In order to achieve a more effective and safe pharmacotherapy, we need to individualize the treatment much more than we do today. Today, the prescription of most drugs is essentially based on a trial-and-error approach, and far from all patients respond adequately.[6,71] Especially for patients with severe chronic diseases, this situation needs improvement. Besides the relatively few CDx assays approved by the US FDA for oncology indications, there is a list containing more than 120 additional drugs that have pharmacogenomic biomarker information included in the drug labeling.[72] A large number of these drugs are indicated for severe chronic conditions within cardiology, endocrinology, infectious diseases, neurology, psychiatry, and more. This information could be important in relation to both identifying drug response and avoiding side effects in the individual patient. However, the assays needed for these pharmacogenomic biomarkers are seldom clinically accessible to the same extent as the CDx assays for the oncology drugs, and their application in standard care is still a long way off.[6]

In 1999, Robert Langreth and Michael Waldholz published an article entitled "New Era of Personalized Medicine—Targeting Drugs for Each Unique Genetic Profile" in The Wall Street Journal, which started the discussion on individualizing pharmacotherapy.[73] Now, more than 15 years down the road, we know that it was a new era that started, and we have already seen the first important results.[74] Especially within oncology, we have witnessed a number of breakthrough drugs that have been developed through the drug–diagnostic codevelopment model and where the prescriptions of these drugs now are based on the result from a CDx assay. The efficacy of these drugs clearly outnumbers the more traditional drugs where the prescriptions are based on nonmolecular data, but we also have to realize that there is still a long way to go before the vision of "personalized medicine" will be realized.[6] The development toward a more individualized pharmacotherapy will continue in the decades to come, and "personalized medicine" will be one of the biggest challenges for the pharmaceutical companies and the healthcare system in the 21st century. The promise of "targeting drugs for each unique genetic profile" is still far from being fulfilled, and what we see right now with regard to the implementation of "personalized medicine" is a stepwise approach, and the first step we have named "stratified medicine" or "precision medicine." Here, drug and CDx are very closely linked together, and the test result is used to stratify the patient to the most optimal treatment.[15] The development we have seen within oncology in the last 10–20 years is a clear example of "precision medicine." The move from "blockbuster medicine" toward "personalized medicine" that we currently experience can be illustrated by a staircase as shown in Fig. 9. Currently, we are slowly moving up the staircase toward the middle step, which is "precision medicine." However, the next step toward "personalized medicine" will be much more challenging, and when it comes to CDx assays, it will involve multiplex assays, which will most likely comprise both proteomic and genomic technologies.

In the years to come, we will likely see CDx assays used in relation to other therapeutic areas than oncology, and one of the first new areas is probably the autoimmune diseases. Furthermore, the way that the CDx assays are currently developed is likely to change, both in relation to the discovery phase, where "system pharmacology" and "big data" approaches will be used, and in the development phase where we will see the new clinical study designs gain ground.

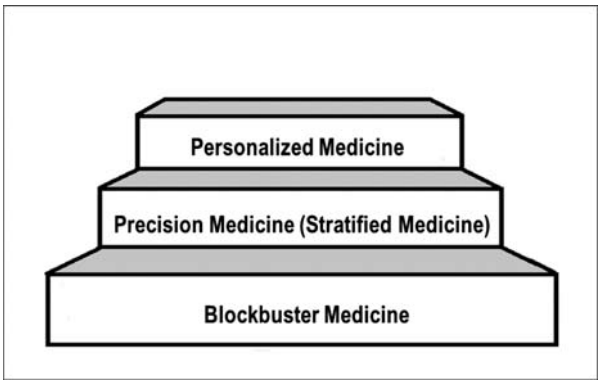

Fig. 9 The move from "blockbuster medicine" toward "personalized medicine" will be stepwise. We are currently on the first step moving toward "precision medicine."

PREFACE

Previous editions of *Comprehensive Medicinal Chemistry*, published in 1990 and 2006, provided an integrated reference source that encompassed all major aspects of drug discovery research. The third edition follows this tradition and considerably expands its scope and content.

The trailblazing scientific discoveries of the 21st century have brought new opportunities for drug discovery research. The discipline of medicinal chemistry continues to evolve as it adapts to these new opportunities and strives to solve new challenges. Covered in the new edition are not only the breakthrough therapies of the past decade in cancer, hepatitis C, heart failure, dyslipidemia, cystic fibrosis, multiple sclerosis, HIV, etc., but also extensive discussion of new business models in drug discovery research, shifting industry demographics, emerging technologies, *in silico* drug discovery tools, experimental ADME and toxicology, and biologics medicine. The tone of this edition is prospective in which contributors identify outstanding issues and paths forward in their area of expertise. The aim is to provide drug discovery scientists in industry, government, academia, and research organizations with a contemporary global perspective on the field that includes a look ahead in selected areas.

The eight individual volumes fulfill these objectives and include extensive discussion of biomolecular therapeutics, drug targeting and delivery, development of chemical biology tools, data collection and analysis, *in silico* models as predictors for biological properties, identification/validation of new targets, approaches to quantify target engagement, new methods for synthesis of drug candidates such as green chemistry, development of novel scaffolds for drug discovery, and the role of regulatory agencies in drug discovery.

The individual volume editors have done an outstanding job to identify topics and contributors to meet these goals and we thank them for their hardwork and diligence. In volume 1, Ana Martinez and Carmen Gil recruited an international group of contributors who provide chapters on the emerging role of organizations other than traditional pharmaceutical companies in drug discovery, the evolving science of chemical biology, and new organic chemistry contributions to the discipline. In volume 2, Helmut Buschmann, Norbert Handler, and Andrea Wolkerstorfer have accomplished a seemingly impossible task and attracted world-leading experts across the wide field of drug discovery enabling technologies, covering contemporary thinking in a wide range of key disciplines that enable modern medicinal chemistry and drug discovery and development. The computational enabling technologies are the focus of volume 3, in which Andy Davis and Colin Edge have assembled chapters covering both ligand-based and protein structure–based advances as well as exciting new methodologies and case studies exploiting these. Alan Wilson identified experts in the fields of pharmacokinetics and toxicology who describe a wide range of contemporary advances in prediction and analysis of pharmaceutical properties and drug safety in volume 4. In volume 5, Ian Collins, Louis Lombardo, and Will Watkins have assembled leading experts to discuss high impact drug discovery accomplishments over the past decade in cancer chemotherapeutics, immunology and inflammation, and infectious diseases therapeutic areas. Ved Srivastava edited volume 6 on biologic medicines, a significant and rapidly evolving area where medicinal chemistry plays an important role. The chapters in this volume provide timely information on not only protein-based drugs, such as monoclonal antibodies and therapeutic proteins, but also peptides and nucleic acid–based therapeutics. Volume 7, edited by Adrian Hall, Santhosh Neelamkavil, and Rob Jones, presents a detailed account of the major advances in CNS, metabolic, and cardiovascular fields over the past decade and the promising new opportunities. Joerg Holenz edited volume 8 that presents case histories of successful drug discovery and strategic differentiation that have resulted in commercialized drugs and candidates in advanced clinical trials.

We are truly grateful to the publishing team at Elsevier that includes Gemma Tomalin, Rachel Gerlis, Marise Willis, and Sean Simms for their assistance and support throughout the process. With their expertise, this project became what we believe is a noteworthy and valuable resource for the discipline of medicinal chemistry. We look forward to the response and feedback of our colleagues who will use this information in their own work.

Samuel Chackalamannil, David P. Rotella, and Simon E. Ward

EDITORS-IN-CHIEF: BIOGRAPHIES

Dr. Samuel Chackalamannil

Dr. Chackalamannil obtained his PhD in chemistry from Yale University in 1984 and subsequently worked in drug discovery research at Schering-Plough Corporation and Merck Research Laboratories, where he was a distinguished fellow when he left in 2011. Since then, he has been teaching at Ernest Mario School of Pharmacy, Rutgers University, New Jersey.

Dr. Chackalamannil has significant accomplishments in the discovery of new medicines. He led the discovery of vorapaxar (Zontivity®), an FDA-approved antiplatelet drug for the prevention of heart attack and stroke. His group also discovered a PDE-5 inhibitor clinical candidate dasantafil and an adenosine A2a antagonist clinical candidate for the treatment of Parkinson's disease. Altogether, he was responsible for the discovery of nine development candidates in cardiovascular, central nervous system, and metabolic disease areas.

Dr. Chackalamannil is a coinventor of 62 allowed US patents and numerous patent applications worldwide. He has published 81 peer-reviewed articles and has coauthored a book. He has also given numerous lectures at international meetings and academic institutions.

Dr. Chackalamannil is a two-time recipient of the Thomas Alva Edison Award for Emerging Technology Patent and a two-time recipient of the Presidential Award for Discovery at Schering-Plough Research Institute. He has chaired several sessions at American Chemical Society national meetings and Gordon Research Conference on Medicinal Chemistry and was an organizer for Chemistry as a Life Science Symposium.

Dr. David Rotella

Dr. Rotella earned a PhD in medicinal chemistry from The Ohio State University and carried out postdoctoral research in organic chemistry at Penn State University. He joined the faculty at Montclair State University in July 2011 as the Margaret and Herman Sokol Professor of medicinal chemistry after a successful career in the pharmaceutical industry. He is an expert in the discovery and optimization of small molecule drug candidates for use in metabolic, cardiovascular, cancer, and central nervous system diseases. His current research is focused on discovering new lead compounds for use in parasitic and central nervous system diseases. He has coedited the seventh edition of *Burger's Medicinal Chemistry* and is a senior editor for the Royal Society of Chemistry's Drug Discovery book series. He has authored over 40 peer-reviewed articles, is an inventor on 8 issued US patents, and has contributed 10 book chapters.

Simon E. Ward

Simon Ward has an MA in natural sciences and PhD in synthetic organic chemistry from Cambridge University, UK. He has a wide-ranging experience of drug discovery in both large and small companies (GlaxoSmithKline, Knoll Pharmaceuticals, Vernalis, Chiroscience, BioCrea) and specialist experience of discovering and developing drugs for central nervous system indications. He has led multidisciplinary project teams and medicinal chemistry groups from target identification through to early clinical studies, delivering multiple clinical development candidates across indications. He is a fellow of the Royal Society of Chemistry. He is currently a professor of medicinal chemistry at the University of Sussex, UK, and the director of the Sussex Drug Discovery Centre, which he established within the University of Sussex in 2010.

As editors of this volume, we two are very complementary. We are of a similar age, both in 50s, and have spent our careers in two of Europe's notable pharmaceutical companies, GSK and AstraZeneca. AD has spent his career as a physical organic chemist specializing in physical properties and quantitative structure–activity relationship (QSAR), and CE has spent his time as a computational chemist. So, together we span the worlds of empirical- and physics-based modeling, which make up our discipline of computational chemistry. Throughout this period we have known of each other's work and admired each other's craft, from afar, and so it is a joy that we have finally been able to work together on this volume. (But enough self-indulgent back-slapping, let's get on to why we agreed to edit this book…)

We are successes in the limited sense that we are Darwin's successes. In a field where we have seen attrition in terms of compounds, companies, and colleagues, we have survived, through a natural selection process of good decisions and blind luck. (Whether we should be aligned to a successful, ubiquitous design like the dragonfly, or a lucky niche-survivor like the coelacanth, we shall let the reader decide.) At the time we didn't know what we were doing, although looking back we can identify some of our successful traits. We hope to share these with you, through these chapters and this introduction, discussing some of the science topics we hold dear and which we think have been the tools of our survival, and hoping to highlight how the science itself has evolved and adapted to the environment we have experienced.

We remember the early days of our career, fresh from University, and the many visits to the company libraries to search through the shelves of *Chemical Abstracts* and its indices and the aisles of bound paper journals, and the Chemistry Bibles of *Beilstein*, *Organic Syntheses*, and the newly published encyclopedic *Comprehensive Medicinal Chemistry*. These were the condensed fountains of knowledge from which we learned our craft. (Although come to think of it, they were not so condensed—even then *CMC*1 was six volumes, and *Chemical Abstracts* filled a wall.) Since those days, while we have developed influential careers, the bound copies of *Chemical Abstracts* have been sent to paper recycling and replaced by access to a web page, https://scifinder.cas.org. Meanwhile, *Comprehensive Medicinal Chemistry* has grown into this third edition eight-volume hardcopy set. It was an honor to be asked to edit the volume on "*In Silico* Tools", the first update for 10 years.

As we reflect on our changing careers, we also remember how our tools and science have progressed. In 1990 our first word processors were IBM PS2s or early Macintoshes and in computational chemistry the display of chemical structures was done on devices such as the Evans and Sutherland PS300, with calculations on mainframe VAXes and the incoming MicroVax, all now dead. Today we have phones many times more powerful than our first desk computer with 200 times the storage capacity, and mobile tablets can render and rotate complex 3-D structures better than those half-million dollar Evans and Sutherland beasts. Indeed Moore's law continues to operate. We now have practically unlimited storage, and huge calculation capacity, and what in 1988 may have taken weeks or months to compute can now be done in real time. But despite all the change we have experienced, some things have remained largely unchanged. A time traveler from 1990 would recognize the science if not the software, with free energy perturbation (FEP) theory, molecular dynamics, quantum mechanics (QM), fingerprints, pharmacophores, and QSAR all mature theories 26 years ago. The big difference is the amount of data, and of course the aforementioned continued to increase in performance of modern computers.

To continue the evolutionary theme, one might wonder how *Comprehensive Medicinal Chemistry* has survived, and whether students of today respect it in much the same way we do. After all, up-to-date authoritative reviews on virtually any subject close to our hearts are available at our fingertips through the World Wide Web, and a visit to a library with real books is such a rare experience. How could a wieldy eight-volume hardcopy set survive? Many research centers no longer have libraries at all. Of course *Comprehensive Medicinal Chemistry* has moved with the times, as PDF chapters are available online for purchase. But out-of-date online reviews cannot be the reason for its survival. So what is the role of *Comprehensive Medicinal Chemistry* today? Maybe it has survived because it is indeed *comprehensive*.

As invited editors, the responsibility of carrying the title weighed heavily us. Our scientific naivety gave us hope we could aspire toward Comprehensiveness. But there is always something left behind, particularly when commercial publishing deadlines meet busy scientists. While the modern world of e-publications would be flexible about late-breaking chapters, the call of the printing presses could not be ignored. So for reasons of time we were doomed as scientist idealists to disappoint the advertised title of Comprehensive, and leave some chapters behind to wither and die under the pressure of selection of the fittest. We have unfortunately had to leave behind such topics as binding thermodynamics, screening libraries, and experimental design. We also wanted to pick up on some of the newer peripheral areas that are expanding toward medicinal chemistry territory, such as solid-state modeling, polymorph risk assessment, large-scale systems, and multicomponent assemblies. Sadly we failed to get chapters completed for these in the time available.

If *Comprehensive Medicinal Chemistry* could not be comprehensive, then for a volume updated every 10 years to be a Darwin success, we believe it is its ability to be deep, reflective, and provocative to judge progress and to look to the future. This became our focus for the volume. We asked our authors to consider the context of their discipline and to look at what has happened and how the discipline could change and thrive. Our authors have delivered. The chapters in this *In Silico* volume are a joy to read, written as they are by some of our industry's leading thinkers, writers, and doers. We relished editing every last one of the 25,000 or so words per chapter.

The first chapter in this volume is one that we are immensely proud of. One of the Nobel Laureates in our field, Arieh Warshel, graciously agreed to write a Perspective on Calculations of Binding Free Energies. This is a great introduction to a field that has been around for years, but is rapidly becoming relevant for medicinal chemists, because of technological advances in computer speed and memory. Yoon and Warshel (University of Southern California) provide a personal journey from rigorous but slow microscopic methods, through to simplified models of electrostatics. They then discuss the pros and cons of using different strategies to apply the models, such as FEP and linear response approximation (LRA) methods. It is interesting to see their view on the "disappointing performance of FEP, even with a polarizable force field," since FEP is being touted quite heavily by some software manufacturers. (Although to be fair, Yoon and Warshel go on to suggest a water flooding method that seems to improve the performance of any free energy method.)

The baton is picked up by Matteo Aldeghi and Phil Biggin (Oxford) in their chapter on "Advances in Molecular Simulation." This has some overlap with Warshel's chapter, but spends more time on the "nuts and bolts," such as processors, algorithms, and molecular mechanics force fields. They then go on to discuss the latest simulation approaches such as Markov state models (MSMs) and replica exchange (RE) methods, which can be used to improve sampling—one of the bugbears of the science. Put simply, we are millisecond animals consisting of huge ensembles of molecules, but we can simulate one or a few systems for nanoseconds. They then go on to discuss methods such as metadynamics, which explore the complex conformational options of a macromolecular system by "filling in" the energy wells that have been found, encouraging the system to explore other conformational states. One comment that struck us when reviewing this chapter was that simulations were starting to be run on the same timescale as some experimental techniques and that we were bound to see more convergence in the future. This is exciting, since the combination of theory and experiment always strengthens theory and sometimes supplants experiment. (Take aeronautical design as an example.)

The third chapter on simulations also takes its lead from Arieh Warshel and discusses FEP methods in more depth. Francesco Gervasio (UCL) gives an introduction to the basic "alchemical" approaches of FEP and thermodynamic integration (TI), when one atom or small functional group is transmuted to another, giving an estimation of a difference in free energy ($\Delta\Delta G$) between two molecular systems. He then goes on to describe various enhanced sampling collective variable methods followed by variable-free methods. This chapter will take you deeper into the mechanics of these methods and point you at some seminal papers.

Another area with a venerable tradition is QM. Graham Richards' influential book, *Quantum Pharmacology*, was one of the reasons that we entered the pharmaceutical industry in the first place. Predicting the properties of molecules from the wave function was cutting edge (and admittedly largely science fiction) in the 1980s, but we could see where QM was going. Many of the leading lights in pharmaceutical computational chemistry passed through Graham's lab. Adrian Mulholland is one such and is now a renowned expert on quantum mechanics/molecular mechanics (QM/MM) hybrid methods. He and Eric Johnson (Bristol) have provided us with an overview of QM at a time when it is really becoming mainstream again, because of the availability of cheap computer power.

One of our favorite chapters is the deceptively simple one on "Molecular Interactions" by Robin Taylor. He delighted us with his update on the state of understanding of drug–receptor interactions. His voice of authority and experience, together with an easy writing style, was a joy to read. This is a discussion of all the intermolecular interactions you will come across as a medicinal chemist, plus some you shouldn't believe, such as fluorine as a halogen bond donor. The author has spent a large part of his career at the Cambridge Crystallographic Data Centre, looking at interactions in crystals, and this chapter is essentially his distilled wisdom on the subject, backed up by lots of examples. This work is highly recommended for those who want to get more from their crystal structures, whether small molecule or protein ligand.

Many computational chemists utilize X-ray structures as the basis for structure-based campaigns or even for validating new computational code. Useful guidance on using X-ray crystal structures in computational programs is given by the editors' own chapter, calling on highly cited reviews they have been contributors to over the last 10 years.

Oftentimes, you are unlucky and there is no structural model available for your target macromolecule. In this situation you may be able to build a homology model. If that is the case, you have two options: send the sequence to one of the automatic model building web sites on the Web, or put some effort in yourself to build the model. Andrew Leach (EBI) and Pamela Thomas (GSK) take you through the steps of building such a model. Crucially, they identify the risks and pitfalls along the way. Even if you have no intention of building a model yourself, this chapter will help you have the right level of appreciation and skeptic doubt about any model you acquire.

While some subjects are welcome refreshes and updates of evolving science, some chapters are new and reflect the way our thinking and capabilities are developing. Miles Congreve et al. give us an insight into drug design using membrane protein structures according to Heptares, surely one of the most innovative high-end science companies of the last 10 years, with science that was virtually unthinkable when the last edition of *Comprehensive Medicinal Chemistry* was rushing to press ink to paper. Membrane-associated targets such as G protein–coupled receptors (GPCRs) continue to be underrepresented in the PDB. Structural models of these targets are still "special" compared to those of soluble monomeric proteins. The chapter tells of a fast-paced discipline where almost every structure was significant in moving the science onward. Will solving membrane-associated structures become routine within the next 10 years? We suspect, "yes and no." Some class A GPCRs are already routine in the hands of experts such as Heptares, but larger many-helix transporters may require us to move away from X-ray diffraction methods to, say, 3-D electron microscopy (3DEM) methods.

Another way to distil knowledge from structure—and then do something with it—is to build a pharmacophore. Richard Lewis and Finton Sirockin of Novartis have provided us with an authoritative chapter on what seemed to us to be a rather stagnant field. How wrong we were! They have shown us that in some ways, pharmacophores are the original and most robust form of medicinal chemistry, in that "they are a property of the training set of molecules rather than the target" and so fall neatly in with medicinal chemistry concepts such as R-group substitution, homologous series, molecular similarity, and the like. Indeed the pharmacophore has the power to transcend these and arrive at truly novel molecules with completely different scaffolds.

An important subset of pharmacophore- or similarity-based approaches is the matched molecular pair analysis (MMPA). Andrew Leach (Liverpool John Moores) was one of the pioneers of this analysis method. He and his colleagues have offered us a history of MMPA from the coining of the term onward and then into the future. This is an excellent treatise on molecular matched pairs, reminiscent of an old style QSAR method—but it's very much a drug design tool of the modern age, being dependent as it does on large-scale cheminformatics structure-matching and statistical data analysis. Again this is a technique that should appeal to any medicinal chemist and it aligns well with R-group analysis and (in some implementations) with scaffold hopping. It is a relatively recent development, so there is still excitement over the next steps, such as expanding MMPA into three dimensions or being used to anonymously compare compound sets between organizations.

The use of molecular interaction fields (MIFs) in computational chemistry goes back to the eighties with developments such as GRID and CoMFA. Nowadays these techniques have had a new lease of life in areas as diverse as water mapping and crystal structure quality assessment. Paolo Tosco and Mark Mackey (Cresset) are world experts in these methods and have continued to develop the XED-based fields pioneered by Andy Vinter. Their chapter is a tour through the how and why of MIFs, from simple alignment and pose prediction through to recent developments such as activity cliff identification and water placement. Although these methods are not as alluring to some as simulation-based methods such as WaterMap, they are quick, simple, and easily interpretable and surely must act as a baseline method in which the likes of WaterMap and SZMAP must strive to outperform. In our experience, MIFs work very well in the cases that do not involve force field complications such as high charge gradients (metals, phosphates in the binding site) and are therefore the first choice.

One area of computational chemistry that we thought had slowed down in the last 10 years was molecular docking, the practice of suggesting poses for ligands within a target site. We cheekily suggested the title, "Molecular Docking – a Solved Problem?" and to their credit, Jason Cole and Erin Davis (CCDC) and Gareth Jones and Carleton Sage (Arena) gamely agreed to write it. The generation of poses does seem to be remarkably successful, as one can see by looking at the docking challenges. The "right" pose is almost always on the list. However, the ranking of poses is by no means a solved problem, as this pose can be far down the ranking. This chapter discusses the reasons why this is the case: there is much work to be done in affinity prediction and coping with protein flexibility. The chapter is written in a very engaging style and is full of hints and tips for the uninitiated and the old lag.

The assumption of a rigid receptor is a risky assumption made by computational chemists using X-ray structures. Protein flexibility is the subject of a chapter by Chengfei Yan and Xiaoquin Zou (Missouri). This develops further some of the ideas in the chapter of Cole et al. It describes some of the tactics and techniques used to try to accommodate the inconvenient motion of the target site when presented with a ligand. These include soft docking, induced fit docking, and ensemble docking as ways to ameliorate poor interactions during a pose calculation. The authors also discuss postdocking methods to address steric clashes or flexible amino acid side chains, such as relaxation methods.

Molecules need descriptors. Dávid Bajusz, Anita Rácz, and Károly Héberger (Budapest) will tell you how to describe them. This chapter is a "comprehensive and reasonably compact" tour through the many ways to represent a molecule in a computer and how those representations can be used. As a bonus, they also discuss the online databases that medicinal chemists might use. Their outlook for the future is interesting. It seems we may have more or less peaked in the number of molecular descriptors available, but the number of ways of manipulating those descriptors continues to grow. More complex manipulations (consensus modeling, multi-y optimization, etc.) have become popular. This is partly due to the improvement in computational power, but just as much

due to helpful toolkits such as MySQL, R, RDKIT, and Python modules focused on cheminformatics. The area will continue to grow, as long as "Big Data" remains popular.

Physical property calculations are equally a critical part of the computational chemistry armory and deserve a place within this volume. So much has happened in the past 10 years to physical property calculations and their applications, and Igor Tetko (GmbH) brings us up to date, while Tudor Oprea (New Mexico) gives us a perspective on the last 10 years focus on compound quality.

While the focus of the volume is on heavy physics, visualization has always been important, and talk of toolkits and descriptors brings us on to Chris Swain's chapter on online databases. You have all these data, but how are you going to organize it and analyze it? Welcome to the world of "data analysis and visualization tools." These range from expensive, monolithic, multipurpose program suites sold by companies such as Schrodinger and Chemical Computing Group down to apps on your smartphone. In between is the hinterland of open-source programs. Chris gives us a summary of data-mining and visualization tools for the practising medicinal chemist with useful web links, case studies, and examples. More recent disciplines such as bioinformatics rely for the most part on free software, much of it also open source. We wondered whether it was possible to run a medicinal chemistry program with no software budget. This chapter suggests that this might be possible in the near future and is possible in some subdisciplines, such as cheminformatics, right now.

Cheminformatics and online databases have also enabled the field of open-source patent informatics, which is neatly reviewed by Chris Southan (Edinburgh). This is a great resource for anyone wondering what they can do with patent data, the most neglected source of free, open information. Chris takes the reader through the various online resources and shows what can be accomplished using fairly simple search techniques and focusing on extracting SAR. The birth of this chapter is very much of the modern age, as it was conceived during a Twitter conversation, and written against very tight deadlines.

Finally we have a chapter where everything is brought together into one huge model. With the recognition that failure in translational science is a major source of attrition, and also therefore a key for future success, Bruce Gomes' (Novartis) chapter on Systems Biology feels very timely in this volume. Systems biology is a very structured way of assembling your biology story. It provides project biology with a formal mathematical framework, and can help with both assays development and clinical trial design, especially when the relationship between mechanism and endpoint is not direct. Systems biology is moving away from toy systems where almost any change in output was judged to be "emergent activity" to models of PK/PD behavior that are genuinely useful. On top of this, the development of huge multicomponent models of, say, the heart or lung is being attempted. Bruce has provided a thought-provoking look at the current state of the art. It makes us wonder, will this be the norm in 10 years' time? It seems too soon, but we anticipate that more and more complex models of physiological behavior will become available at some point.

Where we have had to leave behind some chapters and topics, we can at least point you toward recent authoritative reviews on these many subjects, and isn't that one of the definitions of a great resource?—a pointer to other great resources, and isn't that the definition of a great review?—one that summarizes succinctly key knowledge so you can quickly find what you need to make discoveries of your own… So we can save you a few chapters of 25,000 words each, with a few hints, tips, and key references in a mere fraction of the 25,000 words per chapter—and be as quick and succinct as our tablet computer is compared to our old Evans and Sutherland. So what are the topics not covered in this volume?

Computational Methods in Materials Science

For up-to-date information on the impact of computational methods in materials science, we point you to a number of excellent reviews by Docherty and colleagues,[1–3] They are pioneers of a physics-based approach to materials engineering and if you follow their published work, it will give you a good basis for further exploration of this important field for crystal engineering, polymorph prediction, dissolution, particle flow, aerodynamics for inhaled drugs, and solid-state stability among other material properties.

Advances in Understanding of Receptor Thermodynamics

This is a big subject, and somewhat covered by Robin Taylor's chapter on progress in the understanding of traditional and nontraditional molecular interactions. As editors we were keen to probe the insight gained from measurements of on- and off-rates, and the deconvolution of free energy into measurements of enthalpy and entropy changes on binding of a drug to its target, and how this information has impacted computational chemistry and compound design.

Receptor Kinetics

In many systems, we measure at steady state, so even if the on-rate is slow, we set up assays to measure at equilibrium. Slow receptor binding often indicates conformation change, or changes in solvation, or both. Receptor kinetics can be measured biochemically, with washout experiments, although this is rather laborious. Nowadays Biacore technology allows receptor kinetics to be measured

directly. A number of drugs claim to benefit from slow receptor kinetics, although the off-rate would need to approach the dosing interval to contribute to pharmacodynamics duration. Tiotropium, the long acting M3 antagonist, has a slow receptor off-rate, and this is claimed to contribute toward its pharmacodynamic half-life, but its pharmacokinetic half-life is also long. There has been a long-term literature debate about the molecule driver for the long pharmacodynamic half-life of the β2 agonist salmeterol. Early papers suggested it was due to slow receptor off-rate due to an exo-site binding. Other studies suggested it may also be driven by its lipophilicity and membrane affinity. A recent receptor kinetic study appears to support this pharmacokinetic explanation as its off-rate measurements cannot explain its long pharmacodynamics off-rate.[4] But it is likely that slow receptor off-rate, if slow enough, could contribute to a pharmacodynamic half-life of drugs, after all irreversible compounds are just an extreme case of a slow off-rate. A review by Dahl and Akerud shows that for many drugs with long drug–target residence times, they also have even longer pharmacokinetic half-lives, so the residence time is not the "rate-determining step" for their pharmacodynamics duration.[5] A good start point for those interested in the role of slow receptor kinetics would be David Swinney's review.[6] A recent review by Klebe is also worth a read, which is also a segue into our next and related topic.[7]

The prospective design of slow off-rate compounds may be an area for the future of computational chemistry design. But design of irreversible compounds is already enabled, as exampled by a number of drug introductions, including ibrutinib, carfilzomib, rociletinib, not to mention the older classics such as clopidogrel, omeprazole, penicillin, and aspirin. For recent reviews we point readers to recent reviews by Gonzalez-Bello,[8] Singh,[9] and the article on structure-based design of EGFR T790M mutant irreversible inhibitors.[10]

One other aspect of receptor thermodynamics that has generated a lot of interest, but so far confusing impact, is the deconvolution of free energy changes into the fundamental enthalpy and entropy contributions. While biologists in general measure free energy changes, computational chemists generally estimate enthalpy changes. It would seem logical therefore that the partitioning of free energy into ΔH and TΔS contributions should aid computational approaches to understanding binding, as the entropy term can be considered separately. Indeed Biacore and isothermal titration calorimetry (ITC) enable the measurements to be easily made for amenable systems. Amenable for ITC means if the binding kinetics are fast enough, the protein can be expressed in large enough amounts and is soluble enough to be studied in the calorimeter. For Biacore amenable means if the protein or the ligand can be immobilized on a chip to measure the binding event.

So far the analysis of ΔH and TΔS changes has only confused and complicated the picture rather than aiding it. It has been proposed that best-in-class drugs are more ΔH driven than first in class drugs[11] and that thermodynamic signatures should be used to choose lead series. This is an excellent review, and while it may have some truth, that best-in-class drugs may be more enthalpically driven, this may be more likely a consequence of better control over ligand lipophilic efficiency rather than a fundamental principle of the receptor thermodynamics. A recent analysis of fragment binding to the S1 pocket in thrombin suggests fragments can be either more enthalpy driven or entropy driven.[12] Over congeneric series, ΔG can show a comparatively smooth transition, but a number of examples show that ΔH and TΔS can vary widely and in opposing directions, due to enthalpy–entropy compensation. Prospectively using ΔH and TΔS in drug design can be completely baffling. Many publications have appeared by rather bemused authors, in some high impact journals.[13] Interpretation can often only be made retrospectively, with reference to high-resolution X-ray crystal structures, and water rearrangements, as well as protein and ligand movements are often major contributors.[14] Independent changes to the ligand, such as increasing hydrophobicity and introduction of hydrogen bonds, can also cause cooperative changes in ΔH and TΔS. Increasing hydrophobicity can affect the strength of hydrogen bonds, and vice versa.[15] We believe the deconvolution of free energy into ΔH and TΔS is uncovering complexity and subtlety of drug–receptor interactions that is important information, and reminds us of the complexity of what we are trying to do. But it seems too early to be sure how computational chemistry should or could use ΔH and TΔS measurements prospectively. It seems too complex, and we should stick with ΔG for design. Further work is required in this discipline, and continuing thermodynamic profiling is recommended, alongside the developments in our computational discipline. The editors recommend the readers continue to follow the publications of Ladbury, Frere, and Klebe over the next few years, and see how this field develops.

Design of Experiments in Drug Design

Experimental design was another desired chapter, but it appears that little has happened in this area to justify a chapter on its own. Experimental design and design of experiments has always been important in designing *in vivo* experiments, reaction optimization, protein crystallization, formulation, and other areas of pharmaceutical research, but it has not evolved further as a technique for QSAR and drug design in the past 10 years. A search of SciFinder for the terms "design of experiments" or "experimental design" and "QSAR" only identified six publications since 2004.[16–21] If you are interested in experimental design, read these citations. Multiparameter optimization also continues to be of interest.[22]

Design of Screening Libraries

Finally we dearly wanted to discuss library design. This was a big subject in the second edition of *Computational Medicinal Chemistry*, covered by two chapters. This is not a static area and the design of screening libraries themselves continues to be a focus for drug

discovery. Supplementation of the HTS screening deck by new chemical libraries, or selecting subsets from it,[23–25] continues to be an important topic. Most companies developing HTS screening libraries have computational prescreens to remove ugly and unwanted compounds from compound acquisition activities, or to filter them from hit lists if the compounds are already in the HTS collection.[26] The Leadlike paradigm[27] has had a profound influence on the design of HTS screening collections and stimulated the field of fragment-based drug discovery. Fragment screens (by X-ray or NMR screening) are typically only a few thousand members, and hence design of the best few thousand members has also been a hot topic.[28] HTS is limited to 1–2 million structures, but the use of DNA encoding has allowed the screening of libraries of billions of small molecules, or up to 10^{18} member peptide libraries. The highest cited review on DNA-encoded library design is by Clark.[29] Now virtual screening is taking the numbers game to the next level. Pfizer have constructed a 10^{13} virtual library available for screening of every compound they could make with their available reagents and known reactions.[30,31] Lilly have recently published on their own synthesizable virtual library.[32] The chemical space project has now fully enumerated every compound up to 17 atoms of C, N, O, S, and halogens, a library of 116 billion members, and developed tools to virtual screen it. Clearly library design is still an exciting and developing field, driving the development of new enumeration and screening methodologies, and facilitated by the massive improvement in computational power that is now at our fingertips.

Now for the fun bit. This is where we make predictions about the next 10 years. This is not easy and no doubt there will be howls of derision at what we missed, but we shall have a go anyway. Anyone who knows the science fiction film genre will recognize that predictions have a strong grounding in current culture (e.g., miniskirts in *Star Trek*, phone boxes in *Blade Runner*). We are talking to you from the dying days of 2016, a time of Big Data, Cloud Computing, and gaming-sourced GPU processors. We've seen this before. The rise of Silicon Graphics and Netscape in the early 1990s was based on the supplanting of old technology (Cray, VAX, VMS, Teletype terminals) by parallel hardware and new display technology. The essence of the age was to dispense with experimental design and "just make everything." This is doomed to fail unless you can make some limits to your chemical space (i.e., put back in the design element). Even the 10^{18} and 10^{13} libraries mentioned above are tiny compared to the estimated "druglike" universe of about 10^{60}. After all, $10^{60}–10^{18} = 10^{60}$, to many significant figures, so we are nowhere near full coverage. We are hoping that we do not see a return to brute force methods and have concentrated our predictions elsewhere.

There has been a renewed effort on molecular mechanics force fields in recent years. These seem to have been stuck in the Doldrums since the Merck Molecular Force Field was published in 1996.[33] However, there is a renewed interest in polarizable force fields for proteins and a notable recent contribution is the AMOEBA force field.[34] This extends the charge representation from a simple atom-centered monopole expansion of so-called point charges to a quadrupole at each atom. The advantage is that the constructed atomic model should behave in a more realistic way in high dielectrics, such as water and when in highly charged environments, such as metal and phosphate sites. Although AMOEBA is still being tested, it seems to be an important step forward and other groups are working on extensions to existing force fields such as AMBER.[35] We can expect to see these force fields in routine use in the next 10 years.

One might also expect to see this resurgence of force field development to carry over into the more complex world of druglike molecules, where we need many more parameters than for proteins and oligosaccharides. We are not so sure. Of course, some common atom types that are not seen in proteins will be parameterized, for instance, pyridine nitrogens. However, we wonder whether the march of Moore's law and the cheapness of gaming graphics cards will mean that QM/MM methods will become routine. In a couple of years it wouldn't require that much effort to build a desk-side PC or even a laptop with enough memory and GPU power to run calculations on smallish enzymes with a quantum mechanical treatment of the whole active site and a surrounding shell of molecular mechanics. This is already routine on multithread Linux computers. The advantage of this technique is that the parameterization is limited to the choice of basis set and theoretical model, so we do not need to parameterize new ligands (provided they contain relatively common atoms). Admittedly, this provides a relatively static view of the binding site, consisting of transition states and energy minima, as we don't expect quantum dynamics solutions to be accessible. There are hybrid solutions where one runs alternate phases of molecular dynamics and QM/MM that might become popular.

Like QM, which was used a lot in drug discovery in the 1980s and early 1990s, another technique that we see reestablishing itself is QSAR analysis. This dates back to the work of Hansch in the 1960s and 1970s but fell out of favor somewhat at the turn of the century. This was partly due to the influence of the "we'll make everything so we don't need to design anything" gung-ho spirit of combinatorial chemistry and partly due to the replacement of cheminformatics by molecular simulation at many university departments. There was also the draw of Wall Street. If one is reasonably numerate and understands a little statistics, why get a job predicting the logD of a molecule when you can earn 10 times the amount analyzing stock trends? Anyway, QSAR has been under the radar for a number of years, except in a few very important areas. It has established a preeminent position in ADMET prediction in most large pharmaceutical companies, where various risks can be estimated before molecules are made. For instance, at GSK, we have a complete panel of liability assays, such as CYP450 inhibition, that have been provided as simple web services that can be called from an Excel spreadsheet. We see this influence extending back into lead optimization efforts and perhaps supplanting docking in some cases. This is because there are now simple systems such as Biovia's QSAR Workbench (QSAR-WB) that automatically build and test a huge number of QSAR models, including regression, recursive partitioning, neural networks, random forests, and so on. The results are presented in an intuitive way so you do not need a deep expert in statistics to wade through them. (For instance, it is easy to see overfitting of neural network models.)

The next prediction is the renaissance of structure-based *de novo* design methods. This is another area where disappointing results in synthetic prediction methods and poor scoring functions led to its almost complete abandonment in the early 2000s. (We could not find anyone to write a chapter on *de novo* design for this book; try doing a literature search for *de novo* design

from 2005 onward…) De novo design was replaced by systems using known building blocks and known chemistry to devise large (but relatively limited) chemistry spaces that could be explored using either computational or experimental methods. Yet, there is much more synthetic chemistry literature now, so a Google-like data-driven approach to synthetic accessibility might work. Besides, there are also newer synthetic prediction programs arriving on the scene. We can see a time in the next few years where *de novo* design systems are run on good resolution target structures and provide new designs with a good chance of actual synthesis.

Automation continues to impact on all aspects of our lives, and while it removes the drudgery, so the editors' dishwashers free us up to watch the aforementioned old Star Trek and Blade Runner movies, automation also brings objectivity. We have seen how the Protein Data Bank is encouraging crystallographers to minimize subjectivity in determining X-ray structures, and automated QSAR modeling is removing the subjectivity from QSAR model building. Maybe more automation is also a trend we should encourage as much as possible in the wider computational chemistry discipline.

Ultimately, computational chemists (and those who depend on them) should remember that they are merely purveyors of opinion. We don't make anything nor test anything nor create primary data. This sounds like a bleak message in a book on the use of *in silico* tools. Yet, we have shown that computational chemistry has had an impact for years and it would be an odd drug discovery effort that did not use some sort of computational prediction. The main and perhaps only real job of a computational chemist is to provide testable hypotheses, via a mixture of routine computational methods and some personal inspiration (the equivalent of the chemist's "gut feeling index"). We see the role becoming even more so. If automated systems such as the QSAR-WB take away some of the tedium and QM methods and improved force fields provide better scoring of docking poses, then the job will become even more to do with devising molecules to address issues and optimize potency. That is, if we are not drowning under a sea of output from huge simulation runs and massive lists of alternate molecules…

So that's the end of the introduction from Darwin's survivors, and the start of the book. Natural selection has chosen us three old dinosaurs/dragonflies/coelacanths, and may we continue to roar/buzz/burble(?) for a few years more. It's hard to say which of us Darwin successes will be around in 10 years' time, we hope we are all still deep, reflective, and provocative and that this will help our survival, but our money is on *Comprehensive Medicinal Chemistry IV*.

3.01.1 Introduction

The ability to correlate the structure of protein–ligand complexes with their binding affinity is a challenge of major practical and fundamental importance. A clear example is the need for effective tools in rational design of drugs that would block the activity of proteins that are involved in specific diseases. Thus, reaching accurate prediction in calculations of binding energies is one of the most important aims of computational biology. The starting point for addressing this challenge is the progress in structural evaluations of protein–ligand complexes by X-ray crystallography and NMR spectroscopy. The Protein Data Bank (PDB)[1] continues to grow at an accelerated rate. The enormous structural advances call for a corresponding progress in the use of computer modeling in analyzing the energetics of protein–ligand complexes. An obvious step in such studies is the ability to search for optimal docking of proteins and different drug candidates. Several effective programs have been developed for this purpose (e.g., Glide,[2] GOLD,[3] FlexX,[4] and DOCK[5]). For review see Refs. 6–8. However, this issue is out of the scope of the present review (except in using the docking programs in finding starting points for calculations of binding free energies). Here, we provide some perspective on calculations of binding free energies emphasizing the progress made after our last review.[9] In particular, we will emphasize approaches that are based on "first-principle" free energy estimates.

As far as rational drug design is concerned, the role of first-principle binding calculations is mainly in ranking sets of reasonable candidates, which are obtained from more qualitative approaches. Unfortunately, the advance in the more quantitative direction is still far from being satisfactory. However, at some stage (which might be coming relatively soon), we expect calculations of binding free energies and in particular the corresponding electrostatic contributions should become a major quantitative tool in rational drug design.

3.01.2 Computational Strategies

The key to energy-based drug design is the ability to obtain reliable free energy results in calculations of protein–ligand interactions. Accomplishing this task is, however, far from simple, due to inherent convergence problems and to inconsistencies of some approaches. In this review, we consider different strategies for evaluations of binding free energies. In doing so, we pay major attention to calculations of electrostatic contributions to the overall binding free energy, since we consider this effect to be the most important contribution. However, we will also consider approaches that evaluate all other contributions in the following sections.

3.01.2.1 Rigorous but Slowly Converging Calculations by All-Atom Models

Thermodynamic cycles of the same type as used in chemistry textbooks can describe many biochemical processes. Such cycles allow one to replace the very challenging direct calculations of physical processes by calculations of much simpler either physical or nonphysical processes. The use of thermodynamic cycles in microscopic calculations of free energies of biological processes had been introduced in the early 1980s.[10] These studies focused on the evaluation of the difference between the pK_a of acids in proteins and in water, by considering the nonphysical process of "mutating" the protonated acid to its ionized form in the protein and in water, instead of calculating the binding energies of the protonated and ionized forms of the acid.[10] Another example has been provided by studies of enzyme catalysis[10,11] (see discussion in Ref. 12). Related cycles for studies of ligand binding have been

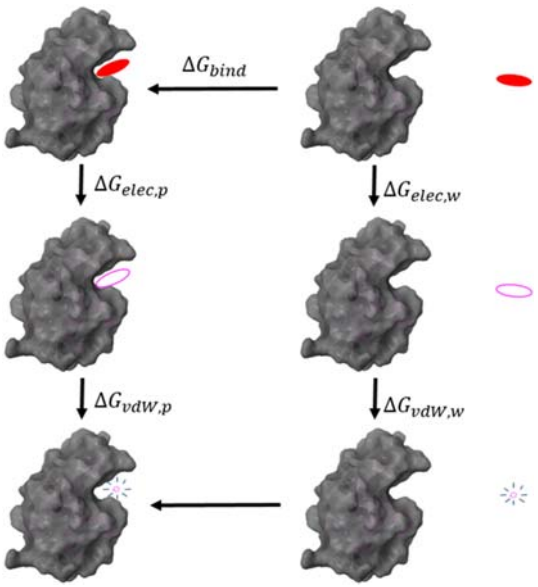

Fig. 1 A schematic description of the free energy cycle for protein–ligand binding. The ligand on the right changes from being polar to nonpolar and to nothing. The cycle is divided into electrostatic and nonelectrostatic parts.

introduced in Ref. 13. At any rate, thermodynamic cycles have become a major part of many approaches in free-energy calculations of biological processes (e.g., Refs. 13–15).

In principle, we can evaluate binding free energies using the cycle of Fig. 1

Of course, the key issue in the evaluation of thermodynamic cycles is the ability to evaluate the relevant free energies. Unfortunately, doing so by statistical mechanical approaches and microscopic simulations is extremely time consuming, owing to the difficulties of sampling the relevant conformational space. We will consider later some approaches that allow one to evaluate the energies in the cycle. Before doing so, it is useful to clarify that the upper part of the cycle can be evaluated by a direct approach (Fig. 2), but the evaluation of the corresponding potential of mean force (PMF) is extremely challenging, since it should reflect the equilibration of the surrounding water molecules during the penetration of the substrate to the active site.

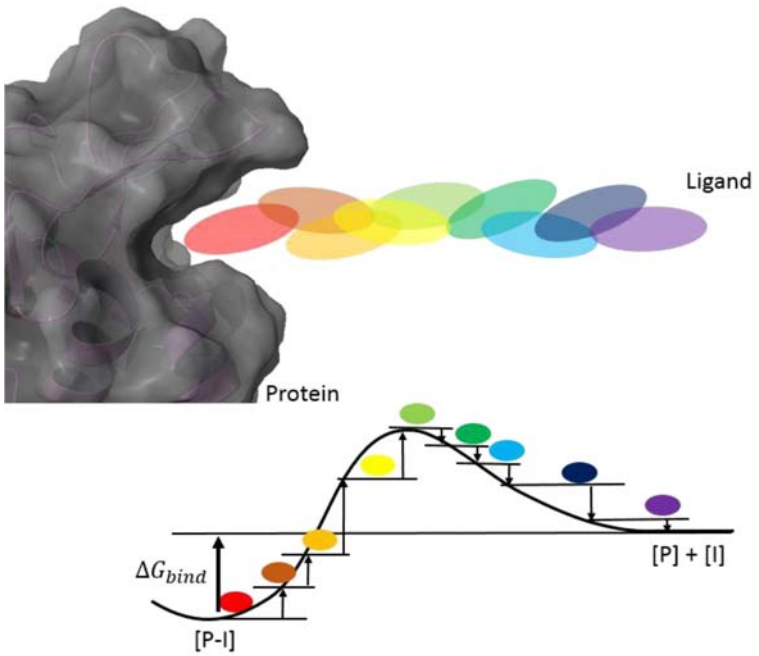

Fig. 2 Showing a direct approach of evaluating the binding free energy by evaluating the corresponding PMF.

To avoid the PMF calculations we can start by considering the thermodynamic cycle of Fig. 1

These contributions can be evaluated in principle by the free-energy perturbation (FEP) method[16,17] and the related umbrella sampling method.[17] The FEP method evaluates the free energy associated with the change of the potential surface from U_1 to U_2 by gradually changing the potential surface using the relationship

$$U_m(\lambda_m) = U_1(1-\lambda_m) + U_2\lambda_m \tag{1}$$

where λ_m is a parameter that changes between $(0 \le \lambda_m \le 1)$. The free-energy increment, associated with the change of U_m, can be obtained by[17]

$$exp\{-\delta G(\lambda_m \rightarrow \lambda_{m'})\beta\} = \langle exp\{-(U_{m'} - U_m)\beta\}\rangle_m \tag{2}$$

where $\langle\rangle_m$ indicates that the given average is evaluated by propagating trajectories over U_m. The overall free-energy change is now obtained by changing λ_m in n increments and evaluating the sum of the corresponding δG:

$$\Delta G(U_1 \rightarrow U_2) = \sum_{m=0}^{n-1} \delta G(\lambda_m \rightarrow \lambda_{m+1}) \tag{3}$$

The FEP approach has been used extensively in studies of free energies of biological systems (e.g., Refs. 14,18) and has been introduced quite early[19] in studies of electrostatic free energies in proteins.

In many cases, it is very hard to perform converging FEP calculations (e.g., binding of large ligands). In such cases, it is very useful to estimate the free energy of biological processes by an equation derived by Lee et al.[20,21] and used in studies of ligand binding to proteins. This equation expresses the free energy associated with changing the potential of the system from U_1 to U_2 by

$$\Delta G(U_1 \rightarrow U_2) = \frac{1}{2}\left(\langle U_2 - U_1\rangle_1 + \langle U_2 - U_1\rangle_2\right) \tag{4}$$

where $\langle\rangle_i$ designates an average over molecular dynamics (MD) trajectories obtained with $U = U_i$. The derivation of this equation was based on the assumption that the linear response approximation (LRA)[22] is valid. Namely, the protein and solvent environments respond linearly to the force associated with the given process. This assumption is, in fact, the basis of macroscopic theory where the free energy of charging a positive ion is given by the well-known result $\Delta G = \S U(Q=1)$, where U is the electrostatic potential of the given charge (Q).[23] Although it is hard to accept that the LRA can provide a reliable way of describing the energetics of macromolecules or of realistic molecular systems, it was found by simulation studies that it is a reasonable approximation, in particular for processes that depend on electrostatic effects.[24–27]

In cases when the nonelectrostatic contribution (the lower part of Fig. 1) is important, we need to augment the LRA, and some ways of doing so are described later.

The FEP and PMF evaluations can be performed by approaches that are rigorous in principle. However, it must be emphasized that the convergence of such approaches is extremely slow and that even a perfect convergence does not guarantee proper results. For example, FEP calculations using models with improper long-range treatments cannot provide proper electrostatic energy. This issue is discussed in great detail in Ref. 28 and can only be appreciated by trying to evaluate known electrostatic free energies like pK_as. Interestingly, the PMF approach, which has the appearance of the most rigorous approach (here one simply pulls the ligand to the active site), may make one "blind" to problems with the simulation model. For example, PMF studies of ion penetration in ion channels do not tell us about the absolute energy of moving the ion from water to the given channel site. Thus, one might tend to believe that the electrostatic model is correct even if the absolute energies are entirely incorrect (see discussion in Ref. 29).

In calculations of binding free energies, it is recommended to use specialized spherical models[30–32] and to avoid the use of the periodic Ewald method[33–35] in estimating long-range corrections (see discussion in Ref. 28). The slow realization that proper treatments of long-range effects are crucial for proper modeling of protein functions is still a major problem in the field. Apparently, many workers still emphasize the length of the simulations and the number of atoms in the simulation system instead of validating the calculated electrostatic free energies.

The convergence problem becomes more serious when we are trying to evaluate van der Waals (vdW) contributions (the transition from the middle stage to the lower stage in Fig. 1). This stage involves mutating the nonpolar substrate from its current size to a dummy atom of a zero size. A direct FEP mutation leads to a convergence catastrophe since the motion on the end point with zero vdW can lead to infinite values for the real potential.[36–38] Several ways have been provided to resolve this problem by replacing the zero vdW potential of the dummy atom by a finite potential[39–41] (see also later).

Another major problem is the evaluation of the effect of water penetration. That is, not only is it hard in such cases to identify the position of the water molecules, but also this position changes drastically during the binding process. In principle, one can try to insert water molecules in a grand canonical Monte Carlo (MC) treatment, but the chance of a water molecule being accepted is extremely small since in most insertion attempts, we will not have a large enough cavity in the protein site. Our strategy for this challenging problem is the water flooding (WF) approach,[42] where (see Fig. 3) we insert clusters of water molecules into the active site, relax and optimize the energy of the cluster, and then use the LRA approach to estimate the energy of each of the internal water molecules in the cluster. Next we take the LRA-estimated energies of the internal water and evaluate the probability that a water molecule will be inside the protein by running an external MC program that postprocesses the energetics by simply iterating on the LRA run relative to the energy of inserting water in aqueous solution (where the free energy is around -6 kcal/mol). Our

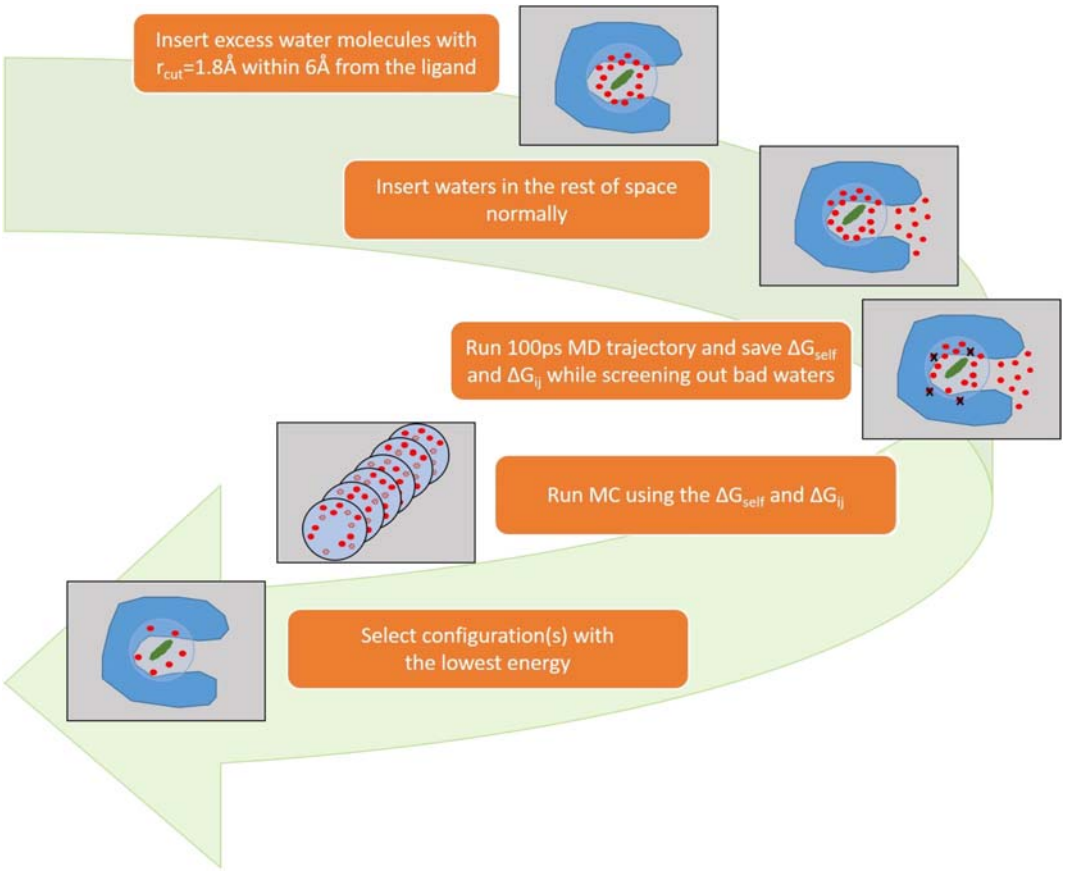

Fig. 3 Illustrating the water flooding procedure.

postprocessing approach means that instead of running MC on actual water insertion we already have energies for inserted water molecules and the MC is performed on these energies.

In concluding this section, we note that despite the early emergence of FEP calculations of electrostatic energies in proteins (e.g., Refs. 19,43), there are still major convergence problems in both FEP- and LRA-type studies (e.g., Refs. 44,45).

Some of these convergence problems can be reduced by the vdW calculations and the WF approach.

3.01.2.2 Using Simplified Electrostatic Models

Calculations of electrostatic energies provide one of the most effective correlations between the structure and function of proteins (e.g., Ref. 23). As explained in Ref. 28 the first consistent treatment of electrostatic energies in proteins[46] represented all the relevant electrostatic interactions microscopically but used a simplified model of Langevin-type dipoles on a grid to represent the solvent. This protein dipoles Langevin dipoles (PDLD) model facilitated studies of the role of electrostatic energies in protein function with the limited computer power of the mid-1970s (see Ref. 23). Such studies considered microscopically the shape of the protein and its local polarity as well as the effect of the solvent around the protein and to a limited extent the effect of the protein reorganization (which was modeled by energy minimization). The subsequent advance in Poisson–Boltzmann (PB)-type models has allowed macroscopic continuum approaches to take into account the shape of the protein.[47,48] Early discretized continuum models involved some of the inconsistencies of the Tanford–Kirkwood (TK) model (see discussion in Ref.28). However, recent PB models have represented these dipoles explicitly, and became increasingly semimacroscopic.[49]

In many cases, one finds that macroscopic and semimacroscopic models give more stable results than the corresponding microscopic models. This interesting feature is due to the fact that the microscopic models involve compensation of large numbers while the macroscopic models assume implicitly that the compensation exists by using a protein dielectric constant, ε_p. Thus, PB models give excellent results when dealing with surface groups but become more problematic when one deals with groups in the protein interiors. Here the problem is that the results depend strongly on the assumed ε_p, which apparently has little to do with the actual protein dielectric but merely with the contributions that are treated implicitly (see Refs. 50,51).

An effective way to exploit the stability of the semimacroscopic models, and yet to keep a clear physical picture, is the semimacroscopic version of the PDLD model (the PDLD/S model[43]). The PDLD/S model takes the PDLD model and scales the

corresponding contributions by assuming that the protein has a dielectric constant, ε_p. Now, in order to reduce the unknown factors in ε_p, it is useful to move to the PDLD/S-LRA model, where the PDLD/S energy is evaluated within the LRA approximation of Eq. (6) with an average on the configurations generated by MD simulation of the charged and the uncharged states (see Refs. 44,51,52). Since the protein reorganization is considered explicitly, we have less uncertainty with ε_p.

In deriving the PDLD/S-LRA binding expression, we note that the cycle of Fig. 1 is composed of electrostatic and nonelectrostatic components and expresses the binding free energy as

$$\Delta G_{\text{bind}} = \frac{1}{2}\left[\left\langle U^{p}_{\text{elec},\ell}\right\rangle_{\ell} + \left\langle U^{p}_{\text{elec},\ell}\right\rangle_{\ell'} - \left\langle U^{w}_{\text{elec},\ell}\right\rangle_{\ell} - \left\langle U^{w}_{\text{elec},\ell}\right\rangle_{\ell'}\right] + \Delta G^{\text{nonelec}}_{\text{bind}} \tag{5}$$

where $U^{p}_{\text{elec},\ell}$ is the electrostatic contribution for the interaction between the ligand and its surroundings, p and w designate protein and water, respectively, and ℓ and ℓ' designate the ligand in its actual charged form and the "nonpolar" ligand where all the residual charges are set to zero. In this expression, the terms $\langle U_{\text{elec},\ell} - U_{\text{elec},\ell'}\rangle$, which are required by Eq. (4), are replaced by $\langle U_{\text{elec},\ell}\rangle$ since $U_{\text{elec},\ell'} = 0$. Now, the evaluation of the nonelectrostatic contribution $\Delta G^{\text{nonelec}}_{\text{bind}}$ is still very challenging, since these contributions might not follow the LRA. A useful option, which was used in Refs. 20 and 53 is to evaluate the contribution to the binding free energy from hydrophobic effects, vdW, and water penetration. Another powerful option is the so-called linear interaction energy (LIE) approach.[26,54] This approach adopts the LRA approximation for the electrostatic contribution but neglects the $\langle U_{\text{elec},\ell}\rangle_{\ell'}$ terms. If we use the PDLD/S approach and the Us that correspond to this approach (see Ref. 55), we can write the binding energy using

$$\Delta G^{\text{elec/PDLD/S-LRA}}_{\text{bind}} = \frac{1}{2}\left\{\left[\left\langle \bar{U}^{p}_{\text{elec},l}\right\rangle_{l'} + \left\langle \bar{U}^{p}_{\text{elec},l}\right\rangle_{l}\right] - \left[\left\langle \bar{U}^{w}_{\text{elec},l}\right\rangle_{l'} + \left\langle \bar{U}^{w}_{\text{elec},l}\right\rangle_{l}\right]\right\} \tag{6}$$

$$\Delta G^{\text{PDLD/S-LRA}/\beta}_{\text{bind}} = \Delta G^{\text{elec/PDLD/S-LRA}}_{\text{bind}} + \beta\left(\left\langle U^{\beta}_{\text{vdw},\ell}\right\rangle_{\ell} - \left\langle U^{w}_{\text{vdw},\ell}\right\rangle_{\ell}\right) \tag{7}$$

where β is an empirical parameter that scales the vdW component of the protein–ligand interaction. A careful analysis of the relationship between the LRA and LIE approaches and the origin of the α and β parameters is given in Ref. 53

It is also important to mention that the increasingly popular molecular mechanics PB surface area (MM/PBSA) model,[56] and the related molecular mechanics-generalized Born surface area MM/GBSA are apparently inconsistent adaptations of the PDLD/S-LRA idea of MD generation of configurations for implicit solvent calculations, while only calculating the average over the configurations generated with the charged solute (the first term of Eq. 6). More importantly, the MM/PBSA and MM/GBSA are problematic on other key levels. The first problem is that the model uses $\varepsilon_p = 1$ without sufficient relaxation, this means that the interaction between ionized groups is overestimated in a major way. The model uses entropy estimates that are simply incorrect (see Ref. 55) and finally it uses a vdW term that sometimes compensates for the error in the other terms. The problems with the (MM/PBSA) have been quantified and demonstrated clearly in Ref. 55.

3.01.3 Calculating Binding Free Energies by Different Strategies

Armed with the computational approaches described in the "Computational Strategies" section, we may now examine different strategies for the calculation of binding free energies.

3.01.3.1 Studies of Drug Binding by FEP Approaches

In principle, we can evaluate binding energies by the two paths depicted in Fig. 1 and Fig. 2. The path of Fig. 2 involves a direct PMF calculation but such a strategy still involves major convergence problems in trying to capture the solvent protein rearrangements associated with the transfer of the ligand from the bulk water to the protein-binding site. The path of Fig. 1 involves a cycle that can be evaluated by the FEP approach. This approach gives reasonable results in studies of differences in binding due to small "mutations" of the given ligand[13,14,57] (e.g., replacement of NH_2 by OH) but it involves major convergence problems when one tries to evaluate the absolute binding free energy of medium-size ligands. In such cases, one has to "mutate" the ligand to "nothing," and at present, the reported results are quite disappointing except in cases of small ligands. Nevertheless, this approach can be used in some well-defined test cases of polar or charged ligands (e.g., Refs. 20,58,59) and it can be considered, at least in principle, as the "cleanest" approach for calculations of absolute binding energies. At any rate, the constant increase of computer power makes FEP calculations more and more practical and thus we try to consider here the current performance. A good example is provided by a case where a careful benchmark of Ref. 60 encountered large deviation and was forced to scale the ligand charge. Our study includes WF and the move from nonpolarized to polarized force field (see Table 1) and showed significant improvement upon moving to polarized force field. Our finding can serve as a useful example for the advantages of using polarizable force field.

Interestingly, as will be shown in the following section, the PDLD/S gives better results than the present FEP calculations. Thus, we leave the more systematic exploration of the current problems of the FEP approach to subsequent studies.

Table 1 The trend in FEP calculations of binding energies of a challenging cases[a]

Ligand	*PDB*	*Experimental (kcal/mol)*	*FEP (kcal/mol)*	*FEP/induced (kcal/mol)*
	4JM8	−5.8	−15.6	−3.9
	4JQJ	−5.8	−18.7	−9.5
	4JPT	−5.7	−14.3	−7.9
	4JQK	−4.7	−13.0	−4.8

[a]The benchmark considered includes cases where Ref. 60 found large deviations for charged drugs.

3.01.3.2 Evaluation of Absolute Binding Energies by the LRA and LIE Approaches

In the general case of large ligands, it is not obvious that the FEP approach is the optimal option and the best alternative is probably provided by the PDLD/S-LRA β method of Eq. (7). This approach is particularly effective in calculating the electrostatic contribution to the binding energy.[20,53]

The idea that conformational averaging is useful for free energy calculations seems quite obvious, generally understood, and widely used.[56,61] What is much less understood, and somehow still ignored by a large part of the computational community, is that a proper LRA treatment requires averaging on both the charged (or polar) and nonpolar states of the ligand. The frequently neglected average on the nonpolar state (the second term of Eq. 6) plays a crucial role in proteins as it reflects the effect of the protein preorganization. The role of this term in binding calculations has been discussed in Ref. 53 and its importance has been illustrated in an impressive way in studies of the fidelity of DNA polymerase.[62] This study found that the crucial process of discrimination between correct and incorrect bases is determined to a significant extent by the preorganization of the binding site plus the template.

A systematic study[55] of the performance of the LIE and LRA β considered the benchmark of **Fig. 4**.

The results of the study are given in **Fig. 5** and show a very reasonable agreement between the calculated free energy and observed results.

3.01.3.3 Semimacroscopic and Macroscopic Calculations of Ligand Binding

As pointed out earlier, although microscopic models are rigorous in principle they may involve major convergence problems and thus it may be useful to explore binding energies by semimacroscopic and macroscopic approaches. This includes the use of Eq. (5) and the PDLD/S-LRA β model of Eq. (7), as well as other approaches mentioned in the "**Using Simplified Electrostatic Models**" section. The electrostatic contribution of the PDLD/S-LRA β is quite rigorous since it considers explicitly the protein reorganization and thus allows one to use less arbitrary ε_p than the one used by more macroscopic approaches. The more *ad hoc* nonelectrostatic term also seems to be quite effective with the proper scaling. An example of the performance of the PDLD/S-LRA β-type approach in binding calculations is given in **Fig. 5**.

Another validation has been obtained recently and is summarized in **Table 2**. In this case, we consider the very challenging benchmark of Refs. 60 and 63 comparing the FEP calculations reported in this works to the PDLD/S-LRA β results.

3.01.3.4 Protein–Protein Interactions

One of the most exciting aspects of rational drug design involves the search for drugs that would disrupt the interaction between proteins that transmit different signals in the cell cycle. Here, the hope is that understanding the nature of the interaction between two proteins will allow one to design drugs that would exploit the same type of interactions, and thus will bind to one of the proteins and compete with the binding between these proteins. An example of this idea is given in **Figs. 6** and **7**.

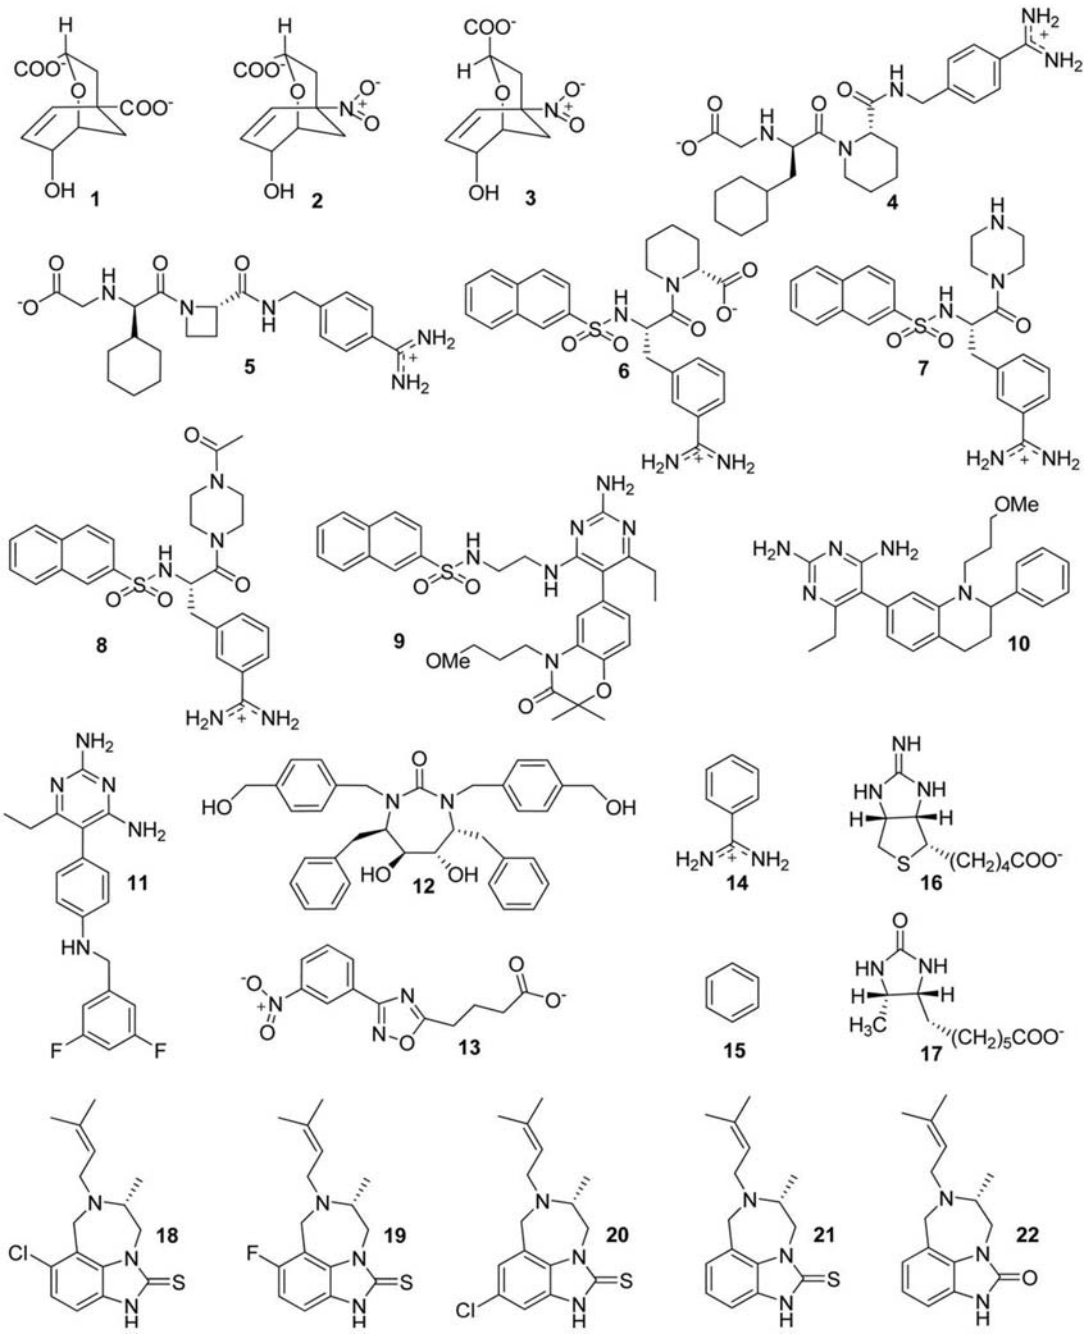

Fig. 4 The benchmark used for the binding calculations of Ref. 55.

Muegge et al. ([64]) explored carefully the effect of the protein reorganization in the Ras/Raf complex. Several approaches and several levels of the PDLD/S-LRA model were explored. However, disappointing results were obtained from the formally most rigorous treatments that consider explicitly the reorganization of the proteins during the binding process while using small ε_p. The most promising results were obtained by using the PDLD/S with $\varepsilon_p = 4$ for dipoles interactions and the simple coulomb charge—charge with large dielectric ($\varepsilon_{eff} = 23$ for charge–charge interaction). This approach was found to be effective in both predicting the effects of mutations on the protein–protein binding energy and in estimating the overall absolute binding energies. Thus, the use of small ε_p for dipole and large ε_{eff} for charge–charge interaction can be quite effective in providing estimates of the contributions of different residues to protein–protein interactions. These types of calculations can be quite useful for designing drugs that would disrupt the binding of Ras and Raf and help fight cancer (see Fig. 6).

Absolute Binding Free Energy Calculations: On the Accuracy of Computational Scoring of Protein–Ligand Interactions. *Proteins: Struct., Funct., Bioinf.* **2010**, *78*, 1705–1723.

3.01.3.5 Binding Entropy Calculations

One of the greater challenges in studies of binding energies is the evaluation of binding entropies. Here, it was realized that the frequently used harmonic or quasiharmonic approximations[65,66] are unlikely to give quantitative results. In a search for a more quantitative model, we adopted our early idea[67] and developed a variational restraint release (RR) approach, which is described in detail elsewhere.[68] This approach was used recently[69] in evaluation of the binding entropy of benzene to bacteriophage T4-lysozyme, and the corresponding thermodynamic cycle is depicted in Fig. 8.

3.01.4 Perspectives

The calculations of binding energies have advanced enormously since pioneering studies that did not include the solvent.[70] However, despite the qualitative and semiquantitative advances in calculation of binding energies, the progress in getting actual quantitative predictions has been quite slow. A part of the problem may have been associated with the belief that approaches that are formally rigorous may have enormous difficulties in converging. This problem has been enhanced by the fact that very few workers tried to validate their approach by comparing the calculated and observed results of challenging benchmarks (see the "Semimacroscopic and Macroscopic Calculations of Ligand Binding" section). Here, as stated earlier, the discrimination between the binding affinities of different ligands in the 2 kcal/mol limit has been disappointing. Our early attempts to evaluate

Table 2 Comparisons of the accuracy of binding energy calculations[a]

Ligand	Exp	FEP	PDLD/S-LRA β			PDLD/S-LRA β with water flooding		
			Intrinsic	Elec	Total	Intrinsic	Elec	Total
(PDB:4JQM)	−7.1	−4.2[60]	−4.6	−6.1	−10.7	−3.6	−5.2	−8.8
(PDB:4JPU)	−6.6	−3.3[60]	−6.7	−6.1	−12.7	−2.1	−6.2	−8.2
(PDB:4JQK)	−4.7	−2.3[60]	5.4	−4.9	0.5	0.4	−3.2	−2.8
 (PDB:3HUK)	−4.5	−1.3[63]	−3.6	0.0	−3.6	−3.4	−0.3	−3.7

[a]Only the cases where Refs. 60 and 63 obtained poor agreement were considered. Apparently the PDLD/S-LRA β results are more reliable than the FEP results for charged ligands. "Intrinsic" designates the results when the charges of the protein ionizable residues are set to zero and "elect" is the change in the binding energies when the effect of the ionizable residues is added by using a charge–charge interaction at dielectric of 40.

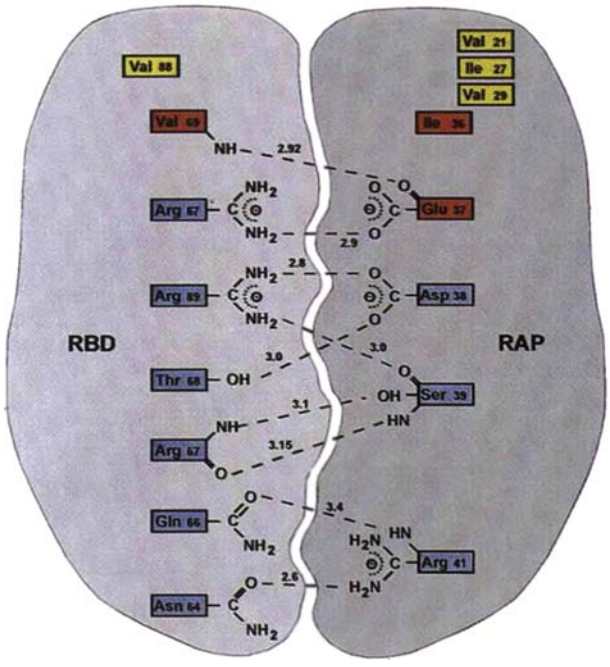

Fig. 6 Showing the residues involved in the Rap/Raf interaction. Taken from Kamerlin, S. C. L., et al. Why Nature Really Chose Phosphate. *Quart. Rev. Biophys.* **2013**, *46*, 1–132.

the binding free energies by the fully microscopic FEP approach were disappointing even with the use of a polarizable force field and the use of proper long-range treatments. Note, however, that the calculations did not include the WF treatment.

As an instructive example it is useful to consider the benchmark of chorismate mutase,[71] where we considered a highly charged active site and ligands in three different charged states (see Fig. 9). Our attempts to use the PDLD/S-LRA semimacroscopic approach were reasonably successful (see Fig. 9), but still far from being satisfactory. In the fully microscopic cycle, we must have significant convergence problems. What comes to mind are the incomplete protein reorganization and water penetration that seems to lead to a major overestimate of charge–charge interactions.[64,72] In dealing with the semimacroscopic estimate, we can handle the

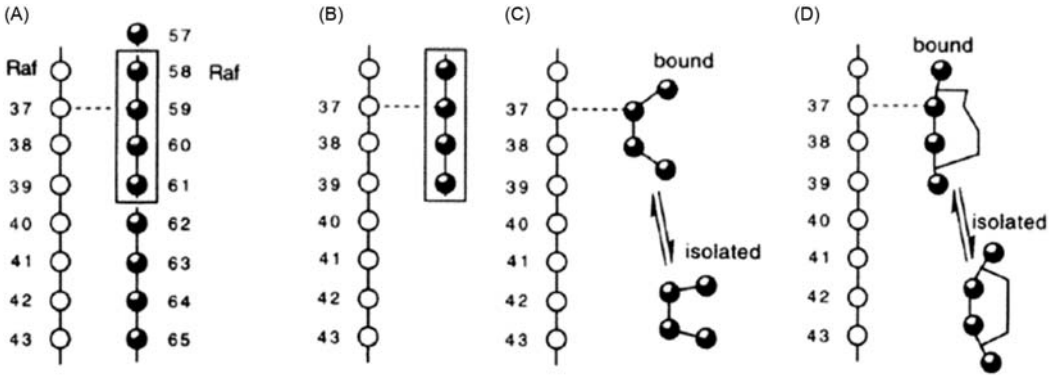

Fig. 7 Fighting Ras/Raf interaction. Outlining a way for exploiting structural information from the Ras/Raf interface, for designing drugs that deactivate defected Ras. In this strategy we (A) identify the regions in Raf with strong contribution to binding, (B, C) examine if the corresponding short peptides also bind strongly, (D) and then examine if cyclic analogues of those peptides also retain strong binding. The resulting constructs would be good drug candidates. Taken from Kamerlin, S. C. L., et al. Why Nature Really Chose Phosphate. *Quart. Rev. Biophys.* **2013**, *46*, 1–132.

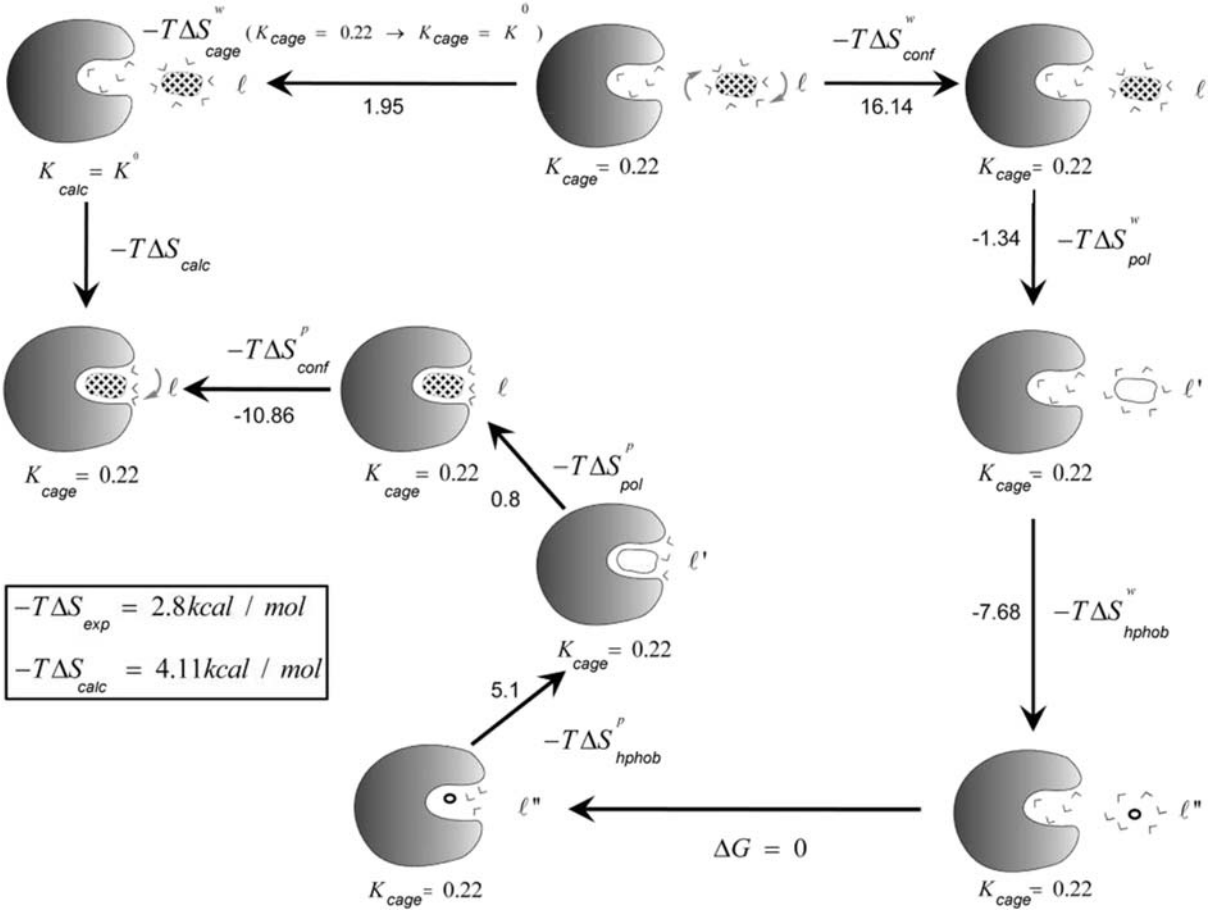

Fig. 8 The thermodynamic cycle used to calculate the overall binding entropy of binding of benzene to bacteriophage T4-lysozyme. ℓ(⬬) and ℓ'(⬭) represent the charged and uncharged (where all of the residual charges of the ligand were set to zero) forms of the ligand, respectively, while ℓ''(○) represents the ligand being reduced to "nothing." "*p*" and "*w*" designate protein and water, respectively. K_{cons} = large designates a large constraint on the molecule(s) for which RR energy is being calculated. The calculations use $K_{cage} = 0.22$ kcal mol^{-1} Å^{-2} and $K^0 = 0.026$ kcal mol^{-1} Å^{-2}, which correspond to a molar volume (1660 Å^2) in the indicated steps. Also, note that the calculations of the polarization and hydrophobic entropies involve a strong constraint on the ligand. The figure does not describe the freezing of the ligands or the solvent molecules explicitly, as this will require more steps.

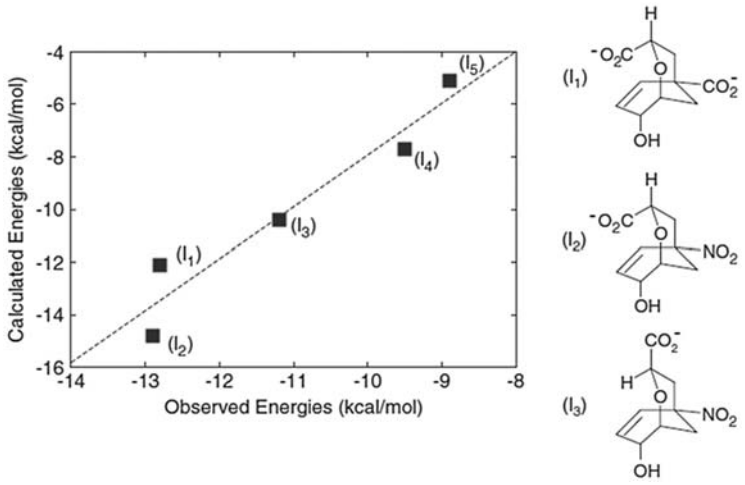

Fig. 9 Calculated and observed binding energies of different ligands of CM. Taken from Kato, M.; Braun-Sand, S.; Warshel, A. Challenges and Progresses in Calculations of Binding Free Energies – What Does It Take to Quantify Electrostatic Contributions to Protein–Ligand Interactions? In *Computational and Structural Approaches to Drug Discovery*; RSC Publishing, 2008; pp. 268–292.

electrostatic problem by using a proper effective dielectric constant for charge–charge interactions, but the nonelectrostatic term still presents a problem.

The difficulties in obtaining reliable results, in fact, an opportunity since they provide clear benchmarks that must be resolved unless one believes in metaphysical missing effects. That is, one can and should require that the PDLD/S-LRA β and the microscopic simulations will both converge to the experimental results. Note that at present only the PDLD/S-LRA formulation can provide a clear bridge between the semimacroscopic and microscopic models.[51] At any rate, requiring that the microscopic and macroscopic simulations will give the same results for each part of the overall thermodynamic cycle should give eventually clear clues about the origin of the problems with these approaches.

One of the most serious problems in obtaining a converging result in calculations of binding free energies is the fact that the binding process involves a change in the number of internal water molecules and that this process is probably associated with a slow relaxation time. In order to overcome this challenge, we introduced the WF approach. This type of treatment is expected to provide a clearer insight into the nature of β and significantly improve the microscopic results.

Despite the earlier and current problems, there is no doubt that computer-aided free energy calculations will eventually become the key quantitative tool in rational drug design. It is also clear that quantitative evaluation of electrostatic free energies will be one of the most important factors in advancing reliable calculations of ligand binding to proteins. Once a more quantitative level is achieved, we can see several promising directions. For example, it will be possible to augment automated screening procedures and to refine the final drug candidates. Here, the ability to understand what interactions are responsible to the optimal binding may help in advancing better ideas about new drugs that were not included in the original refinement process.

Another promising direction where computational approaches can in fact compete with combinatorial drug screening is the fight against drug resistance. Here, the challenge is to anticipate the mutations that will be developed by the resistant strain (e.g., the HIV virus) and design a drug that will still be bound strongly despite the emergence of new mutations. A preliminary advance in this direction has been made in our lab by calculating the so-called vitality value ($\gamma = (k_{cat}/K_M) \times K_i$), which expresses the competition between the attempt of the mutated virus to increase K_i and the requirement that the specific protein (e.g., an HIV protease) will still perform its usual catalytic function. Evaluating simultaneously the PDLD/S contribution of each residue to k_{cat}/K_M (the binding energy of the transition state) for the natural substrate and the K_i for the given drug produces the corresponding contribution to the vitality factor.[73,74] With this predicted value, one can look for mutations that will maximize γ, and thus predict the optimal drug resistance process. Once the next move of the virus is anticipated, the problem is reduced to the design of drugs that will bind strongly to the new, predicted mutants. Examples of proof of principle are given in Refs. 73,74 Other major advances in computer-aided drug design will clearly emerge in the future and the only question is how long it would take to make such approaches fully quantitative. Here, we believe that approaches that would go below the 1 kcal/mol error could be considered as sufficiently quantitative approaches and advance us to a new era in computer-aided drug design. It is quite possible that approaches that involve direct calculations of the PMF for binding will start to be effective with sufficiently long simulation time.

3.02.1 Hardware and Software Advances

The main obstacles to the progress in application of molecular dynamics (MD) to drug discovery have been the computational cost of the simulations, leading to precision and convergence issues, and inaccuracies of the underlying physical model used. Problems with convergence arise from incomplete sampling of all accessible configurations. As the properties of interest often depend on an average of all ensemble conformations, it will not be possible to have a converged estimate of those properties until the simulation has sampled all, or at least many, such conformations. Issues with the physical model arise on the other hand from the assumptions and simplifications made with respect to the classical treatment of atoms and molecules, as well as inaccuracies in the derivation of parameters. The two problems are however interconnected, because in order to be able to rigorously test a physical model and improve upon it, it is necessary to be able to compute the quantities of interest with a precision similar to the experimental counterpart. For the most part this necessitates access to the relevant space- and timescales.

There has, however, been a steady increase in the scales accessible by molecular dynamics simulations over the past few decades. This has arisen, at least in part, from a direct consequence of Moore's Law for semiconductors and computing, which observes that the number of transistors on CPUs and the consequent computer power approximately doubles every 2 years.[1] However, algorithmic advances have also played an important role in expanding simulations capabilities, in particular by maximizing the opportunities presented by new hardware technologies such as graphical processing units (GPUs) for example. In fact, simulation speed has been growing faster than Moore's Law,[2] suggesting that hardware and software innovations have worked in synchrony to deliver necessary improvements in simulation performance as witnessed by both the scale[3] and timescales[4] of simulation now achievable.

3.02.1.1 Special-Purpose Machines

Among the most notable hardware advances since the turn of the century is the development of Anton, a specialized machine designed specifically to accelerate MD simulations, by D.E. Shaw Research.[5] Previous efforts in this direction were not particularly successful due to the fact the production of specialized chips is demanding and, without adequate resources, too slow to keep up with the pace of general-purpose processors. Yet, D.E. Shaw Research managed to develop a parallel machine, based on 512 specialized nodes that interact in a tightly coupled manner through a dedicated high-speed communication network, which performs simulations at about two orders of magnitude of the speed of standard hardware.[5] In the years following its release, Anton allowed ground-breaking simulations of milliseconds in length, two orders of magnitude longer than the lengthiest simulation performed before,[6] which permitted the observation of phenomena such as the folding of small proteins into their native structure,[7] or the unbiased binding of a drug into a binding pocket.[8]

Lindorff-Larsen et al.[9] reported the folding of 12 diverse small proteins through simulation on the Anton chip. The authors observed at least ten folding and unfolding events for each of these proteins using simulations of length between 0.1 and 1 ms. Other than proving how relatively simple physics-based models are able to fold proteins into their native structure, the work suggested the existence of a preferential folding route for the studied systems. The ability to simulate and study protein folding pathways will impact our understanding of misfolding diseases such as Alzheimer's and Parkinson's, and possibly on our ability to develop strategies to tackle such illnesses.

The same year, Shan et al.[10] showed how long unbiased molecular dynamics simulations were able to capture the binding process and final (crystallographically observed) pose of two Src kinase inhibitors; PP1 and dasatinib. These results are potentially significant for drug discovery, as the methodology does not assume any prior knowledge of the binding location and pose. Thus it is conceivable that this approach might be applied to the discovery of allosteric inhibitors targeting previously unknown binding sites. Moreover, it allows the elucidation of the binding pathway, which can significantly affect the binding kinetics. Longer timescales not only allow us to access biologically relevant timescales, but also provide the fundamental framework necessary to test the validity of the force fields, as it will be discussed later.[11–13]

Currently, an upgraded version of this machine (Anton-2) is in use at D.E. Shaw Research, while the previous version was donated to the Pittsburgh Supercomputer Centre for noncommercial use. This new machine achieves the impressive performance of 85 μs/day on dihydrofolate reductase (DHFR), a standard benchmark system of 23,558 atoms and breaks the 1 μs/day barrier on million-atom systems; for instance, using all 512 nodes (33,792 processors) a performance of 3.6 μs/day is achievable for a ribosome system containing 2.2 million atoms.[14]

3.02.1.2 Graphics Processing Units

While special-purpose architectures can deliver extraordinary performances as described above, they are not widely available as a significant investment in human and financial resources is necessary for their continuous development. Recently however, another avenue for simulation acceleration has become available that is much cheaper, namely GPUs. Driven by a $100 billion interactive entertainment industry, large and sustained investments in GPU development have resulted in steady increases in performance alongside decreasing costs.[15]

When rendering graphics, many of the operations required are simple but large amounts of data need to be handled. GPUs have thus been designed with a large number (hundreds or thousands) of simple processors that work in parallel. GPUs are basically a specialized circuit, built in order to perform a large number of floating-point operations per video frame (Fig. 1). Some of the calculations performed during a molecular simulation are of similar nature to the ones that GPUs can accelerate, such as the computing of the nonbonded pair interactions between a large number of atoms, which is typically the most expensive calculation during a simulation.[15,16] It thus became clear that such computations could be solved faster with the use of GPUs, improving the simulation throughput.[16,17]

In the late 2000s, comprehensive MD engines such as ACEMD[18] and OpenMM[19] have been developed specifically to take advantage of the acceleration provided by widely available GPUs. At the time of publication, in 2009, ACEMD using 3 GPUs

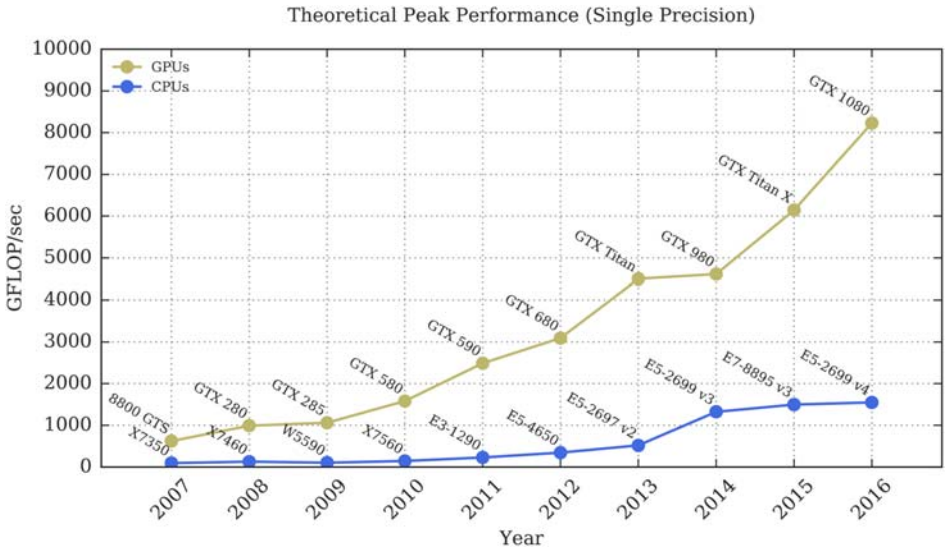

Fig. 1 Performance improvements of CPUs and GPUs in the last decade. The plot compares the GeForce series of Nvidia consumer graphics card with high-end Intel Xeon processors by launch year. Performance for GPUs was taken from https://en.wikipedia.org/wiki/List_of_Nvidia_graphics_processing_units, and for CPU was calculated from data available at https://en.wikipedia.org/wiki/List_of_Intel_Xeon_microprocessors and http://ark.intel.com.

and 3 CPU cores showed a performance on the DHFR benchmark that was roughly equivalent to that of GROMACS on 20 CPU cores.[18] Using ACEMD and a GPU cluster, Buch et al.[20] carried out 50 μs of aggregate simulated time and reconstructed the binding of benzamidine to trypsin. In 2015, the same group carried out similar unbiased simulations for 42 fragments and the protein serine protease factor Xa, for a total of 2.1 ms simulated time and managed to recapitulate binding poses, affinities, and kinetics for a number of the ligands studied.[21] In both cases the use of GPUs enabled such extensive sampling.

Nowadays, most widely used MD software can take advantage of available GPUs to significantly improve simulation throughput and cost-efficiency. Some packages, such as GROMACS, CHARMM, and NAMD, use GPUs in an off-loading approach where the short-range nonbonded interactions are sent to the GPU, while the rest of the calculation is borne by the CPU; in other packages, such as ACEMD or AMBER, almost all of the computation is performed on the GPU. Kutzner et al.[22] recently evaluated a number of hardware setups with GROMACS 4.6 in terms of pure simulation performance, but also performance-to-price ratio, taking also into account the energy consumption of the hardware. From a purely performance perspective, they noted that GPUs increase the speed of a compute node by a factor of 1.7–3.8, with inexpensive GeForce consumer cards also providing a 2–3 factor increase in performance-to-price ratio. As an example, a single node comprising two Intel Xeon E5-2680v2 processors (10 cores each) offered 26.8 ns/day of simulation on a membrane protein system of 81,743 atoms. At the time of their study in 2014 this setup would have cost about 4400€. However, when adding a single Nvidia GeForce GTX 980 card, the performance doubled to 52.0 ns/day, against an extra cost of only ~450€. The peak performance of 66.9 ns/day was obtained with four GTX 980 cards, however, adding the third and fourth GPU improved performance only marginally as the simulation became CPU-bound, consequently not improving the cost-efficiency of the setup. When considering energy consumption, nodes with one or two GPUs have an increased power draw and energy cost, yet still produce from 1.5 to 2 times the MD trajectory per € invested than CPU-only nodes. The authors also remarked that the energy efficiency improvement of the newer Maxwell architecture as compared to the Kepler one, results in a ~20% reduction of trajectory costs. With AMBER14, a soluble test system of 90,906 atoms provided an output of 4.5 ns/day on two E5-2650v3 processors (10 cores each), going to 34.6 ns/day when using one GTX 980 card (almost a 8× speedup) and up to 50.2 ns/day with two GTX 980 cards. It is interesting to note that since the code barely uses the CPU, the performance does not become CPU-bound when using more GPUs, reaching an output of 90.0 ns/day when using four GTX Titan X cards.

3.02.1.3 Cloud and Distributed Computing

In addition to new hardware and faster and larger supercomputers, recent years have seen the rise of cloud and distributed computing.[23–25] Cloud computing involves the use of a network of remote servers to process and store the data[23] and allows access to large computer power with flexible pay-as-you-go pricing schemes. Some private vendors such as Amazon Elastic Compute Cloud (EC2; https://aws.amazon.com/ec2/) or IBM Platform Computing (http://www-03.ibm.com/systems/uk/platformcomputing/solutions/hpccloud.html) have started providing services on the cloud specifically for HPC. Google have instead been supplying computing facilities for academic research for free, but based on a competitive application process. In its first year in 2013, it provided about 1 billion core-hours for projects covering a wide range of science and engineering challenges including antibiotic resistance, drug discovery,[26] and protein structure prediction and design. As a consequence of this trend, software to facilitate the execution of ensemble of simulation on remote cloud services has been developed.[27]

Distributed computing projects such as Folding@Home or Rosetta@Home rely instead on the unused power of volunteers' personal computers, where anyone can contribute by downloading a software client.[25,28] This creates a large network of heterogeneous hardware that is available to the researcher for performing molecular dynamics simulations. Presently, more than 100,000 users are contributing to the Folding@Home project, providing over 20 petaflops of computing power, comparable to the peak performance of IBM Sequoia, the third most powerful supercomputer as of late 2015 (see https://www.top500.org). Since the early 2000s, such computing power has been employed for many important computational studies on protein folding and design.[29–37] Similarly, GPUGRID.net was released in 2007 and uses the graphics cards of volunteers in order to pursue scientific research in cancer, HIV, and neural disorders through the use of simulations.[38–41]

Cloud and distributed computing provide much raw power at low cost. However, they do not provide the same communication and I/O performance as supercomputing. The strength of distributed systems is that they are cheaper than supercomputers, as they tend to use off-the-shelf computers for processors and memory, which also require minimal cooling costs. However, high-speed network and storage, and tight connections between nodes, mean that many nodes of supercomputers such as Tianhe-2, Titan, or Sequoia, can work together on the same tasks since data can move between processors rapidly. Supercomputers are therefore still more suited for highly-complex, real-time applications. For molecular dynamics simulations specifically, it means that running a very large simulation consisting of millions of atoms would perform better on an HPC facility. On the other hand, running thousands of small simulations on cloud/distributed computing would be more cost effective without suffering much performance loss. Moreover, the analysis of large amounts of data also benefits from the communication hardware provided by HPC facilities. The data need to be read in (often as whole data sets) and processed. Consequently, aspects such as data I/O, CPU speed, and node communication become important factors.

3.02.1.4 Novel Algorithms and Parallelization

Hardware advances need to be combined with new and improved software and algorithms in order to maximize any potential benefits that arise. GPUs have provided probably the most significant step change in recent years; since the introduction of general

GPU programming platforms, such as NVIDIA's CUDA in 2006 or OpenCL in 2009, the use of the new hardware for scientific applications has become much more accessible. Prior to these developments, graphics specific application programming interface (APIs) such as OpenGL had to be used in order to perform calculations that were not related to the rendering of vector graphics, making the development of new code time consuming. Similarly, the availability of tools like MPI and OpenMP have allowed the implementation of parallel algorithms for multicore machines, including large supercomputing clusters, greatly increasing the performance of MD codes. As a result, all widely used MD codes have substantially improved their parallel performance in the last decade. For instance, as part of the Blue Gene project, scientists at IBM have been exploring parallel strategies in order to achieve strong scaling for their Blue Matter simulation code; in 2006 they reported continued speedup to fewer than three atoms per node.[42] Scaling is important as the number of cores available increases; there will be the issue of using efficiently a large number of cores for small and medium size systems.

MD algorithms have been constantly refined in order to decrease the communication requirements between processors, resulting in decreased latency. Interprocessor communication is necessary on parallel machines when evaluating forces on interacting particles. In early designs, because of its simplicity and the fact that it was fairly efficient over a limited number of cores, particle decomposition was the main method employed to distribute the computation of near interactions across the available processors.[43,44] In this scheme, at the beginning of the simulation each particle in the box is assigned to a processor, which then computes its interactions at each time step. However, this method does not scale well with system size and number of cores: since the decomposition is static, but the particles diffuse through the simulation box, the interaction partners of a specific particle will be distributed across the whole box and many of the CPUs will be involved in the computation, resulting in a large communication volume.[43]

Spatial decomposition methods on the other hand can really take advantage of the locality of the interactions, by dividing the space of the simulation into a number of cells and dynamically assigning particles to processors based on the location of each particle. In this way, particles in a cell will interact only with other ones in the same cell or in the neighboring cells, improving data locality and minimizing interprocessor communication requirements despite the additional book-keeping necessary to keep track of particles moving between cells. In addition, many modern parallel machines (e.g., Blue Gene/L and Cray's T3D, T3E, and XT3 systems) have networks with toroidal topology, so that spatial decomposition allows matching the box grid to the network grid for faster data exchange.[45]

A number of spatial decomposition methods have been developed during the years, but more recently the so-called "neutral territory" methods have provided a significant reduction in the amount of data that needs to be exchanged between cores.[45–47] Due to particle diffusion across spatial domains of inhomogeneous systems, load imbalance between processors can be an issue as the number and type of particles in each domain determine the load. The issue is however easily solved by dynamically balancing the load on the cores by shifting the boundaries of the domains.[43] For a more in-depth review on a number of decomposition methods see Refs.[43–45]

Other algorithmic advances have been related to the acceleration of floating-point calculations, for instance by the development of custom math functions: Enenkel et al. reported a number of functions optimized for MD, improving floating-point efficiency.[48] Alternatives to the widely used Particle Mesh Ewald (PME) method for the computation of long-range electrostatic interactions have been proposed: the multilevel (or multigrid) summation method provides similar speed and accuracy to the traditional PME, but it can also be used for semiperiodic and nonperiodic systems.[49–52] Semiperiodicity might be useful for the simulation of different solvent conditions across a membrane for instance. Such a method has also been shown to provide improved parallel scalability over PME as implemented in NAMD for a system of size <100 K atoms simulated on over a thousand cores.[50] A number of improved implementations of the traditional bonds constraint method SHAKE have been proposed,[53–56] as well as alternative methodologies that are more easily parallelizable for global constraints such as LINCS.[57,58]

3.02.2 Force Field Advances

In the last decade the trend of force field improvement continued. While their functional forms have remained unvaried, their parameters have been modified in order to better match experimental and quantum mechanical data. One concern that has only recently been addressed, is to what extent force field parameters reproduce longer-timescale properties. In 2012, Lindorff-Larsen et al.[11] used Anton to access long timescale simulations and assessed the performance of a number of modern force fields from the AMBER, OPLS, and CHARMM families through comparison with experimental data. The test evaluated the ability of the force fields to reproduce folded protein structure and fluctuations from NMR data, secondary structure content, and to correctly fold small proteins into their native structure. The results indicated that the force fields considered showed steady improvement during the previous decade, with the most recent versions providing the most accurate descriptions of different protein structural and dynamical properties.

However, despite years of optimization and steady improvement, current models are still far from perfect and there is still plenty of room for improvement. In fact, the same study mentioned above also identified some deficiencies; in particular, the force fields did not manage to capture the temperature dependency of the secondary structure propensities. Piana et al.[13] used the fast-folding variant of the villin headpiece as a test case in order to assess the ability of four force fields to fold the protein into its native structure. While they observed that all force fields correctly folded the protein with rates in agreement to experiment, it was noticed that the folding mechanism and the properties of the unfolded states strongly depended on the force field employed. Rauscher et al.[59] have

instead recently studied the structural ensembles generated with μs-long simulations for intrinsically disordered proteins (IDPs). The group compared eight different force fields for a total simulation time of almost a millisecond, and found that different force fields yielded markedly different ensembles that differed in chain dimensions, hydrogen bonding, and secondary structure content. While IDPs are highly sensitive to force field parameters given their rugged energy landscape, the observation that changing the force field had a larger effect on secondary structure content than changing the entire peptide sequence points to clear limitations in the physical model.

Here, we will focus mainly on some of the most popular fixed-charge all-atom force fields, while an overview of recent developments on polarizable and coarse-grained force fields will be given too. Notable exclusions from this review are improvements on united-atom force fields (such as the improvements to the GROMOS force field[60]), universal force fields,[61,62] reactive force fields,[63,64] and force fields with more complex functional form such as the Merck Molecular Force Fields.[65]

3.02.2.1 Protein Force Fields

A number of researchers noticed that the AMBER ff94 and ff99 energy functions produced an imbalanced proportion of secondary structure elements with over-stabilization of α-helices. In 2006 the backbone dihedrals of the AMBER ff99 force field were improved by fitting the energies of multiple conformation of glycine and alanine tetra-peptides to high-level ab initio quantum mechanical data.[66] Additional backbone torsion improvements by Best and Hummer to correct the α-helical propensity of the model resulted in the ff99SB* and ff03* force fields in 2009.[67] Lindorff-Larsen and coworkers introduced ff99SB-ILDN in 2010, which improved side chain torsions, by fitting energies to QM calculations and comparing microsecond-long MD simulations to NMR data.[12] Other enhanced versions of ff99SB were the ff99SB-nmr by Li and Brüschweiler[68] and ff99SB-phi by Nerenberg and Head-Gordon.[69] At the time of writing, the latest AMBER force field available is ff14SB, which is a result of a complete refit of all amino acid side chain torsions. The work also included multidimensional dihedrals scans to improve the parameter transferability. Additional empirical adjustments were made to protein backbone dihedral parameters in order to better reproduce NMR scalar coupling data.[70]

Analogous backbone dihedral issues have been found for other force fields too. In 2004 MacKerrel and coworkers used QM and crystallographic data to improve the peptide-backbone parameters of CHARMM22, introducing the CHARM22/CMAP[71] force field. Despite some degree of success for protein folding applications,[72] flaws were still present as indicated by the misfolding observed in long simulations of the fast-folding WW domain[73,74] and the discrepancy of the folding mechanism of the villin headpiece subdomain between simulations and experiment.[72] Piana et al.[13] tackled the issue of α-helical over-stabilization[75] by replacing the CMAP correction with new backbone torsion terms, which resulted in a force field they named CHARM22*. A substantial revision of the CHARMM force field parameters by the MacKerell lab, trying to address the above shortcomings, resulted in 2012 in the improved CHARMM36 force field.[76]

Another popular protein force field that has undergone constant refinement in the last 20 years since its initial introduction is the OPLS-AA force field.[77] The nonbonded interactions in OPLS-AA are parameterized in order to reproduce properties of pure organic liquids, such as heat of vaporization, densities, and hydration free energies, while torsional parameters are fit to available experimental or QM data. The original torsion scans were performed at the Hartree-Fock (HF) level of theory with a small basis set due to the computational limitations at the time, but a revised OPLS-AA/L was presented in 2001 where single point energies of HF geometry optimized structures were obtained using local MP2 calculations and a larger basis set.[78] In 2015, the torsional parameters were revised, performing torsional scans with modern hybrid density functionals[79,80] which has resulted in the latest OPLS-AA/M force field.[81]

3.02.2.2 Organic Molecule Force Fields

If simulations are to be used for drug discovery, it is necessary to have a good physical model for small organic molecules in addition to proteins. However, while the chemical space covered by polypeptides has clear boundaries, this is not the case for small organic molecules. The drug-like space is vast with a huge number of possible atom combinations. Even though there are many stable chemical groups in which a molecule can be broken down in to, the properties of such groups can change drastically depending on the neighboring chemical moieties. For instance, the electrostatic properties of an aromatic ring such as benzene depend strongly on its substituents and their relative positions. As a consequence, the development of a general yet accurate organic molecule force field is a difficult task.

Due to the increasing interest in the use of modeling and simulation for drug discovery, since the mid-2000s there has been increasing effort in developing organic molecule parameter sets that are consistent with existing (typically protein) force fields. While OPLS was considered from the beginning as a force field for both organic and biological molecules, others such as AMBER or CHARMM had mainly focussed on proteins. In 2004, the General AMBER Force Field (GAFF) was introduced by Wang et al.[82] and is meant to be compatible with the AMBER family of protein force fields. Since then, the force field has been regularly updated to improve many of the parameters, with these improvements incorporated into each new release (see http://www.ambermd.org).

Following a philosophy that focuses on quality at the expense of transferability, Vanommeslaeghe et al. developed a CHARMM-compatible organic molecule force field, named the general CHARMM force field (CGenFF).[83] CGenFF is actively maintained and constantly being improved.[84] As manual assignment of parameters is cumbersome, prone to errors, and prevents task automation, algorithms for automated atom typing have been developed for both the general AMBER and CHARMM force fields.[85–87] In

addition, due to the fact that encountering missing or imprecise parameters is relatively common given the diversity of existing drug-like species, tools to aid the users in the derivation of new parameters have been developed.[88–91]

Also of note is the proprietary OPLS force field developed by Schrödinger Inc. for proteins and organic molecules. OPLS_2005, OPLS2.1 and the most recent OPLS3 have been developed in order to have a broader coverage of medicinal chemical space and support their free energy perturbation suite for binding affinity prediction.[92,93] In OPLS3, the reparameterization of peptide dihedral angles and the inclusion of off-atom charge sites to better represent halogen bonding and aryl nitrogen lone pairs resulted in more accurate binding free energy calculations.[92] The work reminds us how it is not only the ligand, but also the protein parameters, and how they interplay with each other, that have a substantial effect on modeling approaches to drug design. Overall, it appears that across the different small molecule force fields there has been a focus on the improvement of dihedral parameters and partial charges due to their limited transferability across different chemical species.[94–97]

3.02.2.3 Force Fields for Other Species: Nucleic Acids, Lipids, Sugars, and Water

While proteins represent the majority of current drug targets, there is clearly an interest to model and simulate nucleic acids too. Nucleic acid force fields have historically lagged behind protein force fields; nonetheless, in the last decade there had been significant improvements in the availability of force fields for DNA and RNA simulations. In the early 2000s, the CHARMM27 force field for nucleic acids was released and has been recently updated.[98,99] At the same time, when 50–100 ns long simulation times became available, deficiencies in the AMBER force field for nucleic acids were observed, in particular in the sampling of backbone populations.[100,101] Pérez et al. have provided the improved set of parameters ff99-bsc0[102] and work by Yildirim and coworkers focussed on reparameterizing the RNA chi torsional angles.[103–105] Additional recent work focussed on the derivation of specific improved parameters for both RNA[106,107] and DNA.[108,109] Testing and benchmarking of all these parameter modifications and extensions is still very much an on-going exercise.

With increasing interest in the study of membrane properties and the role of lipids in the modulation of protein functions, dedicated lipid parameter sets that are compatible with other protein force fields are increasingly becoming available and accurate. In 2005, a revised version of CHARMM27 with optimized parameters for aliphatic tails was published and termed CHARMM27r.[110] Later in 2010, the CHARMM 36 lipid FF was developed by improving the parameters of the headgroups and ester links.[111] On the other hand, AMBER had not had support for lipid parameters until 2012, when Lipid11 and GAFF lipid were released.[112,113] Lipid14 was later released in 2014 as a significant advance over the previous AMBER lipid force fields[114] and allowed the artificial surface tension term that was previously required to keep the correct phase to be dropped. Lipid14 compared favorably with a number of experimental properties, such as area/volume per lipid, bilayer thickness, NMR order parameters, scattering data, and lipid lateral diffusion. In 2015, the first example of spontaneous lipid bilayer formation during unbiased all-atom simulations was presented using both the CHARMM36 lipid FF and AMBER Lipid14.[115]

Carbohydrates are fundamental building blocks in biology and have important roles in many cellular processes. Moreover, carbohydrate-based structures are of interest for drug design purposes.[116,117] However, the modeling of carbohydrates presents a distinct set of challenges due to their particular structural and electronic properties. The high number of chiral centers, rotatable bonds, and linkages between units, results in a large number of complex structures. In addition to the high number of polar groups, peculiarities such as the anomeric effect cause complex charge distributions around the molecule, contributing to the difficulty to derive adequate fixed partial charges. As a consequence, carbohydrate force fields are currently not as mature as force fields for other biological small molecules such as lipids and it may well be that more complex functional forms are required to fully capture the properties of carbohydrates properly.[118,119] The main carbohydrate atomistic force fields currently available are GLYCAM06[120,121] and CHARMM36.[122–125] In particular GLYCAM06, which is compatible with the AMBER force field, supports a large collection of carbohydrates with parameters for both anomeric and enantiomeric forms of the compounds. An OPLS version for carbohydrates dates back to 2002,[126] and there have also been contributions to the GROMOS force field.[127]

The quality of the solvent model is fundamental too, as properties such as partition coefficients and binding affinities depend strongly on the solute–solvent interactions. Water models are also deeply entrenched in the fabric of all solute force fields, so that it is difficult to replace water models straightforwardly. However, the prevalent models of liquid water were developed decades ago[128] despite computational advances and larger availability of experimental data. This motivates the development of new models showing better agreement with experiment.[129] Among recent developments on fixed-charge water models, there is the 4-point Optimal Point Charge (OPC) water model, which showed an improved performance for a number of different bulk properties as compared to other popular models such as TIP3P, SPC/E, TIP4P-Ew, and TIP5P.[129] The authors also suggest an improved performance in the results of hydration free energy calculation for small molecules. Similarly, new TIP3P and TIP4P parameters (termed TIP3P-FB and TIP4P-FB) were derived using an automated force field optimization program, and showed much better agreement with bulk properties than the original water models.[130]

3.02.2.4 Polarizable Force Fields

The lack of explicit polarization has long been recognized as one of the crudest simplifications of traditional fixed-charge force fields.[131,132] Indeed, it is known that the environment has a large effect of the electronic distribution of a molecule; for instance, the charge distribution around a peptide depends upon its conformation[133] and that of a ligand changes between the bound and unbound states.[134] Such effects cannot be captured with a fixed-charge model. There have therefore been efforts to develop

polarizable force fields for decades now. However, it has only been recently that there has been an increased interest in these models, facilitated by the computer power now available along with efforts to include them in widely used simulation software such as GROMACS, NAMD, AMBER, and CHARMM. A few different theoretical methods with different degrees of rigor have been explored in order to model atom polarization during molecular simulations.

One such approach is the "fluctuating charge" model, in which the partial charge of each atom is placed on their nucleus but the magnitude of each charge can change during the simulation.[135] Charges are transferred between atoms in a way that equalizes the electronegativities, where the instantaneous electronegativity on an atomic site depends upon the atom's type, charge, and the electrostatic potential it experiences due to its neighboring particles.[135] While it does not require any more interaction terms than classical force fields, it can easily represent polarization that occurs in the direction of atomic bonds.[131] The most extensively applied fluctuating charge model so far has been the charge equilibration (CHEQ) force field developed within the CHARMM program.[136,137]

Another popular method is based on classical Drude oscillators, where a pair of point charges represents each polarizable atom. While the first charge is positioned on the nucleus like in typical fixed-charge force fields, the second charge is attached to the nucleus via a spring as a massless (Drude) particle. The two particles can therefore be considered as representing the nucleus and electron cloud of the atom, and the total partial charge for the atom is the sum of the charges of these two particles. The mimicking of polarization is due to the fact that the second particle is free to move around the nucleus responding to the external field and creating an induced dipole moment.[138–140]

This approach too is easily implemented within already existing force fields and simulation codes. On the other hand it involves a substantially larger amount of charges present in the system, so that many more interactions need to be calculated at each time step. The Drude-2013 model by MacKerell, Roux and coworkers, where Drude particles are added to all nonhydrogen atoms, is currently the most widely adopted for simulation of biomolecules.[141–144] Extra point charges, representing lone pairs and an anisotropic form of polarizability, have been introduced in order to better represent hydrogen-bond acceptors.[145] Lemkul et al.[145] have recently published a comprehensive review on this model and we redirect the readers to it for a more in-depth treatment of the subject.

In the inducible dipole methodology, inducible point dipoles are assigned to each atomic site. The field due to the explicit charges alone is calculated first, and then dipoles are calculated as the field multiplied by the local polarizability, resulting in a new electric field.[133] Dipoles are therefore usually calculated with an iterative procedure to convergence, and the electrostatic energy derived from charge–charge, charge–dipole, and dipole–dipole interactions.[145,146] Such an approach was used with the AMBER ff02 force field and AMBER simulation package.[82,147] A more rigorous approach that includes multipoles up to quadrupoles is employed in the AMOEBA force field.[148–152] Contrary to all the other approaches discussed above, AMOEBA takes into account anisotropic polarization through permanent multipole moments and does not need additional point charges in order to represent anisotropy due to lone pairs. In addition, other instances of anisotropy such as pi-clouds or sigma-holes are naturally taken into account too.[131,153–156]

Most parameterization efforts for polarizable force fields for biomolecules have focussed on proteins (indeed, all of the above-mentioned force fields include parameters for proteins). Polarizability is also expected to have a strong impact on nucleic acids, firstly because they are highly charged and contain a large number of hydrogen bonds, but secondly their high charge density means they are highly polarizing themselves. Amber ff02 and Drude-2013 both contain parameters for nucleic acids. Parameters for lipids and carbohydrates, while highly desirable, are still limited, with the CHARMM Drude and CHEQ force field providing only partial coverage for these species.[131] A broad set of parameters for arbitrary organic molecules is not available yet, but would be extremely desirable in the context of drug design. At present, it is clear that there is a huge potential for polarizable force fields, but much work is still needed to develop and validate them. Consequently, fixed-charge force fields are still very much the standard for molecular simulations of protein-ligand complexes.

While simulations using polarizable force fields tend to be computationally more intensive and used to be limited to very short timescales, there are now instances of simulations with lengths in the tens to hundreds of nanosecond in length. The Drude-2013 force field has been used for simulations of proteins with up to 224 residues and for 100–200 ns,[144] while for smaller proteins simulations of even up to the microsecond timescale have been run.[157] The more expensive AMOEBA force field was used in 2013 with optimized parameters for 30 ns long simulations of 10 different proteins in solution. The simulations showed how the structures were stable with good agreement of the calculated order parameters with NMR data. In addition, the force field showed a correlation coefficient of 0.998 between the x, y, and z components of the gas phase dipole moments obtained with AMOEBA and high-level QM calculation for each amino acid dipeptide at multiple conformations, which is an unprecedented level of accuracy in reproducing the electrostatic properties of peptides using a molecular mechanics based force field.[148] Jiao et al., using the same force field, also found good quantitative agreement between calculated and experimental binding free energies for a series of benzamidine-like ligands binding to trypsin.[158,159] Often, however, polarizable force fields are found to perform just as well as classical force fields. Nevertheless, classical force fields have gone through much more extensive optimization. Assuming the same extent of scrutiny and development will be achieved for polarizable force fields within a few years, we can expect these to yield a more accurate representation of molecular interactions in the near future.

One of the perceived disadvantages of polarizable force fields is the fact that they are slower than fixed-charge force fields. However, this is expected given the higher complexity of the functional form, and once fully developed the more appropriate question will probably be: what level of physical detail of the system do I need in order to study the process/property I am interested in? Conventional additive force fields will likely always provide longer trajectories given the same amount of computation, trading-off accuracy in the electrostatic description of interactions for speed. Therefore, researchers will have to weigh the

advantages of a longer timescale versus greater accuracy and decide which one is more important for the problem at hand. Similar considerations already apply when deciding whether to use an all-atom force field versus a coarse-grained model, or even versus a quantum mechanical treatment of the system. Computational demands notwithstanding, advances in polarizable force fields are among the most promising developments toward the goal of more accurate force fields.

3.02.2.5 Coarse-Grained Force Fields

Despite the increase of computational power available and efficiency of simulation algorithms, the large spatiotemporal jump between the atomistic and mesoscopic scales calls for coarser physical models in order to describe many biologically relevant properties. In fact, important phenomena, such as complex self-assembly or macromolecular crowding, only start to emerge at the mesoscale, where systems are typically of μm in length and several seconds in time. In addition, depending on the scientific question asked, the level of detail provided by atomistic simulations might not be necessary, and sometimes not even desirable considering the computational burden. With access to longer simulation time and space scales we can begin to address more biologically relevant scales, and to have broad overlap with experiments, which is important not only for validation but also for prospective use of such simulations. Coarse-grained (CG) models therefore provide a much-needed representation of biological and chemical systems that bridge the gap between atomistic and continuum models.

In most forms of coarse-graining, groups of atoms are clustered into a lower number of CG beads. There are therefore many different levels of coarse-graining, from models that cluster only a few atoms into one bead, to ones that represent a whole protein with one bead. One challenge when developing a coarse-grained model is therefore to determine the appropriate mapping of atoms on the CG sites for the problem to be studied; too much detail might result in useless additional computation and thus limit accessible spatiotemporal scales, while too little detail might average out useful information about the properties of the systems we are interested into. Thus, Einstein's advice to "make everything as simple as possible, but not simpler" applies here too. The other chief challenge in the development of CG models in general, is to obtain a potential energy function that is able to approximate the atomistic one.[160] Coarse-graining is effectively a dimensionality reduction process, in which atomic interactions are renormalized into a coarser representation. This process results in a smoother free energy landscape where the kinetics is typically accelerated, yet as much of the underlying physics as possible has been retained.

While Levitt and Warshel performed possibly the first CG simulation of protein folding over 40 years ago,[161] it is in the last 10 years or so that the CG field started expanding rapidly, allowing the application of MD to a number of new biological problems. One CG force field that has become popular is the MARTINI model.[162–166] This force field is based on relatively high-resolution models where typically four heavy atoms are mapped to one CG particle, allowing computational efficiency while retaining some chemical relevance (see Fig. 2). The CG beads are of four types (polar, nonpolar, apolar, and charged), where each type

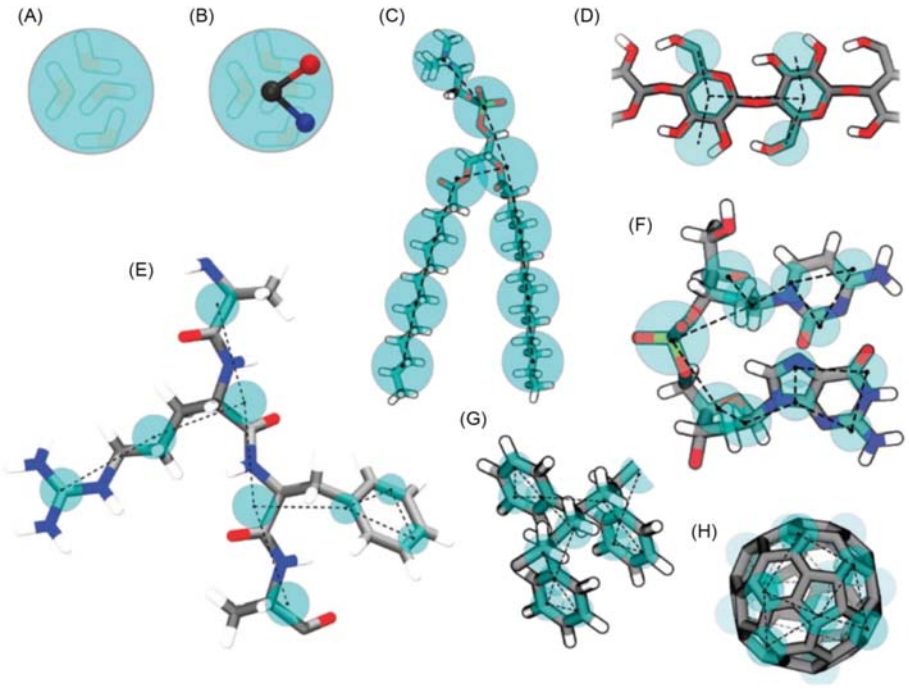

Fig. 2 Martini mapping examples of selected molecules. (A) Standard water particle representing four water molecules. (B) Polarizable water molecule with embedded charges. (C) DMPC lipid. (D) Polysaccharide fragment. (E) Peptide. (F) DNA fragment. (G) Polystyrene fragment. (H) Fullerene molecule. In all cases Martini CG beads are shown as cyan transparent beads overlaying the atomistic structure. From Marrink, S. J.; Tieleman, D. P. *Chem. Soc. Rev.* **2013**, *42*, 6801, reproduced with permission from the Royal Society of Chemistry.

can have different hydrogen-bonding capabilities (donor, acceptor, both, or none) and degree of polarity (from 1 = low to 5 = high polarity), forming a total of 18 fundamental bead types. The nonbonded interaction for the CG particles are based on the standard 12-6 Lennard-Jones potential, with Coulombic interaction too for the charged bead type, where parameters are derived empirically from experimental thermodynamic data such as free energies of hydration, vaporization, and partitioning between water and organic phases.[167] Such a top-down approach, where the model is calibrated based on experimental properties, coupled with the high-resolution of the model, means that MARTINI manages to be quite transferable between different systems. Such transferability and the availability in a number of simulation packages (GROMACS, NAMD, GROMOS, Desmond) have made MARTINI one of the most popular CG models for the simulation of biological systems.[167–179]

Voth and coworkers adopted a different philosophy for the development of their multiscale coarse-graining (MS-CG) methodology. In this bottom-up approach, forces from atomistic simulations are variationally mapped onto the CG potential, with no fitting to experimental data.[160,180–182] Since the approach relies on a variational principle, it allows for a rigorous derivation of CG force field parameters from a corresponding all-atom system. The broad applicability of the approach has resulted in its use for a number of different applications; from the study of simple and complex liquids[183] to nanoparticles,[184] lipid bilayers,[185,186] and proteins.[187,188] On the other hand, being derived for specific systems and conditions, MS-CG potentials might not be easily transferred to others. However, transferability is, in general, inherently reduced in all coarse-graining procedures, due to the simplified representation of a system that causes loss of information.

Multiscale methods that integrate atomistic and CG models in a single simulation are now starting to appear, either in a static[189] or adaptive fashion,[190–193] where the resolution of the molecule depends on its position in space. Some of the main challenges in this case are the parameterization of the interaction between atomistic and CG particles, and the appropriate mapping between all-atom and CG representations.[160,194–196] An alternative approach, termed resolution exchange, is based on the replica exchange methodology and allows Monte Carlo swaps between replicas at different resolutions.[197,198] While this approach avoids the problem of interactions between all-atom and CG particles, the on-the-fly mapping between the two resolutions still needs to be addressed efficiently. So far, however, the most common approach to mix CG and atomistic scales has been to use CG for enhanced sampling and then to convert certain configurations to an all-atom representation[199] that is a reasonable starting point for additional, more detailed, simulations.[194,200–206] A few tools to back-map all-atoms particles onto CG beads have been developed. Stansfeld and Sansom[199] described a fragment-based protocol for the conversion of lipid and proteins from CG to all-atom resolution in 2011. Wassenaar et al.[207] later proposed a general approach based on a geometric projection followed by force field-based relaxation.

3.02.3 Novel Simulation Approaches and Trends

The hardware and force field advances have been complemented in recent years by the development and application of new simulation approaches, some of which we highlight in this final section. We also draw attention to the types of problems that these approaches can begin to address that were not conceivable just 10 years ago.

3.02.3.1 Parallel and Enhanced Sampling

With increasing availability of a large number of processors to the researcher through large-scale facilities or distributed computing, the question of how to exploit most efficiently such computing power arises. In fact, in recent years, while Moore's law still applied, there has been a barrier to increased clock speed due to heat dissipation issues and vendors have rather focussed on increasing the number of cores on chips.[208,209] This means that larger and larger systems can be studied, however a point might be reached where "standard" systems of up to 100 K atoms will not benefit any more from a larger number of cores due to limits in parallelization. In addition, since during an MD simulation a large amount of time is spent sampling the low energy states, the relevant states and transition the researcher is interested in might not be sampled within the timescales currently achievable with MD. Therefore, a number of techniques that aim at accelerating the sampling of a single simulation or at combining information from parallel independent simulations have been pursued. Here we review some of these approaches that in our opinion have made significant progress in the last decade and have started being adopted by the broader MD community. Due to the limitation in space we are not reviewing comprehensively all such methods; we apologize in advance for the inevitable omissions in that regard.

3.02.3.1.1 Markov state models

Perfect parallelism that would make an efficient use of a large number of processors could be achieved by running multiple independent simulations. However, the process of interest might often occur on timescales longer than the individual simulations. Therefore, the challenge becomes to meaningfully combine the data so as to correctly extract information about the long timescale dynamics of the system. For instance, while one might run efficiently a thousand 1 μs long simulations on a supercomputer with enough CPU/GPU power, can we extrapolate information about events happening in the millisecond timescale? Another question that follows immediately is how to process the data in such a way that the results are easily interpretable. Discrete state kinetic models, such as Markov Models, are statistical approaches that have recently been very successful at addressing the above challenges.[210–212] While the theoretical framework has been available for many years, application to biological systems has only really appeared in the last 10–15 years. The increase in popularity in Markov state models (MSM) and hidden MSMs is in part

due to the development of freely available tools[213,214] that allow the user to build such models in a relatively straightforward manner, despite the complexity of the underlying statistical methods.

The idea behind such analysis is to cluster an ensemble of structures from MD simulations based on kinetic rather than on geometric distance, and to derive transition rates between all these states from the simulation data.[210,213,214] In practice, a typical workflow would start with the definition of a set of observables that will be used for analysis. However, in contrast to other techniques we will describe in the next sections, this set does not need to be system-specific, so that there is no need to know a priori the reaction coordinate that best describes, for instance, the opening of a channel or the loop movement of a kinase. These variables could be the Cartesian coordinates of a group of atoms, certain angles and torsions, as well as the distance between all Cα atoms, or contacts between any residues.[213]

Since a large number of variables can be selected in such a way, some of which might be redundant, potentially resulting in an inefficient discretization of the high-dimensional space, a dimensionality reduction is generally performed first. The time-lagged independent component analysis (TICA) has become the standard dimensionality reduction technique employed for the construction of MSM. This is because as opposed to methods using orthogonal transformations such as principal component analysis (PCA), which maximize the variance of the transformed coordinates, TICA maximizes their autocorrelation, that is it finds the slowest-relaxing degrees of freedom.[215–218] This is important because we are interested in studying the kinetics of the system, identifying, for example, metastable states and rare transitions, rather than finding the most similar/different conformations. The transformed input is then discretized into a number of microstates using clustering methods such as k-means, and conditional probabilities of transitioning between these microstates within a certain time-lag are estimated from the MD data.[213,219,220] Such probabilities are the basis for the estimation of the MSM (or the hidden MSM). Using the MSM model one can then estimate equilibrium expectations of observable, free energy surfaces (FES), relaxation timescales that can be compared to experiment, or metastable states. In addition, using transition path theory one can compute fluxes between sets of states and recover the mechanism and kinetics of going from state A to state B.[221–223] Since thousands of states are hard to visualize and hardly comprehensible, kinetically related microstates can be clustered into a few relevant macrostates in order to have a coarser, more interpretable, view of the configurational space and its kinetics.[224]

MSMs have rapidly become widespread and their application to diverse biological problems has been demonstrated in a number of noteworthy studies. Voelz et al.[225] employed MSM to study the folding pathway of the millisecond folder NTL9(1–39). The authors used adaptive resampling techniques in order to improve the sampling of metastable basins and transitions between them. The simulations, revealing a network of possible paths with different likelihoods, identified numerous folding pathways (see **Fig. 3**).

Kohlhoff et al.[26] used Google servers in order to run a large number of simulations of the active and inactive structures of the β_2-adrenergic receptor for a total of 2.15 ms of MD, and then used MSM in order to combine all the trajectories and study the activation mechanism of this G-protein coupled receptor (GPCR). Again, many parallel pathways rather than a single dominant

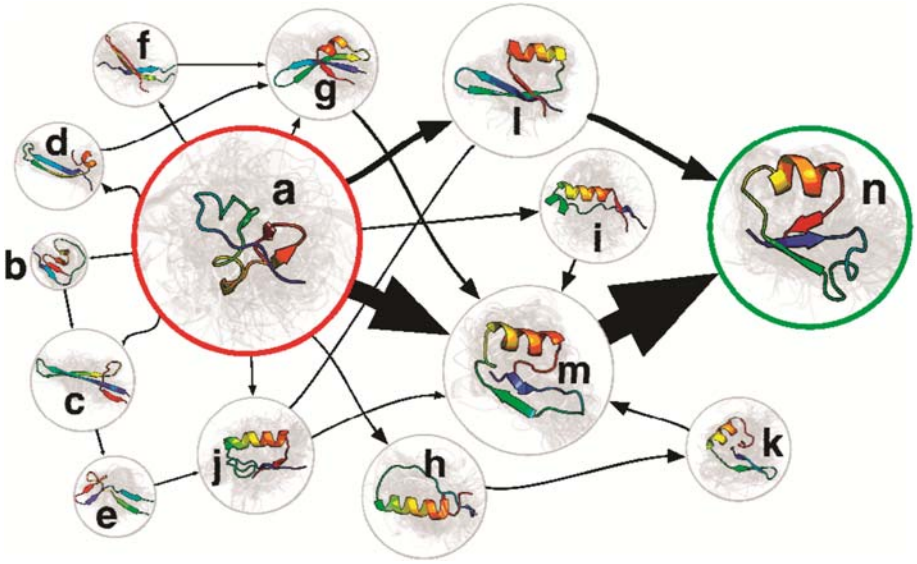

Fig. 3 Schematic representation of a MSM. A 2000-state Markov state model (MSM) was built using a lag time of 12 ns. Shown is the superposition of the top 10 folding fluxes, calculated by a greedy backtracking algorithm. These pathways account for only ~25% of the total flux and transit only 14 of the 2000 macrostates (shown labeled a–n, for convenient discussion). The visual size of each state is proportional to its free energy, and arrow size is proportional to the interstate flux. Reprinted with permission from Voelz, V. A.; Singh, V. R.; Wedemeyer, W. J.; Lapidus, L. J.; Pande, V. S. Unfolded-State Dynamics and Structure of Protein L Characterized by Simulation and Experiment. *J. Am. Chem. Soc.* **2010**, *132*, 4702–4709. Copyright 2010 American Chemical Society.

one were observed. In addition, it was shown how ligands modulate the activity of the receptor by affecting its probability of accessing the active state. Finally, different receptor states along the activation pathways were used for docking, resulting in the enrichment of different chemotypes for different receptor conformations, showing how the use of intermediate states might be beneficial for hit discovery.

Shukla et al.[226] used MSMs, transition pathways, and adaptive sampling techniques on distributed computing in order to study the activation pathways of Src kinase. In such a way they provided a thermodynamic and kinetic description of the activation mechanism of the kinase at atomistic detail. In addition, novel intermediates states that could be targeted by allosteric inhibitors have been identified. Plattner and Noé[227] have instead employed MSMs to study the binding mechanism of benzamidine to trypsin, and in particular the role of protein conformational plasticity in ligand binding. Six different slowly-interconverting (of the order of tens of microseconds) apo-state conformations have been found, with one additional conformation that was accessible only to the bound state. The binding kinetics observed, exhibited both conformational selection and induced fit features. The study showed how conformation and binding kinetics are closely coupled, and how various trypsin conformations can be accessed and stabilized both by ligand binding or protein mutations.

Overall, the use of MSM results in a number of benefits for molecular simulations. First of all, as mentioned previously, the approach provides a means to perfect parallelization, and also takes advantage of the direction of recent hardware trends towards higher number of cores on chips rather than increased speeds of single processors. Moreover, adaptive sampling coupled with MSM should provide more effective sampling of rare events. In fact, many biological systems are characterized by rugged energy landscapes that result in the presence of several metastable states separated by high-energy barriers. As a consequence, most of the time in a conventional MD simulation is spent sampling a few low energy states due to kinetic bottlenecks, and the exploration of transition events or other metastable states is limited. Adaptive sampling would allow one to focus the computational effort into phase space areas that have not been extensively sampled yet by the simulations. In addition, MSMs provide a framework for the study of the kinetics of molecular events such as drug binding and protein conformational change. Last but not least, MSMs allow a human-readable interpretation of large amounts of data thanks to the kinetic clustering and coarse-graining procedures.

3.02.3.1.2 Replica exchange methods

Replica exchange molecular dynamics (REMD) methods enhance sampling by running multiple simulations of the same system in parallel at different thermodynamic states. In the first use of the method, Swendsen and Wang used multiple Monte Carlo replicas at different temperatures to speedup sampling.[228] Sugita and Okamoto later proposed a similar framework for MD.[229] This is often called "parallel tempering" or "temperature replica exchange" (T-REMD), and the idea is to run simulations at higher temperatures than the one of interest in order to explore larger volumes of phase space thanks to the Arrhenius law.[230–232]

A set of simulations with increasing temperatures $T_0 < T_1 < T_2 < T_M$ is prepared, where T_0 is the thermodynamic state we are interested in. All the simulations are run in parallel and the system configurations (i.e., the positions of the particles) are allowed to swap between replicas according to a Metropolis criterion that depends on the potential energy difference between replicas. The exchange probability between replicas i and j is $p(i \to j) = \min(1, e^{\Delta_{ij}})$, where for parallel tempering $\Delta_{ij} = [(\beta_i - \beta_j)(U(r_i) - U(r_j))]$, with β being $1/kT$, and U the potential energy of the configuration r.[232,233] In such a way, energetic barriers are more easily overcome thanks to the larger kinetic energy at higher temperatures, while providing a correct ensemble of conformations at T_0. The acceptance criterion implies that swaps between replicas occur frequently only if the energetic overlap between replicas is sufficient, which affects the number and temperatures of replicas needed for a specific system.[232] Typically, swaps are allowed only between neighboring replicas (e.g., between T_0 and T_1, or T_1 and T_2), however, it is possible to swap configurations across all replicas leading to improved mixing between states.[234] More generally, replica exchange belongs to the group of techniques referred to as *generalized ensembles*, among which are also *expanded ensemble* methods, a serial equivalent of replica exchange.[235–237]

It soon became clear that temperature is not the only alteration between replicas that can be used, and several variants of the original T-REMD have been implemented and widely used in the last decade. Hamiltonian replica exchange (H-REMD) is a more general form of REMD where it is possible to enhance sampling by using parameters other than temperature.[238–241] Interaction energies can be scaled between replicas for example, and as such H-REMD can be used for free energy perturbation calculations, where two systems (e.g., two protein mutants, or the apo and holo forms of a protein) are interpolated by a coupling parameter λ, and the replicas correspond to the two end states plus a number of intermediate ones.[242–245] In replica exchange with solute tempering (REST) the system is divided into two parts, the solute and the solvent, so that the potential energy of the system can be described by three terms: the internal energy of the solute, the one of the solvent, and the interaction energy between the two. As the temperature increases on the replica ladder, the internal energy of the solvent and the solute-solvent interaction energy are scaled, while that of the solute is not. The effect is similar to that of raising the temperature of the solute while keeping the temperature of the solvent constant. This trick removes the dependence of the exchange acceptance probability on the number of waters in the system, which often causes poor scaling with system size. Thus, with REST fewer replicas are needed to explore a certain temperature range.[246,363] In addition, different flavors of multidimensional REMD where replicas are swapped in more than one dimension have been developed, and have been successfully applied, for instance, in free energy calculations.[247–249]

Thanks to its robust implementation in mainstream MD packages,[239,250–252] replica exchange has become a standard technique to accelerate sampling and aid convergence. It has found many applications for the study of protein dynamics and folding,[253–263] free energy calculations,[242,264–268] as well as ligand binding site and pose identification,[269,270] and constant pH simulations.[271–275] The computational cost of replica exchange grows proportionally with the number of replicas, however, it has become accepted that

the sampling obtained is more efficient than can be obtained from a single (long) simulation. In addition, the computational overhead due to the swaps and the Monte Carlo move is negligible, considering that the potential energies of the systems are evaluated anyway for the calculation of the forces. These facts have contributed in making replica exchange methods a standard instrument in the modeler's current toolbox.

3.02.3.1.3 Bias potential methods: Metadynamics

Bias potential methods facilitate the exploration of the FES by introducing additional potential energy terms that encourage the system to move out of free energy minima.[233] Typically, such methods act on a small number of degrees of freedom, often called *collective variables* (CVs). Many methods that fall in this category have been developed, including umbrella sampling,[276] local elevation,[277] adaptive force bias,[278] accelerated molecular dynamics,[279,280] conformational flooding,[281,282] and steered MD.[283] Here, however, we will focus only on metadynamics,[284–287] one of the most popular bias potential approaches, thanks in part to its availability across multiple MD packages (AMBER,[288] GROMACS,[251] NAMD,[252] LAMMPS[289]) through the PLUMED code.[290,291]

Metadynamics allows accelerated exploration of phase space and reconstruction of the FES along selected CVs by adding a history-dependent bias potential.[284–287,292] Such bias is a function of the chosen CVs. Therefore, the choice of CVs is an important step in the setup of the simulations and has important consequences on the ability to enhance sampling and the convergence of the free energy estimates. A CV is a function of the microscopic coordinates of the system, and a wide choice of CVs is available to the researcher. Typical CVs are distances, angles, or dihedrals, as well as the number of hydrogen bonds, radius of gyration, or dipole moments.[290,291] The CVs that best describe the reaction coordinate of interest should be chosen for the bias potential to be added. Broadly speaking, CVs should allow one to distinguish between the initial and final state, describe all relevant intermediates, and include all the slow modes of the system. Moreover, it is suggested that the number of CVs is kept as low as possible (usually not more than three), since higher dimensionality comes with considerable computational cost, in addition to the fact that the interpretation of high-dimensional surfaces can become difficult.[284–287] The a priori choice of CVs is far from trivial. Often, machine learning or dimensionality reduction is performed on preliminary MD runs, in order to identify the most relevant degrees of freedom for the process of interest.[293–298] Knowledge of the physical and chemical behavior of the system can go a long way in the identification of the most suitable CVs for the problem at hand.

Once a set of CVs is determined, the metadynamics simulation biases the potential energy function along the chosen CVs so that configurations that have been visited already are discouraged. The bias potential that is added to the force field-based potential energy can be described by a sum of Gaussians.[284–287,292] **Fig. 4**, adapted from the original metadynamics paper,[287] exemplifies the basic idea behind the approach. In this example a one-dimensional potential energy surface (PES) with three minima is considered. The thick black line represents the shape of the potential surface along a general CV, which is unknown, and the simulation is in fact used to explore it. However, if we start a conventional MD simulation from basin B, the system would remain stuck in this minimum if the barriers are larger than thermal fluctuations. On the other hand, adding the bias potential during the course of the simulation we modify the shape of the PES. At step = 10 the depth of the basin is reduced, but a minimum is still present; at step = 20 the energy minimum is filled by the bias potential and the system can fall into the local minimum A; at step = 40 the bias potential now starts filling basin A; continuing to deposit Gaussian-shaped potentials along the CV, the point where the global minimum C is explored is reached at step = 160; eventually, the PES becomes flat and the system evolution resembles a random walk after step = 320. Once a flat PES is obtained, the bias potential can be used to recover the negative image of the underlying free energy.[287,292,299] Since in a single run the bias potential tends to oscillate around (rather than converge to) the free energy, the well-tempered variant of metadynamics method, in which the bias deposition rate decreases over time, has been developed to address the issue.[300,301]

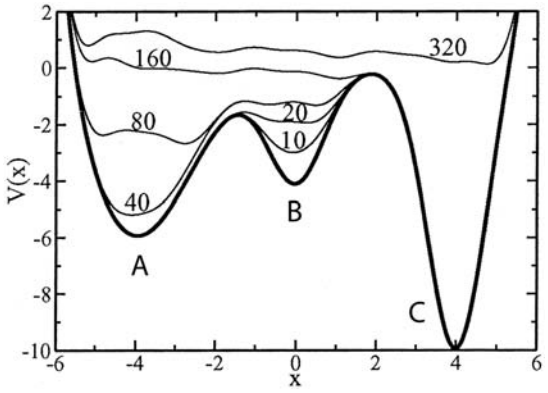

Fig. 4 Time evolution of the sum of a one-dimensional model potential $V(\sigma)$ and accumulating Gaussian terms. The dynamic evolution *(thin lines)* is labeled by the number of dynamical iterations. The starting potential *(thick line)* has three minima and the dynamics is initiated in the second minimum. Adapted from Laio, A.; Parrinello, M. Escaping Free-Energy Minima. *Proc. Natl. Acad. Sci. U. S. A.* **2002**, *99*, 12562–12566.

As compared to replica exchange approaches, metadynamics allows us to overcome larger energy barriers. On the other hand, it acts only on a few selected CVs, which, if inadequate, might provide nonconverged or misleading estimates of the energy barriers between minima.[285,301] The two methods are therefore complementary and can in fact be combined.[302] In such a way, while parallel tempering allows us to cross moderate free energy barriers on all degrees of freedom, metadynamics allows us to cross larger barriers on the specified CVs.[303,304] Alternatively, replica exchange can be used in order to bias different sets of CVs in a number of parallel simulations while allowing exchanges between them, in a paradigm called *bias exchange*. A reweighting procedure that is specific to bias exchange can be used in order to recover the FES as a function of part of the set of CVs.[305,306]

Metadynamics has been used quite extensively in biomolecular dynamics and protein-ligand association.[303,307–321] As an example applied to drug discovery, Limongelli et al.[318] have studied the full dissociation process of SC-558, a highly selective cyclooxygenase-2 (COX-2) inhibitor, through the use of metadynamics calculations based on a distance and a torsional angle as the two CVs. They discovered an alternative binding mode to the one observed experimentally, and suggested this as the reason behind the selectivity and the long residence time of the inhibitor for this isoform. In fact, when simulating the dissociation of SC-558 from COX-1, only one energy minimum, that is, a single binding mode, was observed in the protein binding site. This binding mode was very close to the crystallographically observed pose in COX-2 for the same inhibitor. On the other hand, the simulations with COX-2 revealed a second energy minimum in the binding site, in which the ligand also engages in additional hydrophobic contacts with the protein. Lanzo et al.[322] had previously shown with fluorescence quenching experiments that an analogue of SC-558 would bind to COX-1 in a two-step process, but an additional unidentified step was required to bind to COX-2. The authors also reported slower dissociation kinetics from COX-2 as compared to COX-1 (several hours versus 1 min). Limongelli et al.[318] suggested that the alternative binding pose observed in their simulation is what causes the detection of an additional binding step in the fluorescence experiments.

Grazioso et al.[316] used a similar method to study glutamate uptake from the synaptic cleft and its release into the intracellular medium. The authors managed to describe the opening mechanism, which involved a large-scale hairpin motion, and the associated free energy profile. Herbert et al.[315] reported the discovery of the first extracellular inhibitor of the fibroblast growth factor receptor, a tyrosine kinase receptor involved in cell growth, proliferation, and survival. In this study, bias exchange metadynamics was used in order to study the ligand's mode of action. Experimental methods had hitherto been unsuccessful in identifying the inhibitor's binding site. The simulations correctly predicted the dissociation constant of the inhibitor, as well as for other lower potency analogues, validating the in-silico analysis.

3.02.3.2 Simulation of Large Systems

As we enter an era of exascale computing with highly optimized MD codes, larger and larger systems are starting to be studied through simulation, both in all-atom and coarse-grained detail. Accessing greater spatial scales is important in order to probe the function of biological machineries, which often operate on scales spanning hundreds of nanometers to micrometers.[3] Simulations of viruses,[323] the ribosome,[324] large membranes,[325] and small organelles[326] contain millions of atoms and require highly scalable software.[3] Such systems present both opportunities and challenges for high-performing computing and molecular modeling, and hold the promise to contribute to a deeper level of understanding of living organisms and their behavior at the mesoscale. This, in turn, would enable the design of new therapeutics based on small molecules and engineered biologics with the aid of computation.

Due to the large size of viruses for MD simulations, most initial studies on viruses focused on isolated proteins or fragments of the viral capsid.[327] However, in 2006, Freddolino et al.[328] simulated for the first time a complete virion (capsid and genetic material) atomistically, despite some approximations in the RNA genome structure. The authors simulated the entire virion and both the capsid and RNA core alone of the satellite tobacco mosaic virus for a total of 50 ns of MD. The systems contained about 1 million atoms, and the simulations demonstrated the stability of the virion and RNA core, while showing instability for the capsid without RNA. Since then, other large and complex viral components of, for instance, Poliovirus,[329] Dengue,[330] influenza,[331] and HIV-1,[201,332] have been studied by means of simulation. Reddy et al.[331] reported the microsecond-long CG (Martini) simulations of an influenza A virion. The authors showed how the presence of the Forssman glycolipid altered the mobility of bilayer species, and suggested that the viral spike proteins do not aggregate and are thus competent for IgG antibody binding. In other studies, the spontaneous assembly of the viral capsid, a fundamental step in the replication cycle of the virus, has been studied by simulation at different levels of coarse-graining.[329,333–336]

Through Brownian dynamics, it was shown how the optimal configuration of viral genome is essential for the correct assembly of the capsid.[333,334] Recently, electron microscopy has been integrated with molecular dynamics flexible fitting (MDFF)[337] in order to elucidate the structure of complex viral capsids in atomic detail and in their native environments. Zhao et al.[332] obtained an 8 Å cryo-EM structure of the mature HIV-1 native capsid, a polymorphic capsid with no apparent symmetry; they then docked atomic NMR and X-ray structures of capsid proteins into the density map, modeled the linker and missing loops, and finally refined the model by MDFF to obtain an atomistic representation of the virus. The final model contained 64 million atoms and was simulated in explicit solvent for 100 ns, and demonstrated the importance of the placement of capsid protein pentamers in the structure. Other multimillion simulations of viral structures, such as in the case of the Rabbit hemorrhagic disease virus (RHDV),[338] have been successfully employed in the refinement of crystal structures fitting into cryo-EM densities.[339,340]

The ribosome is an obvious antibacterial target, and in the last decade an increasing amount of experimental data has become available. Consequently, a number of researchers have started simulating the ribosome with MD, trying to bridge the gap between

its structure and dynamics.[324] Similar to viruses, the first ribosome simulations focussed on selected regions due to the computational expense of million-atom simulations.[341,342] However, with increasing computing power available, simulations of the entire ribosome became viable.[343] Recently, Bock et al.[344] performed MD simulations of 13 intermediate translocation states of an entire bacterial ribosome. Such systems comprised ~2.2 million atoms and were simulated for a total of more than 1.8 μs, revealing a description of the time-resolved translocation in atomic detail. Kinetic information was extracted from the simulations and it was found that tRNA motions govern the transition rates within the pretranslocation and posttranslocation states. On the other hand, faster submicrosecond rates were observed for intersubunit rotations and L1-stalk motion. Overall, the results added the time dimension to the structural data available, providing information on transition rates, molecular forces, and correlated functional motions that could not have been obtained otherwise.

Whitford et al.[345] also carried out microsecond MD simulations of a complete ribosome, identifying reaction coordinates for the subunit rotation that were used to estimate free energy barriers associated with the translocation. Given its role as a pharmaceutical target, a number of MD simulations of the ribosome in the presence of antibiotics have been performed in order to elucidate the mode of action of small molecules.[346–350] For instance, Sothiselvam et al.[346] used both biochemical methods and molecular dynamics to show how erythromycin, a macrolide antibiotic, allosterically predisposes the ribosome to translational arrest, without necessarily forming extensive contacts with the nascent peptide in the exit tunnel as previously suggested. MD, in particular, hypothesized the base flipping of specific nucleotides in the catalytic center, which were later confirmed by cryo-EM data.[346,351] With the increasing availability of ribosome structures, including human ribosomes,[352–354] and computer power, molecular simulations have the opportunity to significantly contribute towards the understanding of drug action on the ribosome and to the next generation of much-needed antibiotics.[355–357]

Large membrane bilayers have been simulated at increasing degrees of chemical detail and complexity, trying to include as many lipid species as possible in order to reproduce compositions found in living cells.[3,170,325,358–360] Marrink and coworkers used the Martini coarse-grained model to simulate a large plasma membrane containing 63 different lipid species.[325] The 71 × 71 nm patch included about 20,000 lipids, which with water and ion beads totalled almost half a million particles, and was simulated for 40 μs. The study provided a high-resolution view of the cell membrane and showed an asymmetrical distribution of cholesterol with enrichment in the outer leaflet. Moreover, transient domains with liquid-ordered character were observed to appear and disappear in the microsecond timescale.[325] Similarly, Koldsø and Sansom[170] simulated a complex and large (>100 nm) plasma membrane also using CG MD, where they introduced two types of crowded membrane proteins in order to study the interplay between lipids and proteins in determining mesoscale fluctuations of the bilayer and clustering of receptors. Closing the gap between experiments and simulations in terms of membrane complexity and spatial scales, the study showed good agreement with the dynamical behavior of lipids observed in living cells.[361,362]

3.02.4 Conclusion

In this chapter we have tried to summarize the main advances in molecular simulation in the past decade or so. Progress in both hardware and algorithm design have construed to make it possible to explore length and timescales that are now within the regimen of several experimental techniques. In the next decade we can expect this overlap to be extended. The resulting integration between experiment and simulation will become a powerful way to understand many underlying biophysical principles as well as improve our prospects for the design of new therapeutic approaches.

3.03.1 An Introduction to Free Energy Methods

Since the very first molecular dynamics (MD) simulation of a protein by Karplus and McCammon[1] it was clear that physics-based atomistic simulations held great promise for structure-based drug discovery, due to their ability to track the behavior of ligand–target interactions with atomic precision across different time scales. Indeed, MD allows the understanding and quantification of ligand–target binding events in unprecedented details, with a significant potential on preclinical drug discovery, ranging from understanding how new hits modulate their target biomolecules, to guiding the rational design of more potent derivatives in the hit-to-lead phase. An example of this was the success of the MD-based design of new HIV-integrase inhibitors. Using MD simulations, a new transient binding "trench" was discovered,[2] not observed in crystallographic structures, which led to the development of more effective inhibitors.[3] However, the promise of MD has been long held back by the insufficient accuracy of the available force fields, the limited computer power available and above all, the short time scales accessible. Thus, the articles reporting a successful, prospective use of atomistic MD simulations in drug discovery are still few compared with those relying on more approximate methods.

But there is a general consensus that a number of recent developments will change the situation for the better. The use of graphics processing units (GPUs) as programmable co-processors,[4] the development of highly parallel supercomputers and, more recently, specialized hardware for MD[5,6] finally allows extremely long MD simulations, ranging from hundreds of microseconds up to a few milliseconds. Long MD running on the new hardware were able to sample the reversible folding of a number of small proteins[7,8] and the spontaneous binding of ligand to pharmaceutically relevant targets.[9–11] The possibility of performing very long MD simulations has also had a positive effect on the accuracy of the force fields. Long simulations can be more easily compared with experimental results, leading to better parameterization.[12–17] Still, even on specialized hardware such as Anton,[5,6] specifically designed to run MD and several times faster than conventional supercomputers, it is usually not possible to observe a statistically relevant number of binding and unbinding events. Indeed, the residence time of most drugs is very long (from hours to days) and the observation of a few binding events are surely not sufficient to sample all the relevant conformations and calculate the binding rates and free energies. The accurate prediction of protein–ligand free energies of binding is a fundamental goal of computational chemistry and computer-aided drug design (CADD).[18] The limitations of standard MD with respect to free energy calculations have been historically addressed by a number of "free energy methods" that rely on various MD-based algorithms to compute the free energy of binding $\Delta G^{\text{bind}} = \langle G^{\text{PL}} \rangle - \langle G^{\text{P}} \rangle - \langle G^{\text{L}} \rangle$ where the P, L, and PL superscripts stand for protein, ligand, and their complex, respectively.[19,20]

A reliable, and possibly fast, evaluation of the binding free energy together with a molecular understanding of the features of the ligand and the target contributing to its potency is very useful in the early phases of drug discovery. In particular in the hit-to-lead

phase, predicting the binding free energy of various derivatives and understanding the role of different substituents can speed-up the development of clinical candidates.[18] This vital step has been often delegated to more approximated approaches such as docking, with variable degrees of success.[21,22] Thanks to the aforementioned technical progress in computing power,[4] algorithms,[23] and force fields,[12–17] it can now be routinely performed by more rigorous MD-based free energy methods.

Of the plethora of different algorithms that have been developed in the last decades to allow the calculations of free energies here we focus on those that have passed the test of time by continuous improvements, or have been recently developed. Free energy methods broadly fall into two separate categories. The first class, "end point" methods, are aimed at computing the relative free energy of the bound and unbound states, without trying to compute the full free energy profile along the binding coordinate. These include free energy perturbation (FEP), thermodynamic integration (TI), λ-dynamics, linear interaction energy, WaterSwap, and those which combine molecular mechanics with Poisson-Boltzmann (or generalized Born) implicit solvation and surface areas calculations (MM-PBSA and MM-GBSA).[24–27] These approaches often involve the use of an "alchemical transformation," where the identity of the atoms in the models will change, making them appear, disappear, or change to a different atom during the process. This is achieved computationally by progressively shifting the Hamiltonian of the system H is to a different H' passing through a series of, often unphysical, intermediates. The second class includes methods aimed at calculating the full binding free energy profile along a physical pathway. These classes of methods generally work by enhancing the sampling of standard MD through different approaches, and are often referred to as "enhanced sampling" (ES) methods. End point approaches are generally less computationally intensive (as they focus on the bound and unbound states and in some instances use implicit solvent models), but they do not deliver the same amount of information of the full binding free energy profile, including the binding mechanism, on-path intermediates, and transition states (TS), which have the potential to unleash crucial insight for the design of small molecules. Thus, the two types of methods are complementary and the choice of one versus the other depends on the specific application at hand. Moreover, the boundary between the two approaches is increasingly blurred as many methods combining them are being successfully used in CADD.

3.03.2 Alchemical Methods

Alchemical binding free energy calculations are one of the most established and useful "accurate" computational techniques in CADD. Their advantage with respect to faster and more approximate techniques is that, in principle, they include all the important thermodynamic contributions to the free energy, such as the conformational entropy (for small conformational changes), the discrete nature of the solvent, and are able to include the effect of protonation states or tautomer distributions, all of which are neglected in most fast screening techniques routinely used in drug design. Indeed, these crucial, but often neglected effects are the main responsible of the lack of effectiveness and inaccuracies in many computational predictions.[28] Alchemical methods can be used to compute either absolute binding free energies or relative binding free energies (the difference between the binding free energies of two or more, usually related ligands). Although the statistical mechanic relations used in alchemical methods have been introduced a long time ago[29,30] it was only at the beginning of the 1980s, with the increase in available computational resources, made their use possible with molecular simulations. One of the first examples of their application was the study of proton transfer in lysozymes by Hwang and Warshel.[31] In the same period, a paper by McCammon and coworkers reported the relative binding free energies of a number of congeneric ligands to receptor.[32] These approaches, usually referred to as "alchemical transformations" due to the fact that one ligand is "transmutated" to another one or to a noninteracting "dummy" molecule through a series of "nonphysical" intermediates steps, have now been established as the standard procedure to obtain accurate relative free energy differences by a number of groups, including McCammon's, Warshel's, and their coworkers.[19,33,34]

3.03.2.1 Thermodynamic Integration Versus Free Energy Perturbation

TI and FEP are among the most widely used alchemical methods using explicit solvent simulations.

TI is a classical alchemical method in which the free energy between the end points (e.g., bound and unbound states) is calculated by taking the derivative of the free energy with respect to a continuous parameter λ describing a series of intermediate nonphysical (alchemical) states and computing the average of the derivative from $\lambda = 0$ to $\lambda = 1$

$$\frac{dG}{d\lambda} = \frac{d}{d\lambda}\int e^{-\beta H(\lambda,x)}dx = \left\langle \frac{dH(\lambda,x)}{d\lambda} \right\rangle_{\lambda}$$

$$\Delta G = \int_0^1 \left\langle \frac{dH(\lambda,x)}{d\lambda} \right\rangle_{\lambda}$$

For alchemical changes that result in smooth curves for $\left\langle \frac{dH}{d\lambda} \right\rangle$, TI can provide quite accurate estimates using a relatively small number of intermediate points. However, if the curvature becomes large, as can be the case in alchemical simulations where the molecule "disappears" by turning the Lennard–Jones potentials off, then the error introduced by discretization of the integral can become large.[35] Thus the choice of the alchemical pathway is fundamental to achieve sufficient accuracy.[36,37] Once an optimal alchemical pathway has been devised, the total free energy difference is computed from the individual simulations at different λ

values by using a numerical integration of the integral. To this end, a number of numerical techniques have been applied, ranging from the simple trapezoidal rule to high order integration methods. Higher order integration methods often allow a larger distance between integration points, but are more sensitive to the value of the derivatives of the function, which can become large, especially close to end points.[38]

The term "perturbation" in FEP refers to the alchemical changes in the atom identities, such as bromine to a methyl group. Usually FEP is used to refer specifically to the application of the Zwanzig relationship[30] in which the free energy difference between two Hamiltonians $H_0(x)$ and $H_1(x)$ is calculated as:

$$\Delta G = -kT \ln \left\langle \exp^{-\beta[H_1(x)-H_0(x)]} \right\rangle_0$$

In recent years, FEP calculations have greatly benefited from the improved force fields and the combination with new sampling algorithms.[18,39,40] Historically, FEP had difficulties in converging the free energy of systems undergoing complex conformational changes between the initial and final conformations. However, nowadays, the difference between FEP and TI methods depends basically on the formula used. While FEP uses an exact formula, the TI approach uses a discretized version of the formula, although both are a priori equivalent. Most probably, today, the advantage of FEP with respect to TI is the widespread adoption of the multistate Bennett acceptance ratio (MBAR) approach and the use of discrete points, which allows to (i) equilibrate each point, (ii) add extra points a posteriori if needed, and (iii) apply independent spacing pattern between different λ points to improve the efficiency of the method and minimizing the convergence error.[41] Even so, the use of one technique versus the other depends basically of the kind of simulation protocol used by the researcher.

3.03.2.2 Evolution of the Alchemical Methods

The continuous progress in alchemical free energy calculations is due to several factors. The initial results obtained at the end of 1980s and their comparison with experiment resulted in many early technical improvements.[42] The enormous increase in available computer time due to Moore's law allowed much longer simulations and made it clear that, to obtain a consistent result, significantly longer simulations than those feasible in the 1980s were necessary. The algorithms have been continuously improved during the last 20 years and, more recently, they have been effectively combined with other ES techniques, increasing the accuracy of the results and their use in academic and industrial environments. Finally, the availability of much cheaper high performance computing resources and of automatic setup interfaces made the often complex setup and interpretation of the results more accessible, and allowed the avoidance of a number of common mistakes that marred the results in many past calculations.[40,43–48] In more detail, one of the most common problems in the "alchemical transformations" methods is related to the appearing and disappearing atoms during the transformation of the ligands. This introduces a numerical problem related to the repulsive term in the Lennard–Jones potential. In order to solve this problem, soft-core potentials have been introduced.[49,50] Another important issue is related to the sampling at end points and of different conformations. The dynamics of the system can be unstable due to the vanishing of the atoms especially at the end points of the simulations ($\lambda = 0$ and $\lambda = 1$). This problem was also addressed by the use of soft-core potentials. The exploration of different conformational states by MD simulations is a more complex problem. In most cases, it is the responsibility of the slow (or no) convergence of the methods. For instance, the conformational changes of the target due to the binding of a ligand can be very complex in nature and, due to high free energy barriers, require extremely long simulation to be sufficiently sampled. If the ligand is forced in the binding cavity without the needed conformational changes occurring first, the resulting free energy differences will be wrong.[51] This issue can also explain the dependency of the results from the starting structure. This is a significant issue, since the conformations observed in the X-ray structure of the unbound target can be very far from those needed for binding. Thus the exploration of the correct conformation often requires very long MD simulations or the combination of the alchemical algorithms with ES approaches.[52–55] Similarly, when multiple binding modes are accessible to the ligand, the sampling needed to converge the free energy will greatly increase.[56] These phenomena can easily lead to wrong relative free energy differences, and together with some systematic inaccuracies in the force fields explain most of the observed discrepancies between simulated and experimental results.

These points have been discussed in detail in the review by Chodera et al. focused on the challenges facing the use of alchemical calculations in drug discovery.[26] An interesting observation is that, when validating the calculated free energy results with experimental binding affinities obtained by biophysical procedures, one needs to keep in mind that also the experimental results are affected by significant uncertainties and often contain systematic errors. Thus, the error bars on both the predicted and experimental binding energies limit their correlation. In order to further improve the accuracy of predicted binding free energies high quality experimental data is needed.[57]

The first application of alchemical free energy methods was reported by Tembe and McCammon at the beginning of the 1980s.[32] Later, the success obtained by Wong and McCammon[19] in computing the free energy of three different inhibitors of trypsin and the accurate binding free energies of xenon atoms in myoglobin reported by Herman[58] promoted the use of alchemical applications, with a number of papers appearing at the end of 1980s and at the beginning of the 1990s. However, the abovementioned deficiencies in the methodology and the prohibitive computational cost on the supercomputers then available postponed a widespread use of these techniques until the beginning of the 2000s, when the newly available computational resources and methodological progress heralded the "coming of age" of alchemical transformations.[59] Traditionally the alchemical free energy methods are used in the calculation of relative binding free energy. However, recently a number of successful

examples of the application of alchemical transformations to the calculation of absolute binding free energies[60,61,62] and solvation free energies have been reported.[61,63]

Below, we discuss in some detail a number of interesting examples of alchemical transformations in the calculation of relative binding free energy, which involves the "nonphysical" transformation of one ligand in another one based on the appropriate thermodynamic cycle.

One of the most successful and complete examples was reported by Jorgensen and coworkers and is related to the nonnucleoside reverse transcriptase inhibitors (NNRTIs) of the HIV-1.[64] The HIV-1 reverse transcriptase (HIVRT) enzyme is a critical system to the retrovirus since it is responsible for the conversion of the viral RNA into DNA to incorporate the viral genes into the host cell. Therefore, the NNRTIs have a crucial role in inhibiting this enzyme. However, the HIVRT mutates rapidly, resulting in drug resistance to the NNRTIs, which requires a fast development of new and more potent inhibitors to address the new drug-resistance-inducing mutations. In 2000 there were three drugs approved by the FDA against the HIVRT called Nevirapine, Delavarine, and Sustiva. Two point mutations of HIVRT, V106A and Y181C, result in an increased resistance to the known drugs, with the exception of Sustiva. To understand the causes of this interesting effect, explain the resistance, and thus the effectiveness of Sustiva in countering the mutations, Jorgensen and coworkers used a combination of docking and FEP calculations.[64] Since the X-ray structure of the HIVRT with Sustiva bound to the active site was not available, they first performed docking calculations to determine the probable structural location of Sustiva in the binding site, taking into consideration other available HIVRT–ligand X-ray structures. The best-docked poses provided a plausible structural explanation of the mode of action of Sustiva in the mutated HIVRT. A specific hydrogen bond interaction between the ligand and Lys101, as well as the aryl-π interactions with Tyr181 and Tyr188, favorably contributed to the binding. The thermodynamic cycle considering the wild-type (WT) and mutated enzyme and two inhibitor drugs validated the structural model obtained from docking and provided a quantitative estimate of the resistance. The results obtained were in good agreement with the experimental results, validating the qualitative picture obtained from docking and revealed why Sustiva is the only ligand that effectively inhibits the mutant protein. The calculations also provided a number of specific structural interactions engaged by Sustiva with the mutant protein that can be used in the design of novel inhibitors. In 2004, following a similar computational strategy, the same group studied another crucial drug-resistance-inducing mutation in HIVRT, K103N.[65] It was observed that Efavirenz had a higher potency toward the mutant protein. In this case two crystal structures of the ligand-bound protein were available. However, the orientation of the side chain of Tyr181, a crucial residue for the binding, was different in the two structures. Therefore, the FEP calculations were used not only to clarify the structural origins of the K103N-induced resistance, but also which of the two available structures were in better agreement with the activity data. The calculations showed that only the structure with the conventional orientation of Y181 ("up") in both the WT and K103N mutant provide free energy differences in qualitative agreement with the experimental results. These results reaffirm the importance of a careful preliminary analysis and selection of the available crystal structures for the accuracy of the free energy calculations. They also explain the increased accuracy of combined algorithms, where FEP together with other ES approaches is able to sample different conformations of the target protein that might contribute to the binding free energy. The resistance observed in the K103N mutant enzyme toward most drugs was explained in terms of specific interactions in the holo and apo enzyme. The quinazolinone analogs of Efavirenz present higher activity in the mutated enzyme due to a hydrogen bond network formed between these inhibitors and several water molecules located at the binding site. Finally, a new and more effective NNRTI, Etravirine, was designed with the help of the novel insights and approved in 2008. The problem of the drug-resistance-inducing mutations in HIVRT requires sustained and continuous efforts from the drug design community. To this end the use of FEP calculations to understand the molecular mechanism of drug resistance played a crucial role in guiding lead optimization and the development of new lead ligands.[66] Through the judicious use of alchemical free energy calculations, Jorgensen and coworkers were able to convert the inactive core of a building block in an inhibitor against HIVRT with a potency of 10–20 nM.

Erion[67] used FEP calculations to design a series of inhibitors of fructose 1,6-biphosphatase (FBPase). The AMP inhibits FBPase, which is a potential target for diabetes type II. In a preliminary work,[68] the authors used the FEP calculations to determine the contributions of the individual heteroatoms of AMP toward the inhibition. Later,[67] they predicted the structure–activity relationship (SAR) of AMP analogs taking into consideration the solvation and the binding free energies with the goal of designing potent inhibitors against FBPase. These analyses are very useful since in some cases the desolvation energy cost reduces the binding affinity considerably, while in others the group associated with the high desolvation energy cost also formed strong favorable interactions with the protein compensating the cost of desolvation and leading to a higher binding affinity. Another example of interest was the case of human neutrophil elastase (HNEs).[53] HNEs specifically cleaves small aliphatic amino acids, hydrolyzing the proteins which confers elasticity to the skin. Unregulated HNE activity plays a role in a number of diseases, including cystic fibrosis or pulmonary emphysema. In order to design more effective inhibitors, Streibencher et al. applied TI to a number of bornyl caffenate derivative ligands, showing a promising binding affinity. The combination of ligand docking, with MM-PBSA and explicit solvent TI calculations showed that specific hydrogen bonds formed by the ligand and the placement of the hydrophobic moiety into the S1 binding site of the protein crucially contribute to the binding affinity.

Another interesting study showing the value of alchemical free energy calculations is related to the F1F0-ATP synthase. This enzyme is responsible for most of the ATP synthesis in living organisms.[69] From F1F0 complex, the catalytic subunit F1, which is able to hydrolyze the ATP, is formed alternating 3-α and 3-β subunits located around the γ subunit. The γ subunit is asymmetric and their rotation alters the conformations of the three β subunits of the catalytic subunit for the substrates and products. It is known that the ligand is bound with higher affinity to one of these three subunits, however, the relationship between the binding affinities and the different conformations of the β subunit was not clear. In the first X-ray structure obtained, each β subunit was

crystallized with different analogs, that is, one subunit contains an analog of ATP (ANP) and was called a β_{TP}, another with ADP, called β_{DP} and the third subunit was called β_E because was empty in the crystal structure. However, this subunit in a second X-ray structure obtained was called β_{HC} (from half-closed). It was not clear which of the β_{TP} and β_{DP} subunits had the highest affinity to the ligand. In order to shed some light, Karplus and coworkers computed the free energy differences using TI of the hydrolysis of ATP from both crystal structures.[70,71] The results of the calculations suggest that the binding site with the highest affinity for ATP is found in β_{TP}. These results are also confirmed by the structural information of the binding sites. The charged residues found in the β subunits together with the Mg^{2+} cation contribute to the difference in the binding between the subunits. The presence of these residues stabilizes ATP versus ADP due to the stronger interactions of γ-phosphate of ATP in β_{TP} than in β_{DP}. The calculations clarified the relation between the structural features of the different catalytic sites with the experimental binding affinities. Another interesting and challenging example is related to the 8-oxoguanine DNA glycosylase I (hOGG1), which is able to distinguish between guanine (G) and the mutagenic 8-oxoguanine (oxoG). The question here was how the hOGG1 enzyme is able to discern between these two very similar nucleobases. In order to elucidate the structural features that contribute to the binding, Karplus and coworkers[72] performed free energies calculations with the G and oxoG in the binding site and in the exo sites. The calculations suggest that the binding of oxoG toward hOGG1 is favored in both normal and exo site. The FEP analysis indicates that the change of the lone pair in N7 of the guanine by the N7H in the oxoG favors the hydrogen bond with the carbonylic oxygen of Gly42 backbone, which despite the presence of other repulsive interactions, make a net contribution of 3.5 kcal/mol to the binding.

Very recently, a systematic application of a combination of FEP with an enhanced sampling protocol to a large number of ligand–target systems, has shown such a level of high predictive accuracy and robustness to make it ripe for its routine use industrial drug discovery environments.[15] The protocol builds on the significant improvement in the sampling due to the use of combined algorithms and the concomitant increase in the accuracy of the force fields due to a painstaking reparameterization work of the ligand force field performed in the last years.[15,18,39,40,73,74] The authors demonstrate the effectiveness of this protocol testing $\simeq$ 200 ligands and 10 different targets. Only nine of the predicted free energies deviated more than 2 kcal/mol from the experiment. They addressed most of the challenges discussed earlier.[26] The combination of an improved version of the force field Optimized Potentials for Liquid Simulations (OPLS),[75] with the extensive sampling of the conformational space by the combined FEP/replica exchange with solute tempering[55,76,77] was fundamental to address that aim the implementation of these algorithms into the fast MD package Desmond, made its use computationally feasible.[78] Moreover, the implementation of the algorithms in a package with a robust interface simplified several aspects such as (i) the selection of a specific region of the system where sampling at a higher temperature can be useful, focusing the sampling where it is needed to cross the conformational barriers[55] or (ii) avoiding the problem of torsional barriers limiting the ergodicity of the system (that torsional barriers do not limit the complete sampling of the system over the timecourse of the MD). Moreover, an automatic way to generate the perturbations pathways through a variant of the LOMAP algorithm was implemented.[55] In that way, it was possible to set up 16 independent calculations in approximately 30 min, making it faster and devoid of possible human errors. Finally, the algorithms were implemented on GPUs, with a speed-up of FEP calculation of 5–10 in comparison to running on CPUs. The results obtained show not only an improved scoring with respect to other methodologies like SAR or MM-GB/SA, but also the usefulness of the knowledge of the different physical phenomena involved in the binding that free energy calculations can accurately describe. For instance, this methodology is able to capture the changes in the hydrophobic interactions, hydrogen bonding interactions or solvent effects due to the transmutation of one ligand to another one, providing a very useful chemical insight in the hit-to-lead phase of CADD.

These encouraging results show that the widespread application of combined alchemical/ES approaches together with better ligand force field might have a significant impact on CADD. Although the specific FEP/REST implementation requires special care in the selection of the REST region and the OPLS 3 force field is currently only available in very expensive proprietary software packages, this will undoubtedly change as other, more universally accessible, ligand force fields are improved and alchemical methods are combined with a number of other enhanced sampling approaches.

Therefore, the evolution of the alchemical methodologies in the last 30 years and their combination with other ES algorithms shows real promise, and although there are still a number of open challenges to be addressed, their routine application in drug discovery as one of the accurate computational tool of choice is increasingly feasible and justified.

