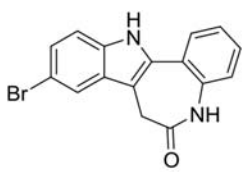
The most recent studies in this area include the use of polysialic acid-neural cell adhesion molecule (PSA-NCAM)-positive neural precursor cells derived from hESCs in a rat stroke model,[207] hiPSCs in modeling and therapy development in epilepsy.[208] The use of GABAergic interneuron transplants, which migrate tangentially from the subcortical forebrain into the cerebral cortex and become synaptically connected with host circuitry, have also been recently reported in the study of disease mechanisms and toward the development of cell-based therapies,[209] as has the transplantation of cholinergic neuron-like cells into APP/PS1 transgenic mice, a model for Alzheimer's disease.[210] Earlier studies included those on neuropathic Gaucher's disease using patient-derived iPSCs,[211] on neurodegeneration using stem cell-derived motor neurons and astrocytes with activated microglia,[212] on PD using iPSC-derived dopaminergic neurons,[213] and on neuroactivity/neurotoxicity with stem cells under the control of neural cell-specific tetralin-α promoter.[214] It has also been shown that cortical neurons can be generated from iPSCs of patients harboring mutations of a key protein involved in PD, namely α-synuclein. The protein NAB2 that affects the E3 ubiquitin ligase Nedd4 was identified as being able to reverse the pathological phenotypes in these neurons.[215]

Chandross et al.[216] have recently reported a high-content phenotypic screening strategy to identify molecules able to elicit the differentiation of oligodendrocyte precursor cells, which could be of use in the treatment of multiple sclerosis. The screen was capable of testing a library of 73,000 compounds from which 22 nontoxic compounds were identified that were capable of selectively stimulating primary rat oligodendrocyte precursor cells but not muscle myoblast cells. A different approach to the production of oligodendrocytes has been reported by Hickman et al.[217] who have described a three-dimensional environment in which human multipotent progenitor cells from umbilical cord were differentiated in the presence of noradrenaline to give committed oligodendrocytes that expressed myelin basic protein.

Previous mention has been made of the rapidly progressing neurodegenerative disease ALS, which is characterized by the death of motor neurons and for which there is currently no effective treatment. However, Rubin has described a high-throughput screen using motor neurons from wild-type and mutant SCPD1 mouse ESCs, which has shown that kenpaullone ((74), **Fig. 51**), a dual inhibitor of GSK-3 and HGK (an STE 20 serine/threonine kinase family member also known as MAP4K4), is able to prolong the survival of both types of motor neurons and, most interestingly, improved the survival of human motor neurons derived from ALS patient-derived iPSCs.[218]

A key necessity for studies of this kind is the reproducible expression of the necessary cell lines and a technique for the differentiation of hESCs and hiPSCs using small molecules including dorsomorphin (43), SB431542 (12), CHIR99021(5), and purmorphamine (28) to early neural progenitors has been described. These NSCs are robust, exhibit immortal expansion, and have the potential to clonally and efficiently differentiate into neural tube lineages, including motor neurons and midbrain dopaminergic neurons as well as neural crest lineages such as peripheral neurons and mesenchymal cells.[219]

Finally and of particular interest to medicinal chemists is the review by Kundu[220] on the range of small molecule inhibitors of epigenetic enzymes which also have been shown to be involved in the regulation of adult neurogenesis.



(74)

Fig. 51 Chemical structure of Kenpaullone (74).

1.13.2.4 Muscle Regeneration Using Small Molecules

There is a vast array of diseases associated with the loss of muscle tone, or degeneration of muscle fibers including ischemic heart disease and cachexia (muscle wasting often found in cancer patients and suffers of COPD, AIDS, and other diseases) through to less common genetic diseases such as Duchenne and Becker Muscular Dystrophies (DMD, BMD). The reversal of muscle loss via the use of stem cells as described in other sections of this article would appear to be an attractive therapeutic option. A comprehensive review describing a wide range of compounds that repair or replace defective muscle tissue has recently been published.[221] However, there are currently no small molecule drugs targeting muscle stem cells, which have been approved for that specific purpose and, more importantly there are, as yet, no muscle-focused cell-based therapeutic agents on the market, though a monoclonal antibody, bimagrumab is making progress in clinical trials of sporadic inclusion body myositis.[222] There is, though, an active body of research into agents that can affect muscle repair and a considerable number of examples of these have been described in the literature.

1.13.2.4.1 Muscle-based applications of small molecule stem cell modulators

During embryonic development, myoblasts, that is, progenitor cells that differentiate to produce muscle cells, fuse to form multinucleated fibers called myotubes en route to muscle fibers. Myoblasts can either undergo an asymmetric cell division or directly differentiate into myotubes, but it is not clear what controls this choice in vivo. In emerging stem cell-based therapeutic approaches to muscle disorders, initial publications have focused very much on the relatively small, but growing, number of well characterized promiscuous small molecules, which have been described as being able to modulate stem cell fate in other target tissues. For example, a number of small molecules including the GSK3β inhibitor BIO ((19), Fig. 52), a p38 MAPK inhibitor (SB203580, (66)), a broad spectrum GPCR activator (lysophosphatidic acid, (106)), and the adenylyl cyclase inhibitor SQ22536 (107) have been described as inducing dedifferentiation to multipotent cells from myoblast-like cells.[223,224] Furthermore, the small molecules dorsomorphin (43) and its derivative LDN193189 (56), both BMP/Activin receptor inhibitors have been described by Knaus and coworkers as inhibiting myostatin (GDF8, growth differentiation factor 8) signaling, with the result of promoting differentiation of myoblasts and their ensuing contractile activity.[225]

In related work, intriguing data has been published very recently by Wagers et al.,[226] in which the administration of a related protein growth differentiation factor 11 (GDF11) was reported to induce functional recovery in the skeletal muscle of aged mice and restore genomic integrity in muscle satellite cells. Indeed, the authors speculate that increased levels of GDF11 in aged mice may act on muscle satellite (stem) cells to restore regenerative function and induce a more promyogenic niche. No small molecules having a corresponding effect have yet been described, although this potentially represents an attractive medicinal chemistry strategy for muscle regeneration.

In a separate study, Ryan et al. have demonstrated that multiday treatment of hESCs with the pleiotropic stem cell modulator retinoic acid ((108), Fig. 53) leads to an increase in expression of the myogenic regulatory factor, which they correlated with an enhanced progenitor population and increased skeletal myogenesis.[227]

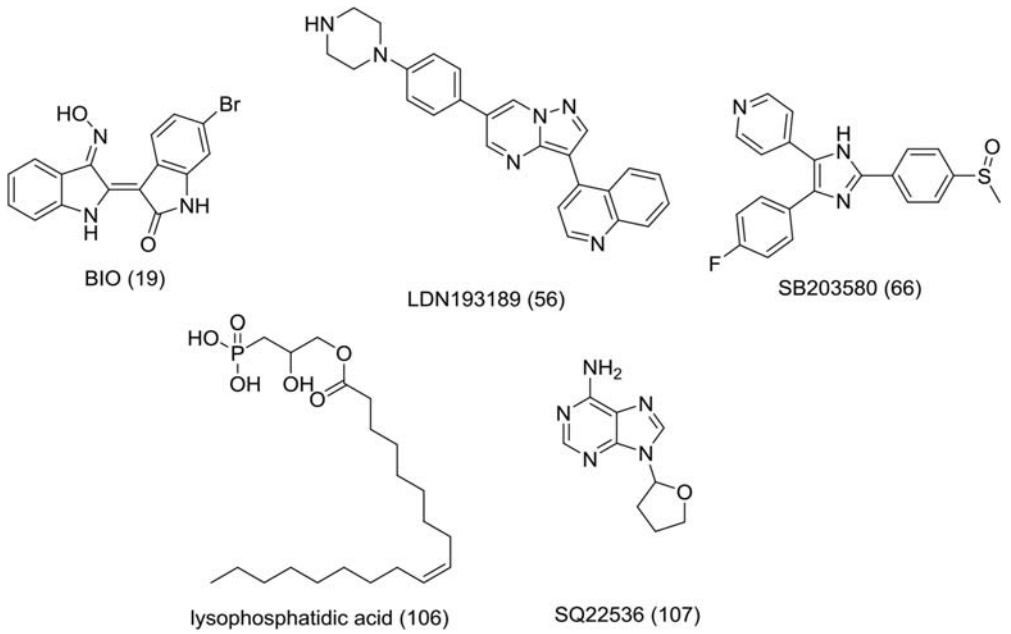


Fig. 52 Compounds reported to promote the differentiation of myoblasts.

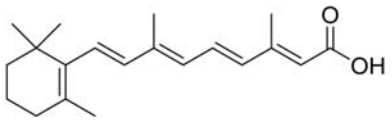
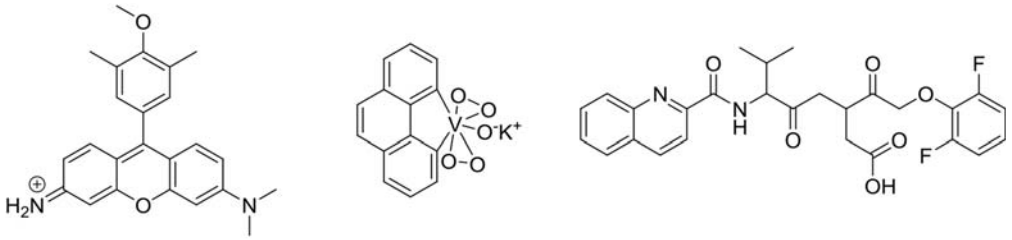


(108)

Fig. 53 Chemical structure of retinoic acid (108).



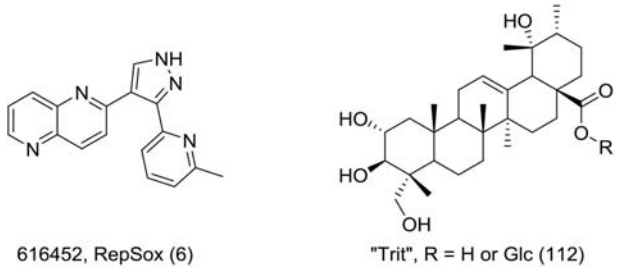
B25 (109) Bpv(phen) (110) Q-VD-OPh (111)

Fig. 54 Compounds reported to dedifferentiate myotubes to progenitor myogenic cells.

A mitochondria-targeted fluorophore has also been reported as being able to block muscle myoblast differentiation.[228] Interestingly, the authors had intended to undertake a screen to identify biosensor molecules, which were capable of distinguishing between stages of muscle differentiation through reporting on differential mitochondrial activity. However, the screen resulted in the identification of the rosamine derivative B25 ((109), **Fig. 54**), which acts to reverse myotubes to a dedifferentiated myoblast-like mononuclear phenotype. Unlike the previously described myoseverin (14), compound (109) did not appear to act via disruption of microtubule stability or modulation of the cell cycle, but rather through a mechanism involving activation of NF-kB signaling. Phosphatase and apoptosis inhibitors BpV(phen) (110) and Q-VD-OPh(111) used in combination have recently been documented as also being able to dedifferentiate myotubes to progenitor myogenic cells with high efficiency (12%).[229] Moreover, the resulting progenitor muscle cells were shown to be functionally competent, and capable of self-renewal and redifferentiation. The latter was demonstrated both in vitro, and, most interestingly, in vivo using SCID mice. Other researchers have shown that the same inorganic chemical, BpV(phen) (110), can also dedifferentiate myoblast cells to a multipotent circulating phenotype as evidenced through phenotypic and gene expression analyses of their progeny.[230]

The Type 1 TGFβ inhibitor (616452, also known as RepSox, (6), **Fig. 55**) has been shown to restore regenerative function to stem cells in muscle in vivo in aged mice. Inhibition of TGFβ following administration of (6) was supported by the observed reduction in the level of, for example, pSmad-3. This study provides additional evidence to support the role of TGFβ modulation in manipulating regenerative potential for muscle.[231] In a separate study of the biological activity of natural product extracts from *Geum japonicum*, a pure fraction was found to stimulate activation and differentiation of quiescent myoblast precursor cells to myocytes in vitro. Subsequent in vivo administration of the active principal "Trit" in a rat model of muscle injury led to reported improvements in myofiber regeneration and more efficient muscle repair, although no comparative quantitative data was presented.[232] Structural elucidation of the active principal was found to correspond to a previously described triterpenoid natural product, although it was unclear whether the corresponding carboxylic acid or its glycone conjugate was isolated, and many of the sterochemical features remain undefined (112).[233]

A recent publication has examined the effect of treating muscle-derived stem cells using in vitro assays with a range of nutritional supplements.[234] Of the 16 supplements tested, a significant number was found to enhance either proliferation



616452, RepSox (6) "Trit", R = H or Glc (112)

Fig. 55 In vivo muscle repair agents.

(ten) or differentiation (four). This is an intriguing finding, but further studies on the precise modes of action associated with these observations would appear to be warranted.

1.13.2.5 The Pancreas

1.13.2.5.1 Chemical manipulation of pancreatic regeneration

Diabetes mellitus, an endocrine disorder in which the natural control of blood glucose levels is compromised, is separated into two types. Type I is the result of an, as yet unexplained, autoimmune attack on the β-cells of the pancreas, which are responsible for the production of the hormone, insulin, and requires life-long daily subcutaneous injections or infusions of insulin for survival. The much more common Type II diabetes is a metabolic disorder in which insulin production is compromised along with the target cells becoming resistant to insulin signaling and probably arises from genetic disposition, obesity, lifestyle, and food choices. It can often be controlled by diet and/or hypoglycaemic drugs but does sometimes require insulin injection. In the pancreas of nondiabetic healthy adults, there are 1–2 g of β-cells dispersed among a vastly greater number of cells that release digestive enzymes into the gastrointestinal tract. A regenerative medicine approach to treatment would replace damaged cells with healthy, functioning ones. It is therefore an archetypical example of the regenerative medicine approach; a clear cause and a clear need for tissue/cell replacement. Of course, to achieve this requires a detailed knowledge of the cell biology, and ideally the biochemistry, of the β-cell.

While Type I diabetes has been treated successfully by transplantation of all or part of the pancreas by tissue recovered from cadavers, this lies outside the scope of this article that concentrates on the use of new β-cells generated either ex vivo or in vivo.

1.13.2.5.2 Ex vivo generation of replacement β-cells

1.13.2.5.2.1 In vitro β-cell expansion

In a series of three detailed papers, Stewart et al.[235–237] have summarized the current understanding of intracellular signaling pathways coupled to proliferation in pancreatic β-cells in both man and rodents. The knowledge of the human situation is, unfortunately, much less complete than that of the rodent but in both species a cell surface receptor specific solely to the β-cell has yet to be identified. While this means that any proliferating agent could, in principle, have similar effects on other cell types in the pancreas, it will be recalled that medicinal chemistry has a good history of finding selective agents in other therapeutic areas. It is also becoming clear that there are very significant differences between rodent and human β-cells; differences that, inter alia, include rats having two insulin genes and humans only one, different glucose transporters, different TFs and different pancreatic architecture. In the human cell, the cell cycling molecules are not found largely in the nucleus but in the cytoplasm for reasons that are not as yet clear. Finally mitogenic signaling pathways are difficult to activate in human cells and mediate only weak effects. Thus the extrapolation of information derived from the study of rodent cells to human ones may not be straightforward. While continually growing transformed rodent insulinoma cell lines are available for study, it is only recently that equivalent human lines have been developed. Thus the creation of a conditionally immortalized human β-cell line, EndoC-βH2, has been reported and should provide more direct information on the cell biology of this cell line.[238]

This is not to say that studies on rodent cell lines have not been useful. In one of the earliest studies Schultz et al. studied the effect of a library of ~800,000 compounds on the growth of a reversibly immortalized mouse β-cell line R7T1 using a luminescent assay to measure intracellular ATP content as a measure of viable cell number.[239] Approximately 80 of the compounds showed significant activity and these included phorbol esters, which probably act by activation of protein kinase C isoenzymes, and small molecules identified as Wnt activators (eg, (113), Fig. 56) or L-type calcium channel agonists (eg, (114)). Further work identified WS6 (115) as being able to induce proliferation of primary rodent and human islets in vitro and, importantly, to increase β-cell numbers in vivo and to correct hyperglycemia in a mouse model of β-cell ablation.[240] Affinity chromatography using a biotin-conjugated analog of WS6 revealed Erb-binding protein and IkB kinase as binding partners, the latter of which plays a role in regulating the NFkB pathway proinflammatory stress response.

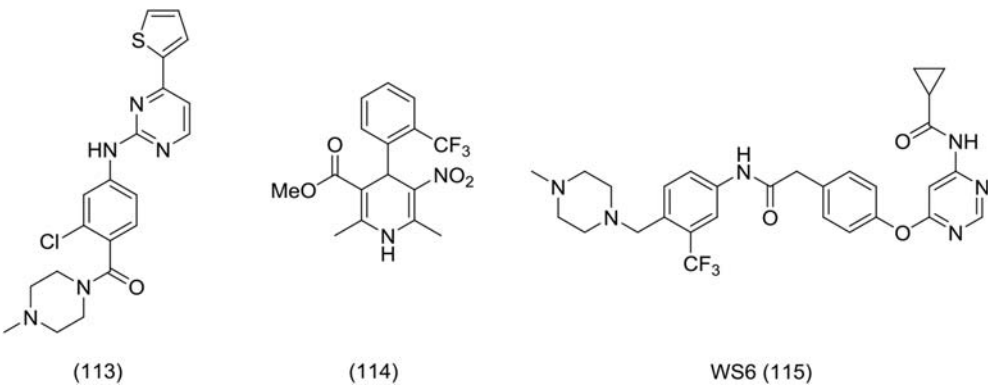


Fig. 56 Compounds reported to affect the growth of an immortalized mouse β-cell line.

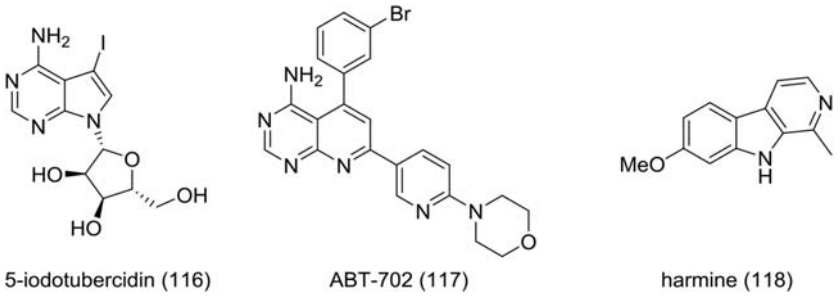

Fig. 57 Compounds reported to enhance the proliferation of β-cells.

Another group has shown that inhibitors of the adenosine kinase pathway, especially 5-iodotubercidin ((116), Fig. 57) and ABT-720 (117) enhance proliferation of β-cells from the islets of rat, mouse, and pig.[241] More recently, Sarvetnic et al.[242] have shown that WS6 stimulates both α- and β-cell proliferation in human islets in vitro while maintaining the differentiated β-cell phenotype. The use of a human hepatocyte cell line HepG2 that expresses a luciferase reporter under control of the human *MYC* gene (a regulator gene which codes for TFs) in a high-throughput in vitro screen enabled the identification of harmine (118) and its analogs as human β-cell mitogenic compounds. Subsequent analyses were consistent with harmine acting, at least in part, to inhibit the dual specificity kinase DYRK1A. Using three different in vivo models based on either murine or human islets, the authors went on to show that harmine can induce β-cell proliferation, increase islet mass, and improve glycaemic control.[243] There are therefore multiple independent lines of evidence that small molecules can be found, which promote proliferation of these cells at least in vitro and in vivo.

1.13.2.5.2.2 β-Cell derivation from stem cells

It is difficult to see how a supply of β-cells for ex vivo expansion could be obtained from the patient, so the challenge of this approach can be expressed very simply, that is, to devise the technology to reliably and economically produce sufficient β-cells from an alternative, more readily accessible source of a patient's or donor's precursor cells. There has been much work done on this but, at the time of writing, very limited clinical work using such cells has been reported.[244] The obvious alternative stem cells are hESCs, the less ethically contentious hiPSCs, or human MSCs derived from the bone marrow.

The pancreas develops from the mesoderm of the blastocyst and the differentiation process whereby the initial stem cell eventually develops into a functioning β-cell has been investigated in considerable detail and this provides the basis for attempts to replicate the process.[245–253] Melton et al.[253] have recently described a six-stage process over 27–34 days to convert hPSCs to generate glucose-responsive "stem cell-derived β-cells (SC-β)" capable of being scaled-up to generate hundreds of millions of cells. Furthermore, these cells behave very similarly to adult β-cells in that they express the same markers, exhibit characteristic Ca^{2+} flux in response to glucose, package insulin into secretory granules, and secrete comparable quantities of insulin in response to multiple sequential glucose challenges in vitro. Most encouragingly, these cells secrete human insulin into the serum of mice shortly after transplantation and ameliorate hyperglycemia in diabetic mice. Different combinations of large molecule growth factors and small molecules are required for each stage (Fig. 58). These include Activin A, keratinocyte growth factor, heparin, betacellulin, CHIR99021 (5), retinoic acid (108), SANT1 (119), LDN193189 (56), phorbol 12,13-dibutyrate (120), triiodothyronine (121), γ-secretase inhibitor XXI (122), and Alk5i ((6), also known as RepSox). The authors point out that the SC-β cells are not exactly the same as adult β-cells in that they produce slightly larger islets and the gene expression patterns are not identical. However, they do produce human insulin in diabetic mouse models and do this very quickly after transplantation. Also they point out that their procedure could make sufficient cells for human transplantation in two 500 mL flasks. Further, a single 500 mL flask could produce sufficient cells to enable 30,000 compounds to be screened in a 384-well plate seeded with 10,000 cells/well in a search for novel compounds able to influence the behavior of this cell type. Ongoing work has apparently generated equivalent cell lines from hiPSCs from diabetics which should provide a resource for fundamental studies on the disease. Incorporation of these cells into tissue-like structures for transplantation is envisaged.

The generation of β-cells from hESCs and hiPSCs by five different protocols has also been discussed by Suresh Kumar et al.[251] Gene expression profiles at the different stages were described, along with a discussion of the various signaling pathways induced or inhibited by the stimulating molecules used in the different stages. The authors also considered starting from MSCs and these can produce functional β-cells but, at the moment, expansion to large scale for clinical use does not seem practical. A detailed account of the likely role of the growth factors, Activin A, FGF, retinoic acid (108), cyclopamine ((37), Fig. 59), wortmannin (123), sodium butyrate (124), betacellulin, noggin, EGF, HGF, KGF, and IGF was also provided (Fig. 59).

A different approach has been taken by Viacyte Inc., who has conducted similar detailed research into the stepwise differentiation of hESCs to functional pancreatic progenitors on a manufacturing scale. These cells are a mixed population comprised of pancreatic endoderm (PE) and polyhormonal endocrine cells. Implantation of PE cells gives rise to functioning islet-like structures through a mechanism that appears to primarily involve the de novo commitment of pancreatic progenitors to the endocrine lineages followed by further maturation to glucose-responsive β-cells. Their protocol goes through four stages, ESC, mesendoderm, definitive

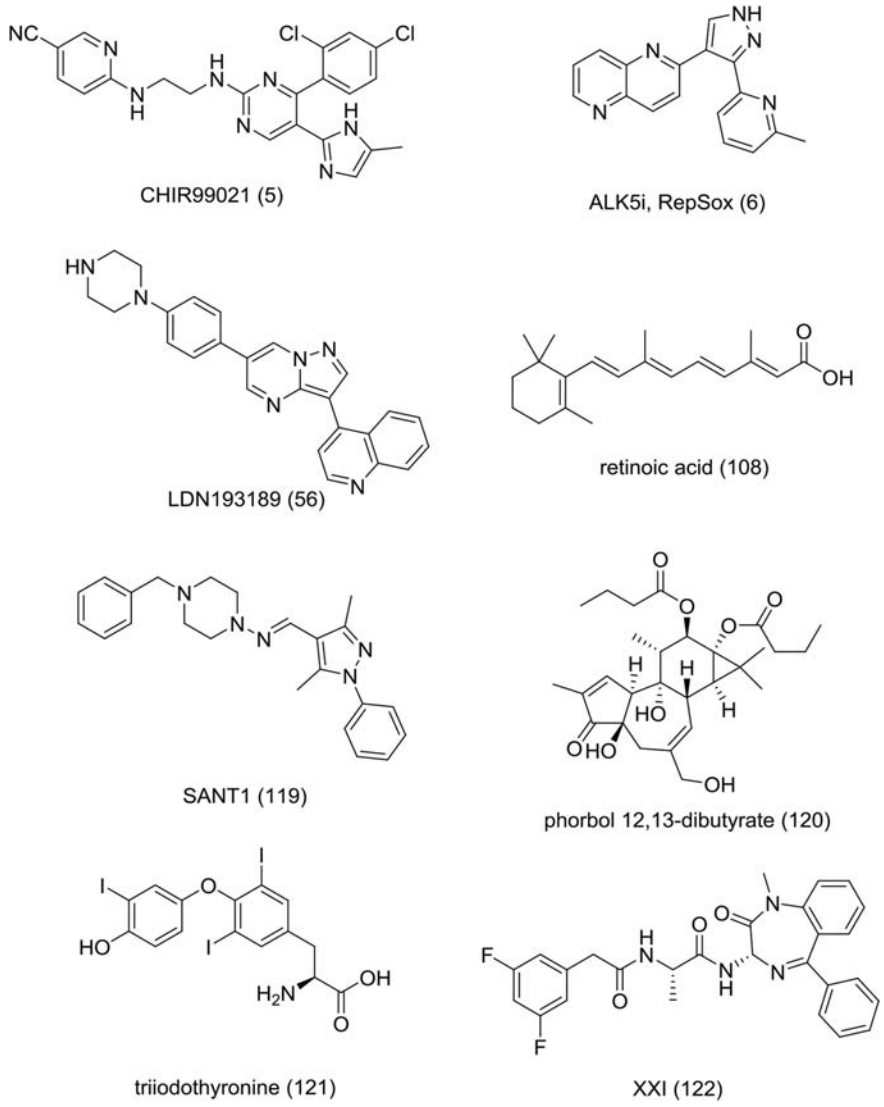

Fig. 58 Compounds reported to form "stem cell-derived β-cells."

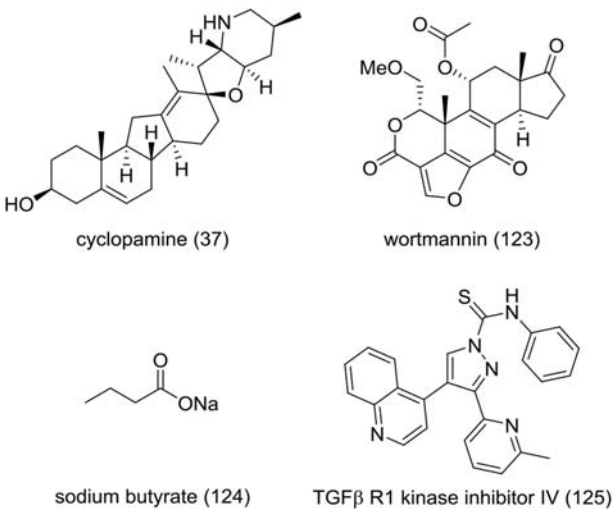

Fig. 59 β-Cell generating compounds.

endoderm, primitive gut tube, and posterior foregut to give the final cell mixture and takes around 13 days of incubation. The growth and differentiation factors involved are TGF-β R1 kinase inhibitor IV (125), insulin–transferrin–selenium, heregulin 1β, cyclopamine (37), and noggin. It is envisaged that the final cells could be transplanted into the patient or the company has developed an implantable delivery system (VC-01™) in which the cells are contained within a semipermeable capsule protected from the immune system but open to the bloodstream so that insulin can be released.[254] The company has stated that permission has been granted for a Phase 1/2a clinical trial of this device. This approach clearly uses the natural mechanisms to finish the differentiation process to the β-cell and shows that interaction of a cell within its native microenvironment it is part of the normal maturation process. Another approach using cell interactions is due to Narayanan,[255] who first grew β-cells on a tissue culture plate which was then decellularized. The derived extracellular matrix and conditioned media were then used for the culture of ESCs. This technique produced up to 38% of insulin-positive cells and gene expression studies indicated the presence of β-cell-specific markers. Subcutaneous implantation of these cells in a diabetic mouse model restored normoglycaemia in a long-term study. However, teratomas developed and this potentially indicates that residual pluripotent cells are still present and that methodologies to isolate the desired β-cells are required.

1.13.2.5.3 Different sources of β-cells

1.13.2.5.3.1 Other pancreatic cells

The transformation of other pancreatic cells to β-cells and the signaling molecules involved has been reviewed by Warnock et al., [249] Koblas et al., [256] and Melton et al.[257] In a seminal study using mice, Melton showed that in vivo adenovirus-mediated delivery of the genes for three TFs, Ngn3, Pdx1, and Mafa resulted in fully differentiated pancreatic exocrine cells being differentiated into cells that closely resemble β-cells and do secrete insulin. Koblas showed that the differentiation of adult human pancreatic nonendocrine cells into insulin-producing cells increased on treatment with the growth factors IGF-1, EGF, and Extendin-4. As all of these are known to act via the PI3K pathways and the effect is reversed on addition of a PI3K pathway inhibitor wortmannin (123), it was concluded that stimulation of this signaling pathway might be used to stimulate the differentiation of the nonendocrine cells into insulin-secreting cells.

It is known that the ventral pancreas and liver arise from the same cell population within the embryonic endoderm and thus efforts have been made to use progenitor cells from the liver as starting material to produce β-cells. While this might be useful for in vitro /ex vivo and transplantation work it is difficult at this time to see how the approach could work directly in vivo. Nevertheless, small cells were isolated from neonatal pig liver and these showed positive staining for immature liver and pancreatic endocrine markers. They could also be cultured to produce pancreatic-like β-cells but no in vivo results were reported.[258] More recently, Han has shown that rat liver epithelial stemlike WB-F344 cells can be transformed in a stepwise manner to functional insulin-secreting cells by use of a combination of large and small molecules.[259]

1.13.2.5.3.2 Mesenchymal stem cells

The ready availability of MSCs cells from bone marrow makes them a potentially attractive source of cells for differentiation to β-cells. Zuo and Yu[260] screened a 2500-compound library and identified XW4.4 ((126), **Fig. 60**), an aminopyrrole derivative, as being able to stimulate differentiation of rat MSCs into cells with the characteristics of insulin-producing cells including islet-like clusters displaying spherical, grape-like morphology, insulin secretion, glucose stimulation, and expression of pancreatic endocrine cell marker genes. Further investigation suggests that hepatocyte nuclear factor 3β may be involved in the pancreatic differentiation process.

Perhaps more remarkably, Wujun-Xue et al.[261] treated mice rendered diabetic by the injection of streptozotocin (127), with an infusion of MSCs and an injection of nicotinamide (128) resulting in raised insulin and decreased glucose levels and higher levels of expression of β-cell-related gene expression than in controls. The mechanism through which nicotinamide operates was unclear, but the authors hypothesized that it both promotes the homing of MSCs to the damaged pancreatic tissue and facilitates their differentiation to functional insulin-producing cells.

1.13.2.5.3.3 Fibroblasts

In a recent report Li[262] and coworkers described a scheme that converts engineered MEFs firstly into definitive endoderm-like cells (DELCs). These were isolated and expanded before being directed into pancreatic progenitor-like cells (PPLCs) by a combination of

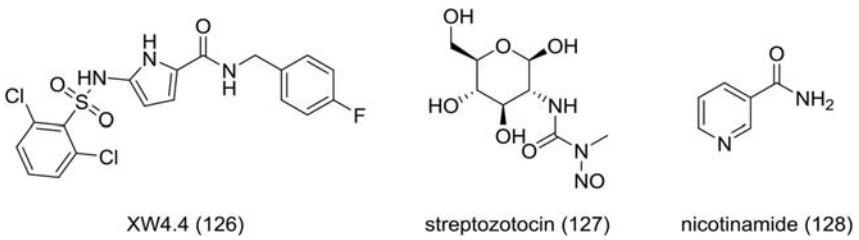

Fig. 60 Compounds reported to differentiate mesenchymal stem cells to β-cells.

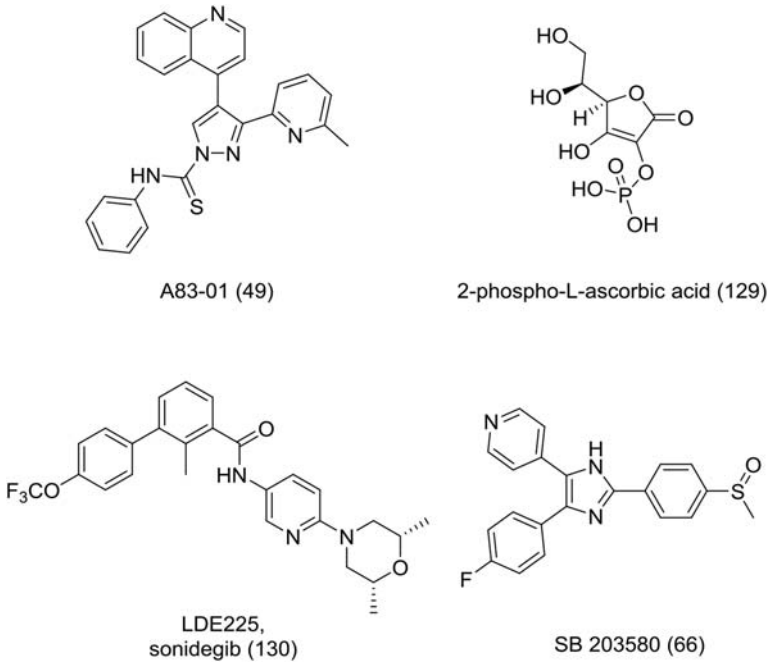

Fig. 61 Compounds reported to affect the formation of pancreatic progenitor-like cells.

signaling molecules and small molecules identified from screening libraries. The three-stage process uses Activin A and lithium chloride to generate DELCs, retinoic acid (108), A83-01 (49), a TGF-β receptor inhibitor, 2-phospho-L-ascorbic acid (pVc) (129) and LDE 225 (130), a hedgehog pathway inhibitor to generate PPLCs and finally SB203580 (66) (Fig. 61) and pVc to increase the yield of active cells. The resultant PPLCs were transplanted under the kidney capsule of immune-deficient mice rendered hyperglycaemic by streptozotocin and found, over time, to reduce glucose levels to normal. Analysis of the kidneys showed the presence of glucagon-producing pancreatic α-like cells, insulin-producing pancreatic β-like cells, amylase-producing pancreatic acinar-like cells, and Pdx1+/Ck19+ pancreatic duct-like cells. Although the authors did not conduct a rigorous lineage tracing analysis in this study, it appears that these cells may be capable of differentiating into cells of all three pancreatic lineages in vivo upon transplantation. Importantly, this procedure did not involve the MEFs passing through the iPSC stage and so it may be safer and reduce the risk of teratoma formation compared to earlier protocols.

1.13.2.5.4 In vivo expansion of β-cells

While the control of type I diabetes may be achieved by the transplantation of new β-cells, a better and less costly approach might be to trigger the renewal process in vivo by dosing with compounds able to provoke the expansion of the remaining β-cells. In addition, of course, as with any proliferation-inducing agent there is the possibility of activating oncogenic pathways. Thus there would need to be devised dosing protocols able to minimize this risk if ever a molecule acting in this way was introduced into clinical practice. One very interesting finding has been that patients who have survived more than 50 years of type I diabetes can still show residual β-cell functionality. Thus even under prolonged autoimmune and metabolic stress, pancreatic β-cells do seem to be able to be replenished but in this study the source of the β-cells was unclear, that is, are the β-cells themselves regenerating or are they being formed from other pancreatic cells?[263] All of this suggests that therapeutic intervention to replenish β-cells may not be a fanciful idea. The human pancreas contains ~1–2 g of β-cells but even in healthy individuals the range of values is from 0.1 to 2.0 g. Further, the rate of proliferation is highest, but still relatively low, in the first 2 years of life and then declines to a very low level by the age of 50. This leads to two considerations; the first being that a proliferation of ~2% such as is found in 1-year-olds might be all that is needed for therapy but on a more negative note the very people likely to need such therapy are the ones most resistant to it.[264]

This may seem discouraging for finding therapeutic agents, but it has also been pointed out that in pregnancy there is an increase in β-cell mass.[265] Although recent analysis of pancreatic sections from pregnant human donors did not find that proliferation contributed significantly to this increase, additional studies to understand the process might lead to the identification of new therapeutic targets. An alternative approach is to inhibit cell apoptosis in β-cells and inhibition of histone deacetylases by compounds such as vorinostat (131) and givinostat (132) (Fig. 62) had protective effects on the development of diabetes in a mouse model.[266]

Panadian et al.[252] have reviewed similar approaches to discovering clinically active agents. Also Wagner et al. have reported that a compound BRD0476 ((133), Fig. 63) suppresses cell death in β-cells and enhances cancer cell death.[267] This molecule acts to

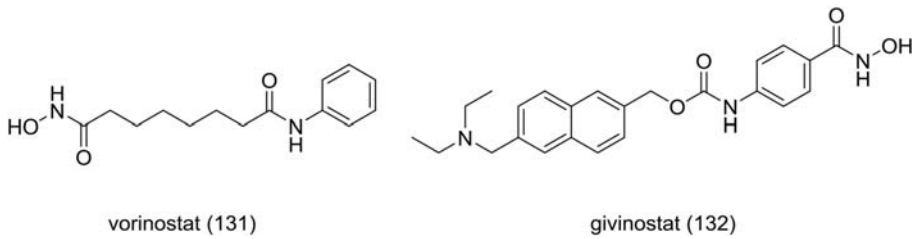

Fig. 62 Compounds with protective effects on the development of diabetes in a mouse model.

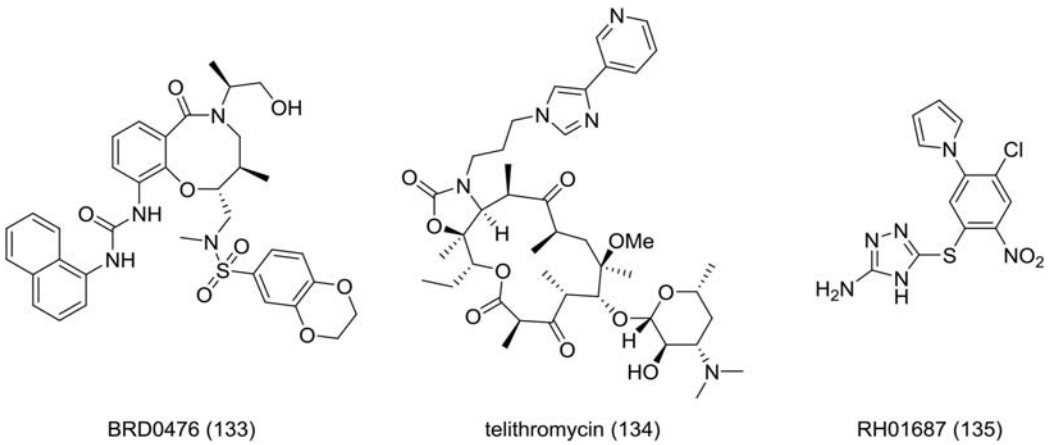

Fig. 63 Compounds suppressing β-cell death.

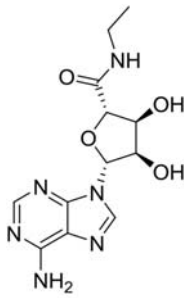
repress interferon gamma-induced Janus kinase 2 and signal inducer and activation of transcription 1(STAT1) signaling to promote β-cell survival. Interestingly, unlike other reported JAK-STAT inhibitors the mode of action was not through the inhibition of JAK kinase activity, but a proteomics analysis suggested the target to be the deubiquitinase ubiquitin-specific peptidase 9X (USP9X). This finding was supported by subsequent USP9X knockdown studies and comparison with another known USP9X inhibitor. Unfortunately, metabolic instability prevents the in vivo activity of this compound being assessed. A different approach to countering pancreatic β-cell death found that telithromycin (134) and RH01687 (135) are able to protect these cells from cell death induced by endoplasmic reticulum stress. The authors went on to show that a number of genes associated with cell survival and the unfolded protein response were upregulated, although the precise molecular mechanism of action of these compounds is not yet understood.[268]

As has been alluded to in other sections, increased levels of β-cells in vivo could be achieved from stem cell differentiation and transdifferentiation of other pancreatic cell types, especially α-cells. Initial work using genetic modification to introduce three TFs, *Ngn3*, *Pdx1*, and *Mafa* differentiated pancreatic exocrine cells in adult mice into cells that closely resemble β-cells.[257] Subsequently, it was shown that the growth factors IGF-1, EGF, and Extendin-4 that are known activators of the PI3K pathway differentiate human pancreatic nonendocrine cells into insulin-producing cells.[256] In addition, the Viacyte work and the finding that the endoderm cellular matrix can direct the differentiation of pancreatic progenitor cells gives some indication that this may be possible. Obviously, further efforts to understand the behavior of cells in the pancreas and, especially, of the interactions between them needs to be done so that the true biochemistry/cell biology of the human cells in the pancreas is properly understood and druggable targets begin to emerge.

1.13.2.5.5 In vivo studies in zebrafish

A number of groups have been studying the zebrafish and have shown significant similarities between its pancreatic development and that of mammals and shown that it is possible to do high-throughput screening to identify molecules able to affect differentiation to β-cells.[269] A transgenic zebrafish embryos were generated engineered to express a fusion protein of CFP and nitroreductase under the regulation of the insulin promotor. Nitroreductase expression allowed the local production toxic metabolites from metronidazole to damage the pancreas with temporary controlled β-cell ablation.[270] A high-throughput screen then identified four compounds capable of regenerating β-cells, all of which modulated the adenosine signaling pathway. Of these the most active was NECA, 5-*N*-ethylcarboxamido-adenosine ((136), Fig. 64). Significantly, the effects of NECA were shown to be specific to β-cells. NECA was also shown to promote β-cell proliferation both ex vivo in isolated murine islets and in vivo in a murine model of



(136)

Fig. 64 Chemical structure of NECA (136).

diabetes. It was later demonstrated that adenosine receptor A2a signaling was the target pathway through which NECA exerted its effects, a discovery that suggests possible molecular targets for the development of future therapies.

A very significant amount of information on the cell biology of the β-cell and other pancreatic cell types has been, and continues to be developed and this knowledge, along with the molecules that have been identified through high-throughput screening gives hope that radical new treatments for both forms of diabetes can be found.

1.13.2.6 Ocular Disease

1.13.2.6.1 Ocular applications of small molecule stem cell modulators

Various diseases of the eye can result in blindness or visual degeneration and impairment, with notable examples including disorders affecting the retina (such as age-related macular degeneration, AMD),[271] and the corneal epithelium (for example, limbal stem cell deficiency, LSCD).[272] Stem and progenitor cell-modulating small molecule therapeutics offer considerable potential for treatment of these conditions, and a selection of examples follows. Therapeutic options and approaches to prolific and debilitating ocular fibrotic diseases such as glaucoma have been recently reviewed,[273] and evidence is also emerging that phenotypic reversion approaches may hold promise in this area.[274] Thus visual impairments involving regions of the eye such as the limbal epithelium are also potentially amenable to intervention with therapies that modulate stem cell function.[275]

As well as new approaches using small molecules to directly manipulate various cell populations for therapeutic benefit, development of new assay technologies to facilitate study and drug discovery efforts is an important area of exploration.

1.13.2.6.2 Corneal disease

The cornea, located in front of the iris and pupil, is the transparent outer layer of the eye, which provides protection against exogenous factors such as bacteria and solid particles. As well as disorders affecting the retina, corneal disease causes blindness and affects vision in a significant number of people worldwide. Of these, around 70% of cases of blindness are caused by LSCD.[276] The underlying cause of this disease is conjunctivalization of the corneal surface due to aberrant maintenance of the corneal epithelium. Cell-based therapies are being investigated clinically for LSCD, but to date no small molecule approaches have reached a similar stage.[277]

In recent years there have been emerging signs of interest in small molecule approaches for modulation of stem cells for potential treatment of corneal disorders. Skottman and coworkers have described the development and use of a new protocol for differentiating hiPSC into corneal epithelial cells using small molecules.[278] As well as offering the first uses of small molecules for applications toward corneal blindness such as LSCD, this work potentially allows for the discovery and development of new assay systems to study eye diseases. In other studies Chen and coworkers have described work that investigated the reprogramming of adipose-derived stem cells (ADSC) into corneal epithelial cells using various factors including small molecules.[279] ADSCs have advantages over use of cells from other lineages in that it is both quicker and easier to obtain significant quantities of these cells from the donor.

1.13.2.6.3 Retinal disease

The inner layer of the eye containing the light-sensitive cells is called the retina, and the structure and function of these cells and tissue is thus essential for effective vision. The degeneration of one or more cell types within the retina is responsible for a number of debilitating conditions, which ultimately results in visual impairment. The various cell types that comprise the retina are derived from multipotent retinal progenitor cells through modulation of a range of signaling pathways including hedgehog and notch, and various biomolecules, including FGF although the details are, at this time, incompletely understood.[280]

Retinal diseases such as AMD (AMD —accumulation of cellular debris between the choroid and the retina), diabetic retinopathy, (DR —degradation of retinal blood vessels), and retinitis pigmentosa (RP —loss of photoreceptors) are prevalent throughout the developed and developing world, AMD for example affects almost 15 million people worldwide.[281] It is often underappreciated

that these diseases do not just affect the more elderly segment of the population but are common across all age groups. This is a group of diseases where significant unmet medical need exists; from both a healthcare and economic perspective the area is lacking in current therapies and is urgently in need of new therapeutic agents and novel approaches.

Current drug treatments for all of the aforementioned diseases are sparse. The mainstay of therapies for AMD are drugs such as Lucentis, Macugen, and Avastin, all of which are anti-VEGF biomolecules. These also enjoy some use in treatment of DR. Currently there are no small molecule drugs that are used to treat the underlying cause of any of these diseases; however, it is not a significant leap to imagine that the multitude of small molecule inhibitors of VEGFr-mediated signaling could be explored in this context. Since current AMD therapeutics are currently delivered by intraocular injection, alternative therapeutic approaches using either orally delivered drugs or drugs delivered topically to the eye such as the aforementioned VEGFr-inhibitors or small molecule stem cell modulators would be an attractive option. A key consideration would of course be the appropriate pharmacokinetic profile of any such agent and its biodistribution in tissues so as to avoid or minimize any undesirable side effects in other tissues.

A number of potential assay systems that have utility in assessing modulation of retinal progenitor cells by small molecules and other agents have been described, and thus could represent a rich resource for drug discovery projects targeting new therapies for ocular disorders.[282]

1.13.2.6.4 Retinal therapies using stem cells

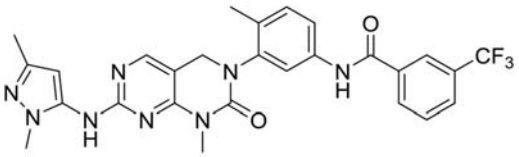
One of the first therapeutic areas to benefit from the discovery and evolution of stem cell therapeutics has been retinal disease, where a number of companies and organizations have initiated clinical trials in recent years.[283,284] This rapid advance is likely due not just to the significant unmet medical need but in no small part to the relatively self-contained nature of the inner eye, and the relative ease with which cell-based therapies can be introduced directly to the disease site by intraocular injection. Furthermore, in the case of cell-based therapeutic agents the immune privilege of the eye might be expected to result in fewer rejection events when using allogenic approaches.

Two therapeutic paradigms are envisaged with current stem cell treatments —regenerative and trophic. Regenerative stem cell-based therapies rely on the introduction of differentiated cell types, such as RPE (retinal pigment epithelial) cells, directly into the eye, the RPE cells having been produced previously from precursor cells such as hESCs or iPSCs. Trophic therapies on the other hand are predicated on the direct introduction of stem cells such as MSCs into the eye, with the expectation that the transplanted SCs rather than differentiating themselves, act to repair the underlying defects through the secretion of trophic factors, which act on resident cell populations through altering the local microenvironment. This latter phenomenon exploiting the paracrine influence of stem cell types in therapy is gaining increasing acceptance.[285]

In the former category, regenerative trials of note include those from advanced cell technology, using hESC-derived RPE cells.[286] The resulting RPE cultures were established as being 99% pure and free of any pathogens. In these studies, patients suffering from advanced vision loss due to either Stargardt's macular dystrophy ($n=1$) or AMD ($n=1$) were treated with subretinal implanations (injections) of between 50,000 and 200,000 RPE cells directly to the diseased area of the eye. The treatment was established as being safe, with no adverse events noted in either arm of the trial after cell transplantation, and also, critically, no rejection or tumorigenic response, the latter of which is a concern that has been associated with pluripotent stem cell-based therapies for some time. Four months after transplantation, improvement in visual acuity was evident in both patients, with assessment of the Stargardt's macular dystrophy patient demonstrating increased levels of pigmentation as assessed by optical coherence tomography. However, it was noted that in the corresponding AMD patient, there was actually no anatomical evidence of engraftment, perhaps due to the fact that the patient had not complied with the immunotherapy regime following transplantation. While the results are encouraging, given the relatively ST nature of the trial, as well as the very small patient numbers, further studies are needed in order to establish in more detail the nature and extent of any derived therapeutic benefit and anatomical consequences of these hESC-derived RPE cell-based therapies for retinal disorders.[287] Appropriate treatment paradigms will also need establishing, particularly the optimal cell numbers and timing of dosing for treatment.

As discussed elsewhere, the use of iPSCs avoids a number of issues associated with hESCs, and accordingly are an attractive alternative. Until recently there had been no reports of clinical studies using iPSCs as treatment for retinal disorders. However, very recently the first human clinical trial of iPSC-derived cells has been announced in Japan.[288] In this small pilot study that has recently been approved and will be conducted by the Kobe Center for Developmental Biology,[289] six patients over the age of 50 years suffering from macular degeneration will be treated with retinal epithelial cell grafts, which are intended to slow the progress of their eye disease.

Direct in vivo modulation of endogenous progenitor and stem cells is the emerging and alternative approach. While there have been relatively few reports to date of small molecule modulation of retinal stem cells, either in vitro or in vivo, with the emphasis being instead primarily focused on cell-based therapies, there is increasing evidence of a shift toward the use of small molecules, with examples now being published of studies using some of the better characterized, more promiscuous stem cell modulator compounds (discussed below). Furthermore, as more detailed investigations are carried out regarding the key signaling pathways involved in directing retinal stem, or progenitor cell fate, the discovery and study of small molecules that modulate these pathways can be expected to follow. For example, disruption of TGFβ signaling in retinal/eye disorders was described in the literature during 2005, although no small molecules were studied in this case.[290] Development of ocular cells of various lineages from the neural crest is reportedly influenced by TGFβ signaling, since disruption of this pathway led to ocular defects and was found to result in downregulation of two TFs known to be important for development of the eye (Pitx2 and Foxc1). Given numerous disclosures in the primary and patent literature since that date of the effect and therapeutic potential of TGFβ inhibitors in other therapeutic



(8)

Fig. 65 Chemical structure of Pluripotin (8).

areas,[291] and also of TGFβ mimetics,[292] it is reasonable to suppose that reports will be forthcoming in the area describing the application of such molecules and whether they recapitulate these findings, or can rescue ocular defects. This also gives confidence that the approach to discovering active small molecules described elsewhere in this article could be applied to the eye.

Details of experiments describing the potential retinal applications of a number of stem cell-modulating compounds from studies on other organs have been published. For example, pluripotin ((8), Fig. 65) has been reported to promoting the production of rabbit limbal epithelial cells in vitro, putatively through a mechanism involving the enhanced proliferation of limbal stem cells.[293] Application of 200 nM of pluripotin enhanced RLEC numbers significantly and also doubled the colony forming efficiency of RLECs (26% vs. 13% in controls). However, concentrations higher than 200 nM were found to show toxicity, raising a concern over a very narrow therapeutic index.

Schultz et al. have recently described the effects of the drug-like small molecule WS3 ((137), Fig. 66) on the proliferation of primary RPE cells ex vivo.[294] Interestingly this compound, and derivatives (eg, WS6, (115)) were originally described by the same workers as being able to stimulate the proliferation of β-cells. RPE cells cultured ex vivo in the absence of compound were found to have significantly reduced doubling rates by the sixth passage. In contrast those cells treated with 25 nM of WS3 were observed to maintain doubling rates even up to passage 15. Analysis of the genomic integrity of the expanded cells showed no genetic alterations, nor were any tumorigenic events observed. These observations were important since the intended clinical application of this methodology is the provision of cells for transplantation therapy, assessment of the safety of the product cells is of critical importance.

The cells were demonstrated to be functionally competent after multiple passages: following removal of WS3 the cells differentiated in vitro to a monolayer with characteristic pigmented and cobblestone-type morphology. These morphological analyses were supported by RT-PCR analyses, which demonstrated the presence of markers characteristic of mature RPE cells, including RPE65, RAX, MITF, and others. Furthermore, implantation of WS3-expanded RPE cells in vivo in using the Royal College of Surgeons (RCS) rat model[295] resulted in retinas with more photoreceptors and lower luminescent thresholds compared with untreated animals, supporting an increase in functional photoreceptor numbers. In accordance with the group's previous target identification studies using WS6 in β-cells, a common target protein, Ebp1, was revealed.[240] In contrast to the studies on β-cells, IKKε was not detected as a target of WS3 in RPE cells.

Retinoic acid ((108), Fig. 67) has been shown to promote photoreceptor differentiation in various vertebrate retinal studies, including zebrafish and human, although the precise mechanism by which it does so has yet to be elucidated.[296]

1.13.2.6.5 Small molecule modulation of hES and iPS cells to retinal cells

Nicotinamide ((128), Fig. 68) has been reported to stimulate the differentiation of human ESCs to RPE cells, via neural precursor cells.[297] Gene expression analysis at various stages of the differentiation protocol was undertaken in an effort to understand in greater detail the underlying mechanisms in the differentiation process. After 4 weeks of treatment with nicotinamide expression, analysis revealed that a number of genes were upregulated relating to differentiation to neural and retinal lineages as well as those relating to hematopoesis and melanogenesis. After 8 weeks of nicotinamide treatment, 70% of cell clusters were found to exhibit pigmented areas and 5% of cells being both pigmented and expressing a marker, MiTF, characteristic of RPE cells. The authors went on to show that these hESC-derived RPE cells were viable and led to functional and structural rescue of the retina 6 weeks after implantation in vivo in the RCS rate model.

The use of a combination of casein kinase inhibitor CKI-7 ((138), Fig. 69), TGFβ inhibitor SB-431542 (12), and Rho kinase inhibitor Y-27632 (81) has been reported to produce retinal precursor cells from hESCs.[298] The authors demonstrated that the resulting hES-derived retinal progenitor cells were capable of differentiating into RPE and photoreceptor cells by induction with retinoic acid and taurine. Finally, it was demonstrated that the same set of protocols was also applicable to human iPSCs, and their differentiation into retinal cells in vitro was illustrated. Other methods have also been reported describing the differentiation of RPE cells from murine or human iPSCs, for instance using delivery of TFs such as Oct4, Sox2, Nanog, and Lin28.[299,300]

The reprogramming of human primary neonatal epidermal keratinocytes to hiPSCs and their subsequent differentiation into RPE cells has recently been described using a cocktail of small molecules and growth factors (Fig. 70). This method used the dual TF "2F" conditions, consisting of either OCT4/KLF4 and CHIR99021 (5)/tranylcypromine (7) or OCT4/KLF4 and CHIR99021 (5)/SB-431542 (12)/tranylcypromine (7)/PD0325901 (13). The single TF "1F" protocol was also applied, which consisted of OCT4 along with sodium butyrate (124)/PS48 (139)/A83-01 (49)/PD0325901 (13).[301] The authors went on to show that the resulting cells expressed the markers bestrophin, CRALBP, and RPE65, consistent with terminal RPE cells. Comparison of the 1F- and 2F-derived RPE cells with human fetal RPE cells through metabolomic and proteomic analyses showed a high degree of similarity. Remarkably, bolus intraocular injection of 1F-derived RPE cells in vivo in the RCS rat model showed that the cells appeared to implant as a correctly polarized and extended monolayer. Preliminary studies of electrical responses of the engrafted retinas to light stimulation suggested that they were also functionally competent. This therapeutic strategy does therefore appear to significant promise for the treatment of retinal diseases.

The field of regenerative medicine as applied to ocular indications continues to move at a fast pace. During 2015 there have been a number of other important disclosures describing methods to differentiate stem cells to RPE cells. A nonsmall molecule approach using new chemically defined media conditions to convert human PSCs to retinal progenitor cells has been described by Zhou and coworkers. A detailed step-by-step analysis of the differentiation process was provided, which elegantly demonstrated how this in vitro approach recapitulates human embryogenesis, and ultrastructures were detected in the hPSC-derived RPE and neural retina that have not been reported in previous conditions.[302] The method appears promising; however, the authors have not yet reported any study on the transplantation of these cells in vivo and so the both the feasibility and safety questions remain to be resolved before any translation to the clinic could be envisaged. Other recent work outlining the use of additional small molecules that promote RPE differentiation has been published. For example, Maruotti et al. have described a high-throughput, quantitative PCR-based screening approach using the "StemSelect" compound library to identify compounds that promote RPE differentiation from human PSCs.[303] Critically, the hit molecules identified in this first assay were tested using an orthogonal assay, using hiPSCs engineered to express GFP under the regulation of an RPE-specific tyrosinase enhancer to confirm activity. Chetomin ((140), Fig. 71) was found to significantly increase the amount of RPE differentiation in a number of human PSC lines, an effect which

was potentiated by nicotinamide. Further studies were consistent with chetomin acting via a previous ascribed mechanism of inhibition of p300-mediated transcriptional activity, but other, as yet undefined pathways were also implicated.

In other work, Westenskow et al. have published a simplified protocol for directed differentiation of retinal pigment epithelium cells using PSCs.[304] The use of nicotinamide along with Activin A, or the small molecule IDE-1 ((141), Fig. 72) was found to significantly enhance the yield of RPE cells.

An important recent study was published by Parvani et al.[305] In this work, using a stepwise process, treatment of hESCs with a combination of small molecules resulted in increased expression levels of eye-field-specific genes, and intriguingly, also resulted in a subset of cells acquiring the features of advancing retinal differentiation, albeit transiently. Three previously described small molecules stem cell modulators dorsomorphin ((43), Fig. 73), the Wnt modulator XAV939 (52), and ALK inhibitor A83-01 (49) were used in the multistep differentiation process.

1.13.2.6.6 New assays and assay technologies

The effectiveness of a medicinal program is critically dependent not only on the chemical matter synthesized by project scientists but also on the testing methodologies employed. An effective and disease relevant assay system is a prerequisite for all drug discovery projects, and the application of stem cells to ocular disease is no exception.

To this end, a number of interesting new assays systems have been described in recent years, and can reasonably be expected to have a significant impact on both the pace and predictability of compound progression toward proof-of-principle experiments for small molecule stem cell modulators for retinal, corneal, and other eye diseases.

Fuller et al. have described an elegant high-throughput assay that monitors for photoreceptor number and survival using primary murine retinal cells.[306] This assay may prove useful in both the identification of compounds with clinical utility for retinal disease, and for probing the underlying mechanisms of differentiation and survival. In related studies, Ferrer et al. have published work outlining a miniaturized 96 or 384 microtiter plate assay for application in screening small molecules, which influence retinal pigment epithelium pathology and physiology in vitro, and thereby potentially have therapeutic benefit.[307]

Improving the reliability, throughput, and physiological relevance of assay systems is also a critical consideration in all aspects of drug discovery. To this end, Lane et al. have evaluated the primary variable in the hESC-RPE differentiation process.[308] The authors document and quantify how factors such as cell density, passage number, and cell line used affect RPE yield. Finally, Jasty et al. have described a new 3D culture system that can in theory be used for modeling small molecule-based approaches to modulating retinal stem cell function.[309]

1.13.3 Conclusion

The purpose of this article has been to draw the attention of medicinal chemists to the challenges and benefits of discovering small molecules able to selectively stimulate stem cells, stemlike, and progenitor cells to produce new tissue to correct diseased and damaged organs in a number of serious disease states. Studies described herein show that progress is being made in this field although significant challenges remain. However, these challenges are familiar to medicinal chemists even if they differ significantly from the usual enzyme modulation/receptor interaction drug paradigm. The search for "hit" molecules in areas where mechanistic pathways are less than fully established will be aided by the use of more efficient phenotypic screening techniques described elsewhere in this series. Of course, as more active small molecules emerge and as more information is gained on the precise signaling mechanisms used by these cells, then the opportunities to use established structure-based drug design techniques will grow.

The discovery of a "hit" compound is of course only the first stage of the development of a clinical candidate and further optimization and downstream development will require the successful resolution and tuning of all the compounds properties such as ADMET, off-target idiosyncratic activity, in vivo animal model activity, synthetic route development, stability, formulation, etc., familiar to all practicing medicinal chemists.

Where this new paradigm diverges from existing approaches can be illustrated by consideration of the systems under study. It is obvious that a high degree of selectivity will be needed so that only stem cells in target organs are stimulated and that the degree of stimulation is controlled so that undesired side effects in other tissues and other outcomes, such as oncogenesis, fibrosis, or even depletion of the endogenous stem cell pool are avoided. However, as achieving selectivity and the appropriate levels of potency have long been the criteria to which medicinal chemists operate, it is reasonable to expect that these challenges will not be insurmountable. Advances in iPSC technology and our understanding of the stem cell niche will surely lead to the introduction of more robust and reliable in vitro screening tools that better recapitulate the in vivo situation, which should facilitate the achievement of these goals.

It will be a major challenge to discover small molecules with all the desired activities and none of the undesired ones but the rewards in terms of patient care will be considerable. Many of the long-term illnesses that cause so much suffering to patients such as diabetes, neuronal degeneration, and cardiac failure and so much damage to the economics of healthcare systems throughout the world could be addressed by this approach. It is to be hoped that medicinal chemists will rise to this challenge.

1.14.1 Introduction

Drug discovery and development is a knowledge-intensive process that implies the generation, management, and analysis of huge amounts of data (see Fig. 1). The first step of the process is the identification and analysis of all the preexisting knowledge that is relevant for the intended project. Regarding the new data to be generated during the project, they start with the results of the wide scope of biological experiments that are required for the discovery and validation of novel biological targets. Currently, the research on new targets uses to include "omics" experiments (genomics, transcriptomics, proteomics, metabolomics, etc.), which generate a huge amount of data. Once a new therapeutic target has been identified and validated, the following step usually is the execution of virtual and experimental screening campaigns, which assign affinities for the studied targets to series of thousands to millions of drug-like compounds and identify hits as compounds with promising biological profiles. The hits are subsequently transformed into leads through modification of their structures in order to improve the biological properties, using information on structure–activity relationships. The lead compounds are then submitted for preclinical assessment, which generates data informing about key aspects such as pharmacokinetics and toxicology. Once a drug candidate enters into clinical trials, another vast collection of data from the enrolled patients is accumulated. Last but not least, the drugs that are finally authorized for being marketed continue generating useful data about the therapeutic and adverse effects of their use in clinical practice. In summary, the whole pharmaceutical research pipeline uses and produces a massive and diverse assortment of data.

A point to be particularly stressed is the high degree of compartmentalization of the information management and analysis between the different stages of the drug discovery and development process. There are silos of information and expertise that hamper the efficiency of biomedical and pharmaceutical research.[1] This is an adverse scenario that requires to be overcome, since the integration of heterogeneous biomedical information (of different types and from different sources) constitutes an opportunity for gaining a more complete and powerful view on diseases and their therapeutics (Fig. 2). In order to maximize the effectiveness of efforts for integrating data in pharmaceutical R&D, it is crucial to identify and adopt relevant standards, or to develop them if they are unavailable. It is also vital for the annotation of the data in terms of their provenance and quality in order to make possible a critical assessment of their suitability for reuse. Another challenge that has to be addressed is the fact that most of the knowledge that is generated in the biomedical research is only disseminated by means of free-text scientific publications. Taking into account

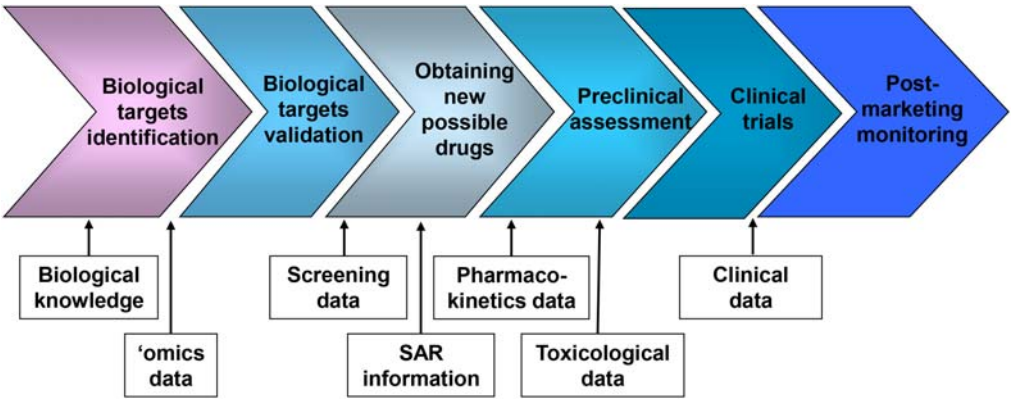

Fig. 1 Data and knowledge generation and use along the drug discovery and development pipeline.

