringent cold chain conditions for storage, shipping, and distribution.[16]

During freeze-drying, most of the solvents used for purification, usually water, are removed under mild conditions under reduced pressure. The basic principle of lyophilization is sublimation, an endothermic phase transition that produces gas (in our case water vapor) directly from a solid state (ice for proteins). Lyophilization proceeds through three steps, that is, freezing and primary and secondary drying in industrial conditions. In laboratory environment, the two drying stages are usually combined. After freezing the aqueous solutions well below 0°C, at research scale down to −20°C to −40°C, at industrial scale to −10°C, primary drying is initiated by introducing vacuum in the drying chamber/container.[30] The internal pressure is reduced below the saturated vapor pressure of ice at the frozen product temperature providing a driving force for sublimation. At research scale, the container under vacuum is immediately placed to ambient temperature. In large-scale lyophilizers, when the frozen bulk water is removed at low temperature, the temperature is raised to ambient values or above, to evaporate the bound water remaining in the product. The cycle is completed when the desired residual moisture level is achieved.

Depending upon the design and quality of the apparatus, the strength of the vacuum applied and the temperature of the frozen cake, lyophilized peptides always contain 20–30% (w/w) residual solvent, usually water, and sometimes solvents remaining from the reversed-phase liquid chromatography steps such as trifluoroacetic acid and acetonitrile. First, it is imperative to repeat the lyophilization cycle from diluted acetic acid to remove all trifluoroacetate liquid and counterions that can significantly change animal responses (cells are usually not sensitive to low concentration of organic counterions). Second, the actual peptide concentration of the lyophilized samples has to be quantitatively identified. In our experience, amino acid analysis is not suitable for that purpose. We calibrated high performance liquid chromatography (HPLC) columns used for nothing else than this purpose with marketed peptide drugs of known peptide content and run the samples through this column before testing in any biological system.[21]

For pharmaceutical proteins, excipients are added to the freeze-drying mixture to avoid the production of unwanted side products or eliminate potentially harmful conditions.[30] These may include buffers (tris, histidine, or citrate) to prevent acidification during freezing; specific ligands or pH conditions to ensure the thermodynamic stability of the protein; carbohydrates, most preferably trehalose or sucrose, to inhibit protein unfolding and provide a glassy matrix, perhaps a bulking agent (e.g., mannitol, glycine, or hydroxyethyl starch); and finally nonionic surfactants to reduce protein aggregation.

6.05.2.4 Excipients Added to Solution Formulations

When the protein or peptide has to be formulated in solution, generally regarded as safe agent excipients are added to prevent the potential physical and biochemical modifications and to ensure safe and efficacious dosing in humans, in veterinary applications, or in experimental animals. It is important to emphasize that one set of excipients that are useful for one protein may be detrimental to others; the optimal solution composition has to be identified for each molecule, administration route and duration, and packaging consideration.[31] Each excipient works with a different mode of action by weakening undesired or strengthening stabilizing forces. The following list gives a first look into the potential additives in liquid formulation of proteins:

- Reducing surface tension
  - (i) *Surfactants*: Polysorbates Tween 20 or Tween 80[32,33] below 0.5% (preventing the proteins to reach the air–liquid or liquid–surface interfaces or agitation-induced aggregation), polyoxyethylene glycol dodecyl ether Brij 35, sodium dodecyl sulfate, and poloxamers Pluronic F-68 and F-127. Protein pharmaceuticals applied to include human growth hormone and hemoglobin.
  - (ii) *Ancillary protein*: Human serum albumin prevents adsorption due to high interfacial activity but needs to be used with appropriate formulation pH and ionic-strength additives.[34]
  - (iii) *Polysaccharides*: Dextran or polyethylene glycol is able to protect against surface adsorption[35,36] and used for albumin, myoglobin, and β-galactosidase.
- Preserving protein/peptide integrity
  - (i) *Reducing and chelating agents*: Ascorbic acid and sulfurous acid salts (up to 1%) are the most popular antioxidants in the food and pharmaceutical industries.[37] When used together with heavy metals, the use of ascorbic acid needs chelating agents.[38] Monothioglycerol as antioxidant helps to maintain the stability of oxytetracyclin but not that of a gastrin derivative.[39,40] Additional chelating agents are citric acid and thioglycolic acid.[41]
  - (ii) *Bacterial growth prevention*: These agents are not true antimicrobials in the sense of medical therapy against bacterial infections. Rather, they simply are organic compounds that prevent bacterial growth in the protein formulation. Some of the most frequently used are phenol, metacresol, benzyl alcohol, parabens, and thimerosal (the latter for vaccines).
  - (iii) *Amino acids*: Histidine, arginine, lysine, aspartic acid, glutamic acid, and glycine.[42] While these excipients were suggested to stabilize proteins by a variety of mechanisms,[43] it is intriguing that except glycine, they all contain positively or negatively charged side chains. These can either directly increase solubility of the large polypeptide or provide charged environment eliminating ionic agents that induce aggregation.
- Adjusting the ionic environment
  - (i) *pH stabilizers*: Buffers in mM concentrations provide optimal solubility and stability of the formulation while maintaining an acceptable environment for drug administration to the patient or experimental animal population.[44] The buffers are

regular pH-adjusting systems used in everyday laboratory practice such as phosphate, bicarbonate, sulfate, nitrate, acetate, and pyruvate. Sometimes, they function as chelating agents. Acidification can be prevented by addition of extra Mg^{2+} or Zn^{2+} salts.

(ii) *Solution tonicity*: In parenteral drug administration, isotonic behavior of the solutions prevents irritation, pain, and tissue damage at the site of inoculation. The isotonic environment is reached by addition of electrolytes (NaCl), glycerol, and/or dextrose.[45]

6.05.3 Biodistribution of Peptides and Small Proteins

6.05.3.1 Reasons of Low Oral Bioavailability of Polypeptides

The intestinal epithelium represents a major barrier through which molecules can be absorbed. The phospholipid bilayer of the plasma membrane of epithelial cells is considered the major factor restricting the free movement of substances from the lumen to the bloodstream through the transcellular pathway.[46] While hydrophobic and small molecules can penetrate this system, the enterocyte membrane is almost impermeable to large hydrophilic biopolymers such as peptides and proteins.[47]

6.05.3.2 BBB Penetration and Renal Clearance

In addition to the intestinal epithelium, proteins cannot enter certain biological barriers restricting their use in diseases developing outside the brain or the urinary tract. The BBB is normally impermeable to proteins in order to prevent circulating biopolymers to enter the central nervous system (CNS)[48] with the largest substance found to cross the BBB being a chemoattractant with a MW of 7800 Da.[49] The glomerular barrier is slightly more forgiving, yet the largest protein showing well-measurable sieving coefficient is myoglobin[50] with an MW of still less than 18,000 Da. In contrast, peptide-based drugs match everything protein therapeutics can offer but do not suffer from size or manufacturing capacity limitations.[51] In fact, as peptide drugs not only pass through the kidneys but also downright undergo renal clearance, kidney-targeting peptide drugs can be concentrated at the desired site of action. For example, one of our antibacterial peptides was inactive in systemic infection but was very efficacious in an *Escherichia coli* urinary tract infection model.[52] Peptides are concentrated in the kidneys as soon as 30 min after administration, with full renal clearance in a couple of hours (**Fig. 2**).

Contemporary oncology treatment modalities target cancer-specific cell surface receptors and frequently employ monoclonal antibodies (mAb) as effector molecules. While this strategy works against many tumor types, the limitations to cross the BBB and enter the kidneys prevent targeted biological therapy to brain or kidney cancers. This leaves us only with bevacizumab (Avastin) to treat metastatic renal cell carcinoma.[54] Likewise, currently, there is no "standard of care" for recurrent malignant glioma, but most frequently patients are treated with a combination of bevacizumab (preventing angiogenesis) and alkylating agents or topoisomerase inhibitors.[55] As with other alkylating agents, temozolomide treatment can be considered only as a palliative care and carries serious toxicity concerns.[56] Clearly, kidney and brain cancer patients would enormously benefit from a targeted biological therapy that promises to be highly efficacious, nontoxic, and widely available. Penetration enhancers across the BBB and peptide drugs targeting the urinary tract could do just that.

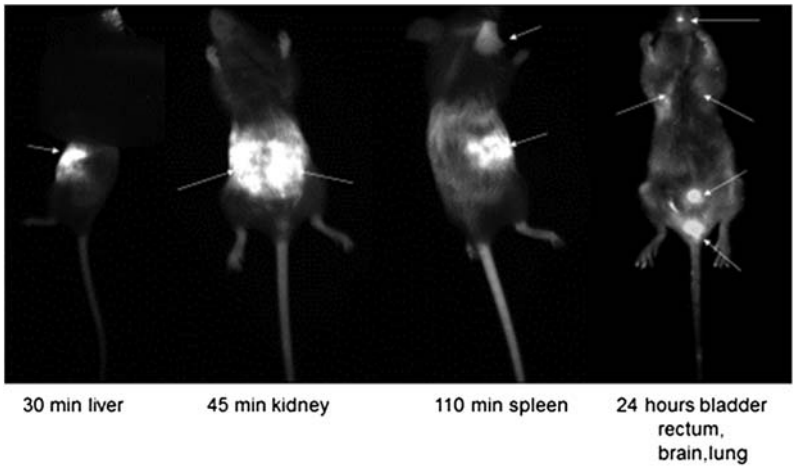

Fig. 2 Biodistribution of the leptin receptor agonist peptide E1Free[53] conjugated to a near infrared dye. Thirty μg-labeled peptide was administered intraperitoneally to mice. In addition to the organs containing the peptide, at the 45 and 110 min pictures, the injection site can also be seen.

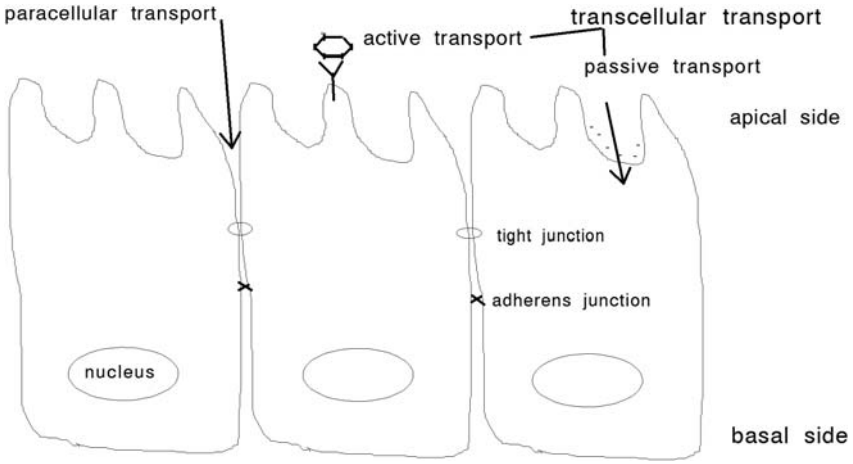

Fig. 3 Summary of the transepithelial intestinal pathways: active transport, transcellular passive transport, and paracellular transport.

6.05.4 Penetration Enhancers

6.05.4.1 Basic Principles

Due to the low bioavailability of peptides and proteins and the fast renal clearance of polyamides below 40–60 kD in size, strategies have to be developed that apply the principle of the "Trojan horse": the peptides have to be smuggled into the cells and tissues by using carrier systems that are compatible with epithelial cell entry.[57]

Potential avenues to solve the problem. As we know it today, there are three potential ways of delivering peptides into cells and across the intestinal epithelial layer (Fig. 3). In some cases, it is enough if the penetration/absorption/targeting enhancers just physically mixed with the peptide and protein drugs. However, in most cases, cosynthesis or postpreparation covalent coupling provides the best and desired results.

6.05.4.2 Active Transport

By using the active transport mechanism of the cells, we can target cell surface receptors that recognize and internalize specific molecules. These include carbohydrate receptors, lipoprotein receptors, transferring receptors, and receptors involved in cell adhesion. The carrier bioconjugates explored so far for this purpose include antibodies, carbohydrates, viral proteins, and some molecules of endogenous origin.[58]

6.05.4.2.1 Carbohydrates

From the active peptide delivery agents, carbohydrate-mediated transport has received the most attention. The reason for this is probably the simplicity of both the synthesis of glycopeptides and the interpretation of the in vitro biochemical and in vivo efficacy results. Appropriately protected and activated glycoamino acid monomers, suitable for automated solid-phase peptide synthesis, are widely available from a number of commercial sources. Glycobiology, as an ever-emerging specialty, provides ample biological background for glycopeptide applications.

6.05.4.2.1.1 Examples of mannose-mediated active transport

It was shown that mannosylation of proteins can facilitate their entry to the cells via the mannose-binding protein.[59] The mannose receptor is highly expressed on the surface of cells, especially dendritic cells, and accordingly, numerous advantages were taken of this mechanism to deliver pharmaceutical agents into cells, ranging from targeted gene transfer,[60] to lymphoscintigraphy by receptor-mediated delivery of a nonparticulate imaging agent,[61] to modulation of pathogenic T-cell reactivity by altered peptide ligands.[62] In this last case, a 100- to 1000-fold lower concentration of a bis-mannosylated peptide was sufficient for complete blocking of the proliferative T-cell response against the agonist peptide compared with the nonmannosylated analog.[62] Around the millennium, we proposed that entry of subunit peptide vaccine candidates into antigen-presenting cells can be facilitated by coupling mannose to synthetic peptide antigens in terminal positions, where the mannose does not interfere with MHC-binding or TcR recognition and prepared a prototype peptide vaccine for this purpose.[63] Although mannosylation appears to improve the antigenic properties of the peptide construct, it has a less favorable effect on the immunogenic properties. Similarly to our results, mannosylation neither enhanced nor impaired the protective effect of peptide vaccination in a reproducible fashion.[64] This may be due to the presence of soluble mannose-binding protein in the serum that scavenges the mannosylated antigens for degradation by the liver before the antigen reaches the specialized antigen-presenting cells. In

addition, macrophages, which are poor stimulators of naive T cells, may compete with the professional antigen-presenting dendritic cells for peptide immunogens.

6.05.4.2.1.2 Bioavailability and in vivo efficacy of glycosylated peptides

A pioneering example for improving the oral bioavailability of a peptide drug by glycosylation was published in 1993, when somatostatin analogs were prepared using the Amadori reaction. Coupling a maltose (α-D-Glc(1–4)-1-deoxy-D-Fru) to the N-terminal of the octapeptide (D)Phe-Cys-Phe-(D)Trp-Lys-Thr-Cys-Throl resulted in about 10-fold increased oral bioavailability while maintaining the selectivity and duration of action of the original peptide.[65] In healthy male volunteers, both 1 and 5 mg kg^{-1} day^{-1} oral doses (over a 14 day period) of the glycopeptide led to the suppression of the fasting level and postprandial release of gastrointestinal and pancreatic hormones.[66] Native glycoproteins carry asparagine-, serine-, or threonine-linked carbohydrates attached *via* true glycosidic bonds. With the advent of high-throughput solid-phase peptide synthesis, glycoamino acid building blocks are readily available in an affordable price, thus ensuing research focused on "real" glycopeptides. When the serine residue located in midchain position in an analog of the antidiuretic drug vasopressin Cys-(D)Tyr-Phe-Ser-Asn-Cys-Pro-Arg-Gly was replaced with a serine carrying a β-D-galactosyl moiety, a significant increase in intraintestinal absorption was observed in rats.[67] The peptide plasma concentration was elevated from 0.4 ng mL^{-1} (unglycosylated peptide) to as high as 2.5 ng mL^{-1} (glycopeptide) 60 min after 100 μg intraintestinal dosing. While the delivery across the intestinal epithelium was improved in this case, the glycopeptide exhibited a decreased level of receptor binding, as indicated by the decrease of the in vitro antidiuretic activity from 810 to 0.31 IU $\mu mole^{-1}$, underlining the importance of the carbohydrate positioning in the peptide sequence.

Replacement of the 20 proteinogenic amino acid residues with modified versions at terminal positions reduces the ability of exopeptidases to digest peptide-based drugs. If sugar is incorporated to these positions, glycosylation serves as both a stability enhancer and a delivery module. Glycosylation of C-terminal serine or threonine in enkephalin analogs improves both stability of the peptide drugs and their penetration across the BBB.[68] After intravenous administration, nine Tyr-(D)Thr-Gly-Phe-Leu-xxx enkephalin glycopeptides produced full antinociceptive effects ranging from 2.2 μmole kg^{-1} IV A50 (95% CI) for the peptide-containing C-terminal D-Gal-α(1 → 6)-D-Glc-coupled serine to 22 μmole kg^{-1} IV A50 (95% CI) for a glycopeptide that contains β-Glc moiety attached to D-threonine.[69] Disaccharide-containing derivatives exhibited potencies that equaled or exceeded that of morphine, but the use of a longer carbohydrate chain (e.g., maltobiose to maltotriose 6.8–10.9 μmole kg^{-1} IV A50 (95% CI)) or more than one monosaccharide in the glycopeptide (e.g., Ser(β-Glc)-Ser(β-Glc) at 140 μmole kg^{-1} IV A50 (95% CI)) diminished the activity figures. While sugar incorporation generally slightly reduced the ability of the enkephalin glycopeptides to bind their receptors, the monosaccharide composition itself or orientation of the anomeric carbon to the peptide side chain had little effect.

We designed 12–14 amino acid long glycopeptides corresponding to the third leptin receptor-binding domain of leptin protein carrying β-*O*-serine- and α-*O*-threonine-linked glucose and *N*-acetyl-galactosamine moieties very close to the N-terminal.[53,70] The representative of the first-generation glycopeptide, Tyr(I_2)-Serβ(Glc)-Thr-Glu-Val-Val-Ala-Leu-Ser-Arg-Leu-Dap(Ac), bound to isolated leptin receptor on solid-phase assays and activated ERK-1/2 signaling in leptin receptor-positive MCF-7 breast cancer cells at 100–500 nM concentrations. In mouse models, the glycopeptides penetrate the BBB more efficiently than unglycosylated leptin protein itself, and this improved BBB penetration results in improved hypothalamic actions, such as appetite control. When added intraperitoneally, the second-generation leptin glycopeptide Tyr(I_2)-Ser-Thrα(GalNAc)-Glu-Val-Val-Ala-Leu-Ser-Arg-Aca reduces weight gain in mice fed with high-fat peanut diet in a dose-dependent manner. Obese mice lost weight, corresponding to a net 6.5% total body weight loss, while similar mice treated with leptin protein did not. In mice undergoing leptin glycopeptide treatment, several obesity-related pathologies (i.e., abnormal metabolic profile and liver histology as well as infertility) were normalized, while unglycosylated leptin protein therapy could not show similar positive treatment outcomes. The studies provide further support to the notion that class I hexose transporters (involved in BBB delivery) do not significantly discriminate between glucose and galactose moieties.[71]

The earlier studies addressed either intestinal drug absorption or BBB penetration. In a more recent report, both of these desired functions are improved by sugar attachment to endomorphin-1, an opioid tetrapeptide with the sequence Tyr-Pro-Trp-Phe.[72] Lactose was attached to the N-terminal through a succinamic ester spacer between the peptide and the carbohydrate and using an N-linked glycosidic bond. Once again, glycosylation improved the metabolic stability and membrane permeability of the peptide, although reduced the μ-opioid receptor-binding affinity from pM concentrations to 15 nM. Significantly, at a single oral dose of 10 μmole kg^{-1}, the plasma concentration elevated from zero to 20 μM in 60 min. The glycopeptide produced a dose-dependent pain relief after oral administration in rats with a paw withdrawal threshold of eight when given at 16 μmol kg^{-1}. These results provide clear evidence that the glycosylated opioid analog was not only adsorbed in the intestinal epithelium but also penetrated into the brain. The oral efficacy of the glycopeptide was comparable with that of morphine. It needs to be mentioned that 1-3β-galactose-containing moieties should be avoided because these are quickly neutralized by the antigalactose antibody, which is the most abundant antibody in humans.

These examples show that incorporation of mono- or disaccharides into terminal or near-terminal positions of peptide drugs improves not only the metabolic stability but also the ability of the peptides to cross biological layers that are otherwise impermeant to unmodified peptide drug leads. In general, glycosylation was repeatedly found to only slightly alter the conformation of the peptides, if it made any change in the peptide structure at all,[73] and therefore, the receptor-binding parameters are not expected to be significantly modulated. Many peptide API manufacturers offer small- and large-scale production of glycosylated peptides.

6.05.4.3 Passive Transport

Passive transport can utilize the abundant negative charges of the cell surface. Endocytosis in this case is initiated by binding of polycationic substances to these negative charges. While generally receptor-mediated uptake is characterized by K_d values in the low nanomolar range and maximum binding capacities of less than 1 pmol mg^{-1} membrane protein, the absorptive-mediated uptake features micromolar saturation constants and several nmol mg^{-1} binding capacities.[74] Enzymatic treatments revealed that the anionic microdomains on the luminal side of endothelial capillaries consist of negatively charged glycoproteins with sialic acid residues, while the abluminal anionic-binding sites contain heparan sulfates.[75] Cationic peptides not only bind to cellular surfaces but also indeed undergo an enhanced cellular uptake. In vitro and in vivo studies with a dynorphin analog and an analog of adrenocorticotropic hormone show pharmacokinetic characteristics of the brain typical for absorptive-mediated transcytosis.[76,77] In vivo, approximately 15% of cationized bovine serum albumin taken up was transcytosed into postcapillary extracellular space. Actually, cationized rat serum albumin accumulated very well after intravenous bolus injection in the kidney and the brain, less significantly in the liver, and not at all in the myocardium and the lungs.[78]

6.05.4.3.1 Cationic antimicrobial peptides as drug delivery vehicles

The potential to deliver drug leads through the anionic surfaces of cells is well represented by the proline-rich native antibacterial peptide family, originally isolated from insects.[79] Similar to other antimicrobial peptides,[80] the proline-rich peptides are also rich in cationic residues, arginine, lysine, and histidine. Cationic peptides, just like cationized proteins, are generally able to interact electrostatically with the negatively charged bacterial phospholipids and then insert into the model membranes of planar bilayers or liposomes.[81,82] Although these processes often involve formation of channels or pores, alternative mechanisms were also suggested. According to these, the peptides either cooperatively destroy the membrane barrier without channel formation[83] or just create brief disruptions in permeability.[84] It is clear that permeabilization of the cytoplasmic membrane to destroy the membrane potential is not lethal per se.[85] This is especially true for peptides that are rich not only in positively charged residues but also in prolines.[86] For example, it was argued that one of the insect-derived peptides, apidaecin, or its mammalian analog PR-39 enters bacterial cells without any disruption of the membrane structure and consecutively meets their intracellular target biopolymer.[87,88]

The special role of proline residues was best documented on buforin II, an antimicrobial peptide acting on bacterial DNA and RNA.[89] Confocal fluorescence microscopic studies show that buforin II accumulates in the cytoplasm.[90] When the key proline is replaced with leucine, the preferred amino acid residue in antibacterial peptides with amphipathic alpha-helix structure,[91] the ability of the peptide to accumulate intracellularly is decreased, and therefore, the antibacterial activity is reduced. The peptides with bacteria-specific target proteins are not expected to be toxic to host cells and organisms, and indeed, we showed that two of the proline-rich peptide family members, pyrrhocoricin and drosocin, lack toxicity to mammalian cells and healthy mice up to 100 mg kg^{-1},[92,93] the highest dose studied. Pyrrhocoricin and some of its derivatives enter not only bacteria but also mammalian cells (macrophages). Native pyrrhocoricin penetrates the susceptible organism *E. coli* very efficiently and the nonsusceptible bacterium *Staphylococcus aureus* to a significant degree.[94] The antibacterial peptide also enters human monocyte-derived dendritic cells. A chimera made of a pyrrhocoricin dimer and two copies of a shorter (nine residues) class I major histocompatibility complex epitope successfully entered bacterial and mammalian cells. The chimera when tested for its immunologic properties activated human dendritic cells significantly more strongly than any of the two independent fragments alone yet lacked mammalian cell toxicity. These results confirm the utility of designed cationic antibacterial peptide analogs for delivery of peptidic cargo across cell membranes in general and their potential as carriers for epitope-based vaccines in particular.

Generally speaking, peptides penetrate into bacteria easier than they do into mammalian cells. The interaction of most peptides with eukaryotic membranes is inhibited by the lack of negatively charged lipids on the surface of such cells, by the rather low membrane potential across the plasma membrane and by the presence of cholesterol, in contrast to bacterial membranes that are abundant of anionic surface phospholipids, have high transmembrane potential, and lack cholesterol.[95] However, peptides with strong membrane-disintegrating activity may overcome these gaps. For example, cecropin, another antibacterial peptide of insect origin, is deadly to mice at a 100 mg kg^{-1} dose.[96] Even less clearly, membrane-active peptides, like PR-39, can penetrate eukaryotes; this peptide rapidly enters human microvascular endothelial cells.[97] These peptides become toxic if they stay attached to the membrane and destroy the eukaryotes. However, if they only cross the membrane to inhibit a bacteria-specific intracellular target, they can selectively kill obligate or facultative intracellular pathogens, and more generally, they can be used to deliver foreign pharmacophores into mammalian cells and hence improve the delivery of nonantimicrobial drug leads.

6.05.4.4 Particle Delivery

Delivery by using nano- or microparticles involves the uptake of biodegradable polymers by the M cells of the Peyer's patches. Particles currently used for oral delivery fall into two classes: (a) nanoparticles, ranging in size from 10 to 1000 nm and (b) microparticles ranging from 1 μm to 1 mm.[98] In general, the smaller the particle, the better the peptide drug is absorbed, due to the difficulty to engulf larger particles and improved hydrophobic/hydrophilic ratio.

Insulin can be encapsulated very efficiently in oil-containing poly(isobutyl cyanoacrylate) nanocapsules, and these nanocapsules show unexpected biological activity after intragastric administration.[99] Salmon calcitonin is a highly water-soluble basic peptide, consisting of 32 amino acid residues. Calcitonin absorption via the gastrointestinal tract is significantly enhanced after

incorporation into nanoparticles.[100] In earlier approaches, nanoparticles were usually made by grafting the peptide drugs to the terminal positions of hydrophobic vinyl monomers.

In contrast, microparticles are almost exclusively made from copolymers of lactic acid and glycolic acid (PLG). The composition and the viscosity strongly influence the release kinetics of PLG microspheres. In our hands, a 50:50 PLG microsphere releases peptide immunogens in a 1-week period.[101] The successful drug delivery by the PLG microspheres was documented by oral immunization with *Bordetella pertussis* fimbriae proteins.[102] When mice were immunized with 10 μg proteins orally, the resulting response was comparable with administering equivalent amounts of the immunogens absorbed onto Alhydrogel or administered intraperitoneally. Exenatide is formulated into 0.06 mm diameter microspheres of PLG that hydrate in situ and form amalgam.[103] The peptide is released in multiple stages, from $<1\%$ in the first few hours to as long as 2 weeks. This formulation is currently in the market with the commercial name Bydureon against type 2 diabetes.

In our experience, immunization of mice with 31D, a T-cell epitopic peptide entrapped in PLG microspheres, improved the antibody response compared with naked antigen, but did not reach the level of antibody production when the peptide was administered in complete Freund's adjuvant. In spite of some initial success, we did not find the PLG microspheres useful for the delivery of synthetic peptides or oligonucleotides on the long run.

6.05.4.4.1 Nanoparticles as modern drug delivery systems

Contemporary particle delivery focuses on nanostructures as vehicles. Uptake of nanostructures has been reported to be 15–250 times greater than that of microparticles in the 1–10 μm range.[104] Nanostructures not only are able to protect drugs from the degradation in the gastrointestinal tract but also allow delivery of drugs into many tissues of the body. Importantly, by bypassing the liver, biological drugs encapsulated in nanoparticles escape first-pass metabolism. Nanometer-size structures are easily taken up by cells and penetrate tissues.

Plasmid DNA-encoding cytokine genes, including mIL-12 and mIFN-gamma, show enhanced antitumor activity and improved survival time in mice compared with naked pmIL-12 when incorporated into 100 nm size poly[alpha-(4-aminobutyl)-L-glycolic acid (PAGA) particles.[105,106] Cholesterol conjugates of linear polyethylenimine, an effective nonviral gene carrier, 250 nm in size, induce protein expression levels higher than the gene product alone without any significant loss in cell viability. The differences in rates of transfection of the lipid/pDNA complexes in Renca cells are partly due to conformational changes upon interaction with the plasma membrane.[107] The preferred nonviral gene delivery vectors are polycation/DNA complexes formed between cationic polymers and DNA through electrostatic interactions.[108] Nanoparticles made from polyamidoamine–polylysine graft copolymers appear to be promising gene vectors with low cytotoxicity, high transfection efficiency, and advantageous serum stability parameters.[109] Inoculation of a dendrimeric version of these nanostructures complexed with the pVEGF165 gene into balloon-injured rabbit carotid arteries results in inhibition of restenosis by increasing VEGF165 expression in vessels.[110] Dendrimers appear to be nonimmunogenic and exhibit the highest efficiency of transfection among other nonviral structures without the drawback characteristic for viral systems.[111] However, the consensus is that further studies are required before the dendrimer/DNA complexes can be used in human gene therapy.

Liposomes are spherical vesicles in which the aqueous compartment is enclosed by a mixed hydrophilic/hydrophobic molecule layer. These structures greatly vary in their composition, size, or surface charge characteristics and used frequently as drug, vaccine, or nonpharmaceutical formulations as carriers. A nanosize multifunctional liposome, containing a magnetic resonance imaging probe, and paclitaxel and the targeting peptide c(RGDyk) overcame the insolubility of paclitaxel and improved drug delivery efficiency to the tumor.[112] Modification of the c(RGDyk) peptide part significantly enhanced the cytotoxicity of the drug in A549 tumor cells. Isolated mouse retinas were treated with liposomes encapsulating either recoverin, an endogenous protein involved in visual phototransduction, or antibodies against it. The contents of intravitreally injected liposomes encapsulating either rhodamine B or recoverin were released in higher amount in the photoreceptor layer than in the other regions of the retina.[113] Remarkably, the released protein functioned in accordance with the current model of phototransduction. From the vaccine field, iontophoresis of antigen peptide-loaded nanogels results in the accumulation of gp100 peptide in the epidermis and subsequent increase in the number of Langerhans cells.[114] As a consequence, tumor growth is significantly suppressed by iontophoresis of the antigen peptide-loaded nanogels, and these structures can represent an effective transdermal delivery system for anticancer vaccination. It needs to be added that liposomes can be made from a great variety of ingredients and protocols making these a very heterogeneous group of nanostructures.

Microemulsions are also generally below 100 nm in size, but for these, the physical properties and the thermodynamic stability of the complexes are the dominant factors.[115] They are composed of two phases of two immiscible liquids that are mixed together and stabilized with surfactants (a main and potentially a cosurfactant). Just like their larger (and unstable) brothers, the emulsions, microemulsions can be prepared either oil-in-water or water-in-oil. Perhaps even more than dendrimers, microemulsions require more studies to exclude some of the observed drawbacks and guarantee their potential for use in clinic,[116] primarily because of phase inversion and the use of toxic alcohols used in the early preparations.[103] When a paclitaxel-containing microemulsion was spiked with penetratin (see section "**Competing Peptide Drug Delivery Technologies**"), a large increase in transepidermal water loss (twofold) was observed suggesting that penetratin addition increases the barrier-disrupting and penetration-enhancing effects of microemulsions.[117] The ratio Δcutaneous/Δtransdermal delivery was the highest among all the formulations studied, suggesting its potential for drug localization within cutaneous tumor lesions. When studying the optimal preparation protocol of these drug delivery systems, a water-in-oil microemulsion was loaded with model bovine serum albumin and cytochrome *c*.[118] In the next step, this phase was dispersed in water resulting in microemulsion formation with a size of approximately

620 nm. The nanostructured particles were able to control the release of the water-soluble proteins freeing only < 10–15% protein in a day.

Nanoparticles are solid colloidal particles that can be made from various macromolecules in which therapeutic drugs can be adsorbed, entrapped, or covalently attached. Nanoparticles are remarkably stable systems, yet they allow controlled release of the hydrophilic biopolymer cargo. Their advantages over larger structures include their ability to pass through small capillary vessels due to their very small volume and increased serum stability by avoiding phagocyte clearance and their ability to penetrate not only tissue gaps to reach distinct organs but also cells themselves. Remarkably, nanoparticles can promote mucosal uptake of incorporated peptides.[119] Incorporation into nanostructural carriers can improve the efficacy of antimicrobial peptides possibly through controlled release properties.[120] Lactic acid, glycolic acid, cellulose acetate, and vinyl alcohol polymers can be used for the preparation of antimicrobial compound-impregnated dressings by electrospinning.[121] Electrospinning is a simple, economical, and thus frequently used technique during which small highly cationic biopolymers concentrate on the surface of the biomaterials allowing controlled but fast release upon contact with moist wound surfaces.[122] For example, electrospun nanofibers deliver LL-37, a cathelicidin peptide, consistently while still maintaining its antimicrobial functions.[123]

In a report receiving much attention, nisin-containing electrospun nanofiber wound dressings significantly reduce *S. aureus* load in a mouse skin abrasion/infection model.[124] We incorporated a 20-mer-modified antimicrobial peptide, called APO monomer, into polyvinyl alcohol nanofibers and polymerized the complex into a solid patch dressing.[125] Mice were subjected to skin excision after which some wounds were infected with a near-lethal dose of multidrug-resistant *Acinetobacter baumannii* strain. When the wounds were subjected to histopathology after 3 days of single patch treatment, APO monomer-containing dressings improved wound appearance and accelerated wound healing. The wound sizes and bacterial loads were statistically significantly reduced compared with similar treatment with colistin, the leading similarly polyamide-based treatment option to Gram-negative infections. Significant to this book article, the nanofiber carrier had more pronounced in vivo efficacy compared with intramuscular administration of the same peptide drug, by using only one-tenth of the API. Considering an average wartime cutaneous abrasion size of $< 20\ cm^2$[126] and even less in the civilian population, antibacterial peptide-impregnated nanofiber wound patches can be developed as effective and economical treatment modalities to skin infections in burn and blast injuries on the streets and in military environments.

6.05.4.5 Competing Peptide Drug Delivery Technologies

The delta sleep-inducing peptide, Trp-Ala-Gly-Gly-Asp-Ala-Ser-Gly-Glu, was reported to be able to permeate biological barriers, although it does not cross the gastrointestinal epithelium-mimicking Caco-2 cell layer system.[127] Other cell-penetrating protein-derived peptides include penetratin (Arg-Gln-Ile-Lys-Ile-Trp-Phe-Gln-Asn-Arg-Arg-Met-Lys-Trp-Lys-Lys), signal sequence-based peptides exhibiting highly hydrophobic α-helical structures, and Ly-Arg-Lys-Lys-Arg-Arg-Gln-Arg-Arg-Arg-Pro-Pro-Gln, corresponding to the 48–60 fragment of the Tat protein from the human immunodeficiency virus 1.[128–131] Synthetic analogs are transportan, the amphiphilic model peptide made of oligomers of Lys-Leu-Ala-Leu, and a Tat analog made of β-amino acid residues.[132] Additional cell-penetrating peptides come from virus proteins, leucine zipper proteins, and yeast transcription factor.[133] Except for the helical signal sequence-based peptides, the common structural characteristic of these protein fragments and synthetic constructs is the abundance of positively charged residues, arginine and lysine, making these peptides often capable of binding to not only negatively charged membrane surfaces but also nucleic acids (compared with buforin II). In fact, hepta- or octaarginine appears to be the best carrier for translocation of cargo into cells.[134] However, increasingly efficient cell penetration is often accompanied by destruction of the cell membrane and hence toxicity.[135] Remarkably, most of these cell-penetrating peptides lack proline residues known to break helices. Indeed, the earlier listed cell-permeating peptides are also helical in membrane environments.[132] When multiple proline-containing drug delivery vehicles are used, the lack of helix formation is expected preventing toxicity to the host.

6.05.4.6 Microspheres and Lipids in Protein Drug Delivery

While microparticle- and lipid-mediated delivery of proteins was partially discussed in previous sections describing the general passive drug delivery technologies dealing mostly with peptides, a separate chapter is justified due to the increased chemical sensitivity of proteins and such making the preparation and applications of the complexes increasingly troublesome. For example, proteins can undergo a series of undesired structural changes upon incorporation into PLG microspheres, including deamidation, thiol-catalyzed disulfide exchange, and conformational modifications.[136] Exactly, this is the reason why coadditives are regularly explored to dampen the erosion processes occurring in PLG polymers.[137]

A typical cargo of PLG microspheres is insulin that lies at the border between peptides and proteins.[138] Biodegradable PLG–polyethylene glycol (PEG; see in the succeeding text) graft copolymer formulations sustain insulin delivery and cartilage repair by chondrocyte cell delivery. With one injection of the insulin formulation, the blood glucose levels were controlled for 5–16 days depending upon the polymer composition.[139] The cartilage defect was also repaired using chondrocyte suspension in the thermogelling PLG/PEG microspheres compared with control. PLG microspheres containing recombinant human epidermal growth factor were prepared using a solvent evaporation method based on multiple water-in-oil-in-water emulsions.[140] After a single subcutaneous dosing, blood concentration of the protein was maintained for 9–11 days culminating in superior gastric ulcer healing effects compared with twice a day subcutaneous administration of the growth factor dissolved in saline solution.

Staying with insulin but moving to lipidic formulations, oral administration of insulin entrapped to various liposomal forms consisting mixtures of dipalmitoyl phosphatidylcholine and dipalmitoyl phosphatidylethanol induces hyperinsulinemia in rats resulting in the decrease of blood glucose concentration.[141] A dose of 2 mg kg^{-1} of liposome-entrapped CuZn superoxide dismutase administered intraperitoneally to Mongolian gerbils increases the endogenous enzyme activity in normal brain tissue and, when given at the late stages of ischemia, counteracts both the ischemic reduction of endogenous superoxide dismutase and the elevated peroxidation level of mitochondrial membranes.[142] While encapsulation of another enzyme, L-asparaginase, into microsize liposomes decreases the circulation time of the enzyme, incorporation into small nanosize liposomes prolongs it by almost tenfold.[143] The survival time of animals bearing asparaginase-dependent tumors is doubled after treatment with selected liposomal formulations compared with treatment using the free enzyme. Factor VIII (FVIII) is a multidomain protein that prevents hemophilia A, a bleeding disorder, but upon exogenous FVIII administration to patients, inhibitory antibodies are generated.[144] When a complex with *O*-phospho-serine (the head group of phosphatidylserine) was administered in mice, the conjugate retained FVIII's in vivo activity in hemophilia suggesting that the FVIII–lipid mimic complex may be beneficial to increase the physical stability and reduce immunogenicity of the recombinant protein preparations.[145]

6.05.4.7 Additional Paracellular Transport-Enhancing Additives

Paracellular transport of larger molecules takes advantage of the tight junctions between epithelial cells[146] by using permeation enhancers[147] to allow the penetration of biopolymers exceeding 11 Å radii that otherwise would be retained at the apical side.[57] For efficient protein delivery, the tight junctions have to be opened only transiently as the free flow of toxins and other biological pathogens can result in dire consequences.[148]

Tight junctions are regulated by Ca ions, and thus, Ca^{2+} chelators, such as ethylenediaminetetraacetate, can open the gap between epithelial cells and promote biopolymer transport.[149] In normal calcium concentrations, paracellular transport enhancers 2.5 mM ethylene glycol-bis(beta-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid, 1.5% w/v trimethyl chitosan chloride, and 0.2 mM palmitoyl carnitine chloride increased the transport of 1–10 mM clodronate in human intestinal epithelial Caco-2 cell cultures by 190 (130)-, 20 (70)-, and 10 (35)-fold, respectively.[150] Along these lines, the intracellular enzyme activity and cell monolayer permeability of anionic (sodium dodecyl sulfate and sodium dioctyl sulfosuccinate) and nonionic (polysorbate 80 and polyoxyl 40 hydrogenated castor oil) synthetic surfactants were studied in monolayers of Caco-2 cells grown on microporous polycarbonate filters.[151] All surfactants, especially the anionic ones, demonstrate concentration-dependent effects on intracellular enzyme activities, cell permeability, and morphology. Hydrophilic marker molecules appear to permeate epithelial monolayers through different pathways. Bile acids sodium taurocholate, sodium taurodeoxycholate, and sodium taurodihydrofusidate function in a highly similar manner, as much as in another study, the bile salt sodium taurodeoxycholate was a more effective enhancer than the more polar sodium taurocholate.[152] Enhancement of the permeability marker phenol red transport was reversed within 2 h after treatment suggesting that surfactant-induced acute intestinal wall damage can be rapidly repaired.

An early report suggested that salicylate ion on rat small intestinal brush-border membrane vesicles can promote drug absorption based on increases in plasma membrane permeability through actions on plasma membrane proteins rather than directly interacting with membrane lipids.[153] Indeed, uptake of insulin into human red blood cells is significantly enhanced by the presence of salicylate and 5-methoxysalicylate in the assay medium.[154] The mechanism of permeation enhancer action depends on an affinity to the protein fraction in the erythrocyte membrane. Medium-chain fatty acids induce rapid increase in epithelial permeability as studied on the hydrophilic marker molecule sodium fluorescein.[155] Enzyme inhibition experiments suggest that the effects on epithelial permeability are mediated through phospholipase C-dependent inositol triphosphate/diacylglycerol pathways. Mechanistically, the increase of calcium levels is considered to induce the contraction of calmodulin-dependent actin microfilament, followed by dilatation of the paracellular route.[156] For both medium-chain fatty acids (caproic, caprylic, and capric acids) and their acylglycerols (mono-, di-, and triacylglycerols), the transport-enhancing effects are correlated with the reduction in surface tension and with a surface energy-lowering coefficient.[157] In order to promote drug absorption, acylcarnitines must surpass a 10 carbon unit chain length to effectively partition into the membrane and have to perturb the lipid order beyond a threshold value of 15–20%.[158] The membrane-perturbing capacity may serve as an indicator of the absorption-enhancing potential of unrelated aliphatic-type compounds. While palmitoyl carnitine has the properties of many commonly used biochemical detergents, palmitoyl coenzyme A produces neither leakage nor solubilization of phosphatidylcholine bilayers forming large unilamellar vesicles.[159]

6.05.4.7.1 Amino acid- and peptide-based transporters

N-acylated, non-α-amino acids were used to demonstrate the oral delivery of heparin in vivo in rats and primates.[160] *N*-(8-(2-hydroxybenzoyl)-amino) caprylate is one of a series of drug delivery agents (Eligen transporters) that interact weakly and noncovalently with insulin, increasing its lipophilicity and thereby its ability to cross the gastrointestinal epithelium.[161] Although these amino acid derivatives are expected to act through the paracellular pathway, confocal microscopy and immunocytochemistry indicate that insulin is rather transported transcellularly without detectable alteration of the tight junctions between adjacent cells. In preclinical and phase I clinical trials, oral dosing with Eligen insulin led to a rapid elevation of plasma insulin and subsequent decrease in plasma glucose levels.[162] In addition, the activity was stronger, and the onset was more rapid with the formulated insulin than with injected insulin. Using the same drug delivery technology, after the first oral dose, salmon calcitonin evoked dose-dependent decreases in serum type I collagen (−60.8% to −81.8% from baseline) compared with placebo.[163] The first clinical trial indicated that the Eligen technology-based oral formulation of calcitonin can potentially be used as safe and effective treatment for

postmenopausal bone loss. In addition to its pronounced effect on bone resorption, this novel oral salmon calcitonin formulation may also reduce cartilage degradation.[164] However, in later clinical trials, the present formulation of oral salmon calcitonin did not provide reproducible clinical benefits in patients with symptomatic knee osteoarthritis.[165]

The combination of *N*-acylated amino acids and the proteins and peptides to be delivered forms an insoluble complex at low pH preventing degradation before being dissolved in the upper part of the small intestine that exhibits higher pH values.[166] By using human growth hormone as a drug to be transported, it was shown that the permeation enhancer has specificity for a particular protein and the enhancer and the peptide/protein drug must be in solution together to be effective.[167] Pretreating the tissue with the *N*-acyl-amino acid transporter and then adding the protein do not increase tissue permeability. These penetration enhancers and/or the human growth hormone does not induce cell damage, at least up to 1 h, and the damage seen after 2 h is also significantly lower than with other known transport enhancers.[168] Indeed, clinical adverse effects are related to the bioactive drug rather than to the carrier.[163] It is worth noting that when *N*-(8-(2-hydroxy-5-chloro-benzoyl)-amino) caprylate was administered together with human parathyroid hormone, the peptide cargo disappeared from the blood faster after oral than after subcutaneous administration.[169] Doses of 2.5–5 mg of oral parathyroid hormone resulted in exposure levels closest to 20 μg subcutaneous teriparatide without an increase of adverse effects in healthy postmenopausal women.

The zonula occludens toxin, secreted by cholera pathogen *Vibrio cholerae*[170], is a close relative of the human zonulin protein that modulates the permeability of tight junctions between cells in the wall of the digestive tract.[171] The C-terminal region of zonula occludens toxin contains an octapeptide Gly-Gly-Val-Leu-Val-Gln-Pro-Gly that is responsible for the binding to a specific receptor in intestinal cell membranes and inducing reversible opening of tight junctions between cells and allows paracellular permeability in a nontoxic manner.[172] Zonula occludens toxin at 4.0 μg mL^{-1} concentration statistically significantly enhances delivery of sucrose, inulin, and doxorubicin in bovine brain microvessel endothelial cells suggesting the utility of this transport enhancer to increase the brain permeability of CNS-active drugs, including anticancer agents.[173] Plasma concentration of cyclosporine A is significantly increased over a range of 1.55–2.50-fold at 10–40 mg kg^{-1} intraduodenal dose of the hexapeptide Phe-Cys-Ile-Gly-Arg-Leu.[174] This synthetic peptide represents the shortest sequence that retains the zonula occludens toxin permeating effect on intercellular tight junctions. A bioadhesive agent, carrageenan, improves the permeation-enhancing effect of the hexapeptide by 2.5-fold as documented by pharmacokinetic measurements after coadministration of ritonavir, the toxin peptide and carrageenan.[175] While the transport peptide itself is instable in neutral to basic pH and with increasing reaction time, coadditives 5% dextrose and a 1% mixture of the constituent arginine, cysteine, and glycine amino acids significantly improve the stability parameters at pH 7.4 for at least 6 h.[176] Functionally, the hexapeptide reversibly reduces the transepithelial electric resistance and increases Lucifer yellow permeability in Caco-2 cell monolayers in vitro and elevates the pharmacokinetic parameters of calcitonin by 5.2-fold.[177]

E-cadherin is a calcium-dependent cell–cell adhesion molecule that plays pivotal roles in epithelial cell behavior and tissue formation being present in all epithelial barriers including in brain endothelial cells.[178] E-cadherin is important for establishing and maintaining apicobasal polarity and for the formation of tight junctions.[179] In bovine brain microvessel endothelial cells, Leu-Arg-Ala-His-Ala-Val-Asp-Val-Asn-Gly, a decapeptide generated from the EC-1 domain of N-cadherin, modulates a distinct Ca^{2+}-dependent cell adhesion mechanism suggesting a possibility of creating channels for paracellular drug delivery across the BBB.[180] An N-terminally acetylated hexapeptide Ala-Asp-Thr-Pro-Pro-Val derived from the EC-1 bulge region of E-cadherin improves mannitol transport 3–5-fold when administered from either the apical or the basolateral side or from both sides simultaneously in Madin–Darby canine kidney cell monolayers.[181] Another acetylated E-cadherin hexapeptide Ser-His-Ala-Val-Ser-Ser was found to enhance the permeation of mannitol and daunomycin through the BBB in a rat brain perfusion model and exhibit a synergistic effect in enhancing the BBB permeation of daunomycin.[182] Synthetic peptides corresponding to the two putative extracellular domains of the tight junction integral membrane protein occludin reversibly disrupt the transepithelial permeability barrier at concentrations of <5 μM.[183] Other occludin-derived peptides were able to impair junction resealing when 0.5–1.5 mg mL^{-1} peptides were included in the apical bathing fluid.[184]

Additional peptides derived from the *Clostridium perfringens* enterotoxin or selected by phage display can reversibly increase paracellular transport and enhance drug delivery and such have a potential to be used as pharmaceutical excipients to improve drug delivery across epithelial barriers and the BBB.[185] The *C. perfringens* toxins act on claudins, a multigene family proteins that constitute tight junction strands.[186] Upon incubation of the carboxy-terminal fragment of the *C. perfringens* toxin and cells expressing claudins, reconstituted tight junction strands gradually disintegrate and disappear from their cell surface. Nasal immunization with the enterotoxin fused with the pneumococcal surface protein A, an important antigen for the induction of protective immunity against *Streptococcus pneumoniae* infection, induces protein antigen-specific antibodies in the serum and bronchoalveolar lavage fluid indicating that the *C. perfringens* toxin is an efficient vaccine delivery system.[187]

6.05.5 Improving In Vivo Circulation Time

In addition to potential immunogenicity issues, the major criticism toward biotherapeutics concerns their short half-life in vivo.[188] This is especially troublesome for peptides and small proteins (below 30–40 kDa in size) that are rapidly eliminated through the kidneys suggesting that the best utilization of peptide drugs is in fact against diseases of the urinary tract where these therapeutics concentrate.[189,190] Even if serum stability of peptide drugs can be improved by incorporating nonnatural amino acid residues,[191] the disconnect between pharmacokinetics and pharmacodynamics due to fast renal clearance while still activating or deactivating

receptors or other target biopolymers poses serious regulatory hurdles.[192] Smart modifications in peptide backbone and side-chain composition can overcome short plasma half-life, but because these do not directly involve formulation strategies, these are not detailed here, and the reader is referred to specialty reports.[193,194] The three major strategies to improve in vivo circulation time reviewed here are equally applicable to both proteins and peptides and come directly from biotherapeutics formulation studies. In addition to pegylation and albumin, and Fc conjugation, further examples will be provided for the formulation enhancement of protein therapeutics by hyperglycosylation and lipidation.

6.05.5.1 Pegylation

6.05.5.1.1 Proteins

Incorporation of PEG moieties (pegylation) to proteins was originally introduced to enable protection from destruction during drug delivery.[195] Indeed, PEG attachment reduces the renal clearance rate of polyamides.[196] However, it quickly turned out that PEG addition provides numerous pharmacological benefits to protein therapeutics. Pegylation of β-glucosidase from sweet almonds and α-galactosidase from green coffee beans results in alterations of the catalytic properties of the enzymes exhibiting increased K_m and decreased V_{max} values.[197] Additionally, PEG-modified adenosine deaminase loses its immunogenicity in mice following multiple intravenous injections providing additional justification for protein pegylation strategies.[198] Early pegylation synthetic protocols used various chemistries to couple activated PEG moieties to side-chain amino ε-amino and the N-terminal α-amino groups on the surface of proteins.[199] The uncontrolled and multiple modifications of lysines provided an assembly of PEG isomer mixtures with different molecular masses.[200] It was subsequently recognized that pegylation can produce a decrease in the in vitro activity of proteins[201] and can influence the binding affinity of therapeutic proteins to cellular receptors resulting in changes in the bioactivity of peptides and proteins.[202] Additionally, large amounts of diol contaminants present in methoxy-PEG derivatives form irreversible aggregates with proteins.[203] Site-specific pegylation has been shown to avoid ubiquitous PEG incorporation, associated heterogeneity in the conjugates,[204,205] and expectedly interference with single target or ligand-binding sites. SsoPox, an enzyme derived from *Sulfolobus solfataricus*, hydrolyzes and inactivates a variety of organophosphate compounds. Mono-N-terminal pegylation of SsoPox with PEG propionaldehyde results in improvement in the thermostability and protease resistance of the enzyme as measured by a functional assay.[206] Additional potentially controlled PEG conjugation chemistries include the use of heterobifunctional and branched PEG derivatives[207] and enzymatic PEG incorporation into less frequently occurring residues in proteins or residues distant from the active sites.[208,209]

As expected from the increased molecular size, pegylation brings about an extended circulation time in vivo due to reduced renal clearance rate together with increased protease stability.[210] In vitro, interferon α-2a decorated with a branched 40 kDa PEG moiety (attached to single lysines) lost 93% of the original activity, but in vivo, it is severalfold more efficacious than naked interferon α-2a.[211] The markedly improved pharmacological profile can be explained by a 70-fold increase in serum half-life and a 50-fold increase in mean plasma residence time concomitant with sustained serum concentrations. Proper selection of the PEG structure can preserve even the in vitro activities. A trimer-structured, 43 kDa PEG conjugated to interferon α-2a by forming an amide bond retained comparable in vitro bioactivities to the native protein while exhibiting slow absorption and markedly reduced clearance in rats, thereby increasing the biological half-life by about 40-fold relative to naked interferon α-2a.[212] Returning to the kidney elimination profiles, pegylated proteins are highly hydrated, and thus, their hydrodynamic radii are in fact 5–10-fold higher than it could be expected based on purely their molecular size.[213,214] This increased aqueous package not only decreases the glomerular filtration rate but also concomitantly improves solubility.[215] However, the increased hydrophilicity may prevent full-body biodistribution, as it was shown on a 5 kDa linear PLG conjugate of uricase, which appears to reach the lowest distribution levels in all examined organs when compared with other polymeric conjugates of uricase of approximately the same size.[216] Uricase carrying a branched PEG moiety behaved better.

Branched PEG-containing enzymes exhibit increased temperature stability and widened pH stability, as well as greater stability to proteolytic digestion compared with linear PEG-containing analogs.[217] Pegylated granulocyte-colony stimulating factor forms soluble aggregates and such avoids precipitation.[218] The stability increase toward aggregation is largely independent from the size of the attached PEG unit. Apparently, steric hindrance by PEG influences aggregation rate, while aqueous solubility is mediated by polar PEG groups on the aggregate surface. While these findings look very attractive at first sight, others reported that conjugation to thiol-reactive PEGs enhances the tendency of granulocyte-colony stimulating factor to aggregate.[219] Aggregation in this case does not involve changes in the secondary structure of the protein because circular dichroism spectra remained unchanged upon PEG incorporation. In general, polydispersity, a natural property of synthetic polymers, over 20 kDa makes PEG-conjugated proteins prone to aggregation.[220] Currently, additional problems are reported with pegylated proteins,[221,222] for example, unexpected immune reactions upon intravenous administration of pegylated liposomes or other particles, and by extension supposedly of any pegylated protein and DNA.[223] Indeed, induction of anti-PEG immunoglobulins when formulated in liposomes was detected resulting in losing their long-circulating characteristic when they repeatedly administrated to the same animals.[224] From a clinical standpoint, PEG interferon can induce pulmonary toxicity that is rare, but fatality can occur.[225] Upon pegylated interferon-α and ribavirin therapy for chronic hepatitis C, ischemic colitis was diagnosed without clear pathogenesis but potential involvement in immunoregulatory, vasospastic, and procoagulant mechanisms.[226]

Having said this, pegylated biotherapeutics made enormous impact on medicine starting with the approval of pegadamase (pegylated bovine adenosine deaminase for the treatment of severe combined immunodeficiency disease) in 1990.[227] Pegylated asparaginase was administered to 24 patients undergoing bone marrow transplantation for acute lymphoblastic leukemia as a consolidation

therapy.[228] Although of these eight remained in remission, the authors could not recommend the drug as a single-agent, postbone marrow transplant chemotherapy. In spite of the observed side effect during hepatitis C treatment, PEG interferon in combination with ribavirin is shown to be very efficacious in reducing hepatitis C viral load and maintaining effective sustained viral suppression in patients.[229] In short-term clinical studies mostly on pretreated, acromegalic patients with pegvisomant, a pegylated growth hormone antagonist, insulin-like growth factor 1 levels were normalized in the majority of cases.[230] Certolizumab pegol is a pegylated humanized Fab′ fragment of an antitumor necrosis factor-α mAb demonstrating high neutralizing potency.[231] In phase III clinical trials, subcutaneous certolizumab pegol administration at 400 mg once every 4 weeks is effective as induction and maintenance therapy in patients with moderate to severe Crohn's disease. Finally, once-monthly peginesatide (a synthetic, pegylated, peptide-based erythropoiesis-stimulating agent) resulted in some decrease in mean hemoglobin levels in individuals on hemodialysis.[232] Although 79% of the patients experienced adverse events, the majority of these were mild or moderate in severity.

6.05.5.1.2 Carbohydrates and nucleic acids

Carbohydrates can be considered biotherapeutics, although their drug properties are distinct from those of proteins and nucleic acids and, thus, are not heavily discussed in this book chapter. However, pegylation efforts are abundant on both the stand-alone sugar structures and the carbohydrate parts of glycoproteins, and a brief introduction of these complexes appears to be justified here.

Just like for nonglycosylated proteins, covalent attachment of PEG moieties to the carbohydrate region of glycoproteins has been mainly used to enhance the pharmacokinetic properties of the polyamide.[233] Glycopegylation is focused on sialic acid-containing proteins with native or enzymatically linked glycan conjugated to the peptide backbone. The PEG adducts can be either enzymatically introduced after sialic acid removal and Sia-PEG retransfer to the uncovered terminal Gal units of the linked glycan[234] or chemically on an *O*- or *N*-linked glycan of a newly created sugar.[235] The in vivo potency and efficacy of intravenous FVIII conjugated with a 40 kDa PEG were no different than before pegylation.[236] Nevertheless, the PEG-containing glycoprotein had a longer duration of effect in FVIII-deficient mouse models with approximately a twofold prolonged half-life in mice, rabbits, and cynomolgus monkeys. From sialic acid-pegylated thyroid-stimulating hormone analogs, a 40 kDa monopegylated conjugate exhibited a 3.5-fold longer duration of action than the naked hormone in rats, as a fivefold lower affinity was more than compensated by a 23-fold extension of circulation half-life.[237] From stand-alone short carbohydrates, several unprotected carbohydrate units of mannose, fucose, or lactose have been incorporated into the surface of pegylated dendritic polymers.[238] The larger dendrimer variants exhibit increased capacity to aggregate lectins. From longer polysaccharides, a natural graminan-type 5 kDa fructan demonstrated a 47-fold increased elimination half-life compared with the nonpegylated parent analog while preserving 74% of the bioactivity of the carbohydrate.[239] Lactobionic acid bearing galactose was coupled with chitosan for liver specificity, and PEG was grafted to the sugar to increase stability in water and enhance cell permeability.[240] Indeed, the PEG–carbohydrate conjugate forms complex with DNA, and pegylation appears to increase the stability of the DNA/carbohydrate complex.

This leads us to pegylation of nucleic acids. Currently, intensive efforts are devoted to overcome the adverse effects of serum protein binding of nucleic acid therapeutics with lipid- and polymer-based systems that efficiently transfer nucleic acids in the presence of serum leading the pack.[241] Pegylated components sterically shield the delivery vehicles from blood constituents[242] as amphiphilic polyacrylamide and polyvinylpyrrolidone modified with long-chain fatty acyl groups are able to incorporate into the liposomal membrane and, similar to PEG, prolong liposome circulation in vivo. The protective efficacy of modified polymers decreases with increased MW of the polymeric structures.[243] Pegylation in general has a clear benefit to circulation time although it is also known to interfere with trafficking involved in intracellular delivery and render nucleic acid vectors more susceptible to agitation-induced damage during processing.[244] After cellular uptake, nonpegylated liposomes efficiently escape from endosomes and release phosphodiester oligonucleotides (PO-ONs) in the cytoplasm ensuing rapid degradation in the intracellular environment.[245] In contrast, pegylated liposomes fail to protect PO-ONs they carry, leading to rapid degradation of the PO-ONs in the endosomal compartment. In addition, the PEG chains inhibit endosomal escape of the degraded oligonucleotides explaining why pegylated liposomes fail to establish an antisense effect. Other studies have reported that pegylation significantly lowers the cellular interaction and uptake of the lipid nanoparticles, resulting in reduced biological activity. Pegylation-induced weakening of the electrostatic binding of cationic liposome–DNA nanoparticles to cells has been considered a possible cause for reduced gene delivery efficacy of sterically stabilized nanoparticles.[246]

From the positive side, sense strand pegylation increased the silencing potency of an α-chemokine receptor siRNA, which had modest activity in its wild-type form.[247] Apparently, PEG chains at the 3′ terminus of both strands of siRNA are well tolerated by the RNAi effector. In another study, pegylation improves the receptor-mediated transfection efficiency of peptide-targeted, self-assembling, anionic nanocomplexes.[248] Pegylation of a multifunctional envelope-type nanodevice composed of a pH-sensitive cationic lipid results in the increase in the accumulation of siRNA in tumor tissue by 240-fold.[249] Administration of siRNA at $3\,mg\,kg^{-1}$ in the complex resulted in 50% reduction in the target gene mRNA and protein. Using a photocleavable PEG moiety, the antisense activity can be regulated with high spatial and temporal resolution, allowing precise regulation of gene expression in biological systems.[250]

6.05.5.2 Conjugation to Fc Antibody Fragments

In the human placenta, the Fc receptor for IgG, FcRn, mediates transport of IgG across epithelial barriers by transcytosis.[251] Transepithelial transport by FcRn explains how humoral immunity transfers from mother to infant. The absorptive epithelial cells that

line the intestine continue to express FcRn in adult life,[252] and as expected, cells in culture expressing FcRn exhibit FcRn-dependent transcytosis of IgG in both directions in vitro.[253] In a fusion protein, consisting of erythropoietin (Epo) and the Fc fragment of murine IgG1, while the Epo part binds to erythroid progenitor cells in the bone marrow and promotes proliferation of the red cell lineage, the Fc fragment binds specifically to FcRn.[251] The Fc fragment promotes transepithelial transport in vivo, measured by reticulocytosis 4 days after administration of the fusion protein to mucosal surfaces. As the transport of IgG across epithelial barriers by FcRn does not depend on transepithelial pH gradients established at epithelial surfaces,[254] it was proposed that FcRn can function as a transporter for proteins containing Fc at any mucosal surface that expresses FcRn.

To exploit this technology in drug development, Fc fusion monomers were prepared with both recombinant FVIII and factor IX.[255] Preclinical and clinical data demonstrate improved pharmacokinetics for both factors. Importantly, in phase I/IIa studies, the two factor proteins showed 1.5–1.7-fold and 3.0–4.0-fold longer elimination half-lives, respectively. Phase III clinical trials verified a clear advantage for patients treated on prophylaxis versus those treated on demand with both Fc fusion proteins without basically any side effect.[256] Only a single injection of the factor IX construct at a median dose of 91 IU kg^{-1} was required in 86% of surgeries to maintain hemostasis during the procedure.

In other types of constructs, Fc fragments harboring a single C-terminal selenocysteine residue (Fc-Sec) are directed against a variety of targets by changing the peptide to which they are conjugated.[257] When a targeting and additional cytotoxic warheads were attached by cycloaddition reactions of tetrazine or azide-containing linker, the Fc-Sec proteins were successfully targeting folate receptor-expressing tumor cells. Other chemistries are also explored to attach Fc to protein and peptide drug candidates. The active peptide fragment of a bicyclic peptide antagonist was fused to an Fc, and the peptide was subsequently cyclized by chemically reacting its three cysteine residues with tris(bromomethyl)benzene.[258] After optimization of the linker and the Fc fragment arrangements, the bicyclic peptide was fully functional with K_i of 76 nM and exhibited an extended half-life of 1.5 days in mice. Even biomimetic carbonate-hydroxyapatite nanocrystals appear to be suitable substrates to produce nanoparticles, which can be functionalized with full antibodies and Fc fragments for efficient targeted drug delivery to tumors.[259] While upon binding of antibody to antigen and Fc receptor none of the conjugates exhibit altered antigen affinity, observed changes in thermostability require consideration for the choice of conjugation chemistry, depending on the actual molecular model and particular application of the conjugate.[260] Dulaglutide, marketed by Eli Lilly, is a long-acting glucagon-like peptide 1 analog (residues 7–37) for the treatment of type 2 diabetes.[261] Dulaglutide consists of the peptide drug covalently linked to an Fc fragment of human IgG4, thereby protecting it from inactivation by dipeptidyl peptidase-4. Indeed, pharmacokinetic studies demonstrated a half-life in humans of up to 90 h, making dulaglutide an ideal candidate for once-weekly dosing.

Protein conjugates to antibodies and Fc fusion proteins seem likely to represent extensively engineered biotherapeutic drugs in the future aimed to improve their performance with enhanced effector functions or extended half-life.[262] Two older concepts for improving antibodies, namely, antibody-drug conjugates and bispecific antibodies, have advanced to clinical success stage. Applying the technology to DNA, anti-CD3 chemically self-assembled antibody nanorings with valencies ranging from two to eight could be employed not only for radionuclide or small-molecule drug but also even for potentially oligonucleotide delivery to T cells without the negative effect of activation of the mAb parts, as has been observed for other antibody conjugated nanoparticles.[263] In a specific application of the concept, two bioorthogonal, enzyme-mediated reactions were used in combination with oxime ligation and self-assembly based on peptide nucleic acid (PNA)–DNA base pairing to couple a synthetic PNA oligomer to the C-terminal of the Fc dimer upon sequence-specific sortase A-mediated transpeptidation.[264] Hybridization of the resulting Fc-PNA conjugate with a tailored DNA aptamer that binds the cancer-related hepatocyte growth factor receptor led to a hybrid construct, which showed strong and specific binding to the target and was readily internalized by target-overexpressing cells.

6.05.5.3 Albumin-Binding

In addition to immunoglobulins, the Fc receptor also binds albumin with high affinity only at a low pH ($pH < 6.5$) in acidic endosomes, preventing its degradation *via* the lysosomal pathway and returning it to the extracellular space (pH 7.4).[265] Human serum albumin is synthesized by the liver and remains in the circulation for weeks (half-life is 19 days).[266] Albumin is able to bind both endogenous substances such as long-chain fatty acids, steroids, and exogenous compounds and drugs, such as warfarin, ibuprofen, chlorpromazine, and naproxen.[267] In addition to the blood, the protein is prevalent in the skin, gut, muscle, and other fluids and secretions[266] significantly increasing the residence time of the substances it binds to.[268] Because solid tumors commonly possess an immature, highly permeable vasculature,[269] retention of albumin was observed in various solid tumors including sarcoma and ovarian carcinoma.[270] The potential of albumin as a protein drug delivery vehicle came after recognizing that it binds a number of endogenous proteins including albondin, its putative receptor,[271] and the market approval of nab-paclitaxel, the paclitaxel-loaded albumin nanoparticle.[272] The paclitaxel–albumin conjugate has a better therapeutic index than paclitaxel alone.[273]

Insulin detemir, an insulin analog in which myristic acid is bound to LysB29, is quickly absorbed after which it binds to albumin in the blood through its fatty acid at position B29.[274] The half-life of the insulin detemir is 5–7 h after subcutaneous administration to type 1 diabetes patients.[275] Ongoing clinical trials employ albumin-antibody fusion proteins for treating HER2/neu positive breast cancer and an antidiabetic glucagon-like peptide-1 agonist analog bound to recombinant human albumin.[276] From the nucleic acid portfolio, introduction of human serum albumin preserves the capacity of branched polyethylenimine to complex with siRNA and protects it against extracellular endonucleases while affording significantly improved internalization and silencing efficiency in endothelial and metastatic breast cancer epithelial cells.[277] Albiglutide is a yet another glucagon-like peptide-1 7–36 analog, this time coupled to recombinant human albumin.[278] This formulation is approved in adults for the treatment of type 2

diabetes mellitus. After once-weekly subcutaneous administration, albiglutide is absorbed through the lymphatic circulation and reaches maximum concentrations in a few days while maintaining exposures for 4–5 weeks. Remarkably, no clinically relevant adverse drug interactions have been observed.

6.05.5.4 Hyperglycosylation and Lipidation of Large Proteins

Earlier, it was discussed how addition of carbohydrate groups can improve the pharmacological properties of peptide drugs. This concept is here extended to hyperglycosylation of protein therapeutics. Polysialic acid is an endogenous carbohydrate moiety and, similarly to PEG, strongly hydrophilic and can be attached to the side-chain amino group of Lys through reductive amination.[279] During polysialylation, proteins are decorated with the naturally occurring, biodegradable α(2-8)-linked polysialic acid. As opposed to PEG that in principle can induce immune reactions to the host upon prolonged accumulation in the body, polysialylated proteins can be engineered to stay nonimmunogenic throughout the therapy course.[279,280] When an L-asparaginase was coupled covalently to colominic acid, a low-molecular-mass polysialic acid, the construct retained the enzymatic activity of the native enzyme.[281] While the hyperglycosylated asparaginase constructs exhibited resistance to proteolysis, most of the native enzyme was inactivated under the same conditions in mouse plasma. In vivo, intravenously administered glycoconjugate exhibited a significant increase in the half-life compared with the native enzyme.

A hyperglycosylated form of Epo is approved in the United States. This analog exhibits a threefold longer half-life than Epo itself and thus can be dosed once a week compared with the weekly three injections of naked Epo.[138] In another model, polysialylation generally increased the blood half-life of a therapeutic antibody Fab fragment resulting in higher tumor uptake in a human tumor xenograft mouse model.[282] One Fab-carbohydrate conjugate had over a fivefold increase in blood exposure approaching the bioavailability of a whole IgG. Likewise, chemical polysialylation can increase the half-life of an antiplacental alkaline and anticarcinoembryonic antigen single-chain Fv by 3.4–4.9-fold, resulting in a 10.6–15.2-fold increase in blood exposure.[283]

Lipid-based drug delivery encompasses not only the microemulsion and regular emulsions and solid–lipid nanoparticles discussed earlier but also liposomes, lipid implants, inverse lipid micelles, and lipid microtubules and cylinders.[284] The activity of small-sized PEG–liposomes-containing superoxide dismutase was compared with that of the same enzyme entrapped in stearylamine liposomes upon intravenous injection in an arthritic rat model.[285] Both lipidic structures showed a superior therapeutic activity compared with the naked enzyme, with PEG–liposomes inducing stronger anti-inflammatory effects than the stearylamine-type liposome formulation.

Experiments in hemophilic and nonhemophilic mice indicate that the circulation time and clotting efficacy of exogenous FVIII are significantly enhanced in PEG–liposome formulation suggesting the feasibility of using pegylated liposomal FVIII to extend the duration of hemostatic efficacy in the treatment of hemophilia A.[286] This protein delivery system seems to be universal as similar formulation of G-CSF extended its circulation time and results in higher G-CSF levels several hours after both subcutaneous and intravenous injection in mice.[287] The pegylated liposomal G-CSF had significantly improved efficacy in the mobilization of hematopoietic stem cells from the bone marrow to the peripheral blood. A series of phase I and phase II clinical trials were conducted to assess the safety and potential activity of liposomal drugs, using anthracyclines as example, in the management of both solid and hematologic tumors.[288] These studies confirmed that liposomal drug formulation is well tolerated, and in fact, the activity spectrum of the drugs can be expanded in lipidic structures. Further clinical studies of liposomal drug therapy are in progress to fully establish their safety, efficacy, and dosing in the treatment of various diseases.

6.05.6 Alternative Administration Routes

While the focus of this book chapter is to introduce the potential excipients, additives, and conjugation partners for biotherapeutics, enhancement of in vivo biological activities can be achieved by merely moving from direct intravenous, subcutaneous, or intramuscular (infrequently intracerebral vein) injections to alternative drug administration modes. Especially so as these delivery techniques often require their own excipient and additive formulations.