3.03.3 ES Algorithms

The general aim of ES methods is to speed-up the sampling of relevant areas of the phase space by MD using ad hoc algorithms. ES algorithms are able to explore "rare events" taking place on time scales that are much longer than those typically accessible to MD. By sampling multiple times different conformations these approaches are able not only to provide an insight on possible binding mechanisms and allosteric effects, but also provide an estimate of the free energy landscape (**Fig. 1**). A large number of ES algorithms have been developed, and an in depth discussion of their characteristics and of the many applications they have in a number of fields is the argument of numerous books and reviews.[23,25,79] Three different subclasses of ES can be broadly defined. (1) Methods based on "collective variables" (CVs) (i.e., a combination of variables approximating the reaction coordinate (RC)) that add an external potential to favor a more effective exploration of the relevant regions of the conformational landscape. (2) Methods that do not make an explicit use of CVs, such as Markov state models (MSMs)[80] and multiple replica approaches (parallel tempering (PT),[81] Hamiltonian replica exchange,[82] etc.). (3) A large class of methods based on a "path" linking initial and final states (such as transition path sampling[83] or milestoning[84]). Approaches in the first class have been most extensively used in

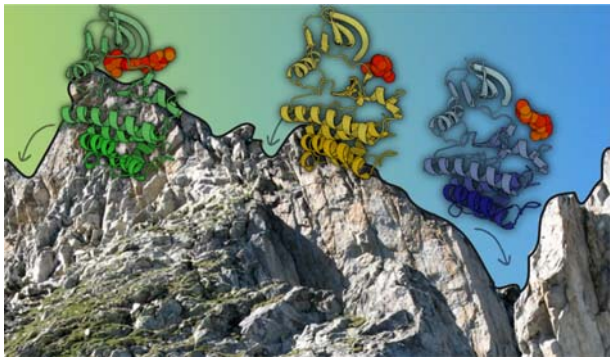

Fig. 1 Pictorial representation of the binding landscape. Methods that rely on a physical pathway are able to predict the full free energy profile of the (un)binding process, revealing transition states and metastable states.

CADD. They require the a priori knowledge and definition of a "collective variable" that approximates more or less precisely the RC. An example of a CV often used to study ligand binding is the distance of the ligand from the binding cavity. Methods from the second class do not need the definition a priori of a precise RC, and are thus at the same time more general (e.g., do not need the knowledge of the binding cavity) and often more computationally expensive. Finally, methods based on paths, which usually require the knowledge of the initial and final states and a guess path linking the two. These path-based approaches have been used less often in CADD as they tend to be very computationally demanding, but they are in principle able to provide accurate binding rates in addition to binding affinities. A common observation is that the more knowledge of the system is available and used to direct the sampling, the more efficient is the reconstruction of the free energy landscape.

3.03.3.1 CVs-Based Methods

Most CV-based methods make use of an external potential to enhance the exploration of the conformational landscape and reconstruct the free energy landscape. For this potential to be effective, it needs to favor the transition to new regions of the free energy surface (FES) that would normally not be sampled due to high free energy barriers or slow diffusion. To maximize the efficiency, the bias potential should act only on the atoms involved in the transition and push the system along the RC of the transition under study. Thus, M "collective variables" $\mathbf{s} = (s_1(\mathbf{R})\ldots s_M(\mathbf{R}))$, function of the relevant atomic coordinates and approximating the real RC are introduced. By acting on these CVs, the bias potential will not affect all the degrees of freedom indistinguishably, but will be instead only focused on those contributing to the transition. Once the relevant degrees of freedom have been extensively explored, it is possible to get a reconstruction of the free energy profile (or of the multidimensional FES). Indeed, the free energy profile as a function of the RC can be written as:

$$F(s) = -k_{\mathrm{B}}T\ln\langle\delta(s(\mathbf{R}) - s)\rangle$$

where the Dirac delta function maps the $\mathbf{R}$ coordinates onto the CV space, that is, all the configurations $\mathbf{R}$ which realize the same CV value s are counted together. The dynamics of the system is biased by the introduction of a potential $V^*(\mathbf{R}) = V^*(s(\mathbf{R}))$ which is a function of the defined CVs, to the real potential $V(\mathbf{R})$.

3.03.3.2 Optimal Choice of the CVs

The efficiency of CV-based methods in reconstructing the FES strongly depends on the choice of optimal CVs. An optimal set of CVs not only has to distinguish between the initial and final state, but also include most slow degrees of freedom involved in the transition. If important (slow) degrees of freedom are omitted, the free energy reconstruction might fail, suffer from hysteresis or take a considerable time to converge. This is due to the fact that the neglected, slow orthogonal degrees of freedom are not biased and are in principle explored as slow as in a standard MD run. A typical example of this is the case of ligand binding mechanisms requiring significant conformational changes. If the chosen CVs do not describe the conformational change, the reconstructed free energy might be wrong or very slowly converging. This was observed in the case of a ligand binding to the deep gorge of human acetyl cholinesterase (AChE). An ES method, metadynamics, was run initially with one CV, the distance between ligand and the deeply buried binding pocket. However, it was soon evident that a couple of aromatic residues lining the gorge blocked the translocation of the ligand. The reconstructed free energy suffered from hysteresis since, depending on the state of the "gate" formed by the aromatic residues, predicted a higher (open state) or lower (closed state) barrier. When a new CV describing the orientation of the aromatic residues was introduced, it was possible to get a well-converged free energy reconstruction in a fraction of the time that would have been needed without it.[85]

The most common choices of CVs for ligand binding applications are simple geometric functions of the coordinates, as distances, angles, and dihedrals formed by atoms or group of atoms. Typically, when computing binding free energies along

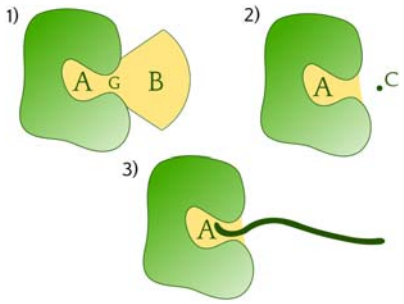

Fig. 2 Optimal choice of collective variables to study ligand binding to a target of interest. *A* is the binding cavity, *G* is the entrance gate, *B* is the bulk solution, and *C* is a point outside the cavity. In (1) an ES simulation is run using a distance and an angle as CV; in (2) the free energy difference between the bound pose and a point just outside the cavity is calculated using a distance and other geometric variables; in (3) an optimal path collective variables (PCV) describes the physical (un)binding mechanism using a series of snapshots along a low free energy pathway.

a physically meaningful association/dissociation path, one distance is used to define the position of the ligand from the target and one or two angles or dihedrals are used to describe its orientation. An additional variable can be used to explore conformational changes of the target. Geometric CVs are both easy to define and to implement in MD codes and have been successfully used together with ES approaches such as umbrella sampling (US) and metadynamics to compute a number of binding free energy profiles.[86–91]

An important issue to consider when computing the binding free energy landscape with CVs based on distances is the need to reduce the amount of sampling needed by limiting the range of distances explored (see Fig. 2). This can be achieved, for instance, by using various restraining potentials ("walls"), a common practice when using metadynamics. Indeed, in most cases, sampling all the possible orientations and positions of a ligand both in the bulk solvent and all possible nonspecific binding sites on the surface of the target is impractical. To this aim, various kinds of more or less complex restraints and walls have been introduced. These range from simply introducing a harmonic restraint acting above a set maximum distance[86] up to inverse-funnel-shaped restraints on the position of the ligand.[92] When computing absolute free energy distances in the presence of such boundaries, a simple correction needs to be applied to take into account the effective volume accessible to the ligand compared to that accessible on average to a ligand at a standard concentration.[40]

For more complex mechanisms (e.g., binding events requiring significant conformational changes of the target), geometric CVs might provide a suboptimal description.[23] In these cases CVs such as the root mean square deviation (RMSD) from a specific conformation or the changes in the target contact map have been successfully used.[93,94]

To tackle this problem, significant efforts have been devoted to develop optimal CVs and CV combinations that are generally applicable to ligand binding to flexible ligands, capturing all the important degrees of freedom involved in a transition. These include, among others, CV based on linear and nonlinear dimensionality reduction techniques such as principal component analysis vectors[95] and path collective variables (PCVs).[96] PCVs are a particularly effective choice to compute ligand binding free energies and (in combination with a path-sampling method) to compute binding kinetics (Fig. 2). PCVs are based on the idea that the main pathway used by the ligand to reach the binding pocket on its target can be described explicitly as a curvilinear path, defined by a series of snapshots along the path itself. In this way, even very complex association paths, that cannot be described by simple geometric CVs as the ligand–protein distance, can be efficiently sampled. Thus, in PCV, the configuration sampled by the ligand is described in relation to the defined path, as the progression along the path $s(\mathbf{R})$, that is, where the configuration is respective to the bound and unbound states, and the distance from the path $z(\mathbf{R})$, that is, how far from the path described in the PCV the configuration explored is. Having a series of snapshots describing the initial path, PCV are defined as

$$s(\mathbf{R}) = \frac{\sum_{i=1}^{N} i \cdot e^{-\lambda \|\mathbf{R}-\mathbf{R}_i\|}}{\sum_{i=1}^{N} e^{-\lambda \|\mathbf{R}-\mathbf{R}_i\|}} \quad z(\mathbf{R}) = -\frac{1}{\lambda} \ln \sum_{i=1}^{N} e^{-\lambda \|\mathbf{R}-\mathbf{R}_i\|}$$

where

$$\lambda = \frac{2.3 \times (N-1)}{\sum_{i=1}^{N-1} \|\mathbf{R}_i - \mathbf{R}_{i+1}\|}$$

and the distance metric $\| \ldots \|$ can be arbitrarily defined. In the software PLUMED2,[97] a plug-in compatible with many MD engines that implements metadynamics and other methods together with a wide range of CVs, the RMSD, the RMSD of distances, and the difference between contact map matrices are the available options for the distance metric. While having a good initial path for the construction of PCVs provides a considerable boost in efficiency, an approximate "guess" path can also be used. Paths obtained through preliminary ES simulations, for example, using steered MD (SMD) or metadynamics[98,99] (see later), are reported in the literature as paths constructed by interpolation of the initial and final states.[100]

3.03.3.3 Umbrella Sampling

The US approach was developed by Torrie and Valleau in 1977[101] and is based on the idea of introducing an external potential to favor the exploration of all the regions of interest (e.g., bound and unbound states of our complex), which will normally be difficult to sample in a single simulation due to high free energy barriers. Introducing the bias potential $V^*(s)$, the system evolves under the action of a modified potential $V' = V(\mathbf{R}) + V^*(s(\mathbf{R}))$ and sample a biased probability distribution $P'(s)$. The effect of the added potential $V^*(s)$ is that of adding an additional weight $e^{-\beta V^*(s)}$ to the Boltzmann weight of every state. Knowing this, and the external potential $V^*(s)$, the real probability distribution $P(s)$ can be recovered as

$$P(s) = \langle \delta(s(\mathbf{R}) - s) \rangle = \frac{\left\langle \delta(s(\mathbf{R}) - s) \cdot e^{\beta V^*(s(\mathbf{R}))} \right\rangle_{V'}}{\left\langle e^{\beta V^*(s(\mathbf{R}))} \right\rangle_{V'}}$$

where the subscript indicates that the averaging $\langle \rangle_{V'}$ is done in a simulation governed by V'. Thus, *Vsr* could be chosen so that the biased distribution $P'(s)$ is uniform and each region of the CV space is equally explored. The efficiency and convergence of the resulting free energy profile depend dramatically on the choice of the applied potential. Generally, the US bias potential is expressed as

$$V^*_{\mathrm{US}} = \frac{k}{2} \cdot (s(\mathbf{R}) - \hat{s})^2$$

that is, as an harmonic potential centered in $\hat{s}$. In most practical cases, however, it is difficult to achieve the desired sampling using a single bias potential. For this reason, it is common to perform US using "windows," each with a different value of $\hat{s}$

$$V^*_i = \frac{k_i}{2} \cdot (s(\mathbf{R}) - \hat{s}_i)^2$$

to cover the entire CV space. The free energy in each window will have an arbitrary offset, so that a matching of the separate segments of the profile is needed. Provided that the different windows have a certain degree of overlap, the statistic from each of them can be combined using the weighted histogram analysis method[102] or the umbrella integration technique.[103]

Different values have been used in the literature for both the number of windows and the force constant k, and, even if attempts to give some sensible guidelines have been made,[104] the choice remains system-dependent. Kästner and Mascarenhas[105] studied the binding of maltose to the maltose-binding protein and the conformational change between the open and close state of the protein using US. They used the distance between the centers of mass of the ligand and of the binding cite as CV and a total of 41 windows covering the CV range between 0.4 and 4.7 nm. However, the final setup was the result of a constant tweaking of the parameters. The authors started with 21 windows with a spacing of roughly 0.2 nm between each window. Later, to increase the overlap and decrease the noise of the free energy profile, they included an additional 20 windows, with a final separation of approximately 0.05 nm between each of them. A similar trial and error procedure was used for the force constant, which was initially set at 1000 kJ mol^{-1} nm^{-2} and increased to 2000 kJ mol^{-1} nm^{-2}, with one window having a k of 3000 kJ mol^{-1} nm^{-2}. Also the length of the simulations, which needs to be sufficient to equilibrate the transverse degrees of freedom not included in the CV, was evaluated for each window independently, monitoring the change in the force over 10 ns in intervals of 1 ns. Thanks to these procedures, the authors achieved a smooth free energy profile and a remarkable agreement between their ΔG^{bind} estimate (-46.1 ± 4.4 kJ mol^{-1}) and the experimental value of -49.1 kJ mol^{-1}. Moreover, they revealed important details regarding the binding mechanism, which they describe as a mixed model, involving both conformational selection and induced fit. Vargiu et al.[106] used US to describe the sliding of two drugs, duocarmycin and anthramycin, along the minor groove of DNA, using 23 windows along the selected CV, the distance between the reactive atoms of the drug and the DNA base. The separation of the windows along the CV in this case was around 0.035 nm. A complex profile characterized by different intermediates states was obtained, and interesting differences were observed for the two drugs.

3.03.3.4 Metadynamics

As discussed above, a bias potential $V^*(s(\mathbf{R}))$ can be used to "flatten" the FES and favor a more homogeneous exploration. The most homogeneous sampling is generally realized for $V^*(s) = -F(s)$, as the bias potential $V^*(s)$ compensates the underlying free energy and allows the system to diffuse freely in the CV space. While devising such a potential would require knowing a priori the $F(s)$ (which we are trying to calculate), several methods have been developed around the concept of an "adaptive" potential that try to "locally" compensate the free energy on the fly. These include Tabu search,[107,108] *local elevation*,[109] *conformational flooding*,[110] and the widely used *metadynamics*.[79,111] Metadynamics was developed by Laio and Parrinello in 2001 and, while it shares several traits with other "self-healing" approaches, it was the first to be used to reconstruct binding free energy landscapes and has a number of advantages over similar approaches. In metadynamics a history-dependent bias potential $V^*(s(\mathbf{R}))$ is built on the fly during the simulation and, as it flattens the local FES it helps overcoming free energy barriers and favors a uniform exploration of the conformational space described by the chosen CVs.[111] $V^*(s(\mathbf{R}))$ has been described in a review by Laio and Gervasio[79] as "computational sand" filling the crevasses and basins of a rough free energy landscape resulting in an easy to explore flat FES. The main idea is that, even without knowing the overall shape of $F(s)$, we can compensate the free energy landscape progressively, so that for a long

simulation, $V^*(s)$ will in time grow to be equal to $-F(s)$. To do so, metadynamics introduces a history-dependent bias potential defined as a sum of small Gaussians

$$V^*_{\text{meta}}(s,t) = h \cdot \sum_{t=\tau,2\tau,\ldots} e^{\frac{-(s(\mathbf{R})-s(t))^2}{2\delta s^2}}$$

where $s(\mathbf{R})$ is the instantaneous value of the CV and $s(t)$ is the value of the CV at time t and τ is the interval between the addition of Gaussians. While in the original algorithm the height h of the Gaussians was kept constant, the well-tempered formulation of metadynamics[112] introduces variable-height Gaussians that decrease their height throughout the simulation according to

$$h = h_0 \cdot \tau \cdot e^{\frac{-V^*(s,t)}{\Delta T}}$$

thus ensuring that for an arbitrary long time the $V(s)$ will not oscillate around the correct free energy, but converge to it, that is,

$$V^*(s, t \to \infty) = -\frac{\Delta T}{\Delta T + T} \cdot F(s)$$

where the first term takes into account the scaling factor ΔT. Thus, at the end of a metadynamics simulation, the added bias provides an estimate of the free energy profile. It is important to know that, at difference with a number of more or less similar approaches, the well-tempered formulation of metadynamics has been mathematically proven to converge to the "real" FES.[113]

Several examples of the use of metadynamics in drug binding are reported in the literature, and have been described in a recent review.[23] The first simulations, carried out by Gervasio et al., correctly predicted the binding pose for several protein–ligand complexes and were found to be able to reconstruct a full FES faster than US. The predicted binding free energies were surprisingly similar to the experimental ones.[86]

This was probably due in part to a cancellation of errors, as the use of simple geometric CVs, a suboptimal ligand force field and the very short length of the simulations impacted the convergence of the reconstructed FES. The importance of selecting an optimal set of CVs was further shown in the study of Branduardi et al.[85] on the binding mechanism of the tetramethylammonium ion into human AChE, as discussed earlier.

As aforementioned, the selection of proper CVs in ligand (un)binding is further complicated by the features of the unbound state, that is, by the large conformational space available to the ligand in the bulk solvent. This translates into a flat and diffusive region in the free energy landscape that is difficult to sample thoroughly. Masetti et al.[88] address this issue assessing how metadynamics performs when the ligand is not allowed to fully explore the unbound state. Indeed, exploration is allowed only as far as the main exit barrier (TS) and thus remains circumscribed to the protein internal cavity. Nevertheless, this approach, denominated "coarse-metadynamics," could successfully rank series of congeneric compounds. An alternative, frequently used in the first binding studies, is introducing restraints on the explored bulk area. This way, the "reduced" unbound state can be easily sampled and the convergence of FESs is faster. The binding free energy can then be corrected for the real bulk volume available to the ligand. The restraints range from simple "wall" potentials on the maximum/minimum value of the CVs, to more complex potential, as funnel-shaped ones.[92] A different approach, which has been applied extensively in the context of metadynamics, is the use of the aforementioned PCVs. Using the PCV, Fidelak et al.[90] studied a congeneric series of CDK2 inhibitors and were able to rank correctly the compounds, obtaining free energies in remarkable agreement with the experimental ones. Using a similar strategy, Provasi and coauthors used the PCV to study the binding mechanism of various ligands to the β2-adrenergic receptor. Several efforts have also been devoted to develop semiautomatic protocols for ligand scoring in a pharmaceutical setup. Saladino et al.[98] correctly ranked a series of p38 inhibitors frequently used to assess the performance of end point methods and scoring functions, running unsupervised metadynamics with PCV and a minimal semiautomatic setup. Mason et al. at Heptares Therapeutics used a combination of adiabatic biased MD and short well-tempered metadynamics runs with PCV to devise a fast and successful protocol to assess the druggability and effect of mutations on the binding of ligands to GPCRs. The approach named "MetaScore" uses the adiabatic biased MD simulations to define an initial binding path and then computes the binding free energy profiles along this path to the WT and mutant proteins with well-tempered metadynamics and PCV.[114]

3.03.3.5 Steered MD

Inspired by the pulling experiments of atomic force microscopy, Grubmüller et al.,[115] pioneered the calculation from MD of the work W needed to pull a molecule out if its binding site. To do so, the authors applied a spring-like potential of the form

$$V^*_{\text{pull}} = \frac{k}{2} \cdot (s(\mathbf{R}) - \hat{s}(t))^2$$

where the center of the potential is moved according to $\hat{s}(t) = s_0 + v_{\text{pull}} \cdot t$, to one of the atoms of the ligand. Similar approaches were later used by Schulten and coworkers[116] and became known as steered molecular dynamics. Conceptually, SMD could be thought as a continuous version of US where the harmonic potential is moved along the RC. The main difference is that, unless the work is performed reversibly and, thus, infinitely slow, the simulation is out of equilibrium. Recovering an equilibrium property, like the free energy, from nonequilibrium simulations, however, has been made possible by the work of Jarzynski.[117] Provided that the simulations are all started from an equilibrium distribution, he demonstrated that $e^{-\beta\Delta G} = \langle e^{-\beta W} \rangle$. Thus, a free energy can be

obtained by exponential average of the work values of multiple SMDs. As high-energy pathways will contribute very little to the average, convergence of the ΔG strongly depends on how far from equilibrium the simulations are and will be considerably slower for higher pulling speeds.

3.03.4 Other Methods

One of the main disadvantages of the methods in the previous section is that their efficiency relies on the choice of the CVs used. When the selected variables are not a good approximation of the RC and, in particular, do not take into account important degrees of freedom, convergence of the free energy profile can be problematic. Due to the inherent difficulty of defining a good set of CVs for complex systems, great effort has been devoted to the development of general methods that do not require an a priori knowledge of an approximated RC. This type of methods will be discussed in this section.

3.03.4.1 Replica Exchange

Free energy landscapes are smoother at high temperature and it is easier for a system to escape local minima and cross energy barriers. Several methods, indeed, have been developed in which sampling is enhanced using simulations at higher temperature. Borrowing some ideas from Monte Carlo methods, Sugita and Okamoto developed replica exchange molecular dynamics (REMD). In PT,[118] the most popular variant of REMD, different replicas of the system are run at different temperatures and exchanges of conformations between neighboring replicas are occasionally attempted. To ensure that each replica samples the correct Boltzmann distribution, exchanges are accepted automatically when the potential energy of the higher temperature replica is lower than the one of the colder replica. When this condition is not satisfied, an exchange can still occur with probability

$$p = e^{-\Delta} \quad \Delta = (\beta_i - \beta_j)\cdot(E_j - E_i)$$

where $\beta = \frac{1}{k_B T}$ and the i and j subscript are used to indicate the energy E and β of two neighboring replica. Other variants of REMD have been developed using different parameters other than temperature, for example, the *Hamiltonian replica exchange*.

Hamiltonian replica exchange MD (H-REMD) has been successfully used in the identification of ligand binding sites, thus improving the predictive value of molecular docking calculations as reported by Luitz and Zacharias[119] and to finding hidden (cryptic) binding pockets.[120] H-REMD allows the sampling of the conformational space around docking sites, using less replicas that the T-REMD approach. Indeed, since the scaling of the Hamiltonian can be applied to specific and small portions of the system, it accelerates the transitions in a more efficient way than T-REMD that increases the temperature of the whole system, including that of the many water molecules. The application of this technique to the analysis of ligand binding sites has been shown to improve the misplaced ligand–receptor complexes obtained by classical docking techniques. Obviously, this combined technique does not replace a standard docking protocol, since it is much more computationally expensive, but it can be very useful in refining selected docking poses and in difficult cases where a significant conformational change is involved or the binding cavity is not visible in the apo structure (cryptic pockets).[120]

3.03.4.2 Accelerated MD

Accelerated molecular dynamics (aMD), developed by Hamelberg et al.,[121] is based on ideas similar to US and metadynamics, that is, on the introduction of a bias potential, but dispenses the requirement for the definition of a CV. The system is simulated under the action of the modified potential $V'(\mathbf{R})$

$$V'(\mathbf{R}) = \begin{cases} V(\mathbf{R}) & V(\mathbf{R}) \geq E \\ V(\mathbf{R}) + V^*(\mathbf{R}) & V(\mathbf{R}) < E \end{cases}$$

where $V(\mathbf{R})$ is the real potential and $V^*(\mathbf{R})$ is a "boost" potential introduced by aMD. Hence, when $V(\mathbf{R})$ is lower than a certain energy value E (called "boost energy"), for example, when the system is in a stable minimum, the current conformation is disfavored by the additional potential $V^*(\mathbf{R})$. Regions where the energy is higher than E, for example, barrier regions, are not affected and the system is simulated under the action of the real potential $V(\mathbf{R})$. The "boost potential" $V^*(\mathbf{R})$ is generally defined as

$$V^*(\mathbf{R}) = \frac{(E - V(\mathbf{R}))^2}{\alpha + (E - V(\mathbf{R}))}$$

where α is a tuning parameter. The boost $V^*(\mathbf{R})$ can be applied on any term of the potential energy function and "dihedral aMD" have been used to enhance the sampling of protein conformations. Boosting of the total potential energy has also been reported in the literature, and the "dual boost" formulation is combined with a separate dihedral boosting.

The main drawback of aMD is that a high boost potential might prevent the reweighting of the different conformations[122] and, consequently, the calculations of a full FES. Other procedures, however, such as restarting multiple MDs from the different conformations explored and using MM-PBSA,[123] have been used to obtain a free energy estimate.

3.03.5 Combining Different Methods

The various methods described in the previous sections have unique advantages and disadvantages and are more or less effective depending on the specific system and the questions that need to be addressed. As also discussed earlier, often the best results are obtained when methods from different classes are combined (e.g., FEP with REST). The use of replica exchange, indeed, can be highly beneficial in cases where optimal CVs (e.g., describing complex conformational changes) are difficult to identify and, more generally, to sample the orthogonal degrees of freedom not included in the CVs and relieve from the eventual omission of important ones. One of the first successful examples is parallel tempering metadynamics (PT-MetaD),[124] which combines the CV-based metadynamics[111] with PT.[81,118] Thanks to the excursion in temperature introduced by PT, hidden degrees of freedom are sampled and the convergence of the FES is significantly improved. Conversely, metadynamics allows sampling of higher energy regions that would not be properly sampled in standard PT, such as TS.

PT-MetaD has been successfully used to compute the free energy landscape associated with the flip of the conserved "DFG" motif in a number of tyrosine kinases.[125] Type II kinase inhibitors, including the successful antileukemic drug Imatinib, selectively bind to a subset of tyrosine kinases by taking advantage of the different free energy penalty associated with the "flip" of the conserved DFG motif. Free energy calculations with PT-MetaD have not only been used to understand the molecular binding mechanism,[125] but also to clarify how drug resistance-causing mutations affect the conformational change.[126] The results of these accurate calculations have been subsequently confirmed by NMR and surface plasmon resonance (SPR) experiments.[99] An approach similar to PT-MetaD that allows the use of many CVs was proposed by Piana and Laio in the form of bias exchange metadynamics (BEMD).[127] Instead of having multiple simulations of the systems running at different temperatures as in PT-MetaD, in BEMD each replica is biased with a different CV. This allows for a more flexible number of replicas and for a higher number of CVs, without degrading the performance of metadynamics. Both methods have been used to investigate the mode of action of SSR128129E (hereafter referred to as SSR), a newly developed inhibitor of the fibroblast growth factor receptor (FGFR),[128,129] and the first inhibitor discovered to bind extracellularly. FGFR is a receptor tyrosine kinase involved in cellular processes, such as cell growth, proliferation, and survival. SSR was discovered by high-throughput screening, but several experimental techniques, including X-ray crystallography and NMR, failed to identify the binding site for the compound. Using BEMD, Herbert and coworkers were able to test a wide range of CVs and to observe the binding of SSR to the D3 domain of FGFR. Interestingly, a conformational change that elongates a small α-helix in the D3 domain was needed to open the binding pocket and for SSR to dock into the receptor. This is a typical case in which the use of combined approaches can help, as the CV is difficult to guess and there are unknown degrees of freedom (such as those involved in the unexpected conformational change) that need to be sampled.

While BEMD allows the use a larger number of CVs than PT-MetaD, it does not improve the sampling of degrees of freedom that are not explicitly included and thus might still suffer from convergence problems due to the omission of an important variable, at difference with PT-MetaD. Thus, several approaches have been developed to contain the demanding computational cost of PT-MetaD (or standard PT). An example of this is constituted by the well-tempered ensemble approach (WTE) developed by Bonomi et al.[130] In the WTE approach, a preliminary metadynamics is run using the potential energy as CV, which has the effect of broadening the potential energy distributions. This way, the overlap between the distributions of neighboring replicas is enhanced and PT-MetaD (or standard PT) can be performed using a significantly lower number of replicas.

Several examples of the use of PT-MetaD together with WTE are reported in the literature.

3.03.5.1 Successful Applications of ES Techniques

ES techniques have been successfully used to study ligand binding and conformational changes in targets of therapeutic interest. ES techniques are able to describe the complete mechanism of the process analyzed, such as the binding/unbinding of a ligand to a specific protein system. This provides relevant information that cannot be obtained from high-resolution structural techniques such as X-ray, or where only a static snapshot of the system is provided. What is more, these techniques allow us to study spontaneous target conformational changes which can take from microseconds to hundreds of seconds, and it would be impossible to study in detail with standard MD simulations. A nice example of a complex binding mechanism revealed by ES techniques (WTE metadynamics) is that of ligand binding to different isoforms of the cyclooxygenase enzyme. The cyclooxygenase enzymes (COXs) are relevant inflammation drug targets that are inhibited by the nonsteroidal antiinflammatory drugs. These drugs block the entrance of the endogenous ligand, arachidonic acid. An important consideration in the targeting of COX enzymes is the existence of two different isoforms (COX1 and COX2), one involved in the therapeutic effect and the other in side effects and toxicity. Thus there is a need for selective inhibition. Interestingly some ligands are able to differentiate between the two isoforms by means of different binding kinetics. The crystallographic data shows that the pocket of COX2 is slightly wider than the binding site pocket of COX1, and this was thought to be involved in the differential binding affinity of the selective inhibitors in COX-2 with respect to COX1. However, the molecular mechanism underlying the selectivity was not clear. Limongelli et al.[92] used well-tempered metadynamics to study the binding free energy profile of a COX2-selective inhibitor, SC-558, in COX2 and COX1. The simulations show that, while in COX1, SC-558 can be only bound to one binding site, in the case of COX2 it can bind both to the "standard" crystallographic binding site and to an "alternative" binding cavity, which had not been reported until that moment. This fact, later confirmed by crystallographic data, explains why the residence time of the inhibitor in COX2 is much longer than in COX1. These results allow the rational design of novel inhibitors with specific selectivity profiles by increasing or reducing the contact with the two binding sites (standard or alternative), producing inhibitors with fine-tuned residence times and kinetics. This work displays

how the use of ES techniques can provide useful mechanistic insights in the ligand binding mechanism, that are usually not available to any other technique.

Another interesting example was reported by Favia et al.[131] They combined metadynamics with SMD simulations in order to predict the binding path and the associated free energy of the type I 11-β-hydroxysteroid dehydrogenase (11 β-HSD-1) with its substrate. The study of the binding/unbinding processes, allowed the clarification of the residues that form the gate, the role of waters and the key role of Y177 in the ligand recognition. Moreover, they observed multiple energy basins corresponding to different conformations, and thus understood the complex interplay between the protein and its ligand.

Combined ES approaches such as PT-MetaD discussed earlier are very effective in exploring complex conformational changes, such as the activation of kinases. As discussed earlier, PT-MetaD has been used to clarify the selectivity of an anticancer drug that binds to a specific inactive conformation.[126] Interestingly PT-MetaD has also been used to clarify the mode of action of cancer-causing and drug-resistance-inducing mutations in the epidermal growth factor receptor (EGFR) tyrosine kinase.[94] Activating and drug-resistance-inducing mutations in EGFR are frequently found in many cancers, including lung cancer. Their mode of action was not clear. It had been suggested that either changes in the equilibrium between its active and inactive conformations or disorder at the dimerization interface were linked to their oncogenic potential.[132] In the paper by Sutto and Gervasio[94] PT-MetaD with CVs based on contact maps was used to quantify the effects of some of the most common single (L858R and T790M) and double (T790M-L858R) oncogenic and drug-resistance-inducing mutations on the conformational free energy landscape of the EGFR kinase domain. The result reconciled a previous proposal showing that, the L858R mutation stabilizes the active conformation at the expense of the inactive conformation and rigidifies the αC-helix at the dimerization interface. Moreover it was shown that the drug-resistance-inducing T790M gatekeeper mutant favors activation by stabilizing a cluster of hydrophobic residues.

A similar approach was used to study the effect of a single mutation (V600E) on the conformational landscape of the B-RAF kinase. This mutation is found in more than 50% of all malignant melanomas. The free energy landscapes of the WT and the V600E mutant reconstructed with PT-MetaD and a contact-map-based CV showed that mutation increases the barrier of the active to inactive transition, trapping B-Raf in the active state and increases the flexibility of the activation loop speeding-up the rate-limiting step of phosphorylation.

3.03.6 Binding Kinetics

In recent years, a lot of emphasis has been put on drug binding kinetics, with many reviews stressing the importance of predicting rates early in the drug discovery pipeline.[133–140] During the different phases of drug development, binding affinity is highly optimized, under the assumption that it constitutes a good proxy for the in vivo efficacy. However, in vivo, the concentration of a drug changes over time as a consequence of the complex physiological mechanisms of adsorption, distribution, and excretion, globally known as pharmacokinetics and the residence time (τ_{off}), that is, the time that a drug spends bound to its target, has emerged as a better indicator of a drug's efficacy.[133,136] The "optimization" of binding rates also offers new attractive opportunities to fine tune selectivity, for example, achieving longer residence times for the desired target even when the affinity for other receptors is comparable, and minimize toxicity, for example, having a faster dissociation in the case of on-target toxicity, such as in the case of dopamine receptor antagonists.[141] While experimental techniques, such as SPR, are able to measure binding rates of a drug dissociation (and association), tuning these rates would require knowledge about the structure and energy of the TS, whose limited lifetime makes it elusive to most experimental techniques. Computational tools are thus the main avenue to achieve kinetically optimized compounds.

Ideally, being able to run arbitrarily long MD simulations, the rates of drug (un)binding could be derived by simply averaging the dissociation/association time over multiple events directly observed in a simulation. Notwithstanding advancements in computer hardware, MD remains too computationally expensive to reach timescales where most biomolecular processes could be observed spontaneously. Purpose-built machines, such as Anton,[5,6] while accurately predicting association rates, still struggle to observe spontaneous dissociation of drugs from their target, for which typical residence times are in the order of seconds to hours, or even days. Thus the calculation of drug binding rates cannot forgo, generally, the use of some kind of "enhanced sampling" technique, able to speed-up the simulations.

Interestingly, while the ecosystem of computational methods for the estimation of molecular rates is flourishing, very few applications to drug binding are reported in the literature and most of these cases are confined to very simple systems, like the binding of benzamidine to the serine protease Trypsin.

De Fabritiis and coworkers[11] used the ACEMD software[142] and a GPU-based distributed computing grid to obtain around 500 short trajectories (100 ns each, for an aggregate time of 50 μs) for the aforementioned benzamidine–trypsin system. They were able to observe numerous binding and unbinding events thanks to the fast kinetics (and limited affinity, around -6.2 kcal mol^{-1}) of benzamidine. Using a MSM[80] they reconstructed a full free energy profile and characterized the binding mechanism in details, identify several metastable states were benzamidine makes weaker interactions with the protein. This also allowed them to infer the on and off rates for the binding, which were predicted to be $k_{on} = (1.5 \pm 0.2) \times 10^8$ M^{-1} s^{-1} and $k_{off} = (9.5 \pm 3.3) \times 10^4$ s^{-1}, both deviating at least an order of magnitude from the experimental results, 2.9×10^7 M^{-1} s^{-1} and 6×10^2 s^{-1}, respectively. The authors associated the large errors to the inherent difficulty of extracting long-time rates from a collection of shorter trajectories and to the lack of sampling of full unbinding events, leading to higher uncertainty for the k_{off}. Noé and Plattner[143] revisited the same system with a similar approach, generating 543 MD trajectories with an aggregate time of nearly 150 μs and using MSM to derive

Table 1 Benzamidine-trypsin binding kinetics: experimental values compared to Markov State Models and Metadynamics predictions

Method	k_{on} ($M^{-1} s^{-1}$)	k_{off} (s^{-1})	*References*
Exp.	2.9	6	
MSM	15 ± 2	950 ± 330	De Fabritiis et al.[11]
MSM	6.4 ± 1.6	131 ± 109	Noé and Plattner[143]
Metadynamics	1.2 ± 1	0.91 ± 0.25	Tiwary et al.[144]

kinetic parameters. While a remarkable agreement was obtained for the $k_{on} = (6.4 \pm 1.6) \times 10^7\ M^{-1}\ s^{-1}$, the dissociation rate was overestimated as in the work of De Fabritiis and coworkers[11] with a predicted value of $(131 \pm 109) \times 10^2\ s^{-1}$, due to the poorly sampled dissociation events. Nonetheless, the authors were able to give a compelling description of the binding pathway and mechanism, which includes features typical of "conformational selection" and "induced fit" models. Tiwary et al.[144] calculated the on and off rates for the same system using a new method based on "infrequent biasing" metadynamics.[145] A summary of the results, compared to those obtained by previous works, is reported in **Table 1**.

An aggregate time of 5 μs of biased simulations were needed to calculate rates, but resulted in a better agreement between the predicted kinetics parameters and experiments.

The prediction of binding rates for more complex systems was recently attempted by Morando et al.[99] who studied the binding of the antileukemic drug Gleevec to the c-Src tyrosine kinase. Using a new method, transition state-partial path transition interface sampling, which combine the free energy calculated by metadynamic with a transmission coefficient obtained through path sampling, the authors obtained a remarkable agreement between the calculated k_{off} ($0.0114\ s^{-1}$) and the experimental results, which they measured using SPR ($0.024–0.19\ s^{-1}$). Using scaled potentials, which enhance the transitions between different minima, Mollica et al.[146] were able to calculate *relative* off rates for several complexes of pharmaceutical interest. This way, the authors were able to rank different congeneric compounds predicting the k_{off} ratio with respect to a reference ligand–target complex, achieving regression correlation coefficients in the 0.85–0.95 range. While being more approximate and providing only partial information, the method is more straightforward and easy to implement, in addition to requiring fewer computational resources.

In summary, recent years have seen significant advancements in the prediction of association and dissociation rates by MD simulations. The field remains, however, in its infancy and, with a limited number of examples reported in the literature, the suitability of the different methods for the prediction of binding rates in a pharmaceutical setup remains an open question.

3.03.7 Conclusions

The accuracy and usefulness of free energy methods have greatly improved in recent years. This, together with significantly improved protein and ligand force fields and the availability of low-cost high-performance computing resources provided by graphics processing units and cloud computing, concur to make free energy methods a fundamental tool in CADD. In this article, we have discussed a number of recent and recently improved algorithms as well as a range of interesting applications reported in the literature. Free energy methods can now not only compute accurate relative and absolute binding free energies, but also conformational free energy landscapes, cryptic binding pockets, binding mechanisms, and (in combination with other approaches) binding kinetics.

3.04.1 Introduction

Among the computational methods used in drug discovery, virtual screening is probably the most popular approach and has received considerable publicity.[1–3] Yet, despite being an extremely powerful method for screening many compounds in a minimum amount of time, the actual number of projects in which virtual screening has been a key factor in the discovery of a new drug are relatively limited.[4] Several factors might explain this, among which the most critical are perhaps the tendency of users to rely on static models for the receptor and even for the ligands and the fact that virtual screening is plagued by the lack of accuracy in determining the relative binding free energy of a ligand along with the associated entropic and enthalpic contributions.[4,5]

Taking into account protein flexibility is fundamental when attempting to discover potent and selective molecules that can either deactivate or activate a particular protein. Indeed, proteins are dynamic entities and their dynamic behavior is intimately linked to their function.[6,7] Therefore when modeling the affinity of a ligand for a protein, one needs to go past the historical lock-and-key model,[8] which is based on the assumption that proteins are rigid bodies, and account for the dynamics of the binding site (see, e.g., Ref.[9] and references therein). Similarly, when it comes to understanding enzyme catalysis at a molecular level, the effect of dynamics needs to be taken into account.[10–14] For example, an enzymatic reaction can proceed via a high-energy conformation different from the predominant enzyme-ligand complex, that stabilizes greatly the transition state (TS) of the reaction and that is accessible thanks to the enzyme structural fluctuations.[15,16] It is, therefore, crucial to account for protein dynamics when studying protein-ligand binding, enzymatic reactions, or any other processes relevant to drug discovery.

Computational methods such as Molecular Dynamics (MD), Free Energy Perturbation (FEP), Quantum Mechanics (QM), and hybrid Quantum Mechanical/Molecular Mechanical (QM/MM) methods are able to account for protein dynamics and also to provide thermodynamics data that are far more accurate than those obtained from virtual screening or molecular docking. This increased accuracy, however, comes at the cost of an increased computational burden, and thus these methods were often disregarded in drug discovery and development. However, considerable progress in both hardware and software[17–23] make the use of these computational approaches much more amenable to the typical time frame of a computer-aided drug discovery project. Moreover, unlike virtual screening, these methods are not limited to studying ligand binding but can deliver extremely valuable information at the atomic level on the mechanisms involved with specific protein functions, thereby providing the necessary framework for the discovery, design, and improvement of active pharmaceutical ingredients.

In this article, we will first briefly review the theoretical underpinning of MD, QM, and QM/MM and then provide an overview of the recent methodological advances that have increased the accuracy, ease of use, and rapidity of these techniques and that could benefit drug discovery. We will then present a number of case studies that highlight the power of these methods in drug discovery

and development. Since the use of MD and molecular mechanics (MM) based free energy methods in drug discovery has been reviewed in great detail elsewhere (see, e.g., Refs.[17,24–31]), here only a few examples of these approaches will be presented and the focus will be primarily made on the applicability of QM/MM methods. Specifically, we will discuss the use of MD and free energy calculations to deciphering antiviral resistance mechanisms, the application of QM/MM to fighting antimicrobial resistance and designing covalent inhibitors, as well as the use of computational methods to predict drug metabolism and to support sustainable drug development processes. We will then conclude by discussing the advantages and limitations of MD, QM, and QM/MM approaches in drug discovery and development.

3.04.2 Theoretical Background

3.04.2.1 About MD

MD simulation is one of the few techniques able to provide direct information on protein dynamics and has been referred to as the "computational microscope" of biochemistry.[32] Several books and reviews present MD in great detail and describe how this technique is implemented in a computationally efficient and robust manner (see, e.g., Ref.[33–36] and references therein). Here, only the theoretical basis of MD will be summarized.

The central concept of MD simulation relies on Newton's second law:

$$\boldsymbol{F}_i = m_i \boldsymbol{a}_i \tag{1}$$

which states that it is possible to determine the acceleration $\boldsymbol{a}_i$ of a particle i of mass m_i by knowing the force $\boldsymbol{F}_i$ applied on it. Since the force acting on each atom of a macromolecule can be expressed as the first derivative of the potential energy V of the system with respect to the atom position $\boldsymbol{r}_i$, and the acceleration corresponds to the second derivative of the atomic position with respect to the time, Eq. (1) can be rewritten in its differential form as:

$$-\frac{\mathrm{d}V}{\mathrm{d}\boldsymbol{r}_i} = m_i \frac{\mathrm{d}^2 \boldsymbol{r}_i}{\mathrm{d}t^2} \tag{2}$$

For atoms with positions $\boldsymbol{r}_i$ at a specific time t, the position a small time step Δt later is given by a second order Taylor expansion.

$$\boldsymbol{r}_i(t + \Delta t) = \boldsymbol{r}_i(t) + \boldsymbol{v}_i(t)\,\Delta t + \frac{1}{2}\boldsymbol{a}_i(t)\,\Delta t^2 \tag{3}$$

This enables the atomic positions to be calculated numerically after a small time step knowing the position, velocity, and acceleration at time t, the acceleration being obtained with Newton's second law. Therefore, starting from an initial atomic model prepared from X-ray crystallography or NMR data, and from initial velocities obtained from a Boltzmann distribution at a given temperature, a trajectory can be calculated by derivation of the potential energy function with respect to the three-dimensional position of each atom.

However, Eq. (3) is, in fact, a truncated version of the Taylor expansion, which includes higher order terms. These terms cannot be simply ignored, as it would lead to important errors. One computationally efficient way to overcome this is to use the Verlet algorithm or one of its variants. Presently the velocity Verlet algorithm is used in most of the MD simulation packages owing to its improvement over the classical Verlet algorithm and its leap-frog variant. Indeed, the Verlet algorithm uses no explicit velocities and lack of precision, whereas in the leapfrog variant, velocities are explicitly calculated but they are not calculated at the same time as the positions. In contrast, the velocity Verlet algorithm does not compromise on precision and velocities, accelerations, and positions are calculated at the same time t by relying on Eq. (3) and also on Eq. (4), which gives the velocities $\boldsymbol{v}_i$ at a specific time t plus a small time step Δt later.

$$\boldsymbol{v}_i(t + \Delta t) = \boldsymbol{v}_i(t) + \frac{1}{2}[\boldsymbol{a}_i(t) + \boldsymbol{a}_i(t + \Delta t)]\,\Delta t^2 \tag{4}$$

The only missing piece is the potential energy of the system to retrieve the acceleration. Even though potential energy can be calculated using QM in order to take into account electronic effects, this is only possible for small molecules due to the computational resources required. For proteins, the potential energy can be calculated by empirical energy functions based on classical mechanics. Both the energy arising from bonded and from non-bonded interactions should be taken into account as shown in the simplified, typical potential energy function described (adapted from Ref.[28]). Bonded interactions, bond stretching, and angle bending are modeled using harmonic potentials, while the steric barriers (as well as electronic effects, depending on the force field) between atoms separated by three bonds are modeled by a torsion angle potential. Non-bonded interactions are composed of van der Waals interactions, modeled by the Lennard-Jones 6–12 potential, and of electrostatic interactions represented by a Coulomb potential. Parameters used in the potential energy function are determined using both quantum mechanical calculations on small systems and experimental data. The potential energy equation and its parameters are collectively referred to as a force field. Several force fields are available, the most common associated with the simulation packages AMBER,[37] CHARMM,[38] and GROMOS;[39] it is important to distinguish between the force field (parameter set) and the simulation package (which may have similar names). Several generations of forcefields associated with each package have been developed, and can be used with different simulation programs.

$$E_{\text{Total}} = \sum_{\text{Bonds}} K_r\left(r - r_{\text{eq}}\right)^2 + \sum_{\text{Angles}} K_\theta\left(\theta - \theta_{\text{eq}}\right)^2 + \sum_{\text{Dihedrals}} \frac{V_n}{2}\left[1 + cos(n\phi - \gamma)\right] + \sum_{\text{Non-bonded}} \left[\frac{A_{ij}}{R_{ij}^{12}} - \frac{B_{ij}}{R_{ij}^{6}} + \frac{q_i q_j}{\varepsilon R_{ij}}\right] \tag{5}$$

The trajectory of each atom can then be solved numerically using a MD software package such as AMBER,[40] CHARMM,[41] GROMACS,[42,43] GROMOS,[44] or NAMD,[45] all of which are specifically designed to run MD simulations on supercomputer clusters. In addition, MD codes allow the microscopic data (atom positions, velocities, etc.) obtained from the simulation to be linked to macroscopic observables (energy, temperature, pressure, etc.), using statistical mechanics. At this point, it is important to note that MD simulations calculate time averages while the macroscopic observables are assumed to be an ensemble average, therefore, to link the results of a MD simulation to macroscopic data, one should rely on the ergodic hypothesis which states that ensemble average equals time average. To satisfy this equality, MD simulations should be sufficiently long to sample enough representative conformations.

3.04.2.2 A Brief Overview of the Foundations of Quantum Chemistry

The theoretical underpinning and computational implementation of quantum chemistry have been detailed in several classical textbooks (see, e.g., Refs.[33,46,47] and references therein) and here only some of the key concepts are introduced.

Quantum chemistry is typically based on the time-independent Schrödinger equation, which requires a number of approximations to be applied in order to find a solution. The first one, the Born-Oppenheimer approximation, consists in considering the nuclei as fixed in space. Indeed, due to the difference in mass between nuclei and electrons, the electrons will move faster and thus their motion can be considered as being instantaneously equilibrated at each nuclear displacement. This approximation helps to greatly simplify the Schrödinger equation but is not sufficient. The next approximation, the orbital approximation, consists of considering the wave function of a many-electron system as the product of one-electron wave functions called orbitals. In the third approximation, each orbital can be described by a linear combination of a set of atomic orbitals that form a basis set.

These approximations form the basis of the Hartree-Fock (HF) method. HF, however, does not take into account electron correlation, that is, the tendency of electrons to avoid each other, and this omission can lead to significant errors. To overcome this problem, other ab initio methods, such as the second order Møller-Plesset (MP2) method, take into account electron correlation at the cost of an increased computational burden. Density functional theory methods (DFT) have been developed with the objective of approaching the accuracy of the post-HF ab initio methods at a lower computational cost. These methods rely on the electron density distribution instead of the wave function in order to calculate the (ground state) energy. However, the functional linking electron density and energy is not known and the different DFT methods seek to approximate it. Several functionals have been developed, among which B3LYP is probably the most famous. Semi-empirical methods (such as MNDO, AM1, PM3, PM6, DFTB etc.), are the least computationally demanding methods. MNDO-types methods are based on a simplification of the HF method whereas DFTB is based on DFT. Semi-empirical methods are typically the least accurate and rely on experimental correction to improve accuracy. However, utilization of a semi-empirical method on a reaction for which the method has been correctly parameterized can lead to results that approach the reliability of a fraction.

3.04.2.3 Hybrid QM/MM Simulations

QM calculations are particularly intensive from a computational point of view and the required computational power increases significantly with the size of the system. It is therefore typically not feasible to model a complete protein (and surrounding solvent) with QM. However, changes occurring during catalysis are usually confined to a small region of the enzyme with only a few residues directly involved. Therefore, a very powerful approach to study enzymatic reactions is to use a hybrid QM/MM scheme in which the active site and substrates are modeled using a QM level of theory, whereas the rest of the solvated enzyme is modeled at the MM level of theory (Fig. 1). This approach enables to model in a computationally efficient manner the reactions taking place within the active site of an enzyme or any other phenomena in which electrons or polarization are important. QM/MM methods are particularly useful in studies of enzyme-catalyzed reaction mechanisms, but are increasingly also finding application in drug discovery and the award of the 2013 Nobel Prize in Chemistry to Martin Karplus, Michael Levitt, and Arieh Warshel, recognized the importance of QM/MM methods in understanding biological function.[48–50]

QM/MM methods have been presented in great detail in various excellent reviews (see, e.g., Refs.[51–56] and references therein) and we focus here on some of the key aspects of QM/MM.

Hybrid QM/MM approaches for modeling enzyme reactions are based on using a QM method to describe the substrates as well as the residues involved in the reaction and an MM force field to describe the rest of the system. The size of the QM region, that is, which atoms are treated by QM, is a trade-off between accuracy and computational cost: the more atoms added the longer the calculations, but the better the accuracy might be. Usually, the substrates, the residues participating in the reactions (in most of the cases their side chain only) as well as other molecules that might be directly involved in the reaction (metal ions, water molecules, inorganic ions, etc.) are included in the QM region.

The total energy of the system can be expressed as follows in the case of the additive QM/MM approach:

$$E_{\text{Total}} = E_{\text{QM}} + E_{\text{MM}} + E_{\text{QM/MM}} + E_{\text{Boundary}} \tag{6}$$

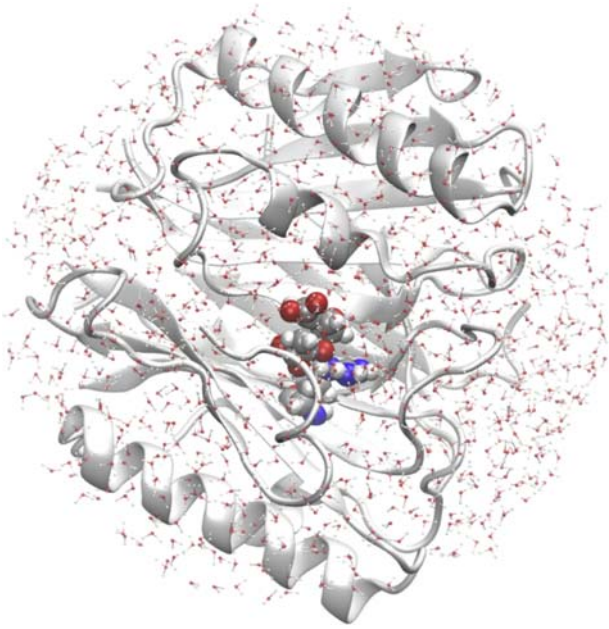

Fig. 1 Typical QM/MM partitioning, illustrated here for chorismate mutase. The protein and water molecules, shown in a *cartoon* and a *balls and sticks* representation respectively, are treated with classical MM, whereas the substrates and relevant active site residues, represented with *spheres*, are treated with QM.

where E_{QM} corresponds to the energy of the QM region, E_{MM} to the energy of the MM region, $E_{Boundary}$ arises from the finite number of atoms in the simulation, and $E_{QM/MM}$ describes the interactions between the QM and MM regions. This term accounts for the electrostatic "embedding" of the QM region within the MM region, allowing the QM region to be affected by the charges of the atoms in the MM region. It also includes van der Waals interactions between QM and MM atoms as well as bounding terms arising when the separation between QM and MM region "cut" a covalent bond (e.g., when only the side chain of a residue is included in the QM region). In this case, the most common approach consists in creating a fictitious link atom (usually a hydrogen atom), which is added along the covalent bond that crosses the QM-MM boundary, so the valence of the QM atom is satisfied. It is important to note that one should avoid "cutting" polar covalent bonds and, when possible, a good choice consists in cutting a C-C bond distant from any functional groups or from the backbone atoms.

There are two main types of QM/MM approaches to model reactions. The first one, adiabatic mapping, essentially relies on performing energy minimization at different values of a reaction coordinate to reconstruct the potential energy surface. The advantage of this approach is that high-level QM methods can be used (ab initio, DFT). The main drawbacks are that the energy minimization can lead to local minima (and thus conformational changes during the reaction cannot be correctly modeled) and the calculations lead to a potential energy profile and not a free energy profile, although the free energy profile can, for example, be estimated by performing frequency calculations in order to include an approximated entropy contribution. The second approach is similar but consists in running MD simulations, more specifically umbrella sampling along the chosen reaction coordinate (QM/MM-MD approach). This has the advantage that it leads to a free energy profile after statistical reweighting of the umbrella sampling trajectories using, for example, the Weighted Histogram Analysis Method, and to a more accurate exploration of the phase space. However, this method requires a large number of calculations of the energy (one per MD step) so only less accurate, semi-empirical methods (e.g., AM1, PM6, SCC-DFTB, etc.) can be used. This can be partially solved by including single point energy calculations along the reaction pathway at a high-level of QM, thereby improving the accuracy of the method.

As conformational and catalytic landscapes are linked and different conformations can lead to different energy profiles of reactions,[10,57,58] it is important several QM/MM calculations starting from slightly different conformations are performed (e.g., obtained from MD simulations) to account for the fact that, in reality, the reactions do not start from a single structure but instead from an ensemble of structures.

3.04.3 Accurate, Reliable, Fast, and Easy to Use Methods for Drug Discovery and Development

3.04.3.1 Recent Advances in MD Simulations

One of the main limitations of MD is the sampling problem: has the simulation run for long enough? If the simulation were to be run for longer, would the results be different? Fortunately, there are various ways to get around this problem. One of the most commonly used approaches is to run several shorter MD simulations starting with different atomic velocities instead of a single

longer simulation. Due to the chaotic nature of MD, these small velocity changes are sufficient to generate completely different trajectories and ultimately lead to a much better sampling of the free energy landscape than a single trajectory.[59]

Another approach, designed to adequately sample the free energy landscape is to run numerous very short simulations, each sampling different parts of the free energy landscape and then to reconstruct the whole process using Markov state models (MSMs).[18,60,61]

Classical all-atom MD can also be modified to access long timescales or sample rare events with reasonable computational resources. These techniques are based on an enhanced sampling of the free energy landscape via various means and include, for example, accelerated MD,[62] metadynamics,[63] or temperature replica-exchange MD[64] among many others.

Methods and protocols designed to address the sampling problems are not the only advances that could benefit drug discovery, the continuous improvements of the various force fields[65–68] with the inclusion of an ever growing number of biologically relevant small molecules, carbohydrates, lipids, and peptides,[69–71] as well as the tools designed to rapidly, automatically, and accurately parameterize any sort of ligands[72–77] can make major differences in the accuracy of MD calculations. In addition, the development of polarizable force fields[78–80] enables to account for the polarizability of molecules in a purely molecular mechanical framework.

3.04.3.2 Determination of the Thermodynamics Properties of Protein-Ligand Association

Free energy calculations[81–83] are an essential element of the molecular modeler toolbox and are used for a wide variety of applications such as calculating solvation energy, binding thermodynamics, or energy changes associated with conformational changes.[84] Of particular interest to drug discovery is the study of molecular recognition and binding using free energy methods that rely on MD, Monte Carlo (MC), or QM/MM for an improved accuracy compared with standard docking experiments that are associated with large errors due to the fact that they do not account for entropy, water effects, electrostatics, and protein flexibility (with the exception of induced fit docking which accounts for some degree of binding site plasticity).

One of the easiest approaches to include protein flexibility is to rely on ensemble-based screening methods in which, for a given protein, an ensemble of structures obtained from MD or MC simulations, NMR experiments, or other approaches are used to dock the compounds of interest.[85–87] This method presents a clear advantage when compared with single conformation docking, but cannot lead to reliable free energy estimates due to the limitations of the scoring functions used in docking. A more accurate estimation of the binding free energies can be obtained using MM combined with continuum solvation models such as Poisson-Boltzmann or generalized Born surface area.[88–90] These approaches are the fastest MD-based methods that provide a fair precision, but they are limited by the large errors on the entropy term which is approximated by normal mode analysis frequency calculations. Alchemical FEP[91,92] (and related free energy methods such as thermodynamic integration) and adaptive biasing force[93] are among the most accurate approaches that can be used in estimating binding free energies and correlate very well with experimental results. In order to facilitate the use and improve even more the accuracy of these high-level free energy simulations, a set of good practices has been proposed,[71,94,95] including the addition of specific geometrical restraints that alleviate the sampling limitations of MD.[96,97] Finally, tools like the Sire molecular simulation package (siremol.org), FESetup[98] that permits a fast and automated setup of the calculations or WaterSwap[99] which enables the calculation of absolute free energies with high accuracy in a simple and efficient way, provide the users with a powerful yet simple framework for running high-level free energy calculations.

Further improvements in terms of accuracy of the free energy methods come from the use of QM and QM/MM approaches[100,101] that enable to account for charge transfer or polarization of the protein-ligand complex. Free energy calculations can now be carried out in a reasonable amount of time with high-level QM/MM methods.[102]

Another approach for studying ligand-protein association consists in running multiple MD simulations in which the ligand is allowed to diffuse without constraints into and from the binding site of the protein and to reconstruct the binding mechanism using MSM.[103,104] This approach is particularly demanding computationally but provides invaluable information on the ligand binding and unbinding pathways as well as on the kinetic and thermodynamic parameters of the phenomenon. Metadynamics has also been successfully used to study binding and unbinding mechanisms and, by following the binding process along representative coordinates and using carefully chosen restraints such as a funnel-shaped harmonic potential, greatly reduces the computational cost of simulations (when compared with unbiased MD binding simulations) while providing detailed mechanistic and thermodynamic insights[105,106] and even recover unbiased kinetic information.[107]

3.04.3.3 Chemical Accuracy in QM/MM Calculations: High-Level Ab Initio QM/MM Methods

Recent progress made in the field of QM/MM makes it possible to predict energy barriers of enzyme-catalyzed reactions with unprecedented accuracy and leads to results in excellent agreement with experimental data.[108] In particular, state-of-the-art QM/MM calculations on chorismate mutase (CM) and *para*-hydroxybenzoate hydroxylase (PHBH)[109] resulted in a calculated activation free energy at 300 K of 13.7 kcal mol^{-1} for PHBH whereas experimental values range between 14 and 15 kcal mol^{-1}, and for CM an activation enthalpy at 300 K of 13.1 kcal mol^{-1} and an entropic contribution of 2.5 kcal mol^{-1}, compared with experimental values of 12.7 and 2.7 kcal mol^{-1} respectively.

In addition, recent pure QM calculations (using linear-scaling DFT) of the reaction catalyzed by CM was in excellent agreement with DFT-based QM/MM calculations for the same reaction,[110] highlighting the fact that QM/MM methods can deliver results similar to large scale QM calculations for a fraction of the computational burden. This work also showed that the MM treatment

of the residues and water molecules, not directly involved in a reaction, correctly approximate the effect of these residues on the reaction.

Methodological developments such as the projector-embedding approach can be applied in combination with QM/MM calculations,[111] and promise an attractive approach for calculations on large biomolecular systems, and makes highly accurate ab initio (e.g. CCSD(T)) calculations of reaction energies and barriers, and other electronic properties.

3.04.4 Examples of Applications

3.04.4.1 Deciphering the Effects of Influenza Virus Mutations on Antiviral Efficiency

Response to the pandemic H1N1-2009 influenza virus led to the massive use of the neuraminidase inhibitors oseltamivir (commercialized under the trade name Tamiflu) and zanamivir (commercialized under the trade name Relenza) which precipitated the appearance of drug-resistant strains of the virus.[112] In order to maintain an arsenal of potent antiviral agents for future pandemics, an in-depth understanding of such resistance mechanisms was required.

Using MD simulations, Woods et al.[113] investigated the molecular basis of drug resistance for neuraminidase mutant I222R and double mutant I223R/H274Y (using N2 numbering, corresponding to H275Y and I223R in the original paper, **Fig. 2**) which dramatically reduce the effectiveness of oseltamivir and to a lesser extend zanamivir.[114,115] Results of this study indicated that while oseltamivir can maintain the 150-loop in a closed conformation in the wild type and I222R mutant, in the I222R/H274Y double mutant, the loss of a key hydrogen bond between the 150-loop and the inhibitor led to the opening of the binding site. The resulting modification of the electrostatic environment that follows this conformational change results in a lower affinity of oseltamivir for its target. It was also shown that the I222R mutation brings about a competitive hydrogen bond that reduces binding affinity. Zanamivir, however, is able to compensate for this by forming a strong hydrogen bond with a neighboring residue thanks to its guanidinium group. The authors then suggested that by designing inhibitors capable of forming strong hydrogen bonds with the 150-loop or with R222, thereby maintaining the closed conformation in the presence of inhibitor, this resistance mechanism should be overcome.

Independently, Chipot and co-workers[116] used FEP calculations to determine the molecular basis of drug resistance in three H1N1-2009 neuraminidase single mutants H274Y, N294S, and Y252H (**Fig. 2**). They found that the resistance in these mutants is caused by water molecules entering the binding site and reorganizing the residues surrounding the active site, thus perturbing the electrostatic environment of the active site. Because of its increased polarity compared with oseltamivir as well as its larger size impeding the entrance of water molecules into the active site, the authors argued that zanamivir is able to maintain a better selectivity toward the mutants than oseltamivir. Finally, the calculated differences in relative binding energy of oseltamivir and zanamivir between the wild-type enzyme and each mutant were in very good agreement with the experimental values, confirming the ability of FEP to provide accurate estimates of free energy changes upon mutation.

The role of water was later confirmed and refined by Woods et al.[117] who ran 500 ns MD simulations of the wild-type, three single mutants (H274Y I222R and S246N) and two double mutants (I222R/H274Y and S246N/H274Y), all complexed with oseltamivir (**Fig. 2**). In the case of the mutants, multiple unbinding and rebinding events took place over the course of the simulations.

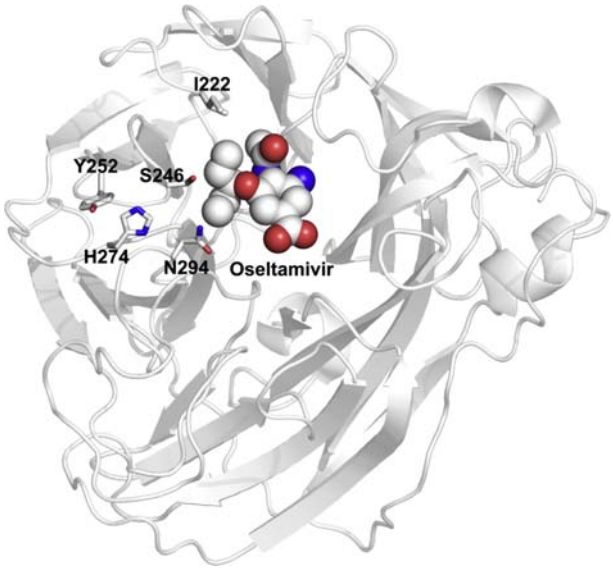

Fig. 2 Monomeric unit of neuraminidase from H1N1-2009 in complex with oseltamivir (represented with *spheres*) PDB ID: 3TI6. Residues which are discussed here are represented with *sticks*.

Careful examination of these unbinding events revealed that the mutations lead to conformational changes that enable bulk water to infiltrate the binding pocket, thereby displacing the drug. In addition, the simulations exposed the role of tightly bound water molecules, in a pocket underneath oseltamivir, as being essential for the binding of the drug. Rebinding kinetic was shown to be strongly affected by the diffusion of excess water molecules out of this pocket, demonstrating the general importance of water in binding and unbinding events. Finally, the study further clarified the role of the 150-loop since the loop opening and closing motions were concomitant with the unbinding and rebinding of oseltamivir respectively. Because oseltamivir resembles the TS of neuraminidase, the authors suggested that the movement of this loop is likely to be functionally important, enabling binding of the substrate and release of the product.

In order to determine whether or not the tightly bound water molecules underneath oseltamivir should be targeted for displacement during ligand design, the absolute QM/MM binding free energy of these water molecules to neuraminidase/ligand complexes (i.e., the free energy difference between the complex containing the water molecule and the complex with an unoccupied water binding site) were calculated. These water molecules being conserved in a range of neuraminidases, the calculations were performed in the N9 variant of neuraminidase[118] for which simulation data of the enzyme in complex with oseltamivir, peramivir (commercialized under the trade name Rapivab), sialic acid, TS analog DANA, and ligand G28 were readily available. QM/MM binding free energy calculations were performed using a MC replica exchange thermodynamic integration QM/MM[102] which enables to greatly improve the treatment of electrostatics when compared to MM approaches. Enzyme and ligands were treated with the AMBER99 force field[119] and the Generalized AMBER Force Field[37] respectively, whereas the QM/MM calculations for the water molecules were performed at the BLYP/aug-cc-pVDZ level for QM and TIP4P[120] level for the MM. Compared to MM free energy calculations, the QM/MM calculations were found to predict a tighter binding of the water molecules, a consequence of the more accurate treatment of electrostatics with QM. Comparison with the same perturbation in solution demonstrated that this effect is important for binding affinity. This study confirmed the importance of a water molecule which presents a strong electrostatic interaction with the protein and thus highlights the importance of taking it into account when designing neuraminidase inhibitors. Moreover, the authors used this as a case study to demonstrate the efficiency and applicability of the used protocol for calculating precise QM/MM binding free energy.

The protocol used to study antiviral resistance in H1N1-2009 proved itself to be extremely valuable to assay the effects of mutation during the H7N9 avian influenza outbreak in 2013. The Effect of the mutation R292K on the binding of oseltamivir, zanamivir, and peramivir was calculated within 2 weeks of H7N9 sequence's availability. MD simulations showed that the R292K mutation altered-drug binding, and WaterSwap[99] calculations confirmed a reduction in absolute binding free energy of the three antivirals for the R292K mutant. The results, submitted 2 months after the first H7N9 cases were reported by the Chinese authorities, compared very well with the experimental results published later that found a weakened binding affinity of all three drugs in the R292K mutants.[121]

3.04.4.2 Improving the Design of Covalent Inhibitors

Despite having a proven track-record of success for a variety of indications, there is a tendency to avoid covalent inhibitors in drug discovery programs, owing to concerns about toxicity, long-lasting effects, and extremely high potency.[122,123] Covalent inhibitors present, however, a number of key advantages over reversible-inhibitors[123,124] and the development of strategies that address the safety and selectivity issues associated with this mode of action has led to the resurgence of covalent inhibitors as drug candidates.[122,125,126]

In order to design highly selective covalent inhibitors, it is crucial to understand the reaction mechanisms, and also the binding modes, of these agents, in particular, the relative orientation between the nucleophilic side chain involved in the covalent bond and the ligand.[126] This sort of information can be provided with great accuracy using QM/MM as it enables the bond formation between the enzyme and the inhibitor to be modeled.

The case of fatty acid amide hydrolase (FAAH) is a striking example of how QM/MM can improve the design of covalent inhibitors. FAAH is responsible for the deactivating hydrolysis of lipid amides and is a promising drug target.[127,128] Carbamic acids, such as URB524 and URB597 (**Fig. 3A**),[129] are potent covalent FAAH inhibitors that react with the active site nucleophile Ser241 (**Fig. 3B**). The exact mechanism by which URB524 and its derivatives are able to carbamoylate Ser241 was, however, unknown. In particular, URB524 can be docked in two possible orientations and previous studies failed to identify the actual biologically relevant binding mode. Lodola et al.[130] investigated the binding mode of URB524 using QM/MM at the PM3/CHARMM22 level and correcting the potential energy by running gas phase QM calculations at the B3LYP/6-31+G(d) level of theory. The resulting B3LYP/6-31+G(d)//PM3-CHARMM22 energy profile showed that only one of the two conformations of URB524 was favorable for the carbamoylation of Ser241, the other conformation leading to higher energy barriers and to an unstable product. This prediction was later confirmed by the crystallographic structure of the FAAH-URB597 carbamoylated adduct,[131] demonstrating the reliability of this QM/MM approach.

In another study on the covalent inhibition of FAAH, Mulholland and co-workers[132] used the same level of QM/MM theory to rationalize experimental results suggesting that FAAH is insensitive to the electron donor effect of conjugated substituents on the biphenyl scaffold of URB524. For the three inhibitors tested in this study, the QM/MM calculations showed that the rate limiting step was always the deprotonation of Ser241 which leads to the formation of a tetrahedral intermediate, that is, the first step of the three-step mechanism characterizing the carbamoylating reaction of Ser241. Electron-donor substituents do not affect significantly the TS of this step as the TS structure is dominated by the proton transfer between Ser241 and Ser217 (**Fig. 3B**). Differential

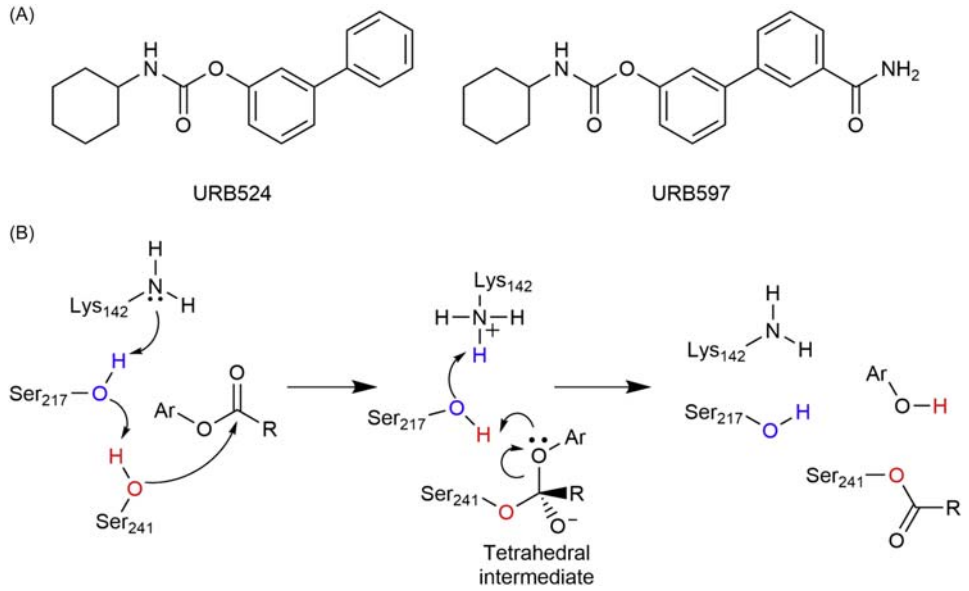

Fig. 3 (A) Structure of carbamic acids URB524 and URB597. (B) Reaction mechanism of Ser241 carbomoylation in FAAH.

transition state stabilization (DTSS), which consists of assessing the contribution of each residue surrounding the TS to its stability,[133,134] performed at the MP2/6-31+G(d) level of theory, revealed that the stabilization of the TS is mainly due to residues involved in the proton transfer reaction. Using QM/MM, the authors were able to demonstrate that the energy barrier of the rate limiting step is not affected by substitutions that greatly affect the pharmacokinetic properties of the carbamates derivatives, thereby opening a new avenue for the development of potent and selective inhibitors presenting an improved absorption, distribution, metabolism, and excretion (ADME) profile.

Further study of the rate limiting step revealed that the tetrahedral intermediate formation in the enzyme (studied at the B3LYP/6-31+G(d)//PM3-CHARMM22 level of QM/MM theory) presents an energy barrier 6 kcal mol^{-1} lower than the reaction in water (studied at the B3LYP/6-31+G(d) level of QM theory). DTSS, at the MP2/6-31+G(d) level of theory, was used to further analyses the active site residues and water molecules responsible for this stabilizing effect. Thr236, Ser218 as well as a conserved water molecule were identified as being the main contributors to TS stabilization. A number of additional residues were found to have a smaller contribution. Multiple sequence alignment confirmed that the key stabilizing residues are also very well conserved across the amidase family. This analysis, which supports the conclusions from QM/MM calculations, revealed that the active site interactions are predominantly electrostatic. Because of this dominance of electrostatic effects, a catalytic field approach[134] was used to identify the regions where significant charge redistribution occurs. These regions, that correspond to the alkyl substituent at the nitrogen atom and the distal phenyl ring, are the most important for modulating the interactions between FAHH and the carbamate derivatives, providing valuable insights for the design of future potent FAAH inhibitors.

Mor and co-workers[135] studied the reactivation mechanism and energetic profile of carbamoylated FAAH using QM/MM calculations at the SCC-DFTB/CHARMM27 level of theory with corrections at the B3LYP/6-31+G(d) level. The authors calculated that decarbamoylation of the covalent FAAH-URB597 adduct involved energy barriers of 28.9 kcal mol^{-1}, to be compared with the 16.6 kcal mol^{-1} barrier calculated for decarbamoylation of FAAH and its oleamide substrate, explaining the irreversible nature of the FAAH inhibition by carbamate derivatives. The authors also found that the secondary carbamic portion of the FAAH-URB597 adduct reduces the active site electrostatic stabilization of the TSs and intermediates, increasing significantly the energy barrier of the reactivation. These results, once again, greatly support the design of novel covalent FAAH inhibitors.

3.04.4.3 Tackling Antibiotic Resistance

Antimicrobial resistance is a global threat to public health and the dramatic increase in the number of bacterial pathogens resistant to multiple antimicrobial agents witnessed over the past decade urges the scientific and medical communities to rapidly identify countermeasures to stop this pandemic.[136–138] Fighting antimicrobial resistance, however, requires a detailed understanding, at a molecular level, of the involved mechanisms, including how drug-resistant pathogens are able to enzymatically alter antimicrobial agents, and QM/MM methods, in particular, can provide extremely valuable insights into these mechanisms. The recent work on carbapenemases provides an excellent illustrative example of how QM/MM can be used to address the antimicrobial resistance problem.

Carbapenems are the most recent class of β-lactam antibiotics and are considered as "last resort" antimicrobial agents for many multi-drug resistant bacterial pathogens, owing to their potency, broad spectrum, and relative stability toward hydrolysis by

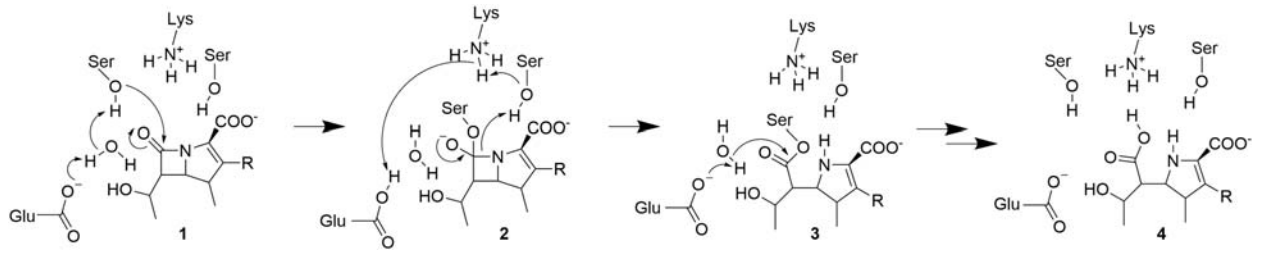

Fig. 4 Reaction mechanism of carbapenems with Class A β-lactamases. Carbapenem (**1**) acylates an active site serine to form the acylenzyme (**3**) via a tetrahedral intermediate (**2**). The acylenzyme can then be broken down via the nucleophilic attack of a deacylating water to release hydrolyzed carbapenems (**4**). Adapted from Fonseca, F., et al. The Basis for Carbapenem Hydrolysis by Class A ß-Lactamases: A Combined Investigation Using Crystallography and Simulations. *J. Am. Chem. Soc.* **2012**, *134* (44), 18275–18285.

β-lactamases. Of particular concern, however, carbapenem-hydrolyzing β-lactamases (carbapenemases) are now spreading among bacteria,[139] threatening to overthrow this last line of defense. The hydrolysis of β-lactam antibiotics in class A β-lactamases takes place firstly via a nucleophilic attack of an active site serine upon the β-lactam amide bond to form a tetrahedral intermediate that yields the acylenzyme.[140] This is then followed by a deacylation step involving the nucleophilic attack of a water molecule activated by an active site glutamate (**Fig. 4**).[141] The acylenzyme is a long-lived species in carbapenem-inhibited β-lactamases,[142] whereas the deacylation occurs rapidly in carbapenem-hydrolyzing β-lactamases. The lack of structural differences that could distinguish carbapenemases from carbapenem-inhibited enzymes prevent the identification of carbapenemases solely based on structural information and requires other approaches to better understand carbapenemase activity in β-lactamases.[143]

Using hybrid QM/MM umbrella sampling calculations, Chudyk et al.[144] have developed a protocol that enables prediction of carbapenemase activity in class A β-lactamases. Starting from the crystal structure of the enzyme, the acylenzyme is modeled based on the acylenzyme complex between carbapenemase SFC-1 and the carbapenem meropenem which has recently been crystallized.[143] Using the AMBER ff12SB/SCC-DFTB[145] level of QM/MM theory, the system is heated, equilibrated and 300 ps of unrestrained QM/MM MD are run from which starting structures for umbrella sampling are extracted using specific criteria that rely partly on previous observations.[143] The QM region consists of the common carbapenem scaffold, the water molecule responsible for the nucleophilic attack, as well as the side chains of the glutamate residue that activate the water and the serine residue covalently bond to the carbapenem moiety. QM/MM umbrella sampling is then performed along two reaction coordinates that capture the proton transfer between the water molecule and the active site glutamate as well as the nucleophilic attack of this water molecule on the carbonyl of the acylenzyme (**Fig. 5**) to generate a two-dimensional free energy surface from which the activation free energy is calculated after identification of the minimum energy path for the reaction. A total of eight different class A β-lactamases were tested using this method and it was found, based on the predicted reaction barriers, that the β-lactamases fell into two distinct groups: one group with energy barriers of about 10 kcal mol^{-1} and a second with barriers around 17–18 kcal mol^{-1}. The lower the activation energy, the more facile the deacylation is, whereas higher barriers indicate long-lived acylenzymes and thus poor carbapenemase activity. Moreover, the calculated energy barriers were in good agreement with experimental data despite a tendency to underestimate barriers, which is a common feature of SCC-DFTB. Overall this method provides a robust computational approach to predict carbapenemase activity in class A β-lactamases and illustrates how QM/MM methods can be used to assay and predict biological activity.

3.04.4.4 Supporting Sustainable Processes in Drug Development and Manufacturing

Over the past decade, the trend in the pharmaceutical industry has increasingly been toward the use of more sustainable methods in drug discovery, development, and manufacturing.[146–148] This approach not only greatly reduces the impact of the pharmaceutical processes on the environment, but it also permits significant cost reductions and improved safety. One of the pillars of green chemistry is to rely when possible on enzyme catalysis,[149–151] however in order to further the use of biocatalysts in the pharmaceutical industry, it is essential to both fully understand the catalytic function of industrially relevant classes of enzymes and be able to design, whenever required, enzymes able to perform a specific reaction. Computational chemistry, in particular, QM and hybrid QM/MM methods, are particularly well suited for these tasks.

In a recent example, hybrid QM/MM modeling was instrumental in identifying for the first time the mechanism of a bona fide natural Diels-Alderase enzyme at the molecular level of details.[152] The Diels-Alder reaction, the [4 + 2] cycloaddition of a conjugated diene to a dienophile that yields a cyclohexene, is one of the most well-known reactions in organic chemistry and has been used in numerous pharmaceuticals, agrochemicals, and fine chemicals manufacturing routes.[153] Nonetheless, despite its potential, Diels-Alder reaction remains underused in the pharmaceutical industry for the development of drug candidates,[154] likely due to the safety challenges that can arise during the scale up of this reaction.[155,156] Therefore, identifying natural enzymes capable of catalyzing Diels-Alder reactions is of prime interest as it would enable to carry out this reaction in a safer and more sustainable way.

Byrne et al.[152] used a combination of experimental and computational methods to demonstrate that the spirotetronate cyclase AbyU catalyzes a Diels-Alder reaction. In order to establish the catalytic mechanism of AbyU, the authors performed an initial

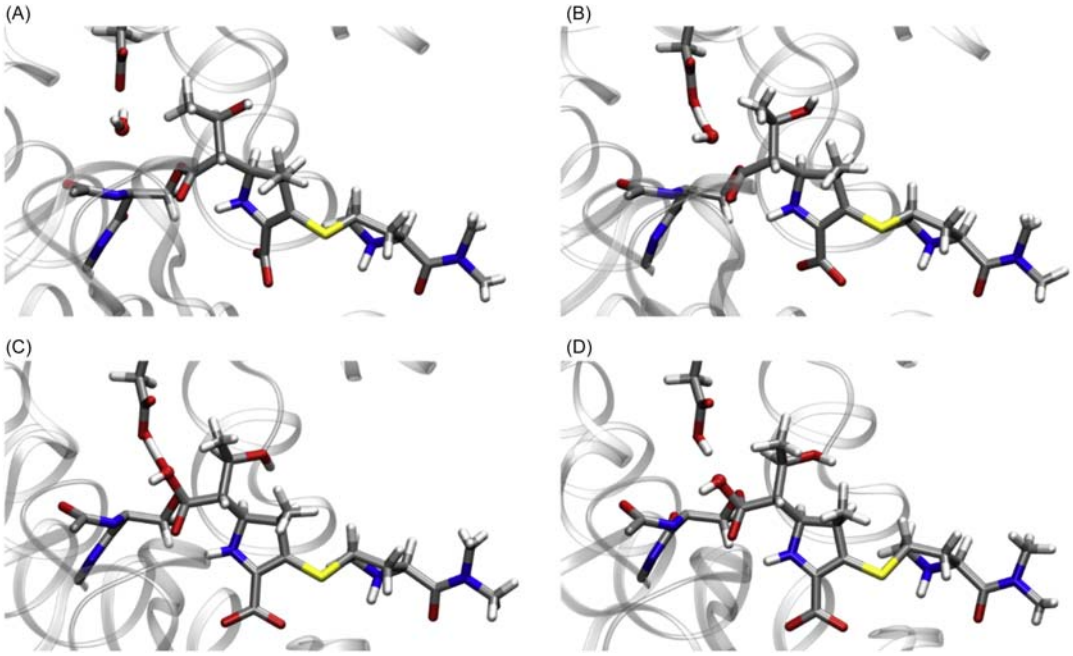

Fig. 5 QM/MM simulation of a molecule of meropenem being broken down by KPC-2 (Class A carbapenemase from *Klebsiella pneumoniae*). (A) An active site glutamate, meropenem, and the deacylating water are represented with *sticks* and the rest of the protein with *ribbons*. The proton transfer from the deacylating water to the active site gultamate (B) is concerted with the nucleophilic attack of this water on the acylenzyme. Transition state is shown in (C) and the resulting tetrahedral intermediate is shown in (D). Adapted from Chudyk, E.I., et al. QM/MM Simulations As an Assay for Carbapenemase Activity in Class A Beta-Lactamases. *Chem. Commun.* **2014**, *50*(94), 14736–14739.

docking of the substrate and product in the crystal structure of the enzyme, demonstrating that the enzyme is able to accommodate the substrate in a reactive conformation. The stability of the binding modes obtained from docking were then confirmed by running MD simulations of the apo, substrate-bound, and product-bound enzyme. QM/MM umbrella sampling simulations at the SCC-DFTB/AMBER f14SB level of theory were then carried out, starting from the product and modeling the reaction in the reverse direction, to investigate the reaction mechanism. Four binding poses were used in the calculation, and for each pose, eight different snapshots obtained from unrestrained QM/MM MD simulations were used to start the umbrella sampling simulations. The results showed that the reaction proceeds via a concerted, asynchronous Diels-Alder mechanism in which one of the C-C bond formation occurs first and represents the energy barrier, whereas the second bond formation occurs essentially after the crossing this energy barrier.

To confirm the TS geometry, electronic structure, and order of bond formation, higher-level DFT calculations were performed in the gas phase. Firstly, the potential energy surface for the reaction in gas phase was obtained following the minimum energy path at the B97D/6-31G(d,p) level of theory, followed by single point energy calculations at the M06-2X/6-31G(d,p) and SCC-DFTB level of theory. High-level DFT calculations (M06-2X/6-31G(d,p)) confirmed the results of the QM/MM simulations and indicated that SCC-DFTB underestimates the energy barrier of the reaction by approximately 7.3 kcal mol^{-1}. The similarity between the gas phase and enzymatic TS suggested that the enzyme essentially orientates the substrate in a reactive conformation allowing the Diels-Alder reaction to proceed via a relatively low free energy barrier. The authors also showed that the enzyme was able to work with non-natural, more stable substrates, and this relative promiscuity coupled with the simplicity of the enzyme makes it an ideal starting point for engineering potent Diels-Alderases.

Another example relevant to industrial biocatalysis is the study by Rommel et al. of the radical reaction catalyzed by glutamate mutase.[157] Using QM/MM at the M06/CHARMM22 level of theory, the authors were able to decipher the mechanism involved in the conversion of glutamate to methylaspartate. They showed that the reaction proceeds via a fragmentation-recombination mechanism involving a rate-limiting hydrogen transfer. By comparing the enzymatic reaction with the solution and gas phase reactions, the authors found that the enzyme influences the reaction electrostatically and, to a lesser extent, sterically and has a stronger impact on the hydrogen transfer steps than on the carbon skeleton rearrangements.

QM and QM/MM methods provide a powerful way to understand reaction mechanisms in known enzyme at a molecular level, but can also be used to engineer enzymes de novo. A good example of such an application is the computational design by Baker and co-workers[158] of an enzyme that catalyzes the Kemp elimination, for which no known naturally occurring enzyme exists. The protocol used by the authors consists in relying on QM calculations to model the theoretical active site which consists in the TS and the catalytic residues that will be the most effective at stabilizing it. Then, using RosettaMatch,[159] the PDB[160] is searched to identify a template that could accommodate the idealized active site. Finally, residues surrounding the TS are mutated and

optimized using RosettaDesign to maximize the stability of the active site and the affinity for the TS. This approach has been successfully applied to various enzymes[161] and represents an attractive and effective way to design de novo enzymes.

3.04.4.5 Predicting Drug Metabolism

Drug metabolism is a key process in which a particular set of enzymes works at deactivating and removing drugs from the organism. This process takes place in two phases, first, the solubility of the drug is increased via the addition of polar groups and is usually carried out by the cytochrome P450 family of enzymes, then an ionizable bulky group is added to the molecule, finishing the deactivation, and making the excretion of the metabolites possible. However, during the first phase of the metabolism, the cytochrome P450 enzymes can generate toxic metabolites that can lead to serious side effects. Similarly, concomitant administration of other drugs or specific food intakes can inhibit the activity of particular P450 enzymes, leading to the detrimental accumulation of an active pharmaceutical ingredient in the organism. It is therefore of crucial, when designing new active pharmaceutical ingredients, to test their ADME properties and computational approaches that can be reliability used to predict drug metabolism are of prime importance. In particular, QM and hybrid QM/MM methods have been successfully used to model the metabolism of several active pharmaceutical ingredients, and to understand the selectivity observed experimentally.[162]

For example, Bathelt et al.[163] used a realistic porphyrin model system to study the mechanism of cytochrome P450 mediated hydroxylation of aromatics compound using the B3LYP level of theory. The authors found that the rate-limiting step was the addition of an aromatic carbon to Compound I (Cpd I, the highly reactive species in P450s capable of oxidizing unactivated C-H bonds and which corresponds to an iron(IV)-oxo porphyrin species, shown in Fig. 6) via a TS with mixed radical and cationic character, whereas the subsequent products formations occur with low energy barriers. In addition, the authors demonstrated that the effect of an aromatic substitution could be predicted thanks to the correlation between the activation energy for Cpd I addition and a combination of radical and cationic Hammett σ-constants.

Bathelt et al.[164] also studied benzene hydroxylation in the more realistic enzyme environment of CYP2C9 using QM/MM at the B3LYP/CHARMM22 level of theory, leading to a calculated energy barrier for the addition of Cpd I to benzene in very good agreement with experimental data. In contrast with gas-phase QM models, the inclusion of the protein environment indicated that face-on and side-on geometries compete during the aromatic addition step. The authors found that in the face-on pathway epoxide and ketone products are formed with comparable ease whereas the side-on pathway tends to favor epoxide formation, providing a good example of the ability of a given CYP enzyme to catalyze different reaction depending on the substrate.[165]

In another example, Lonsdale et al. used QM/MM at the B3LYP-D/CHARM27 level of theory to investigate the CYP-catalyzed hydroxylation of primary amines using the N-hydroxylation of anti-arrhythmic (R)-mexiletine in CYP1A2 as a model reaction.[166] The two potential mechanisms, that is, the direct N-oxidation and the hydrogen abstraction followed by rebound, were modeled for the doublet and quartet spin states of Cpd I. A dispersion correction was added to the B3LYP functional as it was shown to lead to more accurate energy barriers.[167] The calculated barriers indicate that the direct N-oxidation is the preferred mechanism. Moreover, MD simulations revealed that, although not directly involved in the reaction mechanism, a water molecule is particularly important in maintaining (R)-mexiletine in a reactive conformation.

To rationalize experimental results and further the theoretical understanding of selectivity in cytochrome P450s, Mulholland and co-workers explored the oxidation of (S)-ibuprofen, diclofenac, and (S)-warfarin (Fig. 7) by CYP2C9 at different metabolism sites using QM/MM at the B3LYP-D/CHARM27 level of theory.[168] In the case of (S)-ibuprofen, the lower activation barrier was found to be for a hydrogen abstraction at the C3 position rather than at the C2 position, consistent with experimental results. For this

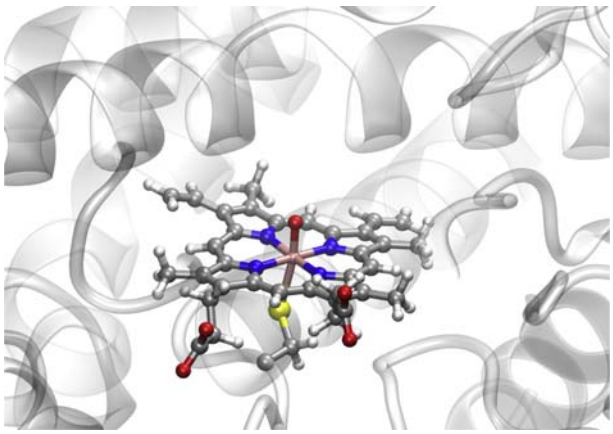

Fig. 6 Compound I modeled in the Cytochrome $P450_{cam}$ from soil bacterium *Pseudomonas putida* (PDB ID: 1DZ9). Compound I and its tethering cysteine residue are represented with *balls* and *sticks*.

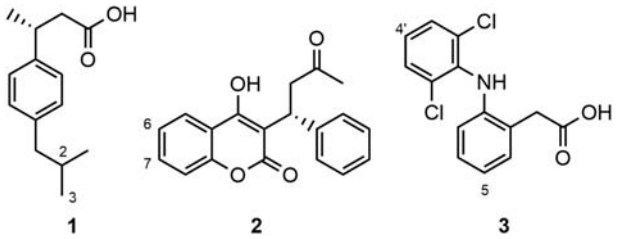

Fig. 7 Structures of (S)-ibuprofen (**1**), (S)-warfarin (**2**), and diclofenac (**3**). Carbon positions discussed in the main text are numbered on each structure.

aliphatic hydroxylation, the role of the enzyme is to promote the regioselectivity of the reaction by restricting the orientation of the substrate and placing C3 at an optimal position and angle for the hydroxylation to take place. In the case of (S)-warfarin, QM/MM calculations predict an aromatic hydroxylation at C7 to be favored, again in agreement with experimental data. As for ibuprofen, the active site residues orient warfarin in a position that promotes the C7 attack, despite C6 being slightly more reactive toward Cpd I. QM/MM study of the hydroxylation of diclofenac suggests an addition in C5, in contrast with experimental results demonstrating a C4′ hydroxylation. This difference was suggested to arise from the fact that the difference in binding energies for the two possible orientations of the substrate is not accounted for in the QM/MM calculations. This hypothesis is supported by the role of Arg108 in stabilizing the binding conformation favoring the C4′ hydroxylation. QM/MM calculations clearly outperformed the QM calculations performed without accounting for the protein, revealing the importance of the active site residues in controlling the selectivity of CYP2C9.

3.04.5 Conclusions

MD simulation, free energy calculations, QM and hybrid QM/MM methods are now well established computational approaches to study protein function and regulation and are becoming increasingly important in drug discovery, design, and development. Software and hardware advances make the use of these methods possible within the timeframe of a typical drug discovery project and new enhanced sampling approaches enable one to access rare events at a fraction of the computational cost previously required to access long timescale dynamics. Improvements in the user-friendliness and methodology of free energy calculations make it a much more accessible tool, enabling one to perform routinely and time-efficiently accurate free energy calculations and to assess the contribution of entropy and enthalpy to the binding free energy. Finally, QM/MM methods have proved to be extremely powerful techniques and highly accurate QM methods can now be applied in QM/MM calculations on enzymes in order to reach "chemical accuracy."

The examples of application presented here provide only a glimpse at the ever growing body of simulations relevant to drug discovery and development. Yet, they demonstrate how MD, free energy, QM and QM/MM methods can be applied in a time-effective and robust manner to support the design of new pharmaceutical agents or to shed light on the molecular mechanisms that govern therapeutically relevant biological processes.

QM/MM methods, in particular, have sometimes been underappreciated in the past. The award of the 2013 Nobel prize in Chemistry, however, has contributed to a renewed interest in this type of multiscale modeling and the advantages QM/MM calculations offer over standard QM or MM approaches have been illustrated above through a number of examples. QM/MM methods can indeed model bond breaking and making, determine likely enzyme mechanisms, identify catalytic and binding interactions, contribute to structure-based design, model covalent inhibition, and drug metabolism and provide more accurate information on binding affinity by taking into account polarization effects.

Computational methods such as those described in this article are not devoid of limitations. It is, for example, almost impossible to sample, using conventional MD, events that take place at the millisecond timescale or above. Drawing conclusions from an under-sampled phase space is also a common error. The number of methods available to compute binding free energy can be daunting and obtaining precise and reliable results that compare well with experimental data requires lengthy calculations. QM/MM methods are limited by the level of QM theory used, and certain methods can yield misleading energy barriers that might lead to qualitatively wrong mechanistic conclusions.

In spite of these limitations, computational modeling using MD, free energy, and/or QM/MM methods is now mature enough to generate invaluable insights into the functionally relevant molecular mechanisms of pharmaceutical targets and provide a clear competitive advantage for the discovery and development of new drugs. As for all computational approaches, these methods can only reach their full potential by being combined with experiment, and it is via the cross-fertilization between molecular modeling and experimental chemistry, biophysics, and biochemistry as well as genetics and molecular biology that the development of the next generation of pharmaceutical compounds will thrive.

Acknowledgments

This work was supported by BBSRC and EPSRC through the BrisSynBio Synthetic Biology Research Centre(BB/L01386X/1). The authors would like to thank Dr Kara Ranaghan, Dr Marc van der Kamp and Dr Christopher Woods for useful discussions regarding the work described here and for their help in preparing some of the figures.

3.05.1 Introduction

The pivotal role of noncovalent molecular interactions in biological chemistry has been recognized since Emil Fischer's *Schlüssel-Schloss Prinzip*, which proposed that a substrate fits into an enzyme active site as does a key into a lock.[1] This notion naturally suggested that another molecule of the same shape as the substrate might also fit into the active site and thereby disrupt the enzyme's function. Fischer's principle has been elaborated over the years. Proteins are flexible, as are most of the small molecules that bind to them, so hand-in-glove might be a better analogy than key-in-lock. And crucially, it is not as simple as matching shapes. Some atoms like to be close to each other and some do not, so even a perfect steric match may be insufficient to yield a high binding affinity. The complexity of optimizing atom–atom contacts is one of the many reasons why drug discovery is dreadfully difficult.

So chemists desiring to invent molecules that will bind to pharmaceutically relevant proteins have long been interested in which molecular interactions are favorable and which are not. Enormous efforts have been made to extend our knowledge of the subject but there remains much to learn. Interactions between aromatic groups are particularly difficult to predict because they are very sensitive to substituents and ring heteroatoms, and the reason for this is still a matter of debate. Halogen bonding has become increasingly *à la mode* over the past few years but doubts remain about the substance behind the hype. Weak interactions such as CH···O, CH···F, and CH···π are viewed as hydrogen bonds by some and of questionable significance by others. Then there are cation–π and anion–π interactions. They sound like opposites; how can they both be stabilizing? The thermodynamics of protein–ligand binding now appears much more complicated than it once did. Hydrogen bonding can be entropically driven, while the displacement of water molecules from a protein cavity by a hydrophobic ligand group can be driven by enthalpy, in contrast to the traditional viewpoint.

Twenty years ago, a chapter like this would have been directed exclusively to those interested in protein–ligand binding. But now molecular interactions have attracted the attention of another group of pharmaceutical scientists, those involved in drug formulation. Their burgeoning interest in crystal forms is motivated both by fear (of metastable polymorphs) and fervor (about the potential advantages of cocrystals). The interactions between molecules in crystals are now just as important to the pharmaceutical industry as those between inhibitors and enzymes.

This article is not a balanced account of molecular interactions; if it were, it would mostly be about hydrogen bonding. Less space is devoted to mature aspects of the subject so that more can be given to those that are still a matter of debate or even controversy, and which have therefore received particular attention over the past 10 years. In order that the article can be read in stand-alone fashion by chemists without a particular knowledge of the subject. The "**Background**" section briefly covers some of the basics—what an interaction is, how interactions may be studied, and so on. The importance of water and entropy is touched upon. The section "**Molecular Interactions or Emperor's New Clothes?**" takes an overview of the multitude of interaction types—strong hydrogen bonds, weak hydrogen bonds, halogen and chalcogen bonds, etc.—and asks whether their relative importance can be assessed in an objective and statistically rigorous manner. The bulk of the article is devoted to a more detailed consideration of each of the major types of interaction. Then the focus turns to the pharmaceutical crystal form: does the consideration of molecular interactions make it possible to spot a metastable crystal-packing arrangement, or help in the design of a cocrystal? The article concludes with a short summary.

3.05.2 Background

3.05.2.1 Methods

Most of our knowledge of molecular interactions comes from three sources: crystallography, measurements in solution (usually spectroscopic or calorimetric), and theoretical calculations. The first of these is the most important for medicinal chemists because of the widespread use of protein–ligand crystal structures in structure-based drug design. Its value is greatly enhanced by the existence of the two main crystallographic databases, the Protein Data Bank (PDB)[2] and the Cambridge Structural Database (CSD),[3] together with the derived knowledge-base IsoStar.[4] The latter is a library of three-dimensional plots, each of which shows the observed distribution of one type of chemical group around another in crystal structures from the CSD or PDB. For example, the plot of OH and NH groups around oxazole (**Fig. 1**) reveals that the nitrogen atom accepts hydrogen bonds much more commonly than the oxygen atom.[5] There are several programs and adjunct databases for use alongside the PDB. They include the search and analysis systems, Proasis3,[6] Relibase+,[7] and the PDBbind database,[8] which stores experimentally measured ligand binding affinities.

It is easy to forget the shortcomings of crystallographic data. In the PDB, the chief problem is the comparatively low observation/parameter ratios of all but the highest resolution structures. This results in relatively low precision and the danger of overfitting, so protein structures must always be interpreted with care.[9,10] Water positions are particularly uncertain but, worse, it is possible for ligand structures to be grossly in error.[11,12] The Uppsala electron density server enables calculation and display of the electron density of PDB crystal structures and is a good tool for spotting poorly fitted ligands and side chains.[13] Other systems provide a variety of options for validation and re-refinement of protein structures.[14–16] These days, structures are usually determined at low temperature to reduce radiation damage, which improves precision but may restrict flexible side chains to a subset of the conformations they can adopt in vivo.[17,18] Temperature also affects pK_a and can therefore alter the protonation states of ionizable side chains.

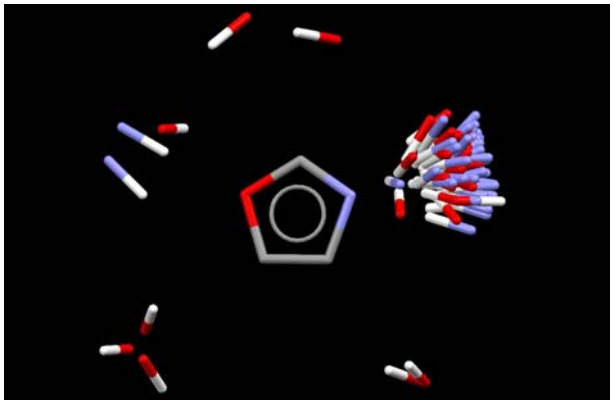

Fig. 1 IsoStar plot showing the observed distribution of OH and NH groups around oxazole rings in crystal structures from the CSD. Only contacts shorter than the sum of van der Waals radii minus 0.3 Å are shown.

The small-molecule crystal structures in the CSD are usually of high precision, bond lengths typically being determined with uncertainties of only a few thousandths of an Ångström. However, there are some systematic differences between the intermolecular contacts seen in small-molecule structures and those in protein–ligand complexes. Interaction geometries in the former can be influenced by the type of symmetry operator relating the interacting molecules. This occasionally results in a bias toward geometries that are favored by common symmetry elements, notably inversion. For example, antiparallel stacking of carbonyl groups (see "**Carbonyl-Group Interactions**") is much more common when the interacting groups are symmetry related by a crystallographic inversion center than when they are not symmetry related.[19] Therefore, this interaction is more often seen in the CSD, where structures with inversion centers are commonplace, than in protein–ligand complexes. Also, inspection of radial density distributions showed that small-molecule crystal structures favor hydrophobic C···C contacts to a lesser degree than do protein–ligand complexes.[20] The result cannot be explained by differences in stoichiometry. Its cause has not been established but may be related to desolvation effects, given that many structures in the CSD were determined using crystals grown from organic solvents.

Moving to solution measurements, a seminal contribution was made by Abraham et al., who measured the equilibrium constants for 1:1 hydrogen-bonding complexation of a large number of compounds with standard hydrogen-bond donor or acceptor molecules. This enabled them to derive parameters similar to substituent constants that measure the capacity of functional groups to accept or donate hydrogen bonds.[21] Similar methodology is being pursued by others.[22–24] These more recent measurements use Fourier transform infrared spectrometry, which often allows deconvolution of overlapping bands in the spectrum. This makes it possible to estimate the individual strengths of the separate acceptor sites in a polyfunctional molecule. Another important technique is isothermal titration calorimetry (ITC). Its application to protein–ligand complexation is giving fascinating and often surprising information about the relative importance to binding free energy of enthalpy and entropy (see "**Water is the Driving Force of All Nature**" and "**Enthalpy–Entropy Compensation**").[25,26] Efforts have been made to capture the results of ITC experiments on proteins in database form.[27]

The use of model systems such as supramolecular assemblies[28] and molecular torsion balances has proved valuable for studying molecular interactions in solution. A supramolecular assembly is a complex of two or more molecules held together by noncovalent interactions. The degree of molecular association can be measured by a range of titration techniques (potentiometric, NMR, fluorescence, calorimetric, etc.).[29] Complexation of guest molecules into cage-like hosts has given insight into how molecular cavities are optimally occupied (see "**The Occupation of Nonpolar Pockets by Ligand Hydrophobic Groups**").[30] Molecular torsion balances are molecules designed to have a limited degree of flexibility, which allows a particular intramolecular interaction to occur when the molecule adopts a folded conformation but not when the conformation is extended. The ratio of folded to extended conformers is measured by NMR, allowing the strength of the interaction to be estimated. The technique has been applied to CH···O, aryl–alkyl, aryl–halogen, aryl–aryl stacking, and aryl–aryl edge-to-face interactions, among others.[31] Its principal drawback is that interactions other than the one of interest might significantly affect the conformational equilibrium. However, the use of chemical double-mutant cycles enables secondary effects to be canceled out so that the energy due to the interaction of interest can be isolated.[32]

Quantum-mechanical calculations can provide invaluable insights into molecular interactions but suffer from two significant problems, basis set superposition error (BSSE) and the difficulty of accounting for electron correlation. The former arises when the basis set used for a molecule (the set of mathematical functions that are combined to represent molecular orbitals) is inadequate; sadly, this is always. When two molecules approach, each makes some use of the other's basis set to help compensate for the deficiencies of its own. This gives rise to an apparent but artifactual charge transfer stabilization, the BSSE. It can be partly corrected by use of the "counterpoise" method but the best defense is to improve the basis set by adding more functions. There is a bewildering variety of basis sets in common use. No doubt with their tongues in their cheeks, Dunitz and Gavezzotti pragmatically advised nonexperts to assume that the longer the name of the basis set, the better it is likely to be.[33]

The Hartree–Fock approximation, which might be described as the entry-level ab initio methodology,[34] fails to reproduce electron correlation effects because it assumes that each electron experiences the average field created by the others. This is disastrous when studying molecular interactions because electron correlation is responsible for dispersion, an important contributor to noncovalent interaction energies (see "The Components of a Molecular Interaction"). There are several higher-level ("post-Hartree–Fock") approximations that can take account of electron correlation with varying degrees of accuracy, but their computational costs escalate at a frightening rate. For example, the compute requirements of the MP2, CCSD, and CCSD(T) methods are dependent on the fifth, sixth, and seventh powers, respectively, of the size of the system being studied. CCSD(T)/CBS has come to be regarded as the "gold standard," being capable of predicting interaction enthalpies to an accuracy of about 1.5%, but at high cost.[35] Lower-level approximations (MP2, CCSD) are less accurate but can be usefully applied to larger systems.[36] Perturbation theory methods such as the widely used symmetry-adapted perturbation theory (SAPT) can also give very good results and have the additional advantage that they decompose molecular interaction energies into their component terms.[37] Unfortunately, the popular and relatively fast density functional theory (DFT) methods are difficult to apply to molecular interactions. Nevertheless, they can sometimes give excellent results when used with dispersion corrections.[38] In summary, while it is easy to get numbers out of a quantum-mechanical program, selection of appropriate methods and interpretation of results require considerable expertise.

3.05.2.2 The Components of a Molecular Interaction

The enthalpy of interaction between two molecules in the gas-phase is comprised of five components: electrostatic, polarization (also called induction), dispersion, charge transfer, and exchange repulsion. The electrostatic term is due to the interaction between the permanent charge distributions of the two molecules and may be energetically favorable or unfavorable. It is often the most important contributor to interaction energy, particularly for hydrogen bonds. Polarization is the interaction of the permanent charge distribution of one molecule with an induced change in the charge distribution of the other. Although it is usually small, it can sometimes have significant effects. For example, when a hydroxyl group donates its hydrogen to a hydrogen-bond acceptor, the electron density on the hydrogen atom is decreased and that on the donor oxygen is increased. This induced change makes the donor oxygen a better acceptor. In consequence, the hydrogen bonds in an ···OH···OH···OH··· chain act cooperatively, each being much stronger than an isolated OH···OH bond.[39] Dispersion (the London force) is due to electron correlation: a momentary dipole in the electron distribution of an atom in one molecule induces an opposite dipole in an atom of the other. Like polarization, it is necessarily energetically favorable. An individual atom···atom dispersion interaction is proportional to the product of the atom polarizabilities and the inverse sixth power of the interatomic distance, and is invariably small. However, the total dispersion interaction of two molecules, being the sum over all atom pairs, can be large enough to have a significant role in determining both protein–ligand binding affinities and optimum molecular arrangements in the crystal structures of organic molecules.[40] Charge transfer is the transfer of electron density from one molecule to the other. If it occurs, there is a degree of covalency in the molecular interaction. It is rarely significant in protein–ligand binding. Finally, exchange repulsion is a quantum chemical effect that causes a rise in energy when the electron densities of nonbonded atoms overlap. It is invariably small, for the simple reason that the energy increase is so steep when molecules approach too closely that in practice they do not. This can sometimes conceal problems from the drug designer. A molecule slightly too large to fit optimally into a protein binding site might still bind, the protein relaxing slightly to relieve the close contact(s). The resulting strain energy is dissipated imperceptibly over the binding site residues, hiding the design fault.

3.05.2.3 Water Is the Driving Force of All Nature[41]

Life for the drug designer would be much easier without water.[42] Firstly, its ubiquitous presence makes it difficult to assess how much free energy will be gained (or lost) by forming a hydrogen bond between protein and ligand, since this can only be done by first desolvating the groups involved. Water is a good hydrogen-bond donor and acceptor, so the outcome of swapping protein–water and ligand–water for protein–ligand and water–water hydrogen bonds is uncertain. In a classic experiment, Fersht et al. demonstrated by protein engineering that hydrogen bonds between tyrosyl-tRNA synthetase and its substrate contribute only modest amounts to binding affinity unless they involve charged groups.[43]

Next on the list is the problem of water molecules that are so strongly bound to the protein that they are hard or impossible to displace when ligands bind. They are not always easy to recognize. Given sufficient crystal structures of the same protein complexed with different ligands, conserved water molecules can be seen by overlaying the binding sites. For example, phosphodiesterase 10 contains two water molecules that are hydrogen-bonded to each other, and to two and three protein residues, respectively. The former was displaced in 1 of 15 ligand series, while the latter could not be displaced at all.[44] Several computational methods have been devised to assess which water molecules can be displaced,[45,46] but the problem is difficult and cannot yet be considered solved. Persch et al. offer a pleasingly simple rule of thumb: ordered water molecules that undergo four bonding interactions to the protein cannot be displaced; those that form three close contacts are very difficult to remove; those that form two can be replaced, but the gain in free enthalpy might be small; those that form one are easily replaceable and can offer substantial enthalpic gains.[47]

A particularly challenging problem is to understand the so-called hydrophobic effect. It is well known that occupying nonpolar binding site pockets with ligand hydrophobic groups is a good way of improving binding affinity. The reason is less clear. It is unlikely to be due to the strength of hydrophobic interactions per se: calculations on the methane dimer suggest an interaction enthalpy of only about -0.5 kcal mol^{-1} at best.[48] The traditional explanation is that water molecules surrounding a hydrophobic

surface form a "cage," which restricts their rotational freedom compared with their behavior in bulk water.[49] Hence, a hydrophobic ligand group that displaces water molecules from a nonpolar pocket results in an increase in entropy and thereby improves the free energy of binding. It transpires, however, that the truth is rather more complicated. Diederich et al. recounted their introduction to the "nonclassical hydrophobic effect."[50] They used calorimetry to investigate the thermodynamics of host–guest complexation between cyclophanes and *para*-disubstituted benzenes. To their surprise, formation of the complexes was driven by enthalpy, partly offset by an unfavorable entropic term. This is the opposite of what the classical hydrophobic effect would have led them to expect. On searching the literature, they found several similar examples. The nonclassical hydrophobic effect is rationalized as follows: (1) stronger water–water hydrogen bonds are formed in bulk solvent than by water molecules at a hydrophobic surface (there is some spectroscopic evidence for this[51]); (2) dispersion interactions between hydrophobic groups are enthalpically more favorable than those between a hydrophobic group and water, because water is less polarizable; (3) entropy is lost when the guest binds tightly to the host. So current thinking is that there is more than one "hydrophobic effect."[52,53] The balance between enthalpy and entropy when a hydrophobic ligand group binds into a lipophilic protein pocket is influenced by several factors, including the degree of protein flexibility, the size and curvature of the pocket, and the extent to which the pocket is hydrated before the ligand binds.

Some particularly fascinating studies have looked at the relationship between binding affinities and the structure of water networks at binding sites. A large difference in potency between two very similar chloro-aromatic fragments binding at the S1 pocket of thrombin was ascribed to the local water networks. The more potent fragment bound with an additional water molecule that incorporated Glu192 in the binding.[54] Attempts to fill a hydrophobic pocket in tRNA-guanine transglycosylase failed to produce the expected gains in binding energy because the ligands disturbed water molecules around two aspartate residues.[55] A pronounced nonadditivity of substituent effects on the binding of four thermolysin ligands was rationalized in terms of the surrounding water network. Three of the ligands allowed a continuously connected network to form between protein and ligand. In the fourth, the network was ruptured and the binding affinity was unexpectedly low.[56] Crystallographic and calorimetric investigations of another series of thermolysin inhibitors also provided instructive results. The inhibitors differed only in the nature of a hydrophobic side chain, and it was found that the addition or rearrangement of even one methyl group could significantly alter the geometry of the water network at the solvent-exposed surface of the complex. This, in turn, affected binding affinities and the enthalpy–entropy signatures of binding;[57] which takes us to the issue of enthalpy–entropy compensation (EEC).

3.05.2.4 Enthalpy–Entropy Compensation

The phenomenon of EEC is often observed in ITC studies of protein–ligand binding. Within a series of ligands with similar free energies of binding (ΔG), the enthalpic (ΔH) and entropic ($T\Delta S$) contributions can vary significantly but in an opposing manner. As an example, a series of trypsin inhibitors with constant structure except for a variable side chain, R, were found to have ΔG values in a narrow range but greatly differing enthalpic and entropic terms.[58] For instance, at 20°C the inhibitors with R = methyl, propyl, and *n*-hexyl had, respectively, $\Delta G = -27.5, -25.7, -28.9$; $\Delta H = -16.7, -9.7, -6.6$; $T\Delta S = 10.8, 16.0, 22.2$ kcal mol^{-1}. The most common explanation for EEC focuses on ligand and protein flexibility: stronger binding (greater enthalpic contribution) is tighter binding, meaning less mobility, hence less entropy. In the case of the trypsin inhibitors, the entropic contribution becomes more favorable as the *R* group increases in length, suggesting that the more flexible alkyl chains retain greater mobility when bound, but in consequence form weaker interactions with the protein pocket. However, EEC can also be connected to differences in the structure of water networks around bound ligands.[59,60]

It should be noted that there is a question mark over the evidence for EEC. Results from ITC experiments can have large unreported errors. In a test, identical aliquots of protein–ligand preparations were sent to 14 laboratories; the resulting ΔH values had a root-mean-square error of 24%![61] Further, the propagation of errors in ITC is such that errors in ΔG tend to be smaller than those in ΔH, which can give the appearance of EEC even when none is present.[62] In a careful study, Olsson et al. modeled the effects of these experimental constraints on 32 ITC data sets relating to diverse proteins.[63] They concluded that the tendency for EEC is strong, but by no means universal. It can be weak, and it is occasionally observed that enthalpic and entropic binding contributions move in the same rather than opposing directions. Overall, theoretical studies have focused on explaining a stronger tendency for EEC than appears to exist. It remains to be seen why some changes to ligands result in compensation and others do not.

3.05.3 Molecular Interactions or Emperor's New Clothes?

3.05.3.1 The Diversification of the Hydrogen Bond

Once upon a time there was the hydrogen bond and that was that. It was acknowledged that molecules interact in a general sort of way through van der Waals (vdw) forces,[64] but the hydrogen bond was the only specific, directional, noncovalent interaction worthy of a name. Its unique influence on physical properties and its role in determining small-molecule crystal structures were soon recognized. As far as biological chemists were concerned, hydrogen bonds could involve only two types of donors, OH or NH, and two types of acceptors, oxygen or nitrogen. That was enough for Pauling to predict the α-helix and for Watson and Crick to solve the structure of DNA.

The first crack in this simple edifice was the suggestion that CH groups could also act as hydrogen-bond donors.[65] Initially dismissed,[66] the idea was resurrected[67] and then enthusiastically evangelized.[68] Not everyone was convinced. From the group of the famous organometallic chemist Al Cotton came this complaint: "While the literature contains numerous allusions to C–H···N

'hydrogen bonds' there seems little if any reason to accept this description. Or, to invoke the parable of the emperor's new clothes, the question of why many people seem to find the emperor well dressed despite any persuasive evidence that he isn't naked, arises."[69] Cotton's disapprobation was countered by Steiner and Desiraju on the not entirely compelling grounds that CH···O interactions tend to become more linear at the hydrogen atom as the polarization of the CH bond increases.[70] Thereafter, an increasingly diverse array of interactions attracted the terminology "hydrogen bond." They included some very weak interactions indeed: CH···F–C,[71] CH···Cl–C,[72] and CH···π.[73] Eventually, IUPAC set up a task force, which proposed a new definition of the hydrogen bond.[74,75] An initial comparison of definitions old and new leaves one wondering what the difference is but, on closer inspection, it is clear that the intent of the new definition is to encompass much weaker interactions (down to 0.5 kcal mol^{-1}). Cotton is no doubt turning in his grave.

Does the new definition add to or clarify our understanding of molecular interactions? No. But the process by which it was arrived at was useful. It highlighted the possibility that even weak interactions may have a significant influence on how molecules associate with one another. The new definition does, however, have a clear disadvantage: it covers such as wide range of interaction energies that, in discussing hydrogen bonds, we must now specify what type we mean. Jeffrey recommended the terms "strong," "moderate," and "weak" for hydrogen bonds with energies in the ranges of 15–40, 4–15, and <4 kcal mol^{-1}, respectively.[76] For present purposes, this effectively means that strong hydrogen bonds involve charged donors or acceptors; moderate are of the type (O,N)H···(O,N); weak is everything else, but most importantly CH···O, CH···N, and NH···π.

3.05.3.2 Every Atom Has to Be Somewhere

While the hydrogen bond was adding new donors and acceptors to its portfolio, other molecular interactions were being discovered, rediscovered, or otherwise promoted. They included halogen bonds,[77] chalcogen and pnicogen bonds,[78] π–π interactions,[79] cation–π interactions,[80] and anion–π interactions.[81] The poor medicinal chemist, staring at an enzyme active site on the computer screen and wondering how to design a new inhibitor, might be forgiven a degree of confusion. Are all these interactions important?

The Irish comedian Spike Milligan once remarked that "Everybody's got to be somewhere."[82] By the same token, every atom has to be somewhere. Further, in organic condensed phases, every atom has to be somewhere near an atom in another molecule unless it is buried inside the molecule to which it belongs. We pay close attention to the idea that short intermolecular contacts might be indicative of stabilizing interactions, but rarely contemplate the possibility that two atoms might be forced into close mutual proximity against their will (if the reader will forgive the anthropomorphism). This argument applies particularly to contacts involving hydrogen, as pointed out by Dunitz and Gavezzotti: "Only atoms on the outer surfaces of molecules can come into contact with atoms of other molecules. Since these are usually hydrogen atoms, CH···X contacts in organic crystals are almost unavoidable. One must therefore be very careful about their significance as main contributors to intermolecular stabilization."[33] The argument could also be applied, of course, to protein–ligand complexes.

These doubts were reiterated recently. Bader's "atoms in molecules" approach[83] argues that, for two atoms to be covalently bonded, there must be a $(3, -1)$ bond critical point. This is a point between the atomic nuclei where the electron density is at minimum along one axis, the bond path, and at a maximum along any direction perpendicular to that axis. The bond path is the line followed by the ridge of electron density between the two atoms. It is often argued that a similar criterion should apply to intermolecular "bonds."[84,85] Dunitz recently questioned whether the condition is fulfilled even by medium-strength hydrogen bonds, let alone weaker interactions.[86] Others made haste to reply,[87,88] contending that criteria based on the atoms-in-molecules approach clearly support the stabilizing nature of many types of weak interactions, including halogen and chalcogen bonds, CH···O, and CH···F–C. We may assume that the matter is not considered settled.

3.05.3.3 Assessing the Relative Importance of Molecular Interactions

Prompted by the argument that CH···X contacts in organic crystals are almost unavoidable, a recent study assessed whether they occur significantly more often, in a statistical sense, than would be expected by chance.[89] They and other types of intermolecular atom···atom interactions in organic crystal structures were ranked on the ratio (R_F) of their observed frequency of occurrence to the frequency expected at random. Expected frequencies were calculated from binomial statistics, assuming that the probability of a given atom forming its shortest (relative to vdw radii) line-of-sight contact to an atom of type X equals SA_X/SA_{TOTAL}, where SA_{TOTAL} is the total surface area of the molecules in the crystallographic unit cell, and SA_X is the surface area contributed by atoms of type X. A line-of-sight contact is one in which the two atoms "see" each other because no third atom intrudes between them. 95% confidence limits for R_F values were determined by bootstrapping, so it was possible to establish whether the R_F of a given type of interaction was significantly greater than 1. If so, the interaction occurs significantly more often than would be expected by chance and is therefore associated with energetically favorable molecular arrangements. Conversely, the importance of an interaction with R_F significantly less than 1 is open to serious doubt. The greater the amount by which an interaction's R_F value exceeds 1, the more influential the interaction can be assumed to be in determining how small molecules pack in the crystalline state.[90]

As would be expected, the interactions with the highest R_F values are strong and moderate hydrogen bonds, which typically occur 5–10 times more often than would be expected at random (some example R_F values are given in **Table 1**). At about the same level is I···N, which is a halogen bond. Other halogen bonds involving iodine or bromine come lower in the ranking, but still have R_F comfortably greater than 1. However, Cl···O and Cl···N interactions have $R_F \approx 1$, which raises doubts about their importance in influencing crystal-packing arrangements. CH···O interactions have R_F significantly greater than 1, the value of the parameter rising

Table 1 R_F values of some intermolecular interactions, with 95% confidence limits[89]

Interaction[a]	R_F	*95% confidence limits*
O(carbonyl)···H(polar)	9.2	7.9–11.2
O(hydroxyl)···H(polar)	5.9	5.2–7.1
O(ether)···H(polar)	4.0	3.6–4.7
N···H(polar)	5.7	4.9–6.9
C–I···N	6.5	5.7–7.6
C–I···O	2.7	2.5–3.1
C–Br···N	1.8	1.5–2.0
C–Br···O	1.5	1.3–1.7
C–Cl···N	0.9	0.7–1.1
C–Cl···O	1.0	0.8–1.2
C(sp)–H···O	5.2	4.5–5.9
C(aromatic)–H···O	2.3	2.2–2.3
C(methyl)–H···O	1.5	1.5–1.6
C–F···H–C	1.7	1.5–1.9
C–Cl···H–C	1.3	1.0–1.6

[a]H(polar) indicates H covalently bonded to O, N, or S; N excludes quaternary and trigonal planar nitrogen.
For a given interaction, *X*···*Y*, R_F is the ratio of the observed number of *X*···*Y* contacts in organic crystal structures to the number expected if determined solely by surface area considerations.
Reproduced from Taylor, R. *CrystEngComm* **2014**, *16*, 6852–6865 with permission from the Royal Society of Chemistry.

as the intramolecular environment of the hydrogen becomes more electron withdrawing; indeed, the acetylenic C(sp)–H···O interaction has the remarkably high value of $R_F = 5.2$. The C–F···HC and C–Cl···HC interactions also have $R_F > 1$. The point raised by Dunitz and Gavezzoti—that one would expect many CH···X contacts given the high surface exposure of hydrogen atoms—is comprehensively answered. These contacts occur significantly more often than can be explained by surface area considerations alone. The emperor is clothed, after all.

3.05.4 The Major Types of Molecular Interactions

3.05.4.1 An Abridged Guide to Hydrogen Bonding

Of all molecular interactions, the hydrogen bond is by far the most important. It is also the most studied, the most reviewed, and the best understood. It therefore presents some difficulty here: what is worth saying in the small space available when so much has already been said? Some of the lesser-known aspects of hydrogen bonding (to π-systems, to halogens, involving sulfur) are dealt with elsewhere in this article but, for the familiar interaction involving OH or NH donating to oxygen or nitrogen, brevity would seem to be in order. Hence, the facts of most relevance in medicinal chemistry are listed below with little amplification. Where references are not explicitly cited, further information can be found in standard text books and reviews.[76,91–93]

1. Charged groups form stronger hydrogen bonds than uncharged.
2. Hydrogen-bond donor and acceptor strengths do not correlate particularly well with acidities and basicities, as measured by pK_a values. For example, thiols are more acidic than alcohols but poorer hydrogen-bond donors.
3. In general, uncharged OH is a stronger donor than uncharged NH.
4. The strengths of uncharged acceptors decrease in the approximate order N-oxide > sulfoxide > amide ≈ pyridine > ketone > nitrile ≈ alcohol ≈ ester carbonyl > alkyl ether > phenol > diaryl ether.[22]
5. The strength of a donor or acceptor group can be strongly dependent on its intramolecular environment.
6. Nearby electron-withdrawing groups increase the strengths of donors.
7. Conversely, electron-donating groups increase the strength of an acceptor, while electron-withdrawing groups decrease it. For example, the acceptor strengths of the nitrogen atoms in 4-ethylpyridine, pyridine, and 4-chloropyridine are, respectively, 2.07, 1.86, and 1.54, as measured by the pK_{BHX} hydrogen-bond basicity scale (higher values indicate better acceptors).[22]
8. Conjugated oxygen atoms (in furan, oxazole, ester, etc.) are very weak acceptors and prefer to form contacts with CH groups rather than OH or NH (**Fig. 1**).[5,94,95]
9. The ability of a 3-coordinate nitrogen atom to accept a hydrogen bond depends on its geometry. It can be a good acceptor if pyramidal; a weak acceptor if slightly pyramidal, as in aniline; and cannot accept if planar, as in an amide group.
10. Bifurcated hydrogen bonds, in which the donor hydrogen interacts with two acceptors, are relatively common.[96,97] By necessity, at least one of the components of a bifurcated interaction must be appreciably nonlinear (D–H···A ≪ 180 degree, where D and A represent donor and acceptor, respectively).
11. Trifurcated bonds are rare, probably for steric reasons.

Table 2 Numbers of hydrogen bonds accepted by various groups[a]

Acceptor group	N*(1)*	N*(2)*	N*(> 2)*	*%(1)*	*%(2)*	*%(> 2)*
Nitrile nitrogen	1399	215	75	82.8	12.7	4.4
Pyridyl nitrogen	5757	285	12	95.1	4.7	0.2
Carbonyl oxygen	32,038	7964	2738	75.0	18.6	6.4
Phosphate and phosphonate oxygen	10	48	211	3.7	17.8	78.4

[a]*N*(*n*) and %(*n*) = number and percentage of groups in CSD that accept *n* hydrogen bonds. Statistics based on 2015 version of CSD, using only nondisordered organic structures with *R*-factor ≤ 5%, hydrogen covalent bond distances normalized to average neutron-diffraction values. Hydrogen bonds restricted to NH or OH donors with D–H···A ≥ 90 degree and H···A ≤ sum of vdw radii plus 0.2 Å.

12. Acceptor groups can interact with more than one OH or NH donor. The ability to do so can be roughly correlated with the number of available lone pairs, so carbonyl groups often accept two donors and phosphate oxygen can accept three, whereas pyridine nitrogen rarely accepts more than one (Table 2). Steric accessibility is also relevant, so nitrile nitrogen is more likely to accept > 1 hydrogen bond than pyridyl nitrogen.
13. H···A distances are almost always shorter than the sum of vdw radii, often by 0.5 Å or more. The corresponding D···A distances are usually shorter than the sum of vdw radii. Stronger donors and acceptors tend to form shorter bonds.[93]
14. Hydrogen-bond distances are easily influenced by their environment. Hydrogen-bond distance distributions typically have 95% limits spanning 0.4 to 0.5 Å.[93]
15. Unless the bond is bifurcated, D–H···A angles usually exceed 150 degree and the energy becomes very small below 120 degree.[98]
16. Shorter hydrogen bonds tend to have larger D–H···A angles.
17. Directional preferences at the acceptor atom are discernible but rather weak.
18. Carbonyl oxygen atoms prefer to form hydrogen bonds in or close to the carbonyl-group plane. However, there is only a slight tendency for the interactions to form in the lone-pair directions within that plane. The tendency may be steric rather than electrostatic in origin.[99]
19. Hydrogen bonds to ether oxygen atoms have no preference for hydrogen bonding in the sp^3 lone-pair directions, but there is a strong preference for the plane bisecting the C–O–C angle.
20. Pyridyl and other sp^2 nitrogen atoms have a tendency to accept from donors positioned approximately along the lone-pair direction.
21. Hydrogen bonds can show cooperativity (two or more proximal bonds strengthening one another).[100]
22. They may also be anticooperative. For example, the dipolar interaction between two donor groups hydrogen bonding to the same carbonyl oxygen atom is unfavorable.
23. Intramolecular hydrogen bonds in conjugated systems are often described as "resonance assisted" but the extent to which this is the case is open to question.[101]
24. NH and OH groups in proteins are almost invariably donated in hydrogen bonds to good oxygen or nitrogen acceptors. This can, of course, include water.
25. Oxygen and nitrogen acceptors are usually hydrogen-bonded to OH or NH groups, but it is also common for them to form contacts only to CH groups.
26. The contribution of protein–ligand hydrogen bonds to binding energy is variable and difficult to predict, but often small because of desolvation costs.[102] It is possible for a hydrogen bond between protein and ligand to be entropy-driven rather than enthalpy-driven.[103]
27. Desolvating a protein donor group without forming a compensatory hydrogen bond to the ligand is almost certain to have a highly unfavorable impact on binding affinity. Acceptors may be more forgiving.[44]

CH···O and CH···N hydrogen bonds have been extensively dealt with in the literature,[104] so, again, the discussion here will be brief. Donor strengths tend to decrease in the order C(sp)–H > C(sp^2)–H > C(sp^3)–H, but even methyl groups are capable of forming stabilizing interactions. Electron-withdrawing groups promote donor ability—for example, the CH groups at the 6-position of uracil and the 2-position of imidazole and imidazolium are better donors than most other CH groups. Hydrogen bonds with CH donors tend to be longer than their OH and NH analogs, with H···O and H···N distances that sometimes exceed the sum of vdw radii. Directional preferences are much weaker, both at the hydrogen atom[98] and at the acceptor. Although they are weak, CH···O hydrogen bonds can be numerous and hence significant in protein–ligand binding[105,106] (eg, in kinases[107]). It has been claimed that they are comparable to NH···O interactions in the context of the forces that hold together the adjacent strands of β-sheets.[108]

3.05.4.2 Interactions Involving Aromatic Rings

3.05.4.2.1 The instructive example of the benzene dimer

Apart from strong and moderate hydrogen bonds, the molecular interactions of most importance in rational drug design are probably those involving aromatic rings. This is partly because of the popularity of phenyl groups and aromatic heterocycles in medicinal

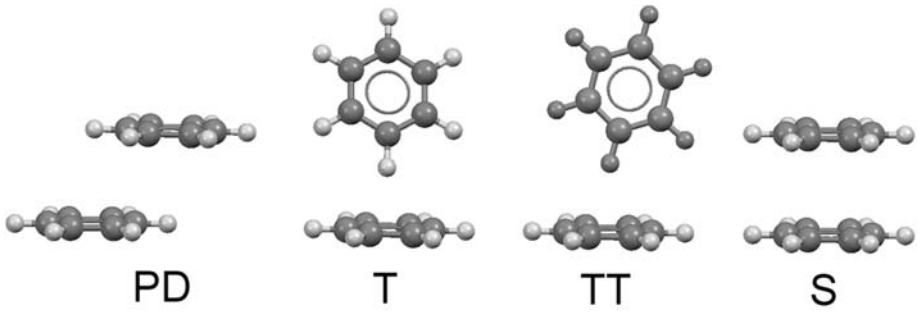

Fig. 2 Four important benzene dimer geometries.

chemistry and also, of course, because phenylalanine, tyrosine, and tryptophan side chains are often present in binding pockets. It is ironic, then, that these interactions have proved particularly difficult to understand and predict. Moreover, the experts' view of them has changed significantly over the past 10 years.

Most reviews of aromatic interactions begin with the benzene dimer, and rightly so, because it is a highly instructive system. It has been studied extensively, both experimentally and computationally, but both approaches have been problematic. The main difficulty with theoretical methods is that much of the stabilization energy of the dimer is due to dispersion. Approaches such as Hartree–Fock and what we might call "vanilla" DFT completely fail to reproduce this physical effect, so higher-level methods are necessary. Computationally, they are much more expensive. In consequence, it has been impossible until comparatively recently to fully explore the potential energy hypersurface of the dimer at an adequate level of approximation.[109–113] The results provided new insights. Until 2006, it had been thought that the two most stable arrangements were the parallel-displaced (PD) and the symmetric T-shaped (T) geometries (Fig. 2). However, SAPT calculations indicated that the T geometry is at a saddle point on the potential energy hypersurface.[111] The global minimum is similar to the T arrangement but with a tilt that improves dispersion interactions (TT; Fig. 2). The PD, T, and TT geometries are similar in energy, all three falling in the range -2.6 to -2.8 kcal mol^{-1}. In contrast, the classic "π-stacked" sandwich arrangement (S) is significantly less stable at -1.8 kcal mol^{-1}. The other recent theoretical studies referenced above differ in matters of detail, but confirm the overall picture of a rather flat potential energy hypersurface with PD, T, and TT geometries most favored, and S distinctly less so. Rotational spectroscopy indicated the presence of tilted T-shaped geometries in the gas-phase.[114] The crystal structure of benzene at normal pressure has pairs of neighboring molecules with geometries approximating TT.[115]

These results might seem irrelevant to medicinal chemists, whose interest in aromatic rings lies exclusively in the substituted variety. And substitution certainly has an effect on optimum geometries: Calculations on the toluene dimer, for example, suggest that the introduction of the methyl group makes the PD geometry more stable than the T arrangement.[116] But three important conclusions can be drawn from the benzene dimer system. Firstly, it is only during the past few years that theoretical methods have become capable of delivering reliable results on this system (and, therefore, on other aromatic complexes). Secondly, the benzene dimer can adopt a range of geometries that are approximately isoenergetic (T, TT, PD), so it is to be expected that the introduction of substituents onto one or both rings may swing the balance in favor of one geometry and against others. This is the main reason why the interactions of aryl groups have proved so difficult to understand. Thirdly, the sandwich geometry is energetically accessible but *not* the favored geometry, despite the assumptions of many that it is.

3.05.4.2.2 The interaction formerly known as π-stacking

An early attempt to understand the effect of substitution on aromatic-ring stacking (the S and PD geometries of Fig. 2) was made by Cozzi, Siegel, and coworkers.[117,118] They used NMR to measure the barrier to rotation about the aryl–naphthalene bonds in variously substituted 1,8-diaryl-naphthalene molecules. For steric reasons, the minimum-energy conformation has both aryl rings approximately perpendicular to the naphthalene system and therefore in a stacked geometry with respect to each other. It was argued that the rotation barrier is a measure of the strength of the aryl–aryl stacking energy. When only one of the rings was substituted, there was an approximately linear correlation between rotation barrier and Hammett substituent constant,[119] the barrier increasing as the substituent became more electron withdrawing. When both rings were substituted, the rotation barrier correlated with the sum of the Hammett constants. The stacking interaction was most favorable when both rings bore electron-withdrawing substituents, and least favorable when they had electron-donating substituents. While stacking produces a favorable dispersion interaction between the phenyl rings, there is also an unfavorable electrostatic term. It was concluded that electron-withdrawing groups reduce the π-electron density and thereby lower electrostatic repulsion between the stacked rings. Electron donors have the opposite effect.

In a seminal paper, Hunter and Sanders presented a similar though not identical argument.[120] Benzene has a large negative quadrupole moment (δ^+ around the edges of the ring, δ^- above and below the ring).[121] The sandwich (S) arrangement is therefore electrostatically unfavorable, T-shaped and PD geometries being preferable. However, if the aromatic system is polarized by substituents or heteroatoms, the strength of sandwich and near-sandwich stacked arrangements is affected. Rings with electron-donating

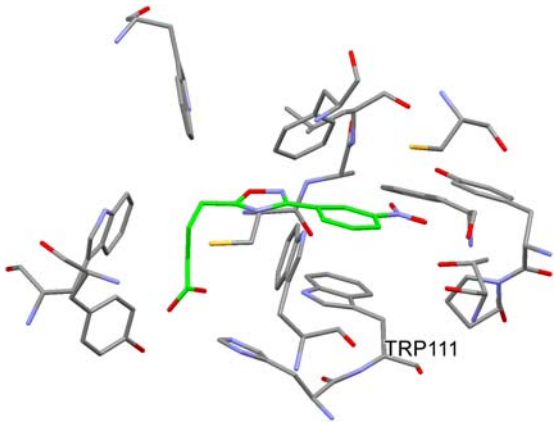

Fig. 3 Stacking of an inhibitor nitrophenyl ring with a tryptophan side chain in an aldose reductase complex (PDB code 2IKG).

substituents such as $-NMe_2$ will have increased negative quadrupole moments and will stack less favorably with benzene than an unsubstituted ring because of a larger electrostatic repulsion. Electron-withdrawing substituents such as $-NO_2$ will have the opposite effect. An example relevant to medicinal chemistry is provided by the aldose reductase complex shown in **Fig. 3**.[122] The *m*-nitrophenyl of the inhibitor stacks with the indole ring of Trp111 and the ligand lacking the nitro group show an activity drop of an order of magnitude. Two π-systems polarized in opposite directions will attract. This explains, for example, the crystal structures of the complexes of perfluorobenzene with methyl-substituted benzenes such as *p*-xylene.[123] They contain stacks of alternating molecules, radically different from the structure of benzene itself.

Both the Cozzi–Siegel and Hunter–Sanders models rationalize substituent effects in terms of the polarization of π-clouds, and this has become the standard viewpoint over the last two decades. However, a radically different explanation has now been put forward that dismisses the significance of π-cloud effects. Doubts about the π-polarization model arose when several theoreticians calculated that all substituents make stacking more favorable compared with the unsubstituted benzene dimer, irrespective of whether they are electron withdrawing or donating.[110,124–126] Further, it was concluded that substituent effects on stacking energy are additive.[127] This is hard to rationalize by π-polarization arguments because the polarizing influence of substituents would be expected to attenuate as more are introduced onto the ring. Also, Dunitz pointed out that 1,3,5-trifluorobenzene has no appreciable quadrupole moment, yet its crystal structure contains stacks of alternating molecules similar to those seen in the cocrystal of benzene and perfluorobenzene, which were rationalized on the basis of negative quadrupole/positive quadrupole attraction.[128]

Then came a short but notable paper that delivered a hammer blow to the π-polarization model.[129] The authors first calculated the energies of 24 dimers of general formula $C_6H_6\cdots C_6H_5X$, all in a stacked (S) arrangement, with optimized monomer geometries and inter-ring distances. The resulting dimer energies could be linearly correlated with Hammett sigma *meta* constants ($r=0.91$), which in itself is unsurprising. All of the complexes with $X \neq H$ had more favorable dimerization energies than that of the benzene dimer itself, supporting the notion that any substituent will stabilize stacking. This is most easily explained by the additional dispersion interactions that take place between the substituent and the unsubstituted ring. In the crucial part of the study, the authors then performed analogous calculations on the systems $C_6H_6\cdots HX$; in other words, the phenyl group of the substituted molecule is replaced by hydrogen. The hydrogen was placed along the original C–X bond direction. Remarkably, the resulting energies showed the same trend. The energies of $C_6H_6\cdots C_6H_5X$ and $C_6H_6\cdots HX$ differed, but the two sets of energies were strongly correlated ($r=0.91$). In other words, the effect of X on interaction energy is more or less the same whether the number of π-systems present is one or two. This implies that π-polarization effects need not be invoked to explain the effects of substituents on stacking energies. Rather, the reason for the energy variations seems to lie in the interaction with the unsubstituted ring of the substituent itself and the dipole associated with its covalent bond.

In a later paper,[130] Wheeler went one stage further and showed that energies of the simpler system propene$\cdots$HX also correlate closely with those of $C_6H_6\cdots C_6H_5X$ ($r=0.94$, excluding two outliers discussed in the paper). He concluded that substituent effects on stacking interactions depend largely on the direct, localized interaction of the substituent and its covalent bond with the closest vertex of the neighboring ring, the remainder of the ring being relatively unimportant. Further evidence was presented to support this contention. He summarized thus: "substituent effects arise from the interaction of the local dipole (or higher-order multipole) associated with the substituent (including the first polarized σ-bond) with the nearby local C–H dipoles of the other ring. As a result, substituent effects are insensitive to changes to the distal side of either the substituted or unsubstituted ring. In cases where both rings bear substituents, our local, direct interaction model predicts that substituents will operate independently as long as they are not in close proximity."[131] Similar arguments have been made for substituent effects on edge-to-face (T-shaped), cation–π, and anion–π interactions.[132–134] Stacking of nucleic acid bases has also been rationalized in terms of local electrostatic interactions between bond dipoles, coupled with dispersion interactions.[135]

If it stands the test of time, the localized substituent effect model should have profound implications for structure-based drug design, with a move away from looking at rings as a whole toward consideration of interactions directly involving substituents and

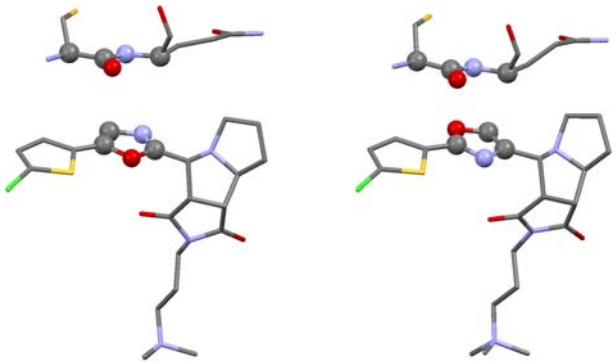

Fig. 4 Binding site detail in two factor Xa complexes. Both have a stacking interaction between the ligand oxazole ring and a protein peptide linkage (relevant atoms shown as spheres). The dipole moments associated with the stacked groups are approximately antiparallel in the tighter binding complex (*left*: PDB code 2Y5G, $K_i = 146$ nM) and parallel in the other (*right*: PDB code 2Y5H, $K_i = 1620$ nM).[140]

heteroatoms. One particular methodological issue is the use of electrostatic potentials. Proponents of the localized substituent effect model argue that, while this is valid for analyzing cation–π interactions,[136] it is of limited use for assessing whether two aromatic groups are mutually complementary and therefore likely to stack with each other. This is because changes in the electrostatic potential above an aryl group do not necessarily indicate a change in π-electron density but may be due to the through-space effect of substituents.[137]

One side-effect of the recent work on stacking is the suggestion in two papers that the terms "π-stacking" and "π–π interactions" are of limited validity.[138,139] It is argued that they imply (1) that aromatic face-to-face stacking is generally favored, which it is not, and (2) that when stacking does occur, the stabilization is primarily due to interactions of the π-systems, which is extremely arguable. Your present author agrees. The terms are confusing at best, misleading at worst, and should be consigned to history; "aromatic-ring stacking" is neutral about the cause of the interaction and is to be preferred.

3.05.4.2.3 Stacking of aromatic rings with amide groups

The amide group is known for forming hydrogen bonds but it can also form less polar interactions above and below the amide plane, including stacking interactions with aromatic heterocycles. This is relevant in drug design, since amide groups from the protein backbone or glutamine and asparagine side chains are often exposed at binding sites. The point was made and exemplified recently by Harder et al.,[140] who concluded that stacking interactions between aromatic rings and backbone peptide groups are important for ligand binding in cathepsin L,[141] phosphodiesterase 10,[142] and factor Xa complexes.[143] The latter example is particularly instructive. Two inhibitors with very similar structures were observed to bind in almost the same way to the protein, both with an oxazole ring stacked over a backbone peptide group (Fig. 4). Since the oxazole was 2,5-linked in one inhibitor and 2,4-linked in the other, the orientation of the ring, and therefore its dipole, with respect to the peptide group dipole was different in the two complexes. It was to this that the 11-fold difference in binding affinities was tentatively ascribed. In the better inhibitor, the oxazole and peptide dipoles were antiparallel, which would be expected to be electrostatically optimum.

In the same study, a series of quantum-mechanical calculations was performed on the dimers between *N*-methylacetamide and a variety of aromatic heterocycles. It was concluded that the stacking energy is indeed optimized when amide and heterocycle dipoles are antiparallel. The most favorable energies were with heterocycles that had large dipole moments; pyridazine and 2-pyridone were the best. It was also established that, in crystal structures containing ligand pyridyl groups stacked on backbone amide groups, there is a tendency toward the geometry corresponding to antiparallel dipoles.

3.05.4.2.4 Aromatic-ring interactions with halogens

Interactions between aromatic rings and halogen atoms were highlighted by Matter et al. in the context of factor Xa.[144] The authors' interest was provoked by the excellent K_i values (3 and 13 nM) of two inhibitors binding with a *p*-chlorophenyl group occupying the S1 pocket of the enzyme. Similar levels of binding were obtained with the *p*-bromo derivatives. By comparison, the unsubstituted molecules bound much less tightly ($K_i = 204$, 478 nM). Crystallography showed that the halo-substituents were pointed toward the face of the Tyr288 aromatic ring, leading the authors to hypothesize that C–Cl···π and C–Br···π interactions can make an important contribution to protein–ligand binding.

Both these authors and other groups have performed CSD searches to characterize the radial distribution of halogen atoms (X) around phenyl rings.[44,145,146] Somewhat ironically, given the interest in halogen···π interactions, all the studies agree that by far the most likely geometry is with the halogen at the edge of the ring, where it can interact with ring hydrogen atoms (Fig. 5). The preference for this position decreases in the order F > Cl > Br > I, and can readily be explained on the basis of electrostatic attraction, $H^{\delta+}\cdots X^{\delta-}$. A similar situation is found in the PDB. In over 2000 PDB complexes involving halogenated ligands, only 189 distinct X···π interactions were found; this contrasts with 1420 C–X···H contacts in 72 NMR and high-quality X-ray structures of protein complexes with halogenated ligands (although many of the latter will be to alkyl hydrogens).[147] The same study

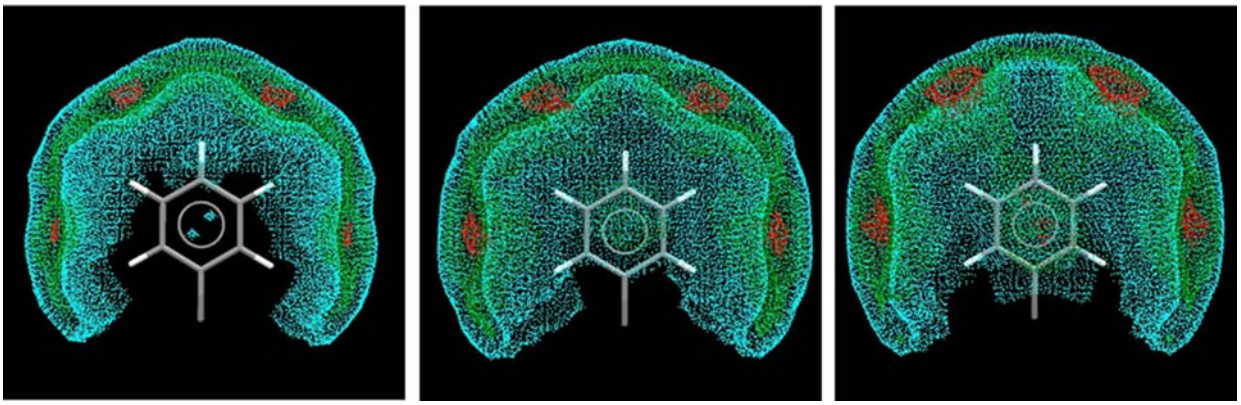

Fig. 5 IsoStar plots showing the density distributions of C–F (*left*), C–Cl (*center*), and C–Br (*right*) halogen atoms around phenyl groups in crystal structures from the CSD. The density levels *red*, *green*, and *cyan* show, respectively, regions where halogen atom density is four, two, and one times the value expected at random, given the stoichiometries of the crystal structures contributing to the plots.[4]

found the mean angles at hydrogen of CH···X contacts to be 119.5, 112.6, 96.8, and 101.7 degrees for X = F, Cl, Br, I, respectively. The interactions show only weak directional preferences, but there is evidence that H···F contacts below 2.6 Å only occur when C–H···F > 120 degrees.[44]

Despite the preference for C–H···X contacts, the radial distribution plots also do show many halogen atoms positioned over the ring and therefore interacting with the aromatic π-system; not for fluorine, but certainly for the heavier halogens (Fig. 5). The nature of these interactions is not entirely clear. Bissantz et al. noted that most of the contacts involving halogens bonded to aromatic rings are clearly the side-effects of aromatic-ring stacking.[44] However, there remain many other X···π contacts to rationalize. Some have argued that they are halogen bonds, stabilized by electrostatic attraction between the negative π-system and the positive area of electrostatic potential along the extension of the C–X bond (the "σ hole"; see halogen-bonding "Background" section). This is supported by a clear preference of C–Cl and C–Br vectors to be perpendicular to the aromatic-ring plane at the closest observed distances from the ring centroid (< 3.4 Å for Cl, < 3.5 Å for Br).[44] However, theoretical work suggests a different explanation. Calculations were performed at various levels of approximation on the T-shaped complexes between *p*-cresol and chlorobenzene and bromobenzene (ie, the geometries with the halogen atoms pointing at the cresol π-system). The higher-level approximations predicted interaction energies in the range −1.6 to −2.2 kcal mol^{-1} for the chlorobenzene complex, and between −2.7 and −2.8 kcal mol^{-1} for the bromobenzene complex. But, crucially, two methods incapable of reproducing electron correlation effects predicted no attractive interaction at all. This strongly suggests that dispersion rather than electrostatics is the dominant cause of stabilization.[148] Matter et al. concurred.[144] They performed calculations showing that the energy of the C–Cl···π interaction has very little angular dependence. This suggests that the major source of attraction is dispersion, since any electrostatic interaction between the halogen σ hole and the aromatic π-system would be expected to have strong directional preferences.

3.05.4.2.5 Cation–π interactions

The cation–π interaction[50,79,80,149] is the interaction between the π-system of an aromatic group and a metal or organic cation. There is general consensus that it is predominately electrostatic in nature,[150,151] the electronegative π-system attracting the electropositive cation. Polarization is also known to play a significant role.[152] The strength of the interaction was investigated in a biological context by Diederich et al., using two pairs of factor Xa inhibitors.[153,154] The S4 pocket of this enzyme is an "aromatic box" defined by the side chains of Tyr99, Phe174, and Trp215. The inhibitors in the first pair were identical except that where one had a *t*-butyl group, the other had a trimethylammonium. Their binding constants were 29 and 0.28 μM, respectively. Crystallography established that the $-NMe_3^+$ group occupies the S4 pocket, as expected (Fig. 6). Since the two groups have virtually identical volumes, the difference in binding affinities can be ascribed to the cation–π effect. It corresponds to a ΔΔG of 2.8 kcal mol^{-1}, equivalent to an average contribution of about 0.9 kcal mol^{-1} for each of the three aromatic side chains. The second pair of inhibitors also differed by the $-CMe_3$/$-NMe_3^+$ replacement. Again, the cationic group gave much better binding, 550 versus 9 nM. This corresponds to ΔΔG = 2.5 kcal mol^{-1}, an average contribution of 0.8 kcal mol^{-1} per ring, pleasingly consistent with the result from the first pair. The authors also established that increasing methylation of the ammonium group has an enormous effect on binding; the K_i values for inhibitors with $-NH_3^+$, $-NH_2Me^+$, $-NHMe_2^+$, and $-NMe_3^+$ groups were 9800, 911, 56, and 9 nM, respectively. This can presumably be ascribed to the high cost of desolvating N^+–H protons.

Dougherty et al. performed an interesting series of experiments in which aromatic residues in binding sites were changed to their fluorinated analogs: for example, tryptophan to 4,5,6,7-tetrafluorotryptophan. They argued that this completely removes the electrostatic component of any cation–π interactions that the residue forms when a cationic ligand binds. Solvent effects are minimized because the ligand itself is not changed. Fluorination reduced the binding affinity of acetylcholine to various proteins by factors of 50 to 500. A ratio of over 10,000 was observed for the binding of glycine to its cognate receptor.[80,155,156]

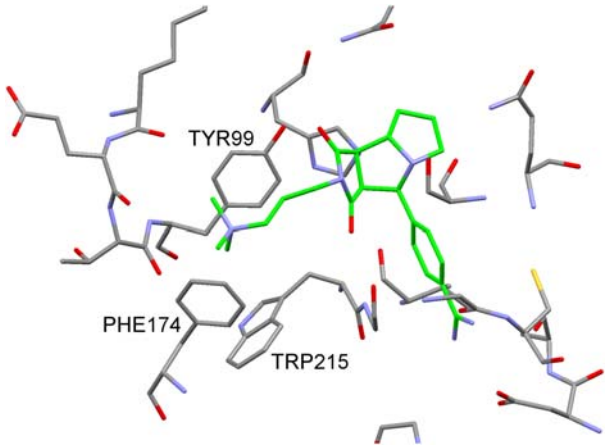

Fig. 6 Cation–π interaction between a ligand $-NMe_3^+$ group and an "aromatic box" defined by three protein side chains of factor Xa (PDB code 2BOK).

Cation–π interactions in protein–ligand complexes can utilize any of the three naturally occurring aromatic amino acid side chains, though there is evidence that tryptophan is most commonly involved (presumably because it has the most electron-rich π-system).[157,158] The aromatic box motif, mentioned above in the context of factor Xa, is found in many unrelated proteins. This has been ascribed to convergent evolution.[159] The motif does not always involve the same number or types of aromatic side chains. The most famous example is probably in acetylcholinesterase (AChE), where it has evolved to bind the $-NMe_3^+$ group of acetylcholine. The binding of this cationic group in a hydrophobic pocket was a surprise to almost everyone when the first AChE crystal structure was solved,[160] the prevailing view at the time being that an anionic site would be needed. The triumphant exceptions were Dougherty and Stauffer, who had correctly predicted the truth a year earlier.[161] In addition to molecules containing $-NMe_3^+$ groups, AChE binds a wide variety of inhibitors, including tetrahydroaminoacridinium and the natural products galantamine and huperzine. They are structurally very diverse, but most have large, electron-deficient hydrophobic groups that can interact with the active-site aromatic side chains, particularly the key tryptophan residue.[162] Enzymes that contain aromatic boxes therefore offer excellent opportunities for designing patent-busting leads with novel scaffolds. Salonen et al. make the point that quaternary ammonium ions do not cross biological membranes but unionized tertiary amines do. In the factor Xa study discussed earlier, binding affinity was reduced by changing $-NMe_3^+$ to $-NHMe_2^+$, but not catastrophically (9 to 56 nM).[79] Therefore, use of weakly basic tertiary amines may give acceptable transport properties in the neutral form combined with the ability, after protonation, to form cation–π interactions at the binding site.

Cation–π interactions that involve guanidinium groups deserve particular mention because of the presence of this group in arginine. In a survey of 83 protein structures, Flocco and Mowbray found that the parallel stacked arrangement, in which arginine guanidinium groups are positioned directly over the center of the rings of aromatic side chains, occurs much more frequently than would be expected by chance. This is particularly so in functionally important regions of proteins. The arrangement leaves all three guanidinium nitrogen atoms free to donate hydrogen bonds, and it was therefore hypothesized that it provides conformational tethering of the arginine side chain while still allowing it to bind ligands. The aromatic ring might also tune the pK_a of the arginine hydrogen bond partner.[163] Arginine is commonly used for suppressing protein aggregation. Mass spectrometry on model peptides suggests that the guanidinium group preferentially binds to aromatic residues and it is hypothesized that this disrupts the aromatic–aromatic interactions that are known to drive aggregation.[164]

In conclusion, the cation–π interaction is seen in many protein–ligand complexes and can be an extremely useful design tool that offers the possibility of scaffold hopping. It is also implicated in protein–protein binding: in a survey, about half of protein complexes were found to contain at least one intermolecular cation–π pair.[165]

3.05.4.2.6 Aromatic rings as hydrogen bond acceptors

There is no doubt that aromatic rings can accept hydrogen bonds from XH donors (X = O, N). This is illustrated by the IsoStar plot showing the distribution of XH groups around indole rings in the CSD (Fig. 7). Many clear examples of nitrogen or oxygen atoms positioned above the center of one or other of the rings, particularly the 6-membered ring, can be seen. A rather old but still definitive study of XH···π hydrogen bonds in the CSD adds considerable detail.[166] The authors searched for XH contacts to substituted and unsubstituted phenyl groups in good-quality organic structures and categorized them by geometry. A minority had the XH group positioned above the ring with the X–H···RC angle greater than 150 degrees (RC = ring centroid). This geometry was more commonly seen for NH groups than for OH. A more common geometry had the XH group above the ring but tilted so that the hydrogen atom pointed toward one of the ring carbon atoms. The most common arrangement had the XH group positioned not over the ring but to one side of it, with the hydrogen pointing at a ring carbon. This was overwhelmingly the preferred

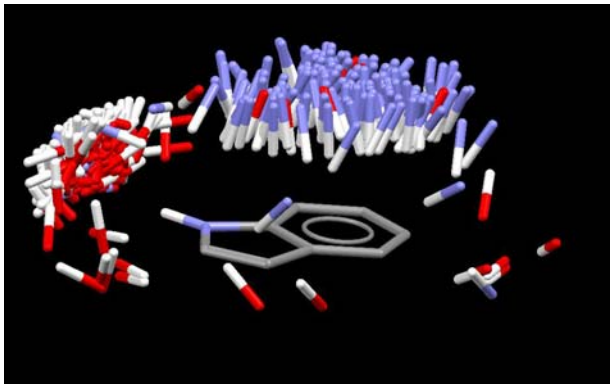

Fig. 7 IsoStar plot showing the observed distribution of OH and NH groups around indole rings in crystal structures from the CSD. Only contacts shorter than the sum of van der Waals radii minus 0.4 Å are shown. The cluster of predominately NH groups above the ring are forming XH···π hydrogen bonds, whereas the OH groups near the indole NH are accepting NH···O hydrogen bonds.

arrangement for OH groups and the authors suggested that these contacts may actually be C(phenyl)–H···OH hydrogen bonds, albeit with very bent C–H···O angles. Their conclusion was supported by a more recent CSD survey.[167]

Calculations on the water–benzene and ammonia–benzene hydrogen-bonded complexes gave interaction energies of −3.0 and −2.2 kcal mol^{-1}, respectively.[168] More recently, calculations on the alanine–benzene system gave a range of energies for the alanine–OH···π and alanine–NH···π hydrogen bonds, depending on the theoretical model used, but they were broadly in line with the earlier results. Using MP2, for example, the OH and NH interactions were calculated to have energies of −3.2 and −1.1 kcal mol^{-1}, respectively.[169] It has been shown experimentally that the stabilization energy of the OH···π hydrogen bonds is primarily electrostatic in origin and can be as large as −3 kcal mol^{-1}. As expected, the strength of the electrostatic interaction decreases in the order OH > NH > SH.[170,171]

A survey of 592 high-resolution protein crystal structures found 1311 putative XH···π hydrogen bonds (X = N, O, S) and concluded that the best of the aromatic acceptors, tryptophan, accepts one hydrogen bond per 5.7 residues.[172] However, the geometric criteria used to define the XH···π hydrogen bond were relatively lax. Further, and crucially, no checks were made that the XH group was not donating to a conventional (oxygen or nitrogen) acceptor. This leaves the possibility that the XH···π contact may be little more than incidental. And an even bigger snag: despite all the evidence that aromatic rings can act as hydrogen-bond acceptors, it is unusual to find convincing examples of NH···π or OH···π hydrogen bonding between proteins and ligands. There are a few, such as the complex of human cartilage glycoprotein-39 and chitotetraose (Fig. 8).[173] The reason for their scarcity is not hard to find: OH and NH groups form much stronger hydrogen bonds to water than they do to aromatic rings. Therefore, the desolvation cost will rarely make protein–ligand XH···π hydrogen bonding a viable proposition and the interaction is consequently of little use to the drug designer.

3.05.4.2.7 Anion–π: An interaction in search of a medicinal role

As noted earlier (see "The interaction formerly known as π-stacking"), the electrostatic potential above and below aromatic rings loaded with electron-withdrawing substituents is positive, in contrast to most aromatic systems; hexafluorobenzene is the classic example. The same can occur in rings with several heteroatoms, such as triazine.[174] The "anion–π" interaction occurs between

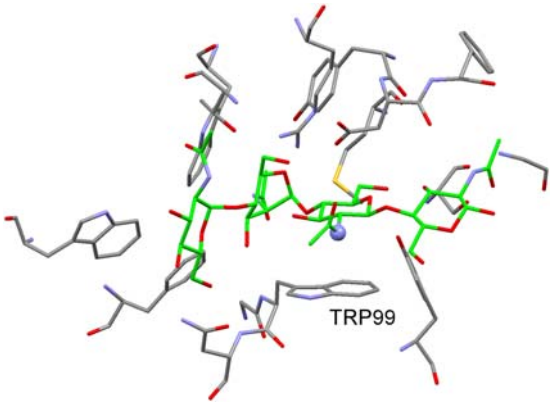

Fig. 8 A rare example of an NH···π hydrogen bond between a ligand and a protein (PDB code 1NWU; donor nitrogen shown as sphere).

a positively polarized ring such as C_6F_6 or triazine and an anion (halide, perchlorate, phosphate, etc.) positioned more or less centrally over the ring. It owes its stability principally to electrostatic attraction, although polarization and dispersion also contribute.[175] The term "anion–π" is misleading, suggesting as it does that π-electrons are important: it is positive rather than negative potential above the ring that is required for the interaction to occur. Theoretical calculations suggest that the interaction energies can be comparable with those of cation–π interactions—perhaps weaker when the aromatic ring is charge neutral but stronger with positively charged rings.[176] Despite some skepticism,[177] it is clear that the interaction has been frequently observed in small-molecule crystal structures, and also in solution and the gas-phase.[176,178,179] It has been exploited in the design of synthetic anion receptors.[180]

How relevant the interaction is in biology is uncertain. It may be implicated in chloride ion transport. As a proof-of-concept, model "anion–π slides" have been synthesized that successfully transport halide ions along electron-deficient aromatic oligomers.[181] Short contacts between anions and aromatic rings have been found in surveys of crystal structures in the PDB, though whether these are anion–π interactions is open to question.[178,182] Moreover, of the aromatic systems found in naturally occurring amino acids, only the protonated form of histidine is electron deficient and therefore suitable for anion–π interactions. This and the requirement for an anionic ligand would seem to limit the potential value of anion–π interactions in drug design. There is more hope, perhaps, in the nucleic acid area, since nucleotide bases contain electron-withdrawing heteroatoms. It has been suggested that interactions between oxygen lone pairs and protonated nucleobases could be significantly stabilizing.[183] For now, though, it seems unlikely that the anion–π interaction will ever be as useful to the medicinal chemist as its cousin, the cation–π.

3.05.4.2.8 CH···π interactions

This section covers all types of CH interactions with aromatic π-systems, including those in which the CH group itself belongs to an aromatic group. The latter are effectively T- or TT-shaped (edge-to-face) aromatic–aromatic interactions (see "**The instructive example of the benzene dimer**"), which some authors prefer to consider separately.

The CH···π interaction is weak but not insignificant. In the gas-phase, the energy of the methane–benzene cluster was measured spectroscopically as -1.03 to -1.13 kcal mol^{-1}.[184] High-quality CCSD(T) calculations on other benzene–alkane clusters showed that the optimum geometries of the dimers invariably have one of the CH groups pointing toward the benzene π-system. After correction for zero-point vibrational energy, binding energies were computed as -1.62, -2.49, -2.63, -2.45, and -2.59 kcal mol^{-1} for ethane, propane, *n*-butane, *iso*-butane, and cyclohexane, respectively.[185] In all of the dimers, the dominant contribution to the interaction energy comes from dispersion, due mainly to the relatively polarizable carbon atoms. There is a monotonic correlation between alkane size and binding energy until the benzene–cyclohexane complex, which is no more favorable than the *n*-butane complex. This suggests that only the closest four carbon atoms of the alkane make a significant contribution to the interaction energy.

However, electrostatics can also play a role. It is accepted that the CH···π interaction becomes stronger as the acidity of the hydrogen atom increases.[186–188] Gas-phase measurements on the benzene–ethylene and benzene–acetylene clusters gave association energies of -1.4 and -2.7 kcal mol^{-1}.[189] The former is not appreciably different from that of benzene–ethane (mentioned previously) but the latter is substantially more favorable, as would be expected from the greater acidity of the acetylenic hydrogen atom. The benzene–dichloromethane and benzene–chloroform dimers are even more stable: -3.8 and -5.2 kcal mol^{-1}, respectively, as measured by two-color ionization spectroscopy.[190] Theoretical calculations by the same authors gave results consistent with the experimental measurements. It was concluded that the benzene complexes with the haloalkanes are stabilized not only by dispersion but also by significant electrostatic attraction between the acidic hydrogen atom and the benzene π system.

On the basis of these and other results, and particularly because of the importance of dispersion, Tsuzuki argues that most CH···π interactions should not be classed as hydrogen bonds, though the descriptor might perhaps be applicable to the interactions formed by unusually acidic CH groups.[188] Other scientists take an opposing view and routinely use the term "CH···π hydrogen bond".[73] For what it is worth, your present author is persuaded by Tsuzuki's arguments.

It is clear both from solution measurements and crystal structures that CH···π interactions are influenced by aromatic-ring substitution patterns. Chemical double-mutant cycles on zipper complexes were used to quantify CH···π interactions of the edge-to-face type (ie, the CH group is part of an aromatic ring). Interaction energies depended on the substituents present on the rings, varying from $+0.2$ to -1.2 kcal mol^{-1}.[191] The energies correlated with Hammett substituent constants, tending to become more favorable with electron-withdrawing substituents on the CH donor ring and electron-donating groups on the ring providing the π system. Cole et al. used the IsoStar database to investigate the spatial distribution of C(sp^3)–H groups around phenyl, *p*-methoxyphenyl, *p*-tolyl, *p*-nitrophenyl, pentafluorophenyl, and 3,5-dinitrophenyl groups in small-molecule crystal structures.[192] As the ring substitution became more electron withdrawing, the density of CH hydrogens above the aromatic ring was observed to decrease. Ring heteroatoms had a similar effect, the CH density being high above indole ring systems and low above pyridine rings (and, in the latter case, displaced from the ring center toward the ring nitrogen).

In another CSD study, Takahashi et al. determined the mean distance between the hydrogen atom and the aromatic-ring plane for contacts involving various types of CH groups.[193] As would be expected, the distance becomes progressively longer as the acidity of the hydrogen atom decreases: 2.53, 2.62, 2.61, 2.72, and 2.75 Å for Cl_3C–H, Cl_2HC–H, C(sp)–H, C(sp^2)–H, and C(sp^3)–H, respectively. CSD analysis also showed that the CH group has a distinct tendency to interact with the center of the ring; this is clearly discerned after correction for a geometric factor.[194] If CP is the closest point on the ring plane to the hydrogen atom, the C–H···CP angle can be very nonlinear, the mode of its distribution being about 140 degrees. In other words, there is not a strong propensity for the CH group vector to be perpendicular to the ring plane.[73]

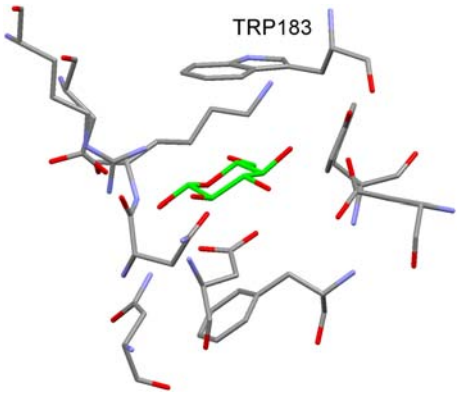

Fig. 9 A common sugar binding motif: the pyranose ring forms C–H···π interactions by stacking with a tryptophan side chain (galactose binding protein; PDB code 2HPH).

There is substantial evidence that CH···π interactions influence protein structures.[73] For example, it has been known for many years that aromatic–aromatic side chain interactions show a preference for edge-to-face orientations.[195,196] From a considerable body of more recent work, three examples will further illustrate the point. The first relates to the 35-residue peptide α_2D, which folds as a dimeric four-helix bundle with two stacked Phe–Phe pairs buried in the hydrophobic core. When one of the phenylalanine residues of each pair was mutated to cyclohexylalanine, the resulting complex was found to be more stable than the original system. This was ascribed to cyclohexyl–phenyl stacking, with the three axial CH groups on one face of the saturated ring pointing toward the π-cloud of the aromatic ring. The stabilization amounted to about 0.7 kcal mol^{-1} per CH···π interaction.[197] Proton NMR studies on short peptides show that the Pro–Pro peptide bond in Pro–Pro–Phe adopts *cis* and *trans* geometries about equally, with the former stabilized by CH···π interactions between the terminal proline and phenylalanine side chains.[198] The stabilization of *cis*-peptide geometries by proline–aromatic interactions is more effective with tyrosine and tryptophan than phenylalanine, suggesting an electronic effect, and the *cis*/*trans* ratio can be tuned by inserting electron-withdrawing or -donating substituents onto the 4-position of the phenyl group.[199]

Of greatest importance to medicinal chemistry is the extent to which CH···π interactions are involved in the binding of protein ligands. Small sugar molecules, for example, often bind by stacking with aromatic residues, particularly with tryptophan (Fig. 9).[200,201] The CH groups on pyranose rings are polarized by the proximal oxygen atoms and therefore well suited to the formation of CH···π interactions. Although many AChE inhibitors bind via cation–π interactions, there are others which bind to the same aromatic residues by means of CH···π interactions involving (relatively) unpolarized CH groups.[202] Changing the morpholine group of a factor Xa inhibitor into morpholin-3-one improved the IC_{50} from 43 to 0.7 nM. The extra carbonyl group did not interact directly with the protein, the inference therefore being drawn that it improves binding by polarizing a ring CH_2 group that is positioned above the face of a tryptophan side chain.[44,203] Similarly, in a series of steroid dehydrogenase inhibitors, binding was improved from 110 to 17 nM by introducing a fluoro substituent between two CH groups in contact with a tyrosine ring.[44,204]

In summary, CH···π interactions are among the most important for medicinal chemistry simply because the participating groups are so common. Although weak, they offer the possibility of being strengthened by introducing appropriate substituents, and several CH···π interactions can add up to a useful amount of binding energy. However, it is rarely appropriate to regard them as hydrogen bonds.

3.05.4.3 The Occupation of Nonpolar Pockets by Ligand Hydrophobic Groups

A classic result from host–guest chemistry was obtained by Mecozzi and Rebek, who determined that optimum binding of a hydrophobic guest is obtained if it occupies about 55% of the volume of the cavity in the host.[30] While this conclusion was based on synthetic host–guest systems, a similar figure has been arrived at for some protein–ligand complexes.[55] A nonpolar side chain in a series of plasmepsin inhibitors was systematically varied in size, ranging from *n*-butyl to *n*-undecyl. The volume of the pocket that the side chain occupied was computed from the X-ray structure and the ratios PC = (volume of side chain)/(volume of pocket) were calculated. A plot of IC_{50} against PC showed a bell-shape curve. At one end of the PC range was the *n*-butyl derivate, with PC = 30%, IC_{50} = 4190 nM; at the other extreme was *n*-undecyl, with PC = 75%, IC_{50} = 1950 nM; the optimum was obtained with 4-isopropylbutyl and 3-cyclopentylpropyl, for which PC = 50, 52% and IC_{50} = 30 nM. Kashiwagi et al. got similar results on the vitamin D receptor, their best in vitro agonist having a PC value of 56%.[205]

While these results are nicely consistent, the full truth is unlikely to be that simple. Although rare exceptions are known,[206] nonpolar cavities in uncomplexed proteins are almost invariably hydrated, and it is often the enthalpic and entropic consequences of displacing the water that drive cavity–ligand binding.[207,208] If the ligand is a little too small, the possibility exists of trapping a water molecule with deleterious entropic consequences. Once the ligand is large enough to displace all the water in the cavity, further size increases may give little or no improvement to binding affinity, and must eventually become counterproductive. The

optimum percentage occupancy of any particular cavity must depend on the nature of the water network within it. One thing is clear: binding affinity can be very sensitive to even small changes in the volume occupancy of a nonpolar pocket. A good example is provided by the S1 pocket of dipeptidyl peptidase IV. An inhibitor pair differing only by a single *meta* methyl substituent on the phenyl group occupying this pocket had K_i values of 200 and 4.6 nM for the unsubstituted and methylated compounds, respectively.[209]

In their perspective on the art of filling apolar pockets, Zürcher and Diederich contrast two enzymes, IspE and IspF, in the non-mevalonate pathway of isoprenoid biosynthesis.[55] The active site of the latter contains a small, hydrophobic pocket that is evidently flexible, since its conformation changes from one crystal structure to the next. Occupation of this pocket yielded little if any gain in binding affinity. IspE, on the other hand, contains a small but much less flexible ("preorganized") pocket. Optimal filling of this pocket delivers an inhibitor with $K_i = 0.29$ μM, compared with 2.6 μM when the pocket is largely unoccupied. The authors conclude that large affinity gains can be obtained by filling preorganized pockets, but the occupancy of very flexible pockets results either in poor enthalpic interactions or a loss of protein flexibility with a consequential entropic penalty.[210]

3.05.4.4 Halogen Bonding

3.05.4.4.1 Background

The strangest thing about the halogen bond is that it has been known for a long time. Perhaps, it just needed some good public relations before it was taken seriously. Whatever the reason, the growth in interest in the interaction over the past few years has been explosive.[211] It is truly the bee's knees, the cat's pajamas, the must-have interaction for the contemporary drug designer.

The first evidence for halogen bonding actually dates back a century and a half, to Guthrie's 1863 preparation (on the island of Mauritius) of the adduct of iodine and ammonia.[212] A considerable time later, Hassel and Hvoslef solved the beautiful crystal structure of the bromine–dioxane complex (**Fig. 10**), which shows the short contact distance (2.72 Å) and the close-to-linear angle of approach (Br–Br···O = 178 degrees) that we now know to be so characteristic of halogen bonds.[213] The authors observed that the geometry indicated "a very strong interaction between the bromine and oxygen atoms." In due course, a succession of CSD surveys and some quantum-mechanical calculations established a number of basic facts. In addition to the dihalogens, carbon-bound halogen atoms (C–X, X = Cl, Br, I) can also form the interaction. While nucleophiles (Nu) preferentially approach with C–X···Nu angles of 165 degrees or more, electrophiles (E) favor C–X···E angles of around 100 degrees. It is the former interaction that is termed the "halogen bond." The attractive nature of C–X···Nu is primarily due to electrostatic effects. X···Nu distances can be much shorter than the sum of vdw radii.[214–217] Subsequent work has not altered this picture to any significant extent, although considerable detail has been added.

The nature of halogen bonding has been widely studied by theoreticians.[218–220] The electrostatic potential around carbon-bound chlorine, bromine, and iodine atoms is not uniformly negative, even though halogens are electronegative elements. In CH_3Br, CBr_4, and CCl_4, for example, the potential is positive in the region along the extension of the C–X bond; elsewhere, it is negative. In CH_3F, on the other hand, it is negative throughout.[221] The positive area is called the "σ hole." Its origins are explained rather nicely by Clark et al.[222] in terms of the hybridization of the bonding and lone-pair orbitals of the halogen atom. Two of the halogen unshared electron pairs occupy p orbitals perpendicular to the C–X direction, resulting in a high electron density and negative electrostatic potential in a belt around the C–X axis. The halogen atom's contribution to the C–X σ bond is predominately a p orbital, meaning that the third lone pair has mainly s-orbital character and is rather diffuse. The consequence is that the nuclear charge is poorly shielded along the extension of the C–X bond, resulting in the σ hole. A nucleophile approaching with C–X···Nu close to 180 degrees therefore feels an electrostatic attraction—the halogen bond. The effect is enhanced by polarization of the X atom if the other groups on the C–X carbon atom are electron withdrawing.