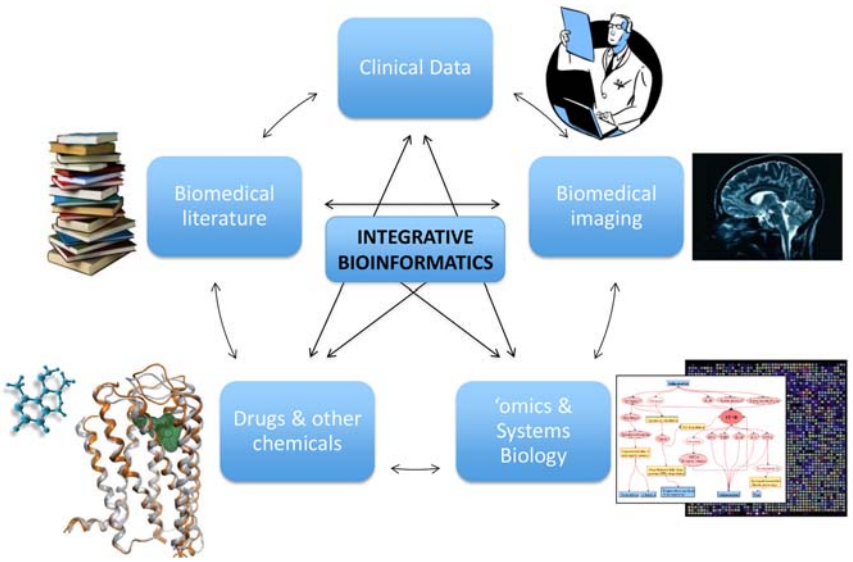

Fig. 2 Integration of heterogeneous biomedical information for gaining a more complete and powerful view on diseases and therapeutics.

the huge amount of biomedical publications that are generated and the fact that all of them are currently published electronically (eg, PubMed is an electronic repository that contains more than twenty million abstracts of scientific publications and to which about 700,000 more are added every year), we need to put in place computational methods for automatically extract information from free-text digital documents. This necessity also applies to the enormous amounts of clinical documents that record relevant evidences and that have free-text format. Finally, it has to be pointed out that the sustainability of data collections should be considered a key policy and the promotion of data sharing should be understood as a responsibility, especially when data are derived from public funding.[2]

The present article reviews different strategies and initiatives in integrative data approaches that facilitate the pharmaceutical R&D. They are presented following the sequence of the different stages of the drug discovery and development pipeline as depicted in Fig. 1.

1.14.2 Seeking Relevant Knowledge for a Drug Discovery Project

As it was previously stated, the first stage of such a pipeline is the identification of existing knowledge that constitutes the background for a particular project. In this respect, we need tools that facilitate the extraction and integration of data and information from different resources. A recent and successful initiative on the matter has been the Open PHACTS project, carried out in the framework of the Innovative Medicines Initiative (IMI), which is jointly funded by the European Commission and the EFPIA.[3] Open PHACTS Discovery Platform uses semantic web technology approaches to enable scientists to easily access and process data from multiple sources to solve real-world drug discovery problems.[4] Open PHACTS was built to address drug discovery questions that are of high priority to the pharmaceutical industry. Most of these frequently asked questions (FAQs) revolve around the combination of data concerning compounds, targets, pathways, and diseases. An example of them may be: *For disease X, which targets have ligands in different stages of the development process with publications and/or patents describing these compounds*? Computational drug discovery using workflow tools and the integrated resources of Open PHACTS can deliver answers to most of these questions.[5]

Another useful resource for reviewing information about marketed and experimental drugs is DrugBank.[6,7] It combines detailed drug data (ie, chemical, pharmacological, and pharmaceutical) with comprehensive drug target (ie, sequence, structure, and pathway) information. DrugBank v4.3 contains 8312 drug entries including 2036 FDA-approved small molecule drugs, 233 FDA-approved biotech (protein/peptide) drugs, 93 nutraceuticals, and over 6000 experimental drugs. Additionally, 4317 nonredundant protein (ie, drug target/enzyme/transporter/carrier) sequences are linked to these drug entries. Each drug entry contains more than 200 data fields with half of the information being devoted to drug/chemical data and the other half devoted to drug target or protein data.[6]

1.14.3 Information Supporting Target Identification

One of the information resources developed in the framework of Open PHACTS is DisGeNET,[8,9] a database that summarizes information on gene–disease associations. This kind of information is crucial in the process of studying the molecular basis of diseases

and to identify putative drug targets for its pharmacological treatment. It has to be pointed out that there is a large volume of biomedical information that connects genomic elements to disease phenotypes, but such information is fragmented across different repositories and hidden in the biomedical literature. Consequently, there was a need for computational resources which *gather*, *integrate*, and *analyze* medically relevant information on the genetic causes of diseases, and that was the motivation of the DisGeNET development.

DisGeNET is a comprehensive resource on gene–disease associations (about half a million of them), which integrates information from publicly available databases and directly from the biomedical literature by text-mining (more than 80% of gene–disease associations). Text-mining is a computational process that first identifies relevant entities in free text (eg, proteins, diseases, drugs). This identification implies the use of adequate vocabularies and tricks for managing the variability of texts associated with a specific entity (eg, *melanocortin-4 receptor*, *MC4R*, and *MC4-R* are different texts referring to the same protein, or *obese* and *obesity* indicate the same disease). Once the entities have been identified, a natural language processing (NLP) algorithm is used to detect relationships between entities within sentences (eg, *MC4R is associated with obesity*). DisGeNET includes a user-friendly interface that facilitates the interrogation of the system (see **Fig. 3**). It has to be stressed that DisGeNET ranks the lists of gene–disease associations by means of a score based in the reliability of the source (greater for resources curated by experts and lower for associations obtained only by text-mining), as well as in the number of evidences that support the association.

Another type of information that is key for the study of the disease mechanisms and their potential pharmacological targets regards systems biology, that is, information about the biological processes and mechanisms. The Reactome knowledgebase[10,11] provides molecular details of signal transduction, transport, DNA replication, metabolism, and other cellular processes as an ordered network of molecular transformations (an extended version of a classic metabolic map) in a single consistent data model.[11] There are also databases that contain information on protein–protein interactions (PPIs), such as STRING[12,13] or the human Interactome database,[14,15] or resources that facilitate the access to this type of information, such as HIPPIE[16,17] or Biana.[18,19]

1.14.4 Information Supporting Hit Identification and Drug Design and Development

The identification of hits for the selected targets and the process that goes from targets to drug candidates benefit from the availability of comprehensive repositories of information about the physicochemical and biological properties of drug-like compounds. A paradigmatic example of this type of resources is ChEMBL,[20,21] which is an open large-scale bioactivity database containing information largely manually extracted from the medicinal chemistry literature. Information regarding the compounds tested (including their structures), the biological or physicochemical assays performed on these, and the targets of these assays are recorded in a structured form.[21] In Jan. 2016, ChEMBL_20 reported data corresponding to activities of 1,463,270 distinct compounds versus 10,774 targets, totalizing 13,520,737 activity data. Obviously, the biological behavior of each compound is only tested in front of minority of the possible targets and most of the compound–target combinations remain undetermined,[22] even been required for an appropriate appraisal of the therapeutic and safety profiles of the drugs. For this reason, there are different methods and software that provide estimates for the missing values based on similarity strategies (see Ref.[23] as an example). It deserves to be pointed out that ChEMBL is complemented by the SureChEMBL database,[24] which is a publicly available large-scale resource containing compounds extracted from the full text, images, and attachments of patent documents. SureChEMBL provides access to a timely set of annotated compound-patent associations. Currently, the database contains 17 million compounds extracted from 14 million patent documents.[25]

1.14.5 Information Sharing and Integrative Approaches in Predictive Toxicology

The toxicological assessment of the potential drug candidates is a key aspect in the preclinical drug development. They imply sequences of long and expensive in vivo studies using different animal species. In the framework of three 3Rs policy (Replacement, Reduction, and Refinement in the use of animals in scientific research), the reuse of the experience accumulated in previous analogous projects for generating reliable predictions on new compounds under investigation is a must. The best historical data for such a purpose remains generally buried in the archives of the pharmaceutical companies. Some years ago, a large group of pharmaceutical companies, in collaboration with academic experts and small- and medium-sized enterprises, decided to launch the eTOX project[26] in the framework of the IMI. This project has the aim of building and exploiting a database that contains legacy in vivo toxicological studies donated by the pharmaceutical companies. The data of the resulting database is shared among all the project partners, and will be made accessible to external parties after the project finalization. In May 2016, the eTOX database contained more than 7000 repeated-dose toxicological studies corresponding to more than 2000 compounds. The studies correspond to different animal species (mainly rat, but also dog, monkey and mouse, among others) and report different kinds of toxicological findings (histopathology, organ weights, clinical chemistry, clinical signs, hematology, etc.), observed in different organs (liver, spleen, thymus, kidney, lung, etc.).[27] The database incorporates the chemical structures of the compounds and, in most of the cases, information about their pharmacological mode of action. The eTOX project also collects and links complementary information from other sources, such the ChEMBL database. All this data is used for developing a wide scope of predictive models, which use different methodological approaches, including multilevel and multiscale strategies.[28] The structure of the eTOX project is

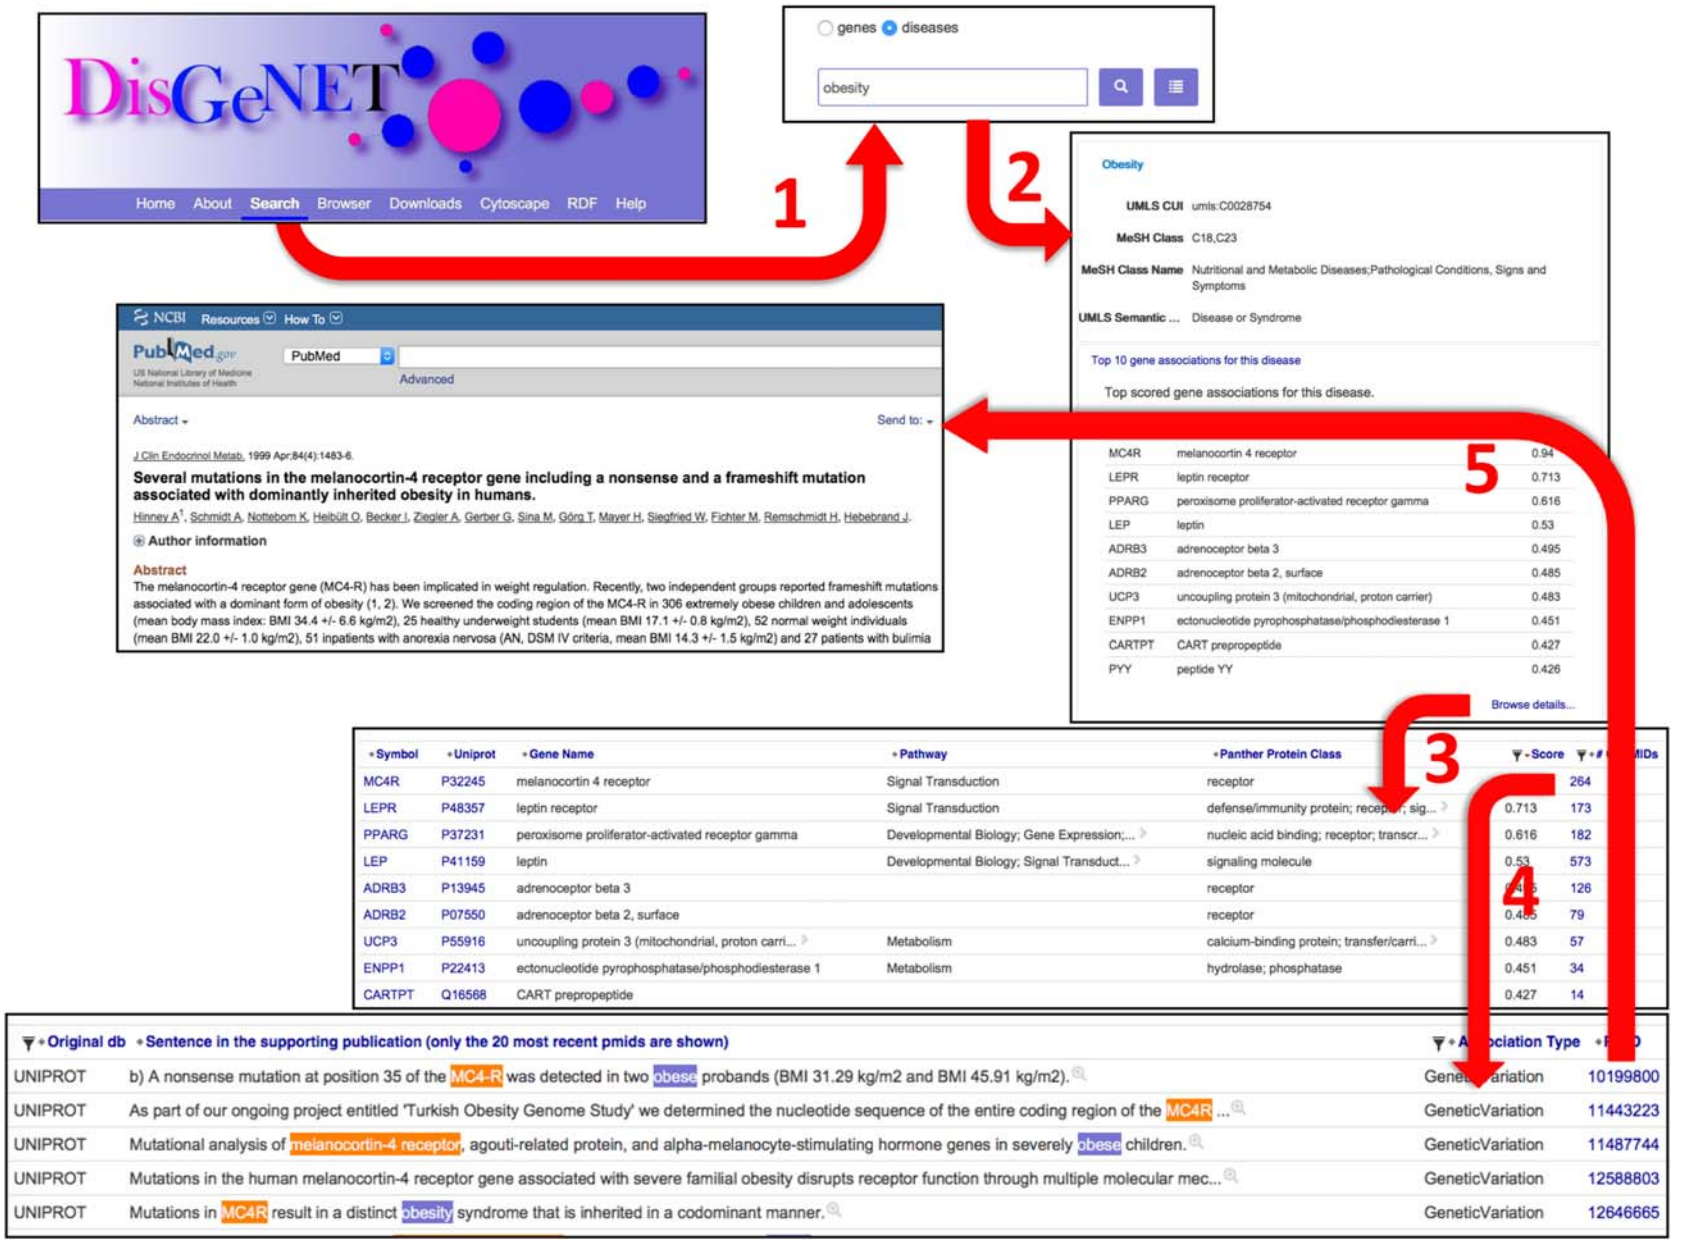

Fig. 3 Screenshots of DisGeNET showing a typical information query.

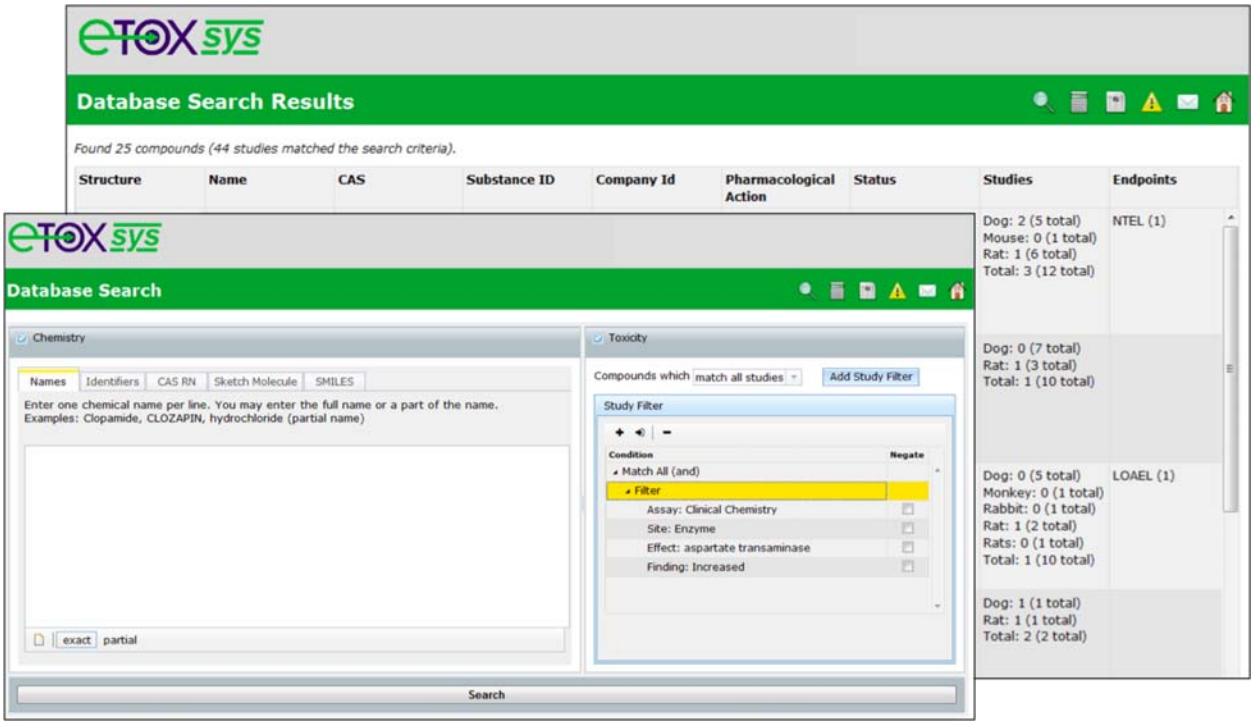

Fig. 4 Scheme showing the data integration and exploitation in the eTOX project.

summarized in the scheme shown in Fig. 4. The interrogation of the database, the selection of the predictive models, and the display of the results are done through an integrated graphical interface named eTOXsys (Fig. 5).

Other resources that contain useful public high-throughput chemical-toxicological data are ToxCast and Tox21, which are promoted by the US Environmental Protection Agency (EPA). ToxCast has data on over 1800 chemicals from a broad range of sources including industrial and consumer products, food additives, and potentially "green" chemicals that could be safer alternatives to

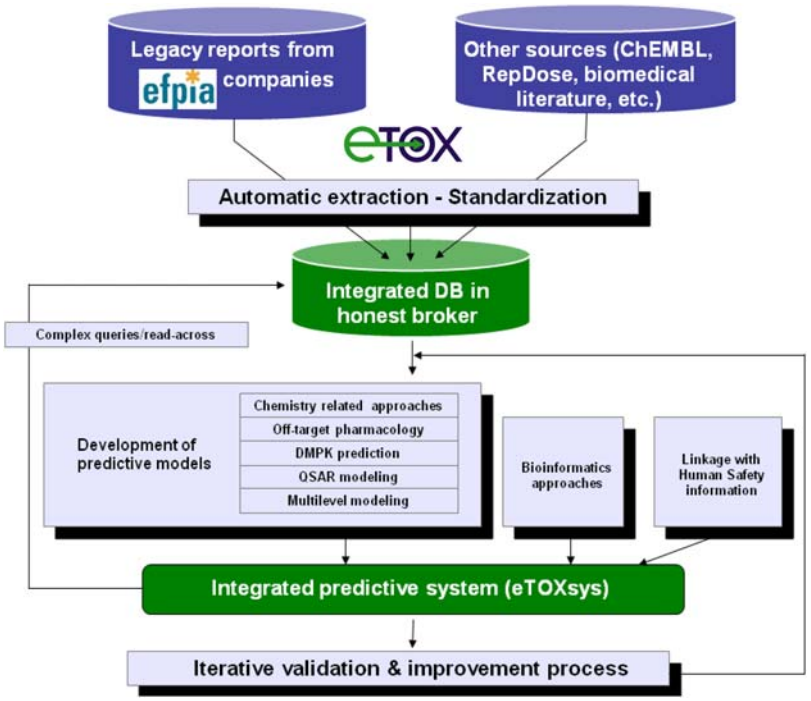

Fig. 5 Screenshots of eTOXsys showing a typical query of the database and the output obtained.

existing chemicals. ToxCast screens chemicals in over 700 high-throughput assays that cover a range of high-level cell responses and approximately 300 signaling pathways.[29] Regarding Tox21, it aims to extend the toxicological screening to 10,000 chemicals.[30] The Distributed Structure-Searchable Toxicity (DSSTox) Database provides a public chemistry resource for supporting improved predictive toxicology, including the ToxCast and Tox21 high-throughput toxicology efforts.[31] Though, it has to be pointed out that ToxCast and Tox21 are not specifically focused to drug-like compounds, but to chemicals at large. Lastly, it has to be pointed out that there is an interesting European-centric initiative (diXa) for depositing and accessing to toxicogenomics data.[32] There is public data warehouse supporting the diXa data operations.[33]

1.14.6 Using and Reusing Clinical Data for Biomedical Research

Nowadays, clinical research and healthcare practice generate huge amounts of data, which in all the cases are stored in electronic format. Regarding the clinical trials, there is a trend toward transparency supported by health authorities and the pharmaceutical industry, which is leading to the creation of useful databases where an increasing amount of public information about clinical trials can be found. This is the case of ClinicalTrials.gov in United States[34] and EudraPharm[35] and EudraCT[36] in the EU.

On the other hand, the electronic healthcare records (EHR) constitute a priceless source of evidence for biomedical research. There are recent international initiatives such the EU-ADR[37] and the IMI EMIF[38] EU-funded projects that reuse millions of EHRs from several European countries for answering to research questions that would not be easily afforded by alternative means. A point that deserves particular attention, and even some societal controversy, is the protection of the privacy of personal data in such type of projects. The most extended position among the scientific community is that such a protection can be reasonability attained if the data is carefully anonymized. There are additional precautions that use to be adopted, such as the approval and follow-up of the projects by health authorities or scientific bodies, or the only dissemination of aggregated data. An additional precaution consisting in the requirement of previous individual patient consent for carrying out observational retrospective studies (opt-in) remains almost impossible to be implemented for databases containing millions of EHRs. In this respect, the only procedure that looks feasible is the implementation of a public and easy procedure for removing patients that wish to be excluded (opt-out).

1.14.7 Integrating Clinical Data and Biomedical Evidence in Pharmacovigilance

In the last section of the present article, we describe with some detail the EU-ADR project that constitutes a relevant example of how the integration of data and knowledge from diverse sources and different types can support pharmaceutical research, post-marketing pharmacovigilance in this particular case.[37] The EU-ADR project was conceived for implementing and testing an alternative approach for detecting adverse drug reactions (ADR) generated by the use of medicines, in a way that goes beyond the traditional spontaneous reporting system.[39] It consisted of several stages depicted in Fig. 6. The first stage of the project was to put in place appropriate data management procedures for making possible the joint pharmacoepidemiological analysis of several (seven) population-based healthcare databases from different countries (Denmark, Italy, and the Netherlands) using anonymized demographic, clinical, and prescription/dispensing data. The studied databases represented 21,171,291 individuals with 154,474,063 person-years of follow-up in the period 1996–2010. The project implied the use of text-mining techniques for extracting the references to drugs and adverse clinical events, the implementation of adequate terminology mapping to address the fact that each database used different terminologies and even different languages, as well as the local implementation of an ad hoc software for extracting aggregated figures from each database in way that they can be integrated with those from other databases. The resulting infrastructure was tested for investigating the potential increased risk of suffering from myocardial infarction after the use of the drugs.[37] An innovative aspect of the workflow implemented in the EU-ADR project was the incorporation of a sophistical computational pipeline for discovering potential biological explanations for the drug-ADR signals detected by epidemiological methods.[40] The biological substantiation process (see Fig. 7) incorporated:

- automatic detection of similar compounds for the drug under study and its metabolites,
- in silico pharmacological profiling (exhaustive computational screening of interacted proteins) for any molecule (drug, metabolite or similar compound),
- determination of the common proteins between the ones that interact with the compounds and those described elsewhere as potentially related to the ADR (using DisGeNET[9]),
- consideration of the potential relationship between the proteins interacted by the drug and those related with the ADR through biological pathways, and
- contemplation of the potential effect of interindividual genetic variants in the drug metabolism or in the involved proteins.

Consequently, the integrated reuse of clinical data and biological knowledge contained in databases and in the biomedical literature offers a powerful way of discovering and biologically substantiating the rare but important ADRs produced by drugs that are used in therapeutics.

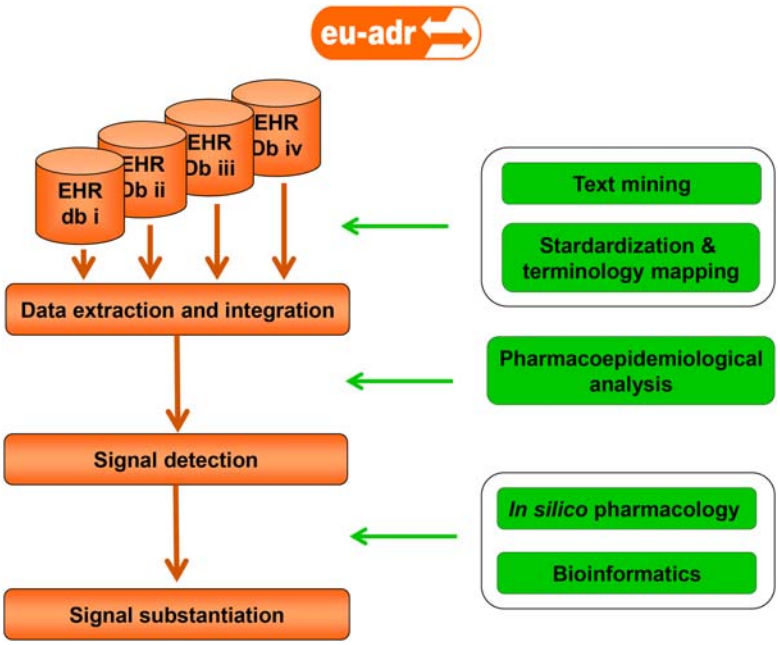

Fig. 6 Scheme of the EU-ADR project workflow.

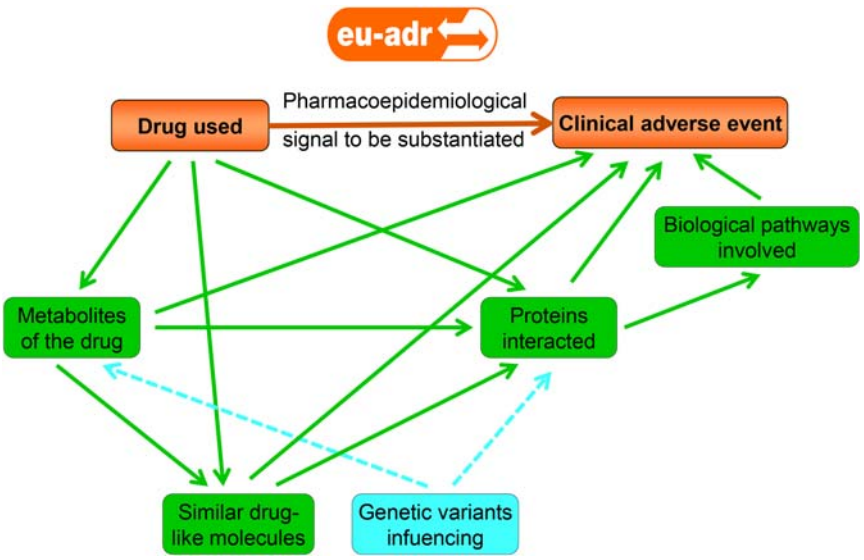

Fig. 7 Signal substantiation in the EU-ADR project by means of integrative knowledge management.

1.14.8 Final Considerations

In conclusion, we have to be aware that there is a plethora of strategies and computational tools that are available for facilitating and empowering the tasks to be done along the drug discovery and development pipeline. Most of such computational tools are publicly available and can be easily used or downloaded through Internet.

The integrative analysis of information from several types and several sources (the biomedical Big Data) offers great opportunities for gaining a more complete and powerful view on the biology, the diseases, and their pharmacological treatment.

1.15.1 Introduction

In the post genomic era, data generation in the pharmaceutical sciences has massively accelerated meaning that new analytic (eScience) approaches are needed to adequately exploit this new chemical and biological information.[1] Many new protein targets have been discovered recently, and it has been shown that clinical efficacy is often the result of polypharmacological action of drug molecules (i.e., the interaction with more than one protein target).[2] In addition, for a drug to be safe, certain off-target activities on other proteins should be avoided. For targets and off-targets, a plethora of different ligand-based and protein-based data are being generated and collected in databanks. For example, the Protein Data Bank (PDB)[3] currently holds 117,240 three-dimensional (3-D) protein structures, while the ChEMBL[4,5] database contains data relating to 13,967,816 biological activities of 1,928,903 compounds and 11,019 protein targets (**Fig. 1**). All these rapidly accumulating data hold great promise for more efficient structure-based discovery and design of ligands with desirable protein selectivity and polypharmacological profiles. Efficient exploitation is, however, hampered because a good approach to efficiently integrate large volumes of heterogeneous data from different disciplines is still missing. The data heterogeneity, volume, and noise levels preclude simple integration of data from multiple sources in, for example, a relational database. The data need to be properly processed and subsequently integrated in order to extract useful information that is manageable and applicable in various life science disciplines.

1.15.1.1 Chemogenomics: Interrogating Protein Targets With (Bioactive) Compounds

The completion of the Human Genome Project (HGP) in 2003 provided scientists with a near-complete reference of the human genome and the opportunity to study diseases at molecular level and accelerate drug development.[6] For example, while the discovery of the gene causing cystic fibrosis took 9 years in the 1980s, the gene responsible for Parkinson's disease was identified

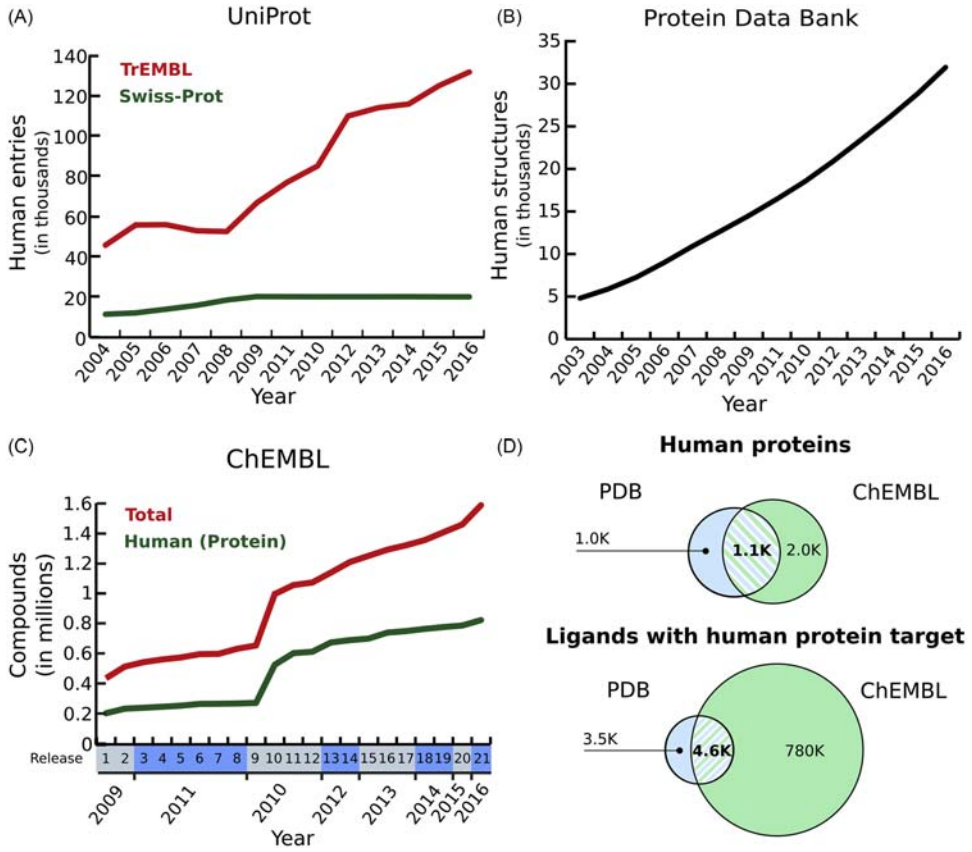

Fig. 1 An overview of the increase of structural chemogenomics data. The amount of (A) protein sequences in TrEMBL and Swiss-Prot (curated TrEMBL entries) integrated in UniProt, (B) structures in the Protein Data Bank (*PDB*), (C) Number of molecules for which biological activity data is available at human protein targets and all protein targets of ligands in ChEMBL, and (D) the overlap of the human protein targets and ligands with human protein targets covered by PDB and ChEMBL. The gene overlap was calculated based on accession IDs extracted from ChEMBL and PDB, while the ligand overlap was calculated based on extracted InChi keys from both databases.

within 9 days in 1998.[7] In addition to that, the human genome provided the potential to uncover new drug targets[8] by assessing the number of human genes, the druggable targets, and their druggability, which is the ability of small molecules to modulate protein targets.[9] The overwhelming majority of approved drugs bind to (specific) protein targets,[10] and these proteins could be used as templates to extend the number of protein targets as "similar ligands bind to similar targets."[11] Hopkins and Groom were among the first to estimate the number of drug targets.[12] By analyzing the overlap of all members of protein families with a precedent for binding drug-like molecules (~3000) and genes related to disease (~3000), they estimated the number of human drug targets to be between ~600 and 1500.[12] This estimation was adjusted to between 2000 and 3000 in 2005.[13] Overington et al. were able to assign 324 drug targets to the 1357 approved drugs up to that time.[14] This showed that all approved drugs up to 2006 targeted only 10–15% of the estimated number of druggable targets. Since the completion of the HGP, the pharmaceutical industry is continuously in pursuit of ways to reduce this gap by introducing new drugs that aim at previously untargeted proteins. For example, in 2014 and 2015, the FDA-approved drugs that had a novel mechanism of action and aimed at novel drug targets constituted of 17 (of 41 approved drugs) and 16 (of 45 approved drugs), respectively.[15] The advances made by the HGP simultaneously provided a new challenge to the pharmaceutical industry—selection and validation of drug targets.[16]

Chemogenomics, defined as the study of the effects of small molecules on target gene families, aims to convert the acquired wealth of genomic data combined with structural, phenotypic, and bioactivity data into drugs.[17,18] This new and highly interdisciplinary field combined medicinal chemistry, bioinformatics, and cheminformatics with the aim to develop novel strategies to tackle the significant challenges that the pharmaceutical industry was facing at the time. In particular, the increasing research costs and low approval rate of drugs aiming at new targets was a major concern.[19–21] In the decade before the completion of the HGP, for example, the approved drugs by the FDA had only three new targets each year on average.[12] In contrast to conventional methods, chemogenomics uses large and diverse compound libraries for screenings and applies interdisciplinary approaches to systematically link the readouts to drug targets.[17] To assist the process of identifying new drug candidates, experimental and computational approaches are commonly used within the field.[17] In the former approach, the workflow typically involves testing of compound libraries in representative biological systems, performing assays to generate readouts, and then analyzing those readouts to identify active compounds. In the case of computational (or predictive) chemogenomics, the workflow involves collecting, generating, and

integrating, (whenever available) genomic, structural, and activity data; and applying machine learning algorithms to predict phenotypic responses and effects of (novel) compounds on targets.[17,22] Given that experimental data are often incomplete because of time and resource savings applied on screening methods,[23,24] the computational approaches provide the means to predict the missing data, discover new protein targets, and lead the field closer to its ultimate aim to identify all drugs for all targets.[25,26]

In the post genomic era, along with the rise of chemogenomics, the industry started to shift away from the rational drug design paradigm—that is "one drug, one target"—toward drug polypharmacology as it became apparent that drugs typically act on more than one target.[2,27–29] Drug polypharmacology builds on these multiple drug–target observations and attempts to utilize this in order to improve major drug development obstacles like efficacy and toxicity by trying to optimize on- and off-target activity profiles, lower the drug resistance, and modulate beneficial pathways.[27,30] Analyses of ChEMBL and PubChem suggest that 30–50% of biologically active compounds and most drugs interact with multiple protein targets and therefore may exhibit polypharmacological profiles.[31–34] The already-established large and continuously increasing sources of publicly available data[35–37] provide input to computational chemogenomics approaches to predict the selectivity and polypharmacological action of drugs.[38–42] The large number of diverse compounds and their annotated targets could indeed serve as a starting point for such an endeavor.

1.15.1.2 Publicly Available Sequence, Structural, and Activity Data

Access to high-quality sequence, structural and activity data provide more than just the ability to study the direct relationships between ligands, targets, and their affinities. It also allows to predict previously unexplored ligand–target interactions and to correlate the predicted interactions to clinical efficacy. This is crucial for drug discovery as drugs typically act on multiple targets and are therefore likely to influence multiple pathways. The GenBank along with its European and Japanese counterparts were used to store the huge amount of sequence data produced by the HGP that started in 1990 and finished in 2003.[43,44] In order to make use of the genome reference to study and diagnose diseases, new human sequences had to be mapped to the reference human genome. The amount of bases in the GenBank increased fourfold in the last 10 years, from 50 trillion bases in 2005 (collected over 10 years) to over 200 trillion in 2015. In 2004, PIR-PSD,[45] Swiss-Prot,[46] and TrEMBL[47] united to form a central resource of protein sequence data: the Universal Protein Knowledgebase (UniProt).[48] Swiss-Prot and TrEMBL are separate sections of the UniProt database: Swiss-Prot consists of manually annotated protein sequence records, while TrEMBL consists of computationally analyzed sequence records that after curation are transferred to Swiss-Prot (**Fig. 1A**). In UniProtKB/TrEMBL, fragments, isoforms, and variants of full-length protein sequences (encoded by the same gene and from the same species) are represented in separate entries. In UniProtKB/Swiss-Prot, all protein products encoded by one gene in a given species, including alternative splicing isoforms, fragments, and polymorphisms, are all reported in a single entry. The manual curation procedure of UniProtKB/Swiss-Prot includes (i) sequence curation (identification of, e.g., alternative splicing, natural variations, frameshifts, incorrect initiation sites, and incorrect exon boundaries), (ii) sequence analysis (predicted annotation of, e.g., posttranslational modifications, subcellular location, transmembrane domains, protein topology, domain identification, and protein family classification), (iii) literature curation (check predicted annotations complemented by additional information summarized in section "**Protein sequence and structure for structural chemogenomics analyses**," and assignment of relevant gene ontology (GO) terms based on experimental data from the literature), (iv) family-based curation (data standardization across homologous proteins), (v) evidence attribution (links to the original information source), and (vi) quality assurance, integration, and update. In 2015, redundant proteomes were removed from UniProtKB/TrEMBL (decreasing the number of entries from 92 million to 46 million entries), and currently, UniProtKB/TrEMBL contains 63,686,057 entries. From 2004 to 2009, the number of curated protein sequence entries in UniProtKB/Swiss-Prot rapidly increased by 3.5-fold to more than 514,292 entries in 2009 (with an increase of 108,200 entries in 2009). In the past 5 years, the number of entries has grown at a slower rate than in 2004–09 and now contains 550,960 entries (with an increase of 3031 entries in 2015).

The PDB, established in 1971,[49] contains a standardized collection of macromolecular structure data derived primarily from X-ray diffraction (89.3%) and solution NMR (9.6%).[50] The PDB format[51] was introduced in 1977 to standardize the crystallographic data. During the years, it became mandatory for researchers to deposit their crystal structures in the databank,[52] which along with the continuously improving technology enormously increased the collection of 3-D structures in the databank—from only 7 initially to 10,000 in 1999[53] and more than 117,000 as of Mar. 2016 (**Fig. 1B**). The PDB is now the single repository of experimentally determined macromolecular structures[3] and among the most widely used structural databases.[52] The rapidly growing amount of protein structures in the 1990s (from 500 in 1990 to over 13,500 in the year 2000) and compound libraries allowed medicinal chemist to use computational approaches to enrich compound libraries and limit the costs and time needed to perform screenings.[54,55] ChEMBL, a database of bioactive drug-like small molecules and annotated bioactivities, was launched in 2009 with 440,055 bioactive compounds, 3622 protein targets, 329,250 assays, and 1,936,969 activities.[5] A year and half after its initial release ChEMBL reached over million compounds for the first time (tenth release, the lower red dot in 1C) and just recently, on its twenty-first release, 1.5 million compounds (the higher red dot in 1C). The total amount of bioactivities annotated in ChEMBL has increased more than sevenfold to 13,968,617 on the 1st of Feb. 2016, covering 1,592,191 compounds (>3-fold increase), 11,019 targets (including 6262 proteins, >3-fold increase), and 1,212,831 assays (>3-fold increase). **Fig. 1D** shows that for 1083 of the 3057 human protein targets (genes) for which bioactivity data is available in ChEMBL, there is also structural information available in the PDB. ChEMBL contains bioactivity data for 4575 of the 8048 ligands for which a protein bound structure is available in the PDB. This analysis suggests that for a large part of the protein targets for which bioactivity data is available, structure-based ligand discovery and optimization approaches may be used to optimize existing biologically active molecules or identify new

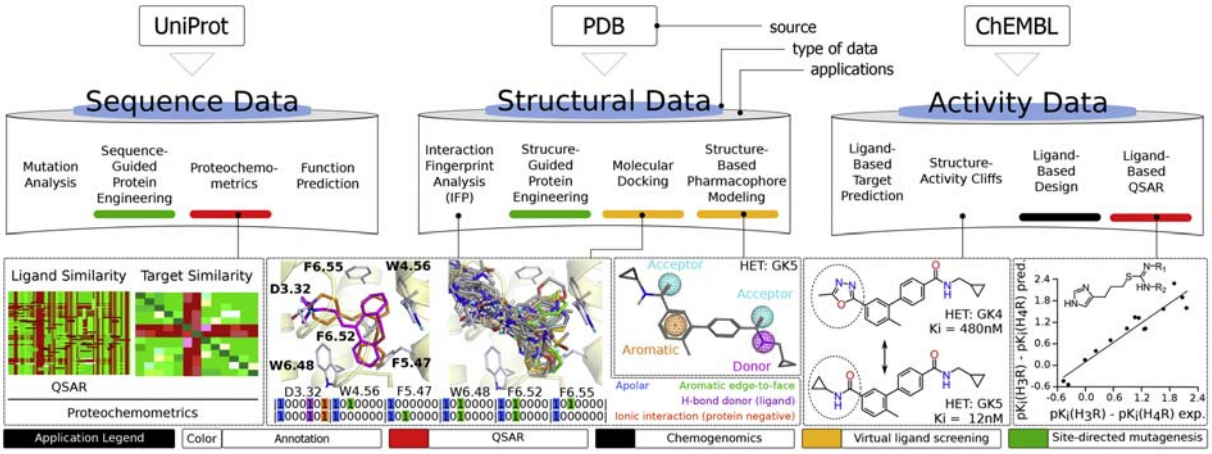

Fig. 2 Application of structural chemogenomics data. Schematic depiction of bioinformatics and chemoinformatics approaches and applications that can be used to transform information in protein sequence (e.g., UniProt[58]), (ligand-bound) protein structure (e.g., PDB[3]), and target-annotated ligand bioactivity (e.g., ChEMBL[5]) databases into models to predict structural protein–ligand interactions. Bio/chemoinformatics modeling applications based on protein amino acid sequence information (e.g., mutational analysis,[59] sequence-guided protein engineering,[60] proteochemometrics,[61,62] and function prediction[63]), protein–ligand structure data (e.g., structural protein–ligand interaction fingerprint (IFP) analysis,[64,65] structure-guided protein engineering,[60] molecular docking,[56] protein-based pharmacophore modeling[66]), and bioactivity data (e.g., ligand-based QSAR,[67] structure–activity cliffs,[68] ligand-based target prediction,[69] and ligand-based design[70]) can be used to, for example, guide site-directed mutagenesis studies, virtual screening to discover new ligands for specific protein targets and identify the protein target(s) of specific small molecules, and the construction and application of QSAR models to guide the design and optimization of ligands with desired protein affinity, activity, and selectivity profiles.

ligands. For a large part of the protein targets for which structural information is available, bioactivity data is still lacking to efficiently elucidate the molecular determinants of protein–ligand binding. Molecular docking of a small set of known biologically active molecules (e.g., drugs) against libraries of binding sites of protein for which few ligands are available (inverse docking) can, for example, be an efficient structure-based approach for ligand repurposing.[56] Only a very small number of the known biologically active molecules have been cocrystallized as a protein–ligand complex (<0.001%), emphasizing the need of computational methods to predict structures of protein–ligand complexes for which no structural information is available. Shan et al. were the first to accurately predict the binding mode of a ligand to a target without prior knowledge of the binding site using molecular dynamics (MD) simulations.[57] Fig. 2 shows examples of different bioinformatics and chemoinformatics methods that can be used to transform information in protein sequence (e.g., UniProt[58]), (ligand-bound) protein structure (e.g., PDB[3]), and target-annotated ligand bioactivity (e.g., ChEMBL[5]) databases into models to predict structural protein–ligand interactions. It should be noted, however, that the predictive power and information content of models (primarily) based on specific data sources can be significantly improved by the *combination* of sequence, structure, and bioactivity data: for example, the use of bioactivity data for optimization and training of pharmacophore models and docking studies,[71] the use of protein structures and bioactivity data in 3D-QSAR approaches,[72] and the integration of sequence information, bioactivity data, and sometimes also protein structures in proteochemometric models for the bioactivity prediction of protein–ligand pairs.[61,73] The current article focuses on the analysis of structural chemogenomics databases that allow integration of bioactivity and structural information for structure-based prediction of protein selectivity and ligand polypharmacology.

1.15.1.3 Structural Chemogenomics Ontology for the Integration of Curated Chemical and Biological Data

Structural chemogenomics data is highly heterogeneous—from experimental bioactivity data in large public databases such as ChEMBL[5] to molecular fingerprints and pharmacophores of ligands (generated using algorithms like ChemAxon,[74] EDprints[75]), protein–ligand interaction descriptors (IFP[64] and KRIPO[76]), and protein–ligand structure databases (PDB,[3,77] KLIFS,[64] PDESTrIAn,[65] and GPCRdb[78,79]). However, most databases use a relatively small set of IDs to link their data and analyses to comprehensive structural, sequence resources such as the PDB and UniProt. To facilitate systematic comparison between the biological and chemical databases reviewed in this article, we prepared a controlled dictionary in the form of a glossary (Table 1). This glossary comprises identifiers that are both relevant to the subject of this article and can, for example, be used to link to resources like PDB and UniProt. All entries in the glossary consist of an identifier, its definition, whether the PDB and/or UniProt have mapped their data to the identifier, a link to the original source (database) for the identifier (if applicable), and an example. In addition to the ontology and data mapping efforts unified in the PDB and UniProt databases, several other integrated databases have contributed to the definition of common ontologies that facilitate integrated structural chemogenomics analysis, ranging from broad platforms to integrated chemical identifiers (UniChem), pharmacological data resources (open PHACTS[93]), pharmacological targets

Table 1 Glossary used to define a structural chemogenomics ontology that facilitates systematic curation, mapping, integration, and comparison protein, ligand, and protein–ligand interaction data provided by the different databases described in Sections **Protein structure-annotated biological activity databases, Structural protein–ligand interaction databases**, and **Examples of applications of structural chemogenomics databases in drug discovery**

ID	*Definition*	*Mapped*	*Link*	*Example*
UniProt ID	ID linked to protein sequence and functional information in the UniProt database[80]	PDB	www.uniprot.org/	P00519
PDB ID	PDB code: four-character ID linked to DNA/protein structural information in the Protein Data Bank[81]	UniProt	www.rcsb.org/pdb	1HW9
HET code	PDB ligand ID: three-character ID linked to ligand information in the Protein Data Bank		www.rcsb.org/pdb	2P5
GI number	The GenInfo identifier is linked to a sequence record processed by NCBI[82]		www.ncbi.nlm.nih.gov/genbank/	62362414
RefSeq ID	The Reference Sequence ID is linked to comprehensive reference sequence information in the NCBI RefSeq database[83]	UniProt	www.ncbi.nlm.nih.gov/refseq/	NP_005148.2
UniGene code	Links to computationally derived transcripts from the same locus and expression data in the UniGene database[84]	UniProt	www.ncbi.nlm.nih.gov/unigene	Hs.431048
ChEMBL ID	ID linked to compound, target, assay bioactivity information in the ChEMBL database	UniProt	www.ebi.ac.uk/chembl/	CHEMBL1862
IUPHAR/BPS ID	ID linked to information on approved or experimental drug or target in the Guide To Pharmacology[85]	UniProt	www.guidetopharmacology.org	5687
PubChem ID	ID linked to compound, target, assay, activity, or patent information in the PubMed database		pubchem.ncbi.nlm.nih.gov/	PubChem CID 5291
SMILES	Simplified molecular input line-entry system describes molecular species in a string form			C1=NC2=C(N1)C(=NC=N2)N
CAS	Links to unique numerical identifier of compound described in the scientific literature			152459-95-5
InChi	IUPAC International Chemical identifier is a character identifier for chemical species			InChI=1S/C5H5N5/c6-4-3-5 (9-1-7-3)10-2-8-4/h1-2H,(H3,6,7,8,9,10)
InChi key	Fixed-length character representation of the InChi			GFFGJBXGBJISGV-UHFFFAOYSA-N
CATH ID	ID linked to information on classification of a protein structure in the CATH database[86]	PDB	www.cathdb.info/	3cs9A01
SCOP ID	ID linked to information on classification of a protein structure in the SCOP database[87]	PDB, UniProt	scop.berkeley.edu/	173427
PubMed ID	ID linked to scientific publication in the PubMed database	PDB, UniProt	www.ncbi.nlm.nih.gov/pubmed	26496949
OMIM ID	ID linked to thesaurus of human genomic information in the OMIM database	UniProt	www.omim.org/	608232
MeSH	ID linked to entry in the controlled vocabulary thesaurus of the US national library of medicine	PDB	www.ncbi.nlm.nih.gov/mesh	D015464
Ensembl ID	ID linked to genetic information in the Ensembl database[88]	UniProt	www.ensembl.org/	ENSG00000097007
KEGG ID	ID linked to genomic and biological pathway information in the KEGG database[89]	UniProt	www.genome.jp/kegg/	hsa:25
TaxID	ID linked to the taxonomy of the target as identified in NCBI Taxonomy[90]	PDB, UniProt	www.ncbi.nlm.nih.gov/taxonomy	9606
EC number	Number linked to information on the nomenclature of enzyme as defined by International Union of Biochemistry and Molecular Biology (IUBMB)[91]	PDB	http://www.iubmb.org/	EC 3.5.1.n3
GO terms	Links to controlled vocabularies used to describe biological, molecular, or cellular component or function[92]	PDB, UniProt	geneontology.org/	GO:0005524

Each entry consists of an identifier, definition including the original database that uses the identifier, whether the PDB and UniProt have linked their data to the original database of the identifier, link to the original database, and an example of the identifier.

(IUPHAR[94]), and target-specific data (e.g., G protein-coupled receptor data in the GPCRdb[79]). These resources are frequently used to combine and integrate data from multiple databases. Partially due to this integration, the amount of readily available data keeps increasing, and data quality, data comparability, and data curation remain important but challenging endeavors. This issue is due to several factors, including reproducibility,[95] errors while processing the experimental data, errors while writing a publication, incomplete method descriptions, quality of data collection, integration, and annotation in databases, assay conditions (e.g., the use of different protein constructs), compound properties (e.g., impure compounds, racemic mixtures, and PAINS[96]), or ligand topology errors.[97–99] As computational drug development approaches rely heavily on the published data,[100] chemogenomics databases are implementing methods to address the challenges regarding data quality and curation.[89] ChEMBL, for example, has implemented structural alerts for compounds containing scaffolds/moieties that could be problematic (e.g., PAINS) and provides a confidence score for each bioactivity entry. PDBBind-CN reduces the amount of annotation mistakes by performing the annotation of each datapoint twice, independently by two persons. Additionally, more and more frequently (computational) curation workflows are applied before using the data for the development of chemogenomics models, which significantly increase the data quality.[101]

For structural approaches, there is the concern of issues in the elucidation of a protein structure. Several factors can impact the experimental determination of protein structure, for example, crystallographic artifacts (e.g., crystal packing), conformational changes due to the creation of crystallographic constructs (e.g., fusion proteins and thermostabilizing mutations), and errors while modeling the structure. Two examples of databases that address the latter issue are ValidatorDB[102] and PDB_REDO.[103] ValidatorDB provides summaries of precomputed validation results describing correctness and errors in the structures of the PDB. The validation protocol analyzes all ligands and nonstandard residues in the PDB and the topology and geometry of the data including atom substitutions, atom naming, foreign atoms, bad root mean square deviation, and conformations as well as overall completeness and chirality. PDB_REDO[103] uses a fully automated pipeline that optimizes the PDB structures by performing iterative refinement and subsequent validation of the crystal structures using R-values and validation scores. The PDB itself is also continuously updating its requirements and policies in order to ensure the quality of the structures that are deposited into the database.[3]

1.15.1.4 Protein Sequence and Structure for Structural Chemogenomics Analyses

The UniProt Knowledgebase (UniProtKB, www.uniprot.org/uniprot/)[80] is a central database that incorporates large collections of functional information on proteins, including the annotation and reference information of the protein name(s) and taxonomy, function, subcellular location and structural topology, pathology, posttranslational modifications, expression, interactions with proteins and/or small-molecule ligands, protein family and domains, amino acid sequence, and structural information. In particular, the UniProt protein name, Enzyme Commission (EC), and gene names provide identifiers (**Table 1**) that are frequently used in structural chemogenomics databases described in sections **Protein structure-annotated biological activity databases** and **Structural protein–ligand interaction databases**. The organism name and NCBI taxonomy identifier are used throughout all databases in which organism-specific information is presented, high-profile examples of which are ChEMBL and PDB. GO (geneontology.org)[92] codes are used to annotate the cellular components where the protein is active. The published or predicted structural topology (e.g., protein crystal structure publication or sequence similarity to an experimentally determined structure), including (transmembrane) helical regions, and beta-strands are mapped on the amino acid sequence of the protein. Also, the predicted or reported posttranslational amino acid modifications, including glycosylation, phosphorylation, and disulfide bonds, reported in, for example, Phosphosite (www.phosphosite.org) and iPTMnet (research.bioinformatics.udel.edu/iptmnet), are mapped on the protein sequence. Protein–ligand and protein–protein interactions are extracted from different databases, including ChEMBL, DrugBank (www.drugbank.ca),[104] GuideToPharmacology (www.guidetopharmacology.org),[85] DIP (dip.doe-mbi.ucla.edu/dip), and IntAct (www.ebi.ac.uk/intact). Protein polymorphism and mutations are extracted from among others BioMuta (hive.biochemistry.gwu.edu) and DMDM (bioinf.umbc.edu/dmdm) databases, while several databases including Bgee (bgee.unil.ch/bgee)[105] and Expression Atlas (www.ebi.ac.uk/gxa/genes)[106] contain information on protein expression levels in, for example, different cell types and tissues. Links to experimental structures are provided via RCSB Protein Data Bank (PDB), Protein Data Bank in Europe (PDBe, www.ebi.ac.uk/pdbe/),[107] and Protein Data Bank Japan (PDBj, pdbj.org),[108] while predicted structural models of the protein entry can be automatically generated via links to ProteinModelPort (www.proteinmodelportal.org),[109] including models extracted from, for example, SWISS-MODEL (swissmodel.expasy.org),[110] ModBase (modbase.compbio.ucsf.edu),[111] and GPCRdB (GPCRdb.org).[79] Links to family and domain databases including InterPro (www.ebi.ac.uk/interpro/),[112] Pfam (pfam.xfam.org),[113] PRINTS (www.bioinf.manchester.ac.uk/dbbrowser/PRINTS/), PROSITE (prosite.expasy.org), and ProtoNet (www.protonet.cs.huji.ac.il) provide protein and protein family classification. All literature resources that are used for the annotation of each entry in UniProt are reported including the specification of which annotation is based on that specific publication. All annotations can be downloaded in multiple formats (plain text, XML, RDF, and GFF), and the protein sequence can be downloaded in FASTA format. Furthermore, from a UniProt entry, one can directly link and submit requests to BLAST, ProtParam, ProtScale, PeptideMass, and PeptideCutter and calculate the molecular weight and isoeletric point of the protein.

The Protein Data Bank United States (RCSB PDB, www.rcsb.org/pdb),[3] Biological Magnetic Resonance Data Bank (BRMB, www.bmrb.wisc.edu),[114] Protein Data Bank Japan (PDBj, pdbj.org),[108] and PDBe (www.ebi.ac.uk/pdbe)[107] are united in Worldwide PDB (wwPDB organization, www.wwpdb.org)[115] and maintain a centralized PDB archive of macromolecular structures. The organization of the corresponding website and search features are however different. In the current description, we will focus on the RCSB PDB website and shortly indicate unique features of the websites of BRMB, PDBj, and PDBe. The RCSB PDB can be browsed by enzyme nomenclature (EC number, enzyme.expasy.org), protein structure class (SCOP, scop.mrc-lmb.cam.ac.uk/scop/),[87] protein domain structure (CATH class, www.cathdb.info),[86] membrane protein class (mpstruc, blanco.biomol.uci.edu/mpstruc/), transporter class (TC, www.tcdb.org), genome location (NCBI gene name, www.ncbi.nlm.nih.gov/gene), biological process, cell

component, and molecular function (GO ID, geneontology.org), source organism (NCBI Taxonomy class, www.ncbi.nlm.nih.gov/taxonomy),[90] anatomical therapeutic chemical class (ATC, www.whocc.no/atc/structure_and_principles), and publication keywords (Medical Subject Headings (MeSH), www.nlm.nih.gov/mesh). The RCSB PDB can be searched based on the structure annotation mentioned earlier (see RCSB PDB browse options), (other) IDs and keywords, deposition information, structure features, sequence features, chemical components (ligands, protein, drugs, and drug–target combinations), biology, experimental methods used to determine the macromolecular structure, and the publication corresponding to the PDB coordinate file. IDs include PDB ID, PubMed ID, UniProtKB AC, Pfam AC, and UniProt Gene name. In addition, drugs and drug targets in the PDB have been mapped to DrugBank. Structure feature search options include protein stoichiometry and symmetry, molecular weight, and secondary structure content and length, while sequence features include amino acid sequence BLAST search, sequence of the wild-type protein (e.g., excluding mutations to facilitate crystallization), and sequence motifs. Chemical component search options include chemical name, chemical formula, SMILES string, InChI or InChIKey, chemical formula or molecular weight, or chemical substructure or similarity (interactive chemical sketcher Marvin JS). Biology search options include expression organism of the protein, in addition to the many browse options described earlier. Methods search options include experimental method (including X-ray crystallography, solution NMR, solid-state NMR, electron microscopy, and electron crystallography), X-ray resolution, X-ray average B-factor, and refinement R factors. PDB entries contain the results of most of the search and browse options. Along more common features like annotations of the structure, classification, reference publication, 3-D view of the structure and ligand, ligand representations, interactions, 2-D structures, and links to bioactivity data, the database provides in-depth overview of the sequence data, sequence and structure similarities, the experimental data and validation, and citations in the literature. 2-D representations of interactions between ligands and proteins are drawn with PoseView.[116] The in-depth analysis of sequence data consists of sequence viewer and the optional third party annotations DSSP,[117] STRIDE,[118] MSDsite,[119] InterPro,[120] protein domain decomposition,[121] calculated alignments,[122] and domain parser,[123] which upon selection will map their predictions on the sequence. The in-depth analysis of sequence similarity consists of prepared with BLAST[124] sequence similarity clusters using 30–100% sequence similarity cutoffs. The in-depth analysis of structural similarity consists of detailed comparison of structural similarities computed with either Blast2seq, the Smith–Waterman algorithm, the Needleman–Wunsch algorithm, and jCE or the external servers TM-align, FATCAT,[125] TopMatch server, and Dali. PDB provides several tools to analyze the structural data, including tools to perform sequence and structure alignment, assess structure quality (backbone Ramachandran plot, clash score, or residue sidechains), and map genomic position to protein sequence and 3-D structure and many links to external tools. The database provides many links to external databases, including general biological and chemical databases (see browse options: Entrez NCBI, ExPaSy, GenBank, mpstruc, Pfam, and UniProtKB), biological activity databases (BindingDB, PDBbind-CN, and Binding MOAD), a database of commercially available compounds (ZINC), other databases that contain molecular structures (CCDC containing small-molecule crystal structures, www.ccdc.cam.ac.uk), EMDataBank containing CryoEM structures (www.emdatabank.org), ModBase (modbase.compbio.ucsf.edu/modbase-cgi/index.cgi) and SWISS-MODEL Repository (swissmodel.expasy.org/repository/) containing comparative protein structure homology models), and protein–ligand interaction analyses (ReliBase, www.ccdc.cam.ac.uk/solutions/csd-discovery/components/relibase/).

1.15.2 Systematic Analysis and Classification of Structural Chemogenomics Databases

1.15.2.1 Database Classification Criteria

While UniProt and PDB represent the largest protein sequence and structure depositories, respectively, ChEMBL is currently the largest curated and publically available database of target-annotated biologically active molecules (**Fig. 1**). We have analyzed additional target-annotated biologically activity databases, including general bioactivity databases BindingDB,[126] Intact,[127] STITCH,[128] SuperTarget,[129] PubChem Bioassay,[130] DrugBank,[104] PDSP K_i[131] (kidbdev.med.unc.edu/databases/pdsp.php), PDBbind-CN,[132] Binding MOAD,[133] the target family-specific bioactivity databases focusing on G protein-coupled receptors (GLASS[134]) and kinases (K-Map[135]), and two mechanism-specific bioactivity databases Platinum (site-directed mutagenesis effects)[136] and TIMBAL (protein–protein interaction modulators).[137] We have furthermore selected representative structural chemogenomics databases containing and combining protein, structure, and biological activity data of protein–ligand complexes that have been based on the following criteria: The database (i) includes structural protein–ligand interaction information, (ii) is up to date (created or updated within the past 3 years), (iii) should be publically available, and (iv) have a web interface to browse and/or search the data. While the bioactivity databases contain information on the pharmacological parameters defining, for example, the affinity, potency, and efficacy of ligands for specific protein targets, structural chemogenomics databases offer (additional) information on the structural features of protein–ligand interactions. It should be noted that there are several extensive commercial biological activity databases, including MDDR,[138] WOMBAT,[139] and Reaxys Bioactivity (www.reaxys.com). Furthermore, several biological activity databases (SuperTarget (insilico.charite.de/supertarget),[129] GPCR SARfari (www.ebi.ac.uk/chembl/sarfari/gpcrsarfari), GLIDA (pharminfo.pharm.kyoto-u.ac.jp/services/glida)[140] and structural protein–ligand interaction databases (KidFAMmap (gemdock.life.nctu.edu.tw/KIDFamMap)[141] and Kinase SARfari (www.ebi.ac.uk/chembl/sarfari/kinasesarfari)) have been set up, but unfortunately, these databases have not been created or updated in the past 3 years and are therefore not included within this systematic analysis and comparison (Apr. 2016). The selected structural chemogenomics databases are classified according to their focus and coverage of protein targets, including general structural protein–ligand interaction databases PoSSuM, IBIS, BioLip, CREDO, PLIC, ProBis, sc-PDB, Bival-Bind, Pocketome, iPfam, and PSCDB; protein target class-specific structural protein–ligand interaction databases focusing on kinases (KLIFS[99]), GPCRs (GPCRdb),[79] and phosphodiesterases (PDEStrIAn)[65]; and mechanism-specific structural protein–ligand interaction databases 2P2Idb (protein–protein interactions and protein–protein modulators)[142] and ASD (allosteric modulation).[143] Databases are analyzed according to the type of data they contain with respect

Table 2 Classification of biological activity and structural chemogenomics databases

Database					Features														Latest Updates
Name	Targets	Compounds	Complexes		Ligand										Complex

to (ligand, protein target, and protein–ligand complex information) (Table 2, Fig. 3), the way the data can be searched and/or browsed, and the frequency that the databases are updated.