Although the distinction from noninvasive administration modes is somewhat artificial, subcutaneous or other long-releasing protein depot systems are considered a separate group of invasive administration methods.[289] In 2004, the FDA approved a 45 mg 6-month depot leuprorelin for the palliative treatment of locally advanced or metastatic prostate cancer.[290] Sustained release of leuprorelin from PLG microspheres as a six-monthly 30 mg peptide dosage was tested for efficacy and clinical safety in a recent European multicenter prospective trial.[291] A 12-month subcutaneous implant was briefly available for clinical use after approval by the FDA in 2000 for treatment of metastatic prostate cancer.[292] Although the implantable leuprolide delivery system was found to provide effective suppression of testosterone in patients with advanced prostate cancer,[293] the drug did not gain popularity and was eventually discontinued by the manufacturer.[290] In an interesting extension, bifunctional peptides that can simultaneously bind to a growth factor and an implantable biomaterial can be used to control the delivery and release of growth factors at the site of implantation as it was shown on a chimeric peptide consisting of a bone morphogenetic protein active site and collagen fragment.[294] Proteins can be used as implantable biomaterials themselves. Based in vitro and in vivo investigations in dogs that had demonstrated cellular ingrowth and tissue regeneration through a collagen scaffold, a feasibility clinical trial was conducted on nine patients.[295] The protein-based biomaterial scaffold was found to be implantable and to be safe over the 3-year period.

A unique family of devices made of silk proteins provides functional biomaterials with built-in optical signal and contrast enhancement without adverse biological effects and ultimately degrades to regenerate native tissue.[296]

6.05.6.1 Intranasal

The nasal tissue is highly permeable and is situated in an extensively vascularized environment while providing only limited proteolytic activity; consequently, intranasal administration is a highly viable option for protein and peptide drug delivery.[297] The predominant proteolytic enzyme is aminopeptidase,[298] whose activity can be easily downregulated by acylating the amino termini of the biotherapeutics.[193] The absorption of peptide drugs can be further improved by using enzyme inhibitors as absorption enhancers. A new class of alkylsaccharide transmucosal delivery enhancement agents overcomes the principal limitations preventing broad acceptance of intranasal administration for biotherapeutics such as poor transmucosal absorption and damage to the nasal mucosa.[299] Intranasal delivery of a modified leptin fragment (targeting the MC4 receptor[300]) is feasible and has significant effects on regulating body weight gain, food and water intake, serum glucose, insulin sensitivity, and bone formation in mice lacking endogenous leptin production.[301] The comparative absorption of intranasally administered insulin relative to subcutaneous insulin is 12.0% (dominant nostril) or 15.4% (nondominant nostril) over a 2 h period.[302] Sneezer patients and those with moderately blocked nostrils experienced lower adsorption rates.

Nasal delivery avoids the hepatic first-pass effect highly accelerating drug delivery, although the enzymatic barrier of the nasal mucosa creates a pseudo-first-pass effect. Agents that enter the olfactory receptor cells by endocytotic or pinocytotic mechanisms can take advantage of the olfactory nerve pathway and thus be transported by intracellular axonal transport to the olfactory bulb.[303] The olfactory nerve is directly connected to the olfactory tract and the olfactory bulb, making possible for drugs to reach the CNS without the control of the BBB.[304]

In patients of type 1 diabetes, peak serum levels of intranasally administered insulin were generally attained in 15–20 min and remained elevated for approximately 1 h.[305] Mean peak insulin levels were dose-dependent, and glucose waned 1.5–2 h postinsulin dosing. A total of 1255 postmenopausal women with established osteoporosis received 200 IU salmon calcitonin nasal spray or placebo after which the risk of new vertebral fractures was evaluated.[306] The intranasally administered peptide significantly reduced the fracture risk of by 33% along with a 12% decrease in bone turnover. Plasma levels of desmopressin administered as a nasal spray to patients were two- to threefold higher than those measured after instilling the peptide as nasal drops with similar increases in FVIII activity.[307] Patients suffering from mild hemophilia A, von Willebrand's disease, or platelet disorders self-administered the nasal desmopressin spray and experienced decreased blood loss and shortened duration of epistaxis, menorrhagia, tissue bleeding, and bleeding in connection with minor surgery or tooth extraction.[308] The efficacy of intranasally administered nafarelin, a gonadotropin-releasing hormone agonist, was compared with that of oral danazol in 213 patients with laparoscopically confirmed endometriosis.[309] The mean laparoscopic scores decreased at the same level, indicating that nasal nafarelin is an effective agent for treating endometriosis and other than hypoestrogenism has only few side effects. In contrast, chronic nasal treatment of patients suffering from prostate cancer with luteinizing hormone-releasing hormone reduces basal serum testosterone concentration levels, but not as much as subcutaneous administration of the same drug does.[310]

6.05.6.2 Pulmonary, Transdermal, Buccal, Rectal, and Vaginal

While intranasal formulation of peptide and protein drug receives the most attention and is considered the most viable alternative to intravenous or subcutaneous drug administration, some other delivery methods are also investigated.

There potential advantages of administering biotherapeutics to the lung as an aerosol include a rapid onset of action, high local concentration by delivery directly to the airways, and needle-free systemic delivery of drugs with poor oral bioavailability.[311] Several studies showed that a dose of 1.0–1.5 $U kg^{-1}$ body weight human regular insulin aerosol controlled fasting glucose levels and postprandial glucose levels although this dose posed an early limitation to this route of administration, since it was approximately 10 times the dose given subcutaneously.[312,313] Although a pulmonary insulin preparation was approved by the FDA in 2006 and others were in late clinical trials soon thereafter, all were discontinued due to transient safety issues, predominantly the increased level of appearance of increased insulin-binding antibodies, coughing, and reduction in diffusing capacity, compared with injected insulin.[34] Second generation of insulin inhalers completed clinical trials and waiting for market approval.[314] In our hands, while an antimicrobial peptide appears to be effective against *Klebsiella pneumoniae* lung infection when administrated pulmonary, it is also more toxic than an intramuscular dosage form.[315] Regarding to nucleic acid therapies, clinical trials with aerosolized gene vectors documented low levels of gene transfer concomitant with lung inflammation and induced humoral and cellular immune responses, shortcomings that have not been overcome.[316]

Transdermal delivery of large and hydrophilic drugs requires the partial disruption of the stratum corneum and as such more belong to the invasive drug-dosing category than to the group of alternative administration technologies. Having said that, microneedles and thermal ablation are rapidly progressing through clinical trials for delivery of macromolecules such as insulin and parathyroid hormone[317] and may become soon successful alternative formulation strategies with minimal discomfort. Theoretically, the buccal mucosa offers advantages over the oral route making it attractive for the delivery of peptides and proteins; however, the buccal mucosa still exhibits permeability-limiting properties, and therefore, for the delivery of macromolecules, the use of chemical penetration enhancers, physical methods, particulate systems, and mucoadhesive formulations is the norm and with promises for

Fig. 4 The market is saturated with miniature needles for type A insulin delivery pen devices. They offer soft, comfortable daily self-injections.

the future rather than current times.[318] This statement appears to apply also for vaginal and rectal administration for biotherapeutics not to mention low patient compliance with these formulation routes.[319,320]

6.05.7 Convenient Subcutaneous and Intramuscular Delivery Devices

Even if subcutaneous or intramuscular administration of peptide or protein drugs is needed, currently, the market is saturated with personalized, reusable, and virtually painless transdermal or intranasal medical devices.[321] For example, electronic autoinjectors are available for first-line therapies against multiple sclerosis.[322] The device features adjustable injection settings and an electronic dosing log during subcutaneous administration of interferon ß-1a. The second major use of autoinjectors is the chronic delivery of mAbs in rheumatoid arthritis. The pharmacokinetic properties and tolerability of subcutaneous administration of golimumab by autoinjector or by a standard needle and syringe are comparable.[323] Modeling the self-administration process, high level of patient acceptance was observed for self-injection with the autoinjector among patients with rheumatoid arthritis.[324] In particular, patients with severe hand disability were able to successfully comply with device instructions.

More than 2 billion pen injectors and multidose syringes are used each year by patients who need frequent injections against diabetes and with growth hormones, which often require weighed dosages or dose titration.[325,326] Miniature needles (punching a bladder at the end of prefilled multidose pens) help avoid needle phobia and reduce the risk of needlestick injury in many self-administered daily dosed drugs such as insulin or the glucagon-like peptide analogs. In addition to painless self-administration drug dosing, multidose pens and cartridges offer a softer impact on the environment and easier disposal (Fig. 4).

6.05.8 Implantable Devices for Subcutaneous Drug Delivery

The initial scientific (as opposed to market) success of leuprolide implants initiated further investigations in continuous subcutaneous delivery of drugs. One such novel subcutaneous delivery system is composed of three technologies: osmotic minipumps, minipump placement technology, and high-temperature therapeutic stabilization processes.[327] In a 6-month extension to a randomized, 24-week phase II study in subjects with type 2 diabetes, ITCA 650 implants induced sustained glycemic control, as measured by reducing HbA1c levels, and sustainable weight loss with only mild and transient adverse effects.[328] If approved, ITCA 650 will represent the first once- or twice-yearly injection-free exenatide therapy. Such devices offer significant advantages over existing drug delivery technologies in the future. At the time of completing this article, the FDA approved Probuphine, the first buprenorphine implant that uses a polymer matrix sustained-release technology[329] for the maintenance treatment of opioid dependence.

6.06.1 Inflammatory Bowel Disease

Inflammatory bowel disease (IBD), which encompasses ulcerative colitis (UC) and Crohn's disease (CD), is a chronic disease that causes inflammation, abdominal pain, diarrhea, and weight loss, as well as fatigue and anemia in severe cases. IBD has an onset in early adulthood and a lifelong impact; this disease poses a significant economic burden to society with annual estimated direct costs of $US 5.9 billion[1,2] and an increasing worldwide incidence.[3,4]

CD may involve any part of the gastrointestinal (GI) tract, but typically affects the distal end of the small intestine (ileum) and the proximal end of the large intestine (colon), while UC is restricted to the colon. CD may affect all layers of the intestine, resulting in deep ulcers that penetrate the bowel wall and lead to abscesses in the abdomen and fistulas that connect the bowel to other organs. UC affects only the mucosa of the colon and is more evenly distributed. A cure is desperately needed for IBD; however, the underpinning etiology is unknown. IBD is considered a heterogenous disease, triggered by a balance between a patient's genetic susceptibility, environmental triggers, immune system, and the intestinal microflora.[5] Increased intestinal permeability ("leaky gut") has been implicated as a pathogenic factor for >20 years.[6] This increased intestinal permeability may lead to microbial antigen exposure, which in turn initiates disease; alternatively, a compromised immune defense caused by genetic defects may lead to abnormal bacterial exposure to the mucosal immune system, resulting in inflammation and leaky gut.

The early onset of IBD, along with its persistent and chronic nature, emphasizes the need for safe and efficacious therapies. Treatment regimens are constantly evolving (e.g., step-up or step-down therapy) but may involve combinations of aminosalicylates, antibiotics, corticosteroids, immunosuppressives, and targeted biologics.[7] Each of these agents has specific side effect limitations. The current clinical approach for treating IBD involves the initial treatment of patients with the mildest form of drug therapy, with subsequent escalation to less-safe drugs in nonresponding patients. Injected biologics target particular proteins that have proven defective, deficient, or excessive in people with IBD. However, injection results in ablation of the same pathway in both healthy and diseased tissues for extended periods, leading to exaggerated pharmacology.[8] Such biologics are used as the last step prior to surgery. The development of anti-Tumor Necrosis Factor-α (anti-TNF) therapies, such as infliximab, adalimumab, and certolizumab pegol, has significantly improved the quality of life of many patients with IBD, but only a third of these patients remain in remission after 1 year, and the need of surgery remains high in patients receiving anti-TNF therapy.[3] Side effects associated with TNF blockers include lymphoma, infections, congestive heart failure, demyelinating disease, a lupus-like syndrome, induction of auto-antibodies, injection site reactions, and additional systemic side effects.[9] Many patients become intolerant to anti-TNF treatment[10]; switching from one agent to another is an established, though not ideal, treatment approach.[11]

6.06.1.1 The Pathological Manifestations of IBD

The pathological manifestations of IBD are localized primarily in the GI tract, though extraintestinal manifestations may be found in most other organs.[12,13] Analysis of the inflamed mucosa from patients with UC and CD has revealed an increased expression of certain proinflammatory cytokines such as IL-1, IL-6, IL-8, IL-23, and TNF-α.[14–17] Fecal TNF has been shown to be a useful marker of disease activity, suggesting enhanced local expression.[18] In mice, mucosally produced TNF has been shown to be sufficient to induce disease, indicating that targeted intestinal blockade of gut-derived TNF would be efficacious.[19] In humans treated with an anti-TNF drug, ~73% of patients with active disease had higher levels of the drug in serum than in tissue, compared to ~33% of patients in remission. The tissue:serum ratio of anti-TNF drug was highest in uninflamed areas and lowest in severely inflamed areas, suggesting that patients with high serum anti-TNF levels have active disease because tissue levels of anti-TNF are insufficient to neutralize local TNF production.[20]

The anti-TNF antibodies infliximab and adalimumab have been injected locally (adjacent to fistulas),[21,22] and infliximab has been administered topically by rectal instillation.[23] In each study, significant efficacy was apparent with local topical delivery, suggesting not only the ability to infiltrate through mucosal barriers but also that local activity is sufficient to treat disease. Similarly, treatment in a chemically induced rat model of colitis with an avian polyclonal anti-TNF antibody (administered orally twice daily for 5 days) ameliorated all disease parameters, whether treatment was initiated before or after the onset of disease.[24] The antibody was found to be localized in the lamina propria, and hence could penetrate inflamed regions of the colon. The orally administered antibody had very low systemic concentrations, and the antibody was not active when delivered IV at these concentrations, suggesting that oral efficacy reflected local tissue concentrations and not systemic exposure. A polyclonal collection of anti-TNF antibodies derived from bovine colostrum was also orally administered to several mouse models of IBD[25] and was effective in treating murine IBD. The antibody was observed in colonic tissue by immunohistochemistry, was thought to be intact, and exhibited minimal systemic absorption.

The localized nature of IBD is supported by the therapeutic effect of aminosalicylates; the efficacy of this class has been correlated with the drug concentration in intestinal mucosa,[26] while systemic drug concentrations may be indicative of adverse events.[27] Numerous studies on the topical/rectal delivery of aminosalicylates and steroids have shown improved efficacy with limited side effects when compared with systemic delivery.[28]

6.06.1.2 Summary

In summary, the major pathological manifestations and sites of target action in IBD appear limited to intestinal tissue. Therefore, an ideal therapeutic would be delivered orally and act from the luminal side (thereby achieving high drug concentrations locally in the diseased mucosa and enhancing efficacy), with limited systemic bioavailability (to reduce the potential for systemically driven adverse effects) (Fig. 1). The extent of gut targeting required to treat disease will be highly dependent on the specific target and the required site of target engagement. Indeed, the required drug levels in the gut can range from no GI tissue absorption for "soluble" targets within the lumen, to a degree of penetration to access membrane-bound targets on the luminal side of the apical membrane, to significant permeability to access targets in the lamina propria or on the basolateral side of the membrane. Given the important roles of cytokines in both inducing and protecting intestinal inflammation, it is not surprising that numerous protein–protein interaction targets are under clinical investigation, including IL-1β, IL-5, IL-13, IL-18, IL-22, and IL-23. Small molecule (SM) approaches are also being pursued, with a predominant focus on inhibiting cytokine-mediated effects by targeting intracellular downstream signaling targets, but these lack the selectivity of blocking specific cytokine-mediated signaling. There is, therefore, significant opportunity to develop orally delivered and targeted drugs that block key cytokine signaling.

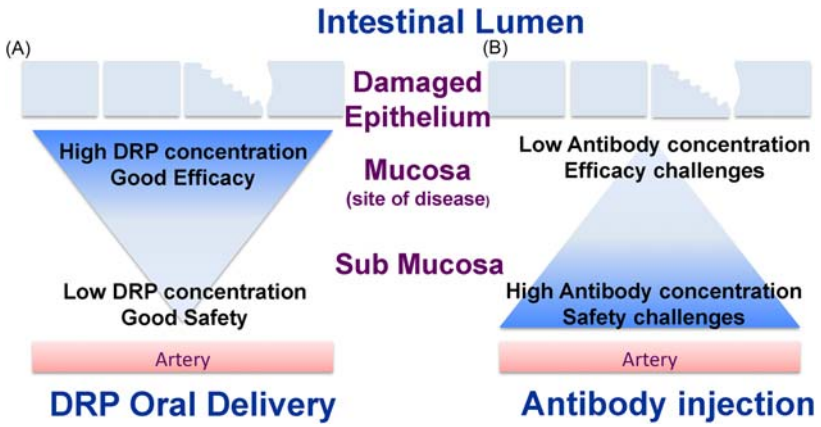

Fig. 1 (A) The oral delivery of constrained peptides will result in high concentrations of drug in the diseased tissue (mucosa) and lower systemic concentrations. (B) In contrast, injected antibodies result in high concentrations systemically and lower concentrations in diseased tissues.

6.06.2 Constrained and Stable Peptides

To achieve oral delivery of targeted drugs, compounds must be orally stable, able to reach and then penetrate the diseased GI tract to achieve high concentrations in the lamina propria, and able to bind the large flat macromolecular surfaces that underpin cytokine-based signaling. The spectrum of available drugs consists primarily of SMs that target deep binding pockets to inhibit enzyme function and macromolecular antibodies to bind and block signaling of large macromolecular protein complexes. SMs can be orally delivered but are unlikely to modulate cytokine (protein–protein interaction) targets, while monoclonal antibodies are able to block cytokine targets but are unlikely to be orally stable and delivered. Peptide-based drugs have gathered momentum as a class of therapeutics, but linear peptides are not generally orally stable. Constrained peptides and macrocycles may offer unique advantages for the treatment of IBD.

6.06.2.1 Disulfide-Rich Peptides

One class of constrained peptides are disulfide-rich peptides (DRPs).[29] DRPs are ideal scaffolds for drug development and have favorable features for diverse clinical applications. These constrained peptides possess disulfide-strained cores that impart extraordinary chemical and biological stability characteristics, along with sequence flexibility that allows the introduction of novel functionalities. DRPs permit the engineering of a large surface footprint in a spatially controlled manner to modulate protein–protein interaction targets.[30–33] DRPs are found throughout nature and have evolved SM-like properties and remarkable chemical stability. It has been shown that some DRPs can be boiled, incubated at 65°C, or exposed to 1 N HCl or 1 N NaOH without a loss of structural or functional integrity.[34] Avimers, a DRP subclass, are derived from human A domains and exhibit stability during incubation for 2 weeks at temperatures between 50°C and −80°C.[35]

Many DRPs are found in protease-rich environments and have evolved stability characteristics that overcome limitations that have plagued the development of peptide-based drugs (**Table 1** and **Fig. 2**). For instance, defensins are a well-characterized family of antimicrobial DRPs[36] that are expressed by epithelial cells throughout the small intestine and colon; notably, these tissues are predominant sites for manifestation of IBD.[37] Trefoil peptides have been shown to be stable for up to 6 days in the stomach contents of rats and for more than 24 h in components of the small intestine of humans[38]; such peptides are excreted intact in the urine when administered parenterally. Due to their stability characteristics and small size, several DRPs have been tested for permeability. For example, conotoxins modified with lipidic amino acids were shown to have improved permeability in Caco-2 assays,[39] and a series of cyclic cysteine knots were shown to have good permeability through rat intestine.[40,41]

6.06.2.2 Examples of DRPs

As a consequence of these characteristics, several DRPs have been evaluated in various disease models of IBD. For example, the trefoil family (TFF) of DRPs comprises TFF1, TFF2, and TFF3, all of which may play essential roles in epithelial restitution and repair within the GI tract. These TFFs have been studied in numerous rodent models of disease, including ethanol-induced gastric injury,[42] indomethacin-induced gastric injury,[42] burn-induced gastric injury,[43] aspirin-induced gastric injury,[44] chemical (Dextran sodium sulfate (DSS) and 2,4,6-Trinitrobezenesulfonic acid (TNBS)) models,[45,46] mitomycin C models,[46] and ischemic reperfusion injury in weaning rats.[47] Depending on the specific model, distinct DRPs showed superior efficacy when administered either orally[45,46] or parenterally.

Kalata is a cyclic DRP that is found in the African plant *Oldenlandia affinis* and was identified as the orally active ingredient in an herbal tea that is drunk by women of the Lula tribe during childbirth. The compound is thermally stable and orally active.[48] Kalata has been used as the base scaffold to engineer new functions onto a peptide while maintaining the oral characteristics. For example, Tam and coworkers used molecular grafting of bioactive peptides onto the kalata B1 framework to develop an orally active bradykinin B1 receptor antagonist for the treatment of inflammatory pain.[49] Other DRPs have been engineered with new activity and oral delivery; for instance, an α-conotoxin Vc1.1 analog has shown potential for treating neuropathic pain when delivered orally.[50] In both of these cases,[49,50] the authors reported oral activity but did not provide systemic bioavailability. Oxytocin analogs incorporating disulfide-bond isosteres were efficacious when delivered orally, but it was suggested the actions of these analogs were predominantly topical (i.e., localized to the gut wall).[51] As extensively reviewed by Craik et al.,[52] there have been numerous cases of engineering DRPs with new functions. Discontinuous surfaces have been engineered[31] onto DRPs resulting in potent and selective cytokine antagonists.[30] A select set of DRP structures that function or are found in the GI tract are shown in **Fig. 2**.

In the context of clinical data, linaclotide (Linzess) is a once-daily orally administered drug for treatment of irritable bowel syndrome with constipation (IBS-C). The compound is a DRP agonist of guanylate cyclase 2C (GC-C); the compound acts locally within the lumen of the GI tract and is minimally bioavailable. Linaclotide was derived from a heat-stable enterotoxin, which is found in the GI tract. In Phase 1 human trials, 3–5% of the oral linaclotide dose was excreted in feces as a pharmacologically active peptide (linaclotide plus a deleted C-terminal Tyr analog MM-419447), demonstrating that orally administered active peptides are available to stimulate GC-C throughout the GI tract. Nonetheless, ex vivo studies showed that linaclotide is rapidly proteolysed in intestinal fluids from mice, rats, and humans under reducing conditions.[53] Plecanatide and dolcanatide, derivatives of a naturally occurring GI DRP hormone (uroguanylin), have been identified for the treatment of several GI disorders. Both compounds are delivered orally; plecanatide is in registration for chronic idiopathic constipation, while dolcanatide is in Phase 2 trials for opioid-induced constipation and Phase 1 trials for UC. Plecanatide is completely degraded in simulated intestinal fluid (SIF) within

Table 1 Sequences and disulfide-bond patterns of select marketed, clinical, or preclinical disulfide-rich peptides that have been delivered orally

Linaclotide	Marketed for treatment of IBS-C. Derivative of an enterotoxin found in GI tract	Plecanatide	In the clinic for chronic idiopathic constipation. Fig. 2 Diverse series of experimental structures of disulfide-rich peptides that have been found or function orally. This includes human defensin, guanylin, uroguanylin, and trefoil that are found in the GI tract of humans, Sphensiscin-2 found in GI tract of penguins, kalata an active ingredient in orally ingested tea, and protegrin that has been orally delivered in human clinical trials.

2 h to form an active metabolite. Dolcanatide is more stable, losing 20% of its biological activity after 24 h incubation in SIF.[54] Desmopressin, another DRP, is relatively stable in the GI tract.[55] Although this compound exhibits low bioavailability (~0.1%), desmopressin possesses high potency and is efficacious when orally delivered. In clinical trials, DRPs of the TFF class have been employed for treatment of the oral cavity, specifically as a mouth rinse formulation of human TFF1 (a *Lactococcus lactis*-induction of secreted human TFF1)[56] and as an oral spray for the prevention of oral mucositis.[57] Formulation strategies for oral delivery of peptides typically involve enteric coating and formulation with protease inhibitors and permeation enhancers.[58] A variety of peptides[58] (e.g., salmon calcitonin, GLP2, GLP1, PYY-(3–36), insulin, parathyroid hormone, and octreotide) have been formulated for oral delivery and are currently marketed or in different stages of clinical development.

6.06.2.3 Summary

In conclusion, there are numerous examples of orally stable DRPs that can be categorized as follows: (1) found and function naturally in the GI tract (e.g., enterotoxin precursors to linaclotide); (2) orally stable characteristics following ingestion (e.g., kalata B1); (3) stable DRP scaffolds with oral bioavailability and/or activity (e.g., conotoxin analog CV1.1); (4) formulated for oral delivery (e.g., calcitonin, insulin).

To be an effective treatment for IBD, an orally delivered DRP must attain appropriate free-drug exposure in diseased mucosal tissue (target site of action) at levels that exceed pharmacological potency over the desired period of time. To achieve this goal, numerous chemical stability constraints need to be overcome. The molecule must be stable to various pHs that range from strongly acidic in the stomach (pH 1.5–1.9), trending toward basic in the small intestine (pH ~7.5), and then weakly acidic in the colon (pH 5–7).[59] Thus, compounds must remain stable and may need to maintain potent biological activity over a broad pH range. There are also various

metabolic and physical barriers that DRPs must overcome to be orally active. A key component of the GI stability hurdle is the required duration of stability. For effective topical delivery, DRPs must be stable during their transit through the various GI compartments.[60] The total transit times in healthy volunteers range from 5.1 to 58.3 h (median 27.4 h).[61] The transit time in the colon is significantly longer and more variable than that in the intestine, with a reported range of 6–48 h.[62] The small intestine transit time, where the proteolytic hurdle is thought to be highest, has been reported to range from 0.5 to 9.5 h, with a mean of ~3 h.[62] The motility and transit in the colon is highly influenced by defecation time in healthy patients. Patients with IBD have been reported to have accelerated intestinal transit times.[63–65] This is relevant given a reported increase in GI absorption of desmopressin with pretreatment of loperamide, presumably due to lowering GI motility.[66]

6.06.3 Protease Stability for Peptides

Protease stability is vitally important for orally delivered peptide-based drug candidates. Compared to other organs, the GI tract contains the highest levels of proteases.[67] Protease metabolism in the GI tract can occur by luminally secreted enzymes (pepsin, trypsin, chymotrypsin, elastase, and carboxypeptidase A/B secreted from the pancreas), by brush border membrane-bound enzymes (various carboxypeptidases, endopeptidases, and aminopeptidases), or by protease secretion by bacteria on the luminal side or by immune and mesenchymal cells in the lamina propria. It is estimated that 40 different proteases are encountered in the GI tract of humans[68] and that the lumen incorporates gram quantities of proteases secreted from the pancreas.[69] Compared to brush border enzymes, the luminally secreted proteases were found to be 16- and 40-fold more effective at metabolizing insulin as a substrate in rats and guinea pigs, respectively.[70,71] The regulated production of proteases is key to intestinal homeostasis; altering this process can lead to gut inflammation and destruction, a key pathological feature of IBD. A fourfold increase in trypsin-like activity has been reported in UC patients,[72] and matrix metalloproteases have been implicated in IBD pathogenesis.[73,74] Increased concentrations of proteases have been found in the feces of patients with IBD.[72,75–78] It is reasonable to assume that in a diseased state, the proteolytic hurdle may be elevated for orally administered DRP therapeutics.

While it is widely reported that the colon is an environment with relatively reduced proteolytic activity,[79] it may still present a significant metabolic hurdle to orally delivered peptide-based drugs. Macfarlane et al. observed that stool from a patient who had undergone a pancreatectomy, and who therefore lacked pancreatic proteases, had proteolytic activity comparable to that of the stool of healthy individuals.[80] Such proteolytic activity is assumed to be derived from enteric microbes,[80,81] which are known to produce an array of aspartic, cysteine, metallo, and serine proteases.[75] The dominant proteolytic bacteria types in the human colon are reported as streptococci, *Bacteroides* spp., and *Clostridium* spp.[82,83] Hence, simply formulating DRPs to reach the colon may be inadequate, as a degree of intrinsic protease stability may still be required.

Proteases typically cleave peptide substrates in extended or elongated conformations.[84] DRPs are tightly knotted globular structures and are considered resistant to proteolysis.[52] However, the GI tract is a reducing environment, likely reducing disulfides to yield linear peptides that would be suitable elongated substrates for numerous proteases.

6.06.4 Redox Stability

Disulfide-bond formation is a reversible process with numerous biological functions, including stabilization of protein fold, enzyme catalysis, and protection against oxidative damage.[85] The ability to form and break a disulfide-bond depends on the disulfide bond stability, the environmental redox state, and the nature of the oxidant and reductant.

The reducing environment in the GI tract is a balance between the glutathione/glutathione disulfide (GSH/GSSG), cysteine/cystine (Cys/CySS), and reduced and oxidized thioredoxin (Trx/TrxSS) redox systems that ensure redox homeostasis.[86] The redox environment supports the gut microflora, aids nutrient absorption, counteracts oxidant-induced epithelial injury, and regulates intestinal cell transformation and apoptosis.[87]

Under these reducing conditions, DRPs may be unstable as a result of thiol/disulfide exchange, yielding linear analogs that would be susceptible to proteolysis. The redox stability of disulfide bonds in proteins can vary over an enormous range.[88] Proteins with the thioredoxin fold have active sites comprising a shared Cys1-Xaa2-Yaa3-Cys4 motif, in which the two cysteines are reversibly disulfide bonded. Despite the structural similarities of these proteins, the redox potential of the disulfide bond can vary by at least 7 kcal mol^{-1}, a 10^5-fold difference in equilibrium constant. The modulation of the redox potential of the disulfide bonds may be due to sequence differences within the conserved fold, in particular the ionization properties of active site residues.[89] These sequence effects also have been observed in the redox stability of DRPs. The high redox stability of octreotide toward GSH was explained by the presence of a Phe residue on each side of the Cys.[90,91] The higher degradation of oxytocin compared to vasotocin was explained by the Arg for Leu change at residue 8, which destabilizes the disulfide bond (due to the presence of the positively charged Arg stabilizing the dithiol).[91,92] Therefore sequence can have a significant impact on redox stability, which bodes well for the design of redox-stable DRP analogs. The redox hurdle may be lower in IBD patients, as both GSH levels and c-glutamylcysteine synthetase enzyme activity (required for GSH synthesis) are decreased in inflamed intestinal mucosa.[93] If necessary, numerous disulfide-bond isosteres can be used to eliminate or reduce redox liabilities.[94]

6.06.5 Stability to Microbes

The concentration of bacteria in the large intestine ranges from 10^{10} to 10^{12} CFU mL^{-1},[95] leading to the suggestion that the GI microflora has the ability to act as an organ with a metabolic potential equal to or greater than that of the liver.[96] Certainly the microbiota is capable of undertaking a large number of chemical transformations,[97] but these organisms also comprise significant proteolytic activity, as described earlier. The presence of GI microflora has implications for DRP-based therapies, as evidenced by the TFF of DRPs (TFF1, TFF2, and TFF3) that are remarkably stable, yet are reportedly broken down in the colon by the action of bacterial proteins.[38]

6.06.6 Permeability

Given adequate stability during GI transit, several physical barriers need to be surmounted prior to drug permeation at the epithelial surface. These include dissolution from semisolid luminal contents, diffusion through viscous mucus layers, and finally transit through an unstirred water layer prior to reaching the epithelial wall.

The stomach has a relatively thick mucus layer, while the intestine has a relatively thin, loose, and unattached mucus layer that harbors high concentrations of antibacterial peptides and proteins.[98] Bacterial exposure is minimized by flushing, which involves coordinated liquid and mucus secretion with intense motor activity; in rats, these processes have been reported to yield mucus turnover times of 40–270 min.[99] In contrast, the colon has a thick, two-layered mucus coating, the inner layer of which is impenetrable to bacteria and has a turnover time of about 1 h in mice.[98] Mucus undergoes some changes in IBD. In CD, the mucus is thicker than commonly observed, whereas in UC patients, the mucus layer is thin.[100,101] The mucins themselves also may undergo changes, including variations in protein length and glycosylation in IBD patients.[102] Underlying the mucus layer and protruding from the apical surface is the glycocalyx, or unstirred layer, which is a glycoprotein–polysaccharide layer that forms another barrier. The viscous nature of the mucus layer, estimated to be 1000- to 10,000-fold higher than water at low shear rates,[103] and its high turnover rate impedes access to the epithelial surface.

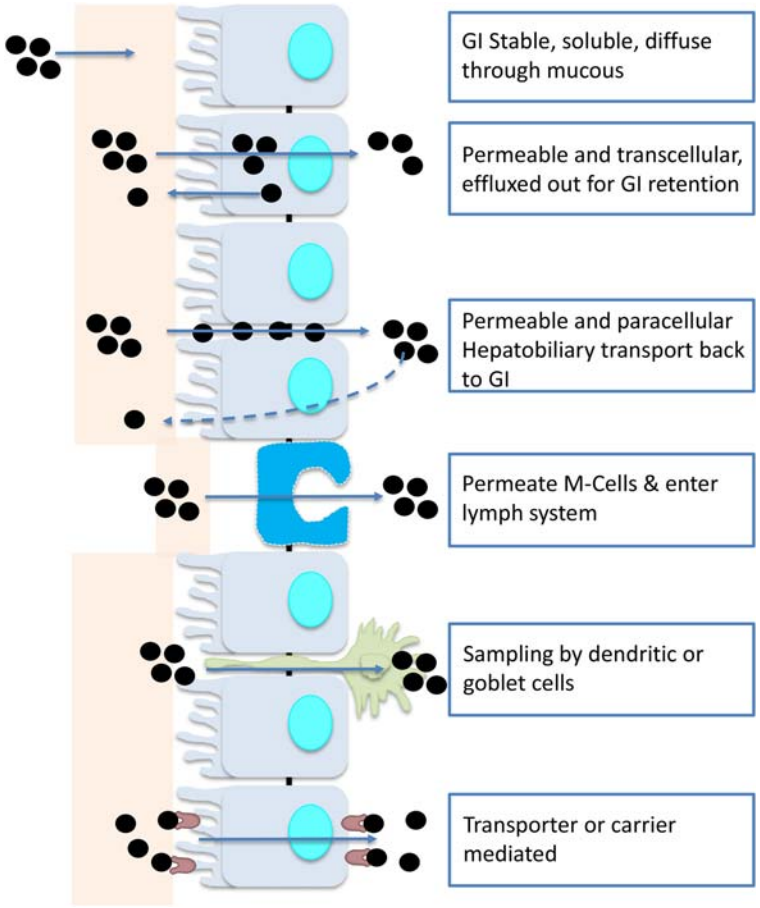

Fig. 3 Select examples of various mechanisms of permeating GI tissue with a focus on GI retention.

6.06.6.1 Permeability at the Epithelial Surface

Having reached the membrane, molecules may enter tissue via various pathways (Fig. 3), including the paracellular route (which involves diffusion between the aqueous pores at tight junctions between intestinal enterocytes), transcellular diffusion across the lipid cell membrane, and/or the involvement of membrane transporters. The paracellular route classically is thought to be used by small soluble compounds that can squeeze between adjoining cells. However, 14 synthetic peptides labeled with an amino acid fluorophore were found to cross the membrane using the paracellular route.[104] For transcellular absorption, compounds need to have the right physiochemical balance between solubility (to be exposed to and interact with the membrane) and hydrophobicity (to penetrate the membrane). The constrained peptide-like derivative cyclosporine is thought to permeate by transcellular mechanisms, specifically involving a conformational change, resulting in the formation of internal hydrogen bonds and exposure of a hydrophobic surface that facilitates membrane absorption and transcellular diffusion.[105] Cyclosporine, valinomycin, and gramicidin D[106] are known to be substrates for efflux transporters, such as *P*-glycoprotein, which decrease intracellular accumulation and ultimately transcellular diffusion across the intestinal epithelium.

6.06.6.2 Transporters on Intestinal Epithelial Cells

Various transporters have been identified on intestinal epithelial cells, including amino and oligopeptide transporters, bile transporters, vitamin transporters, carbohydrate transporters, monocarboxylic acid transporters, and phosphate transporters.[107] Covalent conjugation of carrier molecules to peptides has been used to exploit such transporters.[108] In some cases, such transporters are used to achieve retention or restriction to the GI tract. For example, with lumen or apical targets and permeable compounds, absorption followed by efflux can enhance GI retention and target exposure within the lumen.[109,110] For permeable compounds and targets in the GI tissue, the bile excretion pathway can be exploited due to the excretion of the drug from the liver back to the GI tract where it can be reabsorbed.[109,110]

Once compounds have penetrated the membrane surface, they may be exposed to another series of metabolic enzymes, such as CYP450. While human intestine comprises less P450 than the liver, these enzymes are strategically positioned (concentrated in the villus tips) to maximize exposure to intestinal contents.[111] Inflamed tissues exhibit increased mucosal metabolism and accumulate increased numbers of lymphocytes and neutrophils (which express P450s); therefore, such enzymes may significantly affect local drug delivery. For example, cyclosporine is orally bioavailable but is metabolized by P450s in intestinal membranes, an event that reduces cyclosporine's oral bioavailability.[112,113]

Patients with active CD have shown downregulation or redistribution of the tight junction-sealing proteins such as occludin, claudin-5, and claudin-8.[114] Genome-wide association studies of IBD patients have also revealed several susceptibility genes linked to barrier integrity.[115] The permeability of high-molecular-weight compounds is expected to be enhanced in diseased patients.[116] Indeed, PEG4000 is absorbed to higher levels in CD patients than in healthy patients.[117–119] Similarly, bacteria-derived antigens are known to leak across the gut wall in diseased patients, and systemic antibodies to these antigens are used as biomarkers indicative of more severe disease.[120] Asymptomatic first-degree relatives of CD patients[121–123] have increased intestinal permeability and are at greater risk of developing the disease.[124–126] Furthermore, increased intestinal permeability in patients in clinical remission predicts an elevated risk of early relapse.[118,127–131] The intestinal permeability of IBD patients is more broadly affected in GI tissues and is not restricted to areas of epithelial injury.[114] This enhanced permeability bodes well for the delivery of high-molecular-weight compounds to diseased mucosal tissues after oral administration. However, the bulk of clinical permeability studies have used various combinations of low-molecular-weight and soluble sugars; thus, while a substantial body of data supports a barrier defect in IBD, the impact of this defect on the absorption of high-molecular-weight compounds is not as well defined.

6.06.6.3 Absorption in the GI Tract

As peptides transit the GI tract, there will be regional differences in the thickness of mucus, pH, surface area, exposure time, membrane permeability, and dissolution capacity; all of these parameters will affect absorption. The total surface area of the small intestine has been reported as 2×10^6 cm^2, of which 200–2000 cm^2 (0.01–0.1%) comprise water-filled pores.[132] M cells, which comprise 1% (20,000 cm^2) of the intestinal surface, are more exposed and have a high transit capacity.[133] The colon has a much smaller surface area (30 cm^2), longer residence time, lower proteolytic barrier, and larger microbial metabolic hurdle; however, the nature of the large intestinal contents and the lack of fluid result in dissolution challenges. The lower parts of the GI tract (jejunum and ileum) have lower trans-epithelial electrical resistance and hence leakier paracellular tight junctions,[134,135] which are considered the major sites of drug absorption. It is also important to note that the colon and intestine are not uniform, with a magnetic resonance imaging study suggesting that the small intestine in the fasted state contained 319 mL of water as a series of 12-mL pockets, while in the fed state it harbored 156 mL total as a series of 4-mL pockets.[136] In the colon, the fluid volume is in the range of 1–44 mL, with an average pocket volume of 13 mL.[136] This characteristic could be leveraged to provide localized high-concentration pockets of drug candidates; the resulting concentration gradients might help to drive drug uptake, enabling the delivery from the lumen to the underlying lymphoid tissues.[137–139] Similarly, absorption through Peyer's patches has been explored as a potential route for uptake of orally administered protein and peptide drugs.[140,141] Goblet cells have been reported to sample and internalize relatively large-molecular-weight compounds (BSA and 10-kDa dextran) from the lumen and then transfer such molecules to dendritic cells.[142]

6.06.7 Impact of Food

Food is known to affect the GI environment by modulating gastric pH, changing GI viscosity, and altering the frequency of gastric emptying; food also serves as a matrix for drug adsorption. Food may have minimal effects on the absorption of soluble and permeable compounds, while having large effects on the absorption of insoluble and permeable compounds by virtue of increased GI secretions and biliary solubilization of compounds.[143] Food has been reported to have drastic effects on the oral bioavailability of calcitonin[144] and desmopressin,[66] with conflicting reports regarding the impact on cyclosporine absorption.[145,146]

6.06.8 Orally Delivered and Targeted Agents for Treatment of IBD

There are now several clinical and preclinical examples of orally delivered and targeted constrained peptides to treat IBD. Protagonist therapeutics has described PTG-100, a constrained peptide that is currently in Phase 1 clinical trials. PTG-100 binds to α4β7 and is effectively an oral equivalent of the marketed antibody Entyvio (vedolizumab). PTG-100 has been reported to be a potent and selective antagonist of α4β7, is orally stable, and GI restricted with little or no systemic bioavailability. Daily oral dosing has shown efficacy in DSS-treated mice, and high blood receptor occupancy in cynomologous monkeys.[147,148] Another constrained peptide developed by Protagonist is PTG-200 which is a potent and selective IL-23 receptor antagonist, orally stable with 40% of dose recovered in rat feces, and GI restricted, with minimal systemic exposure. The compound shows efficacy in a TNBS-induced colitis model in rats.[149] With respect to orally administered antibodies and biologics, several different strategies are emerging. PRX-106 is a nonabsorbable orally administered BT-2 plant cell that expresses etanercept and has shown efficacy in weight loss and improved bowel histology in mice.[150] This is in spite of etanercept being ineffective in treatment of CD.[151] Similarly, *L. lactis* has been engineered to express murine-TNF-neutralizing nanobodies; oral administration of the resulting bacterium reduced inflammation in DSS mice.[152] Avaxia recently described an orally administered, milk-derived, polyclonal anti-TNF antibody; in a Phase 1 study, this mixture showed efficacy trends when administered to moderate to severe UC patients at 3.5 g day^{-1}. Other orally delivered SM approaches that are in development include Janus kinase inhibitors (peficitinib, tofacitinib, filgotinib), an immunomodulatory drug (laquinimod), an α4 antagonist (AJM-300), agonists of sphingosine phosphate receptors (ozanimod, amiselimod, and APD334), and an antisense therapy (GED-0301) targeting SMAD7.

Over time, patients may develop neutralizing antibodies to the TNF antagonist drugs, resulting in rapid clearance and patients must be switched to other TNF antagonists.[153] Constrained peptides are expected to have lower immunogenicity[154,155] as they are protease-resistant, making it difficult to present linear epitopes to T-cells, have small size and less epitope density compared to other biologics, lack a hydrophobic core (a key requirement for T-cell recognition[156]), and are orally delivered with low systemic concentrations. Therefore, orally delivered constrained peptides have the potential to achieve longer term remission for patients when compared with systemic biologics.

6.06.9 Conclusion

IBD is characterized by localized inflammation of intestinal tissues and is ideally suited for therapeutic management using orally delivered agents that result in high drug concentrations at the target site of action along with minimal systemic concentrations. Systemically delivered biologics, specifically the anti-TNFs, have revolutionized the treatment of IBD, but surgery is still required in 70–80% of the treated patients.[157] Systemic immunosuppression, immunological side effects, and intolerance are associated with anti-TNF therapy. Compliance issues with anti-TNF antibodies in IBD treatment have been reported to occur in 25% of patients, but can reach as high as 60%.[158–160] Noncompliant patients have a greater need for hospitalization, which increases healthcare costs. Up to 80% of patients would prefer oral treatment alone.[161] Hence a targeted orally delivered therapy approach with equivalent efficacy and enhanced safety may benefit patients through longer remission and better compliance, which would have significant impact on patient quality of life and healthcare costs.

Constrained peptides provide a unique chemical modality for the oral treatment of IBD. They have a proven capacity to modulate the large, flat, discontinuous surfaces that are characteristic of the clinically validated cytokine-based targets in IBD, in combination with favorable chemical and biological stability.[30] These properties are augmented by the clinical features of IBD itself, primarily the reduced integrity of tight junctions, the impact on the intestinal barrier, and the localized nature of the disease. However, orally delivered peptides must be sufficiently stable to transit the GI tract, exhibit maximum solubility for rapid dissolution, and have the required size and physicochemistry to transit the mucus and glycocalyx layers to reach the epithelial surface. Once there, these peptides must possess the required physicochemical and conformational properties to either squeeze through paracellular junctions or to interact with and ultimately permeate the membrane without being effluxed or metabolized. Alternatively, interaction with a transporter or carrier can facilitate membrane crossing to provide access to the appropriate target site, at a suitable concentration, and duration of time to achieve a pharmacological effect.

Despite all these challenges, there is accumulating preclinical evidence that constrained peptides have the required physiochemical characteristics to transit the entire GI tract and provide the concentrations of free drug at the target site of action that exceed pharmacological potency over the desired time frame. There are numerous in vitro, ex vivo, and in vivo systems that can be used to profile candidates for the stability and permeability features needed to render agents orally active. However, the intestinal

physiology (e.g., proteolytic enzymes, bile salts, motility, pH profile, and permeability) can differ between animal models and human systems. These distinctions are exemplified by the differing proteolytic stabilities of trefoil peptides in rat and human intestinal fluids,[38] or the differing permeation of Dextran 4000 in various species.[162] Animal models of disease have played a key role in understanding inflammatory processes that affect disease, but CD and UC are highly heterogenous diseases, and the translational record of such animal models has been questioned.[163,164] Such species differences have been and will continue to be challenging in the preclinical evaluation and optimization of orally delivered candidates and translation to clinical settings.

Pursuing a GI-restricted strategy provides an effective means of achieving high local concentrations of drug at the desired site of action while minimizing concentrations in other regions that could lead to unwanted side effects by minimizing off-target effects or on-target effects in healthy tissue. Targeted agents currently include injectable antibodies that modulate macromolecular cytokine or integrin targets. Constrained peptides would appear to be ideal for blocking such targets, as they are capable of binding and blocking large macromolecular proteins with the potential of being orally stable and orally delivered. There are orally delivered and marketed peptide-based drug and several clinical and preclinical examples for treating GI diseases. Such a GI-targeting strategy using constrained peptides would also have broader therapeutic applications due to the increasing realization that the gut and associated microbiota may play a role in many diseases, including systemic diseases, due to its endocrine role and communication with CNS in addition to absorbing nutrients and minerals. With respect to IBD, dampening the immune response locally in the GI tract may lead to localized safety consequences, for example increased GI infection, which would need to be monitored. With several preclinical and early clinical examples of orally delivered and targeted constrained peptides in development for treatment of IBD, the next few years will be pivotal in the evaluation of such a GI strategy to provide a safe and convenient treatment paradigm for patients.

Acknowledgments

I would like to acknowledge the many colleagues, collaborators, and investors of Protagonist who have helped to contribute to the concepts outlined in this article.

6.07.1 Introduction to mAb Platform Processes

Monoclonal antibodies (mAbs) are the most successful class of biopharmaceuticals today. More than 50 mAbs have been approved and sales of mAbs are expected to cross $125 billion by 2020.[1] The ability to bind to specific targets with high specificity and affinity and the ease of developing human or humanized sequences to a target have been behind the explosive growth of this class of pharmaceutical products. The last 20 years have seen the rapid growth of this class of therapeutics with over 300 mAbs in clinical development today. Today mAbs are approved for a wide range of indications covering oncology,[2] autoimmune disorders, and rare disease indications.

While the ability to target cell surface targets with great specificity has been behind the rise of mAbs,[3] one must not lose sight of the development of process platform technologies that have enabled rapid production of mAbs for clinical trials as well as at commercial scale. The ease and speed of producing mAbs has enabled rapid entry of these product candidates into clinical trials and the scalability and robustness of these processes has hugely facilitated large-scale commercial supply.

Development of a manufacturing process for a protein requires the consideration of many different factors, including removal of impurities, robustness, scalability, and ready availability of raw materials for large-scale production. Consideration has to be given not only to the scale needed for early clinical supply, but also the ability of the process to support long-term supply needs and scales. As a result, utilizing well-established unit operations is a key aspect of developing manufacturing processes. The aspects of robustness, scalability, and reproducibility mean that manufacturing processes often look quite different from those that can be employed in the laboratory for purifying small quantities of proteins. Process development can be a time-consuming activity and require significant amounts of experimentation. As a result, when possible the industry has gravitated toward platform approaches.

A platform approach has distinct advantages from a business standpoint. Speed to clinic is often a key determinant of a company's success. mAb platforms have enabled progression from gene to Investigational New Drug (IND) in less than a year, which is a significant improvement over molecules that require involved development efforts that can extend up to 2 years. This reduced experimentation also implies a reduction in the cost of the development effort. The predictability of a process platform enables organizations such as manufacturing and quality control to adopt a templated set of documents which also reduces the time and resources spent on production and release testing.

mAb therapeutics particularly lend themselves toward the application of platform approaches. Use of a well-developed mammalian cell culture expression system enables development of stable cell lines in a very rapid and templated fashion for mAbs. Several expression vectors have been optimized specifically for mAb production.[4,5] Robust fed-batch cell culture processes have been developed for mAbs. Several of these have been scaled to large-scale production and characterized extensively giving a good idea of the operating parameters that influence these processes.[6,7] Cell line development and upstream cell culture processes lend themselves to a templated approach very well. However, for most proteins the greatest area of divergence comes in the form of the downstream purification process that has to be customized for each protein based on its properties as well as that of key impurities. The Fc region of mAbs binds very specifically to immobilized Protein A which is a cell wall component of *Staphylococcus aureus*. Protein A affinity chromatography has been shown to be widely applicable for mAbs and can achieve >95% purity with very little development on this mode of chromatography.[8] The chief challenge after Protein A chromatography is to remove residual host cell protein (HCP) impurities, high molecular weight (HMW) aggregate, DNA, and have the capability of removing adventitious viruses.

A number of downstream process platforms for mAbs have been developed at leading biopharmaceutical companies.[9–13] The ability to use a generic approach across molecules and starting from a template decrease the amount of experimentation needed compared with a protein that cannot enable the inclusion of an affinity step in the downstream process. These downstream process platforms have successfully enabled the progression of a large number of mAb products into the clinic and commercial space.

6.07.2 Current and Evolving Downstream Process Platforms for mAbs

6.07.2.1 Drivers for mAb Platform Evolution

This section describes several downstream process schemes that have been developed at leading biopharmaceutical companies and successfully employed for mAb manufacturing at large scale. Several aspects are in common across these process schemes. mAbs are extracellularly secreted into the cell culture medium during mammalian cell culture. Harvest and recovery schemes typically utilize centrifugation followed by depth filtration and a series of membrane filters.[14,15] At smaller scales, centrifugation may be dispensed with and a series of depth filters with the coarser pore size filters first may often be utilized. The platform process almost always commences with Protein A chromatographic capture.[16] In some cases, selective washes can be built into the Protein A step operation to further enhance HCP clearance.[17] Non-Protein A schemes have been developed and employed for large-scale manufacturing[18] as for any therapeutic protein but have not caught on given the absence of a generic approach and issues with process robustness. The process will also include two dedicated orthogonal viral clearance steps as per International Committee on Harmonization (ICH) guidelines. Low pH viral inactivation and viral filtration through a parvoviral grade filter are widely employed for mAbs.[19] The low pH incubation step is typically placed immediately after Protein A chromatography since the Protein A column elutes in a low pH buffer. Following Protein A chromatography and viral inactivation, one or two polishing chromatographic steps are employed to clear HMW aggregate,[20] HCPs,[21] DNA, and to provide viral clearance potential. Chief differences among platform approaches lie in the nature of the polishing chromatographic steps. Given the high titer cell culture processes that are increasingly common in industry today (5–10 g L^{-1}), there is a significant need for high column loadings on polishing chromatographic steps.

Each company ends up customizing its mAb downstream platform approach based upon its own expression system and cell culture process as well as the mAb type and subclass they predominantly employ in discovery research. The primary criterion is that the platform approach needs to be robust and applicable across a wide range of IgG molecules without significant modification. Another key criterion is the ability of the platform to fit in the manufacturing schedule and minimize the amount of time spent in downstream processing for any one batch. As a result, another key driver is the loading capacity that is possible for any of the polishing steps.

6.07.2.2 Recent Downstream Platforms for mAbs

Amgen was one of the first companies to disclose its approach to a downstream process platform.[9] A completely templated approach was shown not to be possible, but a small number of development experiments should lead to answers about process parameters that need to be customized.[10] Examples of such process parameters include examples such as the Protein A elution pH and the choice of polishing chromatographic steps depending on the chief set of impurities that need clearance. **Fig. 1** shows the platform downstream scheme in use at Amgen at the time. The polishing steps typically employed were cation-exchange chromatography (CEX) in a bind and elute mode followed by either hydrophobic interaction chromatography (HIC) in a flow-through mode if HMW aggregates needed to be cleared or anion-exchange chromatography (AEX) in a flow-through mode if only HCP

Fig. 1 Platform approach to mAb downstream processing at Amgen.

clearance was needed. In a few cases, hydroxyapatite was employed if specific product-related impurities needed to be removed. In situations in which adequate HCP and HMW clearance were obtained after the first polishing CEX step, anion-exchange membrane chromatography was employed to provide for another step with viral clearance potential.[22]

Another leading company to develop a pipeline of mAbs using a platform approach was Genentech.[13,23,24] Genentech historically employed CEX and AEX as part of its downstream platform (Fig. 2). The trend appeared to initially be to utilize CEX in a bind and elute mode as the first polishing step followed by AEX in a flow-through mode of operation. mAbs usually have a basic p*I* and hence bind tightly to CEX resins and tend to flow-through readily on AEX resins. The CEX step clears both HMW and HCP. The AEX step, however, is noted to require a low load conductivity in order to successfully remove HCPs. This can lead to a bottleneck during plant operation due to the need for large volume in-process hold tanks to hold the AEX load. The possible use of mixed-mode Captoadhere resin in place of more typical AEX resins is mentioned to help reduce the need for significant dilution.

One of the key drawbacks of using AEX is that it only provides clearance for HCPs and not for HMW aggregates. This particular drawback has been mitigated by the development of an AEX step operated in a weak partitioning mode[25] in which the product actually has some measure of retention on the resin. In this mode of operation, the AEX step has actually been shown to be capable of reducing HMW content in addition to HCP species. Mechanistically, we speculate that interactions with the somewhat hydrophobic parts of the resin backbone set in at very low conductivities, enabling some degree of HMW removal to occur.

Both of these schemes suffer from the drawback of requiring significant dilution of the load material for the AEX step. In addition, CEX and AEX alone are often unable to provide adequate HMW clearance. HMW levels can vary for mAbs, but levels of $>5\%$ HMW aggregate after Protein A chromatography are not that uncommon. Such levels often require recourse to a HIC step as has been mentioned earlier.[9] Another innovative approach has been to operate the HIC step under highly overloaded conditions (>200 g L^{-1}) under no salt conditions.[26] This approach entails the use of a highly hydrophobic HIC resin with no additional kosmotropic salt added to the load. pH conditions of the load are modulated to enable HMW removal under these extreme overloaded conditions. The use of such an ultra-high capacity step enables the processing of large production quantities of mAbs and is used as part of the mAb platform at Biogen (Fig. 3) in combination with a flow-through AEX step. The ability to load the polishing steps at very high loads enables a reduction in column cycling and decreases the duration of floor time taken for a batch.

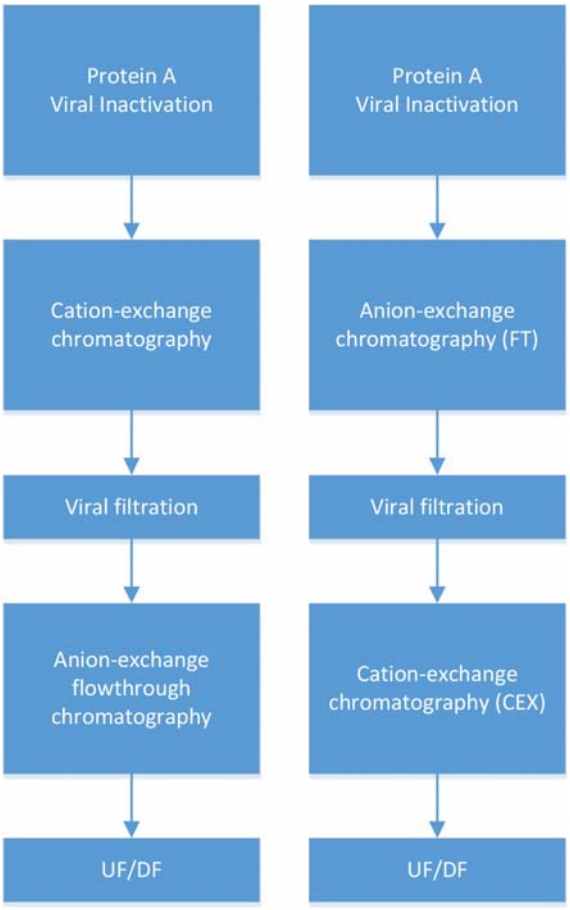

Fig. 2 Genentech mAb downstream process platform.

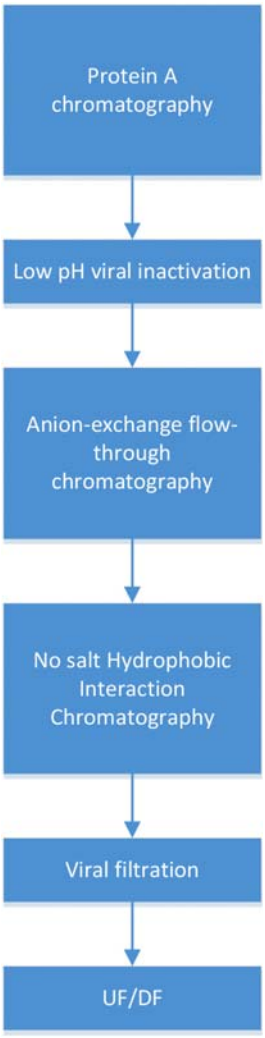

Fig. 3 Platform mAb downstream process at Biogen.

A similar flow-through only polishing scheme has been discussed by Millipore-Sigma.[27] In this proposed format, CEX would be operated under highly overloaded conditions during the loading step. When operated in this fashion, CEX has the ability to clear some level of HCPs. It is again speculated by us that this occurs due to weak hydrophobic interactions with the chromatographic backbone. This polishing step is then combined with AEX flow-through to complete the sequence.

Contract development and manufacturing (CDMO) requires the ability to incorporate many different cell lines and cell culture processes into the downstream platform approach. This places significant challenges on the downstream platform scheme since both HCP and HMW reduction are simultaneously required. These simultaneous demands on the downstream mAb platform are illustrated in Fig. 4.

6.07.2.3 A Broadly Applicable mAb Downstream Platform

CEX and AEX in their traditional flavors do not fulfill this need. A key modification made in this regard has been the use of multimodal chromatography as part of the mAb downstream platform. Multimodal chromatography involves the incorporation of a hydrophobic moiety into the ligands structure for either AEX or CEX.[28] The increased hydrophobicity of the chromatographic resin now enable improved clearance of HMW on both CEX and AEX modes which are arguably most suited for mAb processing. In addition, both these modes of chromatography are also capable of HCP and DNA clearance as well. mAbs do differ in terms of their own hydrophobicity. As a result, the platform downstream process for mAbs at KBI is defined as AEX (with resin hydrophobicity that can vary from Q Sepharose FF or Capto Q to Fractogel SO3 to multimodal chromatographic resins such as Captoadhere and Nuvia cPrime). This modulation of hydrophobicity enables optimal conditions to be tailored for each mAb. Similarly, the CEX bind and elute step is also operated on a range of hydrophobicities ranging from mild to moderate depending on the resin selected.

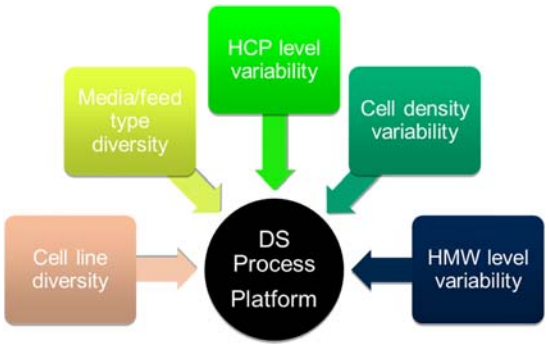

Fig. 4 Range of factors considered in determining KBI Biopharma's platform approach.

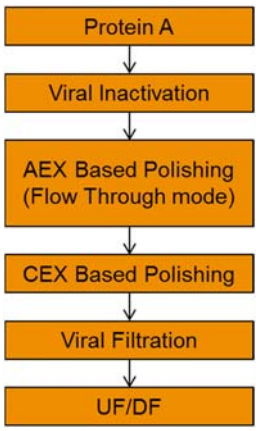

Fig. 5 KBI Biopharma's approach to mAb downstream processing for FIH manufacturing.

While this approach does entail some degree of experimental work, a preferred approach using multimodal chromatography for both AEX and CEX is employed as the primary platform with recourse to less hydrophobic stationary phases should the mAb require it. This approach is illustrated in Fig. 5 and has been useful in terms of its breadth of covering a wide range of mAb constructs, cell lines, and cell culture processes at KBI.

Fig. 6 shows the clearance profiles for HMW aggregates and HCPs through this platform process for a number of mAbs. As can be seen from the figure, HMW aggregate levels of $<1\%$ and low HCP levels <50 ppm are always observed using this platform. The ability to cover a wide range of mAb constructs is a key, especially for a CDMO organization such as KBI.

6.07.3 New Technologies Impacting mAb Downstream Processing

Traditional chromatography is batch process. Steps start from column sanitization, equilibration, and loading through to washes, elution, strip, and column regeneration and storage. A batch operation is limited in terms of its throughput and productivity. First of all chromatographic columns can only be operated at a maximum diameter of 2 m owing to flow distribution limitations. Current resins can only be packed to a maximum of 30 cm bed height (20 cm typically) owing to pressure drop limitations. This inherently limits the amount of product that can be processed per cycle. When multiple cycles are required, product intermediate needs to be held for a longer duration of time. Product holds also end up using valuable tank volume in manufacturing facilities which are also limited. Continuous chromatographic separations can turn this batch operation into a continuous or semicontinuous process[29] as shown in Fig. 7. Combined with a continuous upstream perfusion cell culture process, this can alter the current paradigm of how biopharmaceutical production processes are designed.[30,31] Continuous chromatographic separation can be conducted using one of many formats. Periodic counter current chromatography is one of the formats (from GE Healthcare) and utilizes multiple columns that are continuously operated in different phases of the operation cycle.[32] Other formats include multicolumn countercurrent solvent gradient purification that enables recycling of the front and tail ends of the peaks to boost yield as well as purity via the ContiChrom system from ChromaCon and the BioSMB technology from Tarpon Biosystems (now part of Pall Corporation).

Another means of boosting productivity is to move from chromatographic operations to nonchromatographic separations. Various systems such as selective precipitation schemes using polymers and aqueous two-phase separations (ATPS) can be utilized

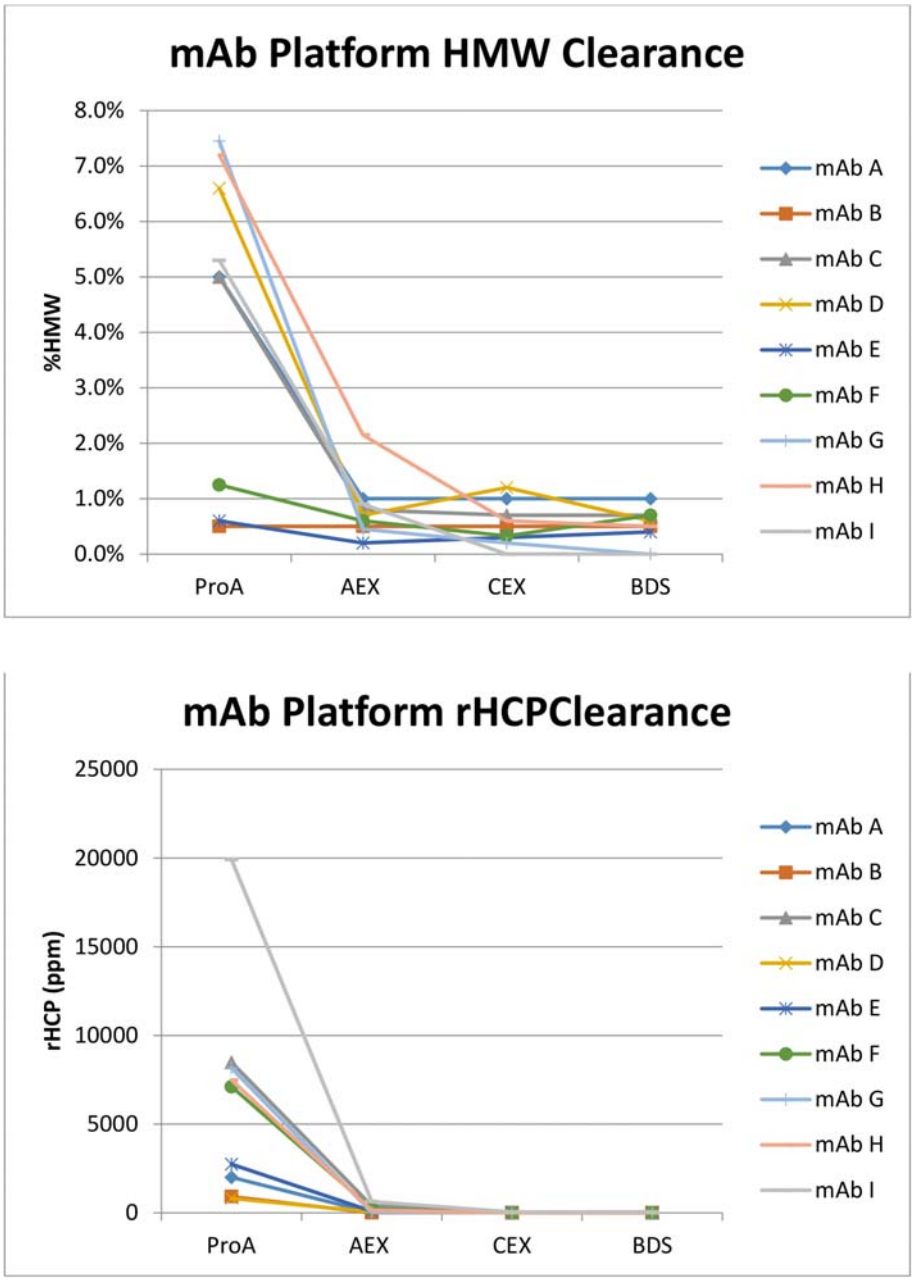

Fig. 6 Performance of the KBI Biopharma platform DSP approach for several mAbs. (A) HMW clearance and (B) HCP clearance.

to capture the entire bioreactor batch in one operation rather than relying on multiple chromatographic cycles. A variety of polymers have been utilized for mAb precipitation including polyanionic polymers to precipitate the product[33] and caprylic acid precipitation of HCP impurities.[34] ATPS rely upon the creation of two separate phases in solution by mixing a polymer and salt or two polymers with each other. Examples include poly-ethylene glycol (PEG)-salt and dextran-PEG ATPS.[35] Both of these separation technologies have interesting possibilities and can significantly raise the bar on throughput that is currently possible from manufacturing facilities. However, both areas need further development to establish themselves as scalable technology that can be applied without significant development for a wide range of mAbs.

6.07.4 Next-Generation Antibody Constructs Impacting the Process Platform

The other major factor that leads to evolution of the platform approach is the specific mAb-like construct that is being developed as a potential therapeutic. The biotechnology industry is rapidly moving beyond conventional mAbs into a variety of constructs

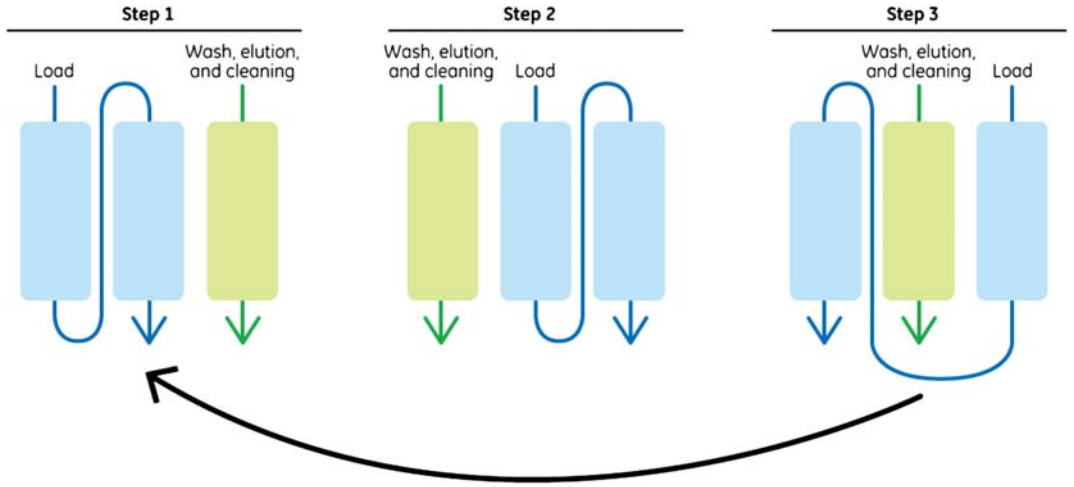

Fig. 7 Principle of continuous chromatography.

including Fc fusion proteins, bispecific antibodies (bsAbs), and antibody-fusion proteins. Each of these new constructs requires modifications of the original mAb platform process to enable their production.

Fc fusion proteins are created by joining the coding sequence for the Fc region of a mAb to the coding sequence for another protein.[36] The Fc region offers several advantages as a fusion partner. Many biologically active peptides and proteins have a short serum half-life reflecting their rapid clearance through the kidneys. The Fc region can bind to the neonatal Fc receptor to extend the half-life of antibodies, and the same benefits are conferred on fusion partners.[37] Seven Fc fusion proteins are commercially available as approved biopharmaceuticals and at least two of them (Enbrel and Orencia) have already achieved blockbuster status with sales of over US$ 1 billion per year. The original platform for mAbs at Amgen included the purification of Fc fusion proteins.[9] However, several key downstream differences do exist for Fc fusion proteins, including the possibility of susceptibility to proteolytic cleavage and the possibility of higher HMW aggregate levels being present than regular mAbs. A typical mAb downstream platform approach usually is effective, with possible adjustments to the polishing steps to account for stability of the molecule and effective HMW clearance.

bsAbs are designed proteins capable of simultaneously binding and neutralizing two different antigens (ligands, cell receptor, or cytokines) or two distinct epitopes on the same antigen.[38] As a result of this property, bsAbs can serve as mediators in redirecting immune effectors and cytotoxic agents like T-cells to tumors or to infecting organisms such as bacteria. The fact that two arms of the mAb are different leads to several processing challenges that are unique to bsAbs. For example, if the two halves of the mAb are expressed separately, a downstream process that requires disassembly of the two halves followed by reassembly to form the heterodimeric species will have to be conducted.[39] In addition to the recombination steps, even if the formation of homodimeric species is discouraged (by use of a knob-in-hole methodology or a similar technology that encourages heterodimer formation), small quantities of the homodimers will form and will have to be removed by downstream processing. As a result, this format of bsAbs requires a more complex downstream process.