A range of groups can play the role of nucleophile, including carbonyl and ether oxygen, pyridine and other sp^2-hybridized nitrogen atoms, amine nitrogen, and perhaps—but very arguably—the π-systems of aromatic groups (see "**Aromatic-ring interactions with halogens**").[223,224] Some calculated interaction energies are given in **Table 3**, together with those of typical strong,

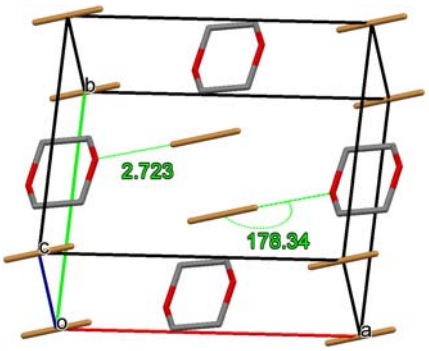

Fig. 10 Crystal structure of the bromine–dioxane complex (CSD code DOXABR).

Table 3 CCSD(T)/CBS calculated energies of some illustrative halogen bonds and hydrogen bonds

Type	*Donor*[a]	*Acceptor*[a]	ΔE *(kcal mol*$^{-1}$*)*[b]	*Ref.*
Hydrogen bonds				
OH···O=C	Formic acid	Formic acid	−9.31[c]	[36]
NH···O=C	Formamide	Formamide	−7.98[c]	[36]
OH···N	Water	Ammonia	−6.49	[35]

C(sp^2)–I···N	Iodobenzene	Trimethylamine	−5.81	[225]

[a]Somewhat confusingly, the halogen atom (the electron acceptor) is conventionally termed the *donor* of a halogen bond while the electron donor (oxygen, nitrogen, or whatever) is the *acceptor*. Think of it as donating or accepting the σ hole.
[b]Calculated interaction enthalpy.
[c]Dimer contains two hydrogen bonds, so value given is half the dimerization energy.

moderate, and weak hydrogen bonds for comparison. Iodine generally forms stronger halogen bonds than bromine, which in turn tends to form stronger bonds than chlorine. As a general rule, halogen-bond energies are comparable with those of weak hydrogen bonds, although they can be stronger in exceptional circumstances. Solution calorimetry was used to determine the enthalpy of formation of the 1:1 complex between iodo-perfluorocyclohexane and 2,2,6,6,-tetramethylpiperidine.[226] With such a highly polarized iodine, the result, −7.5 kcal mol^{-1}, is about as strong as a halogen bond gets. Other experimental data on strong halogen-bond donors are available; for example, association constants of fluorinated iodoalkanes and iodoarenes with a range of acceptors have been measured in solution by NMR titration.[227,228]

While most regard halogen bonding as primarily an electrostatic interaction, this is not a unanimous view. In a recent paper, it was suggested that charge transfer plays a significant role,[229] with donation of electron density from the nucleophile lone pair into the relatively low-lying C–X σ^* antibonding orbital.

3.05.4.4.2 Fluorine as a halogen-bond donor

It isn't. Or at least, only so weakly and in circumstances sufficiently exceptional that the possibility need not trouble the medicinal chemist.[230,231]

3.05.4.4.3 Halogen-bond geometries

The geometric preferences of halogen bonds are well established, both from X-ray data[217] and theoretical calculations.[217–219] Halogen···acceptor distances tend to be short and can be less than the sum of the atoms' vdw radii by 0.3 Å or more. As noted earlier, the most striking feature is the preference for a linear or near-linear geometry at the halogen. Deviations of 25–30 degrees from the linear C–X···acceptor arrangement reduce interaction energies by about 50%.[232] If the deviation is 40 degrees or more, it is doubtful whether an interaction should be called a halogen bond. Calculations on model complexes between bromobenzenes or bromopyrimidines and acetone indicate that a Br···O=C angle of 120 degrees or slightly higher is optimum,[219] corresponding to approach of the halogen along an oxygen lone-pair direction. However, there is evidence from the PDB that halogen atoms can approach carbonyl oxygen atoms from a direction approximately orthogonal to the C=O plane, corresponding to interaction with the carbonyl π-electron density.[233] This is supported by the higher-precision structural data in the CSD. For example, the structure shown in Fig. 11 contains a clear-cut Br···O halogen bond (short Br···O distance, near-linear C–Br···O angle) in a near-orthogonal geometry.[234]

3.05.4.4.4 Halogen bonds in protein–ligand complexes

In an interesting case study, the influence of halogen bonding on the binding affinities of ligands to human cathepsin L was examined.[141] A series of covalently bound ligands was positioned with a phenyl group occupying the S3 pocket of the enzyme. Substituents at the *para* position of the phenyl were suitably located to interact with the backbone carbonyl oxygen atom of Gly61. The IC_{50} value of the unsubstituted phenyl derivative was 0.29 μM, whereas those of the *para* methyl-, fluoro-, chloro-, bromo-, and iodophenyl analogs were 0.13, 0.34, 0.022, 0.012, and 0.0065 μM, respectively. The similar sizes of methyl and chlorine argue against a steric effect. It is therefore reasonable to argue that the increase in affinity along the series H ≈ Me ≈ F < Cl ≈ Br < I is due to halogen bonding, remembering that the C=O···X interaction becomes stronger as the atomic number of *X* increases. The low

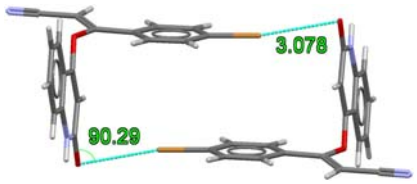

Fig. 11 Br···O═C halogen bonds formed approximately orthogonally to the carbonyl-group plane (CSD structure IDOZAD).

affinity of the fluoro compound can be ascribed to O···F electrostatic repulsion. Other ligand series, with additional substitution of the phenyl ring or its replacement with pyridyl or thienyl, showed similar trends. Crystal structures of some of the complexes established that the halo-substituents were in the correct position for the halogen bond. As the authors pointed out, however, halogen bonding might not be the only factor in play. The complexes may also be stabilized by CH···X interactions, and halo-substitution might affect the stacking energy between the aromatic ring and a proximal section of the protein backbone. Moreover, affinities were little altered by the introduction of electron-withdrawing substituents at other positions on the aromatic ring, although it might have been expected that this would strengthen halogen bonding through polarization.

The halogen bond in the cathepsin L complexes occurs in a polar, solvent accessible region of the protein. In contrast, ligands of MEK1 kinase have been shown to form halogen bonds in a predominately apolar pocket.[235] Again, the acceptor is a carbonyl oxygen atom (of Val127) and the donors are *para* substituents on a phenyl ring. Binding affinity improves as the substituent is varied along the series F (IC_{50} = 0.12 μM), H (0.052 μM), Cl (0.026 μM), Br (0.0077 μM), and I (0.0020 μM). Crystallography on the iodo-derivative confirmed the presence of the halogen bond, with the substituent pointing directly at the oxygen atom. All the other contacts in the pocket are hydrophobic. That the improvement is only modest when changing –H to –Cl was ascribed to a longer than optimal Cl···O distance, a problem not present with the heavier halo-derivatives, where the C-halogen bond lengths are longer and the halogen atoms bigger (note, however, the comments on Cl···O halogen bonds in "**The skeptical chemist's view of halogen bonding**").

There have accumulated numerous other instances of the use of halogen bonding in ligand design, some more convincing than others. As expected, affinity improvements depend on the halogen and the interaction geometry, with iodine being particularly effective. For example, changing –H for –I in a series of adenosine kinase inhibitors improves activity by over two orders of magnitude.[236] In contrast, introduction of an iodo substituent in a series of β-secretase inhibitors resulted in only a modest 26-fold increase in affinity.[237] The I···O distance is very long (4.2 Å) and the C–I···O angle very small (139 degrees), so it is probable that the increased binding is less due to a σ-hole interaction than to dispersion.[232] Several authors have reviewed other examples of halogen bonding in protein–ligand complexes.[44,232,238,239] The importance of halogen bonds involving chlorine is open to doubt (see "**The skeptical chemist's view of halogen bonding**") However, the antibacterial molecule triclosan binds with one of its three chlorine atoms forming a reasonably convincing interaction to a backbone carbonyl oxygen atom at the mouth of the binding site. Although Cl···O interactions are weak, binding affinity could not be improved by replacing this chlorine with hydrophobic or hydrogen-bond donor groups.[240]

Of particular interest is a complex of HIV reverse transcriptase, in which an iodine atom of the inhibitor interacts with the backbone carbonyl oxygen of Tyr188 in a direction approximately orthogonal to the carbonyl plane, allowing the oxygen to maintain a β-sheet hydrogen bond to Tyr181 (**Fig. 12**).[241] This nicely supports the argument of Voth et al. that carbonyl acceptors can accommodate both halogen and hydrogen donors because the former can interact with the C═O π-orbital, leaving the oxygen lone pairs for the hydrogen-bonding group.[233]

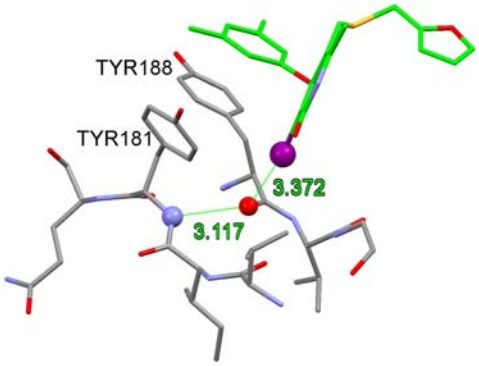

Fig. 12 Halogen bond to the carbonyl oxygen atom of Tyr188 in HIV reverse transcriptase (PDB code 2BE2). The direction of the interaction leaves the oxygen atom free also to form a structural hydrogen bond to Tyr181.

In their extensive review of halogen bonding in medicinal chemistry, Wilcken et al. point out that proteins have other potential acceptors for halogen bonds apart from backbone carbonyl oxygen.[232] They give examples of protein–ligand complexes with halogen contacts to aspartate carboxylate and tyrosine hydroxyl oxygen atoms.

3.05.4.4.5 Halogen-enriched fragment libraries

In a lead generation exercise targeted at the p53 cancer mutation Y220C, Wilcken et al. designed a fragment library enriched in compounds containing the heavier halogens.[242] They had noticed that a drugable surface crevice of the protein contains a backbone carbonyl group suitably positioned to accept halogen bonds. The fragment library was designed using standard criteria but setting an upper limit on the number of heavy atoms rather than a molecular-weight limit. All molecules were required to contain a heavy halogen. Of 79 compounds screened, the best was a di-iodophenol, which bound with a dissociation constant of 184 ± 23 μM. Crystal-structure analysis showed that one of the iodine atoms forms the expected I···O halogen bond to the targeted carbonyl group. Optimization of this lead resulted in a series of iodophenols with binding modes retaining the I···O halogen bond and having significantly improved binding affinities.

3.05.4.4.6 Halogen bonding in drug development

Xu et al. defined the ratio X/F as the number of chemical entities at a given stage of the drug development process that contain X (chlorine, bromine, or iodine) to the number that contain fluorine.[243] They reasoned that X/F might say something about the possible importance of halogen bonding in drug development, since X atoms can form the interaction and F atoms cannot. An interesting result came out of this: the X/F ratios at drug discovery, clinical stage I, stage II, stage III, pre-registration/registered, and launched are, respectively, 0.9, 0.9, 0.8, 1.0, 1.4, and 1.7. The overall percentage of molecules containing one or more X atoms rose from 44.0% at stage II to 63.3% at launch. It appeared that molecules containing X atoms are less likely to fail. The authors suggested that halogen bonding might play a role in tuning ADME/T properties, for example, by enhancing binding to plasma transport proteins. On the other hand, the numbers of molecules in the study with X = Br or I—the halogens best able to form halogen bonds—were small, so the conclusions drawn must be regarded as tentative.

3.05.4.4.7 The skeptical chemist's view of halogen bonding

Halogen bonding has attracted so much attention in recent years that cynics may be tempted to wonder how much of it is justified. After all, if the interaction is genuinely useful in ligand design, why did it take so long to be recognized and exploited? But even for a confirmed skeptic like your author, there is too much evidence to sustain disbelief—from crystallography, theoretical calculations, and protein–ligand binding affinity studies. The halogen bonds formed by iodine and bromine can be useful tools for structure-based design, and, as the Roche group noted, they have the advantage of a lower desolvation cost than classical hydrogen bonds.[44]

Chlorine, however, is another matter, and of 1574 drugs surveyed in 2012, 14.7% contained chlorine, compared with only 1.5% for bromine and 1.1% for iodine.[232] Chlorine forms very weak halogen bonds. This is illustrated not only by the data in **Table 3** but also by the observation that Cl···O and Cl···N contacts in organic crystal structures are no more common than would be expected by chance (see "**Assessing the Relative Importance of Molecular Interactions**"). Only when it is in a highly polarizing environment—for example, at the 2-position of an imidazole ring—does chlorine form significant numbers of these contacts.[89] Theoretical calculations also indicate that polarization is critical. For example, chlorine in CH_3COCl has a positive region on its electrostatic surface, but in CH_3Cl it does not.[244] When analyzing protein–ligand crystal structures, it is debatable whether a Cl···O contact should be assumed important to binding unless the chlorine is in an electron-withdrawing environment and, even then, only if the C–Cl···O angle exceeds 150 degrees.

Some researchers have compared halogen bonds to the hydrogen bonds formed by OH and NH groups as they can both be accepted by oxygen or nitrogen and are both highly directional. Nevertheless, there are important differences: in their relative energies, of course, and also in the extent to which the donor groups are discriminating in the interactions they form. **Fig. 13** shows the relative frequencies with which bromine, iodine, and OH/NH hydrogen atoms form their shortest (relative to vdw radii)

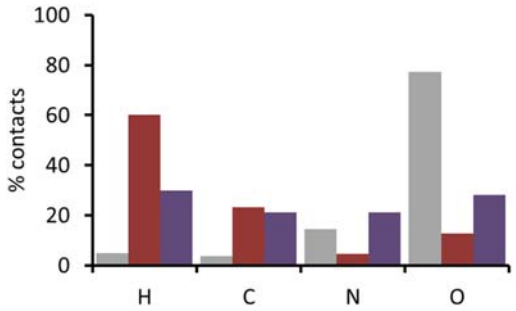

Fig. 13 Relative frequencies with which OH and NH hydrogen (*gray bars*), bromine (*brown bars*), and iodine (*purple bars*) atoms form their primary intermolecular contacts to hydrogen, carbon, nitrogen, or oxygen. Statistics based on well-refined (R-factor $\leq 5\%$, no disorder, all atoms located) organic crystal structures in the 2015 version of the CSD.

intermolecular, line-of-sight contacts to H, C, N, or O in CSD organic crystal structures. The hydrogen atoms overwhelmingly prefer to interact with N or O—in other words, form hydrogen bonds—whereas the halogens frequently interact with H or C rather than N or O. Hence, the halogens are much less discriminating in their interactions than the hydrogen atoms. This conclusion is consistent with a recent experimental study that indicated that hydrogen bonds are more important than halogen bonds in determining packing arrangements in crystal structures.[245]

3.05.4.5 Fluorine, the Little Atom That Couldn't

The importance of fluorine in medicinal chemistry hardly needs elaboration.[246] By 2014, it was estimated to occur in 25% of drugs.[247] It is used for a multitude of purposes: to block oxidative and hydrolytic metabolism, to improve bioavailability by tuning lipophilicity and the pK_a values of neighboring nitrogen atoms, to inhibit racemization, to reduce activity at the hERG channel, and so on.[248–250] As it is so common, it is particularly important to understand the interactions it makes at protein binding sites. They are dictated by the unusual properties of the fluorine atom: small, very electronegative, and difficult to polarize. Hence, although fluorine has similarities with the other halogens, it deserves its own little section in this article. The discussion is confined to fluorine atoms that are covalently bonded to carbon. The title of the section was provoked by a 2005 paper with the arresting title "Fluorine in crystal engineering—'the little atom that could'".[251] The approach preferred here is to focus first on the things that fluorine cannot do. For practical purposes, it cannot act as the donor in halogen bonds; it does not interact favorably with electronegative atoms or π-systems[252]; and it cannot compete with oxygen or nitrogen as an acceptor of hydrogen bonds from OH and NH donors. Between them, these constraints rather restrict what fluorine *can* do.

The last of the three constraints deserves discussion. Two papers in the 1990s both concluded that C–F···H–(O,N) hydrogen bonds hardly ever occur, either in small-molecule or macromolecular crystal structures.[253,254] At first sight this is rather surprising because of the electronegativity of fluorine. It was ascribed to two factors. First, fluorine has a low proton affinity due to its low-lying lone-pair orbitals and tightness of its electron shell. Second, it is unable to modify this by intramolecular electron delocalization or intermolecular cooperative effects. Subsequently, some researchers were at pains to prove that these hydrogen bonds can occur, providing theoretical,[255] spectroscopic,[256] and crystallographic evidence.[257] In fact, this rather misses the point: it was never argued that the hydrogen bonds *cannot* form, simply that they only do so rarely. Fluorine is a much weaker acceptor than sp^2 hybridized nitrogen and virtually all types of oxygen, and hence is out-competed. The best estimate of the energy of the fluoromethane···methanol hydrogen bond is -3.89 kcal mol^{-1},[225] which ,is less favorable than typical hydrogen bonds involving OH or NH donating to common oxygen or nitrogen acceptors.[258]

It is true that C–F···H–(O,N) interactions are occasionally associated with an increase in protein–ligand binding affinity.[44] Further, the authors of a 2004 PDB study concluded that 10% of ligand C–F groups form close contacts to OH or NH groups.[259] However, the mean H···F distance (hydrogen atoms were added in calculated positions) was 2.313 Å. This is much longer than average O···H and N···H hydrogen-bond distances,[93] implying that the interactions are weak. Also, it is not clear how many of the contacts were components of bifurcated interactions, in which the donor group also hydrogen bonds to an oxygen or nitrogen acceptor. From the donor's point of view, an interaction with fluorine alone is a poor option, but a bifurcated interaction with fluorine and oxygen or nitrogen is better. An example is provided by the thrombin complex shown in **Fig. 14**.[260] A backbone NH clearly interacts with a C–F group but the backbone conformation at that point allows an additional (albeit very nonlinear) hydrogen-bonding contact to the carbonyl oxygen of the next residue.

So what does a C–F group do when it is thrown into the milieu of a protein binding site? It is likely to be out-muscled by oxygen or nitrogen acceptors in the competition to interact with OH or NH donor groups. Close contacts to oxygen atoms or π-systems are electrostatically unfavorable. The most viable option, and by far the one most commonly observed,[261] is to interact with carbon-

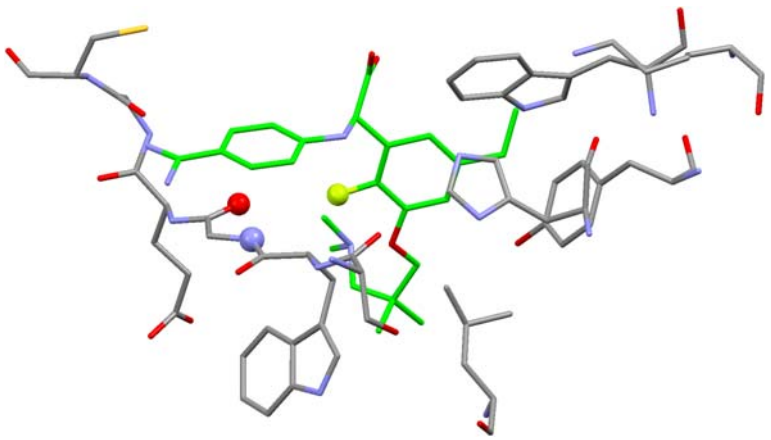

Fig. 14 Bifurcated hydrogen-bonding interaction in a thrombin complex (PDB code 2V3O). The atoms involved are shown as spheres.

bound hydrogen atoms. They are plentiful, accessible, and almost always slightly electropositive. The situation is similar to that seen in small-molecule crystal structures, where C–F···HC has an R_F value of 1.7, indicating that interactions of this type occur almost twice as often as would be expected by chance (see "Assessing the Relative Importance of Molecular Interactions").[89] Intriguingly, the R_F of C–F···HC is significantly higher than that of C–Br···O, although it is undoubtedly the weaker interaction. This can plausibly be explained by remembering that every atom in a crystal structure has to be near an atom in a neighboring molecule. Bromine can form energetically acceptable contacts to a range of atom types. Fluorine, on the other hand, is a fussy sort of atom: carbon-bound hydrogen is one of the few neighbors with which it is comfortable. Hence, there are lots of CH···F contacts. Another possible factor is that C–Br···O interactions have strong directional preferences whereas C–F···HC interactions do not, so it may be more difficult to find molecular arrangements that will accommodate the former.

Another interaction is worth mentioning, less common than C–F···HC but certainly stabilizing. It has been established that C–F groups can interact with carbonyl carbon atoms (which of course carry a net electropositive charge) from a direction approximately perpendicular to the carbonyl plane.[262] This and similar interactions are further discussed in the next section.

3.05.4.6 Carbonyl-Group Interactions

In addition to its more familiar interactions (hydrogen bonds, halogen bonds), a carbonyl group can interact favorably with a polar bond such as C–F, C–Cl, or C=O positioned above the carbonyl-group plane. The best known interaction of this type is between two carbonyl groups. It was first studied in detail by Allen et al.[263] By searching the CSD, they identified three main types of geometry (Fig. 15): a slightly sheared, "stacked" motif with the C=O dipoles antiparallel (observed on 630 occasions); a highly sheared motif with the bond dipoles parallel (130 occurrences); and a motif in which the C=O vectors are mutually perpendicular (116 occurrences). In all three motifs, at least one of the carbonyl carbon atoms forms a close contact to the oxygen atom of the other group in a direction approximately perpendicular to the carbonyl-group plane. The stacked geometry is likely to be overrepresented in small-molecule crystal structures compared to protein–ligand complexes because of crystal-packing effects.[19] The highly sheared geometry is usually seen when the carbonyl groups are bonded to C(sp^2) atoms and the carbonyl–carbonyl interaction is part of a more extended stacking arrangement. A 2002 search for interactions between protein carbonyl groups and ligand ketones found roughly equal numbers of the stacked and perpendicular geometries (13 and 8, respectively) and no examples of the highly sheared, parallel arrangement.[264]

Turning to C–X···C=O (X = F, Cl), the IsoStar plots in Fig. 16 show the density distributions of fluorine and chlorine atoms around peptide linkages in PDB complexes. They clearly reveal a preference for the halogen atom to lie above and below the carbonyl carbon atom. (The secondary maximum in the C–Cl plot is partly due to large series of factor Xa and thrombin complexes, but may also indicate some halogen bonding contacts.) Searches of the CSD confirm that C–F···C=O and C–Cl···C=O contacts are numerous. The X···C=O angle tends to be close to 90 degrees but the C–X···C angle is highly variable and does not correlate with the X···C distance.[265] A histogram of the F···C=O angle and a scatterplot of the F···C distance against the C–F···C angle are given in Fig. 17.

Both the carbonyl–carbonyl and the halogen–carbonyl interactions are widely viewed as being mainly electrostatic in nature,[262] but with dispersion also making a significant contribution.[266] However, some theoreticians maintain that amide carbonyl–carbonyl interactions are stabilized by charge transfer.[267,268] Estimates of interaction energies vary widely. Intermolecular perturbation theory (IMPT) gave energies of -5.3 and -1.8 kcal mol^{-1} for the carbonyl–carbonyl interaction in the stacked antiparallel and orthogonal geometries, respectively.[263] Chemical double-mutant cycles on model systems suggested a free enthalpy of between -0.29 and -0.65 kcal mol^{-1}, depending on solvent, for the orthogonal interaction of two amide carbonyl groups.[266] The same authors calculated lower (more stabilizing) energies using IMPT. However, it was argued that the calculated values will never be achieved in crystal structures or solutions because of packing forces, steric constraints, and solvent effects. The interaction was considered

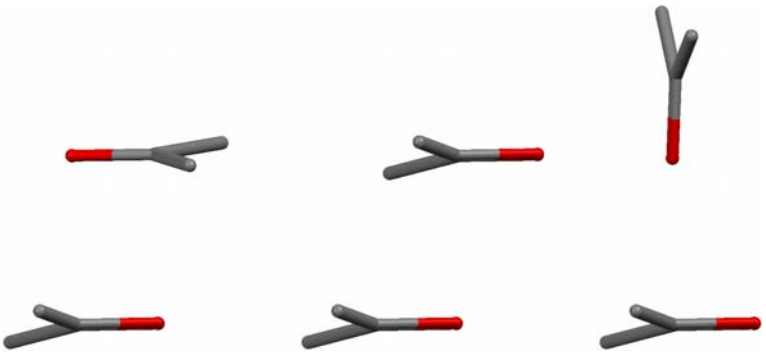

Fig. 15 Schematic representation of the three main types of carbonyl–carbonyl arrangement: stacked antiparallel (*left*), sheared parallel (*center*), and perpendicular (*right*).

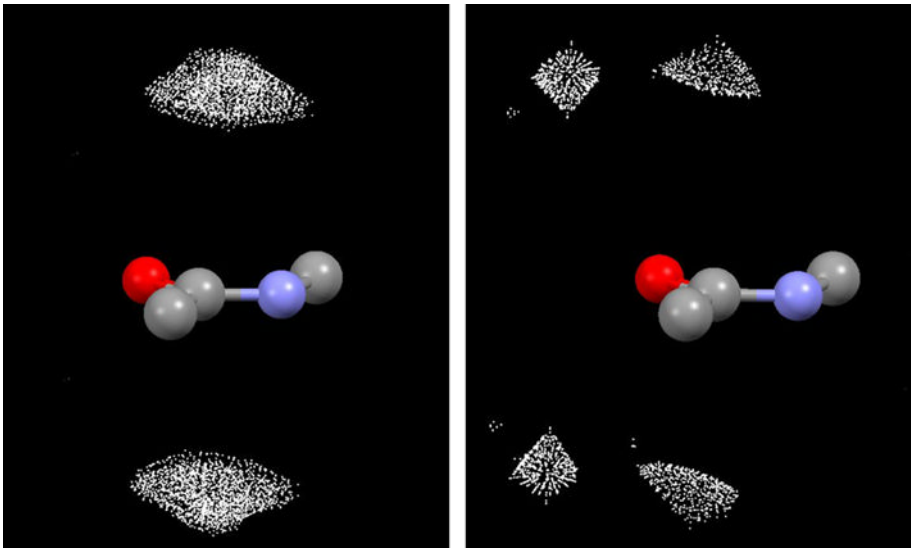

Fig. 16 IsoStar plots showing the density distributions of C–F (*left*) and C–Cl (*right*) halogen atoms around peptide linkages in PDB crystal structures.

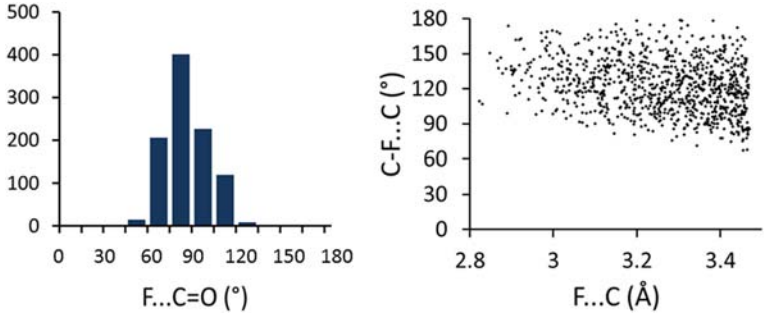

Fig. 17 Histogram of the F···C═O angle and scatterplot of the F···C distance against the C–F···C(carbonyl) angle for C–F···C═O contacts in the CSD.[265]

comparable in strength to aromatic–aromatic CH···π interactions. Other double-mutant cycles showed that a C–F···C═O interaction improves binding free enthalpy by 0.2 to 0.3 kcal mol^{-1} in an apolar environment.[269,270]

Several examples of these interactions have been found in PDB protein–ligand complexes.[262] The Bcr-Abl tyrosine kinase inhibitor nilotinib, for example, forms both carbonyl–carbonyl and C–F···C═O interactions at the binding site, and replacement of its $-CF_3$ group by methyl reduces activity in an autophosphorylation assay by more than 5-fold.[44,271] Of course, the interaction is weak, so the extent to which it causes the enhanced activity is uncertain. Pollock et al. introduced trifluoromethyl groups into thienopyrimidine menin–MLL inhibitors with the specific intention of creating molecules that would form C–F···C═O interactions at the binding site, and thereby obtained activity improvements of up to 5- to 10-fold.[272] Carbonyl–carbonyl interactions have been implicated in stabilizing some protein structural features: the right-handed twist found in most β-strands,[273] and partially allowed Ramachandran conformations of asparagine and aspartic acid residues.[274]

This section has focused on the carbonyl group because of its importance in protein–ligand binding, but similar interactions can be formed by other dipolar groups, such as nitriles. They have been generically termed "orthogonal multipolar interactions" and were reviewed by Paulini et al.[262]

3.05.4.7 Sulfur Interactions

3.05.4.7.1 Sulfur interactions to nonpolar groups

Because of its high polarizability, sulfur is, in its noncovalent interactions, the most versatile of the elements relevant to medicinal chemistry. Depending on its intramolecular environment, it may be capable of donating or accepting hydrogen bonds, forming attractive S···O and S···N contacts, or accepting halogen bonds. Most commonly, though, thioether, thioamide, sulfoxide, and other types of sulfur interact with hydrophobic groups. It is clear from several PDB surveys, which are well summarized in a recent

review,[275] that methionine and cysteine side chains interact favorably with aromatic rings. These interactions can be of various types and geometries, involving either the face or the edge of the ring: S–CH_3···π, S···π, S–H···π and S···HC.[79] Bissantz et al. concluded from PDB and CSD searches that the interaction with the edge of the ring is the more common and pointed out that several other authors agreed.[44] However, other workers have emphasized the importance of methionine interactions with the aromatic-ring face. For this orientation, they performed quantum-mechanical calculations on model dimers between dimethylthioether and benzene, phenol, and indole. The results suggested that the dimers are more favorable than the corresponding propane–aromatic systems by up to about 1.5 kcal mol^{-1}.[276] The stabilization is primarily due to dispersion rather than electrostatics. Methionine is frequently present at adenine binding sites, with the side chain positioned above the adenine ring system.[44] However, interactions are certainly not confined to aromatic groups: Imai et al. found that the most common intermolecular contact formed by methionine sulfur in PDB structures is to the hydrogen atoms of methylene groups.[277]

Sulfur interactions with hydrophobic groups have been shown to contribute to protein–ligand binding affinity on several occasions.[79,275] An instructive example is provided by three inhibitors of tRNA-guanine transglycosylase.[278] The inhibitors differ only in the nature of a side chain, which is either –OPh, –CH_2Ph, or –SPh. They have K_i values of 5600, 3600 and 100 nM, respectively. The superior activity of the sulfur analog was ascribed to several factors. The sulfur-containing molecule is the most lipophilic and therefore partitions more efficiently from solution into the hydrophobic enzyme pocket where it binds. Sulfur is highly polarizable and therefore forms stronger dispersion interactions in the pocket. Finally, the conformational preferences of the sulfur derivative were more favorable for binding than those of the oxygen and methylene analogs. In the same study, two other S/O inhibitor pairs were found with large binding affinity differences in favor of the sulfur analog.

3.05.4.7.2 Hydrogen bonds involving sulfur

The hydrogen-bonding properties of sulfur have been well characterized by surveys of the CSD and PDB. While sulfur is a much weaker donor than nitrogen or oxygen, sulfhydryl groups are often involved in hydrogen bonds. In a set of 753 proteins containing cysteine, there were 314 SH···O=C hydrogen bonds to backbone carbonyl groups.[279] Of these, about a third occurred in α-helices between the –SH group of cysteine residue i and the carbonyl oxygen of residue $i-4$. In a survey of CSD crystal structures, about 70% of SH groups were donated to acceptors, mainly O=C and S=C groups.[280] SH···π hydrogen bonds are possible, and it has been claimed on the basis of gas-phase spectroscopic measurements that "sulfur is not too far behind oxygen, nitrogen, and carbon in regard to forming the π-type hydrogen bond".[281] However, there is no doubt that SH is a much weaker donor than OH or NH.

The ability of sulfur to accept hydrogen bonds is critically dependent on its intramolecular environment. In small-molecule crystal structures, thioether sulfur has a very low propensity to accept hydrogen bonds from OH and NH groups. A CSD search found that only 86 of 1811 (=4.8%) Y–S–Z fragments (Y, Z=C, N, O, or S) formed intermolecular hydrogen bonds of this type with the S···H distance shorter than sum of vdw radii.[280] With a much more liberal distance criterion (S···H shorter than sum of vdw radii + 0.3 Å; S···H–O,N ≥ 90 degrees) the ratio is still only 16.4%.[282] The picture is similar in protein structures, where sulfur atoms rarely accept hydrogen bonds from OH and NH groups.[279] Double-bonded sulfur is rather different. In thioamides and thioureas, electron delocalization from the nitrogen lone pair into the C=S π* orbital induces a significant $C^{\delta+}=S^{\delta-}$ dipole. A 2008 survey of the CSD found that these groups often form C=S···H–(O, N) hydrogen bonds. In contrast, none were found to aliphatic thiones. After correction for vdw radii, the thioamide and thiourea hydrogen bonds were typically about 0.25 Å longer than those formed by amides and ureas, implying that the thio groups are poorer acceptors than their oxygen analogs. The directional preferences at the acceptor atom are also different, C=S···H angles falling in the range 102–109 degrees, and C=O···H in the range 127–140 degrees. IMPT calculations were consistent with these results, suggesting that the interaction energies to sulfur are less favorable than those to oxygen by about 3 kcal mol^{-1}.[283]

3.05.4.7.3 Chalcogen bonding

In a classic early CSD study, Rosenfield et al. showed that divalent sulfur atoms have different directional preferences in their interactions with nucleophiles and electrophiles.[284] Electrophiles tend to form contacts in a direction approximately 20 degrees from the perpendicular to the Y–S–Z plane, whereas nucleophiles (Nu) tend to lie in that plane and along the extension of the Y–S or Z–S covalent bond. The latter interaction is called the "chalcogen bond"[285] and is the Group 16 equivalent of the halogen bond (the Group 15 version is the "pnicogen bond"). Chalcogen bonds are stabilized by dispersion, by electron transfer from a lone-pair orbital on the nucleophile into a low-lying Y–S or Z–S σ* orbital, and by electrostatic attraction between the nucleophile (typically oxygen or nitrogen) and a localized patch of electropositive potential on the sulfur atom (the σ hole; see halogen-bonding "**Background**" section). The balance between these effects depends on the intramolecular environment of the sulfur atom. The interactions tend to be more favorable when the sulfur is strongly polarized by nearby electron-withdrawing atoms, as in, for example, thiazole, isothiazole, and thiadiazole. These matters are surveyed in the extensive review by Beno et al., which also contains numerous examples.[275] These authors argue that the interaction is primarily useful for conformational control, since attractive S···O and S···N contacts are most commonly intramolecular and can strongly influence torsional preferences.[286]

The predominance of intramolecular interactions suggests that steric factors may often prevent close intermolecular approach of oxygen or nitrogen atoms to divalent sulfur in the direction required for chalcogen bonding. Nevertheless, it is not hard to find intermolecular chalcogen bonds. A search of the 2015 CSD for thiophene intermolecular S···O or S···N interactions (C–S···O,N ≥ 160 degrees; S···O,N < sum of vdw radii) found 242 examples in the 5132 structures in which the interaction is theoretically possible, a hit rate of 4.7%. Corresponding figures for thiazole are 93 interactions in 1002 structures (9.3%). The higher ratio for thiazole can be ascribed to the polarizing influence on the sulfur atom of the ring nitrogen. Accordingly, the ratio is even higher

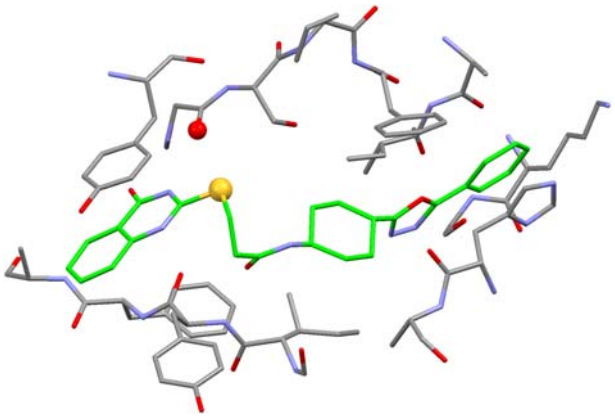

Fig. 18 S···O interaction in a tankyrase complex; atoms involved shown as spheres (PDB code 4MSG).

for 1,3,4-thiadiazole (13.5%; 67 interactions in 496 structures) and higher still in thiazolium (31.4%; 32 in 102). A previous CSD study suggested that, in S···O=C interactions, the sulfur atom can lie either in the carbonyl plane or approximately perpendicular to it, the latter being preferred for amides.[287] This suggests that amides can simultaneously form hydrogen bonds and chalcogen bonds. S···O interactions between ligand sulfur atoms and backbone amide groups have been observed in CHK1 kinase[288,289] and tankyrase (Fig. 18).[290] As expected, the sulfur atoms involved are in polarizing environments.

3.05.4.7.4 Sulfur as a halogen bond acceptor

In the 2015 version of the CSD, there are 186 structures that contain a C–X group (X = Br, I) and a sulfur atom from an aliphatic thioether, thiol, or disulfide. In 24 of these (12.9%), the sulfur atom forms a contact with the halogen with C–X···S ≥ 160 degrees and X···S < sum of vdw radii. Surprisingly, the analogous searches for the oxygen analogs find 284 of 4647 structures containing C–X···O halogen bonds, a lower percentage (6.1%). In only three of the sulfur contacts might the directionality of the contact at the sulfur atom suggest chalcogen bonding; the rest appear to be halogen bonds. C=S···I halogen bonding has been shown to occur predictably in a series of thioamide cocrystals with 1,4-diiodotetrafluorobenzene.[291] Quantum-mechanical calculations on model systems gave energy for the methionine–iodobenzene halogen bond of about -4.3 kcal mol^{-1}, which is quite substantial, with a strong preference for linearity at iodine (C–I···S > 150 degrees). The preferred direction of approach of the iodine is perpendicular, or approximately so, to the C–S–C plane, which is the direction expected for electrophiles (see "Chalcogen bonding"). Interactions with bromine and chlorine are much weaker.[292] Overall, the results suggest that methionine and cysteine sulfur atoms in proteins should be capable of accepting halogen bonds from ligands containing iodine or bromine.

3.05.5 Molecular Interactions and the Pharmaceutical Crystal Form

3.05.5.1 Background

The crystal forms in which active pharmaceutical ingredients (APIs) are delivered became a subject of intense interest following the astonishing events of 1998 surrounding Abbott's antiretroviral drug ritonavir.[293] Almost two decades later, the story still seems more like science fiction than fact. After 2 years on the market, the crystal form of the drug spontaneously changed at the US manufacturing plant. Shortly thereafter, following a visit to the company's Italian site by scientists from the United States, the same happened there. The original Form I could no longer be made at either plant. The new Form II was thermodynamically more stable and less soluble, reducing oral bioavailability and forcing Abbot temporarily to withdraw their oral capsule at eye-watering cost. The difference in physical properties of the two forms—or "polymorphs" to use the crystallographic jargon—must arise from their different crystal-packing arrangements. Form II, being the more stable, must have more favorable molecular interactions. If only it had been possible to spot that there was something suboptimal about the interactions in Form I! Similar problems have since occurred with other drugs, including rotigotine and the blood-pressure medication Avalide.[294] It now appears that many—perhaps most—organic molecules can exhibit polymorphism.[295] Polymorphs may differ in a wide range of physical and thermodynamic properties and are patentable. Hence, it is necessary to perform experimental polymorph screening, varying crystallization conditions such as solvent and evaporation rate in an attempt to find all possible crystal forms of the API.[296]

Almost as important as polymorphism is the possibility of optimizing formulations by delivering APIs as cocrystals, which can improve a variety of properties: dissolution rate, thermodynamic stability, hydration propensity, tableting behavior, and so on.[297,298] Simply expressed, a cocrystal is a crystal which contains two (or more) chemically different molecules—in the present context, the API and another molecule, the "coformer." (The official definition of a cocrystal has been the subject of vigorous and widespread debate but need not concern us here.[299]) Like polymorphs, cocrystals are patentable.[300] Finding a suitable cocrystal

involves two steps: searching for molecules that will act as coformers and characterizing the physical properties of the resulting crystals. Once again, recourse must be taken to extensive crystallization experiments.[301]

Such experiments, whether aimed at polymorphs or cocrystals, are time-consuming and nonexhaustive. In an ideal world, they would be guided or even rendered superfluous by computational crystal-structure prediction (CSP), using accurate energy calculations on a massive number of candidate molecular packing arrangements. Sadly, this is out of reach. In 1994, Gavezzotti brought a wry smile to the readers of his paper, "Are crystal structures predictable?" by starting with the single word "No."[302] The answer was still "No" in 2003, but with some qualifications.[303] And it is "No" today, but with even more qualifications because the occasional crystal structure can now be predicted by the occasional research group, including structures of drug-like molecules.[304–306] There are two main problems. Firstly, and surprisingly, the typical finding for an organic molecule is that there are several possible crystal-packing arrangements with very similar energies. Therefore, it is hard to discriminate between them. Secondly, and crucially, it is clear that kinetic, entropic, and solvent effects are very important and they are horrendously difficult to model. Indeed, the very existence of polymorphism is evidence that the nucleation and growth of crystals is generally under kinetic control. There has been a case in which all three known polymorphs of a molecule were predicted by energy calculations (ie, were calculated to be the three most stable forms). It was argued that previous failures on the molecule were therefore due to inaccuracies in the force fields used rather than the kinetics of crystallization.[307] But even if true for that particular molecule, there is no reason to assume it will be universally the case.

Given, then, that reliable CSP is not yet possible, simpler if less rigorous approaches have been developed to help direct the efforts of the experimentalists. Most commonly, they rely on knowledge extracted from the CSD about how molecules interact, particularly through hydrogen bonding, in known crystal structures. The basic idea is that a crystal structure containing an unusual hydrogen-bond pattern might be a metastable polymorph. And that is where the pharmaceutical crystal form intersects with the subject matter of this article.

3.05.5.2 Hydrogen-Bond Patterns and Crystal Form Stability

In 1990, Etter put forward three general rules about hydrogen bonding in organic crystal structures: (1) All good proton donors and acceptors are used; (2) six-membered intramolecular hydrogen-bond rings form in preference to intermolecular hydrogen bonds; and (3) the best donors pair with the best acceptors.[308] The seminal importance of these rules lies not so much in their accuracy (which is limited) but on the extent to which they galvanized interest in the analysis of hydrogen-bond patterns in crystal structures. Exceptions to the first rule are quite easy to find. For example, in 12 of 50 crystal structures containing carbamazepine, one of the amide NH groups does not form a hydrogen bond. More generally across the CSD, 2.5% of good hydrogen bond donors (NH or OH groups) have no good acceptor within the sum of vdw radii plus 0.3 Å and with the donor-hydrogen-acceptor angle at least 90 degrees. The relatively high proportion of carbamazepine structures containing an NH group that does not hydrogen bond was ascribed to poor steric accessibility of the relevant hydrogen atom (**Fig. 19**).[309] The suggestion was strongly supported by a CSD survey which showed that, in organic structures containing both donors and acceptors, two-thirds of the donors or acceptors which do not hydrogen bond are sterically crowded by neighboring atoms in the same molecule. The cases where the donor or acceptor was sterically accessible but not hydrogen-bonded to a good complementary group were more difficult to rationalize. In some cases, donors were hydrogen-bonded to π-systems instead of conventional acceptors.[310] Other studies have looked at the numbers of hydrogen-bonding contacts formed by different types of chemical groups in organic crystal structures.[311,312] Water, for example, most commonly donates two and accepts one hydrogen bond (39.1% of water molecules surveyed), and almost as often donates two and accepts two (37.4%). Empirical functions have been derived to predict these "hydrogen-bond coordination numbers" for various donor and acceptor groups.[313]

Turning to Etter's second rule, Bilton et al. found all intramolecular hydrogen-bonded ring motifs in the CSD that contain <20 atoms, NH or OH donors, and nitrogen or oxygen acceptors. The different motifs were ranked on the ratio of the number of times the motif was observed to occur to the number of times it could possibly have occurred (P_m).[314] The 12 most common motifs were all planar, 6-membered rings stabilized by a conjugated π-system. Their P_m values ranged from 1.0 to 0.86. In contrast, saturated 6-membered rings had $P_m < 0.2$. Conjugated 5-membered rings were also found to be favorable, but motifs involving 7-membered rings and above are relatively rare. A more recent survey, focusing particularly on intramolecular, hydrogen-bonded rings of medicinal chemistry interest, came to similar conclusions.[315]

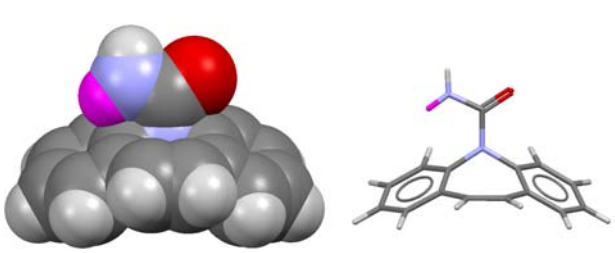

Fig. 19 The sterically crowded hydrogen atom in carbamazepine (colored magenta) is disinclined to form a hydrogen bond.

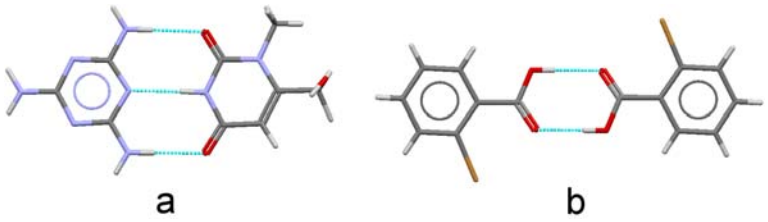

Fig. 20 Examples of (A) the most favored intermolecular hydrogen-bond motif in organic crystal structures, as judged by the P_m statistic;[321] (B) the well-known but much less favored carboxylic acid dimer motif (CSD structures AFABOZ, BRBZAC01).

The intramolecular motifs are interesting, but it is intermolecular hydrogen-bond motifs that have attracted more attention. They were first examined seriously by crystal engineers, who pointed out they could be used to design, or "synthesize", crystal structures with predictable architectures. For this reason, the motifs are often referred to as "synthons" in the crystal engineering community.[316,317] That they might be relevant to CSP and related problems was highlighted in a paper by Sarma and Desiraju.[318] They argued that CSP algorithms based on theoretical energy calculations only take enthalpy into account. Kinetic information is implicitly contained in the CSD, since a motif that is commonly observed is likely to be favored kinetically and, indeed, may play a key role in the process of crystal nucleation. If a CSP algorithm predicts several structures, those containing hydrogen-bond motifs commonly observed in the CSD are therefore the more credible.

Intermolecular hydrogen-bond motifs can have three basic topologies: rings, chains, or discrete dimers.[308] Some common motifs have been well known for decades, including those between carboxylic acid groups[319] and between amide groups.[320] In a study paralleling the intramolecular survey described above, all intermolecular cyclic motifs of ring size <20 were found and ranked on the P_m statistic.[321] The most favored motif (Fig. 20A) had $P_m = 0.97$; in other words, in 97% of the cases where it could have occurred, it did occur. However, this was very much an exception. Most P_m values were much lower, with only eight motifs having $P_m > 0.5$. Even the cyclic carboxylic acid dimer motif (Fig. 20B), commonly assumed to be one of the most reliable synthons, only had $P_m = 0.33$. Recent work has shown that carboxylic acid groups can hydrogen bond to each other in many diverse arrangements.[322]

The most important factor lowering the P_m value of the cyclic carboxylic acid dimer is probably the presence of competing donors and acceptors. Steiner surveyed crystal structures containing the carboxylic acid group and at least one other acceptor group, A. He found many in which OH···A was formed instead of OH···O=C(acid), even for acceptors weaker than acid carbonyl—for example, when A was an ether oxygen.[323] This, of course, is in violation of Etter's third rule (the best donors pair with the best acceptors), which Steiner concluded was only a *tendency*. He suggested that the weaker acceptor is most commonly preferred when the acid group is carried on an awkwardly shaped molecule. The sensitivity of hydrogen-bond patterns to steric factors has also been indicated by other work. Cruz-Cabeza et al. found that even minor changes to the carbamazepine molecule can radically change the crystal-structure hydrogen bonding, and ascribed it to differences in the molecular shapes.[324] Infantes and Motherwell showed that the steric accessibilities of hydrogen-bonding atoms influence the motif adopted in pyrazole and oxime crystal structures.[325] It has also been suggested that hydrogen bonds may form to weak acceptors rather than strong acceptors if there are more of the former in the molecule.[326]

So it appears that motifs are rather difficult to predict after all. The information in the CSD about known hydrogen-bond patterns *can* be used to help discriminate between likely and unlikely molecular packing arrangements, but not simply by looking at synthon probabilities. More sophisticated methods must be used. One such method is the logit hydrogen-bond propensity (LHP) model.[327,328] Given a molecule containing a hydrogen-bond donor *X*, an acceptor *Y*, and other donors and/or acceptors, the propensity for an *X*···*Y* hydrogen bond to form when the molecule crystallizes is estimated by an empirical function. The variables of the function include the chemical identities of *X* and *Y*, those of the competing donors and acceptors, the steric accessibilities of *X* and *Y*, and the aromaticity of the molecule. The function is parameterized by surveying the hydrogen bonds that occur in known crystal structures of similar molecules. LHP predicts a low propensity (0.11) for one of the hydrogen bonds observed in the metastable form I of ritonavir, whereas all those occurring in form II have propensities greater than 0.3.[328] In principle, therefore, the method might have been able to alert development chemists to the problem with form I. A weakness of the method is that it will give identical results for two polymorphs that contain the same hydrogen bonds, a situation that can certainly occur.[329–331]

The LHP approach may also be applied to cocrystal design. Given two molecules A and B, their likelihood of forming a cocrystal is estimated by the difference between the propensity of the best hetero hydrogen bond and that of the best homo hydrogen bond. A hetero hydrogen bond involves a group in A interacting with one in B, a homo interaction is between two A molecules or two B molecules. A high propensity difference in favor of the hetero interaction is taken as indicating that cocrystallization is probable. The method was moderately successful in predicting the outcomes of paracetamol coformer screening experiments.[332] An alternative method for assessing hetero versus homo interactions uses electrostatic potential surfaces, pairing the most positive point on one molecule with the most negative point on the other, then the next most extreme pair, and so on in implicit compliance with Etter's third rule.[333,334] However, the most common approach for prioritizing cocrystallization experiments is to look for molecules with functional groups that are complementary to those on the API, such that a well-known hydrogen-bond motif may be expected to form between them.[335,336] All of these methods ignore factors known to be important, such as molecular shape,[337,338] but more sophisticated approaches, even if effective, are likely to be too slow for practical applications.

3.05.5.3 Impact of Crystal-Structure Interactions on Physical Properties

Aqueous solubility is a function not just of molecular properties but also of the intermolecular interactions that occur in the crystalline state: Strongly cohesive interactions that increase lattice energy result in lower solubility. A 2011, paper described a proof-of-concept study on the benzodiazepine molecule nordiazepam, the crystal structure of which contains a hydrogen-bonded lactam dimer motif and a CH···O hydrogen bond. Solubility was improved by a factor of about eight by adding substituents that prevented the formation of these interactions.[339] The log *D* value was virtually unchanged. Of course, this approach is only viable if the molecular changes do not seriously compromise other properties, most obviously biological activity, but such situations do occur, as the following examples will demonstrate. A group from AstraZeneca improved both activity and solubility in a series of G protein coupled receptor 119 agonists. The changes they made included introduction of an axial methyl group, which disrupted aromatic stacking interactions in the crystalline state, and replacement of a methyl sulfone by a 3-cyanopyridyl group, which removed a CH···O═S interaction.[340] In a second example, stacking and CH···π interactions were disturbed to obtain an approximately four-fold solubility improvement without compromising activity in a series of kinesin spindle protein inhibitors.[341] Introduction of a methyl group on an inhibitor of the phosphoinositide kinase PI3Kβ achieved a remarkable 100-fold increase in solubility by disrupting indoline ring stacking interactions; biological activity was retained.[342]

The interactions of chemical groups exposed on crystal faces are important in the prediction and optimization of physical properties such as morphology[343] and surface adhesion and tableting behavior.[344,345]

3.05.6 Summary

The years since the last edition of *Comprehensive Medicinal Chemistry* have seen substantial changes in our perception of noncovalent molecular interactions. The halogen bond has emerged from relative obscurity and is now regarded as a useful interaction in structure-based drug design. Which it is, but as the halogens most widely used in medicinal chemistry do not form, or form only weak, halogen bonds (fluorine and chlorine, respectively), its value is somewhat limited. A wider appreciation of the chalcogen bond (attractive S···O and S···N interactions) is surely not far away; likewise, the use of sulfur as an acceptor of halogen bonds from iodo- or bromo-substituents on ligands. Statistical analysis of small-molecule crystal structures confirms the significant influence of CH···O, CH···N, and CH···F interactions on molecular packing arrangements. Quantum-mechanical calculations have given new insights into the interactions between aromatic rings, suggesting that they can be rationalized in terms of the localized, through-space interactions of the rings' substituents and heteroatoms. The significance of the electrostatic potential associated with the ring π-systems is questioned. Results from ITC experiments challenge our understanding of the hydrophobic effect and emphasize the importance of the geometry and continuity of the water networks that exist at protein binding sites. Hydrogen-bond interactions in the crystal forms of development candidates have moved into the limelight as researchers strive to relate them to stability and physical properties such as solubility. Interest in cocrystals and the interactions therein has grown at an exponential rate.[346]

It is a human instinct to name things, so there is now an extensive catalog of molecular interactions. Are all the different labels necessary? It would not be a heinous offense if we talked of electrostatic interactions instead of halogen bonds and chalcogen bonds and cation–π interactions and anion–π interactions, etc. Admittedly, dispersion and polarization and, very occasionally, charge transfer make contributions too, and the anisotropy of the electrostatic potential around some atoms has to be borne in mind. But there is an underlying simplicity, a unifying theme: electropositive atoms attract electronegative atoms.

But while molecular interactions are simpler than their nomenclature might suggest, they are also far more complex. The reason can be given in two words: water; entropy. ITC shows us that the classical hydrophobic effect is hopelessly inadequate to explain what goes on in and around nonpolar pockets at protein binding sites. Changes to the environment of an individual water molecule or a cluster of waters can cause substantial nonadditivity of substituent effects on binding free energy. No wonder that structure–activity relationships are a nightmare. Within a series of closely analogous protein–ligand complexes, the relative importance of enthalpy and entropy can swing wildly from one ligand to the next. No wonder that, for all we know about molecular interactions, we are useless at predicting protein–ligand binding affinities.[347]

Still, we *do* know a lot about molecular interactions. The last few years have brought many new insights and so will the next few, particularly given the growing power of the tools at our disposal: quantum-mechanical calculations such as CCSD(T) that are now up to the job; methods such as ITC that can probe the thermodynamics of binding; and the continued growth of the invaluable crystallographic databases, now containing in excess of 750,000 (CSD) and 100,000 (PDB) structures.

But to conclude, some words of caution. Many people believe they are destined to pick the slowest queue in supermarkets. Actually, they only notice the occasions when they do. Cognitive scientists call it confirmation bias. There is a real danger that the same error can influence our perception of molecular interactions. Once we notice an interesting interatomic contact, we are attuned to spotting it again. And, as Dunitz and Gavezzotti commented, the CSD and PDB are so huge that we can find examples of any contact we like.[348] The problem is exacerbated by the exigencies of scientific publishing. When writing a paper on the *X*···*Y* interaction, it is unwise to choose the title "No conclusive evidence that *X*···*Y* interactions significantly influence protein–ligand binding." To get the manuscript accepted, it may be necessary to maintain a position of cautious optimism: "The *X*···*Y* interaction: a new tool in drug design?" The overwhelming majority of scientists are scrupulously honest, so the results presented will remain the same, but the more positive spin can create a climate in which people accept rather than doubt. All of the interactions discussed in this article are real and have been characterized by high-quality scientific work, but most are weak. What we must not lose is our sense of

perspective. Protein–ligand binding is dominated by OH···O, NH···O, OH···N, and NH···N hydrogen bonds and the burial of hydrophobic groups. The importance of all other interactions pales in comparison.

Acknowledgment

Colin Groom of the Cambridge Crystallographic Data Centre is thanked for commenting with his usual perspicacity on a preliminary draft of this article.

3.06.1 Introduction

Computational design based on three-dimensional (3D) protein structural information is now fully embedded in the drug discovery process, with structure-based drug design playing a critical part in many well-known marketed drug stories.[1] The 3D structure information may have come from an X-ray crystal structure, a homology model based on a similar protein, an NMR-derived structure, or more recently from electron cryo-microscopy (3DEM). Other new techniques such as hydrogen deuterium exchange mass spectrometry can also provide complementary information on the location of ligand binding sites, the impact of ligand binding on solvent accessibility, and changes in protein flexibility. However, X-ray crystallography remains the dominant source of 3D data (Fig. 1).

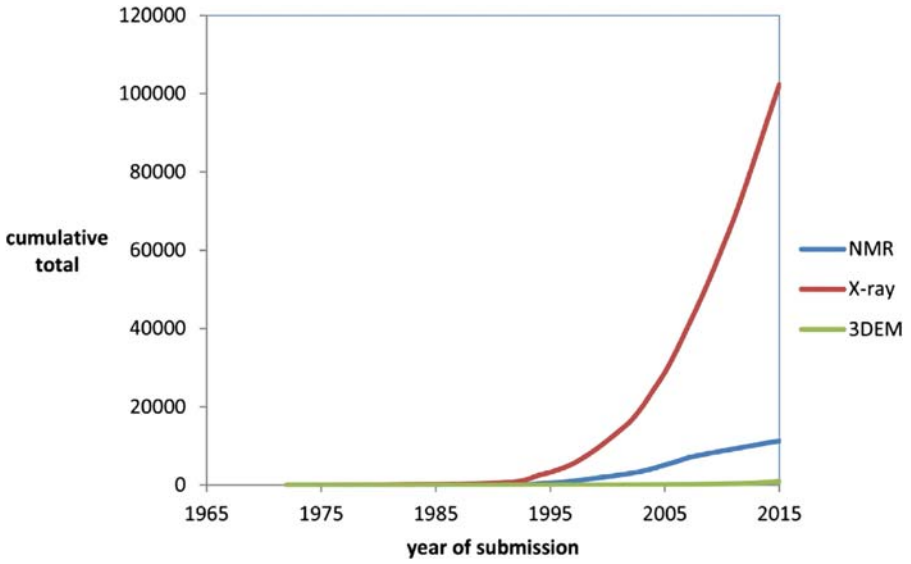

Fig. 1 PDB cumulative deposition by year for NMR, X-ray, and 3DEM structures.

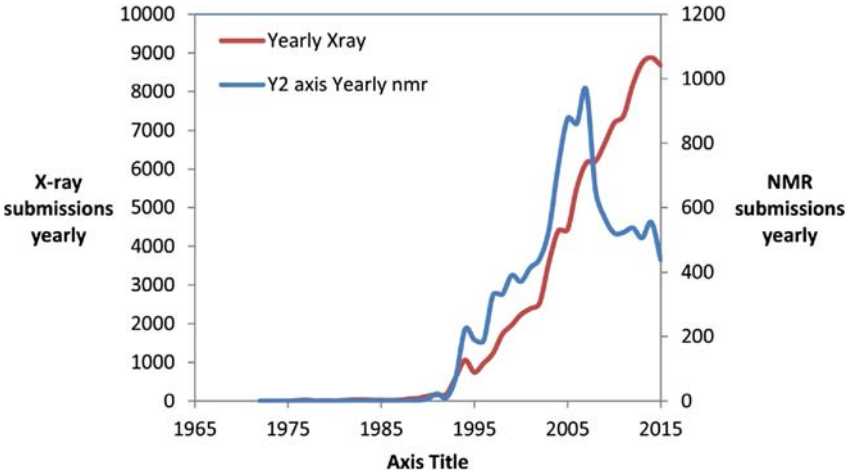

Fig. 2 X-ray and NMR submissions per year to the PDB.

3.06.2 A Brief History of Protein Structure Determination

The first X-ray structure of globular proteins were myoglobin and hemoglobin in 1958, for which Kendrew and Perutz were awarded the Nobel Prize in Chemistry in 1962. This was the result of over 20 years' effort, began by Perutz in 1927 starting with hemoglobin. By the time the Protein Database was established in 191 it contained seven X-ray structures, and by the time of the first PDB newsletter in 1974, 12 had been deposited. The deposition rates increased year-on-year in an almost exponential fashion until 2008, and by 2016, over 120,000 protein structures had been deposited.

In comparison protein structure determination by NMR is a much newer technique. Wüthrich had been working on NMR of proteins since 1967, and the first de novo 3-D protein structure was solved by NMR in 1984.[2] Through the 1990s the number of 3D structures derived by NMR began to increase. It reached a zenith in 2007 with 965 NMR structures deposited that year in PDB. Since then the number of NMR-derived structures has been falling, Fig. 2. Even though NMR hardware and software have undoubtedly improved over the past 10 years, the inherent limitations to relatively small proteins, Fig. 3, the requirement for large amounts of multiply labeled protein and access to expensive high-field NMR machines, have limited the numbers of NMR-derived structures. X-ray crystallography on the other hand, continued an unbroken year on year rise in protein structures deposited to the PDB from 1995 to 2014. The last full year, 2015 showed a significant drop on 2013, and we await what 2016 brings to see if this is a blip, a saturation of delivery from the method, or a reaction to some other global change. The statistics of course do not include the large numbers of X-ray crystal structures (of the most interesting drug targets) that sit behind the firewalls of pharmaceutical companies. Few NMR-determined protein structures exist behind those same firewalls, where NMR, it seems, based on the authors own experiences, has been relegated to fragment-based screening duties.

So far, fewer than 1000 3DEM models have been deposited to the PDB, although the Electron Microscopy Data Bank (EMDB) contains over 4000 volume maps. The resolution achievable with 3DEM has been limiting, but with the introduction of direct electron detectors, this situation is rapidly improving and 3DEM may well be the method of the future even for protein–ligand structure determination.

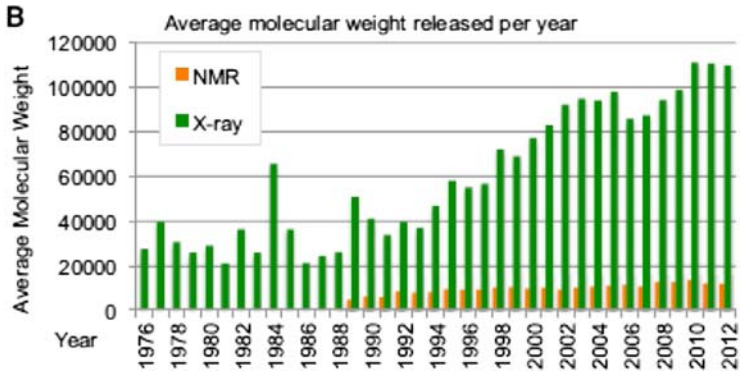

Fig. 3 The average molecular weight of protein structures determined by X-ray crystallography and NMR by year of deposition in PDB.[3]

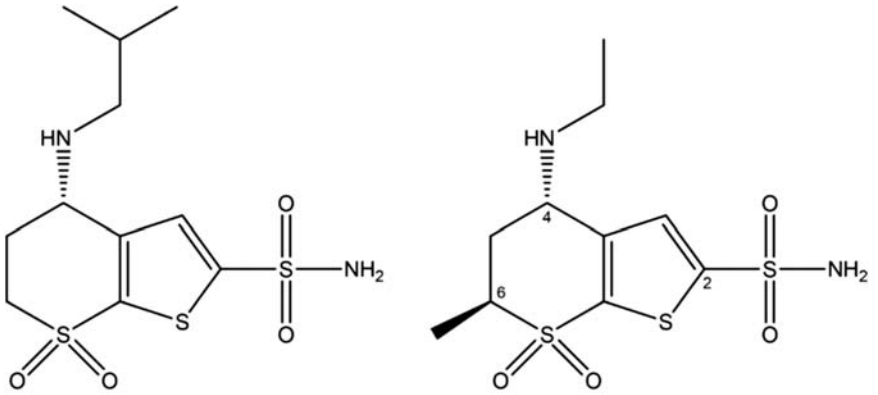

Fig. 4 MK-417, the subject of structural studies and MK-507, the resulting designed molecule.

With the widespread availability of good quality X-ray structures one might think that homology modeling has become rather sidelined. Many drug targets, particularly membrane protein targets are not yet amenable to routine iterative crystallography, although for G protein-coupled receptors (GPCRs) at least, companies such as Heptares are opening up the field.[4,5] So homology modeling still has a role in the arsenal of the computational chemist involved in structure-based drug design, and is reviewed within this volume.

3.06.3 A Brief History of the Use of X-Ray Structures in Structure-Based Drug Design

When we started working in the pharmaceutical business, we were frequently asked what drugs computational chemistry had ever discovered. Thirty years later, "comp. chem." is mainstream and an integral part of most drug discovery efforts. (In fact one could argue that many scientists are too ready to believe whatever numbers are spat out of a computer program.) This section reviews some of the original history of structure-based drug design (SBDD) and tries to draw out lessons for future medicinal and computational chemistry programs.

One of the first SBDD successes was the discovery of dorzolamide by Merck researchers, Fig. 4. They had access to X-ray crystal structures of MK-417 and its enantiomer, both bound to carbonic anhydrase.[6] Both molecules coordinated with zinc in the enzyme active site via the sulfonamide group, but the constraints of the site forced the (*S*)-enantiomer to adopt a conformation with the isobutylamino group in a pseudo-axial position. Ab initio molecular orbital calculations of the isolated ligand confirmed that this was less favorable than the pseudo-equatorial form seen for the (*R*)-enantiomer. More importantly, this led to the hypothesis that a 6-substitution, such as (*S*)-6-Me, would stabilize the favored conformation, leading to MK-0507, (dorzolamide), an antiglaucoma treatment.[7] This is an instructive example, because, although this seems like a small change in structure, the team went to the considerable trouble of calculating quantum mechanics energetics using a 1980s computer, adding evidence to a simple theory of how to stabilize the desired conformation.

Another case that is often cited as an early success of SBDD is that of zanamivir (Relenza), Fig. 5. Glaxo and a group from Monash University, Victoria were interested in neuraminidase as a target for influenza, as it is responsible for the cleavage of mature

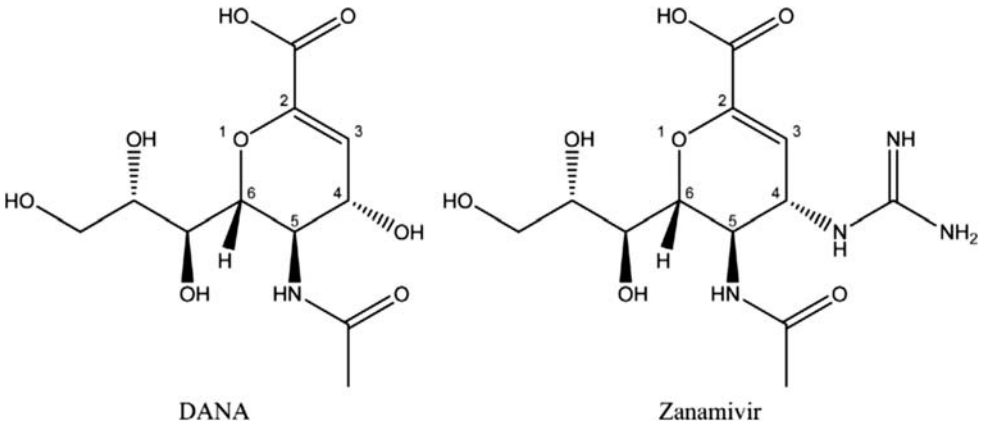

Fig. 5 The prototypical inhibitor, DANA and the designed drug, zanamivir.

viral particles from the host cell. The team had a crystal structure of neuraminidase with a substrate analog 2-deoxy-2,3-dehydro-*N*-acetylneuraminic acid bound in the active site. Although the crystal structure had a number of questionable features by today's standards, it provided a reliable enough template for the use of molecular field analysis, using the GRID program.[8] This allowed the team to identify the 4-hydroxyl group as a candidate for replacement by amino and ultimately guanidino groups, giving orders of magnitude more binding affinity than the natural substrate. The amine and guanidine groups made better hydrogen bonds than the hydroxyl, but optimizing hydrogen bonding is not often a route to markedly better binding, since water itself is such a good hydrogen bonding medium. Subsequent crystallographic and theoretical studies have shown that the key in this case is the water in the region of the 4-position. This makes one hydrogen bond rather than the more usual two or three and is thus a good candidate for substitution by the ligand.[9,10] Two of the guanidino nitrogens also occupy loci of water oxygens in the pocket. It seems that these waters are interconnected in that both positions are favorable sites for water, but only one at a time (J.W. Essex, personal communication). The guanidine nitrogens can occupy both loci simultaneously and "free" the water to return to bulk solvent, thus providing a large binding energy effect.

Another fruitful avenue for SBDD has been inhibition of various proteases. Many groups have used molecular modeling of crystal structures along with ancillary calculations (or just "eyeballing" structures) to design more potent or more selective ligands. The calculations are not only grid-based, like the zanamivir story above, but also include other scoring methods, such as molecular mechanics force field energies, docking scores, and simple steric bump checks. Examples of this type of work include the discovery of aliskiren, a renin inhibitor[11] and boceprevir, an inhibitor of NS3-NS4A HCV serine protease.[12] In both these cases SBDD methods were acknowledged as being at the forefront of the design process.

In the case of aliskiren, **Fig. 6**, the design strategy was to target a particular kind of binding mode, that is, to go for novel S1 to S3 pocket binders rather than the more "traditional" P1 to P4 backbone skeletons that were prevalent in the literature. A hydroxyethylene framework was chosen as a transition state mimetic and a pharmacophore was derived for the P1 to P3 region. The program GRASP was used to characterize the binding pocket and a particular hydrophobic patch ("S3 superpocket") discovered in a crystal structure was targeted for interaction. The eventual design spanned the P3 to P2′ substrate equivalent rather than the P4 to P1, so fit the initial design intentions.[13]

The Schering Plough team who discovered boceprevir resorted to rational design because they had failed to identify any decent leads from screening libraries of compounds.12 (This was a common complaint in the late 1990s and early 2000s, as many corporate screening collections were stuffed with rather unattractive, but easily made combinatorial libraries.) They took

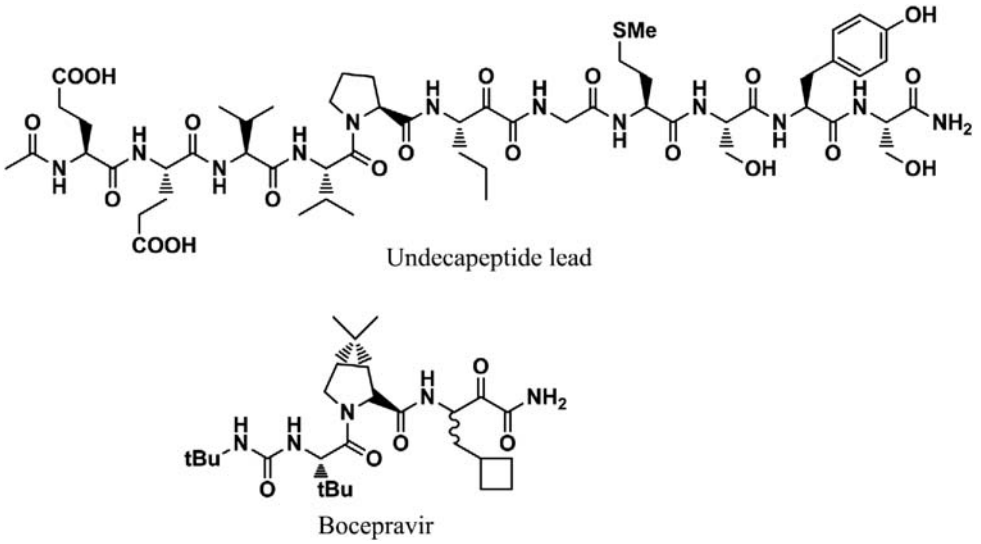

Fig. 7 The original undecapeptide lead, spanning P6 to P5′ and the final designed drug, bocepravir.

a large undecapeptide, which spanned from P6 to P5′(!), and modified it using computational and medicinal chemistry. These included SAR at particular pocket loci, macrocyclic "depeptidation," truncation, and examination of what crystal structures were available. The end result was a reduction in span from P6 to P5′ to P3 to P1, with a drop in Ki from 1.9 to 25 nM, but with far superior PK properties, such as oral bioavailability, Fig. 7.

There are other well-known examples of drug discovery with a computational component that tell similar stories. The interested reader should take a look at an excellent review of structure-based drug design successes (up to 2010) by Talele et al. in *Current Topics in Medicinal Chemistry*.[14] This discusses the above cases in more detail as well as some others. A recent issue of *Trends in Pharmacological Sciences* (33(5), 2012) was dedicated to structure-based drug design and contains articles on recent attempts and successes in areas such as kinase inhibition[15] and G protein-coupled receptors.[16]

Although there is now a good body of success stories in the literature, we are perhaps more interested in cases where things go wrong. We still regularly come across papers in the literature containing words like "surprising," "unanticipated," and especially "unexpected binding." Examples include: unexpected binding modes for JNK3,[17] thrombin,[18] factor VIIa,[19] IspE,[20] IMPCH,[21] NS5A,[22] and BACE,[23,24]; unexpected conformations of Aurora B kinase,[25] the cSrc gatekeeper methionine,[26] human neutrophil elastase,[27] BoNT/A-LC,[28] BpML1,[29] and 15S-LOX.[30] The final case is actually a 2008 rerefinement of a 1997 15S-lipoxygenase crystal structure which seemed to be badly disordered in three segments, suggesting large-scale mobility of helix 2. The refinement, however, assumed that the original crystalline sample was twinned and produced two conformationally distinct LOX molecules contacting in the crystal. Even in this case, the authors were "surprised" to find that only one of the molecules had a bound inhibitor, while the other was empty.

What does all this surprise and unexpectedness mean? Some is obviously just a way to make the story look more interesting to journal editors, but most of the above examples do genuinely contain structures that the authors did not expect. While many computational chemists would argue that pose prediction in docking is a solved problem (but ranking the poses is not), many structural scientists seem to be unearthing structures with issues, such as unanticipated crystal twinning, flipped binding modes, and flexible regions previously thought to be rigid. So while the computational tools may be improving, they are dependent upon the accuracy and precision of the structural model on which they base their work.

3.06.4 Limitations and Lessons in Using X-Ray Crystal Structures

With over 120,000 structures available, and 40 years of experience, one might expect we have become rather good at using X-ray structures in computational design. On the contrary, we are still learning to cope with its strengths and limitations, and learning lessons, structure by structure, and project by project. In 2002 some of these limitations and lessons learned across many projects and protein targets were highlighted to medicinal chemists in a review by Kleywegt, Teague, and Davis.[31]

The three authors, practitioners in crystallography, medicinal chemistry, and computational chemistry respectively, realized that important information was often lost, overlooked, or misinterpreted between the core disciplines which drive structure-based design. The review, targeted at medicinal and computational chemists, built upon the robust literature and self-critique of the X-ray crystallography community, but which had largely failed to permeate into the hands, or should we say the minds, of users of such information, the computational chemists. The review reminded readers that an X-ray crystal structure *"is one crystallographer's subjective interpretation of an observed electron-density map expressed in terms of an atomic model."* The authors went

on to state that "Some published protein models appear to have been more determined by the crystallographer's imagination than by any experimental data."

3.06.5 Where Experts Can Be Fooled, Chemists Should Always Be Extra Wary

The difference between experimental data and imagination can sometimes be hard to distinguish, even by experts. In 2006, it became apparent that a structure of human C3b complement system component[32] from a lab at the University of Alabama may have been based on fabricated "experimental" data. A subsequent 2-year investigation by the university concluded in 2009 that this structure and 10 others were "more likely than not falsified and/or fabricated" by one of the authors.[33] Apparently two of the structures had even been selected as targets for a dengue fever global virtual screening initiative. The journalists at Nature, not known for use of hyperbole, reported the story in 2009 with the headline "Fraud rocks the protein community."[34] For all its condemnation, it was not until 2016 that Nature finally retracted the original paper published in its journal.[35]

In Apr. 2008, the wwPDB had already established an X-ray validation task force (VTF) consisting of experts in the field, to advise wwPDB on approaches to validate structures on deposition. The recommendations and detailed analyses were published in 2011,[36] (with recommendations for 3EDM structures following in 2012 and NMR structures in 2013[37]).

The result was the development by wwPDB of a validation pipeline for X-ray structures incorporating community-consensus methods and software. The pipeline can be used through a stand-alone anonymous server and is also used during deposition and annotation of structures to the PDB. The official validation reports obtained after annotation can be submitted to journals to accompany manuscripts in which structures are described, and several journals have made this a mandatory requirement for manuscript submission. As of 2016, the wwPDB validation pipeline and server can handle structures determined by all current methods, and validation reports for all structures in the PDB are available for download and through the wwPDB partner websites.

The recommendations led to the provision of validation tools that were evaluated on the whole PDB. This in turn led to the provision of diagnostics alongside the structure in PDB, and a validation report on every structure.[38] The tools used in the PDB validation reports are listed within the PDB validation report documentation.[39]

Guides to the validation reports for X-ray structures,[39] NMR structures[40], and 3DEM structures[41] are available. The wwPDB team is working on an application programming interface (API) which will soon be made available so that anyone can access the tools programmatically. The hope is that the API will be integrated in the standard structure determination packages so the users can access it during structure determination and refinement.[42]

While examples of outright fraud may be rare, the human C3b complement system component example highlights how difficult it can be for even crystallography experts to separate and identify reality from imagination, fact from fiction, reliable from unreliable, when examining the beauty of an atomic coordinate model. If experts can be fooled, chemists should always be extra wary.

The advice in Teague, Davis, and Kleywegt's 2002 review is as relevant today as it was 14 years ago. A chemist using an X-ray crystal atomic model should examine it together with the crystallographer and discuss its strengths and weaknesses, areas of confidence, and uncertainty. Put simply, "examine the atomic model with the electron density, and where there is no density, there are no electrons, and where there are no electrons there are no atoms," as an eminent crystallographer once put it. Sounds easy, but it was not until 2008 that deposition of structure factors with the atomic coordinates became mandatory in PDB.[43] On the other hand, thanks to the rapid growth of the archive, the fraction of legacy entries for which the experimental data are not available (and presumably lost for all eternity) is becoming smaller and smaller (as of 2016, approximately 1 in 6 X-ray entries has no experimental data). At least inside pharma companies chemists have the opportunity to work closely with the originating crystallographer, but even so, there still exists plenty of opportunity for misinterpretations, misunderstandings, and over-interpretations to be made.

3.06.6 Uncertainties in Using X-Ray Crystal Structures

Kleywegt, Teague, and Davis highlighted the following uncertainties,[31] among others.

> (Nearly) Isoelectronic atoms and ions cannot be directly distinguished from the electron density, so it can be difficult to determine the relative orientation of the δN and δO of glutamine and γN and γO of asparagine.

If a conscious decision is made over the position of the N and O it is often by inspection of local hydrogen bond patterns, although sometimes before waters have been added to the structure. The switch from a strong donor to a strong acceptor, by the uncertainty of the position of N and O could make a drastic difference to a putative docked ligand interacting with this residue.

A more recent review by Dauter provides a nice example of N/O of asparagine being incorrectly placed. Of the 15 crystal structure depositions for savinase (subtilisin from *Bacillus lentus*), there are three, 1svn, 1tk2, and 3bx1, in which the amide N atom of an asparagine is in the immediate vicinity of the Ca^{2+} ion in the calcium binding site, instead of the O atom. This is not chemically sensible as the amide NH_2 is not a ligand for calcium coordination[44] (Fig. 8).

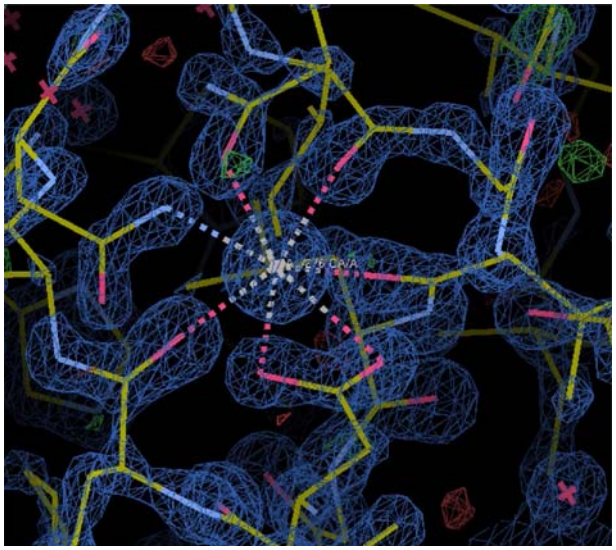

Fig. 8 1svn 1.4 Å structure of savinase 2Fo-Fc map (*blue*) showing the chemically unreasonable asparagine NH_2 pointing directed toward the calcium ion. Also showing the Fo-Fc map with *green* showing positive density (density not described by the model) and *red* showing negative density (features in the model that may be just noise).

Similar uncertainties apply to small molecules bound to the protein, for example, the position of the nitrogen in pyridines can be difficult to determine from the density. As hydrogens are not observed, the tautomeric state of histidines cannot be determined. Similarly the ionization state of the ligand or protein side chains cannot be determined directly, only inferred. Because of the local microenvironment of the protein active site, the pK_as of ionizable groups can be markedly perturbed.

Again Dauter provides a recent example. Inspection of the vicinity of the residue His91 in 3unr shows that its $N^{\delta 1}$ atom and the peptide N atom of Ser93 form a favorable hydrogen bond at 2.97 Å but, curiously, both N atoms are protonated. Since the peptide group undoubtedly has the N—H form, the His91 residue must be neutral, with only one hydrogen attached to its $N^{\epsilon 2}$ atom (Fig. 9).

The assignment of protonation states of ionisable residues can be problematic, as the microenvironment within the protein may perturb their pK_as from their common values. Hydrogen atomic positions are generally only inferred in X-ray crystal structures, as they almost never can be seen in X-ray crystal structure even at the highest resolution. Hence the protonation state of any particular residue is an uncertainty when using an X-ray crystal structure for drug design. Neutron diffraction though provides a means to see hydrogen atoms when resolution is high, and exchange for deuterium atoms makes visualization even clearer, and has been used to determine the protonation states in the active site of HIV protease, *b*-lactamase, dihydrofolate reductase, carbonic anhydrase, and

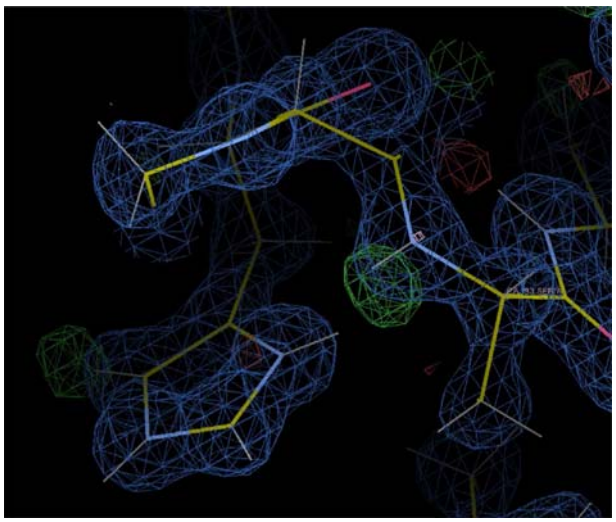

Fig. 9 3 unr trypsin at 1.2 Å 2Fo-Fc map (*blue*) and the Fo-Fc map with *green* showing positive density (density not described by the model) and *red* showing negative density (features in the model that may be just noise).

xylose isomerase.[45,46] The neutron diffraction crystal structure of human farnesyl pyrophosphate in complex with the clinical inhibitor risdronate demonstrated that as expected the pyridine nitrogen of risdronate is protonated and this proton forms a bifurcated hydrogen bond with Lys 200 and Thr 201. However what was surprising was that both risdronate phosphonate groups are deprotonated when bound to FFPS, despite the last deprotonation of the risdronate phosphonates having a $pK_a > 10.5$.

Neutron diffraction has a number of technical hurdles, not least the requirement for large crystals, the limitations of the flux of current beamlines, and the requirement for deuterium incorporation. So far PDB records only 105 structures, based in part at least on neutron diffraction data.[47] NMR can also be used to identify the protonation states of key residues, but requires proteins that are stable to pH titration and the results can be complicated by local environmental changes which may complicate chemical shift assignments and pK_a determinations.

Uncertainties can exist at the level of side chains, loops, or whole stretches of a protein if they are very mobile or otherwise disordered, and hence diffract so weakly as to have no discernible electron density. Obviously, the crystallographer knows they are there from the sequence of the sample and will model them in what appear to be sensible positions and conformations.

Looking at the structure with the electron density map is the clearest way of picking out these problems. At the level of side chains, real space density fits show that the most poorly defined residues are in order of improving average fit to the density Lys<Glu<Arg, Gln<Asp, Asn. [31] Lamb and colleagues in their paper, "You are lost without a map: Navigating the sea of protein structures," provide an illustrative example of an arginine residue in MppR, where the average B factor of the beta carbon is comparable with the main chain atoms, while the guanidinium group has only a "small scrap" of density centered upon the guanidinium group's central carbon.[48]

A further complexity occurs when alternative conformations are possible from the density, as most software will only display one of the possible positions of side chains. For example, Davis, Kleywegt, and Teague[31] cite the example disorder observed in both the nitrite and active site asparagine residues in the mutant Asp98Asn for of *Alcaligenes faecalis* S-6 nitrite reductase.[49]

3.06.6.1 Crystallization Conditions May Not Be Relevant for the Target Biology

In order to get the protein to crystallize, pH or salt conditions far from the physiological state may have been chosen, which can have dramatic consequences on the bound conformation of the ligand and/or protein. In a later review, Kleywegt, Davis, and St-Gallay[50] cite the example of the crystal structure of *Escherichia coli* ketopantoate reductase in complex with 20-phospho-ADP-ribose (a fragment of $NADP^+$ that lacks the nicotinamide ring). In an attempt to crystallize the ternary complex of the enzyme with pantoate and NADPH, crystals were obtained but the density showed no traces of pantoate and only a fragment of NADPH could be located. This fragment was confirmed to be 20-phospho-ADP-ribose by mass-spectrometry experiments. Compared with the complex with $NADP^+$, the ligand binds in the opposite orientation. Isothermal titration calorimetry with several mutants showed that the unusual binding mode is caused by changes in the protonation state of binding groups at low pH. The implication of this observation for fragment-based approaches to ligand design is that a binding mode may be altered profoundly by variations in crystallization conditions as well as by (unexpected or intentional) modifications of ligands.

3.06.6.2 Identification of Water Molecules in the Electron-Density Maps Can Be a Problem

Water molecules are a particular problem. Even at high resolution the presence of a water molecule may be uncertain, as the electron density may be indistinguishable from noise (or other unmodeled moieties that were in the crystallization solution), and thus their placement becomes quite subjective. As water is the third partner in the protein ligand binding interaction, confidence in their presence becomes rather critical. The observation of a density feature across serial X-ray structures provides confidence in the positioning of critical water molecules. Computational water placement algorithms, such as WaterMap[51] and SZMAP,[52] have been developed, and their impact on drug design was recently reviewed by Bodnarchuk.[53]

Subsequent reviews have reinforced these and other solvent ambiguities. For instance Lamb[48] highlighted that many proteins are crystallized from solutions containing polyethylene glycol or ammonium sulfate. Considering that ammonium sulfate contains two ammoniums for each sulfate, while about a quarter of all crystal structures contain sulfate, this is about 2 orders of magnitude more common than ammonium. But many water molecules adjacent to sulfate may in fact be ammonium, and the crystallographer and chemist should be open minded that a solvent molecule identified in the PDB entry could be something other than water. As NH_4^+, Na^+, and Mg^{2+} are all isoelectronic with water, assignment cannot be made on the basis of electron density alone.

Up to 2% of all crystal structures deposited in the PDB contain significant regions of unidentified density, which rises to nearly 6% of all unique structures.[54]

3.06.6.3 The Effects of Protein Flexibility Are Small or At Least Understood

Davis and Teague's review on protein flexility[55] gave many examples where the assumption of a rigid receptor is an unsafe assumption, and indicated that protein flexibility should be considered the norm, not the exception. While there are many surprises, one of

the most impactful was the change induced by oseltamivir on the active site of neuraminidase, which enabled it to supplant zanamivir as the neuraminidase inhibitor of choice for the antiinfluenza market. Oseltamivir replaces a strong guanidinium salt bridge interaction described above as critical for the binding of zanamivir, by an isopentyl chain, accommodated by an induced conformational change of the active site Glu276. This change not only gave similar affinity but also drastically modified the physical properties, and allowed oseltamivir, as a methyl ester prodrug, to become the first oral neuraminidase antiinfluenza treatment. The more favorable oral delivery route of oseltamivir over the inhaled zanamivir made it the influenza treatment of choice, and oseltamivir quickly supplanted zanamivir as the marketed neuraminidase inhibitor of choice.

Deller and Rupp highlight additional factors to be considered,[56]

- consideration of crystal packing, particularly if the ligand is close to the packing interface,
- consideration of the relevance of the asymmetric unit to the biology, as it is possible that a monomer pair in a dimer may not sit in the same asymmetric unit
- consideration of the B-factor of the ligand relative to the protein, or even different parts of the ligand, as ligand occupancy is never perfect

Their review also provides a good summary of validation software, including that used by the wwPDB.

Ligand geometries are a particular problem in protein crystallography and many examples of unusual or unrealistic bond lengths, angles, torsions or conformations can be found for small molecules in protein structures.[50] The problem is that whereas high-quality dictionaries of acceptable bond lengths, angles, and torsions are available for amino and nucleic acids in model refinement, the same is not true for complexed ligands. This is because of the huge diversity of small molecules compared to amino and nucleic acids. Even a ligand as common and well understood as ATP shows a surprisingly wide variety of bond lengths and angles. A review by Leibeschuetz based on years before 2000, 2006, and 2009 showed that up to 70% of the more recent structures could have been improved with better restraints, and 25% had errors that would have lead to misleading interpretation of binding interactions.[57] While computational chemists can postprocess a particular protein crystal structure to remove some of the issues with the ligand, such as QM refinement to reduce ligand strain, Reynolds recommends the problem is dealt with during structure determination.[58]

3.06.7 Validation of X-Ray Crystal Structures

Since the recommendations of the wwPDB X-ray VTF in 2011,[36] an officially watermarked wwPDB Validation Report is issued after annotation by the wwPDB curation staff. A similar report can be generated prior to submission using the wwPDB Validation Server.[59] For ligands, the wwPDB Validation Report includes geometrical and model fit diagnostic information.

The outcome of the first wwPDB/CCDC/D3R Ligand Validation Workshop in 2015 was recently published in Structure and made a number of recommendations to wwPDB for best practices for PDB archive deposition of cocrystal structure data:[60] The workshop also recommended that journals should require submission of the officially watermarked wwPDB validation reports and supplementary material to accompany all manuscripts describing macromolecular structure determinations, and that at least one referee has the technical expertise to evaluate in full the validation report. The group also considered what to do with PDB structures whose report flags unusual features. They not only hoped that original contributors would be motivated to correct entries, but also recognized that for many entries, the original depositors would not be in a position to make corrections. For these, the task force recommended that following a reasonable interval for self-correction, community experts could apply targeted corrections to any remaining PDB entries with poor validation outcomes, particularly for bound ligands of significant bio-medical interest. Indeed *PDBREDO* holds rerefined, and often improved, copies of all structures solved by X-ray, if the experimental data had also been deposited.[61,62]

3.06.8 Using X-Ray Crystal Structures in Docking and Scoring Validation Studies

The PDB provides a rich source of X-ray crystal structures for docking study validation, or even for training of new docking and scoring algorithms. Many datasets have been compiled focusing on size and diversity such as the 780 complexes in SB2010[63] and its update containing 1042 protein–ligand complexes SB2012. Even larger validation sets have been compiled, but the need for curation has been highlighted in a number of reviews. For example, the tetrahedral aromatic carbon in the 3-phenyl propylamine ligand in 1TNK, or the uncertain position of oleic acid in 1ICN, or the chemically unlikely flat methanesulfonyl group in 1PME, which were present within the FLEX-X validation set.[64]

With a focus on quality, a number of "clean sets" have been defined for validation purposes including Astex-85[65] and IRIDIUM.[66] In their validation of OMEGA, Warren and colleagues rigorously reviewed three previous validation sets to define 197 cocrystal structures.[67] Their selections, from others' selections, considered nominal resolution, structure factors that must be present, globally well fit models (Rfree-R must be <0.05), average positional errors assessed using the diffraction-component index (DPI <0.42 Å), poor fits of the ligand to its density [RSCC >0.9, RSR <0.2, OWAB <50, from the Uppsala Electron Density Server (EDS)], no intermolecular clashes, inappropriate physical properties, and structural dissimilarity (pairwise LINGOS similarity <0.9). They highlighted that resolution alone is not enough of a criterion, and provides two 2 Å structures, 1NHU and 1IY7, as comparisons, Figs. 10 and 11. In 1IY7 there is clearly a good fit of the ligand to the density, while in 1NHU, only partial density was observed for the ligand. They also cited two further sub-2 Å structures, 1ATL and 1ETA, where there was apparently no density supporting ligand placement at all (Fig. 12).

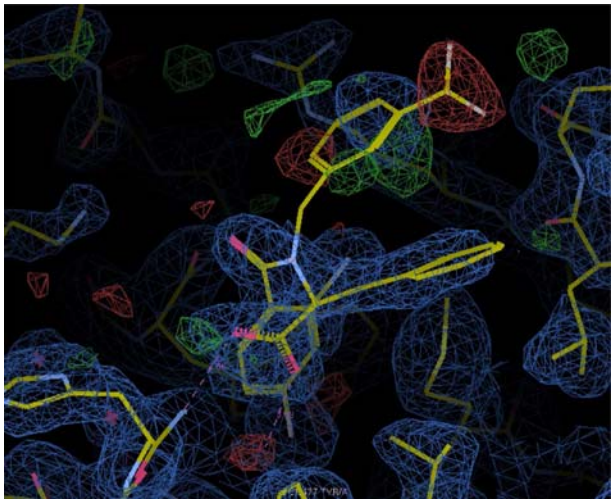

Fig. 10 1nhu, 2 Å structure of Hepatitis C virus RNA polymerase in complex with (2*S*)-2-[(2,4-dichloro-benzoyl)-(3-trifluoromethyl-benzyl)-amino]-3-phenyl-propionic acid 2Fo-Fc map (*blue*) together with Fo-Fc map with *green* showing positive density (density not described by the model) and *red* showing negative density (features in the model that may be just noise).

The DUD-E[68] database focuses on quality, and also includes a database of decoy binders to test docking protocols based on enrichment of true actives. Other validation sets have been compiled for specific purposes such as the LEADS-PEP[69] for peptide docking and the recently published docking validation set for GPCR structures.[70] Montez has recently reviewed the historical development of benchmarking sets for both ligand-based and structure-based virtual screening purposes.[71] PDB codes for the chosen protein–ligand structures in selected validation sets mentioned are shown in **Table 1**. The GPCR workbench set is shown in **Table 2**

Deller and Rupp[56] in their recent review highlight that it is difficult to anticipate every specific use of protein–ligand models, and one may need to define a particular validation set for a particular validation problem. They suggest a number of key questions that need to be considered. Their advice is to follow a three-step validation protocol covering validation of the ligand electron density, validation of the ligand stereochemistry, and validation of the protein and ligand environment. They provide a useful flow chart to follow, including recommendations for validation software for Inspection fit to electron density (**Fig. 13**).

3.06.9 Fitting to Coordinate Versus Fitting to Electron Density

The coordinates of the atomic model are often used to assess docking algorithms, where RMSD deviations from the X-ray-observed poses are typically used as success criteria. But as the atomic coordinates of the X-ray pose are themselves a model, and not the experimental data, this led Yusuf, Davis, Kleywegt, and Schmitt to propose using the electron density as the target to assess the fit.[82] RMSD to atomic positions had a number of drawbacks. First they ignore the protein environment of the docked pose, as low RMSD values can be achieved even when essential binding features are absent in the docked pose. Second, high RMSD values can be obtained even when essential binding features are identified correctly but a group that is unimportant to the binding mode such as a solvent-exposed group deviates substantially from the crystal structure. To overcome these limitations, Yusuf et al. recommended comparison of the docked pose to the crystallographic electron density maps instead of comparing the nonhydrogen atom coordinates from a docking pose against those of the atomic model. In doing so, any ambiguous features of a particular ligand orientation in a binding site environment and alternative placements or conformations are implicitly accounted for. As validation they compared three well-known docking algorithms [Gold (CCDC),Glide (Schrödinger), and Fred (OpenEye)]. As a quantitative definition of fit for the comparison of docking poses against electron densities they proposed the real space R-factor (RSR), which is routinely used in crystallography and measures the compatibility of an experimental electron density map and a group of atoms (here, the ligand atoms). They found that RMSD and RSR were nonredundant measures of fit. Of particular interest were examples with high RMSDs and low RSRs and those with lower RMSD and high RSRs. Inspection of the higher RSMD and low RSR examples showed that they can still be classified as correct when judged by the electron density (i.e., they are false negatives by the RMSD criterion). In many cases, the high RMSD value is caused by a substantial conformational difference in part of the ligand for which there is no convincing electron density.

Where they found RMSD was high but the RSR value low, there were also cases in which the ligand density was ambiguous. In such cases, the crystallographer had made a particular interpretation of the density in terms of the atomic model of the ligand. The docking pose then shows an alternative binding mode that explains the density just as well (or just as poorly) as the crystal structure but emphasizes alternative binding features.

They also found that there are quite a few cases of poses with low RMSD and high RSR. This suggested that there are cases (false positives) in which poses are classified as docking successes by the RMSD criterion even though they apparently do not fit the experimental electron density particularly well. Some of the cases involved ligands that were quite small so that even a moderate displacement could lead to a poor fit with the density. The majority of cases in which the docking solutions have low RMSD values but high RSR values were due to differences in the ligand conformations (in particular, of ring systems). The sampling of ligand conformations in docking calculations is sometimes sparse due to speed considerations and usually aims to produce low-energy conformations. During crystal-structure determination, on the other hand, energetic considerations usually take a lower priority than the need to explain the observed electron density in terms of an atomic model. This often leads to strained ligand conformations that explain the density and that may or may not be accurate representations of the true structures. In such cases, docking programs are unlikely to sample conformations identical or similar to that of the model in the crystal structure. Even if the docking procedure places the ligand in the binding site so that there is good overall agreement with the crystal structure in terms of atomic positions, interactions, and molecular shape, this does not guarantee that it will fit the electron density as well as the "hand-crafted" model produced by the crystallographer. In such cases, ostensibly small differences can result in high RSR values.

The use of the "fit to density" measures RSR and real space correlation coefficient (RSCC) has been investigated in a number of other docking evaluations compared to the more traditional, and philosophically inferior fit to coordinates RMSD measures. During the evaluation of the expert system DOCK Blaster, Shoichet and colleagues used three high-quality X-ray crystal sets developed for docking evaluations, the ASTEX-87 set, the GOLD-114 set, and the DUD set.[83] They found common failures of docking assessment using RMSD, including (a) insufficient conformational sampling of the ligand, particularly of aliphatic ring puckering; (b) symmetric or pseudosymmetric molecule; (c) critical missing water molecules; and (d) ligand pose dominated by electronic (orbital) effects. They also found that semisymmetric molecules gave poorer performance that would be better treated with a density-based pose assessment.

In the Community Structure Activity Resource Benchmark (CSAR) Exercise 2011–2012, RSR and RSSR were considered as an evaluation metric, as comparing back to the experimental data, however the metrics were not reproducible between different versions of the CCP4 (4.1.2 and 4.2.0) and they were not able to reproduce the reported value on the Uppsala Electron Density Server of the original crystal structure, so the method was not used. OpenEye evaluated cognate docking performance of their own software against a high-quality dataset prepared by themselves, called Iridium-HT which contained 121 ligand complexes with 208 separate ligand instances. They found that fit to the density proved a rather fragile measure with large differences in RSR or RSSR for small changes in geometry. They conclude that while fit to the density is scientifically more correct, the methods currently available for comparing density are unsuitable, but further work should be undertaken.

It is now mandated that protein structures deposited in the PDB must also contain the structure factors, so the model can always be checked versus the diffraction data. Some have gone further to suggest that even this is not enough and that raw diffraction images are also needed.[84] After all, even electron density maps and structure factors are derived data, as the raw data are the diffraction patterns. The reinterpretation of crystallographic data collected on the mammalian 15-S lipoxygenase is a cited case in point.[85] The originally deposited structure was solved and modeled on space group R32, but when the structure factors were reindexed to another space group and the structure was rebuilt, the size and shape of the binding site had changed so much that it was no longer able to accommodate the ligands proposed to fit. This is up to this point a still unresolved story and one which

cannot be further checked as only the structure factors were retained. There must be some unwittingly confused chemists out there, as 1LOX and 2P0M have each been downloaded over 34,000 times.[86] The community have been considering the infrastructure required for storing the diffraction data, and what criteria would be applied to decide when and where not to store images or whether it would just be cheaper to store everything.[87] A number of initiatives are now underway including TARDIS http://www.tardis.edu.au, a network of federated repositories at a national (Australian) level,[88] Ecrystals from the University of Southhampton,[89] NIH Big Data to Knowledge (BD2K) initiative,[90] and Structural Biology Data Grid (SBDG; data.sbgrid.org).[91]

While computational chemists wish to base their modeling hypotheses on the best available 3D models, which intuitively may appear to be X-ray crystal structures, all the aforementioned discussion should lead them to be cautious. 3D QSAR in techniques such as CoMFA can integrate the 3D chemistry information with biology measurements to quantitatively predictive models. Cramer and Vend built CoMFA and ComSIA models from datasets where the alignment of the compounds was entirely experimentally derived ligand poses from X-ray crystallography to those where the alignment was generated from ligand-centric template CoMFA.[92] They found that the fluctuations in the positions and conformations of compounds dominate X-ray-based alignments and can yield poorer predictions than those from the self-consistent template CoMFA alignments. Also, when there exist multiple different binding modes, structural interpretation in terms of binding site constraints can often be simpler with template-based alignments than with X-ray-based alignments.

3.06.10 Using Electron Microscopy Structures

3.06.10.1 Use and Limitations of Electron Microscopy

In 2015, a shouty title appeared in Nature, *The Revolution Will Not Be Crystallized*.[93] This promoted 3D-electron microscopy (3DEM) as the coming thing, pointing to a recent publication by groups from Cambridge and Beijing.[94] The collaboration had resulted in an atomic resolution model of gamma secretase, a well-targeted subject of Alzheimer's research. The resolution was quoted as 3.4 A for 1542 residues and was the result of image processing of 1.8 million particles picked from 2925 micrographs [PDB:5A63]. Perhaps more exciting is a subsequent publication by the Beijing group in which different conformational states of the secretase seem to be evident. The second and sixth helices of presenilin—one of the secretase complex components—are claimed to be mobile in some states but immobilized by an inhibitor, DAPT.[95] Thus, in the best cases to date, 3DEM can provide something that X-ray crystallography cannot—the simultaneous examination of discrete populations of conformations or states or assemblies.

Another remarkable recent paper is that by Bartesaghi et al., in which β-galactosidase and its inhibitor (PETG) are modeled at a resolution of 2.2 A, using 3DEM [PDB:5A1A].[96] **Fig. 1** of that paper shows that at this resolution, the EM density even shows a hole in the phenyl ring of Phe627, as can be seen in high-quality X-ray diffraction structures, **Fig. 14**. In addition to the enzyme, the authors identified about 800 water molecules, many of which corresponded to the previously published X-ray diffraction crystal structure model [PDB:1DB0].[97] It is arguable whether the 3DEM structure advances the knowledge of galactosidases that much, but there are some important points to be made. Thus 3DEM acts as a complementary/supporting technique to X-ray crystallography. For instance, the placement of many of the water molecules in the X-ray structure is confirmed in the 3DEM, thus suggesting

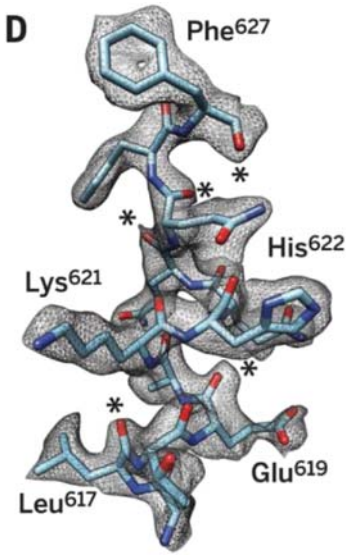

Fig. 14 3DEM density map for Phe627 of *b*-galactosidase, showing reduction of density in the center of the phenyl ring. Reproduced from Bartesaghi, A. 2.2 Å Resolution 3DEM Structure of *b*-Galactosidase in Complex With a Cell-Permeant Inhibitor. *Science.* **2015**, 348(6239), 1147–1151.

that the waters are not crystallographic artifacts, but a representation of the hydration shell. (The 3DEM samples were plunge-frozen direct from solution.) In the case of this paper, the authors are developing earlier 3DEM work by improving specimen selection rather than image collection and processing technology. They thus argue that 3DEM is now becoming a mature structure determination technique, limited by sample preparation rather than technology.

Another possible advantage of 3DEM over X-ray crystallography is that it can be used for the structures of protein assemblies. This is not to say that X-ray diffraction methods cannot; after all, Nobel Prizes have been awarded for crystallography of molecular assemblies such as the photosynthetic reaction center and the ribosome. However, 3DEM holds the promise of routine determination of such complex entities in drug design.[98] The results are not always that interpretable or convincing, though. An interesting recent example is the model of the LRRK2 protein, which has a genetic linkage to Parkinson's disease.[99] An impressive collaboration of scientists from 15 institutions used data from mass spectrometry, chemical cross-linking, X-ray scattering, and electron microscopy to build a model of the LRRK2 dimer. LRRK2 consists of seven domains: Armadillo, Ankyrin, and Leucine-rich repeat (LRR) scaffolds, followed by a Roc-COR dimerization unit, then a kinase domain and finally a WD40 scaffold unit. The authors succeeded in building a plausible model from the experimental data that offers new hypotheses for the functional mechanism of this protein. For instance, the proximity of the ankyrin and LRR domains to the kinase suggests for the first time (we think) that these domains are involved in regulation of the biological activity of LRRK2, rather than just being a framework skeleton for the assembly. Nevertheless, one can quibble with details of the model. Almost everyone who looks at the final model superimposed on the EM map immediately notices two "horns" growing from to structure that have no equivalent in the molecular model, **Fig. 15**. (We leave the readers to test their own perceptions.) Are these features that have not been modeled correctly, or are they artifacts of the EM process? Such features are often seen on EM reconstructions, where the atomic model is unable to completely fill or overfills the EM volume. Of course, this does not invalidate EM methods, but it does strain the credibility of the method as far as some medicinal chemists are concerned.

3D Electron microscopy has been around for years and has made an impact on drug discovery before. One can think of Richard Henderson's important work on the structure of bacteriorhodopsin as a paralogue for GPCRs.[100] This resulted in a number of speculative models of human rhodopsin being built in both industry and academia. These were then used to construct models of therapeutically relevant GPCRs, such as adrenergic, serotonin, and dopamine receptors. Although these models were crude, they gave rise to testable hypotheses for antagonist binding modes that were only improved on by subsequent crystallography work. In this case, crystallography has been used to refine the earlier 3DEM work. One wonders whether the latest generation 3DEM will supplant atomic resolution X-ray and neutron diffraction crystallography or will once again be superseded. The answer is probably, "yes and no." We anticipate that X-ray diffraction methods will remain valuable for ligand–protein pairings of monomeric, dimeric, and simple assemblies—particularly those amenable to crystal soaks for rapid determination of ligand-binding modes. However, where we are interested in larger, more complex assemblies or heterogeneous populations of conformational states, 3DEM will be the method of choice. For those interested in exploring this field more, we recommend the recent review by Bai et al.,[101] Kuehlbrandt,[102] and Milne et al.[103]

3.06.11 Summary

The PDB continues to develop, based on a collaboration between its partners from the United States (http://rcsb.org), Japan (http://pdbj.org), and Europe (http://pdbe.org). They collaborate on everything related to getting the information into the single archive, for example, formats, policies, interactions with journals, and validation. But in the original 2003 wwPDB memorandum of understanding between its constituent members, it was agreed that members would compete with one another to offer different kinds of services and features. The RSCB has extensive search and reporting together with an education portal. PDBe has multiple search and browse capabilities with analysis and bioinformatics tools, and places an emphasis on validation, visualization, experimental data, and integration with other archives (UniProt, GO, Pfam, CATH, ChEMBL, etc.).[104] PDBj also supports browsing in multiple Asian languages. The BioMagResBank has many specialist capabilities to support the NMR community. The PDB archive contains information derived from X-ray/neutron/electron crystallography, NMR spectroscopy, and 3D electron microscopy. A workshop held in 2005 led to the policy that pure in silico models should not be part of the PDB,[105] and instead a separate portal should be established. The Protein Modelling Portal was established in 2007.[106]

The wwPDB are continuing to address validation and quality of 3D structure models, but it is user beware, as for all the best will in the world by the 3D structure community, one cannot mandate how a model will be used or by whom. For the moment X-ray crystallography remains the dominant source of 3D models. 3DEM is a fast up-and-coming technique, and certainly offers opportunities. More and more hybrid application of all these methods are being used,[107,108] and the caveats of the models will become more complex.

All the careful validation work such as the curation of docking validation sets and the scoring of PDB submissions is worthless unless someone (you?) takes advantage of it. If you are in a well-funded pharmaceutical company with its own structural scientists, then you should discuss new structures carefully with them. Remember that it is not just you who is under severe work pressure. They are committed to their work, but sometimes corners are cut, or at least they make assumptions that are logical to structural biologists but not so obvious to computational chemists. Many structures in the pharmaceutical proprietary collections are not of publication quality, because that is not the first priority. For instance, if you have a well-behaved system that is amenable to crystal soaks, then each successive ligand–protein structure will be solved by molecular replacement and any original anomalies will be carried through to new structures and new anomalies might arise too. The density around the ligand binding pocket will be examined closely, but it is unlikely that the whole structure will be rerefined.

If you are in a smaller organization with remote collaborators or outsource partners, then you will have to work harder to ensure the quality of the structures that you are using. If your structure is nonconfidential, the first thing you should do is avail yourself of the excellent tools at the wwPDB validation server. If you have access to Mercury, run it on the ligand to check if there are unusual geometric parameters. These steps are usually enough to catch atom hybridization errors, such as sp^3 benzene and sp^2 cyclohexanes. If you use commercial molecular modeling software such as MOE or Maestro, then run the protein preparation or protein health tools. These overlap somewhat with the wwPDB assessment, but can sometimes identify extra issues to consider. Any issues that do arise should be discussed with the structural scientist, if possible.

The same standard of rigor should be applied to homology models built by computational chemists. You should be aware of weaknesses and ambiguities in the model, such as where the "indels" (insertions and deletions in the sequence alignment) are. Indels are a major source of strain in the internal geometry of a model unless carefully resolved, as they are regions where the homology model deviates the most from the template structure. Just like the industry crystallographers, homology model builders must make a call on what parts of the model need their full attention and what bits can be built to a lower standard. The solution is often that binding sites are carefully built but other parts are left with holes or overlapping atoms. This is fine if the model is only used for docking ligands that are of similar size, shape, and chemistry to an original ligand, but is not good enough for more modern workflows, such as FEP simulations. Be wary of picking up a homology model from a computer disk or corporate database, unless you know its story or are willing to do some quality assessment.

Does this mean we are cautioning against the use of structure models and homology models? Far from it. George Box said, "all models are wrong, but some are useful." This is the case in protein models too. The best models are extremely useful. The reader is directed to look at the work done by the Heptares group, and Miles Congreves's chapter in this volume. They have carefully teased out high-quality X-ray crystal structures of several GPCRs and have also built homology models of others. These are of sufficient quality to run molecular dynamics, WaterMap and FEP simulations on.

The use of 3D structural information by computational chemists is not unlike using any other experimental data on which we base models. We would have the best understanding possible of the data we are using in our models. Equally the medicinal chemists should be aware of the risks they are taking in using our computational models. Dialog between discipline experts remains pivotal in the appropriate use of experimental data in computational chemistry, and computational models in drug design. We all take risks using any experimental or computational data on which we base decisions; we should just be aware of what risks we are taking.

Acknowledgment

We would like to thank Gerard Kleywegt (EMBL/EBI) for many helpful comments and detailed review of the manuscript.

3.07.1 Introduction

3.07.1.1 The Drive to Use 3D Protein Structures in Drug Discovery and Design

Ever since the very first atomic resolution structures of proteins were revealed, drug designers have sought to exploit this information in the design of new therapeutics. Perhaps the first practical example of such structure-based drug discovery was the pioneering work of Beddell, Goodford, and colleagues at the Wellcome Research Laboratories who in the mid-1970s used the hemoglobin X-ray structure to design compounds that bound to and stabilized the deoxy conformation, thereby promoting oxygen liberation.[1] In the subsequent years, the use of protein structure in drug discovery has become well established and pivotal to the discovery of many clinical candidates and a growing number of marketed medicines.[2–4] Further, the opportunity to exploit protein structure for drug discovery has over the past decades provided a major impetus for the development of new experimental techniques in protein structure determination and in the computational tools and techniques that use such structures for the design of new medicines.

Nevertheless, despite significant progress there remain major challenges, both in our ability to generate structural information from experiment and in our computational structure-based design tools and approaches. Unfortunately, there is no guarantee that an experimental structure can be obtained of the specific protein of interest. Given these practical challenges, limitations, and uncertainties, there has evolved a parallel area of science that is the focus of this chapter, which is on methods for the computational modeling and prediction of 3-dimensional (3D) protein structures that are of sufficient accuracy and precision to be of practical value in drug design and discovery.

The chapter is organized as follows: First, we introduce the field, placing protein modeling in the broader context of the biological data explosion. We then summarize the various and changing ways in which protein structural information is used in drug

discovery. The core of the chapter is concerned with an overview of the methodologies that are most commonly used for building and validating protein models within the context of drug discovery applications, including the significant efforts made by the community to objectively assess and compare these methods. Finally, we provide some reflections on the current state of the art and indicate potential future directions. It is not our aim to provide a comprehensive review of the field. Rather, our goal is to provide an accessible introduction for non-experts, who we hope will then be better placed to engage productively and critically with protein modeling experts among their colleagues and will have sufficient background knowledge to access the relevant literature. Our emphasis will be on those applications and problems likely to be of most interest to medicinal chemists and others actively involved in "real world" drug and therapeutic discovery. At the same time, we recognize that this is a broad field whose scope continues to expand in many areas of both fundamental and applied science. We will assume a degree of familiarity with the basic principles of protein structure and function.[5] There are also many reviews of the protein modeling field[6–11] and an ever-growing list of resources freely available on the web.

3.07.1.2 Quantifying the Need for Protein Structure Prediction Methods

Recent years have seen a revolution in the provision of data in the biological and medical sciences, driven initially by the sequencing of the human genome and the subsequent dramatic reduction in cost that has brought the era of the sub-$1000 genome. While DNA sequencing continues to attract the headlines, technological advances are also occurring in many other areas of biology. Fig. 1 shows how the volumes of data held in databases at the European Bioinformatics Institute (EBI) from various "omics" technologies (e.g., DNA sequencing, transcriptomics, proteomics, and metabolomics) have increased in recent years.[12] Nor are these advances in technology and data generation limited to "omics" methods; imaging techniques, to take just one example, are also undergoing rapid technology change and data growth. Pertinent to this chapter is the sobering comparison between the growth in the numbers of deposited protein sequences and the corresponding growth in protein structure data. Fig. 2 shows a comparison between the entries contained in the UniProt/SwissProt and UniProt/Trembl databases[13,14] of curated protein sequences and the worldwide Protein Data Bank (PDB) of 3D structures.[15,16] Both sequence and structure databases continue to show exponential growth but there is a significant gap between the sequence data and the corresponding structural data. In practice this means that there is a large and growing number of proteins whose 3D structure is not known and where some form of predictive computational modeling currently provides the only available option.

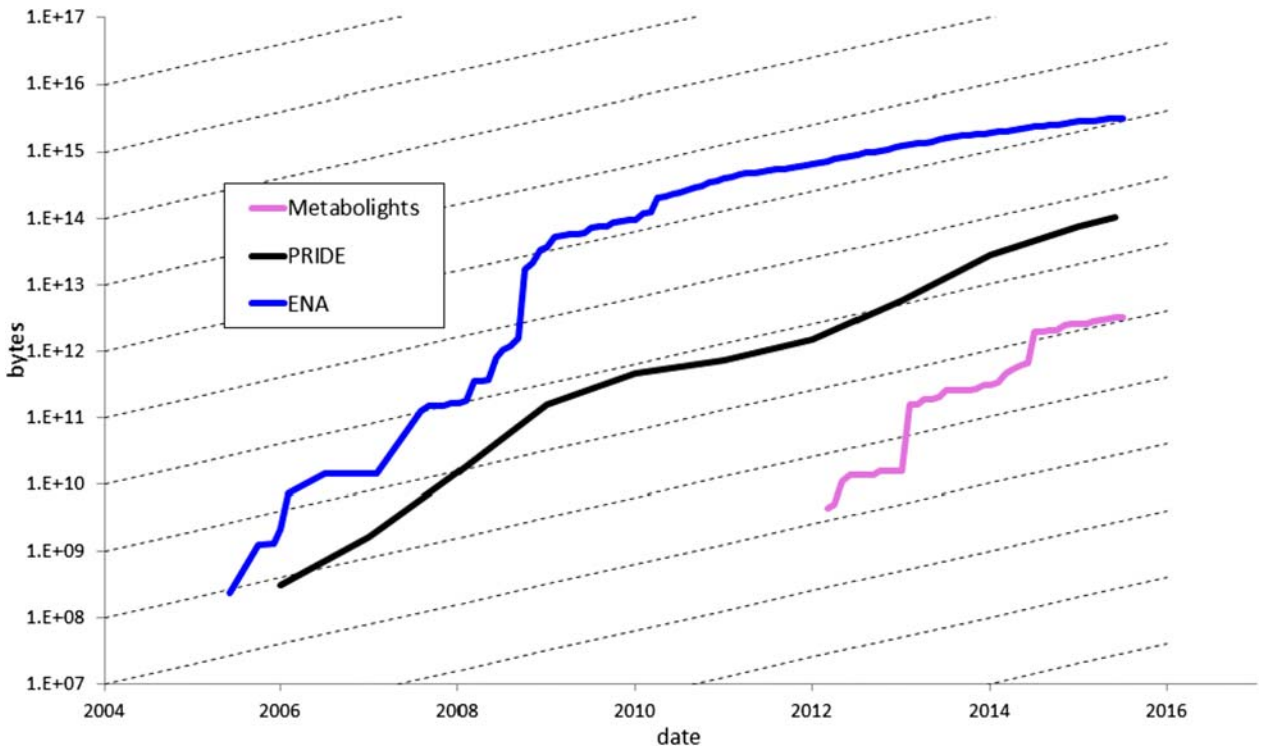

Fig. 1 Growth in data storage for selected resources at the European Bioinformatics Institute (EBI). *ENA*, European Nucleotide Archive; *PRIDE*, proteomics data; *Metabolights*, metabolomics data; The *dashed lines* correspond to a 12-month doubling rate. 3.07.1.3 Why Is the Number of Protein Folds Important?

This oft-quoted comparison between the growth in protein sequence and protein structure data is however only part of the story. A key observation made using the very earliest protein structures was that proteins with similar sequences had similar 3D structures. The pioneering work of Chothia and Lesk quantified the relationship between the degree of conservation of structure relative to sequence, and established the general principle that structure tends to be more highly conserved than sequence.[17] As we will discuss in more detail later, the most commonly used approach to protein model building for drug discovery applications (*comparative modeling*) seeks to identify proteins of known structure that would be expected to adopt the same overall conformation (or *fold*) as the unknown protein (henceforth referred to as the *target protein*). These proteins of known structure thus provide one or more 3D *templates* that can be used as the starting point to construct a structure of the unknown target protein. We also note that the older term *homology modeling* is frequently used interchangeably with comparative modeling; homologous proteins for the purposes of this chapter are those which have similar sequences, structures, or functions according to the context.

More relevant to the problem of protein model building therefore than the absolute number of available protein structures (which in any case includes many copies of some proteins, for example, with different ligands bound) is the number of distinct 3D protein folds that represent the currently known "universe" of protein conformations. Put more specifically, for the target protein that is of (therapeutic) interest to me, are there available experimental structures of proteins from the same fold family from which I can build a sufficiently accurate model?

As we have seen from Fig. 2 the numbers of both protein sequences and protein structures continue to grow rapidly. A key question for protein modeling is: how many different protein folds are there? The CATH[18,19] and SCOP[20,21] databases are widely used resources that characterize experimental structures from the Protein Data Bank into different fold families. They use somewhat different algorithms and strategies to define what differentiates a fold but are broadly similar in scope and intent. A year-by-year analysis of the numbers of new protein folds as new structures are added to the PDB is shown in Fig. 3. As can be seen, until around 1990 there was a slow growth in both the number of protein structures reported and the number of new folds. After 1990 the numbers of structures and folds underwent a huge increase. A practical consequence of this growth in the number of distinct folds over the last 25 years means that it is now much more likely that a 3D template will be available to enable comparative modeling for a new target protein. Indeed, although the number of structures has continued to rise steadily in recent years, no new folds have been reported since 2008, at least according to the CATH/SCOP definitions. This naturally raises the question as to whether we are reaching the point at which all viable folds have been discovered and that we are only limited by our ability to predict which fold a protein will adopt. Of course, this analysis is restricted to the structural data represented in the PDB; certain families such as membrane-bound proteins are underrepresented due to the experimental challenges of obtaining structural data.

A significant proportion of the increase in structural diversity in recent years is a consequence of the various structural genomics initiatives.[22] Recent studies have tried to quantify the impact of these large-scale programs, with one such analysis suggesting that the "structural coverage" for known protein sequences is currently approximately 40%, a value that had increased from 30% between 2000 and 2012.[23] This was a relatively simple calculation, based purely on sequence comparisons of the known sequences, against the sequences of proteins deposited in the Protein Data Bank. When broken down by organism type (eukaryotes, bacteria, viruses, etc.) it was found that viral proteins had the highest structure coverage at almost 60% whereas eukaryotic proteins were the

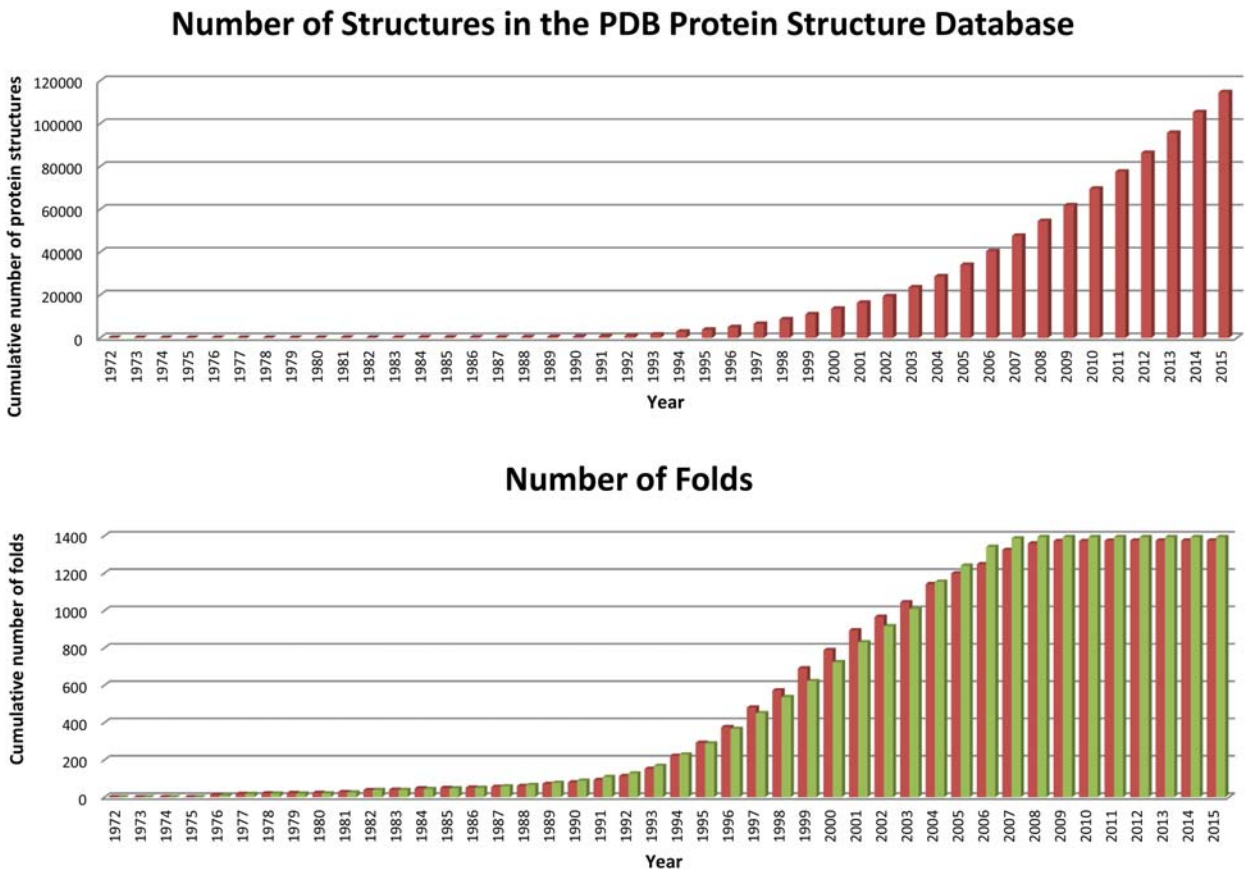

Fig. 3 Comparison of the growth in the number of structures in the wwPDB (*top*) with the number of folds (*bottom*), according to SCOP (in *green*) and CATH (in *red*).

lowest at approximately 30%. This latter figure had changed little in the previous decade and was ascribed to the challenges of generating sufficient material of the right quality for experimental structural studies of eukaryotic proteins. Finally, in addition to all the above considerations it is important to recognize that some proteins are in whole or part natively unfolded[24] although some may fold when complexed with partner proteins. Clearly, our ability to understand the function of these proteins through current approaches to protein modeling will be limited.

3.07.1.4 The Uses and Limitations of Models in Protein Structure Analysis and Drug Discovery

It is tempting to make a distinction between the data and results obtained from experimental sources and outputs from purely computational methods. Experimental results are often considered "definitive" outputs against which computational modeling approaches and predictions are to be compared. However, almost all experimental approaches themselves involve some form of model-building. A data point as apparently simple as an IC50 value is the result of fitting a particular predefined equation to a series of concentration-varying inhibition data. The generation of experimental protein structures involves extensive use of model building techniques.

Historically, the most commonly used and still the "gold standard" method for the determination of protein structures is *X-ray crystallography*, representing around 90% of all structures deposited in the Protein Data Bank. A key step in the crystallographic workflow involves fitting a 3D atomic model to the experimentally determined electron density.[25–29] *Nuclear Magnetic Resonance* (*NMR*) experiments have to date provided the second highest proportion of structures in the Protein Data Bank (approximately 10%). Here again, model building is a key aspect of the workflow, with 3D models being built to satisfy the experimental restraints (for example, distance restraints between pairs of atoms).[30,31] *cryo Electron Microscopy* (*cryo-EM*), limited for many years to depicting proteins as "blobs," is currently undergoing a "resolution revolution"[32–34] as a result of dramatic improvements in microscopes, detectors, and image processing techniques. This has led to a rapidly growing number of structures at 3 Å resolution or better, which enables more detailed information to be resolved than at lower resolution, such as the conformations of protein side chains. Again, model building is a crucial component of the cryo-EM workflow. Other experimental techniques such as hydrogen–deuterium exchange, small-angle X-ray scattering, chemical cross-linking, and light scattering can also provide information that may assist in the

construction and validation of protein structural models even though in general the lower resolution information from these methods cannot be used directly to generate a 3D structure.

Later in this chapter we will discuss briefly the potential sources of errors in protein models and validation procedures to help identify them. It is important to realize that experimental models also can be subject to errors, mistakes and over-interpretation.[35,36] It is therefore important to carefully scrutinize all experimental data prior to use and not to assume that an experimental result is necessarily definitive. On a more positive note, there are clear opportunities for productive synergies between experiment and theory in the area of protein structure analysis, prediction, and modeling. In some cases it is possible to incorporate experimental information (potentially from more than one experimental approach) directly into the model building process, and so deliver structures that take this information and knowledge into account. In other cases the experimental information can be used to filter a number of different possible models in order to identify those which are most consistent with the experiment.

3.07.1.5 Additional Challenges and Considerations When Using Protein Structures

A number of additional caveats should be borne in mind when using protein structural information, data, and models. Three of the most important relate to protein dynamics, solvation, and multicomponent complexes. Proteins in their natural environment are dynamic entities. By contrast, most "experimental" protein structures from X-ray crystallography are represented as static 3D models. In some cases conformational flexibility is explicitly captured (e.g., the different conformations of individual side chains), and certain other aspects of the experiment provide information on protein dynamics (e.g., temperature or B factors). However, such static representations are far removed from the true dynamical nature of proteins. Very similar arguments can be made about solvation and the critical role of water in protein structure and dynamics. Computational techniques such as molecular dynamics simulations may provide insights into dynamics and solvation but rarely capture the "true" environment within the cell and are often unable to run the calculations long enough to reach the timescales of biological processes. A third challenge arises from the fact that many proteins function as part of much larger complexes comprising multiple domains. Although the structures of some very large proteins and protein complexes have been solved, for practical drug discovery projects it is much more common to focus on single, isolated domains as these are more likely to be amenable to the production of diffracting crystals for X-ray crystallography or below the typical upper limit of $\sim$50kDa for NMR. The advent of high-resolution cryo-EM may change the situation as this method is more suited to the study of larger systems. Notwithstanding these caveats, the use of single protein domains that are treated as static entities with minimal account of solvent is still the norm in computational drug discovery. Nevertheless, experienced users of X-ray structures will be aware of these limitations and will take appropriate action when setting up and analyzing calculations.

3.07.1.6 A Timeline of Protein Structure Prediction and Protein Modeling

Ever since the very first experimental protein structures were determined it was recognized that proteins with different amino acid sequences can adopt the same fold.[17] This naturally led to an interest in methods for predicting their 3D structures in order to better understand the critical role that proteins play in driving many biological processes. From a practical drug discovery perspective the driver has often been to make use of the atomic resolution structural information in compound design. More broadly, protein structure prediction has been for many years one of the key unsolved problems in biology: starting from just the amino acid sequence of a protein is it possible to predict its structure? Closely related to this is the protein folding problem: how do proteins form such complex 3D structures when going from random polypeptide chain to complex 3D protein structure?

Some of the landmarks in the history and evolution of protein structure prediction are indicated in **Fig. 4**, including important breakthroughs, the creation of resources such as the PDB, and the introduction of key methodologies. We will touch on many of these innovations throughout the chapter. While the "holy grail" of being able to accurately predict the structure of any protein purely from its sequence remains unsolved, significant progress has been made not only in the fundamental science but also in the influence and impact of the field on experimental approaches, in computational science, and in engaging the scientific community and the general public.

3.07.2 How Is Protein Structure Information Used in Drug Discovery?

The close relationship between protein structure and biological function has a long and illustrious history with many landmarks and the award of a significant number of Nobel prizes. There are in addition numerous ways in which the 3D structure of a protein may be of value in the discovery of new therapeutic agents. The first, and still the most common, is in the design of small "drug-like" molecules that interact via a desired mode of action with the target protein. Closely related to this is the use of structure to design compounds that have no or reduced binding to that protein, for example, because it is a selectivity or liability target. While these two scenarios continue to be the most common for the practising medicinal chemist, there are nevertheless other uses of protein structures in drug discovery. The goal of a *ligandability assessment* is to predict the feasibility of identifying drug-like small molecules that bind to the target protein. *Construct design* involves the prediction of domain boundaries, sites of post-translational modification, and the overall properties of isolated domains in amino acid sequences in order to generate stable protein, often to optimize the likelihood of crystallization. *Synthetic biochemistry* is a relatively new area where, for example, it is desired to optimize the catalytic

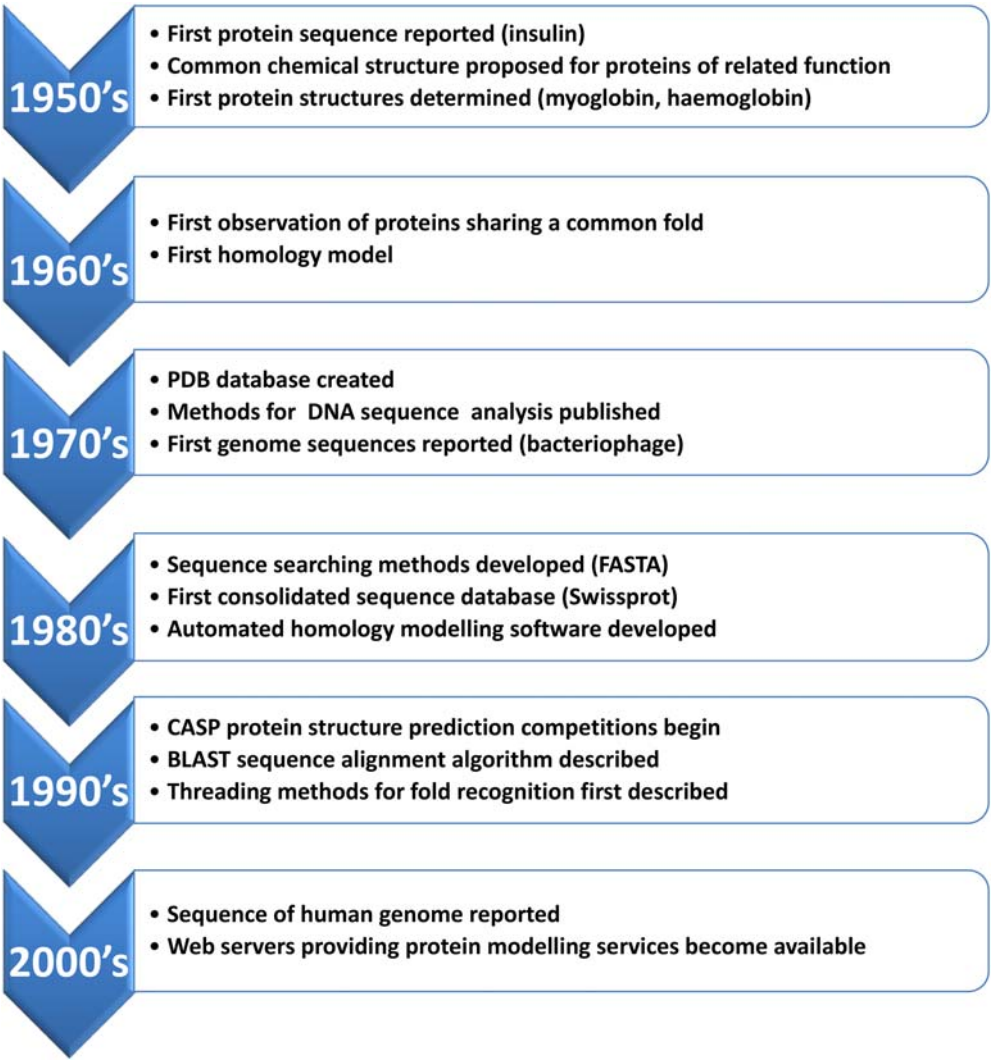

Fig. 4 Timeline showing some of the major landmarks in protein structure determination and protein modeling.

properties of an enzyme, to drive a desired chemical reaction under particular conditions (as might, for example, be required for the "green" synthesis of a drug or chemical). Beyond "small molecule" drug discovery there are increasingly important opportunities to exploit structural knowledge, for example, in the design of protein therapeutics such as antibodies and vaccines.

3.07.2.1 How Accurate Does a Protein Model Need to be?

An important factor when considering practical applications of predictive protein modeling is to have a general appreciation of the level of accuracy that is required of the protein model in order to be useful. The accuracy of a protein model can be assessed in many different ways. The most common method in the protein modeling community is to calculate the "Cα-RMSD" value between the model and the experimentally determined structure. This corresponds to the root-mean-square deviation (RMSD) when the alpha carbon atoms (Cα) of the protein backbone of the model and the experimental structure are optimally superimposed. This metric is straightforward, quantitative, and well understood. However, it may not be the most appropriate measure in practice and a host of alternatives have been developed. These include the "global distance test (GDT)," defined as the largest set of alpha carbon atoms in the model structure that fall within a defined distance cutoff of their position in the experimental structure. It was introduced[37] to address the fact that the RMSD metric for an otherwise correct model can be skewed toward a poor value due to inaccurate predictions in just small parts of the model. A practical limitation with the RMSD, GDT, and similar measures is that these metrics can only be calculated once the experimental structure is available (which in turn is often the reason for building a model in the first place). A further caveat is that measures of overall structure accuracy may not be the most relevant for drug discovery, because only a part of the structure is of practical interest. In small molecule applications it is often the binding site that is most relevant; a model that on the basis of an overall RMSD appears of lower quality can nevertheless be very useful if the binding region is well defined and vice

versa. Further, a very approximate model may be able to provide key insights that are pivotal for progress in one molecular design project whereas a highly accurate model (or indeed a highly accurate experimental structure) may not in practice help another project progress at all, for example because the issues are not related to protein–ligand interactions but rather another aspect such as pharmacokinetics, toxicity, or physical form. Some general guidelines based on practical experience are nevertheless illustrated in Fig. 5.

3.07.2.2 Protein Structure and Protein Models in Small Molecule Drug Discovery

Structure-based design methods are used in both the hit generation and lead optimization phases of small molecule drug discovery. In hit generation the most common use is for *virtual screening*, where the target protein structure is used to search compound databases to identify a subset of compounds for (physical) screening in some form of biological assay.[38–40] In the lead optimization phase, structure-based methods are often a key part of the iterative design, synthesize, and test cycle to enhance interactions with the target protein and in some cases to build in selectivity or eliminate off-target binding properties of the molecular series.

Central to many structure-based design strategies is *molecular docking*, the goal of which is to predict the binding mode of a molecular ligand when bound to its target protein. Many docking algorithms have been developed since the very first methods were introduced in the late 1980s.[41–43] Docking involves two core components. First, a method to explore the conformational and orientational space of the protein–ligand system in order to generate trial docking poses. Second, a method to score these poses such that the closer a pose is to the true binding mode, the more favorable is the score. The relative performance of docking programs is a topic of perennial interest and the field has benefitted significantly from the publication of highly curated, published training sets that have enabled a more consistent and thorough evaluation of docking performance.[44–48] Contemporary docking

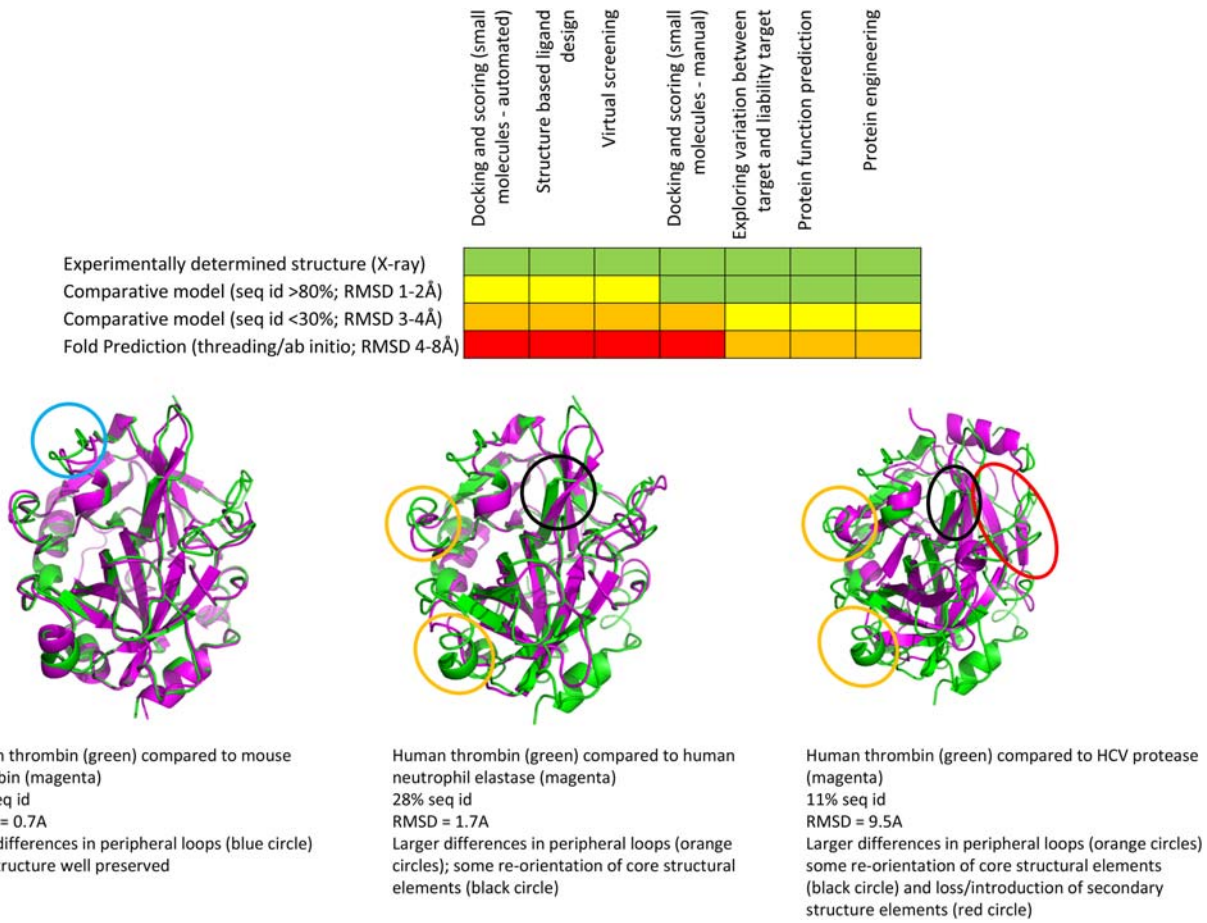

Fig. 5 Top: schematic illustration of the level of accuracy (as measured by RMSD to the experimental structure) required in a model to enable different applications. Color coding from *green* (likely to be useful) to *red* (very limited or no use for this application). "seq id" (sequence identity) is the percentage of amino acids common to two aligned protein sequences, i.e., the target protein being modeled and the 3D template from which that model is built (see Section "**Sequence and Structural Analysis**" for more details). The RMSD values are indicative of the likely accuracy that might be expected for each scenario. Bottom: examples to illustrate the practical comparison between human thrombin and three other proteins with varying RMSD. Protein structure images created using the PyMOL Molecular graphics system, Version 1.7.6.6 Schrodinger LLC.

programs are able to predict the binding mode of a ligand in about 70% of cases, a figure that has changed little over recent years. While clearly important, docking performance on a large, diverse test set is just one of several factors that should be taken into account when selecting a docking method. Other considerations include performance on the specific system(s) of interest, the ability (if required) to handle certain types of ligands (e.g., covalent binders), speed, and usability. Many algorithms are still not able to adequately take account of small or large movements in protein structures that can occur on ligand binding and the development of scoring functions that properly quantify the balance of ligand strain, fit to site, and solvation/desolvation effects continues to be an area of active research. An in-depth analysis and summary of molecular docking methods can be found elsewhere in this volume.

Molecular docking is usually performed using experimentally determined protein structures, but there has nevertheless been interest in using 3D protein models where an experimental structure is not available.[49–52] The literature contains a growing number of examples where protein models have been used successfully in virtual screening applications (i.e., "active" compounds were discovered when the compounds were screened in the biological assay). Of course, success cannot be guaranteed, and we should always be aware that the literature tends to record just those cases that were successful. Several studies have sought to compare the virtual screening performance of protein models relative to the use of a crystal structure. G-coupled protein receptors in particular have been a popular target family for such studies[53–58] but there are also comparisons for other protein families such as kinases.[59]

One might ask why virtual screening should work at all when using a computational predictive model? It should first be recalled that docking and scoring methods are approximate, and that even when using a high-resolution crystal structure for virtual screening there is a natural limitation on performance. Conversely, it may be sufficient for a model to capture just the key elements of the protein active site in order to identify molecules that are active when screened. Further, protein models may access regions of conformational space not explicitly captured in the static snapshots provided by experimental structures. An extension of these ideas involves the integration of structure-based design and ligand-based design methods. The latter encompass approaches such as 3D pharmacophore methods and molecular similarity calculations; ligand-based design is traditionally applied where there are known ligands but no structure of the biological target. Extracting the key features from a protein model for use in a ligand-based workflow may provide an effective strategy that addresses some of the inherent inaccuracies and approximations in protein models. Some groups have developed more approximate representations of a protein binding site (often termed *pseudoreceptors*).[60,61] Finally, a growing trend is for ligand structure–activity data to be used in the construction and (in particular) the validation of protein models, a development that has been much facilitated by the availability of structure-activity relationship (SAR) data from public databases such as ChEMBL.[62]

During lead optimization the focus shifts to the iterative design of compounds from the hit chemical series in order to achieve an appropriate balance of properties (e.g., potency at the target, selectivity, safety, pharmacokinetics, etc.). A wide variety of computational methods may be applied, depending on the particular aspects being addressed. Common examples include: modifying and extending the current chemical series to pick up further interactions with the target to improve potency; improving selectivity over homologous proteins by capitalizing on differences in their protein structures; interaction analysis to identify potential bioisosteric replacements. In contrast to a typical virtual screening protocol used for hit generation, the numbers of structures that need to be processed and modeled in lead optimization are often far fewer. This means that greater use of hands-on modeling approaches becomes possible and can often be successful, particularly if close attention is paid to ensuring that the model continues to be refined in order to remain consistent with the ligand SAR.

3.07.2.3 Target Tractability and Ligandability

Target tractability is often considered synonymous with the term "druggability." There is neither formal definition nor recognized quantification of these terms, but the general concept is based on the idea that not all proteins are linked to disease nor are they necessarily amenable to intervention by small molecule therapies. The link between target and disease is an area of considerable interest, with a particular focus in recent years on the exciting opportunities offered by genetics. Having a highly validated target with regard to disease linkage constitutes only a part of the bigger picture; it is also necessary for that target to be amenable to intervention by a therapeutic agent, traditionally a "drug-like" small molecule. This second, *ligandability*, component aims to characterize, and in some cases quantify, the likelihood that a target protein can bind small "drug-like" molecules with a sufficiently strong interaction. The concept gained particular prominence following the sequencing of the human genome and the recognition that not all of the expressed proteins would necessarily be viable drug targets. This led to the concept of the "druggable genome".[63] Various methods are available for assessing the ligandability of a target. The simplest are based on precedence: if some members of a protein family have been "drugged" then it is assumed that other members of the family will also be tractable to small, drug-like molecules. More complex computational methods for assessing the likely ligandability of a protein from its 3D structure (which may be derived from experiment or from modeling) have also been developed.[64–66] These variously aim to identify, characterize, and assess the putative binding site. Geometrical characteristics such as size and shape can be calculated; sites that are reasonably enclosed with a high degree of concavity are in general considered to be more tractable toward small drug-like molecules than large, flat regions. It is also possible to quantify a binding site's potential for making favorable binding interactions by considering the characteristics of its defining atoms. Machine learning techniques may be used in conjunction with such descriptors to develop mathematical models for quantifying a site's ligandability. There has also been interest in the identification and characterization of allosteric and/or cryptic sites[67]; these may not be visible in the crystal structure, particularly of the apo protein, but are revealed

following conformational change. In all cases, it should be borne in mind that to have any useful (i.e., disease modifying) effect a ligand must do more than bind to the target protein; the binding event must also result in relevant functional consequences.

3.07.2.4 Synthetic Biology and Synthetic Biochemistry

Synthetic biology seeks to design and create new and artificial biological systems with a particular emphasis on the use of engineering principles. It covers an extremely wide range of opportunities and potential applications.[68–70] One application of practical relevance from the perspective of the medicinal chemist is the prospect of using engineered enzymes to catalyze chemical reactions. These may be reactions that are difficult to achieve using traditional organic synthetic methods (for example because the reactants are sensitive to the conditions employed) or may be very costly (due to the use of expensive catalysts or at an industrial level because of poor yields). A more general driver for the use of synthetic biochemistry is the desire to adopt a "green agenda" with the goals of reducing waste and energy.

The advantages of enzymes for catalysis are well known and include the following: (1) the reactions can be performed at ambient temperatures and pressures, (2) reactions can be performed using water as a solvent, and (3) no need for expensive, rare, and potentially toxic metal catalysts. However, many naturally occurring enzymes have limited substrate specificity and may therefore not be suitable for the specific transformation of interest. It may also be desired to enhance the properties of a naturally occurring enzyme such as the need for greater stability or specificity. To engineer a modified enzyme invariably requires amino acid changes to be incorporated into the protein sequence. There are a number of strategies and approaches that can be used to tackle this problem.[71–74] Structural information about the enzyme can be used with knowledge about the enzymatic reaction to suggest suitable modifications. Such structural information can be derived from experiment or a protein modeling approach, though the complexities of enzyme reactions and the modeling thereof may require a very accurate model for any computational work to be successful.

3.07.2.5 Modeling Guiding Experiment: Construct Design and Side-Directed Mutagenesis

A common theme through the history of protein modeling (as indeed is the case in many areas of science) has been the tight interaction and interplay between theory and experiment. In the earliest days, the information flow tended to be in one direction, from experiment to theory, as the modeling community developed new techniques for evaluation against experiment or extracted rules and knowledge from the databases of experimental protein structures. However, the methods and results from protein modeling are increasingly of value when designing better and more effective experiments. Two areas where this interplay can be particularly fruitful are in the design of constructs for X-ray crystallography and to guide side-directed mutagenesis experiments. In construct design, models can provide useful information where one or more domains need to be excised from a larger multidomain protein. Models can help to determine the minimum length of the construct and for the visualization of features such as exposed hydrophobic patches that may compromise protein expression and production. They can be useful in designing mutations to alter protein properties such as oligomerization. Models can also be used to identify and characterize ligand binding sites and then to identify residues within those sites that upon mutation should alter ligand affinity. Matching mutation and SAR data can provide confidence in a model and the ligand binding modes, which in turn can facilitate ligand design.

3.07.2.6 The Design of New Protein Therapeutics

Protein therapeutics broadly covers two areas: antibodies and vaccines. Therapeutic antibodies provide an alternative to traditional small molecules; following direct administration the antibody interacts with the biological target to produce the desired therapeutic response. Vaccines by contrast involve administration of the antigen (e.g., an inactivated virus or a recombinant protein subunit) which stimulates the body's immune response to provide long-term protection from the pathogen.

The numbers and commercial value of new therapeutic antibodies have grown dramatically since the first product came to market in 1986 with more than 50 products approved and many more in clinical development.[75,76] Antibodies have been the topic of protein modeling studies[77,78]; their structures follow a well-understood set of rules that were devised following the earliest crystallographic studies in the 1980s, as we shall discuss briefly later in this chapter.

The development of vaccines is considered one of the most significant developments in the history of human health, with the potential in some cases to completely eradicate major diseases. Nevertheless, there remain many conditions that have hitherto proved intractable to current vaccine approaches or where there is room for improvement. In recent years the opportunity to use protein structural information and knowledge in vaccine design has been recognized,[79,80] with a particular focus on engineering modified antigens that have the potential to elicit a much stronger immune response. One rationale for this approach is that most current vaccine antigens are derived from the natural pathogen which have evolved to evade rather than induce immunity. Knowledge of antigen 3D structures and in particular the potential recognition motifs enables the design of modified antigens with improved properties such as stability and ease of production, and enhanced immunological performance. One example that illustrates this strategy is the development of a single factor H-binding protein antigen from meningitis B.[81] This particular protein has over 500 sequence variants that fall into three groups. An effective vaccine requires antigens specific for all three variants to be included, making the manufacturing process complex and expensive. Having solved the X-ray structure of H-binding protein, the epitopes for each of the three variants were mapped onto the 3D surface. These in turn resulted in a set of protein designs for

further evaluation, which ultimately provided a single protein molecule able to induce immunity against all antigenic variants. In this particular case it proved important to take account of the entire protein surface, rather than just a small number of isolated amino acid changes. The use of structural biology and protein modeling techniques in vaccine design is still relatively new but we can anticipate significant advances in the future.

3.07.2.7 Predicting Protein Function

The landmark publication in 2001 of the sequence of the human genome has in the subsequent few years led to an explosion in the amount of sequence data. The genomes of many thousands of organisms have now been determined and the numbers continue to grow rapidly. From the DNA sequence it is then possible to determine the set of proteins believed to be expressed by that organism (i.e., its proteome). Elucidating the functions of these proteins is a key precursor to improved understanding at the molecular, cellular, organ, and organism levels which in turn may lead *inter alia* to the identification of potential targets for drug discovery. However, experimental determination of protein function is a time-consuming process, providing a clear driver for the use of predictive computational techniques. The development, validation, and application of such computational methods is an active area of research. Many approaches are based on the use of protein sequence information alone, on the basis that proteins with similar sequences possess similar functions. Other methods however make use of 3D structural information, given the higher degree of evolutionary conservation of protein structure when compared to sequence. Some of the early genome-scale annotation experiments helped drive the development of automated workflows that enabled the processing of thousands of protein sequences and the development of databases for depositing protein models for wider community access.[82–86] When a structure is available a more recent development has been to use this in conjunction with virtual screening, to identify potential ligands and substrates that may in turn suggest possible function. A nice example of this approach is described by the Enzyme Function Initiative,[87] a consortium that seeks to assign functions to enzymes from bacterial genomes using a combination of both experimental and computational methodologies (it should be noted that of the approximately 45,000 proteomes currently available more than 40,000 are bacterial in origin, with just under 1000 eukaryotes and just over 3000 viruses). In a specific example, a series of 3D protein models were constructed for an amidohydrolase from a newly sequenced bacterium (Agrobacterium radiobacter K84) and used in docking experiments against a library of more than 57,000 high energy intermediate forms of 6440 metabolites. The hit lists from the docking experiments were observed to contain multiple pterin-containing molecules. This provided the impetus for a series of experiments that confirmed this molecular class as deaminase substrates for this particular enzyme.[88]

3.07.3 How Are Protein Models Built?

To the non-expert, there is a bewildering range of software and algorithms for building protein models and an extensive and growing literature. Given the visibility and importance of the protein folding problem and the new opportunities afforded by the data explosion in biology it is also unsurprising that the field continues to be very active. Broadly speaking, the methods for building protein models fall into two categories. As we have already indicated, *comparative modeling* methods (also referred to as *homology modeling* methods) rely upon sequence analysis methods to detect at least one related (i.e., homologous) protein of known structure that provides a starting point (i.e., a *template*) for building a 3D model of the unknown protein. By contrast, the second category of methods (variously referred to as nontemplate, ab initio, or new fold methods) do not explicitly rely upon the known structure of a related protein but construct the model "from scratch."[89,90] As such, ab initio methods are in principle more generally applicable. However, the ab initio prediction of whole protein structures purely from first principles is an exceedingly challenging problem. The most physically realistic approach to this problem involves the use of computer simulation techniques (typically molecular dynamics simulations) to fold an extended polypeptide chain into the native protein conformation in an effort to replicate as closely as possible the "real" folding event. However, the enormous computational demands of these calculations, particularly if performed using a full atomic representation including solvent, has limited their current applicability to small proteins. Developments in computer hardware and more efficient simulation methods have in recent years enabled more systems to be studied with some promising results, though for practical purposes this approach is currently a largely academic pursuit.[91,92] One particular advantage of the explicit simulation approach is the detailed insights provided into the actual dynamics and mechanisms of protein folding; this can lead to some particularly fruitful synergies with relevant experimental methods. Given these computational challenges and in order to make the problem of ab initio protein folding more tractable, simpler representations of protein structure and energetics have also been developed. Lattice models are a good example of such simpler representations that have provided significant insights into the protein folding problem and have also inspired much method development.[93] Currently, some of the most successful and practical approaches to ab initio structure generation are based around the use of fragments taken from known protein structures. These fragments are then built up into the structure of the target protein, guided by an appropriate energy function.[94] Notwithstanding the many contributions that ab initio methods have made to the protein structure prediction field, from a practical and contemporary drug discovery perspective, such approaches are not generally applicable to a sufficiently wide range of proteins of pharmaceutical interest nor can they yet routinely provide structures of sufficient accuracy for most applications.

From the practical drug discovery perspective, that is the focus of this chapter, the models most likely to be of practical utility are still overwhelmingly built using comparative modeling. There are a number of reasons for this, as we have already alluded. The most

important reason is that, as we have seen, there are now many more protein folds available from experimental studies, making it much more likely that a reasonable template can be found from the Protein Data Bank. Second, drug discovery often focuses on families of related proteins. Familiar examples are kinases, G protein-coupled receptors, proteases, and more recently the various epigenetic proteins such as the bromodomains. The growth of knowledge on a particular family often has a leveraging or catalytic effect, by providing essential "know how" to facilitate subsequent experimental studies and also in providing the knowledge base so essential for computational approaches such as protein modeling. There has in particular been considerable excitement at recent progress determining structures of GPCRs and other integral membrane proteins, discussed elsewhere in this volume. Third, the development of enhanced methods and algorithms and more accessible user interfaces have driven many aspects of comparative modeling, as we will now discuss.

There are three general stages involved in building a comparative model. The first stage involves sequence and structural analysis to identify homologous proteins of known structure that will provide the 3D template(s) upon which the model of the target protein will be constructed. The output of this first step is an alignment of the target sequence to these known structure(s). It has been shown many times that getting this alignment correct is critical for building an accurate model. The second stage involves the actual construction and refinement of the model, based upon this alignment, to give a set of 3D coordinates for the target. The final stage is the validation and evaluation of the model including an assessment of which regions are likely to be predicted with higher confidence.

3.07.3.1 Sequence and Structural Analysis

Where there is detectable homology between two or more protein sequences it can be inferred that these sequences will share the same protein fold. The converse, however, is not true—proteins with the same fold do not always show detectable homology between their amino acid sequences. This then is the first, and often the most important, challenge in comparative modeling—how to unambiguously assign the sequence of the unknown target protein to a fold family. This in turn allows one or more template structures to be identified upon which the physical model can be built. Here, identifying the best alignment between the target protein and a template is key to constructing the most accurate comparative model possible. If the alignment is incorrect then the model will have significant local or global errors depending on the location and type of errors in the alignment. That said, it is important to understand that meaningful alignments in poorly conserved regions of sequences and structures may be difficult or impossible to achieve. In such circumstances, and if these regions are of interest, then it may be possible to generate multiple models for assessment against relevant experimental data where available. Unsurprisingly, it is generally the case that a comparative model-built on a closely related template structure is more likely to be more accurate (all things being equal) than one built on a remote homologue. This relationship between sequence and structural similarity is also shown by the experimental data; as the similarity between two sequences decreases the RMSD between their experimental structures tends to increase, as shown in Fig. 6.[17] More recent studies have probed further this relationship in the context of the type of protein structure and in particular its secondary structural elements.[95]

3.07.3.1.1 Fold identification: Identifying homologues of known structure

The simplest method for finding one or more potential structural homologues of the unknown target protein is to use its amino acid sequence as a query to search the amino acid sequences of known experimental structures from the Protein Data Bank (and

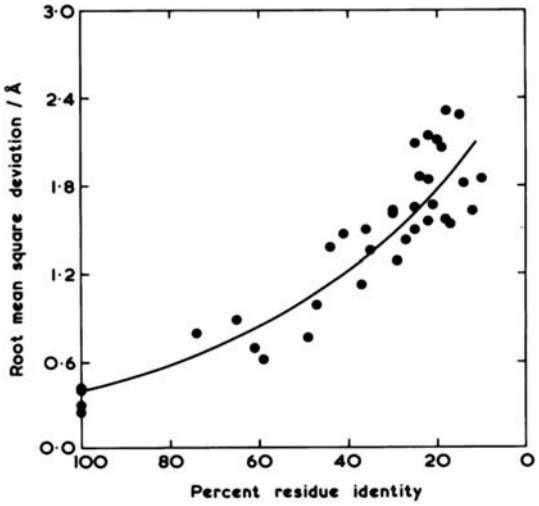

Fig. 6 Relationship between sequence similarity (given by the percentage sequence identity, see text for definition) and RMSD over C alpha atoms. From Chothia, C.; Lesk, A. M. The Relation Between the Divergence of Sequence and Structure in Proteins. EMBO J. **1986**, *5* (4), 823–826.

proprietary structures where available) using a *sequence to sequence matching algorithm*. These methods compare the query sequence of the target protein to each of the entries in a sequence database in order to identify the "best" matches, as determined by a scoring scheme. The score should allow a user to determine if the alignment is significant or not. The simplest and most easily understood metric used to report the degree of similarity between two aligned sequences is the *percentage sequence identity*. This gives the proportion of amino acids that are identical when the two sequences are matched. A simple example of two aligned sequences is shown in Fig. 7. This example also illustrates that to achieve the best alignment it is usually necessary for amino acids to be inserted or deleted in one or other sequence (often referred to as *gaps*).

Many computational algorithms have been devised to achieve the "best" alignment between two sequences. A detailed description of these methods is beyond our scope,[96] but there are some key features common to most of these procedures that it is useful to be aware of as they can impact and influence the results obtained. The comparison of two sequences is usually achieved using a matrix in which each element has a score for the similarity of the corresponding pair of amino acids, one from each sequence. Visual inspection of such a matrix reveals for two related sequences high-scoring diagonals which are the regions where the sequences are aligned. Breaks in the diagonals correspond to gaps where amino acids are inserted or deleted, as illustrated in Fig. 7.

The scores used for the amino acid pairs reflect the probability that one amino acid can be replaced by another. These propensities are typically represented as 20×20 substitution matrices, an example being shown in Fig. 7 for the widely used BLOSUM62 matrix.[97] The values in this matrix are determined from an analysis of alignments of conserved regions in known proteins, with a positive number in the substitution matrix meaning that there is a higher probability of that particular amino acid change occurring randomly and a negative number implying a lower probability. The substitution matrix, when combined with a *gap penalty* for insertions and deletions, enables different alignments to be scored in order to find the "best" match.

Some sequence matching methods guarantee to identify the optimal or best-scoring alignment, given a particular substitution matrix and gap penalty. The most common methods in this category use a technique called *dynamic programming*.[98,99] These are the methods of choice to derive the definitive alignment prior to the model building phase, but they are in general too slow for searching the very large sequence databases currently available. This led to the development of *heuristic methods* for sequence matching. These methods do not guarantee to find the globally optimal solution. However, in practice they rarely miss an important match and are sufficiently fast in execution to enable large database searching. The heuristic methods achieve their improvements in speed by identifying small high-scoring lengths of sequence matches which are then extended locally to generate a longer alignment. The best-known heuristic methods are BLAST[100] and FASTA[101,102]; the former in particular in its PSI-BLAST variant is probably the most widely used tool for searching sequence databases.

When the percent sequence identity is above 30–40%, the most commonly used sequence-to-sequence alignment algorithms are usually able to identify the most appropriate match or matches from the sequence database. More advanced metrics, such as E values that indicate the number of hits one would expect to see by chance when searching a database of a particular size, can in some cases help resolve the significance of matches below this threshold. Unfortunately, when the percent identity is low, the

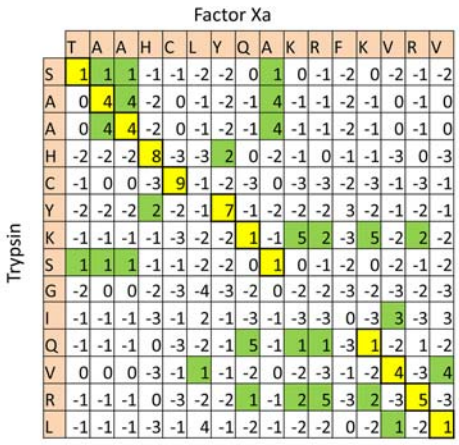

Fig. 7 Illustration of alignment algorithm operation using partial thrombin and trypsin sequences. A scoring matrix such as BLOSUM62 determines the score for each pair of amino acids. High-scoring diagonals (in *yellow*) indicate regions of aligned sequences. The alignment obtained from a sequence comparison is shown together with the corresponding alignment derived from overlaying the two structures in 3D space. As can be seen, there are some differences between the alignments obtained from the two methods, particularly in regions of insertion and deletion.

true hits may lie among other false positive matches and further work to confirm the significance of the match will be required. The phrase "twilight zone"[103] was introduced to refer to those situations where the percent sequence identity is less than around 30%, to indicate the challenges associated with identifying the correct fold (a sequence identity less than 10% is sometimes further described as the "midnight zone"). Alternative methodologies have been developed to address this sensitivity issue in order to identify positive matches, even at low levels of percentage sequence identity.

When comparing just two sequences it is possible that some misleading chance correspondence may occur. This can be in part addressed using a *multiple sequence alignment*, by enabling consensus features and trends to be detected with greater confidence across a whole family of related proteins. The most common way to construct a multiple alignment is by a *progressive alignment method*.[104,105] Here, the first step is a pairwise comparison of all of the sequences to be aligned. This enables a tree to be constructed that defines the relationships of the sequences to one another and can be used to iteratively construct the multiple alignment, starting with the most similar pair. Each step involves combining two sequences, a sequence to an alignment or two alignments, as illustrated in Fig. 8.

Accounting for the variation which occurs across the family provides a way to achieve greater search sensitivity during the fold recognition step. Position-specific scoring matrices (PSSMs)[106] and Hidden Markov Models (HMMs)[107–109] use *sequence profiles* that intrinsically capture the allowed amino acid variance at each position within the family and can be derived from a multiple sequence alignment. A target sequence can be searched against a database of precompiled profiles for known protein families, or conversely a profile can be used to search for new matching sequences. Where a sequence is used to search a database of profiles it may not be immediately clear whether a match to a profile includes a match to a known structure. However, databases such as PFAM[110] include links between profiles and structural information; it is then straightforward to determine if 3D structures are known for members of the family when a significant match is identified. The widely used PSI-BLAST method[111] uses an iterative approach involving multiple applications of the basic BLAST algorithm. The significant matches found at each iteration are used to calculate a position-sensitive score matrix for use in the next iteration, a process that continues until no new sequences are added.

Yet more sensitivity than the sequence-to-profile methods can be obtained by comparing profiles to profiles or HMMs to HMMs.[112,113] A profile or HMM is constructed for the target sequence by finding significant homologues, creating a multiple alignment and then deriving the profile from that alignment. This target profile is then searched against a database of profiles or HMMs as appropriate to determine significant matches. These methods further improve the detection of remote homologues.

The final fold identification method we will discuss is *threading*. Here, a target sequence is fitted to a library of protein folds. A key feature of threading is that 3D information is taken into account during the analysis. This comparison may be achieved by comparing the target sequence to a profile for each fold that includes information derived from the 3D nature of the fold such as secondary structure type and residue burial/exposure. Alternatively, the target sequence can be fitted (or threaded, hence the name) onto the 3D fold itself and an energy function used to score the fit of the sequence to the fold.[114] The fold or folds with the lowest energy value(s) then become potential candidates for that particular target sequence. Threading methods may be combined to obtain the best consensus result as used by the LOMETS methodology in the I-TASSER suite.[115]

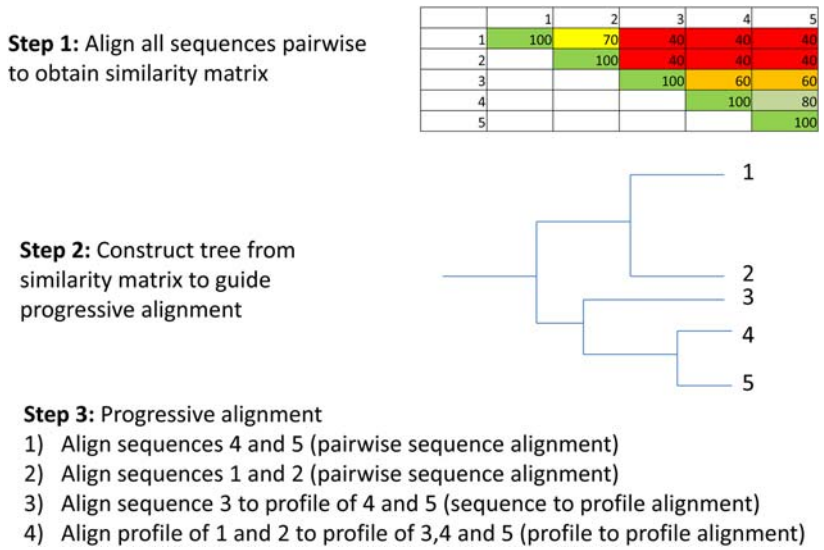

Fig. 8 Steps involved in creating a multiple sequence alignment using a progressive alignment method in which sequences are iteratively added to build upon the final result.

3.07.3.1.2 Generating the critical sequence-structure alignment

The methods used for fold identification will often provide the detailed set of amino acid matches between the target and any potential template(s). As we have indicated, alignments from sequence-to-profile and profile-to-profile searches in general would be expected to be better starting points than those from sequence-to-sequence searches since these also include information from the alignment of family members. It is always a good investment to construct a multiple alignment of the target and its significantly related sequences and the template(s) and its/their related sequences and structures. Many alignment programs are available, but for the purposes of comparative modeling and particularly for drug discovery applications the best tools are often those that allow manual editing of an alignment and visualization of structures in the alignment, or at the very least key structural features such as the location of secondary structural elements. Inspection of the alignment and known structures can uncover features which might indicate alterations in secondary structures such as a local disruption to a helix which may not be present in the potential template structures. Where there is a choice of template structures such visualization capabilities may suggest that one template is a better choice than another even if the homology appears lower.

The finished alignment will generally show two types of regions (Fig. 9). The first of these are blocks of the alignment where there are no insertions and deletions, relatively high conservation between all the sequences and structures used in the alignment and where the local RMSD between the overlaid template structures is low. These are the *structurally conserved regions* (SCRs) that lie at the heart of the comparative model. The SCRs taken from the template structure(s) provide the starting point for modeling the target. By contrast, the second type of region is characterized by insertions or deletions between sequences and/or where the overlaid structures show a high local RMSD. These regions are frequently referred to as *loops* or *structurally variable regions* (SVRs). As we will discuss in the next section, loops are often treated differently during the actual model building process.

3.07.3.2 Building and Refining the Model

The earliest published methods for constructing 3D comparative models broke the problem down into the following distinct steps: (1) construction of the backbone for the core conserved regions, (2) loop modeling, (3) adding side chains, and (4) refinement. This sequential workflow is still commonly encountered; it also provides opportunities for the user to intervene at each point in order to adjust the evolving model if appropriate. Indeed, many of the most widely used software packages provide the user with significant

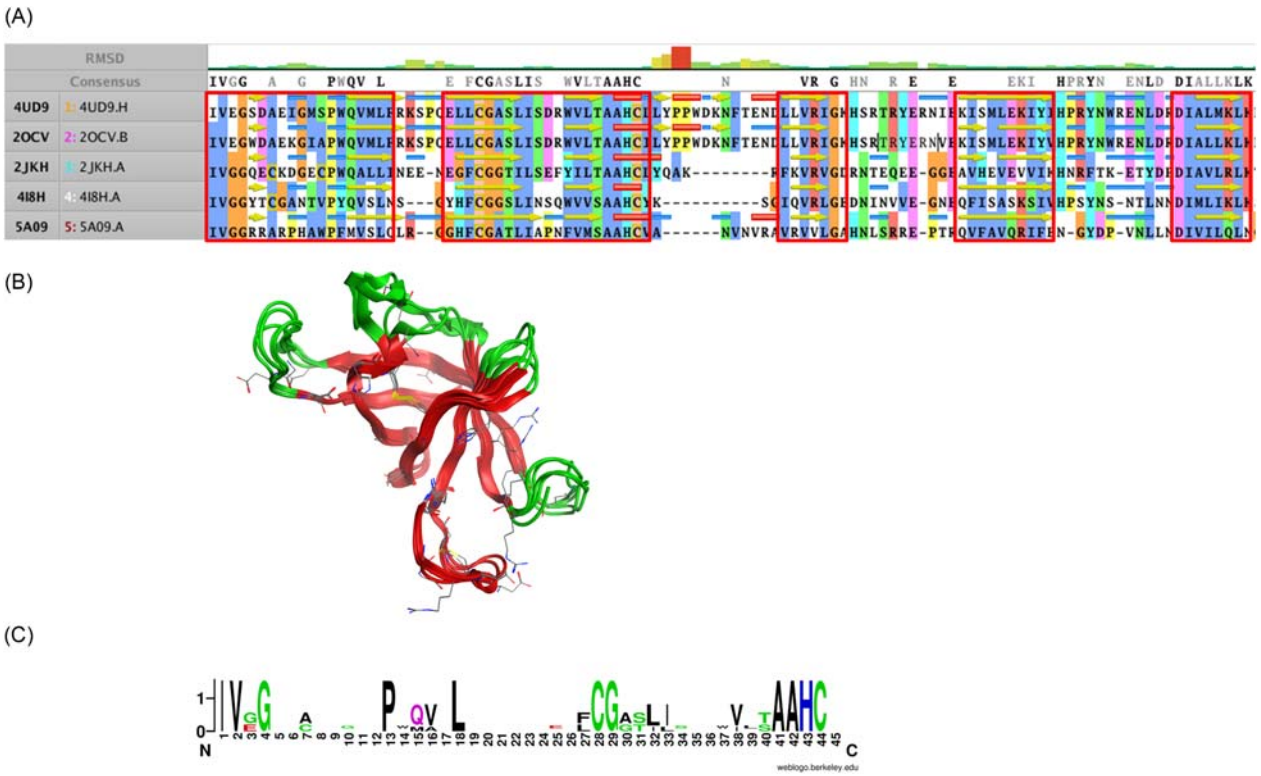

Fig. 9 (A) Section of an alignment of human thrombin (PDB code 4UD9), mouse thrombin (2OCV), Factor Xa (2JKH), bovine trypsin (4I8H), and human neutrophil elastase (5A09) with conserved blocks (*red boxes*) and variable regions (*no box*). Figure created using MOE.[116] (B) set of partial structures with SCRs (*red ribbon*) and loops (*green ribbon*) marked. (C) Weblogo[117] representation of part of the alignment which highlights regions of the sequence where there is absolute conservation, conservative substitution, and no conservation. This type of representation can be thought of as a form of visual profile for the alignment.

flexibility, for example providing direct programmatic access to specific components such as loop modeling or to enable bespoke workflows to be constructed for specific problems. In practice, many drug discovery applications of protein modeling employ a mix of automated, semiautomated, and hands-on modeling techniques, though the development of automated web servers and workflows that can take a protein sequence and produce a 3D model have provided access to a much larger user base. First we will outline the three types of methods used to construct the conserved regions and then discuss loop modeling, side chain addition, and model refinement.