1.15.2.1.1 Data browse and search functionalities

In addition to the analysis of the way that data types can be accessed and analyzed, we have evaluated whether the data can be browsed and/or searched. Most databases allow browsing, sometimes facilitated by predefined classifications of proteins and/or ligands. Search options are in some databases relatively limited and based only on protein or ligand names, PDB, UniProt, or ChEMBL IDs. Most biological activity and structural chemogenomics databases however, include search options based on 2-D chemical structure (SMILES and/or interactive chemical drawer), while several general structural chemogenomics databases (e.g., sc-PDB) and target-customized structural chemogenomics database (e.g., KLIFS, PDEStrIAn, or GPCRdb) include additional search options based on properties of the protein target binding site and/or protein–ligand interactions. More examples of different browse and search functionalities are described in more detail in sections Ligand data types, Protein data types, Protein–ligand interaction data types, and Protein structure-annotated biological activity databases.

1.15.2.1.2 Ligand data types

The following ligand data types are considered in the analysis of the target-annotated bioactivity and structural chemogenomics databases:

- *Physical–chemical properties*, including number of H-bond donors, H-bond acceptors, rotatable bonds, and hydrophobicity/log *P*. Many databases have this feature, including sc-PDB, KLIFS, and SuperTarget, which allow the extraction of entries that contain ligands with specific ranges of physical–chemical properties.
- *2-D chemical structure of the ligands* is included in most databases as 2-D depictions of the molecular structure and/or chemical structures that can be extracted from the database in, for example, SMILES or SDF format. Most biological activity databases include

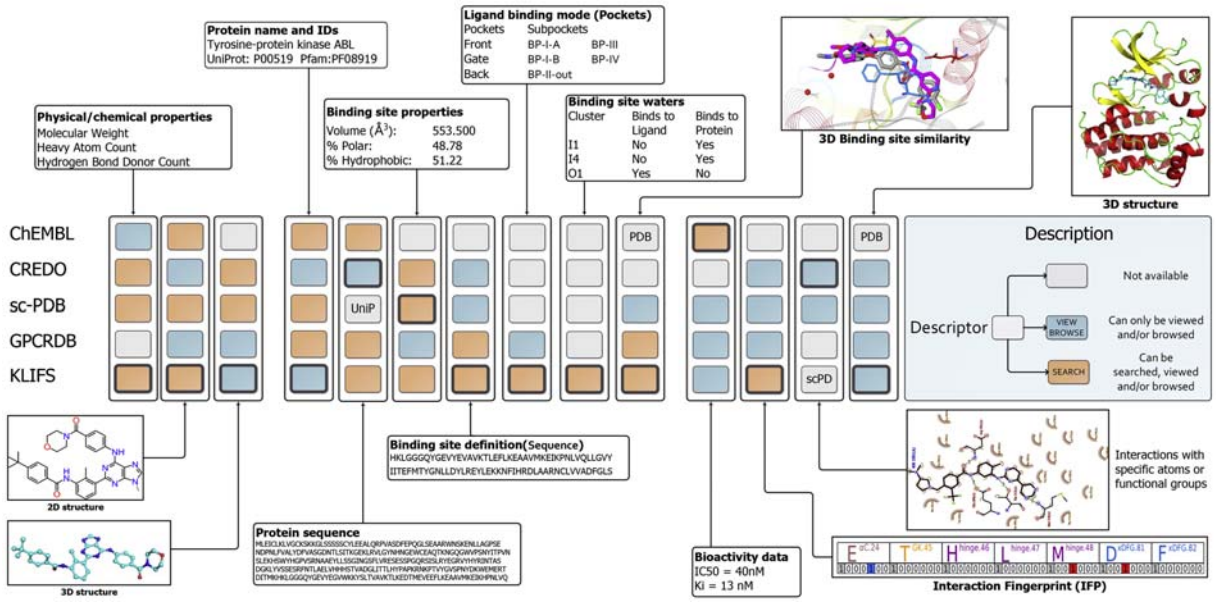

Fig. 3 Systematic structural chemogenomics comparison example. The comparison of representative proteome-wide biological activity (ChEMBL[4]), proteome-wide structural protein–ligand interaction (CREDO[144] and sc-PDB[145]), and protein family-focused structural protein–ligand interaction (GPCRdb[79] and KLIFS[99]) databases enables user to search (*orange*) and/or view/browse (*blue*) different features in the databases. For example, the ligand binding mode comparison shows that searching and viewing ligand binding mode information are possible only in KLIFS. GPCRDB allows to view/browse this type of information but not search, while sc-PDB, CREDO, and ChEMBL do not provide the option to search, view, or browse for ligand binding mode information at all. In addition to that, in some cases, the databases do not provide information directly on their website but instead provide links to external databases that contain that information, for example, UniProt (abbreviated as UniP), PDB, and sc-PDB (*scPD*). In the case of sc-PDB, the database does not show protein sequences in its result pages but provides links to UniProt where users can view it. The analysis of protein structure-annotated biological activity databases (described in Section **Protein structure-annotated biological activity databases**) and structural protein–ligand interaction databases (section **Structural protein–ligand interaction databases**) is presented in **Table 2**.

extensive search options including an interactive chemical sketch application to define queries and select entries that contain ligands with specific substructures, superstructures, scaffolds, and/or chemically similar molecules. In contrast, only three of the structural chemogenomics databases contain 2-D chemical structure search options: sc-PDB, KLIFS, and PDEStrIAn. Bival-Bind and Pocketome provide such information via the PDB. Applications relying on 2-D information include bioactivity data mining and chemical similarity search for ligand-based target prediction (Section "**Combined bioactivity data mining and chemical similarity search for ligand-based target prediction**") and integrated structure-based medicinal chemistry toolbox for drug discovery and design as described in Section "**Integrated structure-based medicinal chemistry toolbox for drug discovery and design**".

- *3-D chemical structure of the ligands* is included in all structural chemogenomics databases and most biological activity databases as coordinate files (e.g., PDB, MOL2, SDF) and/or links to PDB coordinates of cocrystallized ligands bound to protein structures. Only few databases include search options based on 3-D structural information of ligands. CREDO enables shape-based ligand similarity search, while sc-PDB and Bival-Bind provide search options based on indirect 3-D structural ligand information regarding ligand buried surface area (sc-PDB) and distance between two ligands targeting different binding site (Bival-Bind).

1.15.2.1.3 Protein data types

The following protein data types were considered in the analysis of the target-annotated bioactivity and structural chemogenomics databases:

- *Protein identifiers* can be used to search most databases and connect databases with each other allowing efficient data mapping. Frequently used IDs are shown in **Table 1**.
- *Amino acid sequence data*, along with structural data, form the essence when studying binding complexes, and as such, it is almost always either annotated in the databases or linked to databases that provide access to it (e.g., UniProt).
- *Physical–chemical properties* of protein binding sites can be searched in only a few databases to identify, for example, druggable binding sites (e.g., sc-PDB and CREDO).
- *Ligand binding sites* based on, for example, amino acid sequence or ligand distance cutoffs are defined in all structural chemogenomics databases while completely missing in the bioactivity databases. Examples of structural databases that enable users to view this information interactively include KLIFS, PDEStrIAn, PLIC, and BioLip.

- *Subpocket annotations* are reported in protein family-customized structural chemogenomics databases, as these databases allow the systematic annotation of (sub)pockets that are targeted by specific ligands. Complementary information on the chemical scaffolds that target-specific (sub)pockets could be extracted from a structure-based medicinal chemistry toolbox as described for KLIFS and PDEStrIAn in Section "**Integrated structure-based medicinal chemistry toolbox for drug discovery and design**."
- *Binding site water molecule annotations* based on superposed structures in protein family-focused structural chemogenomics databases allow the identification of areas in the binding sites in which a significant number of water molecules have been found within certain proximity. Consistent annotation of water clusters is included in KLIFS and PDEStrIAn databases and can be used to identify water molecules that can be displaced or targeted in structure-based ligand design.
- *Binding site similarity* assessments to other protein targets are provided by structural chemogenomics databases to facilitate the identification of sequentially, structurally, and/or chemically similar binding sites. Several databases allow binding site similarity assessments based on sequence similarity (IBIS, KLIFS, and PDEStrIAn), structure-based similarity (sc-PDB, PLIC, ProBis, and BioLip), or protein–ligand interaction pattern similarity (KLIFS, PDEStrIAn, and Pocketome). Applications of protein binding site similarity assessments for ligand repurposing and off-target prediction are described in Section "**Protein binding site similarity assessments for ligand repurposing and off-target prediction**."

1.15.2.1.4 Protein–ligand interaction data types

The following protein–ligand complex data types are considered in the analysis of the target-annotated bioactivity and structural chemogenomics databases (**Fig. 4**):

- *Bioactivity data* can be searched based on quantitative bioactivity data ranges and/or source data (e.g., PubMed ID and author names) in most biological activity databases. Only parts of the structural chemogenomics databases provide direct information on bioactivity data, including BioLip, sc-PDB, KLIFS, PDEStrIAn, GPCRdb, 2P2Idb, and ASD. Platinum contains experimentally

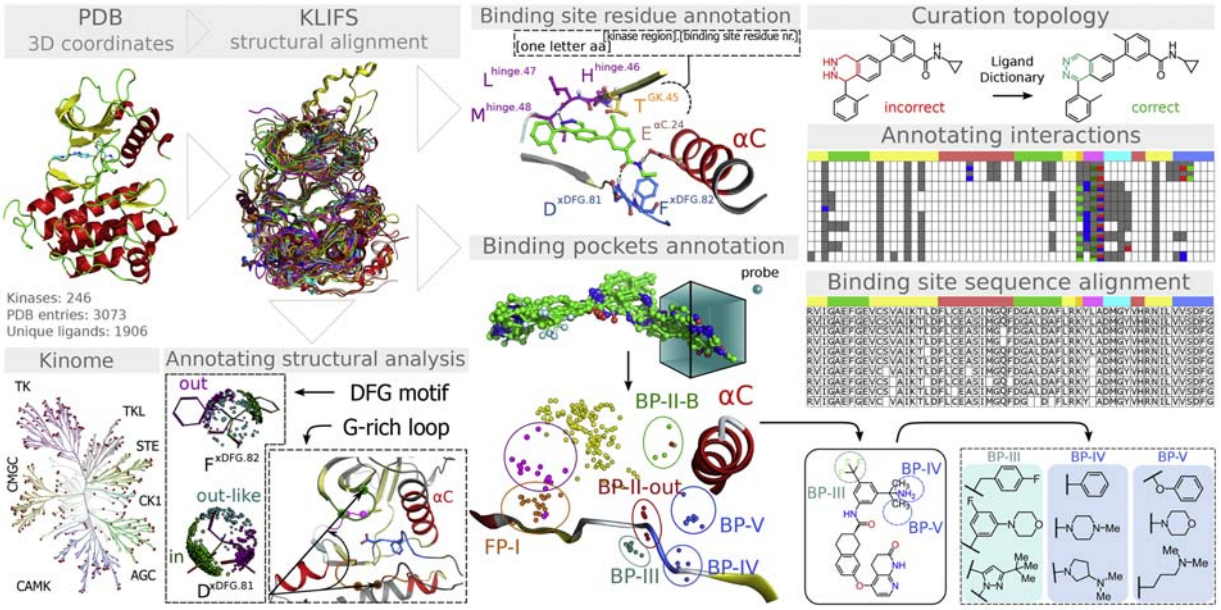

Fig. 4 Example of an integrated structural chemogenomics database to analyze structural protein–ligand interactions. The tools and analysis shown in this figure are extracted from the KLIFS database. New protein kinase structures (*top left corner*) are aligned to manually corrected structural and sequence alignments that allow automatic annotation of binding residues (shown under "Binding site residue annotation"), binding pockets (shown under "Binding pocket annotation") and interactions (shown under "Annotating interactions"). The positions and the residue coding of the aligned binding residues are annotated using the scheme (one letter amino acid)$^{(\text{kinase region}).(\text{binding site residue number})}$ as described by Kooistra et al. 2016.[99] This annotation allows for easy comparisons between different structures—for example, one could effortlessly compare the aspartic acid of the DFG motif in different structures as this residue is annotated consistently in the structures, that is, $D^{xDFG.81}$. The binding pocket annotation method uses probes and sets of aligned ligands to identify sets of probes that describe the binding pockets. Each set of probes (colored with a color) describes a binding pocket by using probes that are found within 1 Å of ligands that bind to that pocket; thus, each set of probes forms a sphere in the 3-D space that is unique to ligands that bind to a particular pocket. The identified probes can then be used to assign binding pockets to new ligands. On the *bottom right corner*, the back pockets(BP) III, IV, and V are annotated for the ligand with PDB ID 0NF. Interactions between ligands and protein kinases can be annotated using interaction fingerprint methods. These methods typically check if any of the atoms of a bound ligand fulfills any of the interaction rules, and if it does, it is annotated along with the type of interaction. Typical interaction rules are distances and angles. The interaction fingerprints allow easy comparison of the interactions that ligands make. The table under "Annotating interaction" shows interactions (represented with unique color) bound ligands make with protein kinase targets (each row represent unique protein kinase target).

measured effects of mutants of a set of protein–ligand complexes for which experimental data is available, while GPCRdb contains a large number of mutation data on G-protein-coupled receptors.

- *Residue-based interaction fingerprint*: Interaction fingerprints are binary representations (yes/no) that encode different types of interactions that a ligand makes with residues of their bound target. This descriptor indicates if such representations are available in the considered databases. It should be noted that the PDB format does not sufficiently annotated chemical topology of non-protein molecules to allow accurate annotation and analysis of protein–ligand interactions. A more appropriate format is, for example, the atom- and bond-type annotated Tripos MOL2 format, which is, for example, used to analyze protein–ligand interaction fingerprints deposited in, for example, sc-PDB, KLIFS, and PDEStrIan. Transformation of PDB into MOL2 format, however, requires careful curation of the chemical topology and protonation of ligands and proteins to allow for proper protonation of the molecules and accurate analysis of protein–ligand interactions, including H-bond interaction networks. In KLIFS and PDEStrIAn, for example, the data in the chemical component dictionary are used to identify and correct errors in atom and bond types complemented by manual curation steps (Fig. 3).
- *Atom-based 2-D interaction information* indicates whether protein–ligand interaction information is available in a 2-D representation. In contrast to residue-based interaction fingerprint that represents the interactions in a simple binary form, atom-based 2-D interaction information shows at least the interacting residues in 2-D and the interaction they make with the ligand, which is also represented in a 2-D. The 2-D representation should make it possible to determine the interacting atoms of both the protein and ligand. Most general structural protein–ligand interaction databases provide this feature. A well-known program that is frequently used to visualize protein–ligand interactions in 2-D diagram is LigPlot.[146]
- *3-D structural information*: All general, target class-specific, and mechanism-specific, structural protein–ligand interaction databases contain 3-D coordinates of the protein–ligand complex. All general and target class-specific structural protein–ligand interaction databases provide processed structural data files in which binding sites are annotated, residues are protonated, and/or the molecular topology is curated, which allow consistent analysis of structural protein–ligand interactions. Most of these databases annotate the interactions with interaction fingerprint and/or 2-D interaction information. Almost all general biological activity databases provide links to the coordinates PDB.

1.15.2.1.5 Database update frequency

To anticipate the continuous growth in sequence information deposited in the UniProt (>5.7 billion sequences over the period between Apr. 2015 and Apr. 2016), structural information in the PDB (9334 structures in 2015), and bioactivity information in the ChEMBL database (>440,000 bioactivity data points over the period between Feb. 2015 and Feb. 2016), it is important to know what the frequency is with which databases are updated and what the latest update was. For the analysis presented in Table 2, we have reported the latest updated on Apr. 2016. The update frequencies of the databases were categorized into weekly, montly, between 1 and 3 months, between half year and one year, not updated in the last 2 years, and never updated. The most regularly updated databases are BioLip, KLIFS, and PDEStrIAN, which are updated weekly to keep in sync the PDB to keep up with the continuous growth in published catalytic kinase domain structures (>337 new structures in 2015) and PDE structures (>18 new structures in 2015). DrugBank, PDSP Ki, and IntAct are updated monthly, while BindingDB and K-Map are updated every 1–3 months. Although ChEMBL used to have very frequent updates (up to six times a year, Fig. 1C), the two most recent versions of the database have been on a yearly basis. GPCRDB, PDBbind-CN, 2P2idb, Pocketome, and TIMBAL are updated every half a year to a year. ProBis used to be updated twice a year, but in the recent years, its update frequency decreased to only once a year or 2 years. GLASS is updated irregularly, but the time intervals between the updates span typically within a year. On the other hand, Binding MOAD, CREDO, PLIC, and sc-PDB have not been updated in the past 2 years (Apr. 2016). iPfam, Bival-Bind, and Platinum have never been updated since their initial release. PubChem is the only database that updates its content daily basis.

1.15.3 Protein Structure-Annotated Biological Activity Databases

1.15.3.1 Proteome-Wide Biological Activity Databases

PubChem[130,147] (pubchem.ncbi.nlm.nih.gov) contains 9960 protein, 19,260 gene targets, and 88,837,058 compounds, of which 2,101,179 tested in 1,154,436 bioassays, resulting in 230,042,050 bioactivity data (Apr. 2016, updated daily). PubChem can be searched by compound, patent, target, bioactivity, or bioassay. Compound searches can be performed based on name/keywords, PubChem CID, SMILES, InChI, molecular formula, and 2-D chemical (sub)structure and chemical similarity. Patent queries can be performed using keyword, inventor, applicant, structure, and molecular formula. Bioassays and bioactivities can be queried by only names, and in the case of bioactivity, the names can be genes or chemical names. The database can be browsed by bioassays and in particular activity types/potency, assay types, cell lines/types, data sources, detection methods, HTS projects, publications, targets, and taxonomy. The results of compound queries contain 2-D and 3-D structures of the compound and information on names and identifiers, chemical and physical properties, related records, chemical vendors, drug and medication information, pharmacology and biochemistry, toxicity, literature, patents, biomolecular interactions and pathways, biological test results, classification, and information sources. The chemical and physical properties consist of computed and experimental properties including MS–MS spectra. Related records provide links to similar compounds, conformers, components, and substances or records with similar connectivity and similar or exact patent. This part also offers links to journals, government organizations, and other

R&D databases to name just a few. The remaining parts provide information about involved disease, pharmacology, protein targets (including action, function, and references), ADME, mechanism of action, toxicity and protein binding, links to PubMed publications, patents, involved pathways, results of bioassays, and links to many external sources. The assay queries contain a description of the assay, tested substances and their outcome and activity, information from ChEMBL and other sources, assays from the same publication, and related bioassays. Target and bioactivity queries return the relevant compounds, their best activity value, and provide links to view the compound information, while patent queries give links to external source of the patent.

ChEMBL[5] (www.ebi.ac.uk/chembl) contains 13,967,816 biological activities for 1,592,191 distinct compounds and 11,019 targets, collected from 65,501 publications (Apr. 2016, v21, latest update Feb. 2016). ChEMBL can be browsed by protein target, drug, drug targets, and drug indications. The molecular structures of compounds in ChEMBL are curated and standardized and provided as SMILES string. Protein targets are classified in 15 main protein classes (7089 in total), 6 main taxonomy classes (10,657 in total), and 3 main gene ontologies (15,642 in total) and can be browsed by name, UniProt ID, and organism, among others. Drugs can be browsed based on 27 parameters, including patent number, applicants, clinical phase, indication class, and administration (oral, parenteral, or topical), and whether the drug is first in class, a prodrug, and whether the targets/mechanisms of action are (un)known (black box). Drug targets can be browsed based on 19 parameters, including drug molecule, drug target name, mechanism of action/action type (activator, inhibitor, agonist, and antagonist, including reference), and binding site. Drug indications can be browsed based on 11 parameters, including MeSH (ID and heading) and EFO (ID and term) information and indication reference. ChEMBL can be searched based on protein target (name/keyword, BLAST search), compound (ChEMBL ID, name/keyword, SMILES string, chemical (sub)structure, chemical similarity, and biological BLAST search), assays (keyword), documents (keyword), and cells (keyword). Protein target entries contain information on the target name and classification (including UniProt ID) and overviews of approved drugs and clinical candidates targeting the protein, associated bioactivities and assays, and analyses of target ligand efficiencies, target compound properties, and cross-references to external sources regarding target gene (including Ensembl, GO, Wikipedia), protein (including UniProt and Guide to Pharmacology[85]), and domain (including Pfam) information. Ligand entries contain information on compound name and classification (ChEMBL ID and synonyms), molecular representations (SMILES string, mol file, InChi, and InChi key), calculated physical–chemical properties, associated bioactivities and assays, protein target predictions, available clinical data, and compound (ChemSpider, Wikipedia) and UniChem (including BindingDB, eMolecules, LINCS, and PubChem ID) cross-references. Bioactivities can be filtered based on activity parameter and value and are described by 54 parameters, including parent compound ChEMBL ID (to allow mapping of similar compounds), compound key (name or code mentioned in the source), SMILES string, bioactivity parameter (value, relationship, and unit), pChEMBL value (to allow comparison of different bioactivity parameters), assay ChEMBL ID, protein target UniProt ID, assay type (binding or functional), cell type, and reference information (PubMed ID, ChEMBL document ID, and citation). The ChEMBL Virtual Machine (MyChEMBL) integrates ChEMBL, PostgreSQL, and the chemoinformatics tools in RDKit in order to provide a user-friendly environment for performing chemogenomics studies.[148]

STITCH[128] (stitch.embl.de, v4.0) contains experimentally determined and predicted protein–ligand interactions between 300,000 small molecules and 2.6 million proteins from 1133 organisms, including more than 2.2 million interactions between human proteins and small molecules (Apr. 2016, updated Oct. 2015). STITCH can be searched by protein information (name, UniProt, Swiss-Prot, sequence, and organism) and ligand information (name, InChi keys, ChEMBL, PubChem, and chemical structure (SMILES, upload)). The resulting STITCH protein–ligand interaction network can be interactively viewed. The individual connections (i.e., edges in the network) contain supporting experimental data and the associated databases (including ChEMBL, PubChem, PDSP-K_iDB, DrugBank, and KEGG), as well as predicted interactions, while the nodes contain information regarding the proteins (Ensemble, UniProt, Genecards, PfAm, and NextProt) and ligands (description, 2-D chemical structure and ChEMBL, PubChem, DrugBank, KEGG, ChemSpider, and Google links) involved in the network.

BindingDB[126] (www.bindingdb.org) contains 1,161,912 binding data of 6929 protein targets and 505,999 small molecules, collected from literature not covered by other public databases (Apr. 2016, latest update Mar. 2016, updated every 1–3 months). BindingDB includes affinity data for protein–ligand complexes of 2291 identical (100% protein sequence identity) and 5816 similar (85% protein sequence identity) proteins for which crystal structures are deposited in the PDB. BindingDB can be searched (and browsed) based on binding data (K_d, K_i, IC_{50}, k_{on}, k_{off}, ΔG^0, ΔH^0, and $-T\Delta S^0$), experimental details (pH enzymatic assays and pH ITC), protein target (name, UniProt ID, amino acid sequence, and PDB code), ligand (name, molecular weight, and SMILES string), 2-D chemical structure (substructure, similarity search), and reference (PubMed and PubChem). BindingDB can be browsed (but not searched) based on source organism, pathway, and reference (author, journal/citation, institution, and US Patent). BindingDB furthermore provides lists of the number of compounds per target, ligands per target (csv), PDB codes per ligand (sdf), and approved and experimental drugs. BindingDB (curated literature) data downloads can be complemented by binding data from ChEMBL, PubChem, PDSP K_i, CSAR, and US Patents.

IntAct[149] (www.ebi.ac.uk/intact, v4.0) contains 586,731 experimentally determined interactions between ligands and 83,536 proteins (Apr. 2016, updated monthly). IntAct can be searched by protein information (protein, RNA, gene name, UniProtKB, RNA, and IMex ID), ligand information (name and ChEBI), and reference (PubMed). Intact entries contain an overview of the interacting protein(s) (name, type, UniProtKB and CHEBI ID/AC links, and organism), the interacting ligand(s) (name, chemical structure, and CHEBI ID), and description of their experimentally determined interactions (interaction detection method, literature reference, and CHEBI interaction AC). Search links are provided based on the individual interacting molecules.

PDSP K_i database[131] (kidbdev.med.unc.edu/databases/pdsp.php) contains 59,239 K_i binding data, of 352 proteins and 5335 ligands, extracted from literature (Apr. 2016, latest update Mar. 2016, updated montly). The PDSP K_i database can be browsed

(but not searched) based on protein UniGene code and PubMed ID, PubChem ID, and ChEMBL ID source reference data. The PDSP K_i database can be searched (and browsed) based on K_i binding data range, protein target (name, organism, source, and anatomic profile), ligand (test ligand name, SMILES string, CAS, NSC code, and hot radioligand name), and reference source (author/date). The database furthermore offers different search options to investigate and visualize protein–ligand selectivity. Querying the database reveals the K_i information for protein–ligand complexes. In addition, PDSP K_i provides links to PubChem, ChEMBL, and PubMed.

PDBbind-CN[132] (www.pdbbind-cn.org/) provides highly curated experimentally determined binding data for biomolecular complexes available in the PDB, including binding data for 14,620 complexes, most of which are protein–ligand complexes (11,987), followed by protein–protein (1807), protein–nucleic acid (717), and nucleic acid–ligand (109) complexes (Apr. 2016, v2015, latest update Dec. 2015, updated every half year to one year). The database is updated on an annual basis and uses a combination of scripts and automation tools followed by double manual curation for the annotation of experimentally measured binding data (K_d, K_i, and IC_{50}) from literature (>27,000 unique references). It furthermore provides a set of high-quality "core" structures containing 195 protein–ligand complexes comprising 65 protein families. This set can, for example, be used for retrospective docking and scoring evaluation purposes. All data is available for download as a set of processed structures and all annotated binding data in plain text and PDF format. The web interface of PDBbind-CN provides four ways of traversing through the data. The first option is *Browse*, which allows the user to browse through the database starting from the first entry. The second option is *Data* and provides several search options: PDB code, ligand name, release year, structure resolution, binding affinity, EC number, and protein name. The third option is *Structure* and allows a user to specify (SMILES or PDB code) or draw a molecule for a chemical (sub)structure or similarity search. The fourth option is *Sequence*, which allows the user to perform blast queries using a PDB entry or a specific fasta sequence. All search results can be downloaded in PDF and Excel format and also provides the option to download the selected structures (ligand, protein, ligand and protein, or pocket and ligand). The detail page of each structure shows a summary of the entry, a 3-D viewer of the structure, a list of database entries with a high sequence similarity, and links to PDB, PDBsum, and PubChem.

Binding MOAD[133] (www.bindingmoad.org, v2014) contains well-resolved crystal structures (resolution ≤2.5 Å) of 25,771 biomolecular complexes of 7599 proteins and 12,440 different biologically relevant ligands (peptide ≤10 amino acids, oligonucleotide ≤4 nucleotides, and small organic molecules) collected from the PDB, annotated with 9142 experimentally determined binding data (K_d, K_i, IC_{50}) reported in the primary reference of each PDB file (Apr. 2016, latest update 2014). Crystallographic additives, salts, buffers, metals, metallic catalytic centers, or solvents are *not* considered as ligands. Database entries can be browsed and filtered based on protein target class (7 enzyme families organized by EC number and 11 nonenzyme groups), the availability and value ranges of binding affinity data, crystal structure resolution, and ligand molecular weight. Entries can be searched based on PDB code, EC number, protein source, ligand HET group and the molecular structure (substructure, superstructure, similarity, fragment, or duplicate), keywords, and author surname.

DrugBank[104] (www.drugbank.ca) focuses on FDA-approved, experimental, nutraceutical, and other types of drugs. The database currently contains 8198 drugs and 4331 protein sequences and many forms of related information (Apr. 2016, v4.3, latest update Feb. 2016, updated every 1–3 months). For each drug, there is an extensive list of annotations and datapoints available, which are categorized into identification, taxonomy, pharmacology, ADMET, pharmacoeconomics, properties, spectra, references, interactions, targets, enzymes, and transporters. Identification provides information on the name, structure, synonyms, approval status, (generic) prescription/over-the-counter products, brands, categories, and chemical descriptors and molecular identifiers. Taxonomy describes the classification of the drug in detail. Pharmacology reports detailed information regarding the indications for the use of this drug, the pharmacodynamics, the mechanism of action, experimental ADMET properties, and the affected pathways. "ADMET" provides a list of predicted ADMET properties (from admetSAR) and the probability of each property. "Pharmacoeconomics" list manufacturers, packagers, dosage forms, prices, and patents of a given compound. "Properties" list both experimental and predicted chemical properties of the drug (e.g., melting point, pK_a, and PSA). "Spectra" provide links to available MS and NMR spectra. "References" links to key patents, scientific articles, ATC codes, and many external resources (e.g., ChEMBL, KEGG, ChemSpider, and IUPHAR). "Interactions" list available drug–drug and drug–food interactions. The final three categories targets, enzymes, and transporters, offer detailed information regarding the interactions between the selected drug and proteins divided in these three categories. For each interaction entry, the type of interaction and the pharmacological classification as well as references to articles listing the interaction including a link to the UniProt identifiers of the interacting protein are given. Besides a browse option, the DrugBank also provides many search options including searching using structure, drug name, pathway name, target name, molecular weight, interaction, sequence, and (MS/GC)MS and (1-D/2-D) NMR spectra. All data are also available as download in XML/CSV/Fasta/SDF format depending on the type of data that is downloaded.

1.15.3.1.1 Protein family-customized biological activity databases

GLASS[134] (zhanglab.ccmb.med.umich.edu/GLASS/) contains 441,667 experimentally validated GPCR–ligand interactions extracted from 811,966 experimental data entries, covering 687 GPCRs (GLASS contains 3056 different GPCR entries, including 825 human GPCRs) and 276,324 ligands (including 192,251 Lipinski's drug-like entries) (Apr. 2016, latest update Dec. 2015). GLASS contains GPCR–ligand interaction data systematically extracted from biological activity databases (ChEMBL, BindingDB, IUPHAR, DrugBank, and PDSP), GPCR diseases association database TTD, GPCR experimental structural data (PDB and BioLiP), and predicted models of GPCRs (GPCRRD), and the respective IDs of these databases can be used to search GLASS. GLASS GPCR–ligand interaction entries are complemented with ligand (PubChem and InChI) and protein (UniProt) data and contain overviews of experimental data for a ligand with all known targets and for a target with all known ligands.

K-Map[135] (tanlab.ucdenver.edu/kMap/kMapv1.0/) contains bioactivity data for 98,312 kinase–ligand complexes, covering 742 protein kinases (including mutated kinases) and 241 compounds (Apr. 2016, updated every 1–3 months). K-Map provides a rank-ordered list of compounds for the queried kinases based on their normalized connectivity scores and *p*-values. The database can be searched by kinase name and browsed by kinase name, family, GO terms, and drug name in combination with IC_{50}, K_d, or both. Additional information about compounds and targets can be found via the following links to external sources: PubMed, PubChem, ChEMBL, ChemSpider, KEGG, GDSC, and clinical trials.

1.15.3.1.2 Mechanism-specific biological activity databases

TIMBAL[137] (mordred.bioc.cam.ac.uk/timbal) contains 18,940 bioactivity data of 8889 small-molecule ligands that modulate protein–protein interactions collected from ChEMBL based on UniProt codes of 50 known PPI targets and their orthologs (1137 entries in total, Apr. 2016, v2015, latest updated Jun. 2015, updated every half year to one year). Data have been selected from binding assays that are directly assigned to either a single protein or its homolog or a protein complex or its homologs.

1.15.4 Structural Protein–Ligand Interaction Databases

1.15.4.1 General Structural Protein–Ligand Interaction Databases

IBIS[150] (www.ncbi.nlm.nih.gov/Structure/ibis/ibis.cgi) contains 381,223 annotated protein–ligand interactions including 5981 protein–DNA interactions, 18,838 protein–RNA interactions, 199,819 protein–protein interactions, 6737 protein–peptide interactions, 53,927 protein–ion interactions, and 95,921 protein–chemical interactions (Apr. 2016, latest update Feb. 2016). IBIS can be searched based on PDB, UniProt, or Gene ID. Each IBIS entry (PDB link) provides an overview of the type and number of interaction sites and the interaction partner (protein, chemical, DNA/RNA, and ion), which can serve as a query to identify similar protein structures. The query result consists of a comparative binding site alignment of the residues interacting with different ligands targeting of the protein target and homologous proteins.

BioLip[151] (zhanglab.ccmb.med.umich.edu/BioLiP) contains 344,248 annotated protein–ligand interactions including 41,038 protein–DNA/RNA interactions, 16,169 peptide–protein interactions, 97,430 metal–protein interactions, and 189,611 regular protein–ligand interactions derived from 74,069 PDB entries (Apr. 2016, updated weekly). In total, 23,492 entries are annotated with experimentally determined binding data (K_d, K_i, and IC_{50}) derived from Binding MOAD (10,971), PDBbind-CN (16,980), BindingDB (7331), and 64 manually collected from original literature. BioLip contains a hierarchical procedure for assessing the biological relevance of ligands present in the PDB structures. BioLiP can be browsed and searched based on PDB ID, PDB ligand ID, ligand name, UniProt ID, EC numbers, and GO terms. BioLiP can be browsed (but not searched) based on ligand binding residues, catalytic sites (derived from Catalytic Site Atlas), and PubMed entry. To facilitate the use of BioLiP for function annotation of uncharacterized proteins, a consensus-based algorithm COACH is used to predict ligand binding sites from protein sequence or using 3-D structure. Each BioLip entry provides a definition of the ligand binding site and global view of protein–ligand interactions.

ProBIS[152] (probis.cmm.ki.si) allows structure-based comparison of specific ligand binding sites with the binding sites in 42,270 protein–ligand crystal structures collected from the PDB (Apr. 2016, latest update Jul. 2015, updated every 1 to 2 years). To search ProBIS, the query binding site can be defined interactively (JSmol) based on distance from specific HET codes observed in the query PDB file. ProBIS entries contain an overview of annotated binding sites, predicted ligands (small molecule, protein, nucleic acid, and ion), and a *z*-score ranked list of similar proteins in the PDB that can be browsed (including links to corresponding PDB entries).

PoSSuM[153] (possum.cbrc.jp/PoSSuM) contains 300,122 known and 5,213,569 putative binding sites collected from 98,458 PDB entries, covering 12,220 unique protein structures and 5312 unique ligands, excluding buffers, water molecules, DNA/RNA, and peptide (Apr. 2016, latest update Oct. 2014, updated every 1 to 2 years). Binding sites extracted from crystal structures ($\leq$4.0 Å resolution) and NMR structures (only model 1) consist of six residues or more that are within 5.0 Å from an interaction probe cluster (consisting of 200 probes or more) generated with Ghecom.[154] PoSSuM can be searched based on protein (PDB code) and ligand (HET code, HET chain ID, and HET residue number) information and customizable search settings considering the ligand binding site (known and/or putative), sequence redundancy, similarity cutoff, and aligned sequence length cutoff to identify 530,989 target binding sites that are similar to 2595 query binding pockets targeted by 194 known small-molecule drugs (covering 1289 PDB entries and 452 UniProt IDs). PoSSuM entries have been annotated with various protein and gene data (UniProt, CATH, SCOP, EC, and GO), and structural alignments of similar binding sites can be viewed in an interactive manner (with JSmol). The annotated drugs in PoSSuM can be browsed based on name/ID (preferred name, HET code, and ChEMBL ID), therapeutic application (WHO ATC classification), chemical properties (heavy atom, rotatable bonds, log*P*), chemical structure (2-D image, SMILES, and InChi key), and the number of query and target binding sites (and number of associated proteins, PDB entries, EC numbers, and CATH codes).

CREDO[144] (marid.bioc.cam.ac.uk/credo/) contains protein–ligand interactions in 95,515 crystal structures collected from the PDB (Apr. 2016, latest update 2013). CREDO entries contain the structural interaction fingerprint (SiFT[155]) analyses of interactions between the atoms of surface-exposed residues of all molecules inside macromolecular structures from the PDB (including proteins, nucleic acids, carbohydrates, and small-molecule ligands) and the annotation of protein structure variations (EnsEMBL Variation). CREDO can be searched based on ligand information, including physicochemical properties, 2-D similarity (substructure/

superstructure, RDKit, OpenEye fingerprints, and TriGRAM) and 3-D (ultrafast shape recognition) chemical similarity search, and nine filters (including amino acid, drug-like and lead-like). CREDO can be browsed based on protein information (PDB, protein type, protein domains (Pfam, CATH), and secondary structure fragment), ligand information (name, type, chemical components, and fragments), protein–ligand interactions (drug-/substrate-/product-/kinase-binding sites, interfaces, grooves, ligand–ligand interactions, ligand–nucleic acid interactions, halogen bonds, and metal complexes), genetic variations, and (disease) phenotypes. The protein, ligand, and protein–ligand information in CREDO entries can be used as reference for subsequent ligand 3-D similarity (USR) searches. In addition to the extensive structural protein–ligand interaction analyses (residue-based and atom-based contact analyses, 13 SiFT interaction types), CREDO provides overviews of structure quality criteria parameters (including identification of disordered regions, diffraction-component precision index (DPI), incomplete residues, and clashes).

sc-PDB[145] (cheminfo.u-strasbg.fr/scPDB/) contains annotated protein–ligand interactions in 9283 PDB entries, covering 3678 proteins and 5608 ligands collected from the PDB and their bioactivity data collected from ChEMBL (v.2013, latest update Feb. 2014). Sc-PDB can be searched based on (i) ligand properties (PDB HET code, ranges of molecular weight, aLogP, logS, rotatable bonds, rings, Lipinski rule of five violations, number of H-bond acceptors, H-bond donors, negatively ionizable atoms, and positively ionizable atoms) and 2-D chemical structure (exact, substructure, superstructure, and fragment), (ii) protein classification (EC number, UniProt (AC, name), organism, TaxID, and kingdom) and experimental structure information (PDB ID, experimental method, and resolution), (iii) binding site properties (presence cofactor, ion, number of water molecules and nonstandard amino acids, number of chains, range in size and cavity volume, and average B-factor), and (iv) binding mode (number of hydrophobic contacts, aromatic contacts, H-bond acceptor (protein) to H-bond donor (ligand) and H-bond donor (protein) to H-bond acceptor (ligand) interactions, cation (protein) to anion (ligand) and anion (protein) to cation (ligand) interactions, and ligand buried surface area). sc-PDB entries contain in addition to the search parameters the following information: (i) ChEMBL ID and activity data; (ii) 2-D structure of the ligand; (iii) comparison of protein and ligand properties to average values in the sc-PDB; (iv) atom- and residue-based report and 2-D (Poseview) and 3-D (AstexViewer) views of protein–ligand interaction distances, angles, and interaction types[156]; (v) assessment of binding site similarity (based on Shaper cavity fingerprint descriptor); (vi) and protein–ligand binding mode similarity (based on Grim[157] interaction fingerprint descriptor) and 3-D structural alignment with respect to other sc-PDB entries. sc-PDB-Frag[158] (cheminfo.u-strasbg.fr/scPDBFrag/, v.2013, latest update 2014) builds on the sc-PDB, contains fragments of protein-bound ligands, and allows users to search for bioisosteric replacements of ligands.

Bival-Bind[159] (agknapp.chemie.fu-berlin.de/bivalbind) contains 9153 crystal structures of bi- and multivalent protein–ligand complexes (containing at least two ligands of the same type) collected from PDB, BindingDB, and Binding MOAD (Apr. 2016, created 2014, not updated since). Bival-Bind can be searched based on PDB and ligand HET codes, distance between two ligands targeting different binding sites, sequence identities between the structures containing the binding sites, and several geometric parameters of the binding sites, including convexity, barrier, depth, and vectors alpha and beta defining the length and orientation of the two binding pockets. Bival-Bind entries furthermore contain the surface height profiles of the different ligands (PDB).

PLIC[160] (proline.biochem.iisc.ernet.in/PLIC) contains 84,846 protein–ligand binding sites in 30,956 proteins and 11,042 ligands collected from the PDB (Apr. 2016, latest update Mar. 2013). PLIC can be searched based on protein (UniProtID, EC number, CATH ID, and name) and ligand (PDB HET code and name) information and text search. PLIC entries (annotated ligand binding sites) contain overviews of similar binding sites, 2-D (LigPlot) and 3-D (Jmol) visualization, the analysis and structural 3-D alignments of binding site clusters (based on PocketMatch and PocketAlign), and detailed analyses of binding sites (based on fPocket shape descriptors) and protein–ligand interactions (atom-based and residue-based protein–ligand contact analyses, and water contacts, and interaction energies (using AutoDock)).

Pocketome[161] (pocketome.org, v15.12) contains conformational ensembles of protein–ligand binding sites of 2744 different proteins (Apr. 2016, latest update Dec. 2015, updated every half year to one year). The Pocketome database includes proteins that have an Swiss-Prot entry and, have been cocrystallized in complex with at least one drug-like small molecule, and are represented by at least two PDB entries. Pocketome can be searched based on protein (protein name, family, domains, UniProt name, and PDB code) and ligand (HET code and ligand name) information. In addition, similar Pocketome binding sites can be searched based on ICM binding site selection. Pocketome entries contain protein (PDB codes associated with the entry, protein, family, domain, and UniProt names of the master chain and second chain, organism), ligand information (HET code), and binding site annotation, atomic coordinates of superimposed structures, contact matrices, and the results of pairwise structure comparison within the pocket ensemble. Pocketome entries provide interactive structure visualization (ActiveICM) and can be downloaded in a variety of file formats including ICB (ICM binary format) and extensible markup language (XML).

Platinum[136] (bleoberis.bioc.cam.ac.uk/platinum) contains experimentally measured effects of 600 (single or double) mutants of 142 unique proteins and 185 ligands, representing 1008 protein–ligand combinations in total (Apr. 2016, created Oct. 2014, not updated since). Platinum can be browsed based on protein name, mutation, ligand ID, and UniProt ID. Platinum can be searched based on ligand type (amino acid, bound, nucleotide, and saccharide), organism category, mutation effect (decrease or increase), 12 protein classes, experimental method (kinetic, ITC, FRET, optical binding, radioligands, SPR, and others), protein structure resolution range, mutation type (all or single-point), and affinity constant ($K_D/K_i/K_m$). Platinum entries contain information on the protein (PDB ID and UniProt ID), ligand (name, PDB HET code, PDBe link, and SMILES string), definition of the mutant and its affinity compared with wild-type protein (affinity constant, unit), the experimental method used to determine the affinity, experimental parameters of the determined protein structure (including experimental method and resolution, R_{free}), and reference source (doi and PubMed ID).

1.15.4.2 Mechanism-Based Structural Protein–Ligand Interaction Databases

2P2Idb[142] (2p2idb.cnrs-mrs.fr) contains structural analyses of 27 protein–protein interaction interfaces and physical–chemical descriptors of 224 small-molecule PPI inhibitors collected from the PDB[3] (v2.0, latest update 2015). PPIs are classified in three classes, and each 2P2Idb PPI entry contains overviews of the structures of the protein–protein complex, free protein target, free protein partner, and protein–inhibitor complex that can be browsed and downloaded. Global PPI parameters (including gap volume, number of contacts, H-bonds, interface secondary structure, and planarity) and atom- and residue-based annotation of structural interactions (contacts, H-bonds, and salt bridges) are reported and visualized with JSmol[162] for each PPI interface. PPI inhibitors can be searched based on chemical descriptors (10 MOE (Chemical Computing Group Inc.) and 13 DRAGON[163] descriptors). Links to external databases provide (additional) information on the protein target and partner (UniProt, PDB, and PDBsum), dissociation constants (K_d) of protein–protein and protein–inhibitor complexes (PDBbind-CN), and small-molecule PPI inhibitor properties (ChemSpider, LigandRCSB, Ligand CREDO, LigandExpo, and HicUp). The information returned by the search or browse options is divided into four categories: protein–protein, free protein (target), free protein (partner), and protein inhibitor. The protein–protein contains 3-D representation of the proteins and provides the possibility to view the contacts and hydrogen bonds per residue (also in 3-D). The free protein sections contain the 3-D structure of the protein (in viewer) and information from Structural Biology Knowledgebase[164] and report additional links to literature. The protein inhibitor contains, in addition to 3-D representation, descriptors of the ligand generated by MOE and DRAGON and 2-D representation of the ligand. This section contains also additional links to CREDO, ChemSpider (www.chemspider.com), LigandExpo (ligand-expo.rcsb.org), and HIC-Up.[165] The combined information of the chemical and structural properties of PPIs and their inhibitors provided by the 2P2Idb database can be exploited by complementary chemoinformatics tools to analyze PPI interfaces (2P2I Inspector), predict the druggability of PPIs (2P2I score), and design focused chemical libraries to target PPIs (2P2I hunter).[166]

ASD (Allosteric Database)[143] (mdl.shsmu.edu.cn/ASD, v3.0) contains 1473 allosteric protein target entries, 71,538 allosteric modulator entries, 75,462 allosteric interactions, 1930 defined allosteric binding sites, 57 structural allosteric modulation pathways, 261 allosteric modulation networks, and 3350 diseases related to allosteric modulation of protein function, collected from scientific literature and web resources, including PubMed, Drugbank, IUPARM, PDB, and US and European patents (Apr. 2016, latest update 2015). Allosteric binding sites can be searched by name and are classified according to family, including 5 E-proteins, 21 phosphatases (30 orthologues), 19 nuclear hormone receptors (26), 42 transcription factors (55), 53 peptidases (59), 98 GPCRs (118), 100 channels (134), 141 kinases (207), and 616 other human proteins (838 orthologues). The allosteric modulation mechanism of each of the 1473 protein targets is annotated according to 87 different mechanisms. Allosteric target entries contain gene information, tissue and cell localization, keywords and summaries of biological function and processes of the target, and whether structural information is available (link to PDB or theoretical model), summary of the secondary structure topology of the target, the ASD ID and 2-D structure of allosteric modulators, and literature references describing the allosteric mechanism and include links to UniProt, EMBL, and KEGG databases. Allosteric modulators can be browsed (but cannot be searched) and are classified by three modulator classes (52 ions, 70983 organic compounds, and 503 polypeptides), three modulator types (33 activators, 26 inhibitors, and 29 regulators), and whether they are endogenous and/or drug-like modulators. Allosteric (and corresponding orthosteric) binding sites are defined in 1930 annotated in PDB files that can be downloaded. For 57 allosteric interactions, the structural allosteric modulation pathway is defined and can be browsed based on target, the amino acid residues involved, and the supporting publication and experimental method used to elucidate the pathway. ASD contains 261 allosteric modulation networks that are classified according to six different network types (cellular processes, environmental information processing, genetic information processing, human diseases, metabolism, and organismal systems) that can be interactively visualized with Cytoscape (including links to KEGG). Comprehensive maps of the allosterome of kinases and GPCRs are provided, including the annotation of allosteric crystal structure complexes. The combined information of the allosteric targets, modulators, structural pathways, and biological networks can be exploited by complementary tools to estimate whether a molecule is likely to be an allosteric modulator (Allo-Like),[167] predict (potential) allosteric sites in proteins (AlloSite),[168] predict the binding affinity of allosteric protein–ligand interactions (AlloScore),[169] analyze and visualize the structural features of allosteric binding sites (Asbench),[170] identify potential novel allosteric targets based on sequence similarity search (P-search), and identify potential novel allosteric modulators based on chemical similarity and/or substructure search (M-search).

iPfam[171] (ipfam.org, v1.0) provides detailed domain–domain and domain–ligand interactions data (DDI and DLI, respectively) on 9516 unique domain pairings, 15,540 ligands, and 50,886 unique domain–ligand pairings (Apr. 2016, created Jun. 2013, not updated since). iPfam can be search by keyword, accession ID, PDB ID, protein sequence, iPfam ligand, and family entries and browsed by family and ligand entry names. The iPfam query results contain a summary from Wikipedia (for both ligand and family) accompanied with references to PubMed articles, the corresponding family and ligand interactions, and 3-D structures. The formula, molecular weight, InChI, SMILES, and the 2-D structure of ligands are also included in the results. The family interactions consist of the interacting families and the number of intrachain and interchain interactions. Furthermore, the database gives a graphical representation of the sequences of the interacting pairs. In this representation, the domains of the sequences are annotated along with their type of interaction; in the case of domain–ligand pair, the domains are annotated along with the ligand interactions. iPfam distinguishes five types of interactions: Van der Waal, hydrogen bond (with backbone and chain), electrostatic, and covalent bonds. As part of its analysis, iPfam also provides a 3-D viewer in the query results in which the users can view dynamically the different domains.

1.15.4.3 Protein Family-Customized Structural Chemogenomics Databases

GPCRdb[79] (www.gpcrdb.org) contains sequence, structure, and protein–ligand interaction information on 18,788 G protein-coupled receptors (including 398 human nonolfactory GPCRs) of 3096 different species collected from UniProt, 134 experimentally determined GPCR structures collected from the PDB, and 12,150 GPCR mutant–ligand combinations and 1063 GPCR–ligand interactions collected from literature (Apr. 2016, latest update Sep. 2015, updated every half year to one year). GPCRdb can be filtered by species (human, all) and source (UniProt, all), searched by name, and browsed by 6 classes, 19 families, and 76 subfamilies. GPCR entries contain information on the name and classification (including UniProt ID, Guide to Pharmacology, and ChEMBL links), structure-annotated amino acid sequence (secondary structure assignment and structure-based residue numbering), and helical wheel diagrams and snake plots that can be mapped with the effects of mutation data collected from literature and protein–ligand interaction information derived from crystal structures deposited in the PDB. GPCRdb contains several tools to analyze the sequence, structure, mutation data, and ligand binding sites of GPCRs. GPCRdb sequence data analyses include structure-based sequence alignments and tools to perform sequence similarity searches (GPCRdb and BLAST) and to construct phylogenetic trees and sequence similarity matrices of specific combinations of GPCRs. GPCRdb structure data analyses include GPCR crystal structure browser and statistics and tools to superposition structures, annotate generic GPCR residue numbers to PDB files, and assess global and local sequence similarities to GPCRs for which experimental structures are available. GPCRdb mutation data, the comparison of the affinity/activity of a ligand at point mutant with wild-type receptor, can be analyzed for specific combinations of GPCRs and mapped on helical wheel and snake plots in an interactive manner. GPCR–ligand interaction data include reports of residue-based protein–ligand interactions (generic residue number, segment, and interaction types), interactive 3-D viewer of the ligand binding site and a 2-D interaction plot (Poseviewer), and tools to identify the GPCR–ligand binding site (manual, derived from PDB) and generate pharmacophore models from ligand substructures. Developers can incorporate the database in local workflows by either using the provided python API or downloading the source code and data that is freely available on GitHub. Recently, GPCRdb KNIME nodes have been developed to allow automated GPCR data extraction and incorporation in integrated structural bioinformatics and chemoinformatics modeling workflows.[172]

KLIFS[99] (klifs.vu-compmedchem.nl, v2.0) contains sequence, structure, and protein–ligand interaction information on 247 protein kinases (human and mouse) covering 3103 PDB structures and 1931 unique ligands (Apr. 2016, v2.0, updated weekly). The database can be searched by PDB code, kinase name, family and group, SMILES, 2-D structure, state of DFG conformation and αC-helix conformation, any combination of interaction pattern, any combination of sequence composition, ligand properties (e.g., number of heavy atoms, log *P*, number of hydrogen donors/acceptors, and number of rotatable bonds), structural properties (X-ray resolution, quality score, G-rich loop angle, G-rich loop rotation, and G-rich loop distance), any combination of 15 annotated ligand binding modes, and any combination of conserved pocket water presence including if they make a hydrogen bond with either the protein or ligand. Furthermore, the database can be browsed independent of a search query. KLIFS contains information on kinase classification (name, family, group, and species); 2-D representations of the ligands (if present); comprehensive structural and binding mode information that include annotations of the conformations of the DFG motif, the αC helix, the G-rich loop (angle and rotation), structure resolution, missing atoms, and residues in the binding site; a quality score that represents the completeness and conformity of the structure and the ability of KLIFS to accurately process the structure; and the pockets and subpockets that the ligands address and cluster water molecules within the pocket. Mutations and gaps in the sequences of the structures are annotated based on a comparison of the crystal structure sequence with the UniProt sequence. If a structure contains a ligand and is present in the ChEMBL database also, all kinase affinity data, including species, kinase name, the type of affinity, the median and average values of the affinities, and the total amount of records, is presented. Moreover, if bioactivity data for the specific ligand–kinase combination is available, it is highlighted in red. Key within KLIFS is the annotation of the kinase–ligand interaction pattern. This interaction pattern encodes seven types of interactions for each binding pocket residue, which again can be used to search for other kinase structures in which a similar interaction profile is observed based on a user-defined cutoff. Additionally, the database allows further exploration of its structure and ligand entries by providing an interactive 3-D viewer, iview.[173] This 3-D viewer also provides users with the opportunity to perform a 3-D comparison of ligand binding modes with different structures. Moreover, all PDB entries are linked to external databases—the PDB, sc-PDB, KIDFamMap, PubMed, and Guide to Pharmacology/IUPHARdb.

PDEStrIAn[65] (pdestrian.vu-compmedchem.nl, v1.0) contains sequence, structure, and protein–ligand interaction information from 18 phosphodiesterase (PDE) subtypes (human, rat, and parasite) covering 245 PDB structures and 185 unique ligands (Apr. 2016, updated weekly). The database can be searched by PDE type, species, ligand (sub)structures and similarity (using SMILES or by drawing the 2-D structure), sequence composition, ligand properties (e.g., number of heavy atoms, logP, number of hydrogen donors/acceptors, and number of rotatable bonds), structural properties (X-ray resolution and quality score), and protein–ligand information (e.g., interaction patterns, targeted subpockets, the presence of conserved waters including their interaction patterns). Furthermore, the database can also be browsed. The browse and search results of PDEStrIAn contain information on classifications (type and species), 2-D representations of the bound ligands (if available), and the option to download the processed complex. The detail pages offer comprehensive binding information, structure resolution, missing atoms and residues, quality scores (that represent both the quality of a structure and the ability of PDEStrIAn to accurately process this structure; the higher the score, the better), the subpockets the ligands address, and the observed water molecules in predefined conserved clusters. In addition to that, the database allows further exploration of its structure and ligand entries by providing an interactive 3-D viewer, iview,[173] and linking its entries to four external databases—the ChEMBL, PDB, sc-PDB, and PubMed. Along its many display and manipulation options, the 3-D viewer also provides the opportunity to compare the binding mode of ligands with different

structures. Furthermore, POVME calculations have been integrated that allow the user to visualize the pocket volume within the 3-D viewer. Mutations and gaps in the sequences of the structures are annotated by comparing the crystal structure sequence with the sequence deposited in the UniProt database. In addition to the 2-D representation and annotation of the binding modes, the structure–ligand interaction pattern is shown. This interaction pattern encodes seven types of interactions for each binding pocket residue, which again can be used to search for other PDE structures in which a similar protein–ligand binding mode is observed based on a user-defined cutoff. Furthermore, data from the ChEMBL database is integrated (and linked) showing all available affinities for PDEs from the ligand that is bound in a structure and provides a full overview of these entries listing the median, minimum, and maximum of the available bioactivities per species, PDE type, and measure type (e.g., K_i/IC_{50}).

1.15.5 Examples of Applications of Structural Chemogenomics Databases in Drug Discovery

In this section, applications of (off-)target prediction, detection of target similarity, ligand design and all-against-all analysis of ligand structures and interaction fingerprints, and using structural chemogenomics databases are described thoroughly. The section contains three examples of using the similarity ensemble approach (SEA) to predict unknown targets for known compounds (the targets were also experimentally validated), two examples of the key representation of interaction in POckets (KRIPO) method to identify off-targets for known inhibitors, an example of detecting target similarity using the SiteAlign[174] method and the sc-PDB database, an example of ligand design using an integrated structure-based medicinal chemistry toolbox and the PDEStrIAn database, and three examples of all-against-all analysis of ligand structures and interaction fingerprints using KLIFS, PDEStrIAn, and an in-house GPCR dataset.

1.15.5.1 Combined Bioactivity Data Mining and Chemical Similarity Search for Ligand-Based Target Prediction

Biological activity databases can be used to construct ligand-based target prediction models that correlate chemical structural features of small molecules to the probability to interact with a specific protein target.[162] ChEMBL compound entries contain ligand-based target predictions, and several webservers like SwissTargetPrediction[175] (www.swisstargetprediction.ch) and SEA[69] (sea.bkslab.org) can be used to perform ligand-based target for individual molecules. The SwissTargetPrediction webserver uses a combination of 2-D and 3-D chemical similarity methods to assess the similarity of the query molecule to 280,000 compounds active on more than 2000 targets of five different organisms. The SEA relates proteins based on the setwise 2-D chemical similarity among their ligands,[69] and the SEA webserver can perform queries against previous versions of ChEMBL, MDDR,[138] WOMBAT,[139] and KEGG.[89] The SEA method has been successfully applied to identify main and off-targets for several bioactive compounds, illustrating the potential of prospective ligand-based target prediction based on target-annotated biological activity databases.[39,176,177] SEA models have been built to predict off-target binding of 3655 FDA-approved drugs for 246 protein targets extracted from three databases (MDDR, WOMBAT, and StARlite), using ECFP4 molecular fingerprints to assess ligand similarity. The resulting SEA models identified 23 new experimentally validated drug–target combinations (of the 30 combinations that were tested),[39] including antagonistic effect of Prozac (fluoxetine) at the β_1 adrenergic receptor, inhibition of the serotonin transporter by Vadilex (ifenprodil), and antagonistic effect of Rescriptor (delavirdine) at the histamine H_4 receptor.[22] In another study, the SEA method was used to assess the safety of 656 marketed drugs against 73 promiscuous proteins that are associated with side effects based on bioactivity data from the ChEMBL database and the ECFP4 and 2048-bit Daylight molecular fingerprints to characterize the ligands of 73 protein targets. The SEA models identified 151 novel predicted drug–target combinations with micromolar potencies (out of the 694 that were tested), including inhibition of cyclooxygenase 1 (COX-1) by the estrogen receptor (ER) ligand chlorotrianisene.[176] The SEA method has furthermore been used to identify the protein targets of compounds that induce a photomotor response (PMR) in zebrafish.[177] A SEA search of the 681 phenotypic hits against 167,000 compounds in ChEMBL biologically annotated toward 2000 targets using ECFP4 and other molecular fingerprints yielded the prediction of 1328 compound–target interactions, of which 12 were confirmed by literature search and 54 novel combinations that were experimentally tested (covering 20 compounds and 31 targets).[177] The activity of 11 of the 20 compounds against 22 of the 31 predicted targets was confirmed in experimental assays. Nine of the 11 compounds targeted G protein-coupled receptors, and 2 compounds targeted protein kinases.