However, use of a common light chain along with the knob-in-hole technology (KiH) enables the formation of a bsAb in cell culture expression.[40] Homodimer formation is discouraged due to the KiH construct. The small quantities of homodimer that are formed can be removed if the sequences selected for those have a biochemical difference. This can be done even in the absence of a common light chain. For example, in the XmAb technology from Xencor, the homodimer and heterodimer have a small difference in charge in their engineered Fc regions that enables their separation on CEX. The other purpose of the engineering approach is the enhance effector function of the bSAb.[41]

An antibody–drug conjugate (ADC) is a mAb conjugated with a cytotoxic agent via a linker with the primary aim of treating cancer.[42] ADCs can be produced in a downstream process identically to conventional mAbs except for a chemical conjugation step at the end of the downstream process. This is typically followed by ultrafiltration/diafiltration (UF/DF) to remove the conjugating chemicals. The chief difference from mAbs is the requirement for more stringent containment and personnel protection due to the toxic nature of the conjugate.

Other next-generation mAb constructs include peptide fusions to mAbs at either the C or N termini to further enhance the ability to bind to more than one target at a time. Examples include anticalins fused to a mAb structure.[43] A whole range of other therapeutic options exist as shown in Fig. 8, including engineered scFvs, diabodies, and tribodies and Fab conjugates in the form of dimers or trimers.[44] Each of these therapeutic modalities can lead to the development of platform process approaches if they become prevalent as a therapeutic modality.

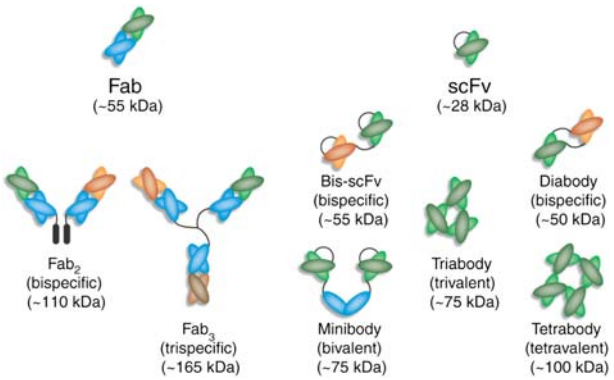

Fig. 8 Possible next-generation antibody formats.

6.07.5 Conclusions

This article has discussed the need for a platform approach for mAbs and its utility in accelerating the progression of many different therapeutics toward the clinic and market. The use of a platform approach has enabled many biopharmaceutical companies to successfully progress mAbs from gene to IND in a year or less. Based upon their internal antibody construct, cell line, and cell culture process, each biopharmaceutical organization has developed its favorite platform approach. Latest trends include the use of multimodal chromatography as part of the process platform and the use of two high loading polishing steps in a flow-through mode of operation. These modifications have enabled even broader applicability of the mAb platform as well as are meaningfully addressing the throughput bottleneck in downstream processing.

As cell culture productivity continues to advance, other alternative formats to help improve the productivity of the downstream process are being advanced. These include the operation of the Protein A chromatographic step in a continuous mode rather than a batch format. Continuous processing could conceivably be extended for the entire downstream process in the future. Nonchromatographic separation steps using precipitation or ATPS are another possible future direction for mAb downstream processing.

More radical alterations of the mAb downstream process platform are being undertaken for next-generation mAb products such as bsAbs and antibody fragments. The next decade will see further evolution of the mAb downstream process platform based on the drivers of productivity and new molecule formats.

6.08.1 Differentiating Aspects of Bioanalysis of Biotherapeutics

Todays' spectrum of biotherapeutic modalities is highly diverse, including recombinant versions of endogenous human proteins, full length and fragments of monoclonal antibodies, protein conjugates including antibody drug conjugates (ADCs), fusion proteins including immunoglobulin Fc fusions, various types of novel scaffolds, synthetic peptides, and oligonucleotides. The high complexity of protein structure and relatively large molecular size of a typical biotherapeutic results in a very common and expected degree of heterogeneity. Although a high degree of primary sequence and structural integrity is expected, the final product will contain a mixture of multiple isoforms varying based on the site of posttranslational modification (e.g., glycosylation), charge and size. The exact degree of heterogeneity will depend on the nature and type of biotherapeutic. In some cases, for example for ADCs, heterogeneity is a direct result of the manufacturing procedure (e.g., conjugation chemistry) and may be controlled.[1,2] In other cases, for example, for monoclonal antibody-based compounds, sequence heterogeneity may be a minor factor. Depending on the type of heterogeneity, biotherapeutic variants could have different pharmacokinetic (PK), pharmacodynamics (PD), or immunogenic properties. Such variants may also be variably detected in bioanalytical methods used to evaluate drug exposure and efficacy.

6.08.1.1 Ligand Binding Assay

Most biotherapeutics are either directly homologous to an endogenous protein or are designed to bind to an endogenous protein component, whether in circulation (humoral) or on a cell surface. Assays can be designed to assess total or target free versus target bound drug concentrations. It is important to understand that administration of a biotherapeutic may directly impact homeostasis through a positive or a negative feedback mechanism, for example, by increased expression or accumulation of drug target, increased expression of the cell surface target, etc. Depending on the bioanalytical assay strategy, induced changes in turn may have an impact on concentration of the measured moiety of the drug, for example, when a target free drug is detected. High homology of biotherapeutic to an endogenous protein presents additional challenge when attempting to determine exposure to the drug in the presence of endogenous protein homologue. This is a common issue for enzyme replacement therapy compounds and resembles analytical challenges experienced when developing protein biomarker (BM) assays. Lastly, typical ligand binding assay (LBA) protocols rarely include sample pretreatment steps. Components of a highly complex biological matrix often present an analytical challenge due to the ability to bind to assay components and reagents. Understanding all of these and other biological considerations are critical to designing the bioanalytical strategy for a biotherapeutic. Some of the topics related to the drug concentration analysis outlined above will be discussed in more detail later in this article.

6.08.1.2 Anti-drug Antibody

In addition to a typical drug concentration analysis (PK), biotherapeutics are expected to be evaluated for the ability to induce an immune response. All biotherapeutics have the potential to trigger an immune response that can result in the production of drug-specific antibodies (anti-drug antibody, ADA) with different specificities. While the production of an anti-drug immune response may have no clinical impact in some cases, it may also lead to a reduction or complete loss of exposure (PK), an impact on pharmacological activity (efficacy impact) or in some cases result in a serious clinical sequelae (safety impact). It is therefore important to conduct a careful risk evaluation and perform ongoing monitoring of immunogenicity potential of biotherapeutics by applying sensitive and specific methods allowing detection and where needed appropriate characterization of immune response to the drug. Generation and characteristics of ADAs is typically expected to be evaluated in nonclinical and clinical studies although the exact goals of ADA evaluation at various phases of drug development are vastly different. Human nature of protein sequences and structure elements of majority of biotherapeutics makes them foreign in nonhuman species resulting in an expected and frequently observed robust immune response. Therefore, for a typical biotherapeutic, immunogenicity in a nonclinical setting is expected and not predictive of immunogenicity potential in a human study. However, an understanding of ADA development in a nonclinical study may facilitate in interpretation of drug PK, efficacy, and toxicity. Information obtained during nonclinical evaluation may therefore be useful for the overall immunogenicity risk assessment of a biotherapeutic. Immunogenicity risk evaluation is commonly viewed as an ongoing process that starts as early as identification of the drug candidate or even at the point of identifying drug modality type. Immunogenicity risk factors include product, patient, and treatment-specific characteristics. Product related factors are the nature of the drug primary sequence, homology to an endogenous protein, presence of contaminants, and drug aggregates, etc.[3] Patients' immune status, frequency, duration and route of drug administration, and drug formulation details are other important factors to be considered. Immunogenicity predictive capabilities and tools are still under development, including in silico evaluation methodologies.[4] Most typically, immunogenicity during clinical development phase includes detection and characterization techniques aiming to detect drug-specific ADAs as well as antibodies able to neutralize drug mode of action (MOA), also called neutralizing antibody (NAb). NAb specificity as well as other drug domain specificities are frequently viewed as an important element of immunogenicity evaluation in the clinic.

ADA response may comprise of various isotype of immunoglobulins including IgM, IgG, and IgEs. ADAs are relatively large proteins (e.g., IgGs are 150 kDa proteins) and may bind multivalent drug molecules simultaneously (e.g., IgM may bind up to 10 drug molecules). Therefore, ADAs may form various size immune complexes with the circulating drug which could potentially lead to an impact on the drug PK. Such immune complexes may be cleared from the system by various endogenous mechanisms, for example high-order immune complexes are taken up and destroyed by macrophages.[5] Induction of ADA and formation of immune complexes therefore has the potential to affect overall drug PK profile. The exact nature of the impact often depends on the drug molecular weight and initial drug clearance characteristics. While for large protein therapeutics with a slow clearance, immune complex formation may lead to an accelerated PK, the opposite could be expected for small peptide-based drugs.[6] In addition to a direct impact on drug PK profile, ADAs may impact bioanalytical methods used to determine drug concentration. Structural complexity of biotherapeutics frequently results in a direct interconnection between analytical protocols used to evaluate their PK and immunogenicity characteristics. ADA may directly interfere in PK assays by binding and forming immune complex with the drug in circulation and therefore blocking it from interaction with the PK assay reagents. In reverse, residual drug is expected to impact ADA detecting assays. When designing bioanalytical strategy, it is important to understand if and how the ADA may impact PK and PD measurements and vice versa. A totality of data, including PK and ADA information, should be considered to understand the true reason for the abnormal PK profile.[6]

6.08.2 Basics of LBAs

Historically and driven by the typically large molecular weight of biotherapeutics as well as high specificity requirements, bioanalysis of biologic compounds has been largely based on various types of LBA protocols. Although other analytical platforms exist

(e.g., direct activity measurement for enzyme-based therapeutics[7] and most recently LCMS applications),[8,9] LBA remains the most commonly applied platform.

LBA procedures can be defined as methods that rely on specific interactions between analyte and its cognate receptor or a specific antibody reagent. Therefore, they are based on high affinity binding to confer the requisite specificity and sensitivity to measure analyte of interest. Typically, specific reagents are required to generate a highly selective assay including monoclonal ADA and recombinant versions of drug target. In the simplest format, the analyte of interest is captured on a solid surface via a capture molecule (an antibody or ligand) and this complex is detected by the binding of a detector molecule (again an antibody or ligand) that generates a signal. Various assay set ups exist based on broad range of analytical platforms, read out technologies, and reagent types. Various LBA analytical platforms have been developed based on the type of the final read out protocol. For example, the most common LBA method is an enzyme-linked immuno-sorbent assay (ELISA) test that is based on a chromogenic, luminescent, or fluorescent read out approach. Other read out technologies include electrochemiluminescence (ECL), radioactivity detection (radioactive immunoprecipitation assay, RIA), fluorescence, time delayed fluorescence, and more. Other systems are based on physical measurements that avoid the need for reagent labeling, for example surface plasmon resonance (SPR)-based technologies. Various technology platforms that are in use and/or emerging are discussed later in this article.

The high flexibility of the LBA approach allows for various assay formats including competitive, solid and solution phase, direct binding, sandwich, and bridge and other formats. The exact choice of LBA assay format is highly dependent on the nature of the analyte in question, type of the assay matrix, required assay sensitivity, specificity, and other expected assay characteristics. Often, assay format reflects modality and MOA of the drug. For example, monoclonal antibody-based compounds are highly homologous to the endogenous human immunoglobulins but can be specifically detected in a LBA method by using drug molecular target or an anti-idiotypic antibody reagent.

6.08.2.1 LBA Assay Types

The following bioanalytical measurements are typically expected to be performed for a biotherapeutic in support of nonclinical and clinical studies:

- Drug concentration assays:
  - Quantitative measurement of drug concentrations in biological matrices designed to enable PK analysis of drug exposure in vivo. PK assays are applied during typical toxicology and clinical evaluations, including comparability studies. PK assays provide critical PK information required to establish accurate and quantitative drug exposure values, including drug area under the curve and clearance. High-quality PK assays are critical when predicting drug efficacious dose, enabling dose projection, or comparing drug product lots. An appropriate LBA protocol should be established and applied during study support to report most relevant drug analyte. This specific topic is discussed later in the article. The majority of biotherapeutic compounds that are approved or currently in development either comprise of a fully wild type human germline sequence or are highly homologous to a human protein analog. Examples include enzyme replacement therapy compounds which are to a large degree identical to a wild type protein. Monoclonal antibodies as biotherapeutic compounds are either fully human or contain limited nonhuman sequence (e.g., humanized mAbs). The specificity parameter of a biotherapeutic PK assay is therefore highly critical. Common PK assay formats are shown in **Table 1**. Due to dynamic equilibrium and saturable nature of binding between assay reagents and analyte in question, LBA methods produce a nonlinear assay response curve against analyte concentration. Most often, LBA protocols produce sigmoidal curves that are best fit using four or five parameter logistic fitting algorithms (4PL or 5PL).[10]
- Immunogenicity assessment assays:
  - ADA detection assays—designed to evaluate immune response to a biotherapeutic drug. In response to administration of a biotherapeutic, a polyclonal ADA response with various immunoglobulin isotypes should be expected. It is a regulatory expectation that ADA assays are capable of detecting all possible ADA isotypes specific to various epitopes found on the drug molecule. The semiquantitative nature of ADA assays is a critical characteristic to understand. Each ADA response is unique producing a distinct collection of anti-drug antibodies with specific range of isotypes, epitope specificities, and binding (Kd)

Table 1 Typical LBA assay formats (see also **Fig. 1**)

Assay format	*Required reagents*	*Applications*
Sandwich PK	Anti-drug antibody, drug target	Most commonly used set up for PK evaluations. Examples include mAb, ERT, and other large biotherapeutic modalities
Bridge PK	Labeled drug target	A variation of sandwich PK assay format. Applicable when analyzing for a Free mAb drug concentration
Competitive PK	Anti-drug antibody	A popular PK LBA assay set up for low MW biotherapeutics, for example, peptides
Direct binding ADA	Labeled anti-drug antibody reagent	An alternative ADA assay format
Bridge-based ADA	Labeled drug reagents	Most commonly used to analyze ADA presence

characteristics. It is therefore not possible to produce a drug-specific reference ADA material to generate assay standards and Quality Control (QC) samples. In a typical ADA assay, results are reported as titer or similar data format. The semiquantitative nature of reported values makes comparison of results obtained for a given biotherapeutic in different studies or between products challenging.

- NAb characterization assays are designed to establish neutralizing specificity of ADAs. NAb specificity can be identified as the ability to block or hinder drug MOA. Various formats of NAb assays can be roughly divided into cell-based and noncell-based protocols. The noncell-based assays are frequently designed as plate based and therefore can be viewed as a LBA protocol. The choice between cell- and noncell-based NAb assay format is driven by several factors; primary among these is the drug MOA.[11] NAb characterization is most relevant during clinical evaluations and typically expected by regulatory agencies at specific stages of clinical development. The nonclinical NAb characterization of ADA response is typically limited and conducted only if can inform on the potential safety or efficacy implications in the clinic.

– BM analysis is a common expectation during drug development including development of biotherapeutics. BM analysis will not be reviewed in this article as it has been described in detail elsewhere.[12]

6.08.2.1.1 Variety of analytes measured by LBA

Depending on the drug type, nature of the drug target, and other biological parameters, circulating drug can be presented in various forms, including free, bound (fully or partially complexed with the target), and total (free + bound). The mass action law provides a relationship between various drug analyte forms given that all system parameters are known, including drug target binding characteristics, soluble target concentration, and impact of microenvironment. Similarly, based on the mass action law, one should expect that any sample preparation (e.g., extraction), dilution, other sample manipulation procedures as well as assay incubation conditions will have an impact on the balance between the drug forms present in the sample. Details of the assay set up, nature of reagents used, and any sample pretreatment applied will define the exact nature of the drug form/analyte quantified in the method.

Free drug analyte can be defined as the active drug fraction that is not bound to either the target or drug-specific ADA, particularly NAbs. In cases when more than one target binding site is available on the drug molecule (e.g., mAb-based biotherapeutic), a partially free drug modality is also possible. Free drug analyte can be detected in an assay that is based on the ability of drug to bind its target. Because drug: target and drug: ADA interactions are dynamic and governed by the mass action law, the in vitro determined free drug concentration may not directly reflect the real in vivo situation. For example, sample dilutions are frequently used to avoid significant matrix interferences and to make sure that drug concentration falls within the assay range of quantitation. At the same time, sample dilution will perturb drug: target dynamic equilibrium and affect final reported free drug concentration. Prolonged assay incubation times and assay reagent concentrations also have a potential to influence final free drug assay outcome.[13]

Bound (or complexed) drug analyte represents drug bound to the target or to a drug-specific ADA/NAb. Bound drug also represents concentration of the drug target complex. Similar to the free drug analyte, assay conditions may impact the final reported concentration in the bound drug assay as the drug—target interaction is typically reversible and not covalent.

A total drug analyte can be defined as inclusive of all subfractions and analytes (e.g., free, bound, and partially free/bound). Depending on the drug type and assay set up and characteristics, total drug analyte can also include products of partial drug degradation in vivo. A significant degradation of a drug will likely completely negate assay ability to detect the remaining fragment. An appropriately designed total drug assay may require a sample pretreatment step in order to remove any interfering factors, including drug bound ADA or other binding proteins found in the assay matrix. Total drug assay may be considered when drug MOA and safety are not well understood or include all drug forms (i.e., free and bound). An example of a total drug assay can be a PK assay designed to detect a human mAb-based compound in a nonhuman matrix and utilizing generic anti-human IgG framework reagents. This assay may still be impacted by the presence of ADA and may require a pretreatment, for example, an acid dissociation step.[14]

In addition to a direct blocking of biotherapeutic binding sites by the drug target or ADA, primary sequence, secondary, tertiary, and higher order structural integrity are critical to maintain activity level of a biotherapeutic. Any small or large modifications to the protein sequence or structure, including posttranslational modifications, small or large sequence degradation in vivo may change final compound activity. Understanding whether the measured analyte is free from the target or ADA may not be in some cases equal to a measurement of an active drug component.[15] An assay measuring active drug concentration would need to reflect the drug MOA which may or may not be accomplished using LBA-based platform. For example, if the drug MOA is primarily based on binding to a soluble target, one can design a LBA method to determine active drug concentration. If on the other hand drug MOA includes activation of a cellular target, cell killing, or an enzyme activity, other analytical platforms would require to be considered to determine active drug concentrations.

Biologics consisting of small molecular weight toxin or synthetic polymers conjugated to protein component represent a growing category of biotherapeutics, including monoclonal antibodies conjugated to a cytotoxic drug (ADCs), polyethylene glycol conjugated proteins, and more. For these and similar categories of biologics more than one analyte may be required to fully describe compound PK. For example, for ADCs, it is not uncommon to consider up to four analytes, particularly during early clinical evaluations,[16] including drug conjugated antibody analyte, total antibody (includes conjugated and unconjugated antibody), antibody conjugated and unconjugated toxin analytes. Only some analytes are tested by LBA protocols while others require application of LCMS methods. Bioanalysis of ADCs represents a growing link between analytical platforms previously exclusively applied for large versus small MW molecules. Critically, application of LCMS for the analysis of large Molecular Weight (MW) analytes has

significantly grown based on the ADC compound example.[17] LCMS protocols used to determine large MW analytes frequently start with an affinity capture (AC) step which is highly similar to a typical LBA procedure. After proteins are partially or completely separated from other components of biological matrix, they are digested to produce unique peptide motifs which are detected by an LCMS application.[17] These AC LCMS protocols can therefore be viewed as an extension of the LBA technique in general but with a highly specific LCMS read out.

6.08.2.1.2 Critical value of assay reagents and controls

The exact nature of the analyte detected in a LBA method as well as the assay sensitivity, accuracy, and reproducibility are highly dependent on the type and specificity of the capture and detection reagents. Assay reagents are among the most critical components of the analytical system with a high impact on the final quality of the assay. Most typical reagents used in LBA protocols include polyclonal and monoclonal antibodies specific to the intended analyte, recombinant drug target, and various types of conjugates allowing to generate the final assay read out signal.[18,19] Other reagent types have been gaining momentum in recent years, including F(ab)2 based and aptamers.[20] Both promise a shorter production time, improved in vitro selection process, and significantly reduced resupply cycle time.

Lack of a sample pretreatment step in typical LBA protocol often leads to a potential interference caused by components of the sample matrix. A reagent's ability to specifically and with a high binding affinity recognize assay analyte is of highest importance. Understanding a reagent's specificity toward drug and its products of degradation could be critical in order to fully appreciate final assay specificity. For example, assays used to measure conjugated antibody analyte in support of ADCs may be sensitive to the number of small molecule toxin moieties conjugated on the antibody, also called drug to antibody ratio. Such ratio is known to change during ADC circulation in vivo, generating products of deconjugation with a lower ratio value. The ability of an assay to detect ADC components with various toxins to antibody ratios will to a large degree depend on the type of reagents used in the assay.[17]

The assay specificity characteristics should be viewed in the context of the biological matrix. For example, an anti-human IgG reagent should be specifically recognizing human mAb-based drug in a nonhuman biological matrix. Assays designed to detect human IgG in nonhuman matrix can be applied to a broad range of human mAB-based compounds and because of this it is sometimes referred to as "generic" assays. These are commonly applied during early discovery phase of drug development. Human IgG reporting generic assays are expected to report a total drug analyte concentration. The switch to an anti-drug-specific antibody reagent based assay is often made later in development and particularly important when developing clinical analytical protocols. A change from a generic anti-human IgG-based assay to a drug-specific reagent based protocol may result in a change in the nature of the analyte detected in the method. For example a change from a total to free drug analyte may occur with further implications for PK data interpretation and extrapolation. The change in the assay reagents may therefore impact overall drug PK data interpretation.

Generation of critical reagents that demonstrate appropriate quality and specificity is often a lengthy process that is highly dependent on the type of required material (**Table 2**). Early review of bioanalytical strategy including the need for required reagents is therefore highly beneficial. For example, during early discovery phase, teams are encouraged to discuss preferred analyte type to be measured and therefore assay set up and reagents needed so the material becomes available by the time clinical assay development is initiated. Relatively early initiation of specific reagents is often viewed as a business risk due to potential project attrition. Yet, it is critical to appreciate the importance of timely access to high-quality reagents to avoid suboptimal assay quality or unnecessary delays in project advancement.

Most assay reagents are produced by various types of biological processes, including in vivo (e.g., polyclonal antibody) or by cell expression (e.g., monoclonal antibody). A certain degree of lot-to-lot variability should therefore be expected and needs to be factored in as a component of reagent life cycle management strategy. For example, polyclonal antibody reagents which may be used during early development phase are difficult to reproduce due to the inherent variability of animal immune response and a potential change of ADA characteristics in a given animal as the immune response continues to mature. A change in a critical reagent lot should be carefully assessed for a potential impact on the LBA method performance, including assay accuracy, precision,

Table 2 LBA reagents characteristics and types

Reagent type	*Time to acquire*	*Characteristics*
Monoclonal anti-drug antibody	6–9 months	High single epitope specificity, high affinity
Polyclonal anti-drug antibody	3–6 months	Multiple epitope specificity, can be high affinity
Molecular drug target	Several months depending on complexity of the molecule	Generally high affinity based on the drug MOA
Generic anti-human IgG reagent	Commonly commercially available	Anti-framework specificity not compatible with human matrix
Aptamers	Potentially <3 months	Potentially high affinity binding. Limited experience across industry
F(ab)2	Potentially <3 months	Potentially high affinity binding. Limited experience across industry

and lower limit of quantification. A successful reagent life cycle strategy should account for a long term, often multiyear support needs including several assay transfers between various analytical labs.

Assay reagents are expected to be appropriately characterized, for example, by determining purity and concentration of the active component. Although routine monitoring of reagent stability is not generally required, assay performance is expected to decline if the activity of any of the assay reagents deteriorates.[18]

6.08.2.1.3 Significance and the nature of matrix interferences in LBA protocols

LBA-based protocols are expected to deliver sensitive, accurate, and precise analyte measurement with high selectivity and specificity. LBA assay performance is expected to be significantly challenged by the complexity of assay biological matrix. Potential interfering factors vary based on the matrix type (e.g., serum, plasma, or urine) but also due to distinct variations specific to disease and patient conditions. Assay interferences related to the presence of endogenous proteins, lipids, peptides, and other matrix components may negatively impact assay performance and therefore result in reporting of inaccurate drug concentration value or an incorrect ADA score.

Many assay interfering factors are matrix components that are present at various abundance levels and capable of binding to assay analyte or reagents with various affinity (**Table 3**). In other cases, presence of drug-specific interfering factors may be expected based on the drug MOA. The exact nature of interference also depends on the set up of the method and type of reagents used. For example, polyreactive (heterophilic) antibodies, rheumatoid factors (RFs), and human anti-animal antibodies (e.g., human anti-mouse antibody (HAMA)) may interfere in PK assays utilizing mouse or other nonhuman scaffold capture reagent (**Fig. 1A–C**). RF interference may lead to either under- or overreporting in PK assays. Performance of bridge format ADA assay is known to be impacted in the presence of multimeric drug target, RFs, or other drug binding proteins often causing false ADA positive sample score. Drug-specific antibodies (ADAs) either present in patients before treatment (pre-existing antibodies) or induced as a result of drug treatment, can also be viewed as highly specific interfering factors. These have been discussed earlier in the present article.

In certain cases impact of potential interference could be predicted based on an understanding of the drug biology and MOA. For example, presence of circulating drug target may impact ADA assay performance as the multimeric target can bind and bridge assay reagents similar to a multivalent ADA protein. A circulating endogenous drug target receptor may interfere in the drug PK assay by binding and blocking target assay reagent. Such potential interferences are typically evaluated early in the assay development phase by testing recovery of quality controls in the presence of endogenously added recombinant versions of known interferants or testing several individual study relevant samples from the disease population with varying levels of interferant in the presence and without the drug.

In other cases, unknown matrix interference may be observed which is typically investigated by analysis of individual matrix samples to determine relative drug recovery (observed vs. expected drug concentrations). It is critical to assess assay performance using individual drug naïve samples versus pooled matrix preparations as in the latter the relative impact of interference may be diluted. Biological matrix composition may also depend on the disease condition. For example, higher than normal amounts of RF are expected to be present in rheumatoid arthritis patient sera versus that for normal population. If study population is expected to include obese patients, an impact of lipemic matrix preparation on the assay may be considered.[21]

Various strategies have been suggested to mitigate matrix interference and improve LBA method performance. Matrix interferences may be removed or blocked via a sample pretreatment step or by applying a particular blocking agent. Both strategies rely on careful evaluation of the nature of interfering matrix component. For example, human anti-animal antibody interference can

Table 3 Common assay interfering factors

Interference type	*Definition*	*Possible cause*	*Potential assay impact*
Rheumatoid factor (RF)	Human antibodies most commonly binding to the Fc fragment of human IgG, other specificities have been described. RFs are most typically IgM isotype immunoglobulins	Disease type or unknown	PK—often leads to over recovery ADA—false positive score
Heterophilic antibody	Natural antibodies or auto-antibodies polyreactive to heterogeneous antigens	Natural Ab diversity Exposure to food antigens, animals, or animal-based proteins	Typically results in false recovery. Impacts varies on the assay type
Human anti-animal antibody (HAAA)	High affinity antibodies specific to a known animal antigen. Examples: human anti-mouse (HAMA) or human anti-bovine IgG (HABIA) antibodies	Exposure to animal proteins	Typically results in false recovery
Soluble drug target	Drug molecular target found in circulation	Drug MOA based	PK—may block drug binding to the assay reagent causing underrecovery ADA—may cause false positive reporting due to multimeric target impact on bridge ADA assay format

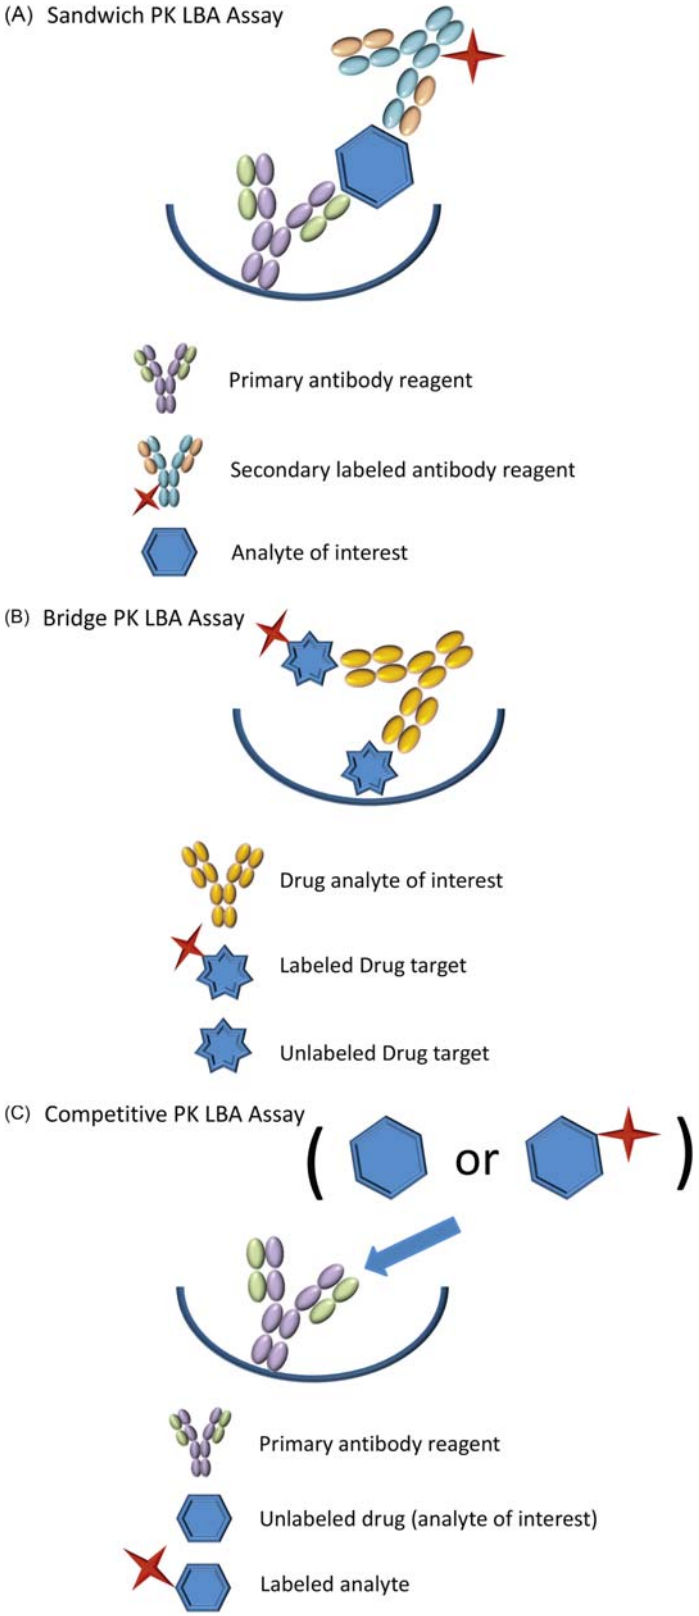

Fig. 1 Typical ligand binding assay set up and reagents. (A) Sandwich PK LBA assay. (B) Bridge PK LBA assay. (C) Competitive PK LBA assay. (D) Direct binding ADA assay. (E) Bridge ADA assay.

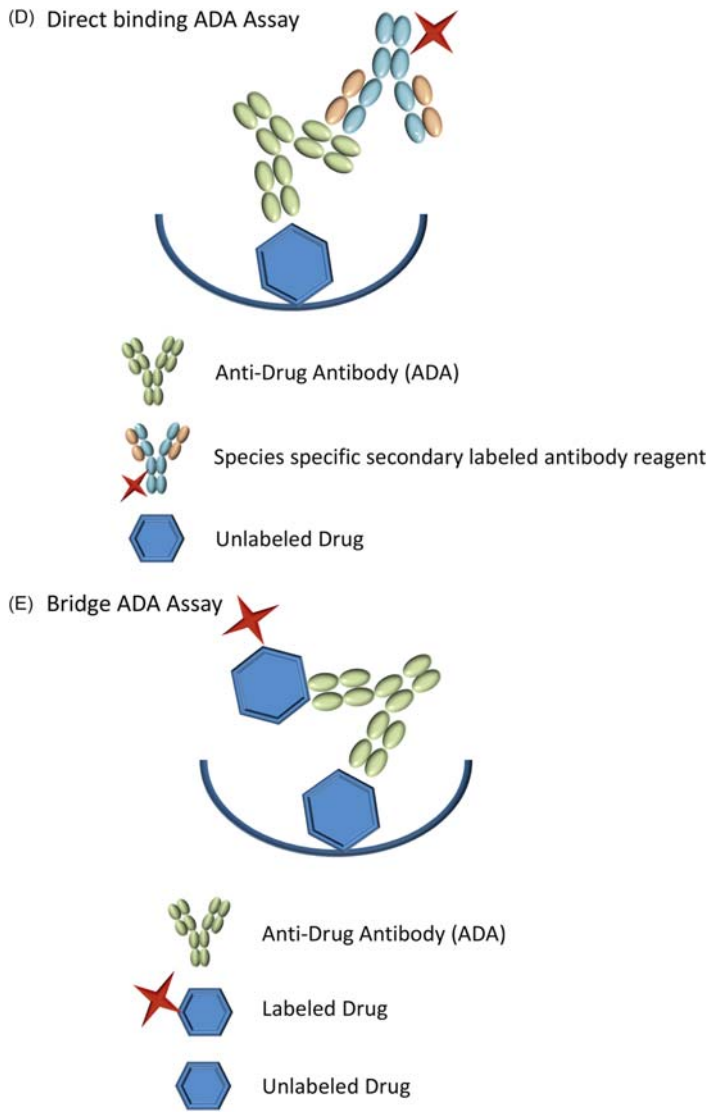

Fig. 1 (*continued*).

be addressed by including serum or immunoglobulins from respective species as one of the assay buffer components. As an example, HAMA interference can be addressed by including normal mouse serum or mouse immunoglobulins. In some cases, a known interference can be removed in a sample pretreatment step. For example, assay interference due to the presence of multimeric drug target can be mitigated by an immunoprecipitation step that removes target from the sample or by blocking drug target from binding to the drug reagent via an unrelated anti-target antibody.[22] RF could be removed from the sample by incubating with an aggregated preparation of human IgG or by using various commercially available RF binding reagents. Other drug-specific methods have also been described.

Initially observed matrix interferences may require a significant change to the assay set up or the type of reagents used. For example, use of a F(ab′)2 was shown to be beneficial versus a full length IgG reagent when mitigating RF impact.[23] Another common approach to reduce matrix interference is to apply high sample dilution. Because interfering components are generally expected to have low affinity to the assay components, high dilution factors will favor high affinity interactions between assay reagents and the analyte. High minimal required sample dilution factors can be helpful but should be expected to impact assay limits of quantitation.

In all cases, in addition to neutralization of an interfering factor, sample pretreatment step may negatively impact overall analyte recovery. For example, RF blocking reagents may also bind and remove a mAb-based drug thereby impacting assay reported results. Removing the Fc fragment from ADA assay reagent may result in an incomplete reporting of anti-drug immune responses as the immunogenicity response to the entire drug molecule is expected.[24]

It is important to note that AC LCMS applications used for analysis of biotherapeutics may be similarly impacted by low affinity binding matrix components based on the nature of the initial AC step.

6.08.2.1.4 LBA method development and qualification requirements

6.08.2.1.4.1 PK assay development and qualification

Similar to other analytical methods, LBA protocols undergo initial development phase followed by qualification or, where required, a formal validation phase. Typical steps taken during LBA PK method development phase are:

- Identification of assay analyte is a critical step generally requiring a consultation with a PK PD project lead.
- Definition of assay format and assay reagents—these are tightly connected with the analyte type but can also be driven by the availability of specific reagents and other assay components (Fig. 1A–C).
- Selection of the biological matrix may be dictated by available PK–PD modeling data, analyte stability and distribution information, impact of various matrix additives (e.g., protease inhibitors, anti-coagulates) on the analyte stability, and assay performance.
- Establishing assay minimal required dilution is a step directly relevant to the matrix interference observed in the assay, expected assay sensitivity, and analytical platform chosen for the method.
- Assay specificity and selectivity characteristics are generally assessed using individual matrix samples tested as neat or spiked with a known potential interfering substance, for example RF or drug target. Assay selectivity and specificity characteristics are tightly linked with the assay format and/or assay reagents type. Use of individual disease or study related matrix material is preferred to appropriately reflect potential matrix effects on the assay.
- Due to nonlinearity of signal response in a typical LBA method, an appropriate fitting algorithm (e.g., 4PL vs. 5PL fit) is established to achieve better assay reproducibility across assay range of quantification.
- Range of assay standard calibrators is established.
- Assay quality control including lower and upper limit of detection samples are evaluated to determine assay range of quantification, precision, and accuracy parameters. Precision and accuracy evaluation is expected to be conducted using separately prepared quality control samples (e.g., prepared at the low limit of quantification, LLOQ). Use of calibration standards in order to evaluate assay range of quantification and assay precision, accuracy/characteristics should be avoided.
- Typically dynamic range of LBA method is narrow leading to a required sample dilution during routine sample analysis. LBA methods are therefore evaluated for the assay dilution linearity by testing a high-concentration QC sample mimicking a study C_{max} concentration.

As a result of above evaluations, assay conditions may require an adjustment or a sample pretreatment step can be a necessity. For example, if a significant under- or overrecovery is observed in a relevant disease matrix, the choice of assay reagents may be re-examined.

If PK assays are expected to be used in support of a regulated study, an additional assay validation step is required. A well-established set of parameters listed below is typically evaluated as described in several regulatory guideline documents as well as in the industry white paper publications.[25–27]

- Assay range of quantification, including concentrations of assay standards used to generate calibration curve. Typically at least six nonzero standards are expected within the range of assay quantification. Additional standards may be included as anchor points outside the range of the assay in order to improve curve fitting algorithm
- Assay precision and accuracy characteristics, including tests conducted at the assay LLOQ; low, mid, and high QC levels and at the assay ULOQ level
- Assay specificity and selectivity characteristics are confirmed using final assay conditions by testing study relevant disease individual drug naïve matrix samples spiked at various QC concentrations
- Stability of the assay analyte is assessed in the assay matrix under conditions relevant to study sample testing environment, for example, −20°C/−70°C (a long-term stability, exact choice of conditions depends on the study set up), room temperature and freeze/thaw cycles
- Confirm assay dilutional linearity under the final assay conditions
- Confirm assay robustness and ruggedness if applicable

6.08.2.1.4.2 ADA assay development and qualification

ADA assays are performed to determine presence of drug-specific immunoglobulins in study samples. General ideas behind ADA assay development and qualification/validation have been carefully described in several regulatory and industry guideline documents and white papers.[28–30] Most commonly, a tier-based approach to testing for immunogenicity induction is applied which involves initial screening for putative ADA positive samples followed by specificity test to confirm drug-specific binding. Additional tests may be conducted to produce final reportable titer value as well as to characterize ADA response for the neutralizing anti-drug specificity (NAb). An example of a testing flow chart is shown in Fig. 2. During initial sample testing, screening assays are applied to distinguish between ADA positive and ADA negative samples by comparing to the screening assay cutpoint value. Samples that generate assay signal at or above assay cutpoint are defined as positive and samples that generate assay signal below cutpoint value

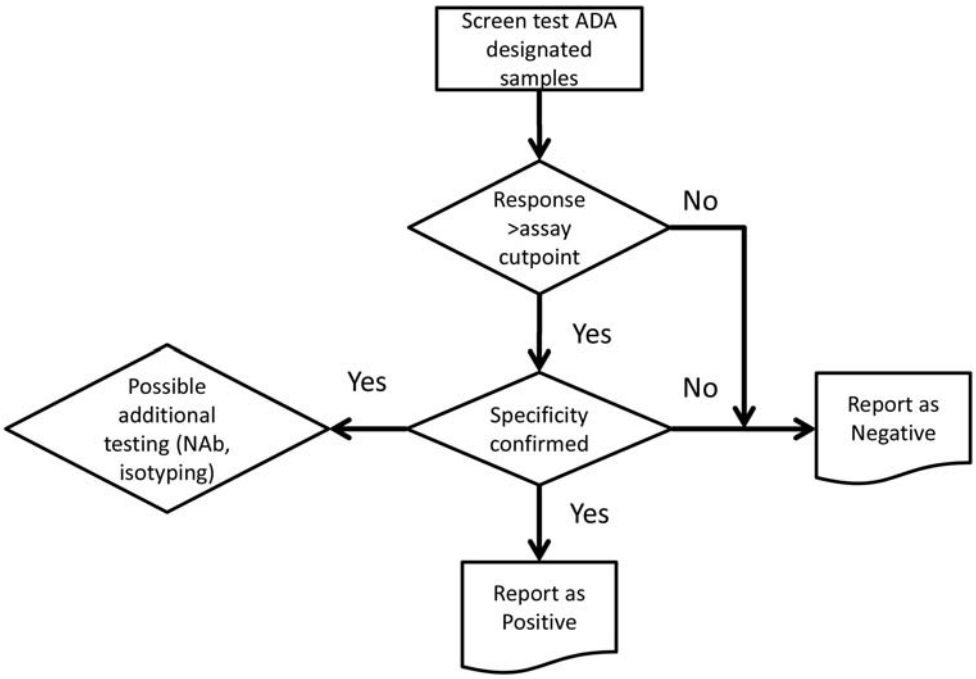

Fig. 2 Example of ADA testing flow chart.

are defined as negative. Screening assay cutpoint is commonly statistically defined as the 95th percentile of the signal distribution generated by analysis of a collection of drug naïve study relevant individual samples.[28]

Subsequent confirmatory test is often based on the ability of unlabeled drug added to sample to inhibit assay signal by blocking ADA binding to the assay reagents. The reduction in the assay signal (% inhibition) is used to determine whether ADA binding is drug specific. Similar to the screening assay, sample specific % inhibition value is compared to the confirmatory assay cutoff value that was established during assay validation phase based on analysis of drug naïve study relevant individual matrix samples. Sample is defined as ADA positive and drug specific if the percent inhibition value is at or above the confirmatory assay cutoff value. If sample produces % inhibition below confirmatory cutoff, it is defined as nonspecific to the drug. Similar to the screen assay cutpoint, confirmatory cutoff value is statistically defined as a 99th (or 99.9th) percentile of the distribution obtained by analysis of drug naïve study relevant individual samples.

Various ADA screening assay formats and analytical platforms are available with the final assay type driven by the specific nature of biotherapeutic and species type. A direct binding format (**Fig. 1D**) may be applied when detecting immune response to a human biotherapeutic in animal studies. The same may be evaluated for a human matrix based assay but developers should be aware of a potentially high background signal due to a high concentration of endogenous human immunoglobulins. A bridging assay format (**Fig. 1E**) provides appropriately specific and sensitive methods and addresses many of the matrix interference related issues. Bridge assay format is commonly applied when detecting immune responses in clinical studies. This allows one to address species specificity as the same assay reagents can be applied in both nonclinical and clinical matrices. Various types of platforms are used in the ADA detecting protocols including methods with chromogenic (ELISA), ECL, luminescence, and radioactivity (RIA) detection. Label-free platforms are also applied (e.g., SPR).

Due to the diversity of a typical ADA response (polyclonality, variations of isotypes and affinities of response found in particular sample), it is not possible to generate a true ADA assay reference material. Positive (PC) and negative (NC) controls are applied to monitor assay performance based on the specific PC and NC performance characteristics that are established during assay validation phase. Assay PCs are typically monoclonal or polyclonal drug-specific nonhuman antibodies obtained by hyperimmunizing laboratory animals, for example mice, rabbits, or monkeys. Assay NC is typically prepared using drug naïve study specific matrix. Assay sensitivity is one of the parameters assessed during assay development based on PC material performance. Although as stated above PC does not appropriately represent incurred study sample, it is a regulatory expectation to ensure that an ADA method should detect at least 250 and 500 ng mL^{-1} of PC material in clinical and nonclinical assays, respectively.

Based on the typical assay set up, ADA protocols are known to be impacted by the presence of residual drug in the sample. ADA assay drug tolerance, or ability to detect ADA in the presence of unlabeled drug, is a critical characteristic of a method. It can be evaluated based on the performance of the assay PC material although direct application of the drug tolerance value toward incurred study sample analysis is discouraged. Various methods have been developed to improve ADA assay drug tolerance parameter including assay method modification and use of sample pretreatment.[31,32]

Typical steps applied during ADA method development phase are listed below:

- Assay reagents identification, including generation and selection of the assay PC
- Identification of the NC and assay matrix
- Selection of the assay analytical platform and format, generation of other assay reagents (e.g., detection reagent)
- Evaluation of assay buffer, reagent conjugation conditions, matrix starting dilution, and incubation times with the goal to minimize irrelevant nonspecific binding but retain assay ability to detect drug-specific ADA
- Evaluation of assay sensitivity and drug tolerance with respect to PC
- Selection of confirmatory assay conditions, including unlabeled drug concentration added to the sample

Similar to PK assays, ADA protocols expected to be used in support of regulated studies require additional assay validation steps. A set of parameters listed below is typically evaluated as described in several regulatory guideline documents as well as in the industry White paper publications.[24,28–30]

- Screening assay cutpoint and confirmatory cutoff values. The same set of data generated using analysis of individual matrix samples allows to understand potential sources of interference
- Assay precision, robustness, and sensitivity are evaluated based on the performance of the assay PC material
- Acceptance criteria for PC and NC materials are established

Similar steps and parameters are typically assessed during NAb assay development and validation.[11,33]

6.08.3 LBA Technology Platforms—Past, Present, and Future

Rosalyn Yalow won the Nobel Prize for Medicine in 1977 for the development of radio-immunoassays of peptide hormones. The technique was introduced as a way to measure insulin levels in plasma and was based on the finding that insulin-binding antibodies are present in the serum of patients treated with insulin.[34,35] This revolutionized the field of clinical chemistry, because it was the first time one was able to measure hormone levels in blood using an in vitro method. Changes to the mode of capture and/or detection can enhance the sensitivity of detection and/or linear range of the assay. Radioimmunoassays use isotope labeled detectors that significantly enhance the sensitivity of the assays. However, nonisotopic methods that do not require the analyst to be exposed to harmful radiolabeled reagents have taken the place of radiometric assays.

LBA technologies have evolved considerably over the years from the birth of radio-immunoassays in 1959 by Berson and Yalow to present day assay systems with a myriad of highly sensitive, nonradiometric methods. In an ELISA, the detector is coupled to an enzyme such as horse radish peroxidase (HRP) or alkaline phosphatase. Upon addition of the corresponding substrate, the substrate is converted to a colored product. The amount of color produced is proportional to the amount of complex captured and therefore provides a means of quantitation of the analyte. Such LBAs are referred to as colorimetric ELISAs. Traditionally, bioanalytical labs have relied on colorimetric ELISAs for the PK determination of biotherapeutics and these have become the gold standard for LBAs. ELISAs continue to be the workhorse of the ligand binding bioanalytical lab and offer several advantages such as ease of execution, nonproprietary reagents, and instruments that are readily available in most bioanalytical and clinical labs. However, colorimetric ELISAs are often limited in the range and sometimes sensitivity of the assay. In addition, they often require multiple washes between steps and when performed manually without automation can be rather tedious. Changing the substrate in an ELISA to a chemiluminescent substrate can enhance the range and sensitivity of the assay even with the same reagents. Technology advances have given birth to many new LBA platforms over the years, several of which have gained wide use in bioanalysis. Some of these technologies are described later, along with some considerations regarding advantages and disadvantages. More information can be found in several recent review publications describing next generation LBA platforms and read out technologies.[36–39]

6.08.3.1 ECL Assays

The application of electrogenerated chemiluminescence or ECL to LBAs began in early 1990s.[40–42] ECL immunoassays may be described as an ELISA with modified capture surfaces and a different readout. The ECL immunoassay platform can be implemented in various formats similar to ELISAs such as sandwich, competitive, or bridging assays.[43] Capture antibodies may be passively coated or biotinylated and captured on streptavidin-coated plates. The basic principle of ECL is the generation of a species at an electrode surface when a voltage is applied, which then undergo chemical electron-transfer reactions to form excited states that generate light. In ECL immunoassays, the detector molecule (e.g., detector antibody) is labeled with an electrochemiluminescent label. Ruthenium bipyridyl derivative [$Ru(bpy)_3^{2+}$] is the most commonly used label coupled with tripropylamine (TPA) as the co-reactant. Immune complexes are captured on the surface of an electrode and voltage is applied to the electrode in the presence of the co-reactant (TPA). Electrical stimulation triggers the reaction of ruthenium bipyridyl with TPA resulting in the emission of light followed by subsequent regeneration of the $Ru(bpy)_3^{2+}$ species which can then cycle multiple times through the reaction for signal amplification. The proposed mechanism of the reaction has been described in detail by Blackburn et al.[41] Instrumentation for ECL immunoassays requires a reaction vessel, a means to conduct electric current and a way to measure the emitted light. ORIGEN-1 was the first commercially available ECL instrument from Igen International Inc. (later BioVeris Corp. and now owned by Roche Diagnostics Corp.) that uses magnetic beads to bind immune complexes, which are then captured on a platinum electrode

which conducts electric current when voltage is applied. The resulting light signal is measured by a photomultiplier tube. This technology platform found widespread use in several bioanalytical labs in the early to mid-2000s. However, this is no longer available as a standalone analyzer for bioanalytical labs and a plate-based system from Meso Scale Discovery (MSD), LLC has become the ECL platform of choice in the bioanalytical lab. This system uses disposable microtiter plates with the electrodes integrated into the bottom of the plates and the signal captured using a cooled CCD (charge coupled device) camera.

6.08.3.1.1 Pros and cons/considerations

- ECL immunoassays have the advantage of being highly sensitive with a wide dynamic range when compared with the ELISA counterpart. These assays are also less susceptible to matrix interferences.
- The MSD system also offers multiplexing capabilities—with multiple capture spots per well, allowing the simultaneous capture and detection of up to 10 analytes per well. Some recent advances allow the user to create custom multiplexed assays in the lab which is an added benefit.
- Ruthenylation is via NHS-ester linkage (similar to biotinylation and takes place through –NH side chains. When labeling detector molecules, particularly if the detector is a small protein one should pay attention to the number and location of lysines in the molecule to ensure that labeling does not render the molecule inert in the binding reaction.
- Bridging across multiple batches of labeled reagents can be tricky with validated assays. Therefore, one should characterize the conjugates thoroughly to obtain information on average number of labels/molecule, species distribution, etc.
- Potential for cross-talk between wells when a high signal sample is next to a low signal sample.

6.08.3.2 Gyrolab

The Gyrolab platform from Gyros AB combines microfluidic technology and fluorescent detection in a fully automated system. The technology is based on the proprietary compact disks (CD) engineered with microstructures and highly reproducible nanoliter microfluidics.[44,45] Each CD contains 12 segments, each comprised of 8 microstructures. Each microstructure contains a sample delivery channel, a column packed with streptavidin beads, a common reagent channel, and hydrophobic barriers to gate and control the flow of liquids when the CD is subjected to different rotational speeds. The instrument contains two carousels—one for microtiter plates that contain samples and reagents, the other for CDs. Delivery of liquids is by a robotic arm that injects excess volumes. The overflow volumes are removed by an initial low speed spin, followed by a higher speed spin that allows the liquid to overcome the hydrophobic barriers. Assay formats are similar to ELISA with a biotinylated capture antibody that is captured on the streptavidin columns and an Alexa-fluor-labeled detection antibody.

6.08.3.2.1 Pros and cons/considerations

- Small sample and reagent volumes, significantly lower than ELISA or ECL even with the dead volume and overflow volumes taken into consideration
- Wide dynamic range, low background, high signal, reduced matrix effects (lower than ELISA and ECL)
- Fully automated system with higher throughput
- Dynamic range can be extended by using CDs of different capacities (20 nL, 200 nL, and 1000 nL). For example, going from a Bioaffy 200 CD to a 20 nL, can increase the ULOQ, whereas the 1000 nL CD can increase the sensitivity (or lower the LLOQ) of the assay
- CDs are expensive

6.08.3.3 Biacore

This is the first label-free technology for the detection and measurement of biomolecular interactions that is based on SPR.[46] The SPR phenomenon occurs when polarized light, under conditions of total internal reflection, strikes an electrically conducting gold layer at the interface between media of different refractive indices: the glass of a sensor surface (high refractive index) and a buffer (low refractive index). When molecules are immobilized on a sensor surface there is a change in refractive index that changes the angle at which reduced intensity polarized light is reflected. This change in angle is proportional to the mass of bound material. The Biacore systems comprise surface chemistry, flow systems, and optical detection methods that generate profiles of binding and dissociation in real time enabling determination of specificity, affinity, kinetic behavior, and sample concentration. This technology has been available since 1990 and came into use in bioanalytical labs in early 2000s, particularly in the characterization of binding interactions and subsequently also used in detection of ADAs.[47,48]

6.08.3.3.1 Pros and cons/considerations

- Provides all the advantages of label-free technologies such as no labeling of reagents or analyte needed. Secondly, removes the risk of affecting protein: protein interactions between the analyte and reagents due to masking of binding sites
- Low throughput on the Biacore X100 (max 15 samples) but increased throughput on the newer T100 (384 samples)
- Sensor chips are expensive and analysts need some training on the platform

6.08.3.4 ForteBio

ForteBio is based on an optical principle called biolayer interferometry which is also a label-free technology for measuring biomolecular interactions.[49] In this system, the interference pattern of white light reflected from two surfaces is analyzed—a layer of immobilized protein on the biosensor tip and an internal reference layer. The ligand is immobilized on the biosensor tip and binding of the ligand to analyte in solution causes a change in optical thickness resulting in a wavelength shift that is proportional to the number of molecules bound to the sensor tip. In the Octet system from ForteBio, the tip of a fiber optic probe is coated with ligand and acts as the biosensor. That tip is then dipped into the sample containing analyte in a microtiter plate. This also earned the technology the name Dip-and-Read ELISA or ELISA-on-a-stick. The assay is read by shining white light down the length of the fiber. Interference between light reflecting off-the reference and immobilized surfaces of the tip creates a distinctive pattern of light returning up the fiber. As molecules bind to the immobilized sensor surface, the interference pattern changes proportional to the amount of analyte bound to the tip. This allows the technology to be used for quantitation of analyte as well as for kinetic measurements. In the bioanalytical lab this technology has gained utility in screening and characterization of reagents.

6.08.3.4.1 Pros and cons/considerations

- The biosensor detector surface is brought to the sample and does not use any microfluidics
- Nondestructive method for detection of analyte
- Minimizes matrix and other interferences since detection occurs at the biosensor tip. This allows the system to be used to screen hybridoma supernatants, cell culture samples, and complex matrices with minimal sample pretreatment
- No labeling of capture or detector reagents required which has a twofold advantage. Firstly, no labeling of reagents or analyte needed. Secondly, removes the risk of affecting protein: protein interactions between the analyte and reagents due to masking of binding sites

6.08.3.5 Luminex

This is probably one of the oldest multiplexing technologies in LBAs and has been in use since 2000.[50,51] It utilizes microsphere beads that are dyed with red and infrared fluorophores of varying intensities. By coating each type of microsphere with a different capture reagent, multiple analytes can be captured simultaneously from the sample and differentially measured based on the intensity of each dye by a flow cytometer. Theoretically, the Luminex system can detect up to 100 different analytes in various matrices such as serum, plasma, cell culture supernatants, and even in tears.[52] This technology has been used particularly in the detection and/or quantitation of multiple BMs from clinical samples allowing researchers to establish correlations with disease indication or treatment outcomes. For example, an assay to detect multiple different pro-inflammatory cytokines was developed on the Luminex platform from the same sample volume that would allow the detection of one cytokine using a traditional ELISA in juvenile idiopathic arthritis where sample volumes from pediatric population are limiting.[53]

6.08.3.5.1 Pros and cons/considerations

- Minimum sample volume of 25–50 μL is required which could be limiting in some cases. However, since multiple analytes can be measured with the same sample volume that would translate to reduced sample volume requirements overall
- Several multiplex kits are available in the market that can be quickly implemented
- For custom assay development, initial effort is required with labeling of individual reagents and establishing little or no cross-reactivity with other analytes in the multiplex
- Range of detection for each analyte cannot be optimized as the assay measures multiple analytes at the same time. For instance, at a given sample dilution while one analyte may be above the limit of detection, another analyte may require lower dilution
- Data acquisition, analysis, and representation is very complex with multiple analytes and increases as the number of analytes in the assay increases

6.08.3.6 Acoustic Membrane Microparticle Technology on the ViBE Platform (Bioscale)

This technology available from BioScale utilizes a nonoptical detection system which determines analyte concentration by measuring changes in the oscillating frequency of a vibrating biosensor membrane made from piezoelectric material. In this system, the capture reagent is on magnetic microparticles and the detection reagent is tagged with a fluorescent label such as fluorescein. Immune complexes are formed in solution and captured by flowing the solution over the membrane, where a magnetic field drives the magnetic beads to the surface of the biosensor. Immune complexes are captured by anti-fluorescein antibodies on the membrane surface. When the magnetic field is removed, only the bound complexes remain while unbound components are washed away. The signal measured in this system is the change in vibrational frequency which is proportional to the mass of magnetic bead complexes that remain bound to the biosensor. Upon completion, the surface of the sensor is regenerated and returned to baseline frequency for another round of analysis. Over the past few years there have been reports in literature of the application of this technology platform to various bioanalytical assays such as BMs, PK, and ADA.[54–57]

6.08.3.6.1 Pros and cons/considerations

- Low interference from matrix and other components; demonstrated utility across several different matrices such as serum, plasma, urine, ascites, tissue extracts, and cell culture supernatants
- Highly sensitive due to amplification of the signal
- Walk-away ability on the ViBE instrument for this technology. However due to limited deck capacity, the throughput is not very high (two to three microtiter plates at a time) despite the automated platform
- Bioscale provides labeling kits for custom assay development as well as off-the-shelf kits for cell signaling, cytokines, and endocrines

6.08.3.7 SIMOA (Quanterix)

This is a proprietary ultra-sensitive technology available from Quanterix and stands for single molecule array (SIMOA). The technology is based on detection of single molecules in femtoliter-sized wells, where immune complexes captured on paramagnetic beads are isolated and sealed in the presence of enzyme substrate. The sealing step confines the fluorescent product of the enzyme–substrate reaction to femtoliter volumes to generate high local concentrations of the fluorescent product, and the fluorescence generated by a single enzyme can be detected on an uncooled CCD camera using a white light excitation source. This is an ultra-sensitive technology that has application particularly in the detection of BMs that may be present in very low levels. Sensitivity of 30 fg mL^{-1} for detection of prostate-specific antigen and 10 fg mL^{-1} for tumor necrosis factor alpha have been reported.[58]

6.08.3.7.1 Pros and cons/considerations

- Ultra-sensitive technology that has begun to gain use particularly in the detection of BMs that may be present in very low levels.
- The platform uses the same reagents as a traditional ELISA to form immune complexes and uses significantly less reagents.
- Ability to multiplex—this platform has been successfully used to detect multiple analytes.[59]
- Data acquisition is a fast process because the final signal acquisition is done on a planar array with standard imaging.
- Fully automated platform where the instrument can perform sample dilution, mixing, washing, incubation, and data acquisition steps.

6.08.3.8 Singulex Erenna

Single molecule counting technology by Singulex is another ultra-sensitive immunoassay system where the first step is similar to a traditional ELISA and involves the formation of an immune complex using capture and detection reagents.[60,61] The immune complexes are then eluted using a modified elution step such that the complex is broken apart and the eluate is drawn into the Erenna system capillary tube which contains a very small interrogation space that is illuminated by a laser. Single fluorescently labeled molecules are detected as they generate flashes of light when they pass through the interrogation space. Fluorescence events are digitally counted by photon detectors. The technology is highly sensitive and limit of quantitation in the fg mL^{-1} range have been reported for measurement of various cytokines in serum[62] and in the pg mL^{-1} range for oligomers of Aβ in Spinal Cerebral Fluid (SCF).[63] Similar to the SIMOA system, the high sensitivity of this immunoassay platform has found application in the quantitation of BMs, particularly those that are present in very low levels and cannot be detected by traditional methods.

6.08.3.8.1 Pros and cons/considerations

- Highly sensitive assay with the ability to measure low pg mL^{-1} and even fg mL^{-1} concentrations of analyte
- Flexibility of bead- or plate-based assays in 96- or 384-well format
- Although pg mL^{-1} sensitivity has been reported for plate-based assay format, this may potentially produce lower sensitivity assays versus that for bead-based format methods[64]
- Method involves several washing, spinning, and plate transfer steps which can increase variability[62] and the system does not offer any automation, although off-line automation may be done
- Relatively low throughput as sampling occurs one well at a time and up to 1 min per well read time
- Cannot be used for multiplexing and carryover can be an issue

6.08.3.9 Maverick (Genalyte)

Technology utilizes a proprietary multiplex detection system based on silicon photonics that utilizes ring resonance to measure binding of molecules to sensors on a miniature silicon chip.[65] Silicon photonic devices comprised of 128 micro-fabricated rings are arrayed on a single disposable chip in a pattern of four per analyte resulting in 32 clusters. The Maverick system detects changes in resonance wavelength as molecules bind to the surface of the sensor for real-time measurement of ligand binding. Calibrators establish concentration-dependent spectral shifts that can be used for quantitation of analyte in unknown samples. Samples

prepared in 96 well plates are loaded into the instrument where an automated fluidics system draws 2–5 μL of sample into the specific array, followed by presentation of the array to the detection system. It can be used as a label-free technology or enhanced using enzyme conjugates (such as Streptavidin conjugated to horse radish peroxidase (SA-HRP)).

6.08.3.9.1 Pros and cons/considerations

- System is a walk away once preparatory steps are completed
- Uses low sample volume
- Multiplexing capability
- Useful for BM measurements
- Limited use to-date for other applications in the bioanalytical lab

6.08.3.10 Imperacer Immuno-Polymerase Chain Reaction (PCR) (Chimera Biotech)

As the name indicates, this technology combines LBA with the signal amplification power of quantitative PCR (qPCR) read out.[39,66] Analyte is captured using an antibody, while the detector antibody is conjugated to DNA instead of an enzyme as in a traditional ELISA. Detection is by amplification of the DNA via qPCR. This technology is proprietary and available from Chimera Biotech. The amplification power of PCR provides the method with high sensitivity which has been applied for the measurement of several BMs such as those for neurodegenerative disorders in the periphery rather than brain tissue or cerebrospinal fluid, microsampling for metabolic BMs, and quantitating cytokines at <1 pg mL^{-1} range. In addition to BM measurements, Imperacer has also been applied in PK measurements and ADA detection in immunogenicity assays.

6.08.3.10.1 Pros and cons/considerations

- High sensitivity due to amplification of signal by PCR; but amplification of nonspecific signals can lead to high background, therefore it is important to use reagents with high specificity
- Nonspecific interactions can be reduced by diluting samples, while still obtaining sufficient sensitivity

6.08.3.11 SQI Diagnostics

This is a dual-layer multiplexing technology with the ability to multiplex at both capture and detection levels.[67] Each well in the microtiter plate contains a grid of 16×13 spots that can be printed with different capture antibodies. Upon binding of analyte from sample, a mixture of detection antibodies that are differentially labeled are added. Detection is by a multiwavelength scanner that allows the simultaneous detection of multiple fluorescent labels. The platform is integrated into a fully automated system that can automate all steps from pipetting, washing, and drying of plates, to reading on the multiwavelength fluorescent microarray scanner and data analysis. The technology has application in immunogenicity testing for isotyping and epitope mapping in one step.

6.08.3.11.1 Pros and cons/considerations

- The large number of spots per well allow inclusion of six to seven replicates for each capture reagent
- Plates have to be printed with capture reagents—this can become costly and rate limiting
- Fully automated system with walk away ability
- Data analysis can be complex due to the amount of data that is generated from each plate

The above list of technologies is by no means exhaustive, but provides a brief overview of some of the available technologies that are available for use in the bioanalytical lab. The choice of platform will depend on many factors such as flexibility of the platform, sample volume requirements, throughput needs, ease of assay development, availability of the platform, 21 CFR Part 11 compliance requirements,[68] costs of instrument and/or consumables, reagent labeling requirements, sensitivity, and multiplexing needs to name just a few. A comparison of some of these technologies with respect to sensitivity, multiplexing, throughput, and real-time measurement was published by the Emerging Technologies working group within the Ligand Binding Assay Bioanalytical Focus Group of the AAPS Biotec section.[36–39] As technologies continue to evolve at a rapid pace, several improvements to the technology, its interface with other systems (such as Laboratory Information Management System (LIMS)' systems) or compliance with the 21 CFR Part 11 may have improved since the time of publication of these review articles.

6.08.4 Evolving Landscape of LBA Technologies and Regulatory Expectations

Advanced LBA technologies are moving away from historical plate-based approaches. Improved robustness and ability to continuously run higher number of samples in some of the new technologies allows for a larger run batch leading to potential need to include more than a single set of standards and QCs with additional QCs placed throughout the run batch. Questions regarding

overall number and positioning of the assay QCs through the run batch will need to be addressed in interactions with regulatory agencies. High precision of some of the new generation LBA technologies also calls into question the need for replicate analysis of QCs and unknown samples. While sample testing in duplicates or even triplicates has been a staple for many years, an active discussion regarding potential use of single replicate testing has been recently initiated.

In addition to advancements within the LBA field, there has been a significant progress in merging traditional LCMS and ligand binding technologies. Hybrid AC LCMS protocols have been developed and reported for a variety of endogenous proteins and biotherapeutics, for example, ADCs[17,69–71] offering specificity and sensitivity obtained through the initial AC step combined with analyte specificity obtained via the use of LCMS methodology.

As pointed out earlier in this article, the landscape of LBA technologies continues to evolve. This is in part promoted by evolution of biotherapeutic modalities which now include various types of alternative scaffold proteins, bi-specific antibodies, ADCs, and nucleotide-based biologics. Often, complexity of the drug structure is tightly associated with a high degree of complexity of the drug MOA. Multifaceted and frequently multistep MOA presents additional requirements to the type of analyte to be measured in the assay, sensitivity and selectivity of the method, requirement to handle smaller sample volume, and need for a broad assay dynamic range. Many of the new generation LBA technologies are designed to address some of these considerations, but new challenges abound. With the rapid pace of advancement in science and technology, and the need for personalized medicine, one can envision a future where drug concentration and other bioanalytical measurements become a routine test that can be run within minutes in a doctor's office or clinic with a tiny finger prick.

6.09.1 Introduction

Analytical and formulation development (AFD) is a key function within chemistry, manufacturing, and controls (CMC) of drug development programs responsible for the evaluation and establishment of consistent product quality and stability. AFD is integral to process development, optimization and manufacturing, and release and characterization of drug substance (DS) and drug product (DP) for use in nonclinical and clinical studies during development, and plays a vital role in manufacturing and commercial supply of therapeutics. The *process is the product*, which means that the manufacturing process including upstream protein expression, the downstream protein purification and formulation, and the analytical and characterization methods used to characterize and optimize the process, together defines the product quality and the stability of the DS and DP. Process knowledge is heavily dependent on accurate and precise measuring techniques used to test and examine the quality of drug components, raw materials, and finished products. The two functions in AFD are also highly interwoven and interdependent and, in many small- to mid-size organizations, constitute a single functional unit, typically part of process/pharmaceutical sciences (Fig. 1).

6.09.1.1 Analytical

Analytical methods including biochemical and biophysical characterization methods are required to evaluate and screen formulations and their stability; while a reasonably stable formulation along with forced-degraded formulations are required to develop, optimize, and qualify the analytical methods. Analytical methods and characterization also are very important not only as in-process tools but also to troubleshoot the DS and DP process, to identify root cause, and to establish corrective and preventative action (CAPA) to mitigate future problems during manufacturing and assessment of product quality and stability. In addition, analytical methods play a significant role in comparability studies at different phases of product development from nonclinical to postapproval of DP as the process, scale, and manufacturing site changes occur.

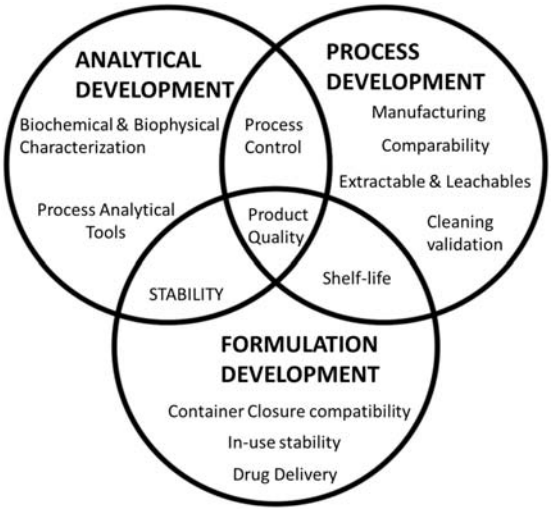

Fig. 1 Interdependence of manufacturing process development and AFD.

6.09.1.2 Formulation

Formulation development not only is involved in developing a stable formulation for a given dosage form but also during life cycle management and typically entails developing additional dosage forms, product presentations, and various drug delivery modes representing different routes of administration.[1] Further, formulation development also encompasses material compatibility, in-use, and long-term stability studies to evaluate and ensure that the DS and DP are adequately stable during different phases of clinical development and as a commercial product. Furthermore, the various dosage forms and complex drug delivery systems, together with combination drugs and devices, significantly expand the scope of this exciting field that enables patient-friendly drug treatments, often times throughout the lifetime.

6.09.1.3 Early Product Development

During the discovery phase of the projects, in start-ups, typically the chemistry/medicinal chemistry and biology groups gain an early understanding of the physicochemical and biological properties of the early hits and lead molecules of new molecular entities. For the development teams (process and CMC teams) that come in later, it is important to establish a rapport and good collaboration with the early research teams to get a comprehensive picture of the structural and functional requirements of the advancing therapeutic candidates. Small-scale expression of the recombinant protein and purification is typically performed by the research groups whose main focus is on establishing the biological activity using in vitro and in vivo assays that form the basis of potency assays and efficacy animal models.

The product development (AFD) scientists can contribute to the project initially by evaluating the in-use stability of the early protein buffered solutions and by a preliminary gauge of the degradation pathways of the upcoming leads, which allows for recommended storage and precautions to be taken during preparation of dosing solutions and sample preparation for in vitro studies. As the discovery phase of the project matures into identifying and optimizing new lead molecules for development, the internal technology transfer from discovery to development teams is the foundation of process and product development that involves developing a well-thought-out strategy and plan for early protein production, analytical, and formulation development. Execution of the development plan in an organized, systematic, and timely manner is critical to meeting the business milestones that is crucial to the investors and shareholders. When performed concurrently, it generally takes 9–12 months to complete AFD work for phase 1 and 2 clinical development, including method qualification, and obtain accelerated and preliminary real-time stability data with the lead formulation.

6.09.1.4 Major Pitfalls in CMC

Some of the major pitfalls[2] in the analytical and formulation development plan are outlined in the **Table 1**. A well-thought-out road map, active project management, establishment of quality systems, and constant project monitoring are crucial to avoid these pitfalls and for successful product development. Strong and experienced leadership and talented personnel with appropriate training experience, motivation, and project ownership, together with corporate and fiscal commitment to dedicated CMC activities, are central to achieving the goals and milestones. The importance of active communication, self-awareness, peer-review, and cross functional collaboration with internal teams and external contract service providers (CSP) cannot be overemphasized.