3.07.3.2.1 Model building directly from template structures

One of the very earliest examples of comparative modeling serves to illustrate the basic principles involved when building models directly from the template structures. In 1981 Greer published a sequence and structure analysis of the mammalian serine proteases,[118] at a time when just three structures had been determined experimentally (those of chymotrypsin, trypsin, and elastase). This analysis then formed the basis for a model of the blood clotting protein factor Xa.[119] First, the three experimental structures were superimposed in 3D space. This enabled those regions where there was clear structural conservation to be determined based on the RMSD of Cα atoms in the superposed structures. The location of these conserved structural regions was then mapped onto the corresponding multiple sequence alignment. An additional eight mammalian serine proteases, whose structures were then not available, were then incorporated into the sequence alignment as a means of obtaining the best alignment between factor Xa and the known structures. As discussed earlier the complete alignment allowed the regions corresponding to the SCRs to be identified. The model of factor Xa was constructed by first assigning coordinates for the backbone atoms in the SCRs, taken in this case from the corresponding atoms in the elastase structure. Coordinates for the amino acid side chains in these conserved regions were also assigned where a match could be found from one of the known experimental structures. The variable regions were constructed by identifying which of the experimentally determined structures had a sequence of the same length and transferring those coordinates. This enabled 9 out of 12 variable regions to be constructed. The remaining three variable regions were not included in the reported model; as these loops were distant from the active site it was not considered essential for them to be physically constructed.

While such a model building exercise might be considered trivial today (and in contrast to the largely hands-on approach used by Greer would likely be performed using much more automated tools) nevertheless this early study captures many of the key components of comparative modeling. In particular, the importance of getting the alignment as accurate as possible, of building first those parts of the model where one has the greatest confidence and then continuing to those parts that are less well defined and being mindful of the question(s) the model will be used to answer. Note also the use of multiple experimental structures to build the model of the unknown target protein, with different parts of the model being derived from different experimental structures according to their similarity. There are now many experimental structures of factor Xa and the other mammalian serine proteases that confirm the high degree of structural similarity between the members of this family. Nevertheless, even today there are some protein families of intense biological and pharmacological interest where our structural knowledge does not necessarily extend to every family member. The protein kinases are generally accepted to fall into this category; these also present some additional modeling challenges due to the conformational changes that accompany phosphorylation/dephosphorylation of the activation loop. One example that illustrates the utility of even a straightforward modeling study is provided by Nichols et al.[120] who constructed a model of the LRRK2 kinase domain as part of a wider series of investigations into this Parkinson's disease-related protein. In this case the LRRK2 homology model was built using a single homologous protein kinase, ROCK1. This protein was chosen as the template due to the similar activity profiles of some inhibitors against both ROCK1 and LRRK2. This example also nicely illustrates that the template should be selected bearing in mind how the model will be used. In this case the focus was on ligand binding and design, and so a protein that also binds the same series of ligands is a good choice, even if there were other proteins that might have a higher overall degree of sequence identity. A comparison of key active site residues not only for the LRRK2 and ROCK1 wild-type proteins but also for LRRK2 mutants and other kinases such as protein kinase A provided further confidence in the model when assessed against compound SARs.

3.07.3.2.2 Segment matching

The very earliest protein structures revealed that a significant proportion of the overall conformation was constructed from common 3D structural features such as the well-known elements of secondary structure as well as features such as β-turn motifs. It was subsequently discovered, initially by Jones and Thirup,[121] that there were many more examples of common local structure beyond these established structural elements. This observation was put to practical use in their program Frodo, at the time widely used by protein crystallographers for building 3D models into electron density maps. The program would search a database of peptide fragments (typically containing 5–7 amino acids) that had been extracted from known protein structures, in order to find the best match for a particular stretch of electron density. This work not only had immediate practical application in protein crystallography but also acted as a catalyst for the development of some of the most successful methodologies in protein modeling.

Most practical implementations of segment matching define a set of non-redundant fragment structures extracted from an analysis over the whole PDB, with an emphasis on fragments from structures of the highest resolution. The use of a non-redundant set minimizes the numbers of fragments that need to be stored and searched while still ensuring appropriate coverage of the conformational space. One of the earliest of the segment matching algorithms was the work of Levitt[122] who developed a program based on this approach that automatically constructs a detailed 3D protein model by combining such fragments (also known as segments, hence the name) onto an initial alpha carbon backbone structure derived for example from the structure of a template protein. The

use of such fragments is also central to the widely used Rosetta suite[123–125] that has found particular application in ab initio structure prediction where fragments are built up from scratch. The group subsequently introduced the RosettaCM algorithm[126] (CM stands for comparative modeling) which aims to combine the advantages of the template-based approach with the complementary benefits of the fragment and torsional modification algorithms in Rosetta. The latter provide a way to deal with unknown parts of the structure and to explore conformational space. Such an approach is a good illustration of how current methodologies will often seek to combine a variety of different approaches in order to benefit from the advantages of each, a strategy that at least in the case of RosettaCM delivered more accurate models than alternative approaches.

3.07.3.2.3 Modeling using spatial restraints

The basis of the spatial restraint method is that a protein's 3D structure can be determined by first defining and then satisfying a set of geometric conditions. The MODELLER program is the best-known example of this approach.[127–129] In MODELLER the restraints are expressed as *probability density functions* (pdfs). The pdfs provide a general way to capture the preferred distributions of various types of geometric features in proteins. Some of these features such as bond lengths and bond angles are straightforward and can be taken from tables of standard geometries. Other features are derived by analyzing known protein structures[130] and in particular by examining specific information in the template proteins. For example, the distances between alpha carbon atoms in pairs of residues along the sequence can provide long-range information that is characteristic of the overall fold. The nature of the pdf specifies how closely a particular distance in the target protein structure needs to match the corresponding (known) distance in the template. In turn this depends on a number of parameters, derived from an analysis of known protein structures. For example, it is observed that the distances between corresponding pairs of amino acids in highly homologous structures tend to be close when their sequences are very similar and the amino acids are buried in the core of the protein. By contrast, if the sequences have a lower percent identity and/or the amino acids are solvent exposed then the corresponding distances are observed to deviate more. These two situations would be represented by the Gaussian probability distribution functions shown in Fig. 10; the more sharply peaked pdf means that the particular distance in the calculated model should be very close to the corresponding value in the template whereas the broader pdf will permit more latitude in the range of distances. For a typical protein, many thousands of such restraints can be defined. Starting from an initial arbitrary 3D conformation of the protein an optimization procedure is then used to derive a 3D structure that best satisfies the combined restraints. By providing the optimization process with different starting conformations (derived for example by adding a random amount to the initial coordinates derived from the template(s) structure(s)) it is possible to derive a number of solutions, from which the best may be selected for visual inspection or further refinement. The methodology is very general and can be used to model complete or partial protein structures and is also able to incorporate many types of experimental data, where these are also converted into appropriate pdf.

3.07.3.3 Loop Modeling

Loops can be important for determining a protein's specificity and function and in differentiating between the various members of a particular fold family. A good example is provided by the so-called ECL2 (extra-cellular loop 2) that links helices 4 and 5 in G protein-coupled receptors.[131] This loop has historically presented a particular challenge for protein modeling due (A) to its role in binding site formation as it often folds deep into the *trans*-membrane core (Fig. 11) and (B) the wide variability in both length and sequence composition. In other systems, loops might be considered less important from a modeling perspective. For example, the loop may be far from the active site or not relevant to the question being asked of the model. Further, some loops are clearly very dynamic with no real structure. In such cases there may be little value in expending a lot of time and energy trying to define an accurate conformation of the loop.

Where there is a high degree of overall sequence identity between the target protein and others from the fold family it may be possible to extract a viable conformation of the loop directly from a known structural homologue. As we have seen, this was the case

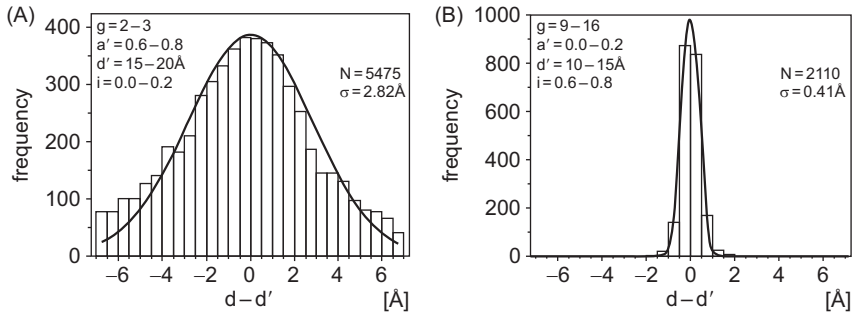

Fig. 10 Showing probability density functions (pdfs) for Cα-Cα distances. (A) The pdf where the residues have high solvent accessibility and there is overall low sequence identity shows a broad distribution of permitted distances. (B) The pdf for buried residues with high sequence identity is much more sharply peaked. From Sali, A.; Blundell, T.L. Comparative Protein Modelling by Satisfaction of Spatial Restraints. J. Mol. Biol. **1993**, *234* (3), 779–815.

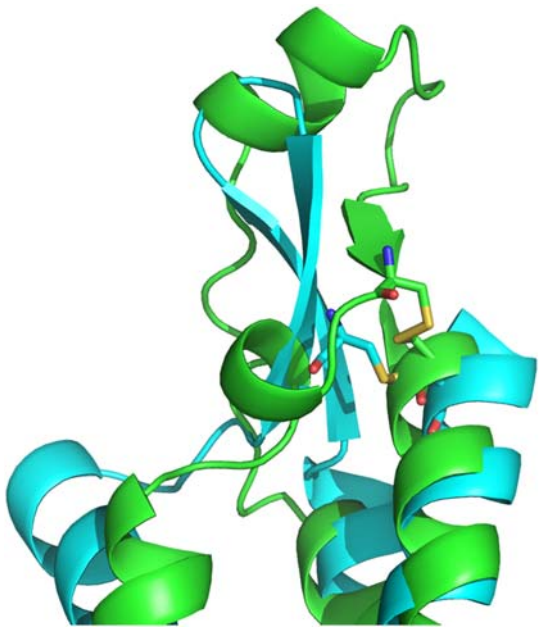

Fig. 11 Showing the different conformations for the ECL2 loop in the mu opioid receptor (PDB code 5CIM, *cyan*) and the adenosine A2A receptor (2YDV, *green*). ECL2 adopts a beta hairpin-like structure in the mu receptor; in the A2A receptor the loop contains alpha helices but is overall less structured. Protein structure images created using the PyMOL Molecular graphics system, Version 1.7.6.6 Schrodinger LLC.

for the early modeling studies on the mammalian serine proteases. However, the addition or deletion of just one amino acid can have a significant impact on the overall conformation of a loop. Moreover, stretches of amino acids can adopt different conformations in different proteins.[132] These features can make loop modeling a challenging problem and there has been a significant effort on the development of relevant techniques.

An obvious practical factor to consider when modeling loops is that they are constrained in space, not only because they need to fit with the leading and following SCRs of the model but also because they need to fit within the bulk of the remainder of the protein. Two general approaches to loop modeling have been developed by the protein modeling community. The first makes use of a database of loop conformations, extracted from known protein structures. For a given loop the database is searched to identify potential conformations of the required sequence length, where there is a geometric match to the ends of the leading and trailing conserved regions and reasonable steric complementarity with the rest of the model. Depending on the number of potential matches the putative loop conformations may be assessed according to these criteria together with others such as the degree of sequence homology or positions of residues such as proline or glycine that have particular influences on backbone conformation. If there are many possibilities for the loop conformation it may be productive to cluster the options into structural families. The highest ranked suggestions are then subjected to further refinement to optimize their conformation. The database approach can work very well where the loop would be expected to adopt a common and well-defined conformation such as a beta turn, for which there are many examples in the PDB. The approach works less well as the size of the loop grows and for which there are fewer examples in known structures.

The alternative to the database approach is to generate conformation(s) of the loop ab initio. The loop modeling problem then reduces to a constrained conformational search of the relevant polypeptide sequence, with the goal being to find one or more low-energy conformations that also satisfy the geometric and spatial requirements imposed by the ends of the conserved regions and the rest of the protein. Just as there are many algorithms for small molecule conformational analysis, so there are many methods in the literature for the ab initio prediction of loop structures. These methods can be characterized by the algorithm used to search the conformational space (examples include systematic and random search approaches, molecular dynamics, and using known torsion distributions from crystal structures) and the method used to characterize the energy of each conformation. The earliest attempts to tackle this problem were limited in particular by the then available computational performance; as computational power has increased it has been possible to introduce more refined conformational search protocols (e.g., that use a finer search grid for a systematic search or more iterations when using a random search or Monte Carlo method) and more complex and detailed energy assessment and optimization schemes. By way of illustration of a contemporary approach, the loop modeling method of Jacobson and colleagues[133] combines a number of such ideas. It first generates a set of initial structures using a hierarchical method for efficiently building up loops in torsion angle space. These initial structures are then clustered to remove duplicates and to select the best candidates for progression. Side chains are added and then each is energy minimized using an energy function with the important inclusion of a solvation contribution.

One final cautionary point applies to those algorithms that add loops one by one to an evolving model. In this case there may be an order dependence in the final results. Thus, the first loop to be added is not influenced by those yet to be built but as more and more loops are added the constraints on those that are unbuilt may increase and consign the last loops to be added to regions of space that they may not naturally explore.

Antibody proteins are a good example where loop modeling plays a particularly crucial role. The familiar "Y" structure of an antibody comprises two Fab antigen-binding regions and the tail Fc region. Each Fab fragment in turn consists of a core region onto which are grafted six so-called Complementarity Determining Regions(CDRs). A large number of Fab fragment structures are known. The SAbDab database[134] has 2553 antibody entries as of November 2016. This means that a suitable structural framework for the core region of a Fab fragment is likely to be available; it is important to carefully choose a pairing of the constituent light and heavy domains in the correct orientation since the antigen-binding site is formed at the interface of these two regions.[135,136] Antibody CDRs also represent a special case for loop modeling. Chothia and Lesk observed[137] that five of the six CDRs in a Fab fragment had a small repertoire of structures dictated by length and the presence of key amino acids, a finding further investigated by others.[138] The exception is CDR H3. These observations simplify the problem of building models for antibodies; from the antibody sequence it is possible to predict which of the canonical forms of five of the CDRs will be present and so select a template structure for the loop appropriately. The main challenge in modeling antibodies is then to obtain a good model for CDR H3 which is important as this loop is often involved in binding interactions with the antigen. Many homology modeling programs have separate antibody modeling modules and in recent years the antibody modeling assessment (AMA) competition has assessed the performance of programs in this particular branch of homology modeling.[139]

3.07.3.4 Side Chain Assignment

The assignment of side chain conformations is a common requirement in many protein modeling methods. Even when there is a high degree of sequence identity between the target protein and its structural homologue(s), there will invariably be some positions where the amino acids differ and so minimally these will need to be assigned.

When the conformations of amino acid side chains in experimentally determined structures are analyzed it is observed that they tend to adopt distinct families of conformations, often referred to as *rotamers*.[140] This observation is often exploited in the methods used to assign side chain conformations for protein modeling, by limiting the conformations permitted to a given side chain to those from a predefined rotamer library. It has further been shown that side chain conformations can also be dependent upon the local backbone structure, an observation exploited in backbone-dependent rotamer libraries[141,142] which further limits the available options for a given side chain.

In the most straightforward cases where there is a high degree of sequence identity between the target protein and one or more known experimental structures it may be possible to assign many of the side chains directly from the structure of the homologous protein(s) or from a rotamer library. Indeed, a number of homology modeling tools assume that where a residue is identical between target and template, the rotameric state will also be identical. More generally, it will be necessary to take account of potential interactions between the side chains, as the conformation adopted by one side chain will influence and impact on the conformational space available to its neighbors. The requirement then is to search the space of potential side chain conformations in order to identify the "optimal" combination of side chains, often determined using an energy function. This is a challenging combinatorial search problem where the total number of potential solutions can be very large. Even for a small loop with a few amino acids there may be tens of thousands of potential combinations; for a whole protein the number can become astronomically large. Nevertheless, methods have been developed that can efficiently explore this space to identify optimal or near-optimal combinations of side chain conformations. One popular approach is to initially assign each of the side chains to a randomly selected rotamer from the library. The side chains are then taken in turn and its rotamers are explored to find the optimal conformation as assessed by the energy function, while keeping all other side chains fixed. This process is applied iteratively until no further changes in side chain conformation occur. Other methods aim to identify the globally optimal solution through the use of specialist graph searching methods. The widely used SCWRL series of programs[143,144] incorporate many features designed to make the calculation run as quickly as possible without sacrificing accuracy, including a highly refined backbone-dependent rotamer library, methods to quickly and efficiently determine whether the side chains of two amino acids are potential interaction partners, a bespoke energy function comprising attractive and repulsive nonbonded terms, and a hydrogen bonding term.

3.07.3.5 Structure Refinement Methods in Protein Modeling

The nature of the algorithms used by many protein modeling approaches means that the initial 3D model will often not be perfect. For example, there may be deviations from the preferred values of bond lengths and angles where a loop has been inserted into an existing template. There may be pairs of atoms closer than the preferred nonbonded distances due to the use of a side chain rotamer library. A simple goal of structure refinement is to "clean up" the initial structure to remove such deviations. A more general objective of the structure refinement step is to generate a final structure that better reflects the balance of interactions in the target sequence, when compared for example to the template structure(s) from which it was built. Structure refinement methods are often performed as the final step in building the model, but in some cases they may be incorporated iteratively into the actual model building process or applied to specific parts of the model such as the loops.

The simplest approach to structure refinement uses energy minimization with a standard protein molecular mechanics force field to drive the conformation to the nearest local energy minimum.[145] This approach is very accessible, being an integral part of most modeling packages with several widely used force fields that are tailored for protein applications. Another popular approach is to use molecular dynamics simulations.[146,147] These enable the structure to explore the conformational space more thoroughly in the vicinity of the initial model. Snapshots may be taken from along the molecular dynamics trajectory for subsequent energy minimization. The temperature of the simulation may be gradually decreased to give a *simulated annealing protocol*; the initial high temperature enables higher-energy barriers and a broader search of conformational space to be performed with a more localized search at lower temperatures.

When structure refinement methods were first incorporated into model building protocols it was often found that the "refined" model was further away from the experimentally determined structure than the initial unrefined structure. Put another way, the energy functions were unable to discriminate native from non-native conformations. Various strategies have been developed to try and address these shortcomings. These include the incorporation of additional terms into standard force fields (such as terms that better represent solvation effects) or to use additional terms that restrain the more highly conserved parts of a model close to their starting locations.

An alternative to using a traditional molecular mechanics force field in protein modeling calculations is to use a *statistical potential* (also known as knowledge-based potentials of mean force) as the energy function. Here, the various contributions are derived from an analysis of experimental structures.[148,149] The basic idea is that features such as torsion angle distributions, levels of solvent exposure, and (particularly) the pairwise distances between amino acids or their constituent atoms all contribute to the overall free energy of a given protein structure, and that the quantitative contribution from each of these features can be determined from an analysis of known experimental protein structures. There are many different functional forms and derivations for protein statistical potentials; to illustrate the concept we will outline the "low-resolution" energy function from the Rosetta suite.[124,150] Here, amino acid side chains are represented as single particles, located at the side chain center of mass. Contributions are included to represent solvation, electrostatics, hydrogen bonding, and steric clashes. As noted, the parameters for each of these terms are derived from a statistical analysis of protein structures in the PDB. For example, the electrostatic contribution due to a particular pair of amino acid residues corresponds to the probability that the centroids of those amino acids are observed at the specific distance separation in experimental structures. The function is designed to provide a smooth energy surface to enable larger-scale exploration of conformational space. As a consequence, structures close to the true global energy minimum have a low calculated energy even if they contain local defects that with a regular force field would result in a high energy. In addition, the smaller number of interaction centers enables the calculations to be performed much more rapidly and a more efficient search of conformational space. Rosetta also includes a complementary high-resolution energy function; this is designed for use in more detailed modeling and uses an all-atom representation of the protein. Not only is the functional form of the high-resolution energy function more akin to a traditional force field, but also some of the parameters are so derived, together with terms obtained from structural analysis. As the energy functions have improved, attention has focused on how thoroughly the conformational space is being explored; the Rosetta group for example have used their comprehensive Monte Carlo search methods to tackle the problem of crystal-structure refinement.[151,152]

3.07.3.6 Model Validation and Sources of Error

Errors can arise at the different stages involved in building a protein model. The purpose of *model validation* is to help identify potential errors and thereby provide information about which parts of a model are likely to be reliable and which parts should be treated with a degree of caution. This can be very important in guiding any subsequent design work or predictions that may be based on the model. Some of the more common sources of error are:

Alignment errors, which may be local (i.e., may only affect a small number of residues) or global. These errors will result in residues being incorrectly located in the model. Some of these may be straightforward to identify if they result in residues being in the wrong environment. Small local errors may be ignored if they are in parts of the model remote from the region of interest. Global errors however cannot be ignored as they render the entire model uninterpretable.

Errors building the conserved regions may arise for example due to poor fitting of peptide fragments to the template. This may disrupt favorable interactions between sections of the core. For example, if two adjacent beta strands are misplaced relative to each another then the hydrogen bonds formed between them may be lost. This type of error is particularly likely to occur where fragments from different family members are used to build a single model.

Many protein modeling methods require different fragments to be joined together in order to create a single polypeptide chain and this can give rise to *fragment joining errors*. A common consequence of such errors is the creation of high-energy hotspots in the model which can be problematic for some refinement approaches unless care is taken to ensure that the structure does not "blow up" due to the large initial force from the hotspot region(s).

The use of fixed-conformation rotamer libraries for side chains can lead to *sub-optimal side chain packing*. This also can lead to energy hotspots. It may be possible to relieve these problems by rebuilding some of the side chains or using an appropriate refinement protocol. However, where an error in the backbone conformation also contributes to poor side chain packing, larger-scale revisions may be required.

There are broadly three types of validation checks that can be performed on the protein model. First, does the geometry of the model conform to the norms for experimentally determined protein structures? Second, do the amino acids occupy an appropriate environment? Third, is the model consistent with the experimental information known about the target or its close homologues?

For the first two categories software tools are widely available[153–156] and should be applied as a matter of routine. A growing number of web servers are also available to validate models.[157–159]

The simplest validation checks compare geometrical features such as bond lengths, angles, dihedrals in the modeled protein structure with the corresponding distributions of values obtained from analyses of non-redundant high-resolution X-ray structures. Many programs also look for significant steric clashes. In practice, small local deviations from normal may be acceptable. A *Ramachandran plot* can be used to assess the overall quality of the fold of a protein. This plot reveals whether the conformations of the constituent amino acids lie in allowed regions of conformational space or not. Large numbers of residues outside allowed regions are indicative of problems in the fold of the model.

An *environment check* on a protein structure evaluates the fitness and compatibility of each residue in the structure to the environment in which it is found. A straightforward way of checking this is to examine the solvent accessible surface area of each residue in the model. Most of the hydrophobic residues in a protein structure are expected to be buried with a low solvent accessible area ($< 10\%$). Hydrophilic residues will typically be exposed or, if buried, will be involved in hydrogen bonds or salt bridges. These characteristics are the norm for most globular, non-membrane-associated proteins. If a model contains significant numbers of amino acid residues in an unexpected environment then this may indicate a misalignment between target and template sequences or poor choices of loop structures. One caveat to bear in mind when modeling a single domain is that if this is normally part of a multidomain protein, then hydrophobic residues may be exposed that would normally be buried in the full length protein due to domain–domain packing.

If a model passes the first two checks then further validation, including against experimental criteria and other features related to the protein's biological function, can be undertaken. Here, there are many possible options depending on the amount of information available and the system being studied. For example, where the protein contains a metal binding site or a catalytic core then are the key residues correctly positioned? Where a disulfide bond is known to form, are the relevant cysteine residues appropriately oriented? Are the locations and orientations of residues consistent with available data on protein mutants? Is the model consistent with known ligand SAR?

Validation checks can help to identify potential issues with a protein model. It is nevertheless possible for a model to appear perfectly acceptable and yet to have major flaws. This is because many validation procedures test only for local factors and may not, for example, reveal a more fundamental problem such as selecting the wrong fold.

3.07.3.7 Evaluating Protein Model Building Methods: The CASP Experiments

The protein modeling community has been a pioneer in the concept of "blinded" challenges. The basic idea is very simple: structural biology laboratories make available to the wider community sequence information on proteins that are in the process of being solved; modeling groups generate 3D structural prediction(s) for these sequences; the experimental structure is published and compared to the predictions; a scientific conference is organized where the community comes together to discuss the outcomes and to assess progress; the detailed results and conclusions are published in the literature. The CASP (Critical Assessment of protein Structure Prediction) series of experiments was launched in 1994[160–162] and has been organized every 2 years since. In recognition of the diverse and evolving nature of the protein structure prediction field, different types of problems are typically defined for each round. For example, the very first CASP was subdivided into three categories: comparative modeling, fold recognition by threading, and ab initio structure prediction. These categories represented the status of protein structural biology and the protein modeling community at the time (threading was a "hot topic" in the early 1990s). The 11th CASP in 2014 had nine categories including template-based and template-free modeling approaches, the evaluation of refinement protocols, the inclusion of limited experimental information on long-range contacts, and methods to evaluate how factors other than alignment correctness impact on model accuracy.

3.07.4 Current Status of the Protein Modeling Field and Future Directions

A casual perusal of the literature might suggest that the protein modeling methods most frequently used in practical drug discovery have changed relatively little over the past 10–20 years. Many of the key methodologies and software in use today were first described in the 1990s or even in the late 1980s. For small molecule drug discovery applications the emphasis remains on comparative modeling, where the core algorithms and workflows are well understood and robust software packages have been developed and subsequently refined over many years. Critical to success continues to be the availability of a suitable template (or templates) from a known experimental structure, assigning the correct fold to the target sequence and then getting the best detailed sequence alignment. In this regard, the amounts of data now available, of course, have made a significant impact on the field.

That the key methods are now reasonably mature does not mean that the field is stagnant or irrelevant. The biannual CASP experiments, mentioned earlier, provide the community with a regular opportunity to come together and assess the current state of the art in a scientifically rigorous and challenging yet supportive environment where established groups and newcomers are all able to participate on an equal footing. The summary reports of the various CASP meetings over the years provide an excellent overview of how the field has evolved to reflect the changing nature of the science and the wider environment. A good example is the contrast between the emphasis on ab initio folding methods in the first CASP competition, where the number of experimental structures and folds was very limited, to the current situation where the number of experimentally determined folds has increased dramatically,

making comparative modeling a much more viable prospect than was the case previously. These changes have been reflected in the areas of focus for CASP, a good example being the assessment of methods for the refinement of initial models, once it had been established that the commonly used approaches at the time were not providing the desired results. At the same time, it is perhaps inevitable that as a field evolves and matures, so the focus tends toward more detailed and specific aspects of the subject where the emphasis is on "marginal gains" that may be of interest primarily to experts in the field.

There is now much wider access to software for protein modeling, with a variety of options available. Commercial software packages provide a reliable way to access established protein modeling methods and workflows, albeit at a cost (though it should be noted that the methods are often available at no or minimal cost to academic users). Another major feature of the protein modeling field is the creation and availability of web servers that provide facile access to good-quality and validated methodologies for building basic models.[163–165] Indeed, the protein modeling community has been a pioneer in the provision of free-to-access web servers. The advantages of such websites are clear: they alleviate the need to install and maintain often complex software on a local computer system, will often provide a good-quality result without the need for access to a local human expert, and are continually refined and upgraded through the active efforts of the host group. Many web servers also provide access to more than one approach for some of the key steps (for example, sequence alignment); this then permits the use of so-called consensus approaches where greater weight can be placed on a result that is obtained from several different approaches when compared to what may be an outlier from just a single method. The I-TASSER server[166,167] has been a consistent high performer in the "server" section in recent CASP rounds and provides a good illustration of the capabilities that can now be provided to a wide audience. As indicated earlier, I-TASSER uses threading algorithms to identify likely folds and potential templates. Continuous stretches of polypeptide chain are then excised from relevant template structures, with unaligned parts of the target protein such as loops being built initially using a 3D lattice-based method that enables an efficient search of conformational space. Subsequent steps gradually refine the putative models so produced, ultimately giving a small number of low-energy models at atomic resolution.

Of course such web servers also have drawbacks: there may be relatively little flexibility over the methodologies and workflows used, and they may not be considered appropriate for confidential work. Nevertheless, they provide a very useful service and will often enable a good-quality initial model to be generated for minimal cost, a model that of course can then be further refined and modified within the context of a medicinal chemistry program, for example.

As with so many other areas of the biological and biomedical sciences the impact of gene sequencing is being felt in protein modeling, not only in providing the challenge of functional annotation but also in catalyzing new methodology developments. One example of this is the development of *evolutionary co-variance methods*.[168,169] The basic principle here is that whenever there is a change in an amino acid at a particular location this will often be accompanied by a complementary change in a neighboring residue in order to maintain the overall 3D structure of a protein (and thus function). Given a sufficiently large set of aligned sequences and appropriate statistical analysis methods it is possible to identify pairs of residues that are predicted to be close in 3D space. This information constitutes a set of constraints that can be used with appropriate conformational search and optimization methods to derive a predicted 3D structure. It is noteworthy that this approach does not make use of any known structures or structural motifs. Encouraging initial results have been obtained with the method alone, generating structures with RMSD errors over the alpha carbons between 2.7 and 4.8 Å relative to the observed structure, over at least two-thirds of the protein. As we have discussed, this level of accuracy may not be sufficient for detailed ligand design applications, but it certainly demonstrates the potential for the approach, particularly if combined with other methodologies.

There are excellent opportunities for continued if not enhanced synergy between experimental techniques that provide information on protein structure and the complementary modeling techniques. The "gold standard" technique of X-ray crystallography looks set for continued evolution with the development of techniques such as the free-electron laser together with progress against more challenging targets such as membrane-bound proteins. Experimental techniques such as cryo-EM and hydrogen-deuterium exchange have experienced significant technology advances in recent years and offer real opportunities for even greater synergy with protein modeling. Cryo-EM in particular is widely considered to offer the greatest opportunities to deliver high-resolution structural data, enabling not only targets that have proved challenging for traditional crystallographic approaches but also insights into higher-order, multidomain structure. Exciting though the highest resolution cryo-EM structures will continue to be, the opportunities for even closer interaction between experiment and theory are perhaps greatest at lower resolutions, where the inclusion of information from experiment may lead to a significant improvement in the accuracy of the predictions, and so make them of practical value in a wider range of drug discovery applications. Moreover, different experimental techniques often provide complementary information; the integration of data from different experiments can in favorable cases be expected to further drive overall performance. In addition to experimental approaches that provide information directly related to protein structure, other types of data can also be valuable when building and validating a model. In particular, the ever-growing volume of small molecule SAR data via resources such as ChEMBL represents a valuable resource for the protein modeling community. Such SAR data can be used for model validation and in some cases more directly as part of the model building processes to guide the search toward models consistent with the binding data.

The synergy between experiment and theory extends far beyond the goal of building and validating protein models. There is a distinct trend toward collaborations that not only enable prospective evaluation and validation of model-building approaches but also represent wholly new areas of scientific investigation in which computational science plays a critical and integral part. The burgeoning area of synthetic biology provides some excellent illustrations of how experiment guided by theory can provide new insights into the design of new proteins.[170,171] The use of structural data in the design of protein therapeutics has the potential to transform this critically important area for tackling unmet medical need. Protein modeling has also been at the forefront of new

computational paradigms, such as the web servers for automated model building and the use of large-scale distributed computing such as folding@home.[172] This latter application uses "spare compute cycles" donated by members of the public to help understand protein folding and misfolding. The Foldit challenge[173,174] recasts the protein folding problem as a computer game, accessible to non-experts, that attracted thousands of users and generated results that in some cases outperformed the best computer algorithms.

The central role of proteins in biology is so dependent upon their 3D structures that we can anticipate continued strong interest in methods for structural biology and protein modeling. The field has benefitted from the development of algorithms and tools that are now quite mature, with understood strengths and limitations. From a practical drug discovery perspective there are well-established workflows and methodologies that when used with care can deliver models that can be of significant value in driving projects forward. It is always important to bear in mind the problem(s) that the model is designed to tackle, to be aware of the potential errors and limitations in the model, and to continue to challenge and refine (and indeed be prepared to discard) the model using available data. The "grand challenge" of predicting ab initio the structure of any protein remains unsolved though there are encouraging signs from recent work that significant progress may be anticipated in the near future.

Acknowledgments

We would like to thank Colin Edge, Paul Bamborough, and Alan Lewis for their comments and helpful suggestions on earlier versions of the manuscript and Guy Cochrane and Mary Todd Bergman from the European Bioinformatics Institute for assistance with Fig. 1.

Generic GPCR residue numbering.[1] The generic GPCR residue numbering system used throughout this article includes two numbers (XN); the first (1–7) denotes the transmembrane helix, and the following number indicates the residue position relative to the most conserved amino acid in the helix (which is assigned the number 50). Different schemes are available for the different GPCR families: Ballesteros-Weinstein (class A),[2] Wootten (class B),[3] Pin (class C),[4] and Wang (class F).[5] A letter (a, b, c, or f) can be included to specify the numbering scheme used. For example, 3.52b indicates the second residue after the most conserved amino acid in class B TM3. If an amino acid is followed by its residue number, the generic GPCR residue numbering is included as superscript (e.g., Tyr109$^{3.28a}$). Where GPCR crystal structure superposition shows a numbering offset due to helical bulges or constrictions, a structure-based number can be appended separated by an $\times$, for example, 5.42×43, or used as a substitute, for example, 5×43.[1]

3.08.1 Introduction

3.08.1.1 Classes of Membrane Proteins

Integral membrane proteins account for approximately 30% of the human genome but represent almost 50% of the targets of pharmaceutical agents.[6,7] Compounds modulating ion channels, transporters, or G protein-coupled receptors (GPCRs) have routinely been among the most widely prescribed therapies for several decades. There are multiple reasons for this, including not only the involvement of membrane proteins in many disease-related regulatory processes but also their inherent druggability arising from binding sites which have evolved to recognize small molecules.

Despite their popularity as drug targets, membrane proteins have consistently been poorly represented in collections of X-ray structures of proteins, primarily due to difficulties in purifying sufficient quantities of high-quality protein stable enough to form regular crystals. Examples were until relatively recently limited to a handful of heroic efforts, such as the photosystem complex.[8] However, between 1998 and 2002, breakthrough structures (described below) were achieved for ion channels, transporters, and GPCRs. A consistent theme for each of these classes of proteins has been the focus on particular family members, which, while still challenging, yielded valuable information before progressing to more difficult examples.

In this section, we will introduce the main classes of membrane proteins, which have been the focus of structural biology efforts. It is not possible to give a comprehensive analysis of the field in a single article; instead, we give an outline of the progress for each major target families here.

3.08.1.2 The Emergence of High-Resolution Structures of Membrane Proteins

3.08.1.2.1 GPCRs

GPCRs transmit signals across the cell membrane by activating G proteins bound to the intracellular face of the receptor. The GPCRs exist in inactive and active conformations, with the degree of signaling dependent on the proportion of each. In the simplest model, agonists stabilize active conformations, inverse agonists stabilize inactive conformations, partial agonists (in which the level of receptor activity when saturated with ligand is less than for a full agonist) bind to both conformations but prefer the active form, and neutral antagonists stabilize both active and inactive conformations in the same proportion as in the absence of the ligand.[9] The structural differences between active and inactive forms and how these relate to recognition of ligands with different pharmacologies have been key questions in understanding the mechanism of GPCR signaling.

The first breakthrough in GPCR structural biology came in 2000 with the solution of the structure of bovine rhodopsin.[10] This confirmed the presence of a bundle of seven transmembrane helices surrounding the retinal-binding site, which is located toward the extracellular surface, and an eighth helix, roughly perpendicular to the others. The conformation of the protein corresponded to the inactive form of the receptor, and while the details of the conformational changes required for activation could only be surmised, it gave a boost for homology modeling of many receptors of therapeutic interest. The rhodopsin used for crystallization was generated from a relatively abundant non-recombinant source of protein (bovine retinas), and it encouraged efforts to produce sufficient quantities of stable protein suitable for crystallization for other receptors. These efforts took until 2007 to yield success, with structures reported for the β_2, β_1, and A_{2A} receptors.[11–13] Each was in the inactive form, with ligand density clearly visible in the presumed orthosteric site. Since then, the number of receptors for which structures have been reported has increased dramatically, with over 25 now being available.[14]

While the first structures solved were for class A GPCRs, the most common, structures have now been solved for classes B,[15,16] C,[17,18] and F.[19] The details of ligand recognition vary considerably, with class A ligands being highly diverse and including small amines, fatty acids, peptides, and globular proteins such as chemokines, all seemingly engaging directly with the helical bundle; class B receptors bind peptides, which span from the helical bundle to an extracellular domain at the N-terminus end of the receptor; class C receptors are active as dimers and bind small neurotransmitters such as glutamate in an N-terminus domain, structurally distinct from the transmembrane region; class F receptors recognize lipoglycoproteins such as Wnt. However, all the structures solved so far are consistent with the hypothesis that the transmembrane region of each GPCRs is designed to exist in multiple conformations, with the inactive, resting state different from the agonist-bound conformation, which favors G protein binding and activation. Hence, for the class C receptors, while agonists bind to the N-terminus domain, allosteric modulation can be achieved by binding to the transmembrane domain and promoting or restricting activation.

Importantly, a number of class A receptor structures are available in inactive and active conformations, allowing visualization of the structural differences between them. Although the details vary considerably, the binding of agonists generally leads to a contraction of the ligand-binding pocket and movement of the intracellular end of TM6 away from the rest of the helical bundle, with a helix from the G protein taking its place.[20] Although the details of ligand binding differ in other classes of GPCRs, the same general conformational changes, allowing engagement of the G protein, are also anticipated. Activation is thus accompanied by changes in the ligand-binding pocket within the helical bundle (described later); hence, when this is the binding site for agonists or antagonists, the structural differences are critical determinants of ligand pharmacology. There is a long history of small changes to GPCR ligands causing a switch between antagonism and agonism,[21] and comparisons between X-ray structures of related ligands with different pharmacologies can explain the structural basis for this.[22] In addition to aiding the understanding of ligand pharmacological preferences, structures of related receptors can explain ligand selectivity profiles. For the 5-HT_{1B} and 5-HT_{2B} receptors, ergotamines such as LSD can bind to both, while the selectivity of most triptans for 5-HT_{1B} can be explained by helix 5 creating a narrower pocket in 5-HT_{2B}, which can only be accessed by those molecules with a flexible linker.[23]

The structures have also revealed the diversity of binding modes possible for GPCR ligands. As the natural agonists for some GPCRs are proteins in their own right, the binding surface can be extensive, and the range of potential locations where antagonists may bind is large, with the location of atoms in antagonists of the class F smoothened receptor spanning approximately 28 Å.[5] An extended binding mode was also observed for the GPR40 agonist TAK835,[24] which was found to occupy the "classical" site between the helices, but it also passes between two of the helices, with part of the ligand projecting into what would be the lipid bilayer. Allosteric ligands are also known for many other GPCRs, with binding sites so far revealed ranging from somewhat anticipated to the totally unexpected. The positive allosteric modulator LY2119620 sits above the orthosteric site of the M_2 receptor,[25] closing a cage of tyrosines around the agonist and blocking its dissociation, while the CRF1 antagonist CP-376395 binds deep inside the receptor, below the orthosteric pocket, and appears to function by blocking the movement of helices required for activation. The $P2Y_1$ structure[26] revealed a "conventional" binding mode between the helices for a nucleotide antagonist, while in contrast, a different chemotype binds in a completely unexpected site on the outside of the helical bundle.

The atomic detail provided by the structures of the receptors, in particular the locations of ligand-binding pockets and details of agonist or antagonist recognition, provides opportunities for structure-based design approaches for these receptors and better starting points for the modeling of related receptors. The number of reports in which receptor structures are used to support drug discovery is rapidly increasing and is reviewed later in this article.

3.08.1.2.2 Membrane transporters

Membrane transporters facilitate the transport of molecules across cell membranes either in response to or against a concentration gradient, with the latter being driven by the simultaneous transport of another molecule down its own concentration gradient. Unlike the ion channels discussed later, which, when open, allow a near-continuous flow of ions, transporters are generally considered to operate on a slower, substrate by substrate basis. This involves a mechanism in which the transporter is initially open to one side of the membrane and closed to the other. Following substrate binding, the transporter flips conformation and is open to the other side of the membrane, allowing the substrate to be released.

The transmembrane region of a transporter is typically composed of two domains, each of which contains five or six helices. The first high-resolution structure that revealed this topology was that of BtuCD,[27] a member of the ATP-binding cassette (ABC) family of primary active transporters (**Fig. 1A**), which are now more commonly regarded as membrane pumps. BtuCD is a vitamin B pump from *E. coli*, where each chain consists of a transmembrane domain attached to a nucleotide-binding domain. Two protein monomers form a symmetrical dimer, with a cavity between them of appropriate size to accommodate the vitamin B, and the two copies of the turn between TM4 and TM5 create a gate at the cytosolic surface. The structure also provided insights into how the energy from ATP hydrolysis could be coupled with transport of vitamin B and refinement of models of the conformational changes that happen during transport. Structures of the sugar transporters LacY and GlpT revealed similar arrangements[28,29] (**Fig. 1B**), with each protein organized into two domains of six transmembrane helices, with N- and C-termini in the cytosol. The substrate

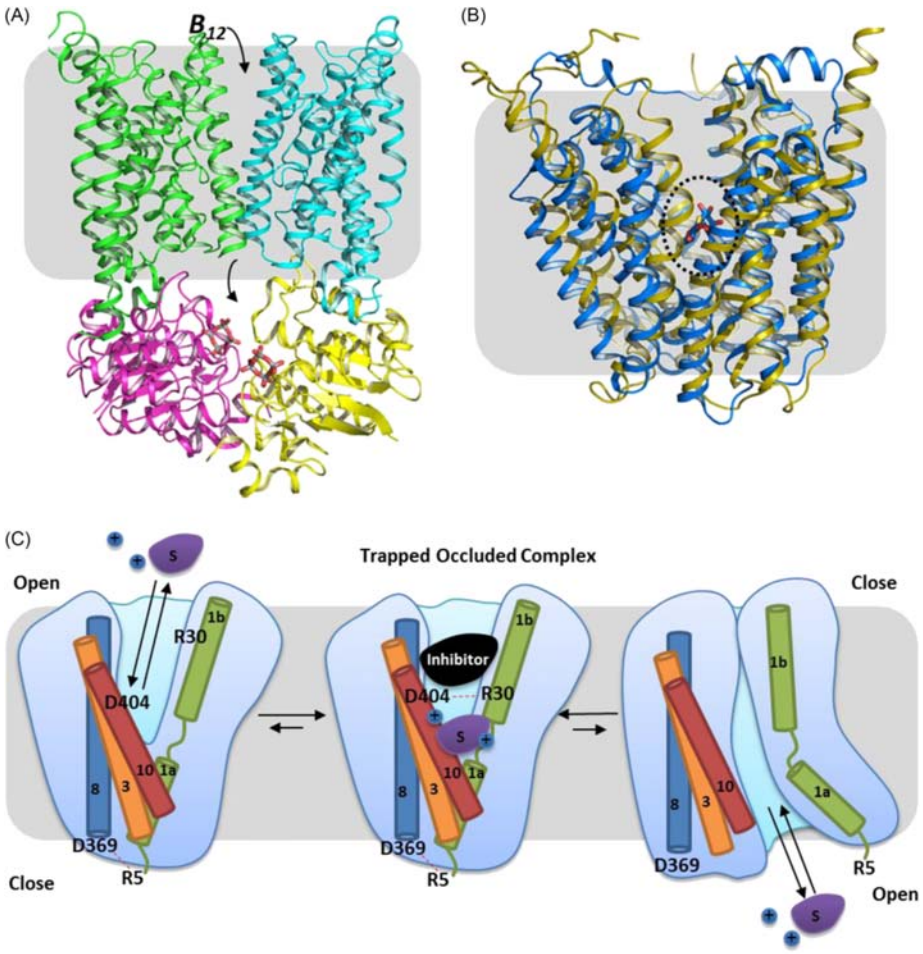

Fig. 1 Examples of transporter structures. (A) Ribbon diagram of BtuCD protein structure (PDB ID, 1L7V[27]) composed by two transmembrane chains (*green* and *cyan*) and two ABC cassettes BtuC subunits (*magenta* and *yellow*). Two arrows indicate the path followed by vitamin B_{12}. ATP-binding sites are occupied by cyclotetravanadate molecules shown as sticks. (B) Ribbon representation of the structures of the sugar transporters LacY (*blue*, PDB ID, 1PV7[28]) and GlpT (*yellow*, PDB ID, 1PW4[29]). The position of the LacY-bound lactose homolog, beta-D-galactopyranosyl-1-thio-beta-D-galactopyranoside, is shown in stick inside a dashed circle. (C) Proposed transporter mechanism (modified from[30]). The substrate (S in *purple*) and ions (*blue* circles) can bind the protein open toward the extracellular side (*left* panel) and progress toward the occluded state (*central* panel). When a noncompetitive inhibition is bound to this state, the substrate is trapped and cannot progress any further toward the intracellular cytosol (*right* panel). In all panels, the membrane region is indicated in gray, with the extracellular side and the intracellular side on the top and on the bottom, respectively.

binding site is located between the two domains, and particularly, enlightening was the fact that the site is approximately halfway across the TM region, consistent with an alternating access mechanism in which the substrate is effectively moved from one side of the membrane to the other by protein helices rearranging around a fixed substrate position.

The most revealing model structure, in terms of relevance for existing drug targets, has been that of the bacterial leucine transporter LeuT, which was solved at a very high resolution of 1.6 Å.[31] This was the first structure to be solved for the sodium symporter family, which includes the monoamine transporters for serotonin, dopamine, and norepinephrine (SERT, DAT, and NET, respectively), which are the targets of many therapeutic agents and drugs of abuse such as cocaine. In the case of LeuT, five transmembrane segments form each of the two domains, but as before, the substrate is bound approximately halfway across the transmembrane region, this time along with two sodium ions that are transported with the amino acid (**Fig. 1C**). The disposition of the helices appears to represent an outward-facing form, but a salt bridge makes a gate separating the leucine and the sodium ions from the extracellular matrix.

A better understanding of the structures of different states of LeuT was achieved with the use of antibody fragments to stabilize the inward- and outward-facing forms in the absence of leucine.[32] Large conformational rearrangements are observed between the outward- and inward-facing forms, as expected, and the gate that had previously formed around the leucine is absent. Sodium ions were bound to the Leu-free form of the protein for the outward-facing state only, with conformational changes in the inward-facing site disrupting their sites, explaining their transport into the cell (**Fig. 1C**). Particularly revealing was a structure with tryptophan, which binds in the same site as leucine, and although the protein adopts an outward-facing conformation, tryptophan sterically blocks formation of the gate, acting as an inhibitor rather than a substrate. Collectively, the structures allow proposals of a general alternating access model in which transport requires an intermediate state with both inward and outward faces blocked. Substrates are accommodated within such an occluded site, while inhibitors can occupy the site when open, but not when occluded (**Fig. 1C**). The model also covers all forms of transport, including cotransport of ions in either the same (symport) or opposite (antiport) direction as the substrate.[33] The sodium/galactose symporter from *Vibrio*, a model for the human diabetes target SGLT2, crystallized in an inward-facing form but with features recognizably similar to LeuT,[34] while the structure of PepT, a member of the major facilitator superfamily of transporters and a bacterial homologue of di- and tripeptide transporters, revealed an occluded state.[35] This was thought to be close to intermediate between inward- and outward-facing states, fully consistent with the alternating access mechanism.

The similarity of LeuT to monoamine transporters prompted investigations of the modes of binding of several drug molecules, with mixed results. The tricyclic antidepressants clomipramine and desipramine bind to LeuT in the presence of leucine, in a vestibule on the extracellular side of the leucine site,[36,37] seemingly inhibiting transport by locking shut the gate on the extracellular side of the leucine site, in a manner that is noncompetitive with leucine and sodium binding (**Fig. 1C**). Mutagenesis experiments on the human serotonin and dopamine transporters suggested that they contain equivalent vestibules and tricyclic binding sites.[37] Further work with three SSRIs showed they also bound in roughly the same pocket of LeuT as the tricyclics but made different interactions with the protein,[38] and substitutions in this region correlated with different selectivity profiles between the transporters for the tricyclics and the SSRIs.

Concerns as to the reliability of LeuT as a model of ligand binding to monoamine transporters prompted investigations in which mutations were added to increase the similarity of the former to the latter. Solving structures of the modified protein with four classes of antidepressants revealed that, like leucine, they each bound to the central cavity and identified three subsites, which the different classes of compounds could occupy differently.[39] They all, however, appeared to lock the transporter into an outward-facing conformation (**Fig. 1C**). This mode of binding and inhibition was also seen with the solution of the X-ray structure of the dopamine transporter from *Drosophila* with the tricyclic antidepressant nortriptyline,[40] where some subtle differences between the protein topologies of LeuT and DAT were revealed. Subsequent structures with a series of DAT ligands, including the substrates dopamine and amphetamines, and inhibitors including cocaine revealed that each bound to the same general central cavity, but conformational plasticity in the protein enabled specific recognition of the diverse range of chemotypes.[41] The substrates promoted formation of the occluded conformation, equivalent to that seen with leucine in LeuT, while inhibitors appeared to be wedging the protein into a fixed conformation, which would prevent the movements required for transport.

Despite the limitations described earlier in using the prokaryotic proteins to model the ligand-binding properties of eukaryotic counterparts, a number of authors have successfully used the structures to generate models of eukaryotic proteins and, by concentrating on the substrate binding site, have successfully identified novel ligands through virtual screening approaches[42,43] demonstrating their potential for drug discovery.

3.08.1.2.3 Ion channels

Ion channels allow the flow of anions or cations across a membrane in response to the electrochemical gradient of the ion, usually at much higher flux than transporters. They are thus key determinants of the electric potential difference across cell membranes, underlying activation processes for electrically excitable cells such as nerves and muscle. A channel can exist in states that are closed or open to the passage of ions, and the two predominant means of controlling this have led to the primary classification of channels as being gated by voltage or ligands. Understanding the interplay between the voltage and ligand sensor, the opening and closing of the channel, and the pore that allows passage of the required ion and selects others has been a driving force behind structural studies.

As for GPCRs and transporters, progress with ion channel structural biology has been enabled through the use of model systems, but in line with the greater diversity of the ion channel family, alternative approaches have also been utilized. In particular, studies of

isolated regulatory domains other than the transmembrane region have been useful. Although initial studies concentrated on how the structure of the ion channel pore allows conductance of some ions and not others, subsequent studies have addressed questions as to how the channels are themselves regulated, including identifying and characterizing the binding sites of some pharmaceutically important ligands.[44]

The first breakthrough structure for the ion channel field was that of the bacterial potassium channel KcsA.[45] Efforts to solve the structure of this channel were prompted by sequence similarities, which suggested it contains a structural motif that represents the fundamental pore domain found in many other channels, meaning the structure would be of high value as a model. The structure revealed a tetrameric arrangement of subunits, with each monomer composed of two transmembrane helices, and a shorter helix leading toward the pore formed by the well-conserved TVGYG sequence (**Fig. 2A**). The oxygen atoms presented by the four copies of this sequence (one from each monomer) coordinate dehydrated potassium ions at four sequential positions as they travel through the pore. The immediate focus of attention arising from this structure was how the channel achieves such high selectivity for potassium over the only slightly smaller sodium ions, with the initial suggestion being that the pore cannot contract enough for the TVGYG sequences to coordinate sodium ions. This hypothesis, however, is not the only one. The nonselective channel NaK, which normally contains two sequential cation-binding sites, was modified to contain one or two additional sites. It was found that only the protein with four binding sites was selective for potassium over sodium; those with two and three sites are nonselective, despite all proteins having pore dimensions equivalent to that of KcsA.[53]

The pores of most other ion channels are recognizably similar to that of KcsA, with notable exceptions being the voltage-gated chloride channels.[54] Structures of voltage-gated (Kv) and inward-rectifying (Kir) potassium channels revealed pores generated by tetrameric assemblies of transmembrane helices and selectivity sequences similar to KcsA, although with additional elements allowing for functions such as voltage sensing or regulation by ligands (**Fig. 2B**).

A fourfold repeat of the motif is observed in eukaryotic sodium channels, although in this case it arises from a single polypeptide chain containing 24 transmembrane helices, arranged in four bundles of six transmembrane helices. In contrast, the structure of Orai,[55] which forms the pore of the calcium release-activated calcium channel (CRAC), reveals a sixfold arrangement of bundles of four helices, with residues from the M1 helix coordinating cations as they pass through the pore. Although once again it appears the ions occupy a sequential set of binding sites as they pass through the channel, the means by which this is regulated and selectivity is achieved appear to be different compared with the potassium channels. In this case, a ring of basic residues near the intracellular surface possibly constitutes a site for negative regulation by anions and hindering the progress of sodium and potassium while allowing calcium to pass through slowly, probably driven by a gradient of approximately 40,000-fold across the membrane.[55]

Fourfold symmetry was also predicted in the ionotropic glutamate class of ligand-gated ion channels (LGICs). The transmembrane region forming the pore was predicted to resemble an inverted potassium channel and is attached to two extracellular domains forming the glutamate binding site. Initial X-ray structural studies focused on the glutamate binding domains, revealing details of the ligand-binding site.[56] These are most expanded in the apo state; slightly contracted in the presence of an antagonist, more with a partial agonist; and most contracted with agonists bound.[57] Although the conformational differences revealed in these structures could be seen as providing a mechanism for opening and closing the pore, formation of symmetrical dimers between domains from two of the four chains from the receptor appeared incompatible with a fourfold symmetry for the pore. The structure of a near full-length AMPA receptor revealed that a symmetry mismatch does occur, with the extracellular domains with twofold symmetry attached to a fourfold symmetrical pore[47] (**Fig. 2C**).

In contrast, a fivefold arrangement of subunits is observed in the Cys-loop class of ligand-gated ion channels. Members of the Cys-loop family can be selective for either cations or anions, with the former including members that are regulated by serotonin and acetylcholine while the latter including receptors for glycine and γ-aminobutyric acid. Each subunit is composed of a large extracellular domain and a transmembrane domain, and the pentamer can be composed of identical monomers or different but related subunits. The first detailed structural information was obtained for the nicotinic acetylcholine receptor. X-ray structures of pentameric acetylcholine-binding proteins from molluscs and annelids[58] have been used as the model for the extracellular domains, which include the nicotine binding sites, and structures with the partial agonist varenicline have been described.[59] Electron microscopy studies of the full receptor from the electric organ of the torpedo fish[48] at 4 Å resolution gave insights into the overall topology of the pentameric complex (**Fig. 2D**). It was not until 2008 when an X-ray structure of a bacterial homologue ELIC[60] showed the detailed arrangement of the pore formed by the five copies of the M2 helix. The absence of a ligand for ELIC caused a switch to another bacterial homologue, the proton-gated GLIC, for which subsequent structural studies elucidated the structural differences between open and closed states of the pore[61,62] and led to structures with propofol and desflurane, revealing a general anesthetic binding site in the upper part of the transmembrane domain[49] (**Fig. 2E**).

The first high-resolution view of a eukaryotic Cys-loop receptor came with the glutamate-gated chloride channel α (GluCl),[63] which contains three distinct binding sites for the endogenous neurotransmitter glutamate, the allosteric agonist ivermectin, and the channel blocker picrotoxin. The X-ray structure of the mouse serotonin $5HT_3$ receptor[64] subsequently highlighted details of the ion conductance path, the neurotransmitter binding site, and the relative arrangement of subunits. Interestingly, despite the fact that a potent inhibitor was used to obtain the structure, the features revealed were not conclusively of an open or closed state. The structure of another Cys-loop receptor, the pentameric human $GABA_A$ receptor,[50] gave the first high-resolution view of this chloride channel, which has been frequently targeted for drug discovery (**Fig. 2F**). Along with explaining a mechanistic role for disease-associated mutations, it showed benzamidine, a previously unknown agonist, bound in the neurotransmitter site, identifying opportunities to develop a new class of $GABA_A$ modulators by structure-based drug design. The structure of the glycine receptor a3 with

Membrane region and extracellular and intracellular sides are indicated. (E) Side view of part of the crystal structure of the pentameric ligand-gated ion channel GLIC (PDB ID, 3P4W[49]) colored by chain. Molecules of desflurane (from the PDB ID, 3P4W) and propofol (PDB ID, 3P50) are shown, respectively, as blue and orange sticks.[49] (F) Extracellular view of the

strychnine bound[65] added weight to the proposal of a general mechanism in which antagonists expand the orthosteric site and cause closure of the pore in the transmembrane domain.

A more complicated mechanism of ion conductance has been made apparent from the recent 3.1 Å resolution structure of the P2X4 ATP-gated sodium channel. The sodium ions appear to need to pass through a series of vestibules in the large extracellular domain, the conformation of which needs to be regulated by the binding of ATP to a site which is 45 Å distant from the pore domain. Subsequent comparisons of apo- and ATP-bound receptors revealed that ATP induces widening of several of the vestibules in the extracellular and transmembrane domains (**Fig. 2G**).[51]

X-ray structures of the TREK potassium channel[66] have revealed sizable rearrangements of helices in the transmembrane region. One of these structures included norfluoxetine, the active metabolite of fluoxetine (Prozac), which is a state-dependent blocker of the channel. The ligand was observed to bind to the transmembrane region adjacent to the pore filter, revealing a binding site that could be the basis of future structure-guided medicinal chemistry.

A recent development in structural biology of membrane proteins is illustrated from the structure of the VR1 potassium channel, obtained using single-particle cryo-electron microscopy methods. Recent advances in cryo-electron microscopy have enabled structures to be determined at resolutions near those obtainable with X-rays. This represents a very exciting development in the structural biology of membrane proteins.[67] Structures of TRPV1 in the unliganded, closed state[52] (**Fig. 2H**) and activator-bound open states[68] have resolutions of up to 3.4 Å and allowed observation of rearrangements to the outer pore helix and selectivity filter and relaxation of a hydrophobic constriction further into the pore, suggesting ion transport may be controlled at two sites. Subsequently, the cryo-EM structure of the TrpA1 channel at approximately 4 Å[69] revealed structural features of channel blocking and an antagonist binding site within the transmembrane region of the receptor, near the ion gate.

The structural information now available for ion channels and transporters is starting to be translated into structure-based drug design applications.[70] One example, reported by Schlessinger et al.,[70] is a remarkable use of structure-based drug design, which illustrates the future potential in the field. The authors created a homology model of the norepinephrine transporter (NET) using LeuT as a template. They then applied molecular docking to screen more than 6000 drugs in silico. Among them, 10 out of 18 high-scoring ligands were found to be NET inhibitors. Overall, our understanding of ion channels and transporter structural biology is evolving steadily, but, due to their added complexity, at a much slower pace compared with the SBDD revolution started in 2007 for the GPCRs with the β_2-adrenergic receptor noted earlier.[11]

3.08.2 Novel Structural Understanding of Membrane Proteins Focused on GPCRs

In the earlier section, the progress in our understanding of the structural biology of the key membrane protein families has been introduced. To date, for transporters and ion channels, despite the number of ligands and also drugs known that act at these targets and the recent increase in our knowledge of how some of these molecules bind to their protein partners, the know-how has just started to be translated to structure-based drug design (SBDD) applications. As such, the remainder of this article, which is focused on case studies of drug design, is largely limited to a discussion of GPCRs. This membrane protein family then serves as an example of how SBDD methods can be applied to the discovery of new ligands and lead compounds. In this section, we discuss in some detail the structural features of GPCRs that relate to their function, influenced by ligand binding. We describe briefly here examples of hit generation using in silico approaches in the various subfamilies of this system and also computational approaches to understanding ligand binding, unbinding, and kinetics for GPCR targets.

3.08.2.1 From Structure to Function

Based on the multiple available GPCR crystal structures, we can define broadly three distinct conformations these receptors can adopt: (I) an *inactive state* when the receptor is crystallized in complex with an antagonist or inverse agonist, (II) an *agonist-bound state*, and (III) an *active state* resulting from a ternary complex composed by the receptor, an agonist, and an intracellular protein (the G protein, a G protein surrogate, or arrestin). Most likely, less stable intermediate conformations link these three states. Overall, these conformations have distinct structural features resulting from differences in the chemical structure of the bound ligand.[71] The mechanisms that control GPCR receptor activation upon ligand binding are highly complex and in the past have been hindered by a lack of structural knowledge. For ligand design, an understanding of what governs the activation process is likely to be very important to relate the features of the ligand to agonism versus antagonism or to allow the in silico prediction of the structure of an agonist form of a receptor from an antagonist structure (or vice versa).

crystal structure of the human $GABA_A$ homopentamer receptor (PDB ID, 4COF[50]) colored by chain. In every chain, benzamidine is shown as spheres. (G) Side view of the crystal structure of the trimer ATP-gated P2X4 ion channel in the closed apo state (PDB ID, 4DW0[51]) colored by chain in *red*, *yellow*, and *blue*. The structural alignment of one monomer of the open ATP-bound P2X4 channel (PDB ID, 4DW1[51]) is included in *green* as ribbon with the ATP ligand as sphere representation. (H) Extracellular view of the structure of TRPV1 ion channel determined by single-particle electron cryo-microscopy (PDB ID, 3J5P[52]) colored by chain. In Figs. A, C, D, E, and G, the membrane region is indicated in gray, with the extracellular side and the intracellular side on the top and on the bottom, respectively.

Of significance, several pairs of active and inactive GPCR structures have recently been solved enabling detailed structural insight into the activation process of GPCRs. Combined with structural analyses, they have enabled Tehan and colleagues[72] to examine several different theories[20,73] proposed for GPCR activation. The authors proposed activation steps that are intrinsically related through their effect on the central hydrophobic core of GPCRs. Transmembrane helix 3 (TM3) and TM6 are at the heart of the common activation pathway thanks to the direct contacts with every other helix except TM1.[74] GPCR activation affects TM3 and TM6 to impart these common movements[75] seen within the active and inactive pairs available to date. These include (**Fig. 3A**) (I) the movement of TM5, (II) the upward movement of TM3, (III) the rotation of TM6, and (IV) the inward movements of TM7 and TM1. The rearrangement of the hydrophobic residues between TM3 and TM6 in the core of the receptor consists primarily of L3.43a, F6.44a, X6.40a (where X is a bulky hydrophobic residue, I, L, V, or M), and to a lesser extent X6.41a (**Fig. 3B**). The rearrangement of these contacts seen in the active-state structures allows for the gross TM movements, which opens a water channel through the hydrophobic core (**Fig. 3C and D**). The active conformation is transiently stabilized by the interactions with the water molecules allowing the creation of an H-bonding network from the extracellular side of the receptor to the intracellular side. The overall result is the opening of the cytoplasmic face of the receptor where G proteins interact. Crystallographic data of the β_2-adrenergic receptor (β_2AR), the M_2 muscarinic receptor, and the μ-opioid receptor (μOR) support that this extensive polar network between the ligand-binding pocket and the cytoplasmic domains has a central role in signal propagation.[78]

The importance of these key residues implicated in the proposed class A GPCR activation process is supported by in-depth conservational analysis and studies resulting in constitutively active mutants.[72] From the comparison of classes A, B, and F, the hydrophobic core residues appear to create very similar, but not identical contacts among the different subfamilies.[79] TM3 is always at the center of the contact network and may be a structural and functional hub, while TM6 is thought to be creating the most distinct network of interactions in the transmembrane domain among the subfamilies. Additionally, class B GPCR activation is likely affected by the presence of large extracellular domains (ECDs). A combination of structural biology approaches now suggests, for example, that the apo glucagon receptor (GCGR) can adopt both an open and a closed conformations associated with extensive contacts between the ECD and transmembrane domain.[80] The peptide hormone agonist acts to stabilize the open state by both interacting with the ECD and also triggering the activation by inducing conformational changes through contacts within the orthosteric site.

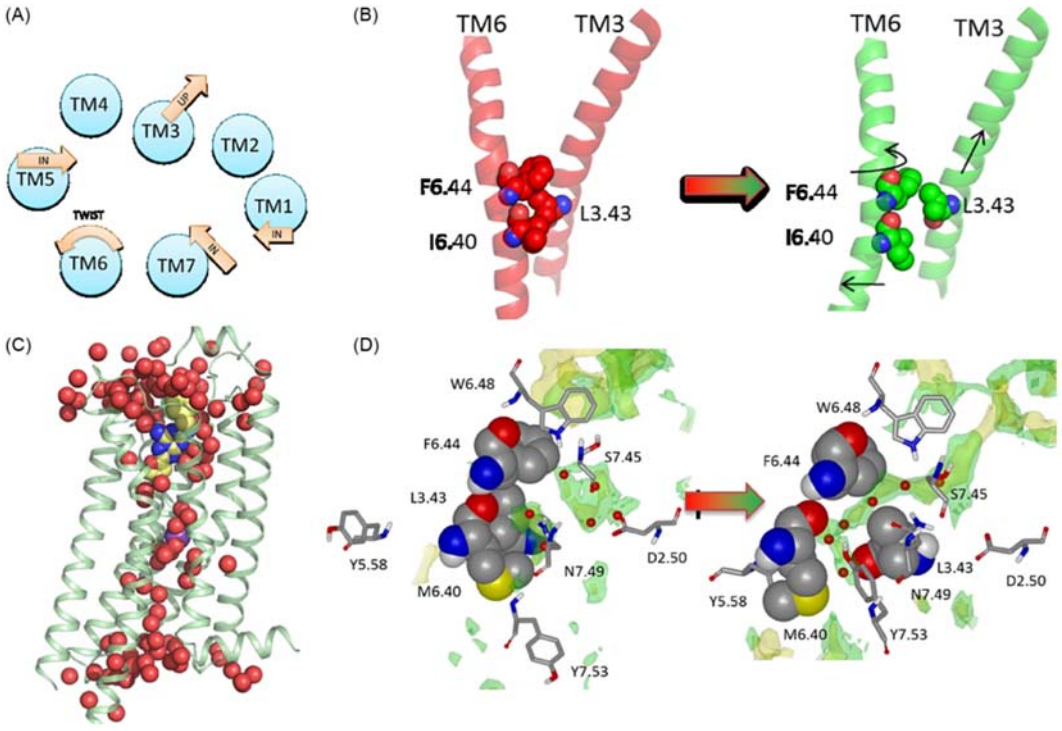

Fig. 3 GPCR activation conformational changes. (A) Arrows indicate the key movements of the transmembrane helices (TM1–7) from an extracellular view point. (B) Conformational changes of hydrophobic core residues in TM6 and TM3 of the β_2AR from the inactive (*red*) to active (*green*) conformation. (C) High-resolution X-ray crystal structure of the adenosine A_{2A} receptor (in *green* ribbon, PDB ID, 4EIY[76]) in complex with ligand ZM-241385 (sphere representation). The fusion protein is not shown. Water molecules linking the extracellular orthosteric site and the intracellular G protein-binding region are shown as red spheres. (D) Comparison of hydrophobic core region in the inactive (*left*) and active (*right*) rhodopsin X-ray crystal structures. The water molecules (*red* spheres) create a continuous water channel only in the active state, which is broken by the hydrophobic core residues (shown in spheres) in the inactive state. Other residues are shown in stick, and the hydrophobic and hydrophilic hot spot regions are included as transparent surfaces, respectively, *yellow* and *green*. These have been calculated using the GRID software,[77] using the OH2 water probe contoured at used −5.0 kcal/mol and the C1 = aromatic carbon probe contoured at −2.5 kcal/mol.

Recently, the publication of the neurotensin receptor NTSR1 structures has provided insight into mechanistic details of an active-like, agonist-occupied peptide GPCR.[81] The binding of the agonist peptide near the receptor surface results in the conserved W321$^{6.48a}$ adopting a conformation parallel to the membrane plane sealing the top of a collapsed Na^+ ion-binding pocket. This movement creates the conformational changes of the hydrophobic core residues (discussed earlier) in the inner half of NTSR1 promoting the productive interaction with G_q protein. The comparison of the X-ray crystal structure of the agonist-bound μOR in complex with a G protein mimetic with other active-state structures additionally reveals a common rearrangement in the packing of three conserved amino acids: I3.40a, P5.50a, and F6.44a.[78] Molecular dynamics simulations illustrate how the ligand-binding pocket is conformationally linked to this conserved triad that may initiate the cascade of structural changes involved in activation.[78]

It is now believed that GPCRs allosterically activate heterotrimeric G proteins and trigger GDP release through a highly conserved mechanism.[82] GPCRs create key contacts with the C-terminus and αN–β1 hinge region of the Gα subunit enabling the transfer of conformational changes to the nucleotide-binding pocket of the Gα subunit.[83,84] The interaction specificity between the G protein and the GPCRs results from disorder-to-order transitions of G protein regions important for the interactions with the receptors. This might explain how the GPCR-Gα system diversified rapidly while conserving the allosteric activation mechanism. Application of solution-state NMR to examine the process of μOR activation showed that the conformational changes in TM5 and TM6 required both the agonist ligand and the G protein.[85] The orthosteric site is likely only weakly coupled to the G protein-binding region, while the intracellular loop 1 and helix 8 may play a role in the initial interaction with the G protein that could be important for coupling specificity. Thanks to the recent rhodopsin–arrestin complex crystal structure, it is now possible to extend this structure-based analysis to arrestins. The structure reveals that the arrangement of TM helices is similar to that in the G protein-bound β_2AR complex, even if the TM6 outward movement is less pronounced.[86] With only four subtypes in vertebrates, arrestins are highly conserved, while the cytoplasmic interfaces of GPCRs are mainly nonconserved. However, electrostatic complementarity has been proposed to be an adaptive mechanism for arrestins to pair promiscuously with the large number of GPCRs in the family.

Agonists and antagonists or inverse agonists can often be identified within the same chemical class, and relatively small changes to the chemical structure can cause a change in the pharmacology (sometimes termed "mode switching"). A very recent review examines in some detail these examples of the structure–activity relationships (SAR) that relate to changes in ligand pharmacology for GPCR targets, and the reader is referred to this paper to explore this topic in more detail.[21]

3.08.2.2 Binding Site Analysis

GPCR X-ray crystal structures provide a crucial insight into the complexity of this protein family. They demonstrate the large diversity of regions in the receptor transmembrane domain that can be targeted with small molecules to affect protein function (**Fig. 4A**). The majority of class A ligands crystallized bind to the orthosteric site in the extracellular half of the receptor, inside the helical bundle, and below the extracellular loops not interacting with TM1. The precise location is highly variable, and as expected, it is linked to the specific properties of the binding site. Interesting exceptions are the GPR40 agonist TAK-875[24] and the negative allosteric modulator BPTU[26] crystallized in quite unexpected binding modes (**Fig. 4B**). The first binds between TM3 and TM4 to some extent near the orthosteric site and partially outside the helical bundle in the membrane. BPTU instead interacts only with the membrane-exposed extracellular side of TM1, TM2, and TM3. They together highlight the complexity and the multiple potential binding regions exploitable in GPCR structure-based drug discovery. This is even more evident when we extend the analysis beyond class A. The negative allosteric modulator (NAM) CP-376395 binds the class B CRF_1 receptor deep in the core of the receptor in a mainly hydrophobic site located among TM3, TM5, and TM6.[15] Class C NAM ligands like mavoglurant[18] bind in a region located between the class A orthosteric site and CRF_1 small-molecule binding pocket (**Fig. 4A**). In contrast, class F ligand binding seems to involve extensive interactions with the receptor extracellular face and loops.[19]

The novel structural information now available allows a detailed computational analysis of the chemical and physical properties of the binding sites and an estimation of the binding site water molecules' relative free energies.[93] These methods have been used to evaluate binding site druggability. Ligands tend to bind to highly specific regions of the protein characterized by a combination of hydrophilic and lipophilic/hydrophobic features, compatible with balanced small-molecule properties in best cases (**Fig. 2C**). Of particular interest are subregions of the binding site with mixed hydrophobic and hydrophilic properties occupied by displaceable water molecules predicted to have a free energy higher than bulk solvent. These areas are often exploited by high-affinity ligands to create productive interactions with the receptors resulting in significant free energy of binding gain. The orthosteric site of the A_{2A} receptor represents an excellent example of a druggable pocket (**Fig. 4C**, PDB ID, 3UZC[87]): the ligand **4g** binding mode allows effective interactions with key lipophilic/hydrophobic regions of the pocket displacing high-energy waters. Interestingly, the high chemical diversity among GPCR antagonists significantly correlates with the binding site hydrophobicity and negatively correlates with the number of hydrogen bond donors in the binding site.[94] In addition, as noted by Levit et al., there seems to be a link between the number of disulfide bridges in the extracellular region of a receptor and the range of molecular weights of antagonists that bind, suggesting the importance of the "entrance pathway" to the orthosteric site in determining the size selectivity for GPCR antagonists.[94]

The increasing number of GPCR crystal structures allows us now to combine experimental ligand binding and functional activity data with high-resolution structural analyses of GPCR–ligand interactions[95]. Potentially, this approach, together with receptor mutagenesis studies, amino acid sequence analyses, and novel insight into GPCR conformational changes upon activation, enables the identification of the molecular and structural determinants of ligand affinity, functional activity, and selectivity.[96,97] Although in its infancy, the observed contraction of the binding site upon activation (**Fig. 4D–G**) allows the use of putative ligand-docking modes to be applied to the active and inactive-state crystal structures to help understand their functional activity and allow an in silico assessment

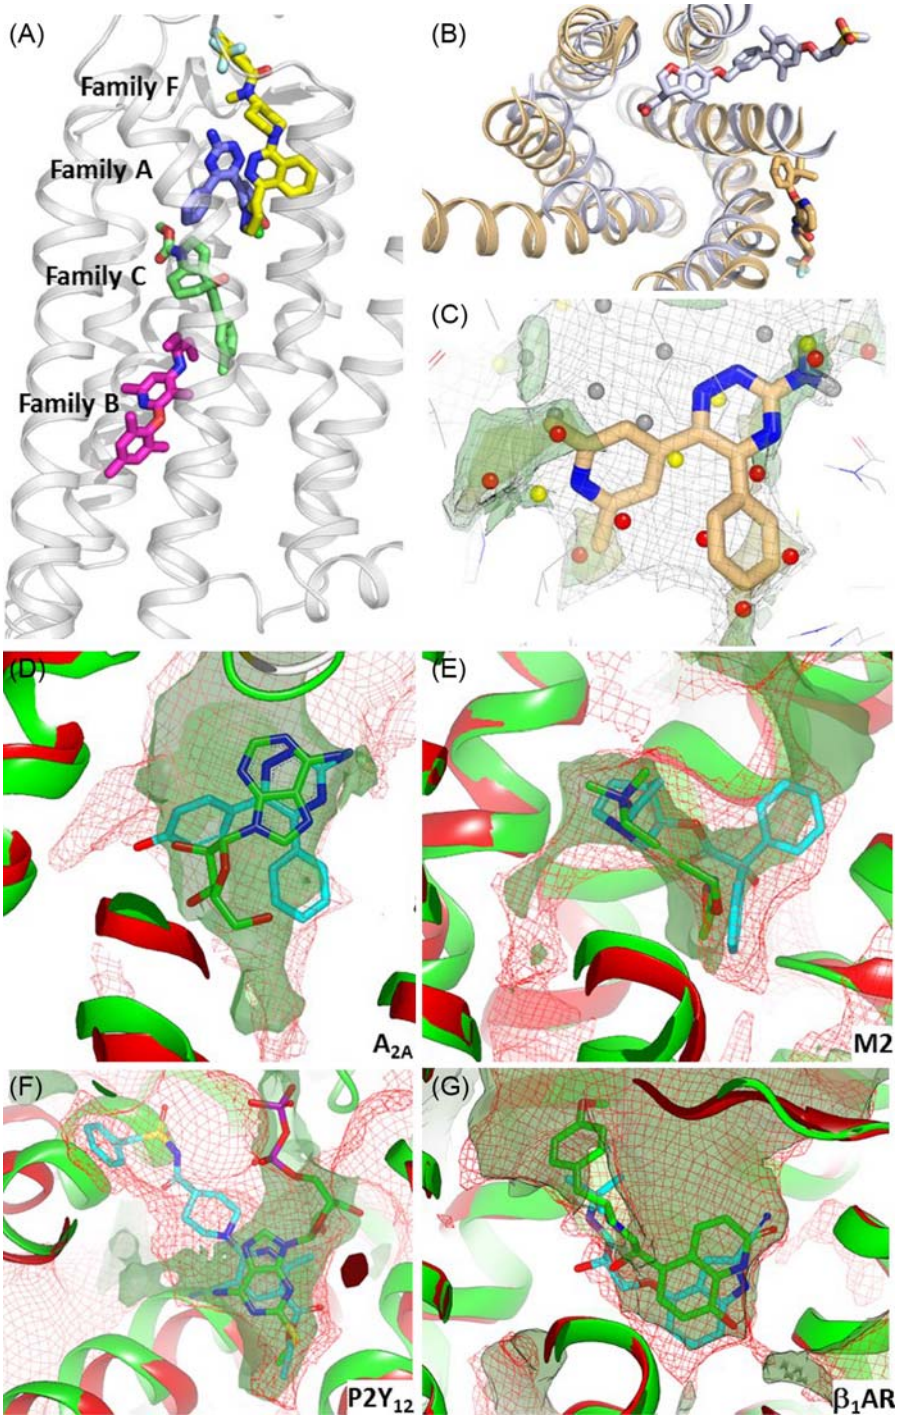

Fig. 4 Small-molecule binding sites in the GPCR transmembrane region. (A) Comparison of the crystallographic ligand-binding site locations for class A (ligand **4e** in *purple*, PDB ID, 3UZC[87]), B (ligand CP-376395 in *magenta*, PDB ID, 4K5Y[15]), C (ligand mavoglurant in *green*, PDB ID, 4OO9[18]), and F (ligand LY2940680 in *yellow*, PDB ID, 4JKV[19]) in a representative helical bundle shown as ribbon (A_{2A} receptor). (B) Binding modes of the allosteric modulators TAK-875 (shown as *light blue* spheres) to GPR40 receptor (shown as *light blue* ribbon, PDB ID, 4PHU[24]) and BPTU (shown as *light orange* spheres) to $P2Y_1$ receptor (shown as *light orange* ribbon, PDB ID, 4XNV[26]). (C) Adenosine A_{2A} receptor binding site druggability analysis based on GRID[77] and WaterMap.[88] Hydrophobic and hydrophilic hot spot regions are included as transparent surfaces, respectively, yellow (C1 = carbon sp^2 probe contoured at −2.8 kcal/mol) and green (OH2 water probe contoured at −5.0 kcal/mol). The shape of the pocket is shown as gray mesh (C3 carbon sp^3 probe contoured at used 1 kcal/mol). The triazine **4g** antagonist (PDB ID, 3UZA)[87] is shown as stick, the protein as line, and the apo WaterMap waters as small sphere color-coded according to their predicted free energy (*red* if $\Delta G > 3.5$ kcal/mol, *yellow* if ΔG between 2.5 and 3.5 kcal/mol, *blue* if $\Delta G < -1$ kcal/mol, and gray in the other cases). (D–G) Active site contraction upon receptor activation. Comparison of the inactive (protein and ligand in *red*) and active (protein in *green* and ligand in *cyan*) ligand-binding site of adenosine A_{2A} (D, PDB ID, 3UZC[87] and

of ligand pharmacology.[9] Ligands with the same functional activity can then be efficiently classified on the basis of their protein–ligand interaction profile. The use of protein–ligand interaction fingerprints derived from ligand-bound crystal structures with known agonists or antagonists may give effective tools to postprocess docking poses to identify ligands with a specific functional effect.[98]

Molecular modeling using the available X-ray GPCR structures is also beginning to be applied to predict GPCR polypharmacology using a structure-based approach to provide a consistent understanding of ligand recognition.[99] However, the use of structure-based methods to discover agonists has so far perhaps been hampered by limited atomic-level understanding of the activation mechanism (described earlier) and a chemical bias toward antagonists in the screening libraries.[100] High ligand complexity is often required for receptor activation, and a library of commercially available small molecules may not be suitable for agonist identification in many cases. Virtual screening to identify antagonist and agonist hits is discussed in more detail in the following section.

3.08.3 GPCR Ligand Design

3.08.3.1 Hit Finding

Virtual screening (VS) represents a widely used approach in modern drug discovery, playing an important role in the identification of novel hit molecules. In general, the approach consists of a fast in silico evaluation of the probability of a molecule having a desired biological activity. The method is typically applied to a large database of ligands, and the output is a ranked list based on the likelihood of relevant activity. VS techniques can be broadly divided in two families: (I) structure-based, taking advantage of known protein target coordinates, and (II) ligand-based, exploiting only the information derived from one or more active ligands. Breakthroughs in membrane protein crystallography have had a crucial impact in computational approaches used in GPCR virtual screening shifting the interest toward SBDD approaches. Before 2007, GPCR VS was mainly ligand-based or using homology models derived from the rhodopsin X-ray data (discussed earlier). Now, the available structural information includes 26 class A, 2 class B, 2 class C, and 1 class F GPCRs (Figs. 5–7). Class A X-ray diffraction crystals currently publicly available consist of eight aminergic, eight peptide, three protein (one is an NMR structure), three lipid, one sensory, and three nucleotide receptors. There is still no structural information for melatonin, steroid, ali carboxyl acids (including hydroxycarboxylic acid, oxoglutarate, and succinate receptors), adhesion, and orphan receptors.

The application of SBDD methods relying on the coordinates of GPCR targets can be further expanded by using homology modeling (HM) techniques. We broadly consider 30% sequence identity between template X-ray data and a target GPCR, the minimum threshold to apply this approach. Based on this general definition, we can divide GPCRs in three main groups: (I) those with experimental structural information, (II) those suitable for homology modeling, and (III) those thought challenging to be evaluated using a structure-based approach (Figs. 5–7). In addition, the success of using a homology modeling approach for VS is directly linked to the ability to improve, optimize, and validate the 3-D model using available experimental data.[103–107] When an X-ray structure is not available, another strategy to increase the success rate of an homology model-based VS depends on the creation of a complex hybrid protocol combining molecular docking with ligand-based approaches. Several examples of VS on GPCRs are reported in Table 1. They include broadly four different strategies: (I) structure-based VS, (II) homology model-based VS, (III) ligand-based VS, and (IV) hybrid protocols involving HM and ligand-based techniques. These studies must be compared with care since there are important differences, for example, protocols/software used, the general druggability of the target GPCR, the conformation of the receptor (active/inactive), important subjective choices in the ligand selection criteria, and the selection of the library for screening. In some cases, the library is restricted to fragment-sized molecules (e.g., <300 Da in size). Not surprisingly, the resulting hit rates are variable (Fig. 8A) but seem overall to support an important positive effect on the hit rate performance coming from the use of an X-ray structure.

When in silico screening millions of molecules, it is only possible to visually analyze the result for a small percent (typically a few hundred) of the top-ranked list. Molecular docking software aims to find the best compromise between speed and accuracy. These methods use efficient algorithms to explore the conformational space accessible to the ligand in the binding site and then evaluate the poses using simple scoring functions estimating the ligand–protein interactions. The so-called enrichment is generally linked to the ability to detect and give a low score to a ligand not able to bind the protein target. The top-scoring ligands will include a high number of false positives that an expert user can often identify and discard. The selection of compounds from a 3-D analysis of hits in a binding site is of course highly subjective and biased, but it represents a crucial part of a virtual screening campaign. Another important aspect often oversimplified in the literature is the preparation of the database used for the VS. Accurate preparation can dramatically reduce the number of false positives that would need to be discarded during the visual inspection step. An example of a protocol to prepare a database for VS and library design is illustrated in Fig. 8B.

It is not possible here to describe each example listed in the table nor is the Table 1 completely comprehensive. Instead, in later sections, we give a number of examples of SBDD efforts where hits have been developed into more advanced hit series or to lead compounds.

2YDO[22]), muscarinic M_2 (E, PDB ID, 3UON[89] and 4MQT[25]), $P2Y_{12}$ (F, PDB ID, 4NTJ[90] and 4PXZ[91]), and β_1AR (G, PDB ID, 2VT4[11] and 2Y02[92]) receptors. Receptors are shown in ribbon, ligands in sticks, and the pocket shape calculated using GRID (using the C3 probe with an interaction energy threshold of 1 kcal/mol) in mesh (inactive states) or transparent filled surface (active states).

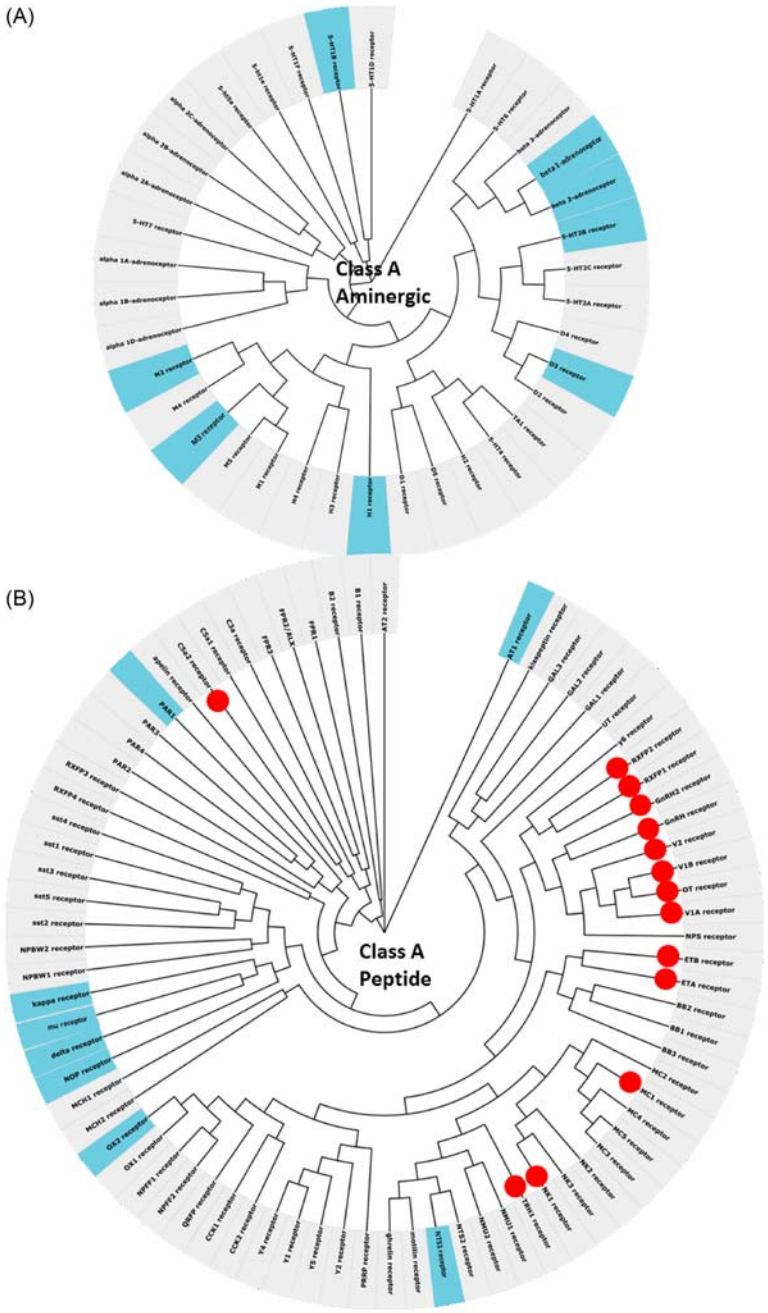

Fig. 5 Phylogenetic tree for class A GPCR aminergic (A) and peptide (B) receptors. Analysis created using the tools available in the GPCRDB.[101] GPCRs with available crystal structure in the Protein Data Bank[102] are highlighted in blue. Red circles highlight GPCRs for which the creation of a homology model can be particularly challenging. For these receptors, only low (less than 30%) sequence identity templates are available.

3.08.4 GPCR Computational Simulation

3.08.4.1 Molecular Dynamics Simulations

The structural plasticity of GPCRs is directly linked to their versatile functional activity.[147] The conformational space accessible to the receptor can be represented as a very rugged energy landscape. It corresponds to a multidimensional hypersurface with a very large number of valleys (stable conformations) and peaks (energy barriers).[148,149] The description of these energy levels can be evaluated more accurately in statistical terms. During that time, the GPCR will follow a temperature-dependent exploration of the different states. GPCR crystal structures represent a static low-energy snapshot of the conformational complexity of the protein.

Recent improvements in the computational algorithms, hardware, and underlying physical models[150] have allowed atomic-level molecular dynamics simulations of GPCRs to reach timescales as long as milliseconds. The full-atomic detailed MD including an

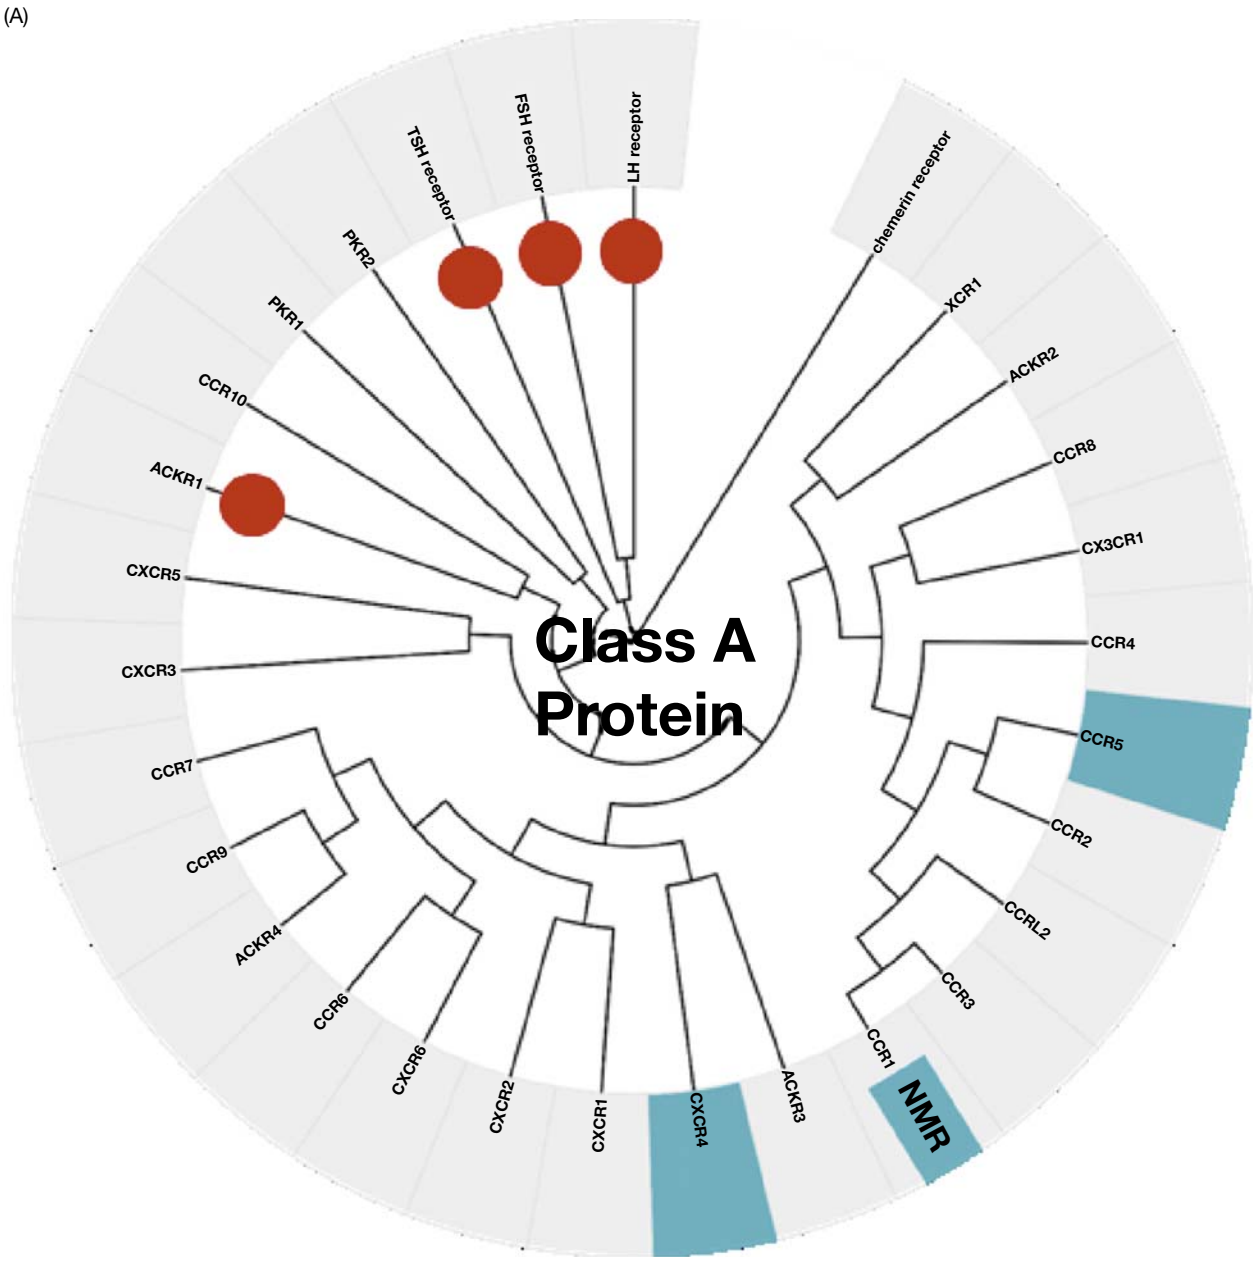

Fig. 6 Phylogenetic tree for class A GPCR protein (A), lipid (B), melatonin/nucleotide/steroid/ali carboxyl (C), and sensory (D) receptors. Analysis created using the tools available in the GPCRDB.[101] GPCRs with available crystal structure in the Protein Data Bank[102] are highlighted in *blue*. *Red* circles highlight GPCRs for which the creation of a homology model can be particularly challenging. For these receptors, only low (less than 30%) sequence identity templates are available.

explicit representation of solvent and the membrane environment can now capture the behavior of biological macromolecules in unprecedented detail.[151] Key aspects that can be investigated include conformational changes critical to protein function and ligand binding. The GPCR energy landscape can be modulated by ligands resulting in direct effects on the conformational equilibrium between the active and inactive states.[148] The overall changes in enthalpy and entropy of the system are affected by the ligand resulting in changes in population and amplitude of motion of given states, suggesting a complex landscape of states and substrates.[152] Indeed, NMR spectroscopy studies support the heterogeneity of conformational states present in agonist-bound and inverse agonist-bound conformations.[153] These states are not necessarily observed in crystal structures suggesting that the link between the orthosteric pocket and the G protein-binding site is not rigid and may be important for GPCRs' ability to engage multiple signaling and regulatory proteins. As such, when considering SBDD optimization of a ligand series based on X-ray data, we need to always take into account that the protein is actually quite mobile and the affinity and potency of a compound are not fully described in any given protein–ligand X-ray data set.

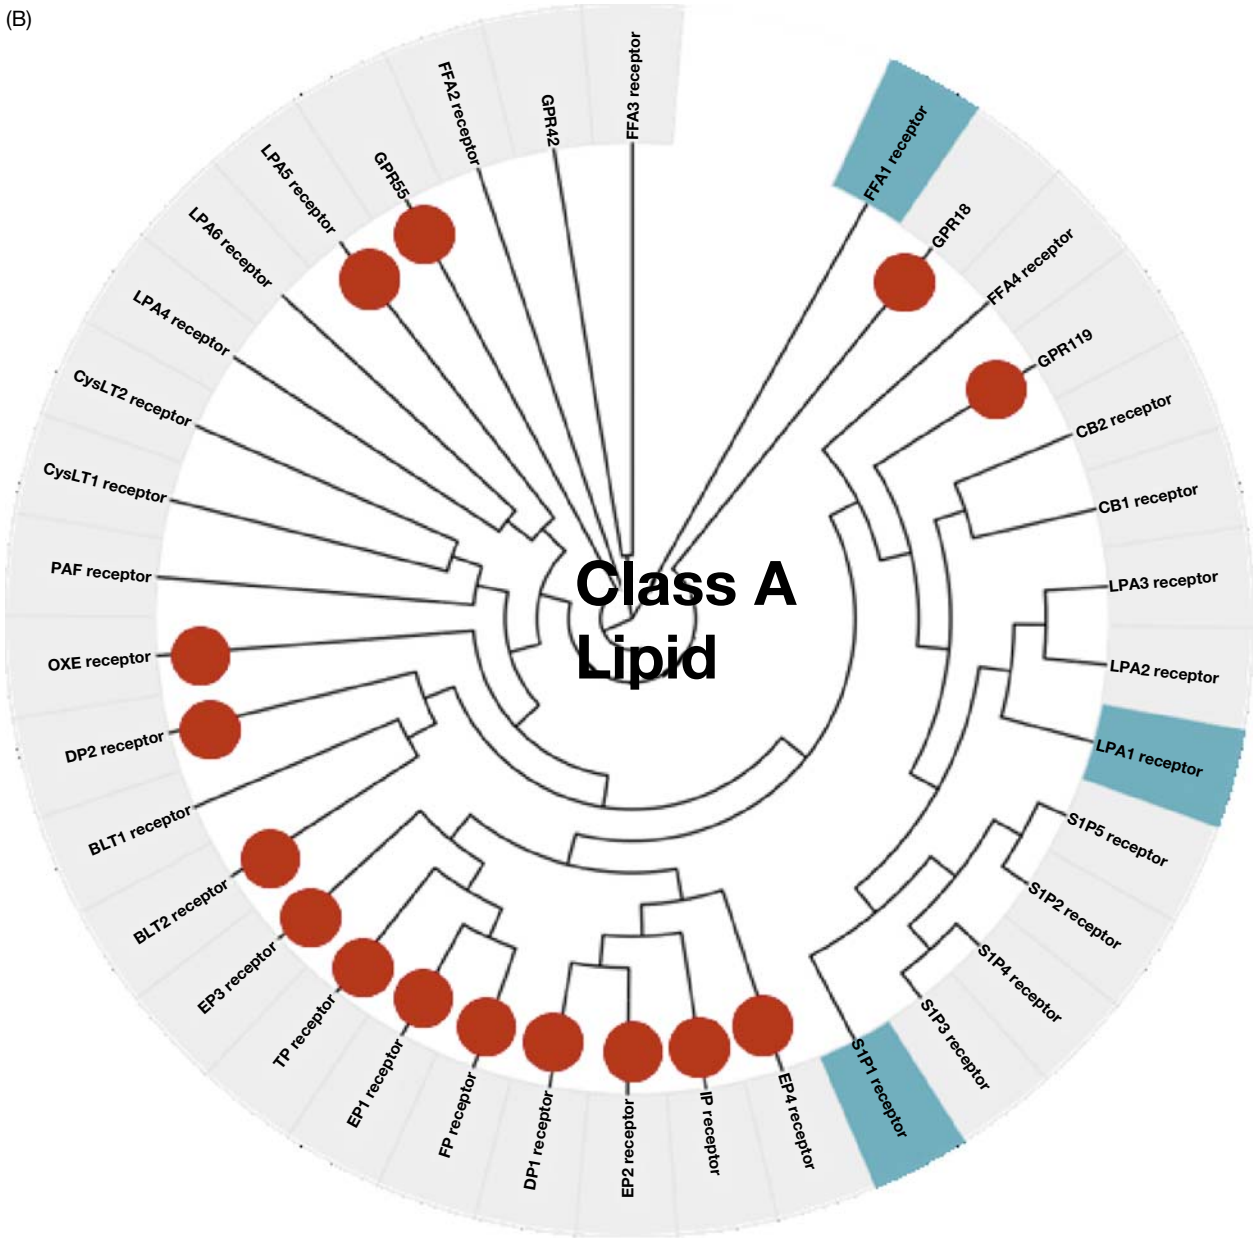

Fig. 6 (*continued*).

MD can now be used to incorporate protein flexibility to improve the virtual screening enrichments for GPCRs.[154] This approach has so far been applied to four GPCRs, and results suggest that selected frames from the MD trajectory can outperform X-ray structures and homology models in terms of enrichment factor and AUC values.[154] The best MD frame improved the early enrichment factor (EF1%) compared with the crystal structures of CXCR4, dopamine D_3, histamine H_4, and also homology models of 5-HT_6, respectively, from 0 to 6.7, from 0.32 to 3.5, from 13.3 to 26.7, and from 0 to 14.1. MD simulation seemed to capture protein conformations representing the key interacting points of the receptor but was less biased toward one specific chemotype. MD simulations have also been applied to evaluate the stability of ligand-binding modes predicted using molecular docking for the adenosine A_{2A} receptor. The proposed protocol successfully combined the rapid sampling of ligand poses into the binding site, typical of docking algorithms, with the thermodynamic accuracy of MD simulations in describing, at the molecular level, the stability of a GPCR–ligand complex embedded into an explicit lipid–water environment.[155] MD allows the simulation of the spontaneous association of ligands to GPCRs achieving final poses in some cases proved to closely match those determined crystallographically.[156] The analysis of the predicted binding event using this approach with several antagonists and agonists of the β_1-adrenergic receptor (β_1AR) and β_2AR shows that ligands follow the same well-defined binding pathway. Initially, ligands have to overcome the largest energy barrier to create initial contacts with a "vestibule"

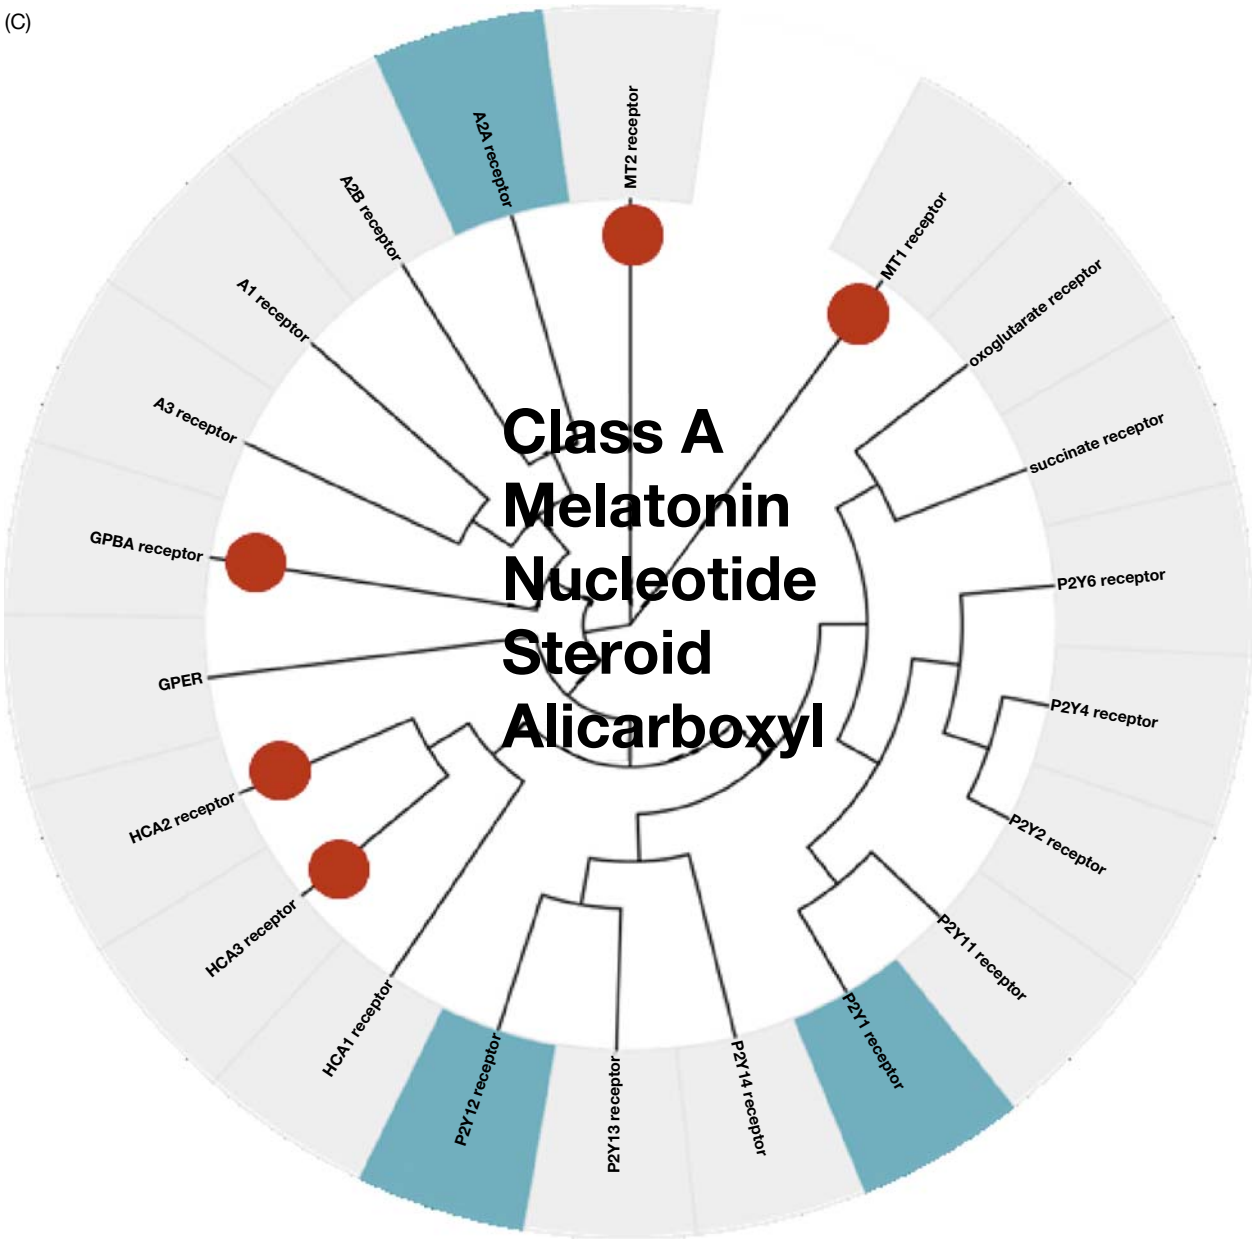

Fig. 6 (*continued*).

region in the extracellular side of the receptor at 15 Å from the final binding site. This early barrier is linked to the desolvation of the ligand and the protein.[156] The understanding of the ligand-binding event at a molecular level potentially provides opportunities for the design of novel ligands and allosteric modulators. MD simulation studies of different muscarinic M_2 allosteric modulator ligands show that they spontaneously associate with the receptor in the extracellular vestibule region forming cation–π interactions with clusters of aromatic residues.[157] Conformational changes and electrostatic interactions between ligands and the receptor revealed mechanisms that seemed to contribute to positive and negative allosteric modulation of classical ligand binding.

Recently, atomic-level simulations have been applied to elucidate the nucleotide release mechanism from the heterotrimeric G protein. The spontaneous opening of the α subunit Ras and the helical domains seems not sufficient for nucleotide release. MD simulation, confirmed by double electron–electron resonance spectroscopy and protein engineering, showed that GPCR binding is required for the structural rearrangements of the Ras domain necessary for rapid nucleotide release.[158] The same computational methods have been exploited to propose a mechanistic model for the sodium/potassium/calcium voltage-gated ion channel superfamily.[159] Again, MD highlighted important molecular switches between activated and deactivated states; on deactivation, the pore hydrophobic collapse rapidly halts ion flow involving an inward S4-helix motion; on activation, S4 moves outward, and fluctuations allow water and then potassium ions to enter the pore.

(D)

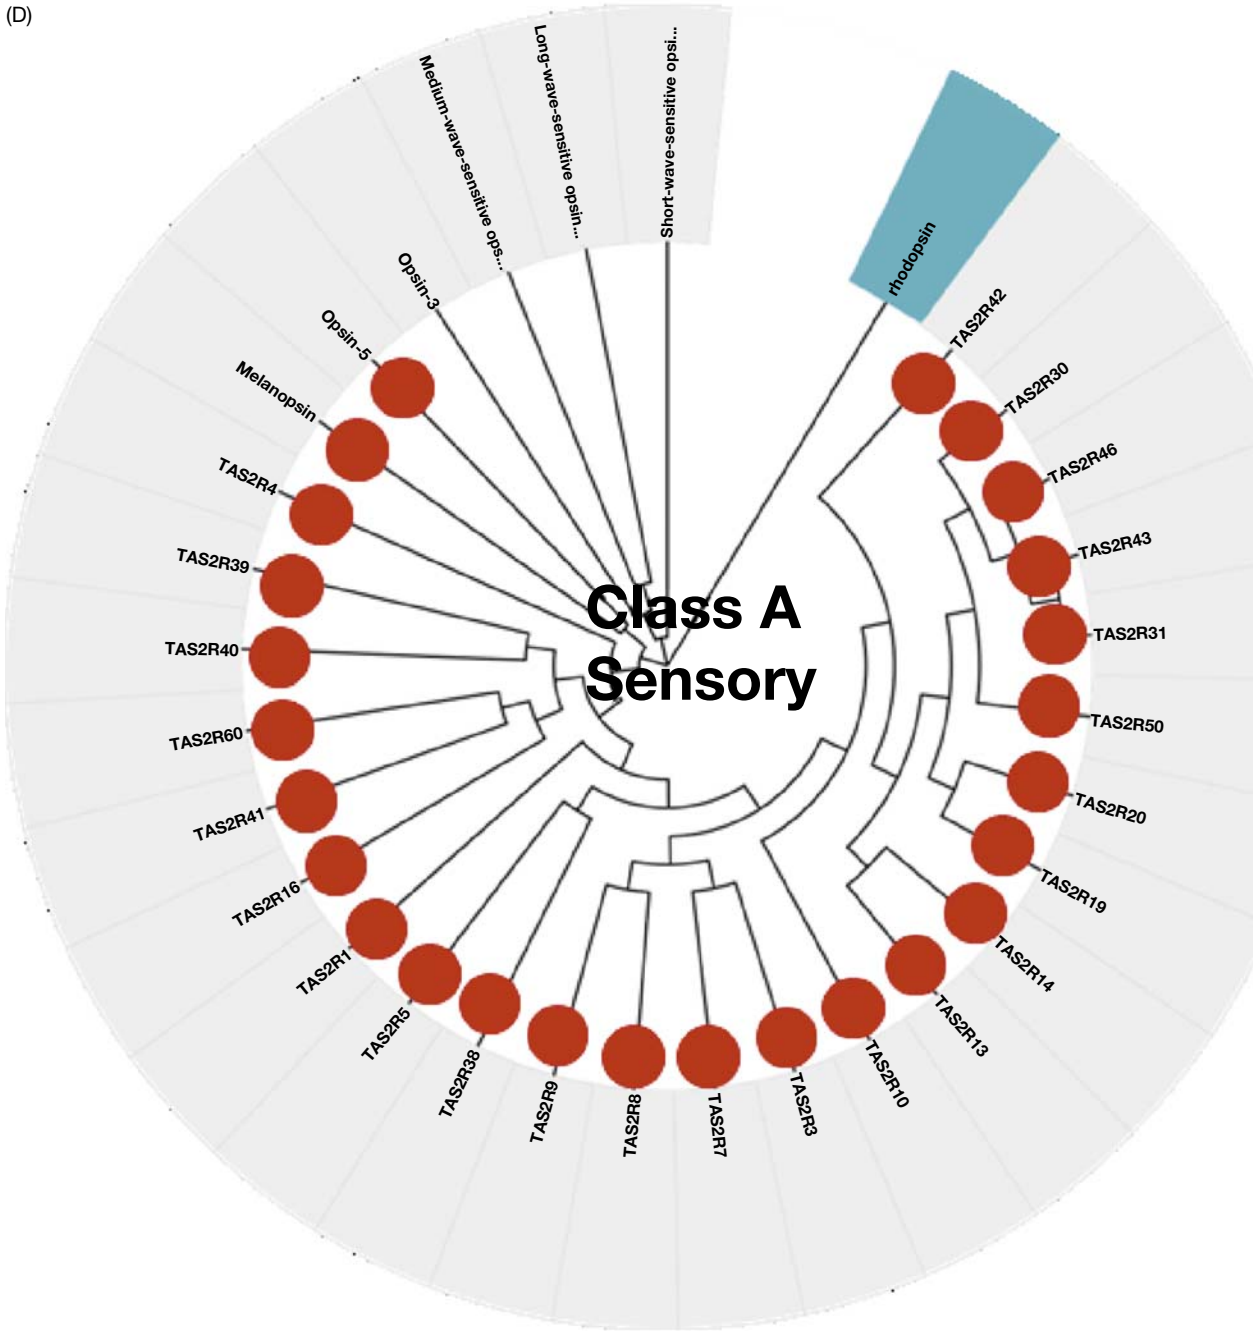

Fig. 6 (*continued*).

3.08.4.2 Binding Free Energy and Binding Kinetics Predictions

Computational predictions of ligand–protein affinity and kinetics of binding represent a key component of SBDD. The thermodynamics of ligand–protein binding (ΔG_{bind}) corresponds to the difference in free energy between the unbound species and the bound state, while the kinetics of the ligand-binding event is characterized by association and dissociation constants. Ligand-binding free energy predictions still remain a challenge for modern computational chemistry, in particular at the level of accuracy needed to guide lead optimization. Recent efforts in structure-based drug design have aimed to improve both the protocols and the force fields used in free energy perturbation calculations.[160] Retrospective results on soluble proteins covering 200 ligands and 330 chemical perturbations resulted in an average ΔG_{bind} root mean square error of 1 kcal/mol. The approach has then been tested in prospective drug discovery projects and fragment optimization[160,161] with similar results. Preliminary results of this approach in the GPCR field are promising; for example, Goldfeld et al. have used free energy perturbation calculations to provide evidence for the mechanism of interaction between ligands and kappa-opioid receptor.[162] They proposed a scoring model (WScore) for the binding

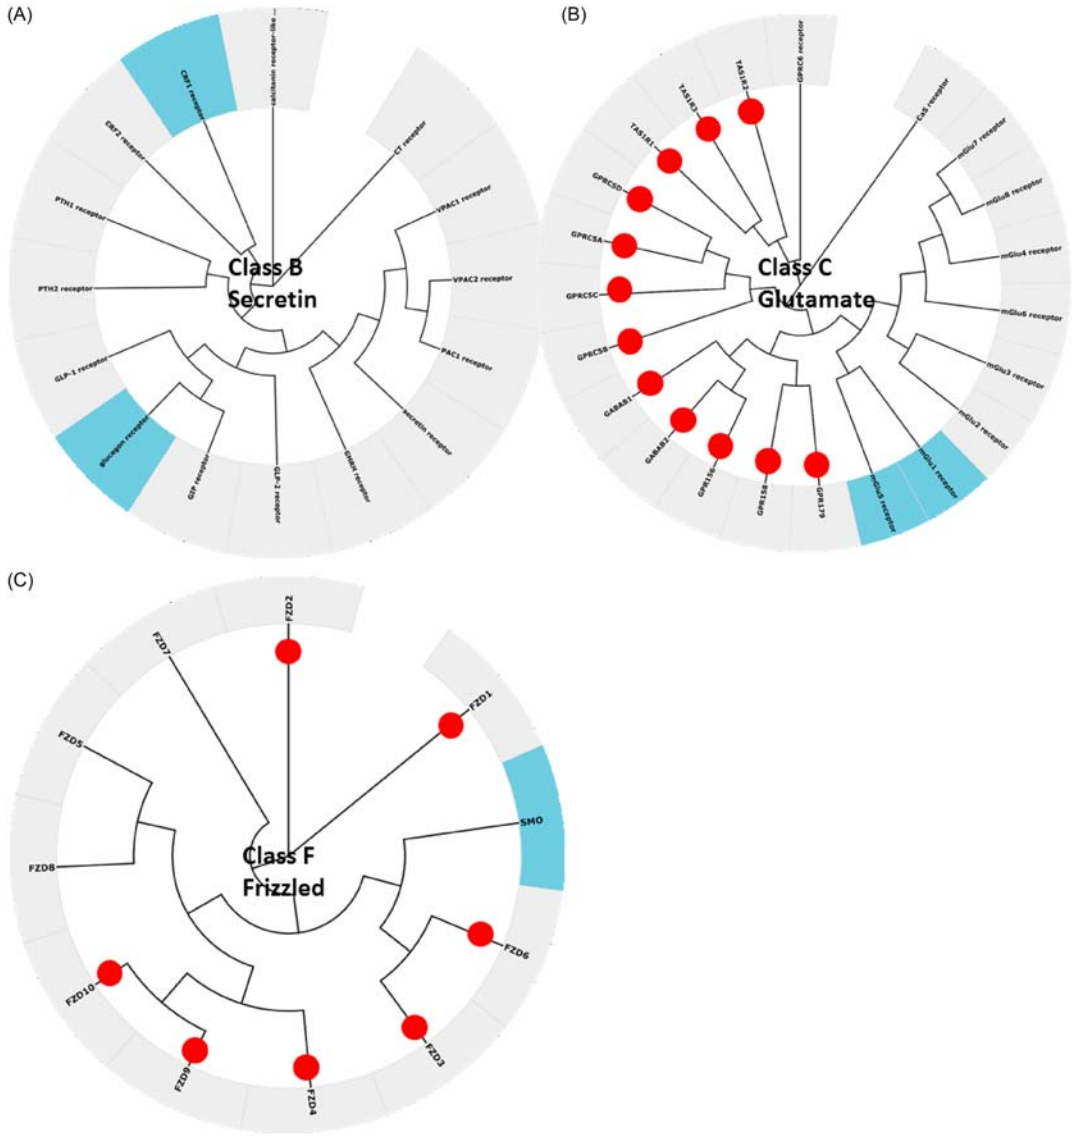

Fig. 7 Phylogenetic tree for class B GPCR secretin (A), class C glutamate (B), and class F frizzled receptors. Analysis created using the tools available in the GPCRDB.[101] GPCRs with available crystal structure in the Protein Data Bank[102] are highlighted in *blue*. *Red* circles highlight GPCRs for which the creation of a homology model can be particularly challenging. to this receptor based on the location of the water molecules in its binding site. WScore used with the docking program Glide resulted in better virtual screening enrichment on this target compared with an older generation of Glide scoring functions. Free energy calculations have been applied also to evaluate single-point mutations and their effect on ligand binding.[163,164] When applied to the adenosine A_{2A} receptor, the predictions were in agreement with the experimental effect of the point mutation on the binding affinity of a potent agonist.

The effect of ligand binding on the thermodynamics of GPCR conformational equilibria takes place on timescales that are not conveniently accessible to standard MD.[165] Enhanced molecular dynamics methods have been applied to GPCRs to study ligand recognition, ligand binding and unbinding pathways, receptor activation, and oligomerization (reviewed in Ref. [147]). Evaluation of the dynamic mechanisms by which ligands bind and unbind GPCRs can be a crucial aspect in lead optimization to understand binding kinetics and selectivity. Residence time, typically expressed as the inverse of the dissociation rate, has been shown in different studies to be important to evaluate GPCR ligand activity.[166] These included, for example, angiotensin II AT_1 receptor antagonists,[167] M_3 muscarinic agonists,[168] μ-opioid receptor ligands,[169] and dopamine D_2 receptor antagonists.[170,171] Enhanced sampling algorithms[172] like metadynamics (MetaD) or the construction of Markov state models (reviewed respectively in Refs. [173,174]) can be useful to evaluate ligand kinetics.[175] Another method uses a multiple-replica scaled molecular dynamics protocol with suitably defined harmonic restraints to accelerate the unbinding events.[176] This approach was able to rank adenosine A_{2A} receptor ligands according to the mean observed scaled unbinding time. Other computational methods available include fast protocols evaluating the role of the binding site water molecules in

affecting the ligand residence times.[177] Shielding hydrogen bond interactions between the ligand and the protein from water molecules results in an increase in the ligand unbinding transition state energy barrier.[177,178] In addition, fast on-rates can be related to replacement of protein H bonds from waters to polar ligand atoms. Fast off-rates instead can be associated with limited displacement of unstable hydration sites.[178] Trapped unstable waters between the protein and triazine-based ligands have been highlighted as important in limiting ligand residence times for the adenosine A_{2A} receptor.[179,180] Another fast approach (aMetaD) uses a combination of adiabatic bias molecular dynamics and metadynamics to simulate the start of the ligand–protein unbinding event.[181] MD trajectories are automatically analyzed and translated into atomic solvation factor values representing the water dynamics during the unbinding event. Using a physics-based and fully flexible ligand scoring function, the aMetaD approach evaluates the maximum energy required to move the ligand from the bound-state energy basin to the next. This scoring scheme has been used successfully to classify the residence time of ligands of the muscarinic M_3, the adenosine A_{2A}, and CRF_1 receptors.

3.08.5 Applications of in Silico Design for Membrane Protein Targets

In the remainder of this article, progress with ligand design using computational methods and SBDD will be highlighted by focusing on a number of examples from the literature. The previous discussion has outlined progress with X-ray structure determination and SBDD methodology for several different protein targets covering GPCRs, ion channels, and transporters. In addition, in silico approaches applied to GPCR hit discovery and to an understanding of how ligands bind to GPCRs have been described in some detail. The scope of the rest of the article is limited to selected examples either where the design process uses the X-ray structure of the target protein itself in the relevant conformation or where homology modeling is used starting from a very similar protein structure (receptor subtype or the same receptor in another conformation, i.e., agonist or antagonist). In addition, due to the recent availability of multiple GPCR ligand–protein X-ray cocomplexes suitable for SBDD, the examples covered will focus on GPCR targets. The authors have attempted to use these examples to outline how SBDD methods can be readily applied to receptors and that many of the lessons learned from soluble targets can be successfully implemented. At the same time, there are some differences between

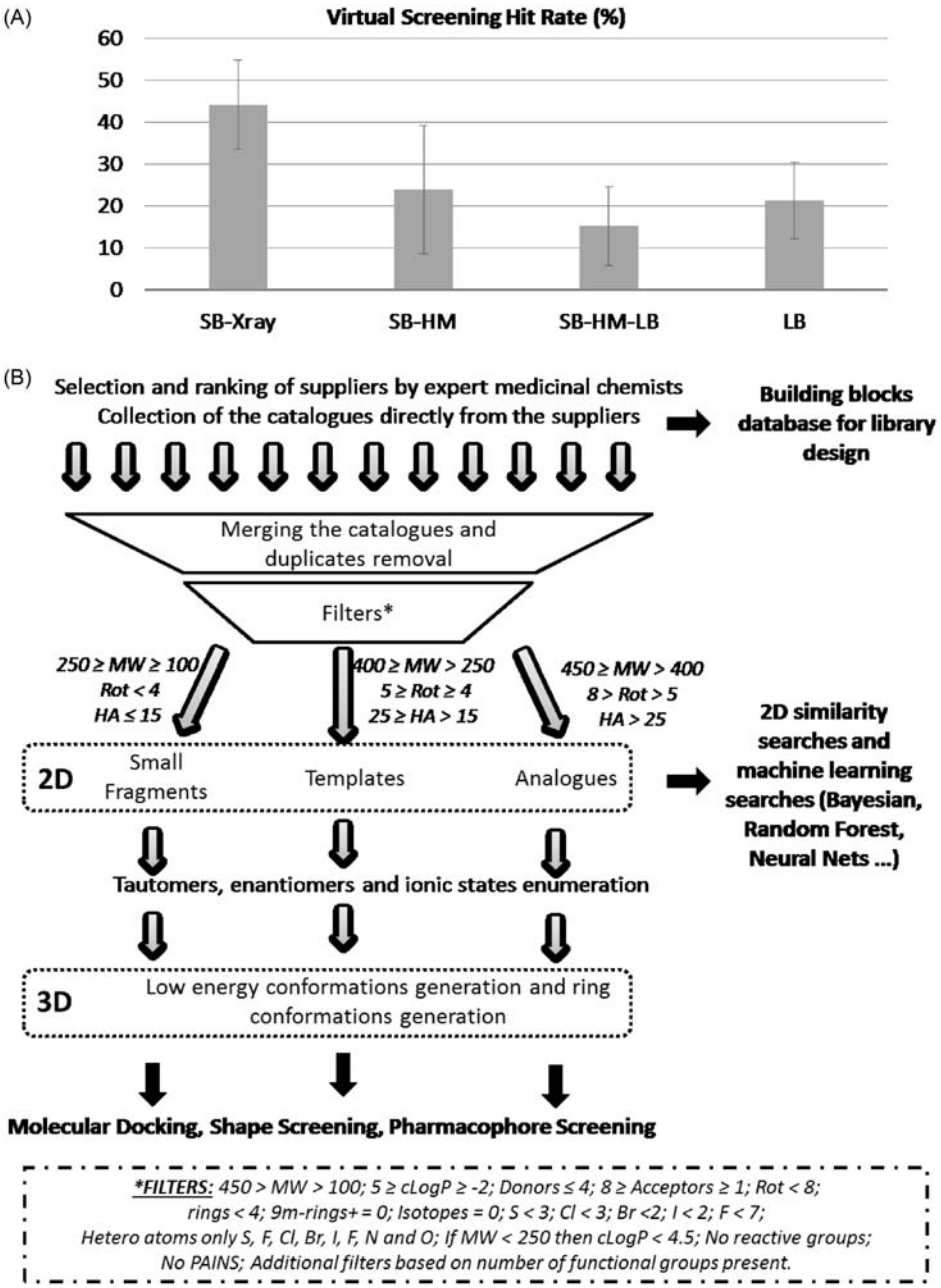

Fig. 8 (A) Average virtual screening hit rate (%) from the published prospective studies included in **Table 1** divided in four categories: structure-based using crystallographic information (SB-X-ray), structure-based using a homology model (SB-HM), combination of ligand-based and structure-based approach using a homology model (SB-HM-LB), and ligand-based virtual screening (LB). (B) Protocol used to generate Heptares' supplier databases of commercially available small molecules for virtual screening applications. The following abbreviations are used: MW, molecular weight; cLog P, predicted Log P (daylight); donors, number of H-bonding donors; acceptors, number of H-bonding acceptors; Rot, rotatable bonds; rings, number of rings; 9m-rings+, 9 or more ring atoms; PAINS, pan-assay interference compounds.[146]

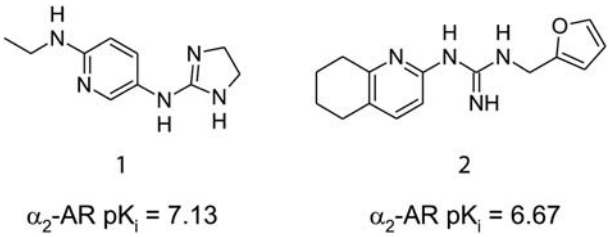
GPCRs and soluble targets in compound binding and molecular properties, particularly if the ligand is bound deep within the protein in regions that are embedded in the cell membrane. We attempt to highlight the impact of these differences on the design process.

3.08.5.1 Orthosteric GPCR Ligands

3.08.5.1.1 Class A GPCR aminergic

α-Adrenergic receptors. The binding pose of a series of α_2-AR antagonists based on the pyridinoguanidine and pyridino-2-aminoimidazoline scaffolds has been elucidated using homology models of α_{2A}-AR and α_{2C}-AR derived from the β_2-AR

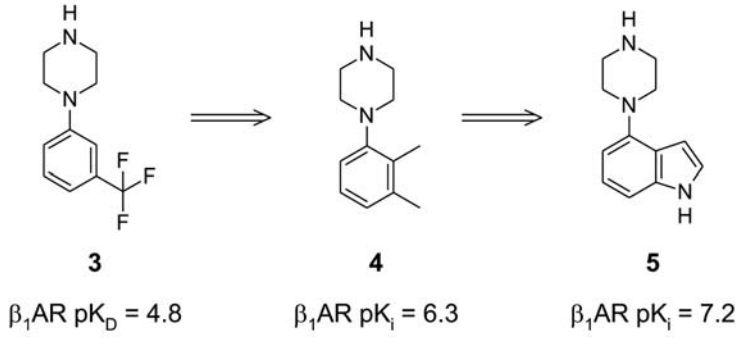


Scheme 1 α_2-AR antagonists **1** and **2** in which the cationic group interacts with the Asp113.

structure.[182] For the monosubstituted derivatives within these series, the cationic group interacts with two residues implicated in catechol ligand binding and receptor activation, derived from the understanding provided by the crystal structure of activated β_2-AR (Ser200$^{5.42a}$ and Ser204$^{5.46a}$ of the α_{2A}-AR and Ser214$^{5.42a}$ and Ser218$^{5.46a}$ of the α_{2C}-AR). Exceptions to this are the ethylamino pyridine derivatives, such as compound **1** in **Scheme 1**, which orientate the cationic group to interact with the Asp113$^{3.32a}$ (Asp131$^{3.32a}$ of the α_{2C}-AR) and fill the Ser200$^{5.42a}$/Ser204$^{5.46a}$ region of the receptor with the pyridyl core. The cationic group of the disubstituted guanidines and 1,4-dihydroquinazolines, such as compound **2**, within this series of compounds is also predicted to interact with Asp113$^{3.32a}$ of the α_{2A}-AR (Asp131$^{3.32a}$ of the α_{2C}-AR) in the homology model, and the substituent on the cationic group is thought to bind in a lipophilic pocket made up of aromatic residues from TM3 and TM7 (Tyr109$^{3.28a}$, Phe412$^{7.39a}$, and Tyr416$^{7.43a}$ of the α_{2A}-AR and Tyr127$^{3.28a}$, Phe423$^{7.39a}$, and Tyr427$^{7.43a}$ of the α_{2C}-AR). This overall binding pose explains the antagonist activity observed for these compounds because the cationic group is not able to interact with Ser200$^{5.42a}$/Ser204$^{5.46a}$ of the α_{2A}-AR (Ser214$^{5.42a}$/Ser218$^{5.46a}$ of the α_{2C}-AR) and causes receptor activation. This binding pose can be used to help in future design of new α_2-AR antagonists useful for the treatment of depression and schizophrenia.

β-Adrenergic receptors. In addition to the docking and virtual screening included in **Table 1**, SBDD has been applied to β-adrenergic receptors (β-AR). Hattori et al. have used structure-driven modifications in a series of biphenyl analogs containing acylsulfonamide substitution to obtain potent and selective β_3AR agonists.[183] The predicted binding pose was used to rationalize both selectivity and potency. A series of high-efficacy β_2AR agonists that are analogs of the known compound sibenadet, lacking the usual benzylic alcohol group found in most potent agonists, were generated by Stocks et al.[184] An induced fit was proposed in which Trp286$^{6.48a}$ moves to produce a new lipophilic pocket that can accommodate the ligand. Soriano-Ursúa et al. have designed boron-containing analogs of β_2AR agonists using the β_2 receptor X-ray structure.[185] Interestingly, one analog had higher potency than the corresponding diol (the usual pharmacophore) in a functional assay. Other analogs were shown to be competitively antagonized by β_2AR antagonists.

Christopher et al. have used the antagonist-stabilized β_1AR (StaR β_1AR; StaR is used to describe a receptor stabilized using mutagenesis) for fragment screening and then subsequently for X-ray crystallographic studies of analogs of the fragment hits.[186] Small phenyl piperazine hits such as **3**, **Scheme 2**, were identified using surface plasmon resonance (SPR) screening of the StaR immobilized on a chip. This is an unusual example of a biophysical screening approach being applied to a GPCR, facilitated by the additional stability introduced into the protein by mutagenesis. A modeling analysis was carried out to suggest binding modes for a number of related hits, which had affinities in the range of 1–50 μM, **4**, at the wild-type (WT) receptor. This led to subsequent purchasing of selected analogs for further screening. Of note, an indole-containing derivative, **5**, was prioritized due to a predicted additional interaction with the OH of Ser 211$^{5.42a}$. Upon screening, this compound was shown to have a significantly improved affinity of approximately 60 nM (assessed using a radioligand binding assay). Crystal structures of two fragment-sized molecules were then solved, confirming the modeling hypothesis and establishing the basis for further possible optimization. Overall, this case study demonstrates that the principles of fragment-based drug discovery can be applied to GPCRs.



Scheme 2 β_1-AR antagonists SPR fragment hits **3** and **4**, and selected analogue **5**.

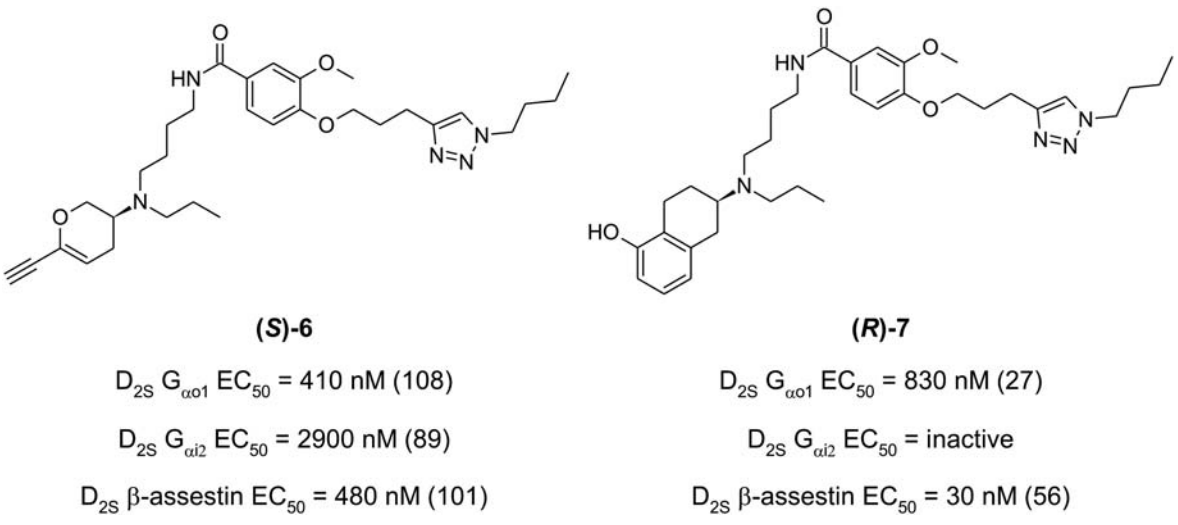
Dopamine receptors. There are five reported dopamine receptors subtypes (D_1, D_2, D_3, D_4, and D_5), and the pharmacological targeting of these receptors in the CNS has proved to be a very effective approach for the treatment of several pathological conditions. Both agonists and antagonists have been investigated clinically to treat a range of disease states such as Parkinson's disease, schizophrenia, bipolar disorder, and depression.

Using a homology model of the D_2 receptor (based on the published crystal structure of the D_3 receptor) and in comparison with the crystal structure of the 5-HT_{2B} receptor in complex with the biased agonist ergotamine, a range of biased D_2 receptor agonists have been rationally designed. Gmeiner et al.[187] have reported a series of D_2-biased ligands that incorporate a pyrazolopyridine-derived headgroup and an enyne motif (as an atypical bioisostere replacement of the catechol group found in dopamine itself). These ligands are predicted to bind in an extended binding site, and interestingly, the docking poses contained ligand–protein interactions in the identical positions as those observed within the crystal structure of the 5-HT_{2B} receptor in complex with the biased agonist ergotamine. This potentially indicates the presence of conserved receptor microdomains at the entrance to the orthosteric pocket that are involved in ligand bias.

Gmeiner et al.[188] then expanded upon this methodology with the discovery of **(*S*)-6**, Scheme 3, which contains an oxaenyne headgroup as an atypical bioisostere replacement of the catechol group and is a biased agonist that displays a strong preference for $G_{\alpha o}$ activation. It has been proposed that the activation of $G_{\alpha o}$ subunits will stimulate outgrowth of neuronal cells and promote synaptic plasticity, which in turn will impact the positive symptoms of schizophrenia.[189,190] Taking this further, using a classical catechol bioisostere replacement led to design of compound **(*R*)-7**, which showed β-arrestin recruitment while being a weak partial agonist for $G_{\alpha o}$ activation and an antagonist for $G_{\alpha i}$. Intriguingly, a β-arrestin-biased ligand could have clinical relevance for the treatment of antipsychotic symptoms in schizophrenia.[191]

Christopoulos and Lane et al.[192] have used a homology model of the D_2 receptor based on the crystal structure of the D_3 receptor to determine the binding mode of the ligand **SB-269652**, which is a bitopic negative allosteric modulator of the D_2 receptor. Bitopic is a term used in some of the literature to describe ligands that bind to two adjacent or contiguous binding sites in class A GPCRs, the deep orthosteric site usually occupied by the endogenous agonist and a "vestibule" site at the entrance to the binding pocket. The 1*H*-indole-2-carboxamide moiety of **SB269652** extends into this secondary pocket between the extracellular ends of TM2 and TM7, while the 7-cyano-1,2,3,4-tetrahydroisoquinoline headgroup occupies the orthosteric binding site.[192] Fragmentation of **SB-269652** led to *N*-isopropyl-1*H*-indole-2-carboxamide **8**, Scheme 4, which was the smallest fragment to still contain allosteric pharmacology. Structure–activity relationship studies based on **8** identified *N*-butyl-1*H*-indole-2-carboxamide, **9**, which had increased D_2 affinity and shows negative cooperativity.[193] Combining this active fragment with the 7-cyano-1,2,3,4-tetrahydroisoquinoline headgroup gave a highly active bitopic negative allosteric modular (NAM) **10**.

Utilizing the D_3 crystal structure and a structural hybridization approach incorporating dopaminergic dipropylamines and arene-carboxamides, Gaimer and coworkers[194] have described an enantiomerically pure biphenylcarboxamide D_3 receptor agonist, **(*S*)-11**, Scheme 5, with a very high binding affinity of 27 pM and good selectivity for the D_3 receptor over the D_2 subtype. AUTODOCK4 was used to dock a range of hybridized molecules into the D_3 crystal structure; the docking pose of **(*S*)-8** showed the expected polar interaction between $Asp110^{3.32a}$ in TM3 and the protonated central ammonium group and the tetrahydropyrazolopyridine headgroup forming a hydrophobic interaction with the amino acid residues $Val111^{3.33a}$, $Ser196^{5.46a}$, $Phe345^{6.51a}$, $Phe346^{6.52a}$, and $His349^{6.55a}$. The propyl group was predicted to bind into a pocket created by $Asp110^{3.32a}$, $Trp342^{6.48a}$, and $Thr369^{7.39a}$ between TM3, TM2, and TM7, while the endocyclic nitrogen of the tetrahydropyrazolopyridine group of **(*S*)-11** forms a hydrogen bond with the side chain of $Ser192^{5.42a}$, a proposal that was supported by site-directed mutagenesis (SDM) experiments. The N-butylbiphenylcarboxamide portion of **(*S*)-11** binds in a pocket created by TM2 and TM3, which is thought responsible for



Scheme 3 D_2-biased receptor agonists **(*S*)-6** and **(*R*)-7**.

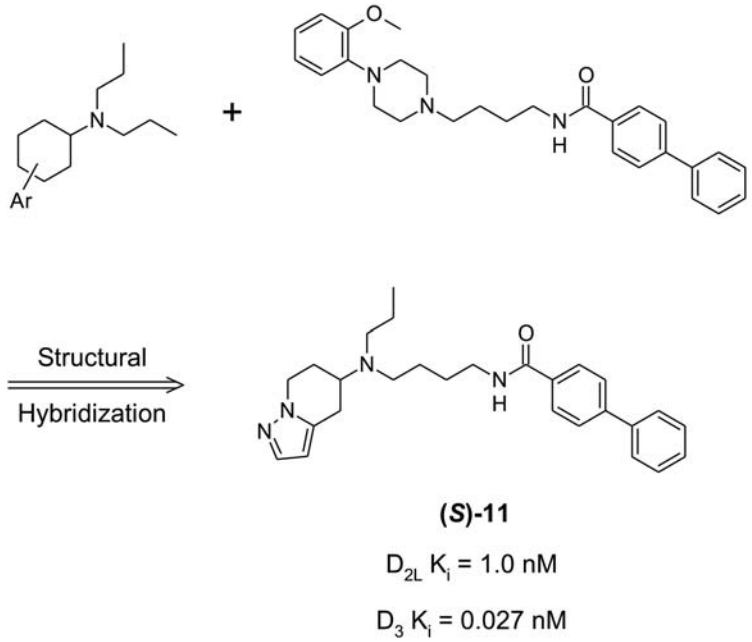

Scheme 5 Structural hybridization approach to give the D_3 receptor agonist **(S)-11**.

subtype selectivity. **(*S*)-11** was shown to have biased signaling with significant preference for [^{3}H]-thymidine incorporation compared with cAMP accumulation.

More recently, Ananthan et al.[195] have reported the discovery of a series of acylaminobutylpiperazines, Scheme 6, as antagonists or partial agonists of the dopamine D_3 receptor, which have subtype selectivity over D_2. Docking of this series of compounds into the reported D_3 crystal structure and a D_2 homology model provided an understanding of the compound attributes, which were contributing to binding selectivity and affinity of these compounds. Selectivity for the D_3 receptor was likely obtained via interactions of the imidazo[1,2-*a*]pyridine group with the tyrosine residue (Tyr365$^{7.35a}$) at the extracellular end of TM7; this region is significantly different in the D_2 and D_3 receptors. **SR21502**, Scheme 6, was assessed in rat in vivo models of cocaine self-administration and conditioned place preference. The compound was shown to be effective at significantly attenuating cocaine reward, cocaine self-administration, cue-induced reinstatement of cocaine-seeking, and blocking cocaine-induced place preference.

Serotonin receptors. There are seven reported families of the serotonin (5-hydroxytryptamine, 5-HT) receptors (5-HT_1, 5-HT_2, 5-HT_3, 5-HT_4, 5-HT_5, 5-HT_6, and 5-HT_7), which all belong to the GPCR superfamily except 5-HT_3 that is a ligand-gated ion channel. For several of these proteins, various subtypes of receptors have been described, namely, 5-$HT_{1A\text{-}F}$, 5-$HT_{2A\text{-}C}$, and 5-$HT_{5A\text{-}B}$. Serotonin receptors are distributed in the central and peripheral nervous systems, the gastrointestinal tract, the cardiovascular system, and the immune cells. Both agonists and antagonists have been developed for this receptor class including various antipsychotic, antidepressant, and antiemetic drugs. However, as the various 5-HT receptors were identified, it became apparent that many of these drugs lack receptor selectivity, making it difficult to determine the specific role of each receptor in these disease settings from the clinical findings.

As GPCR X-ray data have become available in recent years, there have been a number of reports in the literature focusing on 5-HT ligand–protein binding and SBDD efforts. Liégeois et al.[196] have used a homology model of the 5-HT_{1A} based on the published turkey β_1-adrenergic receptor structure to derive a series of carboxamide and sulfonamide alkyl piperazine analogs as exemplified by **12**, Scheme 7. The proposed docking pose of **12** into the orthosteric site was very similar to that found for the full and potent agonist R-8-OH-DPAT. The basic center of the compound was proposed to make an ionic interaction with $Asp116^{3.32a}$ and the 2-methoxyphenyl-piperazine portion of the molecule to interact with the aromatic residues $Phe361^{6.51a}$ and $Phe362^{6.52a}$. The oxygen of the methoxy group was suggested to form hydrogen bonds with $Ser199^{5.42a}$ and $Thr200^{5.43a}$. The naphthalene ring in the ligand was proposed to bind in a lipophilic aromatic pocket formed by the residues $Tyr96^{2.64a}$, $Trp387^{7.40a}$, and $Tyr390^{7.43a}$. Finally, the amide group seemed to form a hydrogen bond with $Asn386^{7.39a}$. Electrophysiological experiments were performed with compound **12** to investigate the effect on the firing rate of serotonergic neurons of the dorsal raphe nucleus (DR) in rat brain slices, and **12** was demonstrated to induce a concentration-dependent decrease in the firing rate of DR serotonergic neurons with an IC_{50} of 179 nM.

Huang et al.[133] have carried out a structure-based virtual screening campaign to identify novel 5-HT_{2B} receptor antagonists by using an induced-fit 5-HT_{2B} receptor antagonist model based on the reported agonist X-ray structure of the 5-HT_{2B} receptor. A series of *N*2-aryl-6,6-disubstituted-1,6-dihydro-1,3,5-triazine-2,4-diamines were identified from this initial screen, and these molecules adopted a similar binding mode in the induced-fit model. Further structure–activity relationship (SAR) studies were performed to identify **13**, Scheme 8, a promising candidate with high binding affinity and high selectivity for the 5-HT_{2B} receptor over eleven other 5-HT receptors. A 30 mg/kg oral dose of **13** produced significant reduction of visceral hypersensitivity in a rat model of irritable bowel syndrome (IBS). This series of compounds employs a protonated triazine ring to form hydrogen bonds with the $Asn344^{6.55a}$ residue and a salt bridge interaction with the carboxylate group of $Asp135^{3.32a}$ in the binding site.

The discovery of **PF-4479745** and **PF-4522654**, Scheme 9, as potent, selective 5-HT_{2C} receptor partial agonists based on the 4-substituted pyrimido[4,5-d]azepines scaffold has been reported by Storer et al.[197] **PF-4479745** and **PF-4522654** have no

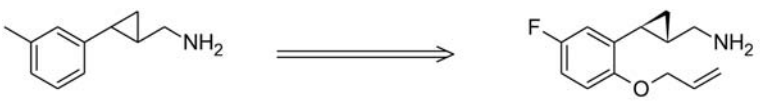
measurable functional agonism at 5-HT$_{2A}$ and 5-HT$_{2B}$ in relevant tissue-based assay systems. Both these compounds displayed in vivo efficacy in a canine peak urethral pressure model of stress urinary incontinence and potentially have desirable human pharmacokinetic profiles based on the measured human liver microsomal (HLM) and human hepatocyte clearances. Homology models derived from site-directed mutagenesis (SDM) data and crystal structures of the active and inactive β_2-adrenergic receptor were used to generate an inactive-state 5-HT$_{2C}$ homology model and an active-state 5-HT$_{2C}$ homology model. These models were used to rationalize the binding pose, affinity, and agonist efficacy of this series of molecules.

Kozikowski et al.[198] have reported a series of potent, selective 5-HT$_{2C}$ receptor agonists based on the 2-phenylcyclopropylmethylamine scaffold. Optimization of this series has led to the discovery of **(+)-14**, Scheme 10, which



(+)-14

5-HT$_{2A}$ EC_{50} = 374 nM (56)

5-HT$_{2C}$ EC_{50} = 4.2 nM (87)

Scheme 10 Selective 5-HT$_{2C}$ receptor agonist **(+)-14**.

has an EC_{50} value of 4.2 nM at 5-HT_{2C}, has no significant activity at 5-HT_{2B}, and was 89-fold-selective against 5-HT_{2A}. At a dose of 20 mg/kg in a mouse schizophrenia in vivo model **(+)-14** completely reversed amphetamine-induced hyperactivity while showing no significant influence on the spontaneous activity of the tested animals. Two homology models were generated to predict the binding pose of this series of compounds. An inactive-state 5-HT_{2C} homology model derived from the inactive-state structure of β_2-adrenergic receptor and an active-state 5-HT_{2C} homology model based on a combination of the solved structure of 5-HT_{2B} in complex with ergotamine and the β_2-AR in its fully active state were developed. Major differences were observed between the binding poses of compound **(+)-14** with the inactive and active homology models. In the active-state homology model, the phenyl ring of **(+)-14** docks into a binding pocket lined by aromatic residues (Phe214$^{5.38a}$, Trp324$^{6.48a}$, Phe327$^{6.51a}$, Phe328$^{6.52a}$, and Tyr358$^{7.43a}$) deeper in the binding site, which creates a network of π–π stacking interactions. The ether bridge was proposed to be involved in two possible H bonds with Ser219$^{5.43a}$ and Asn331$^{6.55a}$ and the alkenyl tail π–π stacking with Phe214$^{5.38a}$. These predicted binding poses allow hypotheses to be developed for further compound design in this series of molecules.

3.08.5.1.2 Class A GPCR peptidergic

Opioid receptors. Opioids exert their function through interacting with one or more of the four opioid GPCRs, designated as the mu-opioid receptor (MOR), the kappa-opioid receptor (KOR), the delta-opioid receptor (DOR), and the nociception receptor (NOP). In recent years, a number of liganded X-ray structures have been published giving the opportunity for SBDD for these important pain targets.[199]

Zhang et al.[200] used a MOR homology model to design three generations of heteroaromatic-substituted naltrexone (antagonist) derivatives. These compounds were evaluated as potential MOR-selective ligands. The first-generation ligands appeared to be MOR-selective, whereas the second and the third generation ones showed MOR/KOR dual selectivity. Docking of MOR-selective and MOR/KOR dual-selective ligands into the three opioid receptor crystal structures revealed a nonconserved residue$^{2.63}$, which appears to facilitate a hydrogen-bonding network and might be responsible for the distinctive selectivity profiles. Overall, one antagonist was identified as a novel lead to develop MOR/KOR dual-selective ligands, which might possess therapeutic value for opioid addiction treatment.

Studies to understand the structure-based SAR of endomorphin analogs have been carried out by a number of groups reporting their results in the recent literature. The MOR endogenous tetrapeptides, endomorphin-1 (**EM-1**, H-Tyr-Pro-Trp-Phe-NH_2), Scheme 11, and endomorphin-2 (**EM-2**, H-Tyr-Pro-Phe-Phe-NH_2), Scheme 12, were originally isolated from the bovine brain and the human cortex. These peptides exhibit high affinity for the MOR and high selectivity over DOR. Wang et al.[201] rationalized the pharmacology of **EM-1** analogs, such as **15**, using flexible dockings into a model of human MOR, and then, the resultant poses were further optimized with molecular dynamics. The poses generated were supported by SDM experiments, and the results were compared with the crystal structure of the antagonist β-FNA in MOR. The study identified some promising new peptides modified with unnatural amino acids, suitable for further optimization. Sacchetti et al.[202] characterized potent analogs of **EM-2**, such as **16**, using a combination of proton nuclear magnetic resonance (NMR) conformational analysis, molecular dynamics, and docking studies into a model of MOR. In solution, the structures showed extended conformations, which were in agreement with the commonly accepted pharmacophore model for **EM-2**. The docking studies used an active form MOR model and generated a credible picture of how the active compounds were binding in a sensible ligand conformation. Again, the results were consistent with SDM experiments. Building confidence in the ligand conformation is particularly important in peptidomimetic drug discovery due to the potentially flexible nature of the peptide scaffolds; in practice, there tends to be only a small number of well-populated conformations in solution and a single form bound to the target receptor for any given analog.

3.08.5.1.3 Class A GPCR purinergic

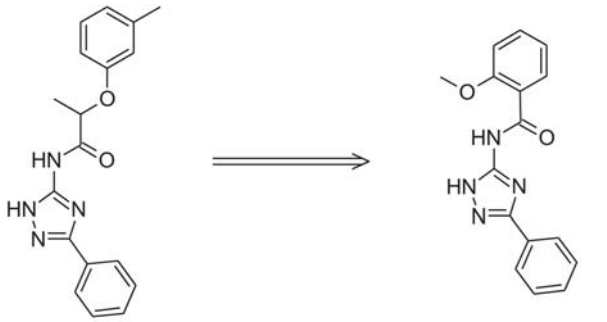
Adenosine receptors. The adenosine receptor family (A_1, A_{2A}, A_{2B}, and A_3) has been extensively researched over many years with a number of agents (both agonists and antagonists) being investigated clinically for the treatment of cardiovascular disease, renal disorders, asthma, Parkinson's disease, and cognitive disorders.[203] Antagonists of the adenosine A_{2A} receptor have also been more recently implicated in cancer immunotherapy.[204] There are now multiple published crystal structures of the adenosine A_{2A} receptor bound to small-molecule ligands in both antagonist and agonist receptor conformations, and this gives the opportunity for a new generation of adenosine receptor agonists and antagonists to be created. Indeed, SBDD approaches to adenosine receptors are the subject of a number of recent reviews.[205–207] Earlier in this article, we outlined some of the in silico studies carried out on this receptor and discussed how certain compounds bind and examined the opportunities for virtual screening.

The availability of stable purified protein has also meant that adenosine A_{2A} has been a work-horse system for fragment screening approaches over the last 5 years. Although not SBDD studies in themselves, fragment screening studies provide low-molecular-weight start points for the development of new series, and in fragment-based drug discovery, SBDD methodology is generally utilized. For example, target-immobilized NMR screening (TINS) is a methodology used to detect relatively weak interactions between proteins and small molecules. The technique uses changes in the NMR spectrum of the ligand upon its binding to the target protein due to a change in the speed with which it is tumbling through solution. The A_{2A} receptor has been stabilized using Heptares' StaR technology to give protein (A_{2A} StaR2) that could be successfully immobilized on Sepharose resin and then screened using the TINS method. A library of 531 fragment-sized molecules was analyzed at 500 μM.[208] After further characterization, five competitive orthosteric ligands with varied chemical structures were identified, with IC_{50} values ranging between 70 and 1880 μM in concentration-response studies with [^{3}H]-ZM-241385. This and other biophysical methods not discussed here have been successfully applied to stabilized GPCR proteins such as adenosine A_{2A}, demonstrating that fragment screening using direct-binding methodologies, previously applied only to soluble targets, has potential to facilitate GPCR drug discovery.

In a follow-up to the NMR fragment screen (in the aforementioned text), Siegal and Carlsson et al.[110] carried out docking studies of the fragment hits to try to predict their binging modes to the adenosine A_{2A} receptor. Molecular docking was able to predict four out of the five orthosteric ligands discovered by NMR among the top 5% of the ranked library, suggesting that structure-based methods could be used to prioritize among primary hits from biophysical screens. In addition, three fragments that were top-ranked by molecular docking, but had not been picked up by the NMR-based method, were demonstrated to be A_{2A} receptor ligands. Encouraged by these results, the authors carried out a virtual screen of a much larger library of commercially available fragments (328,000 compounds). Fourteen new active compounds were identified from biological testing of 22 purchased fragments and preliminary SAR established by screening of analogs of some of the more promising hits.

As noted earlier, the newly available A_{2A}R protein–ligand structures are being extensively applied to ligand design. There is an increasing understanding of the requirements of the pocket for potency, the roles of water molecules in the binding site, and the areas of the pocket important for selectivity for one receptor subtype over the others in the family. In addition, the availability of both antagonist and agonist forms of the receptor gives an insight into the mechanisms of receptor activation for these receptors and is aiding the design of new generations of selective agonists.

Pastorin et al. have reported a number of triazolotriazine derivatives as antagonists binding to the A_{2A} receptor and for which docking experiments using the GOLD software in the A_{2A}R crystal structure were studied.[209] Homology modeling was also carried out for the closely related A_3R to try to study selectivity. The structure–activity relationship for the series of compounds was then rationalized, and it was suggested that the presence of a relatively less bulky amino acid (Val169) in the ECL2 of the adenosine A_3 receptor might be important to affect potency and selectivity for the A_{2A} receptor versus the A_3 subtype. The molecules were then further optimized using SBDD in a separate publication, identifying the best vector to append aqueous solubilizing groups. This overcame some issues with poor solubility in the heterocyclic template itself and successfully generated highly potent and very soluble lead compounds.[210] In a chemically related series, Higgs et al. have investigated the SAR of a series of low-molecular-weight



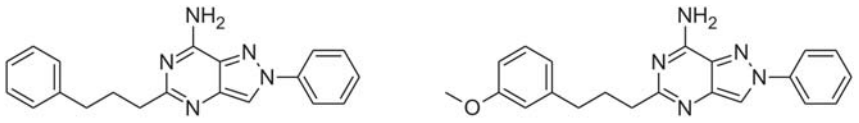
Scheme 13 Development of a series of 1,2,4-triazoles A_{2A} receptor antagonists.

triazolylpurines as adenosine A_{2A} antagonists. The importance of the role of water molecules in the binding site was investigated using the software WaterMap and using the crystal structure PDB ID, 3EML.[12] Interestingly, the SAR could be rationalized in that small substituents were proposed to occupy a region containing stable waters, while larger groups accessed a subpocket to displace unstable waters.

Carlsson and coworkers have investigated virtual screening of the adenosine A_{2A} receptor in the antagonist conformation in a number of contributions to the literature (in the aforementioned text and **Table 1**). In one report, the SAR across a series of 1,2,4-triazoles has been further investigated, again using modeling information.[211] Thirty-three analogs were tested in adenosine A_1, A_{2A}, and A_3 receptor radioligand binding assays and in functional assays for the A_{2B} receptor subtype. Surprisingly, a series of closely related analogs of the initial lead **17**, **Scheme 13**, did not display improved binding affinity or selectivity. Further molecular docking studies were used to guide the selection of more distantly related molecules resulting in the discovery of **18**, a submicromolar adenosine A_{2A} receptor antagonist (K_i 200 nM) with high ligand efficiency but lacking selectivity over the A_3 receptor. The polar core of **18** was proposed to form hydrogen-bonding interactions with Asn253$^{6.55a}$ and Glu169 (ECL2).

Volpini and coworkers have described the synthesis and biological evaluation at the four human adenosine receptor subtypes of a series of 9-substituted 8-(2-furyl)adenine derivatives.[212] Results showed that 8-(2-furyl)-9-methyladenine has high affinity at the A_{2A} subtype. Further modification of this compound with introduction of arylacetyl or arylcarbamoyl groups in the N^6-position modified the selectivity versus the other three adenosine receptor subtypes. A molecular modeling analysis at three different A_{2A} receptor crystal structures provided a preliminary interpretation of the obtained biological results. The authors went on to describe further studies of these 9-propyladenines this time bearing a phenylalkylamino group in the 2-position or a phenylalkyl chain in the N^6-position.[213] One analog 2-benzylamino-8-furyl-9-propyladenine was more active than the parent 8-furyl-9-propyladenine at A_{2A} and A_3 adenosine receptors (K_i A_{2A} = 6.6 nM and K_i A_3 = 29 nM compared with K_i A_{2A} = 18 nM and K_i A_3 = 790 nM). Molecular modeling studies again gave some explanation of the different activities of the compounds at the A_{2A} receptor. In particular, the findings suggested that the introduction of a phenylalkylamino chain in the 2- or 6-positions of 9-alkyl purine derivatives favors the interaction of the resulting compounds with the A_{2A} subtype providing further suggestions for the synthesis of new antagonists of this receptor.

In a recent contribution to the literature, Colotta and Moro et al. identified a promising phenylpropyl-substituted pyrazolopyrimidine derivative as a dual adenosine A_1/A_{2A} receptor antagonist, showing high affinity for both the receptor subtypes, compound **19**, **Scheme 14**.[214] Also described were some highly potent and selective antagonists for the adenosine A_1 receptor with low

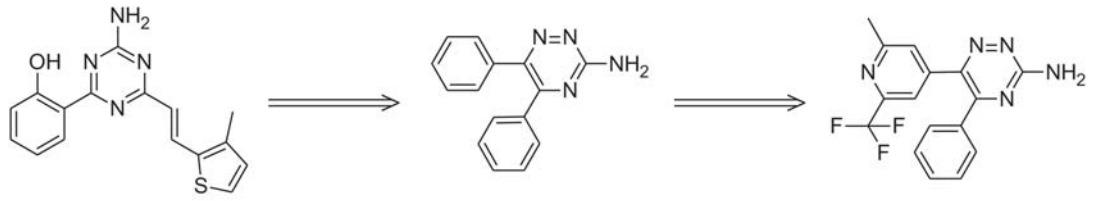


Scheme 14 Dual adenosine A_1/A_{2A} receptor antagonists **19** and **20**.

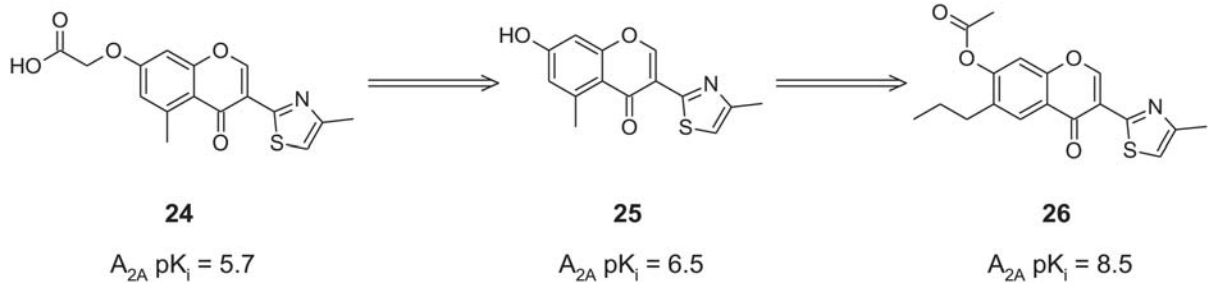
nanomolar affinity, such as **20**. Molecular modeling studies indicated that the selected compounds might adopt a placement in the adenosine A_1 and A_{2A} receptor binding clefts that resembles the crystallographic binding mode of X-ray cocomplex ligand **ZM-241385**. It was rationalized that stabilizing interactions, not shown at the A_{2A} receptor, with Thr270$^{7.35a}$, Tyr271$^{7.36a}$, Ser267$^{7.32a}$, or Glu170^{EL2a} residues might account for the enhanced adenosine A_1 affinity of ortho- and metasubstituted derivatives. These additional electrostatic interactions are either weaker or not detected for the parasubstituted derivatives, consistently with their lower affinity for both the subtypes.

The first GPCR structure-based drug design case study in which crystal structures of analogs were solved and used as part of the lead optimization process was targeted at identification of adenosine A_{2A} antagonists. Congreve et al. described the identification and derivatization of 1,2,4-triazine derivatives targeting the orthosteric site of the receptor.[87] The original highly potent but nonselective hit **21**, **Scheme 15**, was discovered using virtual screening against a homology model of the receptor optimized and enhanced using site-directed mutagenesis data.[112] The various hit series were next characterized using a method called Biophysical Mapping™. SDM in the binding site was carried out in the background of the stabilized receptor, followed by physical capture of each mutated protein sample onto a chip format. A biophysical technique, SPR screening, was then used to study the binding properties of the compounds versus each modified receptor.[215] In this way, a map of the binding site was produced correlating the changes made to amino acid side chains within the binding site and the SAR of the compound series. Using this analysis, the hit **21** (**Scheme 15**) was redesigned and simplified to an alternative regiochemistry aiming to more optimally fit the binding site. This led to identification of hit scaffold **22**.[87] Although less potent than **21**, simple optimization to better fill the binding pocket rapidly delivered potent compounds. Crystal structures of two analogs were presented in the article and illustrated that the molecules bind more deeply inside the orthosteric binding cavity than most other classes of A_{2A}R antagonists creating the opportunity to produce smaller and more drug-like molecules. The X-ray data also indicated that 3,5-disubstitution of one of the aryl rings was likely to be the driver of improved selectivity over the A_1 receptor, due to small differences between the receptors in the part of the binding pocket that this ring occupies. An optimized analog **23** was described in some detail and is a potent, ligand-efficient, 10-fold-selective, and orally efficacious compound representing a good lead compound. These results suggested further progression of the series of compounds. Indeed, Heptares Therapeutics has recently publically announced the selection of a clinical candidate HTL1071 that is being explored for the potential treatment of cancers in collaboration with AstraZeneca.

In a follow-on study, a series of chromone derivatives optimized using SBDD methods as antagonists of the adenosine A_{2A} receptor have been described by Andrews et al.[216] Again, the original hit **24**, **Scheme 16**, was derived from a virtual screening campaign versus a homology model of the receptor.[112] After consideration of the docking poses of the hit compound and in particular the polar interactions present between the ligand and the receptor, further analogs were purchased and screened. For example, removal of the carboxylic acid led to **25** with improved affinity and ligand efficiency. Using a druggability analysis of the binding site, a lipophilic hotspot was identified with a GRID aromatic CH (C1=) probe in a pocket lined by Ile66$^{2.64a}$ and Tyr271$^{7.36a}$. This led to the design of compounds with lipophilic groups at the C-6 of the chromone core. With this modification and the further addition of an acetyl group on the phenol derivative, **26** was designed resulting in very high affinity versus the receptor. Interestingly, in a related compound, removal of the methyl group from the thiazole ring system produced a significant reduction in affinity, and this was



Scheme 15 Identification and optimisation of a series of 1,2,4-triazine A_{2A} receptor antagonists.



Scheme 16 SBDD optimisation of a series of chromone A_{2A} receptor antagonists.

rationalized to be because the methyl group displaces a water molecule trapped at the bottom of the binding site, and when the methyl is absent, this water is then present in an unfavorable lipophilic environment. Examples from the series were screened versus the other adenosine receptor subtypes and shown to have good selectivity for the adenosine A_{2A} receptor.

In addition to the examples described earlier of antagonists of the adenosine A_{2A} receptor, there have been many reports of studies on the other adenosine subfamily members. Included below are some selected examples targeting the adenosine A_3 receptor using homology modeling and starting from A_{2A}R crystal structures. The adenosine A_3 receptor is closely related to adenosine A_{2A} making the modeling of its binding site possible with a good degree of confidence.

Catarzi et al. have investigated a series of pyrazoloquinazoline adenosine A_3 receptor antagonists and carried out docking studies to rationalize the SAR and overall binding modes of the best compounds.[217] A number of docking proposals were considered, each with the tricyclic core interacting with Asn250$^{6.55a}$ and π-stacking with the Phe168^{ECL2}. Despite being a bulky rigid scaffold, a number of proposals appeared credible due to the large cavity predicted for the orthosteric site of the receptor. However, the detailed SAR for the derivatives was used to provide evidence for a preferred pose and allowed for the design of simplified analogs in the compound series, which maintained submicromolar receptor potency. This work has been extended in a recent publication, describing further optimization of related analogs with high selectivity for the A_3 receptor over the A_{2A} receptor.[218]

Pastorin, Spalluto, Colotta, and Moro et al. have extended their work (described earlier) on adenosine receptor antagonist ligands by developing pyrazolo-triazolo-pyrimidines and related compounds focusing on selective adenosine A_3 antagonists.[219–221] For example, using a combination of SAR and molecular modeling-driven hypotheses, a subnanomolar and highly selective adenosine A_3 antagonist has been identified that also lacks the furan ring system present in many adenosine receptor antagonists.[219] The furan ring is a possible source of reactive metabolites in vivo and therefore a potential toxicophore. The selectivity of the new lead compound was proposed to be derived from a significant rotation of the molecule within the A_{2A} binding site relative to the A_3 receptor perturbing the key H-bonding interactions with the critical polar residue Asn$^{6.55a}$. This appeared to be due to interaction with the molecule with Val169 (ECL2) in A_3 versus Glu169 (ECL2) in A_{2A} and that this was causing the change in binding pose in the A_{2A} subtype.

Gutiérrez-de-Terán et al. describe the synthesis and SAR of a series of aminopyrimidine adenosine A_3 antagonists, developed using SBDD.[222] A number of highly potent and selective molecules were identified. Using a homology model of the A_3 receptor, a binding pose for the series was optimized considering the SAR and selectivity. The core polar heterocycle and amide substituent were proposed to interact with Asn250$^{6.55a}$; an overlay of 62 examples was used to develop a 3-D QSAR model, and a detailed rationalization of the selectivity and potency was provided with careful consideration given to residues lining the binding sites in the various receptor subtypes. The robustness and predictive capabilities of the model were then validated by designing further compounds, such as **ISVY130**, **Scheme 17**, that explored new alkyl residues at one of the vectors from the chemical scaffold and that showed high affinity and selectivity profiles for the A_3 receptor.

Baraldi and Preti et al. have reported a new series of 2-heterocyclyl-imidazo[2,1-*i*]purin-5-one derivatives as adenosine receptor antagonists.[223] The 2-heterocyclyl substitution proved to induce excellent affinity and selectivity toward the adenosine A_3 subtype. Molecular modeling studies were helpful in rationalizing the observed SAR along with the selectivity profiles of the new series of ligands. In particular, docking of the most potent compound provided a credible binding mode of the newly described derivatives. A number of the adenosine A_3 antagonists showed good potency and selectivity and were thought suitable for further investigation. The same team has also published a follow-on paper in which urea-based derivatives were reported.[224]

The availability of agonist-bound structures of the adenosine A_{2A} receptor has precipitated a number of studies to reevaluate adenosine-derived small-molecule agonists. In fact, adenosine analogs have been studied for many years as agonists of adenosine receptors, and now, the binding modes and molecular interactions are finally being understood.[203]

Soon after the structures became available, Deflorian et al. compared previous docking studies of molecules into homology models of the receptor with dockings of each compound into X-ray structures of **UK-432,097** and **NECA**.[225] The purine base of the agonists overlays with the heterocyclic portion of antagonist ligands as perhaps might be expected. However, there are key differences between agonists and antagonists caused by the ribose moiety found in the agonists that forms additional important polar interactions with Thr88$^{3.36a}$, His250$^{6.52a}$, Ser277$^{7.42a}$, and His278$^{7.43a}$, which are largely absent in antagonists. Jacobson et al. have reported a number of subsequent studies on adenosine agonists using SBDD, for example, rationally designing adenosine analogs leading to a highly potent and selective adenosine A_3 agonist, demonstrating the high value of the new agonist-bound X-ray structures.[226]

Jacobson and Katritch et al. went on to use the agonist-bound A_{2A} crystal structures to directly design modifications to the ribose motif and create new agonist analogs.[114] The optimization process used in silico design and docking to modify substituents on the carboxylate functional group of the ribose, which is positioned deep in the bottom of the binding pocket of the receptor. In this way, a number of potent analogs were identified, derived from the nonselective ligand **NECA**. Interestingly, some of the new compounds showed differing patterns of selectivity across the closely related adenosine A_{2A}, A_1, and A_3 receptors and also varying degrees of partial to full agonism. For example, compound **27** in Scheme 18 is a potent and selective partial agonist at the adenosine A_1 receptor.

Jacobson et al. have also worked on structure-based optimization of (*N*)-methanocarba nucleosides, in which the ribose sugar has been altered to a carbocyclic ring system.[227] Efforts led to rational design of MRS5474, a moderately selective adenosine A_1 full agonist in which the N^6-substituent of the base had been modified. The compound showed efficacy in a relevant in vivo model. Nucleoside docking into an A_1 receptor homology model characterized distinct hydrophobic subpockets for the new substituents, the larger forming contacts with Thr270$^{7.35a}$, Tyr271$^{7.36a}$, Ile274$^{7.39a}$, and carbon chains of glutamates (EL2) and the smaller subpocket forming contacts between TM6 and TM7. In a related study, (*N*)-methanocarba(bicyclo[3.1.0]hexane)adenosine derivatives containing charged sulphonate substituents have been rationally designed as peripherally restricted adenosine A_3 agonists.[228] The rational design approach based on A_3 homology models successfully predicted sites for sulfonate incorporation, producing compounds designed to delineate adenosine's CNS versus peripheral actions.

Lavecchia and Cappellacci et al. have recently reported dual adenosine A_1/A_3 nucleoside agonists for potential treatment of glaucoma.[229] The ribose ring was substituted by a tetrazole ring rather than the usual amide (e.g., in **NECA** in the aforementioned text). N^6-substitued analogs were prepared and the SAR rationalized in silico using homology models of the receptors, providing a credible interpretation of the data. Example compounds described in the article are **28** and **29**, Scheme 19.

In a recent addition to the field, Louvel et al. report a series on nonnucleoside adenosine A_1 receptor full and partial agonists.[230] The ligands were derived from simplification and recombination of known scaffolds from the patent literature, and example compounds were shown to be relatively selective adenosine A_1 agonists compared with literature standards. Although the putative binding modes of the compounds were only briefly discussed, of interest is that the kinetic binding parameters were included and showed a wide range of on- and off-rates. The structure–kinetic relationships (SKRs) of a series of compounds are an important consideration in GPCR drug design, and yet, data are rarely reported. As the availability of biophysical characterization, such as SPR, becomes increasingly available, we would expect consideration of on- and off-rates will become more common and start to be used more frequently as part of the medicinal chemists compound design process.

Finally, in a recent and elegant study, Baraldi and Cosconati et al. designed hybrid or merged ligands incorporating the features of the selective A_{2A} antagonist **ZM-241385** and the nucleotide agonist **NECA**.[231] The ligands were directly inspired by the crystal structures of these two ligands and subsequent in silico optimization. The extended ligands maintained agonist pharmacology, and a highly potent and a selective A_{2A} agonist, **30**, was identified (A_{2A} $K_i = 4.8$ nM and A_{2A} $EC_{50} = 4.9$ nM), Scheme 20.

3.08.5.1.4 Class A GPCR lipid receptors

GPR40. GPR40 agonists are being investigated clinically as one novel approach to the treatment of diabetes. GPR40 is a G_q protein-coupled receptor preferentially expressed in pancreatic β-cells, and medium- and long-chain free fatty acids have been found to activate the receptor as the natural ligands. GPR40 agonists stimulate insulin secretion only in the presence of high glucose concentrations. Based on this mechanism, GPR40 agonists are promising novel insulin secretagogues with low risk of hypoglycemia. The crystal structure of the GPR40 receptor in complex with a small-molecule agonist TAK-875 has now been described and was discussed earlier.[24]

In a recent publication from Takano and Toda et al., the optimizations of 3-aryl-3-ethoxypropanoic acids were performed leading to the identification of a new agent **DS-1558**, (3*S*)-3-ethoxy-3-(4-{[(1*R*)-4-(trifluoromethyl)-2,3-dihydro-1*H*-inden-1-yl]oxy}phenyl)propanoic acid, which had efficacy on glucose-dependent insulin secretion after intravenous glucose injection in SD rats.[232] Notably, an induced-fit docking study of **DS-1558** was carried out using the X-ray structure of GPR40, in which the molecule docked very well to the same binding site with a slightly rotated side chain of Trp174. The model was thought to explain the series SAR reasonably well. As might be expected, the carboxylic acid moiety in the compounds was highly coordinated by the key basic residues Arg183$^{5.39a}$ and Arg258$^{7.35a}$ forming a strong anchor point. The trifluoromethyl group on the indane moiety had hydrophobic interactions with both protein and hydrophobic portion of the lipid bilayer where the ligand exits the receptor. The (more active) *R* stereochemistry of the indane moiety was more favorable than the *S* form in the binding cavity, especially when there was a substituent on the 4-position, due to steric hindrance with the protein. Interestingly, the ethoxy moiety extending from the propanoic acid side chain was well accommodated in a small side pocket not utilized by TAK-875. Although retrospective, the study highlights further opportunities for the next generation of design of GPR40 agonists. TAK-875 is no longer in development, leaving an opportunity for the identification of new drugs.

3.08.5.1.5 Class A GPCR chemokine

Chemokines are a family of signaling proteins secreted by cells that induce directed chemotaxis in nearby responsive cells so that they are overall chemotactic cytokines. Chemokines are approximately 8–10 kDa in mass and have four cysteine residues in conserved locations that are key to forming their three-dimensional shape. Some chemokines act as pro-inflammatory agents and may be released during an immune response to recruit cells to a site of infection. Other classes of chemokines are considered

homeostatic and seem to be involved in controlling the migration of cells during normal processes of tissue maintenance or sometimes development. There are four main subfamilies, CXC, CC, CX3C, and XC, all of which exert their biological effects by interacting with GPCR receptors (chemokine receptors).

There are approximately 19 different chemokine receptors which have been characterized to date that are divided into four families: CXCR that binds CXC chemokines, CCR that binds CC chemokines, CX3CR1 that binds the sole CX3C chemokine (CX3CL1), and XCR1 that binds the two XC chemokines (XCL1 and XCL2). Chemokine receptors have overall typical GPCR structural features, being ~350 amino acids in length and seven helical transmembrane domains with three intracellular and three extracellular hydrophilic loops. They typically have a short, acidic *N*-terminus and an intracellular *C*-terminus containing serine and threonine residues important for receptor regulation.