Other examples of prospectively validated ligand-based protein target prediction methods based on publically available biological activity data are the target-dependent composite workflow method PROFILER[178] and a ligand similarity-based Bayesian probabilistic activity modeling method (**Fig. 5B**).[179] Meslamani and Rognan et al.[178] constructed workflows that combine four ligand-based (SVM classification, SVR affinity prediction, nearest-neighbor interpolation, and shape similarity)[178] and two structure-based approaches (docking and protein–ligand pharmacophore match). Protein target-customized workflows were trained and evaluated based on target-specific bioactivity data extracted from on ChEMBL, PubChem BioAssay, and Guide to Pharmacology databases, correctly identifying 136 of the main target of 189 clinical candidates and successfully predicting 2 novel off-targets (out of 10 predicted protein–ligand combinations). The adenosine A_1 receptor antagonist Rolofylline was experimentally confirmed to inhibit phosphodiesterase 5, while the phosphodiesterase 10A inhibitor (PF-2545920) binds cysteinyl leukotriene type 1 G protein-coupled receptor.[178] Besnard et al. trained ligand-based Bayesian probabilistic activity models for 784 protein targets based on 215,967 bioactivity data points extracted from the ChEMBL database and used circular ECFP-6 fingerprints to compare ligand similarity.[179] Optimal Bayesian probability cutoff scores were determined by retrospective evaluation of Matthews correlation coefficients (MCC), reflecting the ability of the models to distinguish active from inactive compounds. The validated target-

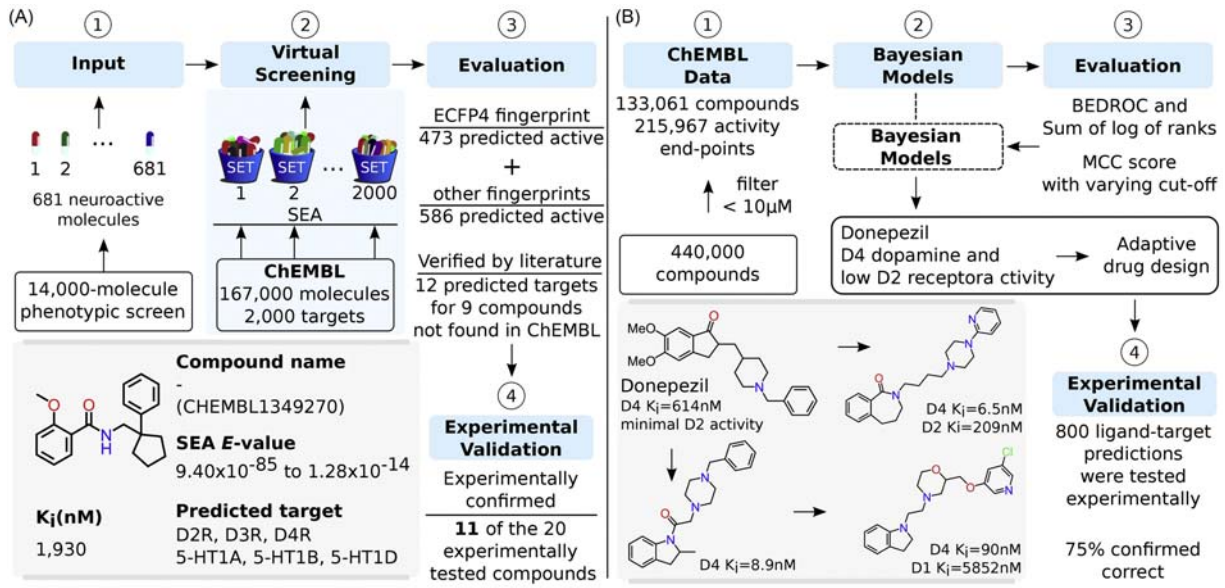

Fig. 5 Examples of ligand-based target prediction by bioactivity data mining. (1A) 681 neuroactive molecules were screened against 167,000 molecules from ChEMBL using the similarity ensemble approach (*SEA*) with ECFP4 and other fingerprints. In order to apply SEA, the molecules from ChEMBL were clustered according to their 2000 targets. Eleven of the 20 tested experimentally compounds were confirmed active. (1B) Bayesian models were trained on filtered ChEMBL bioactivity and compound data using circular ECFP6 fingerprints and applied to assist adaptive drug design. Using donepezil as a starting point (1B, *top left* compound), the authors predicted and experimentally tested the polypharmacological profile for 28 further evolved compounds on 20 G-protein-coupled receptors (GPCR) targets. Examples of highly selective dopamine D_4 compounds and an exquisite selective dopamine D_4 and dopamine D_1 compound are shown in (1B). Overall, 75% of the 800 ligand–target predictions were experimentally confirmed.

customized Bayesian models were incorporated as scoring functions in a multiobjective evolutionary optimization algorithm to design new ligands with polypharmacological activity at 5-HT_{1A} serotonin receptor and D_2, D_3, and D_4 dopamine receptors with selectivity over α1-adrenoreceptors antitargets α_{1A}, α_{1B}, and α_{1D} while maintaining CNS penetration. The resulting ligands were subsequently optimized for D_4 potency and brain penetrability and then for D_4 selectivity (Fig. 5B). Overall, 800 ligand–target predictions of 39 prospectively designed ligands were tested experimentally against 20 aminergic GPCRs, of which 75% were experimentally confirmed.[179]

1.15.5.2 Protein Binding Site Similarity Assessments for Ligand Repurposing and Off-Target Prediction

Diverse methods have been developed that allow for the comparison of protein binding sites based on their shape, pharmacophore features, and/or bound ligands.[180,181] These methods enable the identification of similar binding sites for, for example, ligand repurposing efforts and off-target prediction, as exemplified in this section by the successful prospective applications of the KRIPO[76] and SiteAlign[174] methods to screen large numbers of binding sites extracted from structures in the PDB (Fig. 6). KRIPO[76] is a fingerprinting method that enables the quantitative comparison of binding site (sub)pockets. This method defines a fingerprint for protein–ligand binding sites (and fragments of the ligand) based on the pharmacophore features of the surrounding amino acids and enables the comparison of such a fingerprint to that of all available structures in the PDB. KRIPO has been used to predict the Q_0 binding site of mitochondrial complex III (CIII) as off-target for simvastatin lactone (Fig. 6A).[183] KRIPO pharmacophore models of HMG-CoA reductase binding site were compared to the entries in the PDB revealing the Q_0 and Q_1 binding sites of CIII as possible off-target. Docking studies suggested that simvastatin lactone can adopt a binding mode in the Q_0 binding site of CIII that was consistent with the KRIPO binding site similarity assessment, while simvastatin acid cannot be accommodated due to possible repulsive interaction of the Glu-272 residue. The authors also experimentally validated their findings by reducing the CIII activity in statin-induced myopathies patients by 18%. In another study, KRIPO[76] has been used to identify potential off-targets of the cannabinoid receptor 1 (CB_1R) ibipinabant given the mitochondrial toxicity that was observed in preclinical trials.[184] A homology model of ibipinabant-bound CB_1R served as input for the KRIPO comparison with all available structures in the PDB. From the resulting list of most similar targets, according to KRIPO, only those targets that play a role in mitochondrial ADP/ATP exchange were selected. Two remaining targets were further investigated using docking, which indicated that ibipinabant could potentially bind to mitochondrial adenine nucleotide translocator 1 (ANT1). Subsequent experimental validation confirmed this hypothesized off-target effect as the mode of action for the observed mitochondrial toxicity of ibipinabant. The 3-D binding site comparison method SiteAlign[174] is a fingerprinting method encoding eight topological and physicochemical properties for the amino acids lining the binding site. SiteAlign has been used to prospectively predict the cross-reactivity of protein kinase

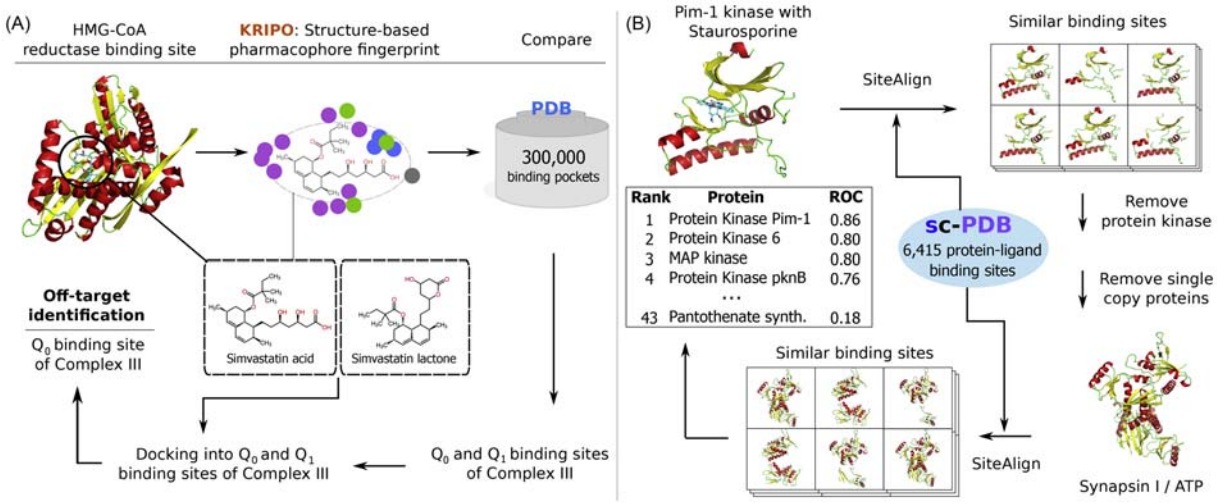

Fig. 6 Examples of protein–ligand binding site similarity search against the PDB. (A) In silico off-target prediction by protein–ligand binding site comparison with KRIPO. The binding site of HMG-CoA reductase was used as input for KRIPO to generate structure-based pharmacophore fingerprint, and then, those were evaluated against 300,000 binding pockets in the PDB in order to find new off-targets. After the screening, docking studies were performed to explore different binding modes of simvastatin acid and simvastatin lactone. The authors identified the Q_0 binding site of mitochondrial complex III (CIII) as off-target of the simvastatin lactone. (B) In silico ligand repurposing by protein–ligand binding site comparison with SiteAlign. The binding site of Pim-1 kinase is compared using SiteAlign against the sc-PDB database. After the removal of kinase structures from the same family and single copy proteins, the only remaining structure, synapsin I, was once again compared with SiteAlign to 978 binding sites in sc-PDB. From the comparison, De Franchi et al. concluded that some of the protein kinases are similar to synapsin I.[182] Part B adapted from Defranchi, E.; Schalon, C.; Messa, M.; Onofri, F.; Benfenati, F.; Rognan, D., Binding of Protein Kinase Inhibitors to Synapsin I Inferred From Pair-Wise Binding Site Similarity Measurements. *PLoS One*, **2010**, *5*, e12214.

inhibitors (Fig. 6B).[182] A pairwise comparison of the staurosporine binding site of the Pim-1 proto-oncogene serine/threonine kinase with over 6000 binding sites in the sc-PDB was made.[145] After removal of all protein kinase hits (given that staurosporine is a known promiscuous kinase inhibitor) and all proteins with only one structure, the only hit that remained was synapsin I. Subsequent in vitro competition assays validated that staurosporine indeed also has an inhibitory effect on synapsin I ($IC_{50} = 0.3\ \mu M$). This study furthermore validated the interaction of other kinase inhibitors with synapsin I.

1.15.5.3 Integrated Structure-Based Medicinal Chemistry Toolbox for Drug Discovery and Design

Protein-family oriented structural databases like KLIFS[99] and PDEStrIAn[65] can enrich a medicinal chemistry program by supporting ligand design with new ideas linked to a structure-based rationale. One way in which this can be obtained is by generating a medicinal chemistry toolbox containing scaffolds and substituents based on available crystal structures and known ligand libraries. The deconstruction of crystallized ligands into core scaffolds and their substituents while annotating their binding regions can yield such a structurally-aware toolbox. This knowledge-based toolbox can be further expanded by, for example, also deconstructing ligands without a crystal structure (e.g., from ChEMBL) that contain one of the core scaffolds of the cocrystallized ligands. The resulting resource can be exploited by medicinal chemists by providing substitution ideas and scaffold replacement options or even be used for ligand merging and novel ligand design efforts. Fig. 7 presents an example from the PDEStrIAn resource in which a selection of the deconstruction of 203 PDE inhibitors into 77 core scaffolds and 244 substituents is presented. Since for each scaffold and substituent the binding region is known, one can efficiently start interchanging substituents to optimally target a (sub)pocket to improve, for example, selectivity, potency, or physicochemical or ADMET properties. One step further, the so-called Markush enumeration of the fragmented ligands (the creation of a combinatorial library by combining the scaffolds with all possible substituents) can be performed in order to obtain (large) datasets with protein family-specific virtual compound sets that again can be explored for ligand discovery, design, and optimization. Such datasets can furthermore be utilized in virtual screening studies and other computer-aided drug design and drug optimization efforts to identify optimal ways to probe specific (combinations) of subpockets in order to obtain the desired polypharmacological or selectivity profile.

1.15.5.4 Combined Navigation of Protein–Ligand Interaction and Ligand Chemistry Space

Structural chemogenomics databases such as KLIFS[99] and PDEStrIAn[65] allow for the direct comparison and integration of ligand, protein, and ligand–protein interaction information. With these data, new insights can be obtained and used in drug discovery and design programs. As a proof of concept, we collected all preprocessed ligand-bound kinase (2662 unique PDBs), phosphodiesterase

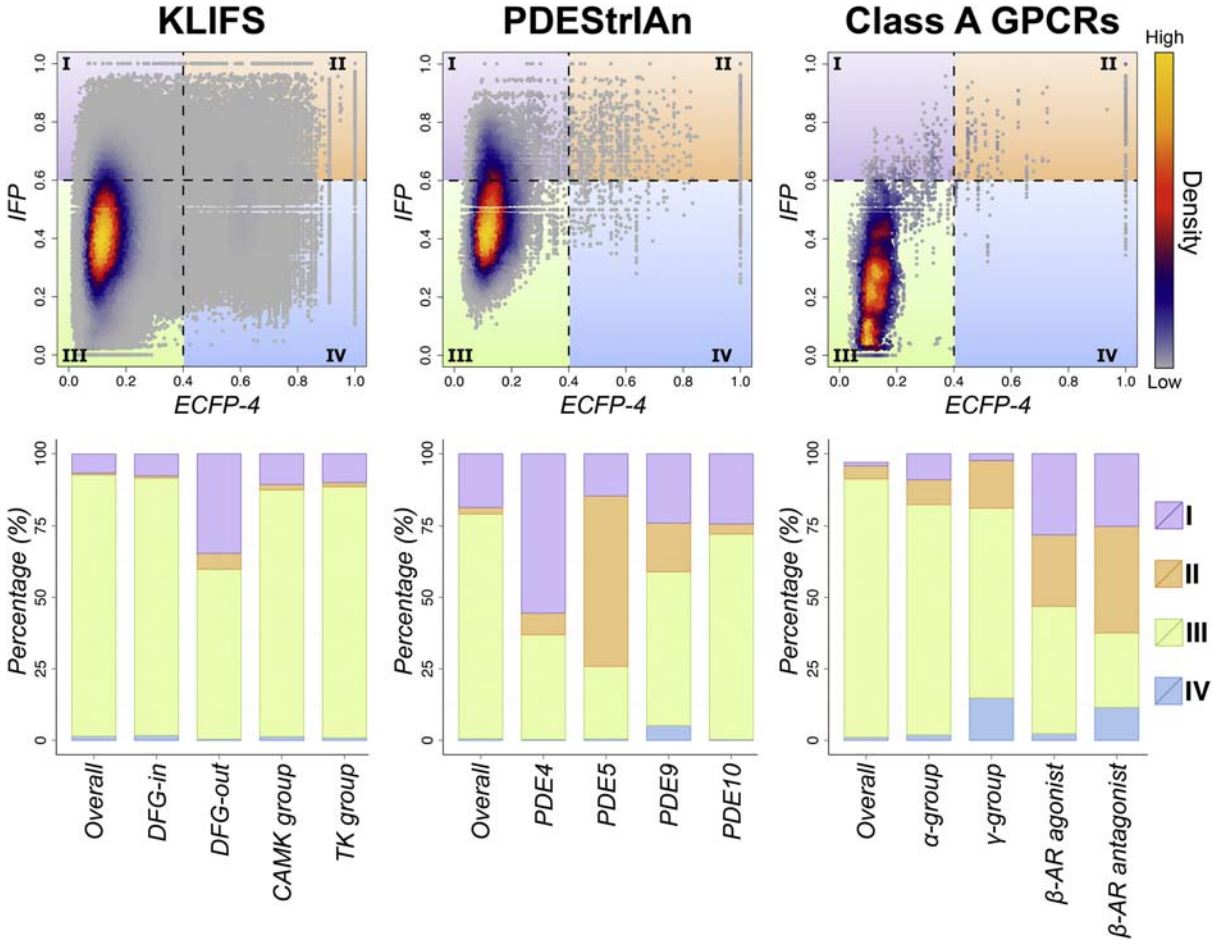

Fig. 7 The PDEStrIAn resource as a structure-based medicinal chemistry toolbox. The binding site of the catalytic PDE domain is colored according to the division into 10 regions: the hydrophobic clamp regions (HC, HC1, and HC2), the metal binding region (MB, MB1, and MB2), the region around the invariant glutamine (Q, Q1, and Q2), and the solvent region (S). Two hundred and three ligands of 220 PDE structures were deconstructed into core scaffolds binding in the HC and Q region, and all remaining substituents were assigned to their respective binding subpockets. This allows for the creation of a knowledge-based and structure-guided combinatorial PDE ligand library by combining all core scaffolds with all substituents from all respective regions providing novel ideas to further explore the chemical space of PDE inhibitors.

(236 unique PDBs), and class A GPCR (105 unique PDBs) structures from KLIFS, PDEStrIAn, and an in-house dataset of processed class A GPCR structures (excluding retinal-bound structures to prevent a bias) and used the interaction fingerprint data and ligand structures to perform an all-against-all analysis (Fig. 8). Subsequently, for each pair of ligands, the ligand similarity was assessed by generating the frequently applied molecular fingerprint ECFP-4 in combination with the Tanimoto coefficient.[187] Since each of these databases uses a consistent pocket definition with the same number of pocket residues (corrected for gaps), all interaction fingerprints of a database could directly be compared with each other, and their similarity was also quantified using the Tanimoto coefficient. The resulting scatterplots are shown in Fig. 8. An ECFP-4 cutoff of 0.4[185] was used to distinguish between high and low molecular similarity, and an IFP cutoff of 0.6[186] was used to distinguish between high and low binding mode similarity. These cutoffs were used to subdivide all data into four categories: (I) high binding mode similarity and low chemical similarity, (II) high binding mode similarity and high chemical similarity, (III) low binding mode similarity and low chemical similarity, and (IV) low binding mode similarity and high chemical similarity (Fig. 8). The highest density for all datasets was observed in category III, implying that most molecule pairs with a high chemical diversity also show a diverse binding mode. Interestingly, for the kinases and phosphodiesterases, category I was the second-most dense category, indicating that despite the difference in molecular structure, a similar binding mode was conserved for these ligand pairs. The pairs in this category have a high scaffold hopping potential as they provide information on chemical moieties that can be interchanged while maintaining the same binding mode (similar to the bioisosteric replacement theory behind sc-PDB-frag[158]). Such resources can be used to design new ligands, to resolve undesired physicochemical properties, and to escape patents.[188] When using IFP as a post-processing and filtering tool in a prospective virtual screening, this is also the category that is aimed for. In such studies, the goal is to discover ligands with diverse chemical compositions while maintaining a binding mode similar to a specific reference ligand (as performed in, e.g., a virtual screening study against the histamine H_1 structure[71] and the *Trypanosoma brucei* PDEB1 structure[189]). Category II is the category that adheres to

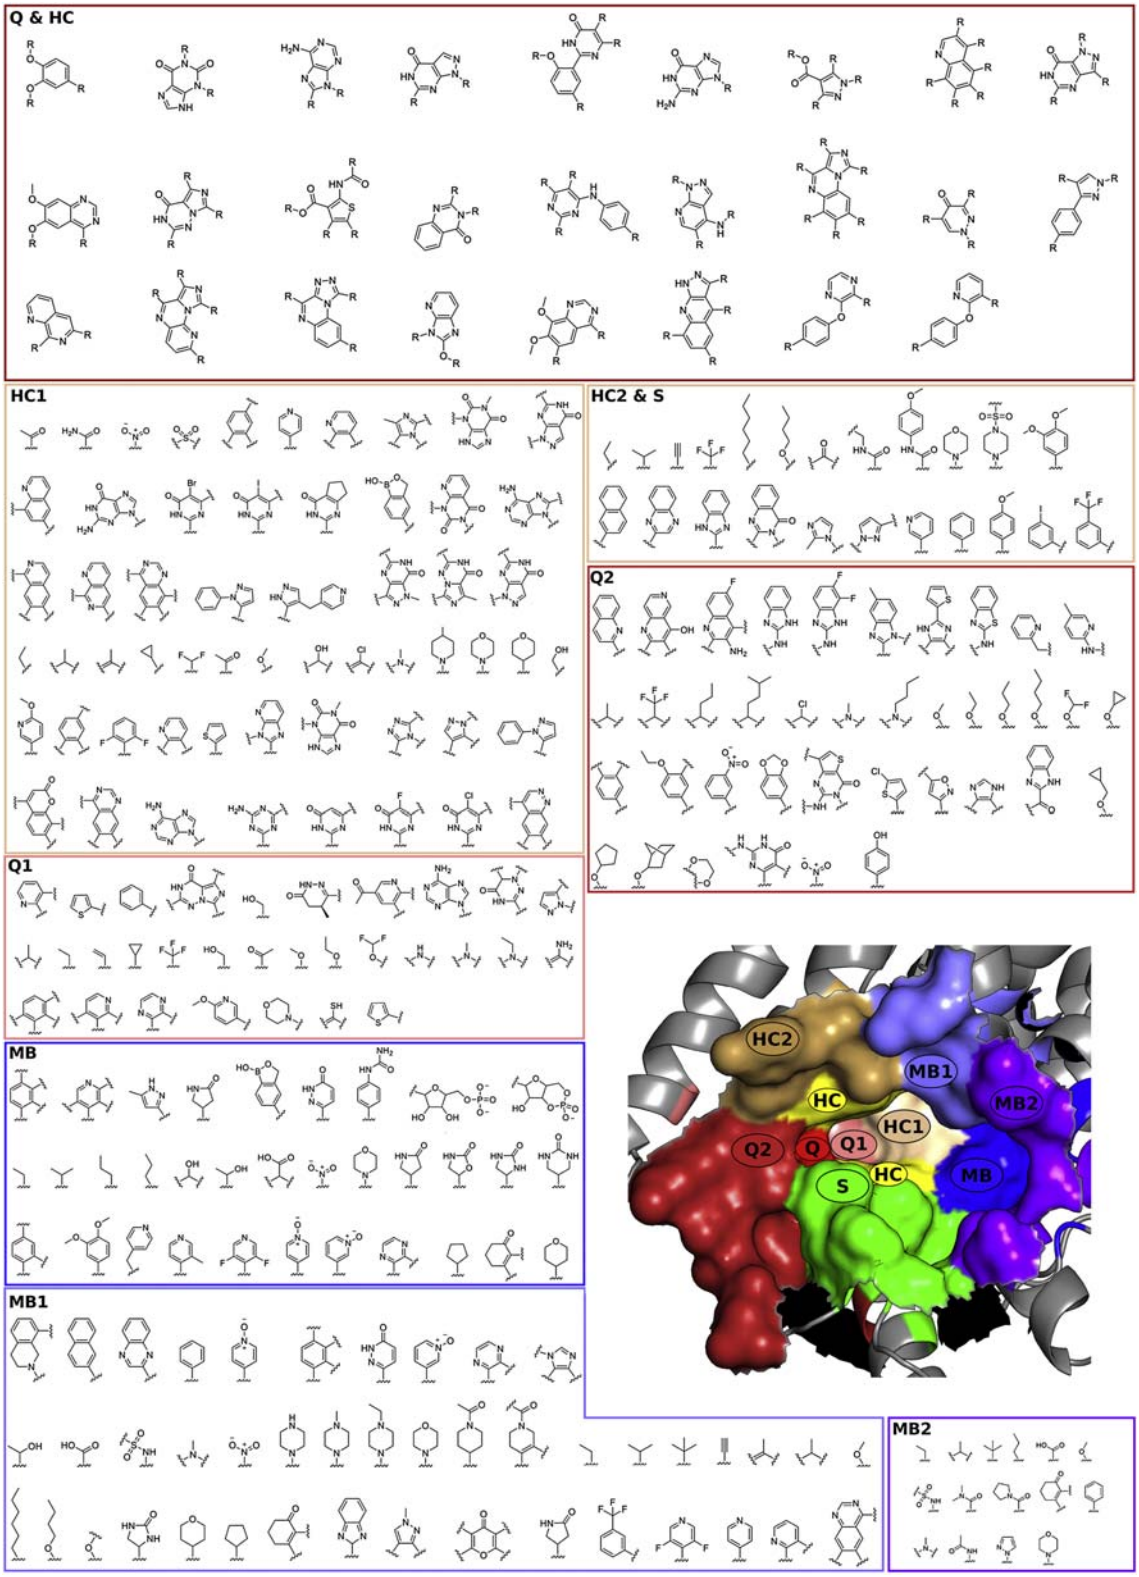

Fig. 8 All-against-all comparison of protein–ligand interaction patterns (*IFP*) versus molecular similarity (*ECFP-4*) for kinases, phosphodiesterases, and class A GPCRs. The scatterplots highlight the molecular similarity versus the interaction pattern similarity of all ligand pairs in KLIFS (2662 unique PDBs), PDEStrIAn (236 unique PDBs), and an in-house GPCR dataset (105 unique PDBs) based on the PDB. The scatterplots have been divided into four categories based on a low/high molecular similarity cutoff (ECFP-4 $\geq$ 0.4[185]) and a low/high binding mode similarity cutoff (IFP $\geq$ 0.6[186]). The stacked bar plots represent the density in each category for each of the datasets and smaller (more specific) subsets.

the chemogenomics principles that similar ligands have similar binding modes (and thus targets). The final category with the lowest occupancy is category IV, which is reserved for ligands with a similar structure but a different binding mode. It can also be seen that in all datasets even identical ligands (with and ECFP-4 of 1) can adopt different binding modes (IFP < 0.6). An example of such a ligand is the PDE-inhibitor IBMX, which can adopt multiple binding modes in phosphodiesterases (e.g., PDE5 PDB code 1RKP versus PDE4D PDB code 1ZKN[65]).

The dataset for kinases is by far the most extensive set with over 2662 ligand-bound complexes and shows a large chemical and binding mode diversity even within specific kinase groups (CAMK and TK) and also within the set of kinase structures in the DFG-in conformation. Some kinase inhibitors inhibit the kinase in a DFG-out conformation and can therefore address a more specific back pocket of the kinase (e.g., BPIII, BPIV, and BPV; see **Fig. 4**).[64] Almost 35% of the ligand pairs in this subset have a conserved binding mode despite the chemical diversity compared with less than 8% of the ligand pairs from structures in the DFG-in conformation. This also reflects the open nature of the front pocket that allows DFG-in inhibitors to address this pocket with a diverse range of binding modes. For PDEs, we see a much larger subtype dependency of the binding mode diversity. For PDE4, more than 55% of the ligand pairs adopt a similar binding mode despite their chemical diversity. On the other hand, there is a low chemical diversity for the ligands in complex PDE5 and therefore, as expected, also adopt similar binding modes. The ligands in complex with class A GPCRs show similar overall trends as the kinases and PDEs. However, only when looking at specific receptors (e.g., β-adrenoceptors 22.8% and 16.8% in categories I and II, respectively) and even ligand function specific subsets (e.g., β-adrenoceptor agonists and antagonists/inverse agonists), a high conservation of the binding mode is observed. IFPs can therefore also be used to predict the function of ligands based on their (predicted) binding modes as was shown in a retrospective all-against-all virtual screening using IFPs of 31 β-adrenoceptor crystal structures.[190] It should be noted that due to the limited number of available structures for GPCRs and PDEs, these statistics can be biased, such as the limited chemical diversity for PDE5.

1.15.6 Conclusions and Outlook

Structural chemogenomics databases allow the integration and exploration of heterogeneous genomic, structural, chemical, and pharmacological data in order to extract useful information that is applicable for the discovery of new protein targets and biologically active molecules. The use of common ontologies allows efficient protein and ligand data curation and mapping that enable the integration of bioactivity data mining, ligand and protein similarity assessment, and structural protein–ligand interaction analyses for the identification of new protein–drug combinations. The UniProt, PDB, and ChEMBL represent the largest databases comprising protein sequences, protein–ligand structures, and target-annotated biologically active molecules, respectively. Complementary integrated structural chemogenomics databases provide proteome-wide, target family-specific, or mechanism-specific information depending on the way that different types of protein–ligand interaction data can be explored. The general proteome-wide target-annotated biological activity databases, like BindingDB, Intact, STITCH, PubChem Bioassay, DrugBank, PDSP K_i, PDBbind-CN, and Binding MOAD, contain 10^4–10^7 bioactivity data points covering 10^2–10^6 protein targets and compounds 10^4–10^6, provide extensive information on ligands, and also contain (links to) general information on the associated protein targets (including IDs, sequence, and links to PDB structures). Target-annotated biological activity databases do not cover detailed structural information on binding sites or protein–ligand interactions, although protein target family-specific biological activity databases like GLASS (GPCRs) and K-Map (kinases) provide integrated and curated protein family-specific information regarding 10^4–10^5 protein–ligand complexes (including consistently annotated links to other databases). Unfortunately, such target family-specific databases are often created and not maintained or frequently updated afterward. Automated data mining protocols provide an alternative to facilitate efficient extraction and post-processing of customized data sets from, for example, ChEMBLdb or other databases in a consistent and automated manner.[148] Careful and consistent annotation of the chemical structure of ligands allows efficient combination of bioactivity data mining with chemical similarity assessment for ligand-based target prediction and the identification of new protein–ligand combinations. Mechanism-specific biological activity databases are generally relatively small, containing 10^3–10^4 data points and covering up to 10^3 protein targets and 10^2–10^4 compounds, but do contain complementary information like pairwise mutation data (Platinum) and protein–protein interaction modulators (Timbal).

Proteome-wide structural protein–ligand interaction databases like PoSSuM, IBIS, BioLip, CREDO, PLIC, ProBis, sc-PDB, BivalBind, Pocketome, iPfam, and PSCDB contain structural information on 10^4–10^5 protein–ligand binding sites of 10^3–10^4 compounds in 10^3–10^4 distinct proteins and provide additional consistent systematic analyses and search options of different properties of the binding sites (including physical–chemical properties) and characteristics of the protein–ligand interactions (using, for example, interaction fingerprint methods). Many proteome-wide structural protein–ligand interaction databases, including sc-PDB, PoSSum, CREDO, PLIC, and Pocketome, furthermore provide precalculated or on the fly binding site comparison and search options that enable structure-based ligand repurposing, target identification, and off-target prediction. Protein target class-specific structural protein–ligand interaction databases like KLIFS (kinases), GPCRdb (GPCRs), and PDEStrIAn (phosphodiesterases) facilitate search options to investigate and compare the protein–ligand binding sites and interactions in more detail, providing systematic analyses of the properties and molecular interactions of amino acid residues, subpockets, and water molecules, consistently annotated based on their position in the aligned binding sites of structures of a specific protein family. The protein family-customized setup in KLIFS, GPCRdb, and PDEStrIAn allows for consistent extraction, curation, analysis, visualization, and integration of structural chemogenomics data for efficient exploitation such as structure-based identification and prediction of the structural determinants of protein–ligand selectivity. The careful curation of ligand topology (e.g., definition of atom and chemical

bond types in customized databases such as the chemical component dictionary) and the consistent construction of binding site alignments are essential for the accurate and systematic analysis, comparison, and visualization of protein–ligand interactions (e.g., the comparison and assignment of interaction fingerprints to specific residues, subpockets, water molecules, or chemical groups in the ligand). KLIFS and PDEStrIAn demonstrate how the definition of a curated ontology of protein family-specific structural chemogenomics data allows for the construction of an automated data extraction that keeps in sync with, for example, weekly (PDB), monthly (UniProt), and (bi)annual (ChEMBL) updates of large sequence, structure, and bioactivity databases. Mechanism-specific structural protein–ligand interaction databases such as 2P2Idb (PPIs) and ASD (allosteric modulation) provide orthogonal information that can provide insights into general mechanisms and structural derminants of specific molecular processes that are relevant for drug discovery. The definition of general ontologies of biological, chemical, and structural information enables the construction of standardized chemoinformatics and bioinformatics workflows to integrate and exploit these data for structure prediction of, for example, protein selectivity and drug polypharmacology.[191] Moreover, the customized integration of structural chemogenomics information with other data sources such as phenotypic, (epi)genetics, and clinical data may ultimately enable the extension and translation of structural chemogenomics analyses, multidimensional analysis, and prediction of patient population-specific drug action.

1.16.1 Introduction

1.16.1.1 Understanding REACH

1.16.1.1.1 The legal framework

In 2006, the European Union adopted the regulation (EC) No. 1907/2006 concerning the Registration, Evaluation, Authorization, and Restriction of Chemicals (REACH).

> Quoting REACH Article 1, "the purpose of this Regulation is to ensure a high level of protection of human health and the environment, including the promotion of alternative methods for assessment of hazards of substances, as well as the free circulation of substances on the internal market while enhancing competitiveness and innovation […]."

REACH brought a revolution in the chemical regulatory world, shifting for the first time the burden of proof for the safe use of chemicals from public authorities to the companies, which are manufacturing or importing chemical substances. With the entry into force of REACH, companies have to register their substances to the European Chemicals Agency (ECHA) according to the "no data, no market" principle, if the manufacture or import of the chemical exceeds 1 ton year^{-1}. The registration includes the preparation of a dossier for each substance, where industry has to show that the chemical hazard and risk are properly understood, adequately controlled, and communicated through the supply chain. The objective of REACH is to reduce and replace the most dangerous substances (known as substances of very high concern (SVHC)) with safer alternatives. This goal is achieved by collecting data (registration, done by industry), assessing these data (dossier compliance check, done by ECHA), and identifying SVHC (substance evaluation and SVHC identification, done by member state competent authorities and coordinated by ECHA). When an SVHC is identified, its use is limited with specific processes like authorization and/or restriction.

A cornerstone of the registration process is the preparation of the dossier containing, among others, hazard information. The minimum set of information to be provided is called standard information requirement (SIR). SIR includes physicochemical, toxicological (also termed as human health), ecotoxicological, and environmental fate endpoints. The amount of endpoints to take into account is proportional to the tonnages of a substance (i.e., the produced or imported volume of a chemical per year). The higher the tonnage, the higher the SIR. This tiered approach guarantees that the toxicity of chemicals produced or imported in larger amounts is studied more thoroughly. Based on such proportionality principle, the endpoints are listed in REACH Annexes VII, VIII, IX, and X for the substances produced or imported in quantities equal or above 1, 10, 100, and 1000 tons year^{-1}, respectively. These annexes are given in the form of tables with two columns. The first column reports the list of the demanded endpoints (SIR), while the second column contains the list of specific adaptation rules, describing the conditions under which the test can be adapted or waived. As an example of column two adaptations, a substance does not need to be tested for skin sensitization if it is already classified as corrosive. More details on the SIRs for toxicological (human health) endpoints are reported in **Table 1**.

1.16.1.1.2 The promotion of alternative methods

The promotion of alternative methods and animal welfare considerations has a central place in REACH. ECHA has the legal obligation to report to the European Commission the status of implementation and use of nonanimal methods for meeting the SIR. So far, ECHA has published two reports on this matter in 2011[1] and 2014.[2]

In order to minimize unnecessary animal testing, REACH offers to registrants several possibilities: using existing data, joining other registrant of the same substance (one substance, one registration principle) in order to avoid double testing, and using the so-called adaptation and alternative methods. If none of these elements is sufficient to meet the requirements, the registrant may perform the standard animal test. However, before performing a test on Annex IX and X endpoints, the registrant shall prepare a testing proposal (TP) that is evaluated by ECHA before the study is conducted.

The general rules for adaptation of the standard testing regime are explained in Annex XI as follows:

- *Testing does not appear scientifically necessary*.

  This is the case when it is possible to use existing data, weight of evidence (WoE), (quantitative) structure–activity relationships ((Q)SARs), *in vitro* methods, grouping of substances, and/or read-across. Please note that the definition of the WoE according to Annex XI is "sufficient weight of evidence from several independent sources of information leading to the assumption/conclusion that a substance has or has not a particular dangerous property, while the information from each single source alone is regarded insufficient to support this notion."
- *Testing is technically not possible*.

  This may happen due to particular physicochemical properties of a substance (e.g., very volatile, very reactive, or unstable substances) making the conduction of the study unfeasible.
- *Substance-tailored exposure-driven testing*.

Table 1 Overview of the toxicological standard information requirements (SIRs) as defined in REACH

REACH Annex	*Toxicological standard information requirements (SIRs)*
Annex VII	Skin irritation or skin corrosion (*in vitro*)
	Eye irritation (*in vitro*)
	Skin sensitization (*in vivo*)
	Mutagenicity (gene mutation in bacteria)
	Acute toxicity (by oral route)
Annex VIII	Skin irritation (*in vivo*)
	Eye irritation (*in vivo*)
	Cytogenicity in mammalian cells (*in vitro*)
	Gene mutation in mammalian cells (*in vitro*)
	Acute toxicity (by inhalation)
	Acute toxicity (by dermal route)
	Short-term repeated dose toxicity test (28 days). Screening for reproductive/developmental toxicity toxicokinetics
Annex IX	Short-term repeated dose toxicity test (28 days). Subchronic toxicity (90 days)
	Prenatal developmental toxicity
	Two-generation reproductive toxicity
Annex X	Long-term repeated dose toxicity ($\geq$12 months). Developmental toxicity
	Two-generation reproductive toxicity
	Carcinogenicity

The reader is reminded that the requirements of annexes are cumulative, that is, for registering a substance falling under Annex IX, the registrant needs to include the information in Annexes VII, VIII, and IX.
Adapted from ECHA, Guidance on registration, version 2.0, **2012**, http://echa.europa.eu/documents/10162/13632/registration_en.pdf (last accessed date, 19 February 2016).

Certain tests may be omitted if the manufacturers/importers document and demonstrate the absence of exposure or unlikely no relevant or no significant exposure.

It is also worth mentioning that in Mar. 2013, the use of animals for testing the toxicity of cosmetic products was banned,[3] making even more relevant for regulatory toxicology the need to find alternative methods and to use optimally existing data.

In this article, we will mainly focus on the "nontest" adaptations foreseen by REACH and particularly on (Q)SAR, grouping of substances, and read-across approach. It is noted that read-across often relies on existing information; however, in some cases, testing of the source chemical may be needed. *In chemico* and *in vitro* studies, which are also alternative methods (to the use of animals) but require testing of the substances, are not discussed here. WoE is also not discussed further in this article.

1.16.1.2 Obligations for Pharmaceutical Companies under REACH

At first sight, pharmaceutical products may look outside the scope of REACH. Indeed, Article 2 of REACH ("Application") exempts "medicinal products for human or veterinary use" from the registration process. The rationale beyond this exemption is that medicinal products are dealt under different EU regulations. Nevertheless, pharmaceutical companies have a number of obligations under REACH. In fact, this regulation still applies to medicinal products if they are produced for any other use. In this case, the information requirements depend on the volume of production (see **Table 1**). Isolated pharmaceutical intermediates, as any other transported or on-site isolated chemical intermediate, have to be registered too. The information requirements for intermediates are less demanding than those needed for substances with nonintermediate use and are listed in REACH Articles 17 and 18. They include, among others, information on substance identity, classification, any (eco)toxicological data available, and risk management measures applied. Furthermore, all the raw materials or any substance used during manufacture is subject to REACH. In practice, this means that, if the pharmaceutical company is producing or importing any raw material in a quantity more than 1 ton $year^{-1}$, a registration is needed. On the other hand, if the company is buying the raw material from a supplier, it should investigate whether the supplier plans to or have already registered it. On the positive side, REACH has improved and will continue to improve the quality of the hazard information available in safety data sheets for substances used also by pharmaceutical industry, with a positive impact on workers and environmental protections.

1.16.1.3 REACH Annex XI Requirements for (Q)SAR and Read-Across

1.16.1.3.1 (Q)SAR

The results of (Q)SAR models have to meet some mandatory regulatory requirements, described by Annex XI—paragraph 1.3 of REACH regulation:

1. Results are derived from a (Q)SAR model whose scientific validity has been established.
2. The substance falls within the applicability domain (AD) of the (Q)SAR model.
3. Results are adequate for the purpose of classification and labeling and/or risk assessment.
4. Adequate and reliable documentation of the applied method is provided.

In this respect, the evaluation of a (Q)SAR result requires the assessment of both the model (as set in condition 1) and its prediction (as set in conditions 2 and 3). In addition, appropriate documentation has to be provided (condition 4). The scientific validity of a (Q)SAR model is assessed in light of the Organization for Economic Cooperation and Development (OECD) principles for the validation of (Q)SARs.[4] These principles were specifically introduced for regulatory purposes and comprise five elements, which are deemed essential for the assessment of the validity of the model.

Once the model has been considered valid, predictions should be individually evaluated through a case-by-case exercise. It might happen that an unreliable or inadequate prediction is derived from otherwise valid (Q)SAR model. To elaborate further this issue, ECHA has made available guidance (Chapter R.6)[5] and practical guides,[6] has produced webinars,[7] and has developed illustrative examples[8,9] explaining how to obtain reliable and adequate (Q)SAR predictions.

1.16.1.3.2 Grouping of substances and read-across approach

The rationale behind the read-across approach[10] is that similar substances are expected to have similar properties. As a result, a property of a chemical that has not been tested yet (named as target) can be predicted by using available data from one or more similar compounds (named as source chemicals).

According to Annex XI, the similarity may be based (a) on common functional groups; (b) on common precursors and/or on the likelihood of common breakdown products via physical and biological processes, which result in structurally similar chemicals; and (c) on constant patterns in the changing of the potency of the properties across the category. In any case, results should

- be adequate for the purpose of classification and labeling and/or risk assessment;
- have adequate and reliable coverage of the key parameters addressed in the corresponding test method;
- cover an exposure duration comparable to, or longer than, the corresponding test method if exposure duration is a relevant parameter;
- be provided with adequate and reliable documentation of the applied method.

Also in this case, ECHA has prepared guidance, practical guides,[11] webinars, and illustrative examples[12,13] of read-across predictions.

In this respect, a recent milestone achieved by ECHA is the publication of the read-across assessment framework (RAAF),[14] whose aim is to provide a structured approach to the scientific evaluation of read-across justifications prepared by registrants in their dossiers.[15] The first publication covers read-across of human health endpoints for monoconstituent substances.

1.16.1.4 Dissemination of REACH Data

It may be of interest for the readers to be aware that ECHA makes available all the nonconfidential information for the substances registered under REACH and information from other regulations (e.g., from classification and labeling inventory).[16] This large database full of physicochemical and (eco)toxicological information on chemicals is available online free of charge.[16] The dissemination website has been revamped at the beginning of 2016 to make the information more clearly available to both general public and stakeholders.

1.16.2 Nontest Methods

(Q)SAR predictions are a cost-effective and efficient option for screening and prioritization of chemicals.[17] They also represent an opportunity for replacement of experimental tests for some endpoints and some chemicals. The need of a harmonized regulatory application of (Q)SAR among the OECD countries has been addressed in 2004 by the publication of internationally agreed principles, known as "OECD principles for the validation, for regulatory purposes, of (Q)SAR models."[4] These principles constitute a solid yardstick for regulators, providing a scientific framework for making informed decisions on the acceptability of (Q)SAR predictions and, in the same time, a chance for enhancement of the transparency of the (Q)SAR models and for improving the consistency of (Q)SAR reporting. The OECD principles provide a useful guidance on how not only regulatory agencies but also (Q)SAR practitioners and (Q)SAR end-users can (a) evaluate specific (Q)SAR models, (b) better understand the usefulness and the uncertainty of (Q)SAR estimates, (c) make regulatory decisions, and (d) support stakeholders with transparent models and documentations. It has to be highlighted that the acceptance of (Q)SAR as a nontest alternative source of data is highly context-dependent (i.e., a case-by-case assessment of the specific prediction from a specific (Q)SAR model for a specific purpose is needed). In this respect, both reliability and transparency represent key elements to evaluate (Q)SAR performances beyond a merely statistical evaluation.

1.16.2.1 OECD Principles for the Validation of (Q)SAR

At the 37th Joint Meeting of Chemicals Committee and Working Party on Chemicals, Pesticides and Biotechnology (Paris, 2004), the OECD member countries agreed to issue the following five principles for establishing the validity of (Q)SAR models for regulatory purposes:

1. A defined endpoint
2. An unambiguous algorithm
3. A defined AD
4. Appropriate measures of goodness of fit, robustness, and predictivity
5. A mechanistic interpretation, if possible

Each OECD principle is not sufficient as a standalone but needs to be considered with respect to all the others. Indeed, there is an interplay among the nature of the endpoints defined in OECD test guidelines for the testing of chemicals and the mechanistic interpretation, domain of applicability, algorithm used, and purpose of the (Q)SAR prediction. Taken all together, the OECD principles are expected to enhance both transparency and validity of (Q)SAR and, thus, to promote an international harmonization in the use of (Q)SAR for regulatory purposes.[18]

1.16.2.1.1 About principle 1: a defined endpoint

The term endpoint refers to any physicochemical, biological, or environmental effect, which can be measured under specific conditions. It can be defined at different levels. An endpoint can be (a) *a specific biological effect* (e.g., binding to a specific receptor); (b) a *test protocol endpoint* (i.e., skin irritation/corrosion as yes/no result or acute oral toxicity in rats in terms of LD_{50}), useful for regulatory purposes and adopting standardized and harmonized toxicological test protocols (i.e., those established in the OECD test guidelines); and (c) a *regulatory endpoint* concerned with a much more complex organizational level of regulatory work, which could require the adoption of different protocols (or similar protocols in different species/organisms) for the purpose of classification and labeling. In principle, the higher is the level of organization of living material tested, the wider could be the variability of the results. In addition, often, there is no established link between a measured molecular event (e.g., EC_{50} of receptor binding) and a quantitative measure of an apical endpoint (e.g., liver or kidney toxicity in repeated dose study). Approximately in the last decade, the theory of the adverse outcome pathway (AOP) approach has been developed by academia with support of OECD and regulatory bodies with the aim to relate one or more key events (including potential molecular initiating events) with potential adverse outcome by understanding the toxicity path between these two.[19]

Some well-established regulatory endpoints can be predicted with a higher level of confidence by (Q)SAR models. For instance, a (Q)SAR model built from a training set (TS) of *Salmonella* mutagenicity data, obtained following the OECD test guideline 471,[20] is expected to return highly reliable predictions for the endpoint *Salmonella* mutagenicity. The reason for this expectation is that the mechanisms of *Salmonella* mutagenicity are relatively simple and well understood. Nevertheless, strain-specific consideration would need to be taken into account for an acceptable prediction (i.e., TG 471 foresees the use of five strains to cover different mutagenicity mechanisms and the (Q)SAR prediction has to take this into account[20]). Conversely, global prediction of a repeated dose lowest-observed-adverse-effect level (LOAEL) from a TS of LOAEL data, which are concerned with a number of different mechanisms and effects, compiled by mixing results from different species using different test protocols, will hardly be reliable.[21]

In REACH legal text, endpoints are gathered in four main groups.[22] The first is related to physicochemical properties (i.e., melting/freezing point, boiling point, relative density, vapor pressure, surface tension, water solubility, partition coefficient, flash point, dissociation constants, and viscosity). The second is the toxicological group (i.e., skin irritation or corrosion, eye irritation, skin sensitization, mutagenicity, acute toxicity, repeated dose toxicity, reproductive toxicity, toxicokinetics, and carcinogenicity). The third is known as the ecotoxicological group (i.e., aquatic toxicity and effects on terrestrial organism). The fourth comprises the environmental fate properties (i.e., degradation and fate and behavior in the environment).

Some basic, although nonexhaustive, recommendations are needed for (Q)SAR developers and users about the endpoints to model: (a) endpoints should be defined along with detailed information about factors affecting variability, knowledge of uncertainties, and possible deviations from standardized test guidelines; (b) differences in the experimental protocols for measuring a given endpoint should not imply significant differences in the results that cannot be explained; and (c) the chemical and response domains of the (Q)SAR and of the test protocol should overlap.

1.16.2.1.2 About principle 2: an unambiguous algorithm

OECD second principle highlights the importance of developing unambiguous algorithms for building (Q)SAR models. In particular, typical algorithms can be mathematical functions or rule-based approaches. Mathematical algorithms for model derivation can be distinguished as (a) linear, that is, the activity is predicted as a linear function of molecular descriptors, or (b) nonlinear, that is, structure–activity relationships (SARs) are obtained by using nonlinear functions. The former are more straightforward and easier to interpret, enough accurate for small data sets of similar compounds. The latter are normally preferred for larger and more diverse data sets, but they could be often difficult to interpret and eventually lead to data overfitting. Rule-based approaches are generally based on an expert knowledge. This knowledge could have been extracted also with the help of computerized methods. One example of expert knowledge system is the Benigni–Bossa rule[23] making use of structural alerts for predicting mutagenicity of chemicals. Providing examples for the alerts is helpful to the user to understand the rules. The higher is the number of examples confirming the rule, the higher is the confidence in it. Another aspect to consider is the confidence in the expert system as a whole, including, for example, the TS used (for some historical models, this information is lost) or the chemical space intended to be covered with the predictions. As a result, unambiguous algorithms should ensure the full comprehension of how a predicted value is obtained, making models reproducible and acceptable from a regulatory perspective. To assess the goodness of an algorithm, it is wise to carefully consider (a) the data set of chemicals, endpoint, and descriptor values; (b) the nature and source of descriptors; (c) the composition of the validation set (VS) and TS with regard to the occurrence of outliers (and a clear justification); (c) the form of the mathematical models employed to sample the descriptor and endpoint relationship; and (d) statistical parameters defining the model performance.

1.16.2.1.3 About principle 3: a defined domain of applicability

The third OECD principle claims the need to report, along with a (Q)SAR model, its AD, or, in other terms, the projection space where the model is expected to produce meaningful predictions. Notably, a (Q)SAR model cannot reliably predict any possible chemical but only those within its AD. Compounds within AD are supposed to have physicochemical, structural, and biological features similar to those of TS compounds. In this respect, TS compounds define the boundaries of the chemical space where predictions could be considered the result of data interpolation. On the other hand, predictions made outside of such space are the result of data extrapolation and, thus, associated with higher uncertainty. Keeping this in mind, the definition of AD can be considered an essential step for both scientific and regulatory purposes being useful to increase the confidence in predictions and to allow the practical use of (Q)SAR models.[24] A definition of AD was given in 2003 at the Setubal workshop.[25] The AD was defined as "the physico-chemical, structural, or biological space, knowledge, or information on which the training set of the model has been developed, and for which it is applicable to make predictions for new compounds […]. Ideally, the (Q)SAR should only be used to make predictions within that domain by interpolation not extrapolation." A more concise definition was proposed in the report of the 52nd European Centre for the Validation of Alternative Methods workshop [26]: "the applicability domain of a (Q)SAR model is the response and chemical structure space in which the model makes predictions with a given reliability." Since then, several approaches have been developed to quantify AD.[24,25,27–30] They are inspired by the three main domains of the (Q)SAR space, explicitly cited in both the earlier reported definitions: (a) the physicochemical, (b) the structural, and (c) the biological (or response) domain.

The physicochemical domain is based on the coordinates of molecular descriptors enabling the allocation of TS compounds into a multidimensional space from which deriving, through interpolation, a space exploitable as AD. In this respect, the use of physicochemical descriptors has led to develop four major approaches[27,29,31] that are (a) range-based, (b) distance-based, (c) geometric-based, and (d) probability density distribution-based methods.

Range-based methods consider the interval of values of each descriptor included in the (Q)SAR model. A test compound exceeding the range defined by the maximum and minimum value for compounds of the TS for even one of the model descriptors would be considered out of the AD. This approach is limited by the fact that it does not account for the occurrence of empty spaces (i.e., interpolation regions where the relationship is not proved) nor intercorrelation among the descriptors.[26,27,29,31] Principal component analysis (PCA) could address, albeit partially, such issues, each principal component (PC) being a linear combination of the original descriptors and being derived to cover the largest possible variance.

Convex hull strategy is instead a geometric-based method, which estimates the model AD by computing the smallest convex area within the *n*-dimensional descriptor space that contains TS compounds (**Fig. 1**). Similarly to range-based methods, such strategy is also applicable on the dimensionally reduced space obtained by PCA. There are efficient algorithms for convex hull calculation, although their complexity increases at the increase of dimensions.[32] However, convex hull is unable, like the range-based methods, to take into account the density of TS data and the presence of potential internal empty regions.[26,27,29,31] To overcome this limitation, it is possible to restrict the convex hull to include a smaller percentage (e.g., the top 98%) of TS compounds on the basis of their closeness to the centroid of data distribution and, thus, to reduce the likelihood of inclusion of underrepresented areas.[33]

Distance-based methods calculate the chemical distance of a test compound from TS chemicals. In this respect, the Euclidean, Mahalanobis, and city block distances are the most employed in (Q)SAR.[26,28,31] The basic rationale is that a test chemical exceeding a user-defined distance threshold is considered chemically different from TS compounds and, thus, outside of the AD. A valuable option is the measure of the leverage (h), which quantifies the distance of a compound from the center of TS compounds. As a result, the value of the leverage evaluates the degree of influence that a particular TS chemical has on the model. Test compounds with $h > h^*$ (being h^* a threshold value equal to $3p/n$, where p is the number of model descriptors plus one and n is the number of chemicals included in the TS) are chemically distant from TS compounds and outside of the AD.[34] The Williams plot allows the graphic detection of compounds that are both response outliers (i.e., compounds with cross validated standardized residuals greater than three standard deviation units) and structurally different chemicals outside of the AD ($h > h^*$) (**Fig. 2**).

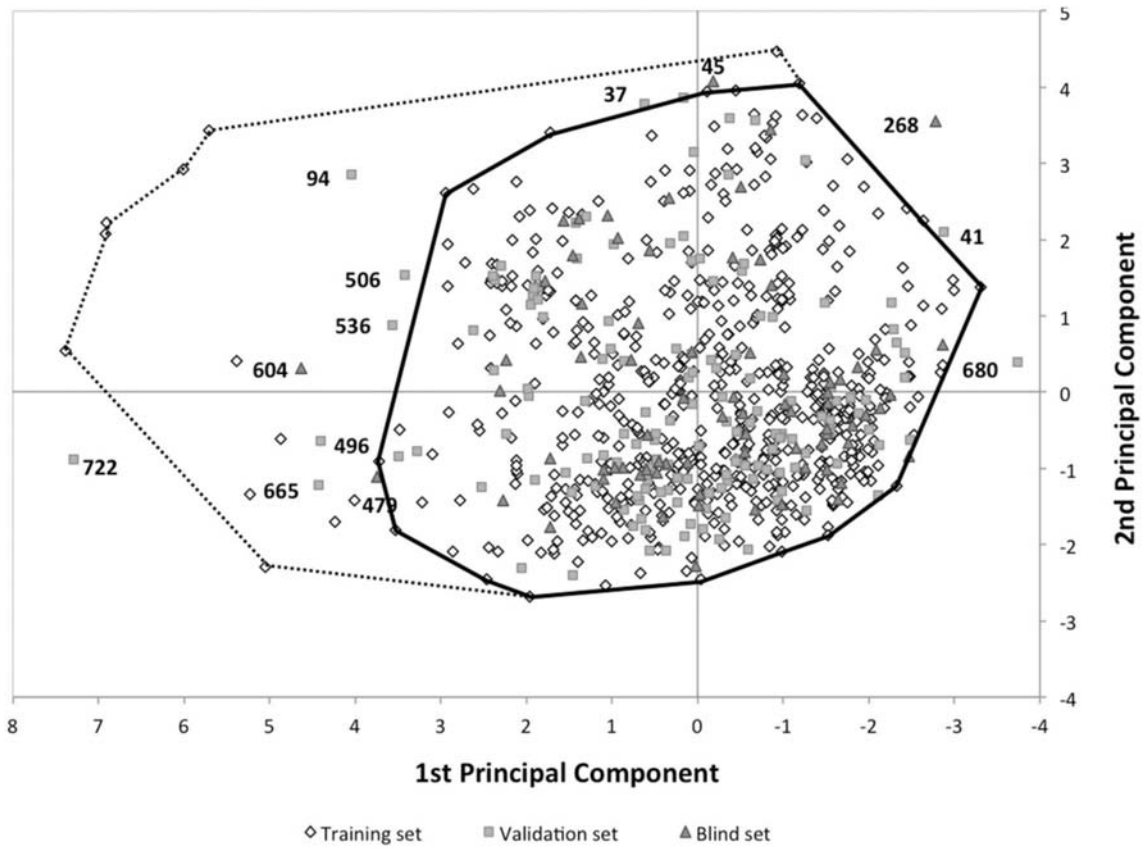

Fig. 1 Example of geometric-based AD. The convex hull is defined on the first two PC derived from the value of the nine descriptors for TS compounds. The outer polygon (*dashed line*) takes into account all the chemicals in the TS (*white diamonds*), while the inner polygon (*solid line*) retains the 98% of them, based on a user-dependent inclusive threshold. Chemicals included into two different validation sets (*gray squares* and *triangles*) outside the inner 98% polygon are flagged as outside AD. Adapted from Gissi, A.; Gadaleta, D.; Floris, M.; Olla, S.; Carotti, A.; Novellino, E.; Benfenati, E.; Nicolotti, O. An Alternative QSAR-Based Approach for Predicting the Bioconcentration Factor for Regulatory Purposes. *ALTEX* **2014**, *31*(1), 23–36.

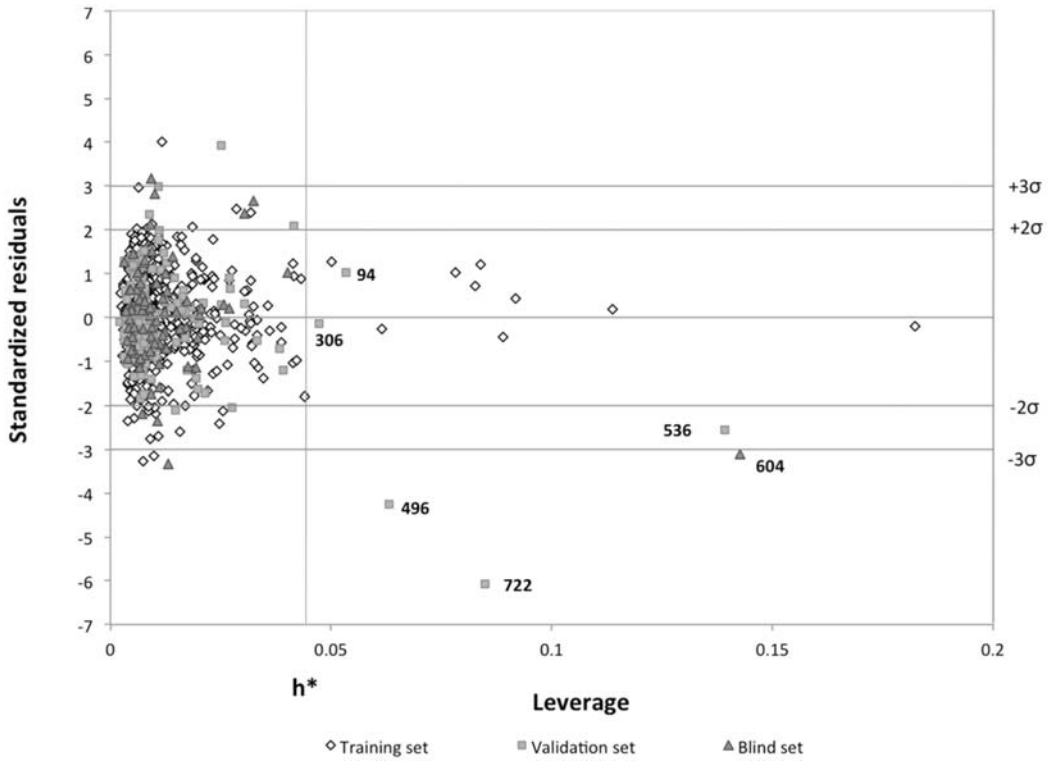

Fig. 2 Example of leverage-based AD. Leverage values computed from model descriptors for TS compounds (*white circles*) are plotted toward the corresponding standardized residuals. Chemicals included into the VS (*gray circles*) and violating the h^* threshold are flagged as outside AD. Adapted from Gissi, A.; Gadaleta, D.; Floris, M.; Olla, S.; Carotti, A.; Novellino, E.; Benfenati, E.; Nicolotti, O. An Alternative QSAR-Based Approach for Predicting the Bioconcentration Factor for Regulatory Purposes. *ALTEX* **2014**, *31*(1), 23–36.

Probability density function-based methods are classified as parametric and nonparametric methods. The former assumes standard distributions of TS data, such as Gaussian or Poisson distributions, while the latter does not make any a priori assumption and, thus, estimates the probability density from the original TS distribution. Unlike previous approaches, these methods allow to capture the real density distribution of data by the creation of concave regions reflecting the occurrence of empty spaces near to the limits of the convex hull.[26,28,31] Most of nonparametric methods focus on low-dimensional densities due to computation complexity. Kernel density estimation methods allow to handle *n*-dimensional densities such as multidimensional descriptor spaces.[35,36]

The evaluation of structural domain relies on the old, but yet valid, concept that a (Q)SAR model cannot be expected to return reliable predictions for compounds whose chemical types are not encountered in the TS.

Similarity-based methods employ the molecular similarity among the compounds in the TS and the target chemical to estimate the uncertainty of predictions.[37] Among the different methods proposed to measure molecular similarity, those based on fingerprints are perhaps the most largely used.[38,39] Fingerprints are fixed-length strings of bits, obtained by detecting all linear patterns encoding bonds and atoms of a structure, including branching points at the end of each linear pattern and cycles. Fingerprints allow to store the molecular structural complexity into simple numerical strings, which can be used to assess the similarity between molecules using, for instance, the popular Tanimoto index.[40]

Approaches based on the k-nearest neighbors (k-NN), the simplest algorithm among those used in machine learning, have been successfully used for assessing AD of (Q)SAR models.[28,37,41] In doing that, the average distance of a test compound from its k closest TS samples (i.e., neighbors) is compared with a predefined similarity threshold to determine its inclusion within the AD. Recently, it was proposed a novel method for the AD definition,[42] which integrates the classical k-NN approach with the ability of kernel probability density estimation methodologies to handle inhomogeneous data distribution. The advantage of this method is that there is not a fixed threshold such as in classical k-NN, since it is able to fit the neighborhood density of each compound, being particularly useful in case of data sets with sparse data regions.

Moreover, the structural domain can be evaluated employing structural fragment-based approaches. The assumption is that the structural closeness of test compounds to those of TS can be straight assessed[26,43] on the basis of the occurrence of known/unknown fragments. A test chemical containing fragments not observed in the TS fragment pool is, thus, considered outside of the AD and could not be reliably predicted. Fragment-based strategies are very effective since they can indirectly capture mechanistic aspects of (Q)SAR. Recurring fragments in TS could represent some reactive functional groups that may undergo a chemical reaction

responsible for a toxic effect.[44] For each test compound, the fragments of TS are, thus, searched to identify matched and unmatched fragments. Normally, only molecules with at least the 75% of matched fragments are considered within the AD, whereas those with 25% or less matched fragments are outside of the AD. Compounds with 25–75% matched fragments are considered questionable, accounting for the "fuzzy" nature of AD boundaries.[26] In addition, the frequency of unmatched fragments could be considered as an indicator of the likelihood that a compound is inside/outside of the AD. Atom-centred fragments (ACFs) are obtained by using other fragmenting strategy for decomposing molecules.[44–46]

The evaluation of response domain is strictly related to the range and mechanism of the response covered by TS compounds. There is no assurance whether a model, which has proved to be reliable in a defined range of activity, is also suitable for the prediction of compounds not comprised in that interval or mechanistic domain. As a result, the range of biological activity and, possibly, the mechanism of toxic action should be also taken into account to define whether a test compound is inside/outside of the AD. However, some concerns in this respect are due to the presence of empty regions in the activity space and the occurrence of sudden activity cliffs (i.e., compounds with high structural similarity and similar properties but unexpectedly high activity difference).[47] Such cliffs can have different explanations. One of these is metabolism, when products with different reactivities than the parent compounds are generated.

The earlier described strategies, which are based on the physicochemical, structural, and biological (or response) domain, should not to be considered mutually exclusive. Instead, an even better definition of the model AD could be obtained by integrating multiple different approaches,[26] thus, ideally intercepting different domain faces. An integrated-based strategy is expected to further increase the level of confidence associated with (Q)SAR predictions.[44] For instance, a stepwise approach[48] was proposed, which consists of four sequential stages. Moreover, there are combined computerized approaches resulting in the so-called applicability domain index (ADI) (implemented in the VEGA software[49,50]), a value ranging from zero to one to quantify whether a test compound is outside/inside of the AD. The ADI is calculated by weighting several other indices, most of them based on the calculation of the most similar compounds[51] found in the TS of the model. Each of the indices provides a particular measure relevant for defining AD, which are (a) the presence of similar molecules within the TS, (b) the accuracy of prediction for similar molecules, (c) the concordance with similar molecules (i.e., the difference between the predicted value and the experimental values of the most similar compounds), (d) the maximum error in prediction among similar molecules, (e) ACFs check, and (f) model descriptor range check.

1.16.2.1.4 About principle 4: appropriate measures of goodness of fit, robustness, and predictivity

Data-driven and *knowledge-driven* strategies can be adopted for model development. The former are particularly useful when large TS are available. Data-driven approaches rely mostly on algorithms for statistical optimization. Knowledge-driven approaches exploit on expert knowledge of chemistry and toxicology and put emphasis on mechanistic considerations rather than focusing on statistical results.

Within a highly context-dependent process, the evaluation of model statistics is important to provide valuable scientific information about (a) *goodness of fit*, (b) *robustness*, and (c) *predictivity*.

The goodness of fit is a measure of how well a model accounts for the variance of the response in the TS. The robustness of a model is related to its internal stability, assessed after data perturbation (i.e., deletion of one or more chemicals from the TS); the robustness could be quantified by the so-called internal validation. A stable model is not significantly affected by perturbations, and thus, stable perturbed models should recalculate values that are similar to those of the base model built by using the whole data set. The predictivity of the model is quantified by the accuracy in predicting test set chemicals during the so-called external validation.

Data-driven strategies make largely use of the regression and classification statistics techniques. The most popular regression technique is the multiple linear regression (MLR). The regression coefficients are estimated by using the least square method, which minimizes the sum of the squared residuals. The relative importance of descriptors is assessed by autoscaling, a process that standardizes variables to have a mean value equal to zero and a standard deviation equal to one.[52] Partial least squares (PLS)[53,54] is an MLR method to derive relationships between an X-block of p predictors and a single y response (PLS1) or a Y-block of r responses (PLS2). It is particularly useful for handling situations where the number of descriptors is much larger than the number of TS chemicals. PLS can tolerate up to 10–20% of missing data and found large application in 3-D (Q)SAR.[55,56]

The coefficient of multiple determination (r^2) and the root-mean-square error (RMSE) are used to assess goodness of fit and are computed following Eqs. (1) and (2), respectively:

$$r^2 = \frac{\mathrm{MSS}}{\mathrm{TSS}} = 1 - \frac{\mathrm{RSS}}{\mathrm{TSS}} = 1 - \frac{\sum_{i=1}^{n} (y_i - \hat{y}_i)^2}{\sum_{i=1}^{n} (y_i - y_{\mathrm{avg}})^2} \tag{1}$$

$$\mathrm{RMSE} = \sqrt{\frac{\sum_{i=1}^{N} (y_i - \hat{y}_i)^2}{n}} \tag{2}$$

where y_i is the observed dependent variable (the experimental response), $\hat{y}_i$ is the calculated response, and y_{avg} is the mean value of the observed dependent variable, for n elements of the modeled data set. The residual sum of squares (RSS) accounts for the gap between experimental and calculated values; the model sum of squares (MSS) quantifies the fluctuation of calculated values around the average of experimental responses; the total sum of squares (TSS) measures the variance associated to experimental data.

Basically, r^2 ranges from zero to one to estimate the proportion of the variation of the endpoint that is explained by the regression,[57] while RMSE is the standard error of estimate and measures the extent of deviations of the observed values from the regression line. High values of r^2 and low values of RMSE, preferably in line with the experimental variability of the endpoint, are associated with statistically good models. It is assumed that r^2 value >0.5 means that the explained variance by the model is higher than the unexplained one. Moreover, it is acknowledged that $r^2 \geq 0.81$ for *in vitro* data and $r^2 \geq 0.64$ for *in vivo* data can be regarded as good.[58]

In this respect, r^2 should be considered cautiously given that its value increases by adding additional variables to the model, even when these variables do not reduce the unexplained variance of the dependent variable, thus returning overfitted models. This means that the model identifies apparent and misleading relationships that fit well TS data points but has poor degree of generalization on external compounds. Such relationships are clearly meaningless and are not suitable for real-life applications. Such models could tend to comprise a large number of intercorrelated variables,[59] thus increasing the model complexity (i.e., the explained variance in fitting) irrespective of the predictive power (i.e., the explained variance in prediction). Similarly, RMSE values smaller than the experimental errors contained into the biological data would likely be indication of an overfitted model[53] since a (Q)SAR model could not generate predictions whose accuracy is higher than that of the experimental data.[60] As a result, good fitting models (i.e., small RMSE and large r^2) need further validation to assess their reliability in predicting new data.

Data used for model derivation are taken from the TS. However, a real predictive power can be claimed only if a model shows good performance in forecasting the activity/toxicity of compounds, which are not comprised in the TS. There is, thus, the need to challenge models through validation. In this respect, a number of statistical validation techniques are largely employed aiming at (a) finding a fair trade-off between the two extremes of overfitted (noisy) and underfitted (too simple) models[61,62] and (b) discarding spurious models resulting from chance correlations occurring when there is an apparent but meaningless and not predictive relationship between the predictor and response variables.[63–65]

A simple way to preassess the model validity makes use of the so-called Topliss ratio, that is, the proportion between the number of chemicals and of selected variables. As a rule of thumb, a Topliss ratio of at least five is recommended.[66]

Internal and external model validation techniques exist. Among internal validation techniques,[67,68] the most popular ones are (a) cross validation, (b) bootstrapping, (c) Y-scrambling, and (d) training/test set splitting.