Table 1 Pitfalls in analytical and formulation development impacting CMC development

1	Not well-thought-out development strategy
2	No pre-IND meeting to obtain agency feedback on CMC issues or consultation with SMEs
3	Not spending sufficient time on development, method transfer/establishment and qualification of robust analytical methods, and development of a robust and stable formulation
4	Setting the specification too tight early in development leads to failed batches
5	Not considering composition of approved DP and determining allowable ranges of generally regarded as safe (GRAS) excipients and researching list and concentration range of FDA inactive ingredients in approved products
6	Not spending sufficient time on investigating OOS and OOT to understand root cause
7	Not employing sufficient resources, utilizing appropriate project management tools, and working collaboratively with QC, RA, and QA to set development strategy and resolve issues
8	Not spending sufficient time and stringency with data integrity and documentation review; and active communication, supervision, and ensuring compliance of GLP and cGMP procedures
9	Wrong choice of CRO/CMO for analytical and formulation development and insufficient real-time and accelerated stability studies

6.09.1.5 The Target Product Profile

At the core of product development is the target product profile (TPP). The TPP is a strategic development tool and usually a living reference document for the most current information on the intended product characteristics and use.[3] The benefit of using the TPP in R&D is that it provides a clear and tangible vision and focus and gives the core team a glimpse of what could be a real product with the goal of improving patient health. In the early phase of development, the TPP typically involves developing a list of product description, mechanism of action, pharmacology, potential indication(s), and a description of the primary and secondary clinical endpoints that are required to evaluate the value proposition of the drug to overcome unmet medical needs. For the development scientist, the TPP is the framework to plan and develop appropriate manufacturing process, the analytical and physicochemical characterization tool box, and a robust and stable formulation required for the intended route of drug delivery during the early phases of development. The TPP is a dynamic summary that changes as knowledge of the drug increases. It is recommended that the TPP be updated regularly to reflect new information about the drug and changes in the clinical development program. Further, regulatory guidance documents from the FDA, ICH, WHO, and other agencies provide a compass to develop a road map to investigational drugs and licensing application for commercialization.

6.09.2 Analytical Method Development

In the very early phase of development, not many analytical methods are required to support discovery research: mainly strength (protein concentration), an identity assay, a purity assay, and an activity assay suffice the lead to hit generation phase. These four assays are generally sufficient for also optimizing protein engineering and selection of lead candidates in concert with pharmacokinetic and efficacy evaluation. However, it is advisable to quickly also develop additional purity assays and characterize the post-translational modifications (PTM) using forced-degradation studies early during development to enable an understanding of the stability of the molecule and determine if additional protein engineering can be employed to replace any potential hot spots in the sequence based on knowledge of the product-specific degradation pathways.

Typically, IND-enabling analytical method development[4] originates after nomination of the lead new molecular entity (NME) for development. Analytical method development generally involves developing distinct product-specific methods and verification of the compendial methods that are required to assess strength, identity, safety, purity, and quality (SISPQ) of the DS and DP. The available regulatory guidance documents and summary basis of approval (SBA) dossiers for approved products are helpful in constructing a plan toward meeting the requirement for IND/IMPD submission; however, they do not offer a comprehensive summary in a single document that allows a step-by-step work flow and detailed planning and development of timelines around various drug development activities. The general chapters in the United States Pharmacopeia (USP) shown in **Table 2** provide guidance on analytical procedures, transfer of methods, and handling of compendial procedures for intended use.[5] Further, it is important to understand the requirements for different phases of clinical development and eventual commercialized drug. For example, validated analytical methods are not necessarily required during product and process development activities or when used in characterization studies. Nevertheless, analytical methods should be scientifically sound (e.g., specific, sensitive, and accurate) and provide results that are reliable during early-phase development. There should be assurance of proper equipment function for laboratory experiments. Procedures for analytical method and equipment maintenance, documentation practices, and calibration practices supporting process development efforts should be documented and described.

6.09.2.1 General Principles Analytical Method Development

General principles and platform approaches to analytical method development can be implemented based on the extensive experience and published literature from hundreds of biologic drugs that have been approved and are in various stages of clinical

development. Table 3 shows a representative list of analytical methods and intended purpose required to release batches of DS and DP after GMP manufacturing for clinical investigation.[4] For lyophilized DPs, additional assays include cake appearance, reconstitution time, and moisture content by Karl Fischer analysis.

Compendial methods, published as general chapters, by various agencies such as USP, EP, and JP, include less complex methods that have been validated in large-scale collaborative studies and can be implemented in a QC lab after brief verification under condition of use, to demonstrate compliance to the published compendia. These methods do not typically require validation and include general physicochemical properties of the DS/DP formulation such as visual appearance, pH, osmolality, extraction volume or container content, and microbiological testing (endotoxin, bioburden, sterility, viruses, and mycoplasma) and process residuals related to ensuring safety, namely, host cell protein (HCP), residual DNA, and residual protein A. These methods are generally available at contract manufacturing organizations (CMO) and contract research organizations (CRO) dealing with release and stability testing of DS and DP. While these methods do not need validation, the role of the sponsor companies is to ensure that proper SOPs are followed by the contracted QC laboratories while implementing these methods, and the analytical results are consistent between laboratories. Depending on the formulation and the chosen method, some amount of time will need to be invested in overcoming any challenges associated with interference (inhibition/enhancement) of endotoxin measurement. The prime advantage of the chromogenic kinetic method over the conventional gel-clot method is the ability to quantify the endotoxins in the sample. The gel-clot method, on the other hand, may be subjective especially in borderline cases where the gel formed may be viscous/semisolid.

In the initial phases of clinical development through phase 2 studies, it is typical to employ platform commercial HCP assays that offer a broad menu of well-validated, robust generic kits to quantify the majority of the host cell protein contaminants derived from the host expression system. These kits typically involve ELISA-based immunoassay using a mixture of polyclonal antibodies to detect and quantify the HCPs from the cell proteome. The use of these kits in the early development phases is common and sometimes can also be justified for commercial products after demonstration of HCP coverage and sensitivity. Although the ELISA-based HCP kits are used as the industry gold standard, there are limitations of these generic kits, especially in relation to the sensitivity of the method to detect less abundant HCPs and identify contaminant proteins representing all host strains. Later phases of process development typically requires development of a process-specific HCP assay that is representative and may be unique to a given upstream and or downstream process, involving design and enrichment of certain impurities.[6] The suitability of use of the commercial kits in later clinical phases will need to be justified on a case-by-case basis with adequate scientific justification of the impurity coverage of the assay. Recently, LC-MS/MS approaches are rapidly being developed to significantly increase the sensitivity. However, the very high sensitivity of the mass spectrometry may prove to be overly sensitive to detect every single HCP at levels that may not

impact the safety of the product. Appropriate guidelines and validation of these newly advancing tools have to be established before adaptation to release products.

Most of the time in analytical method development is dedicated to developing product-specific identity, purity/impurity assays, and potency assay. Protein concentration measurement is usually performed by UV spectroscopy using the Beer–Lambert principle. The theoretical molar absorption coefficient at 280 nm (aromatic residues) derived from the theoretical protein sequence based on the refined Gill and von Hippel equation.[7] At later stages of drug development, the experimental extinction coefficient is determined using amino acid quantitation of highly recoverable amino acids although generally to only confirm the value. Gel-based methods for identity and purity analysis are well described in the literature (Bio-Rad and Life Technologies application notes) and are the initial workhorse methods during the research phase and transition to early development. In the last decade, the capillary electrophoretic methods of denaturing electrophoresis and imaged capillary isoelectric focusing (CE-SDS and icIEF) have been routinely applied to get better quantitation of the well-resolved impurities and oligosaccharide analysis (CE-LIF). Much of the method development around these methods involves optimizing sample preparation, including stabilizers, and treatment conditions; selection of appropriate stationary phase; and improving resolution.[8]

Some of the ICH guidance documents that are relevant to analytical method validation, specifications, and characterization of impurities in DS and DP are listed in **Table 4**.

6.09.2.2 HPLC and UPLC Method Development

HPLC and UPLC method development is at the core of purity/impurity methods and some in-process methods including titer assay, some identity assays, refolding efficiency, peptide mapping, and LC-MS-based characterization methods. The advancement of sophisticated equipment, including sensitive detectors, the availability of a host of different modes of separation, and user-friendly integration and data analysis and reporting software tools, has made this fast-paced separations field extremely efficient for control of product quality and establishing process control and characterization of comparability of manufacturing changes during the life cycle of product development. Traditionally, size exclusion, reversed phase, and ion-exchange HPLC-based methods have been used as orthogonal approaches to identifying, characterizing, and controlling the levels of high and low molecular weight, hydrophobic/polar impurities, and charge-based heterogeneity, respectively. Additional modes of LC-based separations including normal phase and mixed-mode HILIC, HIC, HPAEC, and analytical protein A have been utilized for extended characterization and analysis of glycosylation. Method development with the LC-based separations[9] involves choice of the mode and column packing dimension, selection and optimization of the mobile phase solvent(s) and modifiers, the gradients, and experimental conditions to obtain efficient and robust methods. Software applications and USP column performance criteria such as plates, resolution, peak area recovery, and tailing allow efficient tools to be applied to monitor and standardize the method. Further, with the experience gained and published literature on a variety of nonglycosylated polypeptides and proteins and innumerable monoclonal antibodies, a platform-based initial assessment of method development allows for a much faster and easier path to method optimization. **Fig. 2** shows the various steps in HPLC method development and optimization before method qualification, and **Table 5** shows a few of the common HPLC columns and methods used in DS and DP release of both Mab and non-Mab proteins.

6.09.3 Potency Assay Development

The potency assay is a critical quality attribute from the very beginning of process development and hence needs to be carefully strategized. Typically, an in vitro activity assay is developed by the discovery team early in the project as the principal assay read out to assess the functional capability of the therapeutic, to screen hits and variants, and to select the lead candidates from protein engineering that are advanced for further product development and quality attributes (PK, PD, toxicity, process development, and stability assessment). The preliminary assay format may be representative of the chosen target(s) in regard to the mechanism of action (MOA) involving binding/inhibition or may simply reflect an activity relating to a region of the molecule to demonstrate conformational integrity (proper protein folding). It is important to note that with Mabs where the target is generally defined by

Fig. 2 HPLC method development process and work flow.

Table 5 Some common HPLC methods, purpose, and starting method parameters

Method	*Purpose*	*Example method parameters*
SE-HPLC (size exclusion)	Separation of molecules is by size and shape. The chromatographic elution time is typically characteristic for a particular molecule. The purpose of SE-HPLC analysis is to assess the protein aggregation, dissociation of oligomers, and fragmentation	Tosoh SW3000 4.6 mm × 30 cm, 4 μm 0.2 M sodium phosphate, 0.1 M NaCl, pH 7.0; isocratic; 0.3 mL/min Sample diluted to 1 mg/mL in formulation buffer A280 detection
RP-HPLC (reversed phase)	Separation is based on hydrophobicity of the proteins and variants. The chromatographic elution time is typically characteristic for a particular molecule. The purpose of this method is to assess degradants and variants such as oxidation, disulfide forms, and amino acid misincorporation. The RP-HPLC method can also be used to determine expression titers in harvest samples	Zorbax 300 SB-C3 2.1 mm × 15 cm, 5 μm Acetonitrile/water 0–90% gradient with 0.1% TFA; 0.3–0.4 mL/min Sample diluted to 1 mg/mL in starting mobile phase A214 detection
IEX-HPLC (ion exchange)	Separation is by charge primarily through electrostatic interactions between amino acid side chains and the opposite surface charge of the ion-exchange resin. The purpose of IEX-HPLC analysis is to assess charge variants such as acetylation, methylation, sialylation, proteolytic cleavage, carboxylation, and deamidation	ProPac WCX-10 4.0 mm × 25 cm, 5 μm 0.02 M sodium phosphate, 0.0–0.8 M NaCl gradient, pH 6.0–7.0; 0.5 mL/min Sample diluted to 1–2 mg/mL in formulation buffer A280 detection
NP-HPLC (normal phase)	Determine N-linked oligosaccharide profile of glycoproteins such as Mab after deglycosylation using PNGase and glycan derivatization using 2-aminobenzoic acid (2AA). Separation is based on size, linkage, and structure, using high-to-low concentration acetonitrile	Tosoh TSKgel Amide-80 4.6 mm × 5 cm, 3 μm Acetonitrile/water 100–0.2% gradient with 0.2% TEA and acetic acid; 0.3–0.4 mL/min Remove deglycosylated protein after PNGase and 2AA by SPE; reconstitute dried extract in acetonitrile FLD detection, Ex 355 nm/Em 420 nm

the antigen-binding Fab region, the actual efficacy of the therapeutic in vivo may involve other regions of the molecule (such as the Fc for effector functions involving complement-dependent or antibody-dependent cytotoxicity). Further, while the primary efficacy end points for a chosen indication are generally chosen based on the in vitro activity, the actual MOA in vivo may not necessarily depend on such activity and could be more complex. This is just one of the many challenges sponsor companies face during product development.[10]

The main desired characteristics of a potency assay include representative biological activity that is quantitative and can be used in batch release; property that is stability-indicating and can measure significant loss of potency (preferably >10–15%), and assay consistency with controlled variability. It is typical to explore more than one potency assay initially. These may be concurrent and may represent orthogonal functions of the protein in vitro that may or may not have a direct correlation with the MOA in vivo. These surrogate assays are very useful to gaining an initial assessment of functional activity and typically accelerate the path to batch release and IND-enabling data package. As experience is gained in clinical development and further in-depth experiments are carried out to truly understand the MOA, the regulatory agencies expect development and validation of a meaningful cell-based potency assay at the time of licensure (BLA). Ideally, if there is good correlation between in vitro potency assay and in vivo efficacy, this really helps to define the therapeutic dose and frequency.

Some additional challenges and considerations while developing potency assays are controlling high assay variability (broad specification initially and tighten later), and establishing stability-indicating properties of the assay (using forced-degradation studies).

6.09.4 Method Qualification and Validation

The AFD team is usually responsible for prequalification of the product-specific analytical methods to demonstrate that they are fit for use. Prequalification generally involves assessment of precision (repeatability and variability expressed as % coefficient of variance), accuracy, and where they are intended to be quantitative methods, assessment of linearity, and LOD/LOQ. This subset of validation parameters (accuracy, repeatability and intermediate precision, reproducibility, linearity and range, specificity/selectivity, and robustness) are not evaluated in-depth during the initial R&D phase. However, it is highly advisable to perform some initial assessment of these parameters to achieve some consistency of the methods before venturing to transfer them to a CMO or CRO for method qualification. Qualification and validation terms are interchangeably and loosely used during development, without a full understanding of the differences. Qualification establishes that the assay design is confirmed as being capable of producing reproducible results suitable for the specified purpose, and typically involves evaluation of all validation parameters except robustness. **Table 6** describes the various validation parameters that are required for the different types of analytical methods. During validation, the assay is tested against specific acceptance criteria set in advance to verify that the performance characteristics of the method are suitable and reliable for the intended application. Robustness is generally determined during phase 3 clinical development at the time of method validation, whereas the earlier phases of development only require methods to be qualified for batch release and stability studies.[11] The design of qualification/validation protocols for the individual test methods have to be described and approved by QA, and the successful completion of such studies have to be documented in detailed qualification/validation reports including a summary of the acceptance criteria.

6.09.5 Specification

Once the methods are optimized and qualified, they can be routinely used to analyze samples from the downstream process purification steps to assess the purity and impurity profiles and gain an understanding of the step yields and purity at each unit operation during manufacturing. Initial acceptance criteria around the SISPQ attributes of the purified DS are set based on the process performance and generally targeting >90–95% purity by SE-HPLC, 75–85% by IEX-HPLC, and around 85–90% by RP/HIC-HPLC. As process improvements and optimization are performed (including final formulation selection), one can start to slowly tighten the specification, after some initial assessment of the formulation stability under storage and accelerated stability conditions (ICH Q6B). **Table 7** shows an example of DS and DP specification with release tests

Table 6 Qualification and validation parameters for different classes of analytical methods

Parameter	*Strength*	*Identity*	*Safety*	*Potency*	*Purity*
Accuracy	+	−	+	+	+
Linearity	+	−	+	+	+
Range	+	−	+	+	+
Specificity	+	+	+	+	+
Precision	+	+	+	+	+
Robustness	−	+	−	+	+

Table 7 Example drug substance and drug product specification for early-phase development

Analytical test	*Acceptance criteria*	*Drug substance/drug product*
Appearance	Clear to opalescent Colorless to slightly yellow solution Essentially free of visible particles/some particles may be observed	DS and DP
pH	pH x.x ± 0.3	DS and DP
Osmolality	300 ± 100 mOsmol/kg	DP, DS (optional)
Western Blot	Comparable to reference standard with an apparent MW of ~xx kDa for major band	DS and DP
SDS-PAGE	Comparable to reference standard with an apparent MW of ~xx kDa for major band	DS and DP
Peptide Map by HPLC	Comparable to reference standard	DS
A280 protein concentration	x.x ± 10% mg/mL	DS and DP
RP-HPLC	≥90.0% Main peak purity ≤10.0% Impurity	DS and DP
IEX-HPLC	≥80.0% Main peak purity ≤20.0% Total impurities ≤x.x% Any single impurity	DS and DP
SE-HPLC	≥95.0% Main peak purity ≤3.0% HMW ≤2.0% LMW	DS and DP
Residual DNA	≤0.1 ng/mg protein	DS
Residual HCP	≤100 ng/mg protein	DS
Residual endotoxin	≤1.0 EU/mL	DS and DP
Bioburden	TYMC and TAMC ≤ 10 CFU/10 mL	DS
Potency	x.x± 25% Units/mg	DS and DP
Sterility	No growth detected	DP
Particulate matter by light obscuration	≤600 particles/container for ≥25 μm particle size ≤6000 particles/container ≥10 μm particle size	DP
Extraction volume	x.x± 10% mL	DP

and acceptance criteria. It is important to consider the process capability, the requirements from WHO and regulatory guidance documents for the safety assays (including results from pilot PK and toxicity studies), and the overall stability of the protein and formulation while setting specification for phase 1 and 2 clinical development[12] Setting the specification too tight without adequate manufacturing experience and statistical analysis of process performance/robustness in regard to product purity and control of analytical method variability can lead to failing batches and financial and timeline consequences.

6.09.6 Reference Standard

With the methods qualified and specification defined, GMP batches of DS and DP can be released. Typically, batch release also requires an analytical reference standard[13] that has been derived from a representative manufacturing scale. The reference standard (RS) is qualified using a set of batch release assays defining product strength, identity, purity, and quality. Further, the RS is characterized using a comprehensive set of biochemical and biophysical characterization assays (described in the next section) to compile the primary, secondary, tertiary, and higher-order structure of the protein, along with posttranslational modifications (PTMs) and potency characteristics. This defines a framework of well-characterized RS that is stored under the most stable frozen condition (≤−80°C) to allow maximum shelf life and comparison to new lots of DS and DP that may undergo further process and manufacturing scale changes during the different phases of clinical development. Generally, the first RS is produced from an earlier prototype process development and is referred to as interim reference standard (IRS). Later, as the process is optimized for GMP manufacturing, a primary reference standard is derived from an engineering manufacturing-scale lot or the first GMP lot and aliquoted (1000s) in small containers for single use. The ICHQ7 guidance recommends a two-tier RS system through the development cycle. Essentially, what this means is that a primary RS is produced from a lot representative of the clinical trial material and is qualified. Subsequently, other working secondary reference standard may be used prepared from additional lots representative of the clinical trial material in order to save the primary RS and extend its use as long as possible. It is recommended to not change the primary reference standard as much as possible since it requires extensive testing and characterization to qualify against the original primary RS. If a new primary reference standard needs to be established due to significant manufacturing changes, qualification and appropriate bridging studies should be performed to migrate to using the new reference standard.

6.09.7 Biochemical and Biophysical Characterization and Comparability

The biochemical and biophysical characterization methods are the essence of a comprehensive understanding of the new molecular entity or therapeutic protein. While the purity methods and batch release data provide reasonable assurance that the drug meets the SISPQ requirements, it is the characterization methods that provide a broader picture about the structure of the molecule that allows a comprehensive description of the unique 1-D (protein sequence) to 3-D structural signature of the protein. Consequently, there is a regulatory requirement to perform detailed characterization of the protein and report the methods and the data in the IND package. The common characterization methods used,[14] the principle, and the intended purpose are shown in **Table 8**. Typically, not all of these characterization methods are available in a single laboratory, and it is quite common to utilize several different laboratories to complete the overall characterization.

Major advances in instrumentation, affordability, and standardized procedures have allowed routine use of LC–MS and LC–MS/MS methods to gain an in-depth characterization of the product-related impurities and heterogeneity[15] and help identify very-low-abundance impurities such as misincorporated amino acids and certain rare PTMs such as acetylation, methylation, and some unique clipped protein species. In combination with fraction collection of well-resolved impurity peaks by analytical and semipreparative HPLC columns, and if needed using 2-D LC approaches, it is possible to identify and characterize trace amount of impurities (0.5–1% of the main HPLC peak). LC-based peptide mapping fingerprints have become very common to use as routine identity methods that now replace the traditional Western blotting method. Generally, two identity methods are preferred, although with peptide mapping, it allows a very unique protein sequence signature that is highly specific to the protein of interest. LC–MS/MS methods are also becoming very popular in the identification of trace amounts of HCP due to the very high sensitivity, and the industry is moving toward complementing the ELISA-based HCP methods with mass spectrometry methods to better characterize and understand the risk with certain HCPs.

Certain methods such as analytical ultracentrifugation (AUC) are not readily available, and there are only a few established laboratories that perform this testing routinely, and one needs to plan and get the samples in the queue to enable a finished IND package. AUC is the gold standard for characterization of high-molecular-weight soluble aggregates by sedimentation velocity centrifugation and is the reference method to qualify the workhorse SE-HPLC method. Although very sensitive to detection of HMW > 0.1–0.2% (LOQ of the method), for high-concentration protein formulations, the samples have to be diluted in the formulation buffer, and hence the reversible aggregates are harder to quantify by AUC.

6.09.7.1 Comparability

Manufacturing changes are inherent and typically occur throughout process development. The drivers for these changes are generally optimization of the process to obtain higher yields and purity (including cell strain and upstream fermentation and downstream purification scale changes for larger supply of clinical trial material). The changes include manufacturing site changes associated with this, optimization of the downstream purification process to enhance purity and improve cost of goods for a commercial process, formulation changes including container/closure modifications to enhance stability and shelf life and change in storage temperature, and alternate dosage forms and DP presentations. Accordingly, the aim of the comparability studies is to evaluate the impact of these singular or multiple changes on the SISPQ of the DS and DP and gain an in-depth understanding of the differences between the pre-change and post-change product. The objectives and considerations of selection and interpretation of the battery of characterization tests to be performed to demonstrate equivalence of the product biologically, immunochemically, and pharmacologically, using highly sensitive analytical methods, are laid out in the ICH Q5E guidance.

Depending on the stage of clinical development and the extent of changes, the expectation from the regulatory agencies and the work load will increase, and the specific comparability protocols needs to be tailored, preferably with input from the FDA. During the earlier stages of manufacturing changes, it is common to conduct a precomparability assessment involving preliminary comparison of product quality attributes including biophysical comparison of representative batches of GMP DS from prechange and a batch of representative DS from the scaled-up post-change manufacturing process. This allows building confidence in the comparability between the process changes and performing characterization of any new or increased impurities using HPLC peak enrichment approaches. Side-by-side analysis of pre- and post-change batches are important to minimize minor differences of analytical results from day-to-day and system/analyst variability. The precomparability study is followed by GMP manufacturing using the new process and a more formal comparability assessment using both DS and DP batches from the old and new process.

Further, side-by-side forced-degradation and accelerated stability studies are instrumental in demonstrating comparability of the pre- and post-change product under stress conditions, which may be able to tease out the differences better than under nonstress studies. It is important to remember that comparability does not mean the product is identical but that "they are highly similar and the knowledge gained from comparability studies are sufficiently predictive to ensure any differences in quality attributes have no adverse impact upon safety or efficacy of the drug product." The selection and number of batches to be used for the comparability studies are important considerations and depending on the extent of changes involved (especially upstream in the manufacturing process) may warrant PK and PD studies in animals, and in some cases, perhaps, clinical PK and efficacy would be required as well.[16] Further, the breadth and stringency of analytical methods and biological studies required to demonstrate comparability of pre- and postchange commercially marketed products and to develop biosimilar products are indeed much higher.

Table 8 Common biochemical and biophysical characterization methods and description

Characterization method	*Principle*	*Purpose/output parameters*
Intact mass by electrospray ionization-time of flight mass spectrometry (ESI-TOF)	It is a high-throughput analytical method to determine molecular weights with high accuracy and high resolution. The main purpose of intact mass measurements is to ensure protein identity and to assess degradants and posttranslational modifications	Accurate mass under denaturing condition Disulfide status Qualitative assessment of minor and low abundance variants and degradants based on mass
Amino acid Analysis (AAA)	The protein is hydrolyzed by acid hydrolysis at 110°C, followed by precolumn derivatization using o-phthalaldehyde and 9-fluorenylmethyl chloroformate and separation on RP-HPLC with fluorescence detection	Amino acid composition Extinction Coefficient
Peptide mapping by LC-MS/MS	Proteins are digested using 1–3 different proteases such as trypsin, Lys-C, and Glu-C, and the peptides are separated by LC and/or LC-MS/MS methods	Fingerprint of all peptides from digest with distinct retention times Protein sequence coverage based on intact MS Disulfide mapping, PTM analysis, variants. and impurity characterization
Imaged capillary isoelectric focusing (icIEF)	icIEF separation is conducted by focusing isoforms in an ampholytic pH gradient through an applied electric field using capillary electrophoresis, followed by continuous UV detection of the whole capillary High resolution, efficiency, speed, reproducibility, and enhanced quantitation are the advantages over conventional CE	Isoelectric point Charge heterogeneity
High-pH anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD)	LC-based separation of negatively charged molecules is performed at very high pH with detection of nonderivitized and nonchromogenic glycans achieved through amperometric detection	Separation, identity, and quantitation of glycans, glycopeptides, monosaccharides, and sialic acid
Circular Dichroism (CD)	CD measures differences in absorbance between left and right circularly polarized light and hence asymmetrical properties of the chromophores, such as tryptophan, tyrosine, phenylalanine, disulfide, and peptide. Near UV CD determines the tertiary structure due to asymmetrical environments of tryptophan, tyrosine, phenylalanine, and disulfide. Far UV CD determines the secondary structure due to asymmetrical environments of peptide	Molar elipticity profile vs wavelength; spectral maxima and minima in the aromatic AA region for near UV, and at 210/222 nm for far UV CD spectra Secondary structural analysis and estimation of alpha helix, beta pleat, and rand coil structures
Differential scanning calorimetry (DSC)	DSC is a thermodynamic tool measuring the heat energy uptake that occurs in a protein sample with a regulated increase in temperature. Changes in the heat capacity result from the disruption of forces that stabilize the native protein structure. The thermal transition temperature ™ represents the midpoint of native and unfolded protein and is indicative of any conformational change	# of transitions and transition temperature (Tm) T onset of unfolding
SEC with multiangle light scattering (SEC-MALS)	The intensity of the radiated light depends on the magnitude of the dipole induced in the macromolecule detected by a refractive index detector and provides a measure of the molecular weight and hydrodynamic radius	Mw, weight averaged molar mass of each peak z-averaged mean square radius
Analytical ultracentrifugation (AUC)	Sedimentation velocity, measured in an analytical ultracentrifuge, is an absolute and gold standard method for obtaining information about the protein size, aggregation, association, and conformation. It is based on the principle of differential sedimentation velocity of varying sizes and conformation of proteins	Sedimentation coefficient (Svedberg) % purity based on size distribution

(Continued)

Table 8 Common biochemical and biophysical characterization methods and description—cont'd

Characterization method	*Principle*	*Purpose/output parameters*
Dynamic Light Scattering (DLS)	DLS measures the light scattering associated with Brownian motion and relates the intensity of scattering to the size of the particles defined by the Rayleigh approximation. Larger particles have slower motion and higher light scattering than smaller particles, and the intensity is proportional to the sixth power of hydrodynamic diameter	Particle size distribution, 1 nm–1 μm % polydispersity Z-average diameter in nm Diameter of individual particle populations
Micro flow Imaging (MFI)	MFI combines the direct imaging capabilities of digital microscopy with the precise control of microfluidics. Images of the sample are captured as it passes through the flow cell's sensing and analyzed by applying various filters to create a database of particle count, size, transparency, and morphology	Particle #/mL Particle size distribution 1–100 μm and statistics High-resolution images of particles showing morphology

6.09.8 Formulation Development

The formulation of an injectable protein DS or DP consists of the API, excipients including buffer, tonicity agent, and stabilizers, and the container/closure system. Additionally, in the case of advanced formulations such as sustained-release formulations, one or more constituents representing the delivery platform formulation or a medical device is also included. Further, for combination products, more than one API may be included along with constituent formulation matrix. The goal of formulation development is to ensure that a formulation when packaged in a specific container will remain within its physical, chemical, microbiological, therapeutic, and toxicological specifications until the assigned expiration date based on stability studies.[17] Additionally, the formulation development should strive to minimize the amount of impurities during storage and handling to mitigate safety/immunogenicity issues, demonstrate compatibility with components and stability during administration, evaluate dosage forms that are patient-friendly, and explore enhanced drug delivery approaches using various routes of administration to improve PK and PD parameters. The stages in formulation development include preformulation and forced-degradation studies, formulation optimization, and commercial formulation development. The various activities associated with these phases of formulation development are summarized in **Table 9**.

6.09.9 Preformulation and Forced Degradation

Since the major goal of formulation development is to assess the stability of the molecule, it is important to demonstrate the stability-indicating properties of the analytical methods and characterization methods in the toolbox used to assess formulation performance. Generally, since the protein to be formulated is obtained from either the discovery or downstream process development group, these personnel may have some understanding of the in-use stability of the protein under normal handling conditions (e.g., solubility, turbidity, activity, and some assessment of protein aggregation by SDS-PAGE and SE-HPLC). The formulation scientist should engage in discussions early during development with these groups and learn about the molecule behavior. An in-depth assessment of protein stability is accomplished by first mapping out the potential hot spots in the protein sequence from the protein sequence such as oxidation, deamidation, and proteolysis. Next, working with the analytical development scientists, a comprehensive forced-degradation study[18] is performed to evaluate and quantify the changes at various stress conditions including appropriate control conditions. The data from the forced-degradation study can then be compiled to generate a stress map that provides a quick reference tool to plan the formulation studies aimed at minimizing product degradation. An example of such a stress map is shown in **Fig. 3**. A simple depiction of the susceptibility (to various stresses) and severity (quantitation of impurities) of degradation using a three-color code provides a snapshot of the allowable boundaries during downstream purification, formulation, and the most stability-indicating methods to use in the toolbox for stability assessment and comparability.

It is important to know that during the early development, only small amounts of protein may be available for formulation work. Further, there is a lot of pressure from the preclinical group to quickly provide a "reasonably stable" formulation for pilot toxicity and PK/efficacy studies. So, good planning and collaboration are crucial at this stage to ensure there is sufficient protein available for analytical and formulation development while supporting the preclinical development at the same time and setting realistic expectations. The typical order of preformulation screening (**Table 10**) involves a range of buffers covering pH ranges generally between 4 and 8, with or without any tonicity modifiers; followed by screening of stabilizing excipients such as sodium chloride, sucrose, sorbitol (as stabilizers and tonicity modifiers); solubility assessment at a range of protein concentration without and

Table 9 Formulation development stages and key activities

Formulation stage	*Activities and points to consider*
Preformulation and forced degradation	Understanding physicochemical properties of API(s) Developing stability-indicating methods Estimating product's stability by forced-degradation study Dosage form (liquid, frozen, and lyophilized) and storage temperature decision based on stability and trend analysis Formulation parameters – Buffer – pH – Salt/sugars as tonicity modifiers and bulking agents – Cofactors – API concentration and solubility – Stabilizers (cryoprotectants, lyoprotectants, surfactants, antioxidants, chelators, preservatives, etc.)
Formulation optimization	Maximizing the stability of the API using DOE Evaluate various dosage forms, reconstitution, single- vs. multi-dose forms Dose range and frequency for clinical indication(s); fixed dose vs. variable dose Route of delivery, self-administration, patient's delivery capability, container/packaging, delivery devices Expiration target to cover the clinical trial duration and evaluation of allowable stability excursions Selection of API and excipient(s) sources and alternate vendors Container/closure compatibility and in-use (bed side) stability of clinical dose in infusion bags, lines, and rate of infusion
Commercial formulation development	Commercially feasible formulation that meets the TPP The final formulation should maintain the SISPQ attributes of the drug during all the shipping, handling, and uses specified on the label Commercial storage at Depots, labeling, cold-chain supply and distribution considerations Real-time stability with optimized manufacturing process lasting 1–2 years or more, with expiration target of $\geq$2 years Develop clinical experience with commercial formulation in pivotal clinical trials Container closure and delivery device/technology evaluation (e.g., pens, prefilled syringes, and depot formulations)

with different surfactants and concentrations of surfactants; and finally screening of additional stabilizers to minimize specific degradation pathways (aggregation, oxidation, deamidation, and proteolysis).

Early preformulation work does not need to be performed at high protein concentrations. At this stage, the intended indications and efficacious doses are also not known; so, it is difficult to target specific API concentration in the formulation. For early clinical development, an API concentration is chosen based on efficacy in animal models and the dosing range planned for toxicological studies. After gaining clinical experience from phase 2 safety and efficacy studies, further adjustments in the formulation protein concentration can be made, if necessary, along with evaluation of different fill volumes and presentations of DP to meet the specific patient indications.

For most proteins, it is common to initially develop a frozen liquid formulation for preclinical studies and phase 1/2 clinical trials. The intent is to stage the work and cut costs on in-depth formulation optimization for late stage and commercial formulation development. Also, at this early stage, without a full understanding of the formulation stability under shipping and handling conditions, it is convenient to ship materials between CMO, fill finish, clinical sites, and storage depot sites when the DP vials are frozen. However, it is prudent to evaluate the stability of the early prototype formulation under refrigerated storage condition for an extended period of time (1–2 years) to determine if the same formulation can be used later for a commercial formulation. If certain specific degradation products and higher content of these are observed, adjustments can be made to mitigate the instability (e.g., increasing antioxidants and/or combination with chelators). Additionally, a stability-data-driven decision can be made on committing to a liquid or lyophilized formulation for further development and optimization.

6.09.10 Formulation Optimization

After gaining reasonable experience with the phase 1 and early phase 2 formulation in clinical development, one can use the knowledge to fine-tune the strength, formulation stability, and dosage form to develop a commercial formulation that has extended shelf life and desired product quality and presentation attributes. The changes can vary and include increased protein concentration and fill volume, better buffering capacity, and finer adjustments of pH and excipient concentrations for most optimal formulation stability using design of experiments (DOE).

Stress Conditions	ANALYTICAL TOOLS										
	Visual	A280	A340	Non-Reduced SDS-PAGE	Reduced SDS-PAGE	SE-HPLC	IEX-HPLC	DLS	DSC	Intact mass	
Stability indication	Insoluble aggregates	Strength	Turbidity/ aggregates	Soluble covalent aggregates, fragmentation		Soluble Aggregation	Deamidation; fragmentation	Soluble Aggregates, particle size	Thermal stability, Tm	Chemical modification	Fragmentation
40°C; 1, 2 wk	No Change	No Change	No Change	No Change	No Change	HMW increase from 1% to 4%	No significant change	No change	No Change	No change	No change
pH 3, RT; 1-3d	No Change	No Change	No Change	Additional HMW & LMW bands detected	Additional LMW bands detected	Loss of main peak	No change	Slight increase in diameter	Drop in Tm by >10°C	No Change	fragmentation

Table 10 Formulation excipient categories and common excipient ranges

Excipient category	*Most common excipients*	*Typical ranges*
Buffers (pH 4–8)	Acetate, succinate, citrate, histidine, phosphate, tris	10–25 mM
Tonicity modifiers/cryoprotectants	Sucrose, sodium chloride, trehalose, sorbitol, and combinations	50–300 mM targeting ~300 mOsmol/kg
Bulking agents/lyoprotectants	Sucrose, trehalose, mannitol, glycine	3–5%
Stabilizers		
● Aggregation mitigator	Arginine, histidine	>0.2 M
● Antioxidants	Methionine, EDTA	1–10 mM
● Surfactants	Polysorbate 20 or 80	0.001–0.1%
● Cofactors	Zn, Ca, Mg	Low mM
● Preservative	*m*-Cresol, methylparaben, phenols	0.2–0.5%

Traditional, formulation development focuses on changing one factor at a time. This approach is based on varying one independent factor while keeping other independent factors constant. This approach intrinsically cannot detect interactions between factors and is very time consuming. In contrast, DOE takes into account all input variables simultaneously, systematically, and efficiently. Each single input variable and multivariable interaction can be evaluated, and their effect(s) on each response variable can be identified. The main steps involved in DOE studies[19] are the following:

1. Define the objective.
2. Define experimental factors (buffer type, pH, stabilizer(s), and concentration).
3. Select the design (full factorial, fractional factorial, center point, mixture design, etc.) and run the experiment, typically under accelerated stability conditions to tease out the differences between formulations.
4. Perform statistical analysis including ANOVA and interpret the significant factors that impact product stability using the software generated *p* values, *F* ratio, and desirability factor.

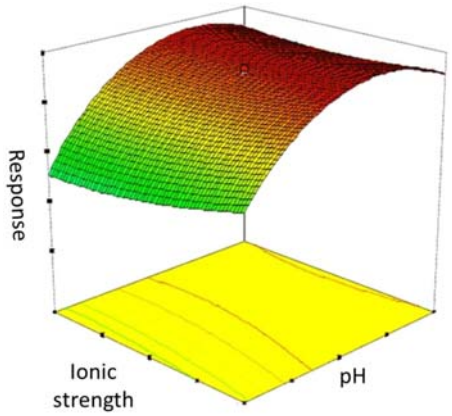

Fig. 4 Response surface DOE showing impact of varying ionic strength and pH on measured response.

5. Choose a model and fit the data to determine correlation. This is then followed by fine-tuning and confirming the statistical model.

A 3-D plot showing the effect of pH and ionic strength to maximize the optimal formulation parameters is shown in Fig. 4. Using a response surface DOE study, the impact of the individual factors affecting the purity and stability of the formulation can be assessed under various stress conditions, and optimal ranges of these parameters can be adapted during the manufacturing process to establish the final most optimal formulation. In the example shown in the figure, both higher pH and ionic strength have a positive impact on the desired response, and a combination of midrange of pH and ionic strength seems to yield the highest desirability.

DOE studies are especially very helpful when the effect of many factors to optimize the formulation needs to be studied. For example, to develop combination DPs involving more than one API/DS, several excipients and stabilizers that are important for rendering the stability to the individual API formulations will need to be tested in combination, and the type and concentrations of these components will need to be balanced using DOE experiments.

6.09.11 Lyophilized Drug Product Development

If the API is inherently unstable (e.g., most antibody–drug conjugates and proteolytic enzymes), then effort is focused on developing a lyophilized formulation early during development. It generally takes additional time to screen several excipients and develop an optimized lyophilization cycle, as well as develop additional methods to characterize, evaluate a reconstitution procedure, and establish in-use stability of the reconstituted product. The different steps involved in the development of a lyophilized formulation[20] are summarized in the succeeding text:

1. Screen combination of lyoprotectants (bulking agents such as mannitol and glycine) and cryoprotectants (sucrose and trehalose) and other stabilizers that are compatible in the liquid DS formulation prior to lyophilization.
2. Preliminary assessment of "lyophilizability" using a conservative lyophilization cycle in a pilot lyophilizer.
3. Determining Tg'/collapse temperature of liquid formulation to enable choice of shelf temperature below this temperature to prevent collapse of the DP freeze concentrate and evolving cake.
4. Cycle optimization including temperature ramp and annealing during freezing (if required), primary and secondary drying steps. Assessment of requirement of N_2 versus argon gas overlay and headspace measurement.
5. Long-term stability and characterization including Tg analysis of the dried lyophilized formulation for appropriate storage condition (refrigerated or room temperature) of lyophilized product. Accelerated stability assessment utilizing cake appearance, reconstitution time, moisture content, and product-specific stability-indicating purity/impurity methods.
6. Effect of high osmolality and development of a reconstitution strategy for high-concentration protein formulations.
7. Tech transfer of optimized lyophilization cycle to CMO for production scale lyophilizer, applying appropriate geometric calculations and freeze/dry parameters, and fine-tuning.

Fig. 5 shows an illustration of the lyophilization cycle in the upper panel involving the following steps:

(a) Freezing of the liquid DS (ice crystal growth and solidification of the amorphous or crystalline cryoprotectant/bulking agent that may also need an annealing step)
(b) Primary drying under vacuum where the majority of the water is removed by sublimation
(c) Secondary drying at elevated temperature to remove the adsorbed water vapor
(d) Back filling of the chamber with N_2 gas and stoppering of the vials

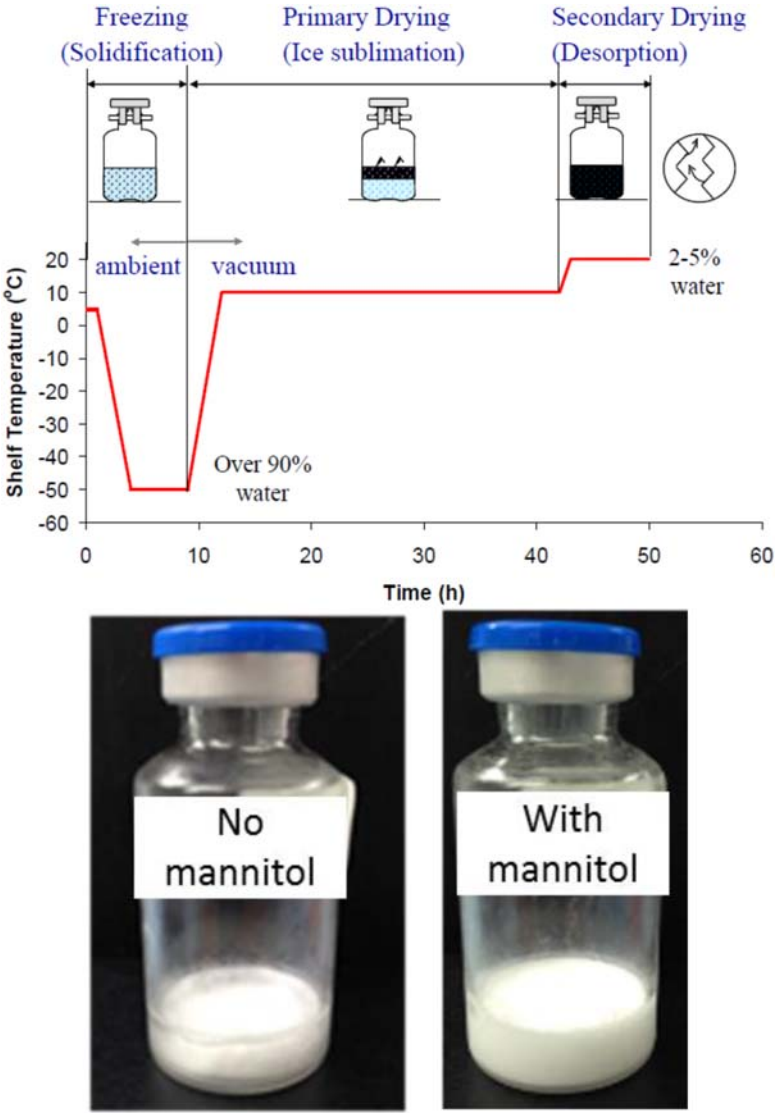

Fig. 5 Lyophilization process (with permission from Samir Sane, Genentech) and cake appearance of formulation without (microcollapsed cake) and with bulking agent (elegant cake).

Typical cycle times involve about 2–3 days for most protein formulations. Cycle times can vary depending on whether an annealing step is required due to the need to include bulking agents such as mannitol and how much water can be tolerated in the final formulation. Cycle optimization can be significantly accelerated and enhanced in some pilot lyophilizers such as LyoStar II using the SMART computerized system. The SMART technology constantly monitors the product temperature using thermal probes and, with a data feedback loop, controls the shelf temperature under a constant vacuum during the primary drying phase in the cycle to minimize cycle times in a single run. Further, secondary drying times can be monitored by using a sample thief to retrieve vials during the run to perform moisture analysis. Formulations that contain some sodium chloride can significantly benefit by the inclusion of mannitol that yields elegant cakes that are more stable and resistant to micro collapse (Fig. 5, lower panel).

For the intended purpose of covering general formulation strategies for biologics, it is not possible to discuss development of specialized formulations such a very high-protein-concentration formulations for certain Mabs and the design and use of sustained-release formulations, drug delivery, and drug/device combinations.[1]

6.09.12 Stability Studies and Expiration Dating

Early preformulation, forced-degradation, and accelerated stability studies provide a comprehensive assessment of the robustness of the formulation and allow a best guess of the long-term stability of the protein formulation. For small molecule and even some

Table 11 ICH stability guidance documents

ICH guidance	*Scope*	*Description*
Q1A	Stability testing of new drug substance and products	General guidance on stability studies involving selection of batches, stress conditions for accelerated testing, long-term testing, testing frequency, acceptance criteria, and evaluation of results
Q1B	Photostability	Photostability guidance covering testing of DS and DP, including controls, in primary and secondary packaging and the final marketing packaging, involving visible and UV light together (option 1) or preferable separately (option 2), and the work flow path
Q1D	Bracketing and matrix design	General principles for reduced stability testing and provides examples of bracketing and matrixing designs
Q1E	Evaluation of stability data	This document extends the main guideline by explaining possible situations where extrapolation of retest periods/shelf lives beyond the real-time data may be appropriate. Furthermore, it provides examples of statistical approaches to stability-data analysis
Q5C	Stability testing of biotechnological/ biological products	This document augments the stability guideline Q1A and deals with the particular aspects of stability test procedures needed to take account of the special characteristics of products in which the active components are typically proteins and/or polypeptides

short peptide APIs, the degradation pathways can be linear with increasing temperature and allow prediction of long-term stability by Arrhenius transformation and extrapolation of shelf life. However, for large proteins, it is generally very difficult to predict the stability of the formulation due to multiple degradation pathways that do not trend linearly in Arrhenius plots and in some cases plateau after some time under accelerated conditions. Hence, real-time stability studies are required to obtain realistic shelf life assessment. Table 11 summarizes the various ICH guidance documents describing the conduct of the stability studies, and Table 12 shows an example of the storage conditions for long-term and accelerated stability study along with the testing frequency.

For the long-term and accelerated stability studies, appropriate stability-indicating methods should be chosen from the panel of release assays including potency assay, to determine the qualitative and quantitative changes during storage. It is important to use qualified stability chambers and qualified assays for this purpose to minimize the assay variability and truly determine the impact of storage conditions on the product. Stability studies are performed using QA-approved stability protocols and are typically performed by QC personnel that are trained in the staging, monitoring, and administration of the analytical methods. The protocol should clearly specify the batch to be used, the container/closure used, configuration of vial staging (upright, sideways, or inverted), the conditions and time points, number of retain containers, and the analytical testing panel. Further, documentation, reporting, trending, and handling of any deviations, out-of-specification (OOS), and out-of-trend (OOT) results should also be captured in the protocol and investigated if there are atypical results.

In addition to the storage condition and accelerated stability studies on both DS and DP, bulk freeze/thaw study on DS that is representative of the container scale used for long-term cold-chain storage and photostability studies on the DP in its primary packaging and secondary packaging should be performed. It is also important to plan appropriate and timely audits of the QC and GMP stability labs, as well as any third-party analytical CRO, and depot storage/labeling service organizations that would be engaged in the storage, shipment, and conduct of stability studies. The Q1E guidance describes how the stability data are evaluated and trended to conservatively project shelf life of the product based on real-time and long-term stability data. While projections can be used as a general guide, stability commitment to continue the studies has to be made to accumulate real-time stability data to compare against the projected expiration date. In the early phases of development, it is typical to have retests performed at regular intervals as part of the stability study and to extend the expiration dating based on the results.

Process development typically involves hold-time stability studies to be performed during the downstream purification steps. In addition to these handling conditions, at later stages of development, appropriate storage, shipping, and distribution stability studies have to be performed to be compliant with USP<1079> good storage and distribution practices. After a comprehensive map of stability study data is obtained, one can use this database of stability knowledge to determine any excursions that may occur through the life cycle of the product lot.[21]

An example of how this can be used to determine impactful events (such as a temperature excursion at a certain elevated temperature) outside of the tested stability studies is shown in Fig. 6. In this example, the excursion at 32°C after 1 week would be questionable in regard to the use of the DP outside of the tested time intervals.

Table 12 Key stability conditions and testing frequency for a refrigerated drug product

	Interval (months)								
Storage conditions	0	1M	3M	6M	9M	12M	18M	24M	36M

25°C/65%RH (Accelerated)		X	X	X					

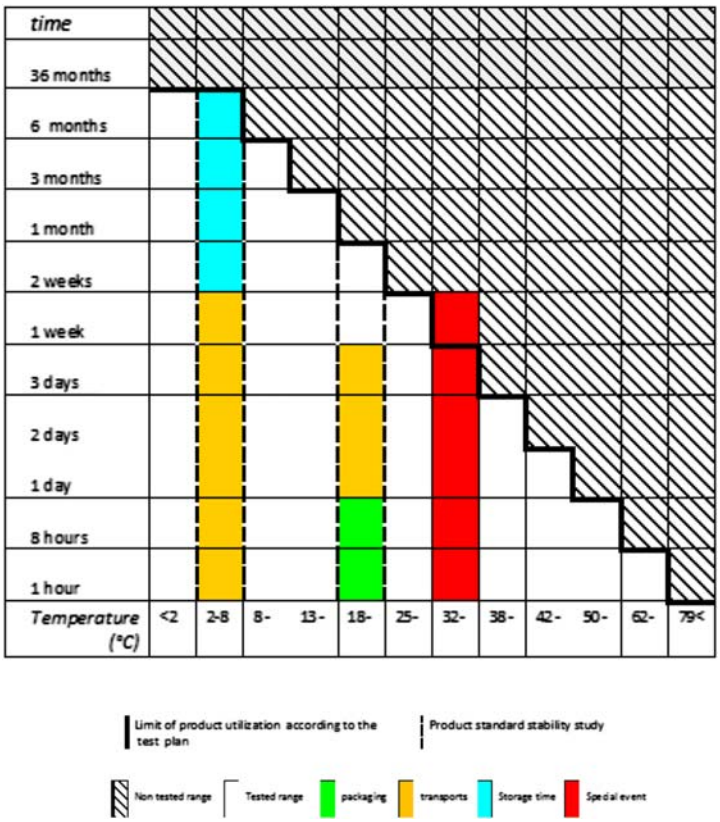

Fig. 6 Depiction of how the stability knowledge can be used to determine impact of excursion with permission from Claude Ammann.[21]

6.09.12.1 Clinical In-Use Stability Studies

In addition to the stability studies of DS and DP in their storage containers, clinical in-use stability studies should be performed to evaluate and establish guidelines of handling during drug dose solution preparation and administration to patients in the pharmacy manual. Intravenous infusion is a common route of delivery for therapeutic monoclonal antibody drug products and many are administered as a continuous infusion at room temperature upon dilution into a carrier solution, usually 0.9% sodium chloride and in some cases 5% dextrose. Compatibility of the diluted DP in infusion bags with contact materials such as polyvinylchloride (PVC) and polyolefin (PO), as well as associated infusion lines, syringes, and needles should all be considered and evaluated in an in-use study. Further, stability testing of lyophilized DPs after reconstitution or dilution, if applicable, should be conducted to provide information for the labeling on the preparation, storage condition, and in-use period of the reconstituted or diluted product. ICH Q1A(R2) and USP<795> pharmaceutical compounding guidelines recommend that this testing be performed on the reconstituted or diluted product through the proposed in-use period, typically up to 24 or 48 h.[22]

6.09.12.2 Extractable and Leachable Studies

During later stages of development, extractable and leachable studies[23] should also be performed with product contact materials that are used during various unit operations of manufacturing, to determine the type and level of impurities that may impact safety of the DP (USP<1663> and USP<1664>). Extractables represent chemicals that are extracted from a product contact material when exposed to a solvent under exaggerated conditions of time and temperature; and leachables are substances that migrate from the containers and closures in to the formulation under accelerated storage conditions. These compounds are generally additives in the container/closure and product contact process materials and include elastomers, fillers, antioxidants, lubricants, stabilizers, and coloring agents. Sources of leachables include storage containers, delivery devices such as syringes, IV bags and tubing, manufacturing equipment, and potentially secondary packaging components as well. These compounds may potentially interact with DP or excipients and cause inactivation and conformational changes of posttranslational modifications that may impact safety and potency of the DP. The extractable and leachable studies are usually performed after the process is optimized. For the earlier clinical development phases, generally, obtaining a list of extractable (LOE) substances from the various vendors of materials is sufficient for assessment of a worst-case scenario. A risk-based assessment on the toxicity of these components in relation to the

drug dose administered is needed to develop and validate analytical methods specific for these contaminants that allow establishment of safety thresholds and assurance.

6.09.13 Conclusions

Overall, analytical and formulation development of biologics play a prominent and significant role in manufacturing, release of batches, and stability of the DS and DP. There is considerable amount of overlap and interdisciplinary activities within process sciences and AFD. Efficient strategy, planning, organization, and highly disciplined and GMP-compliant execution of development, qualification, and routine testing are necessary to build quality by design (QbD) into the manufacturing process and the DP throughout its life cycle.

6.10.1 Introduction to the Medicinal Chemistry of Antisense Oligonucleotides

6.10.1.1 What Are Antisense Oligonucleotides?

Oligonucleotide-based drugs are a new class of therapeutics undergoing clinical trials worldwide to assess their ability to target severe diseases and diseases with no current means of treatment.[1–4] This article will provide an overview of the medicinal chemistry of antisense oligonucleotides (ASOs), a family of intensively investigated and evolving oligonucleotide-based drugs. ASOs are single-stranded oligonucleotides whose sequences are complementary to the intended target RNAs. The target RNA can be of any type, including mRNA, pre-mRNA, and microRNA.[2] ASOs can change the splicing pattern of target pre-mRNA by steric blocking of the spliceosome or inhibit the function of the target RNA. The function of the target RNA can be inhibited by two major mechanisms. One is steric blockage, the approach used by anti-microRNA ASOs, and the other is cleavage of the target RNA with RNase H1, which recognizes DNA/RNA heteroduplexes and exclusively cleaves the RNA strand (**Fig. 1**). Two ASO drugs, fomivirsen sodium and mipomersen sodium, have been approved by the FDA to date. Fomivirsen sodium targets the transcripts of the major immediate early region 2 (IE2) of human cytomegalovirus (HCMV) and is indicated for the local treatment of HCMV retinitis, whereas mipomersen sodium targets apoB mRNA and is indicated for patients with homozygous familial hypercholesterolemia as an adjunct to lipid-lowering medications and diet.[5,6]

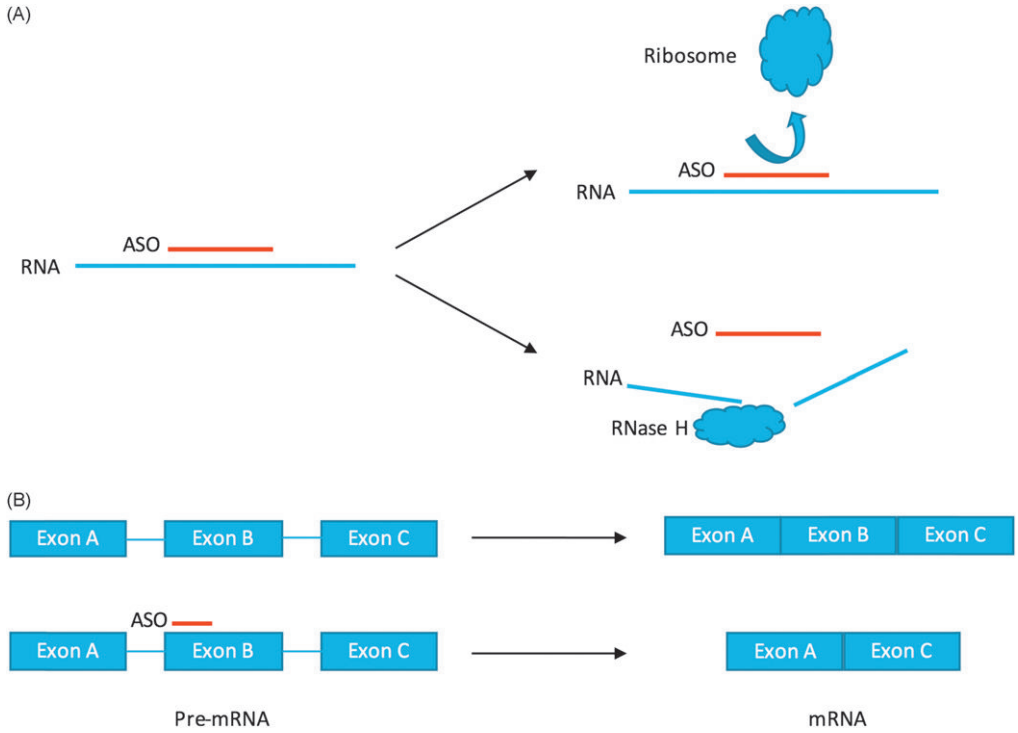

Fig. 1 Mechanisms of action of ASOs. Steric-blocking ASO (A, *upper*), RNase H-recruiting ASO (A, *lower*), and splice-switching ASO (B).

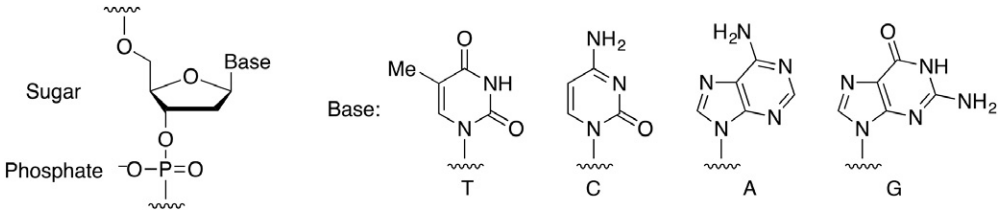

Fig. 2 Chemical structure of DNA.

6.10.1.2 Chemical and Medicinal Chemistry Properties of ASOs

Oligonucleotides are chemically composed of three units: nucleobases, sugars, and phosphodiester backbone (Fig. 2). Each unit comprises many heteroatoms and hydrogen-bonding donors and acceptors. The phosphodiester backbone is strongly acidic, and thus, ASOs are typically synthesized as the sodium salt. ASOs are highly hydrophilic and ionic in nature, and their oral bioavailability is generally very low,[7] thus limiting the route of administration to subcutaneous, intravenous, or local administration (such as intrathecal or intravitreous injection).[4]

A large body of information is accumulated during the discovery process of small-molecule drugs, such as molecular size, lipophilicity, shape, hydrogen-bonding properties, and polarity, and these characteristics are correlated to solubility, membrane permeability, metabolic stability, receptor promiscuity, in vivo toxicity, and chemical stability.[8–10] ASOs are chemically synthesized and are highly chemically modified, so they share some common features with small-molecule drugs. However, due to their unique physicochemical properties and mechanism of action and their unusual drug metabolism, the medicinal chemistry approach taken with ASOs is also rather different from that of small-molecule drugs (Table 1).

Medicinal chemistry studies of ASOs have focused on overcoming the shortcomings of natural DNA and/or RNA oligonucleotides as therapeutics, namely, (i) extreme lability toward nucleases, which makes their in vivo half-lives very short; (ii) limited binding affinity toward the target RNA; and (iii) the lack of ability to distribute to the target organ and/or tissue, thus requiring appropriate drug delivery technologies.

There are two major medicinal chemistry approaches for ASOs, as described in detail in the succeeding text. One is to develop an optimal chemical unit for oligonucleotides, which is what we call "unit chemistry". Examples include the development of a new nucleoside monomer or a new analog for the phosphodiester linkage. The other approach is to choose the best combination of unit chemistries and to optimize the total molecular properties of ASOs such as length, lipophilicity, gap size (required to support

Table 1 Properties of small-molecule drugs and antisense oligonucleotides

	Small-molecule drugs	*Antisense oligonucleotides*
Manufacturing	Chemical	Chemical
Medicinal chemistry	Applicable	Applicable
Molecular weight	~500	~5000
Electric charges	0~±2	Polyanion
Mechanism of action	Bind to protein (3-D structure-specific)	Bind to RNA (sequence-specific)
Root of administration	Oral (if appropriate)	Injection (low oral bioavailability)

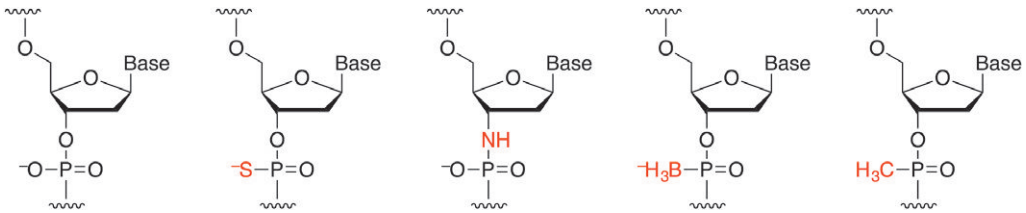

Fig. 3 Examples of phosphate backbone modifications.[18]

an RNase H1-based mechanism of action), and target-binding affinity. These two approaches together have recently significantly improved the stability and potency of ASOs in vivo, but at the same time, new problems have become apparent. For example, some ASOs that recruit RNase H1 activity due to high-affinity modifications (such as locked nucleic acid (LNA)) may cause hepatotoxicity[11–15] and induce significant knockdown of nontargeted RNA; this is called hybridization-dependent off-target effects.[15–17] In light of these recent findings, background information and recent developments toward high-affinity modifications will be discussed in this article, in conjunction with a discussion of the chemical approaches well combined with such high-affinity modifications. The two medicinal chemistry approaches used to develop ASOs will be reviewed from multiple viewpoints, including nuclease resistance, target-binding affinity and potency, absorption, distribution, metabolism and excretion (ADME), target specificity, and safety.

6.10.2 Improvement in Nuclease Resistance

6.10.2.1 Backbone Modifications

Natural oligonucleotides are rapidly degraded in vivo due to the hydrolysis of phosphodiester linkages by nucleases. Consequently, one of the first examples of the chemical modification of ASOs was of the phosphodiester backbone[18] (Fig. 3). The most successful modification of the many reported to date is the replacement of a nonbridging oxygen with sulfur.[19–21] This modification is called a phosphorothioate, and it dramatically improves the stability of ASOs in vitro and in vivo.[21,22] In addition to high nuclease resistance, plasma proteins bind rapidly to phosphorothioated ASOs, enabling the ASOs to escape renal filtration, and thus distribute to the targeted tissues and enter the target cells.[22,23] Another backbone modification found in candidate ASOs in clinical development is the phosphorodiamidate linkage in morpholino oligonucleotides (Fig. 4). This modification provides almost complete nuclease resistance, but in contrast to phosphorothioated ASOs, the plasma protein binding rate of morpholino oligonucleotides is low, limiting their pharmacokinetic profiles.[22] Thus, most ASOs in clinical use or in clinical development are phosphorothioates.

The replacement of one of the two nonbridging oxygen atoms by sulfur introduces chirality at the phosphorous atom of phosphorothioated ASOs (Fig. 5). Most phosphorothioated ASOs currently in clinical use are mixtures of all the possible diastereomers originating from the phosphorothioate linkage (2^{n-1} diastereomers).[24] The chirality of phosphorothioate affects resistance toward hydrolysis by nucleases and other properties of ASOs, as we discuss later in this article.

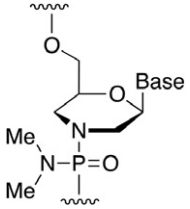

Fig. 4 Chemical structure of morpholino oligonucleotide.

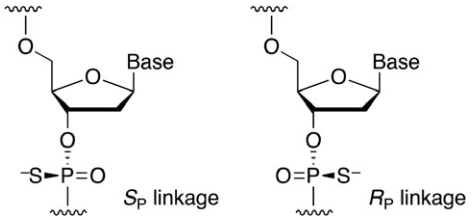

Fig. 5 Stereochemistry of phosphorothioate.

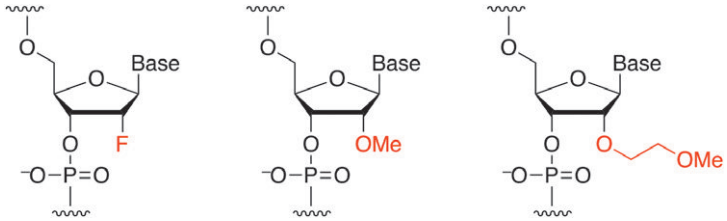

Fig. 6 Examples of 2′ modifications.[25]

6.10.2.2 Sugar Modifications

Another approach for resisting nuclease degradation is to modify the sugar units of oligonucleotides. Most oligonucleotides containing nucleosides with modified sugars exhibit higher nuclease resistance than oligonucleotides composed of natural nucleosides.[25]

The most traditional sugar modification is the introduction of a substituent at the 2′-position, for example, 2′-F, 2′-OMe, or one of the best known 2′-modified nucleoside, 2′-*O*-methoxyethyl (MOE) (Fig. 6). Generally, larger substituents provide higher nuclease resistance.[25] On the other hand, sugar modifications greatly affect target-binding affinity, with larger substituents in particular often decreasing affinity, yet both nuclease resistance and target-binding affinity should be high to achieve good in vivo efficacy. 2′-*O*-MOE achieves this, and this modification is present in the FDA-approved ASO mipomersen sodium, the first approved systemic ASO to enter the world market.[6,26–28]

A newer type of sugar modification is found in bridged nucleic acids (BNAs). BNAs have a bicyclic sugar moiety, and the sugar is locked into the $C_{3'}$-*endo* conformation[29–32] (Fig. 7); consequently, BNAs exhibit extremely high target RNA-binding affinity and also show significantly higher nuclease resistance compared with natural oligonucleotides.[30] Based on BNAs reported to date, a larger ring size or the introduction of additional substituents on the bridging moiety results in higher nuclease resistance. Examples of BNAs exhibiting these characteristics are provided next.

6.10.2.2.1 Ring size

ENA and PrNA are analogs of LNA in which the methylene bridge of LNA (a five-membered ring) is enhanced to ethylene (a six-membered ring) and propylene (a seven-membered ring), respectively[33,34] (Fig. 8). The nuclease resistance of ENA and PrNA toward 3′ exonuclease (snake venom phosphodiesterase) was tested. Under conditions where oligonucleotide containing a LNA was completely degraded within a few minutes, the half-life of oligonucleotides containing a single ENA residue was ~15 min, while approximately 70% of oligonucleotides with a single PrNA residue remained intact even after 90 min of incubation.

6.10.2.2.2 Bulkiness of the substituent on the bridging moiety

*scp*BNA has a cyclopropane ring at the 6′-position of LNA[35] (Fig. 9). The effect of this additional substituent on resistance toward 3′ exonuclease (snake venom phosphodiesterase) was evaluated. Under conditions where the natural oligonucleotide and oligonucleotides with a single LNA residue were digested in 5 and 20 min, respectively, over 50% of oligonucleotides with a scpBNA residue remained intact after 80 min.

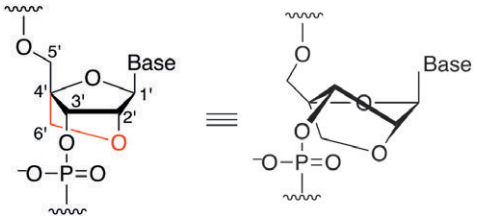

Fig. 7 Chemical structure and conformation of LNA.

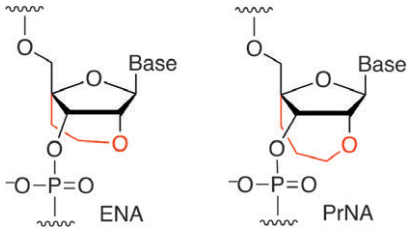

Fig. 8 Chemical structures of ENA and PrNA.

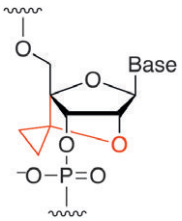

Fig. 9 Chemical structure of scpBNA.

6.10.3 Improvement in Target-Binding Affinity and Potency

Poor target-binding affinity of ASOs will likely limit their potency, so it is clear that improving target-binding affinity is essential for achieving highly potent ASOs.

Target-binding affinity is affected by many factors. For example, sequence context affects target-binding affinity because it defines the total number of hydrogen bonds and stacking interactions of the ASO–RNA duplex. Thus, longer ASOs or ASOs with higher G/C content tend to exhibit stronger in vitro target-binding affinity.

Although stronger target-binding affinity is generally considered advantageous, we recently obtained evidence that extraordinarily high affinity markedly decreases in vitro and in vivo potency for reasons that may depend on the mode of action of the ASO, as discussed later. These observations indicate that target-binding affinity is one parameter affecting potency, but optimization of all the molecular attributes is important to realizing a good lead ASO. Although improved target-binding affinity has provided highly potent ASOs, in vitro affinity as assessed by T_m is just one of the important parameters affecting the utility of ASOs.

6.10.3.1 Sugar Modifications and Bridged Nucleic Acids (BNAs)

Sugar modification impacts the target-binding affinity of ASOs, likely by affecting the sugar conformation. For example, introduction of an electron-withdrawing substituent at the 2′-position of DNA such as 2′-F, 2′-OMe, or 2′-*O*-MOE favors the $C_{3'}$-*endo* conformation due to the gauche effect. This RNA-type sugar conformation improves the affinity of the ASO toward the target RNA.[1,25]

A significant improvement in the target-binding affinity was achieved in 1997 when our group first reported the synthesis of 2′,4′-BNA, also known as LNA.[29–32] LNA has a 2′-*O*,4′-*C*-methylene bridge, and the sugar is locked into the $C_{3'}$-*endo* conformation (Fig. 7). Introduction of the 2′-*O*,4′-*C*-methylene bridge dramatically increases the hybridization affinity of ASO toward the target RNA. Swayze et al. compared the potency of ASOs containing LNA with those containing 2′-*O*-MOE[11] and showed that the LNA modification radically increased the binding affinity, resulting in about five times higher in vivo antisense potency.

This finding by Swayze and coworkers stimulated significant effort to develop analogs of LNA. In the succeeding text, we discuss LNA and its analogs (BNAs), because they are the most important sugar modifications found in current ASOs.

6.10.3.1.1 LNA, alkyl LNAs, and their isomers

6.10.3.1.1.1 LNA

LNA was the first nucleoside analog synthesized with its sugar locked into the $C_{3'}$-*endo* conformation. This analog exhibits significantly increased target-binding affinity (ΔT_m/modification = approximately +5°C compared with natural DNA).[30–32]

6.10.3.1.1.2 Ring-expanded LNAs

As mentioned earlier, ENA and PrNA are homologues of LNA in which the five-membered methylene bridge of LNA is enhanced to ethylene (a six-membered ring) and propylene (a seven-membered ring), respectively (Fig. 8). Compared with LNA, ENA exhibits slightly decreased target-binding affinity (ΔT_m/modification = approximately +3.5°C compared with natural DNA),[33,34] whereas PrNA shows decreased target-binding affinity that is similar to that of natural DNA

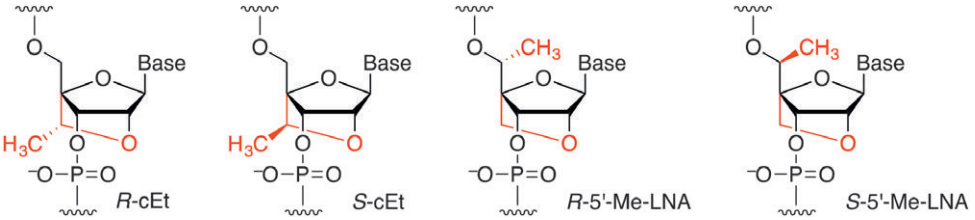

Fig. 10 Chemical structures of cEts and 5′-Me-LNAs.