There has been a great deal of interest and effort within the pharmaceutical industry to find drugs that bind as antagonists of chemokine receptors. Many compounds have entered clinical trials for a variety of indications with only limited success, and progress in the area has been comprehensibly reviewed.[233] There appears to have been two main challenges in the field. Firstly, there is a very complex interaction between the chemokine ligands and their receptors with many ligands binding to more than one receptor such that inhibition of one receptor pathway may not be sufficient to produce the anticipated effect. The situation is made even more complex by species differences in the chemokine system making the prediction of efficacy in humans challenging. Secondly, the chemokine ligands bind very tightly as agonists to their target receptors, and small-molecule antagonists therefore need to be extremely potent and have a long-lasting in vivo effect driven either by excellent exposure after dosing or due to insurmountable receptor kinetics or both to be efficacious.

Despite these issues, two drugs have been so far successfully launched that target chemokine receptors: plerixafor (AMD3100) that targets the CXCR4 receptor and is used for stem cell mobilization, approved by the FDA in 2008 to treat non-Hodgkin lymphoma and multiple myeloma, and maraviroc (UK-427,857) that targets the CCR5 receptor, which is an entry factor for macrophage-tropic strains of HIV-1, approved by the FDA in 2007 for the treatment of HIV infection.

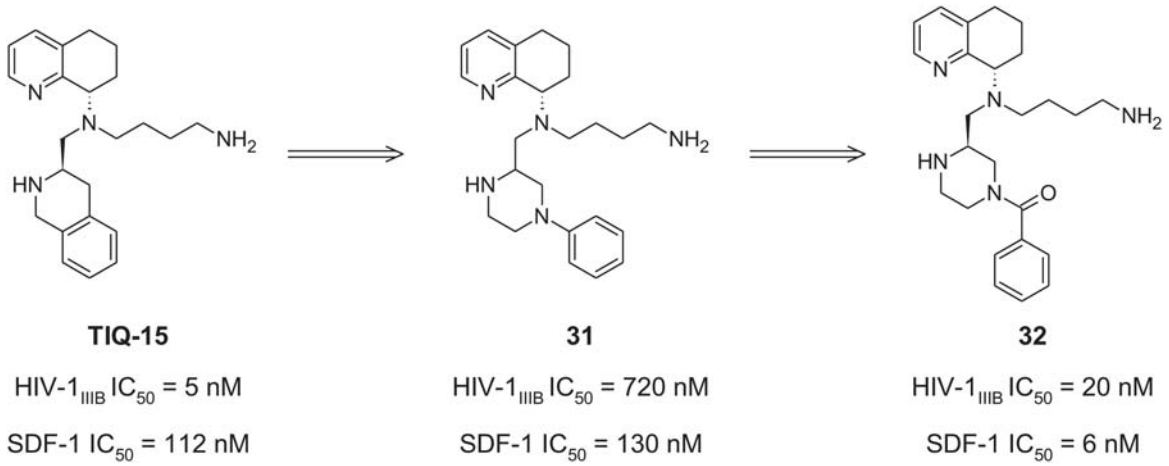
In 2010, the complex of a small-molecule inhibitor IT1t and a number of peptide inhibitors with CXCR4 was published by Wu et al.[234] These data have been very informative for medicinal and computational chemists showing how completely different types of molecule that do not share the same pharmacophoric features can bind to the same receptor. In particular, the interactions of the small molecule appear dominated by hydrophobic contacts, sitting high in the large orthosteric binding site, surrounded by bulk water. The location of this site would have been extremely difficult to predict in the absence of the X-ray data, as docking programs will fit molecules more deeply inside a binding site rather than leave space between the molecules surface and the protein. Consideration of the water-molecule network and energies can help to rationalize the binding, and this type of methodology can now be used to attempt to predict small-molecule binding in other chemokine receptors.[93] In our own laboratories, we have found analysis of the energetics, and placement of binding site water molecules can have a significant role in both the interpretation of why a molecule binds to a GPCR as it does and to inform further rational design.

More recently, the structure of CXCR4 in complex with the viral chemokine antagonist vMIP-II has been revealed.[234] vMIP-II is a CC chemokine encoded by Kaposi's sarcoma-associated herpesvirus. vMIP-II functions as a broad-spectrum antagonist of many human CKRs and helps the virus to escape the host immune response. The protein–protein interaction has a 1:1 stoichiometry with a more extensive binding interface than was anticipated. The structure also helps rationalize a large body of mutagenesis data and in tandem with modeling provides insights into CXCR4 interactions with its endogenous ligand CXCL12, its ability to recognize diverse ligands, and the specificity of CC and CXC receptors for their respective chemokines.

As noted earlier, the CXCR4 receptor has been linked with promotion of metastasis, angiogenesis, and tumor growth.[235,236] Additionally, CXCR4 has been implicated in HIV pathogenesis as a coreceptor for viral cell entry.[237] The crystal structures of both small-molecule and peptide ligands highlighted earlier are starting to impact ligand design for this target, which is a good example of a GPCR with relatively low tractability for drug design. Mungalpara et al. have carried out peptide SAR analysis and computational studies to attempt to rationally design conformationally constrained cyclopentapeptide antagonists of CXCR4.[238] In silico docking into the X-ray structure of CXCR4 in complex with the 16-mer peptide antagonist CVX15 (PDB ID, 3OE0) was undertaken using induced-fit docking protocols. This resulted in a binding pose overall consistent with the SAR. A number of new molecules were designed and synthesized that had increased activity at the target, consistent with the design hypothesis.

Cyclotides are globular microproteins (28–37 amino acids) stabilized by three intramolecular disulfide bonds. These peptides provide a rigid molecular scaffold with improved metabolic stability compared with typical peptides in vivo. Aboye et al. have designed novel cyclotides to target the CXCR4 receptor using the peptide CXCR4 X-ray data as a starting point.[239] The most potent cyclotide was significantly more stable than the peptide antagonist CVX15.

In a recent publication from the Liotta group at Emory University, the United States, a novel series of CXCR4 antagonists containing substituted piperazines were described starting from **TIQ-15**,[240] **Scheme 21**. These compounds showed micromolar to nanomolar potency in CXCR4-mediated functional and HIV assays, such as inhibition of X4 HIV-1_{IIIB} virus in MAGI-CCR5/CXCR4 cells and also inhibition of SDF-1-induced calcium release in Chem-1 cells. Structure–activity relationship studies led to the identification of a series of *N*-aryl piperazines as the most interesting compounds, exemplified by **31**. The SAR examined the optimum type and position of the aromatic ring and linker and stereochemistry. A credible binding pose consistent with the SAR was produced for the lead molecules binding to the CXCR4 small-molecule binding pocket, giving the possibility of further structure-based optimization of the series. Interestingly, the molecules were predicted to overlap with both the **IT1t** and part of the cyclic peptide **CVX15** binding regions discussed earlier. Profiling of several lead compounds showed that one molecule **32** had the best overall profile and drug-like properties when considering both SDF-1 and HIV potencies (6–20 nM). In a further paper

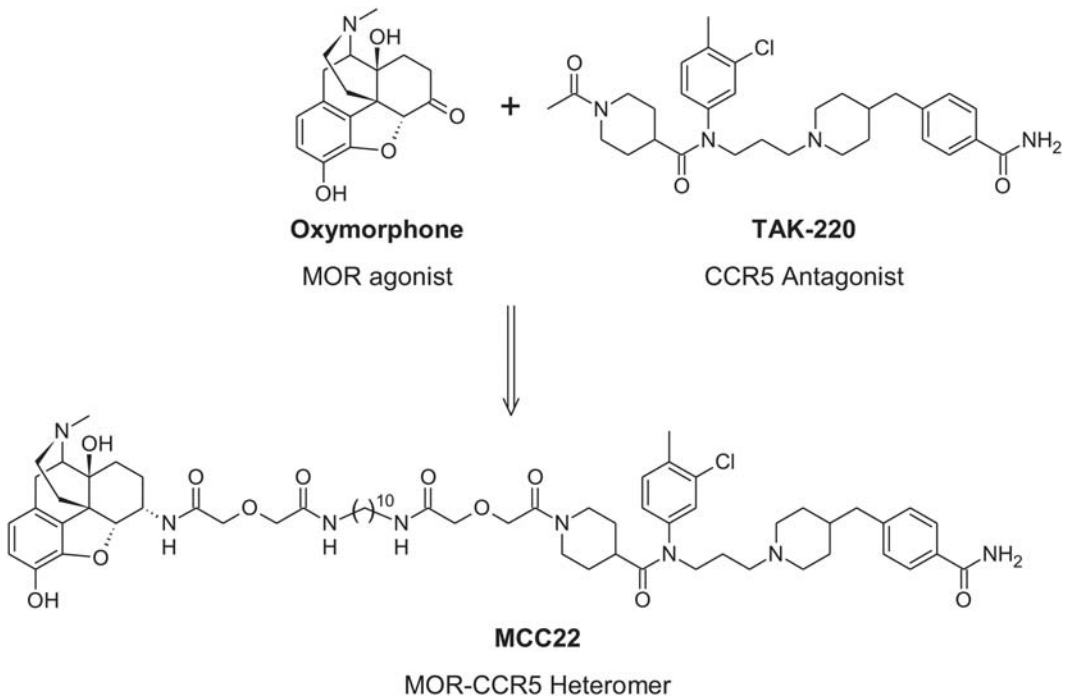


Scheme 21 Identification and optimisation of a series of CXCR4 antagonists based on **TIQ-15**.

by the same team, a series of simplified derivatives composed of a pyrazole-piperidine core have been described that had activity versus both CXCR4 and CCR5 receptors.[241]

In 2013, the crystal structure of a complex of maraviroc with the CCR5 receptor was published by Tan et al.[242] The structure reveals a ligand-binding site that appears to be distinct from the proposed recognition site for chemokines themselves and from the viral glycoprotein gp120. This allosteric binding mode gives an insight into the mechanism of the noncompetitive inhibition of chemokine signaling and viral entry by small molecules. Interestingly, maraviroc has a very slow off-rate from the receptor, which almost certainly contributes to its ability to inhibit viral entry, and the X-ray structure helps to rationalize this being deep inside the 7TM bundle of the receptor below the protein–protein interaction site.

There has so far been limited application of the CCR5 receptor structure reported; however, in a fascinating new paper, Akgün and Portoghese et al. investigated dimeric ligands targeting both CCR5 and MOR (discussed earlier). Chemokine release promotes cross talk between opioid and chemokine receptors that is thought to reduce the efficacy of morphine in the treatment of chronic pain. On the basis of the possibility that an MOR-CCR5 heteromer is involved in such cross talk, the authors synthesized bivalent ligands that contain mu-opioid agonist and CCR5 antagonist pharmacophores linked through homologous spacers (14–24 atoms, Scheme 22). When tested in vivo in mice treated with lipopolysaccharide to induce inflammation, a member of the series (**MCC22**)



Scheme 22 Development of a **MCC22** a dual MOR agonist CCR5 antagonist.

with a 22-atom spacer exhibited profound antinociception (i.e., $ED_{50} = 0.0146$ pmol/mouse) that was 2000× greater than morphine. Moreover, **MCC22** was ~3500× more potent than a mixture of MOR agonist and CCR5 antagonist monovalent ligands given together in the same in vivo model. These data strongly suggested that **MCC22** has its action by bridging the protomers of a MOR-CCR5 heteromer. Molecular simulation studies were described and were consistent with this hypothesis of such bridging and supported the notion that the MOR-CCR5 heteromer is a novel target for the treatment of chronic pain.

In another recent publication, the structure of the human chemokine ligand CX3CL1 (fractalkine) has been solved in complex with the viral chemokine receptor US28 from cytomegalovirus.[243] This structure has the GPCR in its agonist conformation, providing information of this conformational state for a chemokine receptor for the first time. The globular body of CX3CL1 is perched on top of the US28 extracellular face, whereas its amino terminus projects into the central core of US28. Interestingly, the amino terminus projection occupies a similar location to maraviroc in the CCR5 complex noted earlier, suggesting a binding site for small molecules to interact with US28.

SBDD studies are beginning to extend to other chemokine receptors, building on the protein–ligand complexes now available. Blockade of undesired neutrophil migration to sites of inflammation remains an area of interest as an approach to treatment of inflammatory diseases. One long-standing therapeutic target is antagonism of the chemokine receptor CXCR2. Maeda et al. have reported the discovery of 6-(2-boronic acid-5-trifluoromethoxy-benzylsulfanyl)-*N*-(4-fluoro-phenyl)-nicotinamide, an antagonist with activity at both CXCR1 and CXCR2 receptors (IC_{50} values 31 and 21 nM, respectively).[244] The agent exhibited potent blockade of neutrophil influx in a rat in vivo model of pulmonary inflammation. Interestingly, the authors provided the hypothesis that the molecule interacts with a unique intracellular binding site on CXCR2.[245] The compound contains a boronic acid functional group known to be a potential covalent "warhead" reacting with activated nucleophiles on proteins, and the proposal has this group in close proximity to $Cys230^{5.57a}$ in the proposed binding site, although the authors do not propose that a covalent bond is formed. This compound **SX-576** is undergoing further investigation as a potential therapy for pulmonary inflammation.

3.08.5.2 Allosteric GPCR Ligands

Allosteric binding sites on GPCRs are a long-standing opportunity to address drug discovery to more challenging targets where the orthosteric site is highly challenging due to the nature of the natural ligand or due to difficulties in identifying selective ligands.[246] Allosterism also gives the opportunity to modulate the natural ligand in a positive or negative sense (positive allosteric modulators or negative allosteric modulators, PAMs and NAMs) giving drugs with potentially different pharmacological consequences to those targeting the orthosteric site.[247] This is a large field of interest with many contributions to the literature, and here, we focus on just two examples where X-ray structures of allosteric ligands are now available.

$mGlu_5$ receptor. Glutamate, a major excitatory neurotransmitter of the brain, mediates its activities via ion channels and through a family of eight metabotropic glutamate receptors (mGlu) that are part of the GPCR superfamily (class C). The $mGlu_5$ receptor is highly expressed in the basal ganglia, lateral septum, cortex, and hippocampus and has a key role regulating the activity of *N*-methyl-D-aspartate (NMDA) receptors. As such, modulation of the activation of this receptor is implicated in a range of CNS diseases including depression and anxiety.[248] The X-ray structure of the $mGlu_5$ receptor in complex with a negative allosteric modulator (NAM) mavoglurant has recently been published, and the implications of this structure were discussed earlier.[18]

Christopher et al. followed up on the publication of this X-ray complex with a description of the discovery of an $mGlu_5$ NAM HTL14242 (Fig. 9) using fragment- and structure-based approaches.[249] A fragment screening campaign using high-concentration

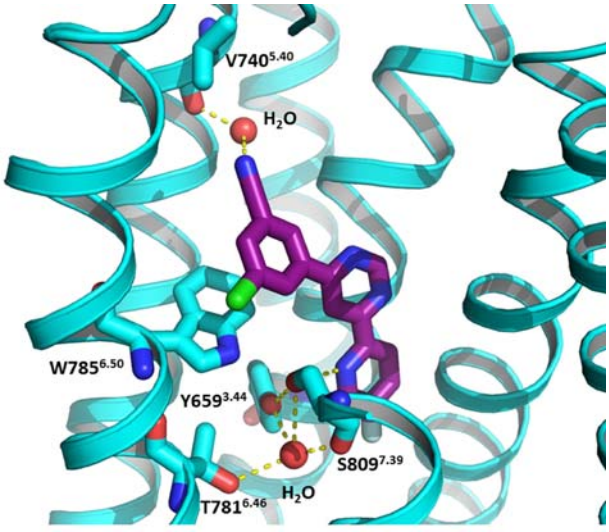


Fig. 9 X-ray crystal structure of HTL14242 bound to the $mGlu_5$ receptor. The allosteric modulator binds deeply in the center of the TM bundle of the receptor in an induced hydrophobic binding cavity. The nitrile group, which is essential for high affinity, binds to $Val740^{5.40c}$ via a water-mediated hydrogen bond. The pyridine ring forms the only direct H bond to the receptor to $Ser809^{7.39c}$.

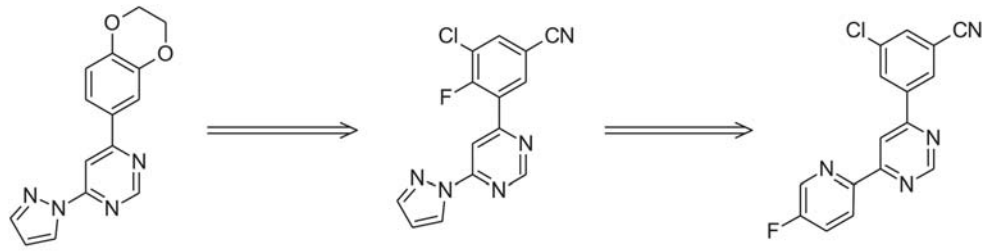

Scheme 23 Identification of HTL14242 an $mGlu_5$ NAM from a fragment screening hit **33**.

radioligand binding identified a number of hits with low micromolar activity including **33**, Scheme 23. Initially, testing a range of hypotheses of how the fragments might bind in comparison with literature ligands via docking into a homology model of the receptor led to compounds such as **34**. A number of X-ray structures were solved during the course of the subsequent lead optimization campaign clearly explaining the structure-based SAR of the series and the critical interactions required for affinity (Fig. 9). The clinical candidate **HTL14242** then emerged as the best molecule not only in terms of its affinity and potency but also based on the pharmacokinetic parameters needed for a CNS drug.

CRF_1 receptor. Corticotropin-releasing factor receptor 1 (CRF_1), a class B GPCR, is thought to play a potential role in the treatment of depression and anxiety. The structure of the CRF_1 receptor has been solved in complex with an allosteric antagonist CP-376395.[15] The molecule binds in the CRF_1 receptor site in an induced-fit pocket much deeper inside the 7TM bundle compared with any class A receptor ligand-binding site. These findings have helped to rationalize the SAR of CRF_1 antagonist small molecules and the slow off-rate kinetics of binding of some of these molecules.[250] In an interesting study by Yao et al., the escape pathway of the ligand has been predicted using molecular dynamics simulations, dynamic network analysis, random acceleration molecular dynamics (RAMD) simulations, and adaptive biasing force (ABF) calculations.[251] The results of dynamic network analysis indicated that TM7 of the CRF_1 receptor has the "strongest edges" during MD simulation. The kink in TM7 formed a pocket with $Gly356^{7.50b}$. $Asn283^{5.50b}$ had high hydrogen bond occupancy during 100 ns MD simulations and was likely the key interaction residue with the antagonist. RAMD simulation identified several possible pathways for CP-376395 to escape from the binding pocket. In the most promising pathway, the free energy was calculated by using ABF simulations. Two energy barriers were found along the reaction coordinates. Residues $Leu323^{6.49b}$, $Asn283^{5.50b}$, and $Met206^{3.47b}$ contributed to the steric hindrance for the first energy barrier, and residues $His199^{3.40b}$ and $Gln355^{7.49b}$ contributed to the second energy barrier through the hydrogen-bonding interactions between the ligand and the receptor. The results overall provide useful information to understand the interaction mechanisms between CP-376395 and CRF_1. These types of studies inform future drug design for the CRF_1 receptor and also give insights potentially useful for the design of allosteric modulators of other class B receptors.

3.08.6 Conclusions

In this article, we have attempted to introduce the findings from the structural biology breakthroughs for the major classes of membrane proteins that have emerged in recent years. The fascinating machinery involved in these pivotal proteins is starting to be uncovered in terms of how they function to engage with a diverse range of physiological molecules and synthetic ligands and how they modulate the function of cells. In a single article, we can only scratch the surface of the field and provide a brief introduction to the major topics. We have also tried to give the reader some insight into the rapidly developing in silico methodology now available to use the new X-ray data for drug design, not only uncovering the interactions made by small molecules with their target receptor (including the role of water molecules) but also considering how they engage with and exit their binding sites and the energetics involved in the binding and unbinding events. Finally, focusing on GPCRs where there is now a wealth of SBDD examples, we have illustrated how these methods are being applied in the design of ligands and potentially new therapeutic agents. Again, we cannot hope to be comprehensive and have selected the studies to showcase a range of approaches.

It is clear that the use of SBDD for membrane proteins and particularly GPCRs is a fruitful and evolving field, despite the relative difficulty of solving the first X-ray structure of each subfamily of receptor. Docking and prediction of binding poses for ligands are still challenging, but structure-based SAR can be carefully developed building confidence in the medicinal chemistry being pursued. Virtual screening is uncovering new classes of compounds, even for very well-worked targets that have been the subject of empirical design for many years, showing that SBDD has good potential under these circumstances. Today, there are still few published examples of new chemotypes being identified for poorly tractable targets; however, the recent publications of several allosteric modulator X-ray structures (discussed earlier) give potential for finding novel druggable binding sites where the orthosteric binding pocket has

poor properties for discovery of small-molecule drugs. Overall, we can expect many more exciting new discoveries in the structural biology and medicinal chemistry of membrane receptor targets in the next few years as the exponential rate of progress seems set to continue.

3.09.1 Introduction

The term pharmacophore has been used in medicinal chemistry for many years, often to describe different concepts. (The true origins of the term pharmacophore have been investigated by Van Drie,[1] who credits Kier with the introduction of the concept in a series of publications in the late 1960s and the early 1970s.[2–5] Ehrlich is said to have coined the term toxicophore,[6] which is a forebear of our term.) In this article, we will cover many of these variations, but we start with the official 1998 IUPAC definition,[7] which is as follows:

> A pharmacophore is the ensemble of steric and electronic features that is necessary to ensure the optimal supramolecular interactions with a specific biological target structure and to trigger (or to block) its biological response.

The variations in this concept, as seen through many examples of incorrect usage in the medicinal chemistry literature, are implied in the notes that accompany the above definition:

> A pharmacophore does not represent a real molecule or a real association of functional groups, but a purely abstract concept that accounts for the common molecular interaction capacities of a group of compounds towards their target structure. The pharmacophore can be considered as the largest common denominator shared by a set of active molecules. This definition discards a misuse often found in the medicinal chemistry literature which consists of naming as pharmacophores simple chemical functionalities such as guanidines, sulphonamides or dihydroimidazoles (formerly imidazolines), or typical structural skeletons such as flavones, phenothiazines, prostaglandins or steroids.

The primary tenet of the pharmacophore concept is the idea that the molecular recognition, or strong binding, of a biological target by a group of (dissimilar) compounds can be ascribed to a (small) set of common features that interact with a set of complementary sites on the biological target. General features such as hydrogen-bond donors, hydrogen-bond acceptors, positively and negatively charged groups, and hydrophobic regions are typically used. As such, there is a close link between the pharmacophore concept and the widely used principles of bioisosterism. We will show that this concept is useful but may not always hold, even in seemingly ideal cases. High-affinity binding is not a direct consequence of the presence of a pharmacophore feature; rather the absence of such a feature has a very negative effect on the affinity.

The next pillar of the pharmacophore concept concerns the three-dimensional (3D) nature of molecular interactions, that is, 3D pharmacophore methods in which the spatial relationship between the pharmacophore features is also specified. Appreciation of the importance of molecular conformation grew during the 1970s and the 1980s, spurred by the increased availability of relevant experimental data (e.g., via the Cambridge Structural Database[8]) and the development of new computational methods for the calculation and visualization of stable molecular conformations. Marshall and colleagues in particular recognized the challenge of identifying the binding conformation from amongst the potentially very large number of accessible structures through their development of the "active analog" approach.[9,10] In addition, it was also recognized that many intermolecular interactions have preferred geometries.[11] This is the idea that not only does a compound need to express a pharmacophore, it should do it without incurring significant penalty, either through internal strain or poor intermolecular interactions (leading to desolvation penalties). This is the concept that a pharmacophore is a necessary but not sufficient condition for activity. We will explore this issue in more detail later.

The early pharmacophore studies were typically performed using small number of compounds in which the key features required for activity could be readily identified by visual inspection of the molecular structure(s). Such molecules also tended to possess limited conformational flexibility and/or limited functionality. These restrictions significantly limited the space of available solutions, possibly down to a single unique pharmacophore. It was thus generally possible to deduce the pharmacophore manually, possibly assisted through the use of interactive molecular graphics visualization programs. The diversity and complexity of molecular structures that characterize drug discovery today have led to the development of sophisticated computer algorithms for the elucidation, manipulation, and use of pharmacophore models. Many possible pharmacophore models may exist for a given training set, and need further work to remove redundancy. Despite this, the basic concept of a pharmacophore as a simple geometric representation of the key molecular interactions remains unchanged. Pharmacophores have found widespread use in medicinal chemistry both for hit and lead identification and during the subsequent lead optimization as counter-screens. The simplicity of the pharmacophore representation, inherent in the coarseness of the feature descriptions, does also inevitably mean that it cannot explain everything; understanding the limitations of the concept is essential to a successful application. This will also be a topic for further discussion. It is worth reiterating the role of

pharmacophore modeling with drug design: it can be used to enrich significantly screening hit rates, particularly in new chemotypes. Its speed lends itself to massive virtual screening campaigns; applying a pharmacophore as a filter can also greatly triage datasets before application of more expensive docking techniques. It can be used in ligand-based drug design, as a precursor to more sophisticated 3D Quantitative structure-activity relationship (QSAR) methods to generate alignments. It can also form the basis for the enrichment of corporate libraries, a topic we will also cover later.

We will start by looking at the biological context of pharmacophores, and the interplay between evolution, endogenous ligands, affinity, and function of targets, to understand when the pharmacophore concept can be usefully applied and when not. Then, we provide an overview of the computational pharmacophore methods most commonly used in drug discovery. We will break down the process into steps: feature definition, conformational analysis, and model selection. The combination of these steps leads to tools for pharmacophore elucidation: the identification, from a set of active molecules and their biological activities, of the key common features and their relative orientations (also called pharmacophore mapping). From this core concept has arisen a number of other widely used techniques, which we also review in outline. These include the use of 3D pharmacophore databases in focused screening, pharmacophore fingerprints, the derivation and application of pharmacophore information from protein structures and application to screening set design, the use of molecular fields as an alternative form of feature representation, and 3D QSAR methods. It is outside of our scope to provide a detailed survey of all recent developments, or a comprehensive historical review, which can be found elsewhere.[2,12–16] Space prevents us from providing much more than outline information on the various algorithms and software approaches; there are many particular details to a tool that are best appreciated by reading the primary literature. Our goal is to provide the interested reader with a fair assessment of the pharmacophore-based methods that in our experience are most widely used, and have the most value, in real drug discovery projects. We will cover both the practical aspects and some of the inherent limitations of such methods.

3.09.2 The Biological Context of Pharmacophores

A question that is often left unanswered in discussions of pharmacophores is whether evolution has needed to recognize one ligand very specifically, for example, in the monoamine G-protein-coupled receptors. These receptors can distinguish between highly similar ligands, to enable highly selective signaling. 5HT receptors do not recognize noradrenaline, for example. Cytochrome p450's, on the other hand, are evolved to metabolize xenobiotics, so driven by parsimony, they have evolved to be not very specific. Other systems, for example, the human Ether-à-go-go-Related Gene (hERG) channel have large binding sites but no known endogenous ligand, so again the binding site is promiscuous. From simple consideration of the function of a target, one can infer whether a well-defined pharmacophore should exist. The observation that these systems cannot distinguish enantiomer pairs[17] indicates that the pharmacophore concept is very weak in this case. Targets in the first category, that have evolved to recognize a very small number of chemotypes ought to yield a good model, if the training set is also of good quality; conversely a poor model might indicate problems in the training set or assay results. A caveat to this is the case when the endogenous ligand has low affinity, that is, the number of recognition elements is also reduced. Targets in the second category ought not to yield a good model, because there are multiple chemotypes that can bind to them, and probably also multiple binding modes. Pharmacophore models that have good statistics against these targets probably suffer from an artificially constrained training set and hence a limited domain of applicability. Users of such models are advised to exercise caution. It is instructive to consider the work of Kratz et al.[18] in building pharmacophore models for hERG. A set of models were built using patch clamp and clinical data. They recognized that the compounds in the training set were likely to have different binding modes, so seven complementary models were built and used. In validation work, the models could pick out the actives from the decoys very effectively. However, in a prospective study in which the models were used to search for hERG inhibitors from untested compounds, there were a large number of false positive structures as well as some hits in the patch clamp assay. In a similar context, methods that employ binding or efficacy data to score pharmacophores should also be viewed with care if the data is not direct, that is, from a biochemical binding study. Data from cellular assays may be confounded by the requirements of permeability, effects of the free drug concentration and so on. We return to this topic in the section on 3D QSARs.

3.09.3 Pharmacophore Elucidation

Pharmacophore elucidation can be formulated as a molecular alignment problem, the aim being to superimpose a set of active ligands, all of which bind in the same way to the same protein of unknown 3D structure, so that the features they have in common become evident. Variants of the problem in which the set of ligands includes inactives as well as actives, and/or the 3D structure of the binding site is known, are considered later. To illustrate the basic concept, we show in **Fig. 1** a series of structures together with the corresponding 3D pharmacophore.[19] The main focus of this article will be on 3D pharmacophores, that is, the combination of features with geometry to form a consistent alignment across a series of active molecules. It is possible to approximate geometry via bond counts, that is, a donor and an acceptor four bonds apart. This approach has value in the generation of pharmacophore keys for very large databases (see later), as one does not need to perform expensive conformational analyses. The main advantage is in speed and simplicity for comparison of datasets rather than in the elucidation of models that can be used for virtual screening. As the descriptors are discrete, they can also be used as descriptors for classical QSAR models and for scaffold hopping.[20]

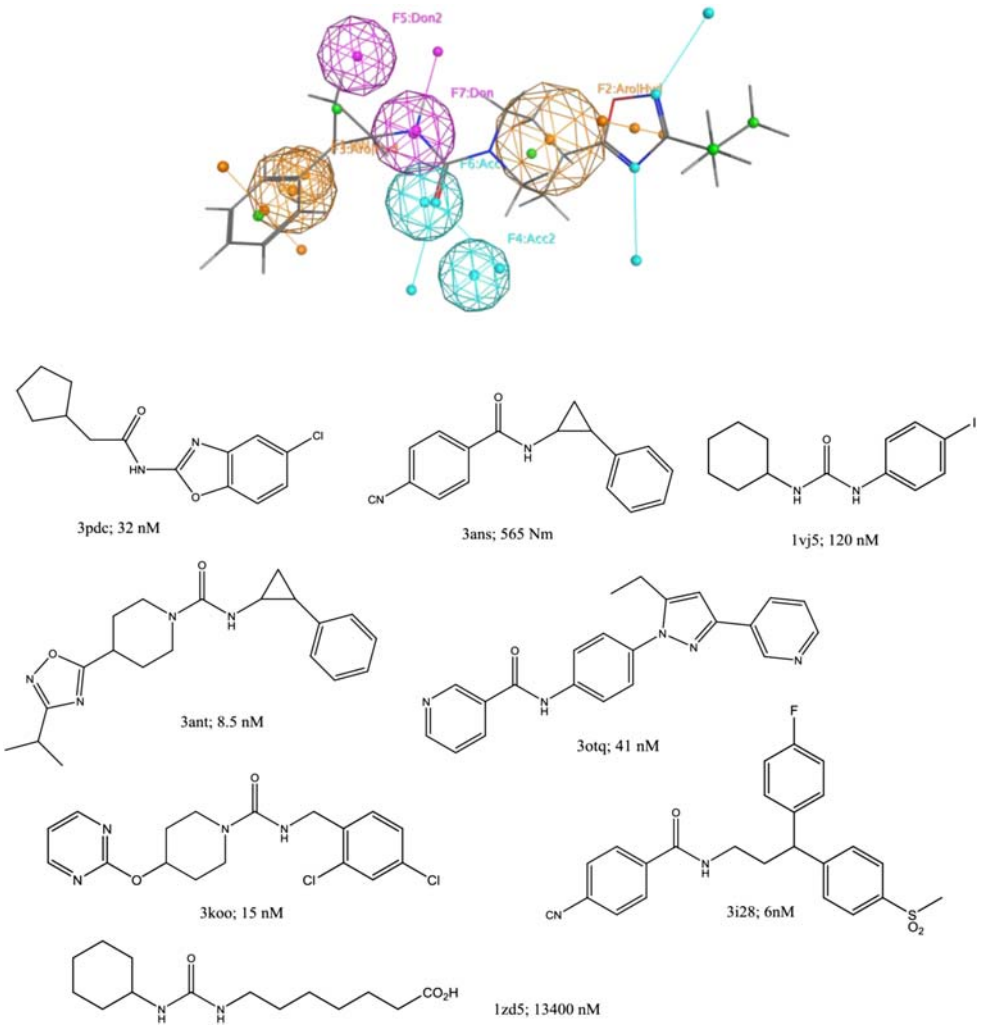

Fig. 1 An illustration of the basic pharmacophore concept. The soluble epoxide hydrolase inhibitors illustrated can be aligned[19] from their crystal structure conformations to generate a 3D pharmacophore model shown with the following color coding: H-bond acceptor *(cyan)*, H-bond donor *(magenta)*, and hydrophobic *(tan)*.

A number of programs for pharmacophore elucidation are widely used due largely to their availability in commercial software packages. These include CATALYST,[21] GALAHAD,[22] GASP,[23] the pharmacophore module of MOE,[24] FLAPpharm,[25] and PHASE.[26] Despite the maturity of these programs, many other pharmacophore elucidation/molecule alignment algorithms have been described, several of which have been published in the last few years or so.[14,27–36] This demonstrates that the problem is not considered adequately solved. Its difficulty stems from two sources. First, the calculation is compute-intensive because it involves searching the conformational space of flexible molecules and finding matching subsets of feature points from the different molecules. We will deal with each of these topics in its own right. Neither has a proven universal solution; the combination of possibilities is therefore formidable. Secondly, identifying the correct solution, if such a solution exists, can be extremely difficult (we return to this point later). In addition, for an algorithm to be useful, it must be able to align nontrivial sets of ligands that have no obvious common core. This might go without saying were it not that pharmacophore elucidation programs are occasionally "validated" by their authors on series of ligands that any competent modeler could mentally overlay in a few seconds.[37,38]

The key and necessary elements of any pharmacophore elucidation algorithm must include methods for: (1) representing the ligands (i.e., placing points on or around the molecules to represent the various pharmacophoric features they contain), (2) searching for candidate alignments, and (3) scoring those alignments. These aspects are considered separately.

3.09.3.1 Feature Representation

This involves two steps. First, the molecule must be partitioned into a set of features, each capable of representing a particular type of intermolecular interaction with the protein. Second, each feature must be represented by one or more points (or volumes) that can

be used for least-squares fitting of one molecule onto another. Greene et al. (henceforth "GKSST") wrote an influential paper describing how these steps were accomplished in the CATALYST program.[39] Many of the popular pharmacophore elucidation methods in use today employ a similar approach to feature representation,[40] and so we use their recommendations as a basis for discussion. In the discussion that follows, we talk about feature definitions in terms of functional groups or substructures. This is easy to understand but implies a hierarchy of detection. For example, the SMARTS query (OH) could match an alcohol or acid function, so the more exacting definition must come first. Later, we will discuss alternative methods based around field or molecular interaction field (MIF) formalisms.

3.09.3.2 Feature Definition

An implicit assumption of pharmacophore modeling is that there is a 1:1 mapping of features to recognition elements in the binding site. It has been known for a long time that for H-bonds, there is a balance between the number formed between the ligand and the solute, and the ligand, and the protein.[41] Certainly an imbalance in the number of interactions would usually have a strong negative effect on binding. We also point out that solubilizing groups (e.g., in many kinase active site ligands) may be necessary for activity not to be limited by solubility, but are not, per se, part of the interaction pharmacophore. Many approaches use feature descriptions that make binary assignments: H-bond acceptor, yes or no? This is one of the advantages of the pharmacophore method over 2D similarity, in that scaffold hopping is encouraged. However, the strength of the interaction is ignored. Should a urea carbonyl H-bond acceptor really be in the same class as an aniline? Clark et al.[42] and Kenny[43] have devised and applied H-bond acceptor strengths, but this has not permeated deeply into pharmacophore methodology. The MOE software offers a scheme for feature definition, which is based on extended Huckel theory[44] to compute an interaction type and a strength, allowing features to be customized by this descriptor. Likewise, the field of docking is starting to quantify the effect of desolvation on scores,[45–48] to change the nature of the best hits. This poses an unsolved problem: either the number of feature classes can be increased (to reflect the gradation of H-bonding strength) but at the cost of diminished scaffold-hopping power, or we need to relate the strengths of a feature with the observed activity (moderate strength H-bond acceptors have more potency than strong or weak ones in a particular training set). This internal weighting of a feature is not the same as weighting of the importance of a feature within the whole pharmacophore. In a thought experiment, it is easy to see that increasing the number of feature classes will reduce their membership, and eventually tend to similar results as obtained with 2D similarity metrics. One way forward might be to apply the concept of matched molecular pairs[49] to look at the differences in activity within the scope of a feature definition. This might give one an indication of the sensitivity of the model to the feature.

3.09.3.3 Tautomers

The assignment of the correct, or the most populated states of protonation or tautomerization, is very difficult,[50–52] but misassignment will have a profound effect on the pharmacophoric signature, turning donors into acceptors and vice versa[53] (**Fig. 2**). An edition of the *Journal of Computer-Aided Molecular Design* has been devoted entirely to the issue of tautomerization.[54–57] One important point is that different software programs employ different business rules for assignment, so that it is quite possible that, for the same query, different hits will be found by different programs. It may even depend on the primary source used to construct the database, making searches across different sources an issue. For this reason, we recommend that common tautomer business rules are described and used to prepare all structures used in query definition and searching. Normally, this is standard procedure in database creation, but the same rules may not be used in manual construction of a query from a set of ligands.

3.09.3.3.1 Hydrogen-bond donor features

Greene, Kahn, Savoj, Sprague, Teig (GKSST) define hydroxyl groups, nitrogen-bound hydrogens, thiols, and acetylenic CH groups as donors. The last two are controversial and many workers exclude them as being too weak. Conversely, some argue that other types of CH, in addition to acetylenes should be considered donors, for example, CH groups are posited to interact with O to form stabilizing interactions.[58] Ionization complicates the picture. GKSST exclude the hydroxyl of $-CO_2H$ as a donor because the acid is likely to be ionized at physiological pH, whereas basic amines (e.g., RCH_2NMe_2) are included because it is reasoned they will be protonated. One approach is to define explicitly all the variants in which hydrogen-bonding groups might be presented to the pharmacophore elucidation program (e.g., the use of a Daylight SMARTS string[55] that matches both RCH_2NMe_2 and $RCH_2NHMe_2^+$ could be used to ensure that both will be counted as donors). Many programs provide algorithms for "cleansing" ligand structures according to a set of business rules in order to achieve compatibility with the subsequent stages of pharmacophore generation and application. Alternatively, the assumption can be made that molecules will be presented to the pharmacophore elucidation program in their

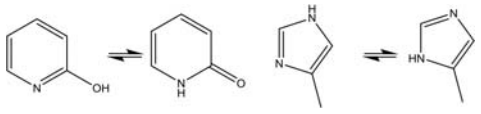

Fig. 2 Two examples of common heterocycles, whose pharmacophore character can be affected by tautomer state or protonation: pyridine and imidazole.

appropriate protonation states, thus delegating the entire problem to specialist ionization-state- and tautomer-prediction programs. The substructural definitions of hydrogen-bonding features then become much simpler. The recommendation here is not to "mix and match" between cleaning or preparation protocols, but to use the one specifically associated with the later pharmacophore elucidation program. The protocol should also match, as far as possible, the protocol and definitions used to build the database if virtual screening is the intended use of the model.

3.09.3.3.2 Hydrogen-bond acceptor features

GKSST define any N, O, or S with at least one available (i.e., nondelocalized) lone pair as an acceptor. There is a strong argument for excluding some types of oxygen atoms, for example, those in rings such as furan and oxazole, which theoretical and crystallographic evidence indicate are very weak acceptors.[59] Despite concern about metabolites, nitrile groups are becoming more common in approved drugs.[60] The nitrile group is a good acceptor group, and can be used as an isostere for hydroxyl or carbonyl. It is also claimed as a pseudo-halogen, through its electrostatic profile. This ambiguity would argue for finer division of pharmacophore feature space, with the counterargument that such divisions only show benefit in retrospective studies, where the interaction motif is shown.

3.09.3.3.3 Halogens

Halogens are not part of GKSST, or most other feature definitions. Surveys of F-containing ligands[61] have shown that C—F interacts with the C of carbonyl and amide groups. Wilcken et al.[62,63] have shown that the sigma-hole on higher aryl halogens could be used as an interaction partner with carbonyl backbone groups. They also describe the geometry and strength of such interactions, and propose them as viable pharmacophore features. While we agree with these findings that aryl hydrogens do constitute viable interaction partners, we return to our concerns with granularity and equivalence. Is a halogen–carbonyl bond worth the same as another donor–acceptor pair (corrected for solvation effects), and how often is this pairing a part of the ligand–protein interaction profile, as opposed to performing some other function? As Wilcken et al. observe, none of the common tools employ this feature, but it might be a very interesting customization when the halogen is known to play a crucial role (e.g., in the Factor Xa complex[64,65]).

3.09.3.3.4 Donor/acceptor feature point positioning

It is not sufficient merely to identify which features are present in each ligand molecule; it is also necessary to determine the locations of the associated feature points that will be overlaid in the resulting pharmacophore, reflecting the directionality of these interactions. Most programs in common use today associate donor and acceptor features not only with the corresponding ligand atoms but also with the presumed location(s) of the complementary protein atom involved in the interaction. For example, GKSST place feature points 3 Å from the heavy atom in the direction(s) of the donor hydrogen or acceptor lone pair(s), provided they are surface exposed. This strategy has the advantage that it permits the overlay of two ligands that form hydrogen bonds to the same protein atom but from different locations and directions (e.g., two ligand acceptors bonding to different H's of a putative amine sidechain,[66] see **Fig. 3A**, or an observed case based on binding to neprilysin, **Fig. 3B**). However, it implicitly makes assumptions about the directionality of hydrogen bonding and, if these assumptions are untrue, the points may be placed at inappropriate positions and the probability of generating a correct overlay reduced. Surveys of nonbonded interaction pairs in the protein data bank (PDB) have been performed, and for the common pairs, the statistics for the preferred H-bond directionality and distance can be obtained. This has been encoded into the ISOSTAR program.[67] Every feature should be characterized using maps generated by an ISOSTAR-like functionality, to see if the directionality is strongly defined, or if a wider spread of distances and angles are observed. This can be used to set tolerances for matches, and whether the ligand atom, the projection or both need to matched. One way of relaxing the directionality assumptions is to place points not only along lone-pair directions but also at intermediate positions (e.g., along the extension of the C═O bond of a carbonyl group). Alternatively, points can be placed on donor-hydrogen and "lone-pair positions" (typically chosen to be 1 Å from the acceptor atom), therefore reducing the leverage the points have when least-squares fitting or on the donor- or acceptor heavy-atom positions. One advantage of the latter is that it reduces the total number of feature points, which simplifies the search space.

GKSST account for the possibility of bond rotation in, for example, an R—OH group, by placing points at intervals on the circle swept out as the R—O bond rotates. This stratagem is unnecessary if hydroxyl groups are explicitly rotated during pharmacophore elucidation. Similar considerations apply to the lone-pair or virtual points associated with, for example, the oxygen atoms of an ionized phosphate.

3.09.3.3.5 Positive and negative features

GKSST define atoms bearing formal charges (taking into account probable ionization states in vivo) as positive or negative features unless they are bonded to an atom with the opposite charge. Delocalized groups bearing a net formal charge are also counted as positive or negative features. Feature points are placed on the centroid of the hetero-atoms of the group (e.g., the centroid of the two oxygen atoms of $-CO_2^-$). Some authors are careful to refer specifically to *ionizable* positive and negative features, emphasizing, for example, that they count RNH_3^+ as a positive feature but not $RNMe_3^+$. This makes sense because the intermolecular interactions of these two groups are very different: the former can donate very strong hydrogen bonds, the latter at best, only very weak hydrogen bonds.

Although most pharmacophore programs offer positive and negative features, it is arguable whether they are necessary. The underlying assumption is that a particular part of a protein binding site will accommodate either an ionized hydrogen-bonding

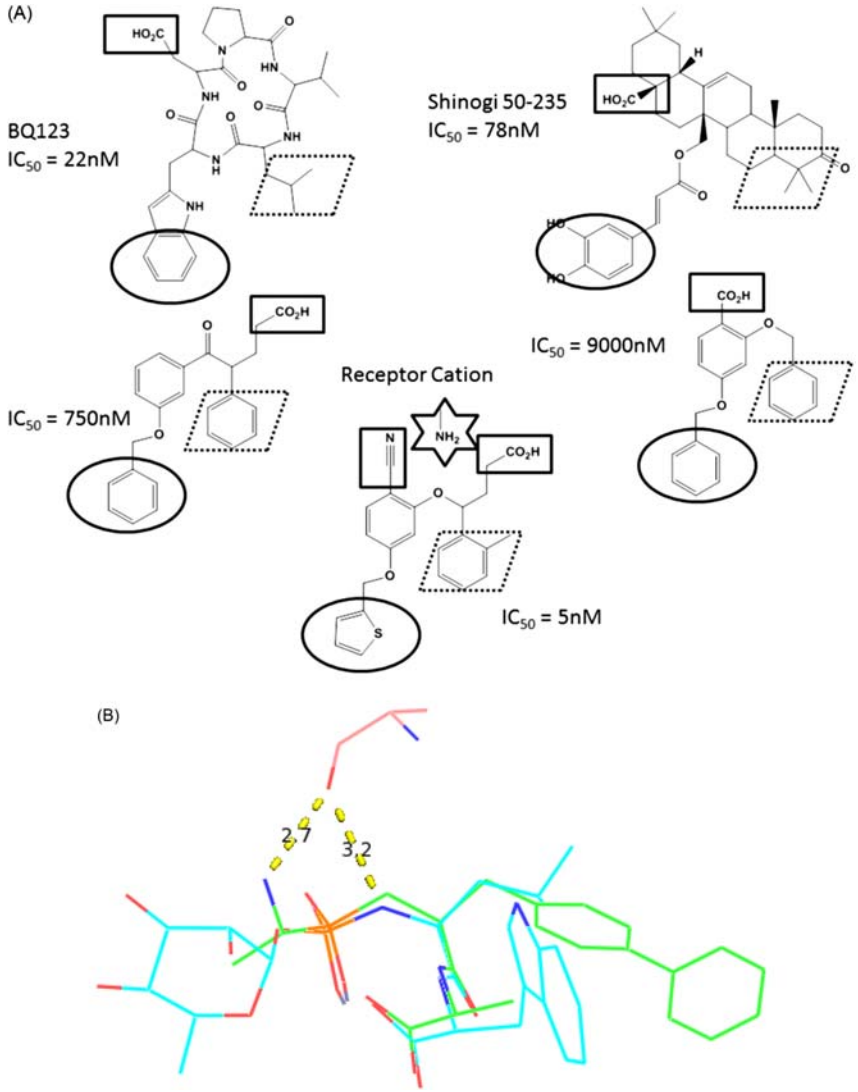

Fig. 3 (A) The derivation of a pharmacophore-based on structures binding to endothelin A, leading to a putative common acceptor-base interaction.[66] (B) Two neprilysin ligands from PDB structures 1r1h (ligand carbon atoms colored *green*) and 1dmt (*cyan* carbons) showing an observed common interaction approached from different recognition events. The $-NH_3^+$ nitrogen of the former and the amidophosphate nitrogen of the latter both donate hydrogen bonds to the backbone carbonyl oxygen of Ala543, but they interact with different lone pairs, so occupy very different positions in the binding site.

group or an unionized group, but not both. In practice, there are certainly exceptions to this rule. An alternative approach is to dispense with positive and negative features and use instead the concept of *hydrogen-bond similarity*. Each donor or acceptor group is assigned a strength (ionized groups having higher strengths than unionized); when subsequently scoring an overlay greater credit is given if groups of similar strength are overlaid on one another.[68–70] Of course, one should always be aware that the specific system under study may not necessarily conform to the general rule, due to the complex interplay between protein–ligand interactions and solvation/desolvation effects.

3.09.3.3.6 Excluded volumes

Excluded volumes are not really features themselves, but instead mark regions in which any structure matching the necessary pharmacophore must not place atoms. This is the natural extension of the concept that the pharmacophore is mapping out intermolecular interactions. A molecule making a potential salt bridge to a protein sidechain should not occupy the same volume as the side chain would. Excluded volumes are very useful if the protein binding site is known, and this topic is covered in more detail later. Even if the binding site is not known, excluded volumes can be used to explain the structure–activity relationship (SAR) between closely related analogs with very different activities.[71]

3.09.3.3.7 Hydrophobic features

Deciding which atoms, or which groups of atoms, should be considered hydrophobic is not straightforward. For example, a peptide linkage, though not at first sight a hydrophobe, often forms contacts to hydrophobic residues above and below the plane of the peptide atoms. The GKSST algorithm for placing hydrophobic feature points first assigns a hydrophobicity value to each atom, using a set of empirical rules based on the judgments of medicinal chemists. For example, a carbon atom three bonds from a double-bonded oxygen is assigned a hydrophobicity of 0.6. Each atom's hydrophobicity is modified to take account of its solvent accessibility (hence the algorithm is conformation dependent; many other programs neglect the solvent accessibility check to avoid this complication and use a set of substructure definitions). Finally, neighboring atoms with sufficiently large hydrophobicity values are clustered together into groups and a feature point placed at the centroid of each. The algorithm looks first for rings (weighting the centroid by the hydrophobicities of the ring atoms), then for groups such as $-CF_3$, then for chains. Chains are divided into contiguous, small groups of atoms. Many other programs in common use (e.g., PHASE and MOE) implement similar procedures, though they vary in detail.[31] Some programs, for example, QUASI,[32] place feature points on all atoms that are not donors or acceptors, which has the merit of being simple and producing a fine-grained representation of molecular shape. These feature points are classified in QUASI as "steric" rather than "hydrophobic," which emphasizes that there are two distinct, albeit closely related, aims: to get a good match of hydrophobic regions of molecules, and to achieve a good steric match. This distinction is explicit in the approach of Cheeseright et al. which has both van der Waals points and hydrophobic points.[72] The role of hydrophobicity is related to the role of solvent, but the methods cannot capture this level of detail. The effect of a hydrophobic point on activity is often to do with displacing (or even trapping, for a deleterious effect) water in the binding site, rather than forming direct interactions per se. Aromatic stacking is the exception rather than the rule here. Ultimately, there is no "right" way of placing the points since the hydrophobic regions of different ligands may not overlay in a tidy group-on-group fashion. For example, a common strategy is to place points at the centers of aromatic rings, but experimentally observed overlays (e.g., **Fig. 4**) do not necessarily have such rings neatly positioned on top of one another. Many programs represent certain types of hydrophobes, notably aromatic rings, by vectors rather than points so that directional interactions like π stacking can be taken into account when overlaying. In general, however, hydrophobic interactions are often not as well-defined geometrically as hydrogen bonds, and so are hard to localize to a small region of a molecule. It is also hard to quantify the relative energetic importance of a match to a hydrophobe feature, whereas the omission of an H-bond feature is usually fatal.

The most important purpose of features is to enable molecules to be overlaid in a sensible way, by least-squares fitting of feature points. In addition, feature points may be used in scoring, that is, the quality of an overlay might be judged by computing the root mean-square deviation (RMSD) between matched feature points. However, scoring can also be done without reference to the feature points, or with reference only to points relating to certain types of features. The placement of feature points is more critical if they are used both for generating and scoring an overlay, rather than just the former. A balance needs to be achieved between including all possible features and having sufficient to give a meaningful and parsimonious model. In particular, if there are many more hydrophobes than other features then these may dominate the alignment, just as putting six features on a carboxylate will do.[73] While this may give a better model according to scoring metrics, as it will be able to easily distinguish the training set from decoys, the model itself might be less useful for further work, as it will be poorer at finding new chemotypes and the domain of applicability will be small. This is similar to overfitting in QSAR modeling.

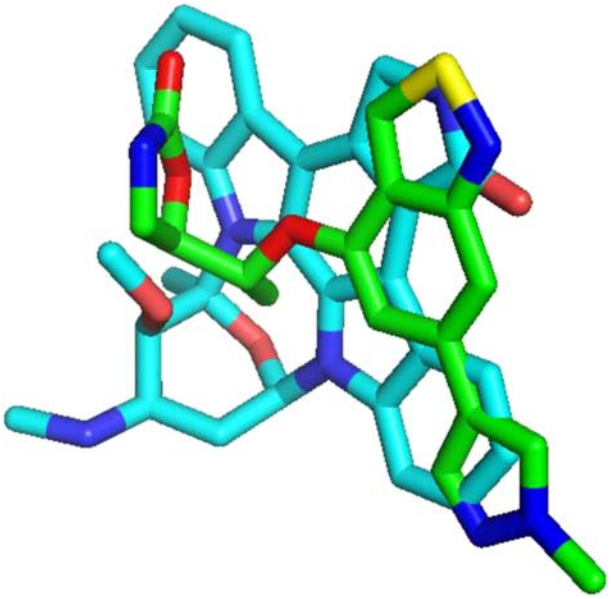

Fig. 4 Experimentally observed overlay of two SYK kinase ligands, from PDB structures 1xbc (carbon atoms colored *green*) and 5cy3 (carbons *green*), showing a poor match of ring centers.

3.09.3.3.8 Customized features

It is unlikely that there is a universally "best" set of feature types, though most would agree on an irreducible minimum of hydrogen-bond donor, hydrogen-bond acceptor and hydrophobe. Depending on the problem, other desirable types might include positive and negative centers, metal coordinators and different types of hydrophobes (e.g., aromatic and aliphatic). Interactions involving halogen atoms have been the subject of recent studies and may in some cases be usefully incorporated into a pharmacophore model.[63,74,75] Further, the user may wish to define a very specific type of feature to exploit a known SAR. For example, a chemist working on carbonic anhydrase II inhibition, aware that most known inhibitors have a terminal sulphonamide or sulphamate group, might wish to define a feature of precisely this type. As a consequence, many programs allow user-defined feature types; this is very useful in screening and selecting from large virtual libraries built around a central feature as a warhead or anchor point.[76]

Another adjustable parameter is feature separation (the minimum distance between two features for both to be counted). Does a carboxamide count as both donor and acceptor, and does phenol count as both aromatic/hydrophobe and donor/acceptor? While these two cases argue for a small separation, does a carboxylate count for two acceptor atoms, or worse four virtual points? This can lead to overweighting of certain functional groups in the model, which is particularly harmful if the main function of the functional group is to improve the properties of the molecule (e.g., solubility) rather than to interact with the protein. The feature separation distance is the same for all pairs of features so cannot be tailored during generation of a model. In the final model, features can be edited out if the user believes that over-emphasis has occurred.

3.09.3.4 Field-Based Pharmacophores

The pharmacophore generation methods described so far are based on the assignment of features to functional groups within the molecules and are, therefore, essentially atom based. An alternative approach is to base the alignment on the molecular fields exhibited by the molecules, recognizing that the interactions between molecules are governed by their overall electrostatic and van der Waals properties. Field-based approaches[77] thus aim to describe what the receptor "sees" in terms of charge distribution and shape rather than focusing on the underlying structural skeleton.

The molecular electrostatic potential (MEP) around a molecule depends on the distribution of atomic charge and is often modeled on a 3D grid or surface. The MEP at each grid point surrounding a molecule is calculated using Coulomb's law as the interaction between a probe atom of unit positive charge (a proton) and partial charges which are centered on the atoms. The resulting grids typically consist of a large number of data points so that direct alignment of the grids themselves is generally considered too compute-intensive to be feasible. However, Nicholls et al.[78] showed that the MEP can be modeled using atom-centered Gaussian functions; these provide an elegant way of overcoming the problem of handling the large number of data points in a grid. The Gaussian approximation allows the rapid comparison of the similarity of two fields using the cosine similarity coefficient. Such a similarity can then be used as the function to be maximized in an optimization of the alignment using, for example, a gradient-based method or a genetic algorithm (GA).

The MIFs produced by the GRID program[71] can be used to represent small molecules. However, MIF fields are not straightforward to model using Gaussians[79] so that identifying the optimum alignment of such fields remains a challenging task. One approach to using GRID fields that obviates the need for alignment is the GRIND method,[80,81] in which extrema in the field are identified and mapped to a fingerprint, to give a vector representation that can then be used in similarity searching as for the pharmacophore fingerprints described previously. It is not trivial, however, to determine which of the grid points should be included in the descriptor and the original GRIND approach requires that the user define the number of points that are extracted. More recently, an automated method for extracting hot spots from a field has been developed, which avoids the need for parameterization.[82] The probes can be of many different characters to reflect the different features driving recognition, but H, O, N1, and DRY probes are recognized as the basic minimal basis set. The MIFs can be combined with volumes and atom-centered features to give a more complete representation of the molecular recognition features.[25]

The use of atom-centered charges can lead to an inadequate representation of the MEP. For example, a carbonyl oxygen will give rise to a single field maximum extended outwards from the C=O double bond. The extended electron distribution (XED) force field attempts to model a quantum orbital description of the distribution of charge.[83] In XED, the charge on electronegative and π atoms is extended away from the nucleus of the atom to give rise to multipoles. For example, the carbonyl oxygen is modeled by two field maxima, which correspond to the positions of the lone pairs. The XED force field is the basis of a method to generate a pairwise alignment of two molecules based on the extrema (called field points) in their respective fields[84] (**Fig. 5**). Four types of field points can be calculated: positive, negative; hydrophobic, and van der Waals, depending on the potential used. Clique detection based on the field points is then used to find starting points for the alignment, which are optimized using a simplex algorithm. Similarity is measured by using the field points in each molecule to sample the whole field in the other, with the size of a "point" determined by the depth of the energy well, to give a more accurate reflection of the field than simply using the points themselves. Using such a multistage algorithm enables large databases to be searched in a reasonable time period.

As with the atom-based pharmacophore elucidation methods, conformational flexibility is most often handled using the ensemble approach in which conformers are precomputed and handled one at a time. It is also possible to vary conformation on-the-fly, usually under the assumption that the partial charges on the atoms are invariant to conformation, so that it is only necessary to recalculate the fields for different conformers.[85]

The most common application of field-based alignment has been to virtual screening where the molecules in a database are aligned, one at a time, to a query compound and scored. Usually, a single conformer of the query (the presumed bioactive conformation)

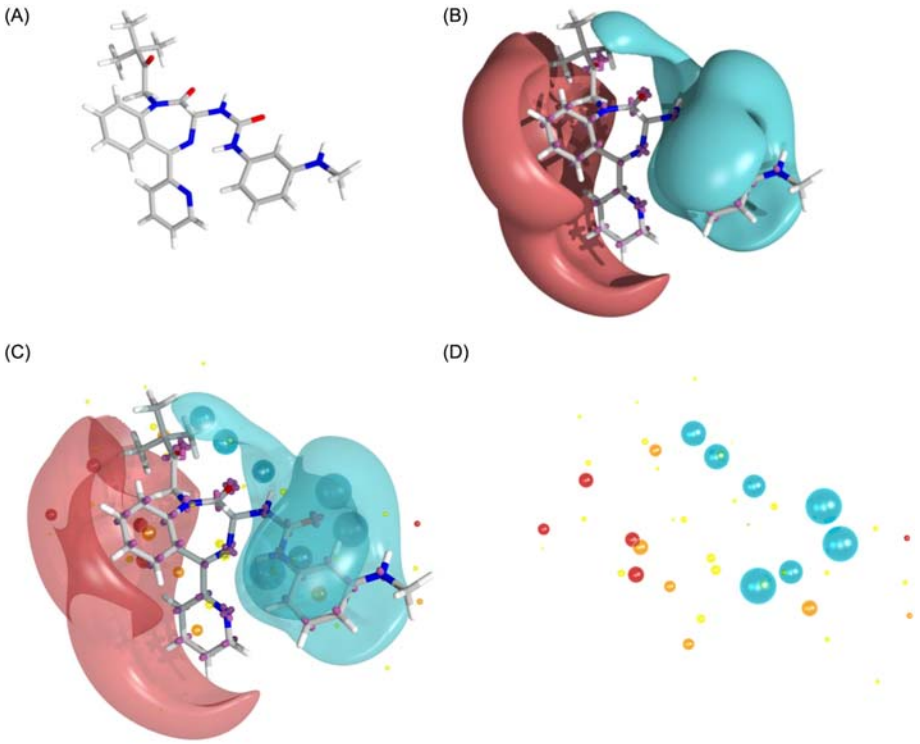

Fig. 5 The steps involved in generating field points around a molecule using the method of Cheeseright et al.[84] (A) a molecular conformation; (B) the electrostatic potential map calculated using XED (C) field points superimposed onto (B); (D) the final set of field points including electrophilic *(red)*, nucleophilic *(blue)*, van der Waals attractive *(yellow)*, and hydrophobic *(orange)* points. Model.* **2006**, *46* (2), 665–676.

is considered with the molecules in the database treated as flexible. Field-based methods have also been used to align multiple molecules. The simplest way to achieve this is to use a single molecule as the template or reference molecule,[86] but this approach is unlikely to lead to an optimal alignment. An improved approach is to first identify an overlay of two molecules by considering all pairwise alignments of the respective sets of conformers.[87] High scoring conformer pairs that share common fields can then be extended to a third, fourth, etc., molecule to give a multiconformer alignment. Such an alignment can then be used as a field-template for database screening.

3.09.3.5 Searching for Candidate Alignments

This is the most difficult part of the methodology to review because of the great diversity of published approaches. Ensuring that the bioactive conformations of the compounds are sampled is a major challenge since, in most cases, the precise form of the bioactive conformation is not known experimentally and most compounds can exist in a large number of conformations. The bioactive conformation does not always correspond to an energy minimum of the ligand in its unbound form. We make the assumption that ligands with strong affinity for their receptor do not have to channel much energy into accessing a high energy conformation. In absolute terms, this would be <2 kcal mol^{-1}, but most force fields are not accurate to this level, nor is the role of solvent taken into account, so a more pragmatic limit of 5 kcal mol^{-1} is usually taken as an upper bound over the lowest energy conformation. This again varies by force field and is one of the parameters that will control the elucidation and use of pharmacophore models. This line of reasoning can be extended to database searching as well: it is better to find matches for a pharmacophore amongst compounds in a very low energy conformation than ones that are strained, so that a first search is often performed against databases containing only a single conformer of a molecule. Obviously, this must be balanced against the number of hits desired. To reiterate: alignment can be conceptually divided into a feature matching problem and a conformational search problem. Perhaps the most telling difference between algorithms is how they deal with molecular flexibility: in particular, whether they operate on a pregenerated set of conformations for each ligand or, alternatively, alter ligand conformations on the fly during the alignment process. (Strangely, few programs do both—i.e., start with a set of pregenerated conformers but then tweak them to optimize the alignment.) Wolber et al. argue in favor of the former[88]: "Methods that tweak the molecule while fitting must dramatically reduce the search space while aligning in order to stay efficient and therefore bear the danger of falling into a local minimum." However, using precomputed conformations is itself a reduction in search space, especially for highly flexible molecules when the granularity of the conformational sampling is likely to be coarse. Thus, the possibility exists that the true answer will not be found because it lies between the conformations available to the algorithm. The ability of widely used programs to search conformational space has been extensively examined in recent years.[89–94]

Some of these studies have also investigated the conformational energy landscape and the strain energy of bound ligand conformations.[44,46] These studies provide useful guidelines for use not only in pharmacophore elucidation but also in applications such as database searching (see later). An important practical point is that whilst most pharmacophore elucidation programs contain their own conformer search procedures they do also permit the import of conformations generated with an external specialized conformer search procedure. Such flexibility provides the user with the ability to choose the best method for each distinct task in the pharmacophore elucidation process. Again, it must be emphasized that the protocols used to generate conformations for model elucidation must be the same as the ones used to generate or search any database. It is worthwhile to use a tool such as Mogul[95] to check the structures in the model as there is an assumption that active compounds will have minimal strain. Reproduction of the conformation observed in an X-ray complex as a criterion for success is more dubious, as many do contain levels of strain.[96] It should also be noted that there can be an order-dependence in the alignment, that is, B may align well to A, and C may align well to B, but C may not align well to A. Each molecule should be used as the base template for alignment to find the best global alignment.

3.09.3.5.1 Algorithms using pregenerated conformers

To avoid confusion, we use consistently the terms defined by Barnum et al.[21]: a *configuration* is a set of points in 3D space, each associated with a type of feature; a *partition* is an object associated with all configurations of a particular type, for example, the DHH partition is associated with all configurations consisting of one hydrogen-bond donor (D) feature and two hydrophobic (H) features. If two molecules both contain a configuration that belongs to the same partition, and which can be superimposed, one onto the other, within a specified threshold RMSD, this configuration is *common* to those molecules.

The classic way to identify common pharmacophore alignments from precomputed conformations is to use clique detection, first employed in the DISCO program,[97] and a mainstay of more recently published algorithms. However, the CATALYST/HipHop algorithm has probably been more widely used than any other. It operates on precomputed conformers and works by finding small common configurations and then attempting to enlarge them. The authors describe it as a "pruned exhaustive search." To begin, one or more molecules in the set to be aligned are chosen as *reference molecules*. All 2-point configurations in all conformations of the reference molecules are found. Configurations are rejected if either of the features is not surface accessible or if the interfeature distance is below a user-specified limit (this is to encourage diversity amongst the final answers). For each of the survivors, a search of the conformations of all the other molecules is performed to see whether the configuration is common to all ligands. If so, it is kept. Eventually, then, a list of all common 2-point configurations is compiled.

The algorithm then enumerates all 3-point configurations in the reference molecule(s). Any such configuration contains within it three 2-point configurations (e.g., a configuration belonging to the partition DHH will contain two DH configurations and one HH configuration). It can be rapidly ascertained (by checking the list of common 2-point configurations) whether these three 2-point configurations are common to all ligands. If this is not the case, the 3-point configuration is rejected (this is the pruning step). Otherwise, the remaining molecules are checked to see whether the 3-point configuration is common to all and a list of common 3-point configurations is built up.

Repetition of the procedure allows increasingly large common configurations to be found until no further increase in size is possible. As well as pruning, computer time is also saved by using a two-step procedure to ascertain whether a given configuration is present in a molecule. First, a precomputed list of all the interfeature distances in the molecule is checked to see whether the configuration might be present. Only if this filter is passed, will a final least-squares fit of feature points be performed as confirmation. Least-squares fitting is used in almost all pharmacophore programs as the final arbiter of whether a configuration is common to two molecules, since it distinguishes mirror images.

The claim that the algorithm is exhaustive is debatable. First, the number of solutions found depends on the granularity of the conformations presented to the algorithm. Second, the decision on whether a configuration is common or not depends on the threshold RMSD. Third, the algorithm will, if the user requests, allow certain molecules to miss a feature in a "common" configuration, provided the total number of such molecules remains below a specified limit. This is a highly desirable option, since such situations occur frequently in reality, but it again means that the number of solutions produced by the algorithm depends on a user-chosen parameter. In truth, no pharmacophore elucidation algorithm is exhaustive, despite occasional claims to the contrary.

The PHASE algorithm employs a tree-based partitioning method that rapidly groups together similar configurations according to their interpoint distances. For each conformer of each molecule, the program determines all k-point configurations that are present. Each configuration is represented by its vector of $n = k(k-1)/2$ interpoint distances. Each interpoint distance is filtered through a binary tree to assign it to a particular distance range. Once all n distances have been filtered, the configuration has effectively been assigned to an n-dimensional box whose sides are equal in length to the range corresponding to the bottom of the decision tree. Now, if two molecules each have, say, a 4-point configuration belonging to the same partition (say, 2 Donors and 2 Hydrophobes or DDHH) and falling in the same box, that configuration might be common to those molecules. (In addition, it is necessary to consider neighboring boxes, since similar distances may happen to fall either side of a box boundary; Wolber et al.[88] and Zhu and Agrafiotis[98] describe methods for circumventing this troublesome problem.) Potential common configurations of various sizes are therefore identified rapidly. A least-squares fit is then performed to determine which of these are truly common. A given k-point configuration is only accepted if it occurs in a user-specified minimum number of molecules. Open3DALIGN[99] is open source code that relies on conformations generated via quenched molecular dynamics (MD) or one of the many standard conformer generators.[94,100] Alignments are generated and scored using an atom-based cost function, which means that the alignment is unsupervised; this is a very useful tool for academics. FLAPpharm[25] takes an even simpler approach of using fingerprints to identify the consensus features that then drive the alignment.

3.09.3.5.2 Algorithms that alter conformations on the fly

An early but instructive example of this type of algorithm is GASP,[23] which uses a GA to optimize an initial population of random overlays. The ligand with the smallest number of features is chosen as a reference molecule. Each population member is represented by a chromosome containing (1) columns specifying torsion-angle values for all the rotatable bonds in all of the molecules, and (2) "mapping columns," which define pairings between features of each nonreference molecule and features of the reference molecule. This is enough information to generate a molecular overlay, by setting each molecule to the conformation defined by the appropriate torsion-angle columns and then least-squares fitting using the feature point pairings in the mapping columns. A scoring function is used to estimate the fitness of each overlay, taking into account the quality of geometric matching between paired feature points, the extent of volume overlap, and the ligand strain energies. In each step of the GA, mutation of one parent chromosome (changing either a torsion-angle or a mapping column) or crossover of two is used to generate a child (two children in the case of crossover), which, if sufficiently fit, can be used to replace the least-fit member(s) of the population.

The successor to GASP, viz. GALAHAD,[17] divides the problem into two steps. In stage one, which operates solely in ligand torsional space (i.e., the ligands are never actually overlaid), the GA is used to find a set of ligand conformations that tend to have large common volume and low steric energy, and are similar in the feature configurations they contain. The latter is determined by generating fingerprints for the ligands that capture the various triplets, quadruplets, etc., of features and their interfeature distances. Stage two employs an algorithm from image recognition to produce the final alignment of the ligands, held rigid in their conformations from the first step.

In summary, while the diversity of approaches defies easy classification, some common characteristics can be identified. Most algorithms have strategies for reducing compute time, most commonly the use of pruning or fingerprints. These may become of lesser importance as we gain access to faster larger computers with more memory. A good example of a fingerprint strategy is the CSD-Crossminer program[101] that allows interactive manipulation of pharmacophore models, which are then converted to fingerprints leading to real-time retrieval of hits. The final refined model can then be used for a more rigorous search. The use of clique detection and search techniques such as GAs are common. Least-squares fitting of matched feature points is almost always used to produce the final alignments.

3.09.3.6 Scoring

Most algorithms rank candidate overlays by means of a scoring function containing some or all of the following terms: feature matching, volume overlap, strain energy, and selectivity. Some of these terms have an underlying physical rationale; others are more subjective, being included to increase the score of the more "relevant" pharmacophores. Often, a particular molecule in the overlay, the *reference*, has a special status in the scoring procedure. The reference may be chosen arbitrarily, or its selection biased toward particularly active or less flexible molecules.

Catalyst/HypoGen takes activity data into account and uses both active and inactive compounds in an attempt to identify hypotheses that are common among the active compounds but not among the inactives. HypoGen builds hypotheses in three steps: a constructive step, a subtractive step, and an optimization step. The constructive step identifies pharmacophore candidates that are present in the most active set of compounds. The subtractive phase then eliminates configurations that are also present in at least half of the inactive compounds. This step needs to be considered carefully. Inactivity may stem from a number of reasons unrelated to the presence or absence of pharmacophore features. Visual inspection of the training set is vital to ensure that the set of inactives really does contain meaningful information that discriminates the causes of activity, and not just the absence of a solubilizing group. Subtraction does add value, if it can be used to eliminate trivial features from the final molecule (for instance hydrophobes). The final optimization step attempts to improve the score of the remaining hypotheses by applying small perturbations. HypoGen, thus, attempts to build hypotheses or SARs that correlate estimated activities with experimental activities and can be used subsequently to predict the activities of new compounds. The cleanest experimental data comes from a binding assay that returns K_d values. This is closest to the isolated recognition event that the pharmacophore is trying to model. Data from cellular assays contain other influences (solubility, permeability, and partitioning) and should be avoided when possible.

HypoGen ranks the hypotheses on their cost value; this consists of three components, namely, the weight cost, the error cost, and the configuration cost. The weight component increases in a Gaussian form as the feature weight deviates from the idealized value of 2.0. The error cost increases as the RMSD between the estimated and the measured activities for the training set increases. The configuration cost represents the complexity or the entropy of the hypothesis space being optimized and is constant for a given data set.

Catalyst first calculates the costs of two theoretical hypotheses, namely, the ideal hypothesis (fixed cost) and the null hypothesis. The ideal hypothesis has a minimal error cost and the slope of the activity correlation is one. The null hypothesis has a maximal error cost and the slope of the activity correlation is zero. Together they represent the upper and lower bounds on cost for the hypotheses that are generated. The greater the difference between them, the greater is the likelihood that a meaningful hypothesis can be found. The closer the cost of the generated hypothesis is to that of the ideal hypothesis, the higher the probability that the generated hypothesis represents a true correlation in the data. The hypothesis with the least cost ideally would map to all the features of the most active compounds in the training set. The cost is reported in bits and a difference of about 50–60 bits between the generated hypotheses and the null hypothesis suggests that the correlation may be significant, which in turn requires a difference of about 60–70 bits between the costs of the ideal and null hypotheses.

Three correlation coefficients are also used to evaluate the hypotheses: the Catalyst correlation score, Pearson's correlation coefficient, and Spearman's rank correlation coefficient. The Catalyst correlation score is derived from the simple linear regression

between the experimental and the estimated activities. The correlation coefficient can range from -1 to $+1$, with positive values indicating a direct linear relationship between the two variables, that is, the experimental and estimated values. Pearson's correlation coefficient indicates the degree of co-variation of two variables and was used to compare the estimated values with the experimental values. The closer they are, the better the correlation. Spearman's correlation coefficient measures the relationship between the relative ranks of the variable values.

The function used in PHASE, which may be written as:

$$\text{Score} = F + w_v V - w_e E + w_m^{M-1} + w_s S$$

serves as a typical example of a scoring function, where w_v, w_e, w_m, and w_s are user-defined weights. F measures the quality of alignment of features in the reference molecule with the corresponding matched features in each other molecule. Two criteria, appropriately weighted, are used: the RMSD of the matched feature points and the average cosine of the angles formed by matched pairs of vector features (e.g., aromatic rings). V is the average over the nonreference molecules of their volume overlap with the reference, measured as (intersection volume)/(union volume). E is the strain energy of the reference ligand conformer from which the pharmacophore is derived. PHASE allows configurations to be found that are common to some but not all of the molecules. M in the term w_m^{M-1} is the number of molecules that contain the configuration; so, depending on the user-chosen value of w_m, this term can be used to reward overlays in which M is large. S is a measure of selectivity, that is, an estimate of the fraction of molecules in a random database likely to match the common configuration of the overlaid molecules. The smaller this fraction is (i.e., the more unusual the arrangement of features in the common configuration), the larger S will be. The logic behind this term is that if the common configuration is unusual, it is reasonable to conclude that it occurs in the overlaid molecules *because it is a requirement of their activity*. It is too time-consuming to estimate S by searching a large database for the common configuration; Dixon et al.[26] and Barnum et al.[21] describe how it may be approximated.

Labute et al. describe a scoring mechanism based on the use of Gaussian functions.[102] In their formalism, all properties to be considered in the scoring (molecular volume, distribution within the molecule of hydrogen-bond donor and acceptor groups, etc.) are described in a consistent manner. Thus, for a given conformation of a molecule, the density of a property P at a point in space x is described by the equation:

$$f_P(x,\ x_1\ \ldots\ x_n) = \sum \left\{ (w_i/n)\left(a^2/2\pi {r_i}^2\right)^{3/2} exp\left(-a^2[x-x_i]^2/2{r_i}^2\right) \right\}$$

where $(x_1 \ldots x_n)$ are the positions of the n atoms of the ligand, r_i is the van der Waals radius of atom i, a is an empirical parameter, w_i is the weight of property P at x_i, and the summation is over the n atoms. For example, if property P is hydrogen-bond donor ability, then w_i could be set to one if atom i is a donor and zero if it is not.

The degree of overlap of property P for a pair of overlaid molecules can thus be calculated rapidly as a sum-of-Gaussians density in the interatomic distances. The degree of overlap of several properties is a weighted summation of the individual property-overlap equations, the weights reflecting the relative contribution of each property to the overall score. The consistent manner in which properties are treated lends itself to programming simplicity and makes it easy to add new properties to the scoring function.

A problem with the scoring methods described so far is that they require weights to be assigned to the different terms, and these weights are inevitably arbitrary. Some programs avoid the problem by Pareto ranking,[36,103] which produces a population of possible overlays, each representing a different compromise between conflicting criteria (e.g., ligand strain energy, volume overlap, and feature matching). Specifically, the aim is to converge on a set of *nondominated* overlays, such that, for any given overlay, there is no other overlay in the set that scores better against all criteria. The approach therefore recognizes that it is impossible to predict, for any given set of ligands, which criterion will be most important.

3.09.3.7 Evaluation of Pharmacophore Methods

The historic lack of good data sets where the "true" pharmacophore is known has meant that the evaluation of new pharmacophore generation methods has tended to be less rigorous than programs in other areas such as protein–ligand docking. Very often, programs have been evaluated on a small number of test cases (sometimes only one) and few comparative studies of different programs have been carried out. While such a situation is natural as a field develops, pharmacophore generation has now reached a state of maturity where more rigorous evaluations are appropriate.

The earliest automated pharmacophore generation methods tended to be evaluated by comparing the generated pharmacophores to those previously published in the literature that had been hand-crafted and/or were amply supported by experimental data. An alternative approach has been to fit compounds that are known to be active but that were not included in model generation to the pharmacophore. Ideally the model should also explain inactive molecules as well; for example, to determine whether the inactive compounds occupy regions outside the common volume of the pharmacophore.

The development of 3D database searching techniques made it possible to evaluate pharmacophore hypotheses in retrospective virtual screening experiments. A database of compounds can be spiked with compounds that share the same activity as those used to construct the pharmacophore. The database can then be either partitioned into those that match the pharmacophore and those that do not, or alternatively the compounds may be scored and ranked on their fit to the pharmacophore. Ideally, all active compounds will be retrieved or appear high in the ranked list.

A common approach to validate a pharmacophore hypothesis is to create a set of known actives and decoys, and look at the enrichment and area under the curve for ROC plots.[104] If the decoys are not chosen properly, this can give a misleadingly good impression. Decoys should be matched on pharmacophore features. If the model requires a basic center, and the decoys only contain such a feature rarely, the enrichment will always be good, and does not tell you if the model can truly distinguish actives from near-inactives. Likewise, a model with 4+ features is probably too specific and will show great enrichment, but be worse at scaffold hopping.

Validation statistics may also not discriminate well between models that can explain the same training set. This can be seen by a study that tried to rebuild pharmacophore models published in good peer-reviewed journals.[105] One factor for this was that key parameters were inadvertently omitted from the methods, the other was that there were several equally good models that could be generated: this is normally the case if there is no potent rigid molecule to act as a defining template. The differences arise not just from the positioning of the features, but in their number and type as well. Pharmacophore analysis is an underdetermined problem and it is very important that authors of new models describe the method appropriately as suggested below.

A template for pharmacophore model description.

	Requirement
1	Complete specification of all stereochemistry and how chiral molecules are treated, and the same for tautomer and protonation states
2	Program version and CPU platform
3	Contents of the feature/parameter file must be declared to be standard, or any changes described
4	Complete details of the conformational analysis technique used including: the technique for initial conformer generation, energy cutoff, the number of conformers generated, issues with stereochemistry, any other preferences
5	The uncertainty value must be given
6	Any feature changes to the standard dictionary must be specified
7	The choice and number of features used in the hypothesis construction, that is, 2*HBA and 5*PI
8	Settings for hypothesis generation, including: weight variation, variable tolerance, spacing, minimum number of total features, minimum numbers of particular features, Mapping coefficient, Feature Misses, Superposition error, check superposition tolerance factor, and other parameters particular to the method
9	The source of all activity data must be specified accurately
10	The number, type, weighting, tolerance, and separation of features in a resulting hypothesis should be given
11	The predicted activity values should be given
12	An independent test set should be used to assess the model

Database searching can also be used to choose between alternative hypotheses that may have been generated. Pharmacophore queries do, however, tend to produce large numbers of false positive hits, especially if used without additional features such as excluded volumes. There has been much discussion in the literature concerning the "proper" ways to perform such retrospective virtual screening evaluations.[106–111] From a practical drug discovery perspective the most important consideration is whether the search provides novel chemotypes that provide a new direction for a project to explore.

The DUD dataset,[112,113] is commonly used for validation, but this is not the correct and original intention of the authors, which was to provide decoys for assessing docking programs. A decoy set can be readily assembled for any set of input ligands.[114] Decoys are selected on the basis of matching physicochemical profiles and 2D similarity to the set of known active ligands. When applied to pharmacophores, it can give over-optimistic results, as ligands similar to the active chemotypes are removed (a particular issue if the pharmacophore training set is based on a single chemotype), and because pharmacophore methods are not as sensitive to the effects of molecular weight as some docking programs are. It would be better to match on a profile of pharmacophore features. The Maximum Unbiased Validation (MUV) dataset[115] is designed to eliminate analog bias, and so gives a better picture of how well a method can retrieve novel chemotypes. It contains less than two compounds per scaffold class. Pradon et al.[116] used this resource to compare the performance of MOE and PHASE methods for effective pharmacophore generation. Their work provides a good framework for comparison, even though the results were specific to the versions of the software at their disposal. They looked at overall retrieval rates, as well as initial enrichments (which may be more important if screening capacity is limited). The use of several models in addition to the top-ranked model was found to increase the overall retrieval rates, but at the expense of the initial enrichment. MOE seemed to perform well using default setting, whereas PHASE could be reliably tuned by addition of diverse models to the best model. Other workers[117] have shown that differences in feature definition (i.e., charged guanidinium groups), exclusion spheres (absolute barrier or only for atom centers and not bonds) treatment of tautomers, and the search strategies lead to different hit lists; these lists should be combined to maximize the effectiveness of scaffold hopping. It also highlights the difficulties in performing any type of comparison in absolute terms, and on the inadvisability of transferring any model generated using one approach to another program.

When the pharmacophore generation method is linked to the building of a 3D QSAR, as is possible in the CATALYST and PHASE programs, the pharmacophores can be evaluated on the statistical quality of the resulting models. In many cases, models have been evaluated on their internal predictivities but, as with all QSAR methods, a more rigorous evaluation involves the assessment of an external test set. In a recent comparison of PHASE and CATALYST, eight series of compounds with known activities against different targets were divided into training and test sets. The compounds in the training sets were used to generate pharmacophore hypotheses which were then tested on their abilities to predict the activities of compounds in the test sets.[118] Acceptable models

were found for only four of the data sets. Moreover, in some cases the programs were found to be highly sensitive to the chosen parameters, as has been found in other comparative studies.[105] Furthermore, the models with the highest predictivity did not correspond to the hypotheses that were scored highest by the programs, suggesting that such scores should be treated with caution.

The increased numbers and diversity of X-ray structures of protein–ligand complexes over the last decade has led to the development of test sets for the evaluation of protein–ligand docking programs. Performance is measured by the ability to reproduce the ligand binding modes. The initial test sets were of limited quality and diversity but these are now of a much higher quality with the data carefully examined for accuracy.[119] The availability of a wide diversity of protein–ligand complexes also provides opportunities for the development of test sets for pharmacophore methods, although this is a more complex task than for docking since each test case requires the identification of diverse ligands bound to the same protein target. Having identified such a set of ligands it is then necessary to superimpose the complexes based on the active site residues in order to generate an alignment of the ligands. Finally, the common features that comprise the pharmacophore can be identified, typically through visual inspection. This was the approach taken by Patel et al. in their evaluation of the programs CATALYST, DISCO, and GASP[120] which involved five protein targets (DHFR, thrombin, CDK2, thermolysin, and HIV reverse transcriptase) with up to 10 ligands for each target. The complexes were visually analyzed to identify the "true" pharmacophore and the three programs were evaluated on their ability to reproduce it. One outcome of this study was that the assessment of the generated pharmacophores is nontrivial. The ultimate goal is clear: the predicted 3D pharmacophore should consist of the X-ray conformation of each ligand superimposed exactly as seen in the crystal structure alignment. However, the definition of an acceptable solution is less clear. How should a pharmacophore be rated that contains the correct feature points (configuration) but the "wrong" conformations? What is an acceptable RMSD on the pharmacophoric distances (and conformations)? What if the variation in conformation is in a region of the ligand that is exposed to the solvent and not directly involved in the pharmacophore? What if most of the ligands are aligned correctly but one does not fit the pharmacophore? Multiple criteria were thus devised for the evaluation of the programs. The results, however, were rather disappointing, demonstrating several inadequacies of the existing programs and also the need for more rigorous evaluations.

Patel's dataset was perhaps the first attempt to develop a standard test set for pharmacophore elucidation and it has subsequently been used by other groups to evaluate new methods. As with the early attempts to develop test sets for docking, careful examination of these initial pharmacophore data sets by other authors revealed some errors (i.e., in protonation states of the ligands) which were subsequently corrected. Thus, as for the docking test sets, it is important that careful consideration is given to issues such as tautomerism, protonation state, and fit to electron density when identifying the true pharmacophore. Furthermore, the small size of the Patel data set leads to a real risk of programs being overtrained on a few examples. Cross et al.[25] used the Patel dataset to validate the FLAPpharm method and showed that they could get better chemotype enrichment rates, even when starting with only the 2D structures rather than the crystallographic poses, probably due to the richer description of the pharmacophore they employ. There is a clear need for the further development of such datasets that are accepted within the community as the minimum required for the evaluation of any new pharmacophore elucidation program. The Cruciani group[121] has attempted to answer this need with the PharmBench data set. The PharmBench validation suite consists of 81 datasets, with 960 ligands that can be aligned from their protein cocrystal complexes (which also have electron density maps available for further validation). The ligands and their conformers should be generated starting from the 2D structures, to avoid any transfer bias, before use as a validation test. With this information, one can test to see if the bioactive conformation is sampled, whether a correct alignment can be generated based on these conformations, and the overall similarity of the model to the X-ray alignment. Applying FLAPpharm to this set, reasonable alignments were found, but which had poorer RMSD statistics, which shows the danger of using distance-based metrics alone as a quality measure. These misses are caused by cases of poorly defined "tail" conformations, something that also affects docking programs. The alignments and the bioactive conformations generated from the proteins could also be suspect, so that a miss is not a disaster but a cause for further investigation, particularly using the electron density maps and the local resolution. Further datasets have been curated and published. The AstraZeneca set[122] includes an interesting assignment of the difficulty of each alignment set, so that one can get an impression not only of the overall performance, but the performance of a method on hard problems, which is really the key factor. The authors used their set to assess the CSD-based alignment tool[36] and found that it could reproduce the "easy" alignments 95% of the time, 73% of the moderate cases, and 39% of the hard cases. There are also infeasible cases, where any alignment is probably more a chance event, for example, when the ligands occupy different parts of the binding site as is the case of the endothiapepsin set. This study clearly shows where a method might fail, and for what reasons. They also introduce a metric for assessing the training set based on the degree of shape and electrostatic similarity and structural diversity. A training set containing molecules with low similarity and high diversity is likely to be hard to model.

3.09.3.8 Causes of Underperformance in the Pharmacophore Concept

There are many reasons why the assumptions behind the pharmacophore concept break down. The pitfalls that are faced by pharmacophore modeling are not markedly different to other methods for virtual screening. These have been well reviewed elsewhere[123] and are only repeated here in brief. Training a pharmacophore model to maximize the retrieval of known actives can compromise the discovery of scaffold hops. It would be unusual to find a new highly potent hit from a pharmacophore screen, as the model is underdefined and assumes a commonality of binding models that might not true. The pitfalls in feature definition and in conformational coverage have already been discussed. There is also the implicit assumption that the binding site is relatively constant, leading to a consistent binding mode. This ignores any possible role of water networks, protein flexibility, and induced fit. If two active ligands interact with the water network in different modes, one by stabilizing it with an H-bonding group, another

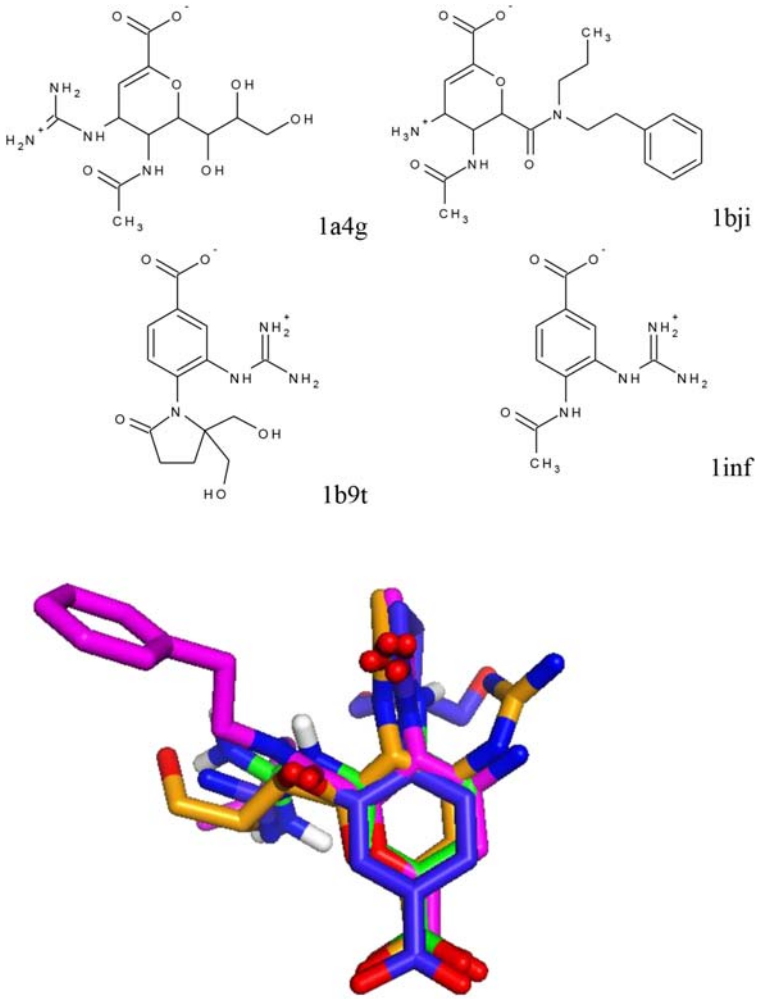

Fig. 6 Four ligands superimposed according to their binding mode to neuraminidase. Whilst the ring systems and the carboxylate group overlay, two ligands align their basic functional group to the west (1ifn in *green*, 1b9t in *blue*), two to the eastern domain (1a4g in *orange*, 1bji in *magenta*). A pharmacophore approach would treat all groups equally and produce an alignment that does not match the X-ray.

by displacing a water with a hydrophobe to form a new network, it will be very difficult to find a common pharmacophore. Likewise for a feature that may only tangentially interact with a binding site and whose main role is to confer improved properties such as solubility. This promotes the idea that pharmacophores should also be tested using feasible compounds that lack one or more of the features, to provide supporting evidence that the feature is important. It is also known that sidechains may take very different conformations even within highly homologous ligand series. A pharmacophore that does not reproduce the crystallographically observed binding mode is not necessarily a failure, but reflects the underdetermined nature of models based only on ligands (Fig. 6). This is very true for ligands with under three recognition features, such as fragment-like ligands. Pharmacophore scores have been used as surrogates for affinity. This is dangerous, as affinity is the balance of interactions in the complex and with the solvent.[41] The absence of a feature might be more important than its presence, but even within features there are changes in this balance that are not reliably predictable.[45,124] Even with the benefits of X-ray structures, free energy of binding is very hard to predict, so one should not hold pharmacophore models to the same standard. As a benchmark, a study[125] found that addition of a single methyl group to a lead structure caused a 10-fold jump in activity in 8% of the 2000 cases examined, and a 100-fold jump in 0.5% of the cases. Apart from conformational effects, this small change of an additional methyl would not be detected in most pharmacophore elucidation methods. Good enrichment of screens should be the primary goal, and that means performing a good deal of experimental validation.

3.09.3.9 Practical Aspects and Applications

It is to the credit of software developers that pharmacophore elucidation methods are no longer limited to a small number of expert computational chemistry practitioners but are much more widely accessible. However, it would be unfortunate when the reader to

assume that such methods have reached a degree of accuracy that they can be used "blind." Software programs such as these are no different to a sensitive instrument that requires knowledge and expertise to obtain the maximum benefit. As we have already indicated many programs contain a number of user-selectable parameters that govern (sometimes dramatically so) the amount and quality of output produced.

Three main stages can be identified in the elucidation of a pharmacophore. First, prepare the data set. Second, generate possible pharmacophores. Third, validate the pharmacophore(s). The compounds used to construct a 3D pharmacophore should all have the same mechanism of action (e.g., agonist, antagonist, inhibitor, and binder) and should preferably have a high affinity as measured in an appropriate biological assay (e.g., full-curve dose response from a binding assay). If a competitive binding assay is available then this may provide additional confidence that the ligands bind in the same region, though it cannot guarantee that they share a common binding mode. Data from cellular assays are less desirable, as the results can be influenced by factors outside of the pharmacophoric concept (solubility, permeability, partitioning, or stability). The ideal data set contains ligands from a number of different chemical series having limited conformational flexibility and without too many hetero-atoms. Each molecule should be inspected to ensure that it is represented as the appropriate tautomer and that the appropriate ionization state is used; depending on the software used these aspects may have a significant impact on the quality of conformations generated. It is also important to check the output from any cleansing procedures that may be applied to the input ligand structures. As the typical pharmacophore elucidation data set contains a relatively small number of molecules it should not be necessary to sacrifice speed for quality; it is also advisable to visually inspect the conformations for potential issues such as *cis* amides, high-energy axial ring substituents, and close contacts. Most pharmacophore generation programs will produce a number of results and will attempt to score them as outlined earlier. These scores can be a useful guide, but it is important to check for the quality of fit of each molecule to the pharmacophore, for a sensible common volume overlap and to ensure that the pharmacophore is consistent with the known SAR. Stereoisomers that show different activities can be very informative in helping to distinguish between possible pharmacophores. Inactive molecules can also be very useful. For example, if an inactive molecule gives a good match to the pharmacophore, then this may help to identify excluded regions. Sometimes it proves impossible to derive a satisfactory pharmacophore model. Clearly this may happen if the fundamental principle of a common binding mode does not apply. It may also be helpful to check the structures for functional groups that may not be involved in molecular recognition with the biological target (e.g., are solubilizing groups). Other strategies include relaxing various criteria (permitting partial matches). Ignoring the inactive compounds on the basis that a pharmacophore is a necessary but not sufficient requirement for activity may also help.

As will be discussed in the next section, 3D pharmacophores are widely used for virtual screening of databases in order to identify new lead series. They also have significant utility in other areas, particularly when no detailed structural information on the biological target is available. Thus a pharmacophore can help guide the design of focused arrays, can help to rationalize the SAR of a chemical series and can enable different chemical series to be combined and information transferred from one series to another. In these and other applications, the ability to visualize a 3D pharmacophore is an especially useful aspect. In all such uses however one should always remember that a pharmacophore is only a hypothesis that should be continually tested, refined, and possibly rejected.

3.09.3.10 3D Database Searching

One of the common purposes of making pharmacophore models is to search for novel chemical matter (scaffold hopping). At the time that the first pharmacophore searching algorithms were implemented in the early 1990s the discovery landscape was quite different. X-ray structures of proteins were relatively rare, and it was much more common to work with leads derived from endogenous ligands or from the literature. At the same time, the first generation of screening and compound handling robots were being developed, together with electronic databases of corporate archives. Most chemists are familiar with 2D substructure-based searches, but these typically find only compounds with similar scaffolds or members of the same structural family. The pharmacophore represents an abstraction that can be used to find alternate chemotypes (i.e., chemical series with a different underlying framework, scaffold, or common moiety). All that matters is the disposition of molecular recognition features, not the underlying pattern of atoms and bonds. The stage was therefore set to search large databases for compounds (both "real" and "virtual") that could exhibit the desired pharmacophore and thus (hopefully) have the same biological activity.[2,126,127] Depending on the precision of the query, one can find numbers of hits from 10s to 1000s, which was in line with the screening capacities available at the time. Many will be false positives and show no activity in the screen, but generally, the hit rates from pharmacophore searches are much higher than from random screening. The hits can also sample very novel and diverse chemotypes, allowing the medicinal chemist the luxury of pursuing the series with the best overall profile. Today, it can be equally cost effective to screen the whole corporate collection as to screen a significant subset. Thus the main role of pharmacophore searching in industry has changed, with a principal emphasis being on the creation of small focused sets for low throughput, higher quality assays to enhance the lead identification process in parallel with high-throughput screening (HTS). The sources of the compounds in such focused sets can be both internal and external (i.e., compound vendor). In academia, pharmacophore searching still plays a useful role in reducing screening set size to manageable proportions due to assay throughput; moreover, the main source of compounds is from commercial catalogs.

3.09.3.10.1 Database generation

All the issues highlighted previously now return in starker form, when a 3D pharmacophore is used as a search query for a large corporate database. It would be desirable to build the database so that it can be used generally, without further modification. The more the information that can be precomputed, the faster the search will be, but the larger the database will also become.

However, if the hard-coded parameters used to build the database do not match those used ad hoc to build the query, the retrieval rates will be greatly reduced. The key parameters to be considered are: tautomerism, stereochemistry, conformational sampling, and feature definition. As the usual approach is to capture as many actives as possible, even if that means more false positives, most databases are built to include all possibilities, that is, all tautomer and stereoisomer forms are added as duplicates. Conformational sampling is a particular headache, due to the trade-off between coverage and size of the database/search time. Broadly, there are two strategies: compute the conformations on the fly, or precompute and store. One can also use single conformer databases; if a good quality structure generation program is used, the single conformer ought to be close to, or even at, the global energy minimum. If this conformation can match the pharmacophore without further adjustment, the physical interpretation is that no strain energy is present, thus improving the energetics of binding. This low-energy match should have a better chance of translating into an experimentally active compound. However, the hit rate using flexible searching has been found to be 2–10 times higher.[56] The business rules used to construct the database need to be clearly documented for subsequent users, so that the pharmacophore queries can be adapted accordingly. The basic workflow involves two key steps: for each structure in the database, determine if the structure contains a predefined number of features from the query, and if it does, can the structure be made to display those features in the right geometry, within a defined tolerance?

3.09.3.10.2 Feature Matching

Feature definition is generally hard-coded, leading to very fast search times; one can prune any molecule from the search that does not contain the partition, before searching for the configuration. The feature definitions are encoded in a dictionary; when the database is built, the type and number of features in each molecule can be determined and stored. The same is done for the query, and only molecules with the same number (or more) and type of features are retained for the time-consuming next step. However, this can lead to a loss of applicability, if the pharmacophore query uses even slightly nonstandard definitions. The alternative approach of making the features very wide-ranging will reduce the power of a query to effectively discriminate between true hits and false positives. In the event that no matches are found, there is often the option of allowing partial matches (e.g., to match four out of five features). This assumes that the missing features can be designed in later (or perhaps sufficient activity can be obtained even with a partial match). Some programs allow relative weighting of features. This facility permits you to designate which features contribute most to the SAR, for example, the basic nitrogen for serotonin mimetics. This can also be done after the search of the final hit list. Feature matching can give high screen-out rates (80–100%), depending on the complexity of the query.

3.09.3.10.3 Geometry matching

Once the structures that might match the query are found, the next step is to examine the conformations of those structures to see if the geometric disposition of the features can be matched. Note also that a pure distance comparison cannot distinguish enantiomers; for this an actual fit (in 3D space) to the query is required. The goodness of fit to the query is defined by the tolerance allowed in the match between features. One might be looking for a donor–acceptor pair separated by 5 Å, but you are prepared to accept a value between 4 and 6 Å. Not all interfeature tolerances need to be the same: they should be set using knowledge of the SAR. Matching of the features should be possible without introducing undue strain into the structure. This is another parameter that can be defined. It is not possible to give specific rules, as the acceptable limit is force field dependent, but a strain energy of more than a few kcal/mol will lead to many false positives. Features can also be negative, for example, excluded volumes. Here the aim is to avoid rather than match. Inclusion volumes, for example, derived from the ensemble of aligned active ligands, can also be incorporated. Conformational analysis of all but the simplest structures quickly becomes very computationally expensive. Three strategies can be used, each with their good and bad points. The first strategy is used in UNITY,[128] which stores single conformers and uses the directed tweak algorithm[129] to perform flexible searches. The query is mapped onto the molecule, feature by feature, and a minimization in torsion space is conducted to satisfy each interfeature distance. The results are then checked for steric clashes. This is important to avoid unreasonable conformations with high internal energy. Multiple mappings of the query are possible, but once one good match is found, the search can be terminated. Essentially, the molecule is pulled by the query into the right shape, so the strain energy is the key parameter. Screen-out rates are lower than for the other methods, but with any rise in true hits found, there will also be a rise in false positives. This is a strategic decision that should be made in the wider context of the project. The second strategy is adopted by MOE, CATALYST, and PHASE, which all use a database of conformations. Each conformation can be quickly matched as a rigid body to the query, and if it does not fit, it is discarded. The strain energy can be preset so that all conformations are reasonable. The disadvantage is that normally only a relatively small number of conformations per structure can be stored (typically 250 or fewer). The selection of conformers may be performed using a poling approach to ensure "conformational diversity,"[130,131] and predefined preferences, for example, *cis*/*trans* ratios for carboxamides, or axial/equatorial ratios for saturated rings. The key issue here is whether the conformational sampling is of sufficient resolution to be useful, especially for more flexible molecules. In the third approach, compounds that pass the feature mapping stage, are subjected to conformational analysis on the fly according to a preset recipe (typically a rule-based enumeration that uses a predefined number of torsional increments for each type of rotatable bond). For each conformation, a rigid body match is performed as before, and the analysis aborted once a fit is found. Only the torsions that can affect the interfeature distances are analyzed. If the query is only loosely defined (few features, wide tolerance allowed in the fit), this approach can be very time consuming. A sensible upper limit for the number of rotatable bonds is usually defined to prevent the search time being dominated by the matching of just a few very flexible structures. The directed tweak can produce strained conformations (leading to a higher false positive rates), but the other approaches can fail to generate the matching conformation (higher false negative rate). This is the reason why it is not possible to say that one strategy is superior to the other: so much will depend on the query and the database

and the nature of the decoys. A final variant used by CATALYST is its BEST option, which is to take structures that nearly match the query, then to tweak them.

A very important test is that the search procedure should find the molecules used to build the original pharmacophore; failure to do so is an excellent way of losing any credibility! As with pharmacophore elucidation, there are a number of locally adjustable parameters. These include the tolerance allowed in the fit, and the number of features which can be skipped; naturally, loosening the search will increase the number of hits returned, so the capacity of the biological screen should be carefully kept in mind. Validation of the search parameters is a very valuable exercise that can be performed on a small test database, seeded with known actives and decoys, to see how changes to the query can change the enrichment statistics. It is strongly recommended to tune a query this way before running the main search.

3.09.3.10.4 Post-processing

A hit list of molecules that match the pharmacophore query should be post-processed. Highly flexible, feature-rich molecules such as peptides can match most queries. Parsimonious matches might be more promising. Where the information exists, exclusion, or inclusion volumes are often used; this will be discussed further in the section on using protein structures. Alternatively, simple measures of how much of the molecule falls within the pharmacophore, and how much outside, can be used to prioritize the virtual hits for inclusion in the final set for screening. Using the same scoring function as that used to create the query is possible, but given the inaccuracy of the scoring function, visual inspection is often a better guide. The simplest score is the RMSD fit to the query. One can also filter using physicochemical criteria (i.e., only returning hits that are druglike or leadlike in nature). However, a drawback of pruning too severely at this early stage is that novel chemical matter that could subsequently be modified to give a viable lead series would be lost.

3.09.4 Pharmacophore Keys

3.09.4.1 2D Pharmacophores

The archetype of a 2D pharmacophore is the Ftrees fingerprint,[132] which has been adapted by Gillet,[133] and in the ErG methodology of Stiefl[20] and others. Features are defined by substructural rules, to capture donors, acceptors, rings, and hydrophobes, under physiological protonation states. Features are joined into a simple tree using bond connectivity as the edge criteria, so that no conformational analysis needs to be performed, and then turned into a fingerprint using length functions. The Ftrees fingerprints can be combined to provide a consensus fingerprint or used to search large databases very quickly to provide possible scaffold hops, based on degree of similarity. It is recommended that the Ftrees matches are used to drive a 3D alignment to verify that the match is sensible, as artifacts can arise due to the abstract nature of the fingerprint. As the fingerprint gives very good screen-out rates, this is justified. In comparison with pure substructural fingerprints, ErG fingerprints could achieve similar rates of retrieval and better scaffold hopping behavior. The only case when the 2D pharmacophore fingerprint performed worse was when there was no clear consensus pattern, but a clearer substructure match. Just as 3D pharmacophore searches are a good prefilter for docking, 2D pharmacophore fingerprints can be a very fast prefilter for pharmacophore searches. The properties of the fingerprints can also be used to perform diversity comparisons during the prioritization of compounds to be added to corporate screening collections.

3.09.4.2 3D Pharmacophores

A 3D pharmacophore key is a binary descriptor of the partitions and configurations accessible to the molecule. Such a key (also called a fingerprint) is generated by performing a conformational analysis for each molecule and abstracting the interfeature geometries for each conformation sampled. Configurations are handled by binning the distances, for example one specific bit in the fingerprint is set if a donor and acceptor can be positioned 4–6 Å apart. By analogy with the use of the 2D fingerprints used in substructure and similarity searching the pharmacophore key can provide a way to improve search speeds for pharmacophore searches of 3D databases: the first phase of searching becomes a simple AND operation such that only molecules that pass this filter are matched further. 2-Center pharmacophore keys, in which bits are assigned to pairs of features, are probably not specific enough. If we consider seven features (i.e., donor, acceptor, hydrophobe, aromatic, positive, negative, and donor/acceptor) and 17 distance bins, the key would contain $7 \times 6 \times 17 = 714$ bits, and many bits would be turned on. The ability to discriminate between the known actives and inactive decoys is diminished. A 3-center key, in which each bit represents a triplet of features needs to be 184,884 bits long. This type of key is sparse, and so much more selective. In addition to binary keys, one can also count the frequency that a triplet is found during the analysis of a structure. 4-Center keys are even larger.[134] Using 6 feature types and 10 distance bins leads to 24 million distinct quadruplets, or tetrahedra. An example of this is the FLAP fingerprint.[135] The advantage is that such keys are now able to distinguish chirality. In contrast to database generation, feature matching is done at generation time rather than at query time. Parameters such as feature separation distances are hard-coded into the keys, so a common workflow for key generation is essential.

Pharmacophore keys capture information about shape and intermolecular interaction propensity. In contrast to the "traditional" pharmacophores described thus far they do not directly identify the particular arrangement(s) of features required for a specific biological activity. They can be a very useful prescreen to identify and prioritize putative alignment, and thus serve to speed up the full rigorous alignment process greatly.[136] The authors of this method use a neat trick of having two fingerprints with overlapping distance bins, to avoid edge effects at the bin boundaries. Pharmacophore keys are also whole-molecule descriptors that

have been used for a variety of similarity and diversity applications, driven in particular by the needs of technologies such as HTS and combinatorial chemistry where the number of chemicals to be processed is very large, for example, screening decks, or virtual combinatorial libraries. In library design one might like to answer the question, if I add this reagent, or remove that reagent, will the properties of my library improve? For example, in designing a library of type I kinase inhibitors, one will want to improve the overlap to the type I pharmacophore whereas if the library is being designed for more general enrichment purposes, one may want to minimize the overlap with the current screening deck, but maximize the overlap with the space of known drugs. Pairwise alignment of even a small library of 1000 compounds against a deck of 10^6 is not generally practical, even if it is feasible. Pharmacophore keys offer an alternate approach for the process of assessing diversity in a corporate archive. The drawback is the presence in the key of many unhelpful partitions, such as Hydrophobe-Hydrophobe-Hydrophobe separated by 12 Å, which probably do not merit a deliberate action to find molecules that fill this bin. We return to this topic in the section on pockets.

Ranking a set of compounds in a database according to their similarity to a query molecule is perhaps the most straightforward application of pharmacophore keys. New and modified similarity metrics have been developed to deal with the particular requirements of the pharmacophore key, which is in general larger and more sparse than a standard 2D fingerprint.[55] Flexophore[137] is an example of this approach. The Flexophore descriptor is constructed as a graph with the nodes as the features and the edge as frequency histograms of the feature separation. MM2 atom types are used to describe the pharmacophore features during the conformational analysis. A customized similarity function to compare the node types and the histogram results was devised: in enrichment studies the Flexophore descriptor did as well as 2D fingerprints at straight retrieval, and much better at scaffold hopping to molecules not in the training chemotypes. The union of the pharmacophore keys for a collection of molecules provides an overall profile that can be considered a diversity metric and can also be used to assess the extent to which the set adds new pharmacophores to an existing collection when purchasing compounds or in library design.[138] A pharmacophore key can also be used as a descriptor vector in QSAR modeling.[139,140] Here, the bits provide the basis of discriminating between actives and inactives. The nature of the pharmacophore key means that such models can in principle deal with multiple binding modes. Depending on the model building technique used it may also be possible to interrogate the resulting model to determine which pharmacophore(s) are responsible for the activity. As always, it is important to ensure that such models are robust and do not suffer from overfitting.

3.09.5 3D Pharmacophores and Protein Structure

Pharmacophores can be derived from the binding site of a protein. This is particularly relevant as the number of protein structures has greatly increased not only in simple numerical terms but also with regard to the breadth of coverage of gene families of interest to drug discovery. Moreover, the distinction between "structure-based" and "ligand-based" drug design methods is now much more diffuse and the judicious use of traditional ligand-based methods such as 3D pharmacophores can greatly enhance the efficiency and effectiveness of structure-based design.

The most straightforward way to derive a 3D pharmacophore from a protein structure is through the direct observation of specific interactions between protein and ligand(s). Such a pharmacophore can then be used in the usual way, for example to search a 3D database in order to identify compounds for focused screening. Database searching methods based on 3D pharmacophores are in general much faster than structure-based methods such as docking and so this can be a more effective way to screen very large databases. Alternatively, the 3D pharmacophore search can act as the first stage in a docking workflow. A large database can be prescreened using a pharmacophore query, to create a much smaller subset for docking. A pharmacophore, if properly constructed, will give very few false negatives (false negatives might arise from different binding modes or poor feature definition). The scores of docked hits may then become more useful.

Knowledge of the protein structure enables the pharmacophore to incorporate more detailed information about regions that are not accessible to the ligand. This is most commonly achieved through the use of exclusion volumes and/or inclusion regions.[141,142] An illustration of how a 3D pharmacophore can be enhanced by the addition of such information, especially when the site might have few discriminating features, or the features do not confer selectivity is given in **Fig. 7** for the development of a pharmacophore to identify inhibitors of liver X receptor agonists.[143] Models that could identify known selective agonists for the A isoform were chosen from the larger set of possible models and were used to screen the Specs virtual library of 202k entries.[144] When used for database searching such pharmacophore queries have the distinct advantage of finding hits that not only contain the key binding elements but are also able to fit into the active site, thereby reducing the false positive rate. In addition, the ligand shape itself was used as a Shape query. Three hits showing some selectivity were found, and there was not complete overlap between hits from the pharmacophore model and the shape query, again indicating the inherent fuzziness of both approaches. The extent to which an ensemble of excluded volumes can represent the atomic detail of a protein structure is obviously limited (though one should remember that proteins can be flexible, so the apparent precision of an atomic-resolution protein structure may be illusory). In addition, the widespread use of a two-stage algorithm further limits their utility. In this approach matches to the underlying pharmacophore features are first identified. The matching conformation is then tested for violation of the exclusion or inclusion criteria, often without any attempt to modify the conformation to fit these constraints. This can lead to potential hits being missed even though a relatively simple bond rotation could alleviate a clash. Conversely, the use of a limited number of exclusion volumes to represent an entire protein active site can result in "holes" through which a ligand may protrude. We also note that widely used shape searching methods provide an alternative way to tackle this problem.[78] Methods based purely on shape have found it expedient to incorporate elements of pharmacophore recognition in order to improve the efficiency and sensitivity of their algorithms.

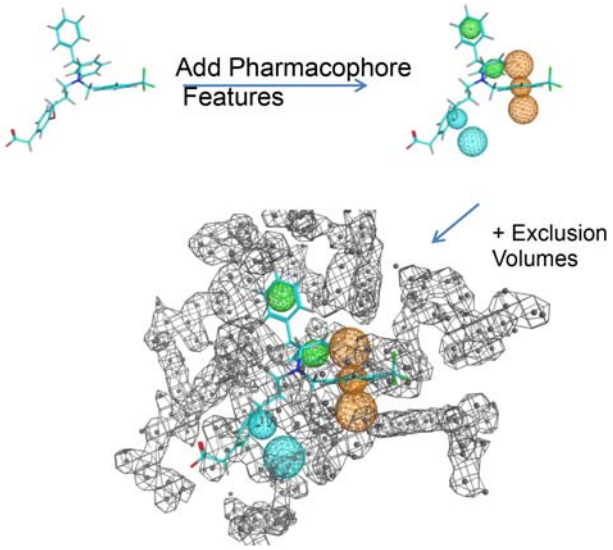

Fig. 7 Illustration of how a 3D pharmacophore can be enhanced by the addition of shape and excluded volume information, to identify inhibitors of liver X receptor agonists. The exclusion volumes are drawn at a reduced radius of 1.2 Å for clarity.

Structure-based 3D pharmacophores derived solely on the interactions observed in known protein–ligand complexes may be unnecessarily restrictive. An alternative is to define pharmacophores based on an analysis of the "hot spots" in the active site. A number of methods can in principle be used to identify such hot spots (or site points). These include programs such as FLAP[145] that probe the site with small molecules or functional groups and calculate the enthalpy of the interaction between the probe and the protein atoms at points on a grid lattice to generate an MIF. These fields can then be contoured by energy to find the most favorable regions for an acceptor or a donor (or any other type of feature) to interact with the protein. Programs such as SuperStar[146] use a knowledge-based approach in which rules are used to generate a set of interaction sites for each atom or functional group of the protein that is capable of participating in a nonbonded contact. The rules are largely based on statistical analysis of experimental structures from the PDB or small molecule crystal structures and take into account the chemical nature of the atoms as well as the directional preferences of features such as hydrogen-bond donors/acceptors. From the locations of the site points it is then necessary to construct one or more 3D pharmacophores. The simplistic approach would be to combine all such points into a single pharmacophore but the resulting query would typically be matched (if at all) only by a molecule filling the entire active site. Rather, all possible 3D pharmacophores (containing 3, 4, or more features) are enumerated from the set of site points. The most important step in such a procedure is to triage the set of pharmacophore queries. Commercially available programs such as LigandScout[147] can perform the entire process from site to pharmacophores. The question is then which features are key, and it is quite possible to select too many or too few. To deal with this issue, it is possible to analyze a trajectory file from a molecular dynamics run of a protein–ligand complex.[148,149] This function is available in LigandScout. This information can help identify stable features that persist throughout the simulation and more transient interactions. Features such as ring normals might rotate but the centroid remains. This type of analysis also protects against over-reliance on the X-ray structures, which might have artifactual interactions, and gives a frequency based score of the relative importance of the feature to the pharmacophore. This analysis can also assist when the interactions involve water. Hu and Lill[150] hypothesized that water molecules that are displaced upon ligand binding can significantly contribute to the free energy of binding depending on the free energy benefit of their release in bulk solvent; they developed a method based on thermodynamic analysis of MD trajectories to compute the free energy of water released. The protein-derived pharmacophore constraints are defined using short (50 ps) apo simulation to simulate limited conformational changes, then interaction potentials for hydrophobic and hydrogen-bonding probes are computed on a 3D grid and finally clustered. Pharmacophoric constraints are then associated with the clusters centers. The protein-derived pharmacophore types associated with the localization of waters that exhibit favorable free energy are selected to generate a reduced pharmacophore model. When compared with full protein-derived pharmacophore queries for three test cases (factor Xa, HIV protease, and pc-dihydrofolate reductase), the authors did not find a significant improvement in enrichment for their reduced pharmacophore but they could observe a sizeable improvement in screening speed, by a factor of 200–500, allowing for screening of very large libraries.

The combination of pharmacophore keys and techniques for site analysis allows one to avoid making (possibly subjective) choices about which features are important, or even which model of the active site is the bioactive form. The 3-center or 4-center key from a binding site is less sparse than the key of a ligand, but is still discriminating enough to be useful; it captures the overall character of the pocket. A comparison between the key of a protein and a ligand can quickly highlight common triples or tetrahedra, allowing fast alignment between the two objects. In the FLAP program,[145] 4-point pharmacophore fingerprints are derived from a GRID analysis of a protein active site and combined with a shape-based description of the binding site. When combined with a set of ligand pharmacophore fingerprints this provides an efficient way to perform structure-based virtual screening. Another well-known

application of this technique is embodied in the Metasite program.[151] Here, binding sites of cytochrome P450s have been characterized using the GRID approach and the key fields selected on the basis of experimentally determined sites of oxidation in substrates. New molecules are aligned to the pharmacophore keys to see which C–H bonds can come close to the oxidation center, and the results can be further ranked according to the reactivity of the C–H bond. In tests, the actual site of metabolism was in the top three predictions over 80% of the time. However, similar results can be obtained using just the reactivity concept embodied in the SmartCyp program,[152] indicating that the discriminatory power of any pharmacophore model is secondary to bond lability in this case, as the cytochromes go about their garbage collection business.

An obvious extension to searching for ligands is to compare site-based pharmacophore keys across proteins. If there is a high degree of similarity, the pockets are likely to bind the same type of chemical moiety. In addition to the CavBase program,[153] Nussinov et al.[154] have developed a much faster method, based in essence on pharmacophore triplets. Desaphy et al.[155] have proposed a method for binding sites comparisons that relies on the assignment of pharmacophore annotation to grid points evenly distributed around ligands complexed to proteins and on gaussian-based shape alignments. After two cavities have been shape aligned, pharmacophore types are assigned to grid cubes in the same framework; matching of the grid cube fingerprint is evaluated by a classical Tversky index. In theory, this pharmacophoric description of the cavity could be used for ligand-based screening and retrieval. Campagna-Slater et al.[156] proposed a method to screen the PDB for cavities similar to known methyl-lysine binding domains. They used a combination of biased pocket detection and protein-based limited pharmacophore assignment focused on the aromatic cage system. The pocket detection algorithm implemented in ICM[157] is focused on pockets exhibiting a specified set of aromatic and acidic residues the authors judged necessary to identify binding sites similar to methyl-lysine binding domains. The resulting set is then classically queried by pharmacophore screening, focusing on aromatic and one acidic pharmacophore type, and finally filtered by a combination of geometric and annotation consideration to prune small surface pockets. The authors could retrieve most of the methyl-lysine binding pockets, but also nonrelated aromatic cages and arginine binding sites, and allosteric pockets on known epigenetic targets. Despite the very specific focus of this work, it can be extended to more general searches by widening the pharmacophoric types used to characterize pockets. As always, there is a balance between speed and resolution, and the pharmacophore features are crude, and not influenced by any local electrostatic perturbations.

Another recent structure-based fingerprint is the structural interaction fingerprint (SIFt),[158,159] in which each residue in the binding site is represented by a 7-bit descriptor that characterizes whether (1) it is in contact with the ligand, (2) any main chain atom is involved in the contact, (3) any side chain atom is involved in the binding, (4) a polar interaction is involved, (5) a nonpolar interaction is involved, (6) the residue provides hydrogen-bond acceptor(s), and (7) the residue provides hydrogen-bond donors. The whole interaction fingerprint is constructed by concatenating these residue bitstrings together according to their sequence order. The SIFts have been used for a number of purposes. One straightforward application is to compare sets of docking results by calculating pairwise similarities between the fingerprints followed by a cluster analysis. This enables distinct groups of docking poses to be easily identified. By comparing the interaction fingerprints from docking results with the fingerprints for known protein–ligand complexes it was possible to achieve enrichments in virtual screening experiments that were superior to those obtained with commonly used scoring functions. Other variations and extensions to the SIFt concept include the use of weighted profile-like fingerprints that represent the interactions of multiple complexes[160] and encoding more detailed information about hydrogen-bonding strengths and geometries.[161] Finally, SIFts and other protein structural fingerprints can be used to cluster and compare the structures of different proteins across a gene family, most notably within the kinases. As with the ligand-based pharmacophore fingerprints the structural fingerprints enable complex data to be stored and manipulated efficiently using well-understood algorithms, albeit with some information loss.

Pharmacophores and shape: We have discussed the use of excluded volumes as a means of improving the selectivity of a pharmacophore model. These volumes may also be derived from the common volume overlap of the actives minus the common volume overlap of the inactives, assuming that the inactives have a full feature match. If there is a good set of actives but no obvious common pharmacophore, then methods for shape-based searching might be of use. This is beyond the scope of this article and the reader is referred elsewhere.[78]

Pharmacophores in de novo design: Pharmacophores can also be used as a constraint in de novo design.[162] In this case, one is searching virtual space rather than databases of known compounds. The construction method is based on the BRICS rules[163] applied to create fragment libraries. Molecules assembled using these rules should at least be feasible to synthesize. The scoring section involves fitting to the pharmacophore, including modification and geometric adjustment to optimize the score, which is a measure of the fit to the model. Pharmacophore features in the generated molecule that do not contribute to the fit are removed. The performance of this approach cannot be validated statistically per se, as one is trying to generate unknown molecules, so should be seen as an idea generator for medicinal chemists. In some well studied pharmacophore models (COX-2, BCR-Abl), the method was able to recapitulate most of the known topologies of active chemotypes.

3.09.5.1 Pharmacophores and 3D QSAR Methods

Field-based approaches have been widely used to generate 3D QSAR models from sets of aligned molecules, for example, in the widely used CoMFA program. In this case, a variety of different methods can be used to generate the alignment prior to model building, including overlays based on a 3D pharmacophore. In addition, some of the more commonly used pharmacophore methods also use 3D QSAR methods to refine their models or closely integrate the two techniques. In the HypoGen algorithm in CATALYST the degree to which each molecule matches the query (in a geometrical sense) is assumed to correlate with the observed activity. The PHASE program also provides a facility for constructing 3D QSAR models. These models can be atom-based

(i.e., taking all of the atoms in each ligand into account) or pharmacophore-based (i.e., only the features involved in matching the common pharmacophore are used). A rectangular grid is defined to surround the molecules aligned to match the pharmacophore. Each cube in this grid is then characterized according to the atoms or pharmacophore features that fall within it, resulting in a set of binary strings (one per molecule). Partial least squares regression applied to these bit strings helps to identify which features at which locations lead to an increase or decrease in activity.

3D QSAR presents challenges even beyond traditional pharmacophore elucidation methods, though in some cases they can clearly provide additional (and useful) information. In particular, the ability to incorporate inactive molecules is very appealing, though this should be done with great care; molecules can be inactive for a variety of reasons too subtle to be captured in the model, and they may only serve to add noise rather than signal. Any 3D QSAR protocol can be used to examine alignments, but bear in mind that pharmacophore models are underdetermined and using powerful statistical tools, it is easy to find patterns in the data that are not physically real and therefore have no utility to find novel active ligands.[164] As with a pharmacophore model, the output of a 3D QSAR protocol can be interpreted as a pseudo-receptor, or as a more refined pharmacophore query. In either case, one should complete a cycle of experimental validation to see if the models find new hits or explain existing unseen experimental data rather than relying only on statistical validation criteria. There is also a paradox between the pharmacophore alignment and the way in which 3D QSAR models are set up. A pharmacophore will emphasize the points of commonality: therefore, the variation in the fields around the common features will be low, so that these descriptor points can be removed from the QSAR model.

3.09.5.2 Exemplar Applications of 3D Pharmacophore Methods

Many applications of 3D pharmacophore methods can be found in the literature. In addition, several reviews and summaries of literature applications are available, often providing a useful practical perspective.[165–168] Here we highlight a very limited number of applications from the recent literature to illustrate some of the main ways in which 3D pharmacophore models are used in contemporary drug discovery.

A major use of 3D pharmacophore methods is for the identification of new hits and leads via 3D database searching. Such applications fall into two broad categories depending on whether the pharmacophore incorporates protein structural information or not. Pavadai and colleagues recently described the development of a *Plasmodium falciparum* dihydroorotate dehydrogenase inhibitor pharmacophore model from eight known active compounds[169] using the CATALYST method. The resulting pharmacophore contained four features. When used to search the NCI compound collection of approximately 265,000 structures almost 3590 hits were obtained, using a strict acceptance level. The authors also found nine other models of varying quality and comment that their models differ from those obtained by another group using a different training set.[170] This is a common occurrence, and underlines the concept that the pharmacophore is more a property of the training set than the target. The authors also describe in some detail how they subsequently reduced this large hit list down to a more manageable size (62 compounds) using a combination of docking scores and cluster analysis. A number of active compounds were identified, four of which had an activity (K_i) of under 10 μM (Fig. 8). The enrichment factor was estimated to be at least fivefold and the substructural similarity of the hits to the training set was also low. This shows the two strengths of pharmacophores as a VS technique, strong enrichment, and novel chemotypes.

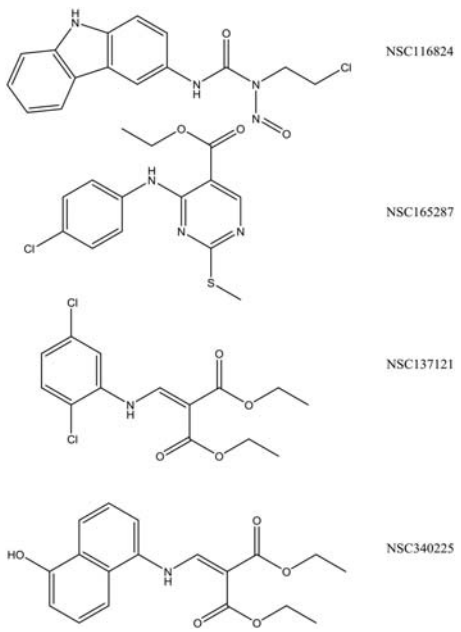

Fig. 8 Four new compounds that showed <12 μM IC_{50} against *Plasmodium falciparum* dihydroorotate dehydrogenase.

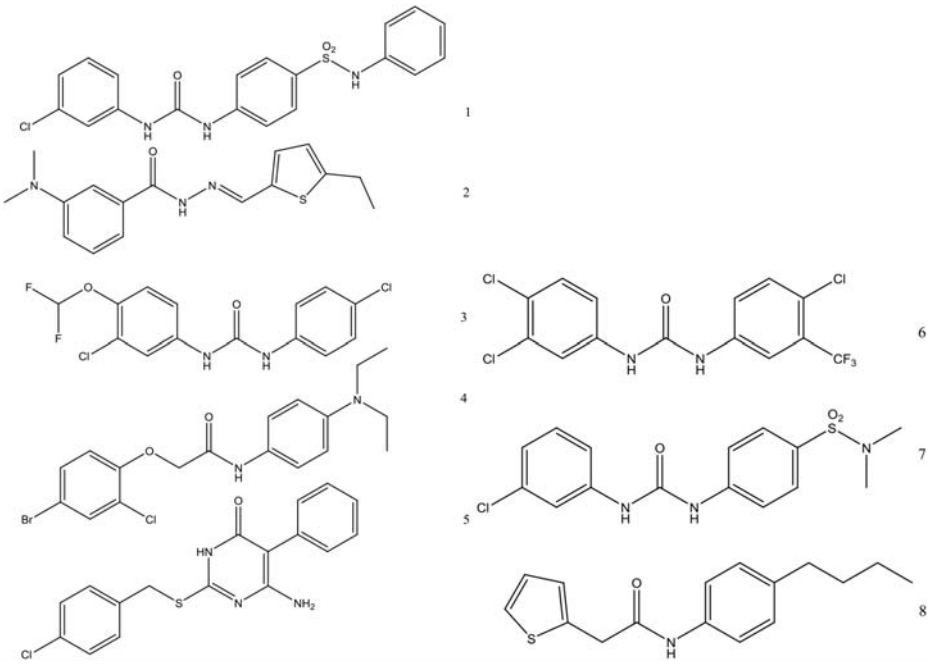

Fig. 9 The chemical structures of eight novel and highly active sEH inhibitors (<10% activity at 10 μM) identified using pharmacophore screens.

The work of Waltenberger et al.[19] to discovery novel soluble epoxide (sEH) inhibitors further illustrates the point made in the previous case study. Their training set came from both protein–ligand complexes and unbound but potent inhibitors. They also had a set of 192 confirmed inactive compounds as decoys. Models were built using LigandScout[147] and DiscoveryStudio (Catalyst[171]) methodology; the CATALYST model is illustrated in Fig. 1. They recognized that there was no one single model that retrieved all the known actives, so they built a series of models to be used in consensus. The six models with the highest combined enrichment were then used to screen the Specs database.[144] Even then, some known actives were missed, indicating again that a pharmacophore is not a unique object associated with a target. Two modeling packages were used as it is known that this will lead to an increased number of active chemotypes.[117] In biological validation of the chosen hits, a hit rate of 40% was obtained, including some novel low to moderate nanomolar inhibitors (Fig. 9). This demonstrates the key role of pharmacophores in finding new chemical matter with good enrichment, even for well studied targets such as sEH.

An example of hit identification using a structure-based pharmacophore comes from the work of Astles and colleagues[66] using the structures of just two structurally distinct and conformationally restricted inhibitors of endothelin A receptor. This provided the pharmacophore illustrated in Fig. 3A. A hit series was obtained with weak 1 μM activity and the model was used to optimize the activity by improving the fit to the model through geometry and conformational restriction, resulting in a final activity of 5 nM. The model required the use of a projected H-bond acceptor point to explain all the SARs; the positions of the H-bond acceptor atoms do not align and using this feature would have hindered the discovery of the pharmacophore model. The next example illustrates the use of pharmacophore models in lead optimization and comes from work to identify nonsteroidal glucocorticoid (GR) agonists.[172] A docking model of an established series of GR agonists was used to define a pharmacophore model. The model was used as a fast screen for screening 20k monomers to identify replacements for a metabolically labile benzoxazinone moiety. A three-step procedure was used for the selection process. First, a large 20k set of potential building blocks was identified and combined with the core template to generate an enumerated library. The virtual products were filtered using modified Lipinski criteria. The remaining structures were then converted to a 3D database and searched using the pharmacophore query. This process resulted in 200 compounds for synthesis, some of which did indeed show activity in a GR binding assay. It is important to note the role of pharmacophores in hit finding. Using these models as a filter during lead optimization is more problematic, as the SAR and the model might diverge, and using a pharmacophore model as a filter would eliminate many structures that would inform the SAR; this is said to be the case in the optimization of Liver Carnitine Palmitoyltransferase.[173]

3.09.5.3 Counterscreening and Target Identification

Pharmacophore models have also been used as counterscreens, to flag structures that might have undesirable activity, for example hERG inhibition or binding to CYP450s (as discussed earlier), or for target identification. Significant care and caution must be applied in these cases. As discussed earlier, a view needs to be taken on whether the target is capable of expressing a well-defined robust

pharmacophore. In the two cases given, many papers have been published claiming a model but it is not general in nature. The best results have been obtained using a number of complementary models to capture the different binding modes.[18] In a prospective study, these models gave a hit rate of 40% (or a false positive rate of 60%). The domain of applicability of a pharmacophore model is hard to describe, in the same sense as one would do for a 2D QSAR model.[174] Hence a match to a countertarget model should be used to promote a binding experiment to that target as first priority, to protect against the high number of false positives expected from this approach. Batteries of pharmacophore models[99] have also been used to suggest likely targets for ligands active in phenotypic screens. Again the results of such models should be seen not as confident predictions but as a means to prioritize experimental testing. Wang et al.[175] recognized the pitfalls in using fit scores to judge likelihood of actual affinity. They have adapted their PharmMapper web service to use *Z*-scores, that is, the chance of binding over random, rather than the absolute score. This works against promiscuous pharmacophores giving too many false positives. There are 7300 models corresponding to over 1500 targets in their system, and they are built using knowledge of the active sites (excluded volumes). Using the adjusted *Z*-scores, they could improve on the enrichment of actives over inactives, and identify with more certainty possible off-target interactions.

3.09.6 Discussion and Future Directions

In this final section, we focus on a small number of issues that seem to us particularly important: the difficulty of aligning molecules and its consequences; the need to improve validation standards; limitations in the way features are typically represented; the growing emphasis on the development of algorithms that take account of the possibility of multiple binding modes; and our views on how pharmacophore methods are most likely to be of value in the next few years. It is helpful to start with a simple summary of the key messages before going into detail later.

In the absence of protein–ligand X-ray data:

1. The pharmacophore is more a property of the training set of molecules than the target, and may have no physicochemical meaning when compared to the X-ray binding mode.
2. The pharmacophore models discovered are dependent on the features, the weight of the features and the conformational analysis method. Pharmacophores derived from the same rigid ligand starting point using different software tools will generate different hit lists.
3. It is not necessary to assume that there is only one possible pharmacophore model, especially for targets that are promiscuous, for example hERG. Consensus models might be better.
4. One should not look for pharmacophore models that are optimized to explaining known data; often this leads to a decrease in their ability to find novel chemical matter, which is still one of the main uses. It is more important to find new chemotypes when pharmacophores are being used for virtual screening, and better enrichment comes with an increase in the fuzziness of the description. However, the false positive rate will also increase, so the two factors are in balance.
5. The use of activity data for building pharmacophores is widespread but should be used with caution, to check that the fit to the model does correlate with the experimental observations, and not some other factor such as solubility or lipophilicity.

3.09.6.1 The Challenge of Molecular Alignment

Sadly, it is almost impossible to predict with confidence the correct way of overlaying a set of ligands that bind to a protein of unknown 3D structure (except perhaps in trivial cases involving small numbers of ligands that share a large common substructure). A typical protein binding site contains many surface exposed functional groups, and different ligands frequently interact with different selections of those groups. In addition, some of the interactions may be mediated by water molecules and the protein may be flexible. Overlaying ligands is especially difficult when the binding is largely driven by hydrophobic interactions, due to the weaker directional preferences than for hydrogen bonds. We discuss below how these problems are manifested in three different situations.

3.09.6.1.1 Alignment of ligands for 3D QSAR

In principle, this is the easiest case as the molecules are likely to be fairly close analogs. A study of protein–ligand complexes found that structurally similar ligands generally exhibit a high degree of structural conservation; changes are more likely to be found in water molecule architecture and/or side-chain movements.[176] Indeed, one might reasonably question whether it is necessary to use a computer program in such cases. Nevertheless, difficulties can arise due to local symmetry or approximate symmetry in the ligand structures. Consider the neuraminidase ligands in Fig. 6 (from PDB structures 1a4g, 1a4q, 1b9t, 1inf). The obvious (and indeed correct) way of aligning these is to superimpose the carboxylate groups and the ring atoms. However, each of the rings has two possible orientations (i.e., can be flipped to place the guanidinium or ammonium group on the "left" or "right" side). Consequently, there is a significant number of permutations from which to choose. Moreover, as is often the case, the correct answer is not obvious: two of the guanidinium groups lie on one side, the remaining guanidinium and the ammonium group on the other. The problem is exacerbated by the fact that substituents on synthetic ligands may have been introduced to moderate physical properties and may not form significant binding interactions with the protein.

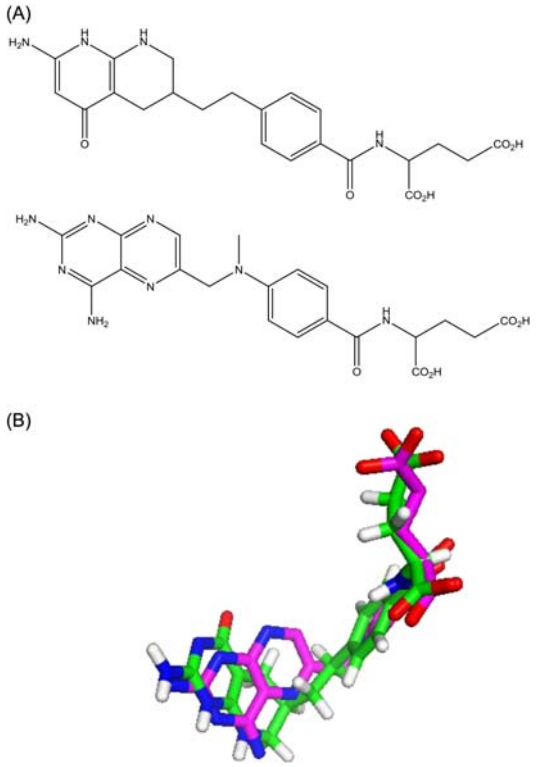

Fig. 10 The heterocyclic moieties of two dihydrofolate reductase ligands (A) do not overlay to maximize steric/substructural complementarity but rather align (B) to optimize the overlap of similar hydrogen-bonding functions (taken from 5ccc in *green*, 4qi9 in *magenta*). The glutamate tails are well aligned but do not contribute strongly to the pharmacophore as they are solvated and do not take part in a specific recognition event.

3.09.6.1.2 Rationalization of the shared activity of two different types of ligands

A frequent requirement is to overlay molecules that fall into distinct structural types in order to understand their common activity against the same target protein. An example is the pair of dihydrofolate reductase ligands shown in Fig. 10 (from PDB structures 1drf, 1mvt), the heterocyclic portions of which famously do not overlay in the way that maximizes steric complementarity but instead align so as to optimize the overlap of similar hydrogen-bonding functions. If the binding site structure were unknown, there would be no reason to favor the correct heterocycle overlay over the incorrect; both would be perfectly feasible given that some of the hydrogen-bonding groups might be solvent exposed.

3.09.6.1.3 Analysis of hits from a random screen

Overlaying a set of diverse molecules (e.g., hits from a random screen) is highly challenging. Consider the four DPP-IV ligands in Fig. 11 (from PDB structures 5ism, 5i7u, 3w2t, and 4a5s). Overlaying these ligands is quite hard as the consensus pharmacophore of the bioactive forms is limited to three features at the center of the overlay, with many other features only partially matched by two out of four ligands, despite the ligands having strong affinity. (We are aware of the argument that the correct pharmacophore can sometimes be predicted even if the correct overlay is not: but getting the right answer for the wrong reason makes us uneasy.)

In addition to the breakdown of the "single binding mode" assumption, it can also be shown that small changes to the parameters chosen for conformational analysis, feature definition, or even, sadly, the order in which ligands are considered and the version of software used, can lead to alternative, equally convincing, pharmacophore models. In one study[99] several published data sets were taken, and attempts were made to reproduce the pharmacophore models, with only limited success. This highlights the dangers of using models without follow-up experimental validation.

Despite these challenges, pharmacophore methods can—and do—make significant contributions to the advancement of drug discovery projects. Our point is that any attempt to rank a set of overlays with the expectation that the top-ranked one will be correct is unduly optimistic, not because of deficiencies in the algorithm but because the problem is underdetermined. We are better off acknowledging this unfortunate reality and accepting that multiple hypotheses must be generated, regarded as equally likely, and challenged experimentally. In the absence of a crystal structure, any pharmacophore model is more a property of the training set than the target.

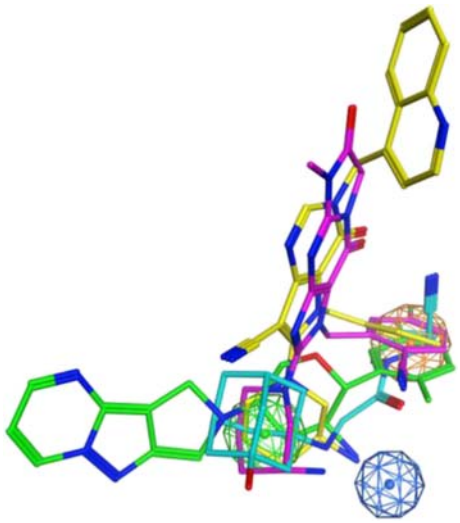

Fig. 11 Overlay of four DPP-IV inhibitors, taken from 5ism *(green)*, 5i7u *(magenta)*, 3w2t *(cyan)*, and (4a5s); only two hydrogen-bonding interactions and one hydrophobe are common to all four ligands. The set of ligands is from the category of moderate difficulty.[36]

3.09.6.2 Validation Standards

The standard sets discussed before are a good starting point but there is still more to be done. In stark contrast to protein–ligand docking, where construction of ever-more exacting test sets is almost a cottage industry, pharmacophore elucidation programs are typically validated on inadequate numbers of ligands, often with large common substructures. Sufficient protein–ligand series now exist in the PDB for this to be no longer excusable.[121,122] Admittedly, test-set construction is a harder task than for docking, since the detailed protein–ligand interactions in each test complex must be identified and properly understood. Nevertheless, test sets of reasonable size can and should be achieved. Of course, the obvious limitation of a validation protocol based on protein–ligand structures means that certain gene families of significant pharmaceutical interest (notably G-protein coupled receptor (GPCRs), ion channels, and transporters) will be under-represented, at least at present. The alternative approach, validation based on retrospective virtual screening experiments, is therefore very popular. As evidenced from the surfeit of papers on this topic there continues to be much debate concerning the "best" way to perform such experiments, from construction of the data set to what performance metric to employ. One major drawback of such studies compared to validation based on 3D structure is that they are indirect; the right answer may be found for the wrong reasons. The challenge is that "real" drug discovery is not so easily quantified and that true success (i.e., that a compound identified by virtual screening leads to a development candidate, let alone a marketed drug) is extremely rare.

3.09.6.3 Pharmacophore Feature Representation

Feature representation has probably had less attention recently than it deserves. With the exception of field-based methods, most programs use features that differ little from those described over a decade ago by Greene et al.[30] While acknowledging the seminal nature of that work, some questions can be posed. Some programs perform a surface-accessibility check before placing hydrophobic points, making the algorithm conformation dependent and hence slower. Is the extra computation justified? Most programs offer positive and negative feature types. Is this necessary, or is the hydrogen-bond similarity method of Jones et al.[18] or the EHT model[44] a better alternative? How important is it to align aromatic ring normals, and, if it is important, is it equally vital to achieve coplanarity of peptide and other groups that are hydrophobic in some directions but not in others (or is that achieved as a by-product of matching the hydrogen-bonding features of such groups)? Is it sensible to generate alignments by least-squares superposition of virtual points, placed along lone-pair or donor-hydrogen directions at the "expected" positions of the complementary protein atoms? It may assume greater hydrogen-bond directionality than exists in practice, especially given that the protein may flex a little from one ligand complex to another. Also, the situation that virtual points aim to deal with (**Fig. 3A**) may be quite rare.

One important observation in protein–ligand docking is that greatly improved results can often be obtained if the user's knowledge of the problem in hand can be exploited (e.g., by allowing constraints to be set). The same tactic can be similarly advantageous in pharmacophore analysis. For example, most programs do not have a separate "metal-coordinator" feature type, effectively assuming that the hydrogen-bond acceptor feature will be a suitable proxy. This assumption can break down, as in the case of the thiol-containing ligands. Thiol is a very weak hydrogen-bond acceptor but a good coordinator of zinc, which normally induces it to deprotonate. A user, aware that the target protein contains zinc, will obtain better results by overriding the usual program behavior and ensuring that the importance of this group is taken properly into account. This customization is becoming easier and more common.

One problem with ad hoc feature definition is that it causes difficulty at the searching stage, since databases are normally constructed with precomputed features, and screens based on those features. These are likely to be rendered useless if the query

contains features assigned according to different rules. Nevertheless, on-the-fly feature assignment on large databases, and searches of unscreened or poorly screened databases, are not impossible. It is perhaps better to get a good answer slowly than a bad answer quickly.

3.09.6.4 Variable Binding Modes

One limitation of the pharmacophore elucidation programs in common use is the assumption of a common binding mode for the ligands in the data set. Some relaxation of this requirement may be permitted (e.g., some compounds can match a subset of the common features) but data sets where the ligands correspond to two or more nonoverlapping pharmacophores will prove difficult or impossible. In addition, the nature of the algorithms can restrict the application of current methods to rather small data sets. Insofar as this may therefore result in a careful examination of the ligand structures, their activities and mechanism of action, such limitations may be considered valuable. However, in an era when large volumes of data can be generated using automated screening technologies it is useful to have tools that can not only deal with larger sets but can also cope with the possibility of multiple binding modes. Some of the QSAR methods, particularly those based on pharmacophore keys, are able in part to accommodate such situations; more recent pharmacophore elucidation methods are also designed to deal with multiple binding modes whilst also retaining the link to the underlying 3D models.

3.09.6.5 The Future: Maximizing the Value of Pharmacophore Methods

We have alluded to a number of challenges in the course of this article and have highlighted some areas for improvement. Nevertheless, it is undoubtedly true that the pharmacophore concept has proved to be an extremely useful one over the past 40 or so years. In part this is due to its simplicity, enabling the complexities of the molecular interaction between ligand and receptor (with attendant solvent, ions, cell membranes, etc.) to be reduced to a handful of features in a geometrical relationship. As such, it is perhaps surprising that it works at all. Pharmacophore methods are now commonly used as part of more complex workflows, for example as a prefilter prior to protein–ligand docking. The development of MD-based pharmacophores is particularly exciting.[149,150] Such workflows will continue to be further refined, driven by the continued growth in the number of protein structures of pharmaceutical relevance. It should also not be forgotten that integral membrane proteins (GPCRs, ion channels, and transporters) constitute many of the targets where pharmacophore analysis has been successfully applied for many years. Recent advances in X-ray structure determination for these families of proteins are providing new insights but it is likely to take some years before we achieve sufficient breadth of coverage and depth of understanding (especially of the more complex mechanisms of action) that will truly enable structure-based design techniques. Until then, simpler models as embodied in the pharmacophore concept will continue to play a key role.

So far as lead discovery is concerned, why not just use HTS? There can be a naïve expectation that HTS will return all known actives. However, HTS will miss some compounds for a number of good experimental reasons. It may also return too many false positives. Pharmacophore analysis is more hypothesis-driven and is intended to target small regions of chemical space for novel chemical matter; this can be of particular value when trying to accelerate lead discovery (e.g., by screening a small focused set prior to running a HTS) or when the available assay has low throughput. More importantly, pharmacophore methods can be used to search virtual chemical space, both in the form of known but not yet executed chemistry[177] and in the form of compounds unavailable in-house but (for example) accessible from a compound vendor. It can also be used to suggest focused screens after an HTS campaign. Corporate archives have a significant turnover of compounds over time. If the issues of a chemotype undergoing optimization only come to light years after the HTS campaign, pharmacophore models can be very useful to identify novel chemical matter to be screened in the lower capacity project-based screens.

It is now 4 decades since the modern-day concept of 3D pharmacophores was first introduced as a concept to explain SARs. It did not take long for scientists to appreciate the potential applications in drug discovery,[178] since when there has been a continuous stream of publications describing its use in the selection and design of new chemical entities with interesting pharmacological properties, a trend that continues until the present day. It is truly a concept that has stood the test of time, and one that is likely to play an important role in drug discovery for many more years to come.

Acknowledgments

We would like to thank our many colleagues in Novartis who have discussed, read, and commented on this manuscript.

3.10.1 What Is Matched Molecular Pair Analysis?

A decade ago, a summary of how matched molecular pair analysis (MMPA) operated was proffered as "identifying every pair of molecules that differ only by a particular, well-defined, structural transformation in a database of measured properties and computing the corresponding change in property."[1] This definition still remains a good one for the scope of the analytic approach. However, it has become clear in recent years that many of those using MMPA have come to see it defined more by the way that they find the pairs than by this more general definition. Although a number of algorithms have been developed, one in particular has come to define the pairs. Thus, many now view MMPA as being about the effect of changing specific groups that arise out of fragmenting molecules according to the protocol outlined by Hussain and Rea.[2] This is unfortunate because, although this algorithm is

extremely powerful (as discussed later), it is not the only way of finding matched molecular pairs. It remains our contention that there is not a single correct way to find matched molecular pairs and some analyses that cannot be achieved (such as the study of enantiomeric pairs) by certain pair finding approaches are highlighted in order to emphasize this.[3,4]

The great power of matched molecular pairs is that they reflect the situation faced by most medicinal chemists seeking to optimize a lead compound in order to transform it into a candidate drug: a molecule that has many desirable properties must be changed structurally in order to reduce or eliminate undesirable properties. In both cases, it is about understanding and predicting what effect changing the structure will have on the properties, ideally retaining or enhancing the desirable properties while reducing the undesirable. Although MMPA as a distinct type of analysis was only introduced in the publication of Kenny and Sadowski in 2005,[5] medicinal chemists have been thinking about the relationship between changes in structure and changes in property for many decades, with notable linked approaches being those of Free and Wilson, who outlined a method to analyze how changes in structure at certain positions change activity, and Topliss, who suggested a set of structural motifs that could be made in a given series in order to probe the link between structure and properties.[6–8]

It is one of the key underlying principles of MMPA that the difference in properties is more easily and accurately predicted than the absolute value of properties. In this sense, it is reminiscent of perturbation theory in quantum chemistry or free-energy perturbation in the simulation field, which seeks to take a calculated value and then makes a small change to obtain more accurate values. In MMPA, the analogy is that the simplest way to predict the property of a compound is to find a similar compound and to assume that the compounds have the same property. Thus, in Fig. 1, P(**A**) is a property of interest of compound **A** and P(**B**), the corresponding property of **B**, where **B** is a compound that has either not yet been made or not yet had property P measured. In order to predict P(**B**), the simplest approach would be to assume that P(**B**) = P(**A**). This is the basis of a *k*-nearest neighbor approach in which $k = 1$. The perturbation to this prediction that would make it more accurate would be to find every previous occasion in which the structural feature represented by the green square had been substituted for the feature represented by the red circle and to compute an average change observed in this set. This difference ($\triangle$) can then be added such that the best prediction is that P(**B**) = P(**A**) + $\triangle$. Although this concept is straightforward, it can be implemented in a number of different ways, and these will be explored in the various sections in the succeeding text.

A further advantage that most MMPA approaches have is that they use only real data. There are no modeling and no extrapolation. Indeed, in its purest form, MMPA is actually just a mechanism for presenting historical data to chemists in a way that helps them to predict what the properties of future molecules might be. As such, one of the important areas of research and development has been devoted to finding good ways to present the output. It is inevitable that each end user and every application might have different requirements; some of the advances in presenting the output of MMPA will also be highlighted in this article.

One of the most important roles of MMPA is to discover new effects and provide insights. For the most part, such scientific breakthroughs are happy coincidences of applying the methods. By focusing on differences in structure and the link to differences in properties, new insights can be provided that would otherwise be challenging. For instance, when modeling human ether-a-go-go-related gene (hERG) blockers with a proposed structure of the channel, relating changes in potency of blockers to docking results was successful where comparing docking scores to IC50s would not have been.[9] Furthermore, the insights can be communicated in a much clearer fashion than having to explain how all parts of a molecule contribute to give the overall binding affinity. A consequence of looking at pairs of molecules and the change in structure between them is that the change in structure and change in property do not reveal anything that undermines patentability and therefore allows sharing of information anonymously.[10,11] Furthermore, as will be discussed, significant benefits can accrue from sharing.

MMPA has inspired people to think about medicinal chemistry differently. For instance, a number of reported lead generation campaigns have deliberately set out to generate and profile compounds that are MMPs.[12,13] Lead optimization chemists have incorporated MMPA into their design process such that compounds are now starting to emerge, which represent real tests of the predictive ability of MMPA as a tool both to design better compounds and to predict the properties of compounds before they are made.[14–17]

3.10.2 How to Find Matched Molecular Pairs

There are two broad classes of methods for identifying matched molecular pairs. These depend upon whether the pairs are found using manual intervention or automatically. Initial work in the area relied upon users encoding the structural change that defined the matched pairs and were usually designed to address the link between specific structural changes and specific properties; that is to say, they were driven by a scientific hypothesis or question. As the technique developed, it became clear that it produced valuable

Fig. 1 Conceptual matched molecular pairs.

insights but that this was limited by the imagination of those who defined the pairs. A new approach was needed in which matched pairs could be identified automatically. Two algorithmic approaches emerged: one based on fragmenting molecules (at selected acyclic single bonds) and indexing the resulting fragments and the other requiring the maximum common substructure (MCSS) between two molecules to be deduced. In both cases, the type of molecules that get paired depend upon the settings used and will be discussed. It has also been made clear that the amount of chemical structure that is used to define the context in which a structural transformation takes place can be important. Chemically more specific transformations can provide a higher fidelity and more relevant view of the effect of a structural change than more general structural contexts, but there is inevitably a trade-off between the specificity and dataset size. Recent years have also seen recommendations published concerning the preparation of datasets and about which types of data can be compared with one another. All of these aspects of how matched pairs are identified will be discussed.

3.10.2.1 Supervised

It is often the case that specific queries or hypotheses can be tested by MMPA. In such cases, the user is likely to have specific chemical structure types in mind, which are defined at a particular level of specificity. This would mean that the user can encode the change in structure and the informatics approaches to doing this are quite well developed; the SMARTS and SMIRKS nomenclatures in particular lend themselves well to this.[18] Such approaches require significant manual input and intellectual oversight, and as such, we classify them as supervised approaches.

The original publication in MMPA described how a molecular editor could be used to identify matched molecular pairs in which substituents are added to a benzene-like ring.[5] The effect of these structural changes on solubility was identified (**Fig. 22**). All compounds (encoded as SMILES strings) that had the substituent of interest on an appropriate ring were found. The molecular editor then deleted the substituent (one at a time in molecules that had more than one of the same type of substituent), and the SMILES string for the unsubstituted example was then used as a search in the original database to discover if the paired compound also existed and had measured solubility data. The editing was encoded using SMARTS strings and implemented in the molecular editor Leatherface.[5] SMARTS strings have the great advantage that they can be encoded to be extremely specific or general but provide exquisite control in terms of chemical structure. The software has now been superseded by the molecular editor MUDO that is provided as source code and has a similar basis but that exploits the advances in the underlying informatics in order to permit the editing of molecules in three dimensions, for instance.[19] The same approach to matched-pair finding was subsequently applied by Leach et al. who expanded the set of structural transformation types that were explored.[1] Specific queries were also implemented as part of a study of reactivity for some covalent binding of nitriles,[20] potency, and some physical properties for glycogen phosphorylase inhibitors.[21] A SMARTS-based approach was also adopted by Dossetter when searching for changes to aromatic rings and methylene carbon atoms.[13,22,23] Gleeson also used a manual encoding of sets of substituents in order to identify matched pairs differing only by the addition or interchange of those substituents.[24]

In a related approach, Lewis and Cucurull-Sanchez encoded the structural transformations linking two members of a matched pair in the RXN format.[25] This permits them to be applied to a set of compounds as reactions, the products of these reactions can then be searched for, and if present, the matched pairs can be identified.

The same approach has, in more recent years, been implemented using SMIRKS to encode structural transformations. In one of the first such publications, Hajduk and Sauer identified a set of 828 substituents present in databases of potency data using the Daylight findsub method.[26] These were transformed into SMIRKS strings that encode the addition of each of the substituents. These could then be applied to a database of SMILES strings, and the product SMILES strings searched against the original database in order to identify pairs that are present and that differ only by addition of one of the substituents. Boström and coworkers used SMIRKS to encode the interchange of oxadiazole regioisomers and Stepan and coworkers to study the variation between cyclic ethers.[27,28]

3.10.2.2 Unsupervised

Naturally, supervised approaches to finding matched pairs have many limitations; notably, the amount of human time required to encode the pairs can be excessive, but, more importantly, the pairs that are found are limited by the imagination of the user. Therefore, a number of unsupervised approaches have also been developed. These have broadly fallen into two conceptual classes: fragment and index or MCSS. In the first, each molecule is first fragmented, and the fragments are compared with those for other molecules. Molecules for which all fragments apart from one are the same can be considered pairs. In the second approach, two molecules are compared by computing their MCSS; if this is large enough, then the remainder of each molecule defines the difference between them. These two approaches will be discussed in more detail. An early first attempt encoded molecules as fingerprints and identified sets of pairs in which the change in fingerprint was the same.[29] This approach does not seem to have been taken forward.

3.10.2.2.1 Fragment and index

Although it was not the first publication to describe a fragment and index approach, the definitive paper in this area came from Hussain and Rea.[2] They highlight the limitation of systems that require the user to define the pairs and propose an alternative: the fragment and index approach.

In the first step, each molecule is fragmented, by breaking selected bonds. Hussain and Rea achieve this by defining the bonds to be broken using a SMARTS pattern. They aim to have this pattern be specific to acyclic single bonds. The SMARTS pattern suggested is "[*]!@!=[*]" that signifies an atom type joined to any atom type by neither a bond that is in a ring nor a double bond. Refinements to this definition have been proposed and are discussed in the following section.

Bonds are broken one at a time, and the resulting fragments are then stored as SMILES strings, which can be manipulated as text. This is the great advantage of the approach: after an initial fragmentation, which requires chemically aware software and time-consuming processing of molecules, all subsequent steps toward the identification of matched pairs involve only rapid text processing that does not require any chemoinformatics technology.

The SMILES strings of the fragments correspond either to the fixed part or to the changing part. Different terminology is used by different scientists to describe these components and is usually influenced by what they are trying to describe. In particular, the fixed part is often called the index, because it is the component in the database that is used to look up pairs. It can also be called the core when changes of substituent are being considered or vice versa. The terms fixed and changing emphasize the link to the matched pair itself in which the difference between the two molecules is defined by the changing part, and the fixed part is what brings that particular pair together. In general, it would be possible for each fragment to be considered the changing part with the remainder defining the fixed part. However, it is frequently the case that chemists expect the fixed part that is shared between two molecules in a pair to be of a certain size before they would consider two molecules to be a pair. If the changing part is very large, then it may be that the molecules might not be considered to be pairs. Similarly, if the two fragments in the changing part of each member of the pair differ in size too much, it may be considered that the change is unlikely to be well characterized by MMPA. All of these considerations have caused a number of limitations to be imposed upon the fragment and index approach. Hussain and Rea only allowed the changing part to contain up to 10 heavy atoms and only allowed up to three bonds to be fragmented. Others have imposed variations on these restrictions.

The fragmentation is illustrated in Fig. 2 for a hydrocarbon. There are two acyclic single bonds, which are fragmented in turn during the single fragmentation phase. Each of the resulting fragments can be considered as a candidate for the fixed part and the changing part. When a double fragmentation is considered, only one is possible, and it can only be considered when the disconnected fragments become the fixed part; otherwise, it would permit changes at more than one point, which defies the usual definition of matched molecular pairs in the fragment and index approach.

Having identified fragments, the indexed entries can then be compared in order to find pairs that are entries that have the same fixed part and different changing parts. Single-bond cuts will tend to identify the sort of pairs that might be considered as variations in substituents as shown in the first example in Fig. 3. In this example, the right-hand side of the two molecules shown is the same and is identified as such when both generate the same fixed part. The variation on the left-hand side is then captured as the changing parts. By contrast, when double fragmentation takes place, the pair type identified tends to be core changes. For instance, as shown in Fig. 3 ("core changes"), the two molecules differ in the central ring but have identical left and right groups. The double cut generates the same two disconnected fragments as a fixed part, and the core change from phenyl to pyridyl is captured in the changing part, which defines the matched-pair type. It should be noted that using this fragment and index approach, it is challenging to distinguish this change from that that leads to the alternative regioisomer shown at the bottom of the picture. The approach also precludes this example from being analyzed as part of a more general query concerning the transposition of an aromatic carbon to an aza nitrogen.

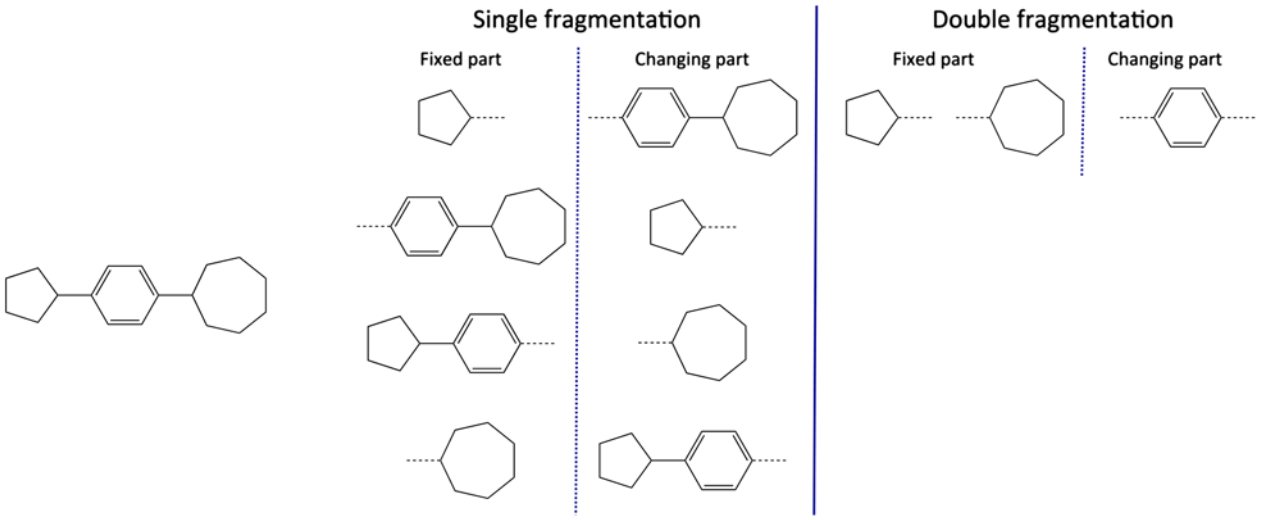

Fig. 2 The fragmentation and indexing output.

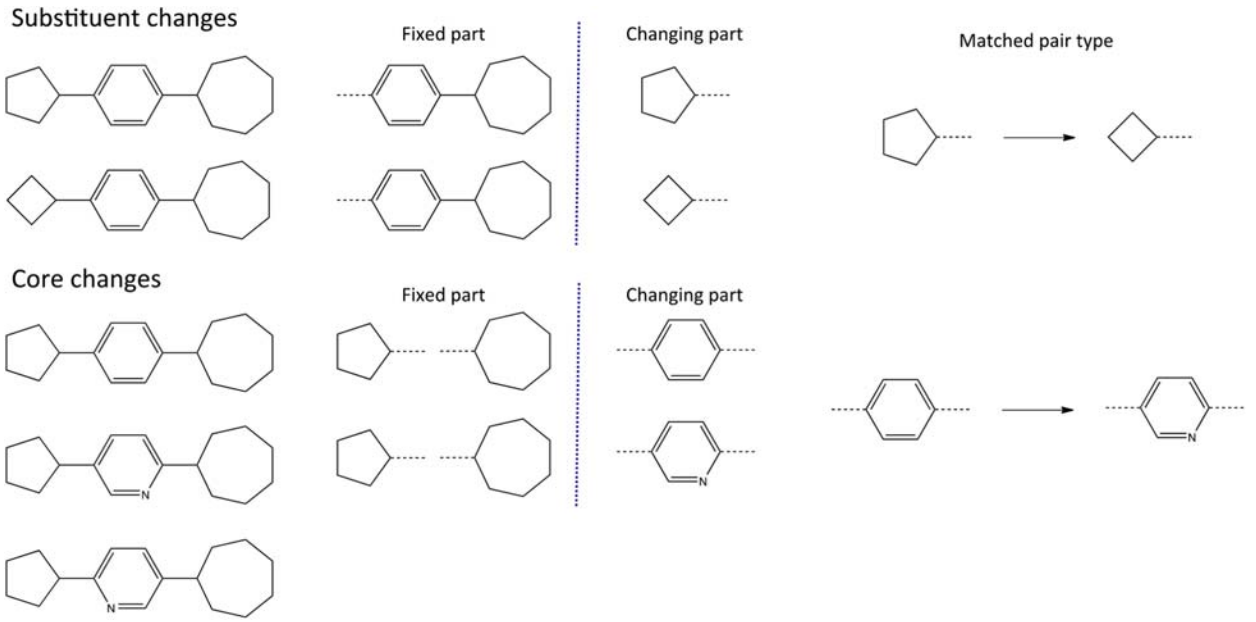

Fig. 3 Combining fragment and index data to identify matched molecular pairs.

When more than two fragmentations are considered, this can be thought of as involving more complicated, more highly substituted cores being changed. It is often the case that chemists find that increasing the number of fragmentations beyond about three or four leads to overly complicated transformations.

Hussain and Rea discuss the particular challenge posed by hydrogen atoms in this approach. Hydrogen is usually implicit in the structures that are stored in databases. SMILES strings require chemoinformatics software to interpret them in order to correctly assign hydrogens. This problem is solved in a subsequent, inelegant, but pragmatic step. Hydrogens are added to the position at which each fragmentation has taken place and the database searched in order to identify if the unsubstituted compound was present.

The output from the analysis can be encoded in many ways, which need not be chemoinformatic. The text corresponding to the two changing parts is sufficient to define the pair. However, Hussain and Rea generate a SMIRKS pattern that has the advantage that it can then be applied as a chemical transformation in order to translate the knowledge gained from the analysis into suggested molecules that are worth making. This is rather similar to the Drug Guru approach advocated by workers from Abbott.[30]

Hussain and Rea applied this technique to the NIH Molecular Libraries Small Molecule Repository, which at that time contained 333,332 compounds that passed their medicinal chemistry filters. The fragmentation took 501 min and led to 21.7 million fragmentations. Indexing took 356 min and identified 5.3 million pairs, which represented 2.6 million different sets of pairs (where a set of pairs represent all pairs corresponding to a given structural change). They discovered that matched pairs tend to have frequencies that follow a Zipfian distribution. That is to say that most sets (78%) of matched pairs have only one example in the database. There is a long tail in which sets containing large numbers of examples are rare.

The first publication to have suggested a fragment and index kind of approach came from Haubertin and Bruneau,[31] who were interested in using MMPA as a tool to aid in lead optimization. They applied only single fragmentations to molecules and so focused on substituent interchanges. The approach was applied in a slightly different way but with the same outcome as Hussain and Rea. They fragmented the AstraZeneca database using a variation of the RECAP protocol in order to identify all of the side chains that are represented.[32] The database was then searched in order to identify compounds that contained these side chains. This provided an interesting comparison with previous studies that assessed the frequency with which certain side chains are used in medicinal chemistry.[33,34]

Many others have subsequently used the Hussain and Rea approach. It has been implemented as a freely available piece of software through RDkit.[35] It is also used to generate analysis in the online chemical modeling environment (OCHEM).[36] The chemoinformatics providers, OpenEye, have encoded a version of the fragment and index approach as part of their toolkit, and MedChemica has incorporated fragment and index alongside the MCSS approach (described in the following section) in their software MCpairs.[37] The approach has been applied in many ways, which are discussed elsewhere in this article.[12,38–54]

One of the great advantages of the fragment and index approach is that once a molecule has been fragmented and added to the database, it is available for matching to any new molecule that is added.

Among the limitations of the fragment and index approach to finding matched pairs are that small changes to rings cannot be identified as pairs, highly substituted core changes are limited by the number of fragmentations considered, and the diversity of the structural changes can be limited by the restrictions that are imposed (usually heavy atom counts or ratios). One specific set of

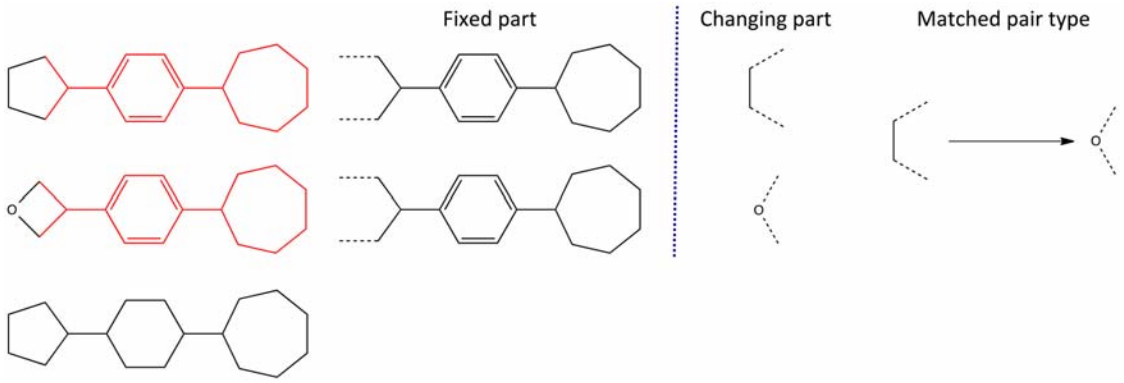

Fig. 4 The maximum common substructure approach to finding matched pairs.

changes that are not readily identified is modifications to macrocylic rings. The SMARTS definition that identifies which bonds are to be fragmented also is not ideal and can lead to fragmentations and grouping into sets of pairs that chemists would not normally consider to be chemically sensible. For instance, fragmentation of the single bond in amides, esters, or sulfonamides and acyclic triple bonds would happen if the original SMARTS proposed by Hussain and Rea was to be applied. Consequently, a refined SMARTS definition has been proposed by Wirth and coworkers and is "[#6+0;!$(*=,#[!#6&!R])]!@!#!=[*]." They also proposed a second rule that allows fragmentations of exocyclic double bonds: "[#6+0;R]=[#7&!R,#8&!R,#16&!R,#6+0&!R]." This definition signifies any atom type connected via a bond that is neither in a ring nor double nor triple to a carbon atom that is not charged and that in turn is not double- or triple-bonded to an atom of any element other than carbon (unless that atom is in a ring).

3.10.2.2.2 Maximum common substructure

An alternative unsupervised approach to finding matched pairs has also been proposed, which uses the MCSS between two molecules to define the fixed part. The first step in the approach is to compare two molecules using a MCSS algorithm. The same molecules as described earlier for the fragment and index approach are shown in Fig. 4 with the MCSS highlighted in red. This becomes the fixed part and the remainder of the molecule the changing part. This means that structural change in this case is then the change from CH_2CH_2 to O. There are a number of MCSS algorithms available, which permit different types of comparisons to be made. For instance, some allow disconnected common substructures, while others limit them to substructures of atoms that are contiguous.[55] The nature of the algorithm is important because it governs the kind of matched molecular pairs that can be identified. An algorithm that only allows contiguous common substructures would not find the most interesting link between the molecules at the top and bottom of Fig. 4 in which the phenyl ring has been replaced by cyclohexyl.

The key paper that sets out a protocol for accomplishing MMPA with an MCSS approach is from Warner and coworkers at AstraZeneca.[56] In an approach that they call WizePairZ, they employ OpenEye's molecular graph encoding.[57] This converts molecules into graphs, which are then amenable to the informatics techniques for processing graphs, many of which represent extremely rapid means to identify commonalities between molecules (subgraphs within graphs). As with the fragment and index approach, the outcome of the MCSS approach is governed by the choices made about deciding what to classify as a pair. Warner et al. elected to use a fast graph comparison technique that does not permit disconnected substructures to be generated and chose to limit the changing part of the molecule to be less than 10% of the fixed part.

As with the Hussain and Rea approach, Warner et al. encoded the output from their pair finding as SMIRKS that permits any structural changes identified as being of interest to be applied to molecules to which they may be relevant. In order to enhance the relevance of their findings, they also encoded the structural context for the transformation. This is discussed in more detail in the relevant section in the succeeding text. The approach was applied to a small library of 13 inhibitors of histone deacetylase. Two examples were excluded to serve as a test set. The remaining molecules were then analyzed with the MCSS algorithm. Pairs were identified and encoded as 68 SMIRKS. These SMIRKS were then applied to all the molecules in the database. This led to the suggestion of 15 new molecules. Of these suggestions, 12 were in the original set. The two test-set compounds were produced. In addition, three completely new compounds were suggested. The analysis was also used to predict the potency of the test-set compounds and was found to give excellent agreement; both were accurate to the first decimal place in terms of predicting a pIC_{50} value. Some of the same scientists also reported the use of the MCSS approach WizePairZ in a study that demonstrated the value of MMPA for designing out off-target effects.[58]

Unlike the fragment and index approach, one algorithm has not become the generally accepted standard that is widely available. Others have reported the use of MCSS approaches. These include Papadatos et al. who increased the speed of pair finding by reducing the number of pairwise comparisons that must be made. They only considered molecules that had a Tanimoto between their Daylight fingerprints of >0.75 and by only considering pairs that have a difference between their number of heavy atoms that is less than or equal to 15. They also require that the fixed part is as big as or bigger than the changing part. They discovered in their

analysis that when they used this approach and a fragment and index approach, they obtained very similar sets of pairs but that the fragment and index approach was significantly faster (it took 8 h as compared with 4.5 days for the MCSS approach).

Subsequently, Weber et al. have reported an MCSS approach that allows them to identify matched molecular pairs in the ChEMBL and PDBbind databases.[59] In particular, they identify pairs that share MCSS with a ligand of known binding mode. The changing part is required to be no more than half as small as the fixed part. The shared substructure is presumed to retain its binding position. Pose refinement in MOE (Molecular Operating Environment from Chemical Computing Group) and conformational sampling were used to position the changing part for the molecule that does not have a crystal structure. This permits matched pairs to be placed in a three-dimensional context. The shared substructure has a dual purpose: facilitating both pair finding and overlaying. The method has since been extended to provide a Web server implementation.[60]

The key limitations of the MCSS approach are (1) that the substructure comparison is slow and (2) that most algorithms for finding the MCSS require all of the atoms to be contiguous and therefore prevent pairs in which linkers change from being found. There are alternative algorithms available that permit disconnected substructures to be identified, but these will generally slow the comparison down further. This area has seen a number of recent technical and algorithmic advances, which hold out the prospect of improvements.[61]

3.10.2.2.3 Comparisons: The influence of settings

Many of the key considerations for the two approaches (fragment and index or MCSS) for finding matched molecular pairs have been outlined earlier, but there are certain factors that become clear when considering them in comparison to one another. A very practical one concerns the computational workload when the two methods are applied to large datasets. MedChemica has applied both methods during the compilation of their database, which is a very large analysis of data from three pharmaceutical companies.[10] They found that, as expected, the fragment and index approach is indeed quick to generate fragments. However, this was offset by the generation of extremely large sets of fragments for indexing. The capacity to store this intermediate information can become limiting quite quickly. There are many molecules that will have 10 breakable bonds, which will lead to more than 50 different fragmentations, even if only three fragmentations are considered. Meanwhile, also as expected, the MCSS suffers from a slow step generating the all-by-all comparison using the MCSS algorithm. Once the MCSS comparisons have been made, the set is reduced, and subsequent steps both are fast and require much less storage capacity than the fragment and index approach. Thus, the trade-off is between large storage requirements or slow comparisons. We note that whereas the processing can be parallelized, file storage is not easily divided up.

In order to characterize the difference between the methods, we have performed an analysis of the ChEMBL dataset of 1010 compounds with measured K_i for inhibition of the epidermal growth factor (EGF) receptor tyrosine kinase enzyme. Typical settings were selected such that (a) for the fragment and index approach, the ratio of the number of heavy atoms in the changing and fixed parts must be less than 0.3 and the changing part must be smaller than 10 heavy atoms and (b) for the MCSS approach, the MCSS must include at least 90% of the heavy atoms. The number of compound pairs that were found by the two methods is illustrated in the Venn diagram in Fig. 5. In Fig. 5A, the individual compound pairings are compared and show that the fragment and index (F+I) approach finds the most sets of pairs and the MCSS finds about 30% less pairs. The two methods pair many compounds in common, but it is striking that the two approaches find many unique compound pairings. In Fig. 5B, the number of pair types that are identified by each method is shown. The fragment and index approach can fragment each molecule in many ways, and so each pair of compounds that involves molecules with many fragmentable bonds will generate many pairs. By contrast, the MCSS finds the single simplest description of the change between molecules; each approach has its merit, but one consequence of this behavior is a very large storage requirement for the fragment and index approach when the number of compounds increases. In Fig. 5C, two pairs are given that are only found by each method and that illustrate some salient considerations. The requirement for the MCSS to be 90% of the substructure prevents the first set of compounds from being paired; this setting will tend to exclude small compounds from the set. The inability of the fragment and index method to fragment rings and study changes in them is illustrated by the second pair, which is nonetheless found by the MCSS approach.