Cross validation is the most applied validation technique to challenge model robustness. It implies the generation of cancellation groups obtained by deleting one or more compounds, once and only once. Each reduced data set is used to predict the compounds left out and, thus, to measure the predictive residual sum of squares (PRESS), from which the values of q^2 (or cross validated r^2_{CV}) and RMSE in prediction are calculated.[69] The leave-one-out (LOO) is the simplest cross validation technique, which implies the removal of one compound at a time. Straight comparisons of different models can be made, being the deletion scheme univocal.

The cross validated coefficient of determination q^2 is returned by comparing experimental and estimated values for each compound, as described by Eq. (3):

$$q^2 = 1 - \frac{\text{PRESS}}{\text{TSS}} = 1 - \frac{\sum_{i=1}^{n} \left(y_i - \hat{y}_{i,i}\right)^2}{\sum_{i=1}^{n} \left(y_i - y_{\text{avg}}\right)^2} \tag{3}$$

where y_i is the observed dependent variable (the experimental response), $\hat{y}_{i,i}$ is the response estimated during LOO, y_{avg} is the mean value of the observed dependent variable, and PRESS quantifies the accuracy of the internal prediction for n elements of the modeled data set.[70]

The value of q^2 increases until the optimal number of components is achieved, for instance, in a PLS analysis, defining the model structural complexity. In this respect, a difference between r^2 and q^2 larger than 0.3 is a warning of overfitted model, indicating the presence of irrelevant descriptor values or outliers in the data (**Fig. 3**).[59]

However, overoptimistic predictions (i.e., high apparent q^2) can be obtained especially when large data sets are investigated, because data perturbation is too small when only one compound is omitted. To avoid this inconvenience, the leave-many-out (LMO) cross validation procedures can be carried out. On the basis of rules set by the user, the data set is divided into a number of cancellation groups so that a group of compounds are left out for prediction under the condition that each compound should be excluded only once.

Bootstrap resampling is another technique largely exploited to perform internal validation.[71] In a typical bootstrap validation, the initial size n of the data set is kept unchanged by randomly selecting with repetition n compounds. In doing that, some compounds can be included in the same random sample several times at the expense of others that remain excluded. The theoretical number of resampling for sample containing, at least, two diverse compounds is given by Eq. (4):

$$k = \frac{(2n-1)!}{n!(n-1)!} \tag{4}$$

The squared differences between experimental and predicted responses of the excluded compounds are counted in the PRESS statistics. Likewise other LMO techniques, a high average of q^2 in bootstrap validation is indicative of model robustness and is, thus, a measure of internal predictivity.

Y-scrambling is a widely used technique to avoid models based on chance correlation. The basic premise for valid models is that endpoint values (i.e., independent variables) are not randomly distributed. If the original model has no chance correlation, a significant difference in terms of quality (i.e., r^2 and q^2) is, thus, expected by comparing it to random models. The procedure is repeated thousands of times to ensure that such difference is kept considering any originated random model.

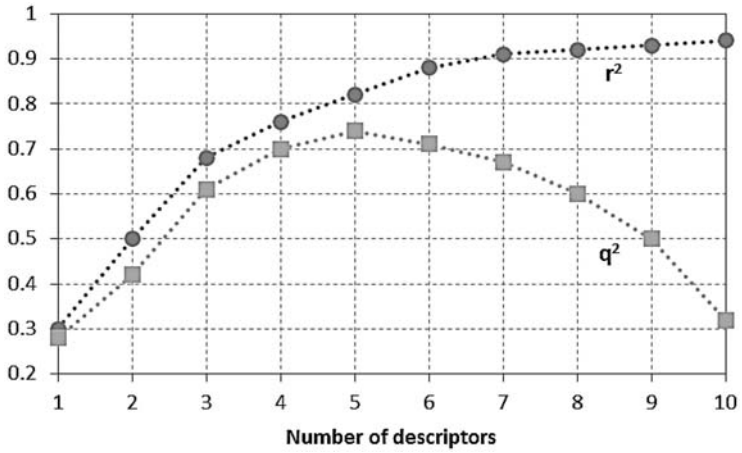

Fig. 3 Comparison of the explained variance in fitting with the explained variance in prediction. In this case, the optimum number of descriptors intercepting the maximum value of q^2 is equal to five. Adapted from Worth, A. P.; Bassan, A.; Gallegos, A.; Netzeva, T. I.; Patlewicz, G.; Pavan, M.; Tsakovska, I.; Vracko, M. The Characterisation of (Quantitative) Structure-Activity Relationships: Preliminary Guidance. ECB Report EUR 21866 EN, 95 pp. European Commission, Joint Research Centre; **2005**, Ispra, Italy.

Training/validation set splitting is perhaps the validation technique more frequently used.

The quality of internal validation depends upon the goodness of fit and robustness. However, internal validation gives almost no information about predictivity, an issue of vital importance when handling large amounts of correlated information and a large number of noisy variables.

No relationship between internal and external predictions has been described so far, and very often, high internal predictivity may result in low external predictivity and vice versa. This dilemma, also known as Kubinyi paradox,[72] represents the ultimate and perhaps unsolvable challenge for (Q)SAR practitioners.

In this respect, a more challenging approach in prediction is known as external validation. Unlike TS, the VS is used to evaluate the model external predictivity. In doing that, the user should ensure that (a) the TS and VS should cover the descriptor space of the entire data set, and (b) the structural types in the two sets are not too dissimilar.[73–76] In addition, the response space should be properly sampled[77] to ensure that TS and VS compounds span the entire range of the experimental responses and are numerically representative of the whole data set. Activity sampling[27,73,78] is a widely used example of rational selection methods and consists in dividing the whole range of activities into bins, randomly (or in some regular way) selecting compounds belonging to each bin that will be assigned to TS or VS.

In addition, external validation can be further challenged by using a blind set (BS). It must consist of compounds with known activities that are not included in either TS or VS. Unlike VS, the BS is selected through a mere random selection from the entire initial data set. The size of the BS should be about 15–20% of the entire data set. The remaining part of the data set is called modeling set, which can be divided into TS (about 80% of modeling set) and VS (about 20% of modeling set).[79] External validation, which should be regarded as a supplementary procedure to internal validation (rather than as an alternative), can be difficult to apply when the number of data of sufficient quality is scarce.

The calculation of external r^2_{ext} and RMSE in external prediction gives an indication of the real model predictivity. Additionally, a series of conditions[73] that a model must meet to be considered predictive have been also established. They are outlined in Eqs. (5)–(8):

$$r^2_{ext} > 0.5 \tag{5}$$

$$q^2 > 0.6 \tag{6}$$

$$\frac{r^2 - r_0^2}{r^2} < 0.1 \quad \text{or} \quad \frac{r^2 - r'^2_0}{r^2} < 0.1 \tag{7}$$

$$0.85 \leq k \leq 1.15 \quad \text{or} \quad 0.85 \leq k' \leq 1.15 \tag{8}$$

where r_0^2 and r'^2_0 are the coefficients of determination of the linear regression with the line of regression forced to pass through the origin of axes. In particular, the former is associated to observed versus predicted values, and the latter is related to predicted versus observed values; k and k' are the slopes of the same regression lines forced through zero, referring to observed versus predicted and predicted versus observed values, respectively.

When the variability of certain endpoints is too large to enable reasonable quantitative predictions or when the endpoints are of qualitative nature, it is wise to derive *classification models* (CMs) (e.g., toxic/nontoxic and mutagenic/nonmutagenic). For instance,

binary classification systems are commonly used to provide a convenient mean of labeling chemicals in regulatory toxicology. Several statistical techniques have been extensively reported in the literature[80] for deriving linear CMs, such as multivariate discriminant analysis, logistic regression, and decision or classification trees. Nonetheless, rule-based models, coded through "if…then" decision rules, can be implemented. Nonlinear CMs exploit other techniques such as embedded cluster modeling,[81] neural networks, and k-NN.

The goodness of fit of a CM can be assessed by using Cooper statistics, introduced in late 1970s to describe the validity of carcinogen screening tests.[82]

In this regard, predictions given by CMs are defined as (a) true positives (TPs), that is, positive compounds correctly classified; (b) true negatives (TNs), that is, negative compounds correctly classified; (c) false negatives (FNs), that is, positive compounds misclassified; and (d) false positives (FPs), that is, negative compounds misclassified.

The results of a CM can be arranged in the so-called confusion matrix,[83,84] where the main diagonal represents the cases where the true class matches the assigned class, that is, the number of objects correctly classified in each class, while off-diagonal elements quantify the types of error in the classification (**Table 2**).

The performance of a CM is quantified through the value of *accuracy* (Eq. 9), *sensitivity* (Eq. 10), and *specificity* (Eq. 11).

Accuracy, also defined concordance, is equal to the ratio between correctly predicted molecules (TP and TN) and total number of compounds:

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FN} + \text{FP}} \tag{9}$$

Sensitivity measures the proportion of chemicals tested as positives that are correctly identified as positives. The parameter takes into account the number of FNs and is defined as the ratio between TPs and the total of the compounds experimentally positive:

$$\text{Sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}} \tag{10}$$

Specificity quantifies the proportion of chemicals tested as negatives that are correctly identified as negative. It takes into account the number of FPs and is equal to the ratio of TNs and the total of the compounds experimentally negative.

$$\text{Specificity} = \frac{\text{TN}}{\text{TN} + \text{FP}} \tag{11}$$

As a result, a high value of sensitivity is associated with a high TP rate, while a high value of specificity is associated with a high TN rate. On the other hand, the FP and FN rates can be calculated from the complement of specificity and sensitivity, respectively. High values of sensitivity are welcomed to consider models adequate for the regulatory context: minimizing the number of FNs is in fact a major concern according to a precautionary approach aimed at the protection of environment and human health. In other words, a high sensitivity value for a model is necessary to consider it adequate to the regulatory context with the aim of avoiding the occurrence of FNs, which are toxic compounds wrongly predicted as not hazardous. There are also purposes for which a high specificity is preferred, for example, in screening activities aimed at finding potentially active (or toxic) substances for further actions. In these cases, it is important for an efficient use of resources that the substances selected for additional studies are TPs.

Cooper statistics are often not suitable in assessing the goodness of classification when the populations of the two classes are unevenly distributed. In this case, a useful parameter is the Matthews correlation coefficient (MCC).[85] The MCC accounts for the uneven distribution of compounds between actives and inactives and ranges between -1 and $+1$ (Eq. 12). A coefficient of $+1$ represents a perfect prediction and 0 no better than random prediction, and -1 indicates total disagreement between prediction and observation.

$$\text{MCC} = \frac{(\text{TP} \times \text{TN}) - (\text{FP} \times \text{FN})}{\sqrt{(\text{TP} + \text{FP})(\text{TP} + \text{FN})(\text{TN} + \text{FP})(\text{TN} + \text{FN})}} \tag{12}$$

The receiver operating characteristic (*ROC*) curve is used to compare the performance of CMs (**Fig. 4**). In the ROC graph, the *x*-axis reports 1-specificity (which accounts for the FP rate) and the *y*-axis the sensitivity (which accounts for the TP rate). A CM with no discriminating power would give a straight line at an angle of 45 degrees, which means equal rates of TPs and FPs [86,87]; beyond/below that straight line, the discriminating power increases/decreases accordingly. The area under the curve (AUC) quantifies the goodness of the CM: the higher the AUC, the better the CM.

Table 2 Confusion matrix for binary classification

	Predicted		
Observed	*Negatives*	*Positives*	*Total*
Negatives	TN	FP	$N_{\text{Negatives}} = \text{TN} + \text{FP}$
Positives	FN	TP	$N_{\text{Positives}} = \text{FN} + \text{TP}$
Total	TN + FN	FP + TP	$N_{\text{Total}} = N_{\text{Negatives}} + N_{\text{Positives}}$

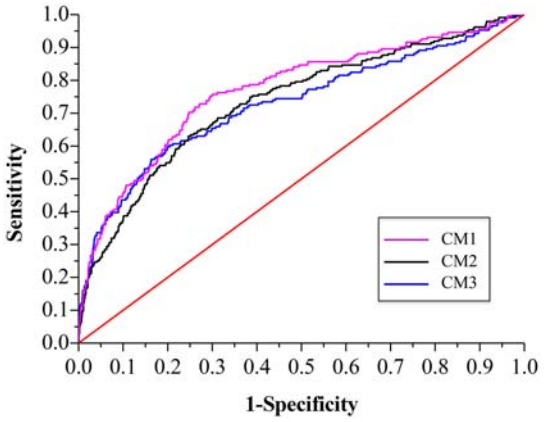

Fig. 4 Example of ROC curves derived from three different CMs. Based on the AUC values, CM1 (AUC = 0.72) is the best performing model with respect to CM2 (AUC = 0.70) and CM3 (AUC = 0.69). Adapted from Trisciuzzi, D.; Alberga, D.; Mansouri, K.; Judson, R.; Cellamare, S.; Catto, M.; Carotti, A.; Benfenati, E.; Novellino, E.; Mangiatordi, G. F.; Nicolotti, O. Docking-Based Classification Models for Exploratory Toxicology Studies on High-Quality Estrogenic Experimental Data. *Future Med. Chem.* **2015**, *7*(14), 1921–1936.

Knowledge-driven models (also known as *expert systems*[88]) are defined as formalized systems making use of specific rational rules for the prediction of the toxicity of chemicals. The rules are conceived to implement valuable information concerned with mechanism-based knowledge and available experimental data. In this respect, the rules can be derived on the basis of mathematical induction by using (Q)SAR models or on the basis of expert judgment about reactive chemistry.[89]

1.16.2.1.5 About principle 5: a mechanistic interpretation, if possible

It is important to provide a comprehensive mechanistic interpretation of a given (Q)SAR model for improving the acceptance of its results. This interpretation[90] relies on the in-depth understanding of the causal relationships relating desirable molecular descriptors to a specific endpoint. In this respect, the mechanistic rationale of a (Q)SAR can be established a priori, by choosing descriptors on a knowledge base before modeling, or a posteriori, by selecting descriptors on the basis of statistical performance, with their mechanistic rationale explained after modeling. A compromise can be found by developing models by trading-off these two approaches. The choice of molecular descriptors is particularly important for the formulation of a solid mechanistic interpretation. The descriptors are defined as "the final result of a logic and mathematical procedure which transforms chemical information encoded within a symbolic representation of a molecule into a useful number or the result of some standardized experiment."[91] Indeed, when a (Q)SAR model provides a wealth of information coherent with well-documented knowledge of mechanisms and existing hypotheses, a higher level of confidence is achieved. In this respect, the clause "if possible," mentioned in the original text from OECD, encourages the attempts of finding mechanistic interpretations, which will add a valuable plus to the model beyond its mere statistical validity. On the basis of this principle, the development of a (Q)SAR model is intended as a continuous process aimed at achieving a rational mechanistic explanation through some basic iterative steps, which are (a) the statistical exploration of data, (b) the hypothesis generation, and (c) the hypothesis testing.

The milestone work of Hansch on a set of esters binding to the enzyme papain[92] represents perhaps the first example of how a (Q)SAR could provide valuable mechanistic information:

$$\log\frac{1}{K_m} = 1.03\pi_3 + 0.57\sigma + 0.61\,MR_4 + 3.8$$
$$n = 25,\ r = 0.907,\ s = 0.208 \tag{13}$$

As reported in Eq. (13), electron-withdrawing substituents (i.e., $\sigma > 0$) favor the formation of the enzyme substrate complex. Such information is coherent with the well-documented evidence that an electron-rich thiol group of a cysteine residue is determinant for binding. The positive molar refractivity (i.e., MR > 0) suggests that bulkier substituents at the position 4 still favor binding. The same biological effect is obtained by the positive hydrophobic substituent (i.e., $\pi > 0$) at position 3.[93] Interestingly, Hansch's approach for interpreting mechanisms represents an early example of ligand-based methods for the indirect sampling of the hydrophobic, electronic, and steric properties of the protein active sites.[94] However, the mechanistic strength of Hansch's approach is obtained at the expense of its breadth of application, being AD made of few and structurally close compounds.

1.16.2.2 Grouping and Read-Across

As the understanding about SARs was growing, more confidence had started to be put into "reading" toxicological data from one substance to another. This process began in the 1980s in the United States, where US Environmental Protection Agency (US EPA) started to assess hazards and risk of chemicals based on grouping of substances. Such an approach was found cheaper, faster, and

applicable to many types of chemicals than traditional testing. In addition, finding the same effect in several similar chemicals increased the confidence of the regulator in the correctness of a prediction. The categorization approach to chemicals for regulatory purposes was taken also by OECD that, for many years, run a successful project for screening and assessment of chemicals and employing chemical categories and read-across (Screening Information Assessment Meeting (SIAM), lately known as Cooperative Chemicals Assessment Meeting), under their hazard assessment program.[95]

In 2007, the OECD Chemicals Program published the OECD guidance on grouping of chemicals[96] (No. 80 in the Series on Testing and Assessment, published by Interorganization Program for the Sound Management of Chemicals, IOMC[97]). It was based on the OECD SIAM experience with building and evaluating categories, and it also provided a basis for the REACH guidance on grouping and read-across. The OECD guidance was updated and published in 2014.[98]

In REACH, a chemical category is defined as a group of chemicals whose physicochemical and human health and/or ecotoxicological properties and/or environmental fate properties are likely to be similar or follow a regular pattern, usually as a result of structural similarity. The read-across methodology as such is based on the premise that similar chemical structures are expected to have similar biological/toxicological actions (Fig. 5).

There are different principles for grouping of substances and building categories for predictive purposed under different regulatory frameworks. Most often, the substances were grouped on a basis of common functional group (e.g., long-chain aliphatic alcohols and primary amines). Grouping and read-across were also applied to a range of substances including substances of unknown or variable composition, complex reaction products, or biological materials, where testing of every substance for every endpoint was not feasible and even not possible. In particular, the OECD program was seeking for a group description and data analysis in order to assess the hazard related to the group as a whole and the need for further testing, if any. It was clearly hypothesized that in a data matrix, where few data points are missing, one can predict them by interpolation or, in certain cases extrapolation, from other members of the group.

For the first time in the European regulation of chemicals, REACH included grouping and read-across as one of the five adaptations to the SIRs in the legal text, that is, in Annex XI, which says that "substances, whose physicochemical, toxicological and ecotoxicological properties are likely to be similar or follow a regular pattern as a result of the structural similarity may be considered as a group, or "category" of substances." In the same context, the interpolation in the prediction (read-across) approach was emphasized.

As a result of two ECHA analyses of registration data,[1,2] it was found that the registrants made a significant use of alternatives and particularly of read-across. It was found that for around 75% of the substances, a read-across adaptation is made, at least, once. It is noted that the analysis was not limited to only endpoints requiring vertebrate animal testing. Read-across was used mostly for complex health endpoints, such as repeated dose toxicity, toxicity to reproduction, and developmental toxicity. Read-across was also used for prediction of acute toxicity (all routes) and skin sensitization. Concerning environmental endpoints, read-across was used mostly for prediction of bioaccumulation potential of chemicals and short-term and long-term toxicity to fish. Noteworthy, it was observed that, in general, read-across was used much more frequently than (Q)SAR, especially in relation to the complex endpoints, which need specific mechanistic considerations. Endpoints such as physicochemical properties and environmental fate are often predicted with (Q)SARs, but this statistics is largely not available from the reports on animal testing for REACH.

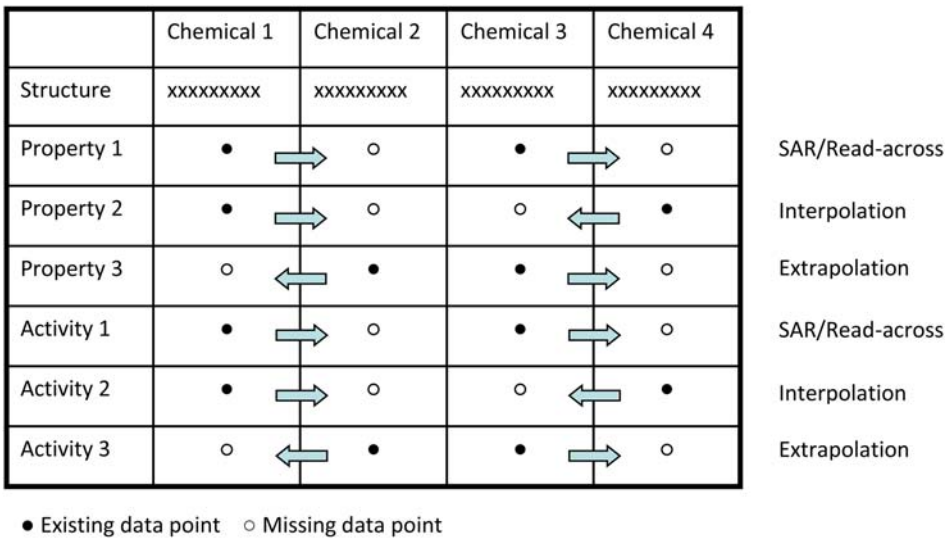

Fig. 5 Graphic illustration of a chemical category. Taken from OECD, Grouping of Chemicals: Chemical Categories and Read-Across, http://www.oecd.org/chemicalsafety/risk-assessment/groupingofchemicalschemicalcategoriesandread-across.htm (last accessed date, 19 February 2016).

The extensive use of read-across by the REACH registrants prompted ECHA to develop a systematic assessment approach in order to increase the transparency and consistency of read-across evaluation. To this end, ECHA developed and published on its website the RAAF.[10] It is important to highlight that RAAF is not a guidance and does not replace the guidance as such. The main REACH guidance dealing with read-across is Chapter R.6[5] of the Guidance on Information Requirements, which is dealing with (Q)SAR and grouping. The RAAF explains the approach that ECHA evaluators would undertake in assessing a case. It highlights the important pieces of information for assessing the read-across depending on which "scenario" the registrant may have. A scenario includes a series of assessment elements, and their integration leads to a conclusion concerning the overall assessment of the read-across adaptation, that is, either acceptance or rejection of the read-across case.

ECHA is making an enormous effort to help registrants in improving the quality of their registration dossiers in general and the quality of adaptations in particular. REACH framework increased the requirements in term of quality of the scientific justification. First, the justification needs to accommodate the definition of substance and to account for the main (or all) constituent(s) and impurities included in the substance. Second, the description of the logical read-across rationale should include the structural similarity as a basic requirement for grouping. Any difference in chemical structure between the source substance(s) and the target needs to be explained, for example, why it is expected under given hypothesis that a structural difference will bring or not bring to additional effect(s) or it will lead to a systematic (predictable) change of effect relevant for the endpoint to be predicted. Third, it should be clear what are the key aspects to be considered given the chemistry of the substances and the set of available data. Only then, the read-across can be built and the prediction model explained.

It is expected that the read-across will continue in the near future. The main aspects that need to be improved include the hypothesis and the justification, including also any nonstandard data that can support the explanation. The evidence may derive from mechanistic studies, AOP, high-throughput data (e.g., ToxCast data), or high-content data such as various omics. Very valuable information to support the read-across justification is toxicokinetics, which could be estimated through measurements or predictions. Expanding experimental methods to include additional toxicokinetics measurements can potentially increase their utility by facilitating their reuse in supporting read-across. Building ab initio predictions without a test result with phenotypic expression of adversity (or the lack of it) for comparison is currently considered uncertain with respect to the complex and expensive human health endpoints.[99] The combination of data in a strategic manner (e.g., IATA, which stands for integrated assessment and testing approaches, an approach supported by OECD) will become more important with the time.

1.16.2.3 (Q)SAR Toolbox

In read-across or category approach, data gap filling on intrinsic properties from source chemical(s) is used to predict property of another (target) chemical(s) belonging to the same category. Two types of uncertainties can be defined for the predicted property of the target chemical(s): the uncertainty related to data quality generated for source chemical(s) and the uncertainty related to grouping principles (how accurate our assumption that both source and target chemicals have same intrinsic property is). The quality of data can be assessed based on many criteria (widely recognized guidelines, good laboratory practice (GLP), and data consistency); the second uncertainty strongly depends on the knowledge about the main factors driving the toxicity effect within the property and experience of the hazard assessor dealing with the case.

In order to standardize the category formation approach, OECD decided to develop a tool, which supports the category building approach: the (Q)SAR Toolbox.[100] Under (Q)SAR Toolbox platform, six main steps in categorization process have been implemented:

1. Substance identification—input
2. Determination of the structural and mechanistic features of the substance—profiling
3. Grouping of substances sharing the same features (many iterations might be needed)—categorization
4. Data gathering for the substances in the category
5. Identification of data gaps and application of various interpolation techniques to fill identified data gaps
6. Reporting the data gap-filling outcome

(Q)SAR Toolbox platform provides a wide collection of tools to fully support the substance categorization process (from substance identification to reporting). The toolbox is therefore not a classic (Q)SAR or a library of (Q)SARs; it is rather a platform for applying category approaches and for deriving and applying customized (Q)SAR models. Such approach gives a unique opportunity to build local prediction, based on transparent empiric/mechanistic features, which normally better address specificity of the target substance compared with general models and, as a consequence, has higher probability for regulatory acceptance. However, the user needs of a certain amount of expertise and knowledge for an informed use.

1.16.2.3.1 (Q)SAR Toolbox main functionalities

As mentioned before, hazard assessment of the substance can be described in six major steps. As a result, the toolbox functionalities have also been structured accordingly.

This section is a brief explanation of these functionalities. Interested users can find more technical details on the (Q)SAR Toolbox website[100] and literature.[101]

1.16.2.3.1.1 Input

The input module allows defining the structure (and composition) of the target substance; the input structure can be defined by

- registry number (e.g., Chemical Abstracts Service – CAS and European Inventory of Existing Commercial Chemical Substances – EINECS),
- name (e.g., common, International Union of Pure and Applied Chemistry – IUPAC, commercial names are supported),
- 2-D structural representation (e.g., Simplified Molecular Input Line Entry System – SMILES, IUPAC-NIST Chemical Identifier – InChi, Structure Data Format – SDF, MOL, and XYZ)
- drawing,
- list of chemicals, inventory, or database.

In addition to the chemical names, regulatory agencies are also using international (or their own) registry numbers. Very often, the explicit structural information is missing from regulatory inventories. Likewise category approach, precise structural information is crucial, and thus, a dedicated substance identity (SID) module has been implemented in the (Q)SAR Toolbox. This module applies a search for all possible relations between CAS, structure, and name(s) in all toolbox inventories and databases. The outcomes of the search are all the chemical structures associated with name or inventory number, with five levels of confidence in the reliability of the retrieved structure (high, moderate, low, conflict, and N/A). Conflicts in relations between CAS/name and structure are resolved based on predefined hierarchy of inventories (which is related to reliability of SID information). Therefore, nonresolved conflicts are very rare and occur where for the same CAS number different structures are found in the sources with equivalent quality.

1.16.2.3.1.2 Profiling

The profiling module provides information about structural and mechanistic features of the target substance—that is, information about reactivity, potential to damage macromolecules, possible interaction mechanisms with receptors, etc. The implemented profilers are not only used to provide brief information about the toxicological profile of the substances. They are used later in the workflow to drive the categorization and data gap-filling processes (because the profiling outcome might indicate some hazardous potential and is used as a basis for grouping similar substances). Profilers in the toolbox are arranged according to the type of information they are providing:

- Affiliation profilers determine the substance affiliation with databases and inventories.
- Generic profilers determine predominantly (bio)chemical properties of the substance that could trigger a variety of adverse effects.
- Endpoint-specific profilers determine substance properties that are related to specific adverse effects such as acute oral toxicity, bioaccumulation, or mutagenicity.
- Empirical profilers provide basic chemical information such as chemical elements or organic functional groups constituting the substance.
- Custom profilers are user-defined.

Important additions to the profilers are the simulators (i.e., S9 metabolism, rat liver, skin autoxidation, microbial degradation, and hydrolysis). In general, profilers are covering the toxicodynamic part, while the simulators are covering the toxicokinetics part of the substance profile. As a first tier, the user can apply the profilers to parent chemicals and later to specific metabolites, if relevant.

1.16.2.3.1.3 Endpoint

The endpoint module allows users to retrieve (eco)toxicological and environmental data from a number of databases. The user has the option to specify which part of data should be retrieved (all properties or only specific ones). (Q)SAR Toolbox contains a wide collection of data on chemicals donated to OECD by regulatory institutions, research organizations, and companies. For user convenience, databases are thematically grouped in the following categories:

- Physicochemical properties, 42,000 substances and 157,000 experimental values [100]
- Environmental fate and transport, 8000 substances and 86,000 endpoint values [100]
- Ecotoxicological information, 12,000 substances and 608,000 endpoint values [100]
- Human health hazard, 19,000 substances and 688,000 endpoint values[100]

In order to normalize the data from different sources, the endpoint module dynamically processes the data and represents it in unified manner (e.g., all units are converted into default one defined by the user). Regardless of the data normalization process, the original information from the source (and about the source) is easily accessible. In addition, statistical information and visualization of the data aiming at improving the user's knowledge and effectiveness of decision-making are also available.

1.16.2.3.1.4 Category definition

This module provides the user with tools for grouping chemicals into a meaningful category based on their similarity with the target substance. Here, similarity is restricted not only to structural similarity but also to physicochemical properties, mechanism of interaction (e.g., same protein-binding mechanism), reactive potency, or toxicological effects. In the regulatory context for category definition, it is necessary to define the specific context of the similarity. As an example, chemicals that are similar with respect to skin

sensitization (which is driven by protein reactivity) can be dissimilar with respect to endocrine disruption (which is often driven by noncovalent receptor-mediated interactions).

Categorization can be performed with and without accounting for transformations of the analogs (metabolic, abiotic, autoxidation, and hydrolysis). In addition, a complete categorization process is normally required for several subcategorization steps. The order of subcategorization steps should start from wide categories and narrow them down later on during the subcategorization. Nonendpoint-specific profilers (e.g., based on organic functional groups, US EPA new chemicals categories, OECD HPV chemicals categories, or nonconservative structural similarity) are suitable for a first broad grouping, while for the endpoint-specific subcategorization, those profilers based on the specific mechanisms could be more appropriate (e.g., biodegradation fragments of BioWIN, classification by Mode of action (MOA) by OASIS,[108] Ecological Structure Activity Relationships – ECOSAR categorization, and carcinogenicity alerts).

1.16.2.3.1.5 Data gap filling

Data gap filling is the process of estimating the property of a nontested member of a category using the test results available for other members of the category. The toolbox offers three approaches to predict such property: read-across, trend analysis, and (Q)SAR model (the latter only if available for the given endpoint).

In normal situations, the toxic property is a multivariable function of many contributing features. Contribution of each feature can be covered in the individual (sub)categorization steps so that the final data gap step can be performed by relating the property (endpoint) data extracted from the category members to the variable that is related to bioavailability (e.g., water solubility, lipophilicity, and Henry's law constant). However, other data can be also used (i.e., endpoint–endpoint correlation, structural similarity between the target chemical, and category members) for more complex endpoints.

Data analysis focuses on the identification of the relevant data pattern. The (Q)SAR Toolbox provides a variety of formal, statistical, and logical approaches to systematically analyze the data patterns. Among them, there are data transformation (e.g., unit conversion) and data filtering by test conditions, marking substances with properties outside of a specified interval. Statistical techniques include correlation and regression analysis, confidence intervals and central data tendency calculation, leave-one-out validation, and residuals distribution.

1.16.2.3.1.6 Reporting

Three types of reports according to fixed formats approved by OECD and ECHA are produced by the toolbox:

- Chemical Category Reporting Format (CCRF)
- Toolbox Prediction Reporting Format (TPRF)
- Toolbox Model Reporting Format (TMRF)

The reports are accommodating the information, which is produced by the Toolbox. They can be used as background documentation for external purposes (such as regulatory submissions). Many fields in the reports can be automatically filled by the toolbox; other fields can only be filled by the users. Each of the three reports fulfills specific goals. The CCRF is based on OECD's guidance on grouping of chemicals.[96] The format is used to summarize information about the formed category.

The TPRF is based on the (Q)SAR Prediction Reporting Format (QPRF) version 1.1 created by the European Chemicals Bureau[102] and was modified to accommodate the functionalities of the Toolbox.

The TMRF is based on the (Q)SAR Model Reporting Format (QMRF) version 1.2 created by the European Chemicals Bureau[103] and was modified to accommodate the functionalities of the OECD Toolbox.

1.16.2.3.1.7 Summary

The popularity and usage of the toolbox are constantly growing since the launch of the first prototype of the system. The total number of registered users by Feb. 2016 exceeds 8600. It seems that the concept of building single prediction platform, which is combining extensive collection of databases, computational tools, theoretical knowledge, and transformation simulators, has a big practical value for regulatory hazard assessment.

1.16.3 Practical Example on the Use of (Q)SAR under REACH: Mutagenicity

The testing requirements for mutagenicity under REACH are designed in a tiered fashion. Positive outcomes from simpler tests (e.g., *in vitro*) trigger more complex tests (i.e., *in vivo*). The standard requirement for registered chemicals at 1 ton or more is the *in vitro* bacterial mutagenicity test (i.e., Ames test). This test is ideal for computational modeling thanks to the availability of large compilation of data, standardized experimental test protocols with high statistical reliability and low variability, and the well-studied mode of action involving DNA binding. Furthermore, already before the entry into force of REACH, the need of pharmaceutical companies of the early identification of potential mutagen substances has led to the development and validation of many reliable models. Most of these models identify structural alerts known to trigger specific toxicological pathways leading to mutagenicity (there are probably around 100 or more known groups). One example is represented by the arenediazonium salts, whose genotoxicity is caused by the interaction with purine bases. Evidence shows that the mechanism of genotoxicity of arenediazonium salts is governed by the arenediazonium salt itself or by the aryl radicals generated, which can react directly with DNA macromolecules or

can be converted by reduction or decomposition to other reactive and genotoxic species. For example, arenediazonium ions can also undergo one-electron reduction to diazenyl radicals, which, by losing nitrogen, can give rise to aryl radicals. Aryl and diazenyl radicals form adducts with DNA at the C8 carbon atom of adenine or guanine.[104,105] The presence of such structural alert would lead a positive prediction implying further testing for the definitive assessment of its mutagenicity. On the other hand, proving the absence of effect using SAR is always challenging, because it is difficult to link the absence of alerts with the absence of toxicity. To support a negative prediction, it is important to prove that the fragments present in the target chemical are also represented in the TS chemicals with negative experimental outcome. Otherwise, the lack of an alert could be just due to the presence of fragments unknown to the model, and the absence of toxicity would not be supported by experimental evidence. It is also important to consider as many models as possible to cover the chemical and toxicological space to the maximum extent. Finally, it is crucial to document all the predictions and expert judgment to allow an independent assessment of the predictions by regulators.

1.16.4 Conclusions

SARs are well known in the pharmaceutical arena, where they have been exploited for decades in the attempt to reduce costs required to design new potentially bioactive substances having high potency and minimal side effects. The onset of their use can be linked to the first documented examples in the literature[106] reporting as the increase in the potency of general anesthetics was related to the increase in the octanol–water partition coefficient (log *P*) of the chemical agents. This evidence laid the foundation to (Q)SAR, the most used nontest method in drug discovery whose history has been retraced in a recent paper.[107] Today, REACH provides an invaluable opportunity for medicinal chemists willing to tailor their purposes toward predictive toxicology, that is, playing a key role in the regulatory context. However, a full awareness of the more restrictive conditions to which nontest methods are subjected in the regulatory world is required to face this challenge. While pharmaceutical applications are more prone to trial and error principle, regulatory ones require high standards of quality and validity of the statements, as thoroughly stated by the OECD validation principles. In particular, the accurate assessment of AD in the regulatory practice is crucial for both (Q)SAR practitioners and downstream users encouraging a greater consciousness in predicting new data and decision-making. The model fit, robustness, and predictivity returned even by highly sophisticated statistical methods are meaningless for chemicals outside of the AD, while even predictions within AD are not necessarily reliable. This happens when the chemical of interest acts by a different mechanism of action, not captured by the model, or metabolism is causing a "cliff" in activity. Importantly, a thorough knowledge of the restrictive conditions of the regulatory field allows medicinal chemists to play a leading role in the multidisciplinary approach required to achieve the ultimate goal of the REACH program: the protection of human health and environment.

Over the last decade there has been a renaissance in the discovery and development of new medicines targeting infectious parasitic diseases, and this has led to new medicines being registered, but also to a range of new compounds entering clinical development against malaria,[1] tuberculosis,[2] other protozoans, parasites[3] and worms.[4] This has been driven by the availability of new high-content assay systems, which have allowed high-throughput screening of compound collections directly against the parasites, rather than against isolated molecular targets.[5,6] This approach has yielded two dividends in many areas: first of all, molecules that can be optimized and moved into clinical development. Second, the technologies for target identification have improved sufficiently that it has often been possible to rapidly identify the targets of these phenotypic screening hits.[7,8] These pharmacologically validated targets have the advantage that they are known to be important, but also demonstrated to be tractable. For malaria, rapid proof of concept in human experimental infection models[9–12] has also allowed us to quickly validate these new targets clinically, further increasing the confidence in this approach.

To achieve these goals, new models of collaboration have been developed, bringing together the strengths of academia and industry, close integration of science and medicine, but most importantly a move to increased sharing of data and transparency. In this review, using malaria as an example, the evolution of pipeline of molecules and targets is discussed. New modalities of collaborations and interdisciplinary teams have been necessary, as well as a continual review of data sharing and openness. These lessons can be translated at least in part to other therapeutic areas, and the next decade should see new models of collaboration permeating other disease areas, which were traditionally seen as profitable, but increasingly are becoming neglected due to a lack in progress using established *modi operandi*.

1.17.1 Parasitic Infections: Neglected Disease and Neglected Populations

Infectious tropical diseases, such as malaria, schistosomiasis, sleeping sickness, and leishmaniasis, are responsible for a significant proportion of the world's mortality.[13,14] More importantly, they have a disproportionate impact on children, which means their impact on global morbidity tends to be even larger than the headline figures on mortality would suggest; in 2013, almost 3.3 million children died before the age of five from infectious disease.[15] The effect is therefore a loss of so much potential for the future. For those who survive, disease causes children to miss significant amounts of schooling, and so the overall education levels are also suppressed. Many of these diseases are chronic with significant comorbidities, especially anemia. Even diseases, such as malaria, which has a relatively acute course of infection, effectively become chronic because in hyper-endemic regions a child may be infected as many as eight times in a year, transforming a short-term illness of a couple of weeks' duration into a long-term underlying health challenge.

These disease areas have often been called neglected diseases, because of the lack of funding in terms of drug development. To be fair, there has always been significant investment in the basic sciences on parasitic diseases, such as malaria, with contributions from national funding bodies, and also from organizations, such as the Wellcome Trust. In the past, this has been boosted by research expenditure in the military, since many of the conflicts from the Second World War through to the end of the Vietnam War involved large numbers of soldiers entering malaria-endemic zones. The difficulty has been twofold. First, that over the last two or three decades, many companies have stopped working on infectious diseases, especially protozoan pathogens, and fungal infections. The pressure within industry has been on finding new drugs with large commercial potential (the "blockbuster"

pharmacoeconomic model[16]). Failure to achieve this in an economically viable manner has now led to an increased focus on disease areas that have fewer and fewer patients,[17] with the double advantage that clinical trials tend to be much smaller and therefore much cheaper, but also that the final product can be sold at a super-premium price. Neglected diseases are in the exact opposite quadrant of this commercial space: millions of patients, with many significant underlying issues, and an inability to pay a significant price. The military today has less of a problem with parasitic infections and is more focused on battlefield injuries and post-traumatic stress. The second problem is that of fragmentation: beyond the big three of HIV, tuberculosis, and malaria, there are officially 17 diseases in the World Health Organization (WHO) list of neglected tropical diseases. Even this hides another level of complexity, as these 17 diseases break out into many more pathogens, and the pathogens themselves have subspecies and strains that may or may not respond equally well to each new drug. The effect is almost fractal: the more one looks into the number of potential diseases, the more of them there are. Clearly, any approach to neglected disease has to have an element of synergy. The lessons we learn from working against one parasite must be translated to other, similar parasites: ideas, targets, and compounds need to be freely shared.

These two issues can be addressed by new models of drug discovery and development. The first requires a reanalysis of the financing of neglected tropical disease. The second needs a more open framework for sharing of information and compounds. Fortunately, these challenges are related.

1.17.2 Drug Discovery in the World of Negative Net Present Value

The first issue can be boiled down to a simple observation. It is often stated that there is no money to be made from developing new molecules for neglected tropical diseases,[18] but this is clearly an oversimplification, and a more in-depth analysis is required. Typically, a project is viewed in terms of its risk-adjusted net present value.[19] This is a composite number. On the positive side, we can take the projected sales, adjusted for attrition (risk of failure). Here the one key advantage that infectious disease has is that the translation between an idea of killing a parasite *in vitro* or in a mouse, and curing the infection in humans is much more precise than the similar translation in, say, neurodegenerative diseases. Second, the molecular target(s) are nonhuman, a clear benefit toward safety. For instance, medicinal chemistry efforts have succeeded in finding molecules that selectively inhibit *Plasmodium* DHODH (dihydroorotate dehydrogenase) rather than its human ortholog.[20] But the opportunities go well beyond orthologous differences: the malaria parasite has a vestigial but essential plastid organelle (the apicoplast[21]), it must export hundreds of proteins into red blood cells that hosts it,[22] and it must also detoxify the heme it produces from degrading hemoglobin[23]; structures and processes that are all eminently druggable and nonexistent in healthy humans. For these reasons, the overall probability of success is much higher for drug discovery in malaria[24] and systemic antiinfectives in general[25] than for other therapeutic areas. On the negative side, there is still the cost of doing the research and development, which again has to be adjusted for the probability of success. The complexity here is working out how much a drug development project actually costs, and striving to reduce these costs. Analyses of the clinical costs of development for a classical antiinfective in industry tend to produce a number over $300 million.[26] In the malaria space, we can show that the cost of clinical development of a new molecule is a fraction of this,[24] which some have used as evidence that neglected disease researchers are somehow more efficient than researchers in other areas. However, this conclusion is premature: many of our projects involve pharmaceutical companies who provide in-kind support. Some, for example AbbVie, do not actually partner in the traditional sense of retaining intellectual property, but help out providing advice, and other services which have significant material value, and thus provide significant cost savings.

On the positive side, there are three areas of value creation that can be discussed. The first is of course sales of the final drug in commercial markets. Typically there are three markets in neglected disease. Firstly, the prices paid by United Nations Agencies, and government tenders for the public health services in developing countries, where volumes are in the hundreds of millions of doses with prices around $1–2 for an adult treatment.[27] The profit margins on these products are negligible, and under constant pressure. Secondly, there is the premium private market with patients buying directly from the pharmacist, where the volumes will be single-digit millions but the price will be around $10 per treatment, with a 90% gross margin. Finally, there are the Western prices; an Artemisinin-based Combination Therapy (ACT) in the United States can cost $100, with a 99% gross margin, but US annual sales are extremely small for antimalarials. (This of course is completely different for products that can be used to protect against infection, where most travellers take some chemoprevention, and for which there is a global commercial market.) From a commercial perspective, therefore, medicines that are used to treat parasitic diseases will never repay their development costs. Companies nevertheless manifest an interest in being involved, to a large extent in the context of Corporate Social Responsibility, but also as part of their overall strategy of having a greater Global Footprint. This means that having new drugs for malaria, for example, is a sign of commitment to the emerging markets, which may support the overall commercial goals in these regions (for other indications and their disease populations). Both of these factors combined mean that a project has a net present value at registration which is positive, an observation that is confirmed by the presence of generic manufacturers in the market place. The question is how to pay for and assume the risks in the upstream research and development process.

The challenge in any drug development initiative is therefore to close the funding gap, and move the projects closer to the break-even point from where expected NPV (or eNPV, expected Net Present Value) becomes positive. Over the last decade, donor money has helped kick-start this process. Molecules that move through development toward the clinic are bound to increase in value, provided they hit their efficacy and safety targets. The challenge is therefore to provide sufficient funding to reach this zero point, but no more. This negotiation is at the heart of the work of Product Development Partnerships, such as Medicines for Malaria

Venture (MMV), Drugs for Neglected Diseases *Initiative* (DND*i*), and the Global Alliance against Tuberculosis (GATB). A second component that drives positive eNPVs is the availability of rewards. In the diagnostics space, rewards such as a £10M "Longitude Prize"[28] for a new Fever diagnostic provide some way of closing this gap. Such rewards have not been made available as cash incentives for new medicines against parasitic disease, and one could argue that these would have to be quite substantial if they were to incentivize end-to-end drug discovery and development, certainly in excess of the $300M figure quoted above. However, one innovative approach that has been put in place is the US Priority Review Voucher.[29] This innovative new scheme allows any group which registers a drug for any one of a long list of neglected infectious diseases to receive a transferable voucher entitling its owner to a Priority Review for a second project, one in a commercial area. The first of these vouchers was awarded to Novartis for their work on artemether–lumefantrine (Coartem), and the voucher was used to accelerate review for Ilaris/canakinumab, an anti-IL1 antibody (an application that was rejected).[30] More recently, the power of these vouchers was illustrated by the purchase of one by Sanofi–Regeneron, who are in a neck-and-neck race with Amgen to launch an antibody against the cardiovascular target PSCK9. Given reasonably similar profiles for the two products, then the 6-month acceleration given by priority review has tremendous commercial potential for a potential blockbuster drug, and Sanofi paid $62M for their voucher.[31] Since then, other vouchers have been sold at ever increasing prices,[32] for $125M to Gilead in 2014, for $245M to Sanofi, and most recently for $350M to AbbVie.[33,34] Clearly, we are now at the stage where the value of the voucher is perceived by some to be higher than the cost of the complete clinical development of a new medicine against neglected disease. This means that with the addition of the voucher, projects already yield a positive eNPV once they enter clinical development. This has had a significant impact in our (MMV's) ability to find pharmaceutical partners for projects in the early stages of clinical development. **Fig. 1** shows that the time to reach eNPV break-even (arrows) is shorter for malaria (A) than for example, Alzheimer's disease (AD; B) with the sum invested "at risk" much lower. Of course the stakes (potential benefits) and risks are much higher for an AD drug. Note also that without a Priority Voucher, malaria projects do not reach positive eNPVs (C, D).

1.17.3 Creating a Pipeline of New Candidates

In many disease areas, investments in R&D over the last decade have significantly strengthened the pipelines of new molecules. There is still a long way to go before we can claim to have reached a critical mass, and there are many gaps, but the overall trend is in the right direction (see **Fig. 2** for the antimalarial portfolio). One exciting observation is that the vast majority of the molecules in "patient exploratory" studies or earlier in the pipeline have been discovered in the last decade. Another encouraging factor is the richness of the portfolio, with an unprecedented number of new scaffolds under development. In many cases, novel targets or underappreciated targets have been brought forward.

These molecules have come from three areas: improvements on existing known scaffolds, molecules rationally designed against molecular targets, and most importantly, from phenotypic screening. For malaria, these have been summarized in a recent review,[1] therefore only the key points are referred to below.

(a) Improving on the current generation of therapies

The gold standard for treating malaria is a fixed-dose combination of an artemisinin derivative, plus an aminoquinoline or aminoalcohol partner drug. The artemisinin activity has been shown to be due to the endoperoxide moiety, prompting the question whether a better endoperoxide could be developed. A collaboration between four academic groups, managed by MMV, was able to optimize synthetic endoperoxides and produce OZ277 (see **Fig. 3**), now sold as arterolane, part of the combination Synriam™, by Ranbaxy.[36,37]

OZ277/Rbx11160 shows potential replacing artesunate in a 3-day treatment and has the significant advantage that it is fully synthetic, and so will not suffer from any of the price fluctuations seen in the artesunate market over the last decade.[38,39] Further refinement of this molecule has produced a next-generation endoperoxide, OZ439, currently in phase II clinical trials. This compound was optimized to reduce the metabolic liabilities, but also to make it stable in the presence of free ferrous iron. The resulting compound has a much longer half-life and has potential to shorten treatment from 3 days down to one day, as well as showing superior safety against granulocytes and leukocytic populations in culture, and embryofetal safety.[40–42] There have also been improvements in the partner drugs: recently, a new version of a 4-aminoquinoline, ferroquine, showed good activity in clinical trials,[43,44] and an historical hybrid of quinacrine and amodiaquine, pyronaridine (see **Fig. 4**) was approved for use in adults and children by the European Medicines Agency (EMA).[45] In all cases where a new version of an old scaffold is produced, it is important to verify that the compounds are active against all clinically identified resistant isolates, and this was indeed the case here.

(b) Better by design

Structure-based design has also had an impact on the delivery of new clinical candidates. The best case so far in malaria is the development of DSM265, an inhibitor of the plasmodial enzyme DHODH. This target had been proposed from genetic validation, and a high-throughput screen was performed in which the original triazolopyrimidine screening hit was identified. This was subsequently optimized to increase potency and to remove both metabolic and genotoxic liabilities (the β-naphthylamine in the original structure; **Fig. 5**).

This compound has now been optimized[47,48] and entered phase I studies in 2013. It was one of the first molecules to take advantage of a human experimentally induced malaria infection model, run at the Queensland Institute of Medical Research in

Fig. 1 Illustrative risk-corrected eNPV for drug discovery projects in malaria (A, C) and Alzheimer's disease (B). The costs and duration in years per phase for antimalarial development, and their probability of success were taken from a MMV portfolio analysis and reference [24] For the graph in A, final revenue was set at $15M drug sales profits, plus an FDA Priority Review Voucher valued at $250M. Panel (C) represents the scenario without the Voucher. For Alzheimer's disease (B), average "out of pocket costs" ($1.4b) was taken from the 2014 Tufts Center analysis (csdd.tufts.edu) and distributed over time as in the antimalarial example. The probabilities of success for the phase transitions were taken from reference [35] and cumulative revenue was conservatively set at $10 billion over the lifetime of the product. The *arrows* in (A) and (B) indicate the time (year) where the eNPV reaches break-even. The *red line* between the graphs (B) and (C) illustrates the difference in scale for their left *Y*-axes. NPVs were calculated using Microsoft Excel's NPV function, set as a discount of 3%, and corrected for revenues by the probability of (final) success. Panel (D) represents the result of an Excel "*What if*" analysis for malaria drug discovery with different profit scenarios (*Y*-axis), showing the eNPVs for each, by year. Under the assumptions of this model, profits of at least $50M are required to produce positive eNPVs. *Reg.*: regulatory submission; *Appr.*: Market approval. The key message is that in malaria, projects do not have a positive eNPV until they reach the clinic and are supported by a Priority Review Voucher, in the absence of additional pull or push mechanisms.

Australia.[49] During the phase I, a dose of 150 mg was tested in human volunteers who had been infected with a very low dose of parasitized erythrocytes, and where the infection was allowed to progress to a state where it can be measured by PCR, while remaining subclinical. The results were positive and were used to model the dose needed in phase II, where the studies were started at 400 mg dose in Peru in early 2015. This type of human volunteer data is useful for de-risking projects, but also helped

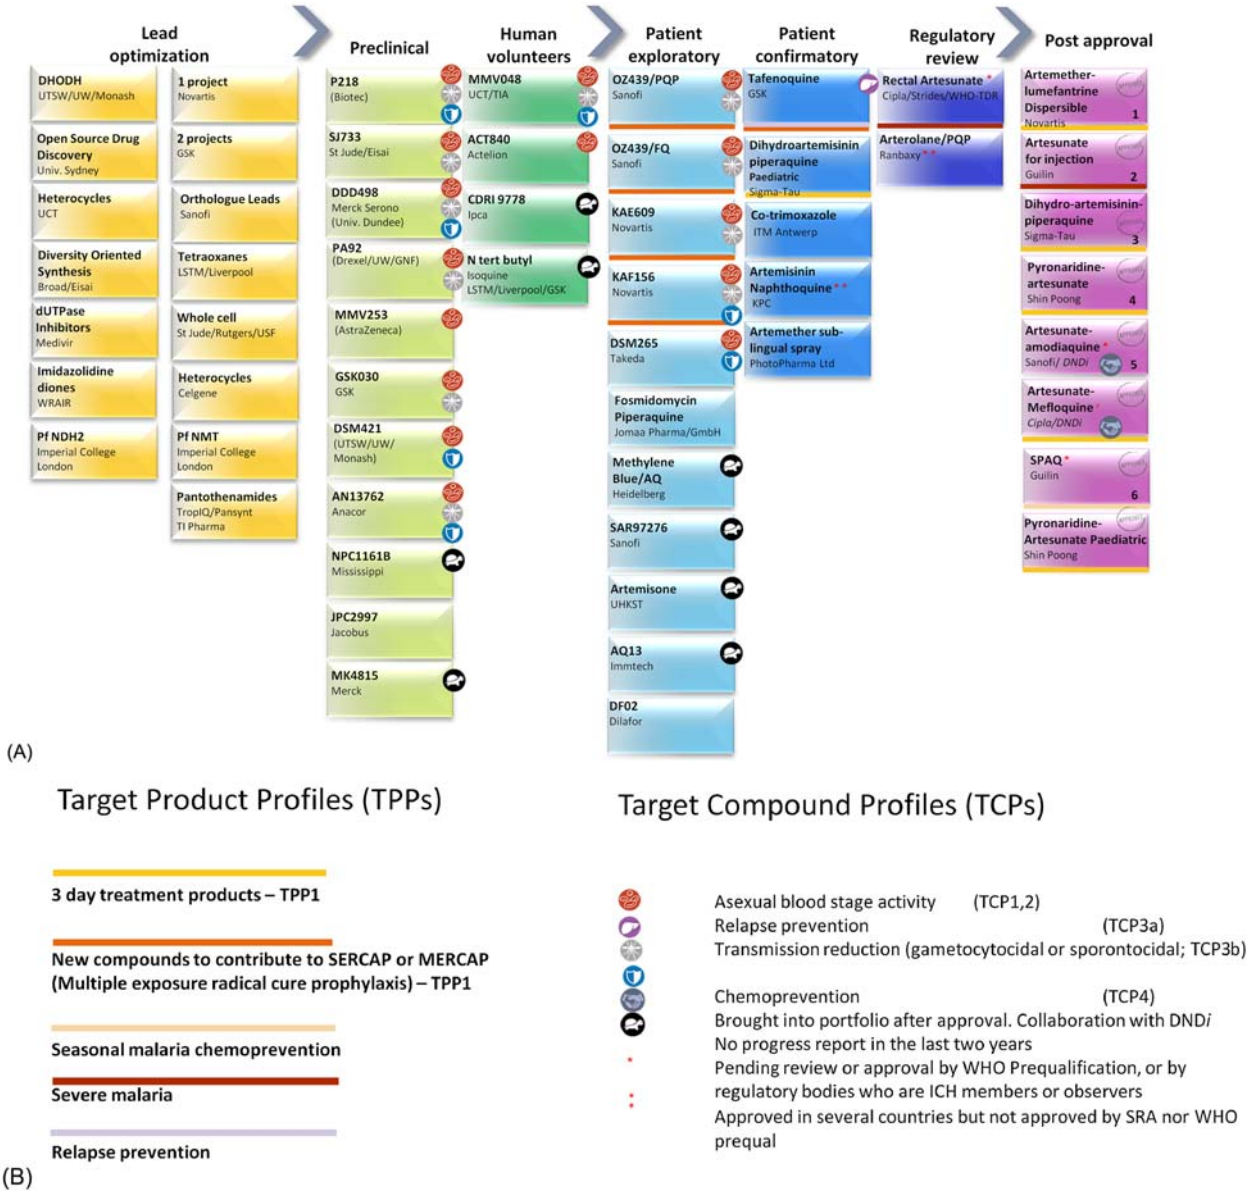

Fig. 2 (*Top*) The global portfolio of antimalarial drugs as of January 2016. The full details of the portfolio and an up-to-date version of this table can be downloaded from the MMV website at www.mmv.org. (*Bottom*) The malaria community has defined two target product profiles (*TPPs*) for medicines to make eradication achievable: *TPP1*: a treatment combination that is ideally a single exposure radical cure and prophylaxis (SERCaP) and *TPP2*: single exposure chemoprotection (*SEC*). To develop the individual compounds for combination into the TPPs, MMV has defined five target candidate profiles (*TCPs*). Footnotes: Brand names are 1: Coartem® Dispersible; 2: Artesun®; 3: Eurartesim®; 4: Pyramax®; 5: Coarsucam™ ASAQ/ Winthrop®; 6: SPAQ-CO™. The black tortoise marks projects which have not reported progress in the last 2 years. One of the consequences of limited funding is that often projects have to wait at each decision point for funding of the next stage to be clarified. This is especially true in clinical development where it is an ethical requirement to have secured complete funding of the trial before recruiting patients.

define critical pharmacodynamic parameters guiding the clinical dose early on. Other human volunteer challenge models are available; one uses sporozoites (the stage which is normally injected by the mosquito during the blood meal) and this is a good way to see the activity of compounds against the initial dividing stages of the parasite in the liver.[50,51] DSM265 is currently also being tested here—activity against the liver stages would be a useful asset for a molecule which could be used to protect against malaria infection.

(c) A renaissance in phenotypic screening: new models for interacting with Industry

The main contribution to the portfolio of new molecules in discovery over the last decade has come from phenotypic screening. It is important that these assays accurately reflect disease relevance—one harvests what is screened for. A compound that kills replicating *Trypanosomes* may leave nonreplicating forms, such as trypomastigotes, capable of reinitiating infection

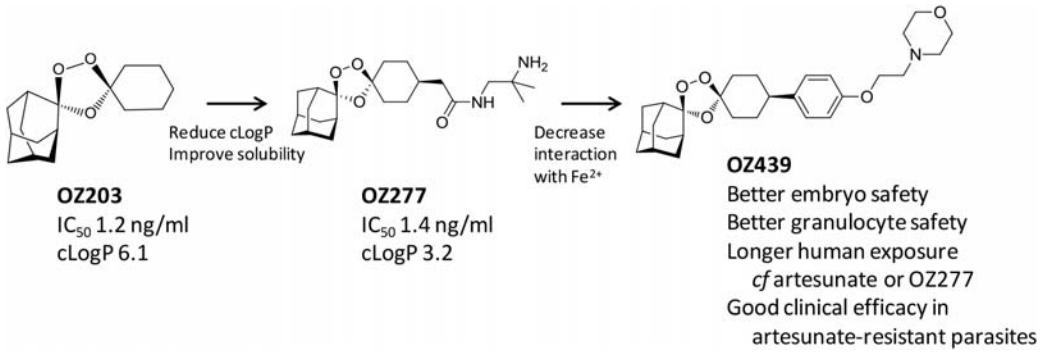

Fig. 3 Summary of discovery of OZ277 and OZ439 from OZ03 starting point.

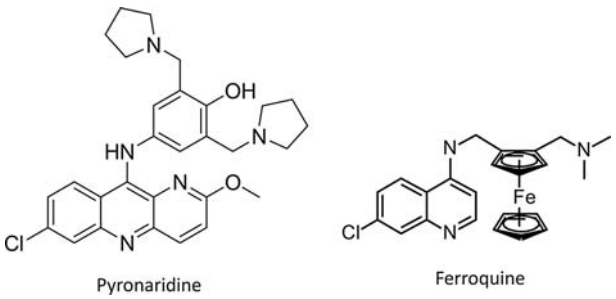

Fig. 4 Structures of pyronaridine and ferroquine.

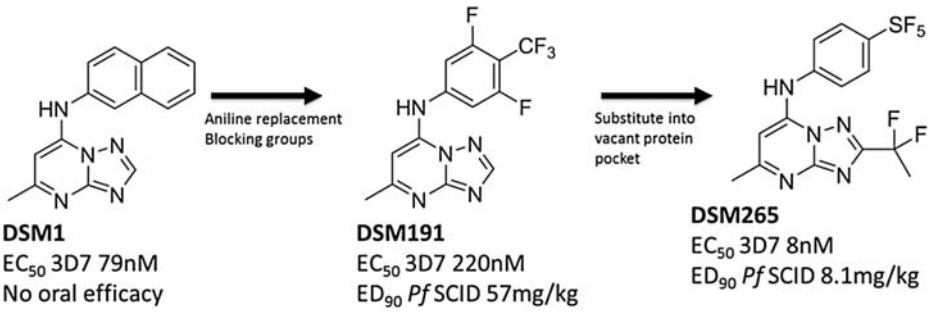

Fig. 5 Progression from the DSM1 "hit" to the DS191 "lead" and finally to DSM265, the preclinical candidate. "3D7" refers to *P. falciparum* strain 3D7. "*Pf*SCID" refers to the humanized mouse (NOD–SCID IL2R$^{-/-}$) malaria model described earlier,[46] with ED_{90} as the dose with 90% efficacy. The EC_{50} refers to the half maximal effective concentration.

long after the end of the treatment.[52] Ivermectin is a wonderful drug that kills microfilaria (*Onchocerca volvulus*), the cause of river blindness, yet does not kill the adult worms that produce these.[53] Compounds that kill *Leishmania* parasites *in vitro* may not reach the amastigotes, which reside inside acidic phago-lysosomes within macrophages. Similarly, *Trypanosoma cruzi*, the parasite that causes Chagas disease infects many cells types, with variable drug exposure. The key challenge for *Mycobacterium tuberculosis* bacteria is that few compounds affect the latent, nonreplicating stage[54]; moreover, bacteria may reside in poorly vascularized lung tissue with challenging drug irrigation. For these reasons, tuberculosis treatments take months to complete in regimens that are eminently designed to generate drug-resistant strains. Considerable efforts have been made to develop assays that address these other aspects so that compounds can be tested against rapidly replicating bacteria[54] but also when metabolically inert in low-oxygen conditions[55] and when residing in macrophages.[56,57] In the symptomatic phase of malaria, *Plasmodium* replicates in a single cell type (erythrocytes), and drugs that kill this stage have the capacity to completely clear patients from the disease (although they often do a poor job in preventing transmission back to mosquitoes, see below). Changes in the technologies for imaging in high-throughput assays, and improved biomass production[58] meant that parasites could be imaged in 384 and 1536 well plates. This meant that antiparasitic assays could be performed outside of the major screening centers of the pharmaceutical industry. This was a critical success factor—the malaria infection assay is relatively straightforward, but still requires live parasites and human erythrocytes—a setting which would not be allowed on the main

screening platforms of many pharmaceutical companies. The other advantage was that the price of screening dropped by almost 100-fold over a relatively short period of time. Three initial projects led by Novartis,[59] GlaxoSmithKline (GSK[60]), and St Jude Children's Research Hospital, Memphis, TN[61] screened large decks of up to 2 million compounds in-house. The technology was also taken up at the Eskitis Institute in Queensland Australia,[62] and over the following 3 to 4 years, over 7 million compounds from multiple libraries were screened, and a large collection of actives were identified. The advantage of the relatively low cost of the assay meant that a new model of interaction with the pharmaceutical industry was possible. The compounds were screened first and positives were identified, before any agreement was made over disclosing the structures. In most cases where positives have been identified, there was a desire by the partner company to carry on the collaboration into the Hits-to-Leads phase. Occasionally, strategic changes within the company meant that the project could not be continued, but in those cases the scaffolds were handed over to MMV for further work.

1.17.4 New Collaborative Models for Partnerships and for Building Teams

Even in cases where companies were interested in progressing compounds, not every company should, or indeed could have all of the assays in house. The role of MMV as a research catalyst was to make sure that standardized assays for all of the different stages of the parasite lifecycle were in place.[63] Thus, a system could be set up, whereby interesting compounds from a variety of different projects could be tested in the same assay—one for blood stages, one for the liver stages, and one for transmission blocking. This also included two standardized mouse models: one using the malaria parasite species *P. berghei*, which can infect mice, and the other using "human" *Plasmodium falciparum*, which infects NOD/SCID/IL2R$\gamma^{-/-}$ (NSG) mice engrafted with human erythrocytes.[46] We also set up a clear set of target candidate and target product profiles[24] which are updated every 2 or 3 years. These are the fruit of an extensive discussion with our advisory boards, which include experts in clinical malaria, but also experts in drug discovery from malaria and other therapeutic areas. The other critical success factor is the definition of standardized stage gates. Working with our pharmaceutical partners, and also with the other product development partnerships (PDPs), we have been able to define the characteristics of a molecule which is at the lead (activity *in vivo*) or the optimized lead stage (active *in vivo*, and with a need for early safety testing prior to becoming a clinical candidate).[64] In addition, we have produced a standardized list of parameters for compounds which can be considered preclinical development candidates. The creation of a standardized vocabulary and criteria between the different projects is critical, as most companies have very similar processes, but often use very different language that describes the phase transitions. This standardization of stage gates using data from standardized assay in the MMV network also means that it is easier for us to track the times taken between different stage gates for different projects, as well as the costs associated.