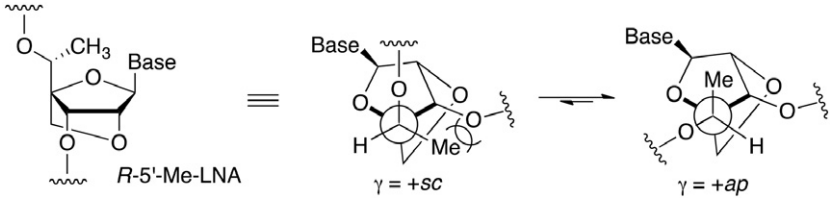

Fig. 11 Conformational change induced by *R*-5′-Me group.

(ΔT_m/modification = approximately $-0.5°C$).[33,34] The lack of increased binding affinity of PrNA is likely due to steric hindrance caused by the large ring.

6.10.3.1.1.3 Alkyl LNAs

cEt, 5′-Me-LNA, and scpBNA are five-membered ring BNAs (Figs. 9 and 10). cEt and 5′-Me-LNA are isomers of ENA and have a methyl group on the bridging carbon (6′-position) or 5′ carbon of LNA, respectively. scpBNA has a cyclopropane ring at the 6′-position. Except for *R*-5′-Me-LNA, these additional modifications to LNA had minimum effect on target-binding affinity; thus, their ΔT_m/modification values were comparable to that of LNA.[35–37] The 5′-Me group of *R*-5′-Me-LNA is believed to induce an unfavorable change in the γ torsion angle due to steric repulsion, leading to a lower binding affinity (ΔT_m/modification ≈ 5°C for *S*-5′-Me-LNA, cEt, scpBNA, and LNA, $\approx -1 \sim +3°C$)[37] (Fig. 11).

6.10.3.1.1.4 Antisense potency of ASOs containing LNA, alkyl LNAs, or their isomers

The higher binding affinity of LNA compared with that achieved by conventional modifications, for example, 2′-*O*-MOE, significantly increased in vitro and in vivo antisense efficacy. The ED_{50} values in the mouse liver of ASOs targeting TNFRSF1A-associated via death domain (TRADD) mRNA were as low as 2 mg kg^{-1} for LNA ASOs and approximately 9 mg kg^{-1} for MOE ASOs.[11] Furthermore, although the target-binding affinities of ASOs containing *R*-cEt or *S*-cEt were similar, in vitro and in vivo antisense efficacies were significantly stronger for ASOs containing *S*-cEt.[36]

Despite the target-binding affinities of LNA analogs being comparable to that of LNA, ASOs with LNA typically exhibit lower in vivo ED_{50} values than do ASOs containing LNA analogs.[36,37]

Modification with LNA seems effective also for antisense-mediated modulation of pre-mRNA splicing. Designed appropriately, 15-mer ASOs containing LNA induced significant amount of exon-skipped mRNA, while ASOs with 2′-OMe-RNA showed exon-skipping activity no higher than no treatment control under the same conditions in vitro.[38]

6.10.3.1.2 Replacement of oxygen with carbon

CarbaLNA and methylene-cLNA are two examples of LNA analogs in which the bridging oxygen in LNA is replaced with carbon (Fig. 12).

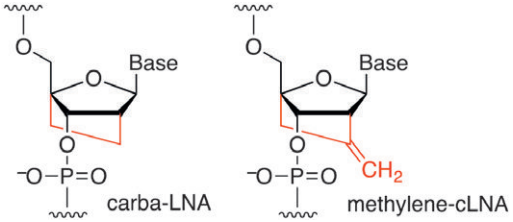

Fig. 12 Chemical structures of carbaLNA and methylene-cLNA.

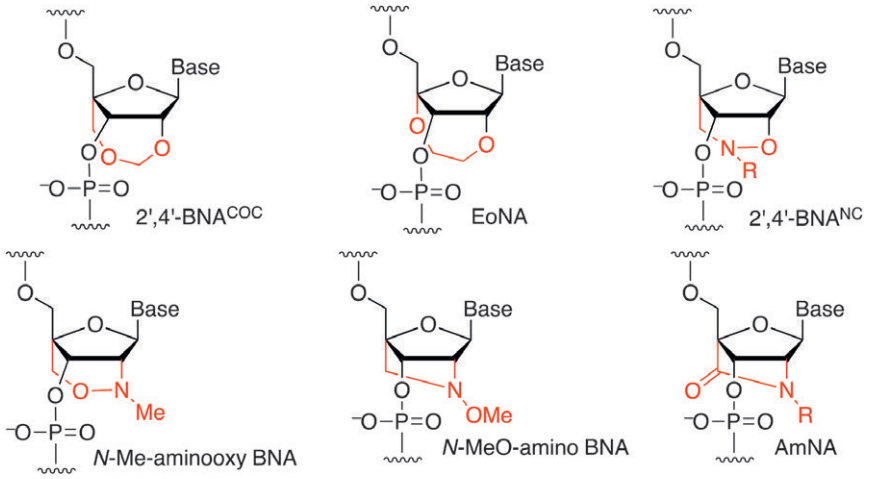

Fig. 13 Chemical structures of 2′,4′-BNA^{COC}, EoNA, 2′,4′-BNA^{NC} and its isomers, and AmNA.

A methylene linkage replaces this oxygen in carbaLNA; this modification slightly attenuates the target-binding affinity compared with LNA (ΔT_m/modification = approximately +3.6°C for carbaLNA vs. +4.5°C for LNA).[39]

In methylene-cLNA, an exomethylene replaces the bridging oxygen. Oligonucleotides with this modification exhibit similar or slightly improved target-binding affinity compared with oligonucleotides with LNA (ΔT_m/modification = approximately +4.8°C to +7.1°C for methylene-cLNA vs. +4.5°C to +6.1°C for LNA).[40]

The crystal structure of methylene-cLNA indicates that the edge of the exomethylene can form a hydrogen bond. Hydration of the duplex is believed to be important for its thermal stability. Therefore, the ability of methylene-cLNA to form a hydrogen bond and the inability of carbaLNA to hydrogen bond may explain their increased and decreased target-binding affinity compared with LNA, respectively.[40]

The in vitro and in vivo antisense potencies of 14-mers and 18-mers of methylene-cLNA ASOs and LNA ASOs targeting mouse *PTEN* mRNA were compared. 14-Mer LNA ASO showed the lowest in vitro IC_{50} and in vivo ED_{50} values (2.8 μM and 3.5 mg kg^{-1}, respectively) of the analogs tested, while the 14-mer methylene-cLNA showed only slightly lower antisense potency (IC_{50} and ED_{50} values of 3.9 μM and 4.9 mg kg^{-1}, respectively). Methylene-cLNA may therefore be considered to be a bioisostere of LNA.[40]

6.10.3.1.3 Introduction of heteroatoms into the bridge

The hydration of the duplex is very important, and thus, the effects of introducing heteroatoms into the bridge structure are of great interest. In the succeeding text, we describe several examples of BNAs containing multiple heteroatoms in the bridge structure (Fig. 13).

6.10.3.1.3.1 2′,4′-BNA^{COC}

2′,4′-BNA^{COC} contains a methylenoxymethylene bridge structure[41,42] and can be considered as an analog of PrNA, with an oxygen atom replacing one methylene linkage. The target RNA-binding affinity of 2′,4′-BNA^{COC} is higher than that of PrNA (ΔT_m/modification = approximately +1°C to 2°C for 2′,4′-BNA^{COC} and approximately −0.5°C for PrNA).[34,41,42] Recently, our group succeeded in replacing the C4′ methylene linkage of PrNA with an oxygen atom (EoNA). EoNA is an isomer of 2′,4′-BNA^{COC} and exhibits higher target-binding affinity than 2′,4′-BNA^{COC} toward some target sequences (ΔT_m/modification = approximately +1°C to 3.6°C).[43]

6.10.3.1.3.2 2′,4′-BNA^{NC}

2′,4′-BNA^{NC} is an analog of ENA in which a methylene linkage is replaced with a nitrogen atom.[44,45] Substituents on the nitrogen atom affect target-binding affinity, as discussed earlier in the section on nuclease resistance. The smaller the substituent, the higher the target-binding affinity (ΔT_m/modification = approximately +5.3°C to 6.3°C for 2′,4′-BNA^{NC} (NH), +4.7°C to +6.0°C for 2′,4′-BNA^{NC} (NMe), +4.7°C to 5.5°C for 2′,4′-BNA^{NC} (NBn), and +5.0°C to +7.0°C for LNA).[45] Although no data for direct comparison are available, the ΔT_m/modification of ASOs containing 2′,4′-BNA^{NC} appears to be typically higher than that of ENA.

There are several reports on the antisense efficacy of ASOs containing 2′,4′-BNA^{NC}.[46–48]

Prakash et al. tested the antisense efficacy of ASOs containing LNA, 2′,4′-BNA^{NC} (NMe or NH), or isomers of 2′,4′-BNA^{NC} (NMe) in mice.[46] Among the isomers of 2′,4′-BNA^{NC}, the ASO containing the original 2′,4′-BNA^{NC} (NMe) showed the highest target-binding affinity and in vitro and in vivo antisense potency (ED_{50} = 6 mg kg^{-1}). While ASO containing LNA showed the least ED_{50} value (3 mg kg^{-1}) accompanied with elevation of alanine aminotransferase (ALT), elevation of ALT was not observed for ASO with 2′,4′-BNA^{NC} even at the highest dose tested (14.8 mg kg^{-1}). Surprisingly, 2′,4′-BNA^{NC} (NH) exhibited quite similar target-binding affinity and in vitro IC_{50} value to 2′,4′-BNA^{NC} (NMe), but ASO containing 2′,4′-BNA^{NC} (NH) was inactive in vivo

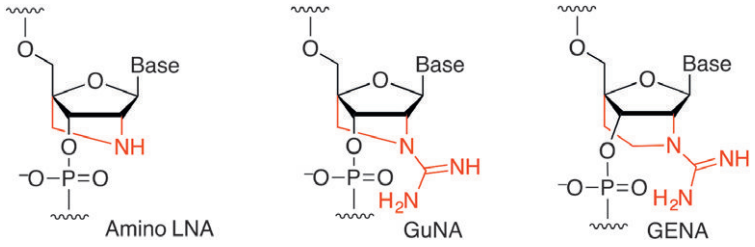

Fig. 14 Chemical structures of amino LNA, GuNA, and GENA.

($ED_{50} > 37$ mg kg^{-1}). The authors confirmed that ASOs with 2′,4′-BNA^{NC} (NH) was absent in the liver even after the highest dose of administration. This is indicating that the presence or absence of the methyl group changes the PK profile dynamically.

6.10.3.1.3.3 AmNA

AmNA is an amido-bridged BNA. The amide moiety in AmNA is hindered, so AmNA (NH) is unstable in the basic conditions generally used for the deprotection of ASOs during synthesis.[49]

Similar to 2′,4′-BNA^{NC}, the smaller the substituent on the nitrogen atom, the higher the target-binding affinity (ΔT_m/modification = approximately +7°C for NMe, +3°C for N*i*-Pr, and +4°C for NBn).[50]

ASO containing LNA reduced liver apoC-III mRNA by 45%, whereas ASOs containing AmNA achieved a knockdown of 40% (AmNA (NMe)) or 30% (AmNA (N*i*-Pr)), and ASO containing AmNA(NBn) showed no knockdown ability.

As discussed earlier, the introduction of heteroatoms into the bridge sometimes improves the target-binding affinity and resistance toward nucleases. However, there are no reports of these analogs exhibiting superior in vivo activity compared with ASOs containing LNA, indicating that antisense potency is defined by more than just in vitro target-binding affinity and nuclease resistance.

6.10.3.1.4 Introduction of cation into the bridge

The interaction of ASO and target mRNA is the hybridization of two polyanionic molecules, so one approach to improve the target-binding affinity of ASOs has been to introduce cations into the oligonucleotide. The introduction of an amine or guanidine into the bridge may improve the binding affinity of such modified ASOs compared with other BNAs due to partial cancelation of the negative charge (Fig. 14).

6.10.3.1.4.1 Amino LNA

Amino LNA has an amino group instead of the bridging ether moiety of LNA.[51] The amino group should act as a cationic center and offer an attachment point for conjugation with other molecules.

However, the introduction of this basic moiety had no effect on target-binding affinity compared with LNA (ΔT_m/modification = approximately +7.3°C for LNA and +6.3°C for amino LNA (NH)).[51]

6.10.3.1.4.2 GuNA and GENA

A BNA containing the basic guanidino-group (GuNA) has also been developed.[52] Our report of a five-membered ring GuNA was rapidly followed by a publication describing a six-membered GuNA, named GENA.[53]

The guanidine group is far more basic than an amine, and the positive charge should be much more stable over a wide pH range.

The target-binding affinity of oligonucleotides with GuNA was compared with that of LNA. In a comparison of oligonucleotides containing five modifications, the ΔT_m/modification of GuNA exceeded that of LNA (ΔT_m/modification = approximately +8.8°C for GuNA and +5.6°C for LNA).[52]

In contrast, the target-binding affinities of oligonucleotides containing GENA were the same as that of natural DNA.[53]

GuNA exhibited increased target-binding affinity due to both the incorporation of cation into the bridge and the conformational locking. To our knowledge, GuNA is the first analog to show substantially increased target-binding affinity compared with LNA.

Given that amino LNA did not exhibit the increased target-binding affinity demonstrated by GuNA and that GENA likewise showed no affinity gain due to the bridged structure, the introduction of cation appears to significantly enhance target-binding affinity only when the spatial configuration of the cation is appropriate.

6.10.3.1.5 Control of torsion angles

High target-binding affinity of BNA analogs is explained by the sugar conformational property strictly locked to $C_{3'}$-*endo*. Paralleled to this approach, attempts to control the torsion angle of sugar phosphate backbone have been made. Appropriate preorganization of torsion angles defining the structure of ASO should contribute to higher target-binding affinity (Fig. 15).

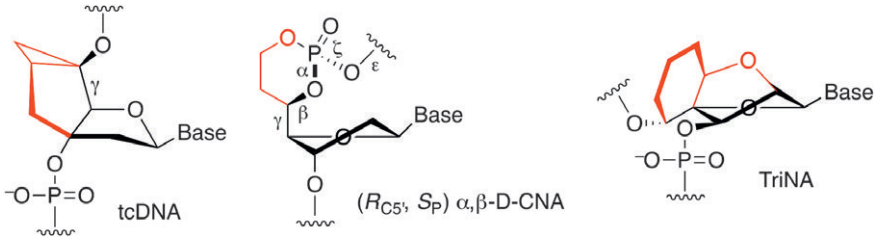

Fig. 15 Chemical structures of tcDNA, α,β-D-CNA, and TriNA.

6.10.3.1.5.1 tcDNA

Leumann et al. prepared tricyclo-DNA to control the γ torsion angle within +*ac* range.[54,55] The γ torsion angle of tcDNA is controlled by linking the C3′ and C5′ carbons of DNA via ethylene bridge and annelated cyclopropane ring. Although γ torsion angle in natural DNA–DNA and RNA–RNA duplexes is within +*sc*, target-binding affinity of this analog increased a little bit compared with natural DNA (ΔT_m/modification = approximately +1°C).[54,55]

6.10.3.1.5.2 CNA

In the same context with the approach taken by Leumann et al., Vigroux and Escudier et al. developed nucleoside analogs locking the phosphate backbone torsion angles, which is called constrained nucleic acids (CNAs).[56–58] α,β-D-CNA has a dioxaphosphorinane ring locking the α and β dihedral angles, which are locked at the canonical (*gauche*(−) and *trans*) conformation, as in A- and B-form duplexes, or the noncanonical (*gauche*(+) and *trans*) conformation depending on the stereochemistry (($R_{C5'}$ and S_P) or ($S_{C5'}$ and R_P), respectively). Expectedly, the target-binding affinity was higher for the oligonucleotides containing α,β-D-CNA controlling the α and β dihedral angles into canonical orientations (ΔT_m/modification ≈ +3°C for α,β-D-CNA locking into canonical orientation and +6°C for LNA while α,β-D-CNA locking into noncanonical orientation destabilized the thermal stability of duplex).[56,57]

6.10.3.1.5.3 TriNA

As described earlier, the locking of the sugar and torsion angle into an appropriate conformation succeeded in improving the target-binding affinity. Hanessian and Seth et al. tried to combine these modifications into one nucleoside analog by making another bridge on the α-L-LNA scaffold (TriNA).[59] As the α-L-LNA skeleton is quite similar to LNA, target-binding affinity of oligonucleotides containing α-L-LNA is comparable to those with LNA[60,61] (Fig. 16). The additional bridge introduced on TriNA was expected to restrict rotation around γ dihedral angle of α-L-LNA.

Target-binding affinity of oligonucleotides containing TriNA was compared with those with LNA or α-L-LNA, and it was shown that TriNA is comparable or superior to LNA and α-L-LNA depending on the sequences introduced (ΔT_m/modification = approximately +4.7°C to 8.3°C for TriNA and +4.5°C to 6.3°C for LNA and α-L-LNA).[59]

6.10.3.1.6 Summary

ASOs containing LNA exhibit higher antisense in vivo efficacy than more traditional chemical modifications, such as 2′-*O*-MOE. This observation supports a trend in the medicinal chemistry of ASOs to develop a nucleoside unit that enhances target-binding affinity. To date, many BNA analogs have been developed, and most show both improved resistance toward degradation by nucleases and increased target-binding affinity compared with natural oligonucleotides, but the in vivo and clinical efficacy data are very

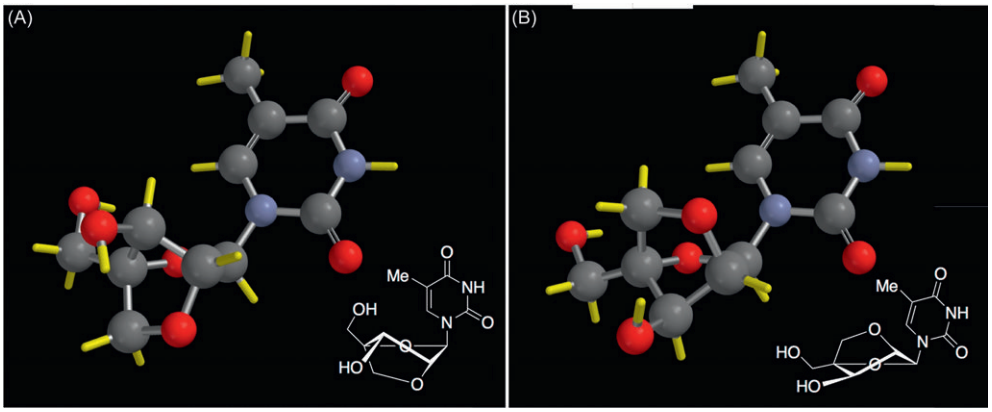

Fig. 16 Structures of LNA-T and α-L-LNA-T.

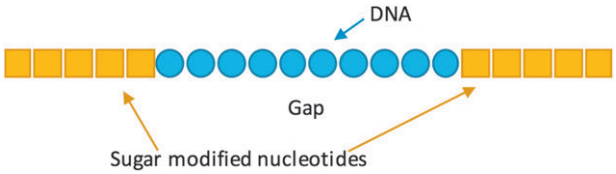

Fig. 17 Schematic image of gapmer (5-10-5).

incomplete for BNA analogs other than LNA and cEt. Thus, a better understanding of the key factors required for highly potent ASOs must await detailed in vivo and clinical data of promising BNA analogs.

6.10.3.2 Number and/or Mode of Introduction of Sugar Modifications

How a chemical modification is used is as important as which chemical modification is used. Further to our discussion of several sugar modifications, here, we discuss strategies for the design of potent ASOs with sugar modifications, focusing on the number of modifications.

6.10.3.2.1 Gapmers

It is essential for ASOs to maintain RNase H1-recruiting activity. RNase H1 recognizes DNA/RNA heteroduplexes and cleaves the RNA strand.[62] Many of the sugar modifications discussed earlier are RNA derivatives, thus making the ASOs RNA-like; consequently, ASOs fully modified with BNAs, 2′-*O*-MOE, or most other sugar modifications do not recruit RNase H1.[11,25,63–65]

Lima et al. studied thoroughly the design of ASOs modified with 2′-*O*-MOE and the RNase H1 cleavage mechanism toward these derivatives.[64,65] They clearly showed that partial modification of ASO with 2′-*O*-MOE, leaving large regions of unmodified DNA, allows RNase H1 to access the ASO/RNA duplex and cleave the RNA. The report by Lima and coworkers suggests the following guidelines for the design of efficacious ASOs:

(1) The introduction of sugar modifications inhibits the cleavage reaction of RNase H1 at both 5′ and 3′ sides of the modifications. Therefore, it is strongly recommended that the sugar modifications be introduced at the ends of the sequence.
(2) Sugar modifications inhibit the reaction of RNase H1, so the number of these modifications should be minimized.
(3) The number of modifications introduced should be the minimum required to obtain the required target-binding affinity.

These guidelines have likely influenced the sequence design of 5-10-5, known as gapmer, which contains five 2′-*O*-MOE nucleotides at each end of the sequence and 10 deoxyribonucleotides between these clusters of 2′-*O*-MOEs. This design motif is common in 2′-*O*-MOE ASOs (Fig. 17).

The concept behind gapmer also works well in LNA. Swaize et al. constructed 20-mer ASOs and reported that LNA exhibited higher antisense potency than 2′-*O*-MOE in a 2-16-2 modification pattern.[11] The number of modifications required for high antisense potency was smaller for LNA than for 2′-*O*-MOE, reflecting its higher target-binding affinity.

6.10.3.2.2 Too high an affinity drastically decreases potency

Koch et al. reported that shorter LNA ASOs work more efficaciously.[66] They showed that 12-, 13-, and 14-mer ASOs with LNA modification patterns of 2-8-2, 2-8-3, and 3-8-3, respectively, exhibit higher antisense activity both in vitro and in vivo than longer ASOs. For example, the in vitro IC_{50}s of expression of apoB mRNA were 0.2–0.4 nM for the 12- to 14-mers and 2.7 and 5.0 nM for the 16-mer and 20-mer, respectively. The longer ASOs were anticipated to show decreased in vivo distribution to the target tissue, but the concentration time profiles of 12-mer and 16-mer LNA ASOs in the murine liver were similar. Taken together with the finding that the target-binding affinity of 12-mer LNA ASO is weaker than that of 16-mer LNA ASO ($T_m = 53°C$ for 12-mer and 63°C for 16-mer), there appears to be an optimal target-binding affinity earlier, which the ASO exhibits dramatically decreased potency. We also demonstrated the importance of "optimum T_m" using 2′,4′-BNA^{NC} ASOs. Intriguingly, ASOs bearing different sugar modifications exhibited similar optimum T_ms (60–65°C) and in vitro potency.[47] Thus, the relevance of "optimum T_m" is not unique to LNA.

The optimum T_m observed in ASOs bearing high-affinity modifications is likely due to the mechanism of action. In the RNase H1 recruitment of ASOs, immediate release of ASO from the cleaved target RNA is essential in order for the enzyme to enter the next cleavage reaction cycle. Our group demonstrated experimentally that the turnover of ASOs is inhibited when the target-binding affinity of the ASO is too high and that the in vivo potency of the ASOs is affected by their turnover ability.[67] Independently, a group from Santaris Pharma analyzed kinetic models, potency, and affinity and showed that the turnover ability of ASOs might be related to their in vivo potency.[68] It is therefore important to consider the effect of sequence length and number of modifications in an ASO on the turnover ability of the ASO, in addition to the criteria discussed earlier.

Splicing-switching ASOs with LNA modifications showed that the apparent favored binding affinity ($T_m = 80–90°C$) was higher than that of RNase H1 recruiting ASOs ($T_m = 60–65°C$), but further increase in affinity impaired exon-skipping potency.[38] It is possible that ASOs with higher affinity with impaired skipping potency form higher-ordered structures form stem-loops and/or homodimerize or homopolymerize.

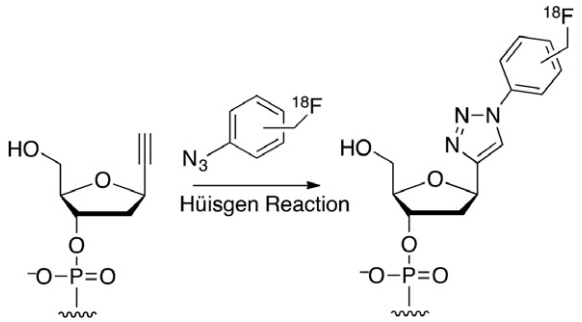

Fig. 18 Labeling of oligonucleotides for PET imaging.

6.10.3.3 Backbone Modifications

As discussed earlier, ASOs are inactive in vivo in the absence of backbone modification, so ASOs are typically fully modified with phosphorothioates, although this generally reduces target-binding affinity (ΔT_m/modification = approximately −0.6 to −0.3°C compared with the phosphodiester linkage).[24]

The target-binding affinity of phosphorothioated ASOs is also affected by the chirality of the phosphorothioate (Fig. 5).

Wan et al. prepared ASOs, with and without control of the chirality of the phosphorothioate linkages in the gap regions. ASOs with all R_P chirality in the gap showed higher target-binding affinity than those with all S_P (ΔT_m/modification = approximately +0.2°C and −0.2°C to −0.5°C, respectively, compared with stereo-random phosphorothioate linkages).[24] The antisense potency of these ASOs was tested in vitro, and R_P ASOs were confirmed to show higher potency than S_P ASOs. However, in vivo tests showed that the antisense potency in the mouse liver of R_P and S_P ASOs was similar and that stereo-random ASOs showed the highest potency.[24] At the same time, the amount of intact ASO in the liver tissue was shown to be very low for R_P ASO. Thus, the higher antisense potency of R_P observed in vitro appears to be canceled out by its weaker antinuclease resistance in vivo.

6.10.4 ADME

The medicinal chemistry of ASOs must take into account their ADME, but the main focus to date has been improving the distribution and enhancing the resistance of ASOs toward metabolism and particularly nuclease resistance, as discussed earlier.

The distribution of ASOs to the target tissue is a critical factor for maximizing efficacy and minimizing adverse effects. Systemically administered naked phosphorothioated ASOs tend to distribute mainly to the kidneys and liver. Suzuki, Watanabe et al., and our group developed a method for ^{18}F-radiolabeling of ASOs utilizing Hüisgen reaction to monitor ADME time profile of ASOs in vivo by positron emission tomography[69,70] (Fig. 18). The ADME profile of ASOs modified with or without phosphorothioate (PS) and/or LNA (ASO-PO-DNA, ASO-PO-LNA, ASO-PS-DNA, and ASO-PS-LNA) was assessed in rats. ASOs without PS modification (ASO-PO-DNA and ASO-PO-LNA) rapidly passed through the liver and kidneys and moved to the renal medulla, bladder, and intestine. On the other hand, ASOs modified with PS (ASO-PS-DNA and ASO-PS-LNA) accumulated in the kidneys and liver.[70] As discussed previously, phosphorothioate modification alters not only the nuclease resistance but also the plasma protein binding pattern. This would be the reason why ADME profile was profoundly affected by backbone chemistry, although the nuclease resistance of ASO-PO-LNA was considered significantly higher than that of ASO-PO-DNA.

To alter or improve the specificity of the distribution profile, many conjugate and/or nanoparticle drug delivery system approaches have been investigated.[71–76] For example, the conjugation of ASOs with GalNAc results in improved distribution specificity toward hepatocytes.[73–75]

On the other hand, here, we introduce two examples of medicinal chemistry approaches to altering the ADME, in particular the distribution of ASOs.

6.10.4.1 Sugar Modifications

The distribution and potency of ASOs were altered by tuning the hydrophobicity of the ASO by chemical modification. AmNA was used as a scaffold because tuning could be accomplished by altering the alkyl substituent on the bridging amide moiety (Fig. 13). The hydrogen was substituted with methyl, isopropyl, or benzyl groups, and the hydrophobicity of the oligonucleotides increased. The in vivo behavior of AmNA-ASOs respectively modified with (NMe), (N*i*-Pr), or (NBn) was evaluated. The hepatic distribution of the more hydrophobic ASOs with AmNA (N*i*-Pr) and AmNA (NBn) was higher than that of AmNA (NMe)[50] (Fig. 13).

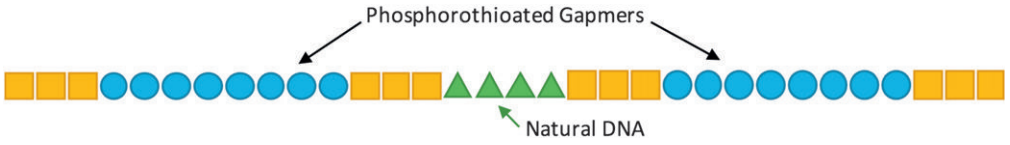

Fig. 19 Schematic image of multimer.

6.10.4.2 Length of the ASOs

Phosphorothioated ASOs are believed to be distributed in vivo by multiple proteins. The phosphorothioated backbone increases the binding rate of ASOs to plasma proteins, but shorter phosphorothioated ASOs show a lower plasma protein binding rate (e.g., ~95% for a 20-mer ASO vs. ~80% for a 13-mer).[77] Since protein binding likely affects the efficiency of distribution to the targeted tissue, longer ASOs with phosphorothioate modifications may be more potent ASOs. However, as discussed earlier, longer ASOs generally show higher target-binding affinity, and the optimal length is typically 12- to 16-mers for ASOs modified with LNA. Krieg et al. linked two 15-mer phosphorothioated ASO gapmers (multimer) modified with LNA via a linker comprising natural nucleotides so that the linker would be cleaved by endonucleases after distribution to the target tissue (Fig. 19). Dosing mice with the same amount of monomer or homodimer ASO (10 mg kg^{-1} and twice a week) demonstrated that the homodimer exhibits much higher antisense potency than its monomer.[78]

6.10.5 Target Specificity, Hybridization-Dependent Off-Target Effects, and Safety

6.10.5.1 Overview of the Safety of ASOs

Target specificity is an important factor strongly related to the safety of a drug and sometimes defines the safety margin of the drug. The effects arising from the contact of the drug molecule with any other molecules than the target molecule are considered an off-target effect. The off-target effects of ASOs are generally classified into two groups: hybridization-dependent off-target effects and nonhybridization-dependent off-target effects.[22,79] Hybridization-dependent off-target effects are defined as nontargeted effects caused by the hybridization of ASOs with other nucleic acids in vivo.

6.10.5.1.1 Class effects of phosphorothioated ASOs

The administration of a high dose of ASO can give rise to off-target effects (known as "class effects") such as prolongation of activated partial thromboplastin time (aPTT) and nonhybridization-dependent off-target effects such as the activation of complement, thrombocytopenia, and immunostimulation.[22,79] These effects can limit the maximum dose in clinical use.

6.10.5.1.1.1 Prolongation of aPTT

Administration of phosphorothioated antisense oligodeoxyribonucleotide molecule targeting human intercellular adhesion molecule-1 mRNA prolonged plasma clotting times in both monkey and human studies.[80] Thorough studies by Sheehan and Lan revealed that the ASO inhibited the calcium-dependent portion of the intrinsic pathway.[80] The authors demonstrated that the sense and randomized sequences of the phosphorothioated oligonucleotides exhibit the same profile on the inhibition of the clotting reaction, whereas an oligonucleotide with the same sequence as the ASO but without phosphorothioate modifications showed no inhibitory activity. Thus, the prolongation of aPTT in monkey and human likely arises from the phosphorothioate backbone and not the sequence. The prolongation of aPTT is plasma concentration-dependent, and thus, clinically controlling the peak concentration may help prevent hemorrhagic adverse events.

6.10.5.1.1.2 Immunostimulation, activation of complement, and thrombocytopenia

Phosphorothioated ASOs appear to be immunostimulatory in nature, and many reports indicate that ASOs act as pro-inflammatory compounds. Common inflammatory reactions observed after the administration of ASOs are injection site reaction, flu-like symptoms, and activation of complement.[22,79] Although correlations with these adverse events are unclear, thrombocytopenia is observed in clinical trials of phosphorothioated ASOs.[81]

The causes of pro-inflammatory effects by phosphorothioated ASOs remain under investigation, but several pathways are believed to play important roles. For example, ASOs mainly composed of DNA and especially sequences containing the CpG motif may stimulate toll-like receptor 9 (TLR9) and induce inflammatory reactions.[22,79]

Maybe independently from the TLR-mediated reaction, the activation of complement occurs with phosphorothioated ASOs. Phosphorothioated ASOs are known to activate the complement cascade alternative pathway. Henry et al. reported that ASOs may bind and interfere with factor H, an important factor in this alternative pathway.[82–84] The authors compared the complement activation profiles of ASOs with different chemical modifications and found that the introduction of a 2′-*O*-MOE and/or phosphodiester linkage in place of a phosphorothioate linkage reduces complement activation in monkey serum.[82–84]

While the activation of complement is clearly observed in monkeys, the sensitivity of activation by ASOs appears to depend on the species. Therefore, the clinical relevance of the activation reaction is difficult to predict from nonclinical data. Moreover,

although it was considered independent reactions, recently, it has been reported that the TLR9 pathway and complement activation pathway may interact with each other.[85] Further investigations are therefore needed to understand and control such adverse reactions.

6.10.5.1.2 Target specificity and hepatotoxicity

As the chemical sophistication of ASOs increases and their antisense effect are optimized, the dose of ASO required to achieve the desired antisense effect will likely decrease dramatically. In addition, the trend in the medicinal chemistry of ASOs to use shorter oligonucleotides should worsen target specificity because shorter oligonucleotides theoretically may have larger number of target RNAs that have perfect match with the ASOs. Thus, ASOs must exhibit satisfactory target specificity, as otherwise dose-limiting toxicity could change from nonhybridization-dependent off-target effects to hybridization-dependent off-target effects, which are much more related to the mode of action of ASOs.

There are many reports of hepatotoxicity induced by ASOs with high-affinity modifications such as LNA.[11–15]

Hepatotoxicity induced by ASOs with LNA can be lethal, depending on the ASO and the dose administered.[11–15] Hepatotoxicity is well characterized in rodents and easily detected by monitoring changes in serum enzymes such as ALT. An elevated serum ALT level is usually observed several days after subcutaneous or intravenous injection of ASO into mice.

Liver damage may be due to nonhybridization-dependent off-target effects and/or hybridization off-target effects, and the severity of the hepatotoxicity of ASOs with the same sequence reportedly varies significantly depending on the chemistry introduced. For example, the replacement of LNA in hepatotoxic ASO with other high-affinity modifications such as cEt or 2′,4′-BNA^{NC} was shown to reduce toxicity without significantly affecting the on-target effect,[36,46] suggesting that a nonhybridization-dependent process contributes to the onset of the toxicity to some extent. In this context, Burdick et al. reported that some highly hepatotoxic ASOs with LNA were more likely to bind to hepatocellular proteins in vitro than nontoxic ASOs with the same modification patterns as the toxic ASOs.

On the other hand, recent reports have supported the hypothesis that hepatotoxicity induced by ASOs with high-affinity modifications is due to hybridization-dependent off-target effects. For example, Kamola et al. reported that ASOs containing chemical modifications that increase target-binding affinity, such as LNA, showed significant hybridization-dependent off-target effects in vitro.[17] In addition, Burel et al. reported that hybridization-dependent off-target effects also occur in vivo and are the cause of hepatotoxicity induced by ASOs containing high-affinity chemical modifications.[15] The authors also confirmed that hepatotoxicity is caused by ASOs containing either cEt or LNA modifications. The authors showed only experimental data from mice, but adverse effects related to hepatotoxicity or elevated serum ALT levels are also reported in clinical trials of ASOs containing high-affinity modifications.[86,87] Therefore, the hepatotoxicity of ASOs is apparently not unique to rodents.

6.10.5.2 Medicinal Chemistry Approaches to Improving Safety Profiles

In addition to the toxic effects of ASOs discussed earlier, acute tubular necrosis and injection site reactions can be the cause of decreasing the dose or discontinuing treatment.[88,89] It is unclear whether these off-target effects are hybridization-dependent or nonhybridization-dependent, but improved target specificity appears crucial for the evolution of ASOs as a promising therapeutic approach.

Minimizing potential off-target effects through sequence design requires choosing a sequence with a minimum number of potential off-target RNAs.[90] Moreover, sequence design and optimizing the combination of chemical modifications may help select a safer ASO candidate with regard to nonhybridization-dependent off-target effects. The escape of ASOs with phosphorothioated modifications from TLR9 may illustrate a structure–activity relationship related to nonhybridization-dependent off-target effects. TLR9 recognizes single-stranded nonmethylated DNA, prompting investigation of the effects of chemical modification of the sugars and nucleobases of ASOs. Vollmer et al. evaluated the effects of replacing the deoxyribonucleoside unit with LNA monomer and demonstrated that partial replacement decreased the immunomodulation property of phosphorothioated ASOs.[91] In addition, the authors showed that modification of the CpG unit by LNA was sufficient to strongly decrease TLR9-mediated signaling. The CpG unit is an important factor for the recognition of ASOs by TLR9; consequently, nucleobase modification of the CpG unit is a powerful approach. Furthermore, chemical modifications on the Hoogsteen side of a nucleobase should not affect Watson–Crick base-pairing ability, and therefore, this approach is also attractive (Fig. 20). Uhlmann et al. demonstrated that replacing the cytosine or guanine of CpG by 5-methylcytosine or 7-deazaguanine resulted in an 81% or 69% reduction in maximum human TLR9 activation, respectively.[92,93]

Further examples of medicinal chemistry approaches contributing to the safety of ASOs are provided in the succeeding text.

6.10.5.2.1 Sequence design

The sequences of ASOs as potential candidates for drug development are generally selected through in vitro and in vivo screening. The screening strategy depends on the developmental strategy and general knowledge of the developer and has led to the sequence design of safer ASOs.

6.10.5.2.1.1 Toxic motif of ASOs

Lindow et al. developed a random forest classifier in which oligonucleotides are regarded as being composed of dinucleotide units. The authors trained the statistical model using highly hepatotoxic and nontoxic LNA ASOs to predict the toxicity of the ASOs.[12]

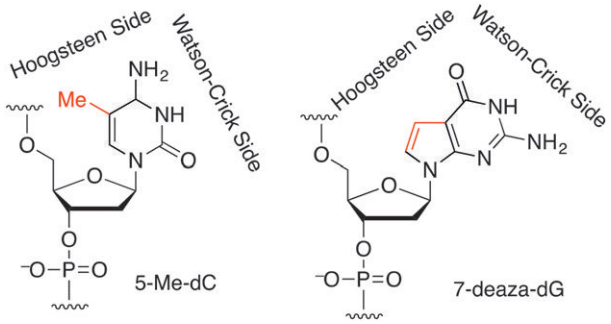

Fig. 20 Chemical structures of 5-Me-dC and 7-deaza-dG.

Hollingshead et al. similarly analyzed statistically and experientially the available hepatotoxicity data of LNA ASOs in mice and found that toxic LNA ASOs are more likely to contain TCC and TGC motifs in their sequences.[13] These studies do not explain why dinucleotide and/or trinucleotide units of ASO affect the hepatotoxicity profiles of ASOs but may nonetheless shed light on how to minimize the potential risk of hepatotoxicity.

6.10.5.2.2 Nucleobase modifications

High-affinity chemical modifications, typified by LNA, generally do not destroy sequence selectivity but do increase binding affinity. It has been reported that the potency of hybridization-dependent off-target effects is highly correlated with the binding affinity of ASO for the target sequence,[17] suggesting that improving the hybridization selectivity between the on-target sequence and off-target sequence would improve the specificity of the antisense effect.

The most stable mismatch is generally the G-T wobble base pair,[94] so off-target RNAs that hybridize with ASOs containing G-T mismatches may show affinity comparable to the intended on-target RNA. 2-Thiothymidine has a thiocarbonyl moiety in place of the 2-carbonyl moiety, and this modification weakens the hydrogen bond in the G-T wobble base pair[95] (Fig. 21). Østergaard et al. tested the utility of 2-thiothymidine for improving the selectivity of the antisense effect between the on-target RNA and an off-target RNA by introducing G-T mismatches. They confirmed that the ASO with 2-thiothymidine shows a larger difference in target-binding affinity between on-target and off-target RNAs than does the ASO with natural thymidine ($\Delta T_m = 2.2°C$ for thymidine and 4.9°C for 2-thiotymidine), but the improvement in in vitro antisense selectivity was small compared with the difference in target-binding affinity (IC_{50} selectivity, 17.6-fold for thymidine and 23.4-fold for 2-thiothymidine).[96] Importantly, they also tested the effects of this nucleobase modification at different positions in the ASO and found that introduction of the nucleobase modification in the gap region sometimes improved the selectivity of the antisense effects between on-target and off-target RNA by affecting the cleavage pattern of RNase H1, independent of affinity.[96] This observation suggests that medicinal chemistry approaches may alter the spectrum or specificity of antisense effects.

6.10.5.2.3 Gap design

Even if the ASO hybridizes to off-target RNAs, no hybridization-dependent off-target effects should occur unless RNase H1 cleaves the RNA. Thus, repression of the cleavage of off-target RNA by RNase H1 is a reasonable approach for improving the specificity of RNase H1-dependent ASOs. As discussed earlier, gap design is one widely used approach.

In 2013, Seth et al. reported that shortening the gap length of ASOs bearing *S*-cEt and 2′-*O*-MOE modifications from nine nucleotides to seven dramatically improved the in vitro antisense selectivity between on-target and single mismatch-containing off-target RNA (IC_{50} selectivity, 6.9-fold for ASO with a 9 nt gap and as high as >133-fold for ASO with a 7 nt gap).[97]

Koizumi et al. had already reported this approach applying into ENA gapmer ASO in 2007. The authors realized the importance of antisense specificity, because they found that the target mRNA was cleaved by RNase H not only at the target site but also at nontarget sites. The nontarget cleavage sites were attributed to partial base pairing between the mRNA and the ENA gapmer.[16]

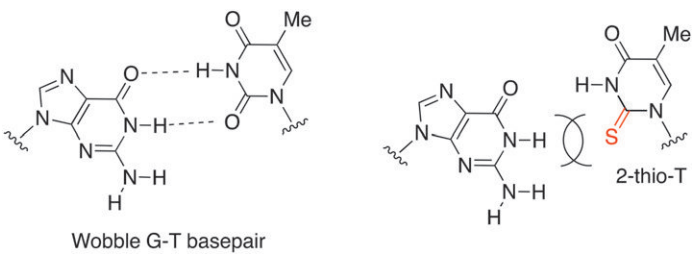

Fig. 21 Wobble G-T base pair and 2-thio-T.

Shortening the gap size of the ENA gapmer significantly reduced cleavage of the target mRNA at nontarget sites, suggesting that this approach could minimize hybridization-dependent off-target effects.

Too small a gap size greatly decreases antisense potency, and therefore, the gap size should be optimized to balance the acceptable risk for potential off-target effects and the anticipated pharmacological effect.

6.10.6 Conclusion

Advances in the unit chemistry of ASOs and our understanding of the design of ASOs have led to dramatically improved nuclease resistance in vivo and in antisense potency. In parallel with the medicinal chemistry approach, DDS has also resulted in exciting advances in antisense technology. For example, ASOs conjugated with GalNAc exhibit remarkable antisense potency in the liver. We now have the ability to design increasing potent ASOs.

Increases in the potency of ASOs have highlighted the need to balance potency and safety, whereas increased potency has mainly been achieved through sugar and backbone modifications; improved safety of ASOs appears to rely on nucleobase modifications feature.

Medicinal chemistry has made major contributions to the advance of antisense technology, but the medicinal chemistry of ASOs may play a decisive role in overcoming the remaining challenges of this therapeutic technology.

6.11.1 Introduction

The concept of using synthetic oligonucleotides (ONs) to control gene expression dates back to the late 1970s, when Zamecnik and Stephenson first demonstrated targeted gene silencing using a short synthetic ON.[1] These pioneering studies were the beginning of a new targeted gene silencing approach termed antisense. Thereby, a synthetic ON complementary to a target mRNA is introduced into cells with the intent to block gene expression through either translational inhibition or enzymatic cleavage of the mRNA target.

Over the years, scientists realized that ONs can have many other modes of action besides Watson–Crick type base pairing with the targeted RNA. Two of the three ON therapeutics approved as of today are working by an antisense mechanism; the other, Macugen, is an aptamer and works through its three-dimensional structure by binding to the 165 isoform of antivascular endothelial growth factor (VEGF), a protein that plays a critical role in angiogenesis.

While only three ON therapeutics have been approved by the FDA as of today, there are many more in late-stage clinical trials. Several more ON drugs are expected to be entering the market over the next couple of years. ON-based therapeutics are poised to become the third therapeutic platform besides small molecule and peptide drugs. Vitravene (Fomivirsen) was the first antisense therapeutic, which made it to the market and was approved by the FDA in 1998.[2] It is used for the treatment of cytomegalovirus retinitis (CMV) in immunocompromised patients and is injected intraocularly. Macugen (Pegaptanib) was approved in 2004 and is also injected into the eye. It is a pegylated aptamer-targeting VEGF and is used for the treatment of neovascular (wet) age-related macular degeneration (AMD).[3] Mipomersen (Kynamro) was approved in 2013 and is used to treat homozygous familial hypercholesterolemia (HoFH).[4] It is targeting apolipoprotein B (apoB) (see **Table 12** in Regulatory Aspects of Oligonucleotides section).

6.11.2 Classes of Therapeutic Oligonucleotides

Most therapeutic ONs currently in clinical trials belong to the following classes: antisense, aptamers, immune stimulatory, decoys, or RNA interference (including small interfering RNA (siRNA), microRNA, and short hairpin RNA (shRNA)).[5]

Antisense therapeutics act by binding to and then cleaving the target RNA in order to interfere with translation and prevent the synthesis of disease-causing proteins. Second-generation antisense ONs are characterized by modifications of the 2′-hydroxyl group of the ribose, usually 2′-*O*-methyl (OMe), 2′-*O*-methoxyethyl, 2′-fluoro or 2′-4′-bridged analogs. Toxicity of these ONs is reduced and target affinity is increased compared with first-generation antisense ONs; however, these modifications prevent the activation of RNase H. This shortcoming can be circumvented by the design of gapmers, which are composed of blocks of modified nucleotides in the termini separated by a central gap of deoxyribonucleotides that induce RNase H cleavage of the target RNA. Second-generation antisense ONs are often further stabilized by the introduction of phosphorothioate groups into the backbone.[6]

A substantial proportion of diseases is caused by missplicing of the pre-mRNA. Antisense ONs are increasingly applied for splicing correction.[7] These ONs are not aimed at cleaving the target RNA; rather, they prevent incorrect splicing or redirect splicing. No stretch of deoxyribonucleotide bases is required for splice switching ONs as for RNA-cleaving antisense.

Early on, it was realized that many antisense ONs were unexpectedly immune stimulatory. The immune stimulatory effect was based on the number and location of CpG motifs in the ON.[8] Later Toll-like receptor 9 (TLR9) was identified as the mediator of the immune stimulatory effect of CpG oligodeoxyribonucleotides.[9] TLR9 recognizes ONs containing unmethylated CpG dinucleotides, which are common in most bacteria and DNA viruses but not in vertebrate DNA. The interaction with this foreign ON and TLR9 leads to immune stimulation. The phosphorothioate modification is an essential element in immune stimulatory ONs.[10] These beneficial effects of CpG ONs provide the basis for improved vaccines and immunotherapeutic for cancer, allergic, and infectious diseases, which are being pursued in a variety of ongoing clinical trials.

Aptamers constitute a special group of ONs whose effect and target affinity lie in their ability to form 3D structures that enable them to recognize and bind strongly to both small and large molecules. In contrast to other classes of ON therapeutics, aptamers interact with and bind to their targets through structural recognition, a process similar to that of an antigen–antibody interaction. However, due to their small size and intrinsic ON properties, aptamers offer several advantages over protein antibodies in both their clinical applicability and a less challenging synthesis process. Aptamers typically act as ligands for proteins, often receptors, in either the intra- or extracellular environment, allowing the aptamer to affect the functionality of downstream effectors.

ON aptamers are being identified and optimized through a process called SELEX (Systematic Evolutions of Ligands by Exponential Enrichment).[11] Thereby, a diverse starting library goes through iterative rounds of selection for binding to the target protein, followed by partitioning and amplification of binding clones. These tools were essential for developing most of the therapeutic aptamers, which are in the clinic today.[5,12] Apart from therapeutic applications where the aptamer is the drug, aptamers have also been used for targeted delivery of ONs. For this purpose, an aptamer capable of entering the target cell through receptor-mediated endocytosis is connected to a therapeutic ON by direct conjugation or containing the functionalized aptamer on the surface of the formulation.

Double-stranded oligodeoxynucleotides are examples of decoy ONs. They are designed to prevent transcription factor binding competitively to the promoter region of targeted genes, thus inhibiting transcription. Decoy ONs targeting NF-ĸB have shown therapeutic effects for several indications in various animal models[13] and in the clinic.[14] Decoy ONs were also applied to the inhibition of signal transduction and transcription factors (STAT).[15]

In 1998, double-stranded RNAs were discovered to be the silencing effectors to regulate gene functions in *Caenorhabditis elegans*.[16] Shortly thereafter, similar phenomena were found also in plants,[17] which uncovered the new world of RNA interference

(RNAi) and heralded a revolution in RNA regulation. RNAi is defined as a mechanism of specific posttranscriptional gene silencing mediated by small RNAs, including endogenous microRNA (miRNA) and exogenous small interfering RNA (siRNA) or short hairpin RNA (shRNA).[18] Double-stranded small RNAs incorporate into the RNA-induced silencing complex (RISC), suppressing the gene expression by either degrading mRNA or blocking mRNA translation.[19] All of these three modes of RNA interference, miRNA, siRNA and shRNA, are being pursued as therapeutics.[20]

Small interfering RNA (siRNA) therapeutics are usually 21 nucleotides long, double-stranded RNAs with a two-base overhang. However, not all siRNAs are created equal; some are blunt ended and not all are 21 bases long. Most siRNAs are chemically modified,[21] with an antisense active strand (or guide strand) that is complementary to a sequence in the target mRNA. siRNAs are taken up by RISC, which ejects the sense or passenger strand, leaving the antisense strand to bind to the target mRNA and mediate its sequence-specific cleavage by the RISC RNase Argonaute 2. This is an efficient catalytic process because after the cleaved mRNA is released, the guide-strand-bound RISC binds to another mRNA and starts a new round of cleavage.[22] A recent review from Wittrup and Lieberman discusses the current state of siRNA therapeutics in the clinic.[23]

microRNA (miRNA or miR) plays essential functions during embryogenesis and tissue development and during cell differentiation, proliferation, and survival.[24] Unlike siRNAs and shRNA, miRNAs are only partially complementary to their target mRNAs' 3′-untranslated region (UTR), regulating their targets via all four Ago proteins (AGO1–4).[25] A perfect match is not a necessity for miRNA to function; thus, the change in the expression of a single miRNA may affect hundreds of different genes.[26]

miRNA mimics and anti-miRs (antogomiRs or miRNA antagonists) represent the two major approaches, which are being developed as microRNA therapeutic agents.[27] miRNA mimics the function of endogenous microRNAs. They represent miRNA replacement therapy that aims to restore the expression of tumor-suppressive miRNAs. Anti-miRs are used to inhibit oncomiRs, tumor suppressor miRs, and metastamiRs when disease results from an overexpression of the miRNA.

Anti-miR-type microRNA therapeutics predominantly function via a steric blockage, in which miRNA function is inhibited by strong hybridization to block RISC loading. Anti-miRs may be designed to trigger miRNA cleavage by RNase H as well, but this has been less common thus far.[72,195] A typical anti-miR therapeutic is a perfect complement to the miRNA target. microRNA therapeutics are single stranded, mostly fairly short, chemically modified oligoribonucleotides to enhance nuclease stability and target-binding affinity.

shRNAs have been developed as therapeutics as well. shRNAs are processed by Dicer and then incorporated into RISC, followed by the same cytoplasmic RNAi process as in siRNA.[196] Other related technologies have recently garnered a lot of attention like mRNA therapeutics and CRISPR CAS9.

6.11.3 Most Common Chemical Modifications in Therapeutic Oligonucleotides

The development of ON for the different therapeutics areas has all shown this class of therapeutics to be highly potent and effective in in vitro cell assays. However, translation from the bench to the clinic has been hampered by significant challenges arising from poor in vivo stability, ineffective uptake into targeted cells, and off-target effects including immunostimulation. Early on it was realized that native DNA and RNA structures had to be chemically modified in order to make them suitable as therapeutics. Chemical modifications were introduced to alter the stability of ONs, increase their affinity toward the target, facilitate cellular uptake, and enhance their bioavailability in vivo (**Fig. 1**). Chemical modifications of nucleic acids can be classified into three categories: modification of the (1) internucleotide linkage, (2) the sugar, and (3) the heterocyclic nucleobase. Besides direct modification of the nucleic acid, conjugation represents another very effective way to improve intracellular delivery or in vivo pharmacokinetics and biodistribution of ONs.[28] Modifications discussed here will focus on alterations frequently seen in therapeutic ONs, currently pursued in clinical trials, and by no means are meant to be exhaustive. For further reading please see recent review article from Deleavey and Damha.[29]

6.11.3.1 Modification of the Internucleotide Linkage

The internucleotide phosphodiester linkages of DNA and RNA are negatively charged at physiological pH and can be readily cleaved by endo- and exonucleases found in serum and within mammalian cells. Chemical modifications of these bonds have been extensively studied, and several chemical strategies have proved very successful for improving nuclease resistance, some of which are still compatible with an RNase H-mediated mRNA cleavage mechanism, and a few impart additional beneficial characteristics to ONs. This review will focus only on the backbone modifications with clinical applications.

One of the most common backbone modification is the phosphorothioate modification, where the oxygen in the phosphodiester bond is replaced by sulfur.[30] The chemical synthesis of the phosphorothioate ONs results in a roughly 1:1 mixture of the two diastereoisomers (R and S). As this results during each phosphorothioate coupling, all phosphorothioate-modified ONs currently in the clinic are a complex mixture of diastereoisomers. However, a stereocontrolled synthesis was achieved first by Stec and coworkers,[31] and more recently an improved synthetic route was introduced by Wade and coworkers[32] and later refined by others,[33] making stereoselective phosphorothioate ON synthesis achievable for the first time at scales suitable for the development of therapeutics.

Initially, phosphorothioates were introduced into the antisense methodology because of the nuclease resistance of the phosphorothioate linkage in comparison with that of the phosphate linkage. However, as experimental data accumulated, it was detected that this chemical modification also facilitates cellular uptake and bioavailability in vivo. This backbone modification

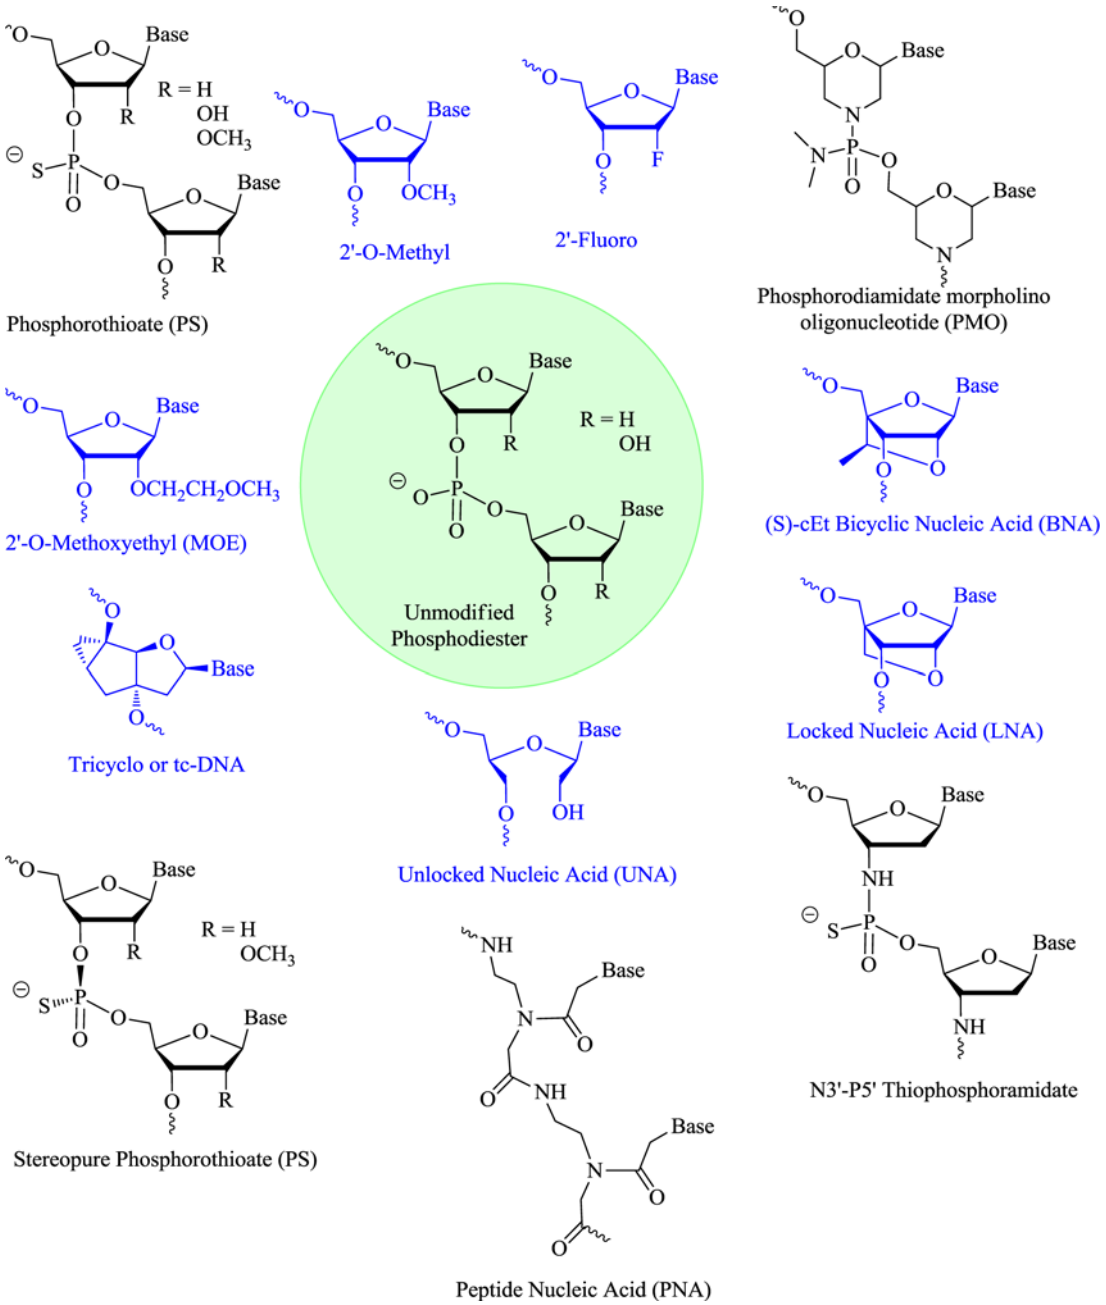

Fig. 1 Most common chemical modifications used in therapeutic oligonucleotides. *Blue color* indicates sugar modification; *black color* backbone modification. The circle in the middle indicates unmodified natural RNA and DNA.

is present in a large proportion of the ONs in various phases of clinical trials. Additionally, both antisense ONs approved by the US Food and Drug Administration are fully phosphorothioated (Table 12).

Peptide nucleic acids (PNAs) are a radically different class of ON analogs that contain a peptide replacement for the sugar phosphate backbone, yet maintain the ability to Watson–Crick base pair with complementary RNA and DNA.[34] PNAs have a neutral charge backbone composed of *N*-(2-aminoethyl)glycine, exhibit significant nuclease and protease resistance[35] and bind to its complimentary target with higher affinity than DNA or RNA.[36] PNAs do not activate RNase H and can act via a translational inhibition mechanism,[37] in siRNA overhangs,[38] and in numerous other biological pathways including splice-switching activities.[39] Despite their uncharged nature, PNAs do not readily cross cell membranes. These limitations have been addressed by the conjugation of PNA to short peptides,[40] which also helps increasing solubility. The short peptides employed were also able to improve tissue distribution. However, both pharmacokinetic and potency hurdles remain for PNA ON drugs, and concerns remain as to whether the modification is too stable in tissues.[37]

In the N3′–P5′ phosphoramidate modification, the 3′-OH group of the internucleotide bond is replaced with a 3′-amine functionality.[41] N3′–P5′ phosphoramidate modifications adopt a North sugar conformation, making them suitable mimics for RNA substitution.[42] As a result, N3′–P5′ phosphoramidate containing ONs lack the ability to activate RNase H-mediated cleavage,[43] but feature good binding affinity for target sequences and high nuclease resistance. Introduction of sulfur in place of one of the nonbridging oxygen atoms does not alter the RNA-binding properties of these compounds.[44] A palmitoyl-conjugated thiophosphoramidate-modified ON, Imetelstat, has shown promise as an anti-telomerase agent.[45]

Phosphorodiamidate morpholino ONs (PMOs) have an uncharged backbone, where the furanose ring has been replaced with a morpholine ring and a phosphorodiamidate linkage is connecting the morpholine nitrogen atom with the 5′-hydroxyl group. Because of the phosphorodiamidate linkage, morpholino ONs are neutral. These modifications are similar in affinity to DNA–DNA duplexes and are nuclease stable. PMOs can have similar or even improved binding affinity for target strands,[46] and can be used as translational inhibitors and anti-miRNAs.[37] Although PMOs lack the ability to trigger RNase H, they have proved resistant to nuclease degradation[47] and show promise for modulating splicing and translation arrest.[48]

Therapeutic ONs are often also conjugated with biologically relevant moieties.[49] ON conjugates have demonstrated increased circulation times, improved cellular uptake and endosomal release, and targeted tissue uptake and cellular localization. The following types of conjugates have been investigated in clinical trials: lipids including cholesterol,[50] small molecules (in particular in combination with aptamers),[51] PEG (polyethylene glycol),[52] nucleic acids (see aptamers), peptides,[53] and carbohydrates in particular GalNAc.[54] For further reading, several recent review articles are available on ON conjugates and their biological activity and synthetic strategies.[28b,49,55]

6.11.3.2 Modifications of the Sugar

Modifications to the ribose provide a remarkable level of control over the sugar conformation in the nucleotide, which determines the ON's binding affinity toward its complementary strand and duplex structure. Sugar puckering can be altered through gauche and anomeric effects of the neighboring hydroxyl groups or via steric restraints.[56] Most nucleotide sugars and analogs adopt conformations characterized as either "North" (C 3′-endo and C 2′-exo), or "South" (C 2′-endo and C 3′-exo). In the B-form, most prevalent in double-stranded DNA, riboses adopt the "South" conformation, whereas in the A-form, most prevalent in double-stranded RNA, riboses adopt the "North" conformation.

The 2′-*O*-methyl (2′-*O*-Me) nucleoside analog is one of the most widely used modification in ON therapeutics. Compared with a DNA strand, incorporation of 2′-*O*-Me units within ONs increases binding affinity for RNA complements[57] and increases nuclease stability.[58] 2′-*O*-Me ribose prefers a North sugar conformation[59] and forms A-form duplexes.[59b] The 2′-*O*-Me modification has been widely applied in antisense ON research, especially when incorporated in the so-called "gapmer" ON constructs. 2′-*O*-Me modified ONs are in many clinical trials[60] and can be found in the first FDA-approved aptamer, Macugen.[61] These analogs are also well suited for siRNA modification. Indeed, 2′-*O*-Me units are well tolerated in siRNAs,[23,27a] although this modification is not tolerated at every location of the RNA duplex, particularly the guiding strand.[62] 2′-*O*-Me modifications have been shown to reduce immunostimulatory properties of siRNAs.[63]

The 2′-*O*-MOE (2′-*O*-(2-methoxyethyl)) modification has been used in several therapeutic candidates undergoing clinical trials.[37] Like with 2′-*O*-Me, the 2′-*O*-MOE modification increases target-binding affinity (2°C per insert)[64] and improves nuclease stability.[64a] 2′-*O*-MOE modifications adopt a North sugar conformation.[37,64a] 2′-*O*-MOE groups have been successfully applied to antisense ON using the aforementioned gapmer design and in siRNA, especially in the passenger strand.[65] One of the approved antisense therapeutics, Mipomersen, is a second-generation antisense ON containing phosphorothioate linkages and 2′-*O*-MOE sugars.[4a]

The 2′-fluoro modification is another popular chemical modification particularly for siRNA. 2′-fluoro, like 2′-*O*-Me, is an RNA mimic, preferentially adopting a North sugar pucker,[66] at least partly due to the strong gauche effect imparted by the 2′-fluorine. Much like 2′-*O*-Me, 2′-fluoro increases binding affinity for target RNA sequences (2–3°C per insert versus DNA) [37,64b,67]. 2′-Fluoro modification is very well tolerated in siRNA, in both the guide and the passenger strands [62b,68]. The 2′-fluoro substitution has allowed for the complete elimination of RNAs from siRNAs without compromising incorporation into RISC, thereby providing duplexes with increased stability and potency that still act via activation of the RNAi pathway.[69] Like 2′-*O*-Me, 2′-fluoro modifications can also be found in the FDA-approved aptamer, Macugen.[61]

Locked nucleic acid (LNA) or 2′,4′-bicyclic nucleic acid (2′,4′-BNA) is a chemically modified RNA analog where a methylene bridge is forming a covalent linkage between the 2′-OH and the C-4′ of the sugar.[70] These nucleoside analogs are essentially locked in a North sugar conformation that closely mimics the A-form prevalent in RNA, which effectively preorganizes LNA for RNA binding.[70,71] LNA shows the highest duplex stability effects of all chemical modifications, with stabilizations of 5–6°C per insert.[70a] As a result, LNAs have proved very useful in anti-miRNA,[72] antisense ON,[71] and siRNA applications [62b,73]. The strong binding properties of LNA make them particularly useful in anti-miRNA applications, where short sequences can be necessary for miRNA specificity. LNAs were found to be excellent antisense ON modifications when used in gapmer constructs.[74] LNA modifications are also compatible with siRNA chemistry requirements.[73] LNA modifications show improved nuclease resistance[74] and can reduce siRNA immunostimulatory response.[63]

Other bicyclic nucleic acids (BNAs) have been introduced over the years.[65] A BNA analog, which has been successfully applied to generation 2.5 therapeutic antisense ONs, is (S)-cEt BNA, where (S)-cEt BNAs are mixed into the 2′-*O*-MOE flanks of a MOE gapmer. (S)-cEt and LNA show similar Tm and in vitro and in vivo activities. However, (S)-cEt BNA ONs showed an improved toxicity profile

relative to LNA ONs. These data suggest that (S)-cEt BNA has the potential to improve the therapeutic index of antisense drugs.[65] Bicyclo[3.1.0]hexane-based nucleoside analogs (2p-deoxy-methanocarba nucleosides [MC]) adopt a North sugar conformation, enhance thermal stability of duplexes, and enhance siRNA serum stability.[75] Another conformationally constrained nucleoside analog, tricyclo-DNA (tc-DNA), has shown promise in early development.[76] It is based on a tricyclic rather than bicyclic ring system. tc-DNA shows enhanced binding affinity to RNA, does not activate RNase H, and is stable to nucleases.[76]

Contrasting the rigid nature of LNA, the highly flexible unlocked nucleic acid (UNA) (or "seconucleoside") modification is also being developed for application in ON therapeutics. UNA, missing the covalent C2′–C3′ bond of a ribose sugar, is not conformationally restrained and can be used to influence ON flexibility.[77] UNA can reduce duplex T_m up to 5–10°C per insert[77,78] but still facilitates antisense strand selection into the RISC complex. UNA modifications placed into the seed region of a siRNA guide strand can significantly reduce off-target effects.[79]

6.11.3.3 Modification of the Heterocyclic Base

Chemically modified nucleobases have also found application in ON analog development. Although perhaps less common than sugar and backbone modifications, modified nucleobases are numerous and can be used to affect thermal stability,[80] reduce immunostimulation, and affect siRNA off-target effects.[81]

Modification of the heterocycle has focused mainly on increasing binding affinity for complementary nucleic acids.[80,82] This may be accomplished through increasing stacking interactions or by increasing the strength of the Watson–Crick base pairs. The 5-bromo- and 5-iodo-uracil substitutes of uracil, and 2,6-diaminopurine in place of adenine have been used to achieve increased duplex stability by increasing the strength of the Watson–Crick hydrogen bonding while maintaining and improving native base pairing recognition.[62b,68,83]

The C5 position has been a common place for chemical manipulation on pyrimidine heterocycles because substitution at this position increases affinity without affecting the ability to serve as an RNase H substrate. Substituting the C5 hydrogen of deoxycytidine with a methyl group improves the T_m of the DNA–RNA duplex by approximately 0.5°C per substitution[84] owing to enhanced base stacking on the 5′-side nucleobase. C-5 propynyl pyrimidine base modifications also increase duplex thermal stability and are compatible with RNase-H-mediated gene silencing but have shown some associated toxicity.[37,85]

6.11.4 Historical Perspective of Oligonucleotide Synthesis

In the beginning of the 20th century, biochemists realized that DNA played an important role as biomolecule in the living cell. Initially, a major emphasis was taken to determine its structure, which was accomplished by Watson and Crick in 1953.[86] Subsequently, in 1955, Michelson and Todd[87] reported the first synthesis of a dinucleotide with proper 3′–5′ orientation. The challenges in the synthesis of DNA were selective protection and deprotection of various reactive moieties present in deoxyribonucleosides. These challenges were successfully resolved by Khorana and his group,[88] who introduced various protecting groups (trityl groups for primary hydroxyl and benzoyl, and isobutyryl for exocyclic amines) in the 1950s and 1960s and also reported the first synthesis of sequence-defined oligodeoxynucleotide.[89] Interestingly, most of these protecting groups are still in use today. The chemical strategy used was termed phosphate diester, as after condensation a phosphate diester was formed. In spite of some of the early shortcomings, this strategy was successfully utilized for the assembly of a synthetic gene.[90]

In the 1960s and 1970s, Letsinger and his team introduced a new synthesis strategy termed phosphate triester methodology, which addressed some of the shortcomings of the phosphate diester approach.[91] The phosphate triester approach was further improved through the introduction of better coupling agents by several groups, in particular Reese,[92] Narang,[93] and Cramer.[94] The introduction of solid-phase synthesis by Letsinger and coworkers[91] simplified ON synthesis to the point of having them readily available to support research in molecular biology, recombinant technology, and genetic engineering.