3.10.2.3 Context Dependence: Set Size Versus Specificity

The chemical context in which structural changes are made can have an influence upon the change in properties that they cause. In their investigation of solubility and plasma protein binding, Leach et al. identified some outliers in the distributions for the addition of small substituents to aromatic rings and found that these were dominated by changes adjacent to amide or biphenyl linkages (Fig. 6).[1] They attributed this to the conformational change caused by substituting at these positions. Similarly, Haubertin and Bruneau used the atom to which substituents are attached to separate the context of the change into crude categories such as aliphatic carbon, aromatic carbon, and aliphatic nitrogen.[31]

This approach was formalized by Papadatos et al. who analyzed hERG pIC_{50}, log(solubility), and logD data in a categorical fashion by assigning changes of +0.3 or greater to the category "increase," −0.3 or lower to the category "decrease," and those in between to the category "no change." Multinomial tests were then used to identify the significance of any changes or chi-squared tests for larger sets of pairs (63 or more pairs in a set). The "no change" category is generally dominant.

They used a number of methods for subsetting by context: the fixed part was encoded as reduced graphs, Murcko scaffolds, and Daylight fingerprints. A similar set of local descriptors were used in which only the attachment point was described: its reduced graph description as SYBYL atom types and those of atoms up to three bonds away provide a compact description of the local

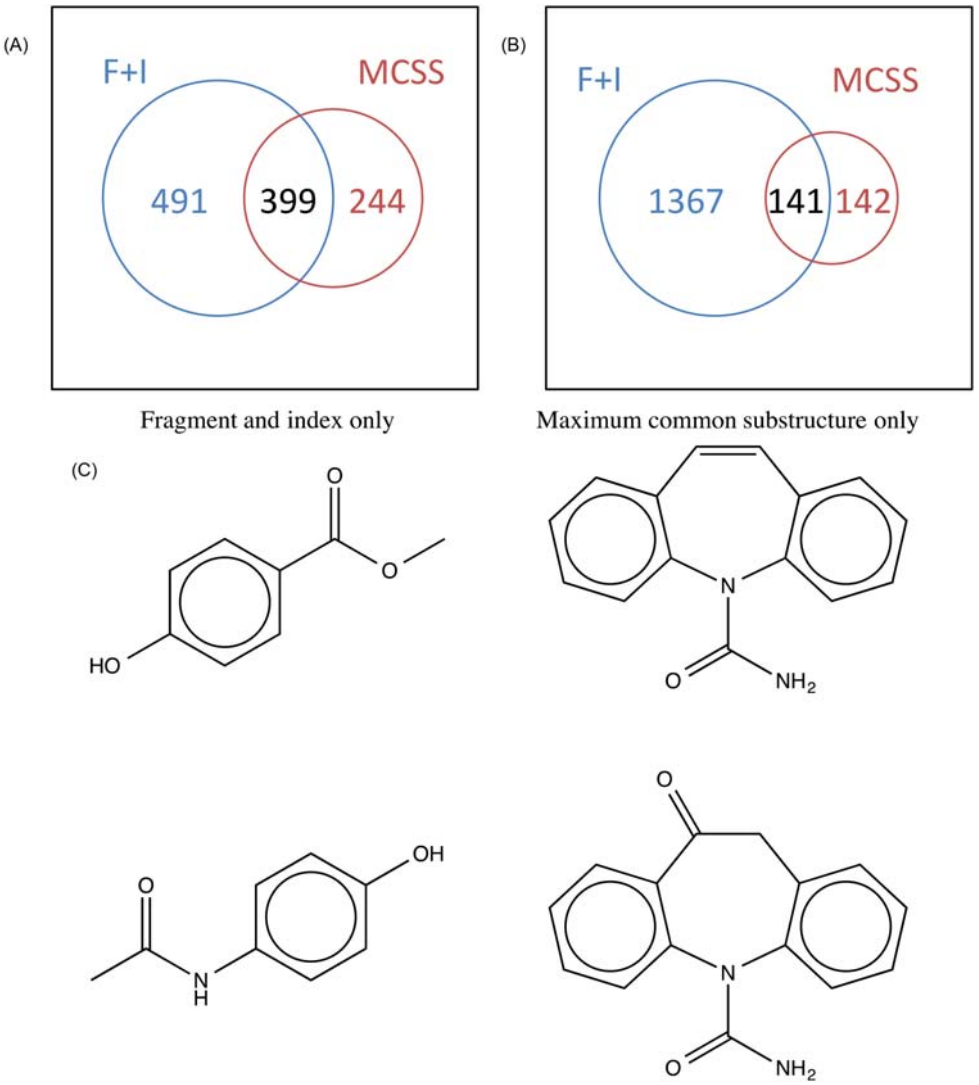

Fig. 5 Venn diagrams for (A) the number of compounds that are found as pairs by the fragment and index (F + I) method and the maximum common substructure (MCSS) method, (B) the number of pair set types that are identified by the same two approaches, and (C) examples of compounds that are paired only by the fragment and index method and only by the maximum common substructure method.

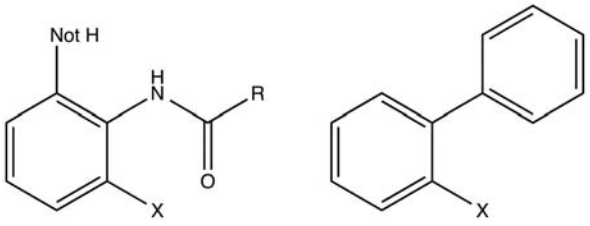

Fig. 6 Matched pairs in which groups added at X are often outliers.

environment. Each of these encodings can be considered a description of the chemical context in which a change in structure takes place. A number of subsets are identified in which the change in property for a subset defined by chemical context is statistically distinct from that for the rest of the set. Some of these changes are described in the relevant sections in the succeeding text. Chemical considerations do not play a part in identifying subsets so it is interesting and powerful that the method provides chemical insights. For instance, chemical contexts are found in which conformational changes occur, or an important pK_a is modified, or other electronics defy the dependence upon lipophilicity. This publication demonstrated that context can provide a great deal of added value but was applied after (and not during) matched-pair identification.

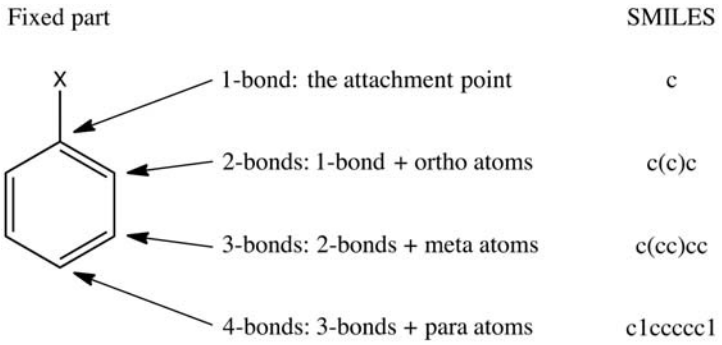

Fig. 7 The encoding of chemical context in the WizePairz approach.

In their publication describing the WizePairZ algorithm, Warner et al. describe how they encode the context of matched pairs directly such that interesting subsets can be identified readily. They chose to encode context using the SMILES for the atoms in the fixed part that are connected to the changing part (**Fig. 7**). They encode four levels of the context: 1-bond context is just the attachment point, 2-bond context is the attachment point plus the atoms attached to it, and 3-bond contexts are those plus the atoms attached to them. They selected to encode as far as four bonds in order to capture some information about positions of substituents around aromatic rings. These contexts were translated into the SMIRKS that they used to describe the change and that can therefore be used to apply context-specific information to only those molecules to which it is relevant.

More recently, Ritchie et al. have highlighted the importance of matched pairs that occur in specific contexts in which the change in structure interferes with intramolecular hydrogen-bonding motifs.[43]

The chemical context can also relate to the position that certain groups are likely to be in when molecules are in a protein-binding site. This aspect of context dependency has been emphasized in a number of the recent publications that have sought to incorporate three-dimensional information into MMPA.[49,59]

An extension of the idea of context was also provided by O'Boyle et al. who identified matched series in which a set of molecules with a common fixed part are linked together.[52] This broader context for each pair allows it to be viewed in a different way in which expectations can be set based on the broader structure–activity information that is available across the matched series.

It is clear that the idea of subsetting groups of matched pairs according to their context has gained a great deal of traction. Many scientists are seeking new ways to do this. Those that have been exemplified thus far include statistically led, chemical structure-led, protein binding site-led, and broader series SAR-led. Doubtless further context divisions will be identified in future. All suffer from the same dilemma: MMPA relies upon sufficient molecules being grouped into a set to permit statistically sound deductions to be made. The more the sets are divided up by context, the smaller the sets must inevitably be and therefore the statistical power must be reduced. This makes it very difficult to extract contextualized information without compromising statistical power. We have recently discovered that the dilemma can be viewed quantitatively. In an analysis of hERG data in Medchemica's very large database, each set of pairs was categorized according to a binomial analysis analogous to the detection of biased coins: heads correspond to an increase in potency, tails to a decrease. Biased sets of matched pairs correspond to ones that are certain (at 95% confidence) to change the potency in one direction or another. Those sets of pairs for which a bias could not be detected were classified as no effect determined (NED); these may be structural changes that cause no change in potency or pairs for which there are not yet enough data to detect the effect. Having established the behavior of the whole set of pairs, the change in the mean pIC_{50} as pairs are added sequentially to the set could be calculated. The value of the mean change above which an increase in potency is the most likely outcome for the group could then be computed for sets with two pairs, three pairs, four pairs, etc. These are then divided into context levels 1–4, as illustrated in **Fig. 7**. This is summarized in **Fig. 8**, which shows that a set of five pairs that are at context level 4 (the most specific) are equivalent to a set of about eight pairs at context level 1. The statistical challenge can actually be reduced when pairs are divided up by context.

3.10.2.4 Available Software

There are a number of software packages that are available to implement the various matched-pair approaches that have been discussed. The molecular editing software introduced by Kenny and Sadowski (Leatherface) is not itself available but has recently been updated and made available as MUDO.[19] An implementation of the F + I approach is available via RDkit and as a KNIME node.[35,62] Several software vendors also have implementations of MMPA and related approaches. In addition, a number of Web services provide access to MMPA such as VAMMPIRE and SwissBioisostere.[54,63]

3.10.2.5 Recommendations

As part of the development of their data-sharing consortium detailed in the succeeding text, MedChemica has created a software suite that is capable of generating matched pairs using either the fragment and index or the MCSS method. In each case, the resulting

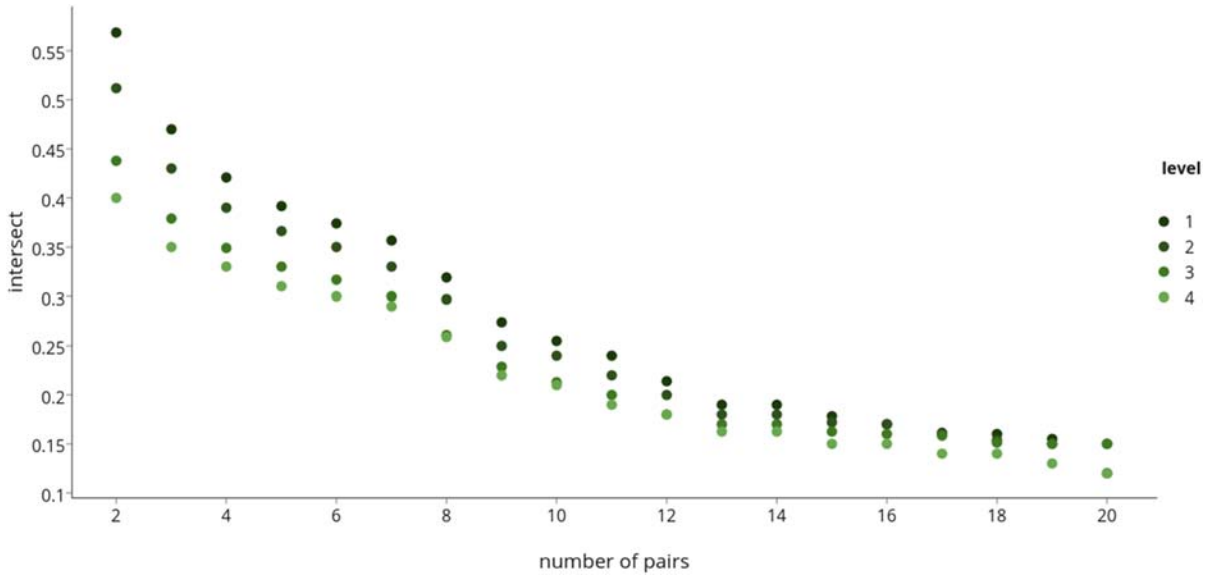

Fig. 8 The value of the average change in pIC_{50} above which a group of pairs is most likely to have a real bias to increase hERG channel block.

pairs are encoded in an identical fashion. As discussed earlier, the settings selected have a significant impact upon the pairs that are found. Determining a priori what the optimum settings are for each method for the question at hand is not currently possible. However, it is clear that the two methods can provide complementary sets of matched pairs. Given the wide availability of significant processor power and storage capacity, it seems to us that the best approach to finding matched pairs is to use both methods and to combine the output in order to gain the best chance of covering chemical scope and revealing the most useful insights that a dataset can provide. Given how much experimental effort goes in to generating the data that are analyzed, it is a false economy not to perform the best analysis that is possible. It is also clear that the more chemically specific a set of pairs is, the more likely it is that the matched-pair set will make a correct prediction and the smaller the set of pairs that is required in order to acquire that correct prediction. As such, it is recommended that context incorporation should be a required part of any matched pair finding algorithm.

3.10.2.6 Dataset Selection and Preparation

The data that are input into matched-pair analysis are of two kinds: the chemical structure and the measured properties. There are a number of considerations when preparing this combination of data for analysis.

3.10.2.6.1 Chemical structure

In this section, discussion is limited to those matched-pair studies that are taking molecular structure input in two dimensions. There are a number of matched-pair studies that are extending into three dimensions, and these are discussed in the relevant section. When handling the structures that are input to MMPA, there are a number of concerns, but most can be reduced to the question of which molecular structures should be considered the same and which should be different. One of the issues that is most commonly experienced and that is reported as troublesome in many of the publications cited in this article is the problem of stereochemistry. Sometimes, the stereochemistry of two molecules can be the same but registered in subtly different ways in a database. A strict matching routine in either the fragment and index or MCSS approach will therefore fail to make connections. For this reason, some methods drop stereochemistry when considering molecules for pairing. This can mean that molecules with different stereochemistry may be paired. This may not be the desired outcome. Further complication arises when the stereochemistry is destroyed upon bond breakage during the fragment and index method; this can be avoided in principle if a marker for the specific position of the break point is retained.

A further consideration that can complicate pair finding is the position of hydrogens. There are two chemical problems: tautomerism and ionization. A further problem is chemoinformatic: SMILES strings do not explicitly capture the position of hydrogens and rely on models to determine aromaticity. Among the chemical problems, the critical issue is that two molecular fragments, which must be found to be identical in order to match, should be represented identically. This requires each molecule to be transformed into a standard tautomer that will always present each fragment in the same form. Unfortunately, while this can be achieved for most cases, there will always be structures in which two tautomerizations interact and where one will perturb the other if only one representation is adopted. This can be avoided by enumerating all tautomeric possibilities, but this will make the task of pair finding much more challenging. Alternative chemoinformatics approaches to avoiding the problem of tautomerism are still being developed and are likely to be impactful in the area of MMPA. A similar challenge is raised by ionization and, as with

tautomers, requires structures that should be matched to be represented in the same way in the input. This is usually simpler than for tautomers. One representational problem that is not commonly understood is that certain functional groups, particularly those that have unusual valencies, can be represented in different ways and again must be standardized to the same form. An example of this is that the nitro group might be represented as $N^{+}(=O)O^{-}$ or as the chemoinformatically simpler but chemically problematic N(=O)=O. Once again, the representation selected is not important, but standardization is required. This is particularly important when taking data from a range of sources that have not used a set of rules to determine how they represent structures.

The chemoinformatic challenge posed by the absence of most hydrogen atoms in SMILES strings can complicate the treatment of tautomers.[5,64–66] Also, subtle changes can cause representation of structures that ought to be paired to be different. This can be particularly the case when the perception of whether a group of atoms are aromatic or nonaromatic differs. This is generally not a problem for smaller delocalized systems but can become a problem when three or more potentially delocalized systems are contiguous.

3.10.2.6.2 Measured property data

As discussed for chemical structure earlier, the key requirement for processed data is that only values that the user is happy to have compared are permitted to be compared. This is relatively easy to achieve for the small-scale manual studies that began the field of MMPA but is more challenging once the scale is increased and unsupervised methods are employed.

In general, MMPA subtracts the value of a property for one member of a pair from that for the other. Therefore, any properties that should usually be compared as ratios should be transformed logarithmically. These include equilibrium constants (such as K_i), IC_{50}s (or similar values), solubility, CL_{int}, P_{app}, and rate constants. Failure to make this transformation leads to the observation of pair sets such as those described by Keefer as multiplicative in which any useful insights are lost because of the nonlinearity of the scale.[39] Some thought also needs to be given about how to summarize the data when a compound has been studied several times and has more than one measurement. This is complicated if one or more of these measurements fall outside the range of the assay. In such cases, it is usually best to work with those who generated the data in order to determine, on an assay-by-assay basis, what the most appropriate means to process the data is. As mentioned in the section on melting point in the succeeding text, the highest T_m is likely the most appropriate one given that the most stable polymorph is usually the one of most interest; by analogy, the lowest solubility is often the best value to use.

The key consideration is to work out which sets of data should be compared. The most important contribution in this area has been from Kramer et al. who studied hERG inhibition as measured in an assay within Novartis and as reported in the ChEMBL database.[38] They emphasized the value of the paired *t*-test for MMPA because of its natural fit with the sort of comparisons being made, although it does require a normal distribution of data, which is not always observed. They demonstrate that matched pairs from the same assay (homogeneous pairs) are to be favored over pairs in which the two measurements come from different assays (heterogeneous pairs). They compute the difference in pIC_{50} that would be required in order to be detected as significantly different from zero within sets of heterogeneous pairs for different levels of experimental variability. They find that very large differences (2–8 log units) might be required for sets of two pairs, but this falls to 0.2 log units or less for sets of 100 pairs. This requirement is much lower for homogeneous pairs where the amount of broadening due to experimental variability is less. They advise that adding heterogeneous pairs only makes sense when adding a very large number of pairs because otherwise the amount of noise that is added outweighs any added signal. The rule of thumb they suggest is that there need to be twice as many heterogeneous pairs as the homogeneous pairs to which they are being added in order for it to be worth adding them. They also compute the number of pairs that are likely to be required in order to determine the effect for a structurally specific pair with 0.1 log units. They suggest that an average of 46 homogeneous pairs is required but that 200–400 heterogeneous pairs would be required.

ChEMBL records the assay that values were measured in, and this can be used to identify homogeneous sets. In their studies of the ChEMBL dataset, Kramer et al. also find that most pairs that fall into significant sets tend to have been measured in the same assay (homogeneous). By carefully analyzing the variation that they expect between pairs, they are able to detect compound pairs where the distribution is wider than expected. They find that this can sometimes be ascribed to the chemical context and note that the transformation from Me to Ph demonstrates this effect, whereas the transformation from F to Cl does not, suggesting that this transformation will cause the expected change regardless of context. They also find that outliers are more often database errors than real outliers and therefore demonstrate one of the unintended consequences of MMPA: by setting expectations of what is to be expected, unusual data points are flagged up, and these can be checked and will often turn out to be incorrect entries (either there was a problem with the experiment or the values have been incorrectly transcribed into the database). The final source of wider-than-expected variation they ascribe to chemical effects is the steric size of a group becoming large enough that it cannot be tolerated and the perturbation of pK_as.

3.10.3 Example Applications of MMPA

3.10.3.1 Specific Structures

3.10.3.1.1 Substituents on aromatic rings

The first publication in the area of MMPA described the addition of some common substituents to aromatic rings and the corresponding change in solubility.[5] The same structural change and its link to solubility, plasma protein binding, and in vivo exposure were explored by Leach et al.[1] An alternative approach to studying the addition of commonly occurring substituents was presented

by Haubertin and Bruneau for solubility, plasma protein binding, logD, and calculated properties.[31] They used a precompiled database of substituents as part of their analysis, which permitted them to explore the frequency of occurrence of these groups. A number of investigations have computed the effect of aromatic ring substitution patterns upon metabolism as measured in human liver microsomes.[23,25] Brown et al. looked at the effect of adding chlorine at different positions around a ring and also the effect of moving the chlorine around the ring in order to investigate the predominance of the para isomer in medicinal chemistry. They investigated potency, hERG, logD, solubility, Cl_{int} in microsomal assays, and permeability in Caco2 assays.

3.10.3.1.2 Oxadiazole regioisomers

Boström and coworkers performed a fascinating and detailed study of the effect of changing the position of the heteroatoms in oxadiazoles.[27] In particular, they investigated the exchange of 1,2,4-oxadiazoles with 1,3,4-oxadiazoles. They showed that the 1,2,4-oxadiazoles have a higher logD by about 1.2 log units(which is not always predicted correctly by logP calculators). Linked to this observation, they find that the 1,2,4-oxadiazoles have lower solubility, slightly higher Cl_{int} in human liver microsomes, slightly enhanced inhibition of the cytochromes P450 (particularly 1A2 and 3A4), and higher affinity for the hERG channel. They ascribe this to changes in the dipole moment of the two ring types and compute hydrogen-bond acceptor strength. The work was discussed by Muller in a commentary that highlighted Boström et al.'s work as a great example of MMPA in action and highlighted it as a useful lesson for medicinal chemists.[67] Related studies found that these general effects hold true in a specific example from a drug discovery program.[68]

3.10.3.1.3 Enantiomers

One of the more challenging structural changes to study is that of inversion of chirality. There are several challenges that make most of the matched pair finding methods ineffectual. The most important problem is that most methods require the pair to be defined as one specific structure type being converted into a second specific structure type. This would require a degree of specification of the chiral center that is usually impossible. Even the labels *R* and *S* are not generalizable because of their susceptibility to changes when the detailed nature of substituents changes. Also, many of the implementations of pair finding deliberately neglect stereochemistry. A further problem is that for molecules that contain more than one chiral center, inversion of overall chirality requires inversion of every stereocenter. As a consequence of all of these problems, the two reports concerning the influence of inverting stereochemistry upon properties have used nonstandard approaches to identifying pairs. Leach and coworkers identified enantiomeric pairs by transposing every occurrence of "@" and every occurrence of "@@" in the SMILES strings and then comparing the resulting SMILES string with the original database.[3] Bagdanoff et al., by contrast, used indexing based on structures with chirality flags removed in order to identify potential pairs in a first filtering step.[4] They subsequently inverted each stereocenter in the structures including chiral flags in order to verify which of the pairs correspond to inversion of chirality. Both studies examined solubility, permeability in Caco2 cells, cytochrome P450 inhibition, metabolism in microsomes, and hERG block. In addition, Leach et al. studied in vivo pharmacokinetic parameters, plasma protein binding, metabolism in hepatocytes, permeability in MDCK cells, and logD, and Bagdanoff et al. studied isocitrate dehydrogenase inhibition as an example of a potency target. Both approaches found that stereochemistry has no measurable effect on logD, solubility, permeability, and efflux. Meanwhile, in vivo pharmacokinetics, in vitro metabolism, hERG block, plasma protein binding, cytochrome P450 inhibition, and isocitrate dehydrogenase all have a dependency that can be detected although in some cases, Bagdanoff et al. suggest that the difference is too small to be of practical importance.

3.10.3.2 Specific Properties

Reports of MMPA now include studies of a great range of different endpoints of interest to compound designers. These have been divided into a number of categories.

3.10.3.2.1 Primary potency

Drug discovery projects typically aim to discover enzyme inhibitors (or activators), ion-channel blockers, receptor agonists, or antagonists. Examples of MMPA in this area are naturally therefore diverse, but progress could impact positively upon every drug discovery project. One of the earliest such studies, from Birch et al., describes the analysis of inhibition of glycogen phosphorylase.[21] As shown in Fig. 9, the effect of changing between the cores of some of the series of interest was examined for their effect upon pIC50 for inhibition, solubility and plasma protein binding.

Warner and coworkers examined effects on two ion channels, one of which (hKCNQ1) was the primary target and the other (hKCNE1) an undesired off-target.[58] They compared predictions made by examining similar compounds (near neighbors) with those made using MMPA and show a reduced RMSE for MMPA-based predictions compared with near-neighbor predictions; RMSEs of 0.33 and 0.39, respectively, were obtained. Predictions made by quantitative structure–activity relationships (QSAR) were less accurate with an RMSE of 0.40. They suggest that MMPA is a more effective means to avoid off-target effects than the other methods that were examined.

An example of MMPA taken from a real drug discovery program was provided by Waring et al. who were seeking activators of glucokinase of the type shown in Fig. 10.[14] They made matched pairs a central consideration in the selection of compounds that were to be made. All structural changes were exemplified as matched triplicates, which is to say that each structural change is very quickly represented as a set of three matched pairs such that MMPA can be performed immediately that the measured data are available. This permitted them to study the effect of structural changes upon pEC50 values for glucokinase activation, logD, and hERG

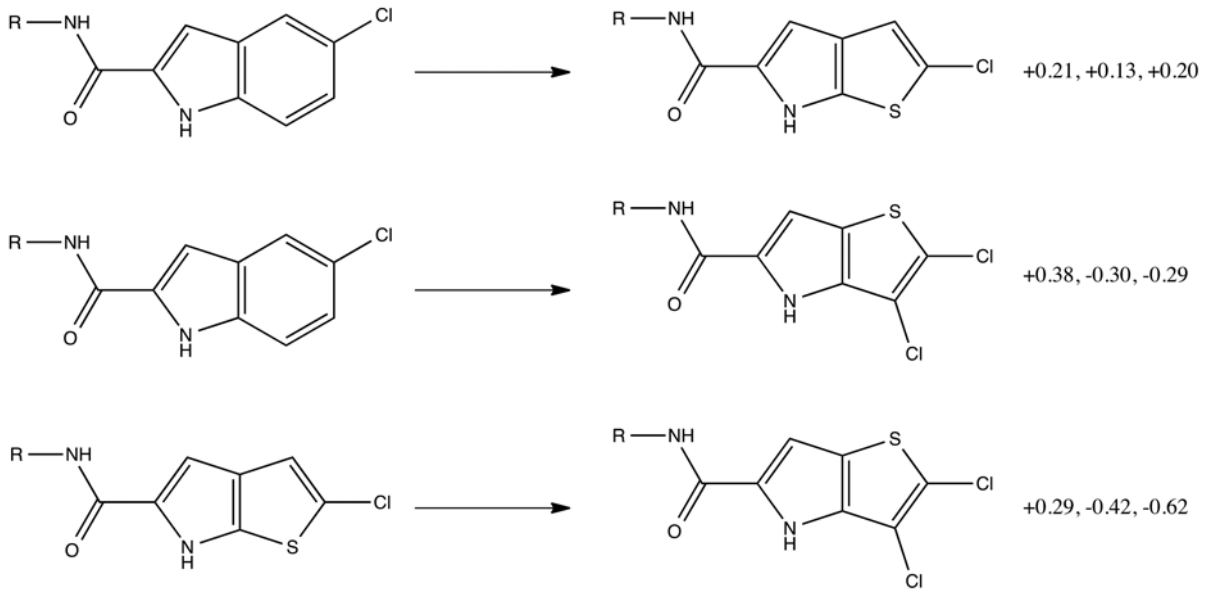

Fig. 9 Matched molecular pair analysis of inhibitors of glycogen phosphorylase. The mean change in pIC_{50}, $\log(f_u)$ for plasma protein binding, and log(Solubility) is given alongside each.

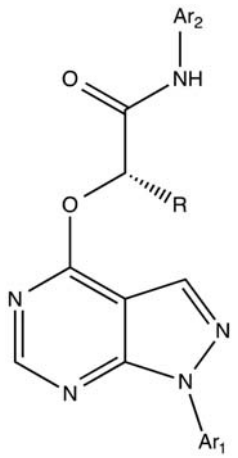

Fig. 10 In order to study the effect of different groups at R, Waring et al. set out to make sets of three representatives of each, in which Ar_1 and Ar_2 are varied.

block. The three representatives also permit them to rapidly build Free–Wilson type models in which representation is better, and therefore the models are more reliable.[6,69] It remains an open question whether three representatives are a large enough group to permit reliable predictions to be made. In a related piece of work, Tye and coworkers, when seeking to optimize dual inhibitors of the receptor tyrosine kinases IGF1R and InsR, emphasized the importance of making pairs of compounds varying only at one position.[17] They only made individual representatives so their analysis is less general and generalizable than that of Waring et al.

A significant effort to identify useful guidance concerning primary potency using MMPA is available as the SwissBioisostere database, described by Wirth et al. and is provided as a Web service.[54] This group has analyzed the ChEMBL database, using all values that have been annotated by the curators as confidence levels 8 and 9. Compounds with molecular weight above 1000 were excluded in order to keep run times down. They used Hussain and Rea's fragment and index method but modified the SMARTS definition for the bonds that are cut in order to prevent the cleavage of amide and similar bonds. The changing part was limited to 12 atoms or less, and context was encoded in a limited way according to whether the attachment point is an aromatic ring, an aliphatic ring, or an aliphatic chain. One of the starkest findings is that 47% of all the pairs that are found fall into sets with only one member. Only 13% of all pair sets have five or more pairs in them. Each pair was annotated according to the change in logP, tPSA, and molecular weight. The chemical diversity within each set is assessed by reporting the number of targets that have been studied, the number of target classes, and the number of Murcko scaffolds that contribute to the set.

Users can query the SwissBioisostere database in two ways: identifying all interesting changes for one substituent and investigating the effect of one specific transformation. In the first, a query substituent is drawn in. The database is then searched for all matched pairs in which that group has been replaced by others, and the changes reported as the number in which potency increased by more than 0.5 log units, the number in which the potency decreased by more than 0.5 log units, and the number where it stays the same (the magnitude of any change is less than 0.5 log units). These numbers are transposed into a score that ranks most highly those substituents likely to improve the activity and that are well exemplified. The changes in calculated physical properties are also provided in order to help the user select which groups to transform their query substituent into. The data can be downloaded as a CSV file. By way of example, the database was searched for replacements for the *t*-butyl group, and sets of pairs with at least five members were selected. The proportion of times that transforming t-butyl into a different group has caused an increase in potency is plotted against the mean change in logP for that transformation. This reveals that a wide variety of outcomes have been observed when replacing *t*-butyl, as is shown in **Fig. 11**. As discussed in the following section, the point in the top left corner of the plot in **Fig. 11** (at −2.8, 100) is for changing R-*t*-butyl to R-N(Me)Ac.

Users can also search for specific transformations in the SwissBioisostere database or drill down into the full set of pairs. The compound pairs can shed light on the applicability of any given change. For instance, the point in **Fig. 11** for R-*t*-butyl becoming R-N(Me)Ac is a set of nine compound pairs that are all histone deacetylase inhibitors. The user can therefore draw their own conclusion about whether this observation is likely to be relevant and effective in their own series. The data can also be searched back to the entries in ChEMBL allowing a very detailed level of scrutiny.

In 2008, Hajduk and Sauer from Abbott attempted to study the effect of adding certain substituents upon a host of different biological targets.[26] They computed the average effect upon potency of a set of 828 substituents. They discovered that for most of these, the mean change is close to 0 but that the widths of the distributions vary considerably. They highlighted a set of substituents that are worth trying in order to undertake an exploration of diversity and a set for when there is a need to increase potency; these groups all have a greater propensity to increase potency than the others (**Table 1**). This was one of the first general attempts to address the challenge that we have styled the "potency problem." When analyzing many properties with MMPA, the various positions around the molecule are not always strongly differentiated, but when considering the interaction with a specific target protein, each position is unique and is expected to have particular preferences. Capturing such effects in MMPA is exceptionally challenging. Recent attempts to use three-dimensional approaches go some way to address this.[47,49]

Dimova et al. also sought to address the "potency problem" by analyzing the ChEMBL database (limited to K_is) with MMPA in order to identify structural changes that reliably increase potency.[44] They found 31 such structural changes in which there were at least 21 examples, all of which change potency in the same direction. These are almost all GPCR modulators, and the structural changes showed mixed effects on logP, PSA, MW, and the number of rotatable bonds suggesting that this is a powerful set of ideas that could be tried during a drug discovery program.

In a study aimed at understanding the popularity of the *para*-chloro substituent on aromatic rings, Brown and coworkers studied matched pairs (among other things).[70] They discovered that *p*-Cl is reported about three times more commonly than *m*-Cl or *o*-Cl in IBEX, ChEMBL, the internal AstraZeneca compound collection, and the protein database of known drugs. Despite this, when they examined assays in ChEMBL to find matched pairs that differed by moving chlorine around a ring, they found that potency is not consistently better for any of these regioisomers, although there were discernible preferences for other properties.

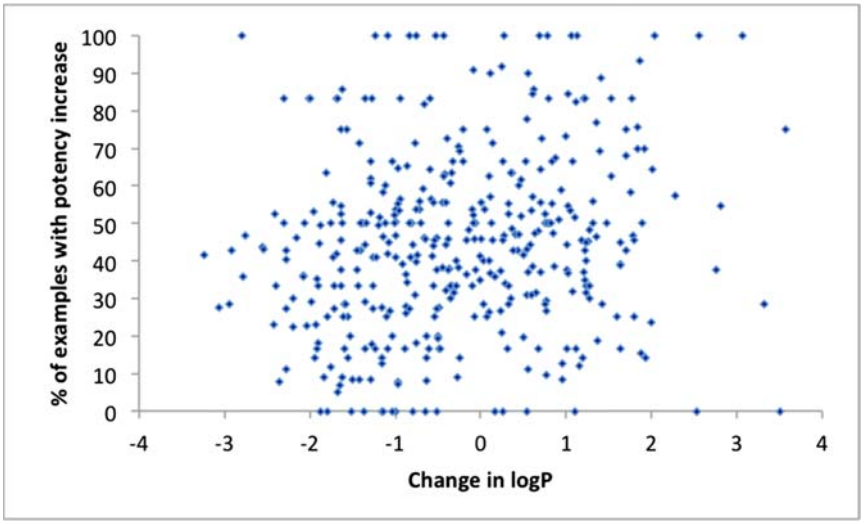

Fig. 11 The proportion of examples in which potency has increased is plotted against the calculated change in logP for a number of structural transformations in which *t*-butyl is replaced. The data are extracted from the SwissBioisostere database.

Table 1 A set of substituents recommended when seeking to sample diversity or to increase potency

Diversity set	*Potency set*
F	Br
Cl	CC(C)C
Br	C(F)(F)F
CC	C=C
C(F)(F)F	CC=C
OC	OC(C)C
N(C)C	OC(F)(F)F

CN1CCCC1	C1CCCC1
CN1CCOCC1	c1c(Cl)c(Cl)ccc1
c1c(C)c(C)ccc1	c1c(Cl)cc(Cl)cc1

Note: Groups are represented as their SMILES strings.

A significant set of contributions to understanding how potency might be improved using insights from matched molecular pairs has come from the extension of the concept to matched molecular series, which are described in the following section.[50,52,53]

3.10.3.2.2 In vivo pharmacokinetics

The ultimate measure of the pharmacokinetics of a compound during the discovery phase is in vivo studies in animals. These observations are complex and with a high degree of variability between them. The parameters derived are dependent upon a very large set of processes including the subtleties of absorption, distribution, metabolism, and excretion. As such, analyses of in vivo data often cannot reveal significant effects. This was exemplified by Leach et al., who contrasted the effects observed on solubility and plasma protein binding with much less distinct effects for the area under the plasma concentration–time curve (AUC) in rats. A significant difference between enantiomers was detected in in vivo pharmacokinetic parameters, despite the experimental variation inherent in such experiments.[3]

3.10.3.2.3 Metabolism

Achieving an appropriate level of metabolism is a requirement across all drug discovery programs. As such, it is unsurprising that it has received a great deal of attention in the MMPA field. It represents an interesting challenge from which certain general insights might be gleaned. Metabolism involves the action of a suite of enzymes (such as the cytochromes P450 and glutathione transferases), which are often viewed as tolerant to a diversity of substrates. In MMPA, the effect of structural changes upon interactions with one specific enzyme is considered challenging to analyze, whereas the effect of structural changes upon systems dependent upon a structurally tolerant enzyme or a large set of enzymes might be more likely to be amenable. Thus, metabolism may well represent the interesting intersection point in which certain specific effects are not captured by the analysis but in which general trends can be ascertained.

One of the most important contributions to understanding metabolism has been provided by a series of papers from Dossetter and coworkers at AstraZeneca. In these papers, the effects of changing the structure of moieties often associated with metabolic liabilities were investigated: aromatic rings and methylene carbons. In this case, metabolism was by human liver microsomes measured as the intrinsic clearance (Cl_{int}) for each compound. These values were transformed to $\log(Cl_{int})$ in order to place them on a linear scale. In the first of the series, the influence of substitution patterns in a set of phenyl rings was investigated.[23] In total, 73 combinations of substituents around the phenyl ring (as well as a small number of heteroaromatic replacements) were investigated. From the observed variations in Cl_{int}, Dossetter is able to produce a recommended sequence of substitution patterns that should be considered when attempting to optimize metabolism. These are compared to the decision tree-type recommendations of Topliss who suggested substituents to consider in order to proceed logically when trying to optimize the substitution

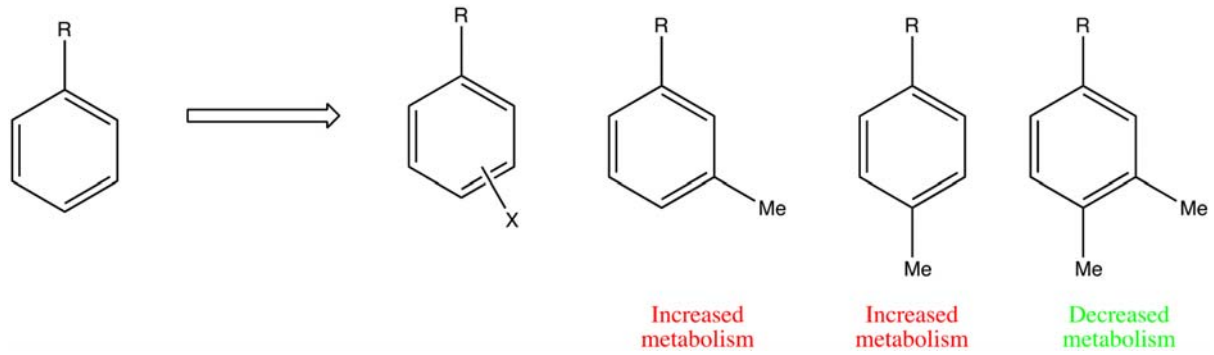

Fig. 12 Dossetter has applied MMPA to understand the effect upon metabolism by human liver microsomes (HLM) of changing phenyl to substituted phenyl. Surprising examples of adding methyl groups are shown.

pattern around phenyl rings. On average, the changes were found to center around zero, and less than 5% of all pairs showed an average change in Cl_{int} of more than an order of magnitude (in either direction). Most substituents were more likely to reduce metabolism at the 4-position than at the 2- or 3-position. Methyl is an exception to this rule and is better at the 2-position. Some interesting interactions were identified, such as that exemplified in Fig. 12 where adding a methyl at the 3-position was found, on average, to increase metabolism, as was adding a methyl at the 4-position. By contrast, adding two methyl groups, at both the 3- and the 4-positions, was found, on average, to reduce metabolism. This example may be one of those that exemplify the dilemma with metabolism discussed earlier. There is a general effect of adding the substituents, which changes the physical properties of the molecules. This increases the general metabolic liability. This is counteracted by a specific effect whereby one methyl group can sterically crowd another and reduce its liability to be metabolized.

It is emphasized that interpreting these observations is challenging because not only can the site of metabolism vary among the different structures, but also the isoform involved in the metabolism can change. Dossetter ultimately recommends using a combination of the Topliss approach (which is based on the electronic and lipophilic properties of substituents) and the metabolism-related approach in order to proceed logically to optimize a series with a minimal number of compounds being required.

The logical extension of the investigation of substitution patterns around phenyl rings was to heteroaromatic replacements. In particular, Dossetter and coworkers looked at disubstituted phenyl rings that were transformed into heteroaromatic alternatives.[13-] When undertaking these studies, several sets were found to be close to having enough pairs to be sufficiently diverse. In these cases, extra compounds were tested in order to expand the coverage with minimal extra testing. By obtaining data in the same run of the same assay, they were able to add pairs in which the data were as directly comparable as possible.[38] They discovered that changes to heteroaromatic rings from phenyl are more likely to lead to increases in metabolic stability than for any of the substitution patterns on a phenyl ring (see earlier) or changes to methylene carbons (see in the succeeding text). They were not able to identify any clear role for lipophilicity in determining the outcome. The various heteroaromatic ring alternatives are summarized in Fig. 13 in which the most stable alternative is on the left and the least stable on the right.

The final structural change considered by Dossetter was replacements for methylene carbons (Fig. 14).[22] Methylene carbons, particularly those next to aromatic rings, are often considered to be particularly liable to metabolism, likely due to the propensity for the C—H bonds on these carbons to undergo homolytic cleavage. MMPA investigated the change in $\log(Cl_{int})$ when CH_2 was transformed into a range of alternatives. These were divided into pairs in which the CH_2 was benzylic or alkyl. In general, and despite some suggestions in the literature, adding a methyl group at a benzyl position was not found to decrease metabolism. The exception to this may be the doubly benzyl substructure $ArCH_2Ar$. Transforming CH_2 to CF_2 was found to be approximately neutral with regard to metabolism for benzyl CH_2 groups but beneficial for alkyl CH_2 groups. Replacing CH_2 with O, NMe or SO_2 is beneficial in $AlkCH_2Alk$, and O and S are beneficial for $ArCH_2Ar$. Some of the observations were found to go in the opposite direction to that that might be expected based on lipophilicity considerations (which should see Cl_{int} increase as logD increases). There was only a weak correlation found when the change in $\log(Cl_{int})$ was plotted against the change in logD.

In a study of a range of properties by scientists at Pfizer, experimental data from studies using human liver microsomes were investigated.[39] They classified the observed changes in several properties, with one interesting class being on or off switches; these are groups that when added always either completely eliminate a property or universally introduce it. It was found that for human liver microsomes, such transformations were relatively common, corresponding to 4.3% of all transformations investigated. They ascribe this to the important role of specific molecular recognition patterns. They showed that changing 2-pyridyl to 1-imidazole decreased metabolism.

Lewis and Cucurull-Sanchez categorized changes in Cl_{int} measured with human liver microsomes according to whether they were greater than a twofold increase, less than a twofold decrease, or somewhere in between.[25] Like Dossetter, they investigated the transformation of phenyl to substituted phenyls. They found that there is a general correspondence with lipophilicity, as illustrated in Fig. 15. They suggest that 4-Me and 4-OMe are worse than might have been expected because they introduce a group that is specifically metabolized more rapidly than might have been caused by the change in physical properties. They also highlight that *p*–

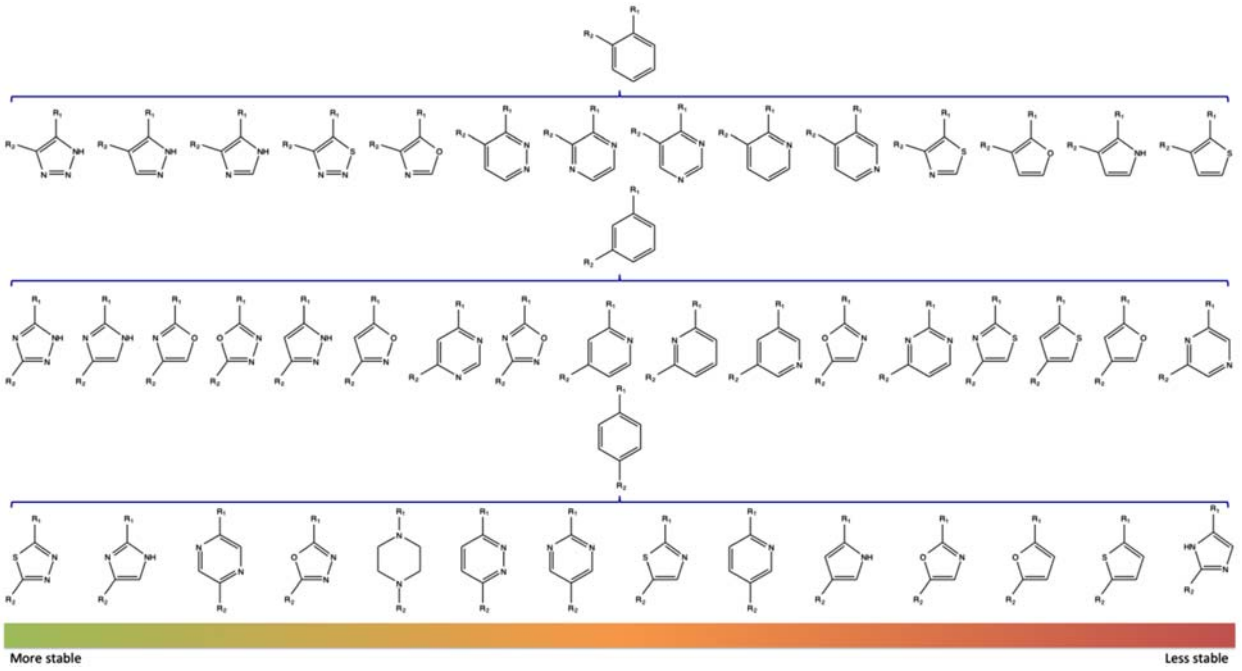

Fig. 13 The heteroaromatic alternatives to disubstituted phenyl rings studied by Dossetter et al. The top set are alternatives to 1,2-disubstituted phenyl, the middle set to 1,3-disubstituted phenyl, and the bottom set to 1,4-disubstituted phenyl. The most metabolically stable alternative is on the left and the least stable (most rapidly metabolized) on the right.

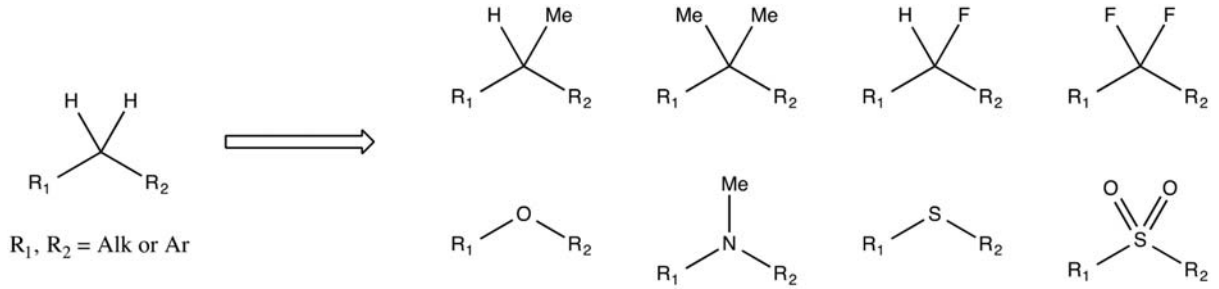

Fig. 14 Transformations of methylene carbons considered by Dossetter in his study of their effects upon metabolism by human liver microsomes.

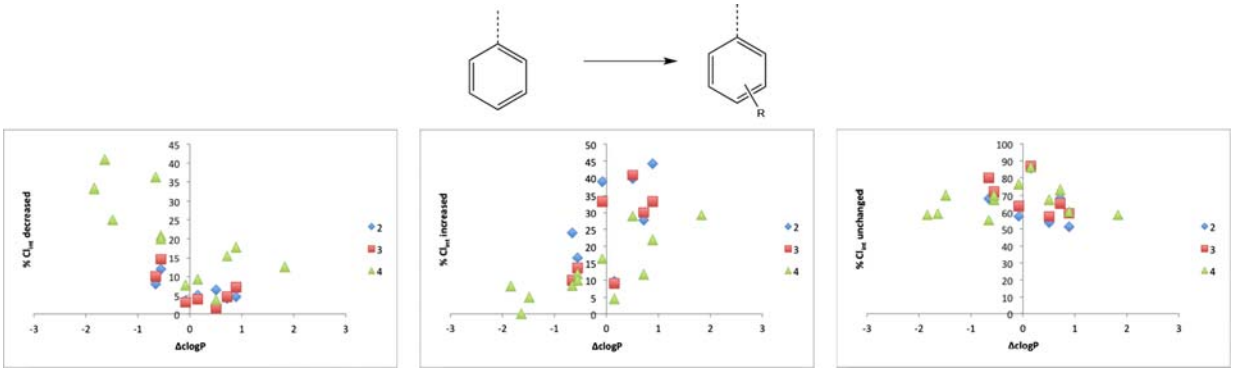

Fig. 15 Lewis and Cucurull-Sanchez investigated the effect of changing phenyl to substituted phenyl upon Cl_{int} measured in human liver microsomes. On the left, the percentage of cases in which Cl_{int} decreased is plotted against the corresponding change in clogP; in the middle, the percentage of case in which Cl_{int} increases is plotted; and on the right, the percentage of cases in which Cl_{int} is unaffected (within twofold) is plotted.

F performs more or less as expected according to lipophilicity, despite its reputation as a group for blocking metabolism. They found (as is apparent in the plots in Fig. 15) that groups at the 4-position tend to decrease metabolism more effectively than the same group at the other positions around the ring. A small number of disubstitutions were also investigated, and a Topliss-like decision tree for metabolism was proposed, much like that proposed by Dossetter.[23]

The effect of inverting chirality upon a number of properties was investigated by Leach et al. and by Bagdanoff et al.[3,4] In both cases, the measurements of metabolism were found to support significant differences between enantiomers. Similarly, Boström and coworkers found that 1,2,4-oxadiazoles tend to have higher rates of metabolism than the corresponding 1,3,4-oxadiazole.[27]

In further studies, scientists from Pfizer investigated the effect that changes to cyclic ethers have upon metabolism as measured by Cl_{int} in human liver microsome assays.[28] They had observed some interesting trends in one particular drug discovery project and wished to investigate whether this was specific to those compounds or a more general phenomenon. They identified matched pairs in which the ring size is changed and in which the oxygen atom is moved around the ring (Fig. 16). They found that reducing ring size always decreases the Cl_{int}, and they rationalize this as primarily driven by reductions in lipophilicity. They also found that 3- and 4-linked rings are generally more stable than the 2-linked equivalents. These changes are often in contradistinction to the small changes expected if lipophilicity were dominant. Given recent interest in the progress of the epoxide-containing molecule beloranib as an obesity therapy, it is a shame that these studies were not extended to epoxides.[71]

Reaction with glutathione (GSH), either chemically or biochemically (catalyzed by glutathione transferases), is also an important component of metabolism. In a study of the chemical reaction with GSH, Morley and coworkers investigated the effect of adding NH_2 to the position para to a reactive nitrile group (Fig. 17).[20] They were specifically interested in tempering the reactivity of covalent inhibitors, but this is nonetheless relevant to metabolism. They discovered that in this case, the reactivity is diminished and the half-life increases by a factor of more than 4.

3.10.3.2.4 Permeability and efflux

Absorption is a property of concern to all programs that seek orally dosed medications that require systemic exposure. Other routes of delivery may also need to pass through layers of cells that form sealed interfaces. The most common assay for measuring the permeability of compounds through such layers is the Caco2 assay in which a layer of cells (deriving from a colon carcinoma) is formed into barriers and the movement of compounds from the apical side of the layer to the basolateral and vice versa is studied. The Madin–Darby canine kidney (MDCK) assay is also used, particularly its variant in which the transporter Pgp is overexpressed. The PAMPA assay replaces the cells with an artificial membrane, usually infiltrated with long-chain hydrocarbons. In their studies

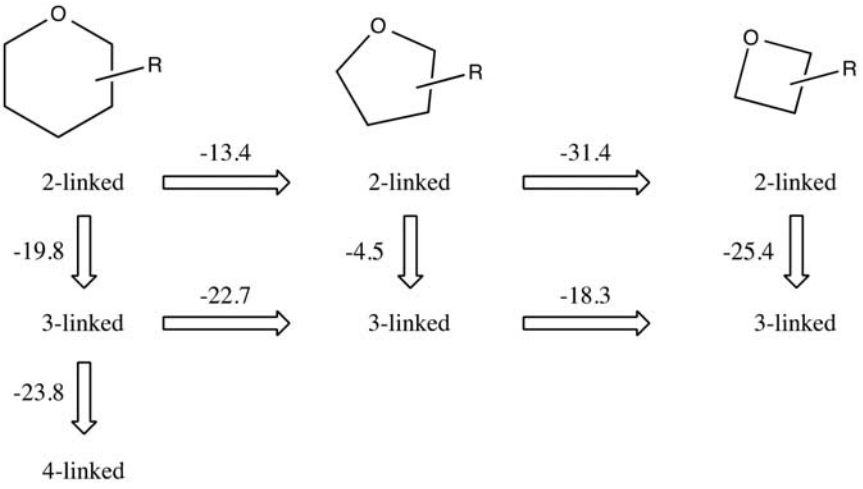

Fig. 16 The mean change in Cl_{int} for changes in the ring size and connectivity of some cyclic-ether-containing compounds.

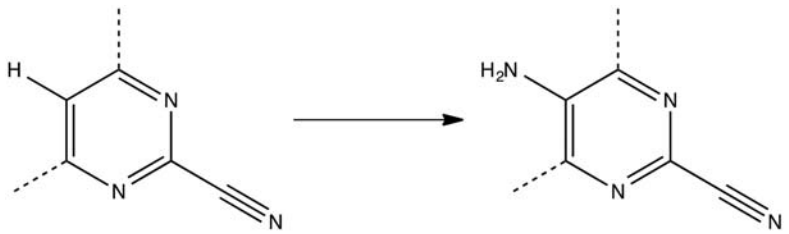

Fig. 17 The structural transformation investigated by Morley et al. for its effect on reaction with glutathione.

investigating the effect of inverting stereochemistry, scientists at AstraZeneca and independently at Novartis discovered that inverting chirality does not have a measurable effect upon absorption in either Caco2 or MDCK assays, even when active transport involving recognition by proteins is involved.[3,4] By contrast, Keefer et al. investigated the effect of structural changes upon Pgp-mediated efflux and found that this is the system in which so-called on switches or off switches were most common; 6.7% of all pair sets had one member of the pair not subject to efflux and the other member of the pair is.[39] This suggests that certain chemical groups can be responsible for the whole molecule property and their presence or absence is the determinant of their susceptibility to efflux. By contrast, such switches were rather uncommon for permeability. They also found that the change 2-pyridyl to 1-imidazole increased efflux. Gleeson and coworkers used MMPA to study permeability measured in PAMPA, which involves only passive processes.[24] They found that whereas many pharmaceutical properties get worse as clogP increases, permeability sees the opposite trend.

3.10.3.2.5 Toxicity

Toxicity is a multiheaded hydra, with many causes that can be linked to the structure of molecules in all manner of ways: direct interaction with specific targets, chemical reactivity (either specific or general), the same for metabolites of compounds, physical disruption of biological systems, or many other causes. The ultimate arbiter of toxicity during drug discovery is typically long-term studies in animals or indeed in humans during clinical trials. Typically, only very small numbers of compounds can be studied in such trials for ethical and economic reasons. As such, very few pairs of compounds that might be considered matched pairs have been studied.

Sushko et al. used MMPA to analyze the differences between measured values relevant to mutagenicity and aquatic toxicity. They also incorporated the differences between values predicted by QSAR models.[36]

During the course of the last few decades, a few targets have been linked with toxic or undesirable outcomes. A few of these have therefore been studied in more detail and with enough compounds to make them suitable for MMPA. Indeed, block of the hERG potassium ion channel may be one of the targets that have been studied most often in MMPA.

3.10.3.2.5.1 hERG

The hERG encodes a cardiac potassium ion channel. Blocking this channel can prolong the QT interval and lead to torsades de pointes.[72] This serious toxicological liability can now be screened for, and consequently, large datasets now exist, which are ripe for MMPA. In their studies of enantiomeric pairs, Leach et al. and Bagdanoff et al. discovered that hERG block has a small but significant dependency upon chirality, suggesting that molecular recognition can be important.[3,4] In what may be a related observation, Kramer and coworkers discovered that certain sets of matched pairs show a broader distribution (a larger standard deviation) than others.[38] They ascribe this to these sets having representatives in which the structural context is important, which is often the signature of effects that depend upon specific recognition at a receptor. By contrast, Gleeson suggests that changes to hERG inhibition are broadly in line with physical property changes.[24]

In their important contribution describing the influence that structural context can have upon properties, Papadatos et al. use hERG block to exemplify some interesting cases. For instance, they find that when a methoxy substituent is added (in place of H), across all molecular contexts, there is an approximately equal likelihood of hERG potency increasing or decreasing. When the same change is limited to adding to alkyl carbon atoms, the change is more likely to be beneficial, just as it is when added ortho to an aza nitrogen (**Fig. 18**). When methyl is transformed to fluorine, on average, it is equally likely to increase or decrease hERG binding. However, when the same change is made ortho to a benzylamine, it is most likely to be beneficial.

Boström et al., in their study of oxadiazoles, find that 1,2,4-oxadiazoles have higher hERG affinity than the corresponding 1,3,4-oxadiazoles, which is in line with their higher logD (**Fig. 19**).[27] They note that the changes in pK_a that are caused by this structural change do not influence hERG potency. A further study revealed that para-Cl is (on average) worse, from a hERG perspective, than the ortho or meta equivalents (**Fig. 19**).

In an example taken from a real drug discovery project, Waring et al. highlight an example in which MMPA was able to suggest changes that would retain potency while reducing hERG block (**Fig. 20**).[15] In a study from some of the same authors, sets of three compounds at a time were made in order to facilitate MMPA and Free–Wilson analysis (**Fig. 21**).[14] A number of effects upon hERG caused by structural changes at two positions around a specific scaffold of interest in a glucokinase program were discussed. These reveal effects that are broadly in line with lipophilicity although the cyanopyridine is an interesting exception to this where hERG potency increases despite a reduced lipophilicity.

In another example from a drug discovery project, Tye and coworkers discovered that for a series of IGF1R/InsR tyrosine kinase inhibitors, changes in hERG potency generally track with logD, with a slope of $\sim$0.4 for the line of best fit.

3.10.3.2.5.2 Inhibition of the cytochromes P450

One well-known liability that can cause dangerous drug–drug interactions is the inhibition of the enzymes involved in drug metabolism of which the cytochromes P450 are the most important group. As a consequence, the inhibition of these enzymes has been measured for a great many compounds, which makes this property amenable to MMPA. Examples of studies of cytochrome P450 inhibition include that by Sushko in which MMPA and QSAR were used.[36] They found that the performance of MMPA was similar when analyzing changes in experimentally derived data or data derived from a QSAR model for the 3A4 isoform. Gleeson examined the differences in inhibition for the isoforms 1A2, 2C9, 2C19, 2D6, and 3A4 and found SAR broadly in line with the known preferences and structures of these isoforms.[24] As with most of the properties he studied, inhibition of the cytochromes P450 tended to

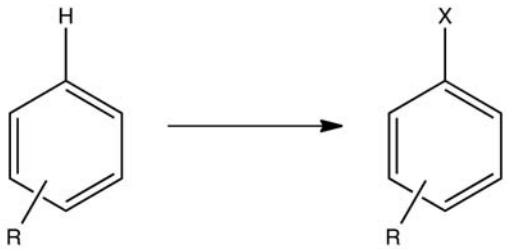
increase with changes that increase lipophilicity. In their studies of the effect of inverting stereochemistry, Leach et al. found a contradictory large difference between enantiomers for several isoforms despite the identical physical properties.[3] The isoforms studied, when placed in order of the difference between enantiomers (largest to smallest), are 2D6, 2C19, 1A2, 2C9, and 3A4. The fact that 3A4 was found to have only a small difference was in concurrence with the findings of Bagdanoff et al. who were unable to detect a difference between enantiomers for 3A4.[4] In studies comparing 1,2,4-oxadiazoles and the equivalent 1,3,4-oxadiazoles, Boström et al. found the former to be slightly stronger inhibitors of the cytochromes P450 than the latter. Geppert and Beck used cytochrome P450 data (from the 2C19, 2C9, 2D6, and 3A4 isoforms) in their studies using fuzzy matched pairs.[45]

3.10.3.2.6 Solubility

The first publication in which the term MMPA was coined included an analysis of the effect upon solubility of adding a small number of substituents to aromatic rings.[5] These are shown in Fig. 22. This analysis was extended by Leach et al. to a wider selection of substituents, and the mean change in log(Solubility) found by them is also shown in Fig. 22. A number of outliers in the distributions were highlighted, and (as discussed in "Context Dependence; Set Size Versus Specificity" section) these were generally assigned to different conformational preferences. The final column, describing the effect of adding methylsulfone, was revisited in a subsequent publication in which it was reported that since the first publication, many more pairs of molecules differing by this structural change had been made, presumably inspired by the attractive positive mean change found. However, these later pairs had been less successful, and the mean had become negative.[73] When the standard error in the mean (shown in the table at the bottom of Fig. 22) was considered, it was found that all the data for methyl sulfone addition are consistent with a mean that is positive but rather smaller than that originally found. The surprisingly weak solubility improvement caused by methyl sulfone addition, despite large decreases in logD, was investigated in a series of GPR119 agonists using small-molecule crystal structures that highlighted the geometric and electrostatic complementarity between the oxygen and CH bonds of these groups and that these form extended interaction networks in the solid state.[74] Haubertin and Bruneau also reported on the effect of substituents upon solubility but were less strict in defining the positions to which those substituents were attached.[31]



Substituent	Br	Cl	F	OMe	Me	CN	CF_3	OH	SO_2Me

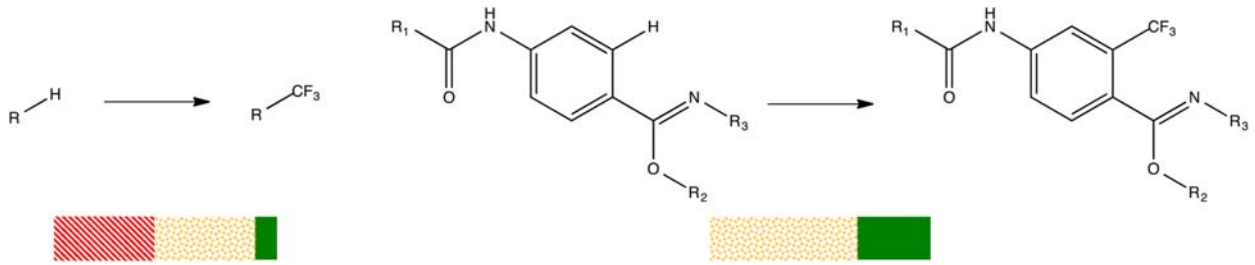

Fig. 23 Context specificity of the effect of adding CF_3 upon solubility. The colored bar represents all of the examples (100%) and is divided into sections that correspond to the proportion of examples in which making the structural change causes hERG block to increase, decrease, or remain unchanged.

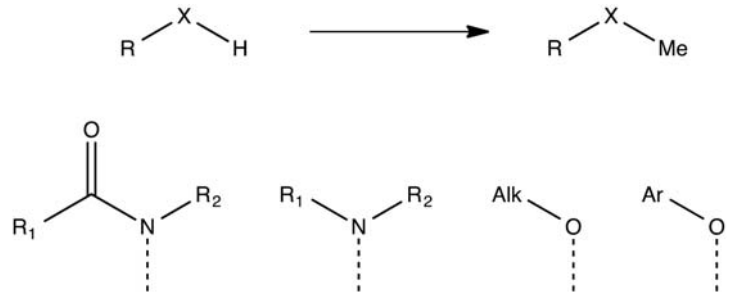
This context specificity was explored further by Papadatos et al. who included solubility in their study of how chemical context can influence the outcome to be expected for matched pairs. They note that in general, adding CF_3 groups is very unlikely to increase solubility but identify a subset in a rather specific chemical context where there is a significant chance that solubility will increase and for which they found no examples in which solubility decreases (Fig. 23).

The effect of adding methyl groups to a number of heteroatom types has also been studied by a number of groups. The first publication in the MMPA area to investigate this was by Leach et al. but had been inspired by the work of Birch et al., which was not published until later.[1,21] Birch et al. reported that methylating the amides present in a series of indan-based glycogen phosphorylase inhibitors led to a surprising increase in solubility. They described some of the conformational and hydrogen-bonding effects that might contribute to this. Leach et al. extended this work to looking at the methylation of a number of heteroatom types, which are reported in Fig. 24.

Ritchie et al. also examined the effect of methylating some oxygen and nitrogen atom types.[43] They examined primary and secondary amides and sulfonamides, ureas, carbamates, amines, anilines, aromatic nitrogen atoms, carboxylic acids, phenols, and alkyl alcohols (Table 2). They ensured chemical diversity within each set of pairs by requiring each to contain at least 10 clusters when clustered using fingerprints, with the exception of a small number of sets that had less than 10 members in total. These studies used solubility as measured from a dimethylsulfoxide (DMSO) stock solution and therefore might not be expected to detect the important solid-state effects highlighted by Leach et al. or Zhang et al.[1,41] It is therefore interesting that methylation of secondary amides is still found to increase solubility. By contrast, methylating sulfonamides universally decreases solubility, in line with an increase in lipophilicity. Methylation of ureas is also found to increase solubility, but the sets of pairs are too small to be confident; they find a hint that the effect of methylation of ureas may depend upon the lipophilicity of the urea in question. Methylation of carbamates has little effect upon solubility. All the methylations of oxygen atoms that were investigated (alcohols and carboxylic acids) suggest that solubility decreases, on average, for each structural type.



Substituent	Amide	Amine	Alkyl alcohol	Phenol

	AlkNHAr	−0.04 (0.02)	+0.78 (0.03)
	ArNHAr	+0.14 (0.04)	+0.54 (0.04)
	Aromatic NH	+0.04 (0.02)	+0.60 (0.02)
Alcohols	AlkOH	−0.19 (0.02)	+1.14 (0.03)
	ArOH	−0.21 (0.02)	+1.13 (0.03)
Carboxylic acids	AlkCOOH	−0.65 (0.04)	+3.02 (0.06)
	ArCOOH	−0.94 (0.04)	+3.36 (0.04)

The same authors also investigated the effect of exchanging an amide for a sulfonamide. They found that for R_1CONHR_2 becoming $R_1SO_2NHR_2$, the effect upon solubility is small, with a mean change of +0.12. However, when the nitrogen has been methylated, the effect of transforming $R_1CON(Me)R_2$ into $R_1SO_2N(Me)R_2$ corresponds to a large decrease in solubility, with a mean difference of −0.52 in log(solubility) measurements.

An interesting impact of chemical context was investigated by Ritchie et al.[43] They reported that when adding methyl to heteroatoms, it is important to consider the possibility that the hydrogen that is being replaced might be involved in an intramolecular hydrogen bond. When this is the case, they find that the outcome can often be very different to that that would otherwise be expected. For instance, methylating an amide in any of the contexts shown in Fig. 25 leads to large increases in solubility and decreases in logD because the hydrogen-bonding partners form better interactions with water in the absence of the intramolecular interaction.

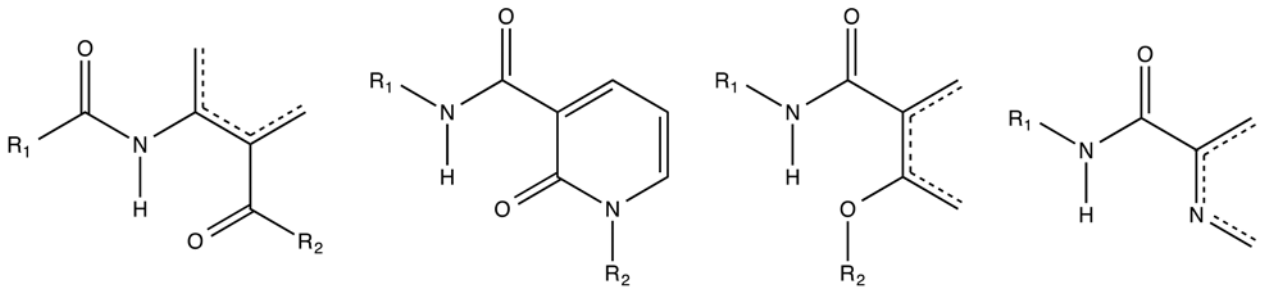

Fig. 25 Chemical contexts in which methylation disrupts an intramolecular hydrogen bond.

It is to be expected that in their survey of enantiomeric pairs, both Leach et al. and Bagdanoff et al. found that there is no difference between enantiomers in terms of their solubility.[1,4] Boström et al. found that 1,2,4-oxadiazoles tend to have lower solubility than the equivalent 1,3,4-oxadiazole, in line with their higher logD.

Zhang et al. used MMPA to study solubility data composed of 720 measurements from the literature and approximately 2000 internal data from Pfizer.[41] They focused upon the effects caused by group addition and by group exchange in sets of pairs that had at least 20 in the set. They compute the median value of the change in solubility and the percentage in which solubility increases or decreases. They highlight the general tendency of halides, pseudohalides (e.g., CF_3), and longer alkyl chains to decrease solubility. Certain polar groups were also found to reduce solubility more often than they increase it. These include primary amides, secondary amides, and reversed amides. Even the addition of a carboxylic acid was found to decrease the solubility in 55% of the matched pairs they studied. They ascribe this to a solid-state effect, with these polar groups forming crystal-packing motifs that stabilize the lattice to a greater degree than they enhance interactions with water in the liquid state. They contrast these findings, which are from an assay that uses solid samples, with an MMPA of kinetic solubility data in which the samples start in DMSO. In this other assay, they see the opposite effect with the polar groups causing an increase in solubility; for instance, almost all additions of carboxylate correspond to an increase in solubility in the kinetic solubility assay. They plot the changes in solubility in the assay from solids against pi values, and this highlights the three amide-containing groups already mentioned and SO_2NH_2 and SO_2Me. All of these groups contain donors and acceptors, which are able to form interactions with one another in the solid, apart from SO_2Me, but other studies found that these groups can form nonclassical hydrogen bonds in which the CH bonds adjacent to the sulfur can act as hydrogen-bond donors.[74] Zhang et al. also examined the effect of exchanging substituents and plotted their findings as heat maps, which provide useful guidance about which transformations might be considered when an increase in solubility is desired.

3.10.3.2.7 Melting point

An alternative means of investigating solid-state effects, such as those that so clearly influence solubility, is to perform MMPA on compounds with measured melting points. Such a study was undertaken by Schultes et al.[42] In order to ensure that, as far as it is possible, their studies related to the most stable polymorph, they used the highest melting point (T_m) that was reported for each compound in an in-house database and in the publicly available MDPI dataset. Each compound was classified according to a number of descriptors: the number of hydrogen-bond acceptors and donors, the number of halogen atoms, clogP, and the number of rotatable bonds. Pairs were identified using the fragment and index approach. In order to generalize their results, pairs were grouped such that all of the calculated descriptors stay the same except for one. This allowed them to deduce that increasing the number of hydrogen-bond acceptors tends to increase the melting point, increasing the number of hydrogen-bond donors increases T_m to a greater degree, and increasing the number of donors while decreasing the number of acceptors tends to still lead to increases in T_m. Increasing the number of rotatable bonds tends to increase T_m, while clogP does not have an influence that is significant once the change in the number of halogens is taken into account. They mention some examples, which illustrate the interplay of melting point and solubility; adding an OH not only increases solubility but also increases T_m suggesting that the enhanced affinity for water overrides the increased lattice energy. They highlight the five changes in each of the two datasets that they have studied, which cause the largest change in melting point, and for which, there are at least five examples. These are shown in **Fig. 26**.

3.10.3.2.8 Plasma protein binding

There are a number of proteins present in plasma at high concentration, which play an important role in transporting molecules including drugs. These proteins include albumin and α-acid glycoprotein. A few reports have been published describing the findings of MMPA applied to the binding affinity observed to these proteins. Leach et al. studied the same structural changes as they had for solubility (described earlier) and found the mean changes reported in **Table 3**.[1] These are broadly in line with the effect of the structural changes on lipophilicity.

Haubertin and Bruneau also investigated the effect of a range of common substituents upon plasma protein binding and also found changes broadly in line with lipophilicity.[31] Birch et al. investigated the effect of the common bioisosteric replacement of a carboxylic acid with a tetrazole and found that the fraction unbound would change by a factor of 0.3 on average suggesting

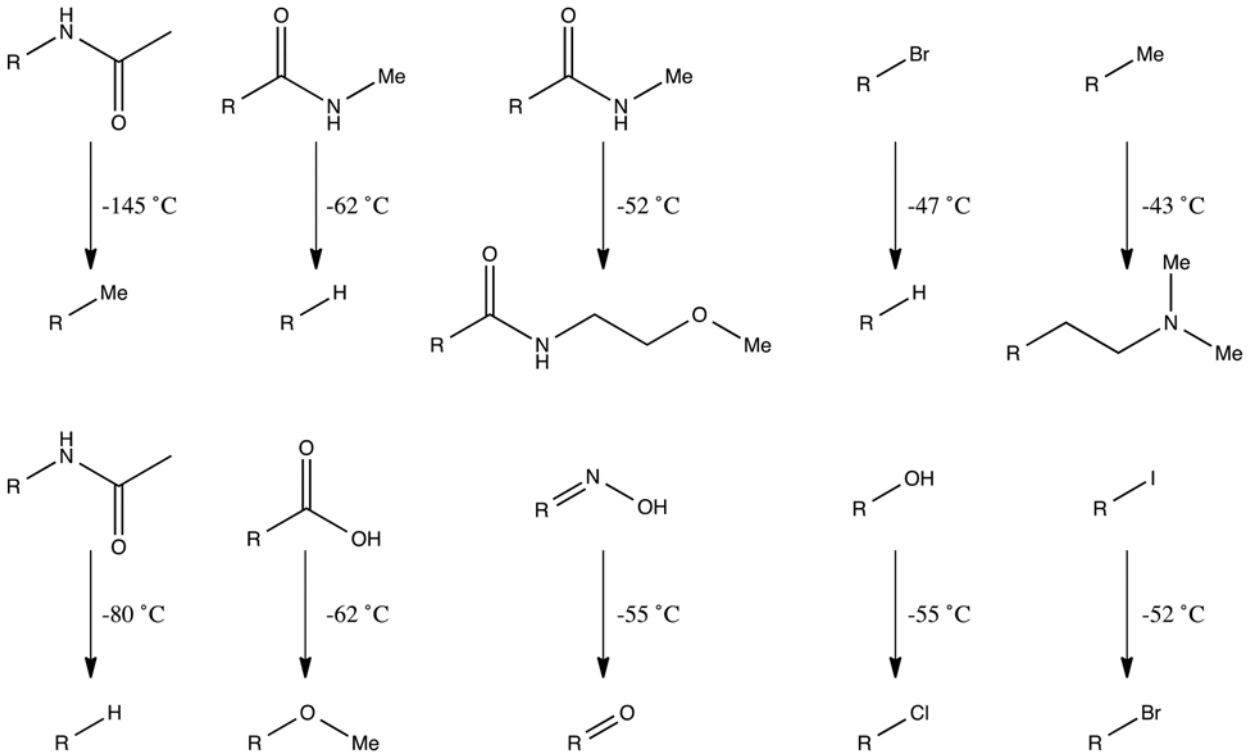

Fig. 26 The largest changes in melting point found for sets of at least five matched pairs.

Table 3 The influence of the structural changes shown in **Figs. 22** and **24** upon plasma protein binding

Substituent	*Br*	*Cl*	*F*	*OMe*	*Me*	*CN*	*CF_3*	*OH*	*SO_2Me*
Mean change in log(K_1) in Leach et al. (SEM)	+0.78 (0.07)	+0.54 (0.02)	+0.15 (0.01)	+0.02 (0.03)	+0.22 (0.03)	−0.06 (0.04)	+0.60 (0.07)	−0.24 (0.06)	−0.55 (0.08)

Substituent	*Amide*	*Amine*	*Alkyl alcohol*	*Phenol*
Mean change in log(K_1) (SEM)	−0.23 (0.03)	+0.17 (0.03)	+0.14 (0.02)	+0.09 (0.11)

that a significant increase in plasma protein binding should be expected for this change. In their investigation of the effect of inverting stereochemistry, Leach et al. discovered a measurable change in the extent of plasma protein binding between enantiomers.[3]

3.10.3.2.9 Lipophilicity (logD)

Changes in measured logD values are often used to support interpretation of other MMPA studies. The change in logD for a structural change permits its effect to be understood and rationalized and, more importantly, allows surprising results to be identified. Investigators who have studied experimentally measured logD by MMPA include Keefer et al. from Pfizer,[39] Haubertin and Bruneau,[31] Waring et al.,[14,15] Boström et al.,[27] Ritchie et al.,[43] and Dossetter and coworkers.[13,22]

Papadatos et al., in their investigation of the importance of chemical context, highlight the importance of certain electronic effects in overriding the usual expectations for the effect of a structural change on logD. For example, a nitrile group added ortho to an aromatic nitrogen atom generally increases logD, whereas addition to most other positions decreases logD. Leach et al. used logD as a benchmark for their studies of the influence of stereochemistry and found that it did not change between enantiomers, as was expected.[3]

3.10.3.3 Sharing Data Among Pharmaceutical Companies

Pharmaceutical companies rely upon keeping their databases of structures and measured properties secret in order to gain a competitive advantage and to protect their intellectual property. These databases contain a great deal of useful knowledge, and many

scientists have long lamented the unwillingness of the companies to share these data. As has been pointed out, MMPA transforms structures into changes in structure and measured property data into changes in property.[38,45] These differences rather than original values contain a great deal of useful information to drug designers but crucially do not disclose any original structures or measured values. As a consequence, they can be shared among companies. The company MedChemica has been facilitating data sharing between companies using exactly this principle. One of the more interesting consequences is that there is the potential when sets of pairs are brought together for the result to be more than the sum of the parts. Sets of pairs that are found to have a significant effect upon a property are referred to as rules.

In an investigation of this cooperativity of datasets, Kramer et al., in their analysis of hERG datasets from ChEMBL and Novartis, compare the derived mean changes in pIC_{50} using ChEMBL data to the mean changes for analogous sets of pairs found in their in-house data and find good agreement. There are some pairs that fall outside the expected range, but when they include a correct treatment of the expected variation by including the experimental variation in their considerations, these outliers are no longer found to be significant. All 69 sets of pairs found to be significant within both sources of data are found to correspond to the same direction of change. Adding ChEMBL homogeneous sets to the Novartis sets (which are all homogeneous) provides a significant enhancement in the dataset. There are 286 sets from Novartis, which become 393 after merging. It is interesting to note that when they are merged, 132 sets that were not significant become significant, but 25 that were lose significance. They do not report the outcome when considered from the other direction of how many pairs become significant or lose significance from the starting point of the ChEMBL set of pairs. There were 227 sets of pairs that were significant but not common to the Novartis set. Their analysis suggests that there has been an increase in the number of significant sets of pairs of between 37% and 116% overall.

When MedChemica arranged the sharing of physicochemical and in vitro pharmacokinetic data between three pharmaceutical companies, they found that there was generally a very substantial cooperativity between datasets. This means that each contributing partner gains on several fronts: if they did not have MMPA on their own data, this is generated giving them all the rules from their own data; they then get all of the rules from the other contributing companies; finally, they get the rules that did not exist until the data were shared. The latter category is often found to be the largest suggesting that the sharing process has generated an inherent benefit.

3.10.3.4 Elucidating Relationships in 3-D

One of the most exciting recent trends in MMPA has been to take the analysis into three dimensions. A number of reports have described tactics for translating the information extracted from MMPA into the three-dimensional context of a binding site or else into the optimal positions for pharmacophoric features.

One of these approaches, styling itself VAMMPIRE, relates changes in ligand structure to their protein context.[59] This work, by Weber et al., extracts data from the PDBbind database and ChEMBL.[75,76] The PDBbind database limits the sets of targets to those with high-quality crystal structure data available. The targets that are present in PDBbind were then located in ChEMBL, and the relevant information for ligand binding was extracted. The set excluded covalent binders, and where there was more than one value reported for a compound, the median was taken unless the values spanned a range of more than an order of magnitude in which case the compound was discounted from the analysis. Matched molecular pairs were identified within the resulting dataset using the MCSS approach, with the changing part constrained to have less than half the number of heavy atoms as the fixed part.

The key assumption of the VAMMPIRE approach is that matched molecular pairs will share a retained binding mode. The binding mode for each is found by overlaying the shared fixed part with a ligand that is present in the PDBbind set. In this way, the calculation of the MCSS serves a dual purpose; it identifies pairs and then permits their binding mode to be predicted. Having positioned the fixed part of each ligand by comparison to a structure with known binding mode, the changing part of each ligand is then constructed using the MOE pose refinement protocol.[77] Once positioned, the environment for this changing part is defined by identifying the three nearest amino acids (that are within 5 Å); any nonnatural amino acids are excluded. This protocol, as originally described in 2013, yielded 8972 matched pairs split across 142 targets. Unfortunately, most sets of pairs had only one pair, so that the usual statistical power of MMPA does not apply. However, by encoding the environment, they are able to use this to make links to pairs in other targets. This is an important attempt to tackle one of the great outstanding challenges of MMPA—identifying structural changes that will retain or enhance potency. They exemplify the method with an example from inhibitors of cyclooxygenase-2 in which SAR from factor Xa and thrombin was transposed to make suggestions about beneficial changes to make to the celecoxib series.

The same authors have subsequently expanded and updated the VAMMPIRE approach.[60] By allowing a conservative set of structures to be generated by docking and crystallography, the set has been expanded to 17,602 pairs. These are subdivided into the following:

Type I: both molecules in the pair are available in crystal structures of the appropriate protein–ligand complex. These account for 10% of the pairs.

Type II: one molecule in the pair is available as a crystal structure, and the second is inferred from a docking pose that places the fixed part (when evaluated as a matched pair with the crystal structure by MCSS) in such a way that the RMSD between the two is less than or equal to 1 Å. These account for 20% of the pairs.

Type III: both binding geometries are generated by docking but where one of the molecules in the pair is also a member of a type II pair. The second molecule's position is then treated analogously to the crystal structure in a type II pair. These account for 70% of the pairs.

As in the original VAMMPIRE paper but in a more specific way, the substituents and their environments are encoded. The user can specify a compound, a receptor, and a substituent of interest. The database is then searched for the same substituent in similar environments, and the SAR from those positions is presumed to have a high likelihood of transferring to the query molecule. A small-scale validation was performed to show that the more similar the substituent environment pairs are (as encoded in a new fingerprint introduced by the researchers), the more likely it is that correct SAR trends will be predicted. In a test using cyclooxygenase-2, 25 substituents were predicted to increase pIC_{50} by at least 0.5; 18 of these predictions were correct and seven incorrect. This protocol is made available as a Web server under the name VAMMPIRE-LORD.[63]

An alternative approach to a similar aim was taken by Posy et al.,[49] who assumed that any compound that has a binding mode revealed by crystallography in any kinase will adopt the same binding mode in any other kinase; their work was focused particularly on studying inhibitors of p38α. Some detailed studies were undertaken in order to investigate this assumption. They used the set of protein–ligand crystal structures in which the same ligand is bound to different targets and concluded that in 88% of cases, exactly the same binding mode is adopted and in 97% of cases, the binding modes are similar enough to be usefully classed as identical. The binding positions were compared using a method that computes the difference in shape and "color" where color is an assessment of the positioning of atom types of different pharmacophoric types. These comparisons provided a cutoff above which the binding mode can be considered the same. This same protocol could then be used to identify ligands that can adopt the same binding mode. Large sets of conformations were generated, and the best shape + color overlay with the most similar ligand that has a crystal structure available was selected as the likely binding mode. Only those ligands that achieve a required level of overlay were retained. This permits the SAR that has been found to be translated into three dimensions. A three-dimensional version of the fragment and index approach to matched-pair finding was adopted. Pairs are encoded according to the position of the attachment point, and attachment points that are within 1 Å of one another are clustered together; no constraints are placed on whether the substituent protrudes in the same direction or not. A large number of compounds can be incorporated into this approach, compared with other three-dimensional methods. The method has analogies to the BREED approach to processing crystal structures.[78] To exploit the set of structures, the user can select the structure of any compound and select a substituent. The system then recalls all substituents that have an attachment point within 1 Å and assumes that the structure–activity relationship from the corresponding compounds can be translated to the query molecule. They exemplified the approach with an i-Pr to c-Pr amide switch that gave a sevenfold improvement in potency against p38α. The results came from a set of pairs in which the c-Pr had replaced any other substituent, but in 79% of these cases, the potency had increased. The technique could also be used in the inverse fashion to identify cases where changing one substituent to another has the same effect on different cores, thereby identifying series with SAR transfer. The approach generates a three-dimensional map of the binding site with annotations indicating the regions in which change is tolerated and those where it is not.

A third approach to translating MMPA into three dimensions was described by Bradley et al. who studied inhibitors of the kinase CDK2 and of SAM methyl transferase.[47] They devised a method that will be applicable when a great many protein–ligand crystal structures are available. All matched pairs are identified in which one member of the pair is a crystallographically studied ligand. The pairs are identified by a fragment and index method. The fixed part is assumed to bind in identical locations for the two members of the pair. A set of 100 conformations for the changing part of the noncrystallographic compound is generated. The conformation with the highest shape overlay with the crystallographic ligand is selected. The structure is annotated by pharmacophoric features and whether potency increases or decreases. A three-dimensional visualizer presents the array of pharmacophoric points around a query molecule annotated according to the feature type and whether they correspond to increased or to decreased potency. These can come from any series and need not be due to molecules that are similar to the query. Indeed, the query may have no matched pairs available. The user is therefore presented with clear trends for which pharmacophoric features are favored in each part of the binding site. For example, the visualization might highlight that hydrogen-bond acceptors in one part of the site are associated with a loss of potency. The user will then know to avoid placing acceptors at that point or to remove any that are already present. The method is illustrated with some convincing examples in which consistent SAR within two different binding sites is clearly mapped. Unlike with two-dimensional SAR, statistical power is not directly available, but an array of similarly encoded points in three dimensions in close proximity is a useful three-dimensional analog.

3.10.3.5 Elucidating Pharmacophores

One means by which sets of pairs can be grouped together in order to make useful connections is to make the structural encodings more "fuzzy." One mechanism by which this can be achieved is by encoding the pharmacophoric elements of a molecule into a reduced graph, as illustrated in **Fig. 27**. By comparing these reduced graphs rather than full structures, MMPA can make connections between molecules, which it otherwise would not. Geppert and Beck explored a number of means by which this might be achieved.[45] They analyzed the ChEMBL data for inhibition of four isoforms of the cytochromes P450: 2C19, 2C9, 2D6, and 3A4. Compounds were classified as active or inactive. Lipinski's SMARTS patterns were used to encode the pharmacophoric elements in each molecule. Matched pairs were identified using the Hussain and Rea fragment and index approach. The changes in inhibition between molecules in a pair were processed in several ways that all entail a degree of "fuzziness."

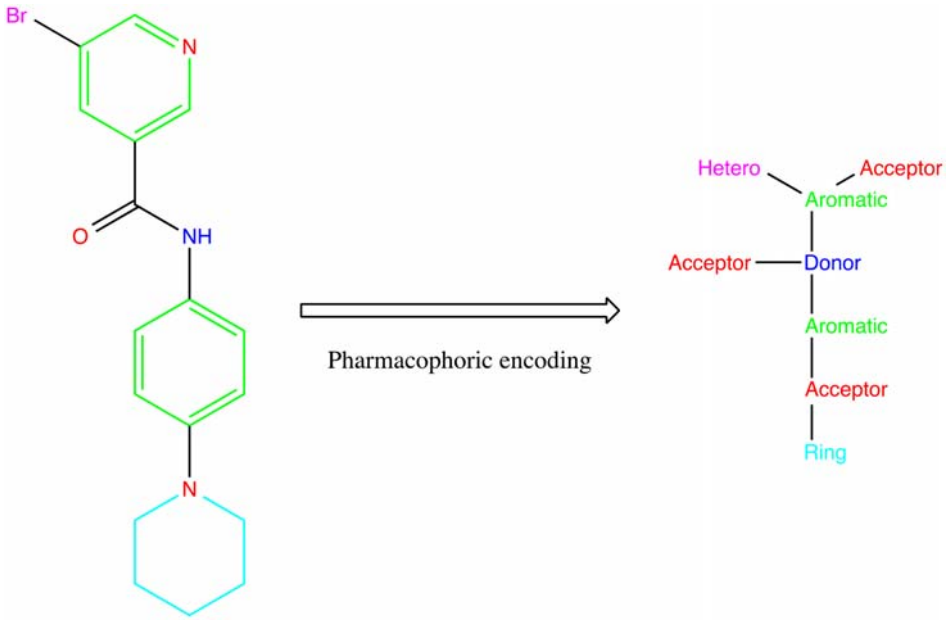

Fig. 27 The encoding of a molecular structure as a reduced graph of pharmacophore features.

The first type of grouping by pharmacophores saw Geppert and Beck define the context for the matched pair by the pharmacophoric encoding of just the attachment point. This is an abstraction of the context definition suggested by Papadatos et al.[40] The next level of abstraction was styled "value fuzzy matched pairs" in which the changing part is examined and pairs are grouped if the change in pharmacophore encoding is the same. This permits many sets of pairs to be grouped together and provides statistical advantages that are set against a reduction in chemical fidelity. Finally, full "fuzzy matched pairs" use the pharmacophoric encoding as shown in Fig. 27 as an input to pair finding, and thus, many more connections are made between compounds with different cores and substituents. This has a double advantage: it not only enhances the statistical strength of many observations but also naturally identifies the pharmacophoric requirements that certain properties have.

An alternative method for identifying the pharmacophoric requirements of certain properties is provided by the work of Bradley et al. who studied molecules in three dimensions and who use MMPA to generate maps of a binding site in which the preference for certain pharmacophoric elements is shown.[47] This method is described in the "**Elucidating Relationships in 3D**" section concerning three-dimensional approaches.

3.10.3.6 Matched Series

When identifying matched molecular pairs, it is quite possible to find that there are many compounds that have a shared fixed part. In MMPA, this information is not capitalized upon, but O'Boyle et al. have highlighted that there is a great deal of value that can be gained by setting each pair within the context of a broader series. For instance, there are (at least) two ways to study the effect of exchanging X_1, X_2, X_3, and X_4 as shown in Fig. 28. The matched-pair way would be to individually study X_1 being transformed into X_2 and then study X_2 being transformed in X_3 and separately X_1 being transformed in X_3. In each set of matched pairs, there might be a different number of pairs in the set. An alternative would be to identify sets with the same fixed part (R in Fig. 28) and thus generate a matched series in which all members are represented by the same number of compounds. This reduces the number of compounds under consideration and hence diminishes the statistical power for each pair, but this is set against an enhanced insight that is provided by placing the pair within a series.

The approach introduced by O'Boyle is styled Matsy and is applied to studying the reported ordering of particular substituent types according to which is the most potent.[52] Matched series are identified using Hussain and Rea's fragment and index method. They highlight some very useful insights that can be gleaned from matched series that address the biggest gap in MMPA—determining which changes are likely to increase potency. The set of substituents H, F, and Cl could correspond to compounds whose potency is ordered in one of six ways: F > Cl > H, F > H > Cl, Cl > F > H, Cl > H > F, H > F > Cl, or H > Cl > F. Some of these orderings are

Fig. 28 An example of a matched series.

observed much more frequently than others; H > F > Cl is the most common in this case. Moreover, this variable frequency allows predictions to be made about whether bromine is likely to be worth making. For instance, when the ordering H > F > Cl has been observed, Br has only been more potent in 7% of cases. Such series naturally provides guidance about what to make next (in terms of potency). The authors also describe the observed frequencies of ordering for small alkyl groups methyl, ethyl, *n*-propyl, and *n*-butyl. They highlight the interesting case of ethyl > *n*-propyl > methyl and suggest that if such an ordering has been observed, the best substituents to make next include *t*-butyl and cyclopentyl.

This work is a natural complement to the decision tree proposed by Topliss, which was based upon the lipophilic and electronic properties of various substituents.[7] O'Boyle et al. find that in many cases, their suggestions of what to make next agree with those proffered by Topliss but that there are some deviations. In more general terms, they suggest that the longer the matched series used to make deductions is, the more likely it is that correct predictions will be made. In a remarkable finding, they investigated the link between series ordering and physical properties and found that there is little link. Indeed, they find in their survey that lipophilic ordering more often gives the reverse ordering than it does exactly the correct ordering.

3.10.4 Related Approaches

3.10.4.1 Activity Cliffs

One interesting subset of matched molecular pairs is those in which the change in property is surprisingly large. A number of researchers, most prominently the Bajorath group in Bonn, have reported the insight that these pairs, which they call activity cliffs, can bring. Notable recent contributions include using Hussain and Rea's fragment and index method to identify matched series within all the high-confidence ChEMBL K_I data relating to activity against human targets. These reveal that coordinated activity cliffs can be identified in which the same structural change causes the same large change in property across several chemical series.[50] A similar method can be used to explore activity within large sets of screening hits.[51] Activity cliffs are analogous to the switches highlighted by Keefer et al. in their analysis of in-house data from Pfizer, which is discussed earlier.[39] Similarly, in their analysis in which they searched for similar compounds that had different kinase inhibition profiles, Milletti et al. and Chen et al. were locating activity cliffs considering multiple-target data rather than a single property.[79,80]

3.10.4.2 Bioisosteres

Bioisosteres have a long history in medicinal chemistry and have been identified as critical to the success of many drug discovery efforts.[81,82] MMPA has provided an approach to both evaluate and discover bioisosteres. For instance, Birch et al. were able to evaluate the effect of the common bioisosteric change of carboxylic acid with tetrazole and discovered that a significant increase in plasma protein binding is generally associated with this change.[21] One of the scientists who have contributed most to the science of bioisosteres in recent years, Brown, has highlighted the value of MMPA for identifying bioisosteres, and this was also discussed in a perspective article by Griffen et al.[73,83] In essence, when investigating the effect that changes in structure have upon properties, the focus is most often on those structural changes that can be determined to change the property, but there is also value in those properties that positively do not change a property. These changes though are more challenging to detect; a change in property can be found not significant because it genuinely does not change the property or because there are not yet enough data to detect that change. These two causes are difficult to disentangle and remain a work in progress for many in the MMPA field. One of the applications of the SwissBioisostere database is to identify sets of pairs in which a particular substituent has been changed many times and the potency has only changed by less than 0.5 log units in any direction. This is the origin of its name and is one of the applications to which the tool can be put. Some of the earliest efforts to consider the comparisons between molecules as a guide to discover bioisosteres were by Sheridan and Ertl who were investigating the prevalence of particular group types and transformations in medicinal chemistry.[33,84]

3.10.4.3 QSAR

One of the connections that have been made most often with MMPA is with QSAR. Both techniques can be used to make quantitative predictions about the properties of a particular molecule. This was compared by Griffen et al., who highlighted the reduced challenge involved in predicting differences in property rather than whole molecule properties.[73] Warner et al. also compared MMPA and QSAR in their study of how to predict potency against two ion channels, hKCNQ1 and hKCNE1. They found that QSAR using a random forest approach was less well able to predict the properties, giving a larger RMSE than MMPA. By contrast, oral reports of work undertaken at Pfizer have suggested that sometimes QSAR can outperform MMPA because it utilizes much more of the data than MMPA that only uses the small amount of data that are appropriate to each structural change.[85] As with much of the discussion earlier, the challenge is to find the optimum trade-off between data quantity and chemical specificity. A recent trend has been to incorporate QSAR more directly into MMPA. For instance, Sushko et al. used property values generated by QSAR for MMPA modeling.[36] An alternative method to permit QSAR to extend the scope of MMPA was shown by Beck and Springer who devised a means to encode structural changes and then built QSAR models for the mean values for the change in property.[86] In this way, they are able to predict the mean change for any structural change, whether it is exemplified or not.

3.10.5 Summary and Outlook

MMPA is about a decade old and as such is relatively young. New developments and directions are being proposed and investigated all of the time. Particular recent highlights include the translation of MMPA into three dimensions and the introduction of structural abstraction, which permits data to be grouped in new ways that remain relevant to medicinal chemistry. We are particularly excited to have demonstrated that MMPA can provide a vehicle for pharmaceutical companies to share data among themselves and to the benefit of others.

We look forward to improvements on many levels. At the algorithmic level, there remain issues about the scalability of pair finding and the storage of the resulting information (what form permits the most efficient exploitation by users). Advances in hardware and software will address some of these, but algorithmic innovations are likely to help too. There remain challenges about how matched pairs are encoded; while each organization has their own method, there remains a language barrier between them, and we feel certain that some standardization here would help. It is clear that a number of ideas for expanding matched pairs into three dimensions have been explored but that these require some refinement and integration in order to obtain the best insights for users. Similar efforts are likely required for the related area of pharmacophores and other structural abstractions. In general, the next decade is likely to see many of the techniques, which are described earlier in their pioneering forms become routine. We believe that MMPA is a necessity for any pharmaceutical company with large sets of data. These can be worth much more when useful knowledge is extracted via MMPA.

3.11.1 Introduction

Biological activity of drug-like molecules is determined by their interaction with biological targets. In turn, ligand recognition by a biological target depends on a number of factors, both enthalpic and entropic in nature. Enthalpic contributions are represented by van der Waals, electrostatic, and hydrogen bonding interactions, while the main entropic contribution is the hydrophobic effect arising from the desolvation step which precedes the formation of a ligand–target complex. While desolvation of highly structured water networks in contact with nonpolar surfaces gives a favorable contribution to binding, desolvation of polar surface segments is unfavorable, and is often only partially compensated by electrostatic and hydrogen bonding interactions established upon complex formation. The currently accepted view is that the hydrophobic effect is the term which contributes most to the free energy of binding, while electrostatic interactions and hydrogen bonds provide specificity.[1]

Molecular interaction fields (MIFs) are a useful tool for characterizing the ability of molecules to interact with other molecules.[2] Their usage in computational and medicinal chemistry has been introduced in the late 1970s by Cramer and Milne,[3] and developed by Cramer and Goodford over the following decade.[4,5] MIFs provide a very convenient way to focus on the enthalpic side of binding interactions as determined by the three-dimensional structure, while at the same time abstracting from the latter; in the following paragraphs, this statement will be expanded and made clearer.

An MIF is a collection of energy descriptors associated with 3D coordinates. The standard way to generate MIFs is to compute the interaction energy between a probe and a target, which may be a ligand or a biological macromolecule, at different positions in space. The nature (hydrogen bonding, electrostatic, van der Waals, hydrophobic, etc.) of an MIF depends on two main factors: (1) the chemical nature of each atom in the probe and in the target (typically defined through atom type/partial charge for force-field-based calculations, or just the element and the total formal charge for MIFs derived from quantum mechanics (QM)) and (2) the potential function used to compute the interaction energy.

The coordinates of each atom in the target and the coordinates at which energy values are sampled influence both the magnitude and the distribution of energy values in 3D space. While both the chemical nature and the 3D arrangement of the atoms involved in the calculation determine the properties of an MIF, collections of atoms which differ in chemical nature and 3D coordinates may give rise to similar MIFs. This explains how MIFs can abstract from the underlying chemical structure of molecules to capture the interaction properties which drive molecular recognition. Most importantly, MIFs inherently encode the concept of bioisosterism, and enable its application both on the ligand side (3D similarity, scaffold hopping, biological activity prediction), and on the target side (binding pocket characterization, cross-target structural homology identification).

MIFs address only the enthalpic contribution to the free energy of binding. Attempts have been made at modeling the desolvation term indirectly through the choice of appropriate probes, designed to detect hydrophobic regions and apply desolvation energy bonuses/penalties depending on their degree of hydrophobicity.[6] Fortunately, the realm of application of MIFs makes the lack of explicit support for the entropic component much less of a limitation than it might appear. An accurate estimation of entropy is crucial to the prediction of absolute binding free energies, but that is not among the goals for which MIFs were designed. To a large extent, molecules which share a significant similarity in their 3D Coulombic and van der Waals potentials implicitly share a similar desolvation behavior.

The wide range of interaction properties which may be computed through different probes/potential functions and the capacity to abstract from the chemical structure of the underlying molecule are among the main reasons for the continuing success of MIFs in drug discovery.[7] In the following, the main applications of MIFs will be reviewed, under separate sections depending on whether they involve mostly small molecules (ligand-based, LB) or biological macromolecules (structure-based, SB). We are aware that there is some degree of overlap between the two fields; nonetheless, we believe that the SB/LB distinction is both helpful and particularly relevant for the pure LB methodologies, which are the only option when the structure of the target is not available. Applications are presented in alphabetical order, along with relevant case studies and success stories. We realize that our list cannot be exhaustive within the scope of this article; we will therefore focus on those methods which have gained more widespread recognition within industrial and academic environments. In describing methods, we deliberately refrain from reporting the mathematical equations, which can be retrieved by the interested readers from the original literature references.

3.11.2 Ligand-Based Applications

All of the MIF-based methodologies cited in this section can be applied in the absence of any structural information about the target and hence can be regarded as purely LB applications. Nevertheless, some of them may usefully incorporate information from the target, if the latter is available; this possibility will be mentioned where appropriate.

3.11.2.1 Assessment of Ligand Similarity

Methods described in this paragraph present a theoretical framework, either based on QM or on molecular mechanics (MM), to assess MIF-based pairwise 3D similarities between small molecules. The first step of these calculations consists in maximizing the overlap between the MIFs of the two molecules through appropriate geometric transformations. As a consequence of these transformations, the underlying molecular structures are aligned based on their field properties. The first attempts to move from an atomistic description of a molecule to a structure-agnostic description founded on steric and electrostatic overlap were made

in 1990 by Kearsley and Smith[8] and by Cramer.[9] In the approach pursued by Kearsley and Smith in the SEAL program, electrostatic and volume descriptors were still connected to individual atoms, while Cramer introduced the concept of using grid-encoded MIFs to superimpose molecules in his Field Fit procedure, as a preliminary step to a comparative molecular field analysis (CoMFA).[9,10]

Over the 25 years which followed these groundbreaking intuitions, a large number of variations on the original methods have been published. The earlier approaches are covered by other reviews, one of the most comprehensive being the one by Lemmen and Lengauer,[11] so only the main points which are either distinctive or common to these methodologies will be summarized here.

The most significant differences involve the theoretical framework used for electrostatics (QM, MM with atom-centered charges (ACCs), MM with more sophisticated charge distributions) and the formalism chosen to describe potentials (numerical evaluation on a discrete number of points versus analytical calculation of atom-centered Gaussian functions). Elegant and computationally efficient, the analytical, Gaussian-based description formalized by Grant and Pickup[12] has become the standard method to assess and compare molecular shape. However, the early attempts by Good et al.[13] and Mestres et al.[14] to apply Gaussians to electrostatic potentials have largely been superseded by numerical descriptions based on discrete sampling, either on the nodes of a regular grid lattice or on a solvent-accessible surface. The reason is that analytical Gaussians describe very effectively fields which can be approximated by overlapping spheres, such as atomic van der Waals volumes, but are less suited to probe-based MIFs.

The common goal of MIF-based methods is to convey the degree of field similarity into a normalized score, ranging from 0 (no similarity) to 1 (identity) through a distance metric appropriate to the functional form used to compute and sample MIF potentials (e.g., Carbó, Tanimoto, Dice[15]). Summarizing the similarity in a single number enables straightforward computation of pairwise similarity matrices, which are the starting point for several clustering algorithms and chemometric data analysis techniques. However, since similarity is assessed in 3D taking into account the whole molecule MIFs, there is actually much more information about the nature and the distribution of local similarities than can be captured in a single number. This information can be conveniently visualized by plotting field isocontours, or color-coding molecular surfaces based on the field nature/value.

The following subsections will briefly describe three recent MIF-based methods to assess molecular similarity, representative of varying degrees of theoretical rigor in the description of molecular interactions and different computational approaches to similarity calculation and optimization.

3.11.2.1.1 *COSMO*sim3D

The COSMO*sim3D* method stems from COSMO-RS,[16,17] a widely used implicit solvation theory which allows the prediction of fluid phase thermodynamic properties of molecules based on QM calculations in a simulated conductor. Following a COSMO-enabled QM calculation, each molecule is characterized through a distribution of surface polarization charge density (σ). The molecular surface is tessellated into several hundred segments, each having defined coordinates, area and average σ charge density. The statistical distribution of the σ charge density across the 3D surface can be captured into a σ profile, a one-dimensional σ charge histogram, usually with a σ bin width of 0.1 e nm^{-2}. The area of each surface segment is assigned to the various bins of the histogram through a smooth and charge-conserving weighting scheme, such that the integral of the σ profile yields the total surface of the molecule, while the σ-weighted integral sums up to the total σ charge of the molecule. The σ profile provides a quantitative description of the amount of surface area of given polarity within a molecule (**Fig. 1**).

σ profiles have proved very valuable to quantify the ability of a molecule to give different types of interactions in the condensed phase. Furthermore, fast molecular similarity assessment through comparison of the 1D σ profiles is enabled by the COSMO*sim* methodology.[18] However, by design no information is included in the σ profiles regarding the localization of the patches with given polarity on the 3D surface. To overcome this limitation, the COSMO*sim3D* method[19] was introduced, which augments the description of the σ charge distribution for a molecule from a single 1D profile to a 3D grid of local σ profiles, one per each node of the grid (**Fig. 2**). The procedure through which σ surface segments are assigned to the grid nodes follows a weighting scheme similar to the one used to generate 1D σ profiles, just extended to three dimensions; the weighting ensures smooth linear interpolation and robustness against changes in the positioning of the 3D grid relative to the molecule. The COSMO*sim3D* procedure effectively yields a 4D description of a molecule, which may be regarded as an array of 3D MIFs, each MIF corresponding to one of the σ bins into which the local σ profiles are partitioned, and describing the 3D distribution of field intensity within the σ bin range.

As detailed in section "Assessment of Ligand Similarity", the 3D grid of local σ profiles enables pairwise 3D similarity calculations by maximizing the overlap between the grids to be compared. This is a global optimization problem, which has been tackled in COSMO*sim3D* by a Monte Carlo approach: *N* different starting configurations are optimized by a local line search along the direction of each of the three unit translations and rotations until a similarity maximum is reached; the highest similarity across the *N* samples is taken as the global similarity optimum. The superimposition of the 3D σ profile grids causes the underlying molecules to become aligned to a single or multiple references (**Fig. 2**).

The generation of a σ surface requires a single-point density functional theory (DFT) QM calculation, which can be carried out at different levels of theory, the more computationally expensive giving more accurate results. While the absence of adjusted parameters apart from the atomic COSMO radii warrants applicability to virtually any kind of chemistry, imparting a significant advantage over MM methods, the time requirements can be significant for larger datasets and/or flexible molecules which require multiple conformations to be considered. The COSMO*frag* procedure was developed to speed the procedure by quickly reconstituting a σ surface from precomputed fragments. While this causes a slight degradation of the surface quality due to imperfect match of the surface fragments, the actual impact on the similarity assessment was shown to be negligible.[19] In case fragments for the

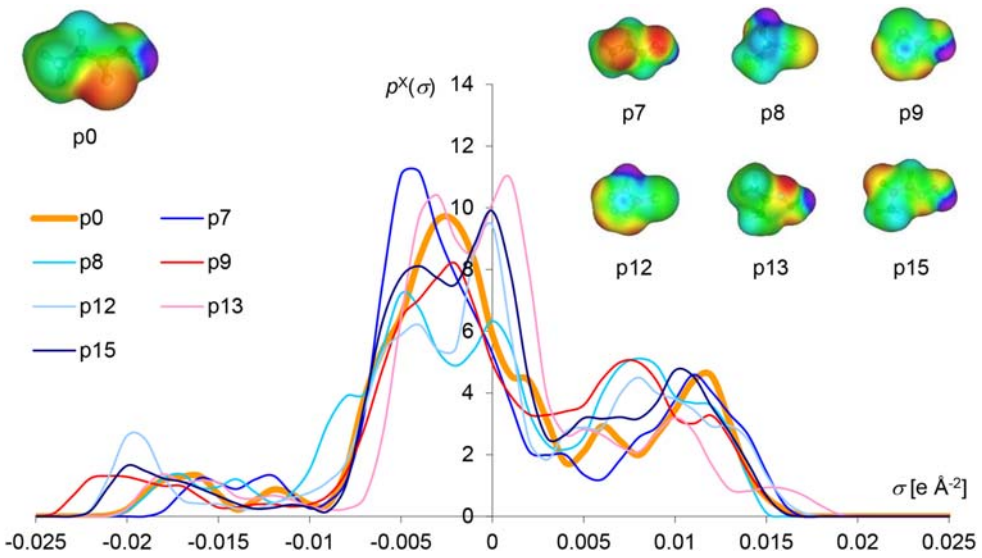

Fig. 1 The σ profile of propionic acid (p0) is compared to the σ profile of six other small molecules (p7, p8, p9, p12, p13, and p15). COSMO surfaces of the seven molecules are depicted, color-coded based on the distribution of their surface properties: strongly negative (*red*), strongly positive (*blue*), or nonpolar (*green*). The chart reports the amount of COSMO surface within a given interval of σ polarization charge density for each molecule (Adapted courtesy of A. Klamt, personal communication).

chemistry of interest are not available in the precomputed fragment database, the database can be extended or the procedure may fall back to the full DFT calculation on the whole molecule.

COSMO*sim3D* was validated in two exercises.[19] Firstly, its ability to separate true bioisosteric pairs from decoys was assessed on the BioSter database,[20] finding that 95% of the decoy pairs had similarities <0.2, whereas the true bioisosteres scored significantly higher. Setting a cut-off value at 0.2 similarity would retrieve only 5% false positives from the decoy set, and miss about 30% true positives in the true-bioisostere set (**Fig. 3A**). Secondly, the ability to identify ligands sharing at least one activity class based on their similarity was evaluated. Approximately 215 K structures were extracted from the MDDR database[21] and used to compute a pairwise similarity matrix by comparing their 1D σ profiles by the COSMO*sim* method. All pairs with a COSMO*sim* score >0.9 were subjected to a conformation/tautomer enumeration and then underwent a COSMO*frag*/COSMO*sim3D* similarity calculation. For COSMO*sim3D* scores <0.1, the probability for the molecule pair to share at least one activity class was in the 7–10% range, very close to the value obtained for random pairs drawn out of the MDDR database. Instead, the same probability increased to 50% for a similarity of 0.3, and to 80% for COSMO*sim3D* similarities of 0.45 (**Fig. 3B**).

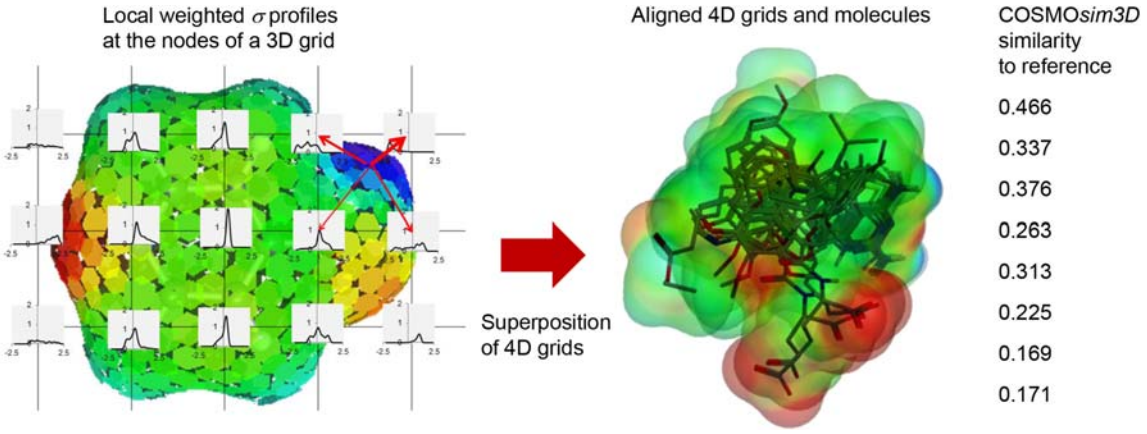

Fig. 2 For each molecule in a dataset, local σ profiles are computed at each node of a 3D grid (a 2D section is shown for clarity). This procedure yields a four-dimensional description of each molecule; superimposition of the grids causes the underlying molecules to be aligned against one or multiple reference(s) and yields a similarity score for each alignment. (Adapted courtesy of A. Klamt, personal communication).

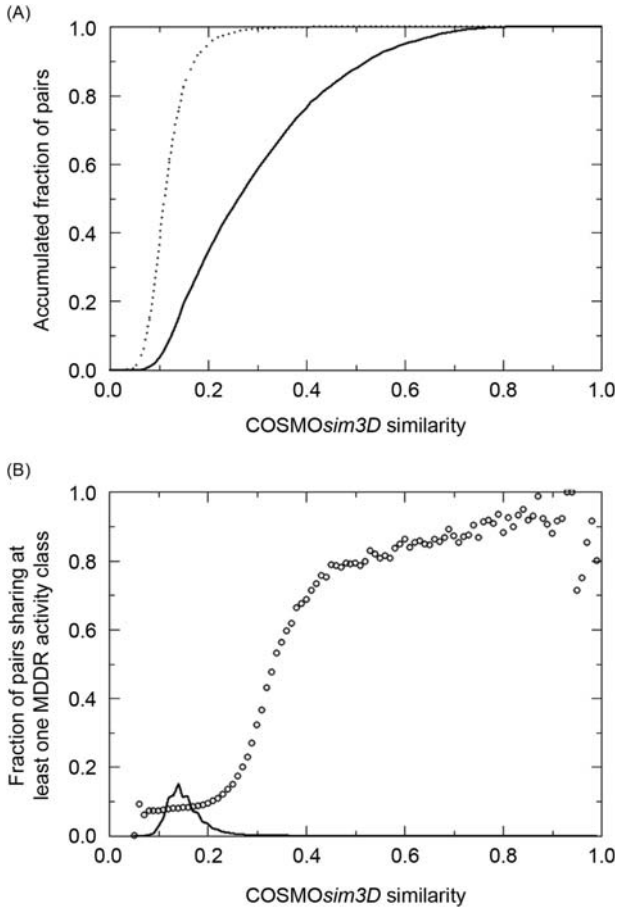

Fig. 3 (A) COSMO*sim3D* ability to separate true bioisosteric pairs (*solid line*) from decoys (*dotted line*) as assessed on the BioSter database. Setting a cut-off value at 0.2 similarity would retrieve only 5% false positives from the decoy set, and miss about 30% true positives in the true-bioisoster set. (B) COSMO*sim3D* ability to identify ligands sharing at least one activity class. When COSMO*sim3D* similarity is <0.1, the probability for the molecule pair to share at least one activity class is $<10\%$, while increasing to 50% for a similarity of 0.3, and to 80% for a similarity of 0.45. The solid line shows the distribution of COSMO*sim3D* similarity values within all tested pairs. Model.* **2012**, *52*, 2149–2156. ACS Publication.

3.11.2.1.2 GRID/FLAP

The GRID program by Goodford[5] was the first to introduce the idea of generating an MIF using a probe which is not a simple neutral atom, but rather a more sophisticated and parametrized entity. In some cases, probes can be multiatomic with a predefined geometry, relevant for directional interactions such as hydrogen bonds. The original application for which the GRID force-field was developed was mapping protein-binding sites (see section "GRID/FLAP"), but the methodology has since been widely applied on small molecules. The molecular system under study is embedded in a 3D grid, a probe is placed at each node, and its interaction energy with the system is evaluated (**Fig. 4**). The range of available GRID probes covers the properties of functional groups commonly found in drug-like and biological molecules, and is meant to reproduce their interactions. GRID probe parameters are determined by the GRID force-field atom type of the constituting atoms; the atom type encodes hybridization, ACC, van der Waals and, when appropriate, hydrogen bond parameters. The GRID energy function uses a 12-6 Lennard–Jones potential for van der Waals interactions and a Coulombic potential for electrostatics; probes which can act as hydrogen bond donors and/or acceptors also feature an explicit hydrogen bonding term. In the latter case, a rotational scan is performed to optimize hydrogen bonding interactions with suitable partners around the probe. When parts of the target are treated as flexible, and therefore the loss of degrees of freedom upon binding needs to be accounted for, or hydrophobic/desolvation effects are to be captured, the energy function is augmented with an entropic term. This is particularly the case for the DRY probe which is tailored toward hydrophobic interactions. In this probe, the electrostatic term is replaced by an entropic term, while the hydrogen bonding potential is inverted to penalize interactions with polar surfaces.[5,6]

GRID MIFs have been used to compute pairwise 3D molecular similarity within the FLAP program.[22,23] The molecules are embedded in a 0.75 Å step grid box aligned to the principal axes of the molecule to avoid dependency from starting 3D Cartesian coordinates. MIFs are computed with a range of GRID probes, which normally include H (small, analyzes shape with good

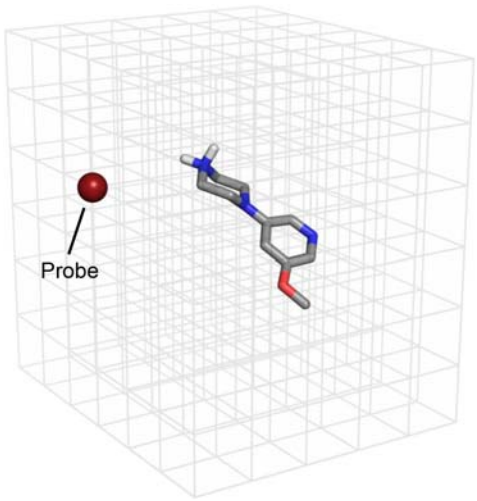

Fig. 4 Grid-based evaluation of the interaction energy between a molecular system and a probe placed at a grid node.

resolution), O (carbonyl oxygen, hydrogen bond acceptor), N1 (amide NH, hydrogen bond donor), and DRY (hydrophobic). The MIFs are then condensed into discrete points corresponding to the locations of energy minima, that is, the most favorable interactions, while providing adequate 3D space coverage across the molecule. These points are combined in four-tuples (quadruplets) according to all possible permutations, giving a set of MIF-based quadruplets. Another set of atom-based quadruplets is obtained out of GRID pseudoMIFs, which consist of electron-density-like fields associated to each atom. Each quadruplet identifies a tetrahedron with four vertices and six edges, whose volume and chirality can be computed (Fig. 5). The information contained in the quadruplet is stored in a fingerprint (FP), which consists of 11 fields encoding the 6 edge lengths (discretized as integer multiples of a small base length, such as 0.2 Å), followed by the indices of the four vertices (which allow accessing volume and chirality data), and finally by a value proportional to the sum of the energies of the four points. FP arrays are stored ordered by the first six fields (i.e., distances between minimum energy points) to enable fast searches. All possible quadruplet pairs are compared between the two molecules through their FPs; the FP pairs which match within a 1 Å distance tolerance and satisfy chirality constraints are used to overlay the molecules. The similarity between the molecules is assessed as the sum or the product of Tanimoto similarities of the individual MIFs, and the highest similarity value is retained as the 3D similarity score for the pair of molecules.[23,24] This methodology is fast enough to allow for similarity evaluations taking into account multiple conformations for each molecule.

3.11.2.1.3 XED/FieldAlign

The FieldAlign methodology[25] is based on the XED force-field.[26] In traditional force-fields, such as AMBER, CHARMM, MM2/MM3, MMFF94 and OPLS, the electrostatic term is modeled as a Coulombic potential generated by a collection of ACCs. ACCs are usually fitted to reproduce a QM-derived electrostatic potential, with the inclusion of appropriate constraints to evenly share charge on

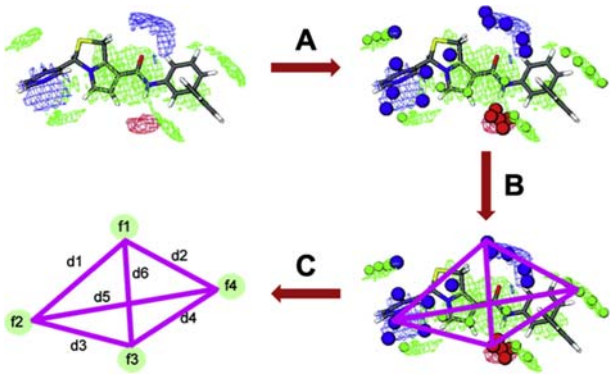

Fig. 5 GRID molecular interaction fields computed around the molecule are condensed into discrete points (A), which are then exhaustively combined into MIF-based quadruplets (B), identified by four vertices (*f1–4*) and six edges (*d1–6*) (C). Adapted from Figure 1 in Cross, S.; Baroni, M.; Carosati, E.; Benedetti, P.; Clementi, S. FLAP: GRID molecular interaction fields in virtual screening. Validation using the DUD data set. *J. Chem. Inf. Model.* **2010**, *50*, 1442–1450. ACS publication.

symmetric groups, such as in the RESP scheme.[27] However, the ACC model is rather crude, and fails to account for the properties of electronically anisotropic functional groups such as carbonyl. Also the interaction properties of aromatics cannot be correctly reproduced by ACC force-fields, with van der Waals stacking interactions dominating over the edge-to-face interactions experimentally observed in crystallographic complexes.[28]

To address these shortcomings, Hunter and Sanders introduced an innovative electrostatic treatment for aromatics, which models the σ-framework separately from the π electron clouds.[29] This paradigm is loosely reminiscent of the distributed monopole analysis (DMA),[30] and models the σ-framework through positive ACCs, while the π electrons are described by negative off-center charges. This model could successfully predict the geometry of intermolecular interactions in crystal structures of aromatic molecules, without the cost involved in computing a QM wavefunction. The seminal concepts proposed by Hunter and Sanders were implemented by Vinter in the XED force-field,[26] where the combination of traditional ACCs and off-center charges, termed XEDs (eXtended electron distributions), provides a computationally affordable way to describe electron anisotropy (**Fig. 6A**). The locations of the XEDs associated to each atom react to the local electrostatic potential, thus modeling molecular polarizability. A maximum of six XEDs is associated with each atom, the exact number depending on its type and hybridization. XED distances and charges were tuned on a number of complexes for which extensive experimental data was available, such as the acetone–water complex. Parameters derived on these specific test cases turned out to be generalizable, reinforcing the theoretical soundness of the XED model. Compared to ACCs, XEDs consistently led to better geometries and interaction energies, as the description of electrostatics is more coherent with the actual electron distributions and orbital shapes. In particular, remarkable successes were obtained in reproducing the experimental behavior of aromatic complexes (**Fig. 6B**).[28]

After undergoing extensive testing in the XEDRAW, XEDOCK, and XEDAST molecular modeling packages,[26] the XED force-field in its mature form was implemented in two programs, XedeX and XedMin, which are respectively a conformational search engine and a geometry optimizer. XedeX uses Monte Carlo randomization of torsions and library-based sampling for rings, falling back to molecular dynamics for rings not represented within the library.

The XED force-field provides the foundations upon which the FieldAlign methodology is grounded. Molecules are characterized through four MIFs, covering the different kinds of intermolecular interactions: (1) van der Waals (neutral probe, Morse potential);

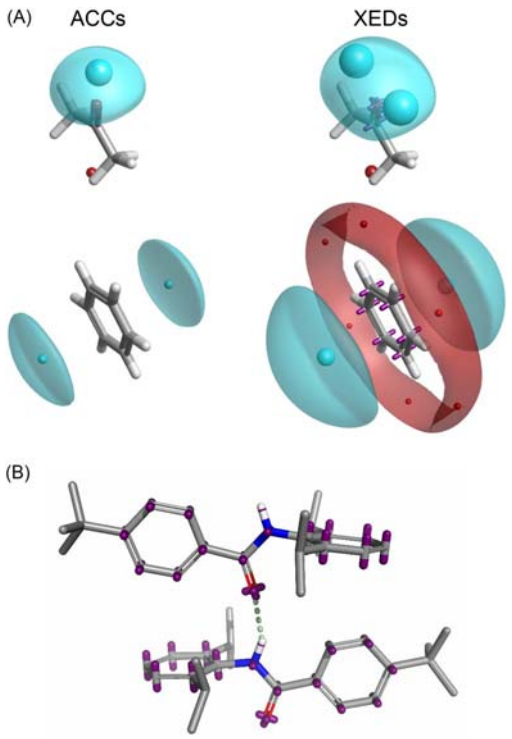

Fig. 6 (A) Comparison between electrostatic potential surfaces using ACCs (*left*) versus XED charges (*right*) for electronically anisotropic molecules such as acetone (*above*) and benzene (*below*). The XED model provides a more realistic description of the electrostatic potential distribution. XEDs are represented as purple dummy atoms; for atoms bearing XEDs, the partial charge is distributed across the atom itself and the XEDs. The XED coordinates can move independently from the respective atom in order to model molecular polarizability (see text). (B) Crystallographic complex of conformationally restricted benzamides which shows edge-to-face interactions between aromatic rings; hydrogens are hidden for clarity, while the hydrogen bond between amide groups is depicted as a *dotted green line*. Interaction enthalpies computed with the XED force-field have an excellent correlation with experimentally determined $\Delta\Delta G$ values ($r^2 = 0.95$), whereas the best ACC force-field, MM2, only achieves an r^2 of 0.69 (see Ref.[28] for details).

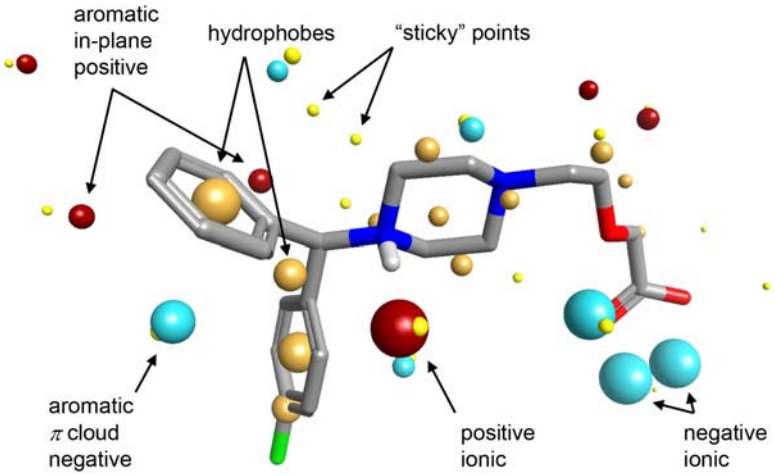

Fig. 7 Field points are shown for a drug-like molecule, cetirizine. While electrostatic and van der Waals field points are located in vicinity of the molecular surface, hydrophobic points are buried in the most hydrophobic regions. The extended charge distribution which characterizes the XED force-field allows a description of the interaction pattern of aromatic rings in good agreement with experimental and QM data.

(2) electrostatic (negative and positive probe, respectively, combined Coulombic and van der Waals potential, dielectric constant = 4); and (3) hydrophobic (neutral probe, attractive potential negatively weighted on atoms more electronegative than carbon and 0.5-weighted on hydrogens). In an attempt to condense the information contained in an MIF to a more succinct and computationally manageable form, the concept of field points was introduced. These four MIFs constitute collections of scalar interaction energies between a probe and the field generated by a molecule; such energies are sampled placing a probe at 120 points located at regular intervals over a slightly reduced solvent-accessible surface of each atom. At each point, the position of the probe relative to the molecule is optimized through a simplex to maximize the interaction energy. Many sampling points coalesce to common extrema, and after filtering out points with low interaction energy values a small set of "field points" is retained (usually comparable in number to the number of heavy atoms), which provides a 3D fingerprint of each molecule. Field points are visually represented as spheres whose color depends on the field type (*red*: electrophilic centers; *blue*: nucleophilic centers; *yellow*: van der Waals, or "sticky", points; *orange*: hydrophobic points), and whose radius is proportional to the MIF value at the field point position. While electrostatic and van der Waals field points tend to be located close to the molecular surface, the lack of the repulsive term allows hydrophobic points to penetrate the molecule and be buried inside the most hydrophobic regions of the molecule, such as ring centers or branched aliphatic substituents (Fig. 7).

Field points capture the concept of bioisosterism, since structurally diverse molecules may give rise to similar field point patterns. Contrary to classic pharmacophoric features, which are perceived in isolation from each other, field points encode interaction properties derived taking into account the whole molecule. Field point ensembles can be used for similarity assessment. As outlined in previous paragraphs, similarity assessment requires molecular superimposition as a preliminary step. To tackle the global optimization issue (see sections "COSMO*sim3D*" and "GRID/FLAP"), a two-step procedure is adopted. Firstly, colored cliques are generated out of those field points which are separated by similar distances across the reference and target molecule. Each clique is scored based on the number of matching points and their respective sizes; the top-ranked cliques are then used in a least-squares fitting procedure to generate aligned molecule pairs (Fig. 8A). In the second step, the clique-derived alignments are rescored by sampling the MIF of each molecule at the positions where the field points of the other molecule lie; all field points are used for the sampling, not only those constituting the clique (Fig. 8B). This MIF-based score is normally complemented by a shape-based score using the standard algorithm by Grant and Pickup (Fig. 8C);[12] the combined score is normally the average of the two, but the weights of the individual scores may be adjusted. Finally, the combined score is normalized through the Dice metric to a similarity value ranging from 0 to 1. The similarity value may then be maximized by a simplex optimizer through small roto-translations of one molecule relative to the other (Fig. 8D). Optionally, the alignment can be biased through user-defined constraints of variable magnitude on selected field points, in order to increase their weight in the molecule overlay algorithm.

3.11.2.2 Bioactive Pose Prediction

Whenever an X-ray structure of a ligand cocrystallized with its protein target is not available, its bioactive pose has to be predicted with computational methods. The general approach consists in looking for a common bioactive conformation across a series of ligands known to bind at a certain target, in the assumption that all of them adopt the same binding mode at the active site. All ligands in the series, when bound in that conformation, should share a reasonable overlap in their MIF patterns. Methods may differ in the size of the series used to derive the common binding mode and in the way the information extracted from this exercise is summarized and used in subsequent steps. In the following, we will describe two of the MIF-based methods most commonly used for this task.

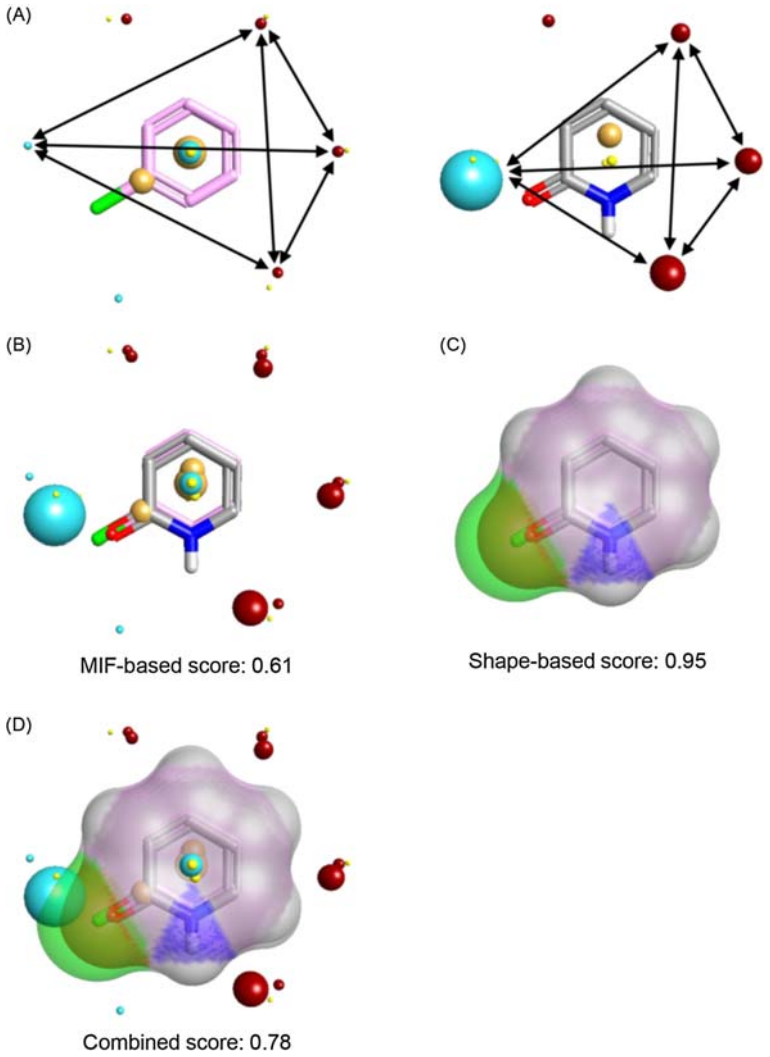

Fig. 8 (A) Generation of colored cliques and scoring based on the number of matching points and their sizes. (B) The best clique-derived alignments are rescored using the whole molecule MIFs. (C) The MIF-based alignment is used to compute a shape-based score. (D) The combined similarity score is maximized by a simplex optimizer.

3.11.2.2.1 FieldTemplater

FieldTemplater attempts to provide binding mode hypotheses for a small number of diverse ligands known to bind a certain target; the underlying assumption is that they bind at the same active site, and that to establish similar interactions with the latter they need to share significant similarity in their MIF patterns. Contrary to the FieldAlign method, FieldTemplater requires no a priori bioactive conformation hypothesis or target structure; instead, it attempts to identify the binding mode of the input structures by searching for common field patterns across their conformations. If multiple, independent, and structurally diverse active molecules can assume conformations characterized by a similar field pattern, then those conformations are likely candidates to represent the bioactive one. The binding mode hypothesis should ideally be unique; in case there are multiple and distinct common field patterns across the input molecules, hypotheses are scored and ranked. Each hypothesis ("template") is therefore constituted by a set of putative bioactive conformations, one per input molecule. Molecules in the template share the same 3D coordinate space, and are aligned relative to each other according to how they are supposed to interact with the surrounding binding pocket, whose structure may be unknown. The FieldTemplater workflow is summarized in Fig. 9.

A conformer pool is generated from each of the *N* input molecules using the conformational search engine XedeX (see section "XED/FieldAlign"). The *N* input molecules are then combined into all possible pairs, and the similarity of each pair is assessed with the two-stage algorithm described in section "XED/FieldAlign", taking into account all possible permutations of their conformations. If a pair of conformations yields a high similarity duo, the corresponding alignment is stored: with the standard settings, the best 100 duos are kept for each molecule pair. In case there are only two input molecules, the algorithm stops here, presenting a list of the best-aligned duos ranked by their combined field/shape similarity. If there were more than two input molecules, duos

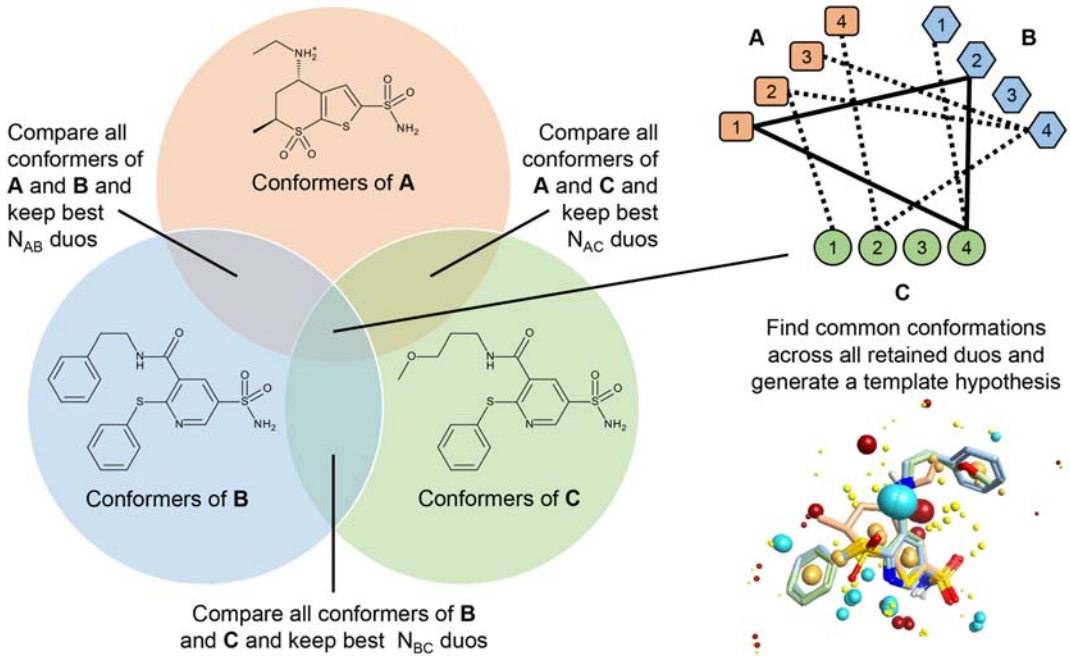

Fig. 9 Summary of the FieldTemplater workflow to generate a template hypothesis (i.e., a putative common binding mode) for three carbonic anhydrase inhibitors. A conformational search is run on each ligand, then pairwise comparisons are carried out among all conformers of each pair to retain the most promising duos. Finally, common conformations across all retained duos are sought and aligned to generate a template hypothesis.

are searched for common conformations: if molecule A, conformation 1 aligns with high similarity to molecule B, conformation 2, and molecule C, conformation 3 aligns with high similarity to the same conformations of molecules A and B, then a trio is formed, featuring a mutual alignment across the three molecules. The number of links required among N molecules is $N(N-1)/2$, so it becomes increasingly hard to satisfy all of them with increasing N; hence, the algorithm can be instructed to generate a template even if only a fraction of the links is found. The templating algorithm can also be biased by defining a set of distance constraints of user-defined magnitude between atoms on different molecules which need to be satisfied by the generated hypotheses.

Once the conformations to be combined have been identified, the template can be generated. The first step consists in combining pairwise alignments in order to minimize the RMS angular and translational deviations between their orientations in the original pair and those in the final template. The generation of a consensus alignment from a combination of pairwise alignments has usually been done in a piecewise fashion, introducing an order dependence, but the FieldTemplater algorithm does this analytically.

After generating a geometric mutual alignment, the template is further optimized in field space yielding the final overlay of conformations and then scored by field/shape similarity. All conformation tuples which satisfy the user-defined fraction of links undergo the same process, to generate a ranked list of templates for the input molecule set. The templates can be used to align a series of molecules against, or as a search query in a virtual screening (VS) exercise, just as would be expected from a more traditional pharmacophore.

To maximize the chances to obtain a small number of high-quality templates, three to five input molecules are required, which should be highly active, with comparable molecular weight (MW) and characterized by high structural diversity. Using only two input molecules most likely leads to a large number of conformation pairs being similar by mere chance, thus leaving a large degree of uncertainty about the common binding mode. Conversely, increasing the number of input molecules makes it more likely that at least one molecule does not have a binding mode in common with the others. It is important to avoid cases where the structures share a common torsion once aligned, as this leads to degeneracy in the solution. Since all molecules in the template could accommodate the same range of possible dihedral angles at that torsion, there would be no way to discriminate among them. For a similar reason, large differences in MW can lead to multiple under-defined templates, since moieties in the larger molecule(s) may not have any counterpart in the smaller one(s), thus making their unequivocal orientation impossible.

FieldTemplater was validated on a series of CCK_2 antagonists for which no structural information was available.[31] The highest scoring template obtained running the FieldTemplater algorithm on three input molecules was used to align the other molecules in the series, yielding a similarity value for each compound. The linear correlation between the experimental affinities (pK_B) and the similarity values had $r^2 = 0.75$ ($p < 10^{-6}$), while the r^2 constrained through origin of the linear regression between the recalculated pK_B values and the experimental ones was 0.67.

3.11.2.2.2 FLAPpharm

GRID MIF-based binding mode prediction has been implemented in FLAP within the FLAPpharm procedure.[32] A stochastic conformational search is carried out on the input molecule using the MM3 force-field, retaining only the most diverse conformations. For each conformation, MIFs are computed and FPs extracted as described in section "GRID/FLAP". Pairwise comparisons are carried out across all possible FP combinations such that for each molecule only the *N* conformations having the highest FP similarity are retained, with *N* being 5 or 10 depending on the desired tradeoff between speed and accuracy. Finally, the common binding mode is sought by taking each conformer of each molecule in turn as the starter molecule; subsequently, for the remaining molecules, the conformer which best fits those which have already been aligned is chosen. The resulting model is scored based on the average pairwise similarities between each molecule and the templates used to align it. The scoring function is a weighted sum of the individual MIF similarities; the shape MIF is down-weighted at 50% because the shape of the binding site is not known a priori, but rather inferred while the model is being built. The five top-ranked models are generally retained for subsequent analysis. For each of the four types of MIF overlaid in the model, a pharmacophoric interaction field (PIF) is derived as the average of the MIFs of individual molecules at each grid node. The PIF retains roughly the same intensity of the original MIFs at those positions where all fields had comparable energies, while it features a fraction of the original intensity at the positions which are not common to the majority of molecules. In addition to MIFs, for each molecule a corresponding set of pseudoMIFs is also generated (see section "GRID/FLAP"), from which a set of common pseudoPIFs can be derived with the same procedure used to extract PIFs. Finally, the centroids of pseudoPIFs are also included as further pharmacophoric points (**Fig. 10**). The pharmacophoric pseudomolecule identified by the collection of PIFs and pseudoPIFs can be used as a template for VS (see section "FLAP") or docked into a macromolecular target (see section "FLAPdock").

To assess the ability of the method to find the correct binding mode, an objective benchmarking suite was assembled (PharmBench[33]). This comprised 960 ligands from 81 different targets having high resolution X-ray structures in the Protein Data Bank (PDB).[34] For each target, the available complexes were manually curated with regards to protonation and tautomerism, and then superimposed using the protein alpha carbons. After the proteins were removed, the ligands were left in a binding site-aligned configuration, thus providing an objective benchmark to assess the ability of a binding mode prediction method to recover the experimental pose. The 3D structures of the cocrystallized ligands were generated de novo starting from their 2D counterparts and their conformations were populated; the FLAPpharm procedure was then applied twice on each target to obtain a pharmacophoric model, firstly using only the X-ray bioactive conformations as input, and secondly using those regenerated from the 2D layout, which are completely independent from the experimental ones. Four different metrics were adopted to evaluate the performance: (1) the ability of the conformational engine to generate the experimental pose within a 2.0 Å RMSD; the success rate was 91%; (2) the ability of the method to retrieve the correct bioactive conformation for each ligand, expressed as % of ligands having a RMSD < 2.0 Å once individually realigned to their experimental counterpart; the success rate was 65%; (3) the ability of the method to reconstitute the original binding mode for each target,[35] expressing results as % of datasets where at least half of the ligands had a RMSD < 2.0 Å from the X-ray pose; the success rate was 93% when starting from the X-ray conformations, and

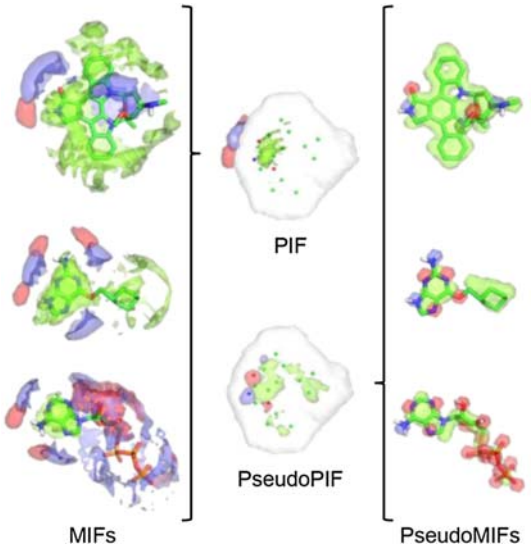

Fig. 10 For each of the top-ranked binding mode hypotheses, FLAPpharm generates a pharmacophoric interaction field (PIF; *top middle picture*) as the intersection of the MIFs of individual molecules (*left*). A pseudoPIF (*bottom middle picture*) is also similarly generated out of the ligands' pseudoMIFs (*right*). The ensemble of PIFs and pseudoPIFs gives rise to a pharmacophoric pseudomolecule which can be used as a template for virtual screening or docked into a macromolecular target. Adapted from Figure 1 in Cross, S.; Baroni, M.; Goracci, L.; Cruciani, G. GRID-based three-dimensional pharmacophores I: FLAPpharm, a novel approach for pharmacophore elucidation. *J. Chem. Inf. Model.* **2012**, *52*, 2587–2598. ACS publication.

67% when using the conformations generated from an unbiased 2D layout; (4) the similarity of the unbiased, regenerated pharmacophoric models to those built out of the experimental ligand coordinates; the average similarity was 0.72 when the X-ray conformations were used, and 0.53 when conformations were rebuilt from 2D coordinates.

3.11.2.3 Virtual Screening

MIF-based methods are very well suited for VS. Once the interaction properties of a molecule have been summarized into a more concise, field point-based or pharmacophore-like description, it is possible to use the latter to query a database of molecules (each represented by a population of conformers) for similar patterns. Since the MIFs are not directly related to the underlying chemical structure, the VS exercise has a chance to retrieve different chemotypes with comparable field properties, rather than just trivial structural analogs. This feature makes MIF-based VS particularly valuable compared to traditional methods based on 2D fingerprints. In the following, applications based on the XED and GRID force-fields will be reviewed.

3.11.2.3.1 FieldScreen/Blaze

One of the first applications of MIFs based on the XED force-field[26] (see section "XED/FieldAlign") was the FieldScreen LB VS methodology,[36] currently available within the Blaze web application. A ligand endowed with high activity is usually chosen as query; since FieldScreen is a 3D method, the bioactive conformation should ideally be used (if known) to maximize the likelihood of retrieving true actives, in the assumption that they bind with a similar conformation. MIFs are computed for the query and condensed into a field point pattern, which is then used to search a database of molecules prepopulated with conformations by the XedeX engine (see section "XED/FieldAlign"). For each conformation, field points corresponding to field extrema are identified and stored as previously described (see section "XED/FieldAlign"). A distance matrix is computed across field points and converted to a fingerprint, which may optionally be used as a coarse prefilter to remove from further consideration conformations with large deviations from the query. Subsequently, pairwise similarity scores between query and database entries are generated with the two-stage process outlined in section "XED/FieldAlign" (colored clique matching/simplex score optimization). The similarity assessment can optionally be biased through user-defined constraints of variable magnitude on selected field points, in order to force certain field features to be matched. If the structure of the macromolecular target is available, it is possible to penalize alignments which clash with the ligand-binding site, such that their similarity score is reduced. The 3D similarity value assigned to each retrieved molecule is the maximum similarity across its conformer pool. Search results are ranked by decreasing similarity; the optimal 3D overlay of the best-fitting conformation onto the search query is associated with each result.

FieldScreen was validated on the DUD dataset,[37] which was initially conceived as a benchmarking suite for docking methods. One of the strengths of DUD is that decoys were chosen to resemble actives not only in terms of MW but also of physical properties, while differing in topology. To extend its use to LB similarity methods, starting from DUD version two each set of actives is filtered for lead-likeness ($A\log P < 4.5$, MW < 450) and associated to a target-specific set of decoys, in order to make the discrimination more challenging for a LB VS application and avoid retrieving overly optimistic enrichment factors. Another well-known limitation of datasets for retrospective VS analysis is the fact that they usually contain many structural analogs; hence, a VS method able to retrieve a certain chemotype will easily retrieve all structures which share it. To correct this shortcoming, Good clustered active structures based on their reduced graph,[38,39] so that enrichment factors may be corrected by down-weighting each retrieved hit by the population of its cluster,[40,41] in order to put more emphasis on the ability of a method to retrieve different chemotypes rather than just trivial analogs. For this reason, FieldScreen validation was restricted to a subset of 13 of the 37 DUD datasets which contain ≥ 15 clusters, and only the dataset-specific decoys were taken into consideration. To enable direct comparison with DOCK,[42] the same ligand used for the active site definition was used as a search query. The conformation of the query was taken from the X-ray complex with the respective protein, except for *pdgfrb* (unavailable) and *vegfr2* (an apo structure), where a homology model and a complex with a different target protein were used. Two metrics were chosen to assess VS performance, namely the area under curve (AUC) of the receiver operating characteristic (ROC) curve, and the ROC enrichment (ROCE). While the ROC AUC measures the VS performance across the whole ranked database, ROCE is an indicator of early recovery, and evaluates the ability of the method to retrieve actives in the top fraction of the database. The latter is particularly desirable, given that in general only a very limited amount of the ranked database generated by VS can actually undergo wet lab screens. ROCE values were reported at 0.5%, 1.0%, 2.0%, and 5.0% of the true decoys having been screened. To account for the fact that actives are clustered by chemotype, both the ROC AUC and ROCE metrics were adjusted for clustering as explained earlier, yielding respectively awROC AUC and awROCE. Results are reported in Fig. 11. As far as the AUC metric is concerned, FieldScreen did not do significantly better than DOCK on average, but awROCE was significantly superior for all four percent thresholds (Wilcoxon signed-rank test, $p = 0.05$). Furthermore, FieldScreen consistently retrieved hits with a lower MW than DOCK, to the advantage of their likelihood to progress to the hit-to-lead development stage. Using the protein target structural information as excluded volume did not have a statistically significant impact on the quality of results.

3.11.2.3.2 FLAP

FLAP enables VS according to different paradigms: (1) LB: database ligands are compared against a query ligand in its putative bioactive conformation based on their quadruplets, as described in section "GRID/FLAP", and ranked based on their combined MIF Tanimoto similarity; (2) receptor-based (RB): the query is a receptor rather than a ligand and hence fields are computed placing a grid in the active site, yielding a series of quadruplets as for the previous case (see section "GRID/FLAP" for a detailed description);

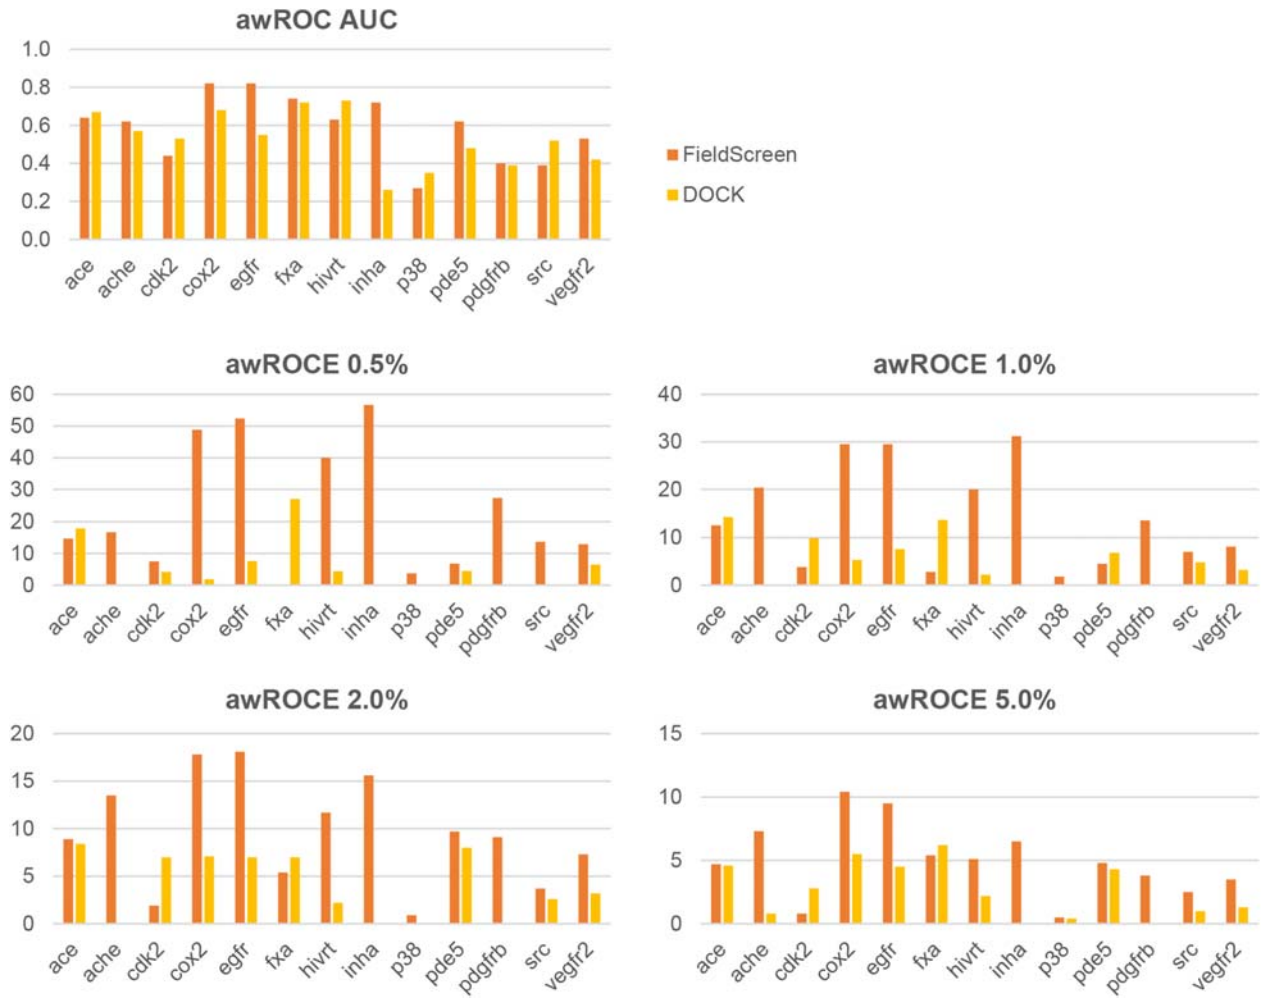

Fig. 11 Results from the VS exercise on 13 DUD datasets described in Ref.[37]. While FieldScreen on average does not perform significantly better than DOCK as far as the AUC metric is concerned, awROCE is significantly superior for all four percent thresholds (Wilcoxon signed-rank test, $p = 0.05$).

similarity is computed comparing such receptor quadruplets with pseudoMIFs (see section "GRID/FLAP" for a definition) centered on heavy atoms of the database ligands; (3) hybrid RB/LB (RBLB): the LB procedure is followed, using shape and features of the protein active site as a constraint in the database search. An early assessment of the RB performance of FLAP was carried out on two series of ligands against Factor Xa and thymidine kinase, respectively; databases were assembled from 10–20 actives and ~1000 decoys with comparable MW taken from the MDDR database. Screening against a crystal structure for each of the two targets gave better enrichment factors than a number of docking engines, and was an order of magnitude faster. LB enrichment performance was better than Catalyst's when tested on an internal Pfizer dataset and on a set of estrogen receptor alpha (ER-alpha) antagonists.[22] At a later stage, a more thorough and robust retrospective validation of the methodology was carried out on the same 13 datasets from the DUD benchmark suite previously used in the validation of FieldScreen,[36] and the results were compared to those obtained with FieldScreen[36] and DOCK.[42] The performances of the RB and the LB methods were substantially equivalent, while RBLB was slightly superior. When comparing the average arithmetic-weighted AUC across all 13 targets, there was no statistically significant difference among FLAP, DOCK, and FieldScreen (Wilcoxon signed-rank test, $p = 0.05$). With regards to early enrichment awROCE metrics, FLAP proved consistently superior to DOCK, as did FieldScreen. While differences in performance could be observed on individual datasets between FLAP and FieldScreen or among the different FLAP methods, on average no statistically significant difference could be detected across the 13 targets (Wilcoxon signed-rank test, $p = 0.05$) (**Fig. 12**). The authors reported other metrics obtained combining results from using multiple active compounds as search queries; however, these metrics cannot be taken into consideration for comparison purposes since they were not applied to the other methods.

With the introduction of FLAPpharm, FLAP can use also pharmacophore-like search queries in addition to individual molecules, simply replacing MIFs and pseudoMIFs with PIFs and pseudoPIFs (see section "FLAPpharm" for definitions).[22,23]

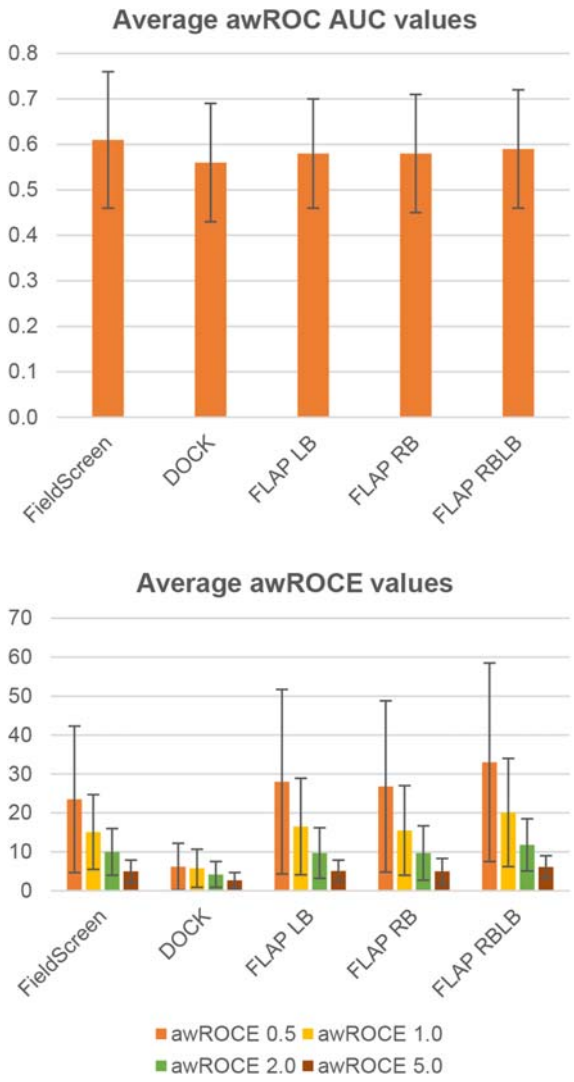

Fig. 12 Comparison of the average performance on 13 DUD datasets across different VS methodologies (FieldScreen, DOCK, and three FLAP methods), as described in Ref.[23]. With respect to the awROC AUC metric, all methodologies were roughly equivalent. FieldScreen and FLAP both proved to be superior to DOCK according to all awROCE metrics, while no statistically significant difference could be detected between FieldScreen and FLAP (Wilcoxon signed-rank test, $p = 0.05$).

3.11.2.4 Scaffold Hopping

Scaffold hopping, defined by Schneider as "identification of isofunctional molecular structures with significantly different molecular backbones"[43] is highly amenable to being implemented through MIFs. One of the virtues of MIFs is the ability to describe the general interaction properties rather than the specific chemical structures, exactly what is required in scaffold hopping. In contrast to VS, the goal of scaffold hopping is not finding novel structures as a whole, but rather replacing part(s) of a structure known to be active or to have favorable interaction properties at a certain target. The most common application is the replacement of a core structure, often a heterocyclic ring system, with a different chemotype, while keeping the decoration substantially intact (Fig. 13). From a medicinal chemistry standpoint, such an operation aims at improving pharmacodynamic/pharmacokinetic properties, selectivity, toxicity profile, or escaping intellectual property (IP) issues connected with patent coverage.

In general, MIF-based scaffold hopping methods provide a description of the moiety to be substituted in terms of geometric and field requirements; this description is used as a query to search conformationally populated fragment databases for possible matching replacements. The synthetic accessibility of the retrieved scaffolds is not guaranteed; however, assembling fragment databases out of available compound collections increases the likelihood of finding synthetically feasible options. While core scaffold replacement can be a purely LB exercise, structural information from the target can sometimes be used if available. In the following, a couple of applications of MIFs to scaffold hopping will be reviewed.

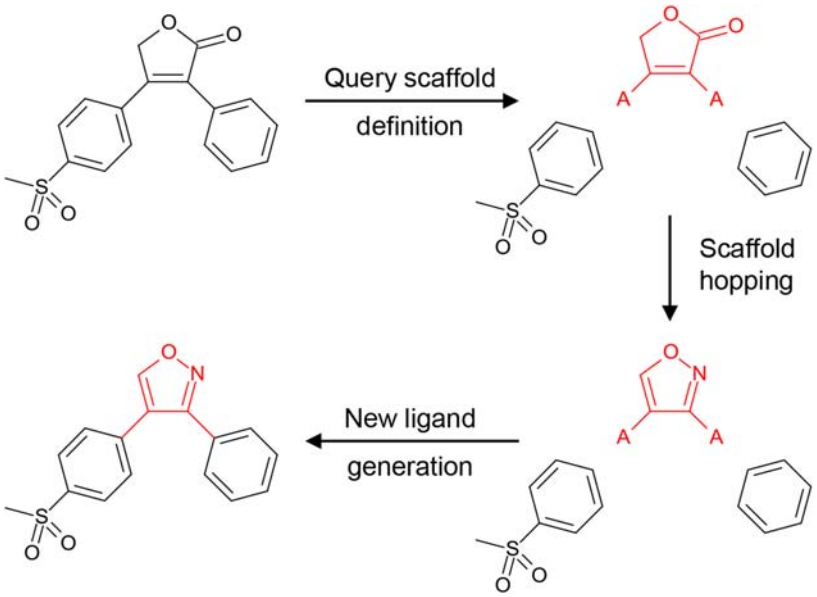

Fig. 13 Scaffold hopping exercise on rofecoxib. The five-membered lactone scaffold is identified as a candidate for replacement, detached from the side chains, and capped with dummy atoms as attachment points. A search is carried out in a database for bioisosteric replacements, and the retrieved scaffold is reconnected to the side chains to generate a new ligand.

3.11.2.4.1 SHOP

SHOP is a method based on GRID MIFs which enables scaffold hopping based on both ligand[44] and receptor structures.[45,46] The core to be replaced is identified through anchor points, namely dummy atoms which replace the side chain atoms originally attached to the core (Fig. 13). There may be a single anchor point or multiple ones; anchor points are converted into hydrogen atoms before the search is started. To enable retrieval of alternative structures from a fragment database, two geometric descriptors are computed for each scaffold: (1) a distance matrix across all anchor points and (2) a set of dihedral angles identified by the bonds from the anchor point to the scaffold atom connected to it (Fig. 14).

In the LB methodology, the geometric descriptors are complemented by a set of interaction energies between the scaffold and five different GRID probes: hydrophobic (DRY), hydrogen bond donor (N1), hydrogen bond acceptor (O), positively charged (N1+), and negatively charged (O−). Energies are sampled at the nodes of a regular 0.5 Å grid which embeds the scaffold to be replaced, excluding nodes which lie beyond a cut-off distance from any scaffold atom, and those lying within 3 Å from any anchor point. Energy values are then assigned to bins according to their distance from the anchor points; each bin is 0.4 Å wide. This procedure, reminiscent of the one used to generate GRIND descriptors (see section "GRIND"), gives rise to a correlogram, which records the most favorable energy value for each distance bin. The positive energy values of the N1 grid are used to evaluate shape, which in a similar fashion to the field energy values is converted into a correlogram, consisting of the binned frequency distribution of distances between anchor points and grid nodes. Distances are described by Gaussian functions to allow some overlap between neighboring bins (Fig. 14). The ensemble of geometric, field, and shape descriptors is used as a query to retrieve potential replacements from a fragment database previously populated with conformations. Fragments are ranked based on their similarity to the query, as assessed by the Carbó index. Each fragment is characterized by eight similarity values (two from geometric descriptors, one from shape, and five from GRID MIFs); the total similarity is a weighted sum of the eight individual values. Weights can be modified based on the features which are thought to be more important for a certain scaffold. The maximum similarity value across alignments obtained by all possible permutations of anchor points is taken as the score for each fragment.

The LB SHOP method was validated on a number of X-ray complexes chosen from three protein families (thrombin, HIV protease, and influenza virus neuraminidase). For each family, complexes were chosen such that the ligands had comparable binding mode and interactions with the target, and that scaffold replacement could be carried out using a variable number of anchor points (2–4).[44] A training set database was assembled from 471 scaffolds extracted from previously published combinatorial libraries, manually introducing anchor points as dummy atoms. For each scaffold, 3D conformations were generated. This database was then spiked with biologically active scaffolds in their X-ray bioactive conformation; unlike the decoys, the spike scaffolds were not subjected to a conformational search. Firstly, the weights for each of the eight similarity values mentioned earlier were optimized in order to maximize the recovery rate of actives for each protein family. The tailored set of parameters for each family was then used to recover scaffolds from a larger test set database, constructed with 2500 scaffolds extracted from the same literature sources as the training set. For each protein family, the 10 top-ranked scaffolds retrieved by SHOP were linked to the side chains originally chopped off the query scaffolds, and the complete ligands thus obtained were redocked in the X-ray complexes from which the query scaffold had been extracted. Binding modes, interactions, and docking scores were largely comparable to those

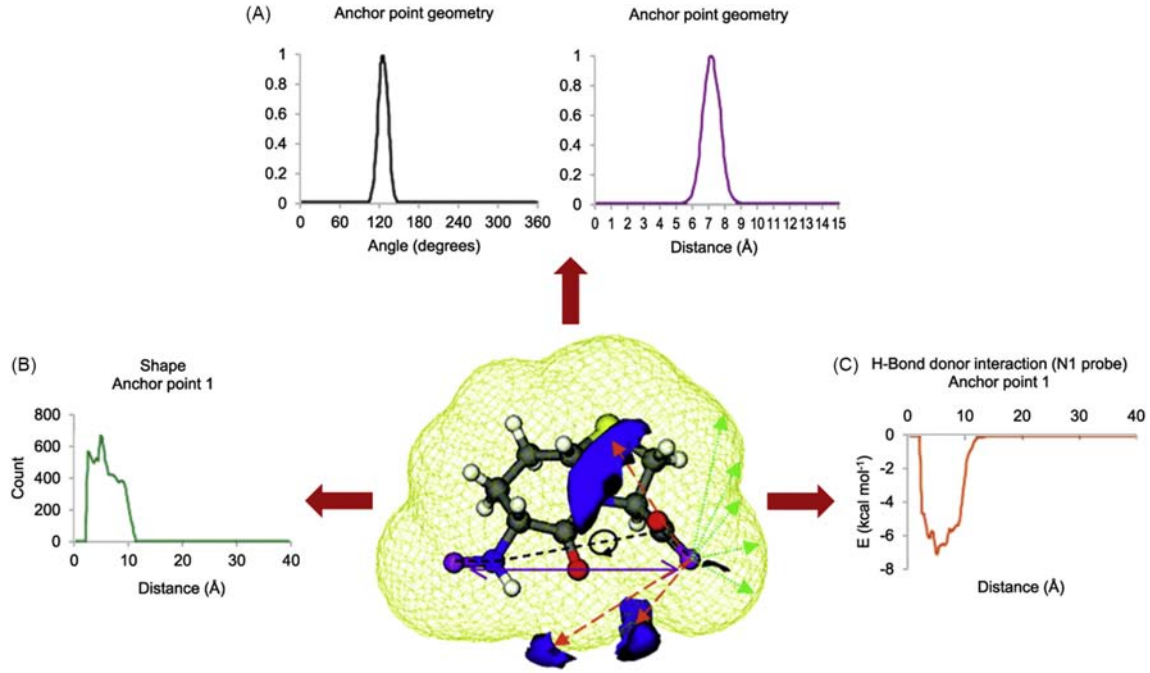

Fig. 14 SHOP descriptors computed for a scaffold with two anchor points (the corresponding dummy atoms are shown in *purple*). (A) Anchor point geometric features, namely distance (*purple full line*) and dihedral angle (*dashed black line*) between anchor points are described by Gaussian functions. (B) Scaffold shape is described by positive energy values of the N1 grid. Distances from anchor points to grid nodes (*green arrows*) are recorded in a correlogram. (C) The most favorable probe-scaffold interaction energies for each distance bin (*orange arrows*) are also recorded in a correlogram. Adapted from Figure 1 in Bergmann, R.; Linusson, A.; Zamora, I. SHOP: Scaffold HOPping by GRID-based similarity searches. *J. Med. Chem.* **2007**, *50*, 2708–2717.

of the original X-ray complexes. A set of default parameters with general good recovery performance was devised, but their performance outside the three protein families used to derive the parameters themselves was not determined.

The RB methodology requires a target–ligand complex as the starting point, from which the scaffold to be replaced is extracted. The procedure is similar to the LB one, the main difference being the fact that the MIF evaluation is carried out on the target binding site from which the query scaffold is extracted rather than on the query scaffold itself. Once the query scaffold has been removed from the complex, the binding site around it is characterized through the five aforementioned GRID probes, and probe interaction energies are binned in 0.4-Å increments based on their distance from anchor points, as for the LB method. An additional set of fingerprint-like descriptors is computed on the database fragments by characterizing each atom as hydrophobic, hydrogen bond donor/acceptor, positively/negatively charged, thus matching the nature of GRID probes used to compute MIFs. Next, anchor point-atom distances are binned in 0.4-Å increments for each atom type, and their presence/absence is recorded in a frequency vector.[45] The similarity between query and database scaffolds with matching numbers of anchor points is assessed by a Pearson similarity index, which takes into account both geometry and field descriptors. For field descriptors, query fingerprints are compared against database MIFs, and vice versa. As with the LB method, the maximum similarity across all possible anchor point alignments is taken. Optionally, a volume constraint can be applied to force database scaffolds to match the query ligand volume. Finally, the ranked scaffolds are linked to the side chains chopped off the original X-ray complex, and the complete ligand undergoes geometry optimization inside the binding site.[46]

The RB SHOP method was probed for its ability to return known scaffolds from a decoy pool, and the chemotype novelty of the results was evaluated. A total of 164 fragments with 1–3 anchor points belonging to 11 different targets were selected from the SHOP database generated from the PDBbind database,[47] and used as queries to search the same database for potential replacements. More than 40% of fragments with a single anchor point were recovered among the top five ranked results; the percentage raised to 90% for fragments with 2–3 anchor points, as they are better characterized from a geometric point of view. The retrieved scaffolds range from close analogs to more structurally unrelated motifs, which are probably the most interesting from a medicinal chemistry perspective, especially those which are able to establish new interactions with the target compared to the original query.

3.11.2.4.2 Spark

Spark is a tool which enables bioisosteric replacement and scaffold hopping based on the XED/FieldAlign technology (see section "XED/FieldAlign"). As with the SHOP methodology described in the previous paragraph, scaffold queries can be used to mine 3D conformational databases of fragments for analogs in property space. However, Spark has several distinctive differences. While in

SHOP the 3D grid description of MIFs is collapsed to a 1D histogram of distance frequencies of atoms or MIF-energy sampling points from anchor points, Spark retains a larger amount of 3D information in the search for potential scaffold replacements. Furthermore, SHOP scores scaffolds retrieved from the fragment database in isolation; the final geometry optimization stage inside the active site does not affect the scoring. Instead, Spark scores the final molecule rather than just the retrieved fragment, that is, it links the original side chains to the anchor points before the scoring step. This allows any electronic or conformational effects of the new scaffold on the rest of the molecule to be evaluated as part of the scoring process.

The Spark algorithm takes as input the 3D coordinates of the molecule which requires bioisosteric replacement (the "starter molecule"), and computes its field point pattern based on the XED force-field as described in section "XED/FieldAlign". The region of the starter molecule selected for replacement can have from one to four connections to the rest of the ligand, flagged by as many anchor points (Fig. 13). Distances between anchor points and angles between bonds connecting anchor points to the main scaffold are taken as geometric constraints in the search for similar moieties in the conformationally populated fragment databases. Further constraints can be set on the kind of scaffolds to be retrieved (alicyclic, aromatic, and acyclic), on the element/hybridization state allowed to be bound to anchor points, or on specific field points which should be matched with a greater weight than others. If available, a protein structure can be used as an excluded volume to rule out fragments that, once merged into the starter molecule, would clash with the binding site.

The search for compatible fragments happens in three stages. In the first stage, fragment conformations are compared to the query according to all possible permutations of the anchor points. If the geometric requirements at each anchor point are fulfilled within a threshold the fragment is carried on to the next stage. When the fragment has a single attachment point, or two collinear attachment points, an underdetermined rotational degree of freedom arises; in this case, a set of alternative rotamers is generated and carried on for subsequent evaluation. In the second stage, the field points of the fragment are merged with the field points of the side chains of the starter molecule in the orientation(s) determined during stage 1; the approximate field pattern thus generated is scored against the whole query. After the second stage is completed, the best-ranked results are carried on to the final stage, where fields are recomputed ex novo and used for the definitive scoring (Fig. 15). The latter includes a simplex optimization of the

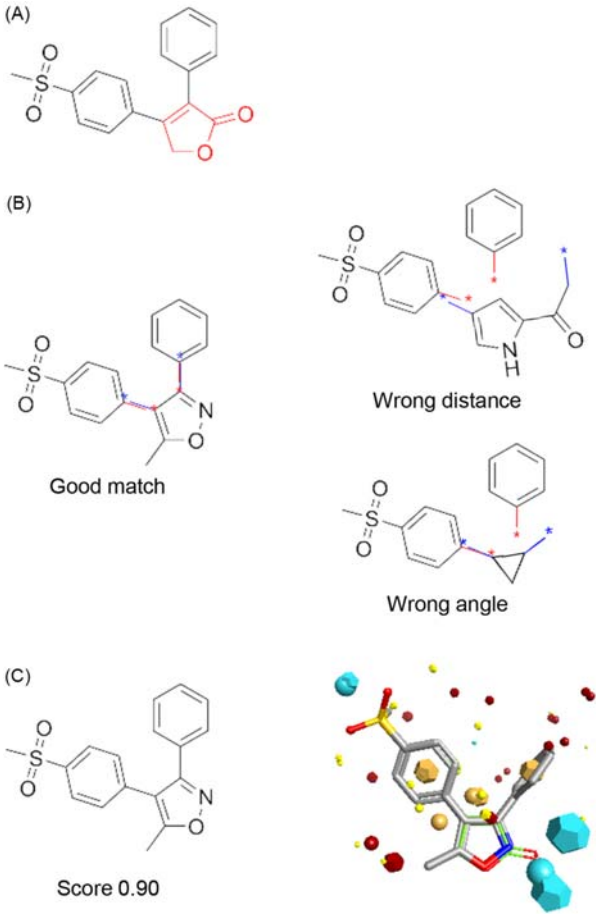

Fig. 15 Scheme describing Spark's workflow. (A) The scaffold to be replaced (*in red*) is identified. (B) During stage 1, a fragment database is searched for geometrically compatible fragments; fragments characterized by wrong distances and/or angles are discarded. (C) In stage 2, retrieved scaffolds are merged with side chains, including their field points; the approximate structures thus generated are scored and the best-ranked results are progressed to stage 3. In stage 3, fields are computed ex novo on the complete structures, and the latter are rescored and ranked.

similarity function through small rigid-body rotations and translations of the fragment relative to the query. Since fragments are scored after replacing the starter molecule's scaffold, it is possible to score the product of the bioisosteric replacement against reference(s) distinct from the starter molecule. This allows merging structural features across ligand series, replacing a core structure in molecule A to make it similar to molecule B, or to a weighted combination of A and B. Spark has been successfully used in prospective scaffold hopping studies to find novel HIV-1 entry inhibitors. Cocklin and coworkers identified through Blaze VS (see section "FieldScreen/Blaze") five hits active against HIV-1 in the high micromolar range, all of which shared a piperazine core with a known class of potent HIV-1 inhibitors developed by Bristol–Myers Squibb. After successfully replacing the piperazine scaffold with a dipyrrolidine core, inspired by an anti-HIV-1 lead developed by Pfizer, Spark was used to explore alternative decorations at the dipyrrolidine system. For this purpose, an ad hoc fragment database was generated out of 453 PubChem compounds which shared 2D similarity to one of the Bristol–Myers Squibb leads, and used to search for bioisosteric substituents. This chemotype merging strategy led to a low micromolar compound, which was further optimized to achieve a nanomolar lead.[48] A further round of Spark scaffold replacement enabled finding five novel alternatives to the dipyrrolidine core, all which were active, two of them in the nanomolar range.[49] Spark has been the subject of a couple of recent reviews.[50]

3.11.2.5 3D Clustering of Molecule Libraries

The assessment of 3D molecular similarity through the XED/FieldAlign methodology (see section "XED/FieldAlign") has been applied to the clustering of a large library of building blocks (~800 K) characterized by a wide variety of heterocyclic scaffolds with a high fraction of sp^3-hybridized carbons (Fsp^3).[51] The structures in the library were relatively rigid, with an average of ~4 conformations each, and featured a methyl handle to represent synthetic conjugation to a parent structure. The goal of the project was to cluster the library on 3D similarity into 25 K clusters, from which a subset of about 2000 compounds would be cherry-picked for synthesis. Analysis of the 2D topology and the 3D cluster network around each of the synthesized building blocks gives access to a number of analogs characterized by (1) similar core, different substitution pattern and vice versa; (2) being super/substructures of the parent; and (3) different 2D structure but comparable 3D interaction properties. If a molecule featuring one of the building blocks elicits promising activity in a high-throughput screening (HTS) assay, this network enables straightforward exploration of the surrounding chemical space.