About half of the molecules in the portfolio come from industrial collaborations, and the other half from partnerships with academia. In all cases, we made sure that the projects had an industrial mentor. One of the advantages of working in neglected infectious disease is that we have been able to draw on the skills of a wide variety of senior experts, often recently retired from the pharmaceutical industry. Therefore even groups with relatively little experience of the early stages of drug discovery were properly advised and able to quickly identify the key issues, and design strategies to solve them. Each project is reviewed at least once per year by our External Scientific Advisory Committee (ESAC), and this review, plus the continual presence of ESAC members as mentors of the projects, ensures that the best practice is shared between projects. One message that comes out of this is that in neglected disease, we have a chance to observe first-hand how peer review across companies works. The increase in transparency and the discussions between companies mean that we can avoid unnecessary duplication, but also that common standards can be applied across all the projects.

The DSM265 project, mentioned above, has an interesting background. The fact that it is accepted that early-stage malaria drug research is in negative NPV territory, and therefore not seen as a commercially viable activity, means that we were able to take the transparency to a new level. Several groups were working on the same target, and we were able to organize a meeting between the University of Texas, Southwestern, Harvard University, GSK, and Genzyme, where the different groups talked about their approaches, and where everyone agreed that any ideas contributed to the existing projects remained with the existing teams. This resulted in unique partnerships in which, for example, GSK chose to support the University of Texas Southwestern in exchange for crystallography efforts. In this configuration, the collaboration fostered intellectual sharing between the teams that contributed to the ultimate success and the first batch of DSM265, that was synthesized by GSK and handed back to the University of Texas team for further characterization. It was not simply the openness of data sharing that was important here, but also the openness of critique. This raises the question about how much more efficient industrial drug discovery would be if all projects had some sort of external peer review: duplication of projects in industry is only wasteful if the individual insights cannot be shared. Clearly, this sharing cannot easily take place in disease areas which are seen to be highly profitable, but the success of this business model does suggest that more work to create open sharing in profitable diseases could significantly enhance success rates (and decrease attrition). It is also important to have a clear view about which diseases are not profitable: there is still quite a split in the tuberculosis community, where some believe there is a small profit to be made, and therefore operate as commercial companies. Others would take a more extreme view and consider many areas of medicine, such as psychiatric disease, to be unlikely to be profitable, and these are areas where more open collaboration models should be considered in the future.

1.17.5 The Circle of Life: Back to New Targets

Initially, it was difficult to convince many medicinal chemists of the possibility of optimizing compounds coming from phenotypic screens, without knowing the mechanism of action nor having a primary biochemical assay. One frequent comment was that it would never be possible to register a drug without having some understanding of the mechanism of action (which overlooks the fact that there are still many safe and effective drugs where the precise mechanism is a matter of debate; indeed, the question of mechanism was not even raised at the FDA review of Coartem®). However, the identification of the target has come naturally as part of the optimization. Two compounds can be used to illustrate this. The first is KAE609, a spiroindolone, under development by Novartis in collaboration with MMV and the Wellcome Trust, which was originally discovered as part of a collaboration between Novartis, the Swiss Tropical and Public Health Institute, and the Dutch Biomedical Primate Research Centre.[65–67] The optimization of this compound included a certain amount of effort to increase its potency, but mainly the removal of metabolic liabilities, knowing that the target candidate profile for this type of molecule ideally requires a long pharmacological duration of cover (Fig. 6).

Once the initial hit was confirmed and some structure–activity relationship data were available, a subproject was launched to identify the target. Early on in any project there is an assessment of the risk of development of resistance.[68] This initially focuses on two factors: the number of parasites that have to be cultured before a resistant parasite can be detected in the presence of a specific drug concentration, and the degree to which the IC_{50} shifts in the cloned resistant parasites. In most cases (with the exception of the endoperoxides and one or two other scaffolds), it has been possible to raise resistant mutants, and then sequence their genomes. Formally speaking, it is actually more important to know the mechanism of resistance than it is to know the mechanism of action—two compounds that hit the same target are clearly still going to add value provided they do not fall to identical patterns of resistance generation. In the case of KAE609, the target identified was the membrane channel *Pf*ATP4,[69] a sodium channel which had been identified and annotated over a decade earlier, but had not been the subject of intense research.[70] Clearly, the technical difficulties of screening against a membrane channel had kept most groups away from it in the absence of compelling pharmacological data. Now that KAE609 has successfully shown activity at an extremely low, oral dose (30 mg) in patients in Thailand[67] there is a renewed interest in what can be done directly on the target. There are a couple of other compounds in development, which are inhibitors of the same target, the second most advanced being SJ733 (SJ557733[61,71]), which is planned to start in phase I human volunteer studies in 2016. Once again this compound came from phenotypic screening. We are not yet at the stage where new scaffolds have been designed jumping between the various active pharmacophores using insights from structural biology(Fig. 7).

The other leading example of new target identification comes from a project led by the University of Cape Town, South Africa. Preliminary screening of an industrial library at the Eskitis Institute in Queensland led to the identification of four members of the same aminopyridine family. Medicinal chemistry optimization of the compound led to the development candidate MMV 390048 ("compound 15" in[727]), which is now completing human challenge studies, and should be ready for phase II studies in 2016 (Fig. 8).

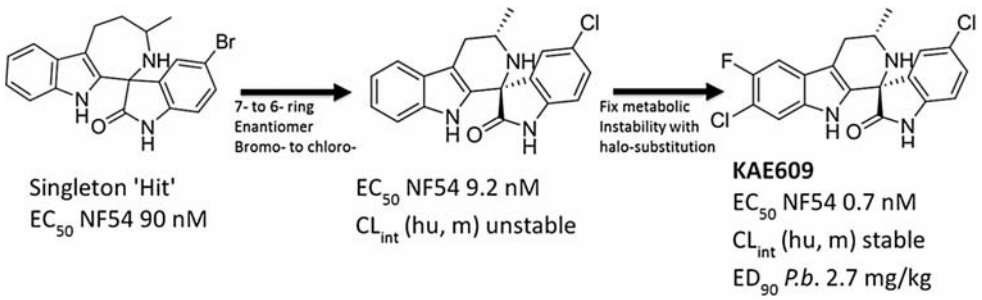

Fig. 6 Efficient optimization of a singleton "hit" from a "natural product-like" library through to KAE609. "NF54" refers to *P. falciparum* strain NF54.

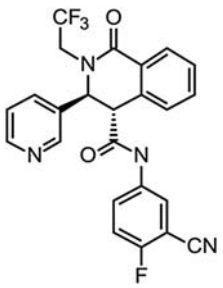

Fig. 7 Structure of SJ733 (SJ557733).

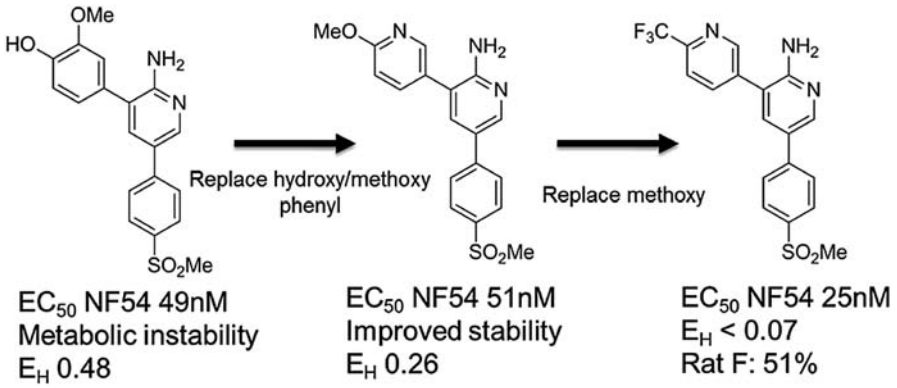

Fig. 8 Optimization of the Softfocus kinase "hit" into the lead and, finally, candidate MMV390048. E_H stands for Hepatic Extraction ratio—*eg* if the E_H is 0.3, it means that the *in vitro* data would predict that *in vivo* 30% of the compound would be removed by a first pass in the liver.

The target for these compounds was identified as a lipid kinase, phosphoinositol (PI) 4-kinase (*Pf*PI4K), by two different methods. First, a different project team independently identified the enzyme target as being the mechanism of resistance for their compound. Second, pull-down experiments using members of this chemical series have identified the enzyme by mass spectrometry.[7]

Chemical biology approaches to identify the targets are clearly going to be very important in the future. As the ideal target is one where it is difficult to raise resistant strains, then any target identification strategy which relies purely on this approach is going to be somewhat limited.

What is fascinating about both of these targets, which emerged from phenotypic screening, is their poor overlap with targets which were prioritized over the previous decade from genetic target validation approaches. In 2010, we could identify over 100 targets, which had been proposed to MMV as part of target-based drug discovery, and these did not include *Pf*ATP4. The list did include a large number of kinases, as would be expected, but the one that was conspicuously missing was *Pf*PI4K. One of the keys to future success is to make sure that the list of targets where there is a pharmacological validation is continuously updated and in the public domain. Naturally, one of the difficulties is to balance the academic needs of the original teams to achieve high-quality publications with the need for this transparency. Currently, the delays involved in preparing a high-quality manuscript submission and having it accepted greatly determine the time required for a new target to enter the public domain. This is something which needs some attention.

There are now quite a few new targets which have been described (the current state of the art is summarized in **Table 1**).

These now offer the chance to go back to primary screening collections and identify new scaffolds. Some of these targets are now validated in human patients, and many more will be validated over the next 3 or 4 years. It is important to keep reminding the community that the entrance of one molecule in the pipeline does not guarantee getting a drug out at the other end. Candidate profiles for inhibitors of each molecular target can be improved with each lesson learned by the front runners. Even when a molecule is in phase II, it still has less than a 50% chance of making it to Phase III.[24]

Table 1 New targets to fight against *Plasmodium falciparum*

Target	*Target name*	*Key molecules*	*Clinically validated*	*Key references*
*Pf*ATP4	Na^+-ATPase 4	KAE609, SJ557733, 21A092	Y	8,71
*Pf*PI4K	Phosphatidylinositol-4 kinase	MMV390048, KAF156	Y	7
*Pf*DHFR	Dihydrofolate reductase	P218	Y	73
*Pf*DXR	DXP reductoisomerase	Fosmidomycin	Y	74
*Pf*DHODH	Dihydroorotate dehydrogenase	DSM265	Y	75
*Pf*CYT bc1	Cytochrome bc1	Atovaquone	Y	76
*Pf*FP2-3	Falcipain cysteine proteases 2/3	Falcitidin	N	77,78
*Pf*HDAC1	Histone deacetylase	SB939, trichostatin A	N	79–81
*Pf*CARL	Cyclic amine resistance locus	KAF156—though uncertainty whether Carl is mechanism of resistance or action	Y	59
*Pf*EF2	Elongation factor 2	DDD107498	N	82
*Pf*PRS	Prolyl-tRNA synthetase	Halofuginone, Febrifugine	Y	83
*Pf*ThRS	Threonyl-tRNA synthetase	Borrelidin	N	84

1.17.6 Data Sharing—Dealing With Fragmentation

Access to data is a key catalyst to drug discovery. The first action which opened up the data for the malaria community was the publication of the primary datasets from the phenotypic screens.[61] The surprise was that the number of hits (roughly defined as a compound that causes significant inhibition of parasite growth at 1 μM) was around 0.7% in many of the screens, and so there are currently some 22,000 compounds where the structures have been placed into the public domain. Beyond this, in 2012, MMV and the European Bioinformatics Institute (EBI) started a collaboration to establish a one-stop shop for malaria drug data, consolidating publicly available malaria drug research into one easy-to-search database as part of the online ChEMBL database, hosted by the European Molecular Biology Laboratory-EBI (EMBL-EBI). One of the difficulties in interpreting these data is the absence of all the negative data, which helps to define pharmacophores. In theory, this could be achieved if all of the original compounds screened were made available. In practice, provided the key molecular descriptors of the inactive molecules are known, then that should suffice to start building models, which could enrich compound diversity proposals for molecules that will show activity. We are currently exploring this as a next step.

The push now is to obtain data on as much of the malaria lifecycle as possible for these compounds: as mentioned earlier, compounds with activities against the dividing liver stages, or hepatic schizonts, have potential use in chemoprotection. Compounds that kill the sexual stages (the ones which are transmitted back to the mosquito in the blood meal) could play a role in blocking the cycle of transmission—only few of today's malaria drugs achieve this. Such transmission blockade is a critical weapon in any campaign to eliminate or eradicate malaria; stopping humans infecting mosquitoes is arguably easier than stopping the mosquitoes infecting humans and certainly easier than specifically trying to cure mosquitoes once infected!

The ultimate goal of malaria research is the eradication of the disease. One of the key tools here is to simplify the treatment of disease down from the current 3-day regimen to a single encounter, as either a one-dose treatment, or as two doses taken with a short interval between them. Bearing in mind that the current artemisinin combination therapies often contain more than 3 g of active pharmaceutical ingredients, plus the excipients, it becomes clear that having more potent molecules will be a challenge that must be met. A second challenge required by the clinical community is to have molecules with improved safety. This translates into weeding out as early as possible molecules with no chance of being safe so that resources can be focused on the compounds which have the highest probability of success. In phase III trials for treatment, then any grade III adverse event is a concern, among the 1,000-2,000 (using the same style as below for 13,000, and 22,000 above) patients on the experimental medicine, and although it is clearly not possible to evaluate this without doing a large clinical study, any hints of adverse activity have to be closely followed up. One significant issue in malaria is that we need to know that the medicines are safe in children, because 85% of the patients are under the age of 5 years, and half of them are under 2, moreover this represents a very vulnerable population with high malaria mortality. In addition, the pregnancy status of many of the female patients may be difficult to assess in the field, so it is important to take into consideration any early flags in embryofetal safety studies. Although the mantra "kill [molecules] early, kill cheap" is beloved by portfolio managers, it is important not to prune the portfolio so thoroughly that nothing remains. It is also important to remember that some adverse event signals have become less significant as more and more patients, and also different types of patients, are added to the clinical trial databases.

1.17.7 Bringing the Compounds to the Biology or the Biology to the Compounds

The TCAMS (Tres Cantos Anti-Malarial Set): One of the major problems in drug discovery against protozoa is to bring together the excellent biology that exists in the academic centers with medicinal chemistry expertise, which still largely resides in industry, and in those who have recently left industry. Having identified over 13,000 screen-positive compounds, GSK has produced the TCAMS, which is available for screening, and groups interested in identifying compounds which hit their target or influence their pathway can collaborate to access the compounds.[85,86] Currently, though, the easiest way to test against such a large number of compounds is to take the biology to the compounds.

Malaria Box: We took an alternative approach and tried to identify a key set of compounds that could be shipped around the world. The first experiment, called Malaria Box[87] started by clustering the available hits into groups, and then purchasing one or more compounds from each group. The resultant compounds were then retested for quality control purposes, as it would be frustrating for biologists to test compounds, which are not known to be active against the parasite. Some 400 compounds were selected, and these were made available to anyone who requested them through a web server at www.mmv.org. There were no restrictions placed on the requestors in terms of intellectual property; if new intellectual property was identified, then the requestors were left free to proceed as they saw fit. (This is the paradox of open source, in that by being open, one cannot compel others to be open.) The Malaria Box has been shipped to over 260 different groups (Van Voorhis et al., submitted) in 30 different countries and in the first 2 years after release has already resulted in over 30 publications and 33 papers being prepared for submission. These assays have shown how producing decks of compounds and making them freely available is one way of overcoming the fragmentation of the community that works on neglected diseases. The sets have now been tested against multiple protozoan parasites as well as helminths and bacteria, with some important insights into the overall hit rates against the various parasites. By making the metabolic and pharmacokinetic data available for the compounds (currently on demand, but the goal is to publish this all as soon as possible), then any group finding a compound with potency *in vitro* can rapidly assess whether the compound has a chance of being active in an *in vivo* assay. Several groups have shown compounds to have significant *in vitro* and even *in vivo* activity.

The compounds do have potential for activity against host targets. Although a preliminary screening against human cell lines (THP-1 and MRC-5) showed no significant activity at 10 μM, subsequent testing against the National Cancer Institute panel of 60 tumor cell lines[88] showed several compounds with activity in the low micromolar range against one or more of these lines. Some of these compounds are being worked up for further analysis and *in vivo* testing. The low micromolar cut-off is also justified by the results seen in the mouse pharmacokinetics. All 400 compounds were subjected to a mouse snapshot pharmacokinetic experiment, and around one-third were capable of maintaining a close to micromolar plasma concentration over the first 24 h, from a single oral dose. This presumably reflects the fact that to kill the parasite, the compounds have to cross a number of membranes, and so the *Plasmodium* assay is already screening for highly drug-like molecules.

Pathogen Box. A second compound collection, known as the Pathogen Box, became available for delivery at the end of 2015. The key differences here were that because of a specific grant from the Bill & Melinda Gates Foundation, we obtained resources to synthesize key compounds, and so were not limited to commercially available compounds. In addition, the source for the original compounds came from a variety of different phenotypic screens including mycobacteria, other protozoan pathogens, a small number of infectious helminths, and some from emerging viruses. Again, the critical metabolism and pharmacokinetic data will be made available for all of these compounds. The selection of the compounds was done by a group of medicinal chemistry experts from the Product Development Partnerships (groups like MMW, DND*i*, TB Drug Accelerator, *etc.*) and our advisors, and so this represents the fruit of many years of screening, but also the insights from a wide variety of medicinal chemists with many different backgrounds.

Further directions for new compound collections. The broad distribution of the Malaria Box exposed the widespread hunger for interesting collections of new compounds to test in biology. In other words: for protozoan infections, most of the biology research groups are far in advance of medicinal chemistry support when compared with other neglected diseases. However, it was quite obvious that the number of groups asking for the compounds coming from disease-endemic countries was relatively small, and so in late 2014, we were able to run a call for proposals for pilot grants of $100,000 to enable researchers from Africa, Asia, and South America to test these compound decks. The hope is that there will be some common success factors here, but also that we can transfer some of the lessons on scientific and medicinal chemistry leadership to these groups. Other compound collections could be considered in a similar vein. There are over 1,500 compounds available in sets of FDA-approved medicines, but searches of the Cortellis Life Sciences information database (Thomson Reuters) show that there are almost 8,000 compounds which have been taken into clinical development for infectious diseases and so far have not been launched (most of these are discarded projects). Many of these will be able to achieve significant plasma exposure, and although some will have been stopped for safety reasons, many will have been stopped because of an insufficient pharmacodynamics effect for the specific indication(s) they were developed for, portfolio decisions and other specific reasons. Ensuring wider access to such compounds would be of great interest to the biological and medical community. The outbreak of Ebola in 2014–15 underlined the need to be prepared and to better understand the activity of known compound sets against potentially pandemic viruses. Ebola itself was not new, but very few compounds had actually been tested against it. There is clearly a need for a compound set similar to the Malaria Box, but made up of scaffolds which have been shown to have activity against a wide variety of pathogenic viruses. The prescreening of such a compound collection against existing strains of viruses, as well as the elucidation of pharmacokinetics and metabolism data would enable the community to have a head start when a new pandemic fever virus emerges. As always, the easiest way to move quickly is actually to start early.

1.17.8 Intellectual Property and Drug Discovery in Neglected Disease

One of the most widely discussed aspects of working in infectious diseases of neglected populations is the role of intellectual property. At its most basic, one of the arguments is that protection of intellectual property leads to a lack of transparency, which then slows down the discovery and development of new medicines. Although in many discussions, patents are seen as a part of the process of secrecy and control, it should not be forgotten that the patent is a contract exchanging rights to some commercial exclusivity in exchange for being transparent. Several factors therefore need to be considered in this discussion. As discussed above, one key impediment to transparency would appear to be the specific need for high-profile publications from the academic community, as discussed earlier in the target identification section. These delays may become quite lengthy, especially when papers are sent to three or four journals before being finally accepted. This sets a natural delay on data arriving in the public domain. One interesting problem we have seen with the Malaria Box is that much of the information is contained in the assays that show no activity for a particular compound, or marginal activity. These data are of course notoriously hard to publish: even with the combined data set of over 200 assays, many journals reject papers which report purely a collection of data. A second consideration about patents and intellectual property, something which has been at the heart of all of our projects at MMV, has been to see intellectual property as more of a responsibility than a right in this area. The traditional thinking that intellectual property is linked to a right to commercial exploitation cannot easily be translated into a world where there is hardly any commercial margin. In this case, the better descriptor would be *stewardship* of intellectual property rather than *ownership*. The goal would be to facilitate as wide an access as possible, with an affordable price. By gaining control of intellectual property, market access and pricing clauses can be put in at a very early stage, and the correct expectations set. Partnership with pharmaceutical companies depends on having a clear vision on the intellectual property and clarity on the freedom to operate.

1.17.9 Conclusions

Over the last decade, there has been a significant improvement in the number of new molecules and new scaffolds entering preclinical development in malaria, and in other diseases of neglected populations. In addition, the results of early screening have also led to new scaffolds in hits to leads, meaning that there should be a steady flow of new clinical candidates over the next few years, provided that funding can be sustained. In the longer term then these new molecules have led to the identification of new mechanisms of action, and the reprioritization of previously overlooked or undervalued mechanisms of action. This means that in the future we should be well-placed to identify backup compounds, for when our current frontrunner compounds fail. The project teams necessary to achieve this success consisted of a mix of academia and industry: bringing the best of both worlds together. One of the other unforeseen boosters has been the community of drug hunters outside of the mainstream pharmaceutical companies, the large numbers of advisors and mentors who have brought their many years of experience to guide and train the next generation.

There remain many gaps. Although the portfolio is numerically quite strong, the attrition rates that we are seeing are no different from the industry benchmarks for infectious disease in general. This means that there will always be a need for new chemical series, and different ways of looking at the old series. The push toward eradication means that more potent medicines will be needed in the future, but also safer medicines as they are to be used in increasingly larger number of patients and (as chemoprevention) in healthy individuals. It will be important to be able to develop a clear view on whether it is possible to realistically achieve both goals, and if not then which one is the higher priority. In any case, one of the lessons from drug discovery against parasitic diseases is that it is possible to achieve a new level of transparency of data and transparency of review, with this transparency resulting in clear scientific peer review. With the combined power of all of our teams, mentors, and advisors, we can be optimistic in the way we approach these very difficult questions. This is very important given the number of lives that depend on our future success.

Acknowledgments

The authors thank Matthew Todd (University of Sydney), Robert Don (DND*i*), and Alejandra Palermo (Royal Society of Chemistry, UK), and their MMV colleagues for helpful discussions.

1.18.1 Introduction

Despite the significant investments and advances that have been made into basic and applied pharmaceutical research in recent decades, the overall success rate in drug discovery remains low.[1,2] As a result, the unmet medical need in virtually all therapeutic areas is still considerable and poses a serious threat to the well-being of society.[3] In response to this, the drug research landscape is constantly modifying itself in search of a more sustainable business model and precompetitive, open innovation approaches are evaluated.[4] In this regard, the focus is on sharing the investment risks and improving the attrition rates of drug discovery by accessing the best ideas and solutions to problems and pooling together complementary talents and resources. With this in mind, the Innovative Medicine Initiative's European Lead Factory (ELF) project was launched with the aim to create a collaborative lead generation platform to seed and execute the early stages of drug discovery.[5] By combining an industrial quality high-throughput screening (HTS) infrastructure (European Screening Center) and the state-of-the-art Joint European Compound Collection (JECL), the ELF is granting any European private company or public entity access to resources that were once the pride and prerogative of only the largest pharmaceutical companies. In the following, we describe the ELF assets in detail and how these are intimately interlinked and successfully exploited in the ELF hit identification, evaluation, and exploration workflow.

1.18.2 The Joint European Compound Library

Identifying drug-like, well-validated, hit-and-lead compounds active against novel biological targets is the central aim of the ELF. Building a competitive HTS library to identify the initial hit matter underpins the efforts of the ELF consortium to achieve this goal. The following describes the dual approach taken by the ELF to assemble and maintain a high-quality compound collection for target-based biological screening.

1.18.2.1 EFPIA-Contributed Collection

The ELF's HTS library (the Joint European Compound Library—JECL) was initially established through the contribution of a total of 327,000 compounds from seven company members of the European Federation of Pharmaceutical Industries and Associations

(EFPIA). Combining these seven subsets into a coherent single library was the first goal and ensuring that the collection consisted of diverse, physicochemically attractive compounds, without duplicates, was crucial.[6] The main challenge in deduplication and assessing compound similarity was the requirement for compound structure confidentiality. The structures could not be exported beyond each company's firewall making direct comparison between subsets problematic. This difficulty was overcome by distributing a Pipeline Pilot protocol[7] to each of the EFPIA members, which calculated a range of physicochemical properties (eg, molecular weight, logP, topological polar surface area (TPSA)) together with the extended connectivity fingerprints (ECFP6) of all the molecules in the subset they were proposing to contribute. This protocol was run internally within each company. The results were returned to a central location at the University of Dundee for analysis and compounds with identical ECFP6 fingerprints were identified and deduplicated. Replacement compounds were requested and after a small number of iterations, a unique set was achieved. Prior to selecting compounds as candidate molecules for the ELF, property-based filtering was carried out within the EFPIA companies to ensure drug/lead-likeness of the library. An example of the filtering done included SMARTS filtering to remove compounds with undesirable features, purity check, physicochemical property filtering, removal of compounds having associated intellectual property, and, crucially, removal of compounds present in commercial databases. As a result, the physicochemical properties of the subsets were already attractive when contributed to the JECL, as shown in **Fig. 1**. Diversity analysis within and between the seven subsets showed that each subset largely sampled different areas of chemical space while within each subset, many compounds had analogs within a Tanimoto distance of 0.5. These analogs are likely to provide structure activity relationships (SAR) and support clustering and activity model-building in the HTS triage process. Consequently, the JECL has a high diversity content, as displayed in **Fig. 1**. This was a highly attractive combination and these compounds form the foundation of the JECL. In compiling the JECL, there was very little overlap of identical compounds prior to deduplication, which is in accordance with analyses done by AstraZeneca/Bayer and Johnson & Johnson/3DP,[9–11] who compared large HTS sets and further highlights that compound swaps are a simple and efficient way to rapidly increase library diversity and fully exploit assets.

1.18.2.2 Public Compound Collection

This initial set is now being complemented with up to an additional 200,000 compounds (here termed the Public Compound Collection (PCC)) in a collaborative effort involving a unique blend of chemistry expertise from 10 academic groups and 6 small & medium enterprises (SMEs), which form the ELF Chemistry Consortium.[12] The PCC will have drug-relevant properties, but also aims to capture novel and biologically relevant motifs that are poorly represented in current compound collections. The PCC is based on proposals for small molecule libraries that are submitted to the ELF via a web-based chemoinformatic tool.[12] Library proposals may be defined by specifying the structure of a scaffold, including the positions of variable substituents (as R1, R2, R3, etc.); alternative possible substituents can then be selected from predefined lists. Before submission to the ELF, the submitter is presented with information on the novelty and molecular properties of the compounds proposed. Once satisfied, that the assessment criteria have been addressed, the submitter may submit the proposal for consideration. Library proposals are considered by the ELF's Library Selection Committee that comprises eight scientists with complementary backgrounds (academic and industrial; synthetic and medicinal chemistry). The proposals are assessed against six criteria (**Table 1**) using a simple scoring system: from 0 (criterion not met) to 3 (excellent fit with the criterion). The committee reaches a consensus by scoring against each of the criteria and decides on an outcome for the proposal. Crucially, subsequent to processing of the proposal, the scores, feedback, and outcome are communicated to the submitter.

The accepted library proposals are then validated experimentally by academic and SME ELF consortium partners. The overall goal of this validation phase is to maximize the probability of progress of a library idea to the final production phase, where the actual library is synthesized in its entirety and added to the JECL. Key success factors, such as chemical feasibility, scalability, and final diversity of the envisioned scaffold, and the derivable library are thus being probed. The chances of success are highest when the chemistry involved is well validated rather than speculative in nature. This includes, for example, the scalability of key synthetic steps and the tolerability of diversity steps to the planned reagent space. Conversely, when only slight relatedness to chemical steps for which an ambiguous precedent is available in the literature is proposed, an increased amount of resources and time need to be invested during validation. Clearly, the majority of ELF library proposals having very high novelty content typically fall into this latter category. For entirely virtual proposals, different routes toward the scaffold are being devised and reduced to practice, commonly on a multigram scale. Routes are being optimized with respect to the required number of synthetic manipulations, upscaling potential, orthogonality of decoration chemistry, and availability of required starting materials and reagents. Once difficulties with the originally proposed and selected scaffold occur (eg, nonscalable chemistry route, limited decoration chemistry), the ELF Validation Chemistry Management Team is tasked with deciding on either further examination involving additional chemistry resources, modification of the original scaffold into a more feasible scaffold, or rejection of the scaffold.

In the following, three distinct examples will highlight (i) a validation attempt that failed, (ii) a scaffold validation project that succeeded within the very short time frame of only 1 month, and (iii) a validation project in which a specific approach was required to handle dangerous intermediates at large scale. **Scheme 1** depicts the envisioned synthetic route toward the final decorated library scaffold **5** clearly highlighting the synthetic step that failed, that is, the amide formation converting acid **3** to amide **4**. The key intermediate **3** was prepared in three steps.[18] During the envisioned amide coupling, the exocyclic double bond isomerized leading to a loss of the stereogenic center, as in by-product **6** (**Scheme 1**).

Library proposal yielding **14** (**Scheme 2**) progressed through the validation process in only 1 month, due to the fact that key steps in the planned route were based on solid literature precedence.[19] Key step in the preparation of **14** is the enantioselective

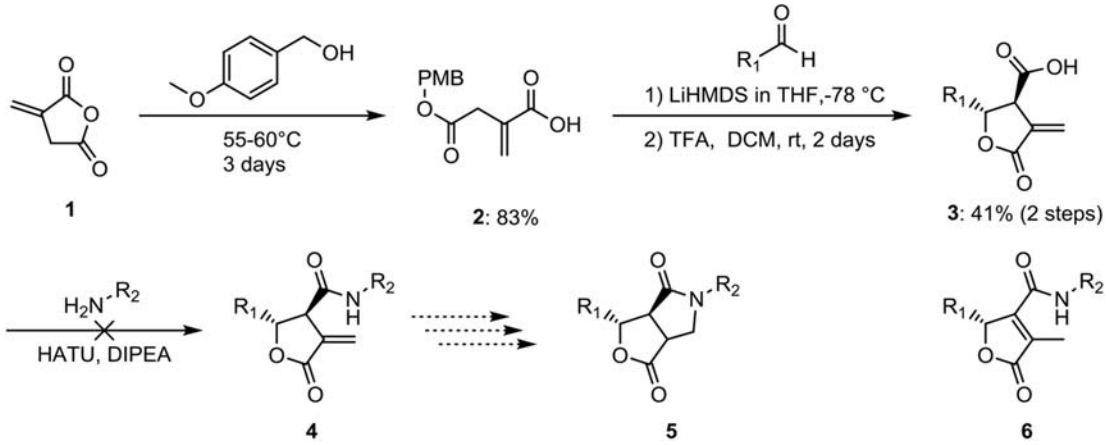
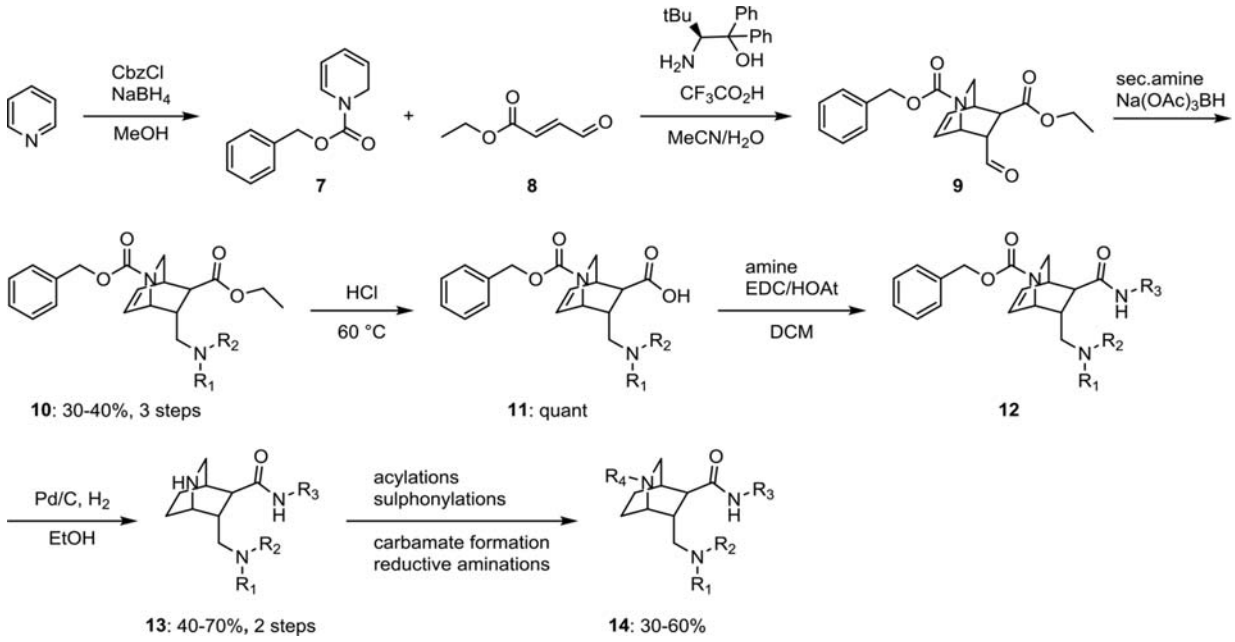
Table 1 Criteria for the review and selection of library proposals for inclusion in the public compound collection (*PCC*) set of the ELF's JECL

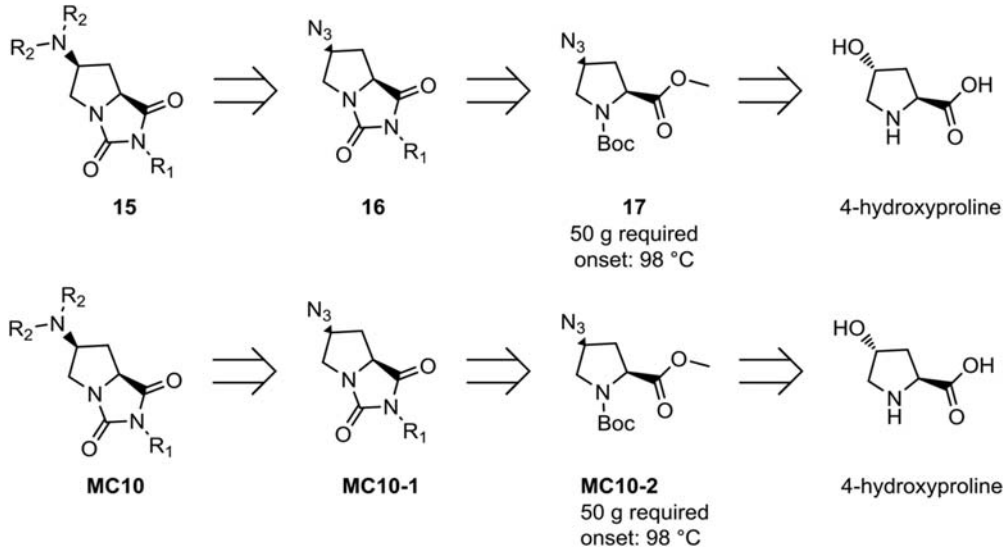
Criterion	*Notes*
Molecular properties	Assessment for drug-relevant molecular properties [13–15]
Structural features	Assessment of structural features that may constitute a liability in screening compounds, as defined by a collection of substructure filters contributed by the pharmaceutical companies participating in the ELF,[6] for example, alkylating agents, or potential intercalating compounds
Novelty	Assessment of novelty with respect to commercially available compounds[16]; patented compounds[17]; existing JECL compounds and compounds based on previous submissions to the consortium. Please note that novelty with respect to the scientific literature is not assessed during the selection of library proposals
Diversity potential	Assessment of the ability to deliver a library of diverse compounds. It is usually preferable for variable groups to be introduced late in the synthetic sequence. Most libraries require at least two diversity points
Synthetic tractability	Assessment of the likely synthetic accessibility of the library based on the precedent provided and consideration of issues of selectivity
Innovative library design	Assessment of the rationale that has been used for library design. Many different approaches might be considered to be innovative; for example, natural product-inspired libraries, or libraries designed to address a particular class of protein targets



Scheme 1 A failed library validation project.



Scheme 2 A successful library validation project completed within a 1-month time frame.

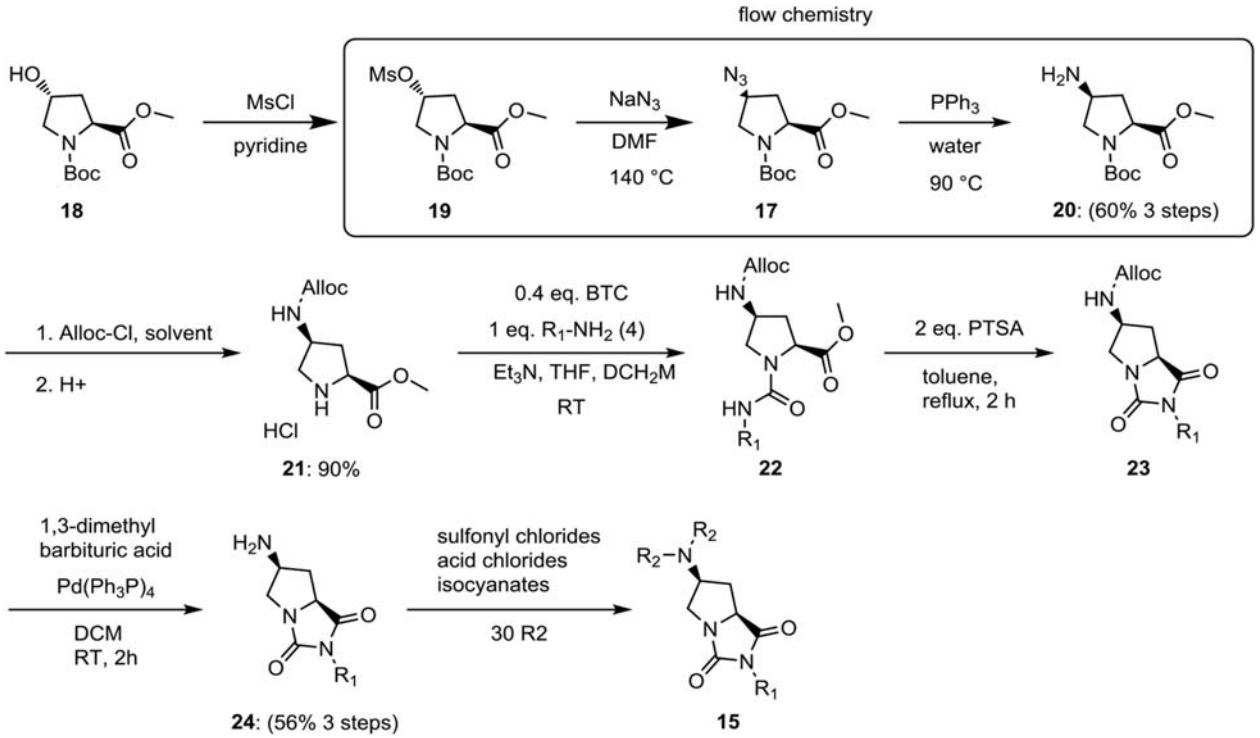


Scheme 3 Retrosynthetic analysis of library scaffold **15**.

Diels-Alder reaction of 1,2-dihydropyridine **7** and aldehyde **8** using an β-amino alcohol organo-catalyst. The isolated isoquinuclidine **9** was not stable and hence was used crude in the subsequent reductive amination affording compound **10**. Further synthetic manipulations proceeded without any issues.

Finally, the chemical validation toward the 6-aminotetrahydro-1*H*-pyrrolo[1,2-c]imidazole-1,3(2*H*)-dione-based library (**15**, Scheme 3) features a chemically interesting detail in that a flow chemistry-based process had to be established to ensure scalability of the scaffold. The retrosynthetic analysis leads to hydroxyproline via azide intermediate **17** that is finally required in a multigram scale.

During chemical validation, the synthesis of azide **17** from mesylated hydroxyproline **19** (Scheme 4) was possible, but only at elevated temperatures. It turned out that the azide is thermally unstable and has a low onset temperature of 98°C, rendering any



Scheme 4 Library validation project in which a flow chemistry approach was required to handle dangerous intermediates at large scale.

production scale synthesis prohibitive. For the synthesis of ELF library **15**, 50 g of the azide was required and safety regulations would not permit the preparation of the material on this scale. To mitigate these safety concerns, a flow process was designed, as depicted in Fig. 2. The preparation of azide **17** as well as its direct reduction was carried out in flow. After isolation of amine **20**, the material was protected as a carbamate. For the introduction of the first peripheral R group, an isocyanate intermediate was prepared, which was reacted for validation purposes with four different amines. Urea intermediate **22** was cyclized under acidic conditions. Removal of the Alloc group using an amine-free scavenger gave building blocks **24**, which were used to probe the library chemistry with acyl chlorides, sulfonyl chlorides, and isocyanates, respectively.

As of the end of Q3/2015, of approximately 450 accepted scaffold proposals, validation campaigns have been completed for 230 proposals. Here, around 170 succeeded in the chemical validation process, thus being progressed to library production. In total, 60 approved scaffold ideas were stopped due to failure during the chemical validation. The longest route that was established for a final library compound comprised 16 distinct synthetic steps, whereas the shortest routes toward final compounds usually employ multicomponent reactions in which a final compound is produced in a single synthetic step. On average, a scaffold is produced over a synthetic procedure of five to six steps, often followed by protective group manipulations prior to introduction of the final decorating R groups. After more than 2 years and 6 months of experience in scaffold and library validation work, best practice routines to aid the ELF library validation process have been defined, as shown in Table 2.

After the chemical validation step has succeeded, for each scaffold approximately 800–900 distinct Public Compounds with an individually optimized decoration pattern are nominated for synthesis considering optimal coverage of the feasible chemical space (also allowing for initial SAR of screening hits) and providing compliance with predefined physicochemical properties of the individual Public Compounds.[19] This target number of Public Compounds allows for attrition due to chemical reactivity, instability, or purification issues in the library production run. Selection of the distinct reagents that will constitute the final set of decorating groups will be furthermore directed by a set of medicinal chemistry-based guidelines to avoid, for example, toxic functionalities and groups with frequent hitter and pan-assay interference potential.[19]

The validated synthetic protocol is then executed during the production phase, and final compounds meeting the JECL quality criteria for purity (LC–MS purity >85%) and quantity (>5 μmol) are then added to the JECL and plated for the ELF high-throughput screens. Data sharing across the various ELF chemistry consortium partners, from the original library enumeration to experimental validation procedures, to the shipment of the final compounds to the screening centers is facilitated by TarosGate 2, a chemistry management solution especially designed for the ELF project. By providing a transparent, centralized repository

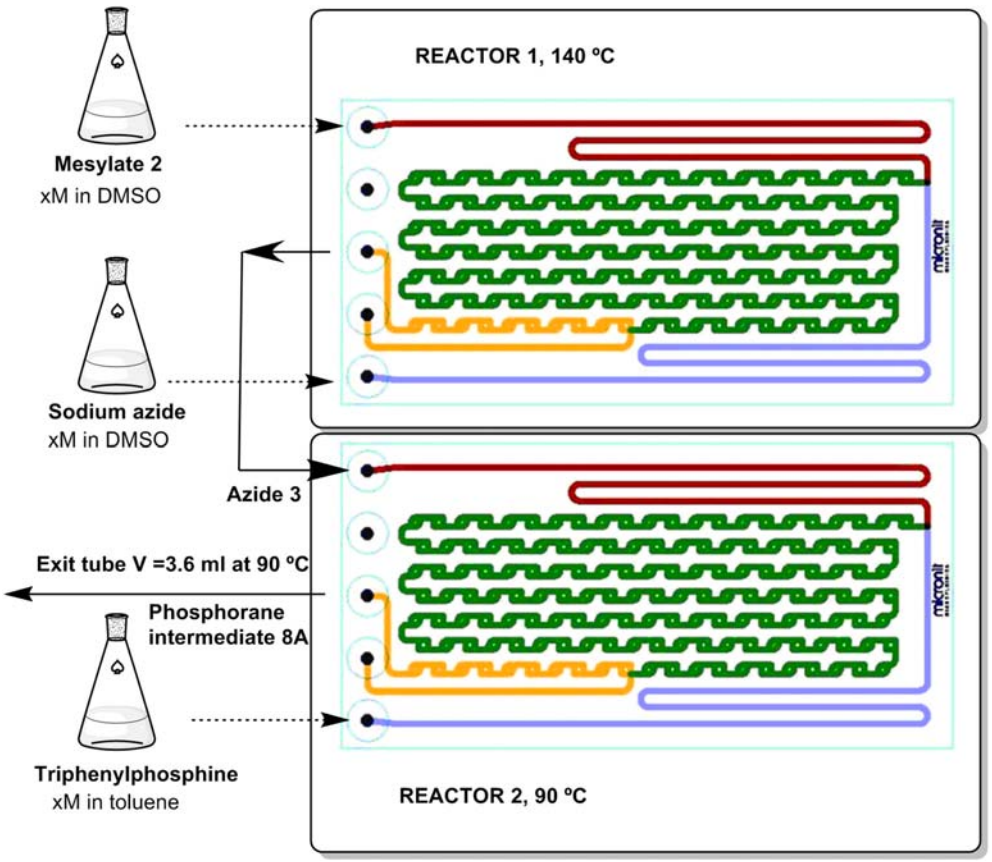


Fig. 2 Flow process to synthesize building block **20**.

Table 2 Key considerations during library validation activities as part of the ELF workflow

Criterion	*Notes*
Synthetic route	● Consider route length as from number of steps including starting materials and building blocks ● Fast track to the rate-determining "high risk" steps ● Definition of a target date to complete validation ● Ensure scalability of synthetic steps ● Demonstrate the synthetic route is robust, safe, and cost effective ○ Validate the exact route that will be used on scale up ○ Assess practical limitations of scale: temperature, equipment, and purification
Library generation	● Use truly representative reagent set to validate diversity step ● Favor well-known, robust, and generalized organic reactions ● Late diversification preferred with 2–3 points of variation ● Evaluate access to suitable building blocks and diversity reagent
Compounds properties	● Test chemical stability and solubility of intermediates and final compounds
Chemical costs	● Assess cost of library when projecting to final library production

of actionable chemical data across the ELF consortium, TarosGate 2 enables the ELF partners to monitor their productivity and efficiency with respect to the final goal of delivering c. 200,000 innovative compounds by the end of 2017. The software combines three important aspects of the collaborative chemistry workflow: (i) work documentation, (ii) management of the project, and (iii) communication. It creates a stable, secure platform for data collection of a daily work in synthetic chemical laboratories and provides the coordinator and project partners with an overview on the current progress of the ongoing library projects, facilitating efficient decisions in real time. Accordingly, it enables the planning of the resources required for project delivery; the monitoring of the status of projects during different project phases; the tracking of the use of resources versus plans and to the compound logistics. TarosGate 2 is filling an important niche among electronic lab-journals in supporting parallel synthesis by having an out-of-the-box plate module implemented representing the process flow in reality (Fig. 3).

As of Q4/2015, more than 100,000 final compounds were successfully delivered to the ELF compound management facilities. This batch of compounds is unique and diverse when compared with commercial sources and typical chemical compound repositories.[12] Furthermore, the delivered compounds share a similar profile in molecular properties space with typical Lipinski rule-of-five[13] characteristics for size and lipophilicity. The main differences between the libraries emerge when the number of chiral centers, fraction of sp^3 hybridized carbon atoms (Fsp^3), and molecular shape are considered. Here, the PCC compounds are markedly more complex in their structure and shape (Fig. 4).

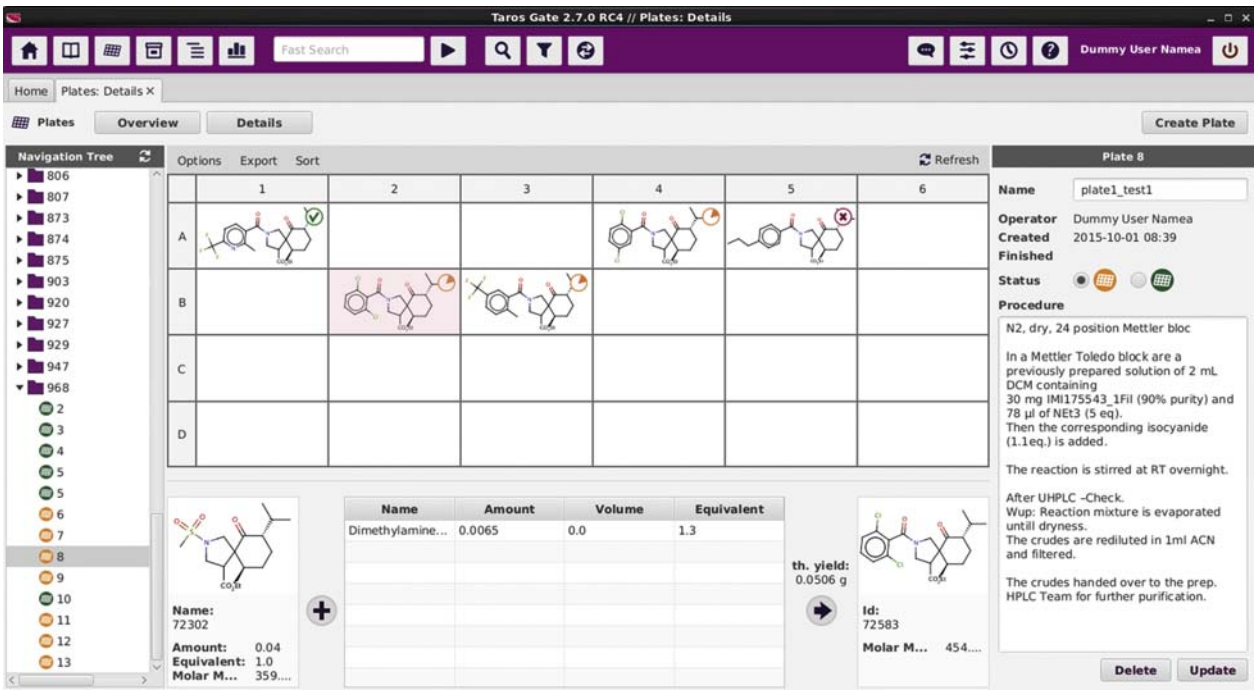

Fig. 3 The plate module that facilitates the parallel chemistry within an e-lab journal functionality of TarosGate 2.

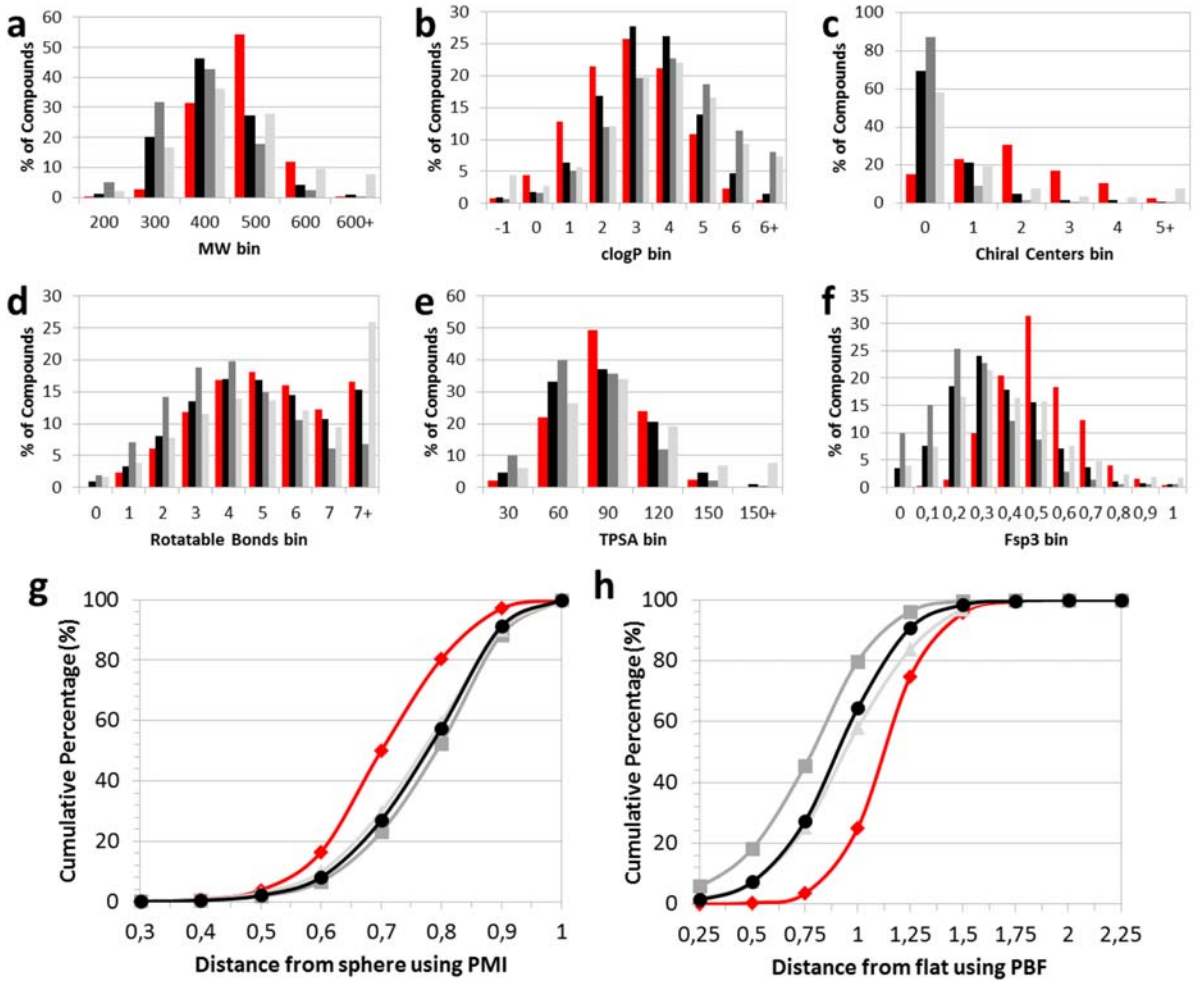

Fig. 4 (A) Molecular weight, (B) calculated logP (clogP), (C) number of chiral centers, (D) number of rotatable bonds, (E) topological polar surface area (*TPSA*), and (F) fraction of sp^3-hybridized carbon atoms profiles for PCC (*red bars*), MLP (*black bars*), Maybridge (*dark gray bars*), and ChEMBL (*light gray bars*) compounds. Cumulative distributions of distances from canonical sphere (G) and flat (H) shapes using principal moments of inertia (*PMI*) and plane of best-fit (*PBF*) descriptors, respectively, for PCC (*red diamonds*), MLP (*black circles*), Maybridge (*dark gray squares*), and ChEMBL (*light gray triangles*) compounds.

An important attribute of the delivered PCC compounds is their high degree of structural novelty. A large proportion (56%) of the Bemis–Murcko frameworks[20] exemplified by the PCC compounds are absent in medicinal chemistry-oriented compound collections.[12] For instance, a significant share of unprecedented spiro, bridged, and fused polycycles with different saturation, conjugation, and substitution patterns have been synthesized as part of the ELF activities.[21–38] This represents a fertile and practical avenue for the design and sampling of novel compound libraries, as the majority of theoretical ring systems remains largely unexplored, [39] and bodes well with the ELF remit of populating areas of chemical space which are not directly accessible from commercial sources or the scientific literature, thus offering a significant opportunity for the generation of intellectual property and innovation.

1.18.3 European Screening Center and Hit List Generation

The JECL comprising the EFPIA-contributed and ELF-synthesized compounds is stored at the state-of-the-art compound logistic facilities of BioAscent Discovery, Ltd. in Newhouse, Scotland. The Automated Compound Store (ACS) houses the JECL samples in DMSO solutions in barcoded tubes. Samples of the JECL collection are distributed among EFPIA members, the Pivot Park Screening Center (PPSC) in Oss (Fig. 5), the Netherlands, and cherry-picked sets to the University of Dundee group at Newhouse. Both the complete collection and selected subsets of the JECL are delivered with minimum turnaround time, ensuring expedient delivery during the hit finding and evaluation process for a given ELF program.

ELF program submissions by Program Owners (PO) include proposals for hit finding on biological targets for all disease areas. Novel molecular target screening programs of high scientific quality are required, for which HTS compatible assays are available. In this context, novel means: new target, new assay approach, or new chemistry required for existing targets. After a technical feasibility assessment of the screening assay by the PPSC, the submitted programs are reviewed and selected by the ELF Screening Selection Committee, consisting of assay developers, biologists, and medicinal chemists working for pharmaceutical companies and SMEs adhering to the ELF, or as independent consultants, all bound by strict confidentiality and nondisclosure agreements.

1.18.3.1 HTS Assay Requirements and Assay Development

Submitted programs should describe assays in 384-well format meeting specified requirements and which preferably are scalable to 1536-well format, the most suitable format for ultra-high-throughput screening (uHTS). Optimizing assays for uHTS is performed by PPSC and requires, among other things, the generation of stable reagents and the logical timing of incubation periods, while taking into consideration the total assay time and maximizing the total number of compounds to be tested. Homogenous assays are required and readout technologies should be compatible with mix and measure formats including Absorbance, Luminescence, Fluorescence intensity, Fluorescence polarization, Fluorescence resonance energy transfer (FRET), Time-Resolved Fluorescence (TRF/HTREF/TR-FRET), and alternatives that give highly specific readouts (eg, AlphaScreen technology, fluorescence lifetime, fragment complementation, or FLIPR for calcium readout). Furthermore, Signal/Background (S/B) in 384-well plate format should be preferentially higher than 3 and Z prime (Z') [40] higher than 0.6, taking into account a maximum assay end volume of 30 μL and a compound screening concentration of 10^{-5} M. If the PO's assay does not fully meet the technical feasibility assessment, scientists at PPSC can provide advice and support on developing the assay further to meet the specified criteria. ELF lab automation and assay specialists develop the majority of assays to run in 1536-well format to run on the uHTS facilities (Fig. 5). Cell culturing is performed at the PPSC, and protein production capability is provided by the University of Oxford.

1.18.3.2 Screening Cascade, Triaging to a Qualified Hit List (QHL), and Development to an Improved Hit List (IHL)

It is well recognized that successful drug discovery depends on high-quality hits, leads, and clinical candidates. Thus, the better the hit identified during screening, the faster the lead optimization process and the sooner the start of clinical trials. It is often not difficult to set the criteria for a hit from a primary screen and most screening campaigns deliver confirmed actives, although many will have suboptimal properties based on the program specifications. Consequently, the follow-up screening cascade involves various steps aimed at triaging the list of hits to identify those with the balance of properties, which provide the highest likelihood of long-term success.

In the ELF project, there are two distinct phases to generating high-quality hits. The first is a multistep triage process, which aims to select the best compounds from the uHTS. This phase will result in a qualified hit list (QHL) comprising up to 50 compounds. The second phase is a development phase, which aims to confirm the results from the original selection and then characterize the nature of the interaction between the hits and the target. The most promising hits can then be used as the basis for the preparation of analogs by carrying out design–synthesis–testing cycles to develop the compounds further and yield an improved hit list (IHL). During both phases, communication between the ELF and the PO is essential. However, due to the constraints applied to protect the associated intellectual property, chemical structures are not shared with the PO until the QHL is generated. Where programs progress beyond the QHL and toward the IHL within the ELF, a full collaboration can be established with the sharing of data, assets, and expertise between the ELF and the PO, thus greatly simplifying project progression.

Fig. 5 Ultra-HTS facilities of Pivot Park Screening Center.

During 2015, a typical ELF uHTS campaign takes place at PPSC and consists of a screen of the entire library of approximately 370,000 compounds using a target-based primary assay. Typically 1000–3000 actives are then cherry-picked and retested to identify a set of confirmed actives. These confirmed actives are further progressed in the screening cascade and triaged to deliver quality hits. This process is conducted both by scientists at the PPSC and at the European Screening Center (ESC) in Newhouse, the University of Dundee. The triaging process of confirmed actives can include both negative selection (eg, use of deselection assays) and positive selection (eg, active confirmation in an orthogonal assay). In addition, dose response curves are generated and Bayesian models are utilized to further increase the information content and confidence level around actives and inactives. Promising candidate hits are further tested to confirm target engagement using technologies, such as surface plasmon resonance (SPR) or microscale thermophoresis (MST). Up to this point in the process all of the decision-making has been driven by experimental and computational data and facilitates the selection of a preliminary hit list (PHL) of approximately 300–500 compounds. The chemical structures of compounds in the PHL are then revealed to the Program Clearance Team (PCT), consisting of expert medicinal chemists at ESC, all bound by confidentiality. The PCT carefully scrutinizes the molecules on the PHL and performs a liability check. Undesired molecular properties (eg, high molecular weight, high LogP, amphiphilicity, strong basicity, presence of electrophilic sites, active ester, or large flat aromatic systems) are highlighted and data/knowledge-based issues (eg, promiscuous motifs, frequent hitters, aggregators, Pan-Assay Interference Compounds (PAINS) [41]) are taken into account. Finally, the most promising PHL hits are analyzed by LC–MS to provide evidence of purity and structural identity. Subsequently, the QHL is generated and a report provided to the PO. This report includes a full description of the steps carried out in reaching the QHL including all protocols and metadata. Vitally, it also includes the structures and biological data of all the QHL compounds together with calculated physicochemical properties, the LC–MS results, an assessment of the novelty of the compounds, and potential suggestions for further hit evaluation work. In order to protect the potential intellectual property of the PO, all the compounds that appear on a QHL are automatically removed from the ELF compound library and will therefore not be available for screening in subsequent ELF campaigns. Following delivery of the QHL, a considerable amount of further work is still required to validate the hits. For example, up to this stage, all work has been carried out on the original screening solution and recapitulation of activity with freshly synthesized compounds is a vital early progression step.

The whole process of generating the QHL is supported by the Honest Data Broker (HDB), a bespoke IT system, which ensures the contractual business rules are enforced, facilitates the protection of intellectual property, and assists the scientific selection of compounds by providing an array of visualization tools, calculated data (eg, clogP, PSA), access to computational models, and cross-program information. The HDB will be described in more detail below.

1.18.3.3 The Intricate Triaging Process, What Is the Context of a Program?

The selection procedure from confirmed active to QHL during a screening campaign is far from a generic process and the investigators need to know the context of the program and its therapeutic target in detail. Here, it should be emphasized that for each target (class), a tailor-made screening/deselection cascade has to be designed. This should originate from considerations about the nature and location of the target in its physiological context as it can influence the desired property set of a molecule. As an example, for a centrally acting target, medicinal chemists could seek leads with low MW and moderate lipophilicity, whereas for a target in the liver high MW and high lipophilicity could be desirable. Additionally, off-target selectivity issues could be more stringent for cardiovascular or diabetes indications than for a cancer target. The desired mode of action (eg, agonist, antagonist, allosteric or orthosteric, enhancing or disrupting a protein–protein interaction) or the target class is also important determinants in the definition of an appropriate screening cascade. For instance, some target classes are especially sensitive to undesirable mechanisms of inhibition. Here, thiol (cysteine)-dependent proteins may be oxidized or react with electrophiles and, therefore, require special deselection assays. Metallo-enzymes may also be susceptible to redox reactions which can be catalyzed by compounds that will appear as positives in the screen but the nonspecific mechanism of action is unsuitable for further development of the compound.[42] In addition, promiscuous metal chelators showing inhibitory activity on many classes of metallo-enzymes may occur.

Screens, which involve enzymes and protein–protein interactions, are susceptible to particular false positive artifacts, such as lipophilic and amphiphilic molecules, causing aggregation or protein precipitation.[43] Primary assays should be established with appropriate concentrations of detergent (eg, Tween) to disrupt the formation of compound aggregates, and deselection strategies can involve changing the detergent concentration to look for changes in hit compound activity, which may indicate aggregation issues. Alternatively, for enzymatic assays, decreases in compound efficacy upon increasing the protein concentration are another recognized technique for identifying aggregators.[44] The identified aggregator compounds can subsequently be removed from the hit list, if appropriate. For targets, such as kinases, many potent inhibitors may appear in the PHL and finding the right selectivity against a panel of related targets could be of interest. This is just one of the areas where cross-program information can play an important role. As data from more screens is stored in the HDB, it can be used to identify compounds, which hit multiple targets either reflecting "frequent hitting" characteristics or because of genuine lack of selectivity at the target. Accordingly, this information can be incorporated into the compound selection for a given ELF campaign.