Newer applications, especially exploration of synthetic ONs for therapeutic and diagnostic purposes, started to emerge in the 1970s and 1980s after Zamecnik and Stephenson[1b] reported the inhibition of Rous sarcoma viral ribonucleic acid (RNA) translation and viral replication in cells. These investigations provided impetus for the development of novel synthesis strategies based on P(III) chemistry.[95] Caruthers[96] in the United States and Köster[97] in Germany, respectively, introduced methyl-phosphoramidite and β-cyanoethyl-phosphoramidite chemistries. During the same time period, Garegg et al.[98] from Sweden and Fröhler et al.[99] from the United States introduced a synthetic approach based on H-phosphonate chemistry originally adapted to diribonucleoside synthesis by Todd et al.[100]

Along with oligodeoxynucleotide chemistry advances, strategies for synthesis of oligoribonucleotides were also independently developed by two groups (Reese in United Kingdom[92] and Ogilvie in Canada[101]). The chemistry developed by Ogilvie utilized *t*-butyldimethylsilyl protection for the 2′-hydroxyl group, whereas Reese's group applied tetrahydropyran and variants. The 2′-*O*-*t*-butyldimethylsilyl group is still the preferred protecting group for oligoribonucleotide manufacturing today. Several review articles are discussing the different chemical approaches used for making synthetic ONs.[102] At present, the β-cyanoethyl-phosphoramidite chemistry is predominantly used in solid support-based ON synthesis. The specific synthesis cycle and steps involved are presented later in this report (**Fig. 2**).

The impurities present in ONs depend on the synthesis methods utilized during their preparation. The chain elongation step in the phosphate diester approach used during the early days of ON synthesis is very slow and results in branching of the chain as the

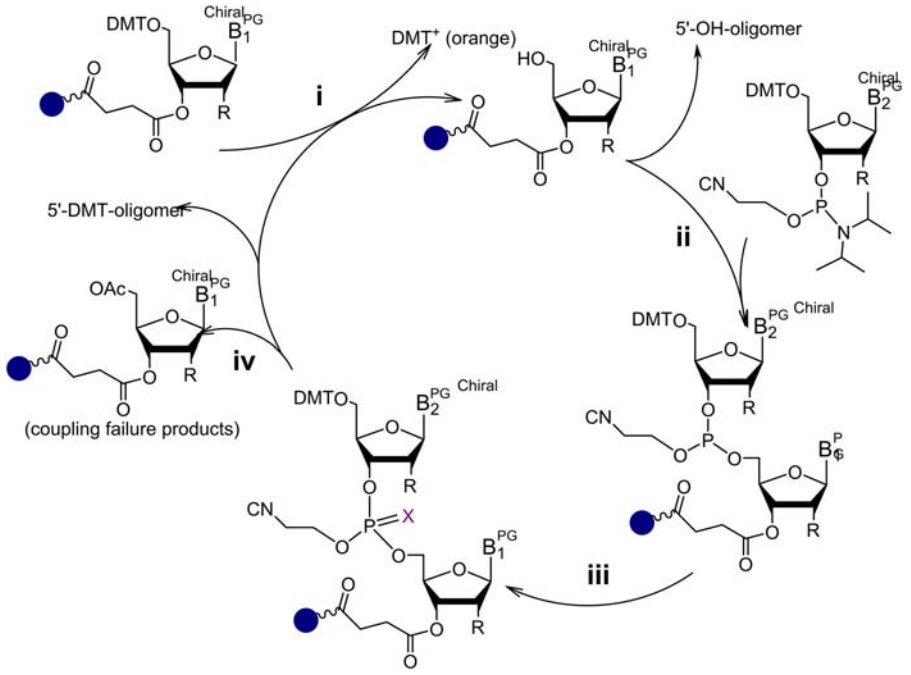

Fig. 2 Solid-phase synthesis cycle for oligonucleotide synthesis.

resulting phosphate diester is exposed to activation and condensation. Subsequently, the phosphate triester approach was developed, where the chain elongation step is much faster and the coupling reaction proceeds without the need for activating agents. The phosphate triester formed is not exposed to further activation, thereby mitigating the formation of branched impurities. However, branching or modification can still occur at the heterocyclic bases especially at the unprotected O-6 position of guanine and the O-4 position of thymine/uracil. Impurities can further result from strand cleavage during the removal of the phosphate protecting groups.

The introduction of the microprocessor in the 1980s allowed automation of ON synthesis. Two synthetic approaches based on phosphoramidite and H-phosphonate chemistries were predominantly adapted for automated synthesis. During early stages of automation, instrument-related impurities such as deletion of monomers or double additions were observed. H-phosphonate-related impurities were based on unwanted capping taking place with the activating reagent pivaloyl chloride or adamantanoyl chloride present during chain elongation resulting in failure sequences. This article will mainly cover impurities introduced when using the phosphoramidite approach since it is being used predominantly today.

6.11.5 Raw Material-Related Impurities

6.11.5.1 Phosphoramidite-Related Impurities

All nucleosides used in the synthesis of therapeutic ONs today are sourced exclusively from man-made synthetic sources and must be certified to be BSE- and TSE-(transmissible spongiform encephalopathy) free. Nucleosides' reactive sites need to be selectively protected before converting them to phosphoramidites. The protection of the 5′-hydroxyl (and the 2′-hydroxyl group in RNA) and all exocyclic amino groups is necessary to minimize side reactions during ON synthesis.

Phosphoramidite impurities are predominantly introduced through the following three sources:

(1) The introduction of nucleoside protecting groups
(2) The quality of synthetic nucleosides (α-anomeric and 3′-substituted impurities)
(3) The quality of the phosphitylating reagent

These impurities may influence the overall quality of ONs as these impurities can be reactive and critical. Based on their reactivity and criticality, impurities are divided into three categories[103]:

(1) Nonreactive and noncritical
(2) Reactive but noncritical
(3) Reactive and critical

For a recent in-depth discussion on this topic, please refer to a recent review article on this topic and the references therein.[104]

6.11.5.2 Nonreactive and Noncritical Impurities

This class of impurities is made up of nonphosphorylated nucleosides and hydrolyzed or oxidized phosphite species. These impurities do not interfere with the synthesis of ONs. Impurities can be either nucleoside-based or phosphitylating reagent-based and are mostly formed during the phosphitylation of the protected nucleoside (PNS) to make the phosphoramidites. Fig. 3 shows the conversion of a PNS to a phosphoramidites and what type of impurities can be formed during this reaction.

6.11.5.3 Reactive but Noncritical Impurities

Reactive but noncritical phosphoramidite impurities are generated from nucleoside impurities with partially modified N, 5′-O or 2′-O (RNA)-protecting groups. These phosphoramidite impurities will also incorporate into the ON chain but will be removed together with the standard protecting groups without impacting the quality of the synthesized ON.

The most commonly used 5′-hydroxyl protecting group is the dimethyltrityl (DMT) group. Impurities are reactive modified trityl chlorides (composed of methoxy, methyl trityl, or monochlorodimethoxytrityl) and nonreactive dimethoxytritanol. Another type of reactive protecting group impurities is those associated with exocyclic amine protection of the nucleoside base. In place of standard protecting groups (Bz on C and A, and iBu on G), chlorobenzoyl protecting groups on cytosine, adenine and *n*-butyryl on guanosine are the most common impurities. Fig. 4 marks the places where impurities can be seen in the phosphoramidites.

6.11.5.4 Reactive and Critical Impurities

Sources of reactive and critical impurities are the following:

(1) Preparation of the unprotected nucleoside
(2) Protection of the 2′, 3′ and 5′-hydroxyl groups of the sugar
(3) Protection of the exocyclic amino group of the base
(4) Originate from reactive impurities in the phosphitylating reagent

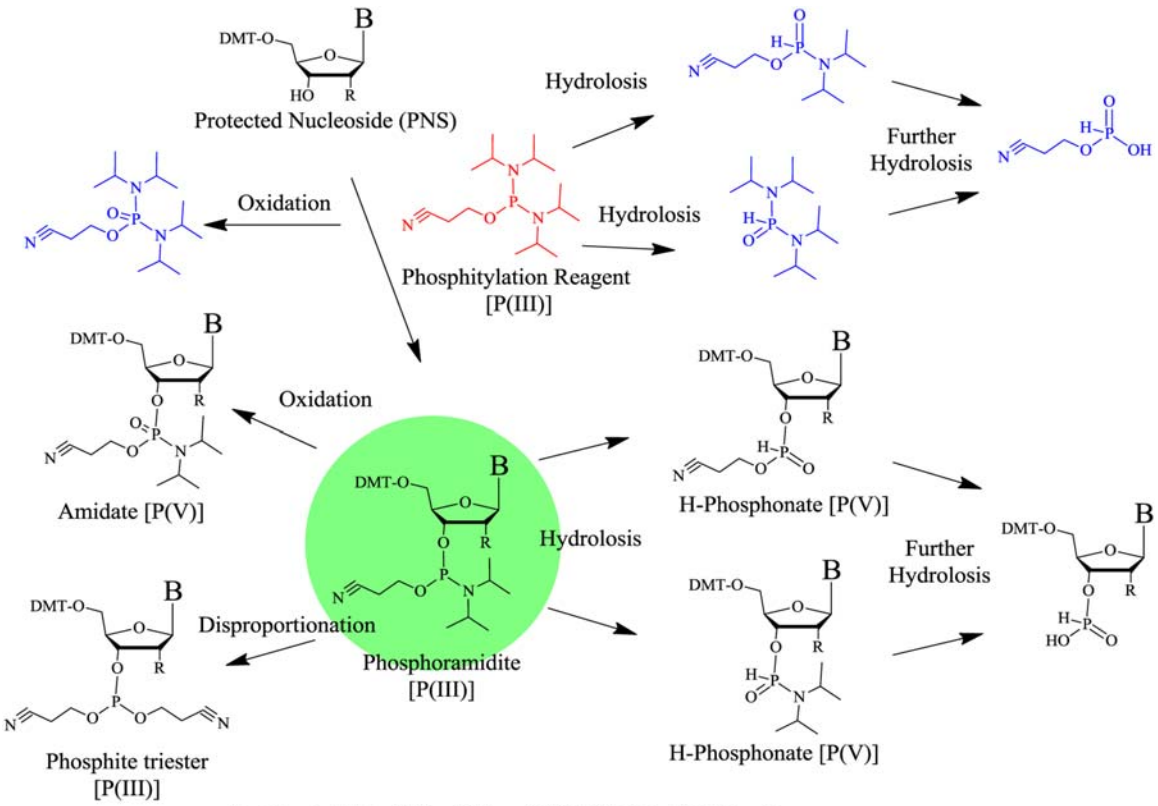

Fig. 3 Nonreactive and noncritical impurities and how they being created during the making of the phosphoramidite. Centered with *green* background shows the phosphoramidite. Structures in *blue* are degradation products from the phosphitylation reagent. Phosphitylating reagent in red if not fully removed would be a reactive and critical impurity.

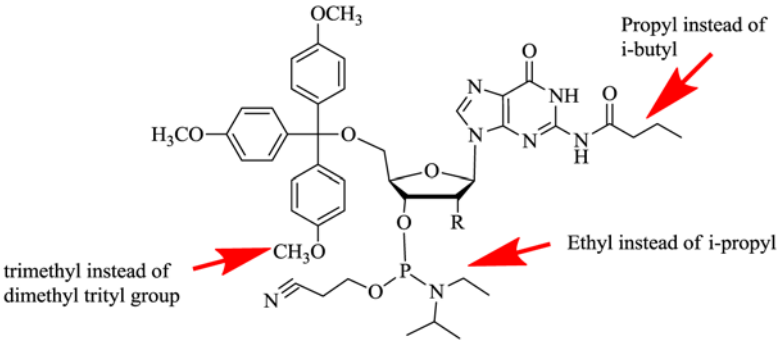

Fig. 4 Example of reactive but noncritical impurities created by impurities in the protecting groups.

Incorporation of these reactive impurities has significant impact on the quality or nature of the ON synthesized. Hence, control of the impurities is of utmost importance. Examples for reactive and critical impurities resulting from impurities in nucleoside-phosphoramidites are given in Fig. 5. Structure **1** in Fig. 5 is α-isomer, structure **2** 3′-phosphoramidite, and structure **3** 5′-phosphoramidite. The 3′-phosphoramidite is a common impurity of all RNA-type phosphoramidites, in particular with TBDMSi-protection. Any isomeric impurities are difficult to detect since they have the same mass and also similar retention time during HPLC analysis and similar chemical field in the ^{31}P-NMR. However, the quality of the nucleosides and phosphitylating reagent has greatly improved over the years, and today, only small levels of most impurities are detected in amidites used in ON manufacturing for therapeutic applications.

Impurity **4** in Fig. 5 results from an impurity in the phosphitylation reagent. The iso-propyl group is not being removed during standard cleavage and deprotection conditions and will form an impurity in the final ON having a mass of +42 Da. Impurities **5** and **6** are being formed when introducing the protecting groups to the nucleosides. The DMT-group in impurity **5** will be removed during detritylation step of the synthesis and then is available during the next coupling reaction to react with the incoming amidite to form branchmers. The same fate will have impurity **6**, the formation of branchmers.

As mentioned earlier, impurity **2** is a common impurity found in 2′-modified sugars and will form a 2′, 5′- instead of a 3′, 5′-linkage. Since these impurities are phosphoramidite manufacturing process related, their complete elimination is unlikely but they can be monitored and controlled using proper analytic methods and appropriate specifications for the phosphoramidites. HPLC-MS analysis is an important tool for the accurate identification of impurities impacting the quality of ONs. ^{1}H NMR and RP-HPLC have been used for identification of nucleoside-phosphoramidites. ^{31}P NMR and RP-HPLC can be effectively used for controlling reactive impurities in phosphoramidites. An example for a phosphoramidite analyzed by HPLC and ^{31}P NMR is illustrated in Figs. 6 and 7. The HPLC analysis (Fig. 6) shows two noncritical impurities and one critical impurity. The noncritical impurities are the hydrolyzed phosphoramidites and a double DMT-protected nucleoside, 5′,3′-*O*-Di-DMT-2′-*O*-Me adenosine. The critical impurity is the phosphoramidite with an additional DMT group in the base. The ^{31}P NMR does not show the double DMT-protected nucleoside, since this impurity does not contain any phosphorous. However, only ^{31}P NMR will detect impurities resulting from the phosphitylation reagent since it does not have a chromophore and is therefore not UV active.

6.11.6 Solid Supports

The solid supports used in ON synthesis also present a potential source of impurities, and a good understanding of the different types of supports and processing conditions is important to reduce the impurity burden in the final product. Traditionally, silica-based controlled pore glass (CPG) was almost exclusively used in phosphoramidite-based solid-phase ON synthesis. CPG supports could be manufactured with predefined pore sizes and space required for a growing ON chain. They are nonswelling and inert to the solvents and reagents used during ON synthesis. Typically, in ONs synthesis, a CPG support with a pore size of 500 Å is used for ONs up to a length of 30 bases and a pore diameter of 1000 Å for up to 50 bases.[105] The lengths of therapeutic ONs are generally under 50 bases long; hence, CPG support with 500 Å or 1000 Å pore size satisfies this need. Disadvantages of glass supports, however, include the instability toward basic conditions used during cleavage and deprotection and low loading capacity, which can lead to formation of impurities.

To mitigate CPG's disadvantages, highly cross-linked polystyrene[106] and methacrylate[107] supports were developed. These initially developed supports have low loadings and are still in use for small-scale ON synthesis.[108] Later, high-loaded macroporous polystyrene supports with loadings of 200 μmol nucleoside per gram of support were developed by Pharmacia Biotech (now part of GE Healthcare). Another high-loading solid support, NittoPhase, originally developed in collaboration with ISIS Pharmaceuticals is being sold by Nitto Denko. Latest developments have led to a support called NittoPhase HL with loadings of 400 μmol nucleoside per gram. Other high-loaded supports have been developed or are in development. ISIS Pharmaceuticals has developed a new polystyrene-based high-loaded support (350 μmol/g), which recently was made available commercially by GE Healthcare

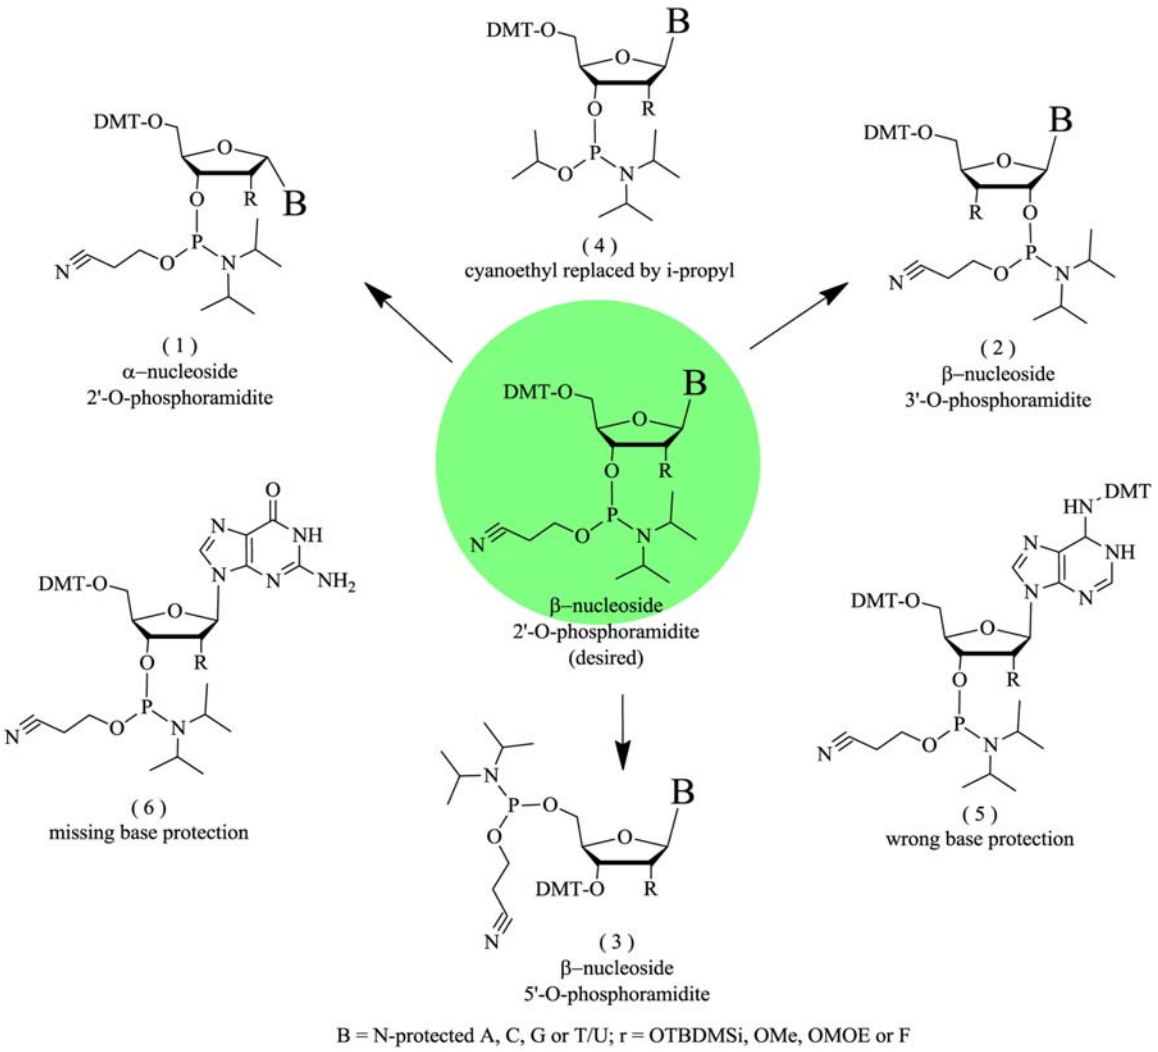

Fig. 5 Example for reactive and critical impurities in nucleoside-phosphoramidites. The structure in the green circle shows the desired phosphoramidite. Structure 1 is the α-isomer, structure 2 the 3′-phosphoramidite and structure 3 the 5′-phosphoramidite. Impurity 4 results from an impurity in the phosphitylation reagent. Impurities 5 and 6 are being formed when introducing the protecting groups to the nucleosides.

under the name Primer Support 5G. The different chemistries used for the development of solid supports utilized in ON synthesis are summarized in Fig. 8.

6.11.6.1 Nucleoside-Loaded Supports

Traditionally, a nucleoside succinate is allowed to react with an amino- or hydroxyl-functionalized support to create a nucleoside-loaded support.[109] The succinate linkage thus created between solid support and nucleoside is stable to conditions and reagents used during solid-phase synthesis. At the end of the synthesis, during basic cleavage and deprotection conditions, the succinate linkage is hydrolyzed, releasing the ON chain from the support. Other more base-labile linkers have been developed such as oxalate[110] and Q-linker,[111] but the succinate linkage is the most widely used one in large-scale synthesis. The stable succinate linkage allows selective removal of cyanoethyl phosphate protecting groups without releasing the ON from the support using on-column base washing. This inhibits acrylonitrile adduct formation of the heterocyclic bases, in particular thymine.[112]

CPG supports require a spacer in between the nucleoside succinate and the functional group of the support to ensure good coupling efficiencies. Thereby, the amino- or glyceryl-functionalized CPG support is derivatized with a long-chain alkyl amine (LCAA)[113] (see Fig. 8) or other similar linkers as described by Sirna Therapeutics[114] or others[105a] before attaching the nucleoside succinate. With polystyrene supports, functional (amino or hydroxyl) groups are reacted directly with the nucleoside succinate, and no additional linker is required.

The coupling of a nucleoside-3′-*O*-succinate to the support can be performed with 2,2′-dithiobis(5-nitropyridine) (DTNP) and dimethylaminopyridine (DMAP) followed by addition of triphenylphosphine (TPP) and LCAA-CPG.[115] Alternatively, the

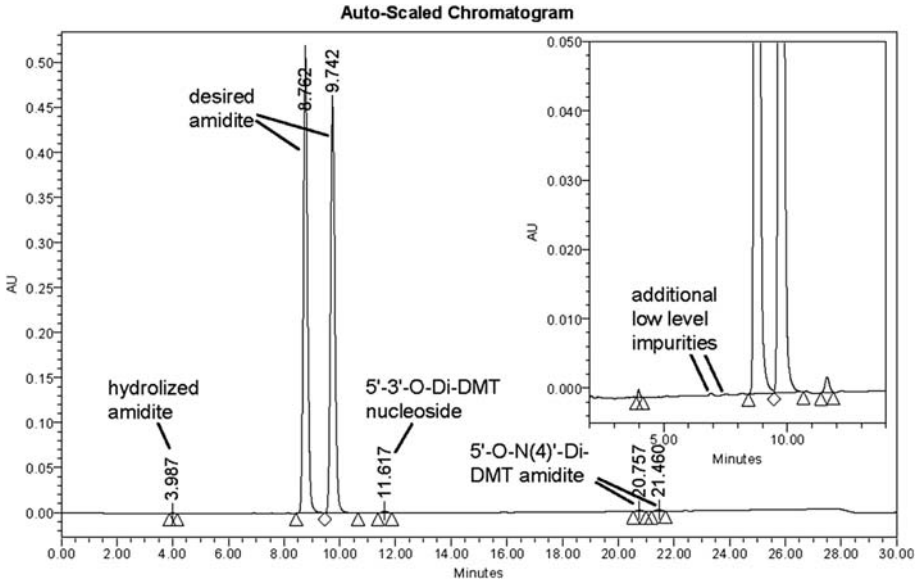

Fig. 6 2′-*O*-Methyl-A phosphoramidite analyzed by HPLC (purity of 99.3%).

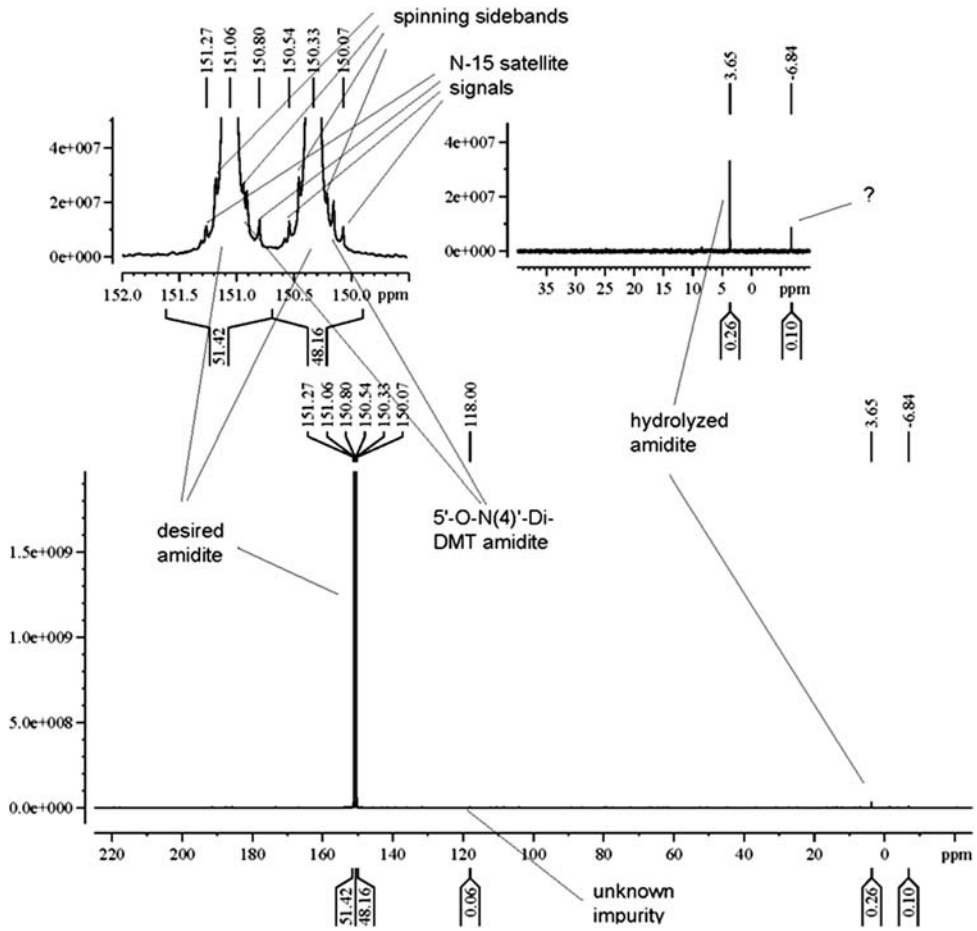

Fig. 7 2′-*O*-Methyl-A phosphoramidite analyzed by ^{31}P-NMR (purity of 99.5%).

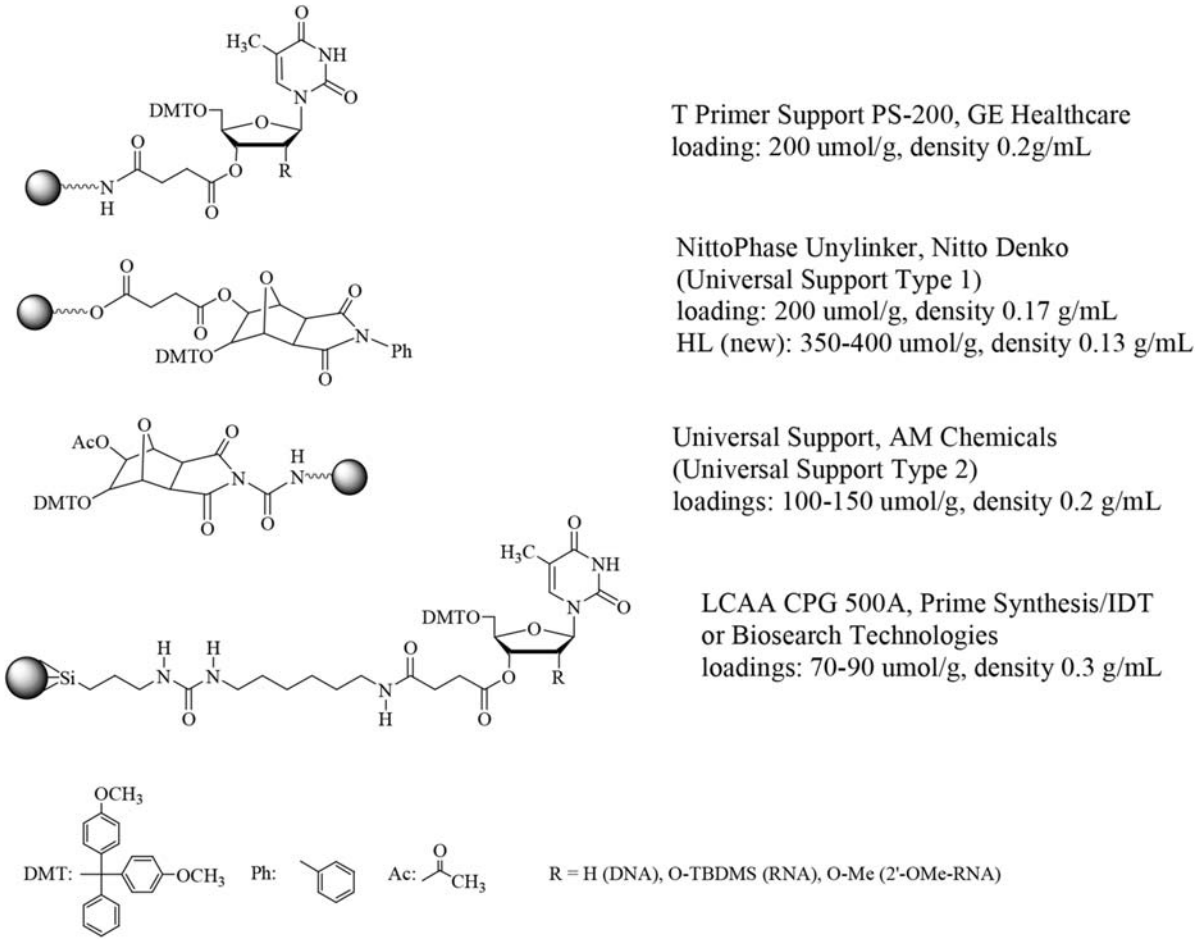

Fig. 8 Common types of supports used in solid-phase oligonucleotide synthesis.

nucleoside-3′-*O*-succinate can be attached to LCAA-CPG using a variety of phosphonium or uronium coupling agents or soluble carbodiimides, namely, diisopropylcarbodiimide[116] and DMAP.[117]

6.11.7 Formation of Branchmers

During manufacture or storage of nucleoside-loaded support, the loss of protecting groups of the heterocyclic base can lead to impurities, called branchmers, in particular for cytidine (C) and adenine (A) nucleoside-loaded supports. Free or unprotected exocyclic amino groups, when exposed to the coupling conditions, will also react with the incoming phosphoramidite resulting in branching and eventually leading to a species having almost twice the molecular weight ($2n-1$).[118] In RNA synthesis, acidic triethylamine trihydrogen fluoride (TEA-3HF) is commonly used for the removal of the 2′-O silyl protecting group. This acidic reagent reacts during desilylation with the amidate group between the exocyclic amino and the first nucleoside after the branching point, cleaving the chain and resulting in the formation of a $n-1$ from the 3′-end carrying a 3′-phosphate group.[119] A capping step prior to the start of the synthesis would limit any free exocyclic amino moiety and thereby prevent 3′-terminal branching. However, any free 5′-hydroxyl group created by the loss of the dimethoxytrityl (DMT) group would be capped as well, resulting in yield losses.

6.11.7.1 Generation of $n-1$ (PS)/$n-1$ (PO) Impurities

$n-1$ impurities containing a 3′-terminal PS/PO group are formed when any unprotected functional group left on the support is able to react with a nucleoside-phosphoramidite. When using a nucleoside-loaded support, this would lead to an ON missing the 3′-base, (called $n-1$) from the 3′-end, since the 3′-nucleoside is part of the support. The $n-1$ would be connected to the support via a phosphodiester (PO, oxidation) or phosphorothioate bond (PS, sulfurization). The cleavage of such a bond will typically result in an $n-1$ impurity having a 3′-terminal phosphate or 3′-terminal phosphorothioate (3′-TPT).[120]

These impurities cannot easily be removed, and therefore, it is important that all functional groups remaining on the support are capped. Amino or hydroxyl groups of polystyrene supports usually react well with regular capping reagents. However, unreacted surface silanol groups of CPG are more difficult to cap and cannot be blocked with standard capping reagents. Silanol groups can be classified as "free" or "associated."[121] The associated form consists of two adjacent silanols with hydrogen bound to each other (vicinal) or a silanol with two hydroxyls located on the same atom (geminal). Associated silanols are reactive to trimethylchlorosilane (TMCS), while free silanols are more reactive toward hexamethyldisilazane (HMDS).[122] Repetitious silanization (monolayer conditions) or single silanization followed by a dual silanol capping treatment with TMCS and HMDS, can provide complete coverage of all silanol groups. The $n-1$ impurity from the 3′-end used to be a common side product in ON synthesis using CPG supports, because of the difficulties in capping free silanols. As standard capping reagents are unable to block free silanols, alternative means of capping using phosphorylation reagents such as diethoxy *N*,*N*-diisopropyl (DDP)[123] or bis-2-cyanoethyl-*N*,*N*-diisopropyl phosphoramidite followed by oxidation[124] have been suggested.

The loss of capping of the support can also occur during storage. Capping loss during storage or incompletely capped support will have the same result, 3′-($n-1$) impurities in the final ON. These 3′-($n-1$) impurities often contain a 3′-terminal thiophosphate or phosphate group. A capping step prior to the first synthesis cycle would prevent $n-1$ (3′-end) formation. While a simple capping step using acetic anhydride would efficiently cap free exocyclic amino groups of the heterocyclic base as mentioned earlier, it would be ineffective in capping free silanol groups of the CPG support. Also, any 5′-*O*-DMT-group lost during storage would be capped as well resulting in diminished yields.

$n-1$ impurities with 3′-terminal PS/PO are also formed when acid-labile nucleosides are loaded onto the solid support. For example, deoxyadenosine and, to a lesser extent, deoxyguanosine supports are prone to depurination at prolonged acid treatments during synthesis resulting in $n-1$ impurity.[125] The amount of N-glycosidic-bond cleavage is highly dependent on the nature of the base-protecting group. Classical protecting groups like benzoyl for adenosine and isobutyryl for guanosine are more sensitive to depurination than fast deprotecting groups such as alkyl formamidine or phenoxyacetyl and p-substituted phenoxyacetyl groups, with formamidine being the least sensitive. Linking adenosine via the exocyclic amino group to the support has been suggested to minimize the $n-1$ impurity.[125a] Then, an adenine loss due to depurination would result in the loss of the ON chain during synthesis; hence, no depurinated impurity would remain in the product.

6.11.8 Universal Supports

Solid supports without preloaded nucleosides are termed Universal support. These supports have several advantages over nucleoside-loaded supports. They do not suffer from the loss of base-protecting groups during storage or preparation. The formation of branchmers, depurinated species, $n-1$ with 3′-terminal PS/PO as described for nucleoside-loaded supports, can be avoided. Additionally, same universal support can be used for oligodeoxynucleotide and oligoribonucleotide synthesis. Many different universal supports have been developed over the years.[126] Today, the most widely used universal supports are UnyLinker[127] (**Fig. 8**) and Universal A-Support[128] (**Fig. 10**). UnyLinker was developed by Guzaev et al.,[127a] and its use was further refined by Ravikumar et al.[127b]

Two different variants of UnyLinker are available. The UnyLinker bicyclic ring system can be connected to the support either via the nitrogen of the maleimide group (type I) or through one of the hydroxyl groups of the diol (type II) (**Fig. 8**). The ON chain grows on the other hydroxyl groups of the diol. In the case of the type II support, the nitrogen of the maleimide group is typically protected by a phenyl group.[127b] Glen Research also offers a methyl-protected derivative called UnySupport[129] for high-throughput ON synthesis. During cleavage and deprotection (C&D), the vicinal hydroxyl group, protected during the synthesis by an acetyl group (type I) or connected to the support via a succinate (type II), is liberated and attacks the phosphodiester (oxidation)/phosphorothioate (sulfurization) group leading to the elimination of the 3′-OH ON.[127b] Incomplete cleavage of type II UnyLinker can lead to an impurity where the 3′-end of the ON is still attached to the UnyLinker via a phosphodiester/phosphorothioate group (**Fig. 9**). The majority of bicyclic impurity created during ammonia cleavage conditions has an additional mass of 261 (PO) or 277 Da (PS). If methylamine is used for cleavage of the support, the mass difference is 275 (PO) and 291 (PS). The bicyclic impurity represented in **Fig. 9** can further react with NH_4OH or NH_2Me, respectively, and open up the succinimide ring. This type of impurity can be avoided with the type II UnyLinker, in which the nitrogen of the maleimide group is connected to the support via a stable amide bond.[130] Incomplete cleavage of this type of UnyLinker would only lead to some yield loss; however, extending the cleavage and deprotection time would minimize any loss in yield.

The hydroxyl group of the diol system required for ON growth is typically protected with a DMT-group. As a secondary hydroxyl group, it is less reactive and more sterically hindered than the 5′-hydroxyl group of a sugar. Hence, its removal requires a longer exposure time to detritylation reagent, dichloroacetic acid (DCA), during detritylation. Once the trityl group has been removed, the resultant secondary hydroxyl moiety reacts more slowly to the incoming phosphoramidite. Both of these phenomena can lead to the formation of $n-1$ from the 3′-end, a common impurity found when using UnyLinker. However, these problems can be mitigated by extending the first detritylation step (or using 10% DCA solution) and extending the first coupling time.

The Universal A-Support was developed by Azhayev et al. and is available on both polystyrene and CPG supports [128] (**Fig. 10**). The cleavage and 3′-dephosphorylation reaction are facilitated by a solution of 4 M anhydrous ammonia in methanol. The labile dichloroacetyl group is cleaved prior to the β-elimination of the cyanoethyl protection group of the phosphate moiety. This is followed by the rapid intramolecular nucleophilic attack on the phosphotriester function by the hydroxyl group. This

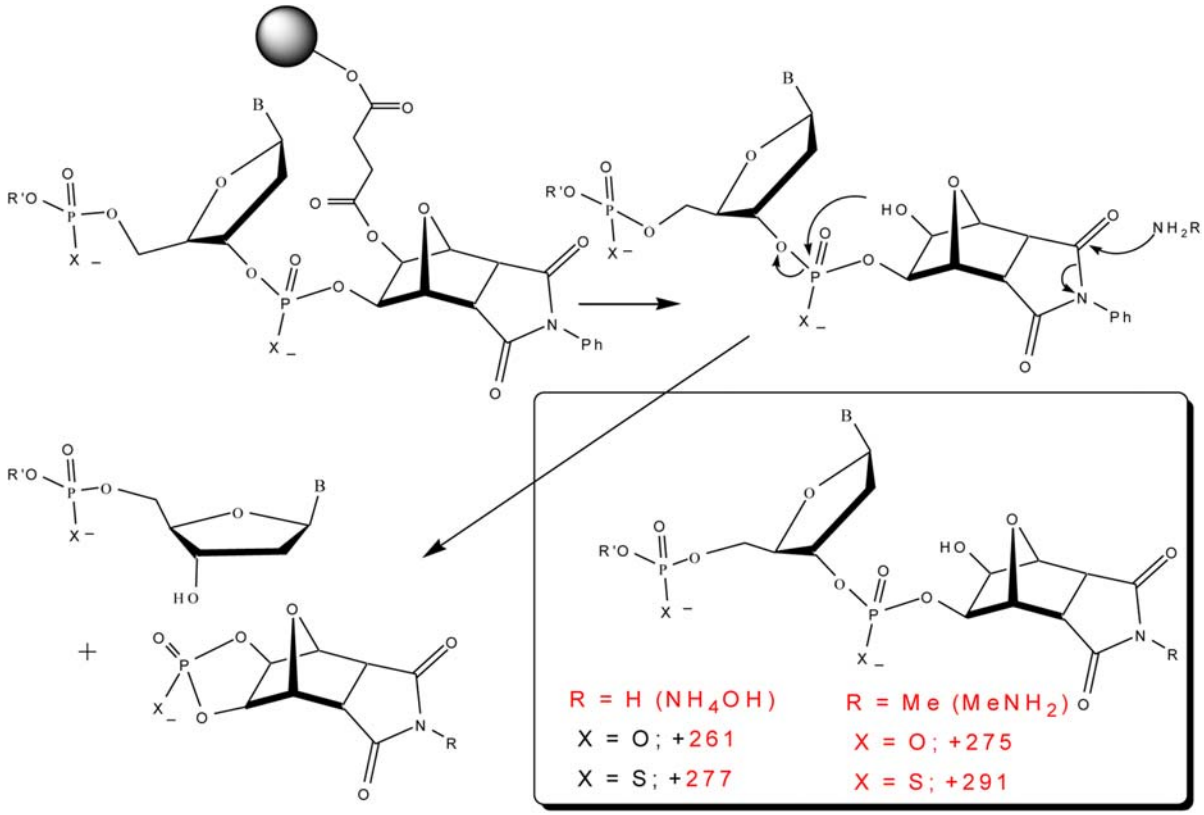

Fig. 9 Proposed mechanism for formation of bicyclic impurity.

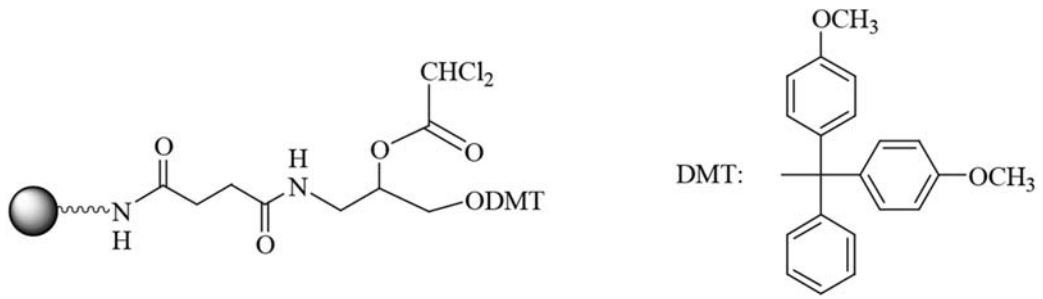

Fig. 10 Structure of Universal A-Support.

reaction is additionally assisted by the neighboring amide function. For a quantitative release of the ON from the support, it is critical that the dichloroacetyl group is cleaved prior to the cyanoethyl phosphate protecting group closest to the spacer of the support. Once the cyanoethyl group is cleaved, the hydroxyl group is not able to attack the phosphorus since it now represents a negatively charged phosphodiester function and the ON remains attached to the support. It therefore is important to use mildly basic conditions for the initial selective removal of the dichloroacetyl group. Universal A-Support is therefore not compatible with the base wash (e.g., DEA (diethylamine) wash) typically performed in large-scale ON manufacturing for the release of the phosphate protecting groups before initiating cleavage and deprotection, in order to minimize the formation of the CNET impurity.

After removing the solid support, further deprotection procedures typically employ addition of aqueous ammonium hydroxide to the solution of ON in methanolic ammonia and overnight heating at 55°C. A more easily accessible Universal A-Support was recently introduced where the succinylamido-linked support is replaced by a urea-linked support.[131]

6.11.9 Reagent-Related Impurities

6.11.9.1 Detritylation Reagent

Traditionally dilute solutions of trichloroacetic acid (TCA, pK_a 0.8) or dichloroacetic acid (DCA, p*K*a 1.5) in dichloromethane (DCM) were used as detritylation reagent for ON synthesis.[125b,132] Later, it was recognized that a high concentration of a weak acid (15% DCA in DCM) is more effective at driving detritylation toward completion than either a low concentration of a weak acid (3% DCA in DCM) or a low concentration of a strong acid such as 3% TCA.[132a] The high volatility (boiling point 40°C) of DCM and its high toxicity and carcinogenicity pose a health hazard for personnel and the environment in large-scale manufacturing of ONs. As a consequence in large-scale synthesis, DCM has been replaced with toluene, without compromising yield or quality of the synthesized ON.[133] Again, the amount of DCA in toluene appeared to be more effective at higher concentrations.[134] However, 3% DCA in toluene is still widely used in the industry as higher concentration of DCA may be more corrosive to the synthesizer and its components, which are typically made of stainless steel.

Increased exposure of ONs to acids leads to depurination, and therefore, the acid contact time needs to be controlled. The detritylation reaction is complex[125b,132] and the amount of acid needed depends on the type of support used and increases with the ON chain length and is therefore not constant. The trityl cation generated during detritylation has an intense yellow/orange color, and it has been used to determine the end point of the detritylation reaction using spectrophotometric methods. Using this approach, the acid contact time can be minimized/controlled without affecting trityl removal. Incomplete removal of trityl can lead to the formation of $n-1$ impurities. Commercial DCA has been found to contain trace amounts of chloral (trichloroacetaldehyde), which can react with free 5′-hydroxyl groups during the detritylation reaction resulting into an adduct with an added mass of 147 Da.[135]

6.11.9.2 Activator

No impurities are known to result from impurities present in the activator solutions. Activators work through an acidic-based mechanism involving nucleophilic attack. Activators work as an acidic catalyst, thus not only making the dialkyl amino group a better leaving group[136] but also replacing the amino group before reacting with the 5′-terminal hydroxyl.[137]

6.11.9.3 Thiolation/Oxidation

After coupling, the P(III) triester linkage formed is unstable toward acidic reagent and is therefore converted to a stable P(V) triester linkage before further chain elongation. The most prevalent oxidation reagent used in ON synthesis is a water-containing iodine solution. The composition of the oxidation reagent used in large-scale manufacturing is typically 50 mM iodine in 90% pyridine and 10% water.[138] Concentrations of iodine used in ON synthesis may vary from 20 to 100 mM, and oxidation reagent for small-scale synthesizers typically includes THF[97a] as a solvent. Sometimes, lutidine is used in place of pyridine.[139] THF is not compatible with some of the components of the pumps and valves of large-scale ON synthesizers prohibiting the use of THF in large-scale synthesis. Lower concentrations of iodine are used for oxidation in the case of sensitive base or backbone modifications. However, some modifications have been found to be unstable to oxidation with iodine-containing solutions, regardless of iodine concentration. Also, in phosphodiester (PO), phosphorothioate (PS) gapmer iodine tends to convert some of the PS bonds into the more chemically stable PO bonds resulting into an ON with a mass of 16 Da less than the desired product.

As the coupling step in ON synthesis is very moisture-sensitive, a nonaqueous oxidation reagent would be preferred to maintain a water-free environment during each step of the synthesis cycle. Low water iodine mixtures have been suggested for the synthesis of methylphosphonates to avoid side-product formation.[140] One nonaqueous oxidizer that has been used for both DNA and RNA synthesis is *t*-butyl hydroperoxide.[141] Peroxides, however, are unstable compounds and not suited for large-scale manufacturing. A very mild oxidation reagent useful for the synthesis of modified ONs has been recommended, which is 0.1–0.5 M (1S)-(+)-(10-camphorsulfonyl) oxaziridine (CSO) in anhydrous acetonitrile.[142] Recently several other nonaqueous and non-iodine oxidation reagents have been described.[124,143] Besides the disadvantages mentioned, iodine remains the oxidation reagent of choice for ON synthesis as other nonaqueous reagents are either expensive or unstable and therefore not suited and/or economical for large-scale synthesis.

During ON synthesis by the phosphoramidite approach, a phosphorothioate is introduced by oxidizing the phosphite triester using a sulfur transfer reagent. The first described sulfur reagent was elemental sulfur.[144] However, elemental sulfur is difficult to keep fully dissolved and is therefore not suitable for automated synthesizers. With phosphorothioate ONs being one of the most important modifications, a large number of efficient sulfurizing reagents have been developed over the years. These include tetraethylthiuram disulfide (TETD),[145] bis(*O*,*O*-diisopropoxy phosphinothioyl) disulfide (Stec's reagent),[146] 3*H*-1,2-benzodithiol-3-one-1,1,-dioxide (Beaucage reagent),[147] phenylacetyl disulfide (PADS),[148] 3-ethoxy-1,2,4-dithiazoline-5-one (EDITH),[149] 1,2-dithiazole-5-thione (xanthane hydride or ADTT),[150] 3-((dimethylamino-methylidene)amino)-3*H*-1,2,4-dithiazole-3-thione (DDTT),[151] dimethylthiuram disulfide (DTD),[152] 3-phenyl-1,2,4-dithiazoline-5-one (PolyOrg Sulfa or POS),[153] and various sulfonic acid derivatives.[154]

Initially, TETD was the most prevalent sulfurization agent. Later, TETD was replaced by Beaucage reagent due to TETD's slow reactivity in particular for RNA synthesis. While Beaucage reagent was more efficient with faster reaction kinetics, it was not very suitable for large-scale applications due to its limited stability in solution and also due to formation of phosphate diester impurity

during thiolation. PADS and xanthane hydride were found to be inexpensive, efficient, and fast-reacting sulfurizing reagents. Therefore, these two sulfurizing reagents prevail in large-scale manufacturing today. Reagents like DDTT and POS offer better stability and/or solubility and are currently being used in small-scale synthesis.

6.11.9.4 Capping Reagent

The capping reaction is a key step in ON synthesis and serves in preventing unwanted chain elongation. Hence, control of the capping conditions is vital to limit impurity levels. Acetic anhydride is the most common capping reagent. Historically, it was used as a mixture with 2,6-lutidine, tetrahydrofuran (THF), and 4-*N*,*N*-dimethylamino pyridine (DMAP), which acts as an acetylation catalyst.[97a] Recent studies[155] have shown that DMAP converts dG and dG-containing oligomers into fluorescent derivatives and in the presence of ammonium hydroxide converts further to 2,6-diaminopurine deoxyribonucleoside (2,6-DAP), a potentially mutagenic nucleoside analog. *N*-Methylimidazole (NMI) has been suggested as an alternative to DMAP, which does not undergo the same side reactions.[155] Today, NMI has replaced DMAP as capping catalyst in routine ON synthesis.

The protection of guanosine by the phenoxyacetyl group precludes the use of acetic anhydride as the capping agent. An exchange reaction occurs between the guanine phenoxyacetyl group and the acetyl group of acetic anhydride during the capping reaction. This impurity is quite stable toward standard cleavage and deprotection and can be detected by HPLC-MS and results in a mass of +42 Da. To avoid formation of this adduct, acetic anhydride can be replaced by phenoxyacetic anhydride[156] or trimethylacetic anhydride.[157] A similar adduct formation was observed for isobutyryl-protected guanosine when using acetic anhydride as capping reagent. Isobutyric anhydride was suggested to replace acetic anhydride for capping.[158]

During synthesis of phosphorothioate ONs, capping needs to be performed after sulfurization. If this reaction occurs after capping, higher levels of the phosphodiester impurity can be observed.[145] For phosphodiester ON synthesis, capping may be performed before or after oxidation.

Acetic anhydride cannot be combined with the acetylation catalyst prior to capping. Therefore, two capping reagents (Cap A and Cap B) are delivered during the synthesis from two different bottle positions, which are being mixed inline. One of the capping reagents contains NMI (or DMAP) and the other contains acetic anhydride. In addition, one of either reagent contains a base, either pyridine or lutidine. THF has been replaced with acetonitrile (ACN) in large-scale synthesis. However, neither NMI nor acetic anhydride is stable in combination with base in the presence of ACN. Therefore, in large-scale synthesis, three capping reagents are used: Cap A, containing 20% NMI in acetonitrile; Cap B1, containing 40% acetic anhydride in acetonitrile; and Cap B2, containing 60% lutidine in acetonitrile. Typically, Cap B1 and Cap B2 are mixed together prior to use.

Capping efficiency is another important factor and if uncontrolled can lead to low yields and increased impurity levels. The efficiency of capping is dependent on the nature and amount of the activating agent, for example, NMI or DMAP[159] in the capping mixture (**Table 1**). DMAP appears to be more effective as a capping activator relative to NMI, though it has fallen out of favor due to its tendency to lead to guanosine modifications (vide supra). To overcome these, Glen Research has introduced a phosphoramidite-based capping reagent called UniCap (**Fig. 11**), which is also well suited for H-phosphonate chemistry.

The activating agent, NMI, has been shown to contain low levels of trimethylhexahydrotriazine, which can react with nucleotides to form a +85 Da impurity.[33] The mechanism of formation of this impurity is thought to involve a Mannich-type reaction between the enolate anion of acetic anhydride and the imine formed from trimethylhexahydrotriazine (**Fig. 12**).

As discussed, capping based on derivatives of acetic anhydride appears to be more complicated and gives rise to more impurities than would be expected. Therefore, capping using a terminating phosphoramidite like UniCap (**Fig. 11**) was suggested not only for the capping of the support[123,124] but also for capping after each coupling step.[159]

6.11.10 Research-Scale Manufacture of Oligonucleotides

The overall manufacture of ONs can be generally broken down into four steps: solid-phase synthesis, cleavage and deprotection (C&D), chromatographic purification, and downstream isolation. As mentioned earlier, the laboratory-scale synthesis of ONs is commonly achieved through the widely accepted phosphoramidite approach in the solid phase.[96,97,160] During solid-phase synthesis, phosphoramidite monomers are reacted sequentially onto a solid support in efforts to generate the full-length ON desired. The manufacture of an ON carrying 20 residues generally requires about ~80 iterative reactions. Following synthesis, the C&D step releases the ON from the solid support and removes the requisite synthesis protecting groups. This step is generally

Table 1 Comparison of capping mixtures (Glen Research)

Synthesizer	*Cap A solution*	*Cap B solution*	*Capping efficiency (%)*
Expedite	THF/Ac_2O (9:1)	10% NMI/THF/Py (8:1)	90.5 ± 1.9

performed in batch mode where the entirety of the solid support manufactured is reacted with deprotection solutions in a reactor. The crude material generated is then purified generally using chromatographic purification to isolate full-length ONs from their related impurities. Finally, isolation through desalting and further lyophilization yields pure ON solid material.

6.11.10.1 Oligonucleotide Solid-Phase Synthesis Cycle

The solid-phase synthesis cycle for the manufacture of ONs can be generally performed in four iterative steps (Fig. 2). Initially, a solid support carrying the first nucleosidic residue is placed on a solid support housing to ensure the requisite anhydrous conditions. As discussed, there are alternative supports for ON manufacturing, most notably the UnyLinker support, which can be used. Their use is similar to base-loaded supports for synthesis but poses challenges during C&D as discussed later in this review. In either case, the support is then treated with 3–10% DCA in either DCM or toluene (i in Fig. 2) to remove the most commonly used DMT-protecting group. The newly released hydroxyl group is then free to react in the subsequent step with the next desired residue in the ON sequence. The next residue is added as a phosphoramidite monomer that is mixed with an activator (to facilitate the reaction) just prior to its addition to the solid support (ii in Fig. 2). Commonly, activators such as tetrazole, 5-ethylthio tetrazole, 4,5-dicyanoimidazole, and benzylthiotetrazole are used. The newly formed phosphotriester (P^{III}) is not sufficiently stable for the remainder of the synthesis and thus is generally oxidized (iii in Fig. 2) to a phosphate triester (P^{V}) using an aqueous iodine solution in either pyridine or pyridine/tetrahydrofuran mixture (X = O in Fig. 2). If a phosphorothioate is desired (X = S in Fig. 2), incubation with a solution of phenoxyaceticdisulfide (PADS) in acetonitrile or xanthane hydride (XH) in pyridine is commonly used to yield the desired P–S bond. Before restarting the next cycle, nonreacted species are terminated by the use of either acetic anhydride or isobutyric anhydride in the presence of NMI in acetonitrile (iv in Fig. 2). This re-masks the nonreacted hydroxyl to prevent further growth in the subsequent coupling cycles. Repeating the four steps (detritylation, coupling, oxidation, and capping) iteratively can generate ONs in the $1–100^{+}$ range.

The fastidious process of solid-phase ON synthesis can be simplified by the use of solid-phase synthesizers that are available from several manufacturers (Table 2). The use of these synthesizers has allowed for the fast synthesis of ONs where a 20-mer

DNA strand can be synthesized in ~4–5 h. The choice of synthesizer is generally dictated by the level of throughput desired. Table 2 presents instruments with low (1–4 concurrent syntheses), medium (5–50^{+} concurrent syntheses), and high (96–768^{+} concurrent syntheses) throughput. The second consideration is the type of chemistry required, which generally dictates the number of amidite or reagent ports necessary. Generally, the preparation of ON primer DNAs only requires a few ports, while the synthesis of heavily derivatized API candidates would require more available ports. The commercially available synthesizers range between 5 and 30 amidite ports and between 3 and 12 reagent ports. The third consideration is synthesis scale range. The different available synthesizers can fall in one of the four general categories: small research scale (0.001–2 μmol), medium research scale (0.020–5 μmol), large research scale (0.050–15 μmol), and lab-scale manufacturing/modeling scale (1–9000 μmol). Although a synthesizer can be selected based solely on the above categories, an additional consideration must be evaluated. Generally, small-scale synthesizers have limited monitoring capabilities if any (i.e., only UV or conductivity), while larger scale synthesizers have multiple monitoring capabilities. Although generating DNA primers might not require diligent monitoring of the synthesis, API candidate synthesis and small-scale modeling prior to large-scale manufacture require diligent monitoring in efforts to optimize the synthesis cycle and prevent the formation of unwanted impurities.

Although the solid-phase synthesis of ONs can generate materials of high purity, there are several major impurities that can be formed if improper cycle conditions are used. A comprehensive review by Cramer et al. summarizes ON impurity formation in detail.[161] The impurities mentioned range from simple termination sequences ($n-1$, $n-2$, $n-3$, etc…) due to process inefficiencies to complex adducts. Given that process inefficiency impurities warrant their own review and most are broadly understood, this review will focus on impurities that can be affected by improper small-scale modeling and improper instrument setups, which are discussed later in this review. Depuration generally occurs in acidic conditions such as during detritylation where the glycosidic bond connecting the sugar and the nucleosidic base is broken.[162] This process generally affects purines, which carry an imino group at position 7 of the nucleosidic base. Nucleosidic base loss generates what is called an abasic site (Fig. 13). These abasic sites are known to be generally unstable and quickly breakdown resulting in ON-strand breakage. Thus, depurination not only results in an abasic site but also can lead to increased levels of failure sequences.

Another common impurity that carried over to the final ON arises from incomplete oxidation/sulfurization where the P^{III} center is not oxidized/sulfurized to the P^{v} center during the oxidation/thiolation step. As this center is sufficiently stable during capping conditions, the impurity carries over to the following detritylation step. During detritylation, release of the DMT^{+} cation and subsequent attack by the P^{III} center can result in a DMT-phosphate formation[162c,163] (Fig. 14). The formed DMT-phosphonate impurity generally elutes long after the full-length product (FLP) by reversed phase chromatography and could carry over to the final API if purified by other means.

A very common impurity generated during deprotection is the formation of a cyanoethyl (CNEt) adduct.[112,164] This impurity is generated when the CNEt phosphate protecting group is released by the C&D reagent as acrylonitrile. This highly reactive molecule is known to add to the N^{3}-position of thymidine (Fig. 15). To prevent the formation of this impurity, generally, an amine wash is

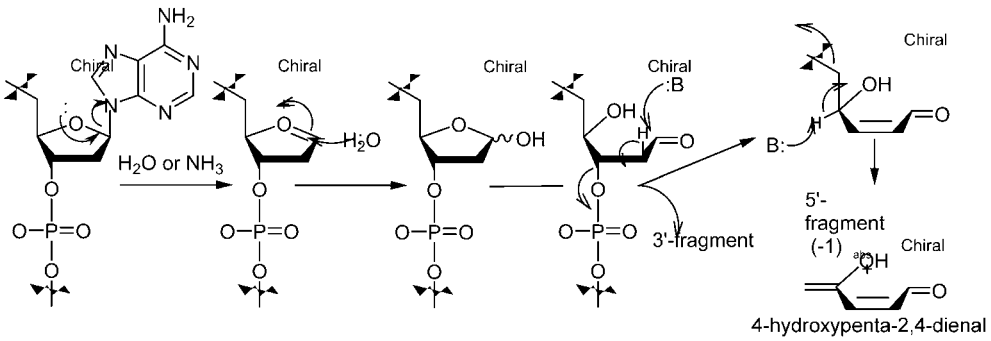

Fig. 13 Depurination of deoxyadenosine followed by strand cleavage via postulated β-elimination

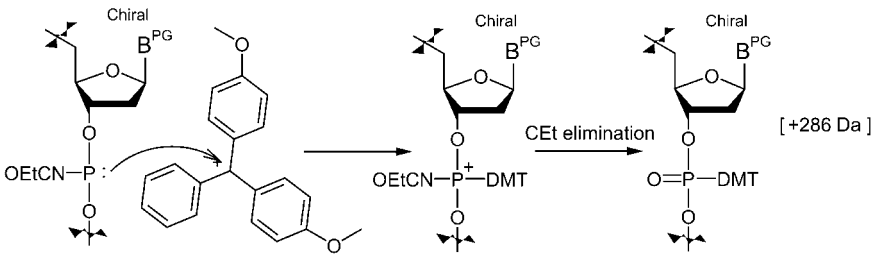

Fig. 14 Postulated mechanism of the DMT-phosphonate formation following inefficient oxidation/sulfurization.

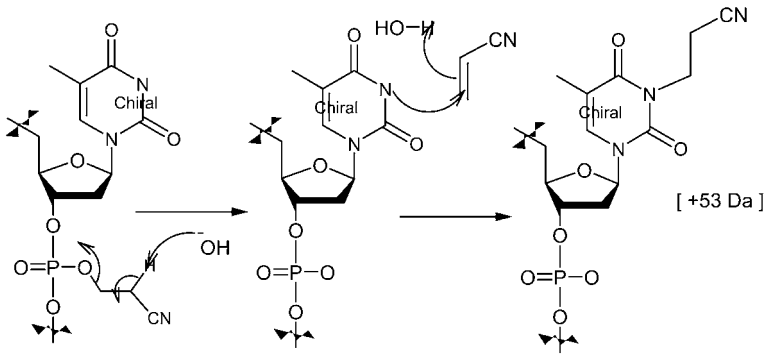

Fig. 15 Postulated mechanism of the formation of the CNEt adduct.

performed at the end of synthesis and prior to the C&D to selectively remove the phosphate protecting groups, while the ON is still attached to the solid support. The physical separation of phases is generally sufficient to prevent the adduct formation.

However, a second impurity can be formed during C&D due to the final amine wash around the phosphorous center. As the final amine wash releases acrylonitrile, P–S-containing residues are particularly susceptible where the CNEt is known to add to the sulfur in the phosphorothioate moiety. Further, this impurity is postulated to be susceptible to nucleophilic attack by a hydroxide, which can be resolved by the release of 3-mercaptopropanenitrile and conversion of the phosphorothioate to a canonical phosphate[165] (Fig. 16).

6.11.10.2 Oligonucleotide Cleavage and Deprotection

ON C&D, as mentioned before, releases the ON from the solid support used during synthesis and removes requisite synthesis protecting groups (Fig. 17). This process is generally carried out in batch mode where the entirety of the solid support manufactured is incubated with C&D reagents. Following deprotection, the spent ON support is filtered and the crude solution recovered.

As mentioned earlier, the reagent choice for C&D has historically favored amine bases, which are routinely used for deprotection (Table 3). Specific reagent choice in this step of manufacture is heavily dictated by the modifications present in the ON. Although DNA primers are amenable to practically any deprotection reagent, certain sensitive modifications require mild conditions. As a general guidance, the C&D conditions to be used are dictated by the most sensitive residue in an ON. Of note, these sensitive modifications often place requirements on the other residues' protecting groups, that is, "fast"-deprotection groups in the case of mild deprotection reagents.

In the case of RNA manufacture, an additional reaction is required to yield the naive RNA. Although, there are alternative technologies developed for 2′-protection;[166] most generally, the 2′-OH of the naive ON is masked with a 2′-*O*-*tert*-butyldimethylsilyl protecting group for synthesis[92,101,102,160a,160c] (Table 4). This protecting group is base stable and thus survives C&D. Therefore, the second step, dubbed desilylation, removes the silyl protecting group. This is generally achieved by the addition of a fluoride reagent in either acidic media or anhydrous conditions to prevent ON degradation. With the use of acidic TEA·3HF reagent, the intermediate ON is not readily soluble in water once the internucleotide phosphates are protonated; therefore, the use of DMSO or similar cosolvents is essential for complete deprotection.

There are several general C&D-related impurities that can be obtained when using improper C&D conditions. As with synthesis, the review by Cramer et al. also summarizes ON impurity formation during C&D in detail.[161] For the purposes of this review, only those impurities that can be affected by improper small-scale modeling and improper instrument setups, which are discussed later in this review, will be reevaluated. As depicted in Fig. 13, depurination can occur with the use of C&D reagents. However, an

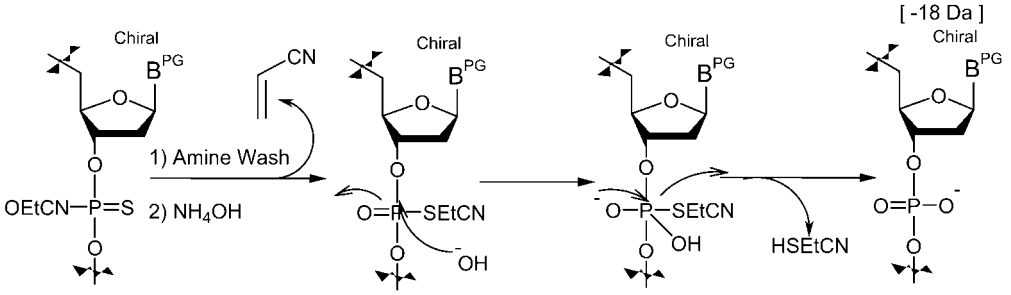

Fig. 16 Proposed mechanism for the loss of sulfur during C&D.

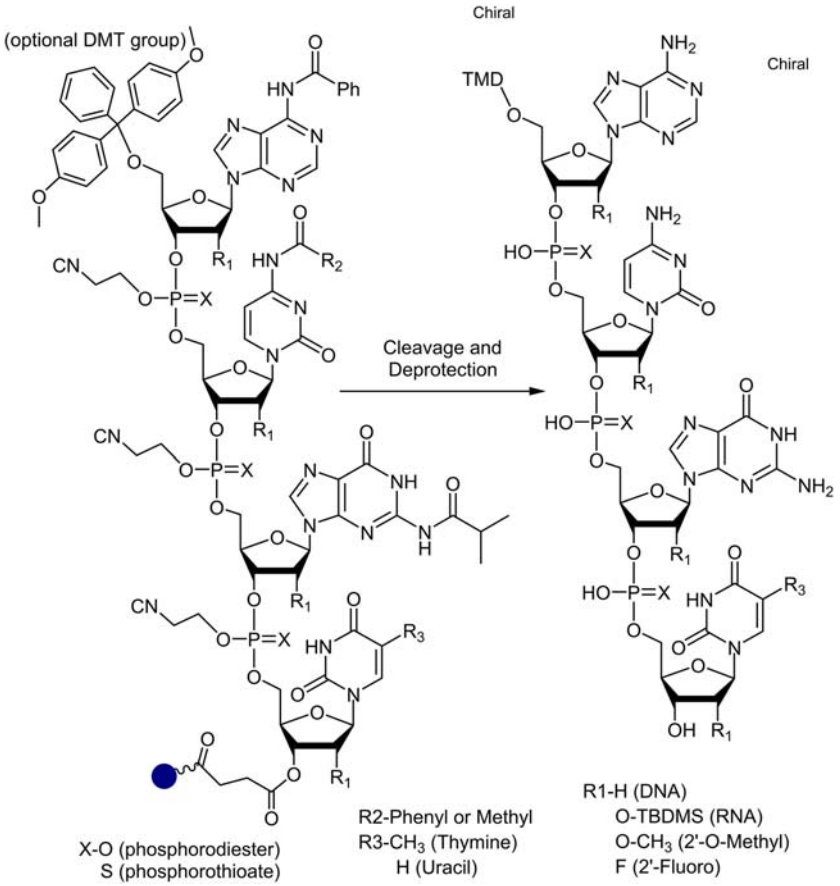

Fig. 17 Oligonucleotide C&D.

additional depyrimidination is prevalent when using ammonia reagents, particularly AMA. The partial and complete loss of the thymidine and uracil moieties due to ammonia can yield a partial ("urea" form) or complete abasic site[167] (**Fig. 18**).

An additional impurity generated from the use of AMA is the transamination of cytidine when a benzoyl protecting group is used for the nucleobase[168] (**Fig. 19**). However, the use of the acetyl protection was found to not lead to the impurity.

Some 2′-modifications, like in the case of RNA or 2′-F, are particularly susceptible to degradation. It is widely known that RNA ONs, carrying a naive 2′-OH, are susceptible to internucleotide strand breakage in the presence of base. Abstraction of the 2′-OH proton by a neighboring base leads to the SN2 attack to the internucleotide phosphate, which through a trigonal bipyramidal intermediate releases the neighboring 5′-OH resulting in strand breakage[169] (**Fig. 20**).

For 2′-F ONs, although strand cleavage is not possible as the 2′-fluoride is not a good nucleophile, an alternative reaction is possible in the case of pyrimidines. The attack of exocyclic electrons to the pyrimidine ring causes a rearrangement of the electron cloud, which can lead to nucleophilic attack on the 2′-position. As the fluoride is a good leaving group, the residue readily adopts the 2′-anhydro configuration. Further, hydrolysis of this structure is known to generate the arabinose final impurity[170] (**Fig. 21**).

6.11.10.3 Oligonucleotide Purification

The purification of ON crude solutions is generally achieved by chromatographic methods.[171] An intermediate desalting operation can be performed prior to purification by simple ON precipitation or by using commercially available desalting solid supports or filtration membranes (discussed later in this report). The choice of chromatographic type and its associated setups heavily relies on the expected ON use. Although ON primers require little to no purification, therapeutic ONs require extensive chromatographic purification to ensure that a high-quality API is manufactured. **Table 5** summarizes the most widely used modes available for ON purification. As the sheer number of electrophoresis boxes and HPLC equipment available to carry out laboratory-scale purification warrants its own report, this review will only focus on the choice of purification support. The use of gel electrophoresis to purify ONs dates back to their applications in biochemistry.[172] As such, the use of agarose and polyacrylamide gels provides a straightforward approach to purifications based mostly on rough size discrimination. Although this is generally acceptable for ON primers and other simple applications, this approach is not generally acceptable for API manufacturing. Taking advantage

Table 3 C&D reagents

Reagent choice	*Incubation temperature (°C)*	*Incubation time (h)*	*Special considerations*	*Additional comments*
Ammonium hydroxide	r.t.—65	2–16	Lower temperature and shorter time should be considered in combination with Pac-A, iPr-Pac-G, Ac-C monomers for base sensitive modifications such as Cyanine Dye derivatives, and BHQ quenchers	
NH_4OH/EtOH (3:1)	Similar to Ammonium Hydroxide		Similar to ammonium hydroxide, recommended for C&D with polymer-based solid supports	
AMA-Ammonium hydroxide:Methylamine (1:1)	r.t.—55	0.2–3	Fast deprotection conditions that require use of Ac-C monomer. Bz-C or Bz-5Me-C monomer would lead to increased amount of N4 transamination by product	Not recommended for most fluorescein analogs. Generates an impurity that does not exhibit absorbance in the visible region
Methylamine	r.t.—35	0.2–3	Fast deprotection conditions. Generates significant levels of N4 transamidation with Bz-C or Bz-5Me-C monomer	
EMAM-Ethanolic AMA	Similar to AMA		Similar to AMA but optimal for long RNA oligos	
Ammonia or Methylamine gas	variable	1	Requires specialty equipment	
0.05 M K_2CO_3 in MeOH	r.t.		Need Pac-A, iPr-Pac-G, Ac-C monomers, (Pac2O) capping reagent. Recommended for oligos with base sensitive modifications	
0.4 M NaOH in MeOH/H_2O (4:1)	80	~0.2	Recommended for Acridines or Carboxylates containing oligo	Generates sodium salt. Can be performed without pressure issues
t-butylamine/MeOH/H_2O (1:1:2)	55	17–20	Recommended for TAMRA derivatives	
t-butylamine/H_2O (1:3)	60	6		
30–50% Ethylene diamine in EtOH	25	0.5–1	Recommended for P-ethyl derivatives	Generates a low level of ethyl loss

of the internucleotide phosphate, anion-exchanged and ion-paired reversed-phase chromatographic purifications on HPLC equipment are widely used for the purification of ON APIs.