The CLARANS *k*-medoids algorithm[52] allows clustering a large dataset around the chosen number of centroids, and it requires an upper triangular similarity matrix as input. Computing such a matrix across ~800 K molecules with a 3D method is too demanding even for a large cloud infrastructure. Instead, the cluster centroids were identified on a diverse subset of ~150 K structures, while the remaining ~650 K structures were assigned to the centroids identified in the first step. The presence of the methyl handle allowed the global optimization problem inherent in each pairwise similarity assessment to be addressed through the following workflow: (1) fragments were aligned by their methyl handle and the four XED MIFs were computed (see section "XED/FieldAlign"); (2) one fragment was systematically rotated relative to the other in 30-degree increments, and their 3D similarity was assessed; (3) the two highest similarities across the 12 samples were used as the starting point for a linear search in 5-degree increments to find the rotation giving the global similarity maximum; and (4) the similarity for each compound pair was taken as the maximum similarity across all pairs of conformations. Each pairwise comparison took 40 ms. The computation of the similarity matrix was split in square blocks of 100 molecules each and distributed over a 2048-CPU cloud computing facility, so that the ~14-CPU-year job could be completed in 4 days (**Fig. 16**).

A comparison of 3D similarity values against traditional 2D similarities based on ECFP4 fingerprints showed almost no correlation. The distribution of 2D similarity values was skewed toward significantly lower values, reflecting the sensitivity of 2D methods to small structural changes which may have little impact on 3D interaction properties relevant to biological recognition. In particular, the lack of stereochemistry awareness in fingerprints causes diastereomers with significantly different distribution of features in 3D space to be considered identical. Visual examination showed that the clusters obtained from 3D similarity metrics featured a much higher degree of internal consistency and appeared better classified from a medicinal chemistry standpoint than those from a 2D clustering.

3.11.2.6 3D-QSAR

Quantitative structure–activity relationships (QSAR) involve the application of statistical and data analysis methods to the prediction of biological activities from descriptors of structural properties. The ambition of QSAR approaches is to convey the similarity principle on which the practice of medicinal chemistry is founded (compounds with similar structures are expected to elicit similar biological activities) into quantitative mathematical equations.[53] Descriptors can be monodimensional (global molecular properties, e.g., MW, log P), two-dimensional (molecular topology-related, e.g., connectivity indices), or three-dimensional (related to 3D conformation, e.g., coordinate-dependent MIF energies); the latter are the focus of this section. One of the most appealing features of 3D-QSAR is its ability to yield a visually interpretable model, which provides information about the determinants of activity and gives hints about the structural modifications which can potentially improve ligand potency. This contrasts with 1D- and 2D-QSAR models which may sometimes provide "black-box" activity predictions which cannot be easily related to the original descriptor space.

A prominent criticism of 3D-QSAR methodologies is that they are not very amenable to being used in a prospective fashion, since they require a fairly large congeneric series upfront to provide meaningful predictions.[54] A recent review reports only a few

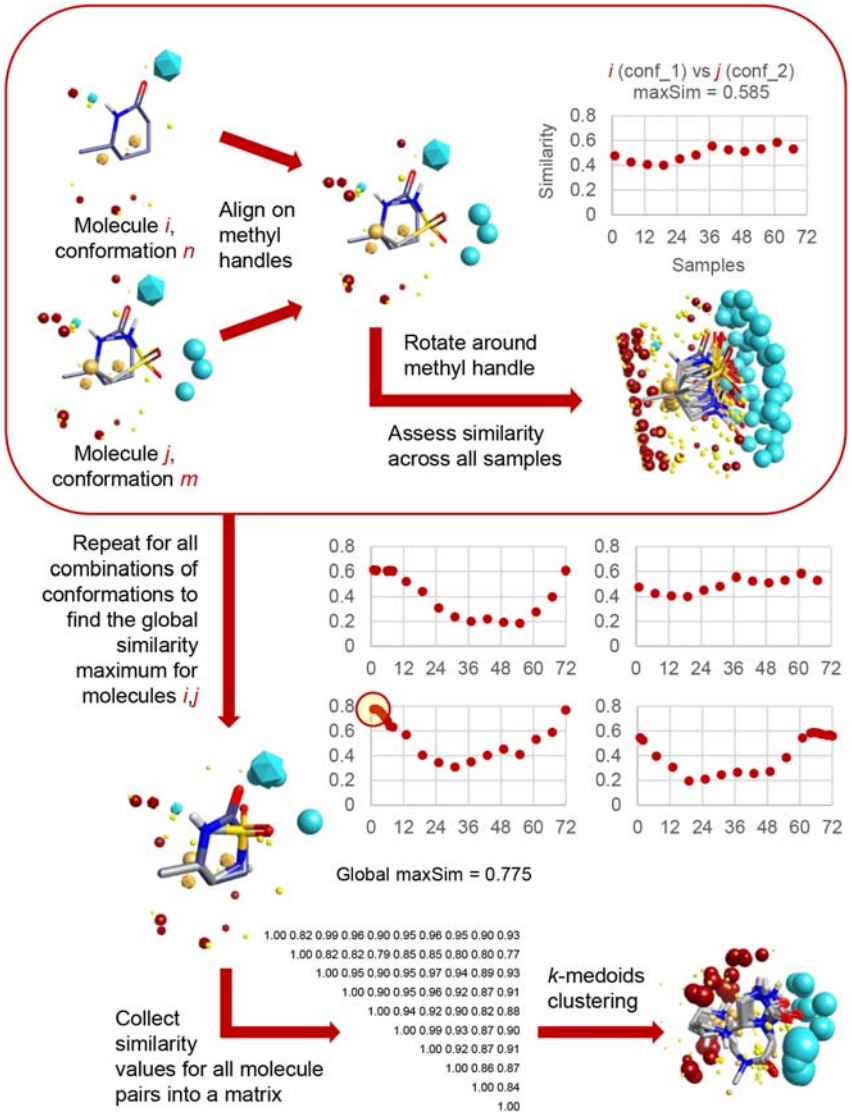

Fig. 16 The workflow depicted above allows clustering a large library of compounds bearing a methyl handle based on their 3D interaction properties as perceived using the XED/FieldAlign technology (see text for details).

cases where these techniques were used prospectively.[55] The majority of 3D-QSAR techniques require ligand 3D conformations to be mutually aligned, and in the absence of a relatively rigid crystallographic template the alignment step can be rather uncertain. The widespread practice of iteratively tweaking the alignment of individual substituents until the leave-one-out (LOO) cross-validated r^2 (q^2) reaches a maximum introduces a large user bias, and increases the likelihood of chance correlations[54,56]; such a procedure is clearly not viable for compounds whose activity is to be predicted.[57] The presence of close congeners in the dataset may partly invalidate the usefulness of LOO cross-validation, as their activity can be rather trivially predicted: more robust leave-many-out (LMO) cross-validation is thus usually recommended. Best practice also calls for the use of large, truly independent external test sets for model validation, and for the routine application of dependent variable scrambling to detect chance correlations.[54]

A full review of 3D-QSAR methodologies, including pros, cons, and pitfalls, is beyond the scope of this article but is covered in dedicated reviews.[58] In the following paragraphs, the most important 3D-QSAR methods which are currently implemented in available commercial or open-source software will be briefly reviewed.

3.11.2.6.1 CoMFA

CoMFA, invented in the late 1980s by Cramer[4] as a development of the earlier DYLOMMS method,[59] is the ancestor of all 3D-QSAR techniques. A set of molecules which share the same binding mode and site are aligned in their putative bioactive conformation; ideally, a crystallographic template should be available to guide the alignment. The set is then typically partitioned into a training set and a test set, and a grid box large enough to extend beyond the largest molecule by 5 Å in all directions is placed around the

compounds. The grid step size is normally in the 1–2 Å range. An sp^3-hybridized carbon probe bearing a +1 charge is placed at each grid node, and its steric and electrostatic interaction energies with each molecule are computed and stored in a matrix. The rows of the matrix hold the different molecules, while columns hold the energy values at each grid node. Columns which are characterized by a low standard deviation across the dataset are removed from further consideration. The matrix of energy descriptors is then regressed against biological activities to find a QSAR equation. Classic multilinear regression is not appropriate for such an underdetermined system, where thousands of independent variables need to be correlated with a number of dependent variables which is usually two orders of magnitude smaller. DYLOMMS attempted to address the problem using principal component analysis (PCA), with only limited success. A more appropriate regression tool, partial least-squares (PLS), proved critical to the acceptance of this method.[60,61] The number of principal components to be extracted is usually chosen as the one which yields the first local maximum of the LOO cross-validated r^2 coefficient (LOO q^2). The external test set is then used to provide more robust external validation to the model (Fig. 17).

CoMFA models are graphically interpretable, since PLS coefficients can be back-projected into the original descriptor space as pseudo-coefficients, optionally multiplied by the standard deviation of the corresponding energy variable across the dataset to amplify the importance of data points with larger variance. Therefore, each of the grid nodes is associated with a field-specific signed coefficient which tells, for instance, if steric bulk in a certain 3D region is beneficial to biological activity or if positive electrostatic potential is detrimental. This information may help to rationally guide medicinal chemistry optimization efforts (Fig. 17).

While CoMFA has enjoyed a vast success, as reflected in several thousand publications, it has some drawbacks. The first, and probably the most important, is common to all 3D-QSAR methods and is related to the initial requirement for aligned dataset structures (see section "3D-QSAR"). CoMFA-specific issues are connected with the grid-based evaluation of the energy function. Discontinuities arise close to atomic nuclei, which have been tempered by introducing steric energy cut-offs and excluding evaluation of the electrostatic potential at grid nodes which exceed the steric cut-off. Connected to the previous point, small translations of the grid relative to the molecules can have a dramatic influence on the energy values at grid nodes in vicinity of atom nuclei, which may acquire a large weight in the PLS analysis and trigger largely spurious correlations. Applying Laplacian smoothing to the grid helps to attenuate these artifacts.[62]

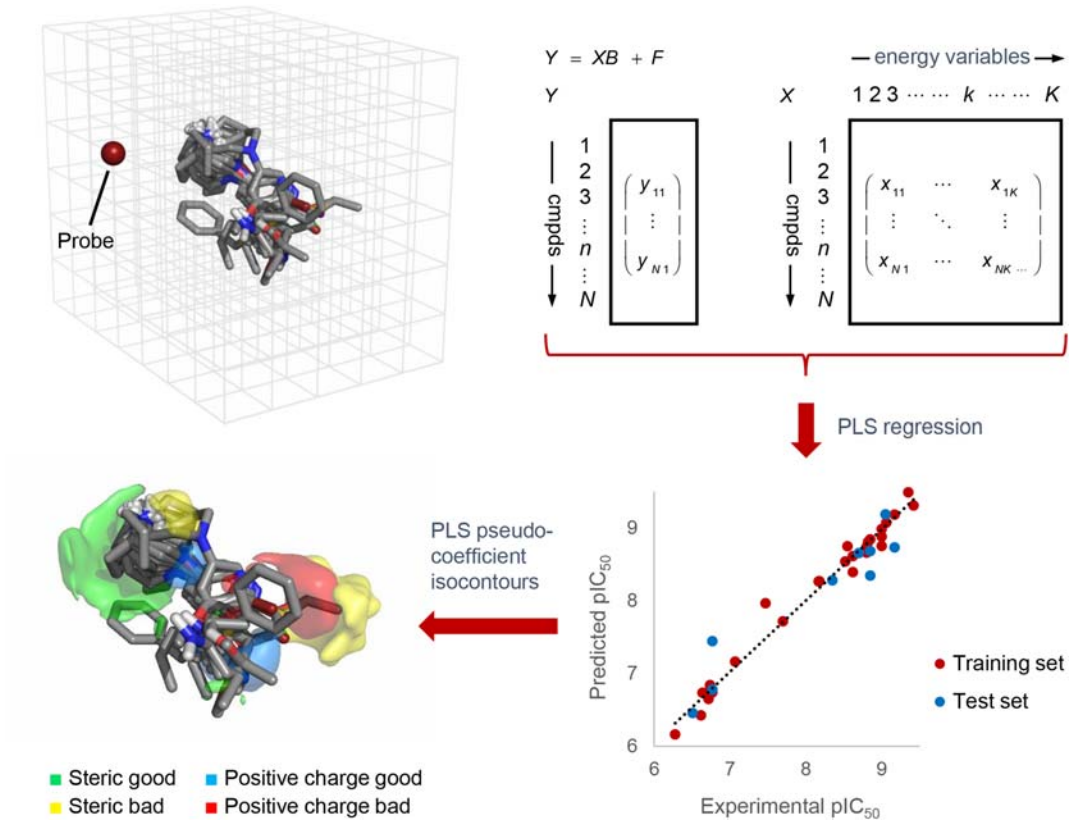

Fig. 17 An sp^3-hybridized carbon probe bearing a +1 charge is placed at each node of an evenly spaced grid surrounding an aligned set of molecules, split between a training and a test set. Steric and electrostatic interaction energies between the probe and each molecule are computed and stored in an *X* matrix, which is then regressed by PLS statistics against the *Y* vector of training set pIC_{50}s (or other logarithmic biological activity metric). The PLS model is used to predict test set pIC_{50}s; furthermore, PLS pseudo-coefficients enable a visual interpretation in 3D space of the impact of steric and electrostatic properties on the biological activity.

3.11.2.6.2 CoMSIA

In 1994, Klebe introduced the comparative molecular similarity indices analysis (CoMSIA), a variant of the CoMFA methodology aimed at improving some of the shortcomings of the latter.[63] In CoMSIA, the Lennard–Jones and Coulombic potentials used in CoMFA to compute the steric and electrostatic grids are replaced by an exponential functional form derived from the SEAL alignment algorithm.[8] In CoMSIA, the distance-dependent similarity of a probe to the atoms constituting the molecules of the dataset is evaluated at each grid node, but unlike CoMFA, grid nodes falling within the molecular volume are also taken into consideration. The exponential dependence from distance avoids singularities which characterize CoMFA potential maps in the vicinity of atomic nuclei, and eliminates the need for setting arbitrary energy cut-offs. Due to the difference in slope of the Lennard–Jones and Coulombic potentials, in CoMFA cut-offs intervene at varying distances from nuclei depending on the nature of the field; this requires block-weighting fields to give them comparable importance in the PLS matrix, which may in turn reduce the information content.

The first CoMSIA formulation consisted of three field maps: steric, electrostatic, and hydrophobic, the latter having the purpose of modeling the enthalpic component of desolvation.[63] Two further fields, encoding the hydrogen bond donor/acceptor character, were added at a later stage.[64] While CoMSIA has comparable predictive power to CoMFA and shares with the latter the requirement for aligned structures, the absence of cut-offs, the fact that all grid nodes are used to compute field maps, and the smoother distance dependence of the CoMSIA functional forms yield more continuous isocontour maps, to the advantage of their interpretability. This feature, together with the wider spectrum of the molecular properties covered by CoMSIA field maps, helps prospective usage of 3D-QSAR to guide further development of a ligand series.

3.11.2.6.3 Topomer CoMFA

Topomer CoMFA was introduced with the purpose of automating as much as possible the generation of a CoMFA model. Automation pursued a dual goal: (1) to remove the most inconvenient, error-prone, and user-biased stage: the choice of a ligand conformation and its alignment to a common template[65] and (2) to make CoMFA a viable scoring step in a VS workflow.[57] The topomer concept had been introduced several years before as a possible alternative to 2D fingerprints to retrieve R-group structures from a virtual database, having in mind the design of combinatorial chemistry libraries where a central core is decorated with variable fragments. A topomer is defined as "an invariant 3D representation of a molecular fragment, generated from its 2D topology by deterministic rules that produce absolute coordinates for each of its constituent atoms."[66] While in general 3D methods aim at providing the most informative and physicochemically sound description of a molecule possible, at the price of increased complexity, the topomer technology goes in the opposite direction. Having acknowledged the daunting difficulty of taking into account multiple tautomeric, protonation, and conformational states for each ligand due to combinatorial explosion of possible permutations, its authors decided to rather adopt a radically simplified approach, trading consistency, standardization, and computational expediency for physicochemical accuracy.[67]

The procedure to convert a ligand into topomers has evolved over time to become almost completely automated.[68] The only step which requires user intervention is ligand fragmentation into R-groups.[62] The procedure for generating a topomer from a monovalent molecular fragment is briefly outlined in the following: (1) cap the open valence of the monovalent fragment with a suitable group (e.g., a methyl) and generate a single 3D conformation out of the 2D topology, considering all ionizable groups as being in their uncharged form; (2) translate and rotate the model to overlay the bond joining the fragment to the cap onto a vector fixed in Cartesian space; (3) adjust acyclic torsions, invert stereocenters, and standardize ring puckering as required to obtain consistent topomer geometries as determined by a set of rules; and (4) remove the cap. Regarding chirality inversion, while the original stereochemistry is stored within the fragment metadata, the stereochemistry in 3D geometry is actually rule-based and independent from the original one, according to the aforementioned trade-off between consistency and accuracy; even eventual internal steric clashes are ignored.[68]

Once invariant topomers are obtained for each of the fragments constituting the molecule of interest, a separate CoMFA is computed for each topomer, after embedding the latter into a 2 Å, 1000-node fixed size grid. Compared to standard CoMFA, two main differences characterize the protocol. Firstly, an attenuation factor is applied to atomic field contributions depending on the number of acyclic single bonds intervening between the atom and the topomer's open valence; the rationale behind this modification is to reduce the impact of groups located on flexible linkers, as they are expected to undergo a larger degree of induced fit upon interaction with the target. Secondly, field values at each grid node are discretized in 2 kcal mol^{-1} increments, in order to simplify QSAR equations by removing many variables with low variance while preserving 90% of the overall variance.

Retrospective validation of the Topomer CoMFA methodology on 15 literature datasets showed that there is a decrease in predictive power compared to standard, whole-ligand CoMFA, quantified in an average $\sim$0.1 reduction in q^2. However, Topomer CoMFA training sets were aligned in a completely automated fashion, whereas the original investigations were most likely carefully tweaked to maximize q^2 (see section "3D-QSAR"). Interestingly, Topomer CoMFA models were on average characterized by a lower number of components, and the external test set SDEP values were comparable to standard CoMFA, which suggests that cross-validated q^2 values in the original publications were most likely inflated by their intentional maximization through individual conformation adjustments.[65]

One of the most appealing features of Topomer CoMFA is that topomers can be used as queries for fast similarity searches in virtual databases, whose topomers are already prealigned according to the same rules. Topomer similarity is evaluated as a combination of shape (as evaluated by the CoMFA steric field) and pharmacophoric features (aromatic, positive/negative charge, hydrogen bond acceptor/donor).[69] The effectiveness of topomer similarity was validated in two separate contexts, prospective

and retrospective. In the first, 308 compounds out of a pool of about 80K candidates having high topomeric similarity to 14 query structures were biologically tested for 13 different kinds of activity. Hit rates by topomeric similarity were 20% higher compared to a random selection. Interestingly, these hits shared a 2D fingerprint-based Tanimoto similarity to the original queries comparable to random compounds, thus indicating that hits had markedly different scaffolds compared to the query. In the second context, the differential ability of topomeric similarity and 2D Tanimoto distances to concentrate structures sharing the same World Drug Index activity class was assessed. Topomeric similarity appeared to be superior to 2D fingerprints by about 30%, again displaying greater propensity toward the correct classification of 2D-dissimilar scaffolds as members of the same activity class.[67]

Furthermore, the activity prediction generated by the model can be partitioned over topomers to yield a per-topomer activity contribution. This enables topomers found through the similarity search to be immediately scored through the CoMFA model to predict the activity contribution they would bring about if included in the ligand. The correctness of these predictions was assessed with a dual criterion: (1) absolute, evaluating the discrepancy between experimental and predicted activity and (2) relative, by evaluating the capacity to correctly rank-order ligands by their potency. Regarding absolute potency prediction, the average predictive r^2 was 0.495. The rank-ordering performance as determined by ROC curves was more encouraging, showing that there is a ~70% probability that the predicted ranking of a compound is confirmed experimentally (Kendall's tau ~0.4). The most prominent concerns about Topomer CoMFA are represented by the loss of information connected with collapsing a 3D R-group to a conformer-, protomer-, and stereoisomer-agnostic representation, by the difficulty in transferring context-ignorant topomer-based CoMFA contours to the full ligand in the context of its receptor, and by the assumption that individual fragments can make independent and additive contributions to pIC_{50}.[57]

3.11.2.6.4 Template CoMFA

Template CoMFA is an attempt to combine the best of standard CoMFA and Topomer CoMFA. While removing the most unattractive feature of standard CoMFA (the necessity to align ligands before the analysis), Topomer CoMFA also removed the possibility to include information about the ligand-binding mode when available (e.g., from an X-ray crystallographic complex between a ligand and its protein target). In fact, Topomer CoMFA operates on disconnected R-groups in isolation, making isocontour plots unable to be easily transferred to the protein context for interpretation. Furthermore, the protocol which generates topomers neglects intramolecular steric clashes, and may give rise to inconsistencies with certain side chain substitution patterns within homologous ligand series, both of which detract trustworthiness from the resulting model.[70]

In Template CoMFA, as in Topomer CoMFA, the alignment procedure is by default completely automatic. However, in Template CoMFA one or more templates must be supplied by the user. In Topomer CoMFA, for each candidate ligand the atom of the R-group topomer which bears an open valence is arbitrarily centered on the origin, and the bond which departs from the open valence is aligned along the *X* axis. In Template CoMFA, the fragmentation bond becomes an anchor bond; the bond which best matches the anchor bond is identified across all templates based on bond type, ring network, types of the atoms at the bond ends, and heavy atom count of their neighbors. Once a potential pairing has been found between the anchor bond in the candidate and a bond in the template, the connectivity graph starting from the anchor bond is compared between candidate and template. The anchor bond which yields the best mapping between candidate and template atoms is chosen among all potential bond pairings. It is worth pointing out that the algorithm used to map atoms between candidate and template is different from classical approaches based on maximal common subgraph (MCS) matching: Template CoMFA uses a two-stage mapping, where the first stage requires an exact match of atom and bond types, while the second relaxes the requirements to further extend the mapping. The atom mapping is carried out in a breadth-first fashion, reflecting the fact that in Template CoMFA, just like in Topomer CoMFA, the farther from the topomer's open valence, the lower is the weight of the atomic steric field descriptors (see section "Topomer CoMFA"), and therefore the less critical is the matching.[70,71]

Once the best atom mapping has been found, 3D coordinates of matching atoms are directly copied from the template to the candidate, while the topomer protocol is applied to atoms for which a match could not be found. In practice, Template CoMFA aims at prioritizing consistency to a template wherever possible, falling back to consistency *tout court* only when no template is available. This avoids unnecessary discrepancies between available data about the bioactive conformation and the rule-based conformation generated by the purely topomeric protocol.[70]

Template CoMFA was reapplied to the 15 datasets originally used to validate Topomer CoMFA without any significant change in the statistical quality of the models, in spite of the markedly different alignment protocol. While this may be interpreted as a greater importance of self-consistency over physicochemical realism,[70] it certainly removes any residual confidence that the statistical quality of the model may corroborate the underlying alignment hypothesis. This means that in the absence of a binding mode hypothesis supported by robust experimental evidence, the interpretation of CoMFA contours can be misleading.[72]

Further large-scale application of the Template CoMFA methodology to datasets extracted from BindingDB[73] and ChEMBL[72] adopting many different and contrasting alignment templates reinforced the absence of dependency of the model statistics on the 3D alignment. Template CoMFA activity predictions were about 50% less uncertain than the null model which predicts an unknown compound to have the average activity of the training set. 2D fingerprint-based Tanimoto distances yielded a similar performance, halving the frequency of false positives compared to Template CoMFA; however, Template CoMFA has a higher propensity for scaffold hopping, identifying actives missed by 2D metrics.[72]

3.11.2.6.5 COSMOsar3D

COSMO*sar3D*[74] is based on the QM-derived COSMO-RS theoretical framework already introduced in section "COSMO*sim3D*" when describing the COSMO*sim3D* method. Compared to traditional 3D-QSAR methods based on steric, electrostatic, hydrogen bonding, or hydrophobic potentials, where a linear relationship is assumed between experimental binding affinities and energy

descriptors, COSMO*sar3D* presents a more rigorous theoretical rationale to back up the expectation of such a linear relationship. In COSMO-RS, molecular interactions are quantified as local contact interactions of surface polarization charge densities within a conductor. This charge density distribution can be computed through a QM calculation at the DFT level, or be approximated by a collection of precomputed surface fragments (see section "COSMO*sim3D*").

The COSMO-RS method has initially been applied mainly to the prediction of the free energy of a molecule in a homogeneous liquid phase, computed as the surface integral of a solvent-specific, homogeneous σ-potential over the σ-surface of a molecule. The σ-potential expresses the affinity of a solvent for a molecular surface characterized by a certain σ-polarity. Subsequently, extensions to inhomogeneous phases such as micelles and biomembranes were presented, based on inhomogeneous σ-potentials.[75] Taking these extensions one step further, Klamt and coworkers conceived a receptor as a pseudo-liquid matrix with a locally varying affinity for a molecular surface characterized by a certain σ-polarity. Within such a model, the free energy of a ligand within a receptor would then be accessible as the surface integral of a receptor-specific, inhomogeneous σ-potential over the σ-surface of the ligand. As the surface integral can be conveniently approximated by a summation over a 3D grid, the free energy of a ligand in a receptor can be expressed as a linear function of the local σ profiles used by the COSMO*sim3D* method to assess molecular similarities.

Once the linear relationship between free energy of binding and local σ profiles has been established, the coefficients of such a relationship can be regressed using PLS against experimental free energies of binding as encoded in binding constants. The local σ-profiles used by COSMO*sim3D* have a resolution of 0.1 $e\,\mathrm{nm}^{-1}$ in σ space, which leads to partitioning the range of σ surface polarity into 61 bins. For the purpose of 3D-QSAR analysis such a degree of accuracy is not necessary, and the number of σ bins can be reduced to 11. The latter can be regarded as 11 MIFs, each describing intermolecular interactions within a defined polarity range. As in CoMSIA, but unlike CoMFA and CoMFA-like fields such as those implemented in Open3DQSAR,[76] COSMO*sar3D* fields are smooth and continuous, thus removing the need for arbitrary cut-offs and conferring significant robustness to translation of the grid relative to the molecules, variation of grid step size, and moderate ligand misalignment (Fig. 18A–C). As σ charges are

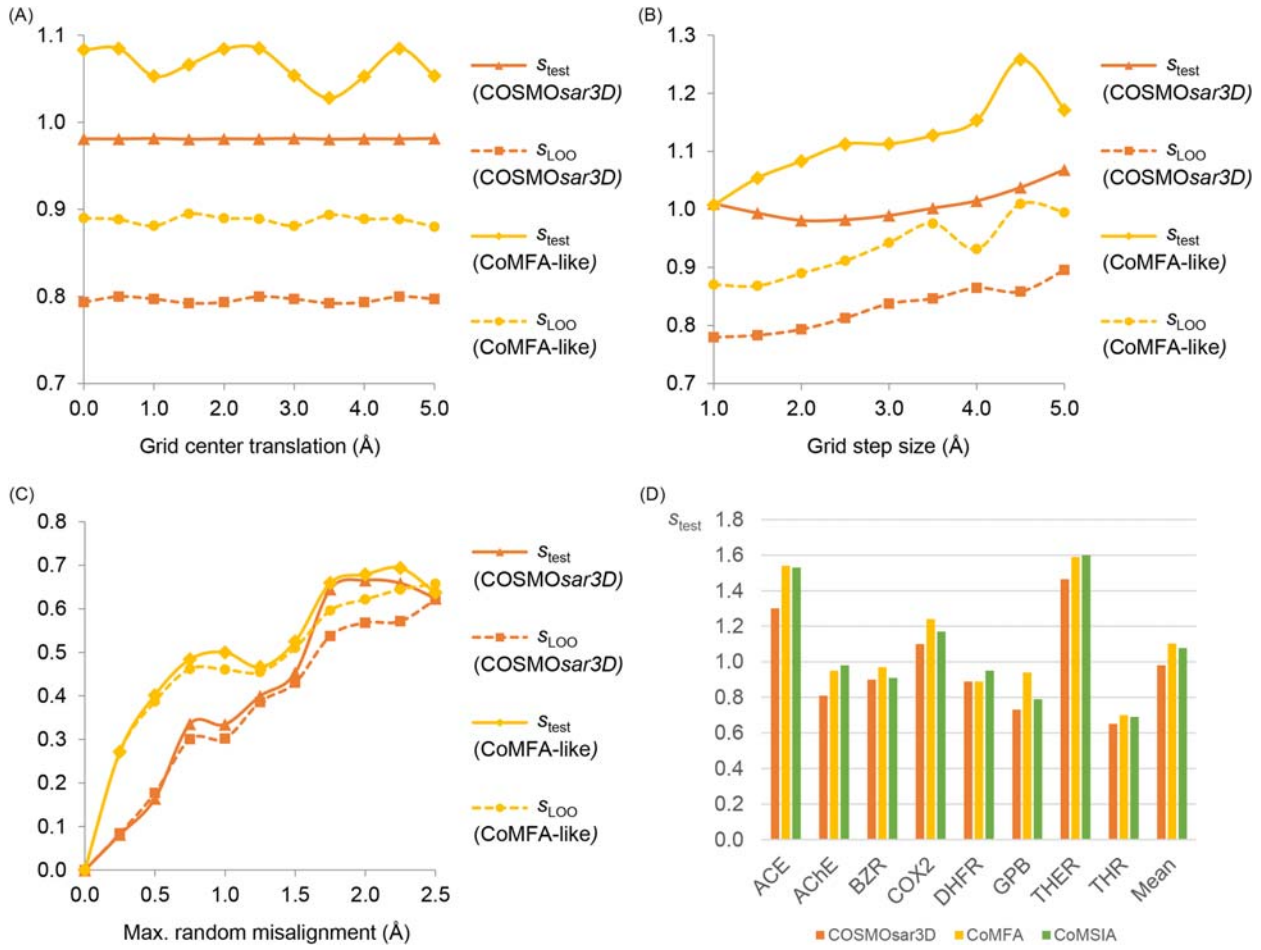

Fig. 18 Charts A–C show the effect on the standard error of external test set predictions (s_{test}) and of LOO predictions (s_{LOO}), as obtained through COSMO*sar3D* descriptors and through the CoMFA-like descriptors implemented in Open3DQSAR, of the following operations: (A) translating the grid center with respect to the aligned molecules by increasing amounts along the three Cartesian axes; (B) increasing the grid step size; and (C) applying random translational misalignments to individual compounds from 0.0 to 2.5 Å along the three Cartesian axes. In all cases, COSMO*sar3D* shows greater robustness against grid-related artifacts. Chart D shows that on the eight datasets of the Sutherland benchmark suite, COSMO*sar3D* consistently delivers a better performance (lower s_{test}) on external predictions compared to CoMFA and CoMSIA.

only defined on the molecular surface, there is also no need to extend the grid beyond the surface as in traditional 3D-QSAR techniques.

When its predictive performance was assessed on the Sutherland benchmark suite for QSAR methods,[77] COSMO*sar3D* outperformed both CoMFA and CoMSIA: the average standard error on external predictions was 0.1 logarithmic units lower(Fig. 18D). The performance loss moving from the computationally expensive QM surfaces to the inexpensive, fragment-derived ones was negligible.[74]

3.11.2.6.6 FieldQSAR

The XED/FieldAlign technology (see section "XED/FieldAlign") enables 3D-QSAR modeling through a somewhat different paradigm compared to the almost ubiquitous grid-based methods. Molecules in the training set are used to derive a common set of sampling points, based on the coordinates of the field points belonging to individual molecules. It has to be noted that since molecules have been aligned using their field points, the latter are likely to be located in close vicinity to each other. Therefore, a sphere-exclusion clustering algorithm[78] is used to reduce redundancy and retain only the largest field points, while keeping the same space coverage as the original set. Finally, for each molecule the value of the electrostatic potential is evaluated at each sampling point and stored in a vector. To avoid issues connected with the steep variations that the steric potential shows near the molecular surface (see sections "CoMFA" and "CoMSIA"), the steric field uses a binary indicator variable which takes the value 0 when the sampling position falls within the van der Waals volume of a molecule, and 1 elsewhere. Sampling positions for the steric potential are pruned with the same methodology described for the electrostatic potential, starting from heavy atom coordinates rather than from field points, and binary descriptors are stored in a vector.

Electrostatic and steric field vectors are mean-centered and block-scaled based on the overall variance of the respective field, in order to give the same weight to each descriptor block. Finally, the data matrix whose columns are constituted by the scaled vectors and the rows by training set molecules is fed to a PLS engine to seek a correlation with the dependent variable (usually some flavor of biological activity). The resulting models can be used to predict the activity of an external test set. Additionally, as in CoMFA, the product of PLS pseudo-coefficients and the standard deviation of the descriptors for each field can be plotted in order to visually grasp how field potentials influence biological activities. Alternatively, the field contributions to the predicted activity can be visualized on a per-molecule basis, such that the regions of the molecule which contribute most to defining SAR can be identified at a glance. To partially overcome a well-known limitation of 3D-QSAR methodologies, their inability to give any indications about the impact of a molecular feature when the latter is ubiquitous across the dataset, descriptor variance can also be plotted. This allows the modeler to attribute zero coefficients in a certain area of the molecule to an actual lack of correlation with biological activity (if the variance is high), or rather to highly consistent field properties across the training set (if the variance is low), as exemplified in Fig. 19.

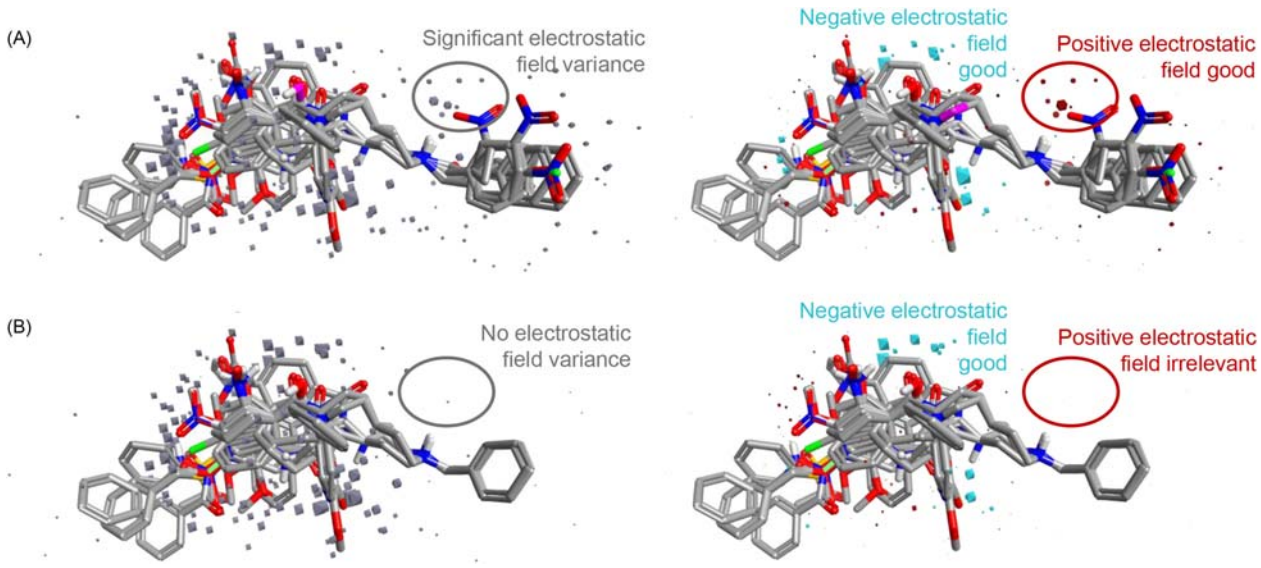

Fig. 19 Effect of descriptor variance on 3D-QSAR models as exemplified by a FieldQSAR model built using the Sutherland AChE dataset. (A) The whole set of 111 AChE inhibitors displays significant electrostatic descriptor variance in vicinity of the piperidine nitrogen (*left*), because in some of the ligands the latter is part of an amide group, hence not basic at all, while in phenylalkyl-substituted ligands its basicity depends on the ring substitution pattern. The PLS pseudo-coefficient plot (*right*) shows that biological activity is positively correlated with increasing positive electrostatic potential, that is, increasing basicity. (B) A reduced set of the 84 inhibitors featuring benzyl-substituted piperazines has no electrostatic descriptor variance in vicinity of the piperidine nitrogen (*left*), and hence the PLS pseudo-coefficient plot (*right*) shows no influence of electrostatic potential on biological activity in this region.

3.11.2.6.7 GRID/GOLPE/FLAP

CoMFA-like 3D-QSAR models based on MIFs evaluated with GRID probes can be built within the GOLPE chemometric tool,[79] as well as in FLAP. In general, there is not much to add from a methodological point of view compared to what has been described in section "CoMFA". The wide palette of available GRID probes expands the accessible range of 3D interaction properties relevant to biological activity beyond the pure steric and electrostatic potentials as in traditional CoMFA; the usual caveats associated with grid-based evaluation of potentials apply.

3.11.2.6.8 GRIND

As already mentioned during the description of Topomer and Template CoMFA approaches, the alignment prerequisite is one of the main drawbacks of 3D-QSAR, which reduces its amenability to high-throughput and unsupervised applications. GRid-INdependent Descriptors (GRIND) were developed by Pastor and coworkers[80] in an attempt to overcome this limitation. The GRIND method uses MIFs from a ligand-centric, alignment-agnostic perspective. The generation of GRIND involves two stages: (1) extraction of a small subset of highly relevant grid nodes from MIFs (usually computed through the hydrogen bond donor probe N1, the hydrogen bond acceptor probe O, and the hydrophobic probe DRY) and (2) computation of correlograms among those nodes.

Finding an efficient algorithm to identify the most relevant grid nodes is not trivial. In the original implementation within the ALMOND program, a fixed number of nodes (100–150) was extracted by iterative simultaneous optimization of two parameters, field intensity at each node (only favorable, negative energies are considered), and internode distances; the relative weights of these parameters could be user-adjusted. While this method guaranteed good coverage in terms of 3D space, it had two major shortcomings. The first was the computational cost, due to the iterative nature of the optimization algorithm which involves the computation of a distance matrix at each step. The second problem was that a fixed number of nodes was extracted, which might be insufficient for larger molecules or overkill for molecules devoid of many significant MIF-energy minima (e.g., a lipophilic molecule analyzed with a hydrogen bond donor/acceptor probe). The original algorithm was superseded by AMANDA,[2] which allows for extraction of a variable number of nodes depending on molecule size and MIF complexity. AMANDA starts by prefiltering MIF nodes based on a cut-off and tagging them by the atom which contributes most to the field energy. Then, for each atom a nonlinear fraction of the total nodes is extracted (one at the very least), prioritizing nodes with low energies initially, and gradually giving more weight to their distance from those already extracted. The ability of AMANDA to extract relevant ligand hotspots was validated with objective metrics on a set of ~800 complexes taken from the PDBbind database,[47] showing a satisfactory ability to identify the interaction partners in the protein just based on hotspot extraction from ligand MIFs.[2]

The subsequent step involves the computation of auto- (within the same MIF) and cross- (across different MIFs) correlograms between hotspot pairs. For each pair the product of MIF energies is computed and binned based on the discretized distance between the nodes (Fig. 20). While in classic autocorrelation analysis all pairs belonging to a bin are summed together, in GRIND only the highest product is retained for each bin, such that it is possible to trace back the descriptor to the nodes which originated it. A similar approach has also been exploited in SHOP (see section "SHOP"). Correlogram descriptor vectors are collected into a matrix, one ligand per row, which is then fed to a PLS engine to find correlations with biological activities. PLS pseudo-coefficients can be associated to a specific pair of nodes, thus making the model interpretable.

GRIND-2 descriptors (the evolution of GRIND obtained via the AMANDA method) demonstrated some promising potential in VS applications,[81] but still have some drawbacks. Even though GRIND descriptors are alignment-independent, they still are sensitive to ligand conformations, as they are based on intramolecular distances between hotspots. While the procedure used to generate GRIND descriptors allows the original hotpots associated with PLS pseudo-coefficients to be traced back, it has to be observed that each descriptor is associated with a pair of nodes separated by a certain distance range. Therefore, it can be not readily apparent which pair of nodes it refers to for a certain ligand, as ligands are not mutually aligned and there may be multiple node pairs whose distance falls within the same bin.[80] In an attempt to address this shortcoming, the Anchor-GRIND evolution of the methodology was proposed, where distances are computed not only between node pairs as in standard GRIND, but also between nodes and an anchor point common to all ligands.[82] While this makes less likely that variables can be confounded with interactions taking place at similar distances but involving different atoms, it can only be applied to homologous series and does not remove the conformational dependence.

3.11.2.7 3D Activity Cliff Analysis

As already mentioned in the introduction to this article, many modeling techniques are based on the assumption that compounds classified as similar by some metric will display similar biological activities; as a consequence, small changes to a molecule should cause only small changes in activity. However, there are cases where the similarity hypothesis breaks down.[83] These cases often turn out to be the most useful parts of the activity landscape for a compound series in terms of gaining a full understanding of interactions with the target protein. Pairs of similar compounds characterized by marked differences in biological activity form the so-called activity cliffs.[84] A quantitative definition of an activity cliff was proposed by Guha and coworkers through the Structure-Activity Landscape Index (SALI),[85] which is defined as the ratio between the difference in potency and the dissimilarity of the compounds. The larger the activity difference and the higher the similarity, the higher the SALI index.

Very relevant to this definition is the criterion used to assess similarity. When 2D similarity metrics such as Tanimoto distances between fingerprint vectors are used, a compound pair is generally only considered as a potential activity cliff if the similarity is above a threshold (0.55 for ECFP4 fingerprints and 0.85 for MACCS structural keys have been suggested). Moreover, an additional

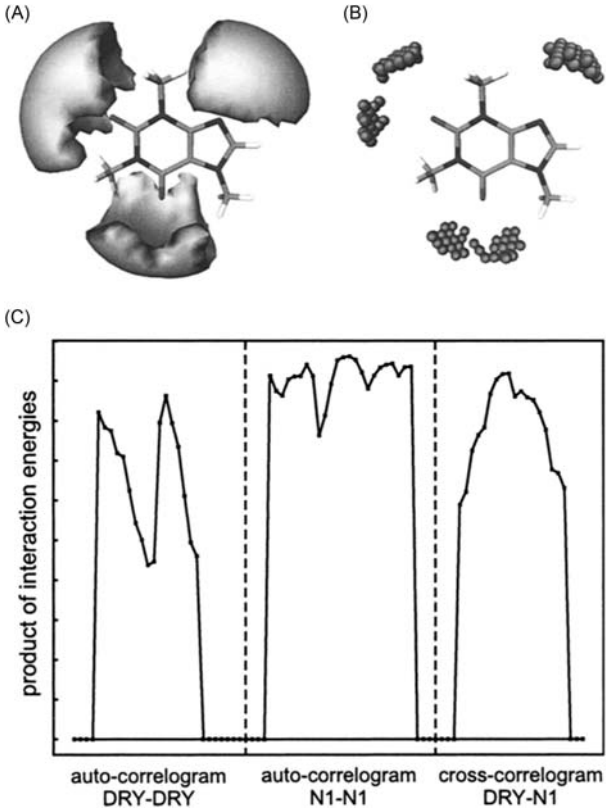

Fig. 20 Workflow to generate GRIND correlograms out of GRID MIFs: (A) A GRID MIF is computed with the N1 probe around caffeine; (B) the most relevant 100 nodes are extracted from the full GRID MIF; and (C) auto- and cross-correlogram profiles are generated with different probe combinations; the abscissa represents the discretized distance between the nodes. Adapted from Figures 1 and 2 in Pastor, M.; Cruciani, G.; McLay, I.; Pickett, S.; Clementi, S. GRid-INdependent descriptors (GRIND): a novel class of alignment-independent three-dimensional molecular descriptors. *J. Med. Chem.* **2000**, *43*, 3233–3243. ACS publication.

constraint is often put on activity, which should be in the nanomolar range.[84] Even though the majority of literature on activity cliffs is based on 2D similarity metrics, some comparisons with 3D metrics have been carried out.[86,87] Interestingly, these reports indicate that the classification of activity cliffs has a strong dependence on the similarity metric employed. In particular, only 40% of 3D activity cliffs were found to be conserved when moving to 2D metrics.[87] This is not surprising, as one of the main strengths of MIF-based approaches is to capture similarities in 3D property space which hide behind different 2D chemical structures. Activity cliffs which are missed by 2D methods can be highlighted by 3D metrics (**Fig. 21**), making their combined use highly advisable whenever possible to enrich the description of the activity landscape for a ligand series.[86,87]

3.11.2.7.1 Activity Miner/Activity Atlas

As described in the previous paragraph, navigation through activity landscapes taking advantage of both 3D and 2D similarity metrics is highly desirable from a medicinal chemist's standpoint. To facilitate this task, a methodology called Activity Miner has been developed,[88] based on the XED/FieldAlign technology (see section "XED/FieldAlign"). 3D Similarity metrics are stereochemistry- and conformation-dependent; therefore, as in 3D-QSAR, all of the structures need to be prealigned. The alignment requires one or more reference structures to act as templates, in the hypothesis that all molecules within the series bind at the same active site and share some common MIF features. Ideally, the bioactive conformation for a representative structure of each chemotype would be known, for example, from X-ray crystallography. If this is not the case, a 3D binding mode hypothesis could be generated with the FieldTemplater methodology (see section "FieldTemplater"), or a suitable low-energy conformer chosen. The alignment procedure is based on maximization of the combined field/shape score between each dataset molecule and the reference(s). As molecules exist as multiple conformations, all conformations are aligned to the reference(s) and the highest similarity value is taken as the similarity for that molecule. When there are multiple references, the final score can be either the average or the maximum across all references. If more emphasis is desired on common structural motifs (e.g., a common scaffold) between reference(s) and dataset molecules, it is possible to copy the coordinates of the maximum common substructure from the reference to each dataset molecule, and carry out the conformational search only on the molecular portions which are not part of the common scaffold. These portions are then aligned according to the standard shape/field paradigm. A similar constrained conformation search protocol has recently been published by Cappel et al.[89]

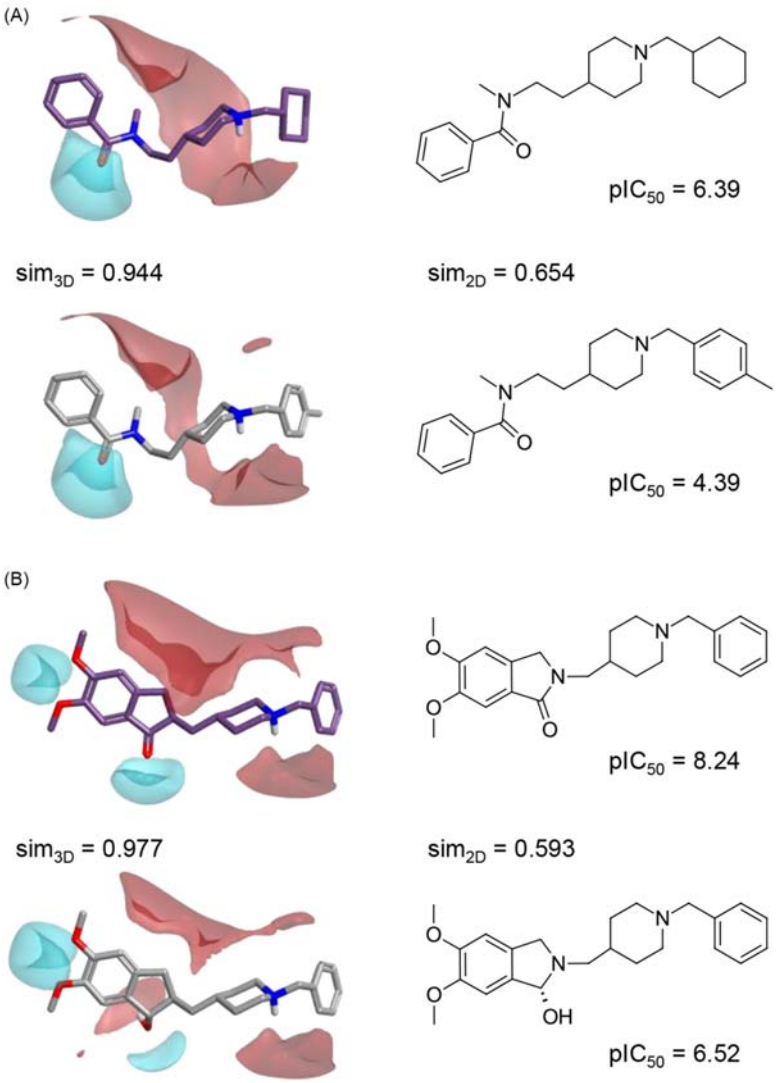

Fig. 21 Examples of AChE inhibitor pairs where the activity cliff missed by 2D fingerprints is captured by 3D metrics. (A) The 2D similarity between a cyclohexyl and a *p*-tolyl substituent is relatively low (0.654), while the 3D shape and electrostatic similarity is quite high (0.944). Although the tolyl group has more electrostatic character than the cyclohexyl, this is relatively weak, while the shape and hydrophobicity match between the two is very high. Conversely, the 2D similarity metric treats aromatic carbons as being totally dissimilar to aliphatic ones, and hence it misses this activity cliff. (B) The reduction of the carbonyl group to an alcohol causes a drop in activity of 1.7 log units. As this structural change occurs near the center of the molecule and involves a change in hybridization, the ECFP4 similarity is only 0.593, and no activity cliff is detected. However, the –OH group and the carbonyl oxygen are both electronegative and H-bond acceptors. The difference in the MIFs of the two molecules is quite modest, and a 3D activity cliff is detected.

Once molecules are aligned, pairwise 3D similarities across the dataset are displayed in a matrix whose cells are color-coded based on the value of the disparity characterizing each compound pair. The disparity is a quantitative measure of the degree to which two molecules constitute an activity cliff. It is defined as a slightly modified version of the above-mentioned SALI index: the maximum similarity of molecules is clipped to 0.95 to avoid discontinuities or overly large disparity values, and the standard error affecting biological activities is accounted for, in order to neglect differences in activity which are not significant. Pairs of compounds which constitute activity cliffs can be examined in 2D and in 3D to determine which differences in their topologies and in their 3D MIFs might be causally connected to the observed discontinuity in the activity landscape. Additionally, the most similar N molecules can be visualized for each member of the dataset, along with their disparity value and 3D structure/fields, enabling a similarity and activity-driven navigation through the dataset (Fig. 22). At any time, the 3D similarity matrix can be replaced by a traditional, fingerprint-based 2D similarity matrix, while keeping the 3D view on the dataset owing to the initial alignment operation. This allows combining most effectively the 3D and 2D classification of activity cliffs to amplify the insight on SAR for a ligand series.

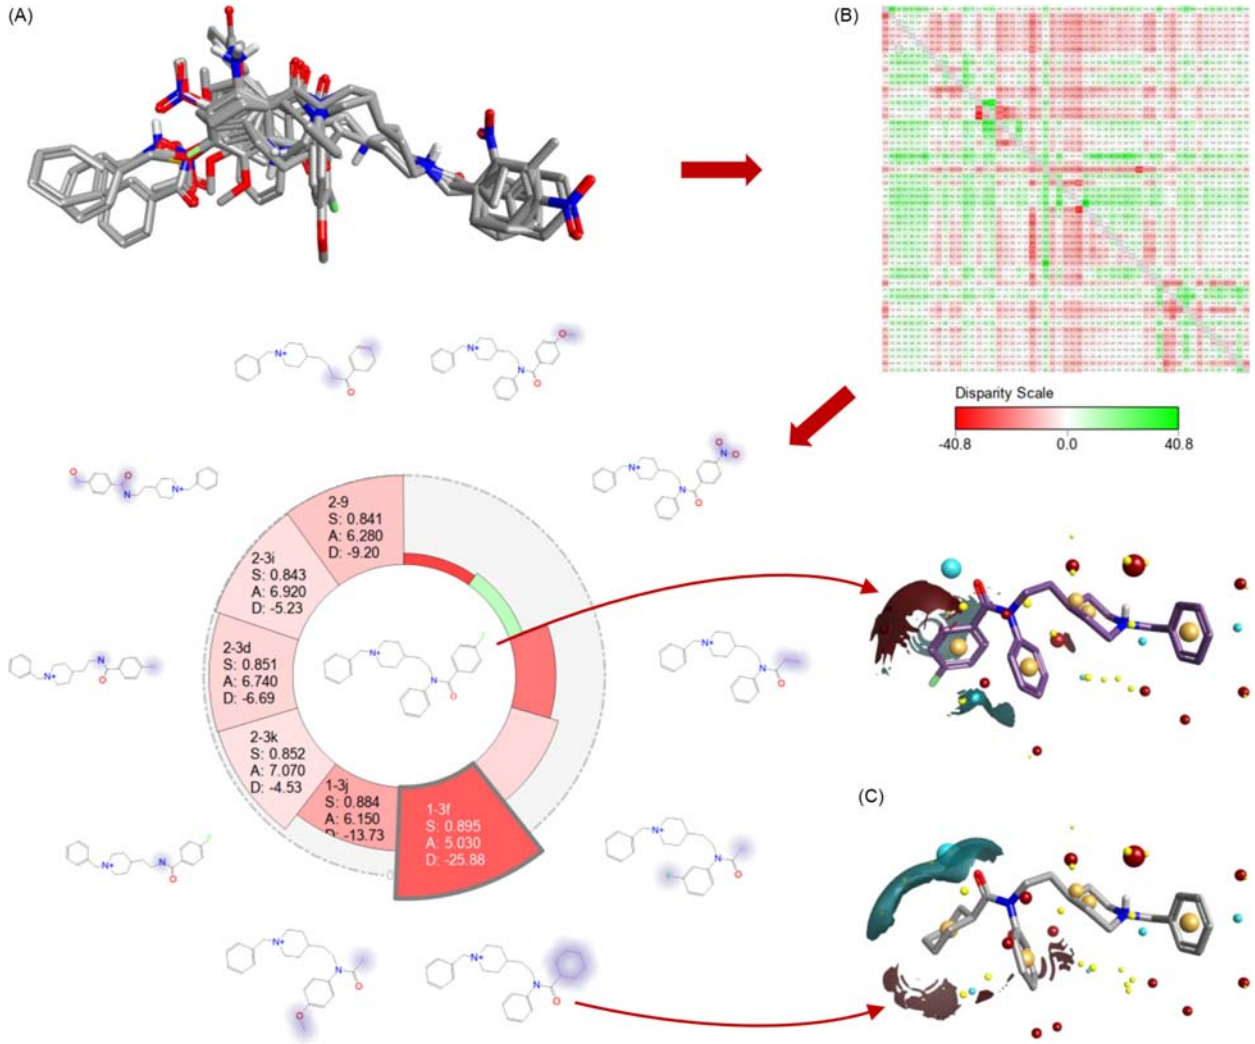

Fig. 22 Summary of the Activity Miner methodology. (A) A 3D-aligned set of 55 AChE inhibitors taken from the Sutherland benchmark suite undergoes exhaustive pairwise similarity assessment to generate a similarity matrix (A), which is colored by disparity: the most intense *red/green* shades respectively indicate the largest losses/gains in activity as a consequence of small structural changes. The similarity matrix is used to navigate the activity landscape of the dataset (B), in order to analyze the changes which give rise to the highest activity cliffs and compare the MIF differences underlying the latter (C).

While 3D activity cliffs do highlight the most informative local portions of the activity landscape (those where small 3D property modifications bring about large changes in the biological response), they are confined to individual compound pairs. In a large dataset, especially when multiple chemotypes are involved, it can be difficult to combine the information from many contrasting activity cliffs in a global picture which may guide further lead development efforts. 3D-QSAR techniques can summarize the SAR content of a dataset in a single picture through visualization of PLS pseudo-coefficient isocontours (see section "3D-QSAR"). However, most 3D-QSAR methods are much more suited for dealing with smooth, continuous regions of the activity landscape, rather than with the abrupt variations that characterize datasets with many activity cliffs. To enable a global view of the most rugged areas of the activity landscape, Activity Miner has been augmented by the Activity Atlas method.[90]

Activity Atlas uses a Bayesian approach to analyze activity and alignment data: each activity cliff provides evidence that a certain change in 3D properties causes a significant change in biological activity, the evidence being stronger for larger disparities. Furthermore, the 3D similarity of each aligned molecule to the alignment template provides an estimate of the chance that the alignment itself is correct: the higher the similarity, the more likely the molecule is to adopt the same binding mode. Based on these assumptions, the aligned molecules are embedded in a 3D grid. At each grid node, and for each pair of compounds, the product of three factors is computed: (1) the disparity value; (2) the field difference between the molecules constituting the pair; and (3) a weight determined by the likelihood that the alignment of the molecules constituting the pair is correct. The grid values are summed across all molecule pairs in the dataset, and the procedure is repeated for each of the MIFs used by the XED/FieldAlign technology (see section "XED/FieldAlign"). Finally, the grids thus obtained are contoured at the desired isolevel to identify the

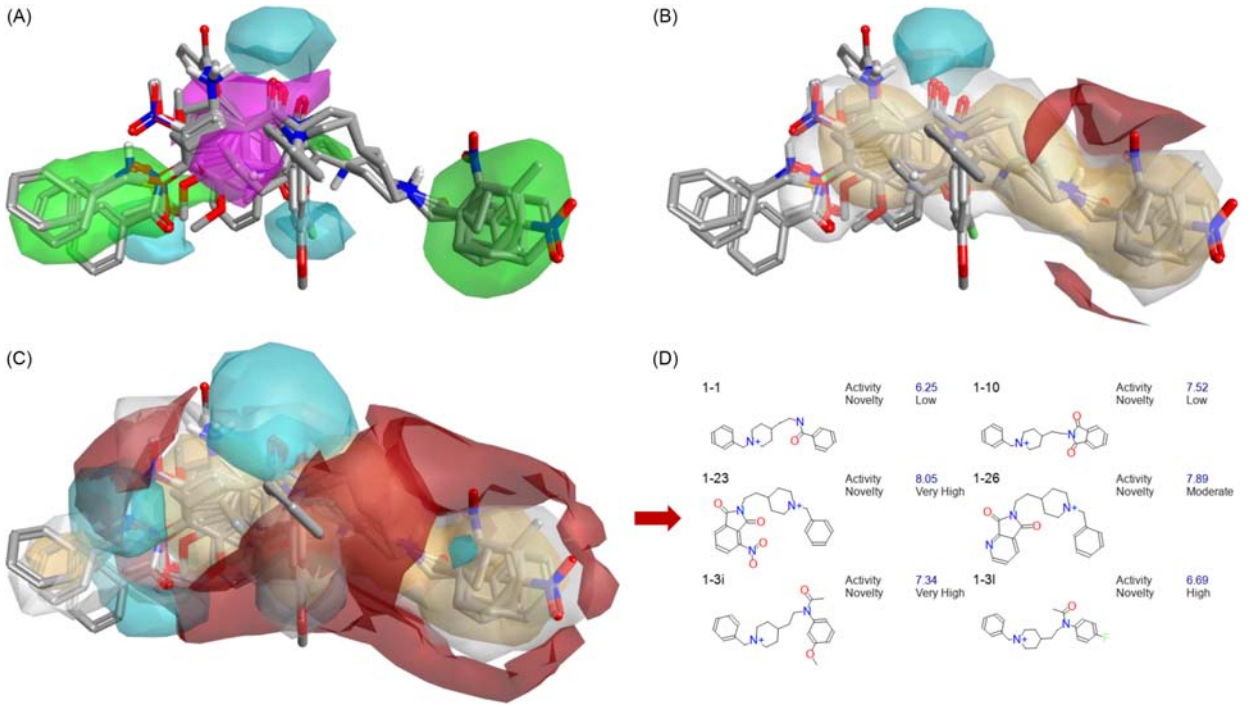

Fig. 23 The three pictorial SAR summaries provided by the Activity Atlas methodology are shown. (A) Cyan isocontours indicate regions where, based on the analysis of activity cliffs across the dataset, more negative electrostatic potential is linked to an increase in biological activity, while *green* and *purple* isocontours highlight regions where greater hydrophobicity is respectively favorable or unfavorable. (B) *Red/cyan* isocontours respectively show regions where positive/negative electrostatic potential consistently leads to highly active compounds, while ochre and white isocontours depict the average hydrophobicity and shape features of actives. (C) *Red* and *cyan* isocontours highlight regions where positive and negative electrostatics respectively have been thoroughly explored within the dataset, while *ochre* and *white* isocontours refer to hydrophobicity and shape. This qualitative map also enables a semiquantitative scoring of the degree of novelty of newly designed candidates (D).

regions where higher intensity in a certain field is linked to a change in activity (Fig. 23A). Contrary to 3D-QSAR models, Activity Atlas models are only qualitative, in that they do not yield an activity prediction, but they can be applied to smaller datasets characterized by a discontinuous activity landscape, which are outside the domain of applicability of the former.

The global summary of the influence of the various fields on biological activity derived from analysis of all compound pairs is complemented by two additional grid maps, one detailing where in 3D space the presence of certain field properties consistently leads to highly active molecules (Fig. 23B), and the other describing the 3D regions where different molecular properties have been thoroughly explored within a series (Fig. 23C). The latter map enables a medicinal chemist to score the degree of novelty of a design idea on a semiquantitative scale. Therefore, compounds which increase the further elucidation of SAR can be prioritized with respect to trivial analogs which do not contribute major novel insight to the already available knowledge about a target (Fig. 23D).[90]

3.11.2.8 ADME Prediction

During the 1980s and early 1990s, the pharmaceutical industry experienced high attrition rates at the clinical trial stage due to unfavorable drug metabolism and pharmacokinetic (DMPK) profiles. The large financial losses connected with such advanced stage failures prompted a search for fast and effective methods to assess the DMPK profile during the lead optimization stage. The widespread diffusion of preclinical absorption, distribution, metabolism, and excretion (ADME) profiling reduced the overall attrition rate in phase I clinical trials due to unfavorable DMPK properties to 16%,[91] whereas in 1991 it used to be ~40%.[92] In particular, during the 1990s in silico methods to predict ADME properties emerged as important techniques to complement medium and high-throughput LC/MS/MS, cell-line and microsomal wet lab assays. Computational methods can be applied earlier in the development pipeline than in vitro assays, even prior to synthesizing the compounds or buying them from an external supplier.[93] The earlier in silico ADME predictions are carried out, the larger the number of molecules that need to be predicted, which in turn limits the acceptable computational expense of the methods. For this reason, starting from the late 1990s technologies based on GRID MIFs became very popular. In the following paragraphs three such applications will be reviewed.

3.11.2.8.1 VolSurf

Bioavailability is related to a number of processes, including membrane permeation, transport, and biotransformation. In particular, the interaction of molecules with biological membranes is mediated by surface properties (steric, electrostatic, hydrogen bonding, and hydrophobic), which can be captured into MIFs through appropriate GRID probes. Subsequently, the large amount of information contained in GRID MIFs can be condensed to a smaller number of descriptors (72 in the original formulation, currently over 120) relevant to the prediction of pharmacokinetic properties, called the VolSurf descriptors.[94]

Two grid probes were originally used to compute MIFs, namely OH2 (water) to simulate solvation–desolvation processes, and DRY (hydrophobic) to simulate interactions between the polar headgroups and the hydrophobic core of biological membranes; subsequently the O (carbonyl oxygen) probe was added to account for hydrogen bonding interactions. Each node of the MIF grids encodes an interaction energy between the probe and the molecule under analysis. As previously mentioned, contouring the grid nodes at a certain isolevel identifies grid voxels (the minimum grid volume unit, depending on the grid step) whose energy value is greater or equal than the selected isolevel. Counting those voxels and multiplying by the voxel size provides a reliable estimate of the molecular, hydrophobic, and hydrophilic volumes and surface areas, provided that the resolution of the grid is at least 0.5 Å. Importantly, the energy level chosen for contouring voxels influences the size and shape of the volumes, hence in most cases multiple energy ranges for each MIF are explored.

VolSurf features five different categories of descriptors:[94,95,96]

(1) Shape and size descriptors: molecular volume and surface area are defined as the water-excluded volume and water-accessible surface as determined through a water probe contouring the molecule at a repulsive energy isolevel of 0.2 kcal mol^{-1}. Additional information about shape and size is provided by the rugosity (ratio between volume and surface), globularity (ratio between the molecular surface and the surface of a sphere of equivalent volume), elongation (maximum extension a molecule can assume), and EEFR (ratio of the elongation and the extension of the molecule's fixed scaffold) descriptors.
(2) Hydrophilic region descriptors: the hydrophilic descriptors describe the regions of the molecule which are accessible to water molecules and have negative interaction energies with the latter. The extents of the water-accessible volume depend on the contouring isolevel; the energy range from -0.2 to -1.0 kcal mol^{-1} covers polarizability and dispersion forces, while the -1.0 to -6.0 kcal mol^{-1} range accounts for polar and hydrogen bonding interactions. Additionally, the three most favorable interactions established by water molecules are recorded as "best volumes", contoured respectively at -1.0 and -3.0 kcal mol^{-1} (six descriptors overall). The last descriptor group is constituted by capacity factors, which represent the hydrophilic fraction of the molecular surface. These are computed at eight different energy isolevels, the same used to compute the hydrophilic descriptors.
(3) Hydrophobic region descriptors: similarly to their hydrophilic counterparts, they define the regions of the molecule which establish attractive hydrophobic interactions in the -0.2 to -1.6 kcal mol^{-1} range; "best volumes" for hydrophobic interactions are determined as well at -0.6 and -1.0 kcal mol^{-1}.
(4) Interaction energy moment descriptors: they capture the imbalance between the center of mass of a molecule and the centroid of its hydrophilic and hydrophobic regions. The larger the interaction energy moments, the less evenly spread hydrophilic and hydrophobic features are across the molecular surface.
(5) Mixed descriptors: they include various kinds of energy minima and distances among the latter, hydrophilic–lipophilic region ratios at different isolevels, the amphiphilic moment (a vector pointing from the centroid of the hydrophobic regions to the centroid of the hydrophilic ones, whose magnitude affects the ability of a compound to permeate biomembranes), critical packing (involves again hydrophilic/hydrophobic balance, but focused on molecular packing as involved, e.g., in micelle formation and solubility), hydrogen bonding and other non-MIF-based descriptors. Log P is also computed through a quantitative structure–property relationship (QSPR) approach by regressing VolSurf descriptors against experimental n-octanol/water partition coefficients.

VolSurf descriptors have been successfully used as independent variables in QSPR models to regress physicochemical properties (e.g., free energy of hydration, water solubility,[94] log P[95]) and pharmacokinetic parameters (e.g., skin and biomembrane permeation, protein binding,[94] volume of distribution,[95] blood–brain barrier penetration (Fig. 24),[96] drug absorption[96,97]) through PLS statistics.

3.11.2.8.2 MoKa

Prediction of dissociation constants (pK_a) is of key importance in medicinal chemistry, as both pharmacokinetic (solubility and lipophilicity) and pharmacodynamic (interaction with charged residues in target macromolecules) properties of drugs are influenced by their protonation state. Milletti and Cruciani have taken an MIF-based approach at pK_a prediction in their MoKa tool.[98] The application of MIFs for this purpose was not unprecedented at the time of their original publication (2007), but until then had been based on standard CoMFA techniques and so was limited to small homologous prealigned ligand series.[99] MoKa is itself a QSPR methodology, but it is based on the 2D topologies of ligands rather than on their 3D structures, which makes it computationally very fast. Contrary to other 2D methods, it is not based on linear free energy relationships derived from Hammett–Taft equations,[100] but rather on three-dimensional GRID MIF-derived descriptors precomputed on a large set of fragments.

MoKa generates its pK_a predictions based on the molecular environment in the vicinity of an ionizable center, using an algorithm reminiscent of the one used to compute circular fingerprints.[101] For each ionizable center in the molecule, the atoms lying within

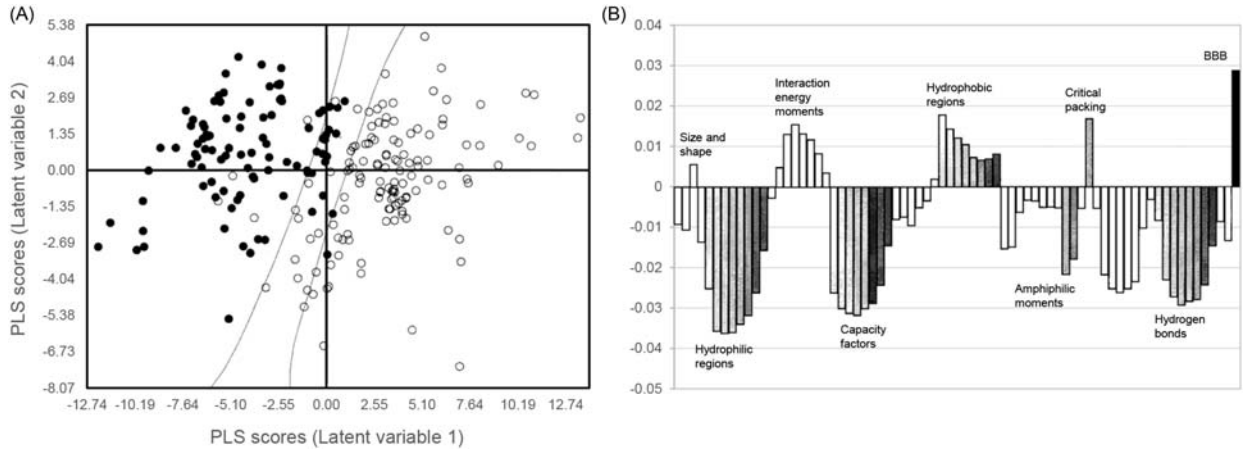

Fig. 24 (A) The discriminant plot between the PLS scores associated to the first two latent variables, as extracted by the PLS analysis carried out on a matrix of VolSurf descriptors, allows a good discrimination between the compounds which cross the BBB (•) and those which do not cross it (○), being able to assign a correct BBB profile to >90% of the compounds. A confidence interval is built in the space where BBB prediction can be doubtful. (B) PLS coefficient plot for the correlation of VolSurf descriptors with BBB permeation. The length of the bars is related to the contribution of individual descriptors, while shading refers to the different energy levels used (see text and Ref.[96] for more details). Adapted from Figures 4 and 5 in Crivori, P.; Cruciani, G.; Carrupt, P. A.; Testa, B. Predicting blood-brain barrier permeation from three-dimensional molecular structure. *J. Med. Chem.* **2000**, *43*, 2204–2216. ACS publication.

a certain topological radius are considered as part of the environment. The extent to which the neighboring topology is explored depends on the aromatic or aliphatic nature of system, which in turn influences the propagation range of electronic effects. GRID MIFs are precomputed using 10 different GRID probes (three positively charged, three negatively charged, and four neutral) on 466 small and semirigid molecular fragments, each represented by a single conformer. In each fragment a single atom, or a small group, is labeled as the center of interest, and associated with an MIF-energy minimum for each GRID probe. Energy minima are discretized and assigned to 25 bins; the energy range of each bin is chosen such that the population is roughly homogenous across bins.

To compute the ionization constant(s) for a molecule, each atom is considered individually: the fragment database is searched for the fragment whose center of interest has the best match to the atom and its environment. The energy minima associated with the center of interest of the chosen fragment, one for each of the 10 GRID probes, are then associated to the atom. Complications arise for charged fragments in polyprotic systems, as under some circumstances the same dissociation product may originate from different precursors (e.g., the fully dissociated anion of *m*-aminobenzoic acid may arise either from loss of the $^{+}$NH proton from the zwitterion or from loss of the OH proton from the carboxyl group in the neutral form); when available, dissociation microconstants are used to determine the most likely dissociation pathway in such situations. Once all atoms in the molecule whose dissociation profile is to be computed have been assigned a binned energy minimum taken from the fragment database, all energy minima having the same topological distance from the ionizable center are summed together, and for each probe and each topological level a vector of binned energies is obtained (**Fig. 25**). At the end of this procedure, each ionizable center is characterized by a number of descriptors given by the product of the number of GRID probes, the number of energy bins, and the number of topological levels.

MoKa was trained on ~19 K mono- and polyprotic molecules, associated with ~25 K pK_a values. Ionizable centers were classified into 33 categories, and for each category a separate pK_a prediction model was built by regressing the autoscaled matrix of descriptors against experimental pK_a values via PLS; as in CoMFA, the optimal number of principal components was chosen as the one which yields the first local maximum in LOO q^2. MoKa was validated on an external test set constituted by 28 different chemotypes chosen in order to include a nonionizable moiety not represented in any training set molecule at a constant distance from the ionizable center; good agreement was found with experimental pK_as (0.90 RMSE, as compared to 1.36 obtained with another 2D method based on Hammett–Taft constants).[98] MoKa has been recently augmented with a tautomer enumerator which uses computed pK_a values to estimate relative tautomer stabilities.[98]

3.11.2.8.3 MetaSite

Zamora and Cruciani have designed MetaSite, a training set-independent methodology based on GRID MIFs (see section "GRID/FLAP") which uses the 3D structures of both the xenobiotic substrate and the protein to predict the sites of metabolism (SoM).[103,104] Even if it uses protein structure information, we include MetaSite in this section because protein-derived parameters are built into the program, while the only required user input is the ligand 2D structure. Knowledge of the possible biotransformation pathways a compound may undergo at an early stage of development, possibly even before it has been synthesized, is of key importance. Labile molecules can either be removed from the pipeline, or alternatively strategies can be implemented to reduce the

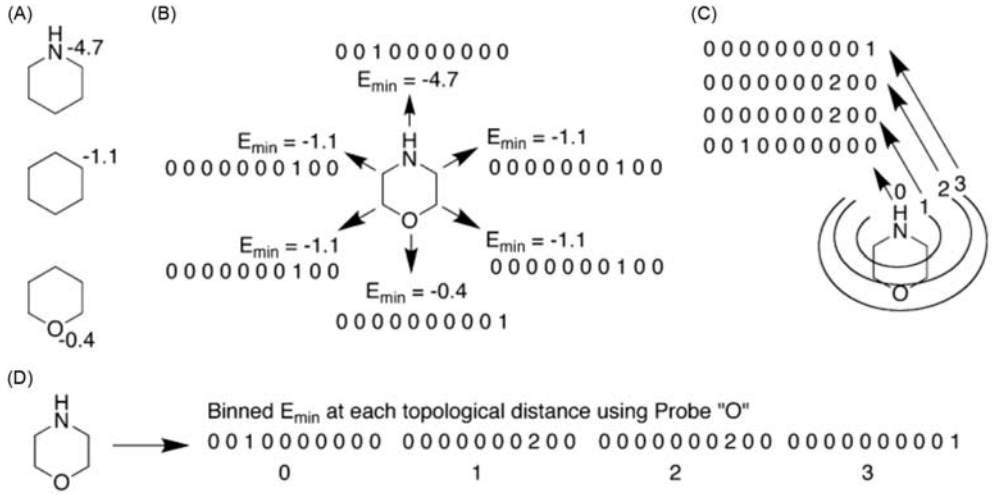

Fig. 25 Example of the workflow used to generate the MoKa descriptors for morpholine: (A) relevant fragments are chosen from the fragment database and used to compute the energy minima (kcal mol^{-1}) for reference atoms (in this example, via the O probe); (B) energy minima are discretized and assigned to 25 energy bins; (C) all energy minima having the same topological distance from the ionizable center are summed together; and (D) finally, each ionizable center is described by a vector of binned energies. Adapted from Figure 1 in Milletti, F.; Storchi, L.; Sforna, G.; Cruciani, G. New and original pKa prediction method using grid molecular interaction fields. *J. Chem. Inf. Model.* **2007**, *47*, 2172–2181. ACS publication.

metabolic lability, such as steric shielding of SoM or chemical protection of labile moieties. Finally, characterizing sites and routes of biotransformation is crucial in prodrug design and pharmacokinetic profile optimization.

While initially MetaSite was limited to the 2C9 isoform of human cytochrome P450 (CYP),[103] it was subsequently extended to four more CYP isoforms (1A2, 2C19, 2D6, and 3A4) and, most recently, also to the FMO3 isoform of flavin monooxygenase.[105] Homology models were used when X-ray structures of the human isoform were not available.[104] CYPs mainly carry out substrate oxidation through electrophilic reactions, which may also involve carbon centers. Instead, FMOs oxidize molecules catalyzing nucleophilic additions to substrate heteroatoms, and are responsible for 6% of phase I metabolic reactions of pharmaceutical interest.[106] MetaSite models two independent mechanisms: (1) recognition of the substrate by the enzyme via comparison of their respective GRID MIFs and (2) mechanism-based reactivity by a combination of ab initio and semiempirical calculations. The workflow, which is summarized in **Fig. 26**, will be briefly described in the following paragraphs.

The protein structure is mapped using three GRID probes: hydrophobic (DRY), hydrogen bond donor (N1), and hydrogen bond acceptor (O). MIFs are computed treating the protein backbone as rigid, while side chains may adapt their conformation to optimize their interactions with the GRID probe. In the original formulation of the method, the 3D GRID MIFs were compressed to 1D fingerprints,[103,104] then interatomic distances were computed between the probe and the catalytic center of the enzyme (i.e., the reactive oxene atom part of the heme-bound oxygen molecule) as in Anchor-GRIND (see section "GRIND"), yielding a 1D correlogram for each probe type. Subsequently, the 1D correlogram was replaced by the more sophisticated 3D algorithms implemented in FLAP. Currently, the shape of the enzyme active site is perceived with a 3D method, and enzyme MIFs (which take into account protein flexibility) are condensed to four-tuples (quadruplets, see section "GRID/FLAP") and stored.[107]

Substrates are modeled as conformational ensembles, and each substrate atom is assigned to one of the GRID probes depending on its characteristics (hydrophobic, hydrogen bond donor/acceptor). In the first incarnation of MetaSite, for each GRID probe type interatomic distances were discretized and binned, then converted to a 1D fingerprint vector as in the case of the enzyme. Comparison of protein and substrate fingerprints would then yield the degree of exposure (E_i) of each substrate atom i to the heme-bound reactive oxygen, as well as the influence of other molecular moieties to individual E_i values.[103,104] As part of the evolution of the method, the treatment of the substrate has undergone major development; currently, each conformer of the substrate is docked into the protein, whose active site is itself treated as being flexible. The docking procedure attempts to find the substrate conformer whose atom-centered quadruplets best match the enzyme's quadruplets. The docking score is not based on the thermodynamics of the interaction between enzyme and substrate, but rather on the complementarity of their respective GRID MIFs. The increased 3D character of the algorithm enables a more accurate estimation of atomic exposures E_i. Similarly, group contributions of the remainder of the structure to individual atomic exposures are computed with greater accuracy.[107]

Besides accessibility, for each substrate atom a reactivity score R_i is computed using QM calculations. R_i represents the activation energy required to generate the reactive intermediate, and it depends on the reaction mechanism, the 3D structure of the substrate, and its protonation state. To avoid the expense of running QM calculations on each substrate, a precomputed database of fragment-based QM descriptors is supplied with MetaSite and a semiempirical QM calculation is only needed for fragments which are not represented in the database. In reconstructing the original molecule from fragments, the R_i value for each atom is corrected taking into account inductive and/or mesomeric effects from neighboring groups. The substrate ionization state, which may be influenced

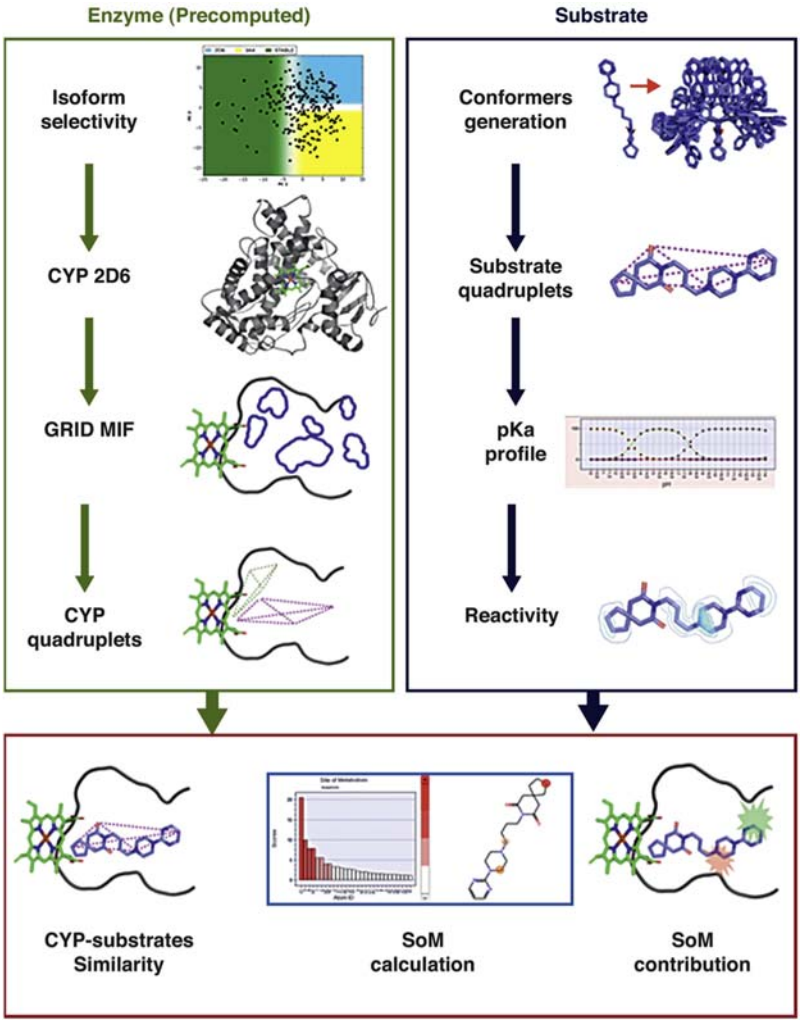

Fig. 26 Scheme summarizing the MetaSite4 algorithm. Once the CYP isoform has been selected, precomputed GRID MIFs and relative interaction hotspot quadruplets, mapped out of multiple enzyme structures to account for protein flexibility, are available for computation. GRID MIFs and ligand atom quadruplets are computed for each ligand conformation; pK_a profiling allows the consideration of multiple protomers/tautomers if required. Based on the complementarity between ligand and enzyme quadruplets an exposure score is computed, which is complemented by a QM-derived reactivity score. The combination of these two scores allows predicting the possible sites of metabolism (SoM), metabolite structures, and their relative ranking. Adapted from Figure 1 in Cruciani, G.; Baroni, M.; Benedetti, P.; Goracci, L.; Fortuna, C.G. Exposition and reactivity optimization to predict sites of metabolism in chemicals. Drug Discov Today Technol. **2013**, *10*, e155–e165. Elsevier publication.

by the environment provided by the enzyme active site, is adjusted using the MoKa methodology (see section "MoKa"), in order to pick the fragments with the appropriate protonation state. Multiple protonation states are considered where needed, and the final metabolism predictions are weighted on the relative abundance of each protomer.

The probability that an atom i may undergo metabolism via a certain mechanism is the product of the exposure E_i and the reactivity R_i according to that mechanism; this probability can be regarded as an approximation of the free energy of the metabolic transformation reaction. While in the original version of the MetaSite algorithm E_i and R_i used to have the same weight, later it was realized that their relative contributions depend on the substrate and enzyme features. For instance, low MW substrates can interact with enzyme cavities in multiple orientations, thus reducing the importance of the recognition factor in favor of reactivity. Conversely, when the volume of the substrate is comparable to the volume of the active site, recognition becomes very important as the substrate can establish several attractive interactions with the cavity, and the role of the reactivity parameter becomes secondary. Therefore, in the recent versions of MetaSite weights are automatically adjusted based on the relative sizes of substrate and enzyme cavity.

MetaSite metabolism predictions used to be only qualitative in nature; the top three solutions were returned and the algorithm could not provide a ranking of those three. In an attempt to provide semiquantitative predictions, a database of all metabolites for which experimental data on the relative abundances were available was compiled. Also an improved scoring scheme was implemented, in order to account for the varying degrees of difficulty in predicting the experimental SoM depending on the number

of possible alternatives, and to provide a consistent foundation to benchmark different procedures. Taking advantage of the experimental references and of the new scoring paradigm, MetaSite proved able to predict the correct metabolite structure and ranking in more than 80% of the cases for CYP 2D6 and 2C9, and in 75% for 3A4.[107]

A recent extension of MetaSite, Mass-MetaSite, provides an interface between experimental determination of metabolites through various mass spectrometry techniques and computational prediction of SoM.[108,109] The purpose of Mass-MetaSite is to automate as much as possible the structural identification of metabolites from experimental data. MIF-based SoM prediction complements the information based on fragmentation rules whenever fragments with identical mass can be resolved to several degenerate structures (e.g., metabolites bearing hydroxyl substituents on aromatic rings). Mass-MetaSite was shown to provide a 77% success rate in the structural elucidation of metabolites using mass spectrometry data from different sources.[109]

3.11.3 Structure-Based Applications

MIF maps of macromolecular targets have been used to identify binding sites and analyze their structural similarities, dock ligands, and determine the most favorable positions for water molecules when the X-ray resolution of the experimentally determined complexes does not allow their localization. The next paragraphs will describe these SB applications of MIFs.

3.11.3.1 Binding Site Identification

Identification of potential binding sites is the preliminary step to druggability analysis and protein function elucidation; some MIF-based approaches are presented here.

3.11.3.1.1 Q-SiteFinder

Q-SiteFinder detects druggable pockets on proteins upon analysis of their MIFs.[110] The methodology computes van der Waals interaction energies between a methyl probe, whose parameters are taken from the GRID force-field,[5] and the protein. The probe is placed at the nodes of a 0.9 Å step size grid embedding the whole protein. Only grid nodes corresponding to favorable interactions are retained, clustered depending on their spatial proximity, and ranked by decreasing total interaction energy.

The performance of the algorithm was assessed on a set of 134 protein–ligand complexes extracted from the PDB,[34] from which ligands, solvent, and ions were stripped before the analysis. Two success criteria were used. Firstly, the accuracy in the match between the predicted binding site and the actual ligand coordinates was determined as the percentage of selected grid nodes lying within a distance threshold from any ligand atom. A percentage higher than 25% was classified as a success, in consideration of the fact that a pocket may be only partially filled by the cocrystallized ligand. Secondly, if a ligand is successfully predicted in multiple sites, it is counted as a success only when the highest ranking site matches the experimental binding pocket. The maximum success rate was obtained setting -1.4 kcal mol^{-1} as the van der Waals energy threshold for a probe interaction to be considered as favorable. Seventy-one percent of the complexes fulfilled both success criteria, and the average accuracy in binding site perception was 68%; for 90% of the proteins, there was a successful prediction among the three top-ranked ones. The performance of Q-SiteFinder was significantly superior compared to Pocket-Finder, an in-house implementation of the purely volume-based algorithm LIGSITE[111] (48% success rate and 29% average accuracy, with 65% of the proteins featuring a successful prediction among the three top-ranked ones).

Since a typical use case for pocket detection algorithms is to identify binding sites on apo structures, a further benchmark was carried out on 35 apo proteins, comparing results with those obtained on 35 homologous ligand–protein complexes. The success rate for the first ranked site was much lower for the apo protein (51%) than for the complexes (80%), while there was a smaller difference in accuracy for the successful predictions (71% vs. 74%). The authors identified the different, more open shape of the main binding site in apo structures as the main reason behind the performance loss, causing other cavities to rank higher; indeed, the success rates considering the top three-ranked solutions were much closer (86% vs. 97%).

One of the greatest strengths of Q-SiteFinder is the good agreement between the average volume of the top-ranked binding site and the average ligand volume, and its weak dependence on the protein volume compared to other methods. Identifying a pocket with the correct size is especially important if the latter is to be used for ligand docking or binding site similarity analysis.

Morita and coworkers reported a significant improvement in the perception of binding sites on apo structures compared to Q-SiteFinder (77% vs. 51%) using a modification of the original algorithm.[112] Apart from the usage of van der Waals parameters from the AMBER force-field[113] rather than from GRID[5] and the adoption of a two-step clustering strategy, the most likely reason for the increased performance seems to be linked to the different selection of sampling points, which were generated in proximity of the surface via the double cubic lattice method[114] rather than across the whole protein.

3.11.3.1.2 SiteHound

SiteHound[115] is largely reminiscent of Q-SiteFinder, the main difference being that MIFs are computed combining steric and electrostatic potentials in a single map; various probes can be selected among the atom types defined in the GROMOS force-field.[116]

3.11.3.1.3 FLAPsite

The FLAPsite algorithm was designed as an augmentation of the purely geometric PocketPicker algorithm[117] with energy-based clustering as in Q-SiteFinder. As in PocketPicker, points in proximity of the protein surface are selected, and characterized through their DRY GRID probe energy rather than using a buriedness index as in the original methodology. Neighboring grid nodes whose energies are favorable according to a predefined threshold are clustered, and then refined through a shrinking/regrowth cycle limited by the protein surface. FLAPsite was reported to return the experimental ligand-binding pocket as the top-ranked one for 94% of 1300 protein–ligand complexes taken from the PDBbind database;[47] a detailed description of the algorithm has not been published.[118]

3.11.3.2 Binding Site Similarity Assessment

The most common approach to protein similarity assessment is the one based on primary sequence homology.[119] This approach has proven effective to group proteins into phylogenetic families as well as to identify common functionality. However, the advent of large-scale structural genomics initiatives has led to the structural determination of a large number of proteins whose function is unknown, because the attempts to match them to functionally characterized proteins via sequence homology failed.[120] At the same time, it has been shown that proteins may share significant local structural similarity in spite of a low global sequence identity.[121] Similarity search strategies comparable to those previously reviewed for small molecules may provide an alternative route to functional role elucidation,[122] in addition to giving hints at drug cross-reactivity, polypharmacology,[123] and repurposing.[124] In this framework, MIF-based methodologies are particularly fit to the purpose of finding similarities in binding site interactions independently of chemical similarity. A few applications of MIFs to binding site similarity assessment are reviewed here.

3.11.3.2.1 GRID/FLAP

The GRID force-field and the relative MIF maps were originally developed with the aim of predicting favorable ligand-binding spots on biological macromolecules.[5] Initially, most of the analysis on proteins was carried out visually, while quantitative 3D-QSAR approaches were mostly LB, and limited to modeling binding affinity. While some success has been reported in modeling selectivity through LB 3D-QSAR models,[125] the increasing availability of protein structural information prompted the search for tools able to extract valuable quantitative information from differences in protein-binding sites, and exploit it to improve ligand selectivity and predict off-target effects. Early approaches were based on the PCA analysis of binding site GRID MIF maps, using pairs (GRID/PCA[126]) or a series (GRID/CPCA[127]) of homologous targets. In particular, the consensus PCA (CPCA) evolution enabled a better discrimination of the differences among binding sites, as captured by different GRID probes, through block scaling of the relative descriptors. Even though some interesting results were reported,[128] the main limitation of both methodologies is their requirement, as in LB 3D-QSAR, for protein structures to be aligned. Since the alignment step is critical to the success of these analyses,[126] their scope is largely limited to proteins sharing a fair degree of structural conservation in the binding site area, such as isoforms or members of the same phylogenetic family.

An important advancement in applying GRID MIFs to the analysis of protein-binding pockets was introduced by the FLAP technology,[22,23] whose application to LB drug design has already been described in section "GRID/FLAP". The application of FLAP to proteins is thoroughly described in a paper by Sciabola et al.,[129] and consists of four steps: (1) binding site detection; (2) binding site characterization through GRID MIFs; (3) fingerprint generation; and (4) data analysis. At the time the paper was published, pocket detection was carried out through CAVGEN, an in-house modification of the purely geometric SURFNET algorithm;[130] recent versions of FLAP adopt the dedicated FLAPsite algorithm (see section "FLAPsite"), which incorporates energetic criteria. MIF and fingerprint generation stages are largely analogous to the procedures described in section "GRID/FLAP" for the ligands: the binding pocket is embedded in a grid and GRID MIFs are computed with four different probes (six at the time of the publication; the charged ones were dropped in later versions). MIFs are then condensed into a small number of MINI points, which consist of grid nodes whose 26 neighboring nodes must all have larger energies; this requirement prevents such points from being located on the outer surface of the grid, due to the lack of neighbors. All MINI points which fall outside the volume identified by the pocket detection algorithms are filtered out. The survivors represent the locations where a ligand atom of the same kind as the probe would establish favorable interactions with the residues lining the binding cavity. These points are exhaustively combined in all possible quadruplet permutations, and each quadruplet is stored as a fingerprint (**Fig. 27**). An array of several million FPs describes a protein-binding site, and can be used in multiple ways: (1) to retrieve analogs from a database of FPs derived from other protein-binding pockets; (2) to build a similarity matrix among FPs describing different binding sites, then identify common patterns through chemometric techniques such as PCA and clustering[129,131]; and (3) to find matches against an array of ligand-derived FPs in a docking-like approach, as described in sections "MetaSite" and "FLAPdock".

Regarding the first use case, the work by Sciabola[129] presents an example where two isoforms of chorismate mutase sharing a sequence identity below 20% were extracted from the PDB[34] and their FPs computed. One of the FPs was used as a query, while the other was added to a database of 990 decoy FPs obtained from random protein-binding sites; the FP from the chorismate mutase isoform was retrieved as the top-ranked hit. Concerning the second application, the ability of the FLAP methodology to correctly cluster protein active sites into families was assessed on a set of 23 kinases, selected from 6 different families (CDK2, GSK3β, P38α, PDK1, Pim1, and LCK), for which a high resolution X-ray structure was available. When two sets of quadruplets are compared between binding sites belonging to different proteins, the number of common quadruplets can be further reduced using a shape filtering criterion, that is, taking into account only the quadruplets which fall within the active site boundaries for both proteins. The FP comparison yields a normalized similarity score ranging from 0 to 1, which is stored in a similarity matrix

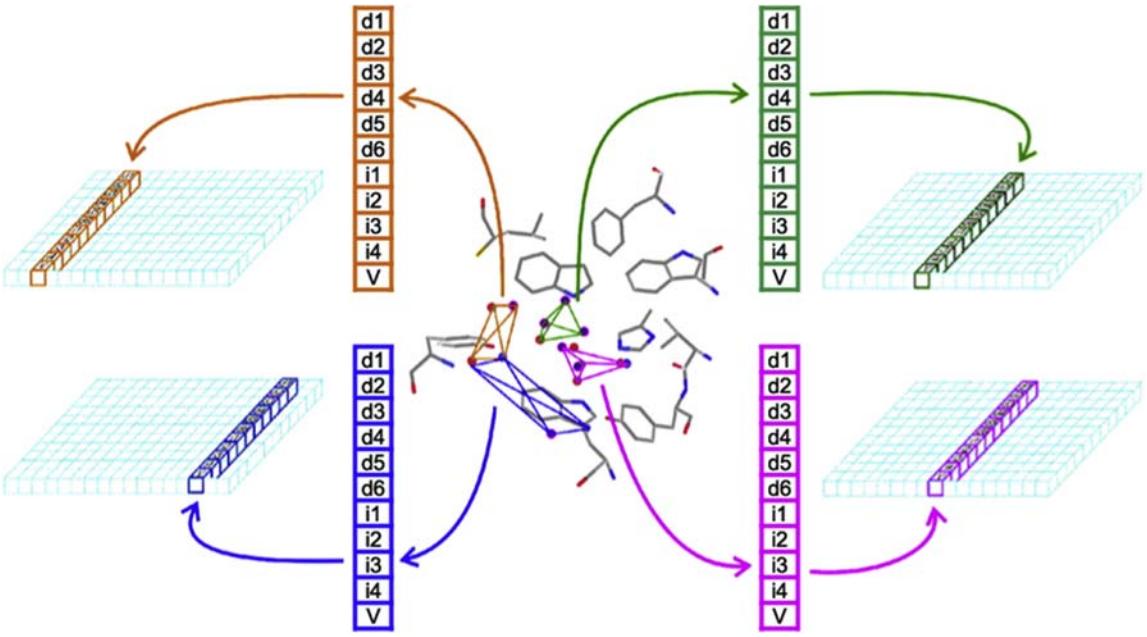

Fig. 27 FLAP encodes quadruplets of receptor MINI points as fingerprints (FPs) containing 11 integer values, corresponding to discretized distances between vertex pairs (*d1–d6*), vertex indices (*i1–i4*), and finally a value proportional to the sum of the energies of the four points (*V*). A protein-binding site is described by an array of several million FPs. Adapted from Figure 2 in Sciabola, S.; Stanton, R.V.; Mills, J.E.; Flocco, M.M.; Baroni, M.; Cruciani, G.; Perruccio, F.; Mason, J.S. High-throughput virtual screening of proteins using GRID molecular interaction fields. *J. Chem. Inf. Model.* **2010**, *50*, 155–169. ACS publication.

for each pairwise comparison. Once the kinase similarity matrix was analyzed by PCA, three main clusters could be identified by the first two components, the first containing Pim1, the second P38α and LCK, and the third CDK2, GSK3β, and PDK1. The fact that Pim1 was classified as a singleton is not surprising, as it features a unique hinge region lacking a hydrogen bond donor; on the contrary, it suggests the possibility to develop selective inhibitors. Interestingly, the analysis of the second and the third principal components enabled further classification into subfamilies of the kinases belonging to the other two clusters.

Finally, two separate SB VS exercises were carried out.[129] In the first, 4 different datasets were assembled, each consisting of 990 randomly selected decoy binding sites seeded with 10 proteins belonging to the same family, respectively HIV protease, L-arabinose binding protein, adipocyte lipid binding protein (ALBP), and ER-alpha. Each database was ranked by similarity against a query of the respective family; for ALBP and L-arabinose binding protein, all spikes were found within the first 4% of the database screened, seven HIV-proteases were retrieved within the first 5% and six ER-alpha were found within the first seven top-scoring hits. The second VS exercise aimed at assessing FLAP's ability to retrieve proteins with low sequence identity known to bind the same ligand as the query. For this purpose, 4 databases were assembled by seeding 990 random decoys with 10 proteins known to bind the same ligand (citrate, maltose, ATP and retinoic acid, respectively). All proteins were retrieved within the top 10% of database screened, except for those binding retinoic acid; however, the top-30 proteins retrieved in this latter case were bound to ligands with a high degree of structural similarity to retinoic acid, which explains the lower performance. Across all four targets, the enrichment was consistently superior to a BLAST[119] search based on primary sequence similarity.

3.11.3.2.2 IsoMIF

IsoMIF[132] is another technique aimed at computing pairwise MIF similarities between protein-binding sites. IsoMIF uses six different chemical probes, whose nature is largely reminiscent of the six used in the original formulation of the FLAP algorithm, with an aromatic probe in lieu of the hydrogen probe. However, the force-field used by IsoMIF is far less sophisticated than GRID, relying on a coarse-grained distance-dependent exponential function. Binding cavities are detected by GetCleft,[133] a reimplementation of the geometric algorithm SURFNET,[130] and embedded into a 0.5 Å step grid. Each of the six probes is placed in turn at the grid node locations, and its interaction energy with the protein is determined through the aforementioned exponential function by summation over all protein atoms. However, the weight of the contribution by individual protein atoms varies depending on the nature of the atom and the probe and on the geometric relationship between the two, which is particularly important for directional interactions such as hydrogen bonds. On each node, probes undergo a binary classification as 1 or 0, depending on whether the sum of weighted energies for that probe reaches a probe-specific minimum energy threshold.

Once the six-probe binary vectors have been defined on each node, an attempt is made to generate an association graph between the binding sites. To become part of the association graph, grid nodes need to share at least one nonzero binary value across the six-probe vectors; neighboring vertices in the association graph are joined by an edge if the distance between the corresponding

nodes in the respective MIF grids is within 3 Å. This threshold is significantly higher than in FLAP, where it is set to 1 Å, in order to allow for flexibility in the protein structure. A search for the largest clique is then carried out using the Bron–Kerbosch algorithm,[134] which tends to find the largest cliques first. Taking advantage of this, and in consideration of the fact that a complete maximal clique search is an NP-complete problem, the search is abandoned after the first 100 cliques have been found. After pruning cliques which do not satisfy chirality constraints (i.e., the respective nodes cannot be superimposed across the two MIF grids), the largest clique is scored through a Tanimoto metric taking into account the number of common probes and the number of those having energetically significant values. Interestingly, while the maximal clique detection does not require protein alignment at any stage, the grid nodes sharing nonzero binary values in their six-probe vectors can be used as superimposition points for a standard RMS fitting procedure, deriving a rotation/translation matrix which can be applied to the protein and the cocrystallized ligand 3D coordinates in order to visualize MIF similarities between binding sites (Fig. 28).

IsoMIF was benchmarked on six datasets, four of which were previously used for other methods. Its ability to retrieve proteins with varying degrees of sequence identity binding the same ligand (true positives) rather than decoy proteins (false positives) was assessed through the ROC AUC. IsoMIF featured the highest average AUC across four different methods. Unfortunately, FLAP (section "GRID/FLAP"), which is the closest methodology from an algorithmic point of view but features quite a different functional form for MIF potentials, was not included among the benchmarked methods.

3.11.3.3 Docking

MIF maps have been extensively used in ligand–target docking. A thorough description of docking algorithms, scoring functions, and their comparative evaluation is provided in other chapters of this book as well as in several dedicated reviews;[135,136] here we will focus on describing the role of MIFs in some commonly used docking methods.

3.11.3.3.1 AFMoC

Gohlke and Klebe made an interesting attempt to complement the knowledge-based DrugScore scoring function[137] with CoMFA-like regression analysis of MIFs, in order to take advantage of known ligand affinities where available to improve binding affinity predictions against a particular protein target.[138] Standard DrugScore exploits the structural information about ligand–protein atomic contact preferences as derived from crystallographically determined PDB complexes indexed in ReLiBase.[139] Docked poses are scored based on a combination of distance-dependent pair potentials (calculated from the frequency with which ligand–protein contacts between a specific pair of atom types have been experimentally observed at the specified distance) and a solvent-accessible surface-dependent potential. DrugScore was able to correctly rank binding modes and predict binding affinities, as well as to predict which ligand atom would bind more favorably at a certain binding site location.[140]

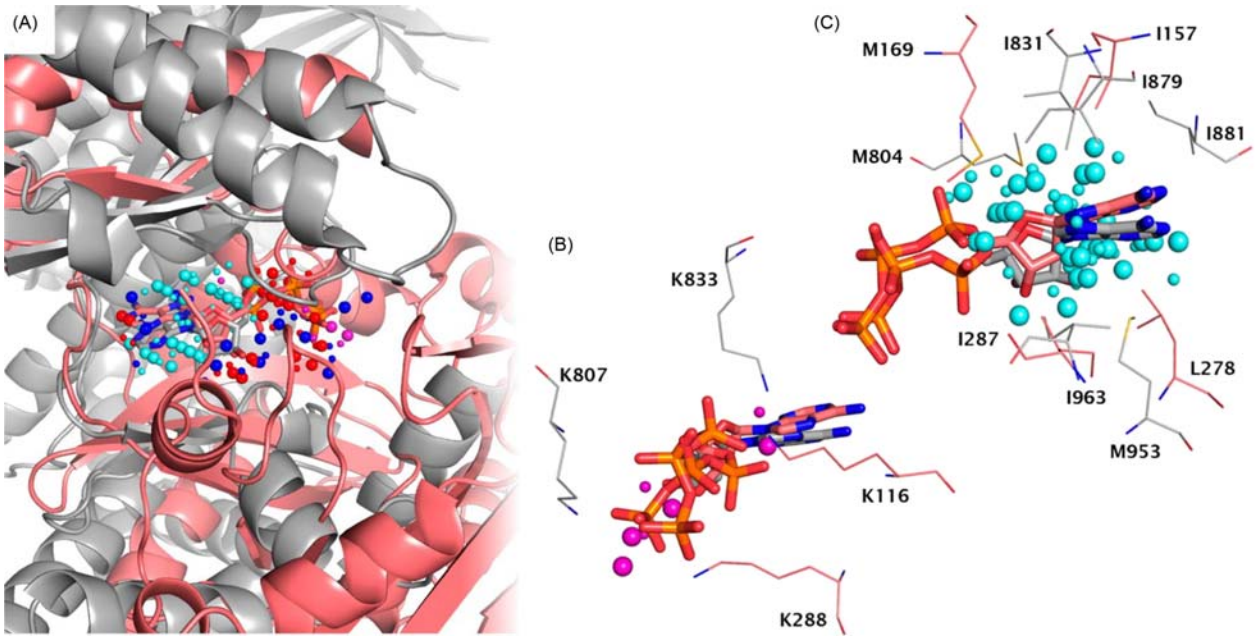

Fig. 28 MIF similarities found between 1E8X (*gray*) and 1DV2 (*light red*). (A) MIF similarities between proteins (*colored spheres*) are used to derive a rotation/translation matrix which is applied to the second protein–ligand complex. (B) Close-up on the bound ATP molecules (RMSD 1.87 Å) showing two lysine pairs (K807–K288 and K833–K116) with terminal amino groups in vicinity of phosphate groups yielding similar negatively charged probes (*magenta spheres*). (C) The adenine region is surrounded by hydrophobic similarities (*cyan spheres*) caused by the presence of methionine, isoleucine, and leucine residues in both binding sites. Adapted from Figure 6 in Chartier, M.; Najmanovich, R. Detection of binding site molecular interaction field similarities. *J. Chem. Inf. Model.* **2015**, *55*, 1600–1615. ACS publication.

With AFMoC, it becomes possible to tailor the scoring function against a specific target depending on the amount of available information about the affinity of existing ligands. The scoring function becomes a linear combination of the original DrugScore and the tailor-made function: the more experimental affinity information is available, the larger weight can be given to the regression-based scoring as compared to the knowledge-based one. The "AFMoC" name comes from the fact that MIFs rely on protein-binding site information, whereas in CoMFA MIFs are computed on ligands. Another difference to CoMFA is that MIFs are computed using atom types rather than simple steric and electrostatic probes.

In the AFMoC method, a grid is placed in the binding site, and distance-dependent pair potentials are mapped on the grid nodes. When an experimentally derived pair potential is not available because the grid node is too close to one of the protein atoms, an artificial repulsion term is used instead. For each training set ligand atom type, a Gaussian distance-dependent contribution is obtained, and multiplied by the potentials of the grid nodes within 6 Å of ligand atoms, which prevents solvent-exposed ligand atoms from having an influence on the binding score. The atom type-specific MIFs thus obtained are then correlated to known binding affinities via PLS regression as in CoMFA, resulting in individual weighting factors for each MIF value. Since some atom types present in the docked ligands might be insufficiently represented in the training set, binding affinities are factorized into contributions from each atom type using the standard DrugScore pair potentials; the contributions from the atom types which are not well represented in the training set are then removed before building the PLS model. The balance between the knowledge-based and regression-based pair potentials can be adjusted depending on the size and range of affinity covered by the training set, and on the degree of atom type similarity with the docked ligands. In principle, the linear combination of the two scoring schemes allows for a progressive increase of the regression-based scoring weight during the development of a drug discovery project, as more experimental affinity values become available.

AFMoC was initially tested on two difficult datasets of thermolysin and glycogen phosphorylase *b* inhibitors, for which standard DrugScore could find no correlation with experimental binding affinities, and it was found to provide a significant improvement.[138] Later, a further case study on a relatively small series of DOXP-reductoisomerase inhibitors was presented, in which AFMoC was able to generate a predictive model whereas classic LB CoMFA and CoMSIA had failed.[141] More recently, an extension of the AFMoC methodology which accounts for multiple ligand and receptor conformations has been developed.[142]

3.11.3.3.2 AutoDock

In AutoDock,[143] a grid box with a default step size of 0.375 Å (corresponding to roughly one quarter of a carbon-carbon single bond length) is centered on the active site where the ligand is to be docked. For each of the atom types present in the ligand, an MIF map is generated by the AutoGrid program by computing the interaction energy between a probe, having the parameters of the corresponding atom type, and the protein atoms located within a distance cut-off. Van der Waals interactions are computed by means of a smoothed 12-6 Lennard Jones potential; hydrogen bonding interactions are evaluated by a 12-10 function which incorporates a directionality term, that is, interactions which deviate from ideal hydrogen bonding geometries are progressively down-weighted. Additionally, a desolvation and a Coulombic map are computed, the latter using a probe with unit positive charge and no distance cut-off, given the long-range nature of electrostatic interactions. MIF isocontours can be mapped onto the protein active site to visualize interaction hotspots for each probe (**Fig. 29**). Since MIF maps do not depend on the ligand coordinates but only on its atom types and protein active site coordinates, a single set of MIF maps can be precomputed for each protein covering all atom types represented in the dataset of ligands to be docked, thus limiting to the conformational search the computational effort for each ligand. The interaction energy of each pose can then be obtained by trilinear interpolation of its atomic coordinates on the relevant potential grid depending on the atom type; electrostatic energies can be obtained multiplying the Coulombic potential by the atomic partial charge.[143]

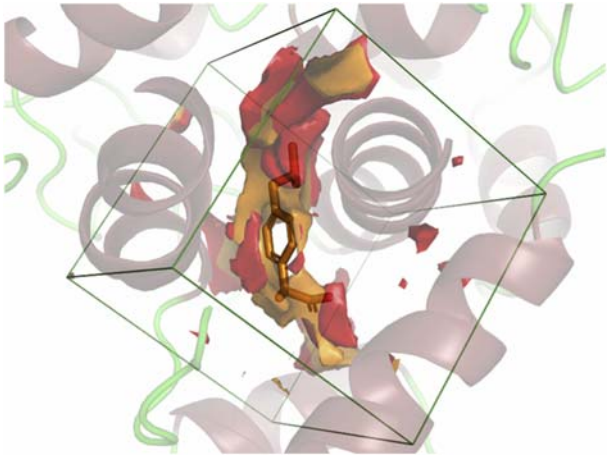

Fig. 29 3D view of the active site of the complex between COX-2 and ibuprofen (PDB ID 4PH9). The cocrystallized ligand is included as a reference and depicted with *orange* sticks. The boundaries of the cubic grid box where AutoGrid computed MIFs are highlighted with thin *green* lines; *orange* contours represent areas which are most favorable for binding of carbon atoms, while *red* contours flag areas that favor oxygen atoms.

3.11.3.3.3 FLAPdock

The FLAP fingerprint technology has already been described quite extensively in section "GRID/FLAP", and can be used to dock ligands into a binding site (e.g., as part of the MetaSite methodology, see section "MetaSite"). All members of a precomputed conformer population are fitted against quadruplets of energy minima derived from active site GRID MIF maps; potential matches are pruned based on their degree of geometric match against protein quadruplets and adherence to shape cavity constraints. The poses which pass these filters are then subjected to an in situ torsional and translational optimization of the ligand–target interaction energy, as assessed through the GRID force-field.[144,7,22] Milletti and Vulpetti[145] reported examples of the usage of FLAPdock in a VS setting and compared its performance against Glide[146] and GOLD,[147] while Ruiu and coworkers used FLAPdock along with Glide[146] and AutoDock[143] to elucidate the binding mode of a series of methoxyflavones at the μ-opioid receptor.[148]

3.11.3.3.4 Glide

Glide,[146] like AutoDock, uses precomputed grids of smoothed van der Waals and electrostatic potentials. Ligand–protein interaction energies and gradients (for minimizations) are obtained by trilinear interpolation on such grids. A peculiarity of Glide is that it uses increasing grid densities (up to 0.4 Å step size) the closer the grid box gets to the protein surface, thus allowing for a much higher resolution only where needed, in order to cut down computational costs and memory usage.

3.11.3.3.5 GOLD

GOLD[147] evaluates the van der Waals interaction energy between a carbon atom and the protein atoms over a fine grid; nodes whose interaction energy is below 2.5 kcal mol^{-1} are flagged as hydrophobic fitting points and used to place hydrophobic ligand atoms in the most favorable binding site locations during the pose generation stage. Fitting points can optionally also be identified using probes constituted by halogen and nonpolar sulfur atoms.

3.11.3.4 Determination of Water Positions

The determination of water positions within protein active sites and the estimate of their degree of "happiness" have been a primary focus over the last decade and have been addressed by many different techniques, among which the most prominent are WaterMap,[149] 3D-RISM,[150] SZMAP,[151] and WaterFLAP.[152] We will briefly describe WaterFLAP as, to the best of our knowledge, it is currently the only MIF-based approach in this arena.

3.11.3.4.1 WaterFLAP

WaterFLAP[152] generates and scores water networks in both apo proteins and ligand–target complexes. A water network is iteratively generated by placing water molecules in the most favorable positions as assessed by the GRID OH2 probe; after each molecule is added, water hotspots are redetermined before the next iteration. Only water molecules below an energy cut-off are considered for addition, and the cut-off is increased at each iteration. The initial network is then relaxed by means of a short molecular dynamics simulation, keeping protein and ligand heavy atoms restrained to their original positions. Finally, water molecules are rescored for their "happiness" using both the OH2 and CRY probes (Fig. 30); the CRY probe combines the C1= and DRY (which includes an

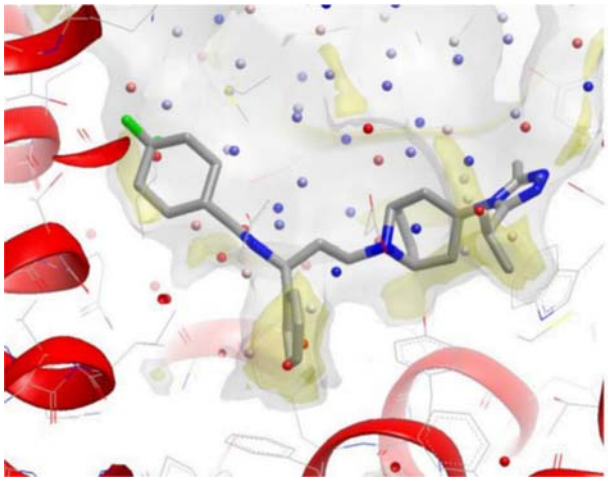

Fig. 30 Water network generated by WaterFLAP for the inactive conformation of the C–C chemokine receptor type 5 (CCR5) in complex with maraviroc (PDB ID 4MBS). Water molecules are scored for their "happiness" using both the OH2 and CRY probes, then color-coded accordingly from *red* (most "unhappy") to *blue* (most "happy"). Adapted from Figure 3 in Mason, J.S.; Bortolato, A.; Weiss, D.R.; Deflorian, F.; Tehan, B.; Marshall, F.H. High end GPCR design: crafted ligand design and druggability analysis using protein structure, lipophilic hotspots and explicit water networks. *In Silico Pharmacol.* **2013**, *1*, 23. Springer publication.

entropy term) probes to provide a more informative mapping of lipophilic, hydrophilic, and π-stacking hotspots in the binding site.[153] Although WaterFLAP is still under active development, it has already been used in production along with other water network characterization methods.[152,153,154]

3.11.4 Conclusions

In this article, we have presented a number of applications of MIFs, ranging from LB to SB drug design. The forefathers of field-based methods, CoMFA and GRID, were introduced roughly 30 years ago. CoMFA boasts thousands of citations; its ease of use coupled with the visually interpretable 3D models, in an era dominated by cryptic 1D and 2D QSAR descriptors, made it extremely popular in its first decade. The GRID-based discovery of zanamivir, subsequently marketed as Relenza, is one of the most well-known success stories in rational drug design.[155] While CoMFA and GRID are still used for the applications they were originally developed for, respectively 3D-QSAR modeling and protein active site mapping, their longevity is mostly due to the reincarnation of the seminal concepts in tools aimed at completely different purposes, in line with the evolution of drug discovery processes. The need for fast similarity-based screening of large virtual databases prompted the evolution of CoMFA into Topomer CoMFA. Likewise, most of the current interest in GRID depends on its application to in silico metabolism prediction, which has become of critical importance from the early stages of lead optimization to reduce the costs of clinical phase drug attrition, and constitutes a field of very active research.[93,156]

Thanks to the progresses in computer hardware, and in particular to the introduction of inexpensive, massively parallel graphic processing units (GPUs), 3D field-based VS has attracted renewed interest, as it can be routinely applied to large corporate collections. VS of a four-million molecule database with Blaze (see section "FieldScreen/Blaze") has recently led to the discovery of tioxazafen, a new broad-spectrum nematicide for agrochemical use.[157] Blaze VS has also been applied to the open innovation drug discovery (OIDD) program fostered by Lilly.[158] The aim of the OIDD initiative is to broaden the exploration of drug-like chemical space by encouraging independent academic and industrial researchers to submit compounds for evaluation on a panel of in-house biological assays, under a framework which protects their IP. The compounds in the OIDD database are available for in silico screening with Blaze; as the similarity assessment is based on comparison of field properties, the screening can be performed even if the chemical structures are blinded, thus safeguarding the IP.[159]

Gazing in the crystal ball, one can foresee a further development of the field-based algorithms to assess protein active site similarity, with applications in repurposing existing drugs, as well as predicting adverse drug reactions. The advances in massively parallel processors will open the way to field-based VS of unprecedentedly large collections. Eventually, the growth in computing power might enable the replacement of force-fields with QM, to the advantage of the accuracy of electrostatic and solvation models. Field-based ADMET prediction will gain further momentum from an even tighter integration with automated wet lab technologies (mass spectrometry, liquid chromatography, tissue cultures). As all good performers, 30 years after their debut molecular fields are still on stage.

3.12.1 Introduction

The question "is docking a solved problem?" is a challenging and somewhat contentious one, and needs definition. Firstly, "what is docking?" Secondly, "what do we mean by a solved problem?"

If docking is merely the prediction of a binding pose of a ligand, of known protonation state, in a well-defined system, then one might be tempted to believe the problem solved. However, such a narrow definition is of little utility in the discipline of drug discovery. Here, we ideally would like to predict ligand activity yet do not know the exact ligand electronic configuration on binding. Additionally, accommodating the variation in the active site that frequently occurs upon ligand binding is important.

Consider the impact of docking on drug discovery if this truly was a "solved problem." Not only could docking techniques make a huge contribution to lead identification and activity prediction, but docking could also inform what is arguably the more challenging aspect of drug design: transforming an active hit compound to a viable lead pharmaceutical. Drug bioavailability is often compromised by off-target binding. Aside from proteins in other pathways, this can include various blood plasma proteins such as albumin and glycoprotein. A drug may be metabolized and cleared from the body by a cytochrome P450 enzyme, or alternatively it may inhibit such an enzyme preventing the clearance of other drugs (one of the primary sources of drug-drug interactions). A major safety concern of new medicines is inhibition of the hERG ion channel which mediates cardiac activity. Each of these interactions could be modeled successfully by a perfect docking program.

The end user of a perfect docking program would be able to sit down and use it without a deep understanding of the targets of interest: for example, they would not think "I need to dock into a model of the hERG receptor and interpret the results," rather they

would ask the question "will my lead show adverse cardiac activity?" and the software would understand how to answer the question and generate a reliable answer.

If we can only say "docking is a solved problem" when we have such a perfect docking program, then current user experience gives a short answer: "It's not." That said, for the lesser question "is docking useful?" the short answer is a resounding "yes."

Addressing whether docking is a solved problem requires extensive thought and elaboration, and inevitably leads to subdivision into a larger set of questions. In this article we try to identify those questions by evaluating aspects of docking, reviewing the literature in the various areas, and analyzing which parts of the problem are solved and which are unsolved.

We have attempted to break down the problem of docking into a number of subsections. The subsections are "When is docking useful?" which showcases some examples where docking has been impactful in medicinal chemistry programs, "defining docking," which tackles the input required for docking programs, "sampling algorithms," which tackles the underlying global search algorithms that are used to facilitate docking in a tractable time. The next three subsections, namely "Treating ligand flexibility," "Treating binding site flexibility," and "Treating solvent in docking" tackle the specific parts of a docking algorithm that require special treatment. We then consider the area of affinity prediction in docking.

Finally, we scrutinize the current state of the art, recommend general approaches for getting the best out of docking programs, and suggest how current or future programs could be improved to create the perfect docking program.

3.12.2 When is Docking Useful?

While it is unclear if docking is a solved problem, we can with certainty state that docking is a useful tool in the medicinal chemist's armory. Docking and structure-based drug design (SBDD) has become a critical tool in the medicinal chemist's armory. Aliskiren, Zanamivir, Lopinavir, and Ritonavir have all been highlighted as cases of marketed drugs that have been discovered by SBDD.[1] Captopril is believed to have been the first drug where SBDD played a major role in its discovery.[2]

There are many published examples of successful programs which have been aided and abetted by docking studies. A recent review[3] highlighted many examples where docking studies significantly contributed to a project's outcome through virtual screening.

There are also many examples in the literature which highlight medicinal chemistry programs in which docking plays a part in a structural optimization program. Indeed, when docking studies are performed they now rarely get more than a cursory line within a publication to note that the method was used and the consequences of their use (e.g., for a recent example, see Ref.[4]). In this study, the authors made a key synthetic choice to increase the affinity of their compound after docking showed that their proposed changes would lead to acceptable interactions with the binding site.

As is usually the case in such publications now, the docking studies are not significantly described. Such studies are regarded as a routine part of a medicinal chemistry program rather than anything particularly unusual. This reflects the success of docking as an approach for medicinal chemistry.

3.12.3 Defining Docking: A Solved Problem?

It is instructive to consider what expectations we may have of a docking program. In general, the docking problem may be defined thus: given an input protein structure and a ligand, the docking program will generate a predicted binding pose and associated score which may be used as surrogates for a crystal structure and activity data. This definition is sufficiently vague so that it is not clear what the exact inputs to the program are: is the assignment of protein and ligand protonation and charge states the responsibility of the user or the software? Likewise, who defines the role of water and the active site location and extent? These spheres of responsibility affect the complexity and difficulty of the docking problem. If a particular program requires input ligands to be correctly protonated for binding, then that is an easier scenario than if the charge state must be elucidated. Such a program may perform well on similar docking studies, but may not perform so well when, for example, docking novel ligands to metalloenzymes.

To an untutored user the expectation may be that a docking program simply requires a protein and a 2D representation of a ligand and the algorithm will return a putative binding mode. In practice both ligand and protein need careful preparation and many of the challenges for successful docking occur prior to the invocation of the docking algorithm. Here we consider the steps that may be required to prepare the protein and the ligand. Other decisions may be required from the user, such as force field or algorithm parameterizations, but most algorithms typically provide a user with reasonable default parameters for these settings.

Preparation of the protein for docking normally requires specification of the location and extent of the active site into which the ligand is placed. The location of the binding site in a given protein is usually specified by user input in most well-used docking programs. However, there are numerous algorithms that automatically identify binding pockets with reasonable accuracy, with success rates up to 75%. For example, Cavity Search,[5] Fpocket,[6] MDpocket,[7] Roll,[8] and KVFinder.[9]

Once a user has identified the active site, additional preparation of the active site may be required. Most programs require that hydrogens be present and, given that crystal structures are not normally sufficiently accurate to resolve proton positions, these have to be added. In most cases, assignment of protonation state is simple enough: at physiological pH it can be assumed that aspartate and glutamate residues are negatively charged and lysine and arginine residues are positively charged. There are, however, exceptions to these apparently straightforward rules: in the active site of aspartic proteases two aspartate residues bind a conserved water

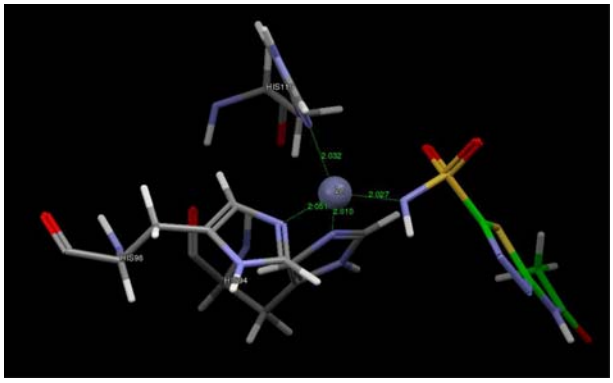

Fig. 1 Zinc ion coordination in 1JD0.

molecule, only one of which is charged. Histidine residues present unusual challenges as there are three protonation states available at pH 7: either or both of the imidazole side chain nitrogens may be protonated. A best guess of the protonation state is normally inferred from the residue environment by the user, but, ideally this is a task best suited to the docking algorithm.

Protonation state is only part of the challenge: one also needs to infer the position of the hydrogen atom. While often straightforward due to the chemical nature of the protein, there is ambiguity for certain residues due to flexibility.

The crystallographically derived protein structure also carries many caveats. It is important to remember that these are complex structures to solve. The model presented is a best fit to a data set of observations. In order to fit the data, crystallographers have to use extensive constraints and restraints in refinement as the volume of observed data is insufficient alone to provide a reliable least squares fit. There may be geometric errors, or imprecise placement of residues in these otherwise very flexible structures. Consequently, relaxation of the protein in a force field may be appropriate after preparation, though such minimizations also need care.

Lastly, decisions need to be made about whether or not to include water in the active site. Some docking programs offer the additional option of incorporation of waters into the search protocol (see below).

The most important decisions regarding preparation of the ligands likewise involve consideration of charge state. For the most part these are straightforward: basic amine nitrogens and groups such as aminopyridines or amidines will be protonated, whereas tetrazole groups or carboxylate oxygen atoms will be negatively charged. However, there are many instances where unusual protonation states are observed on ligand binding, for example, on binding to metalloenzymes. Consider the situation in **Fig. 1**, for the PDB entry 1JD0, where a zinc ion coordinates with three histidine residues and a deprotonated sulfonamide nitrogen in the ligand.[10] As this nitrogen would normally be neutral at physiological pH, it is unlikely that any automated ligand preparation tool would remove this proton. In cases like this, it would be preferable for the docking software to evaluate the protonation state of the ligand dynamically upon binding. Unfortunately, this is not automatically considered by current algorithms and so has to be addressed manually: If a ligand can adopt varying tautomeric states, the user will have to select one, or dock the different tautomers separately.

Some programs, such as GOLD,[11] require a high quality 3D ligand structure as the program does not manipulate bond lengths or angles. Other docking programs such as FRED[12] (assuming it is used, as intended, in conjunction with the OMEGA[13] conformer generator) or GLIDE[14] require only 2D structures as input.

In general, the specification of the docking program and the specification of the protein and ligand can be considered solved (with the exception of those ligands which bind with unusual protonation states). However, this process is often onerous for the end user and software designers could certainly do better in developing new tools and integrating existing tools to further automate this step.

3.12.4 Pose Prediction in Docking

3.12.4.1 Sampling Algorithms: A Solved Problem

As with all complex multivariate optimization problems, the search space for docking is potentially enormous. Even with a rigid receptor and ignoring explicit solvent, a reasonably complex ligand with 10 rotatable bonds gives rise to 36^{10} possible configurations (if we discretize each rotatable bond into 36 10 degree steps). Sampling such a space exhaustively is challenging, even with relatively rapid scoring evaluation, so most docking programs will use global sampling methods to try to find a quicker path to the global minimum.

A wide variety of sampling methods have been used in docking; publications on new methods are common in the academic literature. Algorithms vary from systematic searches across coarse-grained variable grids coupled with local optimization, to using well-established global search methods or metaheuristics such as Monte Carlo sampling (e.g., ICM[15]), Genetic Algorithms (GOLD,[11] AutoDock[16]), Ant Colony optimization (PLANTS[17]), Particle Swarm optimization (SODOCKER[18]), and Tabu searching

(ProLeads[19]). Other software uses algorithms that are not metaheuristic and are more directly related to the problem such as incremental construction (FlexX[20]) or sphere placement (DOCK[21]). GLIDE uses a somewhat original approach.[14,22] Starting from an initial set of ligand conformations, these conformations are placed on likely "site-points" within the active site. A series of filters followed by force-field minimization is used to identify the likely active pose. FRED leverages OpenEye's shape matching expertise to perform a systematic and non-stochastic examination of all possible protein-ligand poses, with shape complementarity and chemical feature alignment filtering.[12]

In order to perform a docking, an algorithm will need to sample the conformational space of the ligand and also the possible binding modes of each conformation. (This is the simpler docking case where the protein is rigid and explicit waters are ignored.) For all but the simplest ligands it is not possible to perform exhaustive search and the optimization procedure will invariably perform selective sampling. Optimization algorithms or metaheuristics such as the genetic algorithm and simulated annealing address this issue by using stochastic sampling to bias the search to areas where binding poses score well. Metaheuristic algorithms typically employ an encoding to navigate the problem space. For example, a naive encoding for docking might comprise a number of real numbers to encode angles of rotation about ligand rotatable bonds so as to generate a ligand conformation, together with six real numbers representing three translations and three rigid body rotations to position the pose in the active site. Improved performance may be achieved by further restricting the search space by constraining the encoding so as not to exhaustively cover all possible poses, but rather to focus the search on likely binding motifs. Such a heuristic strategy is employed by the GOLD program where the encoding used by the genetic algorithm matches features in the ligands to complementary features in the protein. So donor hydrogens in the ligand are matched to solvent accessible acceptors in the protein and vice versa. When this representation is decoded, during stochastic search, a least-squared fitting procedure attempts to form these associations. This encoding ensures that it is unlikely that GOLD explores possible poses that form no interactions with the protein.

In practice, the choice of search algorithm or metaheuristic is rare where the main search benefit is achieved. Well-designed heuristics such as those described above, used in tandem with the search algorithm, will usually have a strong positive influence on the overall performance by guiding the search algorithm to the global minimum. While we know of no known published analyses of such effects in protein-ligand docking, the phenomenon has been observed in the time-tabling problem where five different metaheuristics were tested and none was found to be clearly superior.[23]

We conclude, given the size of the computational problem, the increases in hardware speed and the power of the heuristics used, that sampling in docking is essentially a solved problem for the most common scenarios where typical scoring functions are used.

That said, there is enormous potential for new software in docking to take advantage of new computational architectures, such as GPU systems, cloud computing, or massively parallel computing grids. GPU-accelerated systems for docking have already been developed.[24] The impact of new technologies has been reviewed recently[25]: as is apparent, there are many opportunities for developers to take advantage of the latest hardware developments, though perhaps such technologies would have the most impact on scoring, rather than sampling.

3.12.4.2 Tackling Ligand Flexibility: A Solved Problem

As mentioned above, sampling is essentially a solved problem, due to heuristics in the docking program. One key area where such heuristics are applied is in tackling ligand flexibility. The earliest docking software (DOCK) grew out of the need for graphical visualization of binding in proteins on systems with very limited computational resources. To reduce complexity in this pioneering work, ligands and proteins were treated as rigid entities. With more available resources in computing the opportunity to treat ligand molecules as flexible became more tractable, and consequently tackling ligand flexibility became a component of docking software.

Various approaches to ligand flexibility have been used. Docking packages such as FlexX use incremental construction to sample ligand flexibility. In such an approach, a ligand is fragmented into rigid components which are separated by flexible torsion angles. A rigid part of a ligand is placed in the binding site interacting with the protein, and then the adjacent rigid part is placed such that the torsion angle between the two parts in a region of high likelihood and the binding to the protein is favorable. This is repeated for all fragments until the entire ligand has been placed. Often, the placed structure will then be locally optimized. Such an approach has the advantage that it linearizes the problem of selecting torsion angle values. The disadvantage, however, is that the code has to choose which fragment to place first. Consequently such algorithms are often accompanied by rules to optimize this selection process, or will be run multiple times for a given ligand with different start points to give a diverse range of results. Furthermore, the greedy nature of the incremental construction algorithm may prevent the discovery of global minima.

Some docking programs, such as FRED, avoid the complexity of dynamic ligand flexibility altogether by pregenerating conformational ensembles and then docking each pose in turn, followed by shape and chemical feature alignment-based filtering.

QXP-FLO takes this principle further: Multiple ligand conformations are treated synchronously by using an overlaid ensemble and are all effectively docked at once.[26] The advantage of such an approach is that the scoring of individual atoms can be reduced, as atoms can be shared between ligand poses within the ensemble.

Many stochastic metaheuristics (such as Genetic Algorithms, Ant Colony Optimization, or Particle Swarm Optimization to name but a few) will use a population of individuals in the search. The molecular conformation will be encoded in the representation of each individual. Operations within the search algorithm will in turn allow said values to vary, leading to a diverse set of sampled conformations.

Other stochastic algorithms, such as Monte Carlo simulation or Tabu searching, will instead explore a single conformation at a time, but allow the search algorithm to drive the conformation to favored regions.

All such approaches benefit from search space reduction. Distributions of torsion angles can be derived from the Cambridge Structural Database and can be highly effective in reducing ligand search space. The relevance of torsion distributions to drug-like conformations in binding sites has been studied extensively. We refer readers to work by Brameld and coworkers[27] for an excellent medicinal chemistry perspective on this subject.

By way of a very simple example, the distribution of torsion angles around an aromatic ester fragment is shown in Fig. 2: Such esters show a strong preference for forming a flat "trans" conformation; therefore there is a strong case for only sampling such torsion angles within this region of torsional space.

The ICM docking program uses rotamer distributions to bias the Monte Carlo sampling as an effective heuristic to speed up searching. FlexX and GOLD both use distributions of torsion angles for common substructures to set the ranges of allowed torsion angles in sampling.

Many docking programs essentially treat ligand flexibility by using force field-based terms, so in effect the motion of the structure in the binding site is controlled by the score in conjunction with the sampling algorithm.

The flexibility of ring residues is a challenge for docking programs, and indeed any molecular modeling system that has to allow for molecular flexibility. The most common approach is to treat a ring as essentially a sequence of acyclic fragments, but with the addition of constraints or restraints to reconnect the ring. Such an approach is used in the AutoDock docking program. Other approaches include switching between ring templates or corner flipping. All these approaches have significant drawbacks; choosing fully flexible rings significantly increases the search space for larger rings or multiple ring systems; ring templates are limited by the templates available, while ring flipping is only applicable to unfused ring systems. Ring sampling is an often overlooked area where improvements could be made to docking programs.

Another challenge facing docking packages is the handling of covalently bound linkages within binding sites. Most modern docking packages have systems to allow for specification of covalent linkages between the protein and a putative ligand. The implementations, however, face certain challenges; scoring functions have to be adapted appropriately to account for the nature of the covalent linkage and the reactive warhead in the ligand needs to be identified. CovalentDock, built on top of AutoDock, addresses some of these issues with automatic identification of the likely site of the covalent linkage in the ligand and an additional energy term for linkage formation.[28] An alternative approach describes an automated procedure for identifying reactive electrophilic ligand groups and preparing them for covalent docking using GOLD.[29] Another interesting challenge is the induced motion of the protein in the region of the covalent linkage, which needs to be considered. The Schrodinger protocol CovDock combines the GLIDE docking program with the protein structure modeling package Prime[30]: the reactive protein residue is mutated to Alanine and GLIDE used to perform non-covalent docking; the protein is restored and the binding poses are examined to identify those that can form covalent linkages; Prime is used to refine the complex; finally the ligand is scored using the mean of the GLIDE scores for the non-covalent form of the ligand and for the covalently bound ligand.[31]

Overall, however, with the caveats expressed above, we can say that the sampling of ligand flexibility within a binding site is a solved problem. There are viable and well-described methods that can be used to allow sampling of ligand geometry efficiently and effectively.

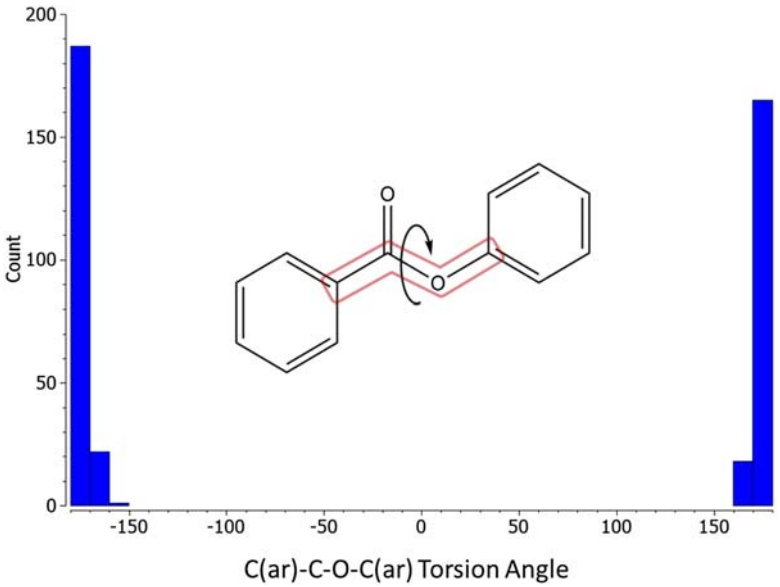

Fig. 2 The distribution of observed torsion angles around an aromatic ester in the Cambridge Structural Database. The distribution was generated with CSD Version 5.37. The search was limited to organic structures with a crystallographic *R*-factor $<5\%$.

3.12.4.3 Tackling Binding Site Flexibility: An Unsolved Problem

The majority of protein binding sites have some degree of flexibility, either by the motions of specific side chains or possibly by larger motions of protein backbones. Often motions are induced, or selected, by the binding of a given ligand, the well-known principle of induced fit.[32]

Historically, docking programs have generally treated binding sites as primarily rigid.

Early efforts attempted to tackle flexibility implicitly in the nature of the scoring function. Scoring functions were "softened" to allow a larger degree of clash against a rigid binding site. Such methods had the advantage that they did not increase computational complexity of the problem but had the disadvantage of only accounting for isotropic expansion of a binding site on binding rather than explicit motions of restricted parts of a given binding site. Furthermore, by allowing softer potentials, the docked results are harder to present and interpret, as typically one observes physically unrealistic contacts in the binding site.

Computational power has increased radically since these early attempts so more recent approaches incorporate some degree of protein flexibility into the docking process explicitly, typically using methods that are analogous to the approaches used for ligand flexibility. For example, an end user can decide to allow individual amino acid side chains to flex in a binding site, or to occupy specific conformational states.

Larger scale motions are handled via "ensemble"-based methods which sample multiple complete conformations of the protein. Any rigid docking program can be made flexible using a naive ensemble-based approach; an end user can dock each ligand multiple times against each different ensemble member and then use the best score attained for each ligand.

Knegtel and coworkers[33] presented the ensemble docking approach with experimental structures. They attempted to solve the problem of relative scoring of ensemble members by using weighted scores for each ligand derived from dockings into all ensemble members.

While the naive approach to ensemble docking is an effective approach, investing time in sequential docking for larger ensembles is computationally challenging. Consequently, developers have invested time and effort into docking approaches that try to remove the need for sequential docking.

FlexE[34] accounts for side chain motions as part of the incremental building algorithm, by treating the majority of the common core as a single protein. Side chains can then occupy variable locations as dictated by observations in the superimposed ensemble. The incremental nature of the algorithm means that the problem is reduced as ligand binding in turn drives the selection of given rotamer positions.

The ensemble approach implemented in GOLD[35] uses superposition of protein structures to inform the docking procedure of conserved regions in the binding site. The fitting points used by GOLD in its underlying mapping algorithm are then pruned to reduce the underlying size of the search space. Further, different ensemble members are distributed across "islands" in the underlying genetic algorithm with migration allowing for movement between members. FITTED[36] also uses a genetic algorithm with genetic operations reflecting switches between different conformations of proteins or different side chain configurations.

An interesting approach has been proposed by Bottegoni and coworkers,[37] who have developed so-called Four-dimensional docking. They try to treat conformational flexibility as a fourth discrete variable in sampling by using the root mean square deviation of the position of critical functional groups in a structural ensemble as a metric to order the structures in the ensemble. The consequence of such an approach is that the steps in the search algorithm from one ensemble member to the next will cause smaller perturbations to the protein model than by sampling ensemble members at random.

Recently, OpenEye have proposed extensions to their docking protocols to HYBRID and POSIT that attempt to incorporate ligand information into docking over ensembles.[38,39] In their approach, bound poses of known ligands in place are used to guide docking of unknown structures.

Ensemble docking methods rely on the availability of structural information to create the docking ensemble. Since the turn of the millennium the volume of experimental information about protein flexibility has increased hugely due to the growth of protein crystallography, which leads to the opportunity for using experimental observation to inform algorithms as to the nature of protein flexibility; in practice, most use of ensemble docking relies on such data sets.

An alternative approach to using experimental structures is to use computational methods to generate ensembles. Typically, a user would use molecular dynamics (MD) to generate snapshots of a structure and use these snapshots as the basis for ensemble docking. It is worth noting, however, that there are significant challenges in using such methods. MD tends to generate many snapshots; many more than would typically be used in an ensemble docking run and so the end user is still faced with having to select a subset of snapshots from the set generated. While it is possible to show that MD can generate a set of ensemble structures that improve docking performance, selecting the best subset to use a priori is very challenging.[40]

It is important to note what the net benefit of using ensembles in virtual screening actually is. The use of ensembles with GOLD has been studied extensively.[35] Interestingly, the authors observe that using an ensemble when undertaking virtual screening rarely improves the performance over a virtual screen using the best performing single structure in the ensemble, but generally gives better than average performance. One can then regard ensemble docking as a means to minimizing risk in virtual screening rather than a panacea.

Another alternative approach to tackling binding site flexibility uses protocols that use a modified binding site model for docking to circumvent flexibility, or treat side chains as partially flexible.

GLIDE's Induced Fit Docking protocol is an example of such a protocol where initially flexible residues are mutated to Alanine in the binding site: the modified representation is then used for initial pose prediction followed by a back mutation to the original site

and re-optimization. The approach still uses an ensemble to identify the flexible regions, but avoids the initial need for sampling into a large number of sites.

Other induced fit protocols tend to dock into a rigid structure and then post-process using relaxation of the binding site. More recently, docking programs such as DOLINA,[41] GalaxyDock,[42] and CDOCKER[43] attempt to handle flexibility without the need for a specific ensemble. BP-Dock attempts to model backbone flexibility as part of the search space.[44] Fleksy combines these methods by first docking into an ensemble and then relaxing the generated binding sites.[45]

Finally, Grebner and coworkers have used Protein Energy Landscape Exploration to explore docking of ligands with a fully flexible target structure.[46] Their method, computationally, lies between quick docking methods and full-blown MD simulations.

Handling binding site flexibility is still a very active area in the field of docking. Many other methods, (too numerous to describe) have been proposed for dealing with conformational ensembles.[47] While programs are improving in this area, we conclude that this is an area where development is still needed, though more effective methods are now becoming available and tractable. That said, we note that the current validation focus is primarily on reproducing observed binding modes. This is undoubtedly a highly desirable property of any docking program, but for us to regard the problem as "solved" the program has to achieve several further predictive criteria, namely the program must rank the correct binding mode highly against alternate binding modes of the same ligand; it must rank the correct binding mode of an active ligand higher than binding modes of alternative molecules of lower affinity; and it must select the correct receptor pose for the observed binding mode.

3.12.4.4 Treating Solvent During Docking: An Unsolved Problem

An additional degree of complexity in docking is presented by the presence or absence of water molecules in the binding site. The importance of accounting for water when docking has been recognized by many groups. For example, in a recent study,[48] the inclusion of water molecules was shown to be able to recover 56% of observed docking failures. In another study,[49] the authors note that it is important to include only key waters. Not all water molecules are beneficial to docking; some indeed can have an adverse effect on docking performance.

Most docking software can allow for the incorporation of water into a binding site as a rigid entity. In such situations, a given water molecule is treated as a part of the binding site into which a ligand is docked. In practice, however, experience with protein structure shows that certain water molecules are labile with respect to binding. It is therefore desirable to be able to treat water as a degree of flexibility within docking.

Again, any docking program can use a naive approach to handle docking by using sequential docking with a binding site containing a given water molecule, and then with a binding site with the water absent, but such an approach quickly becomes intractable when there are multiple water molecules that can be present or absent in a binding site.

A classic example from the literature is the protein OppA. Structures of OppA contain several bound waters (see **Fig. 3**) that contribute to different binding modes of ligands,[50] and can be either included or displaced depending on the nature of the bound ligand. Handling each configuration of the protein with static waters in such a system is impractical due to the combinatorial explosion of possible configurations. Consequently, it is desirable to allow water molecules to vary during docking.

Early work on including water explicitly in docking was carried out by Rarey and coworkers,[51] using the incremental construction algorithm implemented in the docking program FlexX. In their method, the solvent molecules are included as part of the

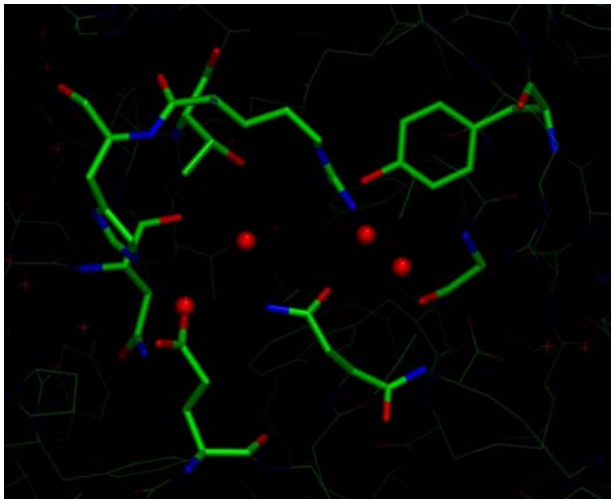

Fig. 3 Water molecules in the binding site of OppA with their interacting side chain residues (Taken from PDB entry 1b5i). The four water molecules can be displaced or retained on binding dependent binding ligand.

incremental construction algorithm used within FlexX: essentially water becomes a single particle that can optionally be switched on or off as a variable in incremental construction.

In the GOLD docking program, water molecules are included in the binding site explicitly at their start positions. Each water molecule is allowed to be switched on or off, controlled by a single discrete variable in each chromosome representation of the ligand. If switched on, additional variables are sampled that express the local rotation of the water and a constrained transformation such that the water remains within a user-specified distance of the original start position. Using this method can significantly improve the quality of docking performance for systems where water molecules form key mediating interactions between the protein and the ligand.[52]

Many other approaches have also been proposed. For example, one approach treats waters as being pre-attached to a ligand but then allowed to switch on or off during docking[53] rather than treating them as a static component of the protein. Such an approach has the advantage that the end user does not need to selectively include waters in the binding site.

It is worth noting that all these approaches introduce new challenges. Removal or inclusion of a solvent molecule in the binding site introduces an entropy change which is tricky to score. Typically, scoring methods either ignore this or treat the change as a constant factor. A recent paper attempts to tackle the scoring issue using a new model for scoring inclusion or exclusion of water molecules.[54] Further, choices as to which solvent molecules to include and to vary as part of the search protocol provide challenges.

Predicting such solvation sites has been an active area of research with tools of varying computational complexity being applied to the task.[55–58] A recent development[59] has seen the application of informatics in this area to provide a relatively rapid means for assessing the likelihood of solvation sites.

The problem of treating solvent during docking has solutions available which can be effective. There is, however, still work to be done: In particular, reliable a priori prediction of solvent inclusion or displacement is still a very active area of research, though recent developments do seem to show promise.

3.12.5 Affinity Prediction in Docking: An Unsolved Problem

3.12.5.1 The Affinity Prediction Problem

Affinity prediction remains a largely unsolved problem in computational chemistry. The reasons for this are rooted in the theory of statistical physics, which describes the energetics of binding. A primer is provided here for the reader, and full details may be found in any statistical physics[60] or physical chemistry[61] textbook. A more exact description of the theoretical principles for computing binding affinities is given in a review by Gilson et al.[62] Ligand binding typically occurs in an aqueous solvent. Upon binding a solvated ligand and protein form a bound complex within the solvent. More specifically, protein binding will occur if the change in free energy upon binding is negative. In other words, the free energy of the complex in solution should be less than the free energy of the separated ligand and protein in solution. For the purpose of this article we define binding affinity as the Gibb's free energy change (ΔG). Note that $\Delta G = -RT\ln K$, where R is the ideal gas constant, T is the temperature, and K is the equilibrium constant for binding. K is the concentration ratio between bound and free ligand and may be determined experimentally for many systems.

Consider a molecular state of the bound protein and ligand. This may be defined by the atomic coordinates of the system (though many methods also require momenta to be assigned to each atom). It is clear that a complex system such as a bound ligand can exist in a large number of differing states with varying energy levels. Statistical physics describes the probability, p_r, of each available state, r, with energy E_r via the Boltzmann distribution such that

$$p_r = \frac{e^{-(E_r/k_B T)}}{Q}$$

The normalization term

$$Q = \sum_r e^{-(E_r/k_B T)}$$

is known as the partition function (where k_B is the Boltzmann constant, equal to R divided by Avogadro's number). Any molecular system, such as ligand bound to a protein, should be visualized as an ensemble of available states where the Boltzmann distribution may be used to determine the relative likelihood of each state using only the energy of that state and the temperature of the system.

As an alternative to the Gibbs free energy, the Helmholtz free energy, A, may be used to predict binding as, under conditions of constant pressure and volume, $\Delta G = \Delta A$. Since $A = -k_B T \ln Q$, the partition function can be used to easily determine the Helmholtz free energy. It should be noted that reliable determination of the partition function requires the identification of many of the higher energy states and thus may be intractable for many systems.

The fact that many states have to be sampled in order to determine free energy reflects the role of entropy in driving ligand binding such that the change in free energy $\Delta G = \Delta H - T\Delta S$, where ΔH is the enthalpy change and ΔS is the entropy change. Entropy may be viewed as a measure of the amount of disorder in the system. For an ensemble system the entropy is

$$S = -k_B \sum_r p_r \ln p_r$$

where p_r is the Boltzmann probability described above for each state. The affinity of a ligand to a protein may be driven more by entropy than enthalpy. For example, the basis of the hydrophobic effect during ligand binding is the displacement of ordered water from within the protein active site and around the ligand to bulk solvent where it is free to adopt a less ordered state. Typically, docking scoring functions are better at capturing internal energies or enthalpies, rather than ensemble properties such as entropy.

Accurate determination of binding energies thus requires sampling of the Boltzmann distribution so as to identify the partition function for the initial system with the ligand and protein separately in the solvent, and for the final system which comprises the solvated complex. Not only will such a calculation require sampling of a large number of states, but also an accurate energy calculation will need to be performed for each state. Reliable affinity prediction is thus a Sisyphean task and remains a major challenge in the field of computational chemistry. Sampling of multiple states to determine binding affinities in this way is invariably too computationally demanding for docking algorithms which focus on the rapid prediction of a single binding pose. Nevertheless, an understanding of the theoretical basis for the calculation of binding energies is important in order to explain the failings of docking scoring functions.

In computational chemistry a standard technique to generate the ensemble of states to be included in a partition function would be to run an MD simulation, sampling from the trajectory once the system attained equilibrium.[63,64] Given this complexity much effort has been made to simplify the calculation of free energies in ligand binding.[65] While most of these techniques are not currently appropriate for docking methods (because of their compute-intensive nature), many may be used to rescore docking predictions,[66] and it is reasonable to imagine that we will see incorporation of free energy calculations into docking algorithms with improvements in computer hardware.[25]

The role of water is a major source of complexity in such calculations. If molecular systems are modeled using explicit waters the number of available states is much larger than the equivalent system in a vacuum, especially for areas of disordered bulk solvent. For this reason there is considerable focus on methods for calculating free energies in solution.[67] In particular, determination of the free energies of solvated systems can be greatly simplified if a polarizable continuum solvent model is used to approximate the free energy of explicit water molecules in the bulk solvent. The continuum potential may be expressed as extra terms in a molecular mechanics potential. Two continuum models in common usage include Generalized Born Surface Area (GBSA)[68] and Poisson Boltzmann Surface Area (PBSA).[69] Not only does the solvent model simplify the calculation of state energy, but the removal of the degrees of freedom required by explicit waters also significantly reduces the number of states in the system. The use of continuum models in docking has historically been restricted to rescoring,[70] though recently it has been included in the WScore scoring function.[54]

Additional techniques exist to further facilitate the calculation of free energy differences such as Free Energy Perturbation (FEP)[71] and Potentials of Mean Force (PMF).[72] During FEP, an ensemble of states created for one system is used for a second system. The free energy difference is readily calculated from the differences in energy between the two systems over each of the shared configurations. For example, an ensemble of states, each containing a set of coordinates and momenta, may have been generated for a ligand containing a Cl atom. Using those same states of coordinates and momenta the energy ensemble for second ligand with Br substituted for the Cl atom can be calculated together with the free energy difference for the substitution. Clearly, this approach works best for very similar systems, though the use of intermediate states allows the comparison of systems that do not share phase space[73] (where phase space comprises the positions and momenta of all atoms in the system). In the example above, where a Br is substituted for a Cl, phase space may be shared; this is not the case if the atom counts of the two systems differ. While FEP calculations are too intensive to be used in docking experiments, they may be used to rescore docking poses.[74]

Thermodynamic cycles make use of the fact that free energy, as a state function, is conserved around a cycle.[64] The use of nonphysical, but nevertheless valid, state changes enables the determination of binding energies while avoiding complex simulations of real-world processes. Consider, the thermodynamic cycle illustrated in **Fig. 4**. The binding energy in solution is

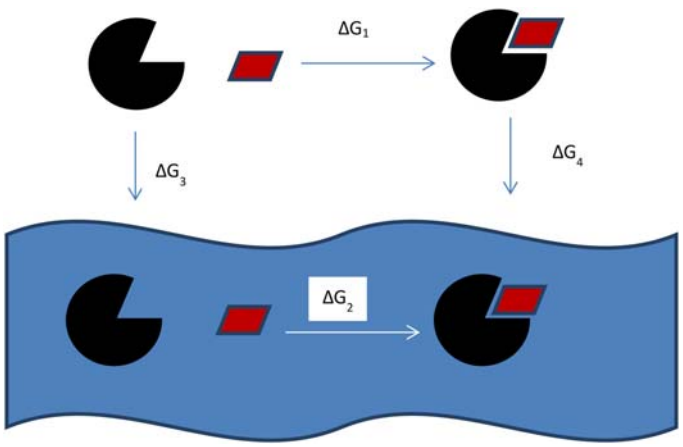

Fig. 4 Thermodynamic cycle as used by Autodock.

$\Delta G_2 = \Delta G_1 + \Delta G_4 - \Delta G_3$, where ΔG_1 is the free energy of binding in a vacuum, ΔG_3 is the free energy change on solvation of the separate molecules, and ΔG_4 is the free energy change on solvation of the bound complex. Docking results may be used to determine the structure of the complex and an estimate of ΔG_1 and the use of a continuum solvent model can facilitate the estimation of energies of solvation (ΔG_3 and ΔG_4).

The Autodock algorithm uses the free energy cycle described above to predict binding affinities in its scoring function.[16] Autodock does not attempt to identify the partition function but rather uses known complexes with associated inhibition data to parameterize docking and solvation potentials.

PMF calculations follow from the observation that, for atom pairs, the partition function is equivalent to the radial distribution between atoms. The radial distribution is normally defined by the distance between atom pairs. Using crystallographic databases the distribution of distances between atom pairs of interest (e.g., between a donor and acceptor or two hydrophobic atoms) may be used to determine the free energy contribution at as particular distance. This technique has been used to determine free energies of atom pairs within proteins[75] and has been adapted to score protein-ligand interactions.[76]

3.12.5.2 Scoring Poses in Docking

As implied above, affinity prediction in docking is a challenging task, but despite this, many research groups have attempted to tackle the problem at varying degrees of approximation. In this section we will review what can be predicted from docking results, given the scores available, how higher levels of theory can be incorporated into docking algorithms and how docking poses may be used to assist advanced calculations.

The scores used directly in docking programs are generally designed to be fast enough to allow them to be evaluated many times a second. This facilitates sufficient sampling in the global search algorithms that accompany docking. This means, however, that by necessity they have to compromise on accuracy in certain areas.

Traditionally, scoring functions are seen to be split into three different categories, namely molecular-mechanics like scoring functions such as the scores PLPScore,[77] Goldscore,[78] GlideScore,[14] and Emodel[14] which try to model the binding interaction energy based on approximations from chemical theory, empirical scoring functions such as ChemScore,[19] ChemPLP,[77] FlexX,[51] Fresno,[79] which are essentially trained for affinity prediction against sets of empirical data on binding, and knowledge-based functions such as PMF,[80] ASP,[81] and DrugScore[82] which are based around statistical potentials derived from databases of observations of interactions in chemical databases such as the Protein Data Bank[83] or the Cambridge Structural Database.[84]

It is worth noting that some scoring functions are specifically designed for rescoring rather than docking. For example, the HYDE docking function attempts to specifically model de-solvation of hydrogen bonding.[85] This score alone is an insufficient description of all the processes of binding, and so is used in tandem with a different score for the purpose of pose prediction: the HYDE score is then used alone to assess the quality of binding of the generated pose rather than to drive a docking exercise.

Rescoring can be a successful strategy in tandem with docking, as it facilitates the use of computationally more expensive methods for the rescoring.[66] Some notable examples where such methods have been applied include MM-PBSA for post-optimization,[86] and using the AMBER force field in rerefining fragment dockings.[87]

3.12.5.3 Validation of Docking Programs and Their Associated Scores

Self-validating docking studies, where a ligand is extracted from a crystallographic macromolecular complex and a docking algorithm is used to dock the ligand back into the protein, are the primary method of validation for docking algorithms. Normally, the docking program optimizes ligand position and geometry using molecular mechanics-like potentials; these typically reproduce observed binding modes by maximizing hydrophobic contact and reproducing hydrogen-bonding motifs.

Results published by algorithm developers are often impressive in this regard: for example, the original GOLD algorithm showed a 71% success rate (using subjective criteria) in self-docking[78] of 100 complexes; GLIDE was successful in two-thirds of 282 complexes, using a 2 Å RMSD cutoff.[14]

Studies by third parties, who are algorithm users rather than developers, show methods to be less effective; this is unsurprising given the sensitivity of these methods to input conditions such as protonation states and active site definitions and the common practice of refining algorithm performance against the validation test set. Third party studies may be broadly categorized as to the metrics evaluated: pose prediction, virtual screening enrichment, affinity prediction, and activity ranking. Here we review many of the third-party evaluations done to date. In view of the large number of algorithm evaluations and proof-of-concept studies we restrict our summary to comparative studies of multiple methods that are either performed by third parties or comprise blinded data. For these reasons we do not include participants' papers from the Docking challenge special issues in the Journal of Computer-Aided Molecular Design.[88] An exception is made for the Comparative Assessment of Scoring Functions (CASFs) papers,[89,90] authored by the developers of *X*-Score,[91] in light of the large number of other scoring functions evaluated therein.

In one of the first reviews of its kind, in 2000, Bissantz et al. evaluated the performance of Dock, FlexX, and Gold in combination with seven scoring functions against thymidine kinase and the estrogen receptor and found that the docking programs were capable of discriminating active from inactive compounds up to 70% of the time if consensus score methods were used.[92] Unfortunately, no clear relationship was observed between docking scores and activity ranking, and predicting binding free energy was not possible.

In a number of later papers, researchers confirmed the utility of docking algorithms for pose prediction (by showing close RMSD to the crystallographically observed binding mode) and virtual screening (by showing improved enrichment of hits over random), but did not evaluate affinity prediction. For example, a paper in 2001 from Stahl and Rarey tested FlexX in combination with four scoring functions (FlexX, PLP, DrugScore, and PMF) across seven systems for virtual screening.[93] A combination of FlexX and PLP scoring functions was found to have broad-based applicability for selecting actives during virtual screening. A similar paper from 2003 described the utility of several docking programs for virtual screening (in this case simply recovering the crystallographic ligand from a set of decoys) and pose prediction on 11 systems.[94]

In an interesting study from 2003, Autodock was employed to create an exhaustive set of bound conformers.[95] Eleven scoring functions were evaluated as to their ability to identify the experimentally observed binding mode, and six were shown to have success rates or 66% or greater (using a 2 Å RMSD criteria). Unusually, considerable success was observed in prediction of binding affinities with *X*-Score, PLP (as implemented in Cerius), DrugScore, and GOLD (as implemented in Tripos' CScore) scoring functions all giving correlation coefficients of over 0.5. This may be more to do with discrimination of active and inactive compounds as the datasets included millimolar compounds, rather than the relationships that would be required for SAR projects. In a later 2004 study by the same group using 14 scoring functions, on a set of 800 complexes from the newly released PDBbind[96] database of protein crystal structures and binding affinities, similar results were obtained in terms of correlation.[97] This later study also looked at the ability of scoring functions to classify ligands into categories of high, medium, and low activity where all methods showed modest ability to classify ligands into the high and low activity categories. The relationship between experimental activity and docking score was further studied using three test systems (HIV-1 protease, trypsin, and carbonic anhydrase II), this time on a per target basis. Reasonable performance was observed for many scoring functions in the trypsin and carbonic anhydrase II dataset though only one scoring function was effective for HIV-1 protease.

In 2004 a further number of papers again showed that docking algorithms were able to both predict binding poses and perform well in virtual screening enrichment studies. One study of FlexX and five scoring functions (FlexX, DOCK, GOLD, ChemScore, and PMF) showed significant enrichment during virtual screening.[98] A study of three docking algorithms (Glide, GOLD, and ICM) in three systems found Glide to be the best method for identifying the binding pose and enrichment performance to be scoring function dependent.[99] A comparison of 8 programs (DOCK, FlexX, Fred, Glide, GOLD, Slide, Surflex, and QXP) against 100 known ligands showed that the best tools for pose prediction (Glide, GOLD, and Surflex) were also the best for virtual screening ranking.[100] Another study focused only on the ability of common docking algorithms to predict ligand binding poses.[101] Interestingly, one study from 2004 using GOLD, FlexX, DOCK, and AutoDock on zinc metalloproteinases showed not only pose prediction but also strong activity correlations using DrugScore ($R^2 = 0.58$) and *X*-Score,[102] though this may reflect the composition of the PDB entries used to parameterize these knowledge-based functions.

One paper from 2004 compares traditional docking scoring functions with the charm force field augmented by continuum solvation models.[103] Nine scoring functions were evaluated across 189 complexes, with 5 scoring functions achieving binding pose prediction rates of over 80%. Surprisingly, despite the inclusion of implicit solvent only the knowledge-based ChemScore scoring function was able to show a reasonable correlation with activity. Another study from the same year used a dataset of known activities of 205 protein-ligand complexes.[104] Binding prediction experiments using four scoring functions failed to show any real correlation between docking scoring functions and activity, though useful correlations were observed in some subsets.

Further enrichment studies performed in 2005 continued to confirm the capability of docking in virtual screening via enrichment studies. Pose prediction and enrichment performance was assessed for three algorithms (FlexX, Glide, and DOCK) together with six scoring functions and the authors' finding was, unsurprisingly, that false positive prediction was lessened when bioactive poses were available.[105] Another study using DOCK, DockVision, FlexX, Glide, and GOLD into five protein test systems found reasonable rankings in virtual screening experiments even when docking programs failed to identify active poses.[106]

In 2006 a virtual screening study from AstraZeneca, FlexX, GOLD, GLIDE, and ICM was evaluated for virtual screening and pose prediction over 12 protein targets. Glide and ICM were shown to be superior in pose prediction and virtual screening enrichment.[107] Interestingly, the author compared the docking programs with 2D (ISIS fingerprint similarity) and 3D (ROCS). For the proteins investigated ROCS outperformed all algorithms except ICM in terms of enrichment and the simple 2D method did better than either GOLD or FlexX.

Also in 2006 a review from GlaxoSmithKline of the performance of 10 docking programs across 8 proteins and 1300 ligands showed that pose prediction success was at best 35%, using a 2 Å RMSD criteria.[108] Although, observing some success in pose prediction, this extensive study failed to show any statistically significant relationship between docking scores and affinity for any program, though a positive correlation was shown for a single compound series (but not for all compounds) against a kinase target. Other positive correlations were from discriminating between active and inactive compounds rather than rank ordering of active compounds. Where possible, the authors repeated this experiment using only dockings for which the pose had been correctly identified. With the exception of GOLD and PPARδ, where a significant relationship was observed, no improvement was observed.

An investigation from 2007 into the performance of GLIDE, GOLD, and DOCK over 21 systems showed that GLIDE outperformed GOLD and DOCK and, while 15 systems comprised the GLIDE training set, GLIDE created the highest enrichments in 5 of the remaining 6 systems.[109]

In 2009 a study by Wyeth also suggested the superiority of GLIDE which, together with ICM and Surflex, proved more effective in pose prediction than DOCK, FlexX, and PhDOCK over 68 protein ligand complexes (where ICM had a median RMSD of 0.98 Å against the observed binding mode).[110] The same study also researched the effectiveness of the docking methods for virtual

screening in 40 targets from the Directory of Useful Decoys database,[111] where GLIDE yielded the highest mean ROC AUC value of 0.72, though all methods had mean AUCs of better than random.

Also in 2009 the first comprehensive CASF was published.[89] Using a curated subset of PDBbind of 195 complexes, comprising 65 different proteins each bound to a high, medium, and low affinity ligand, this study performed an extensive evaluation of the ability of 16 scoring functions to perform pose prediction and to predict binding affinities. Pose prediction was tested by determining if the scoring function could discriminate the active pose from 100 decoy poses. Many functions did exceptionally well here, with the best performing scoring function (ASP) identifying either the active pose or a decoy pose within 1 Å RMSD from the active pose about 70% of the time (and 80% if the cutoff were 2 Å). Affinity prediction was evaluated in terms of correlation between activity and the score of the observed pose in its cognate active site over the entire test suite. Some scoring functions performed surprisingly well here with the best method, *X*-Score (HMScore), showing linear correlation of 0.65 with affinity. It should be noted that this test scenario is not representative of docking in practice: the active poses are known and scored directly and only three activities over a wide range are present for each target. Even with this optimistic system, five of the scoring functions were outperformed by simply using the ligand heavy atom count as a scoring function. The ability of scoring functions to rank order the three ligands by affinity for each of the 65 test proteins was investigated. The best method, again *X*-Score (HSSScore) was able to do this successfully only 60% of the time, confirming the conclusions of earlier studies that compounds of high activity cannot be consistently ranked over those with low activity. The paper also includes further ranking experiments on additional datasets, which show scoring function performance to be system dependent. The authors rightly conclude that the best scoring functions are competent at predicting binding poses, but affinity prediction requires improvement.

In 2011 the extensive CSAR (Community Structure-Activity Resource) benchmark exercise of 2010 was published.[112] This collaborative work of 16 groups evaluated 19 different methods over 343 high quality structures. R^2 correlations with experimental pK_i values ranged between 0.58 and 0.12, indicating that scoring functions were neither able to predict binding affinity nor rank relative activities. Although the results for individual scoring functions were blinded, all types of scoring functions were included and no type, force field, empirical, or knowledge-based, demonstrated any inherent superiority. A detailed analysis was performed to identify the differences between those systems that were amenable to affinity prediction and those complexes which scored poorly. Further illustrating the difficulty in scoring entropic contributions, it was found that, in cases of failure, scoring functions tended to overestimate the contribution of hydrogen bonds and underestimate hydrophobic interactions. Additionally, torsional strain was much lower in underscored ligands.

The results of a second CSAR benchmark exercise were disclosed in 2013.[113] This exercise was based around blinded experimental data for four proteins, 122 compounds with measured activity (or confirmed inactivity) and 30 crystal structures.[114] The compounds comprised of a number of congeneric series. The study metrics were binding pose identification, enrichment, and activity ranking. Twenty-one groups using 18 docking programs submitted predictions. The organizers of the challenge did not identify the particular groups or methods but provided scoring and sampling function categories (e.g., knowledge, empirical, or force field based). In terms of pose prediction the results were poorer than those typically observed-with only 34% of the highest scoring pose predictions being within 2 Å of the experimentally observed binding mode. An analysis of close ligand-protein contacts suggested that the scoring functions were underweighting contacts. Some of the poor results for pose prediction may have resulted from movements in the protein and reflected the challenges of cross docking. No clear winner was identified in terms of the best scoring function category, though there did appear to be an improvement when empirical scoring functions were used. In an interesting insight to the issues around docking inputs the authors provided the groups with a methodology questionnaire and ascertained that pose prediction was more likely to be successful if the active site had been minimized, if histidine residues were assigned correct tautomeric states, if a ligand conformer library were used, and if the method were trained on the native ligand. The results for binding affinity prediction were poor with only two methods averaging a correlation (per protein) of over 0.5 and no group being able to perform any meaningful predictions on one protein (Chk1). The ranking predictions were likewise poor, and the enrichment studies were equally uninspiring. Enrichment was only tested for two proteins, as one protein had no actives and another had an insufficient number of compounds. It was found that most methods were no better or worse than random, three methods were better than random, and three were worse. It should be noted that this enrichment study was somewhat unusual and certainly not representative of virtual screening as there were only a limited number of inactive compounds, which were presumably very similar to active ligands.

2014 saw the publication of the second CASF study.[90] In a design similar to the previous work 20 scoring functions were evaluated against a newly curated subset of PDBbind (the PDBbind core subset, version 2013[115]). In addition to evaluating scoring functions for binding pose prediction, affinity prediction, and activity ranking, a test for virtual screening enrichment was added. As in the previous study, the test set comprised 65 distinct proteins, each complexed with a high, medium, and low activity ligand, for a total of 195 systems. As before, in order to decouple scoring function evaluation from the problem of conformational search, decoy poses were generated using common docking programs, clustered and seeded with the bioactive pose. Further, to evaluate scoring in virtual screening, for each of the 65 proteins the 192 ligands that were active against the other proteins were used as negatives. Using the procedure for generating decoy poses, binding poses were created for over 12,000 protein-ligand negative pairs. The results were not dissimilar to the previous study, with the most impressive performance observed in the pose prediction tests, where the best scoring functions, such as ChemPLP (as implemented in GOLD), predicted the observed binding mode over 80% of the time. Likewise, the new virtual screening test confirmed that docking algorithms are able to discriminate between active and negative compounds, with enrichment rates for the Glide-SP scoring function being almost 20 times over random. As expected, the performance in activity ranking and prediction was much more disappointing. While *X*-Score (HMScore) performed best with

an apparently reasonable correlation of 0.6 to activity, a simplistic scoring function based on the change of solvent accessible surface area was runner-up with almost identical correlation. This naive function also outperformed almost half the scoring functions in the activity ranking test. Again *X*-Score (HMScore) was the best scoring function in this test, successfully ranking each of the three ligands 58% of the time. It should be noted that this is a simple ranking problem (discriminating between weak, medium, and good ligand) and is not indicative of the challenges experienced in SAR programs. Additional analyses of subsets of the test systems indicated that prediction of the binding modes of flexible or hydrophobic ligands remained a challenge. While polar interactions appeared to help scoring functions identify binding modes they fare poorly in activity prediction, suggesting issues in accounting for the desolvation of polar groups.

Another CSAR exercise, conducted in 2013 and published in 2015, contained not only a protein design challenge but also a pose prediction and an affinity prediction challenge.[116] The docking pose test contained two designed proteins that bound digoxigenin (an extremely rigid steroid), together with a set of poses (the binding pose and 199 decoys such that no decoy was within 2 Å RMSD of the binding pose). Fourteen groups submitted 25 methods for analysis with 17 and 18 methods identifying the binding mode for each of the two proteins, respectively. Notably, a submission using MM/GBSA proved unable to identify the binding mode for either protein. A relatively narrow binding pocket and a somewhat rigid ligand may have made this an easy task. For the final test the binding affinities of 10 small molecules (near-rigid analogs of digoxigenin) to one of the designed proteins were determined by the organizers. In this phase, the 14 groups submitted 27 methods and 12 methods showed correlations of over 0.7 between scores and activity, though only seven methods demonstrated similar correlations between ranks. Given the narrow range of activities, between 0.22 and 80 μM, and the similarities of the ligands, rank ordering proved a difficult task. It is also possible that, given the tightness of the activity values, because of error the benchmark experimental rankings were not correct. While anonymity was preserved and the performance of methods remains blinded, the method used were identified and were representative of common scoring and docking algorithms. Interestingly, despite using the same methods, different groups did not submit the same predictions, highlighting the role of input structure preparation and method parameterization in program outcomes.

In the most recently published study CSAR 2014 participants were invited to perform docking studies on three targets using blinded data provided by GlaxoSmithKline.[117] As in the CASF studies an attempt was made to separate scoring from docking and the first phase of the challenge involved selecting an active pose from 200 decoys, where 32 of 52 methods had excellent performance. A second phase involved prediction of binding affinities with few methods being able to rank actives with any statistical significance.

3.12.5.4 Overall Conclusions on Affinity Prediction and Scoring

In summary, an almost unanimous picture of docking capabilities emerges. Most methods are able to perform pose prediction with some accuracy. In virtual screening, most methods also perform well, achieving enrichments well in excess of random, though we should not regard random as the comparative baseline; if a docking study only performs as well as simple 2D properties, such as molecular weight, donor or acceptor counts, or simple measures of molecular flexibility, one can hardly regard that docking study as a success.

Comparative studies indicate that docking methods do not provide greater enrichment than either 2D or 3D ligand-based methods,[118] while the ligand-based methods are clearly easier to set up and computationally more tractable. It is, however, in affinity prediction that docking methods and scoring functions require the most improvements. In general, scoring functions correlate poorly with activity and are unable to rank order compounds by affinity. In fact the CASF studies indicate that current scoring functions are unable to reliably discriminate between compounds of low and high activity. This negates one of the potential gains of structure-based design; namely, that by inclusion of the protein structure, activity cliffs may be identified.

Despite the failure to predict affinity or rank order activity many of the studies showed that docking did result in significant enrichment in virtual screening, indicating that the scoring functions were at least able to distinguish between active and inactive compounds. This would appear to be a direct contradiction of the previous observation from the CASF studies. We suggest that the difference is that in the CASF studies the ligands are more likely to be from congeneric series, where compounds in virtual screening experiments are much more diverse. In fact, a recent extensive review of docking screens confirms this observation and found for many screens that, in terms of hit rate, docking studies for many enzymes were two to three orders of magnitude better than the comparable HTS screen.[3] This would suggest that active compounds may be identified simply by their ability to crudely fit into the active site. Given the simplistic nature of docking scoring functions this is not surprising and it may be that pose prediction requires only a simple geometric recognition. That is, recognition of hydrogen bonding motifs and hydrophobic surface area contact is sufficient to predict a binding pose (though, obviously, this would be insufficient to predict a free energy of binding).

Validations of docking programs are, of course, dependent on the quality of the systems that they can test their programs on and the way in which the user makes use of the program. It is worth noting that the test systems used for development and validation are far from perfect.[119] For example, a common validation method used is to compare relative performance of virtual screening against the results of high throughput screening, but experience shows that the high throughput screening results themselves can contain noisy information. Consequently, the validator must moderate their expectations of the docking program to account for the nature of the experimental data they are validating against.