Apart from target-oriented screening design, more generic issues should also be taken into account, such as "compound interference," which encompasses mode of actions caused by undesired chemical and physical properties of compounds interfering with a wide variety of biochemical and cellular assays. Here, colored or fluorescent compounds and aggregators are well-known examples.[45,46]

1.18.3.4 Development to IHL; Hit Characterization

The overall goal of the IHL is to provide evidence of the quality of the hit series by providing data and physical samples of the compounds. This will hopefully facilitate the PO in securing further investment or funding to develop the compounds to leads and hopefully beyond to clinical candidates and ultimately new medicines. The ELF defines high-quality hits as having: (a) proven chemical structure, (b) on-target activity and selectivity, (c) emerging SAR, and (d) properties favorable for further optimization. The majority of the work toward an IHL is carried out at Newhouse although key capabilities are available at Dundee (SPR, in vitro distribution, metabolism, and pharmacokinetics (DMPK) assays) and Oxford (X-ray crystallography). In most cases, the dose–response assay used to generate the QHL will be transferred from PPSC to Newhouse creating an important opportunity for interlaboratory verification of the results. Samples of the QHL compounds, if still available in the store, are sent to the PO for use in their own assays. Following confirmation of activity at Newhouse and in the PO's lab, a sharing of data and conversation with the PO allows selection of a prioritized list of hits for resynthesis. Confirmation of structure by LC–MS and NMR provides unambiguous proof of structure and purity and recapitulation of the assay results with these new samples significantly reduces the possibility that decomposition by-products or sample impurities were the source of activity in the original screening sample. Further characterization of the compounds is then carried out with mechanism of action studies (ie. reversibility and competitivity) and selectivity measurements across a panel of assays available at Newhouse or with the PO. Cell-based toxicity is routinely assessed at Newhouse and again compounds are provided for testing in cellular disease models run by the PO.

Depending on the results and available resources, an analog program can be initiated to address identified issues with the QHL compounds. Typically, this will aim to explore potency determinants, ideally demonstrating progressive SAR. However, if the final goal of the ELF campaign is to identify a starting point for a drug discovery program, the wider properties of the compounds (eg, physicochemical properties) will also be important to consider. Medicinal chemists at the ELF work in close collaboration with the PO to create and execute a plan of design–synthesis–testing cycles to achieve these goals. Additionally, computational chemists from the ELF are involved in the design process using ligand-based and structure-based modeling techniques together with an array of cheminformatic tools. The importance of biostructural information is recognized and, where possible, data is generated by the ELF to support the medicinal chemistry and to provide further evidence of target engagement. The University of Oxford provides this expertise and aims to generate relevant protein–ligand structures to aid the design process. These experts are engaged from the initiation of the project so that the probability of success is maximized. Finally, as optimized compounds become available, the best examples can be profiled in in vitro drug DMPK and physicochemical assays to assess properties, such as hepatocyte/microsomal stability, plasma protein binding, solubility, and pK_a to further characterize risks and opportunities to further project progression. The final IHL package consists of all data, a report describing the studies, conclusion, and recommendations for further work and the remaining physical samples synthesized during the program. The goal for the ELF Screening Center is to execute a total of 90 screening campaigns from external investigators and 120 from the EFPIA companies adhering to the consortium. As of the end of Q3/2015, a total of 95 target proposals from investigators external to the ELF have been received; 52 of these have been approved and processed, 18 QHLs and 5 IHLs have been delivered to the original POs.

1.18.4 The Honest Data Broker

Reducing the output of the ELF's high-throughput screens to a list of high-quality compounds that could form the basis of a drug discovery or chemical biology project is a key step in the ELF workflow. The HDB is a cloud-based application hosting all of the ELF's chemical and biological data and provides the computational tools necessary to perform this triage while enforcing the intellectual property protection rules of the project. The ELF's HTS triage workflow is unique due to these rules and the workflow is depicted in Fig. 6 and briefly summarized here.

1.18.4.1 Triage Tools

The structure-blinded initial stages of the triage place particular demands on the computational tools to enable accurate selection of the best compounds. Identification of similar compounds to establish plausible SAR has been one of the most frequently used features, and a variety of approaches to achieve this are available. These include clustering by conventional FCFP4/Tanimoto methods, scaffold-based clustering by Bemis–Murcko frameworks [20] and clustering by an implementation of the ScaffoldTree algorithm.[47] These enable the PT members to get multiple perspectives on compound similarity. Compounds can also be used as query molecules for similarity searches within the HDB, again allowing users to understand the chemical neighborhood around their hits. SMARTS filters uploaded by each partner organization are available in the HDB and can be used to identify general undesirable functionality. For more program-specific searches, PT and PCT members can upload substructures of up to 10 heavy atoms to search their lists of hits. This allows the removal of, for example, quinolines in a kinase project if the program owner already feels they have enough examples of this chemotype. Conversely, it could be used to positively identify compounds for retention and further analysis. "Cross-program" information allows a user to see how many times a compound has been active in all the screens deposited in the ELF's HDB. This information can be used to identify frequent hitter or nonspecific compounds. Classical hard cut-off filtering is implemented and an array of calculated physicochemical properties (including molecular weight, logP, TPSA, H-bond donors/

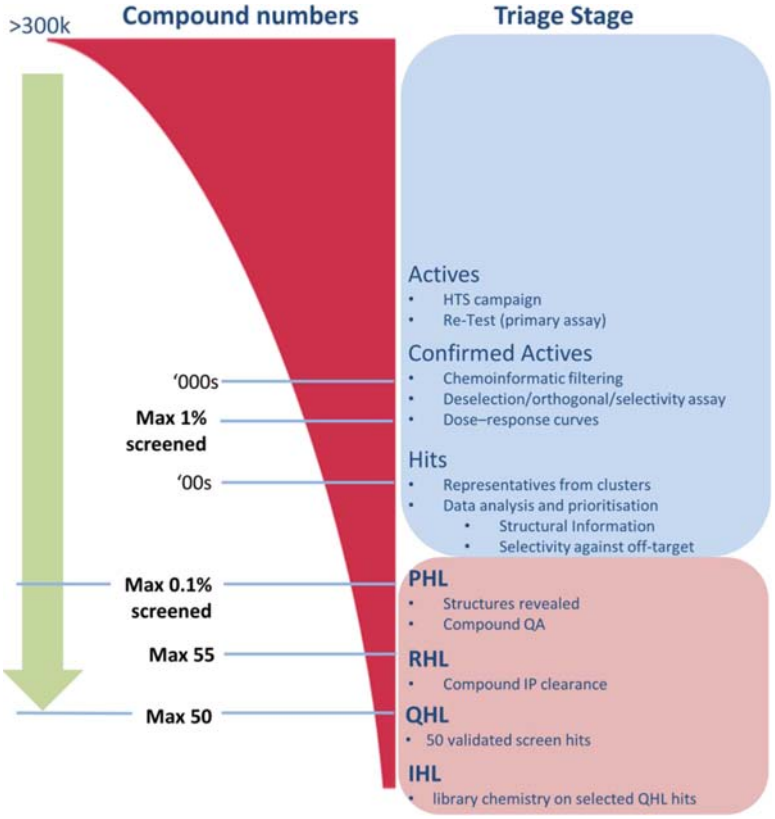

Fig. 6 ELF's HTS triage workflow. *PHL*, preliminary hitlist; *RHL*, refined hitlist; *QHL*, qualified hitlist; *IHL*, improved hitlist.

acceptors) is available in addition to biological data and all these features can be used for filtering. In some cases, desirability scoring rather than hard cut-off filtering can be more successful and Pareto and Derringer desirability methods are also available. List logic to combine compound lists through AND/OR/NOT/XOR operators is also a frequently used tool. A table summarizing the key triage tools is shown in Table 3. Visualization of data is essential in understanding the data for compound selection and this is enabled through the Pipette application.[48] Data can be seamlessly transferred to and from Pipette for visualization and interactive selection.

Table 3 Key triage tools in the HDB

Triage tool	*Function*
Property calculators (logP, Mwt, TPSA…)	Generation of key drug-likeness properties
Scaffold clustering	Group molecules by core structure
On-the-fly clustering	FCFP6/Tanimoto clustering of arbitrary compound lists
Filtering	Filter by Range, Top N, Outlier filtering
Activity model calculation	False negative rescue/unusual hit identification
Precomputed ChEMBL activity models	Off-target biological activity identification
Ligand Efficiency, LLE	Size and logP normalized activity estimation
List Logic	AND/NOT/OR/XOR joining of compound lists
Limited substructure filtering	(De)select compounds with structural feature
Binned similarity search	Identify compounds similar to query molecule
Pareto/Derringer Desirability scoring	"Soft" selection of compounds without hard filter limits
Basic Math & Statistics	
Cross-program Information	Shows activity of compounds to against enzyme/receptor classes to facilitate selectivity estimation
CNS filter	Desirability model to identify likely CNS-penetrant compounds
SMARTS filtering	Substructures encoding structural alerts to identify potentially undesirable features

Emphasis is placed on understanding the similarity relationships between compounds when structures are not visible in the early stages of the triage. Deriving knowledge from data deposited in the HDB to inform triage is also made possible and is an area under active development.

1.18.4.2 Intellectual Property Protection and Enforcement of ELF Rules

The rules of the ELF place a number of limits on the visibility of compound structures and on the use of physical compound samples in the compound store. These preserve the intellectual property associated with a compound and also prevent unnecessary depletion of physical sample. Structure visibility rules have been described[49] but additional rules govern the number of compounds that can be ordered for dose response or LC–MS structure validation, while other rules limit how many compounds can be passed from the SRL to the PHL and on to the QHL. All these rules are enforced by the HDB and prevent users from accessing or ordering too many compounds. A final step in the selection of a compound is an intellectual property check with the company that contributed the compound. This ensures that a compound that has intellectual property entanglement or has become part of an active project internal to that company is not released to the PO. Near the end of the triage process, each compound owner is alerted within the HDB to the compounds that have been selected and has the option to block their release. The compound owner has no knowledge of the PO or biological target and the grounds for blocking release are tightly defined. [49]

1.18.4.3 Project Organization

The ELF is carrying out a large number of HTSs with up to 20 per year being executed in the ESC alone. A core team of PT and PCT members carries out the triage for all of these public programs and these must be dealt with confidentially, to a high scientific standard and on a reasonable timescale. The HDB maintains strict separation of programs and provides a number of tools to organize and facilitate each program. Temporary work-lists can be saved, date-stamped, and shared within the HDB to facilitate HTS triage by scientists based at multiple sites. This eliminates the need for spreadsheets to be circulated and ensures complete control of access to information. The HDB also includes a compound ordering feature allowing PT and PCT members to request compounds from the liquid store for dispatch to user-selected locations in user-selected plate format, again obviating the need for creation and circulation of ad hoc text files. Auditing of the whole ELF process is an important part of the consortium and the ability of project management to track what has happened to compounds and who has access to information associated with a compound is recorded. This is available to project management to view through a suite of reporting tools.

1.18.5 Summary and Outlook

The ELF was established to offer researchers from academia, SMEs, and patient organizations, the opportunity to access a world-class infrastructure dedicated to the early phase of preclinical research. European investigators engaging the ELF can now exploit an innovative compound collection and industrial quality uHTS platform with the aim of discovering novel small molecule hits, suitable for subsequent optimization either to drug candidates or to high-quality pharmacological tools for the experimental validation of targets. In the open innovation model established by the ELF, seven pharmaceutical companies have contributed a total of 327,000 compounds from their proprietary and complementary collections, [6] thus maximizing their intrinsic values through compound collection sharing.[9–11] A crowd-sourcing, collaborative effort involving intersectoral chemistry research groups from the ELF consortium aims to deliver an additional 200,000 compounds to build the final JECL library to a size in excess of 527,000 compounds. Here, following a rigorous compound library design and synthesis workflow focused on chemistry innovation and compound attractiveness, the ELF chemistry consortium has already delivered more than 100,000 novel compounds to the JECL. Importantly, these compounds significantly differ from currently available commercial collections and medicinal chemistry databases in that they are chiral molecules with nonaromatic, nonplanar moieties, and a strong propensity for a globular three-dimensional shape. Their systematic evaluation against biological targets within the ELF will thus provide a very useful test of the general relevance of such compound characteristics to specific target classes, assay types, and ultimately programs' outcome and success.

While the availability of a novel, high-quality screening collection is a clear determinant of successful drug discovery,[50] an appropriate and stringent triage workflow is also a necessity. The ELF has assembled a multidisciplinary infrastructure consisting of state-of-the-art compound management facilities, assay development expertise, target-based uHTS technologies, medicinal chemistry know-how, chemoinformatics and modeling tools, secondary biological assays, X-ray crystallography, and in vitro DMPK readouts. These capabilities are aptly exploited by the ELF to craft and execute individual, project-centric HTS triage programs in order to deliver the best possible set of hits for a given ELF target proposal. This has already resulted in the completion of 52 screening campaigns, out of the planned 90 from external investigators, with 18 QHLs and 5 IHLs delivered to the respective POs. It is interesting to note that, by gathering and managing such critical hit evaluation talent and expertise, and routinely deploying it to a large portfolio of campaigns, the ELF plays an important role in establishing a de facto best practice in hit finding, evaluation, and hit-to-lead activities, critically contributing to training and formation of scientists in such phases, and eventually serving as a center of excellence in lead generation. Because of the collaborative, multidisciplinary nature of the ELF, the intellectual property sensitivity of lead generation activities, and associated competitive advantages, the need to establish a complete, functional, and safeguarded environment is paramount. The ELF has therefore invested significant efforts in establishing an "honest data broker" system allowing seamless execution of hit triaging campaigns in perfect compliance with the scientific and legal requirements of modern-day drug discovery. It is noteworthy that the ELF's HDB set-up provides a potential model for an IT system able to support a large, public–private, precompetitive consortium by enabling diverse organizations to collaborate and by providing a highly effective array of scientific tools for HTS triage.

In response to productivity pressures from multiple stakeholders, the pharmaceutical industry is attempting to explore alternative business models and precompetitive, open-source options have attracted significant attention.[4] The ELF has made significant progress in establishing an integrated lead generation platform that builds on intersectoral, complementary strengths and expertise within the consortium. Successful exploitation of the ELF model and infrastructure by adhering pharmaceutical companies and investigators external to the ELF across Europe will provide sound information on the overall sustainability and effectiveness of such approach.

Acknowledgments

We thank Stuart McElroy, Angus Morrison, and Silvia Stotani for useful comments and discussions on the article. The research leading to these results has received support from the Innovative Medicines Initiative Joint Undertaking under grant agreement no. 115489, resources of which are composed of financial contribution from the European Union's Seventh Framework Program (FP7/2007-2013) and EFPIA companies' in-kind contribution.

1.19.1 Introduction

The three decades since the first breakthrough in biotechnology have seen a huge rise in the industry–university collaboration in the development of biotech-based novel medicines, diagnostics, and new discovery techniques. The first biotechnology product (insulin) was approved in 1982 and, although the scientific revolution involving biotechnology has been slower than expected, there are more than 200 biotechnology products commercially available, and more than 900 biotechnology products in clinical trials.[1] At the beginning, the pharma industry engaged with biotechnology companies only to a small extent with their in-licensing of a few recombinant molecules, led by Roche, Eli Lilly, and Johnson and Johnson. Subsequently, over the last 25 years, biotechnology has become a cornerstone in new product development in all pharmaceutical companies. Currently, they are substantially engaged in both the clinical development of these products and their commercialization. To achieve this result, pharma companies have shifted their focus from blockbuster medicines, which are progressively declining due also to the patent expiration, to the progressive application of biotechnology, which includes, among others, the increasing trend of personalized medicines.

The global pharmaceutical industry is facing several challenges stemming from a variety of sources. One of the major issues is the high and risky investment in research and development (R&D) to create profitable blockbusters. In addition, the huge expansion of generics implies that big pharma are devoting more attention to two distinct strategic paths that are respectively: (1) improving clinical margins, and (2) increasing biotech opportunities. The former refers to companies that are investing in acquisitions of generic companies to counterbalance patent cliff and to gain access to emerging markets. Some examples include Novartis owning an in-house generics arm in Sandoz, and Sanofi-Aventis making takeover bids for the generics company Zentiva. The latter refers to pharmaceutical companies that are seeking to diversify their product portfolios to foster a more flexible and broad-ranging business model. These include Novartis, no longer exists-now is part of Pfizer, Abbvie, BMS and Roche, but also other big pharmaceutical companies more generally. Overall, the pharmaceutical industry is paying attention to the novel healthcare trends that are personalized medicine based on patient genomes, combined with the application of biotechnology.

Therefore, it is not surprising to learn that biotechnology firms are growing far more rapidly than the pharmaceutical firms, with US biotechnology recording a unique year in 2014, setting a new all-time record in total capital raised (US$45.1 billion) as well as funds raised through IPOs (US$4.9 billion) and debt (US$23.3 billion).[2] Also the European biotechnology firms have achieved these exceptional financial outcomes, although not quite as robust as that of its US counterpart. **Table 1** briefly highlights the key numbers of the biotechnology industry, comparing the latest 2 years (2013–14).

The pharmaceutical industry is, therefore, looking to close this gap by investing more in biotechnology, including acquisitions, in order to address revenue shortfalls that have arisen due to pricing pressures, slower growth in emerging markets, and R&D challenges. Accordingly, the marriage of biotechnology and the pharmaceutical industry is based both on industry dynamics and an evolution in technology and product innovation.

Against this background, this article provides an overview of the key evolutionary dynamics occurring in the biotechnology industry since its inception. This technological breakthrough has required new forms of division of labor and collaboration from both the pharmaceutical industry and basic researchers in academia to bridge the translation into new biotechnology-based medicines. This article describes upstream and downstream strategic partnerships and the different modalities of cross-fertilization between university and the dedicated biotech firms (DBFs) within the pharmaceutical industry. Two key factors in this important translational bridge can be identified: new governance of both partnering organizations to open up for new and, sometimes, disruptive ideas, and creation of trust-based relationships between different institutional partners (private–public

partnerships) enabling long-term scientific collaborations, while acknowledging that value creation and value appropriation are essential factors for successful collaboration.

The article is structured as follows. Section "**Development and Commercialization of Biotechnology-Based New Drugs**" briefly describes the evolution of biotechnology and the key role played by DBFs in closing the gap between academia and market. Section "**The Recent Evolution of DBFs: An Empirical Assessment**" highlights descriptive findings from our sample of 146 DBFs and their upstream and downstream collaboration during the period 1993–2013. Section "**Conclusions**" focuses on the implications stemming from empirical findings. "**Limitations and Further Research**" conclude the article.

1.19.2 Development and Commercialization of Biotechnology-Based New Drugs

1.19.2.1 The Upsurge of Biotechnology

During the 1980s, the pharmaceutical industry witnessed an upsurge of a technological discontinuity (biotechnology) that dramatically and persistently changed the way in which new drugs were conceived and developed, and dramatically affected the organization of the industry that had existed since its origins in the second half of the 19th century. While until that moment the knowledge base of pharmaceuticals was mainly based on organic chemistry, biotechnologies were based on a completely new paradigm drawn upon molecular biology rather than organic chemistry. For this reason, the technological breakthrough introduced by biotechnological research challenged severely the core competences of pharmaceutical firms.[3,4]

Historically, the origin of biotechnology has to be dated back to 1953, when Watson and Crick discovered the double helix structure of DNA. However, it was only 20 years later, in 1973 that a modern biotechnology industry could emerge, thanks to the breakthrough finding made by Cohen and Boyers of the recombinant DNA methodology. Following that invention, the first biotechnology firm, Genentech, was founded in San Francisco in 1976 and the US Food and Drugs Administration (FDA) approved the first biotechnological outcome, recombinantly produced human insulin, in 1982. The discovery of recombinant DNA represented a radical process innovation, capable of manipulating microorganisms, thanks to the convergence of multiple technologies such as molecular biology, genetics, combinatorial chemistry, immunology, and more recently, bioinformatics.[5] In this sense, biotechnology embodied a radically new combination of existing technologies, whose outcomes cover a wide range of disciplines and scientific and technological fields, ranging from health (both diagnostic and therapeutic phases), to agro industry, environmental protection, and so forth.

Both the technological bases composing biotechnology and the various application domains were not, however, part of traditional technological portfolios of incumbent pharmaceutical companies. As a consequence, following the development of this new technological paradigm, (large) pharmaceutical companies were forced to find the most efficient way to interact with (small) dedicated biotechnology firms (DBFs), which were specialized in developing biotechnologies and were in possession of the competences to master the new knowledge base.

Traditionally, large pharmaceutical companies have thus reacted to the upsurge of biotechnology by seeking alliances with new entrant DBFs that possessed R&D competences and capabilities they were lacking. To these new firms, large pharmaceutical companies were offering downstream complementary assets (such as clinical trials, manufacturing and marketing capabilities, access to market) that allowed innovative technological solutions to be converted into new drugs to be introduced into the market. As a matter of facts, seven of the top-ten biotechnology drugs that have been marketed during the late 1990s have been introduced by pharmaceutical companies, even though all of them have been originally developed by small biotechnology firms.[3]

1.19.2.2 The Traditional Contribution of DBFs in Drug Development and Commercialization

Since their original appearance, dedicated biotechnology start-ups have traditionally represented the organizational bridge between the upstream phase of biotechnology-based new drug development and the downstream phase of new drugs' market introduction. In performing their role, DBFs have thus engaged in two different types of vertical collaborative agreements: on the one hand, they have collaborated with universities and other public research organizations to enlarge their knowledge base, acquire new research

skills and expertise, and refine their technological capabilities; on the other hand, they have collaborated with incumbent large pharmaceutical firms for the commercialization of biotechnology products. For example, firms like Millennium Pharmaceuticals have built their business models by focusing on the early portions of drug development and then seeking the collaboration with large firms (such as Pfizer and Merck) to pursue the later stages of drug development and commercialization (from clinical trials to market introduction). DBFs that have been the original and largest founders of the US biotechnology industry during the 1980s (e.g., Amgen, Quintiles Transnational Corporation, Genentech, Genzyme Corporation, Allergan, Dow Agro Science, Chiron) have followed similar patterns.

In performing their bridging role, DBFs have organized R&D activities by following an open innovation model. According to the Open Innovation paradigm,[6] the innovation process can be subdivided into five stages: (1) seeking opportunities, (2) evaluating innovativeness and market value; (3) recruiting partners for the development stage; (4) valuating invention's commercialization opportunities; (5) extending the innovation offering. In the case of the pharmaceutical sector, stages 1–3 characterize the macrophase of "drug discovery," while stages 4–5 compose the macrophase of "drug development and market introduction."[7] In each one of these stages, scientific and technological knowledge in-flows and out-flows from an organization to others and the final outcome of a new product (drug) introduction is, indeed, the result of the complementary effort of a set of diverse actors possessing specialized knowledge, skills, resources, and capabilities. Within this network of relationships DBFs have often acted as focal point, by coordinating various partnerships with academic institutions and research organizations, upstream, and with pharmaceutical companies, downstream.

The vertical (downstream) relationships between DBFs and pharmaceutical companies were beneficial to both types of firms. From the point of view of a DBF, pursuing an alliance with a well-known pharmaceutical company was seen not only as a possibility to get access to the final market (i.e., to get access to downstream complementary assets), but also as the means to build credibility and, eventually, improve the firm's reputation.[8,9] From the point of view of a large pharmaceutical company, pursuing a set of alliances with promising DBFs was seen as a means to acquire expertise and know-how on the emerging biotechnological solutions (i.e., to acquire the needed absorptive capacity to explore the biotechnology sector[10]), integrate external knowledge with internal R&D capabilities, maximize the returns from investments done in manufacturing and marketing capabilities, and eventually support over time the firm's competitive position.[11–13]

This model of division of labor at the industry level has allowed the growth of the biotechnology industry and the commercialization of a growing share of biotechnology-based new drugs. To secure a consistent share of biotechnology drugs within their product portfolios, in some cases large pharmaceutical companies have moved a step forward, by integrating backward in the value chain, and by replacing vertical alliances with DBFs with the acquisition of the same biotechnology firms.[14–17] It is worth noticing that, while these cases of vertical merger and acquisitions have been clearly beneficial to large pharmaceutical companies aiming at acquiring new capabilities, knowledge, and technologies protected by intellectual property rights (e.g., patents), they have received acceptance also by most DBFs, incapable of facing the complexity and costs of regulation concerning new drug introduction. For DBFs, merging with large pharmaceutical company thus represented the possibility to exploit the strengths of big pharmaceutical companies, pertaining to their regulatory and marketing expertise.[18]

Even though this model of division of labor has worked well for almost two decades, during the last years a new model of industry organization is emerging, with DBFs evolving from their traditional "bridging" position between science and market, to assume a more active role in the development and commercialization of biotechnology products, in direct competition with large pharmaceutical companies.

1.19.2.3 The Recent Evolution of the Biotechnology Industry

The main problem with the traditional pattern of industry organization was that DBFs were often exposed at an excessive bargaining power by large pharmaceutical companies, with the consequent risk of losing control over property rights on new technologies or, at least, the impossibility to secure a consistent share of revenues arising from the commercialization of drugs based on the new technology. For this reason, DBFs have started to engage more and more in alliances with other DBFs (bio-to-bio alliances), with the aim of expanding their knowledge base and exploiting stronger economies of scale. In doing so, some DBFs have started to build those capabilities in downstream activities (such as clinical trials, FDA's market approval, manufacturing, commercialization, and marketing) they were originally lacking. They have started to become relevant competitors to traditional large pharmaceutical companies, having acquired in some cases the capability to reach the final market autonomously. Furthermore, contrary to bio-to-pharma alliances, bio-to-bio alliances reduce the risk of knowledge leakages for DBFs and the possibility to get involved in legal disputes and litigations over the control of property rights. By contrast, allied DBFs have the possibility of integrating their resources, knowledge, skills, and capabilities to create value and compete successfully. Such firms have transformed themselves from specialized high-tech developers to specialty biopharma companies,[19] competing with incumbent large pharmaceutical companies in an increasingly competitive and fragmented market,[20] in which a specialized biotech niche is emerging.

As for incumbent pharmaceutical companies operating in this changing environment, their traditional competitive advantage may slowly disappear due to the fact that the largest biotechnology firms have started to develop the needed complementary capabilities to operate in the final drug market.[21,22] As a matter of facts, several new firms have entered the pharmaceutical market in the last few years, and the number of bio-to-bio alliances has strongly increased in the same period of time. While traditional DBFs were focused on shaping the knowledge building blocks of a nascent technological trajectory, by collaborating with and expanding the knowledge base of universities and public research organizations, the new model of biotechnology firms seeks to pursue

a commercial exploitation of the technological solutions they have contributed to develop. Such firms both compete and cooperate with large pharmaceutical incumbents, and simultaneously take part in a larger network of collaborations and alliances with a diversified plethora of actors located at different levels of the value chain. Vertical partnerships have been complemented with (but not replaced by) horizontal partnership and the consequences for the processes of drug discovery and commercialization have to be fully understood, yet.

1.19.3 The Recent Evolution of DBFs: An Empirical Assessment

To better understand how DBFs contribute to closing the gap between academia and market, and to assess how their role has been evolving during the last years, we performed a descriptive statistical analysis focused on the behavior of a sample of biotechnology firms. Specifically, we included in the sample all biotechnology firms having closed at least one biotechnology-related deal during the period 1993–2013 (data were drawn from the Thomson Reuters' Recap IQ database, which reports in-depth information on most recent deals in pharmaceuticals, ranging from licensing agreements, merger and acquisitions, marketing deals and manufacturing agreements). Overall, 146 national and international DBFs were included in the sample. As **Table 2** shows, most firms have headquarters located in the United States (94 out of 146) and have been created at the end of 1990s. Even though most firms are small in size (a half of them have obtained revenues of no more than $120 millions), some of them (among which Amgen, Applera, Arcion Therapeutics, and Cambridge Antibody Technology) are characterized by a much larger size, having obtained revenues of billions of dollars during the last year.

On these firms, we addressed two complementary issues. On the one hand, we explored how DBFs cooperate with universities and public research organizations to develop new biotechnological solutions suitable to be patented. On the other hand, we explored how DBFs seek the exploitation of possessed technologies by engaging in partnerships of different types with external firms.

1.19.3.1 Upstream Vertical Relationships Between DBFs and Academic Institutions

In order to pursue the first goal, we analyzed the patent portfolios of sampled firms. Data on patents has been drawn from the Orbit-QPat database (ORBIT-QPAT is a service powered by Questel IP Business Intelligence providing information on patent documentation. It collects more than 100 databases for specialists in patents and designs. It covers more than 95 national patent offices, and reports patent information grouped by invention-based families and enriched with full-text data). For each patent possessed by samples firms, we explored whether it was coowned with other organizations, and, specifically, with universities and public research organizations. It is worth noticing that patent coownership reveals the existence of a cooperative agreement between the different coowners. Indeed, when two or more organizations perform joint research and decide to seek patent protection for the innovative technological solutions they jointly develop, they might decide either to allocate full property rights of the invention to only one of the partners, or to share ownership of property rights (coownership). In this sense, coowned patents can be considered an underestimated measure of cooperative agreements among coowners, and information on coowned patents can be used to assess whether and with whom a focal firm engages in research collaborations.

We performed a similar analysis on the total number of family patents possessed by our sample firms (**Table 3**). Among all these patents, we searched for those patents that sample firms coown with academic partners (universities, colleges, and other research organizations). As **Fig. 1** shows, the share of patents that DBFs coown with academic partners has remained almost stable over the last decade, thus revealing how the recent changes (as outlined earlier) that have characterized the organization of the biotechnological and pharmaceutical industry have not affected the importance that academic research and knowledge generated by universities has for the development of biotechnologies.

Nevertheless, if the number of academic institutions that sampled DBFs partner with is taken into account, then it is possible to observe a gradual evolution of collaborative agreements among the two organizations. As **Fig. 2** shows, over time, the share of academic patent coowners has constantly increased, by shifting from an average of $<4\%$ academic coowners at the beginning of 2000s (with respect to the total number of patent coowners), to more than 10% at the beginning of 2010s. Jointly with **Fig. 1**, this figure thus highlights a singular trend in the relationship between DBFs and the academia. It emerges that while the "quantity" of research produced (in terms of numbers of patents registered) in collaboration with academic actors has remained almost

constant over time, the number of academic actors involved in patenting with DBFs has been constantly growing over the last years. This trend reveals an increasing need by DBFs to diversify and increase the number of knowledge sources, thus suggesting that the development of new biotechnology solutions currently requires the integration of a knowledge base which is larger than what it was a decade ago. Put differently, the fast pace of technological change in the biotechnology industry and the market demands require continuous innovation, which derives from multidisciplinary research through a transformation process that converts science-oriented knowledge into marketable products. Findings reveal that some certain transition mechanisms from monodisciplinary collaboration to multidisciplinary university–industry alliances are emerging. These relationships are a useful channel to accelerate the knowledge transfer from the university to industry aiming at the effective transition of science into products.

Alternatively, these figures may reveal that DBFs tend to reduce the risk of remaining locked-in in strict relationships with a reduced number of academic institutions by enlarging the portfolio of research alliances. More in details, in order to contrast patent expirations on blockbuster drugs and declining innovation in the industry, DBFs are restructuring their (R&D) operations and are pursuing an aggressive strategy of licensing deals and research collaborations in an attempt to fill the gaps in their product pipelines.

1.19.3.2 Downstream Vertical Relationships Among DBFs, Pharmaceutical Companies, and Other Organizations

In order to pursue the second goal of our analysis, we explored the different partnership agreements that DBFs belonging to our sample signed during the last decade. Data has been obtained from the Thomson Reuters' Recap IQ database, which includes all

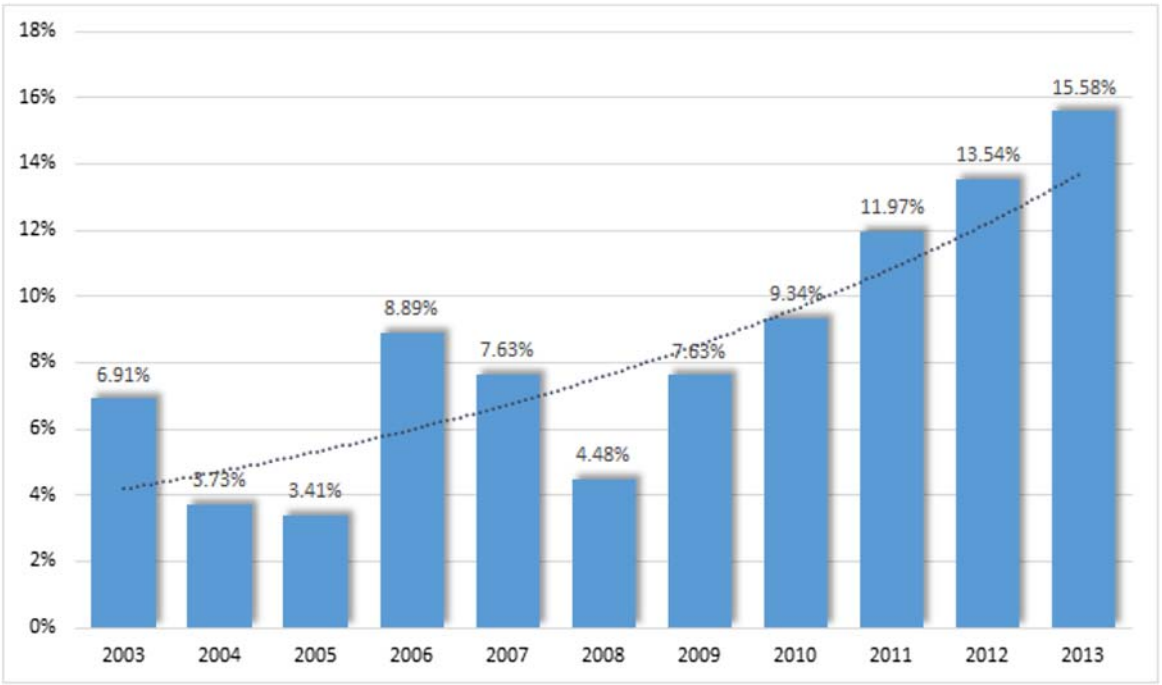

Fig. 2 Share of academic patent coowners (with respect to total patent coowners).

market deals closed in the pharmaceutical industry during the 2003–13 period. Within this period of time, DBFs have undertaken partnerships with various organizations (other DBFs, pharmaceutical companies, biopharma companies, and firms from other industries), both as promoters (i.e., acquirers or investor companies with an active role in promoting the partnership agreement) and as targets (i.e., recipient companies being "object" of the deal). Partnerships may take different forms, ranging from "research and discovery" agreements aimed at performing collaborative research activity on a specific molecule, methodology, or technological component, to "comarketing" agreements aimed at pursuing a collaborative marketing strategy in order to introduce into the market or to sustain the sales of a given drug or biotechnology product. In most cases, transactions take a complex form and include several single agreements joint together. For example, it is very likely that a technology license contract also includes an agreement on the acquisition of property rights (or an option to acquire property rights) on the licensed technology. Similarly, often a manufacturing contract also includes an agreement to subsequently commercialize the manufactured biotechnology product. Furthermore, all the possible types of agreements can also be classified into two main categories, namely "Drug Research and Development" and "Drug Exploitation and Commercialization." These two categories of deals correspond to the two stages of "drug discovery" and "drug development and market introduction" that compose the Open Innovation model described in the previous section, which characterize the activity of DBFs. As for the case of disaggregated agreements, also in this case it is possible that a deal between two companies takes a complex form, by including both elements of Drug Research and Development, and elements of Drug Exploitation and Commercialization.

Overall, our analyses confirm most of the tendencies suggested by prior research. As far as agreements in which a DBF appears as the target company are concerned, results show (Table 4) that most deals (290 out of 409 in total, equal to 70.90% of total deals) refer to Drug Exploitation and Commercialization agreements, while the remaining cases concern to Drug Research and Development agreements (199 deals, equal to 29.10% of total deals). This result confirms that DBFs act primarily as integrators of knowledge, skills, and resources related to biotechnology. DBFs thus aim at developing new biotechnology outcomes, which then they transfer to other organizations that are in charge of developing the technology further, create new products out of it (mainly, drugs), and introduce the new products into the final market. In some cases, however, agreements with external organizations are also aimed at performing research for the development of new biotechnologies, much before the exploitation and commercialization stage. Such deals complement those collaborative research agreements that DBFs sign with academic institutions and public research laboratories, and which we analyzed in the previous section by making use of patent statistics.

Table 4 also provides information on the type of organization that has promoted the agreements involving DBFs. It emerges that most of the deals in both drug development and drug exploitation stages are promoted by pharmaceutical companies. As suggested by prior research, these companies often lack updated know-how and competences to develop biotechnological-based new drugs and thus need to cooperate with specialized DBFs in possession of complementary capabilities. Furthermore, for the pharmaceutical companies such agreements also present the advantage of avoiding to remain locked-in with existing resources and competences. Since biotechnology research evolves very rapidly and entails a growing number of scientific disciplines (see, e.g., the case of

bioinformatics), outsourcing biotechnology research from external providers (DBFs) allows large pharmaceutical companies to modify the setting of controlled competences without incurring the high costs of re-training internal staff. Furthermore, compared to pharmaceutical companies, DBFs can exploit their smaller size to move quickly towards new promising technological trajectories, investing in the exploration of new research possibilities, without facing the heavy fixed costs of larger companies.

However, Table 4 also shows that other DBFs also act as promoters of deals with their peers. As suggested by recent managerial literature, albeit always existed, these types of agreements have become more and more common in the last years (i.e., those covered by our data), revealing the tendency of some DBFs to acquire enough size to compete in the final market for drugs and other biotechnology products. As a matter of facts, most of bio-to-bio agreements do not concern the stages of Drug Research and Development, but those of exploitation and commercialization. This evidence thus confirms that the main aim of DBFs promoting agreements with other DBFs is that of acquiring and/or developing those downstream complementary assets in manufacturing, commercialization, and marketing that are needed to address final consumers. In this, their goal is to start competing with incumbent pharmaceutical companies in specialized niches of the market for biotechnology products.

To better explore this issue, we further analyzed in greater details the agreements that DBFs have signed during the period 2003–13 by taking the role of promoter (either, acquirer, partner or investor company). As Table 5 shows, gross results clearly mimic those obtained by Table 4—most of the agreements (148 out of 202, equal to 73.27% of total agreements) concern the Drug Exploitation and Commercialization stage, while only a minority (54 out 202, equal to 26.73%) refer to the stage of Drug Research and Development.

Nevertheless, results reported in Table 5 also provide insightful suggestions on how DBFs are attempting to move downward the value chain to reach the final market. First, it emerges that the largest share of downstream agreements are signed with other DBFs, and take primarily the form of technology licensing agreements. This result confirms what has been already expressed earlier, of an attempt made by DBFs to consolidate their market position by partnering with organizations having similar bargaining power, thus avoiding (or, at least, limiting) the risk of knowledge leakage and loss of control over property rights on possessed technologies.

Second, it emerges that not only DBFs are the target of agreements promoted by pharmaceutical companies, but also that in many cases the same DBFs do promote agreements with pharmaceutical companies for the exploitation of owned technologies. As a matter of facts, while licensing agreements do remain the preferred form of agreement as in the case of DBFs, manufacturing, commercialization, copromotion, and marketing deals are promoted almost exclusively with pharmaceutical companies. With these organizations, DBFs thus seek to get access to those downstream complementary assets they lack.

Finally, Table 5 also reveals that an important target of deals promoted by DBFs is biopharma companies. Such firms are usually identified as companies making a large fraction of drug revenues (usually, at least 50%) from selling biologics and vaccines. As such, these firms are those that have a research profile very close to that of biotechnology firms and that may benefit the most from

partnering with DBFs. In some cases, these firms are, indeed, prior DBFs that have integrated downward in the value chain to reach the final market. Results of our analysis seem to suggest that sample DBFs consider biopharma companies in a similar vein as large pharmaceutical companies, since with them too they seek various types of agreements, from technology licensing to manufacturing, commercialization, and marketing. Also in this case, the attempt is that of getting access to downstream complementary assets.

1.19.4 Conclusions

Over the last decades, the scientific revolution of biotechnology has drawn an increasing attention both from academia and industry and is producing truly novel therapeutics for unmet patient needs. Our findings from the analysis of both university–industry and industry–industry collaborations during the period 1993–2013 reveal that new interinstitutional and cross-domain relationships are emerging due to the novel technological trends and the new industry landscape. The pharmaceutical industry is facing significant barriers in the continued patent expirations that are eroding firms' profit margins, challenging market dynamics, and existing forms of pricing and reimbursement.

A number of biopharmaceutical patents are due to expire in the next few years, or have already expired. The subsequent production of follow-on products, or "biosimilars" has aroused interest within the pharmaceutical industry as biosimilar manufacturers strive to obtain part of an already large and rapidly-growing market. This represents a new challenge that pharmaceutical firms have to face.

Another challenge for the pharmaceutical industry stems from developing countries. To successfully develop a local biotechnology industry in these countries, it is critical to understand and improve the system of health innovation, as well as the role of each innovative sector and the linkages existing among sectors. Accordingly, academia and public research centers have to improve their capabilities to create nonlinear linkages and strong interrelations among players throughout the entire innovation process. These relationships generate and transfer knowledge related to commercialization of the innovative health products. The private sector is one of the main actors in healthcare innovation, contributing significantly to the development of biotechnology via knowledge, expertise, resources, and relationships that translate basic R&D into new commercial products and innovative processes. Thanks to these relationships, several developing countries that have been actively involved in health biotechnology are becoming the main players in this industry (e.g., South Korea, India, Brazil).

Our findings reveal that DBFs are adopting a flexible concept of collaboration in R&D and technology exploitation. This concept represents one new approach chosen by the DBFs to tackle current challenges posed by declining internal R&D success rates and emerging novel technological trends. For this reason, DBFs have gradually modified their partnering strategy, now seeking to larger

extent than it was in the past collaborations with actors in possession of downstream complementary assets they lack. In doing so, their aim is to get closer to the diversified final application markets (among which, the health sector), thus granting themselves a greater ability to control property rights and to secure higher and more stable flow of revenues.

Indeed, the identification and development of novel breakthrough medicines have recently undergone significant changes, in part because of the extraordinary complexity that is associated with tackling diseases of high unmet need, and also because of the increasingly demanding requirements that have been placed on the pharmaceutical industry by investors and regulatory authorities. Taken together, these trends have led DBFs to increase the diversification of actors they partner with in drug discovery and development. This trend has in turn led to increasing partnering interactions between the specialized biotechnology sector and the more diversified sector of big pharma. In addition, as our analyses revealed, the biotechnology sector has itself become further engaged in partnering with other biotechnology companies to accelerate the knowledge transfer and create a translational bridge able to increase the probability of success associated with identifying novel medicines to treat unmet medical needs.

1.19.5 Limitations and Further Research

The analyses presented in this article clearly suffer some limitations that require further research to be addressed and fixed. First, our patent analysis aimed at exploring the linkages that DBFs establish with academic institutions by observing the frequency of coownership. This event, however, only represent one among several other mechanisms of university–industry interaction. Not only, patent coownership does represent an explicit and formal interaction means, which only marginally captures the complexity of forms of interaction between the two institutions that often prefer to operate at an informal level. In turn, further research should address the problem at hand by complementing patent coownership data with information drawn from other sources.

Second, in analyzing the partnership strategies of DBFs, we only focused on the last 11 years (from 1993 to 2013). Even though such period of time has been characterized by dramatic changes in the biotechnology and pharmaceutical industries (for reasons that have been highlighted in the previous sections), a longer period of observation is needed to obtain a more complete picture of the dynamics of the two industries. Thus, further research should take a longer perspective and make a clearer distinction between long-term trends and short-term fluctuations.

Finally, our analysis has been mainly descriptive and quantitative. While we spent effort to infer from our results possible implications for company strategies and industry dynamics, more sophisticated econometric quantitative estimations would be needed to discover the exact causal relationships that may explain observed phenomena. Similarly, qualitative analyses (e.g., in-depth case studies) would help disentangling the picture of what motivates firms' moves, what obstacles impede their strategies to be fully implemented, and what directions firms should take to shape the boundaries of the future pharmaceutical industry.

1.20.1 Introduction

In this article, a reflection on the possible threats to intellectual property caused by the design of laboratories as open spaces and the extended use of new technology devices is presented. Further, a review of information on intellectual property, mainly patents, available on the Internet for free, is performed, including recommendations on how to use it reasonably.

1.20.2 Open Laboratories

Both public and private research institutions are increasingly designing their research facilities as "open" laboratories. The aim behind this kind of design is mainly to support team-based work and inter-team work, rather than isolated individual work: researchers do not only share the research space itself but also all the equipment, tools, their bench space, meeting spaces, and their support staff, often not only with colleagues from their own team, but also with colleagues from other teams. Modern science is expected to be an intensely social activity, the individual scientists being aware of the work and style of their colleagues, as the communication and exchange of information between the scientists is intended to be strongly increased.

Nevertheless, besides the main complaint expressed by scientists who are working in an open lab environment (ie, typically, the lack of sufficient capacity for concentration), there are also some relevant problems of various nature that should not at all be underestimated. In the following sections, some of the possible complications are explained. The effect of these complications on intellectual property is also highlighted.

1.20.2.1 Maintenance of Confidentiality in Open Lab Spaces

Maintaining the integrity and confidentiality of scientific information and results is absolutely crucial. Scientific research leads to the generation of immense amounts of information, which encompasses the accomplishments of the scientific staff and represents the real assets of any research institution, and as such due care has to be taken. The confidentiality of scientific information is especially relevant if at some point of the research a patent application is intended to be filed; but also if a publication in a peer review journal is envisaged; or sensitive information from third parties is handled with; or the information is intended to be withheld from the public as a trade secret; among other scenarios. Maintaining confidentiality of all the information is essential, as any disclosure can have adverse effects for any of the abovementioned actions or activities.

Nevertheless, in open lab spaces, especially those that are occupied by different organizations, such information, know-how, and results may be exposed to high risks, due precisely to the laboratory's design.

Regarding the request for patent protection, the risk may be especially high. It is well known that in order to obtain such protection, three main requirements have to be fulfilled: the invention has to be novel, involve an inventive step, and have some defined utility ("industrial applicability"). The latter requirement is not sensitive to prior disclosures, and as such will not be considered here. Nevertheless, the first two requirements will be adversely affected by any disclosure related to the object of the invention. As a reference, for example, according to the *Guidelines for Examination* published by the European Patent Office (EPO), paragraph G-VI-1, an "invention is considered to be new if it does not form part of the state of the art." On the other hand, the state of the art is defined within the same guidelines as, "everything made available to the public by means of a written or oral description, by use, or in any other way, before the date of filing of the European patent application." It will be noted that such a definition is wide, without any restrictions regarding the geographical location, the language or manner in which the information was made available to the public. That is, a disclosure of even only part of an invention could mean that the invention is not considered novel, and as such is not patentable. Although a resource from the EPO has been used herein to better explain this concept, the novelty requirement exists worldwide and is interpreted very similarly from country to country.

With respect to the inventive step (according to the *Guidelines for Examination* by the EPO, paragraph G-VII-4), "an invention is considered as involving an inventive step if, having regard to the state of the art, it is not obvious to a person skilled in the Art." Once more, the inventive step is evaluated with regard to the state of the art as was already defined above with regard to the novelty requirement. Further, the person skilled in the art "should be presumed to be a skilled practitioner in the relevant field of technology, who is possessed of average knowledge and ability and is aware of what was common general knowledge in the art at the relevant date […]. He should also be presumed to have had access to everything in the 'state of the Art'." That is, again a disclosure of even only part of an invention could mean that the invention is not considered patentable, in this case due to lack of inventive step. The requirement of inventive step also exists worldwide, although different terms may be used therefore, for example, non-obviousness in the case of the United States Patent and Trademark Office. Although the interpretation of the terms also varies slightly from country to country, in any case a prior disclosure would most probably be hazardous for the compliance of this requirement.

In view of the above, it will become clear that it is immensely important that public and private institutions working in an open lab environment take the necessary measurements and actions to protect and assure the confidentiality of the information held and generated by their staff. This includes corresponding confidentiality agreements, both with the staff and with anyone that has access at some point to the open lab and also an intense raising of awareness among their staff, by corresponding training and education, and serious repercussions in cases of breach of confidentiality.

The same confidentiality policy should also apply, if not even more, to information acquired by collaborations or agreements with external institutions. Such institutions expect that the information provided to third parties is treated with maximum confidentiality, and in such a case any minimal leak of information is absolutely unacceptable. Some institutions may even be thrown back when considering collaborating with an institution having an open lab, once they are aware of this circumstance, unless an impeccable reputation precedes the lab, and strong confidentiality agreements are signed before exchanging any information. Any minimal leak of information may irreparably harm the reputation of a lab and may lead to negative effects of other institutions avoiding collaborations with the lab.

Summing up, the socialization happening in open labs seems to be a great spawning ground for the generation of potentially patentable scientific advances. Nevertheless, precisely such socialization means also a hazard to the same inventions, as the confidentiality of the information underlying such inventions is at risk. Delicate information may be disclosed, displayed, or discussed in the presence of other laboratory staff not related to the project itself. Therefore, it is immensely important to make sure that all the staff with access to the laboratory (including not only scientific staff, but also maintenance or cleaning staff) signs corresponding confidentiality agreements. Also any temporary staff has to be made sure to sign such agreements regarding any information they may have access to in the open lab environment. But this arrangement should not end with one's signature on a confidentiality agreement, which may easily be broken without having the certainty of who is liable. It is increasingly important to raise the awareness of the staff regarding the importance of confidential information and the responsibility they share for understanding and respecting the importance of such information and maintaining such confidentiality with regard to their own and their colleagues' work.

1.20.2.2 Inventorship in Open Lab Spaces

The socialization intended by the open laboratories design leads to a further issue that is never simple, but may become even more problematic in open lab spaces: the determination of inventorship, the monitoring thereof, and the registering thereof.

At this point it seems important to define inventorship versus authorship: the terms "inventor" (the term used for patents and utility models) and "author" (the term used for scientific publications) are not synonymous.

1.20.2.2.1 Some definitions

The phrase "Authorship on a publication is determined by custom; Inventorship on a Patent is determined by law" (source: www.unemed.com) very well reflects the difference between the two terms.

Authorship is generally determined by custom: for a scientific publication, a large variety of people may be legitimately considered as authors, including those persons involved in the experimental design, who actually performed the experiments, who wrote or edited the manuscripts leading to the actual publication, or even those persons who contributed their general expertise. Authorship is sometimes also granted for the recognition of hard work or for financial support, or simply professional courtesy to collaborators and mentors.

In contrast, inventors of subject matter in patents have to be determined by law and on the basis of judicial decisions, and may differ from country to country. Any violation of the law regarding inventorship may have severe impacts on a resulting patent, and "corteous" giving of inventorship may have serious negative consequences in some countries (including, eg, the United States). Such a violation includes both an erroneously designated "inventor," who did not actually contribute to the conception of an invention, or an omitted inventor. In the extreme, such mistakes can result in the patent being invalidated. Inventorship is therefore a crucial issue in patent law.

1.20.2.2.1.1 United States

The legal meaning of the term "invention" is composed of two aspects:

(i) Conception of the invention, that is, the formation of a definite idea of the complete and operative invention in the mind of the inventor and
(ii) Reduction to practice of the invention, that is, the process of showing on the basis of experimental data that the claimed invention in fact works for its purpose.

Thus, an inventor is a person who made some inventive contribution to the invention as defined by the claims of the patent application, particularly the inventive contribution must go to the conception of the claimed invention. Therefore, in a first step it has to be determined when complete conception of the invention occurred. When the original conception is complete enough to enable another person, that is, the practitioner, to reduce the invention to practice, without contributing anything further than mere routine skill, the contributor to the conception of the claimed invention is an inventor; the practitioner reducing the invention to practice, without a contribution to the conception of the invention, will not be entitled to be designated as an inventor.

It is important to keep in mind that the claims are the part of a patent (application) that define the invention, and the contribution to the invention has to be determined based on the claims. During prosecution, particularly during examination of the patent application, claims are frequently amended or even deleted, and inventorship should necessarily be reviewed after each amendment, as it may be that a person listed as inventor in the originally filed patent application, is not anymore entitled to inventorship in the patent having amended claims.

1.20.2.2.1.2 European Patent Convention (EPC)

In the European Patent Convention (EPC) and its case law, no explicit, accurate definition of who exactly is an inventor is provided. The definition may slightly vary from one European country to another. Inventorship is generally not considered to be a patentability criterion under European patent law.

1.20.2.2.2 Inventorship: concerns in open lab spaces

As outlined before, the intention of open labs is to promote and encourage not only team-based work but also inter-team work, that is, the interaction between different teams to incite the generation of new and creative ideas. So far, the laboratory work was normally discussed, organized, and designed mainly in formal or informal team meetings. Especially for formal meetings, ideally some kinds of minutes were written as a record of the meeting. Also each of the scientists should be daily completing a laboratory notebook, or introducing the corresponding information into their computer with particular software, to record all the work and ideas he or she has generated during the work day. But what about those informal meetings that are intended to be promoted by the open lab design? Those aisle conversations encouraged by the open lab design? How may the information generated in such meetings and conversations be recorded?

As noted before, an inventor is a person who made some inventive contribution to the invention to the conception of the claimed invention, and not a person who reduced the invention to practice by performing experimental work in the laboratory; the latter could be easily followed, and it would be easy to determine who carried out the extensive experimental work; nevertheless, the former, that is the conception of the invention, is a much more subtle, ephemeral concept. And such a conception may in any case happen in such an informal meeting, which contents are difficult to be recorded or with hindsight be determined what was discussed during such meetings.

The only "legal" way of recording the content of such meetings (as I do not believe any worker would accept permanent voice recording, nor will any law on protection of personal data allow it, nor would it be humanly possible to review hours and hours of recording!) seems to be making references to such improvised meetings, if they seemed to refer to some information that could become relevant for generating an invention, in the individual notebooks or notes in the corresponding software.

Nevertheless, the issue of inventorship is always a complicated item (firms in countries where the inventors have a right to a retribution on the basis of their percentage of participation in the conception of an invention have particular departments in their structure, committed to determine such percentages as a basis of calculating the retribution), but it will become increasingly complicated within the open lab environment.

1.20.3 Lack of Control Over Information in the New Technological Era

An additional risk, which in some cases seems to be highly underestimated, in my view and experience, both in the personal and the professional environment, are also the risks arousing from the use of e-mail, social media, modern smartphones, and online storage ("the cloud").

1.20.3.1 Smartphones and Computers

Things have been changing rapidly during the last decade or more. Nowadays everyone owns a smartphone having high resolution camera, ready to take pictures and videos at any time, as well as a sound recorder, right there in their pocket. Prohibition signs regarding their use are not always respected, see for example the behavior of people at hospitals or at the cinema; there will always be someone that unfortunately does not follow the rules. And at work, everyone will have their mobile phone (mainly smartphones) ready to answer any calls, and as ready also to take any pictures. A similar landscape will apply to computers or laptops, equipped with webcams and microphones. Additionally, both smartphones and computers are constantly connected to the Internet. Any information recorded by any of such devices may immediately be shared with others by e-mail, shared folders, messaging programs, etc., or immediately a safety copy is stored in some part of "the cloud": many people's devices are configured to automatically make a safety copy of all the generated information or files, either intentionally, due to panic about losing any of their valuable information, or unintentionally, as their devices are automatically configured that way, once connected to, for example, Google or Apple iCloud. Many of us have been surprised about how much of your personal information, pictures, contacts, files, etc. are back-copied automatically, without asking for confirmation. Also our social behavior has been changing: things that were normally shared over a cup of coffee or tea, or over a telephone call, are now shared over social media, e-mail, messaging, etc., that is, in written form, and even if deleted, traces will for sure be maintained somewhere.

1.20.3.2 Multiple Devices

It is also common than people do not only work on one technological device, many having two or more devices out of a PC, a laptop, a tablet, and a smartphone, for example, or do not only work from one localization, but from more than one branch office or from the office and from home, or during travels; this fact, in combination with the wish of immediacy, that is the made-up necessity of immediately being able to access all the files from any device and from any location at any time, increasingly is leading to the use of online storage, which is accessible from anywhere whenever an Internet connection is available. Many providers offer such an online storage service, many of them even for free (subject to publicity). Nevertheless, with the exception of some providers, who against a fee, offer an encoded storage, that is, an encoding of the information stored that should make the information, even if accessed by third persons, illegible and useless, the security of such online storage is not guaranteed. This should be a concern with regard to personal information, such as family pictures or lists of addresses, but even the more with sensible information generated during work, for which confidentiality may be absolutely crucial. Therefore, in order to avoid any unwanted confidentiality breaks caused by online storage of information, the service offered by the corresponding provider should be thoroughly checked before use. The use of such storage should also be checked and confirmed with the employer, as internal policies may exist that such storage is not allowed, or a particular storage only is allowed.

1.20.3.3 E-Mail

Something similar occurs with e-mail communications: lots of information is shared through corporate or personal e-mails, repeatedly, both with individuals and groups of contacts. Generally, the communications should be secure, but it seems that someone with superior computing skills could be able to hack most of the e-mail communications if an interest therein exists. Therefore, for especially sensitive information, it should be considered to use some encoding software: such software encodes the information shared through the e-mail before sending, and may be decoded, by the use of shared passwords, by the receiver.

1.20.3.4 Publications in Scientific Congresses, Now and Before

As a particular example, only a decade ago, the only information that most probably would have been considered to have entered the state of the art in a poster session of a scientific congress is the poster itself; attendees would have made some manual notes from the corresponding oral exposure, but it would have been difficult that the integral exposure itself would have been considered to form part of the state of the art. Nowadays, it is highly probable that at least one attendee will be taking pictures of the PowerPoint slides for later referral, or even record the exposure, with or without the additional recording of images. That is, the information may get out of control. You will never become certain regarding the treatment the attendee will make of such information. Will (s)he be sharing it with friends or colleagues? Send it by e-mail? Publish it in social media? Or on a website? In any of such cases, the information would most probably be considered to have become part of the state of the art. Thus, it becomes increasingly important to thoroughly consider the content of any poster or exposition, even more than some years before.

In view of all of the above, the determination of the state of the art, in order to decide on the compliance of an invention with the requirements of novelty and inventive step has never been a simple issue, but increasingly there will be new challenges in said determination, and interesting situations may arise in this sense, both during prosecution and corresponding lawsuits later on.

1.20.4 Patents in the Internet: Is "Do It Yourself" a Reasonable Option?

Internet, with its many uses, is widely used as a source of information. The Internet has become the best source of information, as there seems to be nothing on which you cannot find information by browsing the Internet, whether about technology, science, engineering, mathematics, medicine, intellectual property, patents, geography, jobs, hobbies, history, sports, arts, games, music, gardening, wood working, sewing, etc. Online encyclopedias, video browsers, journals, newspapers, and innumerable sites on various subjects make the task of gathering information about a topic, even if it is the first contact with said topic, an easy task, for any field of study, research, or interest.

Nevertheless, one has to be careful when making contact with a topic for the first time. On the one hand, one must be careful to choose the appropriate correct information, as any individual can upload information on the Internet, and no one can be sure of the accuracy and correctness of the information, unless you are already knowledgeable about the topic; also may the information not be updated. On the other hand, the immense amounts of information available on the Internet, often very detailed or in the form of tutorials, may give the impression to have all the information necessary for a new task right there at your fingertips, without the hiring of an expert anymore; this may be a risky action.

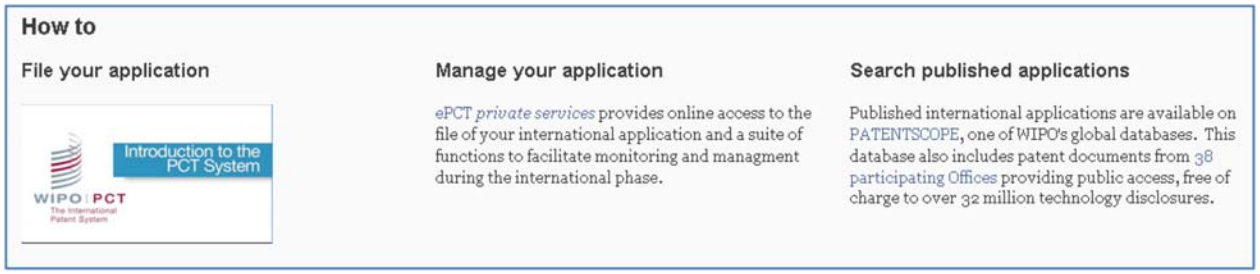
1.20.4.1 Some Useful Information Resources in the Internet

In the following, a review of some of the most valuable information sources available on the Internet, related to patents, will be made. Later on, a consideration of what a layman, that is, someone without an expertise in patents, should make use of and for what (s)he should be asking for help to an expert.

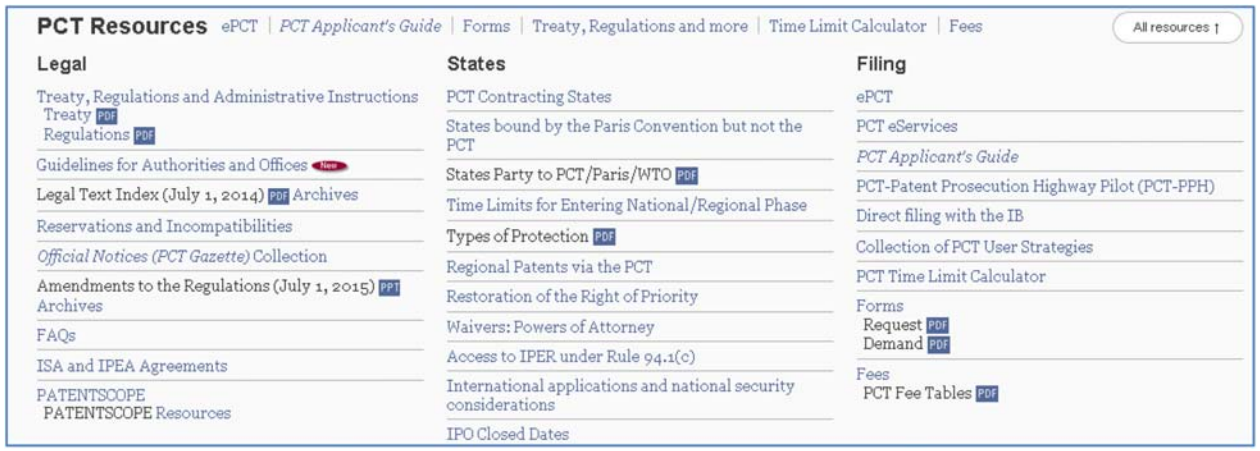
Most of the websites pertaining to national patent or intellectual property offices, to regional patent offices, or to the WIPO (World Intellectual Property Organization, in charge of the PCT applications (Patent Cooperation Treaty)), provide useful, interesting, and free general information about patent applications.

1.20.4.1.1 World Intellectual Property Organization (WIPO)

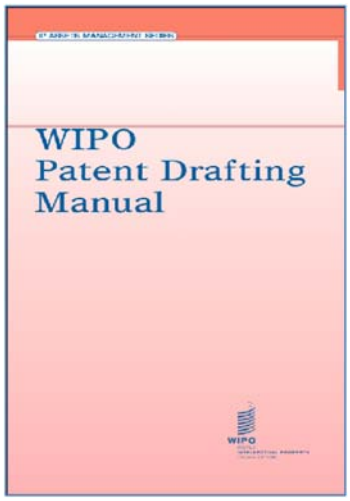
On the WIPO website (www.wipo.int), various information is offered, which may become useful at some point for anyone having an interest in patents, either due to the intention of filing an application themselves, or due to the need of knowing about third parties' patents. For example, information about how to file, manage, or search applications is provided (http://www.wipo.int/pct/en/):



Also several guidelines are available, such as a PCT Applicant's Guide, which provides detailed information about the intricate PCT system and peculiarities of the national offices adhered thereto, as well as links to the laws that are relevant to PCT applications.