The use of the anion exchange technique[171a,171d,171g,173] (particularly with Q Sepharose and TSK Gel resins) ensures that fine separation between ONs and their closely related $n-1$, $n-2\cdots$ and $n+1$, $n+2\cdots$ sequences, and even PO impurities for phosphorothioates are discriminated. Additionally, as the elution is generally performed with sodium salts, the process in turn ensures that synthesis- and C&D-related counterions are removed, and the purified ON is isolated in its desired sodium form. On the other hand, the use of IP-RP approaches ensures that not only charge-based residues but also charge-neutral lipophilic impurities are

discriminated.[174] However, as IP-RP chromatography requires the use of a counterion, generally triethylamine, an additional salt-exchange step is required to yield the purified ON in its sodium form. Further, the purification power of both techniques can be harnessed in the use of anion-exchange resins, which at their core carry slightly lipophilic matrices (Source 15Q). This is currently a trend where now fully multimodal purification resins are being developed for finer purification discriminatory potential.

Alternative considerations for purification resin choice are reusability, safe pH range, operational backpressure, purification loading, and recovery. Resin reusability plays a big part of fixed purification systems that would handle heavy purification schedule workloads. This factor is mostly determined by the resin type and attachment chemistry. Although attachment chemistries are generally proprietary, polymeric supports like styrene and methacrylate are generally accepted as more reusable when compared with silica supports. Safe pH range is a consideration when strict GLP practices are in place, which require heavy cleaning schedules, for which the trend generally follows reusability. Operational back pressure is generally a consideration in semiprep HPLC systems that can have prohibitive pressure limits. For this consideration, smaller-sized beads are generally observed to exhibit higher operating pressures. Further, disparate choice of purification support nature to selected eluents (i.e., aqueous buffers on silica-based resins) also exhibits high operational back pressure. However, for all laboratory-scale purifications, operational backpressure is seldom an issue. Purification loading and recovery are an important consideration when dealing with high-throughput applications. Generally, IP-RP resins have lower loading limits and generally exhibit lower recoveries than their anion-exchange counterparts. Given all the considerations, purification resin choice is highly sequenced and application-dependent with additional considerations like available equipment setups playing an important part in the final decision.

6.11.10.4 Oligonucleotide Isolation

Following purification or if purification was not performed, following C&D, downstream isolation is performed by simple ON precipitation or by using commercially available desalting solid supports or filtration membranes (**Table 6**). The choice of approach heavily depends on the manufacturing scale and the expected application. By far, the most widely used isolation method in research-scale applications is the use of precipitation using sodium salts (generally acetate) and alcohols (generally ethanol for DNA and isopropanol for RNA sequences). The use of this approach in research scale is generally straightforward and does not require significant equipment investment. However, the conditions need to be optimized in order to maximize yield and to avoid the coprecipitation of salt in the final product. For this, the conditions are significantly varied with ON type, length, and concentration. A more elegant approach at research scale is the use of desalting columns. For this, generally, three approaches are used. For the first approach, the use of reversed-phase media (Pierce™ columns from Thermo or SepPak® columns from Waters) allows for the desalting of ONs by adhering them to a C18 or similar lipophilic media with the use of an ion-pair reagent (generally triethylamine—TEA). Following binding, a water rinse is performed to effectively desalt the ON bound on the support. Final elution is performed with a volatile organic solvent (generally acetonitrile), which then is removed through lyophilization. However, through this approach, the TEA salt of the ON is obtained. For the second approach, a cation-exchange resin is used to trap the counterion salt itself, while the unbound ON flows through in the effectively desalted water (PD 10 or NAP 25 columns from GE). This approach yields an ON of whatever salt state was loaded onto the column. These two approaches can be performed in a matter of minutes with minimal equipment investment but require the use of disposable specialty columns. The third approach uses a spin filter, which is used to concentrate a particular sample using an appropriately sized filter (Ambicon® filters from Millipore). Repeated water additions and concentrations can lower the effective salt concentration significantly. This approach is time-consuming and generally does not result in good recoveries. A similar but more optimized method for ON isolation and one more adapted to API manufacturing is the use of tangential flow filtration (TFF). This approach also employs an appropriately sized filter membrane (membranes available from Pall or Millipore) but now uses a pump to circulate the sample through the TFF setup making the process more efficient (**Fig. 22**). For TFF, a sample placed in a feed vessel is fed against the membrane holder, which houses an appropriately sized membrane filter. Given a feed pressure higher than the osmotic pressure of the solution, the salt solution passes through the membrane's pores, while the ON is diverted back to the feed vessel. As the solution concentrates,

Table 6 Oligonucleotide downstream isolation

Method	*Ease*	*Specialty equipment requirements*	*Manufacturer*	*Scale*	*Isolated ON form*	*General application*
Precipitation	+++	Centrifuge	N/A	Varies	Na form (excess NaOAc salt)	General lab and some API manufacturing

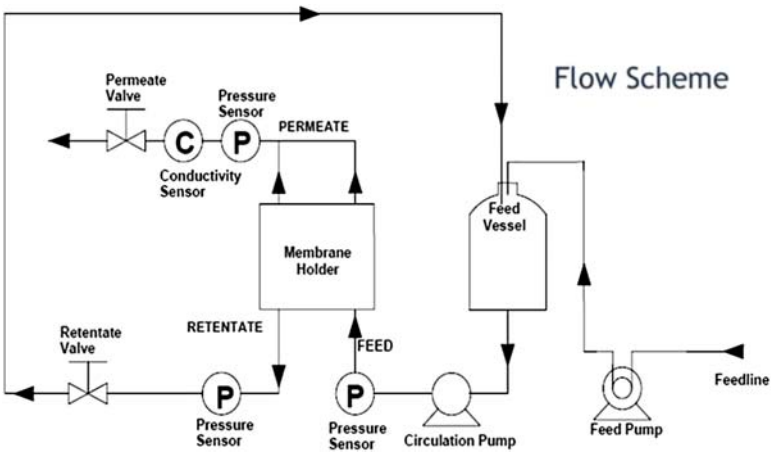

Fig. 22 Tangential flow filtration schematic.

concerted addition of purified water effectively desalts the solution. The main drawback of this approach is the requirement of a large solution volume due to the system void volume.

Following desalting, the ON either isolated or reconstituted in purified water can be used directly for its intended application or isolated as powder through lyophilization. The choice of lyophilization equipment is generally based on the size of batch needed to be processed as a single batch. As this is not generally prohibitive in research scale, further considerations on lyophilization equipment choice are discussed later in this report.

6.11.11 Manufacturing Process and Equipment for Oligonucleotide Used as Therapeutics

The increase in demand for pharmaceutical-grade ON quantities has been accompanied by the development and innovation of cost-effective manufacturing technologies. As discussed earlier, ON synthesis quality has been improved by using raw materials with the highest purity specifications possible. At the same time, yields and throughput have been increased by the introduction of high-loaded polymer supports like NittoPhase™. Therapeutic oligo manufacturers have also developed and optimized technologies that allow them to access ONs with a wide variety of chemistries. However, the manufacture of ONs in the 50 g to kilo scale and beyond is still not trivial.

As has been discussed in Research-scale manufacture of oligonucleotides section above, the ON-manufacturing process consists of five to six major steps depending on the type of oligo being manufactured. Of these, the synthesis step is the most complex and requires the use of sophisticated equipment with their associated control software. The key steps for large-scale ON manufacturing are shown in Fig. 23. During manufacture, each of these steps uses specifically designed equipment with associated in-process controls (IPC) to ensure batch reliability and ON quality.

6.11.11.1 Oligonucleotide Synthesis Equipment

Table 2 delineates the commercially available ON synthesizers that are routinely used for research scale/grade synthesis. Among equipment manufacturers, only GE has synthesis skids from the μmol scale (ÄKTA oligopilot 10/100) to 5 mole (OligoProcess) scale. OligoProcess and Oligo Process Industrial systems are generally custom-built and can be tailored to meet the end user's needs. As such, each individual system is customizable to operate within a dynamic range of ~10, that is a system with a maximum scale of 1000 mmol has a lower end of 100 mmol and so on. The advantage of GE systems is that they all employ the same "flow-through column" technology and are controlled by the versatile UNICORN software. This allows for seamless scale up from the ÄKTA oligopilot plus. For mid-scale production runs (10–50 mmol), GE has the OP400 system which bridges the gap between the ÄKTA instrument and the OligoProcess equipment.

There are other players in the large-scale ONs equipment like LEWA and ASAHI KASEI. These companies have traditionally occupied the chromatography and downstream processing space but are capable of building custom synthesizers by using their existing pump and valve technologies. Such custom jobs are normally done in collaboration with the end users.

6.11.11.2 Oligonucleotide Cleavage and Deprotection Equipment

Oligo deprotection involves three steps: removal of the CNET protecting group from the phosphate backbone, cleavage of the oligo chain from the support, and base deprotection. Depending on the C&D reagents and the type of oligo being processed, the phosphate deprotection may be performed during the synthesis step. However, irrespective of the reagents and conditions being

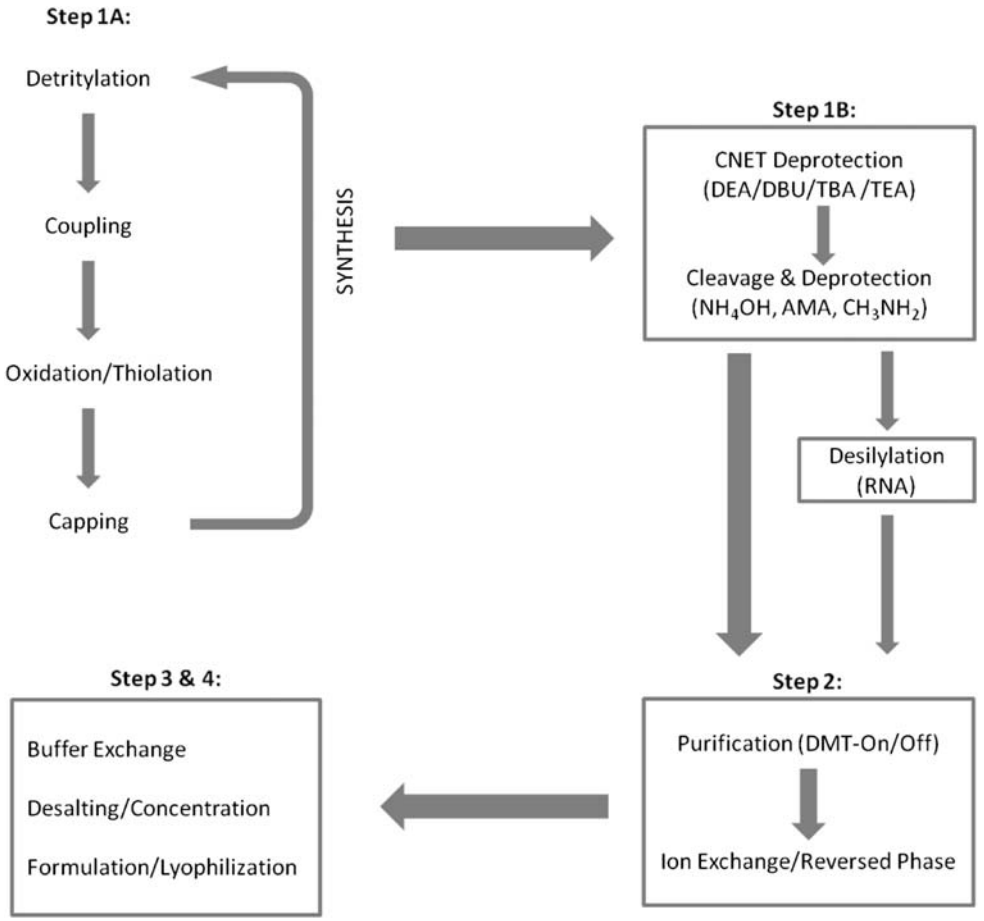

Fig. 23 Oligonucleotides manufacturing process steps.

used (Table 3), the C&D step involves soaking the oligo-bound support in the reagent and shaking the mixture using temperature-controlled orbital shakers. When using reagents that can build pressure like ammonia, it is recommended to use shakers with either heating blocks or water bath. The process also requires the use of custom-built reaction vessels that can handle the C&D conditions.

For certain production applications, the batch size might require larger than commercially available shakers, and even if available, such a process may not be performed safely. In such instances, an on-column cleavage and deprotection strategy can be used. In this strategy, the oligo-bound support is not unpacked from the column housing following synthesis. A customized heated reservoir/reactor and pump system is used to deliver the C&D reagents into the column. The solution is then recirculated until the process is complete. The solution containing the deprotected ON is then recovered and further processed as desired. Fig. 24 shows an on-column cleavage and deprotection schematic.

For RNAs, the 2′-OTBDMS group must also be removed (desilylation) prior to further processing. This is typically achieved by treating the already deprotected solution from the C&D step with a fluoride source as described in Table 4. These reactions are carried out in jacketed reactors with overhead mechanical stirrers. As this step involves heating, cooling, and tight pH control, the system used must have both an efficient heat transfer and mixing capability for scalable and reproducible operations. Fig. 25 shows typical jacketed reactor systems with heater/chillers for different scale desylilations.

6.11.11.3 Oligonucleotide Chromatography Equipment

Unlike ON synthesis that requires highly specialized equipment, which may not be readily available especially at large scales, chromatography systems are more accessible since these systems have wider applications ranging from biopharmaceuticals to small molecules. The key to efficient therapeutic-grade ON purifications therefore lies mostly on the stationary phase, eluent, and conditions used. Equally important is the purification column and column packing strategy employed. Nonetheless, for purification equipment designed for ONs, GE is among the industry leaders with the ÄKTA purification platforms, which complement their synthesizers. Just like in synthesis, GE provides skids from the research-scale (ÄKTA purifier/pure) to large-volume manufacturing (BioProcess/ÄKTAprocess). The ÄKTApurifier and BioProcess have been discontinued and replaced with AKTApure and ÄKTAprocess, respectively. The ÄKTAprocess can deliver flow rates up to 2000 L/h, whereas the UNICORN software makes processes

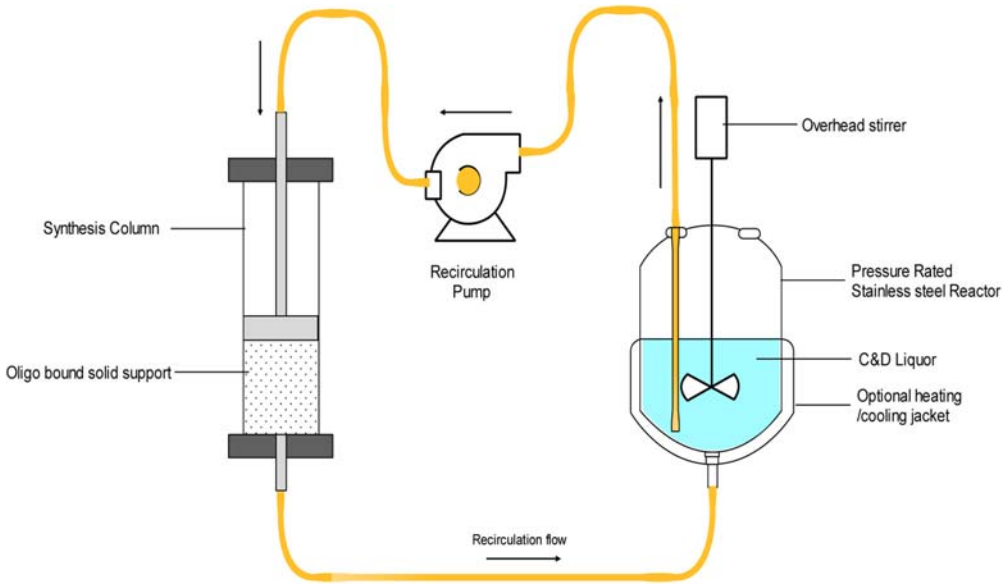

Fig. 24 On-column cleavage and deprotection schematic.

Fig. 25 Typical jacketed reactor systems with heater/chillers for different scale desylilations.

developed on GE's purification platforms easy to scale up and transfer; the systems suffer from their both pressure and low temperature ratings and are not amenable for processes, which require high pressure and sufficient denaturing temperature conditions. Similarly to the equipment, GE's purification columns are generally designed for low-pressure applications at temperatures below 40°C.

For high pressure and temperature purification equipment, ASAHI KASEI, LEWA, and Novasep are among the major players. For purification columns, Load & Lock stainless columns (Agilent and Agar Machining) have high-pressure dynamic axial compression (DAC) packing, which provides improved bed stability and higher loading. They can also be jacketed for use at higher temperatures.

6.11.11.4 Oligonucleotide Ultrafiltration & Diafiltration Equipment

As discussed in the Research-scale manufacture of oligonucleotides section above, the UF/DF approach used depends on the manufacturing scale and the expected application. For 500-μmol scales and above, a tangential flow filtration system (TFF), as shown in Fig. 22 and described in the section therein, is recommended. TFF systems are the easiest to set up and are readily amenable to scale up. All that is needed is membrane holder, two pumps, pressure gauges, tubing with fittings, and a sample reservoir. The ease of setting these up allows the end user a lot of flexibility. Membrane holders and accessories can be obtained from key manufacturers like EMD Millipore, PALL, or Sartorius.

However, for those in need of fully automated systems, GE's ÄKTAcrossflow is available for small-scale applications. The attendant UNICORN software allows for instant in-process control (IPC) and process log. For pilot and manufacturing-scale applications, GE's UniFlux system is available in sizes of 10, 30, 120, and 400 LPM. Fully automated large-scale TFF skids like

the Allegro series are also available from PALL. Not to be left behind, EMD Millipore also recently launched the fully automated Mobius® FlexReady Solution. A versatile system, this machine can be switched from a TFF to chromatography skid with minimum component changes. There are several other manufacturers of TFF systems for applications beyond ON purification and desalting.

6.11.11.5 Oligonucleotide Lyophilization Process and Equipment

Since the pH of double-distilled water is about 5.5, ONs in aqueous solutions will slowly undergo acid-catalyzed depurination over time. At the same time, there is a considerable risk of contamination from microorganisms, which might lead to degradation. Therefore, for long-term storage and easier handling, purified ONs are typically lyophilized (freeze-dried) to powder in the final manufacturing step. As briefly discussed earlier in this report, during the TFF step of large-scale manufacture, the desalted ON API is concentrated to a predetermined concentration. This concentration, usually a range, is a controlled process parameter to ensure that upon lyophilization, a product with a consistent morphology is obtained.

Lyophilization is performed using a freezer dryer, which is a machine consisting of a sample chamber, a condenser, and a vacuum pump. The ON API is frozen and lyophilized to obtain the final product in powder form via sublimation. Common benchtop freeze dryers are manufactured by Labconco, while pilot and production freeze dryers include VirTis Genesis and Hull.

There are four main steps in the lyophilization process, namely, sample preparation, freezing, primary drying, and secondary drying. In the sample preparation step, the desalted ON API solution is filtered through a 0.2-μm filter to remove bioburden and in-process particulates from the drug product. The filtered solution is then transferred into vials for small-scale batches or into freeze-drying trays or containers. These containers, like Gore LyoGuard® trays, are specially made with optimal volume capacity and fitted with membranes that allow for water removal without product spills or contamination.

The container or tray with the product is then placed inside the sample chamber shelf and frozen, usually at -40°C. The rate of freezing depends on the temperature of the shelf, the amount of product in each tray, and the height of the solution in each tray. These factors alongside the concentration of the ON will in turn impact the drying rate and the morphology of the product obtained. It is therefore critical that these factors be put into consideration when developing the lyophilization recipe. During this step, the frozen water exists in the product solution in two forms:

(a) Water free (unbound) from the ON solid
(b) Water trapped within the solid product

After the freezing step, the primary drying step kicks in. In this step, the condenser temperature is lowered to a temperature much lower than that of the lyophilization chamber, usually less than -70°C. The chamber pressure is then lowered by pulling the vacuum. These sets of conditions result in a phase change from solid to gas, that is the free water frozen water sublimes to vapor, which is then instantaneously trapped in the -70°C condenser and turned back to ice. Since the sublimation process is accompanied by a decrease in product temperature, the chamber shelves are heated to keep the resultant product cake at constant temperature. It is typical to monitor both the shelf and the product temperatures during this process. When both temperatures reach equilibrium, it is an indication that the primary drying step is complete.

After the completion of the primary drying step, no "free water" is left in the product. But the trapped water is still within the solid product. Since this water is more difficult to remove, the shelf temperature is increased gradually, usually to $25 \pm 5^{\circ}$C at the same or lower pressures used for primary drying.

6.11.12 Small-Scale Modeling for Oligonucleotide Manufacturing

The precarious relationship between production-scale manufacturing and small-scale modeling approaches requires diligent scrutiny. Lowered yield, changes in impurity profile, and process deviations are among the most common critical scale-up issues that are attributed to improper small-scale models. Therefore, any work to ensure reliable scale-up manufactures needs to focus around critical processing steps and establish scalable operating parameters. This section will cover several case studies where appropriate small-scale models were developed, some after painfully gained scale-up experience, to ensure reliable manufactures. The case studies discussed will include at least a single parameter from each of the ON-manufacturing steps.

One of the most complex manufacturing operations to model given the sheer number of critical operating parameters is solid-phase synthesis. Although each step during synthesis has a scalable critical parameter worth discussion, this review will focus on the most critical and one of the easiest parameters to model during synthesis process development work: synthesis support bed height. This parameter is critical as it bridges the relationship between scalable process flow rates and reagent contact time. The experience discussed is based mainly on a case study centered on the relationship between bed height and detritylation-dependent depurination.

For the study, the synthesis of a fully phosphorothioated 18-mer oligodeoxynucleotide was performed at three different bed heights keeping all other parameters constant (Table 7). As mentioned earlier, performing the syntheses in this manner would lead to a positively linear relationship between bed height and reagent contact time. Although for most reagents, this is generally not an issue, extending the contact time of the detritylation reagent with oligodeoxynucleotides, which are sensitive to acid-based depurination and further strand cleavage during C&D, would lead to lower FLP purity (Fig. 26). The first three experiments in the

Table 7 Influence of synthesis bed height on depurination[175]

Scale (mmol)	*Bed height (cm)*	*Column volume (mL)*	*Detroit flow rate, cm/h (mL/min)*	*Detroit flow rate (CV/min)*	*FLP purity (%)*
0.25	2	6.3	400 (21)	3.3	87
1.69	4.5	43.8	400 (65)	1.5	83
3.37	9	87.5	400 (65)	0.7	78
0.25	2	6.3	200 (10)	1.6	83
0.25	2	6.3	65 (3.5)	0.6	77

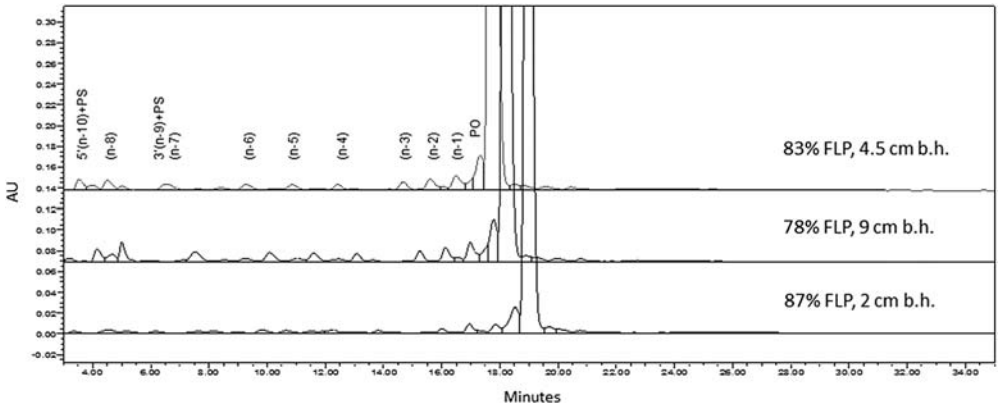

Fig. 26 Influence of synthesis bed height on depurination. Acid-induced depurination of an 18-mer PS DNA followed by strand breakage during C&D leads to lowered FLP content in the crude at higher bed heights.[175]

experimental set demonstrate this fact where the synthesis at 9-cm bed height results in higher levels of prepeak impurities as compared with the synthesis at 2-cm bed height. To demonstrate that this is generally not attributed to other reagents' contact time and is mainly due to detritylation-dependent depurination during extended detritylation contact times, performing an additional two syntheses at the short 2-cm bed height but using reagent flow rates for detritylation reagent that mimic the higher bed height also causes the crude material quality to drop. Therefore, the relationship between reagent flow rates and synthesis support housing proportions needs to be scrutinized on the basis of critical reagent contact times to ensure reliable scale-up manufactures.

As C&D processes are generally performed in basic media at elevated temperatures, the most critical and challenging parameter to model during process development work is heat transfer. Although a solution in a small vessel might reach the desired internal temperature in a fraction of an hour, larger vessels require significant more heat to be transferred to reach the optimal internal deprotection temperatures. As this process is heavily influenced by vessel proportions, materials of construction, and even heating element characteristics, developing a small-scale model for C&D is deceptively simple. In some instances, after determining ramp-up rates, simply adjusting incubation time at large scale is sufficient to ensure reliable manufactures. However, as ramp-up rates for larger scales are generally harder to determine and as the large-scale equipment is significantly different from lab-scale heating elements, the process can be challenging. This process is complicated further in the case of oligoribonucleotides. In addition to C&D considerations, following ON removal from the solid support and base deprotection, the removal of the requisite 2′-OH protecting groups needs to be carried out in an acidic media with an organic cosolvent. As the reaction pH is being adjusted from ~11 to ~5, a large exothermic reaction needs to be controlled. Additionally, as both the 2′-protected ON and the several reagent byproducts precipitate during this transition, precise heat control is critical to ensure reliable manufactures. Therefore, diligent alignment of heating/cooling capabilities needs to be established. In the next case study, a set of three C&D reactions are presented (Fig. 27). In the first experiment, the crude material for a 24-mer ON conjugate with 2′-OH, 2′-OMe, and 2′-F modifications that underwent C&D using an appropriate heating scale-down model is presented (PD model in Fig. 27). Attempting a similar reaction at manufacturing scale using equipment setup with nonmodel heating/cooling characteristics generates a significantly lower quality crude material. As the heat generated is uncontrolled and the ramp-up/down rates are slower, significant ON damage is evident from the impurity profile (nonmodel heating in Fig. 27). Finally, ensuring that the heating/cooling capabilities of the large-scale equipment are in line with the small-scale model ensures a reliable manufacture.

Another process operation where large-scale equipment is easily misaligned is ON purification. For this process operation, myriad parameters need to be taken into account to ensure a successful manufacture. Although column packing methodologies, column conditioning, incoming crude matrix, loading/elution flow rates, eluent preparation, operating backpressure, among others, are important to a successful purification, one of the most challenging parameters to align is purification temperature. Given that heat transfer differs widely between scales and equipment setups and that temperature might even vary within the equipment

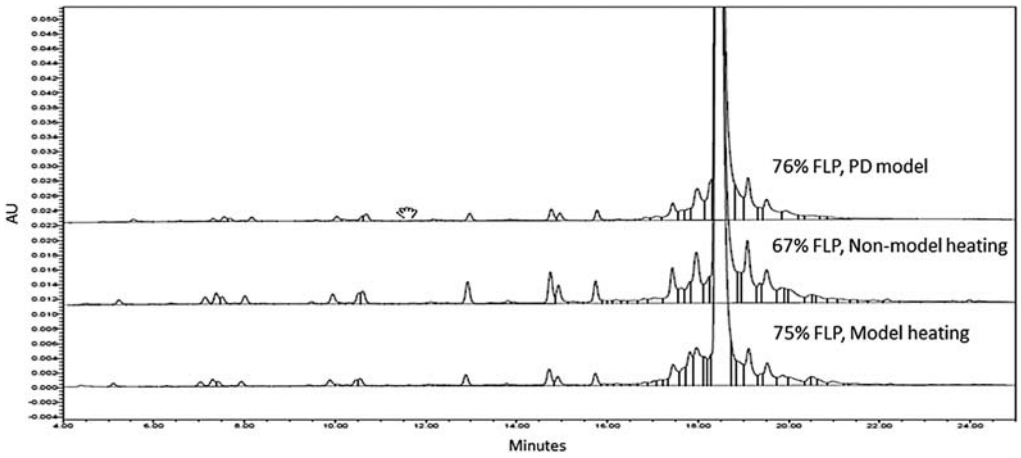

Fig. 27 Influence of C&D heat transfer on crude quality.

itself (between eluent tanks, pump system, eluent heaters, column inlet, column outlet, and even fractionation temperature), it is critical to ensure that not only the purification temperature wherever measured but also the actual heating and cooling rates at every step are being modeled. The following case study presents the heated purification of a 21-mer RNA mix-mer conjugate. From Table 8, it is clear that high temperature is necessary to denature the RNA during purification. Any attempts at purifying this material at temperatures lower than 30°C resulted in low-quality fractions. However, there is a balance between denaturation for purification and heat-generated degradation. For this material, it was found that purification at 40–50°C resulted in high quality fractions. However, further addition of 5°C of heat resulted in lower quality fractions again mostly due to degradation. Further, it was found that the time spent at temperature within the heating elements before interaction with the column was also critical, thus implicating ramp-up rates. Overall, tight temperature control and maintaining heat transfer rates during purification among other critical parameters are critical for a smooth scale up of heated purifications.

As mentioned earlier in this report, the most widely accepted choice for ON isolation following purification at manufacturing scales is TFF or diafiltration (Fig. 22). In this process, a solution is fed against an appropriately sized membrane to remove the purification salts and other byproducts. Additionally, this process allows for the concentration of the purified material to ensure that the subsequent lyophilization step is simplified. As such, diligent modeling of ON concentration throughout the diafiltration process and control of the system physical parameters such as transmembrane pressure (TMP), membrane flux, and diafiltration volumes fed need to be controlled. For this, the most straightforward approach at developing a predictive small-scale model is to build a proportionally scaled version of the large-scale TFF system. As the large-scale batch sizes are generally proportionally larger than their respective system void volumes, developing small-scale models for TFF generally requires the use of custom-built pumps, vessels, tubing, and even sensors that will both minimize void volumes and be able to operate within the large-scale operating conditions. Table 9 summarizes parameters for a standard TFF operation with particular focus on critical scalable parameters to ensure reliable TFF operations.

The generally last step in the manufacturing process is the isolation of ON API powder through lyophilization (Fig. 28). As discussed earlier, a desalted ON solution is shelf frozen in an appropriate tray inside the lyophilizer equipment (denoted freezing in Fig. 28). Once the solutions are frozen, strong vacuum is applied to the chamber to begin the process of lyophilization. Once the system reaches strong vacuum, to aid the process of water sublimation, slight heat is applied gradually to the frozen trays (denoted shelf heating in Fig. 28). Through the primary drying process, as lower amounts of water are being removed and heat is still being

Table 8 RNA purifications are highly sensitive to purification temperature

Scale (mmol)	~0.6

Final concentration (after rinse) (mg/mL)	71	71

supplied to the product shelves, the observed tray temperature slowly rises to the desired set point until it equilibrates to the system (plateau in Fig. 28). To remove strongly associated water molecules (secondary drying in Fig. 28), stronger vacuum is applied, and the instrument set temperature is set to ambient. As one can imagine, the process as described is such highly dependent on equipment capabilities and sample volume that the process of small-scale modeling seems prohibitive. However, a simple solution is available. As the lyophilization rates are system-dependent but the evaporation from one tray is expectedly independent from another at a particular equipment load, a model where a single tray (*red arrows* in Fig. 28) carries ON material while the remainder of the trays that would form part of the manufacturing scale are filled with water provides a simple and reliable small-scale model for that lyophilization equipment. This approach ensures that the capabilities of the particular system to be used in the manufacture are taken into consideration while minimizing the cost of the development study.

Overall, diligent scrutiny and control over scalable parameters and diligent manufacturing equipment modeling provide a route for reliable large-scale manufactures. Careful attention to system proportions, void volumes, heat transfer, equipment loading, and sample concentration, among other critical operating parameters, ensures that any process development activities are useful in predicting large-scale manufactures. Through this responsible process, development approach, batch reliability and ON quality can be maximized and maintained.

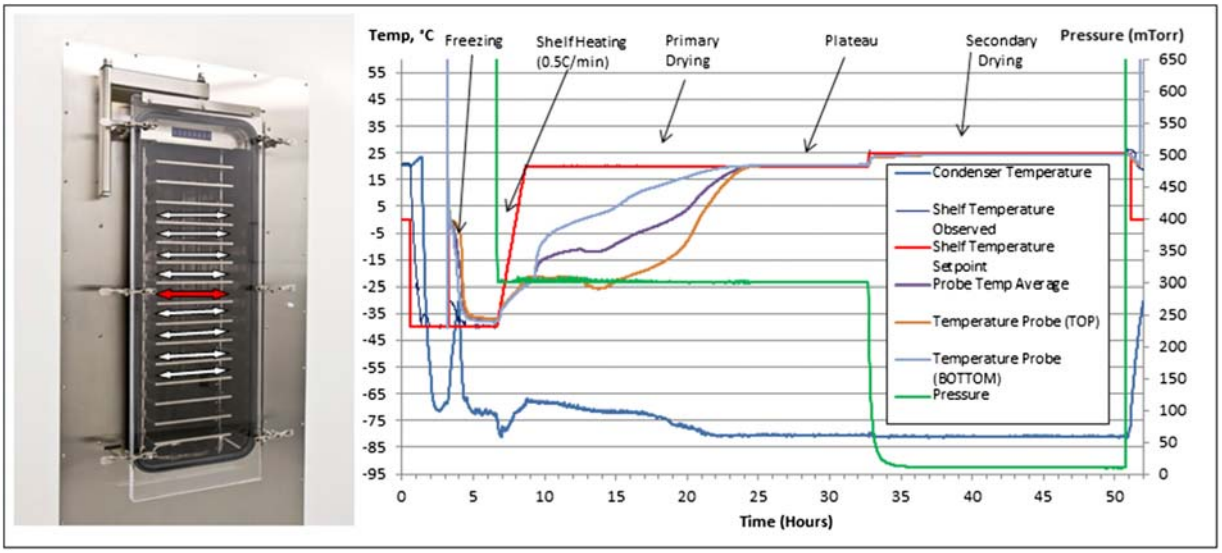

Fig. 28 Lyophilization small-scale modeling considerations.[175]

6.11.13 Analytic Tools to Support Oligonucleotide Manufacturing

Analysis of ONs can be a challenge due to their size and the structural similarity of their process-related impurities. Analytic techniques such as NMR, FT-IR, Raman spectroscopy, and total molecular weight by mass spectrometry are, by themselves, not suitable for ONs. Purity analysis of ONs can also be challenging, and HPLC, one of the most common techniques for measuring the purity of small-molecule drugs, has not always been adequate for measuring purity of ONs. Just a few decades ago, HPLC methods did not provide sufficient resolution of ONs and their process-related impurities. Alternative techniques such as denaturing polyacrylamide gel electrophoresis (PAGE) and capillary gel electrophoreses (CGE) had to be employed, but these techniques did not always have the attributes needed for routine QC testing. Fortunately, recent advances in analytic instrumentation and chromatographic packing materials provide today's analysts with an array of analytic methods that are suitable for establishing identity and measuring purity of synthetic ONs. The method(s) selected will depend upon the structure of the ON and the intended purpose of the test. Method characteristics such as analysis time, sensitivity, specificity, robustness, test complexity, and availability of instrumentation must also be considered.

Table 10 shows the methods that are most commonly used to analyze ONs manufactured for therapeutic use. The two most important analytic techniques used to support ON manufacturing are HPLC and mass spectrometry. HPLC methods such as reversed-phase ion pair, anion exchange, and size exclusion provide critical information about the purity of the ONs. Mass spectrometric methods such as MALDI-ToF, ESI-MS, and tandem mass spectrometry can all provide critical structural information. The combination of HPLC with mass spectrometric detection provides a third powerful technique. For this reason, the role of HPLC with mass spectrometric detection in the analysis of ONs will be discussed in its own section separate from HPLC and from mass spectrometry.

6.11.13.1 Commonly Used HPLC Techniques for the Analysis of Oligonucleotides

Reversed-phase ion-pair chromatography utilizes a hydrophobic stationary phase and a mobile phase containing an ion-pair reagent, which is typically an alkylated amine added at low concentration. Although the name of the technique suggests that the separation mechanism is driven by the electrostatic formation of an ion pair between the negatively charged ON and the positively charged alkyl amine, the actual separation mechanism is more complex. The amine's alkyl chains can bind with the lipophilic stationary phase leaving the cationic portion of the molecule exposed to analytes migrating through the column. The retention time of negatively charged analytes increases as a result of the electrostatic interaction with the modified stationary phase.[178] Commonly used ion-pair reagents include triethylammonium acetate, hexylammonium acetate, tetrabutyl ammonium acetate, and triethyl amine with hexafluoroisopropanol. Hexafluoroisopropanol is not considered an ion-pair reagent, but it has been shown to enhance separations.[179] The ion-pair reagent selected depends upon the needed selectivity and whether or not compatibility with mass spectrometric detection is required. The longer the ON, the more difficult it is to resolve the full-length product from process-related impurities due to their very small differences in hydrophobicities. The incorporation of phosphorothioate modifications results in the formation of a mixture of diastereomers that can also lead to peak broadening and further diminish resolution. In spite of these limitations, ion-pair chromatography is an important analytic technique for analysis of in-process samples and API. The technique's utility has been further enhanced by improvements in commercially available stationary phases.

Most separations are carried out on silica-based sorbents. Column manufacturers have significantly improved these packing materials through increased cross-linking, introduction of polar functional groups, and use of hybrid phases with silica coated onto a solid core. These new stationary phases operate at wide pH ranges, have good mechanical stability, and are available in particle sizes as low as 2 μm. Smaller sorbent particle sizes not only lead to increased plate counts but also require an HPLC system capable of operating reliably at backpressures as high as 1000 bar. Because of the high-molecular weight of ONs, mass transfer through the pores of the stationary phase can be slow and lead to peak broadening, but these effects can be minimized through the use of sorbents with a solid core coated with silica. A more detailed discussion of these topics and a comprehensive review of ion-pair separations for ONs was written by Cramer et al.[180]

Anion-exchange chromatography is widely used in the analysis of ONs.[181] Anion-exchange methods tend to be robust and well suited for in-process control or final product testing. The anionic ON interacts with the cationic functional groups on the stationary phase. Neutral and weak anions elute first followed by strongly charged molecules. Gradient separations are achieved by increasing the ionic strength of the mobile phase over time until all species of interest have eluted. Stationary phases usually consist of pellicular resin with a quaternary amine-functional group. Some column manufacturers produce anion-exchange columns that are designed exclusively for the separation of ONs. Anion-exchange columns are stable at pH as high as 12.5 and temperatures as high as 85 degrees centigrade making them excellent for use in separations involving ON single strands that are prone to forming strong secondary structures or duplexes that one wishes to analyze in the denatured state. Anion-exchange chromatography was shown to be capable of separating a full-length phosphorothioate ON from mono- and diphosphodiester species.[182] Like ion-pair chromatography, anion-exchange chromatography may not be capable of resolving all process-related impurities and degradation products from the full-length product, so drug sponsors may choose to utilize both chromatographic techniques to measure impurities and characterize their ON.

Size-exclusion chromatography (SEC) can be utilized to separate single strands from duplex and to separate single strand from their corresponding polymer conjugates. Molecules are separated based upon their size. Molecules too large to diffuse into the pores of the stationary phase elute first, and smaller molecules that are capable of diffusing through the stationary phase are retained

Table 10 Commonly used analytic techniques for analysis of oligonucleotides

Purpose	*Analytic technique*	*Application*
Confirmation of identity	Mass spectrometry (single mass analyzer)	ESI-MS and MALDI-ToF are commonly used to measure total molecular weight. For research-grade ONs, this test is typically accepted for establishing identity since the probability of synthesizing an incorrect, isobaric sequence is low. Total molecular weight alone is not sufficient for establishing identity of an ON used in clinical applications. The correct order of nucleotides must be established through another technique. ONs can be enzymatically digested to form a series of fragments that may then be analyzed by MALDI-ToF to confirm the correct sequence of nucleotides is present
	Tandem mass spectrometry	Tandem mass spectrometers generate ions *in situ*, and the ions pass through two or more stages of analysis. An electrospray ionization source coupled to a single-quadrupole mass analyzer followed by a time of flight mass analyzer is an example of a tandem mass spectrometer commonly used to analyze ONs. Tandem mass spectrometry is useful for analyzing an ON's sequence and confirming identity. Enzymatic digestion of the sample prior to analysis is not necessary since fragmentation is performed in the gaseous phase. Complete sequence coverage cannot be obtained for some longer sequences (typically longer than 30 nucleotides) and some chemically modified sequences. In instances where 100% sequence coverage is not obtained, additional techniques may be used to positively establish identity for ONs for therapeutic use
	UV spectroscopy for measurement of duplex melting temperature (T_m)	The melting temperature, or T_m, is the temperature at which half the population of complementary single strands exist in the duplex state and half exist in the denatured state. The T_m is a characteristic of the nucleotide sequence and thus can be used as an identity test. UV spectroscopy is the most common method for measuring T_m, although alternative techniques such as differential scanning calorimetry and circular dichroism may also be used. Annealed single strands in the duplex form have lower UV absorbance than single strands that are denatured. A duplex solution can be placed in the cell of a UV-Vis spectrophotometer with heating/cooling capabilities. As the temperature of the UV cell is increased, the duplex structure is disturbed and begins to denature. During the denaturing process, the corresponding increase in UV absorbance at 260 nm is measured, and the T_m can then be determined[176]
	^{31}P NMR	Unmodified ONs contain phosphate diester linkages with a ^{31}P NMR signal between 0 and 1 ppm. Many ONs are synthesized to have some or all of the nonbridging oxygen atoms of the phosphate diesters replaced by sulfur atoms to enhance their chemical stability. The resulting PS bonds yield a ^{31}P NMR signal between 50 and 60 ppm. ^{31}P NMR can measure the ratio of the PO to PS bonds in an ON making it suitable for confirming the correct molecular backbone is present. Other identity tests should be used in combination with ^{31}P NMR because this technique cannot demonstrate that the sequence of nucleotides is correct. ^{31}P NMR may also be used as a purity/impurity test to quantitate the amount of PO impurity in certain phosphorothioate ONs. A comparison of ^{31}P NMR and LC-MS for measurement of PO impurity has been studied and was shown to be in good agreement.[177] Anion-exchange chromatography may also be used to measure PO impurities as well
	Elemental spectroscopy (flame atomic absorption spectroscopy (FAA), inductively coupled plasma optical emission spectroscopy (ICP-OES), inductively coupled plasma mass spectrometry (ICP-MS))	Any of these techniques are capable of confirming identity of the counterion and determining the quantity of counterion present. Nearly all therapeutic ONs are produced as sodium salts. Testing for sodium serves to both establish the identity of the salt form present and confirm the purity of the ON. Many ONs are purified using anion-exchange chromatography with buffers containing sodium salts. Confirming that sodium levels are within preestablished ranges proves that purification buffer salts were removed from the ON prior to lyophilization. ONs intended for therapeutic use should also be tested for heavy metals. Frequently, ICP-MS can be used to analyze the counterion and confirm heavy metals are below the required acceptance criteria. Sodium counterion is usually present at 5–7% by weight, whereas heavy metal acceptance criteria are usually in the low ppm range. Multiple sample preparations typically must be made if ICP-MS is the technique selected for measuring both sodium and heavy metals in order to stay within the linear dynamic range of the instrument
	Ion chromatography	Ion chromatography with conductivity detection may be used to quantify the counterion and confirm its identity based upon retention time. Ion chromatography can also be a useful technique for testing for residual reagents used during manufacturing such as buffer salts and sodium acetate
	Sodium ion selective electrode	Sodium ion selective electrodes (ISE) may also be used to quantify the sodium counterion. ISE is attractive due to its low cost, ease of use, and short analysis times. These attributes make ISE an attractive technique for in-process testing and analysis of nonclinical samples, but techniques such as ICP-OES and ICP-MS are typically favored for analysis of the final drug substance

Table 10 Commonly used analytic techniques for analysis of oligonucleotides—cont'd

Purpose	*Analytic technique*	*Application*
	HPLC	HPLC retention time compared with a reference standard is a commonly used identity test for small-molecule drugs, but HPLC retention time is not a sufficient identity test for ONs due to the structural similarity of process-related impurities and degradation products. If a specification is established to determine identity based upon HPLC retention time, additional more specific analytic techniques such as sequencing by tandem mass spectrometry and Tm should also be used to confirm identity
Purity and assay	UV–vis spectroscopy (260 nm)	UV spectroscopy is used to quantify the amount of ON present through simple application of Beer's Law. A theoretical calculation of the molar extinction coefficient can be made if the ON sequence is known. UV spectroscopy is used during manufacturing to quantify the amount of ON present so that yield may be determined after a manufacturing step. UV spectroscopy is frequently used to measure total ON content in the final lyophilized ON
	HPLC—single strands	Anion-exchange chromatography with UV detection and reversed-phase ion-pair chromatography with UV or UV-MS detection are the two most common methods for measuring single-strand purity. If a well-characterized reference standard is available, then these techniques may also be utilized to perform an assay analysis
	HPLC—duplex	Size-exclusion chromatography, nondenaturing anion-exchange chromatography with UV detection, and nondenaturing reversed-phase ion-pair chromatography with UV or UV-MS detection are the most common methods for measuring duplex purity. If a well-characterized reference standard is available, then these techniques may also be utilized to perform an assay analysis
Other QC Tests	Bacterial endotoxins	Limulus Amebocyte lysate (LAL) test is commonly used
	Microbial testing	Testing should be conducted in accordance with the appropriate compendial methods
	Karl Fischer coulometry	This technique is used to determine the amount of water present in the ON. Oven attachments are frequently used to avoid direct introduction of the ON into the coulometric cell
	Gas chromatography with flame ionization detection (FID) or electron capture detection (ECD)	Residual solvents from the manufacturing process can be quantified with this method
	ICP-MS	ICP-MS is now widely used to test for heavy metals and any other elements that may be a residual from the manufacturing process. For example, silicon may be an element of interest if the manufacturing process contains a purification step utilizing silica-based chromatography packing

longer. Stationary phases most commonly used include chemically bonded porous silica gel and hydrophilic polymeric resins. Silica-based columns are typically used for separations of duplexes and single strands because of their ability to separate molecules ranging from 7 to 15 kDa. Polymeric resins may be a better choice when separating larger analytes such as pegylated ONs and high-molecular-weight multiplexes.[183] SEC may be used as an in-process control test to monitor the annealing process and determine when sufficient quantities of each single strand have been combined. Some ONs are conjugated to other molecules, such as polyethylene glycol (PEG), that are polydisperse. For these polydisperse conjugates, SEC may be used to determine the polydispersity index (PDI), which is a measure of the distribution of molecular weights of a polymer.[184]

Mass spectrometry can be used to measure an ON's molecular weight and determine its nucleotide sequence. The two most commonly used instruments for determining molecular weight are the matrix-assisted laser desorption ionization time of flight mass spectrometer (MALDI-ToF) and the electrospray ionization single-quadrupole mass spectrometer (ESI-MS). The MALDI-ToF has the advantage of generating and separating singly charged ions, which makes interpretation of mass spectra simpler. ESI-MS generates multiply charged ions that are separated based on their mass-to-charge ratios (m/z), and although this can make the mass spectra more difficult to interpret, it allows ONs with molecular weights above the upper mass limit of the spectrometer to still be analyzed. Deconvolution software must be used to transform the m/z data into the final mass spectrum. Both techniques are hindered by the formation of cationic adducts (usually Na^+ and K^+) that reduce sensitivity, so care must be taken that samples and reagents are free of interfering salts. Fountain et al. utilized HPLC desalting prior to ESI-MS analysis and developed a high-throughput method capable of analyzing one sample every 1.5 min with an average mass accuracy of 80 ppm.[185]

Confirming the correct nucleotide sequence is performed using one of two methods. The first involves enzymatic digestion of the ON to form a series of nucleotide fragments. Enzymes that digest from the 5′ direction to the 3′ direction may be used. The mixture of fragments is analyzed by MALDI-ToF, and the series of masses can be used to generate a sequence ladder that confirms the correct order of nucleotides. Since MALDI-ToF generates and separates singly charged ions, the mixture of fragments can be analyzed without prior separation. ESI-MS is not capable of separating such a complex mixture since each fragment would produce multiple ions having different mass-to-charge ratios making the spectra too complex to decipher. Tandem mass spectrometry is another option for determining an ON sequence. Fragments are produced in the gas phase. The ON backbone can be cleaved in four

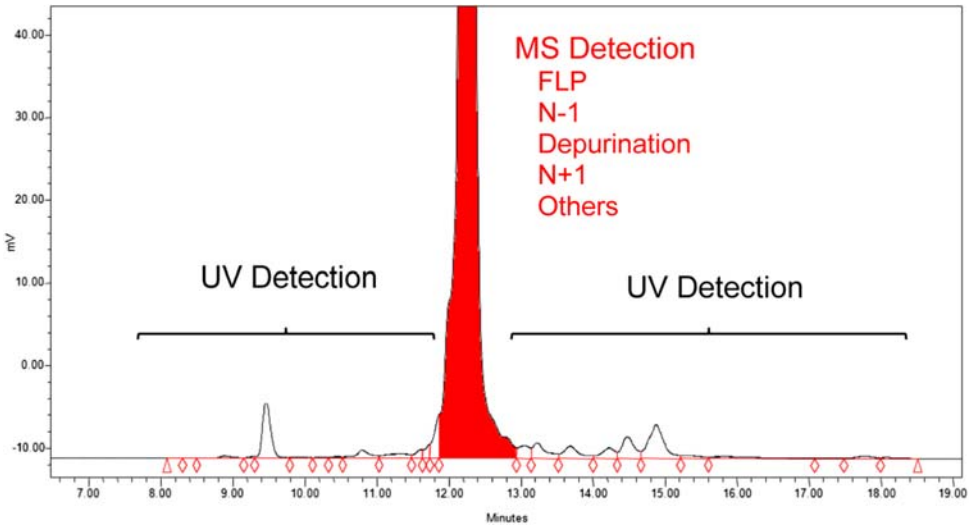

Fig. 29 Impurities quantified by UV detection and MS detection.[177]

possible positions across the diester bridge, namely, the two P–O bonds and two phosphoester bonds.[186] Nomenclature proposed by McLuckey et al. is widely accepted and typically used when reporting MS/MS sequencing data.[187] The lack of commercially available software can make data analysis tedious especially if one is attempting to perform de novo sequencing. MS/MS sequencing is most commonly used to confirm a known sequence, so the analyst has an indication of the fragments to expect.

Ion-pair chromatographic separation coupled with UV and mass spectrometric detection (LC-MS) is a very powerful tool for identifying and quantifying ONs and their related substances. Ideally, one would optimize the chromatographic separation so that as many species as possible could be quantified by UV detection and identified by LC-MS characterization. Only those species that cannot be resolved would be quantified by mass spectrometry. Given recent development in UPLC technologies, the separation capabilities of analytic methods have improved drastically. Well-developed UPLC methods (as demonstrated in Fig. 26) are providing the means to analyze most closely related impurities via UV quantitation, which significantly reduces analysis time. However, for impurities that do not separate well from the main peak, LC-MS is still capable of providing both structural and purity data and allows for quantification of such analytes. Mass spectrometry quantitation requires that individual ions be extracted from the total ion chromatogram (TIC) in order to quantify individual species, so processing of data tends to be more cumbersome than processing of UV data. Fig. 29 shows a UV chromatogram from an LC-MS separation and the species that are quantified by UV and those that are quantified by MS. Analysts should take care that the ion-pair reagents used are volatile and do not suppress ionization.

6.11.14 Regulatory Aspects of Oligonucleotides

ONs are an emerging therapeutic class, and no formal regulatory guidelines specifically addressing chemistry, manufacturing, and control aspects (CMC) of ONs have been published. Table 11 shows the only ON therapeutics approved by the US FDA.

In 1993, when the therapeutic ON field was in its infancy, representatives from the FDA published guidance in the scientific literature rather than in the form of a guidance document.[188] Subsequent guidance from regulatory agencies has come in the form of presentations made at industry conferences.[188,189] Consultants and industry experts have also published guidance based upon their experiences with regulatory agencies.[190]

Table 11 Oligonucleotide therapeutics approved by the US FDA

Drug name	*Approval year*	*Indication*	*Manufacturer at time of approval*
Vitravene™ (Fomivirsen Sodium)	1998	Cytomegalovirus	Isis Pharmaceuticals, Inc.
MACUGEN® (Pegaptanib Sodium)	2007	Neovascular (wet) age-related macular degeneration	Co-developed by Eyetech Pharmaceuticals, Inc., and Pfizer Inc.
KYNAMRO® (Mipomersen Sodium)	2013	Homozygous familial hypercholesterolemia (HoFH)	Genzyme (a Sanofi company)

Information from US FDA Website.

Therapeutic ONs are produced via a synthetic chemical process that utilizes chemically derived starting materials. ONs are frequently referred to in the industry as *big small molecules*. They are regulated as new chemical entities (NCEs), typically being reviewed by FDA's Center for Drug Evaluation and Research (CDER) unless the ON is a vaccine component or an element of a combination product.

Most ICH guidelines applicable to small molecule drug development are applicable to ONs. ICHQ3A(R2) (Impurities in New Drug Substances) and ICHQ6A (Specifications: Test Procedures and Acceptance Criteria for New Drug Substances and New Drug Products: Chemical Substances) specifically state that ONs are excluded from the scope of the documents, but the spirit of these documents still applies even if some specific details such as the impurity thresholds in ICHQ3A(R2) do not. The size and chemical structure of therapeutic ONs are such that special consideration must be given when setting specifications, developing an assay, and characterizing the ON. Therefore, only these three unique aspects will be discussed further here.

6.11.14.1 Setting Specifications

Specifications consist of two elements, the analytic method to be used and the corresponding acceptance criteria. Acceptance criteria should be established based upon patient safety considerations, but process capabilities and analytic method capabilities should also be considered. Acceptance criteria are meaningless if the analytic methods used are not capable of measuring within the targeted range. Furthermore, either a process that cannot consistently produce material meeting specification should be redesigned or the specification should be examined to determine what acceptance criteria are achievable with available manufacturing technology and within product's safety profile.

Identity of the ON must be established through a combination of tests. Tandem mass spectrometry may be capable of confirming the correct nucleotide sequence, but even in this case, an additional test is required to confirm the counterion present. For ONs that cannot be fully sequenced, a combination of identity tests may be applied such as T_m, total molecular weight by mass spectrometry, and HPLC retention time to confirm identity. Each of the three tests is not specific enough to independently establish identity, but identity may be confirmed when the tests are viewed as a group. Identity of individual single strands should be established prior to formation of a duplex, and additional identity tests should be conducted on the duplex to confirm that the correct single strands were annealed during production. Identity of ONs conjugated after solid-phase synthesis should be established prior to the conjugation reaction, and then, additional identification tests should be performed on the conjugate. Table 10 shows the tests commonly used to establish identity of ON products. The tests selected will depend upon the molecule's structure and the capabilities of the analytic method. Identity tests must demonstrate suitable specificity in order to unequivocally establish identity of the ON.

Purity is assessed by one or more techniques capable of separating ONs by their chain length. Process-related impurities and degradation products are structurally similar to the full-length ON making it difficult to analytically resolve these species. A single chromatographic technique may not be capable of resolving all species of interest. Orthogonal methods such as anion-exchange chromatography and ion-pair chromatography may be used when it is not possible to resolve all impurities with a single method. Alternatively, a single chromatographic method with orthogonal detectors (LC-UV-MS) may be used.

Tracking and reporting of ON impurities can be difficult because a single chromatographic peak may represent a mixture of impurities. For example, the $n-1$ impurity does not represent a single failure sequence but rather a group of failure sequences, all having one less nucleotide than the target sequence. The deleted nucleotide may be at any position in the chain. In addition, low-level impurities may not be baseline-resolved from one another, and small peaks may merge with one another from run to run only to reappear later. Development of a robust method and establishment of appropriate system suitability controls help to minimize these issues, but they cannot be eliminated entirely. Automated integration methods do not always work well with ONs due to the lack of baseline resolution for some low-level impurities. One approach is to integrate and report these low-level impurities as groups to help minimize variability from run to run and allow for better tracking and control of impurities. Quality control test methods involving chromatographic separation should also contain explicit instructions for integration to avoid variability from analyst to analyst.

Small-molecule drugs are routinely produced with purities in excess of 98%, but typical purities for therapeutic ONs may range from 85% to 95% as measured by HPLC. The achievable purity depends upon the ON's length, the characteristics of the sequence, and the chemical modifications incorporated into the molecule. Drug sponsors are encouraged to adopt state-of-the-art analytic methods even if doing so results in lowered measured purities. ICH Q3A(R2) provides dose-dependent thresholds for reporting, identifying, and qualifying impurities in small-molecule drugs, but these thresholds are not appropriate for ONs. The current view of most regulators is that the drug sponsor must develop and support the thresholds used for a particular ON based upon toxicology data and sound scientific principles. Nevertheless, the lack of general guidance can be daunting to those new to the field, and having some knowledge of thresholds typically used in the industry is useful. Table 12 shows the thresholds proposed by

Table 12 Thresholds for therapeutic oligonucleotides proposed by McArdle

Reporting	0.20%
Identification	0.50%
Qualification	1.50%

McArdle[191] for therapeutic ONs. These thresholds are not binding, and what is achievable may vary depending upon the specific ON. The thresholds presented in Table 12 are consistent with the thresholds used by many ON drug sponsors.

Purity specifications should be established for duplexes and the single strands that form the duplex. Chromatographic methods do not have sufficient resolution to separate imperfect duplexes, so having purity specifications for individual single strands is critical to ensure the resulting duplex has the necessary purity. A nondenaturing chromatographic method is used to determine the amount of duplex and single strands present. The duplex purity specification is based upon the amount of total duplex present. Some drug sponsors establish a specification to define the identity and maximum allowable quantity of excess single strand in the final duplex product.

The approach taken when setting purity specifications for ON conjugates is dependent upon the method of conjugation and the nature of the conjugate. A single purity specification may be established if the conjugation is performed during the solid-phase synthesis and the unconjugated ON is never isolated. If the conjugation is conducted after the solid-phase synthesis, then a purity specification is typically established for the unconjugated ON and the conjugated ON.

Most therapeutic ONs are produced as lyophilized powders. A specification for water content is frequently established to ensure that the lyophilization process is under control. Acceptance criteria as high as 15% are common due to the hygroscopic nature of ONs. Some chemically modified ONs may be more prone to degradation in the presence of water, and more stringent specifications may be established for these molecules. If lower water content is required, then special precautions must be made during lyophilization and packaging to ensure a dry environment that will prevent the ON from adsorbing atmospheric moisture.

A bioassay is not required for most ONs when identity, purity, and potency can be suitably established with other analytic methods. Aptamers are a particular class of ONs that require a specific three-dimensional conformation in order to exhibit their characteristic biological activity. For this reason, a bioassay is frequently included in the specifications for aptamers but not for most other ONs. The necessary three-dimensional structure is highly dependent upon the sample matrix, so bioassay may be part of the drug product specifications rather than the drug substance specifications. Perhaps after a suitable body of data has been generated to demonstrate that aptamers with the correct identity and purity in a given sample matrix will always assume the correct three-dimensional structure, then bioassay might be eliminated from product specifications. Some bioassays have high-method variability making them difficult QC tests to implement and validate. Nevertheless, the body of data to support elimination of bioassay is not currently available, and hence an aptamer bioassay is typically expected by regulatory agencies.

Other specifications such as bacterial endotoxin, bioburden, residual solvents, and heavy metals are established using the same methodology applied to other small molecule drugs, and the reader is directed to consult the relevant regulatory guidance documents if further information is required.

6.11.14.1.1 Assay

In the early phases of drug development, a quantitative assay against a high-purity reference standard is typically not needed. The UV absorbance of a solution prepared with a known weight of ON may be measured, and a theoretically derived extinction coefficient can be used to determine the total ON content. Multiplying the total ON content by the percentage of full-length product obtained using an analytic method capable of separating by chain length can provide an assay value suitable for the early stages of development.

During the later stages of development, a well characterized, high-purity reference standard should be prepared for use in a weight-based assay. A chromatographic method with UV and/or MS detection is typically used. The hygroscopic and electrostatic nature of ONs makes it difficult to weigh small quantities of sample and introduces a source of variability into the assay. Aliquots of reference standard may be stored as aqueous solutions to minimize these effects to speed preparation of calibration curve standards. Some methods specify that samples must be prepared in a dry box to avoid the adsorption of atmospheric humidity. Other methods specify that sample be allowed to equilibrate to atmospheric humidity before the sample is analyzed. This technique is referred to as conditioned moisture.[192] Assay methods should clearly define how the reference standard and the sample are to be stored and prepared to ensure the accuracy of the results obtained. The method should also clearly state what corrections the analyst should make for water, residual solvents, excess counterion (e.g., Na^+), and any other impurities.

6.11.14.2 Characterization of Oligonucleotides

Table 10 lists tests that are commonly performed as part of routine QC testing. Additional characterization testing is typically performed on one or more batches, usually a reference standard, in order to establish the ON structure and physicochemical properties. The following analytic tests are frequently used to characterize ONs:

- *NMR*—ONs yield complex ^1H and ^{13}C NMR spectra, but NMR can still be a valuable tool in the characterization and structure elucidation of ONs. 2D NOESY and 2D TOCSY/COSY can be used to identify base pairs and show connectivity in duplexes. ^1H and ^{13}C NMR experiments are typically included in characterization testing used to support regulatory filings. A summary of the NMR experiments that can be performed to characterize ONs has been described elsewhere.[193]
- *Base composition analysis*—Samples are enzymatically degraded into their constituent bases. The bases are quantified to demonstrate that they are in the correct stoichiometric ratio. This is a useful technique especially when 100% sequence coverage cannot be obtained by mass spectrometric sequencing methods.

- *UV-vis spectroscopy*—A wavelength scan should be obtained that shows the λ_{max} and λ_{min}. Novel chemical modifications may cause the actual extinction coefficient to differ from the theoretical value, so an experimentally derived extinction coefficient should be obtained.
- *X-ray powder diffraction (XRPD)*—Used to show that the ON is an amorphous solid.
- *FT-IR*—Spectra should further confirm structure.
- *Dynamic vapor sorption*—Measures the adsorption of atmospheric moisture over time.
- *Circular dichroism*—Useful for measuring conformational properties of ONs in solution.
- *Solubility*—A range of common solvents should be tested.

Forced degradation studies performed per ICH guidelines are also necessary to ascertain if analytic methods are stability indication. These studies also elucidate degradation pathways and produce degradation products that can be further characterized. For duplexes and conjugates, forced degradation studies may be performed on the individual single strands and the final duplex or conjugate.

Most ONs in clinical development are being produced by contract manufacturing organizations (CMO), so some comments about the roles and responsibilities of drug sponsors and CMOs are appropriate. The relationship between the drug sponsor and the CMO should be viewed as a potential long-term partnership, so proper diligence should be performed in the CMO evaluation and selection phase. A drug sponsor should select a CMO after careful review of the CMO's capabilities and technical expertise. Consideration should be given to the CMO's ability to support drug manufacturing through clinical development, process validation, and commercialization. A thorough quality audit should be performed at the CMO prior to manufacturing of clinical materials, and a quality agreement should be established, so roles and responsibilities are clearly defined prior to manufacturing. The CMO may provide guidance on setting specifications based upon knowledge of the capabilities of the manufacturing processes and the analytic methods to be used. However, the drug sponsor is ultimately responsible for ensuring that appropriate specifications are established based upon toxicological studies, final dosage form, route of administration, and anticipated dose. The information of the CMO is to provide the drug sponsor regarding analytic methods and raw materials, and the manufacturing process should be clearly defined in a business contract. Some information might be proprietary to the CMO, and restrictions upon how this information can be shared and used may exist. Clear communication by both sides throughout the drug's development is crucial to the overall success of the program.

The scope of work to be conducted by the CMO should be carefully planned and realistic timelines established. Although standard methodology is used to synthesize most ONs, individual sequences may have unique properties that require further sequence-specific optimization of standard methods. In 2011, a survey was conducted of people working at biopharmaceutical CMOs. Respondents were asked about the most common mistakes made by clients. Ninety-two percent responded that clients do not build in sufficient time for their project, and clients want to contain cost by doing limited development runs but still expect successful full scale manufacturing.[194]

6.11.15 Summary

Synthetic ONs have been explored for therapeutic and diagnostic purposes for more than two decades. These efforts have presently culminated into FDA approving two drug products. Many ONs (c.100) are currently undergoing clinical trials and are at various stages of investigations. The drug development requires, apart from successful clinical trials, understanding of the quality of drug substance/drug product and proper characterization of any impurities it may contain. In this article, we have tried to describe the potential sources and measures that can be taken to control these impurities. In solid-phase ON synthesis, based on phosphoramidite chemistry, sources of impurities have been subdivided into three categories: building block-related (nucleoside-phosphoramidites), synthesis reagent-related (solid supports and ancillary reagents), and process-related impurities (side reactions during synthesis).

The structure of nucleoside-phosphoramidite related impurities has been provided for clear understandings. Of the three types of impurities present in nucleoside-phosphoramidite, only reactive and critical components are incorporated in ON synthesis and contribute to impurities in the drug substance. The nature of these potential impurities has been elucidated as far as possible. Impurities in synthesis reagents including various solid supports have been described. Potential impurities generated in the ON due to impurities found in reagents and solid supports have been illustrated, and means to alleviate and control these impurities have been suggested.

The lab-scale manufacture of ONs including critical equipment, raw material, and process options has been described in detail. ON impurities originating from the synthesis process (detritylation, coupling, capping, oxidation, or sulfurization, release of the ON from the support, and removal of protecting groups) have been explained, and possible mechanisms to their formation have been provided. Further, large-scale manufacturing equipment considerations have been summarized. Additionally, small-scale modeling approaches to develop each of the manufacturing process operations for large-scale manufacture have been described. The discussion is focused around how scalable parameters affect ON quality.

Additionally, the related analytic tools that are involved in the development of processes and used to analyze ONs are also summarized in full detail. Finally, clinical development considerations based on regulatory guidance for ON programs have been described.

6.11.16 Outlook

Over the past two decades, concurrent to ON-based therapeutic investigations, significant developments have been made in the characterization and manufacture of ONs. Analytic techniques such as strong anion-exchange HPLC, matrix-assisted light desorption ionization-time of flight (MALDI-TOF) MS, IP-RP-HPLC, HPLC-MS, UPLC, and MS/MS have been instrumental in identifying and characterizing various impurities. Impurities detected and identified in nucleoside-phosphoramidites and synthesis reagents provide a means for controlling quality of ONs. Similarly, optimizations of the manufacturing process and developments in large-scale manufacturing equipment have ensured that manufacturing technology can support the rapidly expanding ON field and maturing ON-based API pipelines. Further, strict modeling and in-process optimization minimize impurities and ensure robust manufacturing processes, thereby building confidence in the quality of ON drugs manufactured. These advancements pave the way for future ON clinical applications.

Acknowledgments

We thank Gary Burt from Avecia for providing 31P-NMR, HPLC, and mass data of phosphoramidites released by the QC Department of Avecia.

6.12.1 Introduction

The emergence of nucleic acid based therapeutics dates back to 1978 when Zamecnik and Stephanson first reported inhibition of viral replication using short oligonucleotides that bind complementary viral RNA targets.[1] The discovery of these functional DNAs, aka "antisense oligonucleotides (ASOs)" along with the progress in solid phase DNA synthesis technology opened a new era of therapeutic drug discovery as nucleic acid–based therapeutics have been recognized as potential alternatives to conventional small molecule based drugs. Shortly after the report of first ASOs, catalytic function was discovered in protozoan and bacterial RNAs by a Czechian group.[2] This breakthrough discovery made over 30 years ago uncovered regulatory function of RNAs in cells and sparked wide spread researches on biological functions of RNAs. In 1993, the first microRNA, lin-4 was discovered by two groups.[3] Over the past two decades, numerous miRNAs have been identified in a variety of organisms including humans. It has been also shown that miRNA dysregulation is associated with a number of diseases.[4] Another important RNA function was reported in 1998 by Fire et al. who discovered RNA interference as antiviral immune system in the nematode *Caenorhabditis elegans*.[5] Shortly thereafter, synthetic short exogenous double-stranded RNAs, or siRNAs were introduced into mammalian cells and achieved sequence-specific gene silencing.[6] Since then, siRNA has been widely accepted not only as a research tool but also as a potential therapeutic intervention. Other classes of functional RNAs being considered for development as therapeutics include, riboswitches,[7] PIWI interacting RNAs[8] and CRISPR/Cas9 system.[9] Interestingly, whole human genome sequencing and studies of human transcriptomes

revealed that 98% of human genome which was previously thought to be nonfunctional "junk" DNA is actually transcribed into RNA[10]; these long noncoding RNAs[4b] have potential regulatory functions and thus are potential targets for medical intervention These series of discoveries shed light on significant roles of RNA in cells, and at the same time, also gave rise to the idea of utilizing these functional RNAs as therapeutics.

Rapid progress in sequencing technology has uncovered a number of disease-related genes that are "undruggable" by conventional pharmaceuticals. Mechanisms of action of most nucleic acid based drugs are based on Watson-Crick base pairing with target DNA/RNA in sequence-specific manner. Thus, nucleic acid based drugs can in theory, target virtually any nucleic acid gene products including these undruggable targets. In addition, it has been shown that some single-stranded nucleic acids, so-called aptamers can interact with proteins, nucleic acids, and small molecules. Often regarded as "chemical antibodies," aptamers can be engineered to complex with multiple different proteins and small molecules by forming specific secondary or tertiary structures for molecular interactions.[11] Given these attractive features, the functional nucleic acids have gained escalated attention by academic and industry researchers from all over the world and extensive research has been performed for the purpose of developing new classes of therapeutics. ASOs have made the most significant advances as therapeutics. Two ASO based drugs have been approved by the United States Food and Drug Administration (FDA) and many clinical studies are ongoing for a variety of diseases.[12] This remarkable progress was made possible by chemical modifications that stabilize ASOs and improve their functions as well as bioavailability in biological fluid.[13]

Technological knowledge and skills developed during early researches on ASOs and ribozymes made a significant contribution to the rapid progress of emerging RNAi-based drug development. Despite tremendous effort and billions of dollars invested over the past two decades, the development of RNAi-based drugs has been facing serious challenges because of their unfavorable physiological nature for intracellular delivery.[14] However, recent clinical studies of RNAi-based drugs showed potential benefit and promising therapeutic efficacy which could potentially lead to approval in near future.