3.12.6 Other Unsolved Docking Problems

We note that there are yet more areas where docking could have impact but where the solutions offered as yet are somewhat limited. Some software features the ability to perform covalent docking, for example, but the methods used could be significantly enhanced. Further, we are currently unaware of solutions that try to tackle significant conformational change on covalent binding to the protein in a structure agnostic way. Typically, the end user has to inform a program of the nature of the covalent linkage prior to docking and set up the docking appropriately rather than allowing the software to make choices regarding the nature of any covalent bond, or recognizing that the actual chemical reaction occurs.

Another area of interest would be the automatic recognition of dynamic changes in tautomeric state and protonation state of ligands that might occur on binding. Currently, tautomerism and protonation states are usually considered on input creation, and so rely on user choices to yield good results.

A longer term challenge lies in using docking to identify small molecules that could cause disruption of protein-protein interfaces. This growing area of interest has its own community, and has been subject to its own CASP-like collaborative effort (CAPRI[120]) in assessment of methods to aid the development of new and existing approaches. Finally, protein-protein docking itself is a very active area of research in its own right which is becoming of more interest with the development of biologic therapeutics.

While the focus here is medicinal chemistry, it is worth noting that docking can be applied to a wide variety of other problems. For example, docking of substrates into metallo-organic frameworks or zeolites,[121] or clefts into surface cavities of small molecule crystals could be useful in a variety of broader chemical applications, such as the understanding of the behavior of crystal growth inhibitors. (For an example of such an approach, see Coveney et al.[122])

Such problems present their own challenges: in particular, a broader range of atom types require parameterization, solvation effects are less predictable, due to the wider choice of solvents used in crystallization, and the nature of the problems in question mean that researchers have to consider behavior at non-ambient temperatures and pressures. These are potentially rich unexploited areas of research for a future generation of docking developers.

3.12.7 Democratization of Docking: An Unsolved Problem

The final area of contention in the area of docking, as with any software, is in "democratization." The definition of "Democratize" from Merriam-Webster's Dictionary says: "verb: to make (something) available to all people: to make it possible for all people to understand (something)." While commercial docking programs may not be freely available to all people, they should be easily understood by all users.

How is the idea of democratization translated into docking? For a docking package to be democratized, any user should be able to prepare the necessary inputs (a small molecule or set of small molecules, and a protein structure or PDB code) and return the same list of compounds as any other user inputting the same data.

From an end user's perspective, democratization is far off. There are dozens and dozens of programs that will take these inputs and return a ranked list. There are companies that argue that each has the "best" product. The problem starts way before the inputs (themselves often representing a large degree of uncertainty) are chosen and thrown against the virtual wall to see what sticks.

Let us just list the choices one has as one descends down the rabbit hole. There are many docking programs (we estimate at least 70) available to the community, some commercial, some academic.

Most of the stand-alone tools also make the user choose from a set of charge state models, force fields, conformational sampling approaches, water utilities, scoring functions, rescoring functions, and speed.

If we just assume that we have 70 programs, each with 10 features and there are 3 choices for each feature, we get a bewildering (70×3^{10}), that is, 4 million options for docking molecule collection A into protein B. Even if we only took a carefully curated crystal structure data set for validation, such as Iridium[123] (which has 728 structures), we would still have to somehow try to measure the performance of more than 4 billion dockings.

On the flip side, every single docking program available will return a ranked list of compounds that will help the user reduce the search space "worthy" of a closer look. Given the bewildering set of choices available then, what is the user of docking software to do?

Furthermore, the end user also has to consider not just how to do docking but also whether or not to use docking in the first place for the task at hand.

3.12.8 Help! I am a Medicinal Chemist … What Do I Do Now????

3.12.8.1 When Should I Use Docking?

The answer to this question will depend on the ethos of the organization in which an end user works, and the task that the end user is addressing. We note that all we can express here is opinion borne out of experience. Docking is typically applied in virtual screening and in lead optimization. Each use case is subtly different. In an excellent review, Irwin and Shoichet[3] recently analyze the impact of docking and other screening techniques on medicinal chemistry programs, and suggest good strategies and approaches that can lead to success. They show validated examples where docking is successful at identifying leads. Their choice

of examples was predicated against whether they could say with confidence that the discovered hits had led to new biology: that is, they were interested in cases where the resultant hits were validated against an organism. They conclude that while care is required, useful hit rates of 10% can be achieved if docking is applied with due care and attention in very high throughput virtual screening, both in the application of software and in the interpretation of results.

One notable element of this review is the need for attention to detail in the processes undertaken. A key issue to consider with any software is the age-old principle of "garbage in, garbage out": in effect the end user has to have a high degree of confidence in the inputs to the program to get good insights from the results.

Some organizations will have a large array of high quality protein structural data available to them which provides a bedrock for docking studies; other organizations may be relying on alternative models, such as homology models which, while valuable, are generally at a lower degree of accuracy than a high resolution crystal structure. One may not then expect such models to generate reliable docking results. In the context of virtual screening, it is possible that alternative approaches may yield comparable results in a shorter time frame.

We would recommend using docking prospectively when you have carefully validated protein crystal structures with a resolution better than 2.5 Å. Where possible, we would recommend testing the docking program by confirming the program can reproduce the poses of known bound actives against non-cognate protein structures; however, we accept that this may not be feasible in many early-stage projects.

Docking can, however, also be useful in protein structure validation. Protein crystal structures will typically only have ligands resolved in one binding mode. Docking can sometimes suggest alternate modes that might fit the electron density equally well. Using the docking program to cross-validate the refined pose can suggest alternative structural interpretations of the protein structure that may not have been originally considered.

3.12.8.2 How Should I Use Docking?

As illustrated in the introduction to this section, the choices available to an end user are bewildering. Some of this, however, can be ameliorated.

3.12.8.3 Learn How to Love the Software

Working with docking software is a labor of love; understanding the complexities and quirks will provide the best results. How can a user really get to understand the complexities and quirks? Firstly, stick to the best practices advised, at least initially. Use the approaches that are used in the detailed recipes, examples and tutorials that the software provider gives you and stick with that until you have an understanding of the ramifications of straying from it. Get to know its good points and bad points and gain an understanding of the likely outcomes of using it. This is, of course, easier said than done, but the investment of time is worthwhile: be annoying to your local experts, make use of your vendor's training materials, courses, and support options, and try to gain a level of expertise that allows you to make informed choices. When starting a new project, use the newest version of the software and ask for support from your software provider if necessary.

These recommendations may be surprising to some, in that it may seem obvious, but anecdotally, vendors have experience through support queries that indicate that not all end users gain a full understanding of the software they are using. For example, the CCDC has experienced a number of support queries where the end user has not understood that the docking program expects a three-dimensional representation of a chemical structure as its start point, and has tried to dock input files that contain two-dimensional structural representations only. Other problems seen include cases where the protein structure model being used had not had any explicit hydrogen atoms added or where cognate ligands were left in the binding site thus making it impossible for the docking program to place ligands there.

It may be that a reasonable expectation of the software is that it would attempt to automatically resolve these issues, and indeed many vendors provide preparation tools that aid the end user when using their software. The support queries mentioned above indeed sparked development at CCDC to improve the end user experience when setting up docking, but it is unrealistic to expect software to be able to resolve every possible mistake that could be made in user input.

It may not be possible for every end user to gain the requisite level of expertise: in such cases knowledge sharing is highly desirable. Where resources are available, it is better for end users to use software in a controlled environment. Many organizations will provide simplified (possibly web-based) interfaces to docking that provide access to specific target protocols. Such interfaces can allow an expert user to create predefined protocols that are best suited to a given target, which have been shown to be effective in practice.

Such interfaces also have a huge advantage of streamlining work. Rather than many users setting up their own protocols, one expert can take project responsibility for docking setup, meaning all end users are using the tools in the best way.

3.12.8.4 Invest Time in Your Input Protein Structure!

Docking relies on the input protein structure to generate reasonable results, and results can be influenced significantly by the way the initial protein structure is configured. Crystallographers place significant effort into getting a good structural model that fits the data they have collected, but end users need to understand the caveats associated with crystal structure determination. In particular:

1. Bear in mind that a crystal structure is an atomic model that fits experimental data; the quality of the model is dependent on both the experimental data quality (usually expressed via its resolution) and the modeling effort made. For example, it is quite easy for a crystallographer inadvertently to assign element types incorrectly; the effect on the fit to the model is quite small. For example, glutamine residues contain a carbonyl oxygen and a primary amine: The electron count of these two groups differs by just one electron and so they can be easily exchanged in a protein structure. Indeed, it may be impossible to decide which is which without additional evidence such as the interaction patterns the group forms. Similarly, water molecules can be erroneous; it is always worth understanding whether a water molecule is forming sensible interactions to the protein. For example, there have been cases in published structures where metallic ions such as sodium have been misinterpreted in binding sites as water molecules.
2. Unlike small molecule crystal structures, hydrogens are not generally resolved in protein crystal structures and are so placed at geometrically likely locations. This can lead to issues with tautomeric forms of side chains in protein residues that need careful resolution.
3. Side chains may be more labile than would be apparent from the input structure: the structural model will contain information such as occupancy factors and thermal parameters to inform the end user where this is the case, however such information can sometimes be lost to the end user: referring back to the original information is always worthwhile. In addition, note that there may be side chains in disordered states.
4. If possible, try to refer to the original crystallographic model files: they contain a lot of information, such as atomic occupancies, thermal parameters, or remarks regarding the approach taken to modeling structural data, that may not be apparent in your favorite modeling environment.
5. Remember that a crystal structure is not a model of an isolated protein, or even a whole protein. On occasion, neighboring crystallographically related molecules can interfere with the binding site and so can influence ligand binding, so it is worth ensuring that the structural model you are using is free from such issues. By that same token, it can often be difficult to crystallize a whole protein, so subunits are often crystallized individually. While these subunits are excellent guides for docking, do bear in mind that the structure can be impacted.

3.12.8.5 Incorporate What You Know

End users are often experts in a given target, or have access to experts on a given target, particularly in lead optimization. End users operating in pharmaceutical companies may have access to experimental information about a target from other sources beyond crystal structures. An example might be mutagenesis studies that inform the end user of the critical residues for substrate binding. Such information could be invaluable as it can inform the end user of key interacting residues within the binding site.

Most docking programs allow end users to incorporate prior information. Examples of such information might be to force a docking to form a particular interaction with the protein (e.g., a specific hydrogen bond) or forcing occupation of a particular part of the binding pocket. Some docking programs or protocols[38,124,125] can take advantage of known bound poses of ligands to bias docking toward related binding poses; in the case of lead optimization, such a docking approach can be useful in assessing the feasibility of functional change to a ligand as it forces docking to maintain the known binding mode of all ligands trialed, making the scores that result from docking more discriminating. On the downside this approach can bias against the identification of similar ligands that exhibit different binding modes.

3.12.8.6 Consider the Features That Are More Important to Your System, for Your Software

As we have explored above, docking software can vary substantially in its approach and strengths. Consider the biological system you are exploring, and prioritize docking features that are important to you. Below is a list of common features that could play important roles depending on your system.

Preparation
- Automatic assessment of ligand or receptor structure quality and indication of potential errors
- Automatic and intelligent protonation of protein and ligand
- 1D or 2D ligand conversion to 3D ligand

Docking
- Ability to treat ligand as flexible (via conformational database or creating conformers on the fly are popular routes). And do these mechanisms cover full conformational space?
- Receptor flexibility—popular mechanisms are via side-chain rotamer libraries, ensemble docking, and soft docking potentials
- Solvent handling—accounting for solvent displacement or water-mediated hydrogen bonding
- Ability to handle metal coordination
- Ensemble docking—often how protein flexibility is handled, also very useful for consensus crystal structures.
- Covalent docking
- Shape matching
- Pose refinement

- Ability to use crystallographic data as a docking guide
- Geometric or pharmacophore constraints
- Multiple scoring functions.

3.12.8.7 Do Not Over-Interpret Scores

All docking programs will generate a score for a given pose. An end user should regard their absolute values with caution, and avoid the tendency to rank values very close to each other in a strict hierarchy. This is particularly true when comparing scores between two different molecules which may have different molecular weights; each atom that is added to a structure increases the maximum theoretical score that a molecule could achieve. Indeed this effect is, to a certain extent, related to the ligand efficiency metric[126] which is used frequently in medicinal chemistry programs.

Given the observation that a relatively small change of interaction energy (1.4 kcal mol^{-1}) can lead to a 10-fold change in activity, one might expect relatively small score changes to be useful for predicting significant activity changes.

In practice though, for scoring functions, the above observation is a curse. Firstly, scores are built of compromises which make the score generated an approximation to either enthalpy or free energy. Secondly, the scores rarely account for uncertainty in the positions of atoms in the protein that remain fixed. Thirdly, it is possible that the docking program will find a local minimum close to the global minimum: while such a pose provides the end user with a lot of useful information and indeed may be a perfectly valid representation of the binding mode that a given ligand will adopt, it is eminently possible that its score will differ by a few score units from the true global minimum, which taken at face value would indicate a large change in binding affinity, but in practice is within the bounds of precision of the underlying algorithm.

An interesting question then is, "what should I use my result for in lead optimization?" Docking's main strength is in exploration of binding poses, and thus allows the end user to explore ligand structure-function, asking important questions beyond docking scores, which are all relative. For example:

- "What binding hypotheses are there for new ligand X?"
- "If I make chemical change 'X,' will I cause a significant change in the likely binding mode?"
- "If I make chemical change 'X,' will the new ligand occupy additional regions of my binding site?"
- "Can I improve the geometry of a specific interaction I observe by making a chemical change?"
- "Can I extend my ligand to form additional strong interactions to the binding site?"
- "How does the binding of my ligand differ between protein A and protein B?"
- "What is the preferred length of side chain Y in my series of analogs, based on predictive binding?"
- "Are there areas of potential positive interaction could be utilized by adding functionality to my ligand?"
- "Given the preferred binding motifs of my ligands, can I make structural changes to conformationally restrict them into preferred geometries?"

If one uses scores for direct affinity prediction, one needs to be fully aware of the level of approximation that is inherent in the score. These scores are, at best, relative to scores from the same run, under the same conditions, with the same system. The end user then should act accordingly and cautiously to avoid disappointment. However, as noted in examples above, the docking pose may be an acceptable starting point for rescoring using a higher level of theory. Similarly, if using a given method, understand its limitations (e.g., as earlier noted, ensemble docking minimizes the worst case outcome of docking rather than guaranteeing best possible performance).

3.12.8.8 Help! I am a Software Developer, How Do I Make My Users Love My Software?

Software developers want to see their programs used and loved. There are several things that the development community can do to achieve this goal. In considering software improvements one should discriminate between scientific improvements and the incorporation of existing technologies to improve usability. Obviously, new scientific breakthroughs, such as accurate affinity calculation or better treatment of protein flexibility, will increase the appeal of a developer's product. Fortunately, there are also plenty of available improvements that can leverage existing technology.

3.12.8.9 Make the Results Less Susceptible to the Input Provided

One constant frustration for end users is that results obtained with docking software can be adversely affected depending on the way in which inputs to the program are configured. For example, some sensitivity on the input provided has been shown in docking.[127] In another study, both GOLD and GLIDE were shown to have some dependence on input setup using different modeling environments.[128] Paradoxically, it appeared that GLIDE's performance was better with a setup protocol that used MOE, rather than the preparation tools provided with GLIDE. GOLD's scoring was shown to be improvable by using the score normalization factors in the docking to account for variations in molecular size. The authors of GLIDE have further studied the impact of preparation on their docking program and note the sorts of issues that can occur.[129]

In practical terms, users do not want to have to worry about such nuances, so ideally providers of software should try to improve the preparation and analysis tools to achieve optimal performance out of the box. For example, in most cases it would be simple to automate the preparation of the protonation states of ligand structures.

3.12.8.10 Make it Easy for Your End-Users to Become Experts

Software providers usually include tutorials, use case examples and documentation as part of a given docking package. Often this is accompanied by reference to published examples. Unfortunately this is hard for an end user to disentangle into principles of best practice.

Providers could improve the situation by providing more practical use case examples that reflect best practice and that highlight the pitfalls and issues that the end user needs to avoid in live use. In practice, the tutorials provided tend to "just work" and consequently become an exercise in handle turning, rather than truly educational.

Making the software easy to use is another way in which providers can improve an end user's lot. In development, fundamental "User eXperience (UX)" approaches should be adopted: the software should tackle the most common use cases easily and intuitively and avoid flooding the naive user with large numbers of options and settings (though these more advanced options should be easy to find, and intuitive when used.). Docking program developers are often scientists first, and software developers second. As scientists it is very easy to forget or down weigh the impact of these principles, as the fundamental science is the thing that a scientist finds most interesting, but in practice UX principles such as this can be the difference between great science being used or not.

3.12.8.11 Make Your Docking Software Self-Critical

A docking program generates one or more results for a given ligand. It is rare for the program to also generate a measure of confidence in its prediction. By way of example, a rule of thumb with the GOLD docking algorithm suggests that if the program repeatedly predicts the same pose, the pose is more likely to be similar to the truly observed pose. If GOLD predicts a wide range of poses with similar scores one has less confidence in the top ranked pose.

Such information could (and should) be more transparent to an end user. Ideally, a given docking would be accompanied by a confidence metric that would help the end user in result interpretation. Some effort is being made in this area. We note, for example, that the implementation of the HYDE score provided by BioSolveIT attempts to reduce the need for interpretation of scores by using visualization and color scales to present results in a more interpretable way.

3.12.9 Concluding Remarks

In being asked to review whether docking is a solved problem, we were presented with a challenge. The plethora of docking programs, approaches, and publications is, in a way, testament to the fact that the community clearly does not feel that docking is a solved problem, as this is an area of active research.

By reviewing the current state of the art, the deficiencies in current performance become very apparent. It may be a challenge too far to hope that any scoring method can achieve a level of predictive accuracy that would allow us to regard docking as solved, but we can at least see an active area of research and development and exciting changes which are leading to better systems year on year.

Acknowledgments

Colin Groom is thanked for careful reading of this manuscript.

3.13.1 Introduction

Proteins are flexible entities, which often undergo conformational changes when associating with other molecules such as small compounds or macromolecules. The flexibility of a protein is highly related to its intrinsic dynamics, i.e., the thermal fluctuation of a protein structure in cellular environment, which occurs on a broad range of time scales (*ps* to *s*) with varying amplitudes, including simple side chain motions, backbone motions, major domain rearrangements, partial refolding or unfolding, and even disorder-to-order transition (see **Fig. 1**).[1] Experiments such as NMR spectroscopy and biological small-angle scattering illustrate that a protein should be considered by a dynamic ensemble rather than a static entity, with a unique structure.[2–5] The nonstatic nature of protein plays an essential role in carrying out its functions.[6–8] Because of its dynamic characteristics, a protein is able to adapt its conformation to respond to the presence of other molecules and the environmental changes, which is crucial for many cellular processes such as signal transduction, immune response, and enzyme catalysis. For example, allosteric regulation is often a result of the protein conformational change caused by the effector's binding at a site (allosteric site), other than the enzyme's active site.[9] Modern theories of molecular recognition consider the protein binding as a process which couples the conformational-selection and induced-fit rather than a shape complementarity-based lock-and-key recognition process, which will be described in detail in the next section.[10]

3.13.2 Models for the Mechanisms of Protein Binding

The lock-and-key model is the earliest and also the simplest model to explain molecular recognition in enzyme actions. It was first proposed by Fischer in 1894.[11] The lock-and-key model assumes that the enzyme (lock) recognizes the substrate (key) through the shape complementarity between the enzyme's active site and the substrate. This model is insightful, but too simple to reflect the reality. In general, both the enzyme (i.e., a protein) and the substrate (e.g., a small compound or a protein) are dynamic entities as revealed by many experiments.[12] The comparison between the structures of a protein in complexes (i.e., holo structures) and unbound protein structures (i.e., apo structures) demonstrates that the protein often undergoes certain conformational changes when forming the complex structure with its binding partner.[13] The induced-fit model was first proposed by Koshland in 1958 to explain the protein conformational changes in the binding process.[14] This model suggests that an enzyme, when binding with its substrate, optimizes the interface through physical interactions to form the final complex structure. The induced-fit model is supported by the fact that many ligands are buried in the protein binding sites in the protein–ligand complex structures in the Protein Data Bank (PDB),[15] which suggests that these ligands may very probably be wrapped around by the binding-site residues after the initial binding event.[16] However, conformational changes such as backbone collective motions, domain rearrangements, and disorder-to-order transition for highly flexible proteins cannot be fully explained by this model.[9] In the late 1990s, the conformational-selection (population shift) model was proposed by several researchers.[17–19] The conformational-selection model suggests that the unbound protein receptor fluctuates among multiple conformational states, with their occupancy probabilities being determined by their relative free energies according to the Boltzmann distribution. Only a subset of these states allows the binding of its partner. The encounter with its binding partner shifts the distribution toward these states to form the final complex structure. The main difference between the induced-fit model and the conformational-selection model is whether the holo structure preexists before forming the complex. A schematic illustration of the three binding models is provided in **Fig. 2**.

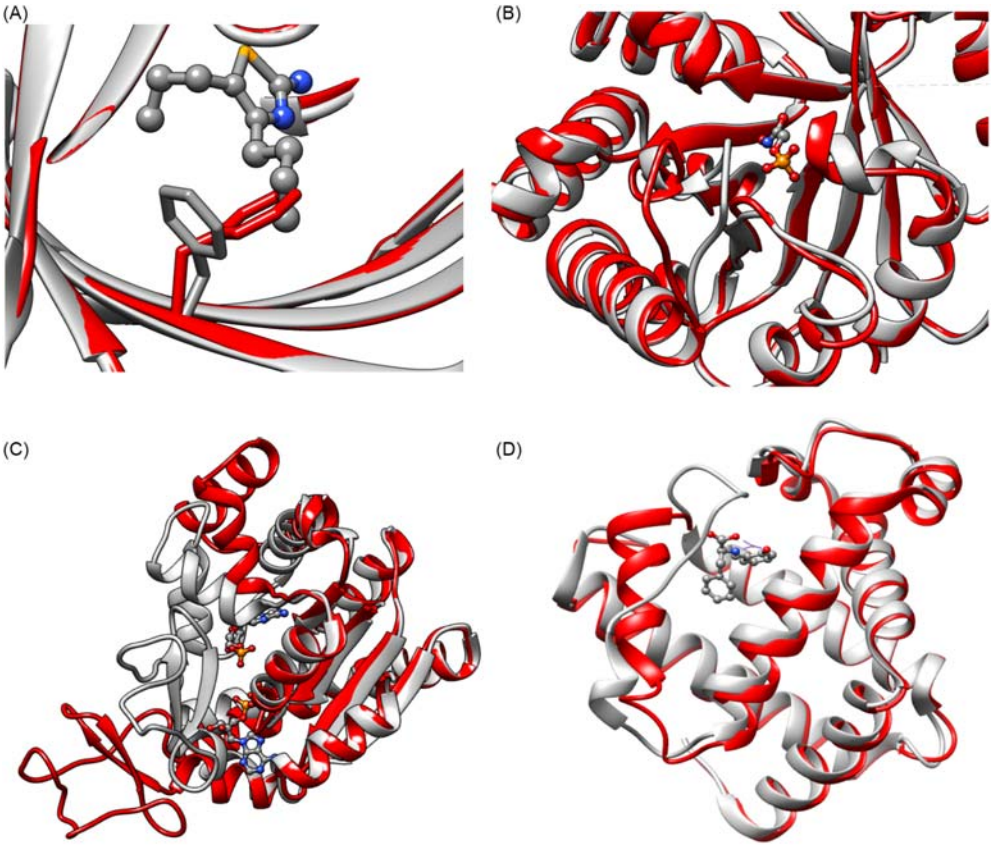

Fig. 1 Four examples of protein conformational changes in ligand binding, which represent four typical protein structural motions, respectively. (A) Protein side chain motions, (B) protein backbone motions, (C) protein domain motions, and (D) protein partial unfolding. For each case, the unbound protein structure is colored *red*, the bound protein structure in the complex is colored gray, and the ligand structure in the complex is colored by atom types. The unbound protein structure is superimposed on the bound protein structure.

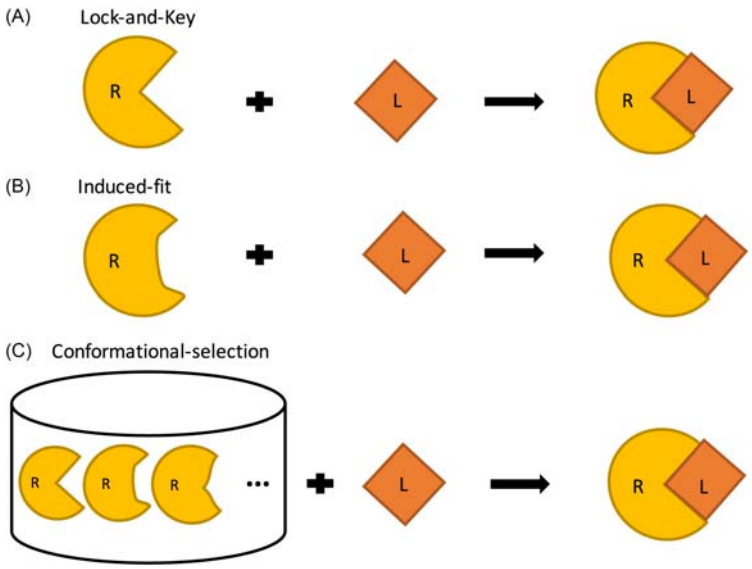

Fig. 2 Schematic diagrams for the three binding models. (A) The lock-and-key model, (B) induced-fit model, and (C) conformational-selection model.

Recent studies suggest that induced-fit and conformational-selection may co-exist in many cases.[20,21] Efforts were devoted to reconciling these two models into a unified model by coupling the induced-fit and the conformational-selection in a "serial" or "parallel" way.[1,22–25] In the serial coupling scenario, multiple protein conformations preexist in the unbound state, and the ligand recognizes a subset of these conformations to first reach a loose complex state, which is followed by the induced optimization to form the final complex structure. The parallel coupling provides a different scenario, for which the induced-fit pathway and the conformational-selection pathway co-exist and compete with each other. The fluxes of the two pathways determine the relative importance of the two mechanisms, which is often influenced by the concentration of the binding partner.

3.13.3 Computational Modeling of Protein–Ligand Interactions and Protein–Protein Interactions

Computational modeling of protein–ligand interactions and protein–protein interactions has great applications for mechanistic investigation of binding processes and also for the development of therapeutical interventions. Molecular dynamics (MD) simulation and molecular docking are two major computational methods to model bindings between molecules. MD simulation simulates the binding process using a physically based force field with explicit solvent models or implicit solvent models through integrating the equations of motion.[26–28] MD simulation simultaneously considers protein flexibility, ligand flexibility, solvent effect, and other environmental factors. The binding dynamics can also be obtained from MD trajectories. However, MD simulation is computationally demanding, which hinders large-scale applications, and simulating the whole binding process from scratch is only limited to several special cases.[29–31] In fact, MD simulation is often used for protein flexibility analysis before molecular docking, or it is used for refining the promising binding modes from molecular docking.

Molecular docking aims to predict the binding mode and binding affinity by employing efficient sampling algorithms and simplified scoring functions.[32–39] Molecular docking is much more efficient than MD simulation. However, the binding dynamics cannot be obtained from the results of molecular docking. A typical molecular docking method generally consists of two major stages, the sampling stage and the scoring stage. In the sampling stage, putative binding modes are generated using efficient searching algorithms. In the scoring stage, the sampled binding modes are scored with scoring functions; the binding modes associated with the lowest energy scores are predicted to be the binding modes, and the corresponding energy scores are used to evaluate the binding tightnesses.

There are two classes of molecular docking techniques depending on the molecular types: protein–ligand docking and protein–protein docking. Protein–ligand docking aims to model the interaction between a protein and a small compound, but protein–protein docking is developed for predicting interactions between two proteins. In protein–ligand docking, generally the ligand conformational space is exhaustively explored, but the protein structure is fixed or largely restricted. In protein–protein docking, both protein partners are fixed or largely restricted, and the shape complementarity between the interacting proteins plays the dominant role in the binding pose generation. Moreover, small compounds often bind to a pocket on the protein surface (often the largest pocket), and thus sampling during protein–ligand docking is often restricted to a specific binding pocket, whereas protein–protein docking often requires global sampling. After decades of development, molecular docking methods have achieved great successes and have played an important role in structure-based drug design (SBDD). For example, protein–ligand docking is widely used for initial-stage screening of huge chemical libraries for drug candidates, and protein–protein docking is often integrated with experiments for protein–protein interaction prediction and protein interface design.[40,41]

Despite numerous successes, incorrect predictions are often produced by molecular docking. One of the greatest challenges that limits the performance of molecular docking is the modeling of protein flexibility. Because the holo structure of a protein bound with a specific binding partner is generally unavailable, often the apo structure, the protein structure from a different complex or even the computational modeled protein structure, which often shows certain structural variations in comparison with the holo structure, is used in molecular docking. These structural variations, particularly the structural variations in the binding site, often exclude the generation of correct binding modes in the sampling stage of molecular docking. Properly modeling the protein flexibility is of great importance for improving the docking accuracy. In the next section, we review the methods to model protein flexibility in molecular docking.

3.13.4 Modeling Protein Flexibility in Molecular Docking

Although protein–ligand docking and protein–protein docking are quite different in the sampling stage, the methods to model protein flexibility in both protein–protein docking and protein–ligand docking can be classified into three groups: soft docking, induced-fit docking, and ensemble docking.[42–45] In soft docking, the protein flexibility is implicitly considered by allowing minor overlaps between atoms through the employment of soft molecular surface representation or soft interaction potentials. In induced-fit docking, the protein structural motions are sampled on the fly in the sampling stage of molecular docking. In ensemble docking, the protein structural motions are represented by a structural ensemble, which contains multiple protein conformations. The optimal protein conformation is automatically selected in the molecular docking (except for the united structure-based ensemble docking). To some extent, induced-fit docking can be considered as a class of methods inspired by the induced-fit model, and ensemble docking can be considered as a class of methods inspired by the conformational-selection model. Many docking programs integrated two or even all the three methods.

3.13.4.1 Soft Docking

Instead of explicitly modeling the protein conformational change in molecular docking, soft docking methods account for the protein flexibility through tolerating minor atomic clashes between the interacting molecules. Jiang and Fan developed the first soft docking algorithm for protein–ligand docking, in which both the protein surface and the ligand surface are represented by molecular surface cubes, and the binding poses are produced through matching the surface structures of the protein and of the ligand on the basis of their surface complementarity, allowing minor surface overlaps.[46] Because it is not convenient to explore the ligand conformational space with the surface representation, soft surface-based docking methods are more often used in the rigid-body protein–protein docking, in which certain amount of interface penetration is allowed.[47–49] In fact, in protein–ligand docking, the soft potential-based docking methods are more often used, in which both the protein and the ligand are represented with atomic models, and minor atomic overlaps are allowed by using scoring functions with attenuate repulsive terms in molecular docking. For example, the 12–6 Lennard-Jones potentials for calculating the van der Walls interactions were replaced with 9–6 potentials in many studies.[50–52] Soft docking is computationally as efficient as rigid docking, however, it can account for only minor protein side chain motions in the binding process.

3.13.4.2 Induced-fit Docking

Induced-fit docking represents a class of docking methods in which the protein conformational space is explored on the fly in the sampling stage of molecular docking. It is impractical to consider full protein flexibility because of the extremely high dimensions, thus many docking programs based on induced-fit docking only focus on the side chain motions. The side chain conformation can be sampled by exploring its discrete rotameric states or by continuously exploring its torsional angle space. Gray et al. developed RosettaDock, a protein–protein docking software.[53] RosettaDock starts the docking with a low-resolution search followed by a high-resolution refinement stage, in which the protein side chains and the rigid body displacement are simultaneously optimized using a Monte Carlo minimization (MCM) protocol. In the early work, the side chains were optimized in the discrete rotamer space. Later, the side chain modeling protocol was improved by introducing a gradient-based minimization step during the rotamer packing to allow the sampling of off rotamer conformations.[54] Currently, RosettaDock also allows to consider the protein backbone flexibility by including the backbone perturbation and refinement in the MCM procedure; it also allows us to employ structural ensembles to model the protein flexibility, which will be described in detail in the *Ensemble Docking* section.[55,56] The RosettaDock approach was extended to protein–ligand docking, which was referred to as RosettaLigand.[57,58]

AutoDock Vina, another program for protein–ligand docking, allows the user to specify several residues, and the side chain conformations of these residues are explored and optimized in the torsional angle space during molecular docking together with the ligand binding configuration.[59] Although the protein backbone and most of the side chains are fixed in docking, AutoDock Vina is much more computational efficient than RosettaLigand, which makes Vina suitable for large scale virtual screening.

In comparison with soft docking, which is extremely limited in considering protein flexibility, induced-fit docking is able to model protein side chain flexibility and even backbone flexibility at additional computational cost. However, as the induced-fit model cannot explain protein motions such as large backbone collective motions in the binding process, generally, the induced-fit docking methods are unable to deal with the cases in which proteins undergo significant backbone conformational changes.

3.13.4.3 Ensemble Docking

Ensemble docking approaches model the protein flexibility using protein structural ensembles. Specifically, a protein structural ensemble consisting of multiple protein structures (MPSs) is used in molecular docking, in comparison with soft docking and induced-fit docking for which only a single protein structure is used. The inclusion of diverse protein conformations in the ensemble provides the possibility to model large conformational changes. A typical ensemble docking method includes two major stages: preparing the protein structural ensemble, and molecular docking against the ensemble.

3.13.4.3.1 Preparing the protein structural ensemble

The preparation of the protein structural ensemble is a very important stage of ensemble docking. Whether the holo structure-like protein conformations are included in the ensemble largely determines the docking performance. Either experimental protein structures or computational structures can be used to form the structural ensemble.

First, protein structures determined by NMR spectroscopy can be conveniently used for ensemble docking. NMR spectroscopy, unlike X-ray crystallography, is able to provide tens of structures (NMR ensemble) rather than a single static structure. The NMR ensemble reflects the protein dynamics in solution. Thus, if the conformational-selection mechanism dominates the molecular recognition process, the holo structure-like conformations are likely included in the NMR ensemble. Huang and Zou tested their ensemble docking algorithm on the NMR ensemble of the HIV-1 protease.[60] The ensemble docking result was compared with that of single protein docking, and yielded significant improvement in both the binding mode prediction and the enrichment of virtual screening. Second, the crystal structures of the same protein from different sources, such as apo protein structures solved in different conditions or holo structures bound with different ligands can also be collected and aligned to form the structural ensemble.

In the cases that there are a few high-quality experimental structures to form the structural ensemble, computational modeling, and simulation techniques can be used to produce models to complement the experimental structures. First, in the absence of experimental protein structures and homologous protein structures, *ab initio* protein structure prediction techniques can be used to generate structures for the protein. However, for many proteins, *ab initio* protein structure prediction techniques are unable to produce sufficiently accurate models for molecular docking. If the experimental structures of a protein are scarce but the experimental structures of homologous proteins are available, the homology modeling techniques can be used to build models to form the structural ensemble. Moreover, the protein structural ensemble can also be constructed through exploring the conformational space from a single protein structure. Computational methods like MD simulation and normal mode analysis (NMA) are two popular methods to explore the protein conformational space.

MD simulation explores the protein conformational space by integrating the equations of motion, thus a continuum of protein conformations can be extracted from the trajectories of MD simulation. Carlson and colleagues developed dynamic pharmacophore models for HIV integrase from protein conformations produced by MD simulation.[61] This method, later referred to as the MPS method, was successfully applied to find novel inhibitors for targets including human MDM2-p53 and HIV-1 protease.[62,63] McCammon and co-workers developed the relaxed complex scheme (RCS), in which the structural ensemble generated by MD was used for molecular docking with AUTODOCK.[64–66] Based on the RCS method, the inhibitors of HIVp, avian influenza neuraminidase, and other disease-associated protein targets were successfully identified.[67–70] However, MD trajectories are easily trapped in local minima, thus simulating large motions of the protein is time consuming and can be very difficult. Methods such as replica exchange, simulated annealing, coarse-grained MD simulation, and metadynamics are developed to enhance the conformational sampling of MD simulation or accelerating MD simulation.

On the other hand, NMA approximates the potential energy function in the vicinity of a minimized protein structure through harmonic approximation or employs simple elastic network models (ENMs). The vibrational normal modes of the protein can be computed through diagonalizing the Hessian matrix to obtain its eigenvectors (movement directions) and eigenvalues (vibrational frequencies). Because functional motions in proteins often correspond to low-frequency normal modes, multiple protein conformations can be generated by perturbing the protein structure along the directions of several low-frequency normal modes. Benchmarked on 14 targets, each with 2 holo structures bound with different ligands, Rueda et al. showed that cross docking using an equilibrium ensemble of the binding-site conformers derived from all heavy-atom ENMs predicted 20% more near-native binding modes in the top-scored modes than using a single protein conformation.[71] Because collective motions in proteins can be explored at much lower computational cost than MD simulation, NMA is more suitable than MD simulation to prepare structural ensemble for flexible proteins, which may undergo collective backbone motions in binding processes. However, localized protein conformational displacements, such as loop motions, often correspond to high-frequency modes, which cannot be well modeled using NMA. Therefore, for modeling high-frequency protein structural motions, MD-based methods are generally better choices.

Besides MD simulation and NMA, MC-based methods and flexibility analysis-based methods can also be used to generate a structural ensemble for ensemble docking. For example, RosettaDock allows one to employ the computational ensembles created by RosettaRelax[72] as inputs in its ensemble docking protocol. RosettaRelax is a multiscale MC-based structural refinement algorithm, which integrates small backbone torsional angle perturbations, side chain packing, and energy-gradient-based minimization in the torsion space to sample the local protein conformational space. Zavodszky et al. integrated FIRST (Floppy Inclusion and Rigid Substructure Topography), a graph-theoretical approach to identify rigid and flexible regions based on protein bond network, and ROCK (Rigidity Optimized Conformational Kinetics), a restricted random-walk sampling approach to search the protein conformational space, to prepare the protein's main chain ensemble for docking with SLIDE, in which the protein's side chain flexibility and the ligand flexibility were handled by SLIDE based on induced-fit docking.[73]

An important question in preparing the protein structural ensemble is how many protein structures need to be included in the ensemble. Unfortunately, there is no general answer to this question. Many factors need to be considered, such as the source of the structures, the level of protein flexibility, and the docking method to incorporate the structural ensemble. The size of the experimental structural ensemble is limited by the number of the experimental structures available, whereas the computational methods are able to produce as many conformations as possible. Generally speaking, small structural ensembles may increase the risk of under representing holo structure-like protein conformations, but large structural ensembles require long computational time for docking and may reduce the docking performance due to the increase of false positives produced by imperfect scoring functions. Methods were developed to reduce the size of the structural ensemble. For example, in the improved version of RCS, McCammon and co-workers used hierarchical clustering based on pairwise root mean squared deviation (RMSD) between the MD snapshots to reduce the number of protein conformations generated by MD simulation.[65] Bolstad and Anderson developed a method to prune the structural ensemble by selecting protein conformations that preserve the geometry of the protein active core.[74]

3.13.4.3.2 Molecular docking against a structural ensemble

For protein–ligand docking, several protocols have been developed to dock a ligand against a structural ensemble. The straightforward way is to dock a ligand into MPSs in the ensemble independently (referred to as sequential docking), such as the method used in the RCS.[64,66] The advantage of this protocol is that a whole spectrum of binding scores is obtained in the docking. The ligand can be ranked based on the properties of multiple docking scores (e.g., the ensemble average) rather than a single score to reduce the risk of obtaining false positive results. However, docking the ligand into MPSs independently is time consuming, particularly when the ensemble size is large.

The computational cost can be significantly reduced by docking the ligand to a united protein structure averaged from the structural ensemble. For example, in the early work by Knegtel et al., a composite grid (energy-weighted grid or geometry-weighted grid) calculated from MPSs through DOCK3.5 was employed to consider the protein conformational variability.[75] Benchmarked using HIVp, ras p21, retinol binding protein, and uteroglobin, the results showed that the experimentally determined binding orientations and computed binding energies from standard grids can be successfully reproduced. However, in the cases with variable protein structures in the ensemble, the artificial average structure loses the geometric accuracy of the structures and may even have an unphysical conformation. In such cases, docking a ligand to an average structure may often produce incorrect results.

Claussen and colleagues developed a different united-protein-based docking method, referred to as FlexE.[76] In this method, similar parts of the structures in the ensemble are merged to one structure, whereas varying parts are explicitly treated as separate alternative conformations. In ligand docking, these alternative conformations are combinatorially joined, thus novel valid protein structures that are not included in the original ensemble can be created. FlexE was tested on 10 protein ensembles, and was compared with sequential docking that was performed using the single docking tool, FlexX. The result showed that FlexE performed comparably with sequential docking on binding mode prediction with only a little more than half (0.57-fold) of the computational cost. Shoichet and colleagues developed a method which is similar to FlexE but with higher computational efficiency.[77] In this method, the flexible parts of the protein are allowed to move independently, and the conformation of each part that best fits a given pose of the ligand is identified separately. Then, the identified conformations are combined and joined with the rigid parts to form a single, composite representation of the protein for ligand docking. In this way, the protein conformational space is significantly reduced, and the computational time grows linearly rather than exponentially with the degrees of freedom of the protein.

In the MPS method developed by Carlson and colleagues, MPS pharmacophore models are derived from computational ensembles produced by MD simulation or experimental ensembles (NMR ensembles or collections of crystal structures).[61,78] The MPS pharmacophore models are then employed to screen the compound library to find compounds with good chemical complementarity, and have achieved much better performance in identifying active inhibitors than the single-structure (static) pharmacophore model. It is notable that the MPS method is one of the few ensemble-based methods that has been successfully used to find novel active inhibitors.

In the ensemble docking method developed by Huang and Zou, the protein conformational state is considered as an additional dimension.[60,79] The protein conformational index is simultaneously optimized with the ligand position and orientation in molecular docking. The computational efficiency is prominently improved by not wasting time on searching/docking into obviously irrelevant protein conformations. The computational time of this ensemble docking method is comparable to that of the single protein docking method. The ensemble docking method was extensively tested on diverse protein targets by using either NMR ensembles or structural ensembles collected from different co-bound crystal structures, and performed comparably to the sequential docking in binding mode predictions, binding energy score predictions, and enrichment tests of virtual screening. This ensemble docking method was implemented in the molecular docking software, MDock, from the Zou lab.[80] A similar method was also developed by Abagyan and colleagues later, which was referred to as the four-dimensional (4D) docking approach.[81]

Ensemble-based methods were also developed to model protein flexibility in protein–protein docking. In the early work of Nilges and colleagues, MPSs were derived from representative MD snapshots for unbound receptor and ligand structures of 17 protein–protein complex structures.[82] Rigid docking was performed for all combinations of the multiple receptor and ligand structures (ensemble cross docking). The docking result suggests that the ensemble cross-docking approach can increase the likelihood of finding near-native binding modes.

Bastard and colleagues developed an ensemble docking method to model the loop flexibility during protein–protein docking.[83] In this method, multiple copies of loop conformations are systematically sampled in advance. Then, the weight of each copy for docking is adjusted according to the Boltzmann criterion, which gives the loop conformation a higher weight if it is associated with a lower binding energy. The receptor protein and the remaining residues in the ligand protein that interact with the loop experience the mean field of the loop ensemble. This mean-field approach was later implemented in the ATTRACT[84] and was tested on eight protein–protein complexes, in which either one binding partner presents large conformational changes within the loop region between its unbound and bound forms or the unbound structure has a missing loop at its interacting residues.[85] The result showed that this method significantly improved the predictions in comparison with rigid protein–protein docking.

RosettaDock was also extended to allow users to use computational ensembles from Rosetta or NMR ensembles as inputs to model the protein backbone flexibility in protein–protein docking.[56] In the ensemble docking of RosettaDock, an extra step was added to the low-resolution docking following the rigid-body move step, and preceding the Metropolis evaluation step. In this step, the ensemble is superposed along the interface residues. For each protein conformation, the centroid mode binding energy is calculated to generate a partition function, followed by conformational selection based on the Boltzmann-weighted probability. The Metropolis criterion is then applied to the combined rigid-body/conformational selection move, followed by the high-resolution refinement of RosettaDock. The whole docking procedure integrates the ensemble docking and the induced-fit docking in a serial way, which can be considered as a method inspired by the coupling of the conformational selection model and the induced-fit model.

3.13.5 Modeling Protein Flexibility in the Postdocking Stage

Following the computationally efficient docking calculations, more accurate and time-consuming methods are often employed to refine and rescore the promising binding modes from molecular docking. Comparing with modeling protein flexibility in the

molecular docking, modeling the protein flexibility in the postdocking refinement stage has the advantage of modeling the induced-fit conformational changes, because the crude binding pose has already been determined and computational efforts can focus on the internal dimensions of the protein near the interface.

MD simulation is the most commonly used method for structural refinement of the docked protein–ligand complexes. Protein flexibility, ligand flexibility, and the solvent effects are simultaneously considered in the MD simulation-based refinement. Moreover, the binding free energy is calculated with a physics-based method such as free energy perturbation, thermodynamics integration, MM/PBSA, and MM/GBSA from the trajectories of MD simulation. In addition, the kinetic stability of binding can also be studied from the MD trajectories, which is helpful for binding mode selection, because incorrect binding modes are likely to produce unstable trajectories. For example, Park and colleagues integrated molecular docking and MD simulation to study differential inhibition of two cyclin-dependent kinases (CDKs), CDK2 and CDK4, through simulating the dynamics of the docked complexes with three different selective inhibitors.[86] It was found that the mobility of a disordered loop of CDK4 was significantly reduced in the presence of the inhibitors, but not with the loop of CDK2. The CDK2 complexes have more water molecules diffused into the active site than the CDK4 complexes, which resulted in greater exposure of the interfaces of the CDK2 complexes to bulk solvent. Thus, weaker hydrogen bonding interaction with the active-site residues and greater exposure to the solvent are possibly responsible for the less stable CDK2 complexes than the CDK4 complexes. Okimoto and colleagues combined molecular docking and MD simulation in *in vitro* screening.[87] In this study, the binding modes obtained from molecular docking were refined by MD simulation and were then rescored with MM/PBSA. Benchmarked by four target proteins (trypsin, HIV-1 protease (HIV-PR), acetylcholine esterase (AChE), and CDK2), the enrichment performance of the top 100 compounds was improved by 1.6–4.0 fold in comparison with the enrichment performance of molecular docking.

MD simulation was also used to refine protein–protein complex structures from protein–protein docking. For example, in HADDOCK,[88] a protein–protein docking program, the rigid docking stage is followed by two refinement stages: first, a semiflexible refinement is performed in the torsional angle space of the protein–protein interface, with both the backbone and side chain atoms are allowed to move. Second, a restricted simulated annealing MD simulation with explicit solvent is performed to refine the whole complex.

Besides MD simulation, NMA can also be used for the postdocking refinement of complex structures from protein–protein docking. Wolfson developed FiberDock,[89] a flexible backbone refinement method for docking refinement. In this method, NMA is performed for the flexible protein (receptor) using anisotropic network model (ANM) prior to the docking refinement, and the docking solution is then refined by iteratively minimizing the backbone of the receptor along the most relevant normal modes to model the induced-fit backbone conformational changes. The pose-dependent NMA-based method for protein–protein complex structure refinement was developed by Ritchie and colleagues recently.[90] Comparing with FiberDock, the NMA is applied to the docking pose rather than one of the flexible binding partners, thus the flexibility of both binding partners can be modeled in this method. This is important, for both the binding partners may undergo conformational changes in the binding process. This method was applied to 63 "rigid body" targets in the Protein Docking Benchmark 2.0. It was seen that both the sampling performance and the rescoring performance were modestly but consistently improved.

3.13.6 Modeling Peptide Flexibility in Protein–Peptide Docking

Besides protein–ligand interactions and protein–protein interactions, protein–peptide interactions are another class of prevalent protein-involved interactions and play an important role in many cellular processes including signal transduction, immune response, and transcriptional regulation.[91] Moreover, peptides have also become attractive drug candidates.[92] Thus, computational modeling of protein–peptide interactions is of great importance for mechanistically investigating these cellular processes and developing peptide therapeutics. Molecular docking methods for modeling protein–peptide interactions, referred to as protein–peptide docking, have been developed in recent years. Protein–peptide docking is challenging particularly due to the high flexibility of the peptide. In fact, many peptides are disordered in the unbound state, and the binding of the peptide with its protein partner stabilizes the peptide to form the final bound structure. In some cases, the association of the peptide with its protein partner is a process that couples binding and folding, and the peptide undergoes a disorder-to-order transition in this process. Because peptides often do not have well-defined unbound structures, the traditional shape complementarity-based protein–protein docking methods cannot be directly used for predicting protein–peptide complex structures. Neither can protein–ligand docking methods be directly used for protein–peptide docking, because peptides usually contain many more rotatable bonds than small compounds and thus the peptide conformational space is too large to explore exhaustively in molecular docking.

Starting with the sequence of the peptide and the crystal structure of the protein, the majority of the existing protein–peptide docking methods focus on the flexibility of the peptide, and fix or largely restrict the protein structure. To reduce the computational requirement, the sampling stage of protein–peptide docking often uses a coarse-grained structural model or/and restrictive flexible sampling. For example, Raveh et al. developed Rosetta FlexPepDock *ab initio*, which performs simultaneous docking and folding of the peptide from an extended conformation onto the protein receptor with an approximate specification of the peptide binding site.[93,94] This method integrates the induced-fit docking protocol and the fragment-based *ab initio* protein structure prediction protocol. In the low-resolution stage, the peptide backbone conformations and the rigid orientations are sampled simultaneously over the protein surface of the given peptide binding site through the assembly of Rosetta's fragment library with a coarse-grained representation of the peptide and the protein. The low-resolution sampling stage is followed by all-atom refinement, which includes

fine backbone modeling and full side chain packing for both the protein and the peptide. Validation on 26 bound docking cases (i.e., with bound protein structures) and 14 unbound docking cases (i.e., with unbound protein structures) showed that near-native binding models can be sampled for 96.0% of the bound docking cases and for 69% of the unbound docking cases. However, Rosetta FlexPepDock is computationally demanding. Generally, it takes 24 h on a cluster of 120 processes for a typical protein–peptide docking. Trellet et al. extended the protein–protein docking protocol, HADDOCK, for protein–peptide docking.[95] This protein–peptide docking approach is a unification of the conformational selection and induced-fit mechanisms. Specifically, three typical peptide conformations (extended, alpha-helix, and polyproline-II) are rigidly docked into the binding site of the receptor for conformational selection, then the favorable conformations selected in the rigid docking stage are flexibly refined to improve the protein–peptide interface through the flexible refinement protocol of HADDOCK (i.e., the semiflexible refinement of the protein–peptide interface in the torsional angle space followed by the MD simulation-based refinement) as inspired by the induced-fit mechanism. This method was tested on the peptiDB[96] database, and was able to generate near-native binding modes for 79.4% of the bound docking cases, and for 69.4% of the unbound docking cases. Based on the similar idea, Schindler et al. developed a fully blind protein–peptide docking method, referred to as pepATTRACT.[97] In pepATTRACT, three peptide conformations are docked onto the whole surface of a protein rather than a specified peptide binding site. Encouragingly, without knowing the peptide binding site, pepATTRACT shows comparable performance on sampling near-native peptide binding modes with the aforementioned HADDOCK-based method. Kurcinski et al. developed CABS-dock, another blind protein–peptide docking method.[98,99] CABS-dock employs the coarse-grained CABS model, in which each amino acid is represented by up to four interaction centers and statistical potential-based force fields are used. The simulation dynamics is controlled by the Metropolis MC. Starting from random peptide conformations and positions, CABS-dock explores the peptide binding configurations over the global protein surface, allowing for full flexibility of the peptide and small backbone fluctuations of the protein receptor through Replica Exchange Monte Carlo dynamics. CABS-dock was also validated on the peptiDB database, and encouragingly, CABS-dock successfully generated near-native binding modes for over 80% of both the bound docking cases and unbound docking cases.

Recently, MDockPeP, a fully blind docking method at the atomic level for predicting protein–peptide complex structures, was developed in our laboratory.[100] In this work, first, the fragments of monomeric proteins are used as templates to model peptide conformations, and then these modeled peptide conformations are employed for sampling the peptide binding modes via our integrated global/flexible sampling approach, in which the peptide conformation is restricted to be close to the modeled peptide conformation (with backbone $RMSD < 5.5$ Å). It is noted that MDockPeP uses the all-atom peptide model in the process of flexible sampling and that the integration of peptide modeling and restrictive flexible sampling significantly reduces the configuration space for docking, allowing effective sampling of the peptide binding modes over the global protein surface at the all-atom level. MDockPeP was also assessed on the peptiDB database. In the peptide modeling stage, at least one of our top three modeled peptide conformations showed a similar structure to the bound peptide (with backbone $RMSD < 4.0$ Å) for 95% of the cases. In the sampling stage, near-native peptide binding modes were generated for more than 90% of both the bound docking cases and unbound docking cases.

3.13.7 Conclusion

Protein flexibility plays an important role in the binding of a protein with other molecules underlying the protein function. However, computational modeling of protein flexibility is challenging because of the extremely high dimensions of the degrees of freedom. In this article, we have reviewed the existing methods for modeling protein flexibility in two classes of molecular docking techniques, protein–ligand docking and protein–protein docking. For both classes, the methods for protein flexibility modeling can be classified into three types, soft docking, induced-fit docking, and ensemble docking. Soft docking is basically rigid docking but implicitly considers very minor side chain motions. Induced-fit docking simultaneously optimizes the protein conformation and the ligand binding configuration in the sampling stage of molecular docking, however, due to the extremely high dimensions of the degrees of freedom in a protein, induced-fit docking methods can model only moderate protein conformational changes. Ensemble docking employs the protein structural ensemble in molecular docking, which has the advantage to model large protein conformational changes. However, the preparation of the structural ensemble and the employment of the ensemble in docking calculations are not trivial, as previously discussed in detail in this article. Moreover, the induced-fit conformational changes can also be modeled in the postdocking stage through MD simulation and NMA.

Being different from protein–ligand docking and protein–protein docking, protein–peptide docking is an emerging docking technique. Modeling peptide flexibility is a big challenge in protein–peptide docking, because the peptide often does not have a stable 3D structure before binding and because the peptide often has much larger conformational space than a small compound. To some extent, modeling the peptide flexibility can be considered as a preliminary effort to model the disorder-to-order transition in the binding process. In this article, we have also reviewed the recent progress in modeling peptide flexibility in protein–peptide docking.

3.14.1 Introduction

Molecules possess an abundance of properties. 3D structure, atom connectivity, shape, and physicochemical descriptors such as molecular weight or log*P* (logarithm of the *n*-octanol/water partition coefficient) are just a few of such properties that are usually of interest in the overlapping domains of cheminformatics, molecular modeling, and drug design. Many of these properties have a quite intricate nature: for example, 3D structure, which can rarely be characterized with a single conformation (but instead an ensemble of conformations), or even simple properties, such as molecular weight that depends on the isotope distribution of the composing atoms. The affinity of the molecule toward various types of environment (such as a physiological solution, a mixture of solvents, or a particular protein-binding pocket)—which is of particular interest in the mentioned fields—expands the property space of even a single compound beyond comprehension.

As such, it is currently impossible to give a perfectly accurate and complete computational representation of a molecule that accounts for its every possible aspect; however in most cases this is not necessary. Nonetheless, one should always be aware of the implied simplifications in the computational representation of molecules, especially when making predictions based on them. In other words, the main responsibility of the computational chemist (or drug designer or cheminformatician) is to know, which aspects of a molecule are important to be considered for the given application. If it is so, then one can utilize the predictive power of computational chemistry techniques to provide invaluable guidance for medicinal chemistry endeavors.

In the recent decades, medicinal chemistry has been armed with a growing number of large, highly featured, and annotated databases. These databases contain the ever growing public (and proprietary) knowledge that is being aggregated by medicinal chemistry research, and they provide an invaluable foundation for retrospective analyses and prospective/predictive work. Databases containing chemical information can be queried in a number of ways, each of which requires specific types of molecular representations. Substructure searches require an efficient chemical query language (e.g., SMARTS), while similarity searches need means to quantify the similarity of two molecules and appropriate structural representations that allow for such operations (e.g., molecular fingerprints). It is also common to query databases for specific values or ranges of quantifiable molecular properties such as molecular weight or log*P*.

In this chapter, we provide a comprehensive overview of molecular representations, including file formats, fingerprints, and molecular descriptors—with an emphasis on those that are widely applied in works involving large databases. We also dedicate a section to molecular similarity (and the diverse methodologies that have been developed to elaborate this sub-field), as a ubiquitously applied concept in cheminformatics and drug design. Last but not least, we provide a short overview of the most prominent online resources of molecular information that ultimately fuel most of the computational chemical research that involves a consideration of large compound sets.

3.14.2 Chemical File Formats and Data Structures

The means to store chemical information started to develop in parallel with the first computers (in fact, earlier than computers became standard work tools). Since that time, generations of file formats have been developed (and have occasionally become obsolete). Since each file format was developed with a specific purpose, each encodes different aspects of the structure and

properties of a molecule. Some of them are optimized for compactness, while others allow the storage of various properties or other information besides the 3D structure of the molecule.

A complete overview of the available chemical file formats would be a futile effort—and probably pointless, as there is little relevance (from a cheminformatics point of view) of covering file formats that are developed for, e.g., specific molecular dynamics or quantum chemistry programs. Instead, we will dedicate this section to introduce the reader to today's most widely used, cross-platform, human-readable chemical file formats, with an emphasis on their use in database searching and other subfields of chem-informatics. Throughout these subsections, we will occasionally refer to the structural representation of L-phenylalanine (see **Fig. 1**) in the various file formats as a common example.

Before proceeding with the description of specific file formats, we make note of a convenient means for the interconversion of various chemical file formats. While many modeling software suites are capable of handling multiple file formats (and consequently, to convert them), computer programs dedicated specifically for this tasks also exist. Probably the best-known example is Open Babel, an open source software for the interconversion of chemical structures between an abundance of file formats (over 110 for the current version).[1] Also, we offer a quick overview of the contents of this section in **Table 1**.

3.14.2.1 Line Notation Formats

The principle of line notation formats is to store chemical structures unambiguously, but as compactly as possible (usually on a single line). In fact, the IUPAC Recommendations on Organic and Biochemical Nomenclature can be thought of as a line notation system as well.[2] (Though ironically it is not necessarily more human-readable than, e.g., the simplified molecular-input line-entry system (SMILES) format, especially for large molecules.) In that "format," the representation of L-phenylalanine would be *(2S)-2-amino-3-phenylpropanoic acid* (or somewhat less intuitively, *(2S)-2-azaniumyl-3-phenylpropanoate* for the zwitterionic form). While IUPAC names can unambiguously describe arbitrarily complicated molecules, the names themselves are often very complicated as well. Also, a substructure can usually be specified in multiple ways (depending on other groups, the order of priority, etc.), which essentially removes text-based IUPAC name queries from the toolbox of substructure searching.

From the available tools for chemical identification and documentation, today's standard is the CAS (Chemical Abstracts Service) Registry number.[3,4] CAS maintains a constantly updated database (the CAS Registry) to store every reported chemical structure (c.111 million at the time these lines are written) with a uniquely assigned identifier, the CAS Registry number (e.g., for L-phenylalanine: *63-91-2*). In addition to the database itself, the CAS Registry powers the two major chemical information services of CAS: Scifinder (for querying chemical structures and reactions, primarily in the literature)[5] and STN (a search engine that provides access to patent content).[6] While CAS Registry numbers are quite compact linear notations, they do not provide direct, human-readable information on molecular structure, or relation/proximity to another substance (e.g., the CAS number for racemic phenylalanine is *150-30-1*).

Efforts to provide compact means of chemical structure representation using line notations date back to the late 1940s when the Wiswesser Line Notation (WLN) was introduced.[7] Nowadays, multiple line notation formats are available. While we will only briefly cover those that are mostly of historic interest (e.g., WLN and ROSDAL), we introduce today's standard tools such as SMILES and International Chemical Identifier (InChI) in more detail.

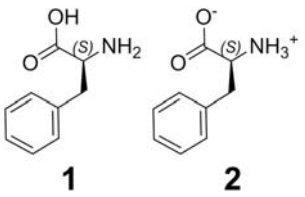

Fig. 1 Neural (1) and zwitterionic (2) forms of L-phenylalanine. The α-carbon is annotated with the absolute configuration of the stereogenic center.

Table 1 Chemical file formats presented in Section "**Chemical File Formats and Data Structures**"

Subsection	*Subsection*	*Comment*
Line notations	SMILES	The most widely used, human-readable line notation system and its extensions (e.g., SMARTS)
	InChI	A free, open-source and readily canonicalized line notation endorsed by IUPAC
	Other	Other, feature-rich or historically important line notation systems
Chemical tables	Ctab-based	The most widely used family of chemical table file formats, including *mol*, *sdf*, and *rxn* files
	Tripos *mol2*	A more flexible, free format file type, capable of storing various types of information
Other file types	PDB	A fixed format file type for macromolecules (introduced for the Protein Data Bank)
	FASTA	A compact format for storing DNA and protein sequence information
	CML	Chemical Markup Language, an XML-based free, open-source, portable, and versatile file format
	Structure recognition tools	Current solutions dedicated for the extraction of chemical structures from text and images

3.14.2.2 Simplified Molecular-Input Line-Entry System

SMILES was introduced by Weininger in 1987.[8] By that time, several line notation systems have already existed, and their flaws were also well known, which provided a need—but at the same time also a knowledge base—for the development of a mature, but easily understandable line notation language. SMILES provides a structure specification tool that is easily handled by both computers and humans, which is probably the main reason for its success in the past three decades. During this time, SMILES have become the de facto standard of molecular line notations, and a basis of inspiration for other line notation systems, such as SLN (see subsection "**Sybyl Line Notation**"). A concise overview of the format follows (a more complete documentation is available in the original SMILES paper[8] and on the website of Daylight[9]).

A SMILES string is a series of characters specifying primarily the heavy atoms (and optionally, hydrogens and bonds) of the molecule. Atoms are represented by their atomic symbols (first letter in upper case, second letter in lower case), and by default must be enclosed in square brackets: however, this is not required for elements in the "organic subset": *B*, *C*, *N*, *O*, *P*, *S*, *F*, *Cl*, *Br*, and *I* if the number of hydrogens conforms to the lowest normal valence minus those bonds that are explicitly given. Neighboring atoms are connected by bonds (single by default), and branches are enclosed in parentheses. Atoms in aromatic rings are denoted with lower case letters. Hydrogens must be explicitly specified by default, but they are implied in the absence of square brackets (which is most often the case). Single and aromatic bonds are implied, but they can be specified explicitly as well with "–" and ":", respectively (double and triple bonds are denoted by "=" and "#"). Attached hydrogens, charge, stereochemistry, and isotope numbers can be specified inside the square brackets of the given atom, e.g., *[15NH4+]* denotes an ammonium ion with a ^{15}N atom. As an example, SMILES strings of L-phenylalanine are provided in **Fig. 2**.

In the context of cheminformatics, canonicalization is a process through which a unique (*canonical*) representation of a molecule is achieved, which is essential for storing and identifying molecules in databases. Probably the greatest drawback of SMILES is the lack of an internal canonicalization approach: as seen on the above example, atoms can be mapped to the SMILES string in an arbitrary order. (In other words, while the conversion of SMILES to chemical structure is unambiguous, the inverse process is not, i.e., the relationship between SMILES and chemical structure is not *mutually unambiguous*.) While Weininger and colleagues have published a canonicalization algorithm shortly after the release of the SMILES format itself, their approach could not handle stereochemistry.[10] Moreover, this method was originally only included in the commercial software of Daylight,[11] resulting in many different variations of canonicalization being implemented in several cheminformatics toolkits. Recently, a universal SMILES representation based on the InChI canonicalization procedure was introduced by O'Boyle.[12] Schneider et al. have developed and published a robust, open-source, freely available SMILES canonicalization algorithm.[13] They conclude that their canonical labeling algorithm (which is also available in the open-source cheminformatics package RDKit[14]) "could be combined with the universal SMILES representation proposed by O'Boyle."

SMILES is also able to specify reactions. Notably, two available "grammars" for specifying reactions in SMILES are *reactant* ≫ *product* and *reactant* > *agent* > *product*. Disconnected molecules (e.g., two reactants) are separated by a dot (this is also available for single compounds that have, e.g., counterions). The functionality of SMILES has also been extended to support substructure querying and matching (SMARTS) and the description of generic reactions (SMIRKS). We will briefly cover these extensions in the following subsections.

3.14.2.3 Smiles Arbitrary Target Specification

Smiles Arbitrary Target Specification (SMARTS) is an extension of the SMILES language that was developed with the explicit intention to provide a query language for substructure searching.[15] As a result, any SMILES string is an acceptable SMARTS query by definition. To facilitate substructure searching, a number of additional features have been implemented for SMARTS, to allow for more general queries. These include atomic primitives (e.g., "**" denotes any atom, while *a* denotes any aromatic atom), bond primitives (e.g., "~" for any bond, "@" for any ring bond), and logical operators (e.g., "*!*" for *not*, "*&*" for *and*). Another interesting feature is recursive SMARTS, which enables to define an atomic environment starting with the atom of interest in the following form: *$(SMARTS)*. With these features, quite complex queries can be formulated, e.g., *C[$(aaO)&$(aaaN)]* would match any molecule that has a methyl carbon as a substituent of an aromatic ring with an oxygen in an *ortho* position and a nitrogen in a meta position. (For the reader's convenience, we refer to an easy-to-use, online SMARTS viewer.[16])

Like SMILES, SMARTS is able to handle, and in particular to query, reactions. A reaction query may consist of reactant, agent, and product parts (all optional), as introduced briefly above. The queries can be run against a set of "target" reactions (also specified in the SMILES format). Atom mapping is also supported in the query and the target, thus changes on a specific atom can be specified.

```
N[C@H](C(O)=O)Cc1ccccc1
[NH3+][C@@H](Cc1ccccc1)C([O-])=O
```

Fig. 2 SMILES strings of the neutral (*above*) and zwitterionic (*below*) form of L-phenylalanine. Breaking points of the phenyl ring are labeled as number 1. Attached hydrogens, charges, and stereochemical information are provided inside the square brackets. Note that the order of the substituents of the α-carbon is interchangeable but affects the specified stereochemistry of the α-carbon: looking from the nitrogen toward the α-carbon, the three following substituents (in sequential order) can appear counter-clockwise (@) or clockwise (@@).

For example, while C═O ≫ C−O would match any reaction that has a molecule with a C═O group on the reactant side and a molecule with a C−O moiety on the product side, [C:1]═O ≫ [C:1]−O is specific to the same carbon atom with a doubly bonded oxygen on the reactant side and a singly bonded oxygen on the product side. However, this would still match, e.g., a carboxyl group that is unchanged during the reaction as the oxygen was not specified to be the same atom on the reactant and product sides. Transformation of the double bond to a single bond is thus specified with the [C:1]═[O:2] ≫ [C:1]−[O:2] query. (However, to produce any matches, the atoms must be mapped in the target reactions as well!) A complete documentation of SMARTS is available on the website of Daylight Inc.[15]

3.14.2.3.1 SMIRKS

SMIRKS is a hybrid of SMILES and SMARTS, developed to provide a means to specify generic reactions.[17] It is a restricted version of reaction SMARTS with a set of rules that act as constraints. For example, the transformation of the oxo group in the SMARTS example above (see previous subsection) can be specified with the following SMIRKS transform:

$$[^*:1][C:2](=[O:3])[^*:4] >> [^*:1][C:2]([O:3][^*])[^*:4]$$

In some sense, SMIRKS can be considered the opposite of reaction SMARTS. While the latter can be used for querying already defined reactions, the former can be applied to enumerate reactions based on a generic reaction. A recent example is a paper of Guasch et al., describing the enumeration of ring-chain tautomers.[18] A complete description of SMIRKS is available on the website of Daylight Inc.[17]

3.14.2.4 Molecular Query Language

The Molecular Query Language (MQL) was developed in 2007 with the intention to provide a way to define more complex, feature-rich substructure queries.[19] MQL is based on the SMILES language and a context-free grammar, implementing concepts from Unix-style regular expressions such as brackets for grouping, "(…)?" for optional singular occurrence, "(…)*" for optional occurrence zero or more times, etc. MQL is open-source and was developed to be compatible with external cheminformatics toolkits, such as the Chemistry Development Kit (CDK).[20,21]

3.14.2.4.1 International Chemical Identifier

While it is slightly less human-readable than SMILES (especially for complicated structures), InChI is a fully featured, flexible, and standardized line notation.[22,23] It was developed with the support of IUPAC (International Union of Pure and Applied Chemistry)[24] with principal contributions from NIST (U.S. National Institute of Standards and Technology)[25] and is maintained by InChI Trust, a nonprofit organization established for this purpose.[26] This signifies some of the main advantages of InChI, i.e., that it is free, open-source and is maintained by a single organization (meaning that there are no concurrent, parallel implementations).

Compared to SMILES, InChI employs a greatly different logic (see **Fig. 3** for the InChI of L-phenylalanine as an example). An InChI code is made up of several layers separated with forward slashes ("/"), each of which presents specific information on the molecular structure. While some layers are mandatory, other layers (providing more subtle structural features) are optional. Hence, InChI is capable of providing molecular information at different levels of detail. We summarize the most important InChI layers and their syntax in **Table 2**.

A great advantage of InChI codes is that they are readily canonicalized at the time of generation, thus the relationship between substance and InChI code is mutually unambiguous. (Canonical atom numbers are assigned to elements in the order they appear in the empirical formula, i.e., first to carbons, then nitrogens, etc.) Further standardization was achieved with the introduction of the Standard InChI, which was designed to enable interoperability between large databases and web resources and "distinguishes between chemical substances at the level of 'connectivity', 'stereochemistry', and 'isotopic composition'."[23]

3.14.2.4.1.1 InChIKey

A drawback of InChI strings is that they can be really long for big molecules, which makes them unfit for web search queries. To remedy this deficiency, InChIKey, a compact hashed code derived from InChI was developed.[23] InChIKey compresses the information content of an InChI string to a fixed length of 27 characters in the following format:

AAAAAAAAAAAAAA-BBBBBBBBFV-P

```
InChI=1S/C9H11NO2/c10-8(9(11)12)6-7-4-2-1-3-5-7/h1-5,8H,6,10H2,
(H,11,12)/t8-/m0/s1
```

Fig. 3 InChI string of L-phenylalanine composed of the following layers: prefix ("InChI = 1S/"), empirical formula, skeletal connections ("/c"), hydrogens ("/h"), and stereochemistry, composed of three sublayers: tetrahedral centers ("/t") and two indicator layers ("/m" and "/s"). The InChI string for the zwitterionic form is identical to the neutral form, as they are derived from the same core parent structure and have the same number of protons.

Table 2 InChI layers and sublayers (with L-phenylalanine as an example, where applicable).[23]

Layer	*Syntax example*	*Comment*
Prefix	InChI=1/InChI=1S/	Denotes the major version number (currently 1, or 1S for standard InChI)
Formula	C9H11NO2	Represented according to the Hill convention (carbons first, then hydrogens, then other elements in alphabetical order). Canonical numbers are assigned to heavy atoms in the order they appear in the formula
Skeletal connections	/c10-8(9(11)12)6-7-4-2-1-3-5-7	Connections between skeletal atoms specified with their canonical numbers. Branches are specified in parentheses
Hydrogens	/h1-5,8H,6,10H2,(H,11,12)	Comma-separated list of the positions of hydrogen atoms in three sublayers: (i) bridging hydrogens (if applicable), (ii) immobile hydrogens, and (iii) mobile hydrogens. For L-phenylalanine, no bridging hydrogens are present, heavy atoms 1 through 5 (phenyl ring) and 8 (α carbon) are bonded to one hydrogen atom, while 6 (methylene) and 10 (nitrogen) to two. One hydrogen is shared between atoms 11 and 12 (carboxyl oxygens)
Charge	/q+1	Charge sublayer: net charge of the core parent structure
	/p+1	Protonation sublayer: net number of protons removed from or added to the core parent structure
Stereochemistry	/b4-3+	Z/E configuration of double bonds
	/t8-	Configuration of stereogenic centers
	/m0	Indicator sublayer of "/t": specifies the stereo arrangement relative to the canonicalized core parent structure ("/m0" for identical, "/m1" for inverse. Only for "/s1")
	/s1	Indicator sublayer of "/t": specifies if absolute ("/s1") or relative ("/s2") stereochemistry is provided
Isotopic	/i12+1	Specifies nonnatural isotopes. In the example: atom 12 consists of the isotope with mass increased by unity with respect to the natural value. May have its own stereochemistry sublayer
FixedH	/f10H3	Lists the exact positions of tautomeric (mobile) hydrogens. May have its own formula, charge, and stereochemistry sublayers

The first 14 characters encode the core molecular constitution (formula, connectivity, hydrogens, and charge), while the first 8 characters of the second block encode advanced structural features (stereochemistry, isotopic substitution, exact position of mobile hydrogens, metal ligation data). F is a flag for Standard (*S*) or nonstandard (*N*) InChI, V denotes the version (currently *A*, meaning version 1), and P is a protonation flag (*N* for neutral and other letters for various protonation states). By definition, the first block is the same for substances sharing the same molecular skeleton. As an example, the InChIKey of L-phenylalanine is: *COLNVLDHVKWLRT-QMMMGPOBSA-N*.

A key consideration in the design of the InChIKey was the compatibility with search engines. Thus, InChIKeys only contain uppercase letters and are restricted to a fixed length. While InChIKey collisions (i.e., two structures having the same InChIKey) are theoretically possible, their likeliness has been shown to be practically nonexistent in theory and in practice as well.[27] A disadvantage of InChIKey is that the chemical structure cannot be restored algorithmically. However, publicly available InChI Resolvers provide a lookup service for this task.[28]

3.14.3 Other Line Notation Formats

3.14.3.1 Wiswesser Line Notation

Once a widespread tool in chemical database searching,[29] the WLN is now mostly of historic interest. It was the first computer-processable line notation system, introduced in 1949.[7] It uses alphanumerical characters and a set of special characters (to indicate rings and substitution positions).[30] It makes use of letters not only to encode individual atoms, but also—quite intuitively—to denote common structural features (e.g., the letters *X* and *Y* denote branched chains of X- and Y-shapes). This approach has enabled a high degree of compactness (e.g., the WLN code for phenylalanine would be "*VQYZ1R*"—only six characters!), and WLN was applied for indexing large chemical databases, such as the Chemical Structure Index (CSI) or the Index Chemicus Registry System (ICRS).[31] However, the notation was error-prone and difficult to code, and with the advent of connection table formats, it has gradually lost its importance.

3.14.3.2 Representation of Organic Structures Description Arranged Linearly

The Representation of Organic Structures Description Arranged Linearly (ROSDAL) notation was developed in 1985 in the Beilstein Institute and has powered the Beilstein DIALOG system (or Beilstein-Online).[31] It is quite intuitive, but not easily readable: each atom (other than hydrogens) is assigned a unique number and the connections between the atoms are listed sequentially, e.g., for

phenylalanine: "1O-2=3O,2-4-5N,4-6-7=-12-7". As seen, heteroatoms (but not carbons) are specified with their chemical symbols, while bonds are denoted with the special characters - (single), = (double), # (triple), and ? (for any connection), and alternating bonds can be simplified, e.g., the substring denoting the phenyl ring is "7=-12". A great drawback of this notation is that atoms are arbitrarily numbered, and there is no unique representation of a molecule. Despite being mostly obsolete, some chemical drawing packages (such as ChemDoodle) still support the ROSDAL notation.[32] A common deficiency of WLN and ROSDAL is the lack of support for important structural features such as ions and stereochemistry.

3.14.3.3 Sybyl Line Notation

The SLN was developed at Tripos (now a subsidiary of Certara), and it was published in 1997.[33] In many senses, SLN is very similar to the SMILES notation although they employ different concepts regarding the representation of certain features. For example, in SLN, aromaticity is a property of the bonds, not the atoms (in contrast to SMILES): aromatic bonds are always explicitly represented with a colon. Each atom with a ring closure is assigned an ID number in square brackets (e.g., "*[1]*"), and subsequent connections to a previously defined ring closure atom are specified with a commercial at symbol, e.g., "@1". In addition, square brackets are also used to specify properties of atoms and bonds in a [*property=value*] format, e.g., a double dative bond is encoded by the following substring: "=[type=dative]". As an example, SLN strings for L-phenylalanine are provided in **Fig. 4**.

In 2008, the functionality of the SLN language was substantially expanded: support for reactions, queries, and virtual combinatorial libraries was implemented.[34] While SLN is a fully featured and versatile line notation language, its use is less common nowadays, possibly due to the decreased popularity of the Sybyl modeling suite.

3.14.3.4 Chemical Table Files

Chemical table files are the standard formats for the 3D representation of small molecules, but they are widely used to store 2D structures as well. Though not as compact as line notations, they are capable of storing specific 3D conformations, partial charges, database fields (such as molecular properties), etc. We briefly review the two most prominent tabular formats in this subsection: the Ctab-based format family (MDL molfiles) and the Tripos *mol2* format.

3.14.3.4.1 Connection table (Ctab)-based file types

Several file formats have been developed at Molecular Design Limited (MDL) that are built around the common concept of connection table (Ctab) blocks.[35] These include most notably *mol* files for storing a single molecule, *sdf* files (or SDfiles) for storing multiple molecules and associated data, as well as *rxn* and *rdf* files (or RDfiles) for storing single and multiple reactions, respectively. While the Ctab format is quite rich in features and optional fields, some of its functionalities are now rarely used or obsolete. Here we will only review its most important features, while we refer to the work of Dalby et al. for a more detailed description.[35]

The connection table (Ctab) consists of various blocks in a fixed order: the counts line, the atom block, the bond block, two optional blocks (atom list and Stext), and the properties block. The counts line specifies the total number of atoms and bonds in the molecule (among others), the atom and bond blocks list the coordinates (and other properties) of the atoms and the specification of the bond, while the properties block contains additional information on charge, radicals, isotopes, etc., and is always terminated by "*M END*". (See **Fig. 5** for the Ctab of L-phenylalanine.)

The Ctab itself is preceded by three lines—which can contain the molecule title and information about the program used for the production of the file—and is followed by data fields in *sdf* files, specified in a two-line format, where the first line is the *data header*—starting with ">" and specifying either the field name or the field number in the associated database—and the second line contains the data value. In multiple molecule formats (such as *sdf*), entries are separated with a line containing four dollar signs ($$$$).

While Ctab formats are "the closest thing cheminformatics has to a universally adopted standard," some argue that they are out-of-date.[37] It is worth noting that the format has been updated several times to resolve known issues. In 1995, the next-generation V3000 format was introduced by MDL (Molecular Design Limited) to overcome known limitations of the V2000 format, such as the hard limit on the number of atoms and bonds (999 in V2000) or the handling of partially defined stereochemistry. However, the position of V2000 as the de facto default format has been more or less unchanged ever since. In 2011, Clark proposed further changes to enable the handling of zero-order bonds and explicitly specified count of attached hydrogens in a backward compatible manner, thus extending the scope of Ctab files to store nonorganic substances, such as metal complexes.[38] Nonetheless, the superfluous atom specification and the lack of extensibility (among other known issues) constitute a valid base to criticism of the MDL Ctab format and call for an alternative, 21st century *lingua franca* for chemical information management.[39]

```
NC[S=S]H(C(O)=O)CC[5]H:CH:CH:CH:CH:CH@5
N[+]H3C[S=S]H(C(O[-])=O)CC[5]:C:C:C:C:C:@5
```

Fig. 4 SLN strings for the neutral (*above*) and zwitterionic (*below*) forms of L-phenylalanine. Hydrogens may or may not be specified explicitly. Formal charges are implemented as atomic properties, as well as absolute configurations, here specified with the "[S=S]" substring.

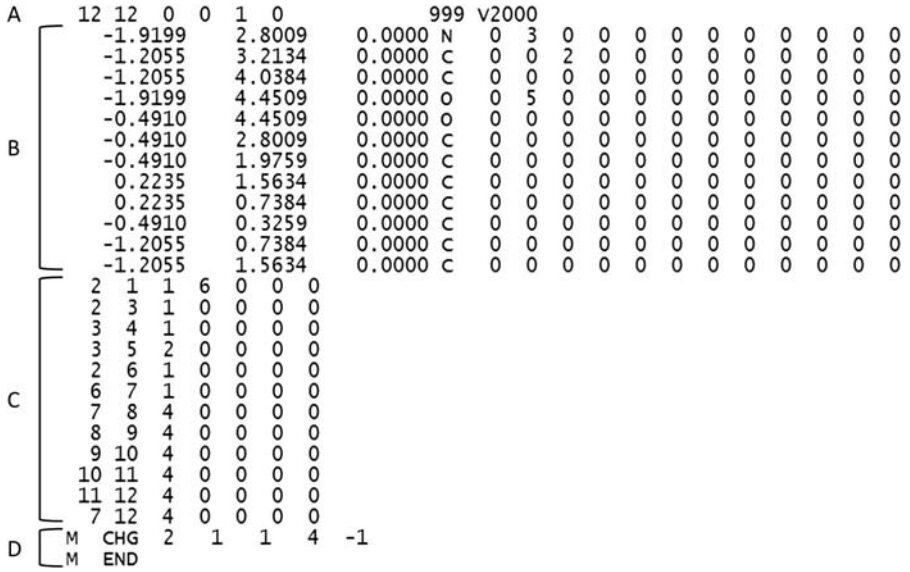

Fig. 5 Ctab block of the zwitterionic form of L-phenylalanine. (Written with Chemaxon Marvin.[36]) (A) The counts line contains the numbers of atoms and bonds (both 12), the chirality flag (1, as the molecule is chiral), the Ctab version (*V2000*), and some additional properties. (B) The atom block specifies the 3D coordinates, atom symbol, and various properties (such as mass difference, charge, hydrogen count) of each atom. In particular, the second column after the atom symbols contains formal charges (where 3 and 5 encode a charge of +1 and −1, respectively), and the third column specifies the atom stereo parity (see the work of Dalby et al. for a detailed specification).[35] (C) The bond block lists the bonds, specifying the numbers of the first and second atoms, the bond type (1 for single, 2 for double, etc.), the bond stereo specification, and a few additional properties. (D) The properties block can have a number of "*M XXX*" entries that specify additional properties and is always terminated by "*M END*". Here, the "*M CHG*" line specifies (from left to right) that there are two atoms with formal charges: atom number 1 with a formal charge of 1 and atom number 4 with a formal charge of −1.

3.14.3.4.2 Tripos mol2 format

Compared to Ctab files, the *mol2* format (developed at Tripos) offers a more flexible (and customizable) structure for chemical data storage.[40] One of the most important changes is that *mol2* files are "free format" files, meaning that the widths of the various data fields are not fixed. (Also, empty lines are ignored and comments can be specified on lines starting with #.) Additionally, a *mol2* file consists of so-called records (similar to the sub-blocks of the Ctab block) that may specify diverse types of information. Most of the records can be omitted, but the *MOLECULE*, *ATOM*, and *BOND* (and for some programs, the *SUBSTRUCTURE*) records are universally used. Other important features are the inclusion of partial charges by default and the concept of substructures, which effectively extends the usage of the *mol2* format to the domain of macromolecules (e.g., proteins). As a reference, the *mol2* entry of the zwitterionic L-phenylalanine is presented in Fig. 6.

Drawbacks of this file format include the lack of stereochemistry support in the absence of 3D coordinates, and the lack of a unified format specification: while *mol2* was originally developed for the Sybyl software suite of Tripos, now each program implements the *mol2* format with slight differences.

3.14.3.4.3 Other formats

The file formats covered so far are optimized for their usage in chemistry-related applications, mostly covering the domain of small molecules. The treatment of macromolecules (such as proteins and nucleotide chains) requires specific features, which led to the evolution of the specialized file formats of this domain. Of these, we will concisely cover the two that are probably most often encountered by computational medicinal chemists: pdb files and FASTA sequences. In addition, we briefly introduce the reader to novel chemical data management formats and tools, such as the Chemical Markup Language (CML) and structure recognition approaches.

3.14.3.4.4 Protein Data Bank file format (pdb)

The *pdb* format was introduced in 1992 as the official format specification of the Protein Data Bank (the standard global repository of experimentally solved macromolecular structures).[41] Since a great portion of medicinal chemistry-related modeling work deals with macromolecules, the use of *pdb* files is ubiquitous in this field.

Pdb files are fixed format, and they consist of single-line records (starting always with the record type). The diversity of record types allows for the specification of highly detailed information. Atom information is stored in *ATOM* and *HETATM* records (the latter is used for nonpolymer entries, such as waters or small molecules), while bond information is stored in *CONECT* records. Atom blocks (corresponding to polymer chains) are terminated with *TER* records. A more thorough overview of the different types

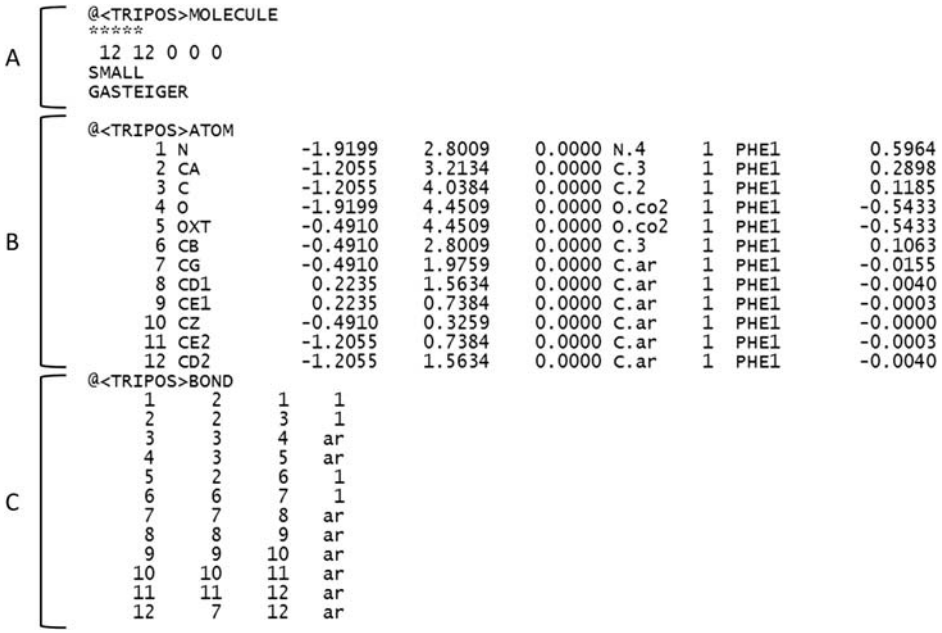

Fig. 6 Zwitterionic phenylalanine, *mol2* entry. (Written with Open Babel.[1]) (A) The *MOLECULE* record by default lists the molecule title (here, ***** denotes that it was not supplied), a line containing the numbers of atoms (12), bonds (12), substructures (0), features (0) and sets (0), the molecule type (*SMALL*), and the charge type (*GASTEIGER*). (B) The *ATOM* record lists the atoms in the following format: atom number, name, 3D coordinates, atom type, substructure ID, substructure name, and charge. (C) The *BOND* record lists the bonds in the following format: bond number, first and second atoms, and bond type (with *ar* for aromatic).

of records is provided in the official documentation of the PDB file format.[42] As an example, we provide the *ATOM* section of a phenylalanine residue from an actual PDB entry in **Fig. 7**.

A great advantage of the *pdb* format is the standard atom typing that was introduced for the common amino acids, nucleotides, cofactors, etc. These atom names are based on IUPAC rules,[43] and they are also listed in an appendix of the original *pdb* format documentation.[44] Their use eliminates the need to explicitly specify the bonds in the mentioned residue classes, saving a great amount of space in *pdb* files (however, they do have to be specified if nonstandard atom names are given).

Another widely used format for crystallographic data is the Crystallographic Information File (*cif*).[45,46] A merit of *cif* (in comparison with *pdb*) is that it is a free format—allowing for more flexibility (and removing any limitations on the number of atoms, residues, or chains). On the other hand, it is slightly less human-readable than *pdb*. By default, structures can be downloaded in both formats from the Protein Data Bank (in fact, the standard archive format of PDB is *PDBx/mmCIF*—a customized version of *cif*—since 2014).[47] In addition, an XML-based representation of the *pdb* format, PDBML (Protein Data Bank Markup

Fig. 7 *ATOM* section of a phenylalanine residue from a PDB entry. The record type (*ATOM*) is followed by the atom number, atom type, residue type, chain identifier, residue number, the 3D coordinates, the occupancy and temperature factor values, and element symbol (followed by the formal charge, where applicable). This example highlights a drawback of fixed format files: structures with more than 9999 residues would be problematic to represent, as only four character positions are specified for residue numbers (characters 23–26), and the format does not allow any overflow (character 22 is reserved for the chain identifier).

Language) has been developed and published, and is available in the Protein Data Bank.[48,49] While the XML implementation can provide better interoperability (see subsection "Chemical Markup Language"), this format currently lacks the compactness of *pdb* files.

3.14.3.4.5 FASTA

FASTA is a format that was introduced in a DNA and protein sequence alignment software of the same name, and it has been the de facto standard format for DNA and protein sequences ever since, owing to its simplicity.[50] It is essentially a sequence of one-letter amino acid (or nucleic acid) codes and special characters (*X* for any residue, – for gap, and * for sequence termination) with a single description line (the first line of the file, starting with ">").

Due to their compactness, *fasta* files (or more generally, one-letter amino acid sequences) are the ideal format for querying macromolecular databases on the basis of sequence identity/similarity. (This type of database querying is often needed in homology modeling and other domains of computational medicinal chemistry.) Such tasks can be decomposed to two (consecutive) questions: (i) how can I find the optimal alignment of two protein sequences, and (ii) how can I quantify the homology/similarity between the two aligned sequences?

While the basics of sequence alignments have been established as early as in the 1970 work of Needleman and Wunsch,[51] the BLAST (Basic Local Alignment Search Tool) algorithm (which is considered the standard tool for sequence-based similarity searches) was introduced in 1990 by Altschul et al.[52] In contrast to the approach of Needleman and Wunsch, which optimizes the overall alignment of the two sequences, BLAST is a local similarity algorithm, seeking only relatively conserved subsequences. BLAST (along with its numerous specialized versions) powers a web service of the same name, maintained by the National Center for Biotechnology Information (NCBI).[53]

For quantifying the similarity between two aligned sequences, scoring functions based on substitution matrices are usually applied. Substitution matrices contain additive score contributions for each possible exchange of amino acid A to amino acid B. After summing these score contributions, the alignment with a higher score is better. (The two most commonly used substitution matrix types are Point Accepted Mutation (PAM) matrices[54] and Blocks Substitution Matrices (BLOSUM).[55]) The introduction of gaps is usually allowed but penalized in the overall score. The BLAST web server also returns an Expect value (or E-value) for each alignment, which is the number of BLAST hits that are expected to result by chance with the observed score (or higher). While a low E-value alone does not prove that two sequences are homologous, it is a useful guideline to infer some sort of biological relationship.

3.14.3.4.6 Chemical Markup Language

The Chemical Markup Language (CML) is an application of XML (eXtensible Markup Language) for the management and integration of chemical data.[56] It was first introduced by Murray-Rust and Rzepa and has been extended numerous times in the following years.[57–64] The main goal of CML is to provide a portable data type that allows for the production of interoperable and reusable documents. In addition to chemical structure, it is capable of storing crystallographic, spectral,[63] and reaction[62] data and has been integrated with, e.g., RSS aggregators[61] and Microsoft Word.[65] It operates using various conventions, allowing for applicability by various subdomains of chemistry.[66] While CML provides interoperability with an explicit specification of properties via markup text, the *cml* format is still fairly compact in comparison with, e.g., the tabular file formats presented above. (The *cml* entry for L-phenylalanine is provided as an example in Fig. 8.) The Chemical Markup Language is entirely open-source and is developed on a voluntary basis. (In fact, it is considered as a project of the Blue Obelisk Movement, an Internet community dedicated to the development of open-source, interoperable cheminformatics software.[67]) Its flexibility, interoperability, and open-source implementation make CML (in the authors' opinion) a strong candidate for being the next-generation standard for chemical data storage and exchange.

Although it is independent of CML, we make note of a novel XML-based query language, the Chemical Subgraphs and Reactions Markup Language (CSRML).[68] CSRML was recently developed (together with the ChemoTyper software and the ToxPrint library) to support chemotypes as a novel approach in substructure querying. (Here, chemotypes are defined as a way of representing chemical entities with three objectives: they should be (i) publicly accessible, (ii) coded in a unique and reproducible manner, and (iii) capable of combining both connected and nonconnected chemical patterns as well as atom, bond, and molecule-based properties into a single query.) CSRML provides serious advancements over existing query languages in multiple respects, for example, it provides a way to produce canonical representations of queries (i.e., a query can be specified exactly one way). Also, complex queries can be formulated by defining chemotypes based on molecular properties (in addition to structural patterns). CSRML was developed based on the CML language, extending it with additional features.

3.14.3.4.7 Structure recognition tools

Besides the enormous amount of data that is publicly available in standard chemical information formats (such as those detailed above), chemical knowledge of similar (or even greater) multitude is gathered in "traditional" formats, such as text and images in scientific publications and patents. While the conversion of images and text to chemical data is manually cumbersome and time-demanding, recent advances in text mining and optical structure recognition (OSR) are already paving the way toward the seamless, automated processing of textual and pictorial chemical information. These applications provide researchers access to invaluable chemical information that can be utilized for many purposes, e.g., for supporting drug discovery and navigating in the intellectual property (IP) space. In this subsection, we present a brief overview of current sources and services dealing with chemical text mining

Fig. 8 CML entry for L-phenylalanine. (Written with Chemaxon Marvin.[36]) The <*cml*> element contains the CML specifications (such as the applied schema and convention), the <*molecule*> element summarizes all the sub-elements that belong to the given molecule (titled *m1* in this example). The <*atomArray*> and <*bondArray*> elements consist of <*atom*> and <*bond*> elements, respectively, with the relevant properties listed in a *name*="*value*" general format. It is worth noting that simultaneous storage of 2D and 3D representations is also possible with the *x2* and *y2* (2D structure), and the *x3*, *y3*, and *z3* (3D structure) attributes. (Here, only the 2D representation is stored.)

and image recognition. (Since a detailed review of the related techniques and methodologies would be out of the scope of this chapter, we only refer the reader to recent, well-written reviews in this respect.[69–71])

Currently the most complete set of chemical text mining tools is provided by ChemAxon in their commercial Chemistry Text Mining Suite.[72] The software package includes naming applications (such as Name to Structure), supports text mining from Asian languages (with Chinese Name to Structure and Japanese Name to Structure), and processes whole documents for extracting chemical data (Document to Structure) with the integration of current optical structure recognition software (see below). Most of these functionalities are also provided free of charge on the web server *chemicalize.org*.[73,74]

Current, freely available chemical text mining and named entity recognition (NER) tools include OSCAR (Open-Source Chemistry Analysis Routines),[75] CheNER (Chemical Named Entity Recognizer),[76] and OPSIN (Open Parser for Systematic IUPAC Nomenclature).[77] Although there are many challenges still unsolved in optical structure recognition—such as extracting chemical data from complex arrangements, such as SAR tables—this field is also quickly progressing. Several commercial and open source solutions are available as well, including CLiDE,[78] Imago,[79] OSRA,[80] and MLOCSR[81] (the latter two also operate as web services).

Since traditionally the analysis of the patent literature is a cumbersome task, possible applications in this sub-field provide great motivation for the development of text mining and structure recognition tools. In particular, Markush structures (i.e., generic representations of a compound class consisting of a core structure and multiple R-groups) are quite extensively used in patent documents.[82] Recent developments describe novel methods for the visualization of Markush structures,[83] as well as deconvoluting complex (nested) Markush structures,[84] mapping specific structures to Markush structures[85] or encoding and searching Markush structures.[86] Current research efforts also include the introduction of a unified Markush language for the two major Markush databases (CAS and Thomson Reuters "Derwent") with the potential to serve as a common, generalized description of Markush structures.[87] We anticipate that coupling these techniques with the text mining and OSR approaches mentioned above will effectively multiply the speed of patent analysis tasks, enabling the extraction of even more information from even more complex data structures than what state-of-the-art programs can currently handle.

3.14.4 Molecular Fingerprints

Fingerprints are an important and ubiquitous concept in the domain of cheminformatics. Their primary purpose is to provide numerical representations of the structure or certain features of molecules, thus enabling the quantification of the similarity of two molecules. While fingerprints are often represented as bit strings (streams of zeros and ones), in a general sense, any vector

of continuous, discrete, or categorical numerical values can be considered a fingerprint. Depending on the fingerprint, various similarity metrics can be used for similarity calculations between molecules. We will cover these options in detail in Section "Similarity—Dissimilarity Measures, Distance Metrics."

In general, molecular fingerprints are not applicable for chemical data storage, as they are generated with algorithms that, e.g., check for the presence of a predefined set of substructures or use hashing functions to set the values of certain bits in a bit string—thus converting fingerprints back to structures is not possible for most fingerprint types. This is not necessary however, as there are various options for the compact storage of 2D structures, as well as for more detailed representations including 3D structures and an arbitrary number of molecular properties, including even molecular fingerprints (see Section "Chemical file Formats and Data Structures").

On the other hand, various molecular fingerprints are used in ligand-based virtual screening approaches. In typical setups, novel bioactive molecules are sought based on their similarities to one or more reference compounds with known activity profiles. The greatest advantages of fingerprint-based virtual screening approaches are computational feasibility and minimal setup and configuration requirements.[88] On the other hand, fingerprint-based methods often fail to identify activity cliffs,[89] and their performance depends greatly on the particular fingerprint type.[90] (Although the latter issue can be addressed with data fusion techniques,[91] which we cover in more detail in Section "Similarity—Dissimilarity Measures, Distance Metrics.") Fingerprint similarity searching was compared to other virtual screening methods (such as shape similarity searching and ligand docking) in several works, with varying conclusions, but such comparisons are out of the focus of the present work.[92–94]

This section is dedicated to a thorough overview of current fingerprinting methods, an at-a-glance summary is provided in Table 3. Before moving on to an itemized description, however, we highlight some recent, well-written reviews of this field,[88,95] as well as some detailed, in-depth analyses of molecular fingerprints, dealing primarily with the similarities and differences among the fingerprinting methods themselves,[90] and the effects of various parameters (such as the addressable space, atom-typing schemes, and bit scaling rules) on fingerprints and their virtual screening performances (in particular on hashed fingerprints implemented in Schrödinger's Canvas).[96,97] In addition, a review by Heikamp and Bajorath summarizes fingerprint engineering strategies, i.e., methods for designing fingerprints with an optimized search performance.[98]

Addressing the need for standardized methods for the evaluation and comparison of fingerprints and their screening performances, Riniker and Landrum have assembled and published a standard benchmarking platform for fingerprints,[99] based on the open-source RDKit cheminformatics toolkit.[14] Earlier, the same authors have published *similarity maps*, a useful, open-source tool for the visualization of atomic contributions to the similarity between two molecules, which—depending on the fingerprint method—is not always straightforward to see.[100]

While a comprehensive collection of cheminformatics and molecular modeling applications have recently been published by Cereto-Massagué et al.[88] (and we also refer to them throughout this chapter), we make note of Cinfony, a Python-based common application programming interface (API) for integrating several cheminformatics toolkits, including Open Babel, RDKit, CDK, and others ("the toolkit of cheminformatics toolkits").[101,102] Another, recent addition to the set of publicly available fingerprint-related tools is ChemDes, an online platform capable of generating a rich selection of molecular fingerprints and descriptors, integrating the functionality of multiple popular cheminformatics packages.[103,104] While the former encompasses a larger scope of functionality, the latter offers a user-friendly graphical interface.

3.14.4.1 Substructure Key-Based Fingerprints

In key-based fingerprints, the bits are set according to the presence or absence of predefined substructures (*structural keys*), as shown in Fig. 9. The fingerprint length is determined by the number of structural keys, and each bit corresponds of a single, specific key. While key-based fingerprints are useful for molecules that are likely to be covered by the structural keys, the treatment of novel or

Table 3 Fingerprint types discussed in Section "Molecular Fingerprints"

Subsection	*Subsection*	*Comment*
Key-based		Fingerprints based on predefined substructure keys, such as MACCS
Topological	Path-based	Hashed fingerprints based on linear or branched fragments, e.g., Open Babel FP2 or OpenEye Tree fingerprints
	Circular	Hashed fingerprints based on circular atom environments, including the popular ECFP
	Topological subsets	Fingerprints based on other topological subsets, such as atom pairs or topological torsions
	Pharmacophore	Fingerprints based on a 2D or 3D representation of pharmacophore features
Hybrid		Fingerprints based on more than one concept, or optimized for a predefined goal
Other	Text-based	SMILES-based fingerprints employing text-processing algorithms
	EDPrints	Electron Density Fingerprins, based on chemical shifts and partial atomic charges
	Affinity	Fingerprints based on measured or predicted biological activities/affinities
	Interaction	Protein–ligand interaction fingerprints based on cocrystallized or docked complexes
	FLAP	Fingerprints for Ligands and Proteins: molecular interaction field (MIF)-based pharmacophore fingerprints
	Reaction	Extensions of molecular fingerprints to encode reactions

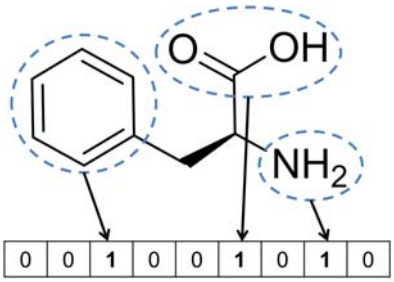

Fig. 9 In substructure key-based fingerprints, bits are set according to the substructures that are present in the molecule. (**1** or "on" if the given substructure is present and **0** or "off" if absent.) Thus, each bit position corresponds to a specific substructure.

less common substructural features is problematic. Nonetheless, several programs allow for customized keysets, thus the substructural keys can be easily updated, if needed.

Key-based fingerprints account for a set of specific structural features, which limits their ability to identify molecules that are similar to the query (on the level of, e.g., atom environments) but contain diverse fragments, rings, ring systems, etc. (In contrast, this is usually considered advantageous for several applications in drug discovery, such as hit expansion or scaffold hopping.) On the other hand, they are the tools of choice if the aim is to retrieve molecules that contain identical substructures with those found in the query molecule. As such, the use of key-based fingerprints with similarity metrics can be thought of as a transition between substructure searching and similarity searching. (In fact, structural keysets were historically used for substructure searching: in this case, molecules that did not have the same bits set as the query molecule were filtered out.[105])

MACCS (for Molecular Access System, a program developed by MDL) can be considered the prototype of key-based fingerprints—or at least it is the best-known. It was developed by MDL (Molecular Design Limited, now a subsidiary of BIOVIA[106]) and has two variants: one contains 166 keys, while the other contains 960 keys. While the former is almost universally implemented in cheminformatics applications (e.g., in RDKit[14] or Open Babel[1]), the latter is quite rare (it is available in BIOVIA's Discovery Studio, however[107]). The reason for the popularity of the 166-bit version is that while short, it covers most of the interesting features for drug discovery and virtual screening.[88] However, its application in virtual screening is somewhat ambiguous: while MACCS fingerprints show reasonably good retrieval rates in the work of Bender et al.,[90] they clearly perform weakly in the comparative study of Sastry and colleagues.[96] Nevertheless, Durant and colleagues have published useful guidelines for the reoptimization of MACCS keys, allowing for its optimization for specific scenarios.[108]

The PubChem fingerprint consists of 881 structural keys that encode quite diverse features.[109] It can be divided into seven sections, each corresponding to a given feature type (e.g., atom counts, bonded atom pairs, rings, etc.). It is implemented in the PubChem database for similarity searching, as well as some cheminformatics toolkits, such as CDK.[20,21] Further examples of key-based fingerprints include the modifiable BCI (Barnard Chemical Information Ltd., now Digital Chemistry) fingerprints,[110] two fingerprints of Open Babel (termed FP3 and FP4),[1] and two fingerprints implemented in CDK, based on the work of Klekota and Roth (a set of "privileged" substructures for biological activity),[111] and the electrotopological state formalism of Hall and Kier.[112]

A somewhat special substructure-based fingerprint is the set of MQNs (molecular quantum numbers) introduced by Nguyen et al.[113] MQNs are a set of 42 integer value descriptors of molecular structure, which count atoms, bonds, polar groups (such as H-bond donors and acceptors), and topological features (such as five-membered rings or acyclic tetravalent nodes). Consequently, they are not "traditional" key-based fingerprints in the sense that instead of encoding the presence or absence of substructures (either 0 or 1), they encode substructure counts. (On the other hand, feature counts are much more commonly applied in topological fingerprints, as detailed in the next subsection.) MQNs were primarily introduced as a tool to define, analyze, and visualize large chemical spaces (i.e., large databases), for which principal component analysis is proposed as a convenient dimension reduction method.[114]

3.14.4.2 Topological Fingerprints

Many molecular fingerprinting methods are inspired by more abstract concepts than substructure matching. In general, these methods perceive unique, nonpredefined (sub)structural features of molecules. Since there are no predefined substructures, no bit positions are assigned to specific features. Instead, mapping the features to a bit position (or more bit positions) is usually carried out with an appropriate *hashing function* (thus, topological fingerprints are often referred to as *hashed* fingerprints). Since the number of bit positions (the length of the fingerprint or *addressable space*) is finite, it can occur that two features are mapped to the same bit position: this phenomenon is called a *bit collision*. Bit collisions cause a loss of information and have been shown to deteriorate virtual screening performance in the work of Sastry et al.[96] (They can be avoided by increasing the addressable space although that results in a loss of speed as the individual fingerprints get larger.) Due to the possibility of bit collisions, hashed fingerprints would be—by default—inappropriate for substructure searching. However, with a large enough addressable space, the frequency of bit collisions becomes negligible: in this case, substructure searching can be carried out in the same way as mentioned in the previous subsection.

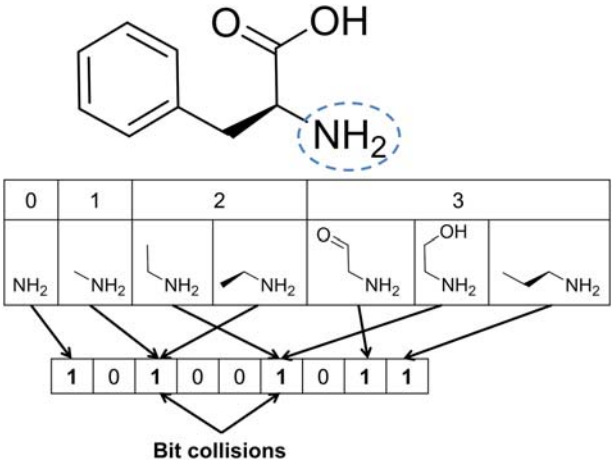

Fig. 10 In path-based fingerprints, linear (or in some cases, branched) paths up to a certain length (here three bonds) are enumerated and encoded. (In this example, the paths start from the nitrogen atom of L-phenylalanine, but in practice, the procedure is repeated for each heavy atom.) Note that depending on the applied fingerprint, the two paths (fragments) with 2 bonds of length can be treated as identical or different: this depends on the atom-typing scheme used (see main text).

3.14.4.3 Path-Based Fingerprints

Path-based topological fingerprints operate by enumerating all fragments of a molecule based on linear or branched paths up to a certain number of bonds and hashing them to the addressable space (see **Fig. 10** as an example). This removes the limitation of predefined substructures, i.e., any imaginable molecule produces a meaningful fingerprint.

An early example of path-based fingerprints is the Daylight fingerprint, consisting of 2048 bits and encoding all possible connectivity pathways of a molecule up to a predefined length.[115] (Interestingly, the original implementation employed a pseudorandom number generator as the hashing function that produces typically 4 or 5 bit positions per pattern.) The Daylight fingerprint and its variants are still popular: for example, Open Babel has implemented a similar fingerprint (FP2), which consists of 1024 bits and enumerates fragments with 1–7 atoms.[1]

For generating path-based fingerprints, a variety of atom-typing schemes are available. In Pipeline Pilot, functional classes (similar to pharmacophore features), A log*P* codes and *mol2* atom types can be used for this purpose (besides element types).[116] For example in **Fig. 10**, the two paths (fragments) with 2 bonds of length would be treated as identical (N-C-C) if element symbols are used for atom typing, but they are differentiated by mol2 atom types (N-CA-C vs. N-CA-CB, see **Fig. 6** for reference). Schrödinger's Canvas implements an even wider set of atom-typing schemes, ranging from "generic" (where all atoms and bonds are equivalent) to complex ones such as RTXHB (which takes into account ring size, aromaticity, H-bond acceptor/donor type, etc.).[117] Both programs implement the possibility to account for feature counts (rather than the mere presence or absence of the features), while Canvas also includes a variety of bit scaling rules to account for the fact that larger fragments (features) usually dominate the frequency distribution.[96]

Some path-based fingerprints employ an extended representation of molecular paths (or fragments) by involving branched fragments in the fingerprint generation. Notable examples are OpenEye's Tree fingerprints[118] and Schrödinger's Dendritic fingerprints.[117]

3.14.4.4 Circular Fingerprints

Instead of paths, circular fingerprints encode circular atom environments starting from the central atom and expanding to a given diameter. Circular fingerprints cannot be used for substructure searching (since a particular substructure in a different environment sets a different bit) but are ideal (and popular) choices for similarity searching. Two typical examples for circular fingerprints are Molprint2D and extended connectivity fingerprints.

Molprint2D was introduced in 2004 by Bender and colleagues.[119] This fingerprint encodes atom environments (for each heavy atom) within a distance of two bonds in the following way: the atom types found at distances of one and two bonds are listed and converted to the form *type-freq-distance*, where *freq* is the number of *type* atoms at the given *distance* from the central atom. These entries are sorted by distance and then by type, and hashed to a bit position. A 3D version called Molprint3D was also developed and published in the same year.[120] Molprint2D is available in many software packages, including Open Babel[1] and Canvas.[117]

Extended connectivity fingerprints (ECFP) can be considered as the de facto standard of circular fingerprints. They were first introduced in 2000 in Pipeline Pilot[116,121] but have since been implemented in various cheminformatics packages, including ChemAxon's JChem[122] and Schrödinger's Canvas.[117] A thorough description of extended connectivity fingerprints was published in 2010 by Rogers and Hahn.[123]

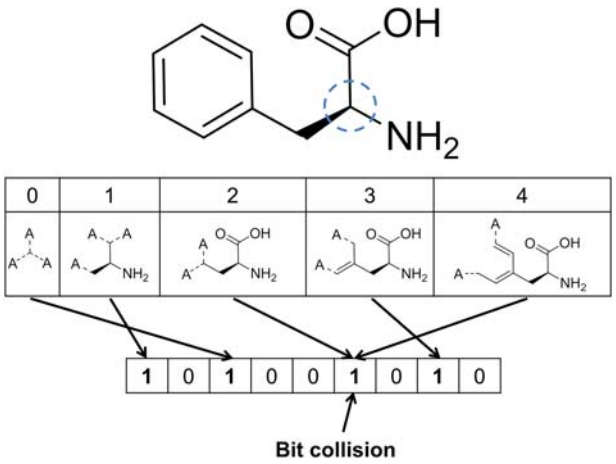

Fig. 11 Extended connectivity fingerprints encode full atom environments up to a predefined diameter (here, 4 bonds). For the terminal atoms, any other bonds (that are not part of the fragment) are also accounted for (here, the letter "A" denotes "any atom"). In this example, the central atom is the α-carbon, but in practice, the procedure is repeated for each heavy atom.

ECFPs are based on a modified version of the Morgan algorithm, which was originally introduced as a solution for the molecular isomorphism problem, i.e., to determine whether two molecules—with different atom numberings—are the same.[124] The ECFP generation process consists of three consecutive steps: (i) initial assignment, where each atom has an integer identifier assigned to it (based on atomic properties, such as atomic number, formal charge, etc.); (ii) iterative updating, where each atom identifier is updated to an array containing the atom identifiers of the central atom and the neighboring atoms (up to n bonds of distance, where n is the iteration number), which is hashed back into a new, single-integer identifier; and (iii) duplicate removal, where multiple occurrences of the same feature are removed (or counted, if feature counts are requested). The process is illustrated in Fig. 11.

ECFPs are highly customizable: in particular the diameter, the addressable space, the consideration of feature presence/absence vs. feature counts, and the atomic properties used for generating the atom identifiers are all influential parameters that affect the virtual screening performance either slightly or substantially. In Pipeline Pilot, there are a number of options for atom typing (similar to path-based fingerprints), such as *mol2* atom types, functional classes or Alog*P* codes and the diameter is variable as well. To distinguish between the various alternatives, a naming convention was introduced: *xyFz_n*, where *x* is the atom typing (*E* for atom type, *F* for functional class, *A* for Alog*P* code, and *S* for Sybyl *mol2* atom type), *y* is the fingerprint type (*C* for extended connectivity, *P* for path fingerprints), *z* indicates the presence/absence of a feature (*P*) or feature counts (*C*), and *n* is the diameter (e.g., ACFC_4 would be an extended connectivity fingerprint with Alog*P*-based atom types, a diameter of 4 and feature counts). Canvas includes some other options for configuration, such as bit scaling and bit filtering rules, while in JChem, the atomic properties used for identifier generation are highly customizable, and the whole configuration can be supplied in an *xml* file.

3.14.4.4.1 Topological subsets

Besides paths and circular atom environments, other topological subsets can also be used for fingerprint generation. Here, we briefly mention two examples whose theoretical basics have been laid down about 3 decades ago but are still implemented in current software packages.

Atom pairs have been introduced in 1985 by Carhart et al. as a topological descriptor for structure–activity studies.[125] Two years later the same laboratory published topological torsions for the same purpose.[126] The authors have also developed an atom-typing scheme for these descriptors, where an atom is characterized by its element type, the number of its heavy (i.e., nonhydrogen) neighbor atoms, and the number of its π electrons (e.g., the α-carbon of L-phenylalanine has three heavy neighbors and zero π electrons, so it could be represented as *C_3_0*). While alternative atom types (based on physicochemical properties) have been proposed by Kearsley et al., no general superiority is observed for any of these atom-typing schemes.[127]

Atom pairs are defined as two atom types and the topological distance (i.e., number of bonds in the shortest path) that separates them and are calculated for each pair of atoms in the molecule to produce the (hashed) atom pair fingerprint. For a molecule with n heavy atoms, the total number of atom pairs will be $n^*(n-1)/2$. On the other hand, a topological torsion is defined as four, consecutively bonded atom types and represent the topological analogue of the basic conformational element, the torsion angle. Similar to atom pairs, topological torsions are also enumerated for each quartet of consecutively bonded atoms of the molecule and hashed to a fingerprint.

The two descriptors capture different aspects of molecular topology. For example the original authors note that while atom pairs are generally sensitive to small changes (e.g., changing a single atom changes the $n-1$ atom pairs involving that atom), topological torsions provide local information and are hence less sensitive to such small local changes. In addition, atom pairs and topological torsions have provided a conceptual basis for the development of further, similar methods, such as geometric atom pairs (the 3D

analogue of atom pairs)[128] or fluorine environment fingerprints (a specialized implementation of topological torsions, focusing on fluorine atoms).[129] Meanwhile, the two core methods are implemented in a number of current software packages, including Canvas[117] and RDKit.[14]

APfp, a 2D atom pair fingerprint (not to be confused with the APFP_n fingerprints of Pipeline Pilot) published recently by Awale and Reymond is a simplified version of the atom pair fingerprints detailed above.[130] APfp is a set of 20 integer values, counting the total number of atom pairs in a molecule at distances of 1–20 bonds, while Xfp is a related 55-dimensional extended fingerprint that also encodes atomic properties: both have been shown to perceive molecular shape quite effectively. 3D analogues of these methods (based on through-space distances and atom pair Gaussian functions) have been published in 2015 by the same research group.[131]

3.14.4.5 Pharmacophore Fingerprints

While the category of pharmacophore fingerprints substantially overlaps with the fingerprints that were already covered (e.g., topological fingerprints with "functional class" or similar atom-typing schemes), we dedicate a separate subsection for pharmacophore fingerprints as a group of methods that are based on different considerations or design concepts. Pharmacophore fingerprints employ a similar concept to that of atom pair fingerprints (see previous subsection) in the sense that they provide a simplified representation of key interacting atoms/groups (i.e., pharmacophores), which are not necessarily bonded to each other—they can be separated by any number of bonds. On the other hand, in pharmacophore fingerprints, subsets consisting of more than two (typically three or four) features are often encoded: these subsets are called three[132,133] and four-point pharmacophores, respectively.[134] In addition to comparing and screening small molecules, pharmacophore fingerprints can also be used for protein-binding site similarity calculations.[135]

Among popular software packages, the Molecular Operating Environment (MOE) is particularly rich in pharmacophore fingerprints, with a total of seven choices, encompassing two-, three-, and four-point pharmacophores.[136] The two-point fingerprints TGD (Typed Graph Distances) and TAD (Typed Atom Distances) can be considered an implementation of atom pair and geometric atom pair fingerprints, respectively, with a different atom-typing scheme (H-bond donor, H-bond acceptor, cation, anion, hydrophobic, polar). Thus, TGD uses a 2D (graph-based) representation of the molecule, while TGT uses a 3D conformation. The three-point fingerprints TGT (Typed Graph Triangles) and TAT (Typed Atom Triangles) are extensions of TGD and TAD, using triplets of atoms instead of pairs. It was shown that the implementation of overlapping atom types, as well as feature counts, could improve the virtual screening performance of TGT fingerprints.[137] GpiDAPH3 and piDAPH3 are also three-point pharmacophore fingerprints, but they employ a different atom-typing scheme, in which atoms are differentiated based on three properties (in π system, is H-bond donor, is H-bond acceptor; a total of eight possible combinations). GpiDAPH3 is graph-based, while piDAPH3 is 3D conformation-based. The four-point fingerprint piDAPH4 is an extension of piDAPH3, which considers quartets of features instead of triangles. 2D (configurable) pharmacophore fingerprints are also available in JChem[122] and RDKit,[14] while 3D (three- and four-point) fingerprints are available in Canvas.[117]

3.14.4.6 Hybrid Fingerprint

In a general sense, the term "hybrid fingerprint" encompasses any method that utilizes more than one fingerprinting concept, but in a wider sense, we can also include in this definition single fingerprints that are optimized *post hoc* based on some known rationale or predefined goal.

An early example is the Unity 2D fingerprint of Tripos (now Certara), which is a 988-bit fingerprint that includes both structural keys and path fragments.[138] More recently, Xue and colleagues have introduced the concept of MFPs or "minifingerprints" (short binary fingerprints)[139] and designed various improved fingerprinting methods,[140] including MP-MFP, a hybrid fingerprint that contains 61 property-based and 110 structural key-based bits.[141] The more recent PDR-FP (Property Descriptor Range Fingerprint) employs solely property-based descriptors, selected systematically to correlate with activity-relevant molecular features.[142]

A common design concept behind these fingerprints is the selection of the most relevant pieces of information that will constitute the final fingerprint, which is often shorter than "traditional" fingerprints but retains their screening performance (or even improves upon it). In general, there are two (somewhat alternative) principles that underlie the design of such hybrid fingerprints: the recombination of bits (or features) from two or more different fingerprints[143,144] and the weighting (or scaling) of the bits (or features) of a single fingerprint, based on relative importance.[145,146] (The latter is not to be confused with the bit scaling rules implemented in Canvas, which is related to the feature counts of certain fingerprints.[96,117]) Due to their highly customized implementation, hybrid fingerprints can provide serious improvements over individual fingerprints even in tasks that are traditionally considered to be particularly difficult for 2D fingerprints—such as scaffold hopping.[144,147]

3.14.4.7 Other Fingerprint Types

All of the fingerprint methods presented so far are based (one way or another) on the topology or structural features of the molecules. In this subsection, we present several additional fingerprint types that are based on slightly or radically different ideas. (Nonetheless, these fingerprints are influenced by the molecular topologies as well, but this influence is more or less indirect.)

3.14.4.7.1 Text-based

SMILES strings (see subsection "Simplified molecular-input line-entry system") are very compact representations of molecular structure. Thus, it has been proposed that introducing a means to compare SMILES strings (and calculate their similarities) would speed up virtual screening, since the generation of molecular graphs or connection tables could be omitted. Here, we briefly include two, conceptually diverse SMILES-based fingerprints, LINGO and SMIfp. For a recent, detailed comparison of SMILES-based similarity methods, we refer to the work of Öztürk et al.[148]

LINGO is based on the fragmentation of the SMILES string into substrings.[149] In particular, "a q-LINGO is a q-character string, including letters, numbers, and symbols, such as *(,)*, *[,]*, #, etc. obtained by stepwise fragmentation of a canonical SMILES molecular representation." For producing these substrings, LINGO uses canonical SMILES strings. (Although multiple SMILES canonicalization approaches exist—see subsection "Simplified molecular-input line-entry system," the use of alternative canonicalization schemes provides very similar or identical results for property or similarity calculations, as long as the same canonicalization scheme is used consistently for the whole process.) For a SMILES string of length n, $(n-q+1)$ substrings of length q are extracted, and their occurrences are counted to provide the final LINGO profile. Such profiles can be thought of as fingerprints, and their similarities can be calculated with, e.g., the Tanimoto coefficient.

In contrast, SMIfp applies a fixed-size chemical space by counting the occurrences of 34 different symbols in the SMILES strings.[150] For SMIfp, the *city block* (or Manhattan) distance is proposed for similarity calculations. This combination has been shown to perform well in recovering several series of active molecules from multiple databases. SMIfp powers a series of SMIfp-browsers for searching popular chemical databases, available at the website of the authors.[151]

3.14.4.7.2 EDPrints

The recently developed EDPrints (Electron Density Fingerprints) approach of Kooistra et al. is based on a unique idea: chemical shifts (i.e., shifts in frequency of NMR spectroscopy signals), as well as partial atomic charges can represent the particular molecular environment of an atom (due to the asymmetric distribution of electrons in chemical bonds).[152] Therefore, both values are useful representations of the chemical and structural properties of molecules, thus they can be utilized in the construction of a fingerprint (as alternatives to the topology of the molecule). In EDPrints, ^{13}C and ^{1}H chemical shifts are calculated with the BatchNMRPredictor program,[153] and Merck molecular force field (MMFF94)-type nonpolarized partial atomic charges are calculated with Balloon.[154] These values are transformed into nonnegative integers and mapped to a bitstring, where each bit position reflects a particular descriptor value. The authors have found that EDPrints is able to achieve similar (and sometimes better) screening accuracies compared to other 2D ligand-based screening methods and exceeds their speed in terms of the time needed to compare a pair of molecules.

3.14.4.7.3 Affinity fingerprints

Instead of focusing on the molecular structure, affinity fingerprints encode the experimentally determined binding potencies of a compound against several target proteins. (Hence, an activity fingerprint is by default a vector of real numbers.) The concept was introduced in 1995 in the work of Kauvar et al., reporting the design of a small reference panel of eight proteins, which was used to define the affinity fingerprints of 122 structurally diverse compounds.[155] With the application of statistical methods (in particular, multivariate regression techniques), the authors were able to predict binding potencies quite effectively and concluded that affinity fingerprints can be useful tools in a number of applications, including chemical classification, compiling diversified chemical libraries, and guiding combinatorial chemistry efforts. Interestingly, a linear combination of the measured binding affinities can provide quite precise predictions for the binding affinities to proteins that are not included in the panel.[155,156] The methodology was further elaborated and compared with a structural fingerprint (MOLSKEYS) by Dixon and Villar.[157] Possibly the best-known and most extensively used public reference panel is the cancer cell line panel operated by the National Cancer Institute (NCI).[158] The panel consists of 60 human cancer cell lines, on which 50-percent growth-inhibitory concentrations (GI50) are determined for compounds submitted by research groups from around the world, and the results are published in NCI-operated databases.

The concept of affinity fingerprints was later expanded to *in silico* data with the introduction of "virtual affinity fingerprints," encoding interaction energies derived from docking (instead of experimentally determined affinities).[159] Since docking was not (and is still not) a reliable method for the prediction of ligand affinities, Bender and colleagues have introduced "Bayes Affinity Fingerprints" as an alternative of virtual affinity fingerprints.[160] In this approach, class-specific Bayes models are employed to predict a wide panel of bioactivities, and the resulting Bayes scores constitute the Bayes Affinity Fingerprint. Besides reporting consistently higher retrieval rates compared to ECFP_4 fingerprints, another valuable conclusion of the study is that information-optimal "bioactivity spaces" of low dimensionality can be utilized to answer complex questions about bioactivity profiles, e.g., "can I modulate off-target activity B independently of on-target activity A?". (A more general formulation of this question would be "can I predict possible targets for an arbitrary molecule?", which is the main question of an approach called target fishing that can be considered the inverse process of virtual screening.[161]) An alternative approach for the prediction of affinity fingerprints, called PASS (Prediction of Activity Spectra for Substances) was introduced in 2000[162] and was successfully applied in many subsequent works, including the discovery of novel cognition enhancers.[163] The further development of biological fingerprints—and chemogenomics (the study of systematic relationships between targets, based on their ligands) in general—was reviewed by Bender et al.[164]

3.14.4.7.4 Interaction fingerprints

As the name suggests, instead of chemical features, interaction fingerprints (IFP) encode information about the interactions between the molecule and its environment, usually a protein target. In this manner, protein–ligand complexes resolved with X-ray crystallography (or other experimental methods) or predicted with docking (or other computational methods) can be processed and compared. Consequently, interaction fingerprints can mostly be utilized in docking-based virtual screens or database analysis studies.

Interaction fingerprints consist of a fixed number of bits per residue, corresponding to a predefined set of general or specific interactions between the ligand and the residue. These interactions are checked based on standard cutoffs (in terms of, e.g., H-bond distance or angle), and the corresponding bits are set to either 1 (there is an interaction) or 0 (no interaction). The process is repeated for every residue of the protein, and the resulting substrings are concatenated in the sequential order of the residues to produce the final interaction fingerprint.

There are multiple reported methods for generating interaction fingerprints, the earliest of which to our knowledge is SIFt (Structural Interaction Fingerprints),[165,166] which implements seven different interaction types (including "any contact," "any backbone contact," and "any sidechain contact"). A somewhat modified version of SIFt is implemented in the Schrödinger Small-Molecule Drug Discovery Suite.[167]

Several similar (and similarly named) methodologies were introduced in the following years. The IFP implementation of Marcou and Rognan omits the most general interaction types of SIFt and enables the configuration of the fingerprinting algorithm, including the addition of weaker and scarcer interaction types such as cation-π interactions or metal complexation.[168] Mpamhanga et al. have designed interaction fingerprint based on an alternative concept: their IFPs are fixed-length bit strings that are as long as the number of heavy atoms in the binding site.[169] Pérez-Nueno and colleagues have introduced an atom-pair-based interaction fingerprint (APIF) that considers the relative positions of interacting atom pairs.[170] An implementation of interaction fingerprints (termed PLIF, or Protein–Ligand Interaction Fingerprints) is also included in the MOE.[136] A more recent approach is SPLIF (Structural Protein–Ligand Interaction Fingerprints), developed by Da and Kireev, in which "three-dimensional structures of interacting ligand and protein fragments are explicitly encoded" (as a result, the interactions themselves are encoded implicitly, in contrast to, e.g., SIFt).[171]

Trivially, interaction fingerprints can only be compared between the complexes of the same protein structure (as the length of the fingerprint varies according to the total number of residues). Alternatively, with a prior residue selection, such comparisons can be extended to multiple structures, or even multiple, similar proteins (in this case, a prior 3D alignment is needed to match the residues in the different proteins). These methodologies are utilized in recent works of the research group of de Graaf at the VU University of Amsterdam, where interaction fingerprints are employed to power class-specific protein–ligand structural databases such as KLIFS (for kinases)[172–174] or PDEstrian (for phosphodiesterases).[175,176]

3.14.4.7.5 Fingerprints for Ligands and Proteins (FLAP)

FLAP (Fingerprints for Ligands and Proteins) was developed in 2007 and is currently distributed by Molecular Discovery.[177,178] FLAP uses a unique approach for fingerprint generation and employs a wide range of important concepts from cheminformatics/molecular modeling, such as pharmacophores, molecular interaction fields and molecular shape. As such, it is quite distinct from the interaction fingerprints detailed in the previous subsection, even though it also encodes information about the interactions between the protein and the ligand.

FLAP uses molecular interaction fields (MIFs) based on the GRID force field to identify the active site of the protein. MIFs are then condensed into a few target-based pharmacophoric points (i.e., points where specific interactions with the protein would be favorable). To define FLAP fingerprints, one has to select (manually or automatically) a set of such pharmacophoric points. Then, all possible arrangements of four pharmacophoric points are generated and stored in a so-called protein fingerprint. Ligands are fitted to these pharmacophoric points to identify favorable interactions, and the resulting poses are filtered according to the complementarity of the shapes of the ligand and the binding site (to account for steric clashes).

3.14.4.7.6 Reaction fingerprints

Similar to line notations, the concept of fingerprints has also been extended to encode reactions (in addition to compounds). Reaction fingerprint generation has been a quite intuitive process since the earliest reported examples of such methods: molecular fingerprints or vectors (consisting of various descriptors) are generated for both the reactants and the products, from which a difference fingerprint (or vector) is calculated. The difference is calculated with a *bitwise OR* operation in the case of Daylight Structural Reaction Fingerprints,[115] and with a vector subtraction in the case of descriptor-based reaction vectors.[179] These methods have been successfully applied for a number of tasks, including metabolite prediction,[180] *de novo* molecular design,[181] and local QSAR analysis.[182] Most recently, Schneider and colleagues have developed a novel reaction fingerprint method based on atom-pair fingerprints of the products and reactants and a physicochemical property-based representation of the agents.[183] The method was successfully applied for building machine-learning models, assessing the similarities of reactions and classifying a large set of reactions based on reaction type.

3.14.5 Numerical Descriptors and Similar Representations

In the past few decades numerous books with hundreds of pages were published in the field of molecular descriptors. Although the topic is indeed huge, more and more novel molecular descriptors appear from year to year. In this section we would like to provide a general view of the world of molecular descriptors.

A basic definition of molecular descriptors (molecular representations) is that they are measured or computationally calculated properties of molecules. Another definition is stated in the popular and largely useful encyclopedia of Todeschini and Consonni[184]: "The molecular descriptor is the final result of a logical and mathematical procedure which transforms chemical information encoded within a symbolic representation of a molecule into a useful number or the result of some standardized experiment." These molecular representations can be used mostly for similarity searching, virtual screening, and QSAR (or related) models.

The molecular descriptors can be classified in several ways. There are binary, discreet, and continuous values, and we can also calculate other new descriptors from previously defined ones. Usually they are classified based on their dimensionality as 0, 1, 2, 3 … *n*D descriptors. We should mention the obvious confusion that while fingerprints can be calculated from the 2D or 3D representations or properties of the molecules, they are often termed 1D descriptors.[185] Another, truly 1D descriptor is reported in the work of Dixon and Merz, based on the projection of a 2D graph or a 3D conformation to a single dimension.[186] As for higher-dimensional descriptors, the term "2D descriptor" means that it is calculated from the 2D (graph) representation of the molecule, and in the same manner 3D descriptors are based on the 3D representation of the molecule. In the group of zero dimension descriptors are the molecular weight, the number of different atoms, etc. Thus, 0D descriptors are independent of the molecular structure and can be calculated from the molecular formula.

On the other hand, we can differentiate between physicochemical, structural, topological, electronic, geometric, and simple indicator parameters (based on their theoretical backgrounds). The term "whole-molecular descriptors" encompasses descriptors that can be calculated from the 2D representation of the molecule. Here we can distinguish between simple descriptors (number of H-bond donors and acceptors, number of ring systems and rotatable bonds, etc.) and physicochemical descriptors. When using molecular descriptors, one always has to decide between the computational demanding but precise, and the time-saving but less precise methods. Usually 2D descriptors are less time-demanding than 3D descriptors.

An overview of the most popular molecular descriptors, which are discussed in Section "**Numerical Descriptors and Similar Representations**" in details, can be seen in **Table 4**.

3.14.5.1 2D Descriptors

As it was mentioned above, 2D descriptors are always calculated from the 2D representation of molecules. 2D descriptors are also called graph invariants,[184] as their values do not depend on the numbering of the atoms in the molecule. Here the two main categories: whole-molecular and topological descriptors, as well as other smaller groups will be discussed.

3.14.5.1.1 Whole-molecular descriptors

Whole-molecular descriptors can be categorized into simple and the physicochemical descriptors. Simple 2D descriptors are the number of H-bonds acceptors, H-bond donors, the number of rings, or other countable parts of a molecule. They can be easily calculated.

Physicochemical descriptors are a larger and more diverse group. There are several parameters and several calculation types. The easiest ones (like molecular weight) are included in 0D descriptors, while we summarize the more complex ones here.

One of the most important physicochemical descriptors is the lipophilicity index, log*P*. Log*P* is part of Lipinski's rule of five to predict drug-likeness. Usually, log*P* means the logarithm of the *n*-octanol (organic)-water (aqueous) partition coefficient, but if

Table 4 The molecular descriptors discussed in Section "**Numerical Descriptors and Similar Representations**"

Subsection	*Subsection*	*Examples*
2D descriptors	Whole-molecular descriptors	Simple and physicochemical descriptors (log*P*, pK_a, solubility)
	Topological descriptors	Wiener index, Zagreb group index, Randic branching index, Balaban J-index, Kappa shape index, etc.
	Indicator variables	Free-Wilson descriptors, Fujita-Ban analysis, etc.
	Thermodynamic descriptors	Heat of formation, Bond dissociation energies
	Molecular identification numbers	BCUT descriptors
3D descriptors	Electronic descriptors	(Electric) Dipole moment, Highest occupied (HOMO) and lowest unoccupied (LUMO) molecular orbital energies, εLUMO, etc.
	Size descriptors	Radius of gyration
	Volume descriptors	McGowan's characteristic volume, Molecular volume index, Geometric volume, etc.
	Shape descriptors	Shadow indices
	Van de Waals parameters	Van de Waals molecular surface
	Molecular Shape Analysis descriptors	Receptor Surface Analysis descriptors
	Molecular Field Analysis descriptors	Steric field, electrostatic field
	Receptor Surface Analysis descriptors	Steric field, electrostatic field
	3D descriptor families	WHIM, GETAWAY, MEDV, EVA, VolSurf, etc.
4D and other descriptors	4–6D descriptors	Grid cell occupancy descriptors, etc.
	Other descriptors and approaches (outlook)	Shape-based approaches (ROCS), etc.

there are more lipophilicity indices at hand, it should be denoted as log $K_{o/w}$. It plays a role in drug absorption and distribution, thus this descriptor is one of the oldest and most important members of the descriptors applied in drug discovery. The log *P* and hydrophobicity descriptors are frequently used in quantitative structure–activity (and structure–property) relationships (QSAR, QSPR). Lipophilicity can be decomposed into two parts: hydrophobicity and polarity. While hydrophobicity and lipophilicity are often used interchangeably (the words themselves are synonyms in a grammatical sense), they denote slightly different concepts. Hydrophobicity entails the contribution of nonpolar interactions to lipophilicity, while lipophilicity itself is dominated by the entropic driving force of removing hydrophobic surface area from water. The equations relating the partition coefficient (log *P*) to the π substituent constant—which is a classical approach to quantify the lipophilicity of a chemical group—are the following:

$$\log P = \log K_{o/w} = \log \frac{[C]_{n-\text{octanol}}}{[C]_{\text{water}}} \tag{1}$$

where [*C*] is the concentration of the solute in different phases, and

$$\pi_X = \log P_X - \log P_H, \tag{2}$$

where the P_X and P_H values represent the substituted and the unsubstituted molecules' partition coefficients.

Several opportunities are developed for not just measuring, but also for calculating log*P* descriptors. Nowadays the use of *in silico* log*P* descriptors is also acceptable in the field of drug design. The work of Hansch and Fujita has pioneered the calculation of *in silico* log*P* descriptors.[187] Log*P* can be measured with the traditional shake flask method, with HPLC (high-performance liquid chromatography) or with TLC (thin layer chromatography) methods manually. It can be calculated *in silico* in several ways based on, for example, quantum chemical or semiempirical calculations. Two larger groups of *in silico* calculations are substructure-based and property-based methods. Some calculations—based on the summation of log*P* contributions of molecule fragments—were reviewed by Leo.[188] Typical *in silico* log*P* calculation methods are ALOGP, MLOGP, Clog*P*, XLOGP2, XLOGP3, etc. Nowadays there are several software packages that are freely accessible online. Due to the large number of choices, a careful evaluation of this descriptor is very important in every field of pharmaceutical science. In the past years some detailed comparisons of log*P* calculation methods were published.[189–192] They can help to decide and to answer questions like "what should be used" or "what is the best technique," etc. In the latter article the authors show that *in silico* calculations usually give more reliable results than TLC measurements.

Another highly important descriptor is the acidic dissociation constant and its negative logarithm (pK_a). It is connected not just to the pH value (and other descriptors like lipophilicity), but to many other ADME-related properties, such as membrane and blood–brain barrier permeability. The definition of the acidic dissociation constant is the following:

$$K_a = \frac{[A^-][H^+]}{[HA]} \tag{3}$$

where *HA* is the acidic form and A^- is the conjugate base.

There are several ways to measure pK_a values, for example, direct potentiometric titration and measurements based on chromatographic retention or UV absorption, etc.[193] One can also use *in silico* pK_a predictions, which have a serious advantage compared to experimental methods. Namely, the preparation of the molecules is not needed for the analysis. Most of the *in silico* pK_a prediction methods and commercial software are based on linear free energy relations (LFER) and the Hammett equation:[194,195]

$$pK_a = pK_a^u + \rho\Sigma\sigma \tag{4}$$

where pK_a^u is the dissociation constant of the unsubstitued molecule, ρ is the constant for an ionizable group, and σ is the constant of an exact substituent.

Other principles among *in silico* pK_a prediction software include fragment-based methods, QSAR models, and *ab initio* methods. Similar to *in silico* lipophilicity indices, comparisons between the pK_a predication methods and software have also been published.[196]

Last but not least the third crucially important physicochemical descriptor is the (aqueous) solubility (and its negative logarithm). In drug discovery the aqueous solubility of a drug candidate cannot be increased endlessly because strongly hydrophilic molecules cannot cross lipid membranes. Thus solubility has to be in an optimum range. There are many options for the *in silico* calculation of solubility, some of which are based on other physicochemical descriptors, such as the melting point or lipophilicity. The well-known Yalkowsky equation is a good example for this:[197]

$$log(S_0) = -0.01(\text{MP} - 25^\circ\text{C}) - logP + 0.50, \tag{5}$$

where S_0 is the water solubility, MP is the melting point, and log*P* is the lipophilicity index.

This equation has larger bias, due to the use of the melting point, which is hard to predict based on the molecular structure. The other opportunity for *in silico* solubility calculation is the use of different QSPR models. In this case we can use several chemometric tools for the prediction, such as partial least square regression (PLSR),[198] multiple linear regression (MLR),[199] random forest (RF),[200] and artificial neural network (ANN).[201] A comparison of the general solubility equation (GSE) and the above mentioned chemometric tools has also been published.[202]

One can find further physicochemical (molecular) descriptors, which are not discussed here in Todeschini's encyclopedia of descriptors.[184]

3.14.5.1.2 Topological descriptors

Topological descriptors (or topological indices) are numerical descriptors that can be calculated from the molecular structure. Topological descriptors are one of the most populated (and popular) members of the molecular descriptor (and 2D descriptor) family. Their importance is emphasized, as they can provide simple and useful information about the structures of the molecules. However, they do not contain any information about the stereochemistry and the 3D conformation. (With the words of Hugo Kubinyi: "The topology and topography of a molecule may be compared to the skeleton of a human being. How boring would life be if we recognize each other only by our skeletons and not by shape, behavior, and spirit!")[203] Thus, topological descriptors can be calculated without the optimization of molecular structure. With the combination of other molecular descriptors (such as physicochemical descriptors), they can be quite useful in QSAR and QSPR studies.

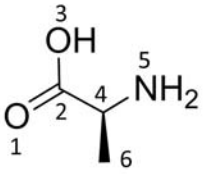
These descriptors are based on the 2D graph of a molecule. The calculation of the topological descriptors is closely connected to graph theory, where the molecular structures are built up from vertices (which symbolize the atoms) and edges (which denote covalent bonds). There are two types of these molecular graphs (or maps), the H-filled (contains the hydrogen atoms) and H-depleted (without hydrogen atoms). From these molecular graphs we can also create a graph theoretical matrix, where the relations between edges or vertices can be examined (defined). From another point of view we can distinguish between the adjacency matrices and the distance matrices (based on the original molecular graph). The former matrix contains the nonhydrogen adjacent atoms (for the H-depleted version) and assigns each pair of them as one (if they are adjacent) or zero (if not), while the latter one counts the number of edges between two vertices in the shortest path (topological distance). See **Fig. 12** for an example of a simple molecule's adjacency and distance matrices. Topological indices can be calculated from different molecular maps in an unequivocal way as they are based on the topological distances between the atoms of the molecule (through-bond indices). The topological indices can be topostructural (using only the atomic distances) or topochemical (using also atomic properties, like chemical identity or hybridization states).[204] The molecular graphs are also used for the creation of molecular signatures, which are also an appropriate way to calculate several topological indices.

In the following part the most popular and "good-to-know" examples from the huge pool of topological indices will be discussed in detail. Nowadays, it is a very hard task to select those ones, which are highly recommended to know from the enormous amount of literature in this field. In the work of Randic and Basak the question has already been posed: do we need more molecular descriptors?[205] (Naturally we do, because we want to have as diverse of a toolbox as possible and to cover the various possible descriptions of molecules as fully as possible. It is worth noting that this is true for other fields of science as well, in fact it is the essential part of making progress in science. Although there are some novel topological descriptors in the literature, most of the widely used ones were developed in the second part of the last century.

Wiener index: The most well-known first-generation topological index. First generation means that the integers are based on such graph properties like topological distances.[206] It is calculated by the half sum of all distance matrix entries. It was defined originally in 1947 by Wiener,[207] but there are several modified versions of it in the literature, for example, Hyper-Wiener or All-path Wiener indices, etc.[184] Basically we can conclude that in the past century the Wiener index has not just become popular, but it was used for the development of several other descriptors. The basic equation is the following:

$$W = \frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N}\delta_{ij}, \tag{6}$$

where N is the number of atoms and δ_{ij} is the distance matrix entry (shortest possible way between atoms i and j).



A	1	2	3	4	5	6
1	-	**1**	0	0	0	0

4	2	1	2	0	1	1
5	3	2	3	1	0	2
6	3	2	3	1	2	0

Fig. 12 Adjacency (A) and distance (D) matrices of L-alanine. In the adjacency matrix, an entry $a_{i,j}$ is **1** if atoms i and j are connected with a bond and 0 otherwise, while an entry $d_{i,j}$ in the distance matrix is the topological distance of atoms i and j. Both matrices are symmetric (i.e., their information content can be represented by either their upper or their lower triangular alone).

Zagreb group index: Another first-generation topological index, which is based on the vertex degrees of the atoms (denoted with δ and representing the number of σ bonds of the atom) in the molecule graph. The two types of this index were published in 1975.[208]

$$M_1 = \sum_a \delta_a^2 \text{and } M_2 = \sum_b \left(\delta_i \cdot \delta_j\right)_b, \tag{7}$$

where a runs over the A atoms of the molecule and b over all of the B bonds of the molecule. δ_i, δ_j are the vertex degrees of the atoms incident to the considered bond.

The first Zagreb index (M_1) is nowadays also called *Gutman index*, and the second Zagreb index (M_2) is also a part of the *Schultz molecular topological index*.

Balaban J-index: It was called "averaged distance sum connectivity" in the original article of Balaban.[204] The formula is connected to the Randic index (see below), but here the vertex degrees are changed to the averaged distance sums, thus the equation was modified.

$$J = \frac{1}{\mu + 1} \sum_b \left(\bar{\sigma}_i \bar{\sigma}_j\right)_b^{-0.5} = \frac{B}{\mu + 1} \sum_b \left(\sigma_i \sigma_j\right)_b^{-0.5} \tag{8}$$

where B is the number of edges (bonds), μ is the cyclomatic number (the number of bonds that needs to be deleted to break all rings—which in the majority of cases is equal to the number of rings), σ_i and σ_j are the distance sums of the vertices i and j (i.e., the sum of the distances in the ith and jth row of the molecule's distance matrix), and $\bar{\sigma}_i = \sigma_i / B$ is the averaged distance sum of i.

Kappa shape index: these are second-generation topological indices, based on the work of Kier.[209,210] Second-generation indices are real numbers based on integer graph properties. This group of indices has current applications in drug discovery.[206]

The first, second, and third ordered shape attributes can be calculated in the following ways:

$$^1\kappa = n(n-1)^2 / \left(^1_0P_i\right)^2 \tag{9}$$

$$^2\kappa = (n-1)(n-2)^2 / \left(^2P_i\right)^2 \tag{10}$$

$$^3\kappa = (n-1)(n-3)^2 / \left(^3P_i\right)^2, \text{ when } n \text{ is odd} \tag{11}$$

$$^3\kappa = (n-3)(n-2)^2 / \left(^3P_i\right)^2, \text{ when } n \text{ is even} \tag{12}$$

Where ^lP_i represents the number of paths of length l in molecule i, and n is the number of atoms. The maximum and minimum values of ^lP_i are:

$$^1P_{\max} = \frac{n(n-1)}{2} \tag{13}$$

$$^1P_{\min} = (n-1) \tag{14}$$

The kappa shape index was modified with a specific correction (α value), which can be calculated as:

$$\alpha_X = \left(\frac{r_X}{r_{Csp^3}}\right) - 1, \tag{15}$$

where α is the decrement or increment of n for a noncarbon element (X), r represents the covalent radius of atom X relative to sp^3 carbon atom. The modified kappa shape indices can be found in the work of Kier and Hall[211] or the article of Estrada et al.[206]

Randic branching index: also called connectivity index, it was the first connectivity index, developed by Randic[212] more than 40 years ago. He introduced it at first for alkanes, with the intention to produce a graph invariant topological index. The equation is the following:

$$\chi = \sum_{\text{all edges}} \left(\delta_i \delta_j\right)^{-0.5}, \tag{16}$$

where δ_i and δ_j are the number of nonhydrogen atoms bonded to atoms i and j and forming an edge (bond) ij.

In the past decades several modifications of connectivity indices were created, such as *mean Randic index*, *modified Randic index* and *edge connectivity index* (ε).[213] Regarding these, the reader is referred to the encyclopedia of Todeschini.[184]

Other important topological indices are the E-state index[214,215] or the valence molecular connectivity index.[216,217]

There is a third generation of topological indices as well, which are real numbers based on real-number local vertex invariants (LOVIs). Some third-generation types are based on information theory, which is applied to nonsymmetrical matrices or terms of distance sums. Balaban was the pioneer of this topic in the 90s.[218–220]

3.14.5.1.3 Other 2D descriptors

3.14.5.1.3.1 Indicator variables

Indicator variables are one of the simplest or easiest way to describe constituents of a molecule, thus they have been applied in QSAR and related analyses for many decades. They can take positive, negative, or zero values based on the state of a property (characteristic), for example, it can indicate the *cis*, *trans*, or no *cis*/*trans* isomer forms in the following way: -1 represents the *cis* isomers, $+1$ represents the trans isomers, and 0 means the characteristic is not applicable, i.e., no *cis*/*trans* isomers. Some well-known examples for indicator variables are the following: Free-Wilson descriptors (*de novo approach*),[221] Fujita-Ban analysis (modified version of Free-Wilson analysis),[222] Hansch or Hansch-Free-Wilson models.[223] In the latter cases the models or descriptors contain not just indicator variables but also their combinations with other parameters such as physicochemical descriptors.

Indicator variables are also called dummy or Boolean descriptors if they define the presence or lack of structural elements (1 or 0). They can indicate the presence of hydroxyl, carbonyl, etc., groups or even the different positions of substituents like *ortho*, *meta*, and *para*.[224] (Note that they are closely related to substructure key-based fingerprints, see subsection "**Substructure Key-Based**.") A typical example for Boolean descriptors can be found in the work of Devillers in which the descriptors indicate biodegradability.[225]

In a related example, the recent work of Borysov et al. introduces the concept of extreme descriptors as "those variables that have the same value for almost all compounds and only a few values that are different from the common median." Although it is a common practice in QSAR modeling to exclude such descriptors from model building, the authors have shown that they can be useful for activity prediction in a standard binary classification setting, and for the identification of mislabeled compounds.

3.14.5.1.3.2 Thermodynamic descriptors

Thermodynamic descriptors are a smaller segment of 2D descriptors, with some of them using 3D parameters of the molecules as well (at least optionally). A typical example is the *heat of formation* (ΔH_f) which can be calculated based on the method of Singh et al.[226]

3.14.5.1.3.3 Molecular identification numbers

In his 1989 work, Burden has introduced the concept of "molecular identification numbers," calculated from the matrix representation of the connection table of a molecule (without hydrogens).[227] It is useful for substructure searching and diversity/similarity searching tasks. This approach was refined and further developed, first by Rusinko and Lipkus and later by Pearlman and Smith to produce what is now known as the BCUT approach.[228] BCUT descriptors are calculated as the first few highest and lowest eigenvalues of such matrices, with several options for the property that defines the diagonal elements (including, e.g., partial charges, polarizabilities, and hydrogen-bonding properties).[229]

3.14.5.2 3D Descriptors

3D descriptors are calculated from the 3D representation of the molecule. Thus, 3D chemical structures (conformations) are needed, which in best case can be bioactive conformations of the molecules in the field of drug design. 3D descriptors are as useful and better known as their 2D siblings, but they were typically developed later than 2D descriptors, and their calculation is more time-consuming and computationally demanding. 3D descriptors (like 2D ones) are frequently applied for QSAR and similarity searching. Some of the descriptors are sensitive to the position and orientation of the molecular structure, but some of them are insensitive for these properties (in other words, they are *alignment-independent* or *alignment-free*). The alignment of molecules is often a time-consuming step of the procedure and not necessarily unambiguous. 3D descriptors can be classified in several ways, for example, based on the work of Kunal et al.[185] or Todeschini and Consonni.[184] Some of the typical and frequently used descriptor classes in the literature are the electronic, size, volume, shape, Molecular Shape Analysis (MSA), Molecular Field Analysis (MFA), and receptors surface analysis (RSA) descriptors. The family of 3D descriptors is too large to cover every aspect of it, thus in the following subsections the most popular ones will be discussed.

3.14.5.2.1 Electronic descriptors

Electronic descriptors can be defined in the group of 2D descriptors as well (see the Hammett equation and related descriptors). They can be local or global descriptors, i.e., they can define the electronic properties either of specific regions of the molecule or the whole molecule.[230] Electronic charges and electron densities play an important role in different chemical reactions and physicochemical parameters. Charged partial surface area descriptors are also built up from electronic descriptors with the combination of shape and steric descriptors. One important class of electronic descriptors are *charge descriptors*, which contain for example the *total absolute atomic charge (electronic charge index) descriptor*. Some typical examples for electronic descriptors are detailed below.

(Electric) Dipole moment: This is a quantum-chemical electronic descriptor (or also classified as electric polarization descriptor), based on the strength and orientation of the interaction of the examined molecule with an external electrostatic field. The magnitude of the dipole moment and its components μ_x, μ_y, and μ_z are usually calculated. The SI unit of dipole moment is *coulomb meter (Cm)*, but for practical reasons, *Debye* ($\approx 3.34 \times 10^{-30}$ Cm) is used more frequently. The components of μ are calculated in the following way:

$$\mu_x = \sum_i q_i \cdot x_i, \tag{17}$$

$$\mu_y = \sum_i q_i \cdot y_i, \tag{18}$$

$$\mu_z = \sum_i q_i \cdot z_i, \tag{19}$$

where x, y, and z are the coordinates and q is the charge of atom i.

Highest occupied (HOMO) and lowest unoccupied (LUMO) molecular orbital energies: They are also quantum-chemical descriptors. ε_{HOMO} is the energy of the highest energy orbital that contains electrons. A molecule with high HOMO energy values can donate electrons easily. The ionization potential (IP) is closely connected to this: IP = -ε_{HOMO}. Sometimes the energies of the second or third highest occupied orbitals are also used as descriptors. These descriptors are closely related to the nucleophilicity of a molecule.

ε_{LUMO} is the energy of the lowest energy molecular orbital that does not contain any electrons. A molecule with low LUMO energy values can accept electrons easily, thus this is connected to the definition of electronic affinity (EA): EA = -ε_{LUMO}. In other words, it measures the electrophilicity of a molecule.

3.14.5.2.2 Size descriptors

In addition to 3D descriptors, size descriptors can also be simple ones like molecular weight or the number of bonds and atoms. We can also find size descriptors in the group of topological indices, but several 3D size descriptors exist as well. Size, volume, and shape descriptors are often connected to each other, for example, steric descriptors account for the size and the shape of the molecule. On the other hand there are some volume descriptors, such as van der Waals volume, which can also be considered a size descriptor (see later). A popular 3D example is detailed below.

Radius of gyration: This descriptor characterizes the distribution of atomic masses in a molecule[231] and provides an absolute measure of molecular compactness.[232] It is defined as:

$$R_G = \sqrt{\frac{\sum_{i=1}^{A} m_i \cdot r_i^2}{MW}} \tag{20}$$

where r_i is the distance of ith atom from the center of mass of the molecule, m_i means the atomic mass, A is the number of atoms, and MW represents the molecular weight.

3.14.5.2.3 Volume descriptors

Volume descriptors are either steric or size descriptors (or both). There are both experimental and theoretical ways for determining the volume of the molecules. Some examples of volume descriptors are listed here (van der Waals volume is discussed later in detail).

McGowan's characteristic volume (V_x): As a steric descriptor it is calculated as the sum of the atomic volume parameters in the molecule. It can be used for example for cavity term measurements. The equation is the following:

$$V_x = \sum_{i=1}^{A} w_i - 6.56B, \tag{21}$$

where w_i means the McGowan volume parameter and B is the number of bonds. McGowan atomic parameters for the calculations can be found in his article from 1987.[233]

Molecular volume index (MVI): This volume descriptor is based on the summation of van der Waals volumes of each groups of the molecule.[234] With the double summation, each pair of nonhydrogen atoms is involved. The equation is the following:

$$MVI = \sum_{i=1}^{A} \sum_{j=i+1}^{A} \frac{V_i^{vdw} \cdot V_j^{vdw}}{D_{ij}^2}, \tag{22}$$

where V^{vdw} represents the van der Waals volume of each group and D_{ij}^2 is the square of the topological distance of v_i and v_j.

Geometric volume: The atoms can be defined as point masses, which construct the solid geometric shape of the molecule. Thus the geometric volume is the volume of this solid geometric shape. In the concept of this volume, the atoms are interconnected and form some regular and irregular tetrahedrons. The volumes of these tetrahedrons are computable in analytical and numerical ways as well.[235]

3.14.5.2.4 Shape descriptors

Molecular shape descriptors are very useful in the modeling of physicochemical processes. This topic has a large scientific literature and in the past 30–40 years several novel shape descriptors were developed.[232,236] Some of the most popular ones are *shadow indices*, *WHIM shape descriptors*,[237] or *molecular shape analysis* descriptors (see below in details).

Shadow indices (Jurs shape indices): geometrical descriptors related to the size and shape of the molecule. The basic principle is the projection of the molecular surface onto three mutually perpendicular planes *XY*, *XZ*, and *YZ*.[230] The descriptors encode the conformation and also the orientation of the molecule. Rotational invariance is obtained by the previous alignment of the *X*, *Y*, and *Z* axes along the three axes of principal inertia.[238,239]

3.14.5.2.5 van de Waals parameters

Another interesting part is the *van der Waals molecular surface (or area)* (SA^{vdw}), which can be included in the aforementioned descriptor groups as well. It is also called *total molecular surface area* (TSA), and it is connected to the hard-sphere model. The total van der Waals surface is calculated as the sum of the atomic van der Waals surfaces. This is related to binding, solubility, etc.

The *van der Waals volume* (V^{vdw}) is the volume of the space inside the van der Waals molecular surface. The van der Waals volume is closely connected to the *van der Waals radius* (R^{vdw}). The van der Waals radius is the distance, where the attractive and repulsive forces between the two nonbonded atoms are equal. Its calculation was originally described by Bondi,[240] but less time-consuming calculations have been developed as well by Zhao et al.[241] There is a vast literature in this field between the 1980s and 1990s, for instance molecular mechanics based methods,[242] as well as other techniques.[243]

3.14.5.2.6 Molecular Shape Analysis descriptors

Molecular Shape Analysis (MSA) is a common technique in QSAR analysis, which combines the molecular shape similarity and commonality measures (with other descriptors) to determine the similarities between molecules and build appropriate QSAR models.[244] In this section we do not cover MSA QSAR in detail, only the commonly used molecular shape similarity descriptors (MSA descriptors). Molecular shape similarity is applied to the comparison of 3D molecular shapes, which are represented by atomic properties. On the other hand, molecular shape commonality is using conformational energy and molecular shape together to measure molecular similarity. The basic concept of MSA in QSAR analysis is that the shape of the molecule is related to the binding site cavity (or pocket), thus it is related to biological activity as well. Some popular molecular shape similarity descriptors are listed below:

Common Overlap Steric Volume (COSV): It represents the overlapping volume of two superimposed molecules.[245] Van der Waals volume of the molecules is used for the determination.

$$M_0(i,j) \equiv V_0(i,j) = V_i \cap V_j \tag{23}$$

Non (Common) Overlap Steric Volume (NCOSV or V_{non}): It is defined as the volume of molecule *i*, which does not overlap with the volume of the reference molecule *j*. (Thus, it can be related to steric misfit.) Basically V_{non} is the difference between the $V_{i,j}$ composite steric volume of two aligned molecules and V_j (reference molecule).[245]

3.14.5.2.7 Molecular Field Analysis descriptors

Molecular Field Analysis (MFA) is also a frequently used technique in QSAR. It is a grid-based QSAR technique, mostly applied in Comparative Molecular Field Analysis (CoMFA) based on the work of Cramer et al.[246] (Here, we only briefly mention CoMFA, as a detailed introduction would be out of the scope of this chapter.) The molecular field can be represented by a 3D rectangular grid. MFA analysis is based on the calculation of interaction energies (steric and electrostatic interactions in the case of CoMFA) between some probes (H^+ or CH_3) and the molecule, represented by a rectangular grid. Thus the field of molecules can be described by MFA grids, and the energies associated with MFA grid points may serve as inputs (descriptors) for the calculation of QSAR models.

3.14.5.2.8 Receptor Surface Analysis descriptors

Receptor Surface Analysis (RSA) is another modeling method, primarily for such cases when the 3D structure of a receptor is unknown.[247] A hypothetical model can be created with this predictive tool for the receptor site. On the other hand, RSA descriptors are also useful in QSAR model building when the receptor surface is known. The RSA approach clearly differs from pharmacophore approaches, as it captures information about the receptor instead of the ligands. From receptor surface models, one can derive descriptors, which provide 3D information about the (steric or electrostatic) interaction energies between each point of the receptor surface and the ligand. RSA descriptors can be combined with other 3D or 2D descriptors for QSAR analysis. Some typical examples for RSA descriptors are *IntraEnergy*, *InterEnergy*, *StrainEnergy*, *MinIntraEnergy*, etc.[185]

3.14.5.2.9 3D descriptor families

3.14.5.2.9.1 WHIM descriptors

Weighted Holistic Invariant Molecular (WHIM) descriptors are based on statistical indices calculated on the projections of atoms around the *x*, *y*, and *z* axes.[237] The algorithm involves a principal component analysis (PCA) of the centered molecular matrix (coordinates of the molecule). Depending on the six different weighting schemes (such as atomic mass, van der Waals volume, etc.), different covariance matrices (and principal components) can be built. Directional WHIM descriptors can also be calculated. Typical groups of them are size descriptors (constructed from the eigenvalues of the covariance matrix), shape descriptors, symmetry descriptors, density descriptors, etc. In summary, there are 66 directional WHIM descriptors (11 for each weighting scheme). Global WHIM descriptors are calculated as combinations of directional WHIM descriptors.

3.14.5.2.9.2 GETAWAY descriptors

GETAWAY (GEometry, Topology, and Atom-Weights AssemblY) descriptors are based on the molecular influence matrix (**H**), which is calculated in the following way:[248]

$$\mathbf{H} = \mathbf{M} \times \left(\mathbf{M}^{\mathbf{T}} \times \mathbf{M}\right)^{-1} \times \mathbf{M}^{\mathbf{T}}, \tag{24}$$

where **M** represents the molecular matrix (containing the centered Cartesian coordinates of the atoms of the molecule).

The diagonal elements of the **H** matrix are called leverages. The combination of the molecular influence matrix with geometry matrix (**G**) is called the influence/distance matrix (**R**). It is very important because a set of GETAWAY descriptors are calculated from both of them based on different concepts and matrix operators. The GETAWAY approach also employs different atom weighting schemes, similar to WHIM. Some examples are: geometric mean of the leverage magnitude (H_{GM}), total information content on the leverage equality (I_{TH}), standardized information content on the leverage equality (I_{SH}), mean information content on the leverage magnitude (HIC), average row sum of the influence/distance matrix (RARS), etc.

There is another group of GETAWAY descriptors (denoted as R-GETAWAY), which combines the information mentioned above with geometric interatomic distances in the molecule.

3.14.5.2.9.3 EVA descriptors

EVA or EigenVAlue descriptors are based on the extraction of chemical structures from mid- and near-infrared spectra. The basic concept was developed in 1997 by Ferguson et al.[249] The fundamental molecular properties can be characterized potential energy functions (vibrations). The normal coordinate eigenvalues (and eigenvectors) from vibrational frequencies or atomic displacements can be calculated with the use of quantum and molecular mechanical methods.

EVA descriptors are 3D descriptors providing information about molecular size, shape, and electronic properties. A modification of the original conception is EEVA (Electronic EigenVAlues), which defines a set of vectorial descriptors.[250,251] Here the eigenvalues of the Schrödinger equation are used instead of the vibrational frequencies.

3.14.5.2.9.4 MEDV (MEDV-13) descriptors

The Molecular Electronegativity Distance Vector (MEDV) is a vectorial descriptor, which includes 91 terms that contain information about the relative electronegativities.[252] The electronegativities are represented by the modified E-state indices and topological distances between each possible pair of 13 atom types. In the first step of the MEDV descriptor calculation, one has to assign each atom in the molecule to one of the aforementioned atom types. The atom types are based on the most frequently occurring atoms in organic molecules and also the number of bonded nonhydrogen atoms (vertex degree).[230] The single molecular descriptor can be calculated with this equation:

$$h(u,v) = \sum_{i\in u}\sum_{j\in v}\frac{S_i^* \cdot S_j^*}{d_{ij}^2}, \quad u,v = 1,\ 2,\ \ldots,\ 13, \tag{25}$$

where u and v are the atom types, S^* represents the modified E-state index, d_{ij} is the topological distance between v_i and v_j vertices.

There is also an extension of MEDV-13, called Molecular Holographic Distance Vector (MHDV).[253] It is developed to describe more specific molecular structures like peptide sequences, which contain heteroatoms and multiple bonds.

3.14.5.2.9.5 GRIND descriptors

Grid-Independent Descriptors (GRIND) are based on molecular interaction fields (MIF), which can be calculated with the GRID method and software[254] (or other programs).[255] The calculation of the descriptors involves two main steps. The first step is the computation of molecular interaction field (MIF). The second step involves a particular type of autocorrelation transform to create alignment-independent variables. On the other hand, we can also construct the steps in the following way: (a) computing the MIF, (b) filtering the MIF, and (c) encoding the virtual receptor site (VRS) into GRIND (GRIND encodes geometrical relationships between the VRS regions). The molecular descriptors can be used for the creation of "correlograms" and also for different types of chemometric analysis. The original MIF descriptors can be generated with appropriate software from the autocorrelation transform.

3.14.5.2.9.6 VolSurf descriptors

VolSurf descriptors have a quite similar basis to G-WHIM and GRIND descriptors. These descriptors also encode information about molecular interaction fields (MIF) with a GRID force field parametrization.[256] The final descriptors are alignment independent and are related to molecular size or shape, distribution of hydrophobic or hydrophilic parts of the molecule, etc. Different probes such as H_2O, DRY (hydrophobic), or O (carbonyl oxygen, represents hydrogen-bonding donor groups) are used for the calculation of interaction fields. Some typical descriptors are: water-excluded volume (V) with H_2O probe, accessible surface (traced also with H_2O probe) of the water interaction field, rugosity (R), polarizability (POL, traced with DRY probe), elongation (E), volume of the interactions with the probe O (Wp1–Wp8), Integy moments (INTEraction enerGY moments), etc.

3.14.5.3 4D and Other Special Descriptors

3.14.5.3.1 4D descriptors

4D descriptors are also grid-based descriptors (but they are not derived from molecular interaction fields.) The fourth dimension represents ensemble sampling or conformational flexibility, which is defined by the *conformational ensemble profile* (CEP). The CEP is calculated with molecular dynamics (MD) simulations. 4D descriptors help identify the active conformations of the flexible molecules, and they are also useful tools in alignment problems. The pioneering work of Hopfinger et al. in 1997[257] has introduced 4D

descriptors to QSAR analysis. Hence, 4D descriptors are among the youngest members of the family of (now thousands of) molecular descriptors. There are two forms of 4D QSAR: receptor dependent and receptor independent.[258]

4D descriptors can be assigned to the occupancy frequencies of the different atom types in the cubic grid cells during the molecular dynamics simulation.[259,260] The generation of the descriptors has some basic steps, which are discussed here in detail. First the molecular structures are generated with a conformational search, and the conformers with the minimum energies are kept as the initial structures. The cell grid (with a default grid spacing of 1.0 Å) is constructed based on the largest compound in the data set. In the next step the interaction pharmacophore elements (IPE) are introduced. Every atom of each molecule can be classified into one of the IPE classes: "any type" or generic, nonpolar (NP), polar-positive charge (P+), polar-negative charge (P−), hydrogen-bond acceptor (HA), hydrogen-bond donor (HB), and aromatic (Ar). These types are created based on the interactions between the active site and the pharmacophore groups. The third step of the process is the estimation of the conformational ensemble profiles (CEP) with MD simulations. After that, each conformation of the CEP for each molecule is implemented in a reference grid cell based on the trial alignment. Finally, the grid cell occupancy descriptors are calculated from CEPs. This is important because we use a conformational ensemble profile of each compound instead of using only one starting conformation (which is the essence of the fourth dimension).

3.14.5.3.2 Other special descriptors and approaches (outlook)

The list does not stop at 4D descriptors, as one can easily find interesting articles about the application of higher (such as five or six) dimensional descriptors.[258] These are connected more to QSAR and related topics, thus they are only briefly mentioned. Five dimensional QSAR descriptions are calculated with the Quasar technology (and software) and are an extension of the 4D siblings with the multiple representation of the topology of the quasiatomistic receptor surrogate.[261,262] Another dimension is introduced in 6D descriptors for QSAR modeling, enabling the simultaneous consideration of different solvation models. It can be achieved, for example, by mapping parts of the surface area with solvent properties.[263]

Another interesting field is the discrimination of molecular shapes. Gaussian approximations can be used to optimize the alignment of two molecules, but Gaussian functions can also provide very good and realistic representations of molecular shapes.[264] The rapid overlay of chemical structures (ROCS) program applies the atom-centered Gaussians for the discrimination and optimal alignment of molecules.[265,266] ROCS alignments can be applied not just for similarity searching and virtual screening, but also for 3D QSAR and SAR analyses. Further examples of shape-based approaches include the normalized PMI (principal moments of inertia) ratios introduced by Sauer and Schwarz,[267] and Ultrafast Shape Recognition (USR), which employs three statistical moments (average, standard deviation, and kurtosis) of atomic distances in four reference locations, providing a vector of 12 shape descriptors for each molecule.[268]

3.14.6 Similarity—Dissimilarity Measures, Distance Metrics

The old adage dates back to the ancient Roman-Greek period: "similis simili gaudet" [like rejoices in like] and corresponds to the observation that similar entities behave similarly.

In the scientific domain of (medicinal) chemistry, there are some common formulations of the similarity principle, for example:

(i) Structurally similar molecules are presumed to exhibit similar properties and similar biological activities.[269]
(ii) "Molecular similarity in descriptor space is often called the "neighborhood principle" or "neighborhood behavior axiom."[270]
(iii) Other scientists formulate the same principle as the "concept of similarity", where molecules may be grouped according to their biological effects or physicochemical properties.[271]
(iv) "Structure–property similarity principle": similar structures generally have similar properties.[272]

The similarity principle plays a ubiquitous role in rational drug design, lead discovery, synthesis design, molecular diversity analysis, and compound optimization (e.g., optimization of ADMET properties, that is, similar absorption, distribution, metabolism, excretion, and toxicity). Virtual screening is able to find similar molecules from large databases. Finding a "patentable" compound with a desired property value is an important aim to be pointed out.

Naturally there are many examples violating the similarity principle. A small change in the molecular structure (changing the configuration of a stereo center, introducing a small molecular weight substituent, etc.) can lead to a dramatic increase (or decrease) in biological activity (e.g., dramatic difference in the toxicity of dioxins, or the carcinogenicity of polycyclic aromatic hydrocarbons (PAHs), etc.). On the other hand, a lot of compound classes (steranes, amphetamines, sulphonamides, etc.) possess very similar biological activities. If there is insufficient information about a new compound, the scientific community should resort to similar compounds and make estimations from "similar" molecules.

Similarity analysis can be simplified according to the following: First a molecule should be represented with an appropriate computational construct, such as a fingerprint or a set of descriptors (see Sections "**Molecular Fingerprints**" and "**Numerical Descriptors and Similar Representations**"). Then, a similarity measure (metric) should be applied for quantifying the similarities between pairs of molecules, and finally an algorithm can be applied for, e.g., clustering the molecules according to their biological activity, properties, etc.

As the available computing power has dramatically increased in recent years, application of similarity methods to large databases became feasible even with moderate computing resources. The goal of such calculations is usually either the identification of

Table 5 Section "Similarity—Dissimilarity Measures, Distance Metrics" at-a-glance

Subsection	*Examples/comments*
Common Measures of Similarity	Tanimoto, Euclidean, Cosine, Tversky, etc.
Similarity Fusion	MAX, MIN, SUM, RRF fusion rules, etc.
Clustering Algorithms	*k*-nearest neighbors, *k*-medoids, etc.
Similarity Measures for Special Tasks	See below
Symmetric field-based	Quantum chemical similarities
1D similarity	Similarity measures for 1D objects
Graph-based	Graph and tree-based metrics, including business similarity measures
Semantic	Text-based similarity measures
Supervised	Implementations and applications related to bioactivity, e.g., SALI
Chemometric/Spectral	Similarities for high-dimensional data, e.g., (N)IR spectra
Fuzzy	Similarities between fuzzy sets
Other	Interesting examples/applications from diverse fields

molecules that are similar to one or more reference molecules, or the compilation of a subset of molecules that are as diverse as possible. (The latter application is particularly important in early hit discovery where diverse molecular databases are desired.) The reader is referred to some straightforward reviews about similarity and diversity in the cheminformatics field.[270,273–275] For the present section, we provide a brief overview in Table 5.

3.14.6.1 Common Measures of Similarity and Dissimilarity (Distance)

Similarity and dissimilarity (distance) are used more or less interchangeably, in spite of some important differences, e.g., their directions are reversed, their scales are different by definition, etc. It is also important to note that there is an inherent asymmetry in the distributions of these metrics.

Holiday et al. have used three different clustering approaches and distinguished three types of measures: distance metrics, association coefficients, and similarity (correlation) coefficients.[276]

A distance metric $D_{A,B}$ between objects (molecules) A and B should obey four rules:[277]

$$\text{Distance values } (D) \text{ must be positive for non} - \text{identical objects}: \; D_{A,B} > 0 \tag{26}$$

$$\text{The distance from an object to itself must be zero}: D_{A,A} = D_{B,B} = 0 \tag{27}$$

$$\text{A distance value must be symmetric}: D_{A,B} = D_{B,A} \tag{28}$$

$$\text{A distance metric must obey the } \textit{triangular inequality}: D_{A,B} \leq D_{A,C} + D_{C,B} \tag{29}$$

If a distance coefficient fails to obey either of these four rules, it cannot be called a metric.

Similarity measures (S) are reversely scaled (the higher the more similar) as opposed to dissimilarity or distance (the lower the more similar). A similarity measure has to obey three rules[278]:

$$\text{Similarity values for non-identical objects must be}: 0 < S_{A,B} < 1 \tag{30}$$

$$\text{The similarity of an object to itself must be unity}: S_{A,A} = S_{B,B} = 1 \tag{31}$$

$$\text{A similarity value must also be symmetric}: S_{A,B} = S_{B,A} \tag{32}$$

(It should be noted that Eq. (6) is erroneous in the original publication.)

Similarity and distance values are almost always nonnegative, but their scales differ greatly: $S \in [0; +1]$ (or $S \in [-1; +1]$ for some correlation-based similarity definitions) and $D \in [0; +\infty]$. In practice, an inherent asymmetry is present in similarity/dissimilarity calculations in terms of the resulting value ranges. It is relatively simple to convert from similarities to dissimilarities:

$$D_{A,B} = 1 - S_{A,B}, \text{such special distances will bear the constraint of } D \in [0; +1]. \tag{33}$$

However, conversion in the opposite direction is somewhat less straightforward, as similarity values should be recalculated between zero and one, while distances can be arbitrarily large. Thus, a suitable conversion rule is:

$$S_{A,B} = \frac{1}{1 + D_{A,B}} \tag{34}$$

It is easy to see that similarity values calculated with this equation will always have a value between 0 and 1 (with 1 corresponding to identical objects, where the distance is 0). It should be noted that the typical value ranges of different similarity metrics can be different,[279] even though they cannot fall outside of the predefined range (i.e., $0 \leq S \leq 1$).

As distances are measured on different scales, their comparison should be preceded by appropriate scaling. Four basic scaling methods are to be used: (i) range scaling (between 0 and 1), (ii) standardization (autoscaling, i.e., centered and scaled to unit standard deviation), (iii) rank transformation, and (iv) normalization (scaled to unit length).

Table 6 summarizes the most frequently used similarity and distance measures. The first 10 items in the table are distance measures, and the remaining ones are similarity coefficients. For more binary similarity measures, the reader is referred to the work of Todeschini et al.[280] Additionally, several graph-based similarity measures have been proposed in the literature for molecular similarity calculations.[281,282] Some more specific similarity measures are defined in part 5.5.

The Minkowski distance is a generalization of distances; if $p=q=1$, it equals the Manhattan distance, whereas $p=q=2$ equals the Euclidean distance. The Tversky coefficient can also be considered as a generalization of similarity coefficients. The α and β parameters are always nonnegative, but in medicinal chemistry applications, they are usually set within the unit interval [0, 1]. If $\alpha \neq \beta$, then the Tversky coefficient is asymmetric. The case $\alpha=\beta=1$ equals the Tanimoto similarity. Similarity indices are intrinsically symmetric in nature, but asymmetric indices have some advantages: asymmetric forms allow for measuring and modulating the similarity of one molecule in the context of another, i.e., they have the potential of alleviating the size dependency often observed in chemical similarity searching. Inspired by Tversky's work, Mestres and Maggiora have defined an entire family of field-based molecular similarity indices.[283]

Distance and similarity metrics have been the subject of several comparative studies focusing on their applications in several fields. Bender et al. have compared a vast selection of molecular fingerprints and visualized their similarities (i.e., the similarities between the methods themselves) with principal component analysis.[90] Additionally, they have included some of the fingerprints in combination with the Cosine similarity metric (replacing the Tanimoto coefficient). Sum of ranking differences (SRD)[284] corroborates the authors' original observation that the exchange of the similarity metric from Tanimoto to Cosine does not affect the ranking behavior of these fingerprints significantly (see **Fig. 13**). In addition, all of the examined fingerprint methods have ranked the datasets significantly differently than random ranking.