In parallel to the works on ASOs and siRNAs, aptamer development has been taking place since 1990s. Aptamers are obtained by a multiround selection process called "Systematic Evolution of Ligands by EXponential enrichment" (SELEX).[15] Due to their monoclonal antibody-like properties, aptamers are potentially useful as therapeutic agents for multiple diseases. They are also being explored for various other applications such as diagnostics, biosensors, imaging, biomarker discovery, and targeted drug delivery. One aptamer therapeutic is currently commercially available and many are in clinical trials.

Recently, the CRISPR/Cas9 system has emerged as an important new genome engineering approach that has been quickly adopted by laboratories around the world.[9] This powerful and highly specific genome editing technology can target, edit, or modify genomic DNA in a variety of cells and organisms including humans. Interestingly, in the CRISPR/Cas9 system, RNA molecules play critical roles in determining target specificity. A clinical trial of one application of the system will soon be opened. We will briefly overview this highly promising RNA-guided technology below.

This chapter is divided into two broad categories; (1) synthetic therapeutic oligonucleotides and (2) biochemically produced therapeutic RNAs. We will discuss the current advances and potential challenges in the development of nucleic acid therapeutics along with mechanisms of action and some examples for applications. The challenges in developing nucleic acid based therapeutics include their extremely unstable nature in biological fluid, poor PK properties, and potential activation of innate immunity. In addition, intracellular delivery remains the major obstacle in application of nucleic acid therapeutics. We will address how scientists approach these challenges.

6.12.2 Synthetic Therapeutic Oligonucleotides

6.12.2.1 Antisense Oligonucleotides (ASOs)

The basic concept underlying ASO technology is very simple: antagonizing cellular RNA molecules via Watson-Click base pairing. Unlike small molecule and antibody based drugs, most of which target proteins, the most common target of ASOs are messenger RNA (mRNA). An ASO recognizes and binds the complementary sequence in the target mRNA, thus inhibiting translation. However, ASO targets are not limited to mRNA which also include viral genomic RNA, pre-mRNA, miRNA, and other noncoding RNA categories. For example, the pioneering work by Zemecnik and Stephanson demonstrated inhibition of viral replication in chick embryo fibroblast tissue cultures infected with Rous sarcoma virus (RSV) using 13-nucleotide (nt) long DNA, ultimately called an "antisense oligonucleotides," that was complementary to the reiterated terminal sequence of RSV 35S RNA.[1b]

Typical ASOs are short, synthetic single-stranded DNA molecules (~15–25-nt long) that bind complementary sequences in target RNA molecules which are subsequently degraded by various cellular mechanisms.[13] Certain ASOs sterically block the access of cellular machinery to target RNA, resulting in translation or splicing inhibition.[16] This steric-blocking strategy can also be useful for repairing defective RNA or for splicing modulation. Of the target cleavage mechanisms, the RNase H-dependent cleavage is well studied and the best understood antisense mechanism.[17] This requires recruitment of RNase H enzyme that recognizes DNA–RNA hybrid, cutting the RNA component. As different mechanisms lead to different outcomes, ASO design depends on the intended use.

6.12.2.1.1 Chemical modification

Single-stranded DNAs and RNAs are extremely instable in body fluids as well as extracellular environments. Unmodified or naked ASOs can be quickly degraded by circulating nucleases in a body. Moreover, their poor intracellular uptake, pharmacokinetic (PK) and pharmacodynamic (PD) properties, and potential activation of innate immunity are also major obstacles to their use as

therapeutics. Thus, scientists have devoted substantial effort over the past 30 years to developing numerous chemical modifications that confer drug-like properties to ASOs. These modifications have been introduced to phosphate backbone, sugar moiety, and/or bases of ASOs.[18] The earliest and most widely used chemical modification is the phosphorothioate (PS) backbone modification (first-generation modification, Fig. 1), wherein one of the nonbinding oxygen atoms in the phosphodiester (PO) backbone on the natural DNA and RNA molecules is substituted by a sulfur atom.[19] The sulfur substitution in the ASO backbone creates a chiral center at the phosphorus atom, leading to a Sp or Rp diastereomer at each chiral center during synthesis resulting in a $2^{(n-1)}$ diastereo mixture of *n*-mer PS-ASOs. Generally, the Sp configuration provides higher nuclease resistance to ASOs compared to Rp, whereas Rp-ASOs show higher binding affinity than Sp-ASOs. Thus, the overall mixture has a higher nuclease resistance but lower binding affinity (about $-0.8°C$ per linkage) compared to its corresponding unmodified PO-ASO.[20] The PS modification shows high solubility and is also one of the few modifications that supports RNase H activity. Increased protein affinity is also a notable feature of the PS modification[21] and high plasma protein binding enhances circulation time while reducing elimination of PS-ASOs by renal excretion. In addition, it may also contribute to tissue distribution and cellular uptake.[22] Despite continuous controversies regarding various side effects, the PS modification is currently used as one of the essential parts of therapeutic ASOs. A major milestone in ASO development was achieved in 1998 when fomivirsen (Vitravene), developed by Ionis Pharmaceuticals (formerly ISIS Pharmaceuticals),[23] became the first FDA approved ASO therapeutic for the treatment of cytomegalovirus (CMV) retinitis in AIDS patients. This 21-nt PS-ASO targets CMV mRNA, inhibiting production of the IE2 protein that is essential for viral replication. Intraocular injection of fomivirsen at 330 μg dose every other week as induction and monthly as maintenance thereafter significantly delayed disease progression in patients (~90 days). This limited local injection eliminated systemic exposure, avoiding potential systemic side effects. However, the common side effects reported in clinical trials were increased intraocular pressure and mild to moderate intraocular inflammation.[24] Since the emergence of other highly active drugs for CMV retinitis and highly active antiretroviral therapy, the number of CMV retinitis patients has significantly dropped. Due to poor demand, fomiversen has been withdrawn from market.

Modifications on the 2′-position of the sugar moiety have provided enhanced drug-like properties to ASOs. Such 2′-substituents include 2′-*O*-methyl (2′-OMe) and 2′-*O*-methoxyethyl (2′-MOE) (Fig. 1). Sugar pucker of these 2′-*O*-alkyl modified ASOs, causes

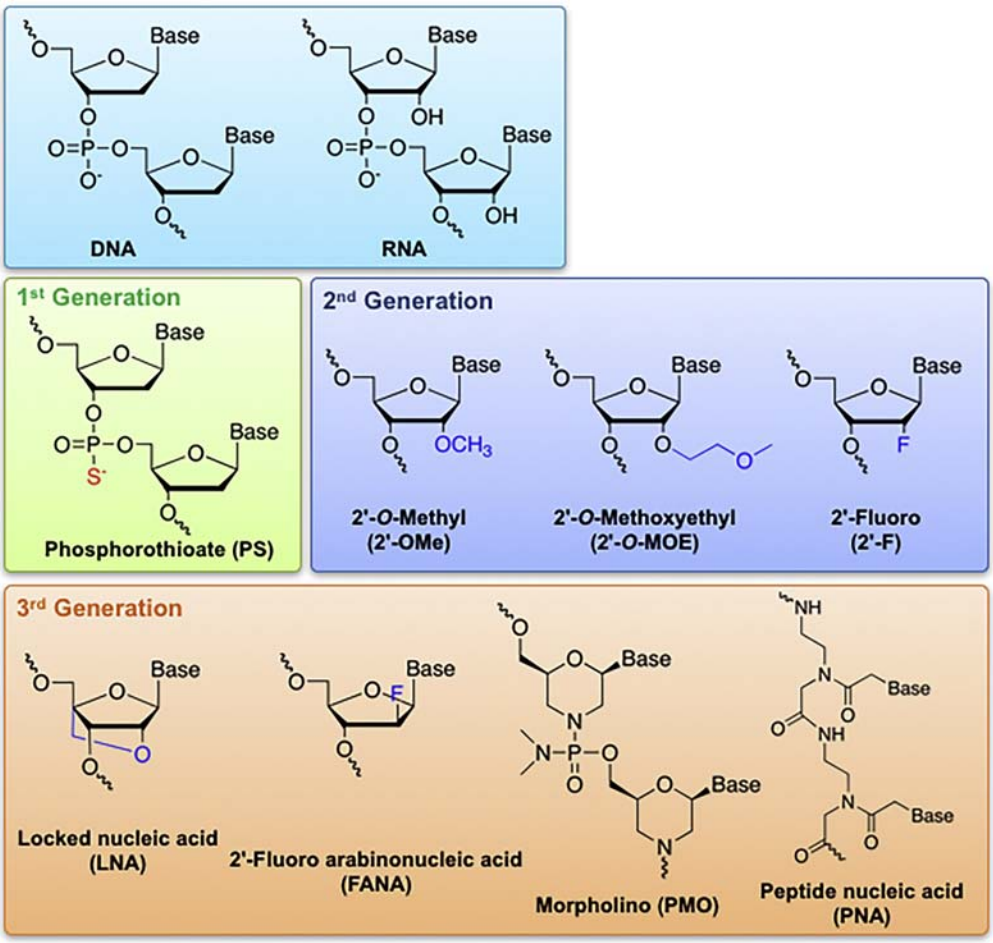

Fig. 1 Chemical modifications of oligonucleotides.

these so-called second-generation ASOs to adopt an energy favorable *C3′-endo* conformation in the furanose pseudorotation cycle, thus increasing binding affinity to RNA.[25] Substitution to these bulky alkoxy groups has also shown to dramatically improve nuclease resistance. 2′-OMe is one of most well characterized nucleic acid analogues. 2′-OMe modification increases T_m by about 1.7°C per modification against its complementary RNA compared to its corresponding unmodified DNA. The advantage of the 2′-OMe modification is that it is a naturally occurring posttranscriptional RNA modification in cells (e.g., tRNA, mRNA cap); therefore, 2′-OMe modified ASOs generally do not activate the innate immune response. 2′-MOE modification is currently the most intensely studied and most advanced in therapeutic ASO development. 2′-MOE modification also offers high binding affinity to its complementary RNA (+2°C per modification) and enhanced nuclease resistance.[25] X-ray crystallography analysis of 2′-MOE modified oligonucleotides revealed a unique structural feature of this nucleoside analogue.[26] Multiple gauche effects around the 2′-MOE substituent locks the sugar pucker in the *C3′*-endo conformation, and that in turn traps water molecules in the ethylene chain of 2′-MOE, assisted by the adjacent phosphate residue. This supports extensive hydration of the molecule and the increased nuclease resistance. Despite their therapeutically favorable properties, these second generation chemistries lack the capacity of recruiting RNase H for target RNA cleavage. Although these modifications are quite useful for steric blocking, there is some limitation in modification patterns for ASOs for RNase H-dependent cleavage. Introduction of gapmer design, where a central DNA region is flanked by several 2′-modified residues, has greatly minimized this limitation. This design allows RNase H recruitment to the central DNA region, whereas the 2′-modified ends stabilize duplex and protect the ASO from nuclease degradation. Many of the second-generation ASOs have been tested or are currently being tested in clinical trials. A 2′-MOE-PS ASO, Mipomersen (KINAMRO, Ionis Pharmaceuticals) has been approved by FDA in 2013 for treatment of homozygous familial hypercholesterolemia.[27] Details will be discussed below.

The third-generation ASOs have been developed to further enhance target affinity and specificity, nuclease resistance, and pharmacokinetics. Among these modifications are peptide nucleic acids (PNAs), 2′,4′-bicyclic nucleic acid (BNA) or locked nucleic acid (LNA), phosphorodiamidate morpholino oligomers (PMOs), and 2′-fluoro-arabinonucleic acids (FANA) (**Fig. 1**).

Unlike other nucleic acid analogues, PNAs have a pseudopeptide backbone in place of phosphodiester backbone which still maintains the ability to Watson-Crick base pair through nucleobases attached to the peptide backbone via methylene carbonyl linkage.[28] PNAs are noncharged nucleotide analogues that show high binding affinity to both DNA and RNA, nuclease/peptidase resistance, and target specificity.[29] PNA based ASOs are mainly used for steric blocking purpose as they are unavailable for the RNase H dependent cleavage mechanism. It is also known that PNA can form PNA/DNA triplex or double duplexes with double-double stranded DNA, as such PNA can elicit antigene activity. Despite these interesting features, they have problems related to solubility and cell-membrane penetration. These have been addressed by the use of charged peptides in the backbone, conjugation of short peptides[30] or cell-penetrating peptides.[31] Substantial studies have been done to assess efficacy of PNA-ASOs in vitro as well as in vivo. Although delivery and pharmacokinetic properties of PNA remain to be solved, recent studies of splice modulating PNAs targeting dystrophin mRNA for treatment of Duchenne muscular dystrophy (DMD) demonstrated promising therapeutic efficacy of PNAs in mice models.[32]

LNA is also one of well known nucleic acid analogues. LNA structure is characterized by a methylene bridge connecting the 2′-oxygen and the 4′-carbon atoms in the sugar moiety, which locks the sugar pucker in *C3′-endo* conformation resulting in a significant increase of binding affinity to complementary RNA.[33] Single LNA substitution raises T_m of duplexes by 2–8°C compared to the corresponding unmodified duplexes.[34] Like the second generation modifications, LNA modifications offer high nuclease resistance, but are not capable of recruiting RNase H, unless the gapmer design is used. Several LNA modified ASOs have already been tested in clinical trials. Among these, a microRNA-122 inhibitor, Miravirsen (Roche, formerly Santaris Pharma),[35] is the first and currently the most advanced antimicroRNA LNA-ASO, (phase I and phase II) which will be discussed later in this section. Although LNA modification related toxicity is reported in some cases,[36] LNA modified ASOs still hold promise and potency in clinical development.

Another unique but potential chemical modification is PMO. This modified analogue consists of a morpholine ring in place of the furanose, and a neutral phosphorodiamidate backbone between the nitrogen atom of the morpholine ring and the hydroxy group of next residue.[37] The binding affinity of PMO to its complementary RNA is only slightly higher than DNA but it is highly sequence specific and extremely stable against nuclease degradation.[38] In contrast to PNA, which is also a noncharged analogue, PMO shows excellent water solubility. This is probably because the nucleobases of PMOs are well stacked in aqueous solution whereas PNA shows poor stacking of the bases.[38] Because of its lack of RNase H activation ability, PMO is primarily used in steric blocking mechanisms or translation arrest. Some PMOs have showed great promise in preclinical and clinical studies. Eteplirsen (Sarepta Therapeutics), a PMO designed to skip exon 51 of dystrophin mRNA in DMD patients is currently one of the most successful therapeutic ASOs and has shown encouraging outcome in clinical studies.[39]

While many 2′-modified analogues show RNA-like properties, FANA is considered to be a DNA mimic in terms of its structure. The fluorine atom which is placed on the β position (top-face) of the nucleoside franose ring of FANA has a significant influence on nucleoside conformation and stability. Because of the high electronegativity and small steric effect of the fluorine atom, FANA adopts a more DNA-like β-type helix conformation,[40] not through the DNA-like *C2′-endo* conformation, but through *O4′-endo* conformation.[41] Interestingly, unlike other sugar modified analogues, studies have shown that FANA can elicit RNase H mediated cleavage probably due to its DNA-like conformation, relatively high conformational flexibility, and lower steric hindrance.[42] FANA modification also increases melting temperature of duplexes and offers high nuclease resistance.[43] Various FANA modified ASOs with PS or PO backbones against clinically relevant targets have been tested in vitro as well as in vivo. For example, FANA modified ASOs that target different isoforms of phosphodiesterase type IV (PDE4) to treat chronic obstructive pulmonary disease showed dose-dependent inhibition of target mRNAs in cells.[44] Treatment of mice with combined PDE-FANA-ASOs exhibited significant

protection from the smoke-induced inflammation. Compared to existing PDE inhibitors, the ASOs showed more potent and broader antiinflammatory effects. Another interesting feature of FANA has been revealed in a recent study showing that FANA modified ASOs with PS backbone were compatible with gymnotic delivery and were as effective at gene expression as corresponding LNA modified oligonucleotides.[45] These unique characteristics of FANA could be great advantages in future clinical development.

6.12.2.1.2 Pharmacokinetic properties of ASOs

Due to their large size, multiple negative charges and hydrophilic nature, oligonucleotides naturally lack drug-like properties that follow Lipinski's rule of five stating that pharmacologically active drugs have molecular weight of less than 500 Da and high lipophilicity. Moreover, as mentioned above, unmodified oligonucleotides are extremely susceptible to serum nucleases resulting in degradation. Chemical modifications can improve not only physical properties but also PK properties of ASOs. PK and biodistribution of the first- and second-generation ASOs have been intensely studied both in preclinical and clinical studies. Most ASOs that have been developed for the purpose of therapeutic use contain PS modifications known to facilitate plasma protein binding, thus enhancing tissue bioavailability. It has been reported that more than 85% of administered ASOs are bound to plasma proteins such as albumin.[46] Additional modifications on the 2′ position improve binding affinity to target RNA and significantly increase tissue and serum stability. When administered by intravenous (IV) infusion or subcutaneous (SC) injection, these second-generation ASOs go into systemic circulation and are rapidly distributed into various tissues (minutes to hours) with high bioavailability (>90%).[22,47] In contrast, uncharged ASOs such as PNA and PMO and unmodified ASOs have less binding affinity to plasma proteins, resulting in inefficient tissue bioavailability and rapid renal excretion.[48] To elicit the desired pharmacological effect, ASOs must cross plasma membrane to reach their targets in the nucleus or cytoplasm. Protein bound ASOs are taken into cells via nonproductive pathway resulting in accumulation of lysosomes or functional uptake where ASOs gain access to target RNAs. A study showed that the functional uptake is dependent on a clathrin-associated adopter protein, AP2M1 but by a clathrin- and caveolin-independent process.[49] Once ASOs enter cells, they exhibit a long half-life of generally 2–4 weeks. The main intracellular metabolic pathway of the second-generation ASOs is nuclease degradation. After tissue absorption, the ASOs are slowly degraded by nucleases and eliminated via excretion in urine. Reported PK properties of the second-generation ASOs are generally similar and independent of sequence but rather depend on chemical modifications, making it easy to predict clinical PK properties that facilitate rapid drug development.

6.12.2.1.3 ASOs in clinical development

Despite early failures in clinical trials and relatively slow initial progress, numerous ASOs are currently being tested in clinical trials against various diseases (listed in **Table 1**). Many of these have shown promising pharmacological effects and properties, which will soon be tested in advanced phase clinical trials. Until now, two ASOs have been approved by the US FDA. Although the first ASO drug, fomivirsen has been retracted from market, newly approved mipomersen is actively being used for treatment of patients. Here, we discuss clinical trial progress and result of some potential ASO therapeutic candidates.

6.12.2.1.3.1 ASO mipomersen (KYNAMRO)—2′-MOE-PS modified gapmer

Mipomersen (KYNAMRO, Ionis Pharmaceuticals) is a 2′-MOE and PS modified ASO gapmer that binds to apolipoprotein B100 (ApoB100) mRNA resulting in inhibition of ApoB100 protein synthesis via RNase H mediated cleavage mechanism in the liver.[50] The drug was approved by the US FDA in 2012 with an orphan drug status for treating patients with homozygous familial hypercholesterolemia (HoFH).[27] HoFH is a rare genetic disorder with two mutant alleles at the *LDLR*, *APOB*, *PCSK9*, or *LDLRAP1* gene locus. The HoFH patients have very high level of plasma low-density lipoprotein cholesterol (LDL-c) (untreated, >13 mmol L^{-1} (>500 mg dL^{-1}); treated, ≥8 mmol L^{-1} (≥300 mg dL^{-1})) and high risk for cardiovascular disease. In a phase III study, a weekly subcutaneous injection of 200 mg mipomersen for 26 weeks reduced LDL-c level by 25% compared with placebo (3.3%).[27] Significant reductions in levels of apoB (27%) and lipoprotein (a) (31%) and no change in high-density lipoprotein cholesterol (HDL-c) were also observed. Adverse events observed in mipomersen treated patients include injection site reactions, flu-like symptoms, elevated alanine aminotransferase, and increased liver fat. Mirapomersen has also been tested in heterozygous FH patients. With the same treatment regimen, the phase III study in patients with severe HeFH met a primary efficacy endpoint, a significant reduction in LDL-c, which was similar to that observed in the phase III study in HoFH patients.[51] Long-term efficacy and safety of mipomersen has been examined in open-label extended dosing study in patients with FH taking maximally tolerated lipid-lowering therapy.[52] The patients received a weekly subcutaneous injection of 200 mg mipomersen for up to 104 weeks. The mean decrease in LCL-c was ~28%. Mean reductions in apoB and lipoprotein (a) levels were ~30% and ~17%, respectively. Common adverse events included injection site reactions and flu-like symptoms. Despite the treatment efficacy, mipomersen was not approved by the European Union due to concerns regarding potential liver toxicity.

6.12.2.1.3.2 IONIS-TTR_{Rx}—2′-MOE-PS modified gapmer ASO

Transthyretin (TTR) amyloidosis is a rare but fatal genetic disease which is caused by a mutation of TTR gene. The disease is characterized by deposition of abnormal forms of TTR amyloid in various tissues and organs including heart and peripheral nerves. Patients with FAP experience ongoing debilitating nerve damage throughout their body resulting in organ failure and loss of motor functions. IONIS-TTR_{Rx} (IONIS Pharmaceuticals) is a second-generation 2′-MOE and PS modified ASO gapmer that targets the TTR mRNA, leading to reductions in both mutant and wild-type TTR protein. In an open-label phase II study in patients with TTR amyloid cardiomyopathy, a weekly injection of IONIS-TTR_{Rx} for 12 months decreased left ventricular mass by 1.9% from baseline

as measured by MRI.[53] A phase III study is being conducted with a weekly injection of 300 mg IONIS-TTRRX to measure efficacy and safety of the drug in patients with familial amyloid polyneuropathy.

6.12.2.1.3.3 Eteplirsen—Exon skipping PMO

DMD is a genetic disorder caused by a mutation of the dystrophin gene at locus Xp21 (X chromosome). A variety of specific mutations can cause translational frameshifts and thus abrogates dystrophin protein synthesis. Dystrophin protein connects actin filaments to the plasma membrane of muscle fiber. The absence of distrophin protein causes progressive loss of mobility and death. The disease affects one in 3500–5000 boys worldwide and the symptoms usually appear at a very young age (2–3 years old).[54] Eteplirsen is a PMO based ASO that targets exon 51 in the dystrophin pre-mRNA. Upon binding eteplirsen, exon 51 is skipped and excised during the pre-mRNA splicing, restoring the downstream reading frame of dystrophin in some mutations. It has been reported that exon 51 skipping is applicable to the largest group of DMD patients (13%). In a recently reported phase IIB study where DMD patients were continually treated with a weekly intravenous injection of eteplirsen (30 or 50 mg kg^{-1}) or placebo for

over 3 years, eteplirsen-treated patients showed a statistically significant advantage in 6-min walk test (6MWT) at 36 months.[39] The most common adverse events seen in eteplirsen-treated patients include headaches, procedural pain and proteinuria, but none of them was serious. In September 2016, Eteplirsen received an accelerated approval from the US FDA. Other PMO ASOs designed to skip other exones are also under development. Among these, SRP-4053 and SRP-4045 have also entered phase 3 clinical trial.

6.12.2.1.3.4 Miravirsen—LNA modified ASO for microRNA inhibition

Miravirsen is the first antimiRNA ASO that entered clinical trials. Miravirsen is a 15-nt LNA-PS modified ASO for treatment of hepatitis C virus (HCV) infection that targets miR-122, a highly abundant miRNA expressed in the liver that regulates HCV replication.[35] A Phase IIa study was conducted to examine long-term efficacy and safety of miravirsen in patients with chronic HCV genotype 1 infection.[55] Five weekly subcutaneous injections of miravirsen at doses of 3, 5, or 7 mg kg^{-1} resulted in dose-dependent and prolonged reduction in HCV RNA levels. In the following 14 weeks after treatment, no virus was detected in total of 5 out of 27 treated patients. In the subsequent long-term safety and efficacy study, one patient showed a prolonged undetectable HCV RNA period until 29 weeks. No serious adverse affects or mutations in miR-122 binding site of HCV RNA were observed among the treated patients.[55]

6.12.2.1.4 Challenges and future perspectives

While significant advantages have been made in ASO so far, clinical progress is limited by a number of challenges. These include, but are not limited to, cytotoxicity, off-target effects, and efficient delivery. Among these, efficient delivery of ASOs to target tissues and organs is the primary challenge for many ASOs being tested in clinical trials. Systemically administered ASOs broadly distribute in various organs. Given that liver is one of the organs that exhibit the highest concentration of systemically administered ASOs, ASOs targeting liver diseases, for example mipomersen, are currently the most advanced and successful in clinical development. Besides systemic administrations (SC and IV), various routes of ASO administrations have been tested including intradermal and intraocular delivery. Although ASOs do not cross the blood–brain barrier, intrathecal delivery has been used as an alternative route to deliver ASOs to the central nervous system (CNS) to treat neurodegenerative diseases. For example, IONIS-$SOD1_{Rx}$, a second-generation ASO designed to target superoxide dismutase 1 (SOD1) to treat familial amyotrophic lateral sclerosis (ALS), was tested in phase I clinical trial by intrathecal administration using an external pump over 11·5 h at increasing doses.[56] Widespread delivery of the ASO to the CNS was observed. The conjugation of a specific delivery ligand is another strategy to facilitate target cell specific uptake of ASOs. Triantennary *N*-acetyl galactosamine (GalNac), a ligand for the hepatocyte-specific asialoglycoprotein receptor, for instance, has been tested in clinical trials as an excellent delivery platform of siRNAs that target multiple hepatocellular targets.[57] Conjugation of GalNac has also shown to improve potency of ASOs approximately 10-fold for gene silencing and enhance duration of pharmacological effect in mouse liver.[58]

It has been almost 40 years since the first report of ASO. Only two ASO therapeutics have reached the market so far. Compared to other classes of therapeutic agents, ASOs have unique mechanism of action and physical and pharmaceutical properties, thus holding a great potential for becoming first-in-class drugs for undruggable molecular targets with other classes of therapeutics (e.g., small molecules and monoclonal antibodies). Considering recent significant improvement in technologies including chemistries, delivery strategies, and cost efficient synthesis, PK properties of ASOs have significantly improved and many ASOs being tested in clinical and preclinical trials exhibit drug-like properties. Indeed, a number of ASOs are being tested in advanced stages of clinical trials (phase II and phase III), suggesting that ASOs therapeutics will become cutting-edge treatment approach of various diseases in not-too-distant future.

6.12.2.2 RNA Interference (RNAi)

RNA interference[59] is a nearly ubiquitous pathway in multicellular organisms used for cellular immunity and developmental regulation that employs small microRNAs (miRNAs) for specificity. In mammals, miRNAs[60] regulate many aspects of development and are expressed in nearly all cells. MiRNA biogenesis[61] starts in the nucleus, where long primary miRNAs transcripts (pri-miRNAs) containing partially mismatched RNA duplexes are initially cleaved by the Microprocessor complex.[62] Microprocessor is a heterotrimeric complex consisting of one molecule of the RNase III protein Drosha and two molecules of the cofactor DGCR8. Drosha measures 11 bp from the pri-miRNA single stranded RNA-double stranded RNA (ssRNA-dsRNA) junction at the base of the pri-microRNA to excise the ~70 nt pre-miRNA hairpin. DGCR8 provides efficiency and precision to the excision.[63] The resulting pre-miRNAs are exported to the cytoplasm,[64] where they are recognized and further processed by the Dicer[65] enzyme to produce 22 nt RNA duplexes. Subsequently one strand of the cleavage product is inserted into an Argonaute[66] protein by the RISC loading complex (RLC)[67] to become the guide strand for a mature RNA induced silencing complex (RISC) (**Fig. 2**).[68]

RISC uses efficient mechanisms to scan cytoplasmic mRNAs for sequences complementary to the guide strand.[69] Matching mRNAs are inhibited from translation, and destabilized, or degraded via catalytic means (**Table 2**).[70]

Several factors make RNAi a highly attractive mechanism for therapeutic applications.[71] Among these factors: (1) it allows prolonged and efficient inhibition and degradation of mRNAs and other targeted RNA transcripts; (2) the sequence based targeting mechanism allows inhibition of targets that are not druggable by small molecules; (3) the ability to inhibit different targets by changing the guide sequence makes RNAi a platform technology that could simplify drug development for disparate targets.

Over the past decade, a number of groups have developed synthetic RNAi triggers that utilize the cytoplasmic portions of the RNAi loading pathway to assemble RISC using synthetic guide strands. We will discuss the elements of this pathway that are

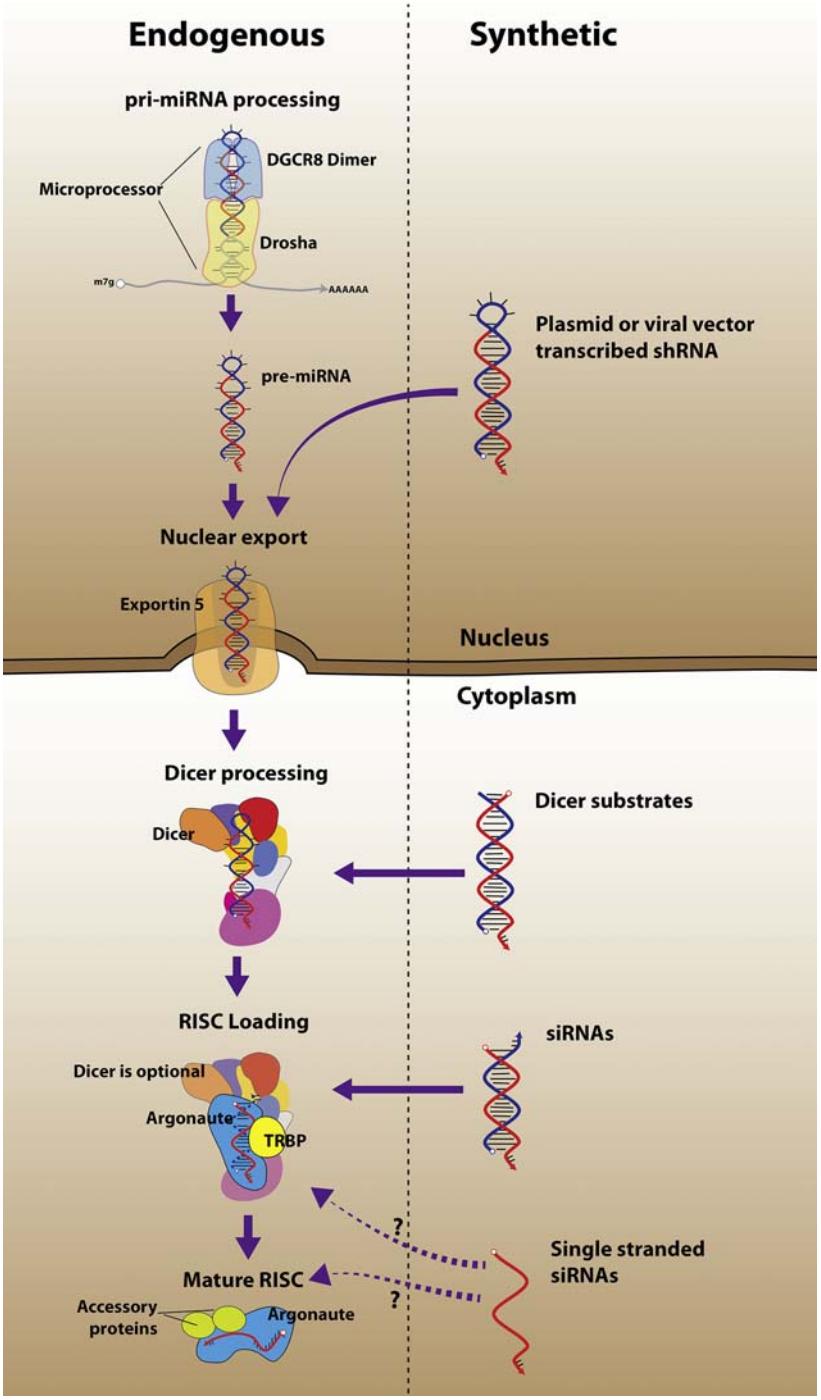

Fig. 2 Select steps in the biogenesis of mammalian microRNAs and points of entry into the pathways for select synthetic RNAi triggers. For single stranded RNA, it is unclear at this point how the chemically modified strands actually enter RISC, although Dicer cleavage is not involved.

important for their functioning, review the major variants of these substrates, summarize the important technical issues, and survey the current state of clinical development (Fig. 2).

6.12.2.2.1 Cytoplasmic RNAi processing

To understand how synthetic RNAi triggers function, it is illustrative to look at the functioning of the cytoplasmic portion of the mammalian RNAi pathway (Fig. 2).[61b] Mammalian pre-miRNA[64,72] are usually ~70 bp or longer RNA hairpins with a number of mismatches in the stem. The 5′ and 3′ termini of the hairpins result from cleavage of pri-miRNAs by the Microprocessor complex.[62c] Ideally, this produces a Dicer substrate with a blunt 5′ terminus bearing a terminal phosphate, and a 3′ two-base overhang.[73]

Listed clinical studies are found in clinicaltrials.gov. Most advanced clinical studies for each RNAi therapeutic are listed.

Dicer[74] is the enzyme that processes pre-miRNAs in the cytoplasm. Human Dicer is a ~82 KD protein consisting of PAZ, dsRBD, Ribonuclease III, and helicase domains. The PAZ domain binds to the 5′ phosphate and 3′ overhang of the pre-miRNA, anchoring the hairpin in place while the dsRBD domain interacts with the stem to further stabilize binding.[74] This places the RNAse III domain at fixed distance from the PAZ domain binding site, resulting in cleavage of the opposing sides of the hairpin at the 19 and 21 bps from the terminus, producing a 19 bp duplex with a 5′ phosphate and 2 nt 3′ overhangs on both ends.[74] (The functioning of the helicase domain on Dicer is not completely understood, but it appears to increase the rate of processing for mismatched RNA hairpins at the expense of slower kinetics for perfectly matched duplexes.[75] In addition, there is some evidence for relatively large scale conformational changes in the Dicer-pre-miRNA complex during Dicer processing[76].)

6.12.2.2.1.1 Strand selection

After Dicer cleavage, a RISC loading complex (RLC)[67,77] forms around the RNA duplex, and one strand is loaded by an Argonaute protein while the opposing strand is removed. Guide strand selection[78] is known to favor incorporation of the strand whose 5′ terminus is at the weaker base-paired end (the last ~6 bp) of the RNA duplex.[78a,79] Thus, RNA duplexes with the same number of G–C base-pairs at either end tend to result in an ~50% probability for loading either strand, while those with a markedly more AU rich terminus tend to favor loading of the strand with the AU rich 5′ end.

6.12.2.2.1.2 RISC structure and function

While mature RISC can have multiple associated proteins, the most basic element is an Argonaute protein with bound guide strand. The crystal structure of human Ago2 with bound guide strand has been reported.[68,80] The 5′ terminal phosphate of the guide strand is held in Ago2's PAZ domain. Bases 2–8 are arranged in an alpha-helical configuration by numerous protein-RNA contacts, leading to a distinctive domain that favors rapid base-pairing.[68,80] Corresponding to this structural picture, functional assays of Ago2 activity show that the guide strand is divided into domains with distinct functions,[81] with the seed region being most important for target recognition. Experiments further show that preorganization of the seed region bases increases speed of target site recognition and stability of base-pairing[69a] and surveys of miRNA binding sites show a preeminent importance for base-pair matches in the seed region.[82] In addition to preorganization of the guide strand, Ago2 apparently executes a dynamic search process where a three dimensional diffusional search for mRNA targets is followed by one-dimensional diffusion along the mRNA to find the cognate target site.[69b] Together, these mechanisms allow RISC to efficiently and correctly recognize small (~7 base) target sites on large mRNAs.[69c]

6.12.2.2.1.3 Target inhibition

Endogenous miRNAs usually have targets sites in the 3′ UTR of multiple mRNAs (although there are also sites in open reading frames).[82] Each target site is usually complementary to the seed region of the guide strand, but not complementary to the entire guide strand. When miRNAs are attached to a target mRNA, protein cofactors destabilize binding of mRNA bound protective proteins, resulting in an increased rate of mRNA degradation.[70a] There is also evidence for direct inhibition of protein translation, although this is believed to be a less important mechanism.[70a]

In contrast to endogenous miRNAs, most synthetic RNAi substrates utilize guide strands with full length complementarity to target sites in either the 3′ UTR or the protein coding region[83] which typically are referred to as small interfering RNAs or siRNAs. Full length base-pairing allows Ago2 to directly cleave target RNA transcripts between the 11th and 12th base-pair (counting from the 5′ of the guide strand) via its integral slicer activity.[81,84] However, Ago2 is the only human Ago with slicer activity and there is currently no know method to direct guide strand distribution specifically to Ago2. Past studies on the distribution of miRNA guide strand between different human Argonautes seem to indicate an even distribution for most miRNAs.[85]

6.12.2.2.2 Transcriptional silencing and activation

In addition to inhibiting or degrading mRNAs and other target transcripts in the cytoplasm, small RNA is known to induce transcriptional silencing in yeast, plants and other organisms.[86] The extent to which this effect occurs in humans is currently under investigation.[87] Also, a number of investigators have reported small activating RNAs[88] that can stimulate gene expression by targeting certain promoter regions. Although there is currently not a clear understanding of the mechanisms by which transcriptional activation occur, small activating RNAs may become an important class of RNAi therapeutics.

6.12.2.2.3 Types of synthetic RNAi substrates

Synthetic RNAi substrates are RNAi triggers that are produced exogenously via chemical synthesis and then transfected into target cells (Fig. 3).

A major difference between synthetic duplex RNAi triggers and endogenous miRNAs is that the synthetic triggers are usually completely base-paired, whereas endogenous miRNAs have mismatches that can affect passenger strand sequence, Dicer processing, and RISC loading. Thus, even when a synthetic RNAi trigger has identical intended guide sequence as a natural miRNA, it could still have considerable functional differences.

There are two main types of synthetic RNAi triggers:

- Dicer substrates have duplex regions that are longer than 19 bp, and enter the RNAi loading pathway via cleavage by Dicer followed by RISC loading.
- Non-Dicer substrates have duplexes that are 17–19 bp, and enter the RNAi pathway without Dicer cleavage.

Currently, both types of RNAi triggers are under active development for clinical applications. Here, we survey some representative variants.

Small interfering RNA (siRNA) are 19 bp RNA duplexes with two base 3′ overhangs on either end.[89] They are not cleaved by Dicer and do not require Dicer for RISC loading. siRNAs are one of the first and most widely used synthetic RNAi triggers, with advantages such as low synthesis cost due to the short component strands, mature technology development, high potency, and good stability resulting from extensive incorporation of chemical modifications in some variants.[83a] They are widely available from commercial sources and a number of siRNA based therapeutics are under clinical or preclinical development (Fig. 3).

Short-hairpin RNA (shRNA) are RNA hairpins that are efficiently processed by Dicer. The hairpins usually have 19–29 bp duplexes, at least 4 nt in the terminal loop, and a siRNA like blunt end geometry.[90] These substrates are more difficult to synthesize chemically due to the length of the strand and are thus most often produced via in vitro transcription systems. Clinical applications of shRNAs usually involve delivery of bacteria that excrete shRNAs[91] or viral vectors that produce expressed shRNAs in transduced cells,[92] and will be discussed elsewhere in this chapter.

Dicer substrate siRNA (DsiRNA) are 23–28 bp RNA duplexes that are cleaved by Dicer.[93] The duplex termini are asymmetric. The putative guide strand has an siRNA like two base 3′ overhang. The 3′ of the putative passenger strand is blunt ended with the last two bases being DNA.

In direct comparisons with canonical siRNAs with identical guide strand sequences, DsiRNAs exhibited more efficient RISC loading, better persistence of the guide strand, and better loading selectivity for the guide strand.[94] These combined effects lead to significantly improved RNAi performance.

DsiRNAs are compatible with stabilizing 2′-F and 2′-O-methyl chemical modifications[95] and can use delivery methods similar to those for siRNAs. They are sold commercially for scientific research and are under preclinical and clinical development by Dicerna Pharmaceuticals for therapeutic applications.

Synthetic small hairpin RNAs (sshRNA) are small hairpin RNAs with 19 bp or shorter RNA duplexes.[96] They are not processed by Dicer. Instead, they are incorporated into RISC via one of two pathways, depending on the position of the guide strand.[96b]

If the guide sequence is at the 5′ terminus of the sshRNA, then the strand is directly loaded into Argonaute. The passenger side of the sshRNA is then either cleaved by Ago2's slicer activity or decoupled from base-pairing with the guide strand side by the Ago. (Compare with AgoshRNAs below.) If the guide sequence is at the 3′ terminus of the sshRNA, then the terminal loop of the strand needs to be cleaved by endonucleases such as RNAse A. The resulting duplex then enters RISC much like a regular siRNA. sshRNAs are currently under preclinical development for treatment of Hepatitis delta virus and wound healing applications.

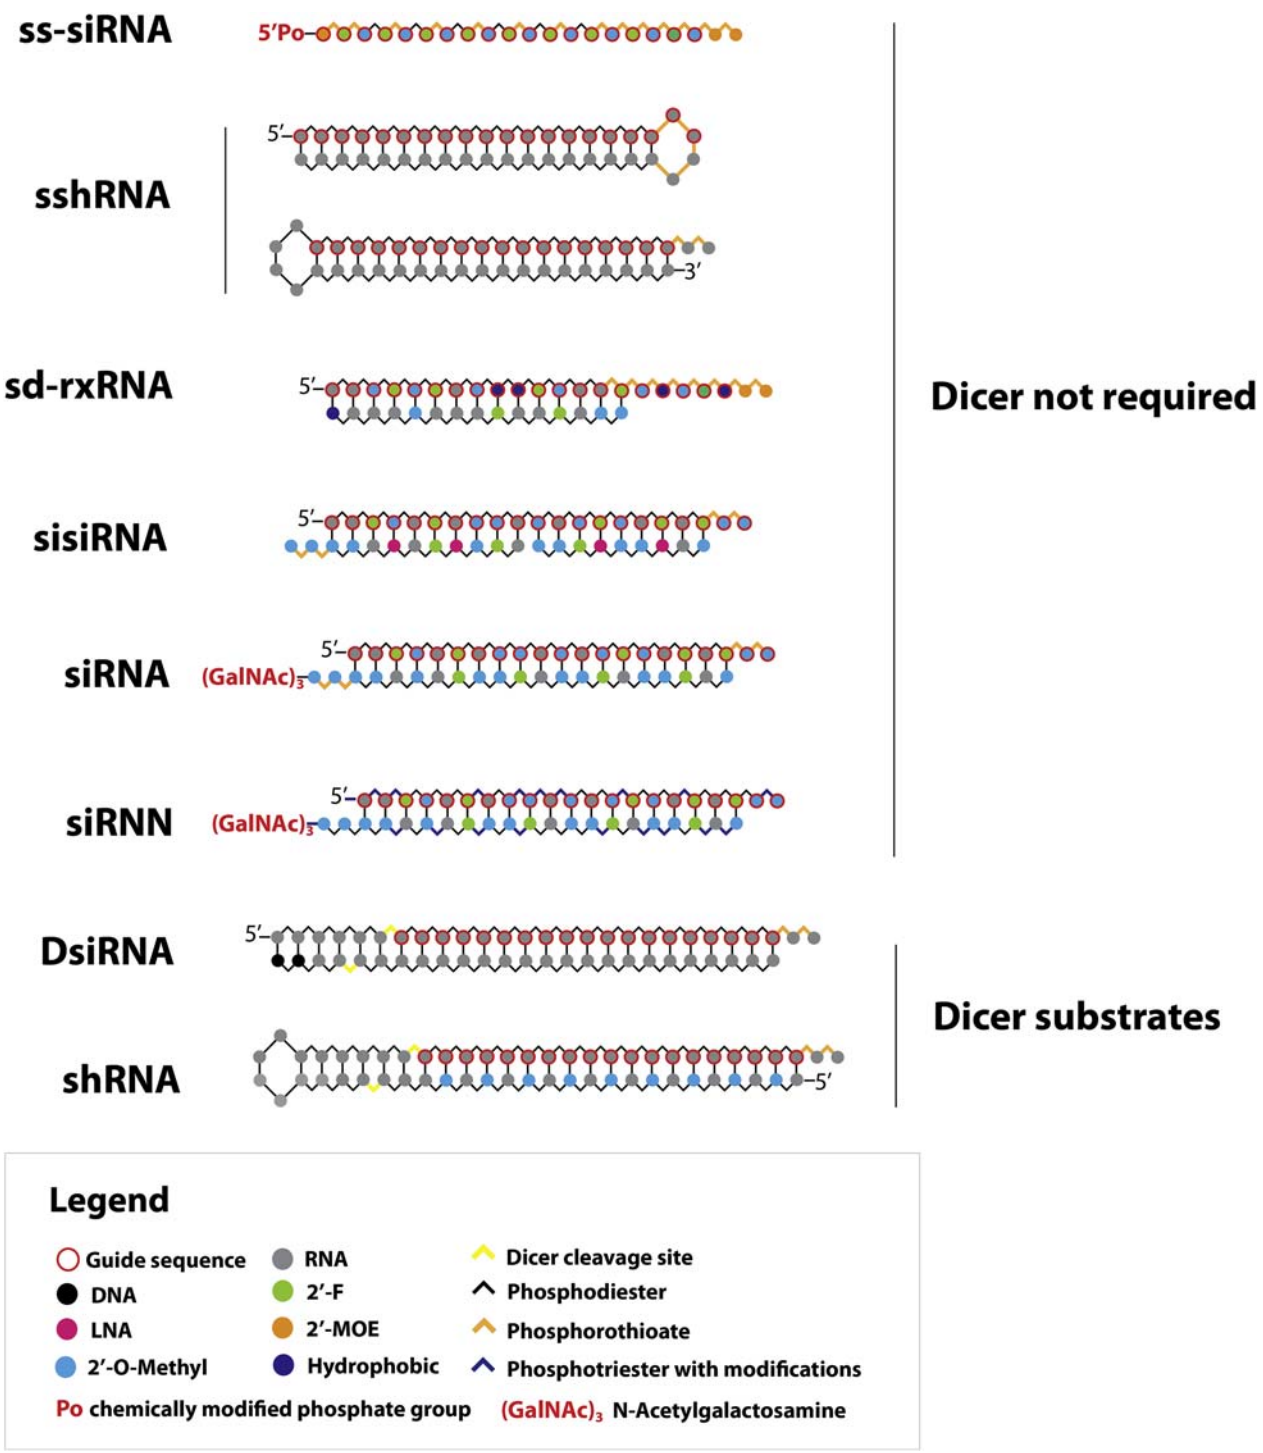

Fig. 3 Select synthetic RNAi triggers and typical patterns of chemical modification for therapeutic applications. RNAi triggers are frequently modified with 2′-F and 2′-OMe bases to enhance in vivo stability and safety. Additional modifications, such as hydrophobic moieties, can impart additional function such as enhanced cell entry. In general, a therapeutic RNAi trigger will undergo a number of rounds of development to find optimal modification patterns for in vivo potency and safety.

Short-interfering ribonucleic neutrals (siRNN) are a new variety of RNAi trigger developed by the Dowdy group at UCSD.[97] siRNNs are ribonucleic duplexes with neutral phosphor-triester backbone linkages instead of negatively charged phosphor diester backbone. The neutral backbone linkage allows easier cell entry and facilitates conjugation of additional targeting or endosome disrupting ligands. Inside the cytosol, enzymatic processing converts the phosphor triesters into phospho diester linkages that are

compatible with the RNAi pathway. Thus, this allows a synthetic RNAi trigger to have favorable self-delivering properties without compromising RNAi efficiency. siRNNs have been licensed to Solstice Biologics for further development.

Single stranded siRNAs (ss-siRNA) are under development by Ionis Pharmaceuticals and collaborators.[98] The key motivation for developing single stranded RNAi agents is that phosphorothioate modified single stranded oligonucleotides can have significant systemic tissue distribution and can enter cells via gymnosis. As such, a potent single stranded siRNA could have significant advantages in ease of delivery, and simplicity of formulation (and by extension regulatory approval).

However, in order to enter RISC, single stranded oligonucleotides have to utilize extensive chemical modifications to be significantly resistant to exonuclease and endonuclease degradation without having these modifications compromise the ability of the oligo to interact with Argonaute and act as a guide strand.

Recently, Ionis Pharmaceuticals and collaborators published results showing that extensively chemically modified, partially phosphorothioated single stranded oligonucleotides can enter RISC to guide RNAi silencing.[98a] Although the best achieved activity was still $\sim 10\times$ less efficient compared to a double-stranded siRNA, ss-siRNAs may become an important new class of RNAi triggers with further improvements in RNAi efficiency.

6.12.2.2.4 Focus areas for improving potency and safety

Clinical application of synthetic RNAi triggers requires careful optimization of sequence and composition to improve potency and safety. Important considerations include

1. Avoiding passenger strand activity.
2. Avoiding nonspecific toxicity.
3. Enhancing construct stability
4. Identifying effective target sites.

Passenger strand RISC loading is a significant concern for RNAi drugs because the passenger strand could direct RNAi activity towards unintended targets, resulting in toxic side effects. A number of solutions have been devised to address this problem via sequence design,[83b,99] structural motifs,[93,100] or chemical modifications.[101] One example is small internally segmented siRNAs (sisiRNA).[102] These are novel siRNA variants in which the passenger strand is divided into two 10–12 nt segments that are too short to be loaded into RISC. To thermodynamically stabilize the small duplexes, locked nucleic acid modifications[103] are used.

As an alternative to changing the structural characteristics, it is also possible to use chemical modifications. Snead et al. reported that modification of the 5′ of the siRNA passenger strand with an unlocked nucleic acid[104] eliminates passenger strand loading.

Avoiding nonspecific toxicity. In addition to spurious passenger strand activity, nonspecific toxicity can arise from immunogenic responses to RNA duplexes.[105] There are now well established routes for avoiding immunogenic toxicity.[106] First, RNA duplexes should be kept to a minimal possible length as immunogenic activation by PKR and other sensors for RNA duplexes are length dependent. Secondly, judicious incorporation of 2′-OMe and other chemical modifications in RNA duplexes can reduce immunogenicity. Thirdly, preclinical testing for oligonucleotide based therapeutics need to utilize primates in order to adequately assess toxicity in humans.[107]

In addition to immunogenic toxicity, phosphorothioate[108] modified oligonucleotides and LNA[109] modified oligonucleotides are known to have nonspecific toxicity in animals. Clinical development strategies include minimization of the use of such modifications, avoidance of certain problematic motifs for LNAs, and iterative refinement and testing, which will be a theme in general for all of the issues involving clinical development.

Enhancing construct stability. Achieving potent therapeutic effects require construct stability against disassembly or degradation during in vivo delivery. A number of potent and safe chemical modifications have been developed for therapeutic oligonucleotides and a subset of these is compatible with RNAi triggers.[83a,99,110]

The effects and compatibility of chemical modifications in RNAi triggers is often position dependent. For example, long contiguous stretches of 2′-OMe or 2′-fluoro (2′-F) on the guide strand and at the Dicer cleavage sites of DsiRNAs significantly inhibited RNAi activity, but alternating patterns of 2′-OMe modifications on the passenger strand enhanced nuclease resistance without significantly compromising RNAi efficiency.[110]

In general, it is reasonable to expect that chemical modifications that do not inhibit Dicer processing or eliminate favorable contacts between the guide strand and Argonaute can lead to effective RNAi activity. Indeed, McRae and colleagues recently published crystal structures of chemically modified guide strands with human Ago2,[111] showing position dependent effects of different chemical modifications. Recent clinical experiences indicate that careful application of chemical modifications can result in safe and potent RNAi triggers.

Identifying effective target sites. There is a significant body of work on the rational design of siRNAs for clinical applications.[83b,112] Basic target site considerations should take into account the conservation of the site across pertinent transcript variants, possible homologies with other genes that could cause off-target effects, the local predicted secondary structure, the asymmetry of the cognate guide strand for biasing strand loading. However, due to the unpredictable nature of secondary and tertiary structure in long RNA transcripts, the effects of protein binding and translation, and the incomplete understanding of how these issues affect RISC binding, and the vast complexity of the transcriptome and mammalian cells in general, target site selection will require extensive experimental evaluation of potential targets.[107]

6.12.2.2.5 Effective delivery

Delivery is a major challenge in RNAi therapeutics because synthetic RNAi triggers are hydrophilic macromolecules that cannot cross the cell membrane and are subject to rapid clearance by both the kidneys and the reticuloendothelial system. Delivery methods must allow RNAi triggers to safely cross multiple physiological barriers for effective distribution to target tissues, uptake by target cells and escape into the cytosol.[113] Generally, 10 mg kg^{-1} dosing levels are considered an upper limit for clinical applications, and <1 mg kg^{-1} levels are preferred. Current methods under development include:

- Polymeric nanoparticles[114]
- Liposomes and lipid nanoparticles[115]
- Antibody conjugated delivery[116]
- Aptamer conjugated delivery[117]
- Polymeric materials[118]
- Conjugation of molecular ligands[119]
- Backbone modified siRNAs[97b]
- Spherical nucleic acids[120]
- DNA and RNA nanostructures[121]

6.12.2.2.6 Potential therapeutic applications of RNAi

6.12.2.2.6.1 Nanolayered siRNA delivery for wound healing

The Hammond lab at MIT has been developing electrostatically assembled coatings that incorporate siRNA for sutures[122] and dressings.[123] A substrate material, such as nylon, is first coated with alternating layers of positively charged polymer and negatively charged dextran sulfate, then positively charged chitosan and negatively charged siRNA are added layer by layer, resulting in μg cm^{-2} loading levels. At the site of application, siRNAs are shed together with chitosan, resulting in effective delivery.

In an animal study, a dressing coated with an siRNA targeting matrix metalloproteinase 9 (MMP9) was able to inhibit MMP9 expression and increase wound healing at model wound sites in mice. The mean level of MMP9 activity was decreased by ~50% at the 2 week time point, and there was significantly better wound closure.[123]

6.12.2.2.6.2 Tat/rev DsiRNA with gp120 aptamer for HIV treatment

GP120 is a glycoprotein expressed on the surface of HIV-1 and associated with HIV infected cells. The Rossi lab at City of Hope has developed a 2′-F substituted gp120 RNA aptamer for inhibition of HIV-1 activity and delivery of siRNA to HIV infected cells.[124] The aptamer binds gp120 at 50–100 nM K_d, and are internalized in gp160 expressing HIV infected cells.

Subsequent work utilized this aptamer to delivery anti-tat/rev DsiRNAs to HIV-1 infected mice.[117,125] The tat/rev siRNA was conjugated to chemically synthesized gp-120 aptamers via either a polycarbon linker[125] or a polycarbon linker conjugated 2′-OMe RNA duplex adapter region.[117] In the first study,[125] treatment of mice 3 weeks after HIV infection with weekly treatments of 0.38 mg kg^{-1} of aptamer-conjugated DsiRNA resulted in reduction of viral load to undetectable levels by week 5 or week 8, with viral rebound after end of treatment. In contrast, treatment with siRNA alone gave no detectable benefit.

In the second study,[117] utilization of the RNA adapter allowed multiplexed delivery of three different anti-HIV siRNAs. Weekly injections of this cocktail at ~0.4 mg kg^{-1} levels (0.25 nmol total of the three DsiRNAs) resulted in an ~100× to 1000× reduction in plasma viral RNA after 5 weeks of treatment (9.5 weeks post infection). A second independent experiment using biweekly injections at 22.5 weeks after treatment resulted in elimination of detectable viral RNA from plasma.

6.12.2.2.6.3 Tat/rev DsiRNA with PAMAM dendrimers for HIV treatment

Poly(amidoamine) (PAMAM) dendrimers are well defined branching polymers with exact molecular weight, size, and composition that is controlled by the dendrimer generation. At pH ≤ 7.4, terminal amine groups in the dendrimer at the surface of dendrivers are protonated, giving it high cationic charge suitable for electrostatic association with RNAi triggers. At endosomal pH (~5), the interior tertiary amines of PAMAM dendrimers become also protonated, leading to endosomal disruption and release of RNAi triggers.

Zhou and collaborators[126] loaded G_5 PAMAM with anti-HIV DsiRNA, resulting in 100 nm nanoparticles. These were tested in an HIV-1 infected humanized mouse model via weekly intravenous injection of 0.15 mg kg^{-1}-DsiRNA (combination of anti-tat/rev, anti-CD4, anti-TNPO3). This resulted in suppression of plasma viral RNA by ~1000×, with treatment effects persisting for 3 weeks posttreatment. Retreatment at 24.5 weeks post infection using biweekly injections of DsiRNA-dendrimer conjugates resulted in suppression of viral loads to undetectable levels.

6.12.2.2.7 RNAi in clinical development

6.12.2.2.7.1 ALN-TTR02 (Patisiran), siRNA—lipid nanoparticle

Transthyretin amyloidosis (ATTR) is a rare, fatal, and inherited neurodegenerative disease driven by deposition of liver produced transthyretin (TTR) amyloids in the peripheral nervous system and the heart.[127] Alnylam identified at potent siRNA targeted against the 3′ UTR of transthyretin and encapsulated this siRNA in two generations of lipid nanoparticles[115](ALN-TTR01 and ALN-TTR02) for delivery to hepatocytes.

In a phase I clinical trial, both ALN-TTR01 and ALN-TTR02 demonstrated reduction of circulating transthyretin. 0.15–0.3 mg kg^{-1} doses of ALN-TTR02 achieved maximum reduction of 82.3–86.8% circulating transthyretin at approximately

1 week after single dose administration, and the reduction level ranged from 56.6% to 67.1% after 28 days. The single dose infusion was well tolerated, with mild to moderate reactions observed in 7.7% of participants receiving ALN-TTR02.

A subsequent phase II open label study on ALN-TTR02 (renamed Patisiran)[128] on 27 patients showed >80% sustained serum reduction of transthyretin over the course of 2 years with intravenous injection at 0.3 mg kg^{-1} every 3 weeks, and the drug was well tolerated. Clinical data supported the hypothesis that TTR knockdown has the potential to halt progression of neuropathy.

A phase III clinical trial has been initiated.[129]

6.12.2.2.7.2 ALN-TTRSC (Revusiran), chemically modified siRNA with tri-GalNAc ligand

Revusiran[130] is Alnylam's second candidate against ATTR. Unlike patisiran, revusiran is formulated as a chemically modified siRNA with a conjugated GalNAc ligand that targets the siRNAs to asialoglycoprotein receptors on the surface of hepatocytes.[119] Compared with earlier LNP formulations, GalNAc-conjugated siRNAs are simpler to produce, have well defined, uniform molecular composition, and allow highly efficient delivery to the liver via subcutaneous injections at <10 mg kg^{-1} dosage levels.[119]

In a phase I study on healthy volunteers,[131] revusiran achieved >80% knockdown of serum TTR for up to 50 days on single 5 and 10 mg kg^{-1} subcutaneous injections with mild, rapidly resolved side effects, and a phase II study has begun.[130b]

Alnylam continues to refine the potency of its GalNAc conjugated siRNAs. Extensive lead optimization using proprietary stabilization chemistries in conjunction targeted at enzymatic cleavage sites identified from metabolic profiling resulted in >10× improvements in potency. ALN-AT3, an siRNAs targeted at antithrombin, achieved sustained ~50% knockdown of antithrombin in nonhuman primates via 0.5 mg kg^{-1} weekly dosing followed by 0.125 mg weekly dosing.[132] In October 2016, following reports of cases new onset or worsening peripheral neuropathy in patients taking Revusiran, and findings by an independent data monitoring committee of unfavorable benefit-risk profile in the Phase III ENDEAVOR trial, Alnylam annouced that it was discontinuing the development of revusiran. The company noted that the decision does not affect its other clinical programs.[133]

6.12.2.2.7.3 CALAA-01, RRM2 siRNA—cyclodextrin nanoparticle with transferrin targeting ligand

CALAA-01 was a nanoparticle delivered siRNA for treatment of human solid tumors. The system combined a PEG protected, transferrin (Tf) conjugated cyclodextrin nanoparticle[134] with an siRNA against ribonucleotide reductase subunit 2 (RRM2), a target that was previously shown to be active against solid tumors.

The particles were formulated as a two vial system. One vial contained the cyclodextrin polymer (CDP), adamantine-PEG and adamantine-PEG-Transferrin. A second vial contained the siRNA. When the two vials were combined, the components self-assembled to form ~70 nm diameter nanoparticles.

The nanoparticles were designed to accumulate in tumors via the enhanced permeability and retention effect,[135] achieve preferential endocytosis by cancer cells via Tf ligands, and escape the endosome when imidazoles in the CDP were protonated around pH 6.[134]

A phase I clinical trial was the first to demonstrate evidence of RNAi in target tissues via systemic administration of nanoparticles.[136] CALAA-01 was administered to three patients with metastatic melanoma at doses of 18, 24, and 30 mg m^{-2} siRNA. Biopsy samples from the three patients showed reduction of RRM2 mRNA ranging from 32% to 77% up to 1 month post administration.

However, a subsequent phase Ia and Ib clinical trial involving 24 patients showed dose limiting toxicities in five patients at higher doses of 18–27 mg m^{-2} in the absence of any objective responses to the medication. The study was not able to trace the source of the toxicity but it was likely from components of the nanoparticle, possibly the Tf, but possibly exacerbated by inclusion of the siRNA.[114]

A problem that may have affected the efficacy was the low serum half-life of siRNAs of ~30 min. This was likely due to disassembly of the electrostatically assembled particles at the kidney glomerular basement membrane,[137] which caused the particle formulation to be ineffective at achieving long circulation times for the siRNA.

6.12.2.2.7.4 DCR-MYC, MYC DsiRNA—lipid nanoparticle

DCR-MYC is a Dicer substrate siRNA targeted against the MYC oncogene that is delivered using Dicerna's proprietary EnCore lipid nanoparticle delivery platform.[138]

A phase 1, multicenter, dose escalation trial was initiated in Apr. 2014. Thirty-seven patients with solid tumors or hematological malignancies have been treated in nine dose cohorts ranging from 0.1 to 1.25 mg kg^{-1} once weekly for 2 weeks, followed by a 1 week break.

In a recent press release,[139] Dicerna reported that the medication has been well tolerated. Antitumor activity has been observed in two of three patients with advanced, treatment refractory low-to-intermediate grade pancreatic neuroendocrine tumors (PNET). One patient had a 34% reduction in tumor size. A second patient achieved a complete metabolic response based on F-18 fluorodeoxyglucose positron emission tomography (FDG-PET) imaging. The patient had a 12 month drug holiday before recurrence, at which time the patient was treated again with DCR-MYC and again achieved complete metabolic response while demonstrating a 28.6% reduction in tumor size.

Based on these results, Dicerna began an expansion of the trial focused on enrolling patients with low to intermediate grade PNET who have demonstrated disease progression after treatment with standard therapies.

6.12.2.2.7.5 ARC-520, anti-HBV siRNA with dynamic polyconjugate excipient

ARC-520[107] is a combination of two chemically modified, cholesterol conjugated siRNAs targeting hepatitis B viral transcripts and a coinjected dynamic polyconjugate[118] polymer excipient. The siRNAs are targeted at hepatocytes via the cholesterol group while the Dynamic Polyconjugate (DPC) excipient assists in endosomal escape via pH activated unmasking of membrane disrupting constituent groups.

Arrowhead Pharmaceuticals underwent an extensive clinical development process to formulate ARC-520. It began by identifying conserved sequences that were cross-reactive with >90% of HBV genomes, then cross-screened these sequences to eliminate spurious matches with human mRNA. This resulted in identification of ~140 sequences which were used to generate siRNAs for in vitro testing.

Four lead siRNAs were chosen. 2′-F and 2′-O-methyl modifications were added to increase nuclease resistances and decrease immunogenicity. A phosphorothioate backbone medication was added between the 3′ terminal overhang nucleotides, and a cholesterol group was added for liver targeting.

The lead candidates were transfected in mouse models of chronic hepatitis B together with a DPC excipient (NAG-MLP) and all achieved 10× to 1000× knockdown of hepatitis B surface antigen after a single intravenous injection at 3 or 6 mg kg^{-1} dosage levels (equal doses of siRNA and NAG-MLP), with >10× knockdown lasting approximately 1 month after a single injection. In contrast, no knockdown was observed when siRNAs were injected without NAG-MLP. After further testing, ARC-520 was formulated using two of the lead siRNAs (99.64% coverage of all known HBV genomes) together with NAG-MLP. ARC-502 was tested in a chimpanzee that was chronically infected with HBV, achieving >80% reduction in HBV markers at 3 mg kg^{-1} dosage levels.

A phase I clinical trial showed that ARC-520 was well tolerated in healthy human volunteers at up to 2 mg kg^{-1} intravenous administration, with no severe adverse reactions. Preliminary results from a phase IIa, randomized, double-blind, placebo controlled study showed that single intravenous doses of ARC-520 was well tolerated at up to 3 mg kg^{-1} and resulted in dose-dependent reduction of serum Hepatitis B surface markers. A 50% reduction was observed at 2 mg kg^{-1} dosage levels, with statistically significant reductions seen up to 43–57 days.[107]

6.12.2.2.8 Challenges and future perspectives

With the recent spate of exciting clinical results for patisiran, revusiran, and other hepatocyte-targeted, chemically modified RNAi therapeutics, the regulatory approval of the first RNAi drugs maybe imminent. This is the culmination of 15 years of improvements in the design, stability, safety, and delivery of synthetic RNAi triggers.

There are now a burgeoning number of hepatocyte targeted RNAi drugs under clinical investigation due to the availability of safe and efficient methods for delivery of RNAi triggers to the liver, but it remains challenging to achieve effective delivery to other tissues. Although a number of exciting technologies for systemic delivery are under development, and indications of clinical success in some solid tumors, the field will likely need new ideas or novel combinations of technologies to solve complex challenges involved in tissue distribution, cell selective uptake, and endosomal escape. Prior clinical experiences indicate that delivery methods must balance pharmacokinetics, targeting selectivity and safety, with complexity in manufacturing and regulatory approval. Pharmacokinetics and targeting selectivity could favor nanoparticle formulations, but safety and complexity tends to favor molecularly well-defined molecular constructs. Going forward, the field may have to weigh these issues carefully for different tissue types, and may have to design constructs that combine the best features of nanoparticles and molecular constructs while assimilating new clinical knowledge such as the tendency of electrostatic assemblies to disassemble in the human kidney.[137]

Despite these challenges, there is every reason to believe that the synthetic RNAi field will continue to advance at a rapid pace and provide exciting new therapeutic options for difficult to treat medical conditions.

6.12.2.3 Aptamers

Aptamers are structured nucleic acid ligands that are naturally found or artificially designed to inhibit a wide variety of targets including proteins, cultured cells, and whole organisms[140] via a technology called SELEX. As they hold their three-dimensional structures by well-defined complementary nucleic acid sequences,[15a,141] aptamer structures are stable even when exposed to biologically induced reducing conditions. For therapeutic molecules, they offer significant advantages over antibodies: high specificity, better structural stability, lower toxicity, and lower immunogenicity.[142] Moreover, the affinity and specificity of aptamers is comparable to, or even greater than, the affinity and specificity of antibodies.[142] Another advantage over antibodies is that aptamers can be fine-tuned and their size reduced after selection through the chemical synthesis.

6.12.2.3.1 Chemical modifications

SELEX allows the incorporation of modified nucleotides so that aptamers can be generated that are highly nuclease-resistant and it is applicable for clinical trials. 2′-OMe and 2′-F pyrimidines are the most commonly employed modified RNA aptamers. As described previously, the 2′-OMe modified RNAs have been widely described as being able to evade innate immune recognition. Lee et al. discovered that RNAs containing 2′-F pyrimidines differentially controlled the activation of pattern recognition receptors (PRRs).[143] They found that the activity of RNAs that stimulate Toll-like receptors (TLR) 3 and 7 was abrogated by employing the incorporation of 2′-F pyrimidines. They also reported that RNAs containing 2′-OMe pyrimidines and triphosphates at 5′ end

completely abolished the induction of cell death and cytokine expression in the cells. It suggests that 2′-F and 2′-OMe modifications can be used to reduce adverse and off-target effects of therapeutic aptamers development.

6.12.2.3.2 Potential therapeutic applications of aptamers

6.12.2.3.2.1 Antagonistic aptamers

Some viruses naturally express short and structured regulatory RNAs (aptamers) that bind and antagonize cellular proteins. These aptamers demonstrated therapeutic applications; an example is HIV-derived stem–loop TAR regulatory RNA that represses the viral protein Tat and inhibits HIV replication.[144] Here we discuss the antagonistic aptamer for therapeutics.

Anti-PD-1 antibodies have now been approved for the treatment of melanoma. As antibody mimics, DNA aptamers against the murine extracellular domain of PD-1 have been developed.[145] Anti-PD1 aptamer blocks the PD-1:PD-L1 interaction and functionally inhibits the PD-L1-mediated suppression of IL-2 secretion in primary T-cells. A PEGylated form of anti-PD1 aptamer retains the ability to block the PD-1:PD-L1 interaction, and significantly suppresses the growth of PD-L1 positive colon carcinoma cells in vivo with a potency equivalent to an antagonistic anti-PD-1 antibody. Importantly, the anti-PD-1 DNA aptamer treatment is not associated with off-target TLR-9-related immune responses.

Cancer metastasis is a major cause of death in various cancers. However, metastatic cancers are yet to be treated with current therapeutics. An RNA aptamer inhibiting the enzymatic activity of prostate-specific membrane antigen (PSMA) has been developed in a preclinical model system.[146] Treatment of prostatic cancer cells with the aptamer resulted in reduced cell migration/invasion in culture and metastatic disease in vivo. Pharmacokinetic and biodistribution studies in vivo confirmed target specificity and absence of nonspecific on/off-target effects.

The surface glycoprotein hemagglutinin (HA) of influenza virus is responsible for viral attachment to sialic acid-containing host cell receptors and facilitates the initial stage of viral infection. An RNA aptamer which is specific to the glycosylated receptor-binding domain of the HA protein (gHA1) has been isolated.[147] The anti-HA aptamer specifically binds to the target protein and suppressed viral attachment to host cells by neutralizing the receptor-binding site of influenza virus HA. Consequently, it inhibits viral infection in host cells. These results indicate that RNA aptamers can be used as a neutralizing antiviral reagent against virus through appropriate therapeutic formulation.

Fibroblast growth factor 2 (FGF2) plays a crucial role in bone remodeling and disease progression. A number of anti-FGF2 monoclonal antibodies (mAbs) have previously been developed to neutralize various activities of FGF2. No anti-FGF2 mAbs have entered clinical trials; however, development of a specific RNA aptamer for human FGF2 has made considerable progress in both in vitro as well as in vivo characterization.[148] The anti-FGF2 aptamer blocks binding of FGF2 to each of its four cellular receptors, inhibits cells proliferation, and restores osteoblast differentiation. The PEGylated form of anti-FGF2 aptamer effectively blocks the bone disruption in mouse and rat models of arthritis and osteoporosis. It also shows that treatment with the anti-FGF2 aptamer exerts a strong analgesic effect, equivalent to morphine, in a mouse model of bone cancer pain. These findings support the dual therapeutic action of the anti-FGF2 aptamer in bone diseases and pain, providing a novel promising approach to the treatment of bone diseases.