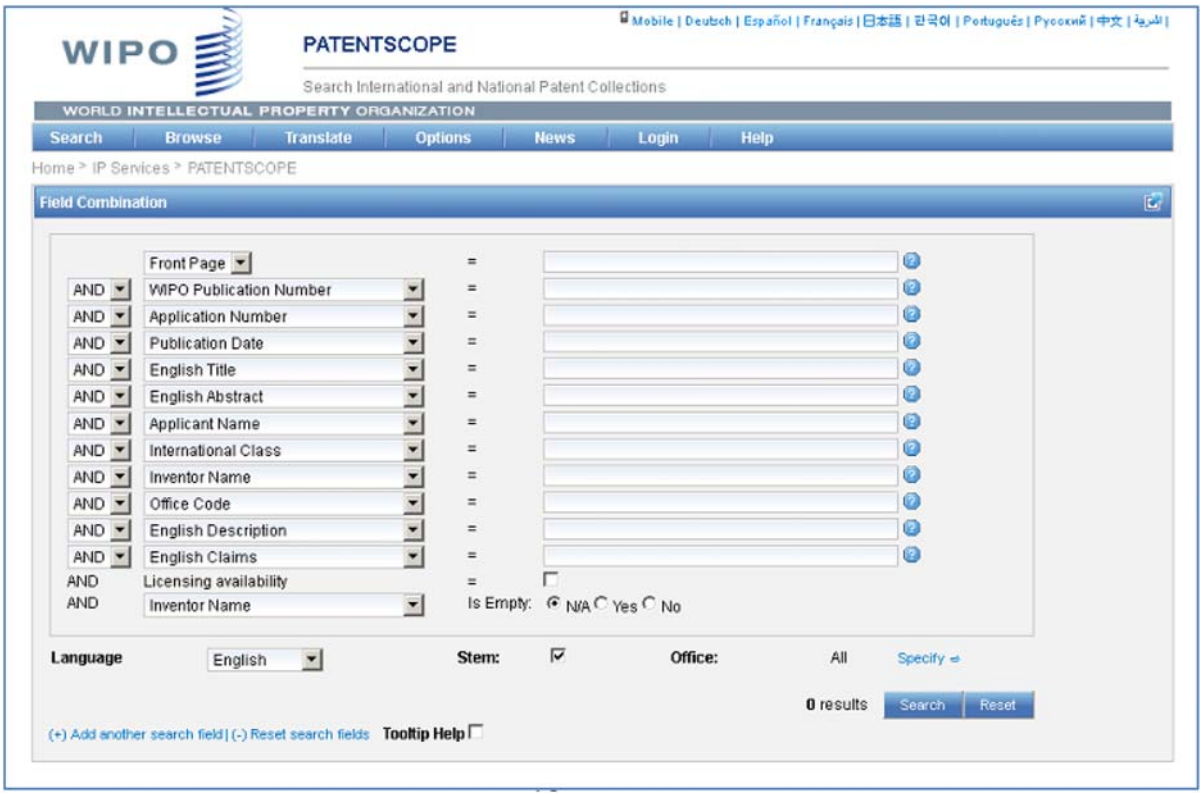


Even a detailed guideline regarding patent drafting is made available: the 138 pages long *WIPO Patent Drafting Manual* may be downloaded (http://www.wipo.int/edocs/pubdocs/en/patents/867/wipo_pub_867.pdf):



Therein a lot of information regarding what is a patent or patent application, what may be the subject/object of a patent, the legal requirements for patentability, recommendations about how to search prior art and which are the parts of a patent application, is provided.

A further, very useful utility offered by the WIPO website is the search interface Patentscope, which provides the possibility of searching for international patent applications by the use of various search fields, such as publication or application number, terms in the title or abstract, inventor names, applicant name, or international class code (https://patentscope.wipo.int/search/en/structuredSearch.jsf). The relevant documents, including publication document, search report, etc., may be downloaded for the corresponding patent application.



1.20.4.1.2 United States Patent and Trademark Office (USPTO)

The USPTO website (www.uspto.gov) provides general information concerning patents (http://www.uspto.gov/patents-getting-started/general-information-concerning-patents, http://www.uspto.gov/patents-application-process/search-patents), including basic information, such as what is a patent, what can be patented, and which are the parts of a specification, or more advanced information regarding the conditions for obtaining a patent, fees that have to be paid, or information about the examination procedure and other proceedings before the USPTO.

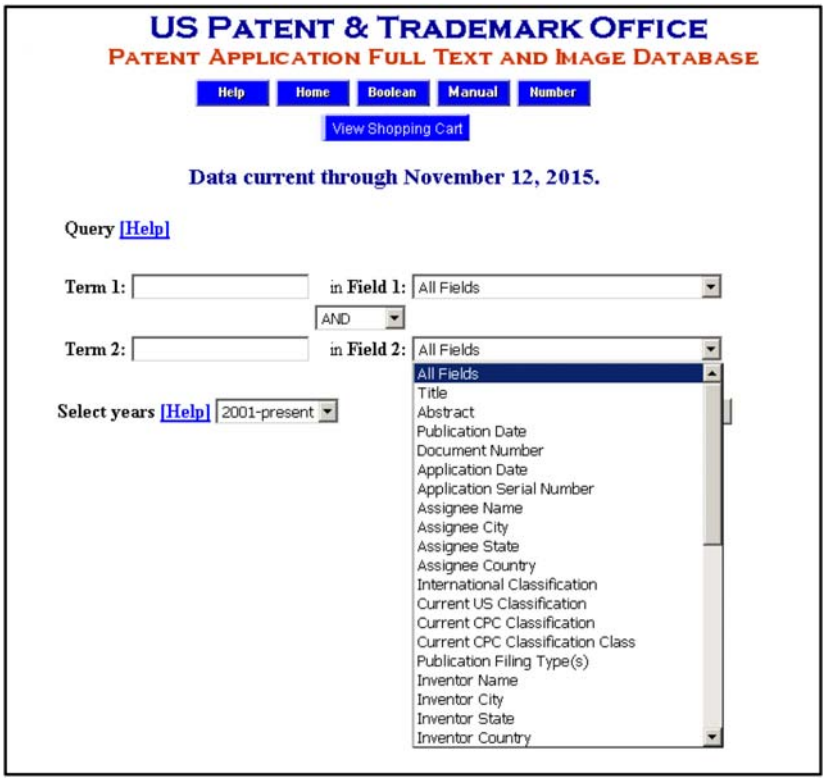
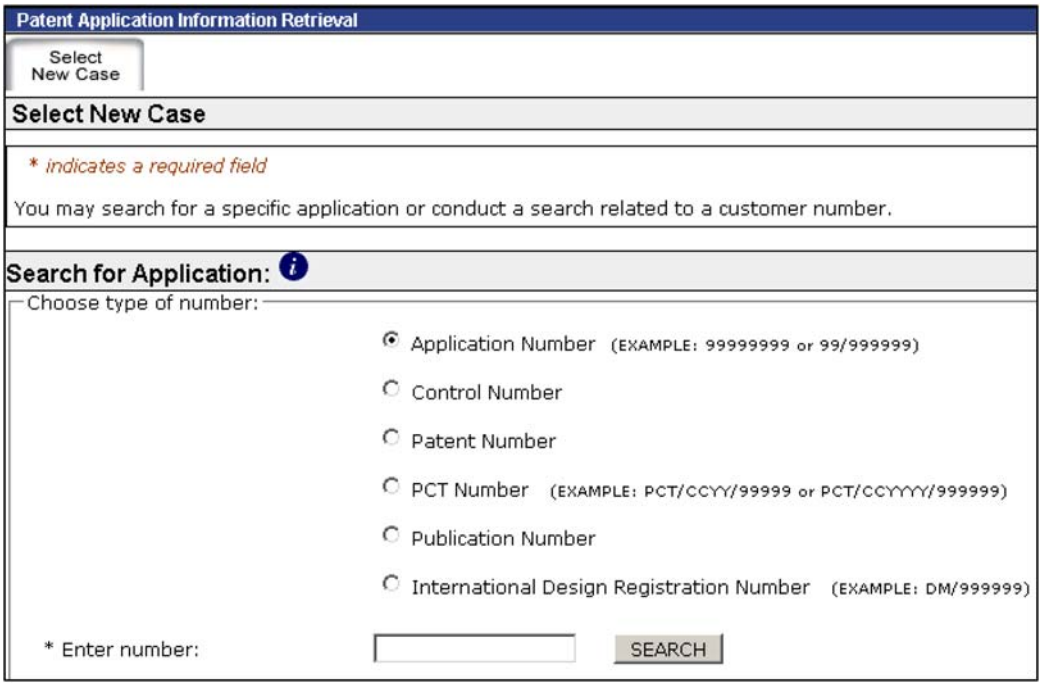
Regarding searching for patents, the USPTO offers to the user a range of different searches, in dependence of the particular needs (http://portal.uspto.gov/pair/PublicPair).

One utility that may become useful to the layman are the searches by terms, contained in any of the fields related to the application, including words in the title or the abstract.



This allows easily retrieving and downloading publications of patent applications related to a technical field of interest.

Another useful search is the PAIR (Patent Application Information Retrieval; http://portal.uspto.gov/pair/PublicPair), which allows to retrieve and download information regarding the application status of particular applications, also including most of the documents from the file wrapper. The search is performed by any of the file numbers related to the application, that is, application number, patent number, or corresponding PCT application number.



1.20.4.1.3 European Patent Office (EPO)

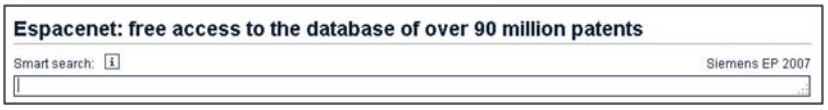
The EPO is in charge of prosecuting and granting European Patents, which are a regional patent that enables the applicant to seek patent protection in up to 40 European countries. The EPO is supervised by the Administrative Council; the Office is the executive arm of the European Patent Organisation.

On the EPO website (www.epo.org) again numerous, free resources are offered online, from which only a few will be referred to herein.

The EPO offers a complete "Guide for applicants" (https://www.epo.org/applying/european/Guide-for-applicants.html, which provides basic information around the European Patent Convention, general recommendations for the best route of protection to choose (ie, national applications, European Patent application, PCT application, etc.), an explanation of the patentability requirements, how to prepare and file a patent application, information about the European patent grant, opposition and appeals procedures, among many other information. The guide is available online, as a downloadable PDF, or may be ordered in printed form.

A more detailed guideline regarding examination at the EPO is also available online (https://www.epo.org/law-practice/legal-texts/guidelines.html). That is the case of the *Guidelines for Examination*, a document which has already been referred to in the present article (please refer back to http://www.wipo.int/pct/en/).

The EPO also offers access to a search facility known as Espacenet (http://worldwide.espacenet.com/?locale=en_EP), which allows searching and retrieving worldwide patent applications and patents. This database is very easy to use, as it offers a "Smart search" interface, which makes searching extremely simple to the layman.

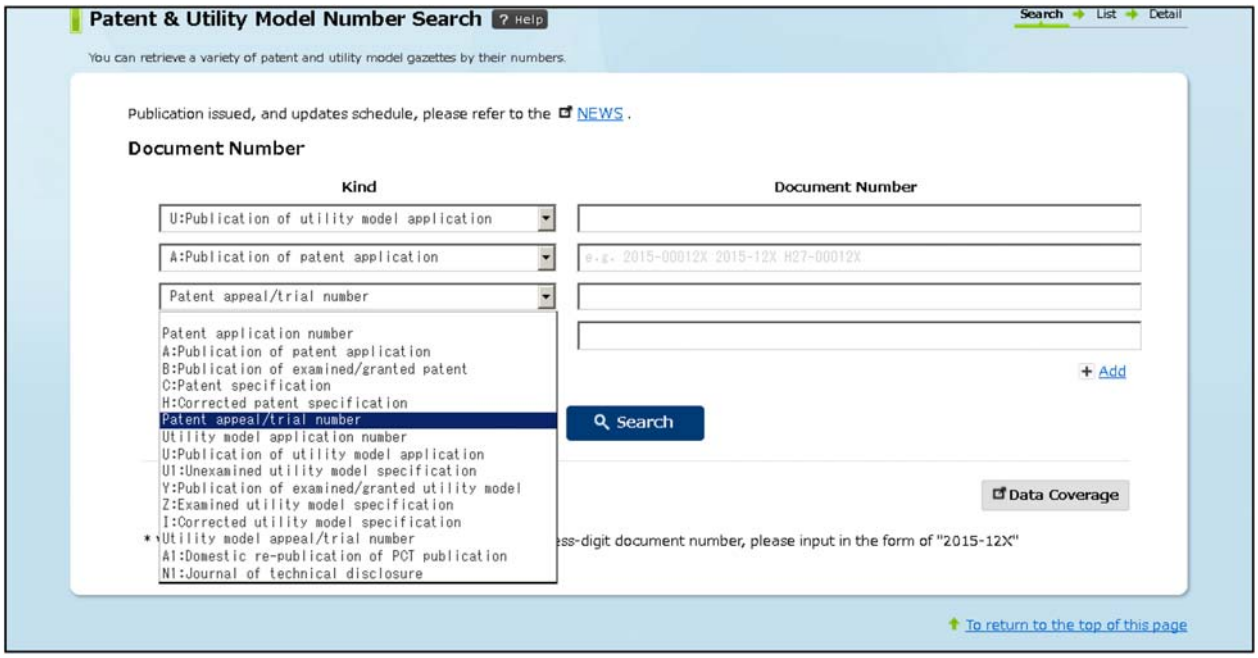


Nevertheless, also an advanced search interface is offered, which makes searching, in particular fields, simple.

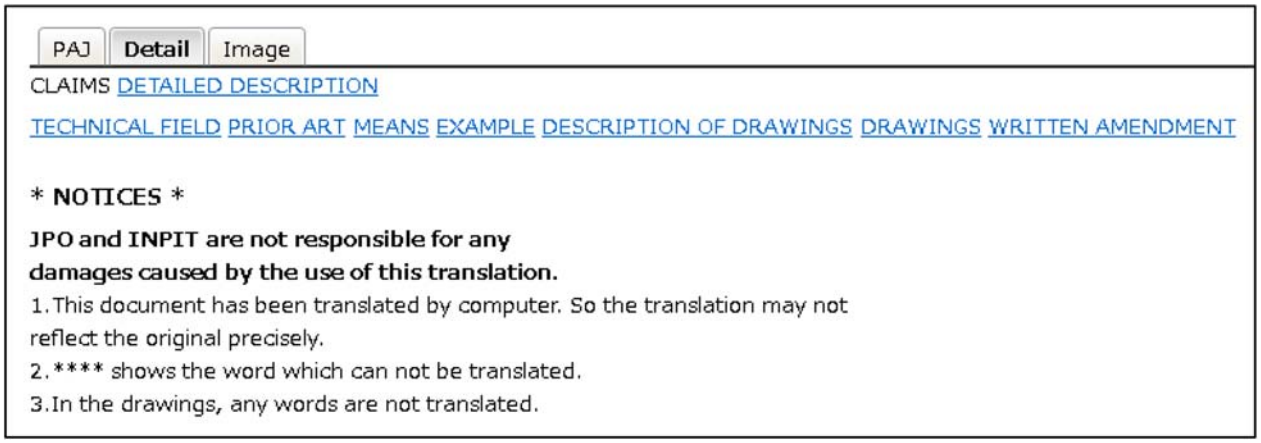
1.20.4.1.4 Japanese Patent Office (JPO)

Searching at the Japanese Patent Office (JPO) (www.jpo.go.jp) may also provide some useful information, by use of a tool that is quite unknown for laymen.

If an interest in a Japanese patent document arises, either due to a prior search performed in one of the before mentioned search facilities, due to the results provided by a professional search, or as a reference made in another document, it may be interesting to check out the contents of said document. The JPO offers a search interface (https://www.j-platpat.inpit.go.jp/web/all/top/BTmTopEnglishPage, https://www4.j-platpat.inpit.go.jp/eng/tokujitsu/tkbs_en/TKBS_EN_GM101_Top.action) where any Japanese patent document, either an application or a granted patent, may be retrieved by number:



Nevertheless, as Japanese may not be within our language skills, and a translation into Japanese is a cost-intensive matter, at a first glance this information may not have any utility. However, the JPO also offers a free service of computer-assisted, automatic translation of the complete patent document. Once the document is retrieved through the search interface, at the top of the website three tabs will appear; when clicked on the "Detail" tab, automatically a translation into English language will be offered, separated by the parts of the application (ie, prior art, examples, claims, etc.).



Of course the obtained translation will under no circumstances be a perfect translation, but it will provide the reader with a good idea of the actual contents of the document, beyond the abstract of the patent document. In some cases the computer-assisted translation may be enough for our needs, in other cases it will provide us with the information necessary to decide which parts of the document we would need to have fully translated by a specialized translator.

1.20.4.2 How to Make Reasonable Use of the Available Resources

The abovementioned information resources are only a small sample of the information that may be retrieved from the Internet, and a specific search in one of the known search engines will provide the link to much more information.

Nevertheless, one should not lose sight of the importance intellectual property and patents may have. Therefore, in the following a short explanation of what should be done and what should not be done with the information available is provided.

1.20.4.2.1 Searching

Patent and patent application publications (in the following, the term "patent publications" will be used in short, but is meant to include both patents and patent applications) usually provide lots of useful information regarding the technical field in which they are encompassed, in many cases very updated information, with cross-references to other documents with further useful information. As such, when starting to work at a new project or research, or when a new aspect is entered into a project, it would be a good habit to search for patent publications related to the matter in one or more of the available patent databases, and read through them to obtain useful scientific information, but also information regarding whether someone may have followed the same path earlier, and thus it may save a lot of work, or it may become clear that it makes no sense to work in that direction. This may become especially relevant if it was intended to apply for a patent at the end of the project, as subject matter which is already part of state of the art may not be patented.

Nevertheless, if a search is needed, either to evaluate the patentability of an invention or to evaluate the potential risk of infringing third parties' rights by bringing a project's result to the market ("freedom to operate"), it is highly recommended to ask for help to a patent attorney or a person with similar knowledge. This may avoid that unnecessary risks taken while taking a decision, and in the long term it will save a lot of money: the initial investment will for sure mean significant cost savings in the future.

1.20.4.2.2 Drafting and Prosecution

Regarding the drafting, filing, and prosecution of a patent application, it would for sure make sense to get used to some of the most relevant patent terms, especially to improve and speed up the communication with the corresponding patent attorney (reducing the time invested and consequently reducing the associated costs), who should at the end be in charge of the drafting, filing, and prosecuting of the application. Drafting a patent application, by use of the available information and examples in the Internet, may seem a trivial matter at a first glance. Nevertheless, the drafting of a patent application is a skill acquired during years of education, experience, and intensive dedication, and errors in the initial drafting and later during prosecution, may have fatal consequences, which may reach up to the loss of a patent, or at least mean high expenses to try to solve problems that may arise. Therefore, the drafting and prosecution of a patent application should be entrusted to a specialist, that is, a patent attorney.

1.20.4.2.3 Legal status of patents and patent applications

Most national patent offices, but also regional patent offices such as the EPO, offer online information regarding the legal status of applications of patent applications. Making such online consultations may save money, by avoiding the costs of a corresponding patent attorney. Nevertheless, this should only be made in cases where the correctness of the result obtained is not crucial to a decision (eg, check the legal status of a patent, which may be infringed by a product we are launching); in any other case, the legal status check should be performed once again by a specialist, that is, a patent attorney, as it may become tricky and more than one status resource should normally be checked.

1.20.5 Conclusion and Perspective

In the coming years, the tendency of designing laboratories as open spaces is expected to continue; also the use of electronic devices and the Internet is most certainly going to extend even more. Simultaneously to the beneficial consequences, an awareness of the new existing risks has to be awaken at all personnel levels of the corresponding institution, public or private, in order to take any possible preventive measures, to avoid any kind of information leak or unwanted publication of information. "*Scientia potentia est*" (knowledge is power) since time immemorial, and will increasingly be in the future; therefore, it is essential to take due care of knowledge and information.

1.21.1 Introduction

The discovery of new drugs has changed the history of human healthcare. From the advent of analgesics to treat pain, anticonvulsants to treat seizures, control of hypertension, and antibiotics to treat infection, novel medicines have altered the probability of survival of humans radically, also impacting quality of life according to multiple dimensions. Nonetheless, there remains substantial unmet medical need, and therefore, further drug discovery efforts are in demand. This means that the ethical considerations inherent to the drug discovery process continue to be required as much as ever.

All stages of the drug discovery process generate a need to consider ethics. The selection of the areas of medical need before the process even starts raises ethical concerns. Historically, certain categories of healthcare have been underserved. Included among these are rare diseases, conditions that having increasing impact as the world population ages, and neglected infectious disease in the developing world.

The discovery of new drugs relies heavily on the use of nonhuman animals. In many regions, drug discovery mandates safety and toxicology testing that is a legal or regulatory requirement. Consideration of the ethics of animal experimentation has led to legislation and guidelines seeking to ensure animal welfare and appropriate experimentation.

Investigational medicines selected after safety and toxicology testing are advanced into clinical studies to investigate potential benefit and determine a safety and tolerability profile. Inherent to clinical studies is the ethical need to balance the risks of drug discovery against the benefit that may be obtained for affected patients. There is, therefore, an ethical need to ensure that clinical studies are optimally designed and able to fulfill the purpose of defining the profile of an investigational medicine, as well as ethical need to protect the welfare of study participants.

Once clinical study has led to a drug being approved for marketing as a medicine, the promotion of that medicine in the market and the price charged are not presently governed by formal ethical guidelines.

1.21.2 Ethical Reasons to Perform Drug Discovery

Drug discovery is the process of inventing new medicines to treat conditions that negatively impact human health. There is an obligation on scientists and humanity generally to implement this process since the personal, societal, and economic cost of human disorders and diseases has such an impact. We can illustrate this need by considering a number of categories of human ill-health as exemplars.

1.21.2.1 Medical Need in Orphan Populations

Orphan diseases are rare disorders that occur with a prevalence that is low. The definition of low varies between, for example, 4 in 10,000 of the population in Japan, and 7.5 in 10,000 of the population in the United States. These definitions of rarity are enshrined

in relevant national legislation and regulations in such territories as the United States, EU, Australia, Japan, and Singapore. This legislation was first put in place to stimulate drug discovery in disorders, which were under served and neglected due to the small size of the patient population affected and, therefore, the perceived commercial return. A series of incentives offered under this legislation are intended to increase the commercial viability of efforts in this area. Further, the regulators in relevant territories offer protocol assistance during discussion of the design of clinical studies required to be conducted in order to allow authorization for marketing of novel medicines for orphan disorders. This is of relevance since the rarity of the disorders in question means that design of studies with numbers of patients conventionally used is unlikely to be feasible.

There are at least 7000 orphan drug disorders, which are invariably serious in terms of their presentation. Most such disorders are genetically determined and first manifest in infancy. Only 5% of rare diseases do have any form of approved treatment.[1] The mortality and morbidity associated with these disorders is high. For example, 30% of children with rare disease will not live to see their fifth birthday and rare diseases are responsible for 35% of deaths in the first year of life.[1] In disorders with an onset early in childhood, where affected individuals survive, morbidity is high. For example, consider the condition congenital myotonic dystrophy. Congenital myotonic dystrophy is a life-threatening disorder, with a mortality rate of 25% by age 1.5 years and 50% by age 30 years.[2] This study also reports 50% of subjects unable to walk unaided with 4% of subjects requiring wheel chairs. Less than a quarter of congenital myotonic dystrophy patients were able to attend mainstream schooling due to intellectual disability, 15% were still fecally incontinent at 5 years of age, and in patients who lived to 20 years of age 79% were unemployed. Complementary data were reported by Ekström et al.,[3] who reported learning disability in 95 and 89% of congenital and juvenile myotonic dystrophy patients, respectively. Ekström et al.[4] also report that 68% and 50%, respectively, of individuals with congenital and juvenile congenital myotonic dystrophy type 1 (or Steinhert's disease) have an autism spectrum disorder. This is just one example if a disorder where there is a clear imperative to develop novels treatments via drug discovery.

The process of drug discovery in orphan drug disorders can make a difference. Following the introduction of orphan drug legislation in the United States, in the period 1999–2006, orphan drugs were estimated to reduce premature mortality in rare diseases by 3.3% (against a predicted increase of 0.9%).[5] The fact that rare disorders are clearly treatable when drug discovery is directed toward them makes the ethical case for further effort to prevent mortality and suffering in this field.

1.21.2.2 Medical Need in Older Age

Health conditions of older age represent a large and presently incompletely unaddressed problem. The developed world is aging. Life expectancy has increased dramatically over the past century, for example, in the United States increasing from 45 years in 1902 to 76 years in 2004. However, the health and capability of aged persons has not necessarily kept pace. As the proportion of the population that is older increases, so the relative impact of age-specific health concerns will increase.

For example, the UK Alzheimer Disease Society Dementia Report Update[6] estimates at the current estimated rate of prevalence, there will be 850,000 people with dementia in the United Kingdom in 2015. The number of people with dementia in the United Kingdom is forecast to increase to over 1 million by 2025 and over 2 million by 2051.[6] The current cost to the United Kingdom of dementia is £26.3 billion a year. Similarly, in the United States, it is predicted that the size of the population with Alzheimer's disease will increase from 5.3 million to 10 million by the middle of the century, with total payments for healthcare for Alzheimer patients expected to be $226 billion in 2015.[7]

Other health concerns related to older age also have a significant economic burden and impact on quality of life. Osteoarthritis affects over a third of individuals over the age of 65 years[8] and the cost of hospital treatment of osteoarthritis was already $42 billion in 2009.[9] The national economic burden of Parkinson's disease for the United States was estimated as exceeding $14 billion in 2010, with the prevalence of Parkinson's disease is expected to be double from 2010 levels by 2040.[10] Approximately one-third of individuals over the age of 65 have hearing loss, with the numbers of older individuals affected predicted to increase by between 18.4% and 49.7% according to geographic region between 2010 and 2010 according to the World Health Organization. Cardiovascular disease is the leading cause of death in people over 65 years of age. In the age range 60–79 years, over 42 million US citizens have cardiovascular disease.[11] The global cost of cardiovascular disease is forecast to rise from $863 billion in 2010 to $1044 in 2030.[12]

From these data it is apparent that the human and societal cost of an increasing proportion of presently untreated age-related disorders represents an enormous need requiring further drug discovery effort.

1.21.2.3 Medical Need in Developing World Populations

According to the World Health Organization, in low-income countries, nearly 4 in every 10 deaths are among children under 15 years, and only 2 in every 10 deaths are among people aged 70 years and older.[13] People predominantly die of infectious diseases: lower respiratory infections, HIV/AIDS, diarrheal diseases, malaria, and tuberculosis collectively account for almost one-third of all deaths in these countries. Accordingly, the World Health Organization lists 17 neglected tropical diseases to be treated as a priority.[14] According to the World Health Organization, these infectious conditions "are a diverse group of communicable diseases that prevail in tropical and subtropical conditions in 149 countries and affect more than one billion people, costing developing economies billions of dollars every year."[14]

Traditionally such conditions have not been a priority for drug discovery efforts progressed by institutions based in the developed world. There is a compelling ethical case for further work in this field. As of 2014, the 20 largest pharmaceutical companies are

active in this area, with 18 of the largest 20 companies implementing equitable pricing strategies and 11 having drug approvals relevant to this need.[15]

1.21.3 Ethics in Animal Research

Drug development typically progresses through a number of stages that can be grouped into categories. After chemical design and synthesis, potential novel medicines are assessed to determine their efficacy using in vitro or test tube methods. Following this, testing will be conducted to establish proof of the concept that benefits could be achieved by the medicine using animal models of disease. Then the potential for harm in humans is assessed using tests of pharmacokinetics, safety, and toxicology in nonhuman species. Assuming the profile of the molecule is acceptable, then clinical studies in human beings will be initiated. Clinical studies will be progressed through a number of stages (Phase I, Phase II, and Phase III) and the accumulated data presented to the regulatory authorities to determine whether a marketing authorization for the medicine can be granted.

The advent of transgenic animals has led to the ability to investigate a large range of disorders including rare orphan disorders. For example, transgenic mouse models of disorders, such as Fragile X Syndrome and Rett Syndrome, have stimulated clinical studies of novel therapeutics in these disorders.[16]

The nonhuman pharmacokinetic, safety, and toxicology testing is intended to establish predictions of the likely profile in humans. These tests are required by law in all territories where drug discovery takes place. Pharmacokinetic testing is intended to determine how much of the potential medicine is exposed to the tissues of the body. For example, although a given amount of medication might be administered via a tablet, not all of the medicine will be absorbed into the body and gain access to the blood stream. Therefore, it is important to know the actual exposure rather than make safety calculations based on the amount given. The level of exposure to the potential medicine achieved after administration of different doses of the medication can then be correlated to any side effects seen. These data overall can be used to generate a predicted maximum safe dose to be administered in clinical studies.

The use of nonhuman species in drug discovery is the subject of ethical review and regulation in many territories. For example, in the United Kingdom, use of animals is controlled by the Animals (Scientific Procedures) Act 1986. Enshrined within this legislation is a commitment to the "3Rs," meaning reduction, replacement, and refinement. This translates to a requirement to reduce the use of animals in testing, replacement of animal studies with alternatives wherever possible, and refinement of techniques so as to minimize pain suffering and distress. There is also a requirement that institutions authorized to conduct animal research establish an Animal Welfare and Ethical Review Body to provide local independent oversight. The number of procedures conducted on genetically normal animals has fallen by about half since 1990 under this legislation.[17]

Similar legislation and regulation is present in the United States (the Animal Welfare Act of 1966), the European Union (Directive 2010/63/EU), Japan (Law for the Humane Treatment and Management of Animals, 2005 and The Standards Relating to the Care and Management, and Alleviation of Pain and Distress of Experimental Animals, 2006) with regulations also being in place in, for example, Canada, Australia, and New Zealand.

Ethical considerations around the use of nonhuman species in drug discovery are, therefore, highly relevant.

1.21.4 Ethics in Clinical Studies

Once the process of drug discovery has identified novel potential therapeutics that have successfully completed preclinical development, human studies can begin and the novel therapeutic becomes an investigational medicine. A variety of ethical issues arise as a consequence of progression into studies in the clinic. These ethical issues relate to the exposure of human subjects, who have vulnerabilities, to a new potential medicine with associated risks. The potential for detection of benefit in these studies needs to be balanced against the risks to the participants concerned. This means putting in place specific protections and also ensuring that the studies conducted deliver the optimum output.

1.21.4.1 Benefits to Participation in Clinical Studies of Potential Medicines

The enrollment of human subjects into clinical studies of investigational medicines requires consideration of multiple ethical issues. These involve processing of the potential benefits of involvement in such studies, the risks inherent in participation, and the ability of the potential enrollee to understand these considerations and agree to participate.

There are three ways a human subject may benefit by participation in the clinical study of an investigational medicine. In Phase I studies, healthy volunteer subjects undergo administration of a novel potential medicine during the first exposures of human subjects to the substance in question. Commonly, participation in studies of this kind is subject to a financial inducement. The ethics of financial inducements to participants in Phase I studies have been the subject of review.[18] For example, The National Research Ethics Advisors Panel (an independent panel hosted by the National Health Service Health Resource Authority in the United Kingdom) has issued guidance on incentives and payments in this area.[18] This guidance discusses the distinctions between coercion and undue inducements (the former involving threat, the latter excessively attractive offers), the issue of whether payments should be related to risk in Phase I studies, and whether patients should be rewarded for participation above and beyond

reimbursement of costs. The same guidance endorses the premise that children and incapacitated adults should never be offered financial inducements above and beyond reimbursement of expenses. In general, the guidance is that ethical review should consider payments that are proportional to burden, rather than risk, burden meaning inconvenience and effort. Otherwise, the ethical review should consider the study justification in terms of weighing other potential benefits against the risks of participation.

A second way human subjects may benefit is by virtue of any efficacy inherent to the novel potential medicine. The importance of this benefit may be great, particularly for rare and life-threatening disorders. For example, initial clinical study of the drug Rilutek™ (riluzole) in amyotrophic lateral sclerosis used survival as an endpoint—a benefit to participating subjects was, therefore, an extension of their life.[19] Multiple rare genetic diseases can be life threatening, examples including congenital myotonic dystrophy, in which less than half of affected individuals survive to adulthood.[1] Another example is spinal muscular atrophy, the type 1 form (Werdnig–Hoffmann's disease) having a 50% mortality rate at 2 years of age.[20] As well as receiving potential benefit during placebo-controlled phases of clinical studies, many studies of investigational medicines include open-label extension phases. These extension studies allow patients optional access to more extended treatment with the investigational medicine. An extended follow up of a clinical study of the experimental medicine idebenone revealed persistent benefit in patients suffering from Leber's hereditary optic neuropathy, a condition causing blindness.[21] Lastly, as it has previously been proposed that participation in clinical studies may benefit even subjects receiving placebo treatment, as study protocols specify care and attention at a high level, and the placebo effect itself can reduce reported severity of symptoms.[22]

Aside from treatment effects related to the investigational medicine, patients and their caregivers may benefit from participating in development of research into therapeutics for the condition affected them. In orphan drug disorders, it may be the case that few or no clinical studies have been conducted in the disorder previously. In such cases, progression of initial clinical studies provides the opportunity to establish outcome measures and agreement with regulators as to requirements for approvals of potential marketing authorizations, as well as encouraging drug discovery efforts by other sponsors. Therefore, the general contribution of information is an advance in the specific field concerned, as well as providing a test of the scientific hypothesis driving the rationale behind study of the investigational medicine.

1.21.4.2 Ethical Consideration in Study Design Including Consent and Assent

Participation in clinical studies of investigational medicines is associated with risks. All medicines have the potential for induction of adverse events and during the early stages of drug discovery the safety and tolerability profile is still being developed. Therefore, the risks of participation need to be acceptable and balanced against the potential benefit. Further, this assessment needs to be made independently and needs to be understood by the participants. Beyond an individual risk-benefit consideration, the study itself needs to be considered, since if it is not capable of providing useful information then the risks involved cannot be justified. These elements can be considered separately.

1.21.4.2.1 Study design

Clinical studies of investigational medicines need to be optimized to have the best chance of success. An inadequate study will not only fail to provide a test of the underlying scientific rational for the study, and therefore fail to benefit the community via provision of new information, but will also fail to justify the potential risk or risks assumed by the individual participants. The study design needs to weigh multiple factors that might impact on risk versus benefit. The following sections describe these factors in greater detail.

1.21.4.2.1.1 Use of placebo

As mentioned earlier, participation in a study in and of itself may induce a placebo effect. In the absence of a placebo control group, delineation of a true effect of treatment might not be achievable and, therefore, the lack of such a control might complicate detection or interpretation of treatment effects. However, the use a placebo group may not be ethical. Where a condition is life threatening, historical data on the course of the condition might serve as an adequate reference against which to gauge treatment effects in a design that seeks avoid denying potential benefit to critically ill patients. Likewise, the use of a placebo treatment condition may be ethically challenging where an existing approved treatment is available for a serious disorder. Guidance for these issues is enshrined in the Declaration of Helsinki, a set of ethical principles for human experimentation developed by the World Medical Association.[23] Interpretation of the Declaration of Helsinki in relation to the ethics of use of a placebo group has been discussed in a variety of publications.[25]

1.21.4.2.1.2 Assessment of safety

For a study to have an acceptable risk-benefit profile, the risks of administration of the investigational medicine need to be monitored and recorded. This involves a variety of safety assessments. Monitoring is conducted by an independent review board to determine the presence and severity of adverse events. An adverse event is any untoward medical occurrence associated with the use of a drug in humans, whether or not considered drug related. Adverse events can be recorded as nonserious, serious, or severe, and related or unrelated to administration of the investigational medicine. A serious adverse event not predicted by the adverse event profile known for the investigational medicine is classified as a suspected unexpected serious adverse reaction or SUSAR. Adverse events detected will commonly be coded according to systems such as the Medical Dictionary for Regulatory Activities or World Health Organization Drug Dictionary Enhanced, for example.[38] This coding process will categorize the nature of adverse events

in order to aid analysis of the profile of safety and tolerability of the investigational medicine and to facilitate comparison of, for example, frequency or incidence of adverse events compared to placebo treatment.

1.21.4.2.1.3 Assessment of efficacy

Determination of the potential benefit of an investigational medicine produced via the process of drug discovery is made by the use of quantitative and/or qualitative outcome measures that are predefined by the sponsor. The art of developing an outcome measure to reliably and reproducibly translate the benefit produced into a number amenable to statistical analysis. Outcomes may be a biochemical or physiological marker that substitutes for a clinical endpoint, or an actual clinical measure that relates to the benefit in the context of the indication being treated. A clinical endpoint in a study in oncology might be shrinkage of the size of a tumor, or survival over the duration assessed. In many indications, the endpoint study can be objective, such as automated determination of blood pressure. In other indications, the outcome might be more subjective, such as patient reported experience of severity of pain. Selection of outcome measures is vital for success in detecting benefit. Conventionally, a primary outcome is prioritized and selected. Metrics relating to the primary outcome will be used for power analysis (see section "Study Size") and a criterion set for defining a study as positive on the basis of change on the primary outcome.

1.21.4.2.1.4 Study size

The size of a clinical study, in terms of the number of subjects recruited, may be planned by statistical modeling. By making an assumption about the likely magnitude of the effect of the investigational medicine, and inputting the known variability of inherent to the outcome measures selected, statistical power can be calculated.[26] Statistical power represents the ability to detect a statistically significant effect assuming there is genuine benefit, usually expressed as a percentage. A proposed study size associated with low statistical power may not be justified as subjects will be exposed to risk without real potential for successful detection of benefit.

There is a need for ethical consideration of the size of a study, in terms of the number of subjects that will be enrolled. Exposing large numbers of subjects to early-stage clinical investigations where there is limited available information on safety and potential benefit may not be warranted. Conversely, very small studies will have limited ability to distinguish true increases in adverse events and therefore very small studies are potentially futile and, therefore, not justified. The ethical determination of appropriate study size is not the same analysis as determination of the optimal study size for statistical purposes. The determination of the optimal study size purely in terms of ability to detect an effect is determined by statistical means in derivation of acceptable power to detect an effect (frequently desired to be 80% or 90%). The ethical determination of appropriate study size has been proposed as a function of the summed burden incurred by individual patients contrasted with projected study value. This measure shows that lower conventional statistical power does not make a study less ethical.[26] In general in drug development, Phase I studies are fairly small, as these studies are initial "first-in-man" study. Phase II studies for conventional investigational drugs are larger in size as Phase I studies have derisked somewhat with respect to safety and, therefore, greater numbers of subjects can be recruited in order to give a better opportunity to detect signals of efficacy and inform on choice of dose. Phase III studies are typically largest of all since at this point there is a need to have a safety database of sufficient size to detect rarer safety signals, and to show the robustness of reported benefits in broader patient populations and increased numbers of study sites. These rules are not hard and fast and may be significantly changed in orphan drug disorders where scarcity of patients to be enrolled for study needs to be taken account of in study design.

1.21.4.2.1.5 Study population

Selection of subjects eligible to participate in has an ethical dimension. Clinical study of investigational medicines conventionally uses study and treatment-specific criteria to determine which subjects can be included for enrollment into a study and which subjects will be excluded. Typically such criteria will be intended to attempt mitigation of safety considerations and to increase the probability of the study providing useful information. Subjects might be excluded from initial studies if they have health concerns above and beyond the indication intended to be investigated, as a protection for such individuals. Other inclusion/exclusion criteria might seek to make the study population more homogenous in order to reduce variability in the data obtained or to ensure the presentation of symptoms under study is sufficient to detect a treatment effect.

One consideration is that these criteria should not be discriminatory in entitlement in respect of eligibility to benefit from study participation. Therefore, restriction according to, for example, gender or ethnicity would need to be justified ethically. There may be valid reasons for such a consideration relating to the scientific rational for the treatment, the nature of the medical condition, or, for example, gender or ethnically specific pharmacokinetics and metabolism. For example, tacrimolus, a medicine used in prevention of rejection of transplants, achieves greater plasma levels in white and Latin-American subjects than in African–American subjects.[27] Similarly, the commonly prescribed anticoagulant warfarin achieves higher plasma levels in Asian subjects than whites, whites achieving greater levels than African-Americans.[27]

Other groups who may be under researched or inappropriately excluded have reduced entitlement to participation include children and the elderly. Concerns over the participation of children in clinical studies have related to age-specific safety vulnerabilities and the ability of younger subjects to report and inform on beneficial treatment effects. However, a lack of investigation in these populations may result in off-label use in children where formal investigation has not validated this use. Pharmacokinetic parameters in children may not always be accurately estimated by adjusting adult data for weight—children are not always "small adults." Concern that there is a potential gap in the available data guiding prescription has lead the European Medicines Agency, for example, to develop a priority list for studies on off-patent pediatric medicinal products.[28] Relative under study of elderly subjects,

who may also have altered drug absorption and metabolism and differing background comorbid medical conditions, represents a similar concern.

The participation of subjects with intellectual handicap in clinical studies of investigational medicines represents a further ethical consideration. Exploitation and abuse of such subjects during medical investigations during the mid-20th century has stimulated a need for clear ethical protection of vulnerable individuals.[29] Conversely, recent neurobiological advances have led to the development of novel therapeutics with potential to ameliorate cognitive deficits in such conditions as Fragile X Syndrome.[30] Therefore, the importance of protection may need to be balanced against the potential for benefit. Beyond this, there is a need to determine the relevance of benefit. Empirically, it is known that the presence of intellectual disability reduces the probability of the individual affected gaining employment, living independently, or forming adult relationships.[31] However, while such outcomes are concerning for caregivers and societally, such outcomes might or might not represent an issue for the individual themselves.[32]

1.21.4.2.2 Consent and assent

An ethical concern impacting drug discovery is the consent of subjects to participate in the study of investigational medicines. There is a requirement that study subjects fully understood the implications of their participation in research and agree to take part. The need for informed consent raises special considerations in children and those with intellectual disability, including analysis of capacity to consent and consent on another person's behalf.

Consent is a central tenet of the Declaration of Helsinki and has two key features—that the subject understands the purpose, method, risks if any, uses, and potential benefits of the study, and that the subject agrees to participate of their own volition and without coercion. Consent therefore is a process, not a single decision. The methodology used to establish consent conventionally will be the subject of independent review by a specific convened panel who will have the ability to refuse endorsement of commencement of the study in question. The independent ethical review will examine the information and materials provided to ensure the subject is properly informed, and the process for obtaining consent. The materials used during the process should clearly define what the study will involve, potential known and unknown safety risks, and procedures that will be implemented. The materials and explanations given must be appropriate and understandable. For example, regulatory guidance issued by the US Food and Drug Administration (FDA) alerts researchers preparing consent that one-third of US adults, being 77 million people, have basic or below basic health literacy.[33] Explanation of the detail of the study needs to include information on, for example, the use of placebo treatment, the nature of the investigational medicine under test, how often the participant will need to undergo assessment, and the duration of the study. Reasonably foreseeable risks should be outlined without being understated, covering the nature of the risk, its magnitude, and duration. Risks to others and in relation to pregnancy should also be covered, as should discomforts associated with study procedures. Currently unforeseeable risks should also be discussed by mentioning such risks exist. Benefits in terms of intended relief of signs and symptoms should be stated as well as benefits more broadly and in the future as a result of generation of knowledge. Payments to patients should not be identified as a benefit. The consent should also point out alternatives to participation in the study. If an alternative is participation in another study, the consent needs to highlight any exclusion criteria restricting participation in other studies. Procedures for patient confidentiality must be explained, as does compensation and handling of medical treatment required as a consequence of study participation. The participant also needs to be given contact information relevant to the study, such as the telephone number of the investigating clinician who can be contacted in the event of medical concerns and their care, as well details regarding voluntary or involuntary withdrawal from the study. The subject should also be told the size of the study to inform their thinking on the significance of the data to be obtained.

Consideration of consent may differ in some populations such as children, those with intellectual disability, or those affected by a medical emergency. In some regions, it may not be legal for a minor to consent to study participation, and the ability of young children to fully understand the information required to be understood for truly informed consent can be questioned. Generally, it is the parent or legal guardian of the child who gives consent for study participation on behalf of the child. However, it is generally the case that a child should be required to give assent to participation. Assent is given via a form that covers similar concepts to the consent form, but in language appropriate for a child. While assent may not be legally binding, the assent process gives the opportunity for the child to determine their willingness to participate.

Consent by subjects with intellectual disability requires ethical consideration. As discussed previously, subjects with intellectual disability may be under-involved in participation in clinical studies as an intended consequence of measures designed to protect against their vulnerability.[34,35] A key question for ethical debate is the ability of a subject with intellectual disability to understand the information provided in the consent process and, therefore, the risks and benefits of participation. However, the assumption that intellectual disability is a barrier to informed consent may not be correct.[36] Therefore, streamlined methods for assessing capacity to consent should be developed.[37] Some authorities and institutions require consent by a surrogate with accompanying assent by the subject with intellectual disability.

Another situation with requirement for specific ethical consideration is enrollment in study of investigational medicines intended to treat traumatic brain injury. Traumatic brain injury is a medical emergency that can render a subject incapable of conventional informed consent. Recent scientific advances have generated plausible hypotheses of potential benefit with novel potential medicines. Therefore, there is potential benefit for subjects with this condition being enrolled into clinical study without the ability to consent. Frameworks have been developed to address the situation of exempting from consent requirements in a life-threatening situation. For example, in the United States, FDA and the Department of Health and Human Services have developed such regulations[24] (cited in Ref.[37]). This process involved allows subjects to be enrolled in an emergency setting if the legally

authorized representative of the subject cannot be contacted within a specified time window and prior consultations over the study have been undertaken.

1.21.4.2.3 Role of the independent review board

Consent and assent takes place in the context of an independent review, conducted by a specific institutional body. The role of the Independent Review Board or Ethics Committee is to protect the welfare of human subjects participating in clinical studies. The Board may be local to the institution carrying out the study, or a central specialized facility undertaking the review process on behalf of one or more participating institutions. The Board will usually consider some form of risk-benefit analysis and the justification and rationale for the study, materials describing the investigational medicine, as well as approving the materials used to recruit participants into the study and obtain their consent. The Ethics Committee will also consider the suitability of the investigator(s) and the institution.

The review board should be constituted appropriately and regulatory authorities make recommendations on their constitution. For example, the Clinical Trials Directive of the EU (Directive 2001/20/EC) defines the role of the Ethics Committee under Good Clinical Practice in European states, and in the United States FDA regulation 21 CFR 56.107 sets out the role of the Institutional Review Board. In both cases, the constitution will require a minimum number of members for a quorum (often more than five), that members are independent of the investigator, and that there is scientific and lay representation. The membership should also have the ability to evaluate medical aspects of the proposed study.

The review board should evaluate all of the materials used to recruit subjects and guard against undue influence or coercion. The board should also examine financial interests relating to the study. As well as reviewing the materials involved and their suitability allow informed consent, the board needs to evaluate the process for obtaining and maintaining the consent, and the board may have the ability to observe the consent process and will need to review changes to the material and consent as a consequence of any changes that occur or new information that is generated during the conduct of the study. As the investigator running the study is responsible for implementing the consent process, the investigator will need to disclose their sources of funding in conducting the study, and any financial interests in the study. As well as the independent review board, some regulatory authorities such as the FDA will require to review materials such as the informed consent form. The review board will also have to make provision for situations in which subjects might be recruited who do not speak the language used for the consent process and materials. The review board will also consider matters pertaining to assent by, for example, children. Actions pertaining to suspension or termination of a study will also require involvement of the board.

1.21.4.3 Reporting of Clinical Study Results

Consideration should be given to ethical issues in the reporting of clinical study results. A clinical study may be successful in detecting benefit associated with an investigational medicine that has an acceptable safety and tolerability profile. An accumulation of such data will be considered during assessment by regulators ahead of a potential approval for marketing and grant of marketing authorization. However, not all clinical studies are positive in the sense of detecting benefit. A failure to detect benefit in a negative study might be the consequence of more than one cause. It is possible that the study conducted was designed in such a way that genuine benefit was not detected. In this case, a failed study has occurred. Alternatively, an appropriately designed study may show that no genuine benefit can be attributed to the investigational medicine. In the latter scenario, the drug has failed to meet study goals. It is reasonable to determine a novel medicine is useful, even when some of the studies conducted with the investigational medicine have been negative, if these failed studies lead to corrected designs leading to positive data. However, the rationale for concluding negative studies do not reflect failure of the drug and can, therefore, be discounted in determining safety and efficacy needs to be presented and reported appropriately. Failure to report negative studies has been an issue historically, and the World Health Organization has drawn up proposals for prompt reporting and public disclosure of study results.[39] Relevant examples include data on the antidepressants seroxat[40] and reboxetine.[41]

1.21.5 Ethics in Sales and Marketing

Approval of a new medicine at the end of the drug discovery process is an approval to market the medicine. Marketing is conducted in relation to the label of the medicine, which is a list of approved claims approved by the regulator that can be justified on the basis of the data submitted to the regulator as part of the application for approval. The label determines what can be proposed in promotion of the new medicine, and also impacts the price that can be charged. A medicine linked to a broader and more significant label can be promoted to more patients and as more attractive than alternative medicines for the same indications.

1.21.5.1 Accurate Representation

During advertising and promotion, the language used to describe a medicine must be accurate. Analysis of direct to consumer advertising for medicines on television, for prescription, and nonprescription medicines proposes that misleading claims can occur.[42] The marketing of medicines is a complex and extensive activity. Expenditure on marketing by pharmaceutical companies on drug promotion was estimated as $70.7 billion globally in 2014.[43]

1.21.5.2 Pricing

The price charged for supply of a medicine is determined by multiple factors, including the claims that can be made about the effectiveness and safety described on the label, the number of patients that may be prescribed the medicine, the impact of the condition being treated, the cost of producing the active ingredients of the medicine, and competition from similar medicines. Expenditure on medicines is increasing—the US total prescription sales in 2014 were $360.7 billion, 12.2% higher than the preceding 12 months.[44] Average prices for medicines increased by more than 10% in 2015.[45] The cost of modern medicines for cancer and rare diseases has been the subject of reporting. The most expensive medicines available include treatments for rare diseases, such as Soliris® and Glybera®, which treat the rare diseases paroxysmal nocturnal hemoglobinuria and familial lipoprotein lipase deficiency, respectively. The pricing of medicines for rare diseases integrates recouping the cost of the research and development spend on drug discovery by the companies that produce the medicines, the need to make a profit from a small number of patients, and the affordability of the medicine for individuals and national healthcare systems. Reconciling these factors is an important issue in the context of future provision of new medicines in rare conditions.[46] Pricing for medication is not generally governed by formal ethical review, but is the subject of debate from an ethical perspective.[47]

1.21.5.3 Role of Regulators

The regulation of advertising of medicines is conducted by organizations such as FDA in the United States and EMA in Europe. Regulators are able to level fines in the event of inappropriate marketing practices. Kessel details fines of $100 million and over in the years from 2009 to 2014[48] with violations resulting from promotions for unlicensed uses such as prescriptions to the elderly, promotion of unapproved doses, and filing false price reports.

1.21.5.4 Conclusion

The process of drug discovery is vital for healthcare, particularly in relation to developing new treatments for underserved areas that include rare diseases, disorders relating to the increasing age of the populations, and neglected diseases in the developing world. Every stage of the discovery process, from selecting indications to address through to marketing of medicines once approved carries the need for consideration of ethical issues.

1.22.1 Introduction

Many factors have contributed to explosive growth in the number of patient-advocacy organizations around the world in recent years. Typically started and run by people affected by a specific disorder, these organizations seek to improve current and future quality of life in a number of ways. While there is certainly a role for patient and family support, increasingly patient-run medical foundations aim to change actual disease outcomes. By improving public awareness and rates of diagnosis, these groups can increase the chances that disease sufferers get the best available treatments. By lobbying governments, they can increase public funding dedicated to their disease. By raising private funds and directly supporting biomedical research, they may speed the development of new disease-modifying therapeutics. By collaborating with industry (biotech and pharmaceutical companies) they can facilitate clinical trials of new treatments.

This article will focus on the ways that rare disease foundations (RDFs) can directly facilitate and expedite the drug discovery process, based on the author's direct experience in this field. Many of these basic principles apply to more common diseases, or to those with nongenetic origins. For the purposes of this discussion, we will focus on the case of the rare genetic disease as an example of how patients, their friends, and families can make a difference in the drug discovery process and accelerate the development of new therapeutics.

1.22.2 The Early Days: How Treatments Used to be Discovered

Astute clinical observation and pure serendipity were the most common sources of medical advances throughout the history. Indeed, most of the common therapeutics in use today were derived from such ancient discovery mechanisms. The classical medical education emphasized the study of anatomy and physiology, as well as physical examination and a decidedly low-tech approach to the diagnosis of disease. This approach may have lacked the sophistication of modern medical diagnostics, but it cast a wider net, allowing for novel observations. The causes of major diseases were generally not known, their genetics were often poorly understood, and basic mechanisms of disease were purely a matter for speculation.

Ironically, in today's diagnostics-driven medical environment, serendipitous observations of novel drug effects may be more difficult to make. As understanding of disease mechanisms has increased, clinicians have fundamentally changed their approach to patients over the past century, with a much greater focus on "evidence-based medical practice," which generally assumes that it will always be possible to develop treatments for diseases via basic research.

As James Le Fanu notes in "The Rise and Fall of Modern Medicine":

> These, and a multitude of other developments, have been of immeasurable benefit, freeing people from the fear of illness and untimely death, and significantly ameliorating the chronic disabilities of ageing.
>
> This post-war medical achievement is well recognized, but much less appreciated is the means by which it was brought about. For the previous 2000 years doctors had sought in vain for the "magic bullets" that would alleviate their patients' suffering and then, quite suddenly and without warning, they came cascading out of the research laboratories just as if medicinal chemists had hit the jackpot (as they had). Or again, in 1945, desirable objectives such as transplanting organs or curing cancer were rightly perceived as being unattainable, as there was simply no way of overcoming the biological problems of the rejection of foreign tissue or the selective destruction of cancer cells. But these and many other obstacles were surmounted. The past fifty years have been a unique period of prodigious intellectual ferment that, quite naturally, invite investigation.
>
> …yet their significance has for the most part been concealed from view by the common perception, profoundly influenced by medicine's historic achievements, of it being on a continuous and upward curve of knowledge. Here the unknown is merely waiting to be known with, in principle, no limits to its further beneficent advance.[1]

1.22.3 Major Diseases, Large Foundations: Attempts to Shift the Paradigm

Disease-focused charities are a relatively new concept. Although charitable organizations often played a role in the care of the sick, only recently did they attempt to tackle the diseases themselves. This is not surprising, given that doctors traditionally rarely attempted to cure disease outright, but rather tried to provide supportive and palliative care to allow time for natural healing. With a growing understanding of infectious diseases (the major cause of mortality at the time) in the 18th and 19th centuries, physicians had the opportunity to utilize public health measures and vaccination to decrease disease burden. At the same time, advances in surgical techniques and aseptic methods allowed for the possibility of surgical cures in some cases. Thus, during the course of the 19th century a major change in thinking occurred: disease was no longer simply the illness of an individual, it was increasingly seen as a foreign entity which could be fought.

Naturally, the most common and most deadly diseases were the first to be joined in this battle (for there is little point in tackling rare diseases (RDs) when many more common threats to health and life abound!). Examples of advocacy organizations founded to address major health concerns of the time include the American Lung Association (ALA),[2] founded in 1904 as a response to the toll exacted by tuberculosis (TB). Public health efforts promoted by the ALA were so successful that TB declined in prevalence long before antitubercular drugs were widely used. With the virtual disappearance of TB as a major cause of morbidity and mortality in the United States, the AMA changed its focus to prevention of lung cancer by advocating smoking cessation. This is an early example of a now common transformation among larger patient-advocacy groups: successful organizations may accomplish their primary mission, but that rarely results in organizational retirement. More often, larger organizations have simply taken on new missions.

The American Cancer Society[3] was founded in 1913 in response to rising rates of cancer, with a primary strategy of destigmatizing the illness and promoting early diagnosis. It seems almost inconceivable today, with regular, well-attended fundraising events for virtually all types of cancer, that there could be a stigma associated with this disease, but this is an intriguing window into changing cultural perceptions of disease. While research funding would come later, early detection and treatment were seen as the best option for helping the most people with the technology of the time. As efforts to destigmatize cancer were met with success, to the point that "cancer survivor" is now considered a badge of honor, the organization shifted its goal to funding of clinical research to improve cancer treatment and basic biomedical studies of mechanisms of disease. It is worth noting that massive funding of cancer research, totaling hundreds of billions of (US) dollars, has yet to produce the kind of "silver bullet" cure that many have hoped for. Indeed, while some improved therapeutics have emerged from research on cancer disease mechanisms, these improvements have been surprisingly slow and incremental. This supports the notion that it may be more difficult than first thought to promote a specific scientific advance, such as a cure for cancer, regardless of the investment of resources. If science and medical technologies advance by capitalizing on serendipitous discoveries, then we will continue to see progress, but we may not be able to determine its course as precisely as we might hope.

In similar fashion, the American Heart Association (AHA)[4] began in 1924 with the goal of enhancing clinical management of heart disease, but quickly moved to improve public health by making dietary recommendations that might reduce the occurrence of heart disease. Again, prevention was seen as far more efficient and more likely than a cure. The AHA became an early proponent of diet and lifestyle modifications which were seen as the best way to prevent heart disease, only later funding research on actual disease mechanisms.

When poliomyelitis became the scourge of western societies in the pre-World War II era, the March of Dimes[5] was founded in 1938 by President Franklin Roosevelt, a polio patient himself, to combat the disease. Much of its early funding was devoted to treatment of polio patients rather than research into any disease-modifying strategy. Once again, public health measures began to reduce the impact of the polio virus even before a vaccine, but the steady push from patient advocates (and the governments they lobbied) certainly sped the development of the polio vaccine, which rendered this condition a rarity in the modern era. Since polio is no longer a major public health concern, the March of Dimes has shifted its mission and its methods entirely to focus on prevention of birth defects, and has moved to more direct funding of biomedical research.

1.22.4 The Human Genome Project Spawns a Vast New Generation

Genetically based RDFs have blossomed as the Human Genome Project (HGP) has revealed the genetic underpinnings of many conditions.[6] In many cases, these conditions were long recognized as heritable diseases, but the precise mutations responsible for them were unknown. While medical genetics could offer counseling to prevent the occurrence of some of the classically Mendelian autosomal recessive conditions, along with occasional screening for some of the better-recognized diseases (eg, Tay-Sachs), medicine rarely had much to offer to those diagnosed with RDs. This changed rather abruptly with the advent of modern genetic technologies.

In the modern era, the idea that virtually any problem can be solved via technology is widely held by the general public.[7] Science has advanced and we are surrounded by technological wonders; this is easy to see as inexorable progress which will continue ad infinitum. So it is with medical science: we have come a long way in recent years, and it only seems reasonable to expect more great things. As the HGP uncovered the genetic basis for many long-recognized but poorly understood conditions, RDFs have formed rapidly (sometimes 2 or 3 per disease) to exploit this new information. It is now estimated that there are over 7000 distinct, recognized RDs,[8] the vast majority with no specific treatment available.

1.22.5 Social and Economic Inputs Driving These Trends

The explosion of RDFs in recent years cannot be attributed entirely to the HGP, nor to general advances in medicine and technology. While the hope offered by the HGP undoubtedly motivated the formation of many patient organizations, private charitable funding of biomedical research requires a considerable amount of financing. The social and economic context is thus critical to understanding the rise of RDFs.

Economic expansion following World War II, and accelerating after the end of the Cold War, led to widespread prosperity in the developed world. Unprecedented credit expansion and increasing affluence have led to greater charitable giving, especially in the United States and Western Europe. Charitable giving can be roughly divided into two basic categories: major and minor philanthropy — "high net worth" donors giving very large (often one-time) donations versus much larger numbers of less affluent donors making (often repeat) smaller donations. Economic expansion and globalization simultaneously increased the general affluence of western populations, increasing minor philanthropy, while also increasing the proportion and absolute numbers of very affluent major philanthropists. As traditional religious organizations have decreased in their relative influence, a larger proportion of charitable giving has flowed to health-related charities. This confluence of factors has fueled a dramatic expansion of disease-specific charities in general, and RDFs in particular. Of course, patterns of charitable giving vary dramatically by country, and are profoundly affected by tax laws and overall levels of affluence. Nonetheless, these economic factors have permitted RDFs to flourish, and have fueled a movement which allows even those of modest means to finance a rather expensive undertaking.[9]

One of the biggest obstacles facing RD groups is that there are, by definition, few motivated people in any one place. One goal of RDFs is to bring people together to work for a common cause; that task is considerably more difficult when very few people share that cause. Even the simplest support group becomes logistically complex when the target audience is spread out over a large area. The Internet and modern communications have made that problem tractable. It is now possible for RD patients and families to connect entirely via the Internet, with no need for physical meetings at all.[10] While businessmen may still feel the need for personal contact, people with severe disabilities do not always consider this essential, and much can be done in the virtual arena.

Thus, a convergence of advancing medical and genetic technology with worldwide economic expansion and a radical transformation in communications has enabled a boom in the formation of patient-driven organizations attempting to address unmet medical needs.

1.22.6 Stages of Therapeutic Development

Most RDFs follow a plan of rational drug discovery with emphasis on different stages of the process, depending largely on the maturity of their field. RDFs involved in relatively newly discovered genetic conditions, for example, may focus largely on understanding basic disease mechanisms, whereas organizations working with well-known conditions (ie, muscular dystrophy, cystic fibrosis) will typically focus on more preclinical and clinical research. Note that while the basic plan of attack parallels the drug discovery process in the pharmaceutical, it is not the same. RDFs will rarely take a direct interest in activities such as toxicology or lead optimization. Rather, most foundations prefer an "open source" approach beginning in university-based labs. That approach can be summarized in Fig. 1.

The emphasis on the particular stage in the product development cycle of any given RDF will depend on the overall maturity of the research field, but the key for any RDF is to leverage each step of this process to the maximum extent possible, and to take advantage of partnerships and collaborations to do something significant with funding which will always be inadequate to the task. These "force multipliers" and opportunities for leverage will be described at each step.

Fig. 1 Stages of research for rare disease foundations attempting to develop new therapeutics for rare and neglected diseases.

1.22.7 How RDFs Can Help

Summarized in Table 1.

1.22.7.1 Basic Research

The most obvious way that RDFs can assist in the development of new therapeutics for rare and neglected disorders is to fund basic biomedical research investigating mechanisms of disease. This is typically the way most RDFs start, and this type of work can be especially valuable in otherwise neglected disorders.[11] In most cases, this process begins when a relative handful of established authorities in the field are funded to extend their studies. As funding increases in a small field, more scientists are drawn into the field, with a concomitant infusion of new ideas. With any luck, pilot projects funded by an RDF lead to more substantial funding by more traditional sources (government, larger medical research foundations, etc.). Leveraging the RDF's funding by increasing financial support from these other sources is crucial, since few nonprofits have the finances to go it alone. Fortunately, most governmental agencies are responsive to the needs of neglected and rare disorders, and pilot funding can often attract much larger grants.[12]

Table 1 Methods used by rare disease foundations to further their goals

Stage of research	*Major goals*	*Methods*	*RDF contributions*
Basic	● Understand basic mechanisms of disease ● Develop disease models for future studies	Basic biology (primarily university-based)	● Direct funding ● Organize scientific meetings ● Distribute critical reagents ● Distribute animal models ● Facilitate collection and distribution of human tissues
Translational	● Identify and validate targets for therapeutic intervention	Rational drug discovery versus high-throughput screens versus genetic "fix"	● Direct funding ● Focused meetings ● Distribute advanced transgenic animal models (conditional, inducible, double knockout, knock-in, reporter constructs, etc.)
Preclinical	● Validate specific therapeutic agents in model systems ● Enable clinical trials	In vitro rescue experiments In vivo rescue experiments Biomarker studies	● Direct funding ● Facilitate MTAs with pharma ● Contract studies (CRO or university-based) ● Collaborative studies with pharma partners
Clinical	● Test promising therapeutics in disease patient population ● Enable marketing of new drugs ● Establish efficacy of available drugs	Pilot studies (small/inexpensive) Open trials (medium/moderately expensive) Randomized controlled trials (large/very expensive)	● Direct funding ● Patient/family organizing ○ Specialty clinics ○ Registries ○ Recruiting for trials ● Pharma industry liaison

However, it is critical for RDFs to understand that this leveraging is the goal, and to direct pilot grants toward the projects and the scientists who are most likely to secure these other sources of funding.

It seems entirely logical that greater understanding of the disease process would lead to enhanced therapeutics for any given condition. However, as noted previously, the history of medicine does not contain many examples of success for this method. Major advances in medicine have more often occurred serendipitously, with rational drug discovery methods more often providing rather gradual improvements over existing treatments.[13] However, there is a method which can be seen as a way of inducing or accelerating serendipity: high-throughput screening (HTS), where hundreds, thousands, or even hundreds of thousands of compounds are tested (often robotically) for therapeutic effects in a disease model system. This is an attractive proposition for an RDF, and it is a standard approach in the pharmaceutical industry. Part of its attraction lies in the brute force approach of simply trying every known drug in the disease model of interest to find beneficial effects which could not be anticipated otherwise. This bypasses entirely the need for detailed understanding of the disease process, and it would seem like potentially valuable shortcut. Unfortunately, HTS results are often disappointing. As many pharma companies have come to appreciate, the choice of model system is critical — the wrong choice of model system "readout" for the disease can lead to identification of many false-positive results, which will all require extensive validation. Conversely, false negatives are also a distinct possibility if researchers do not have an adequate understanding of the range of desirable outcomes. For example, a drug screen may be established to look for compounds which could increase transcription of a silenced gene; however, this approach would likely miss entirely other compounds which could generate compensatory downstream effects. Either way, a poorly chosen HTS readout can lead to much lost time and money. How can optimal readouts be devised? One of the best ways is basic research on disease mechanisms, but of course this brings us full circle, minimizing the advantage of the shortcut.

With these caveats in mind, what can a modest-size RDF expect to accomplish in the basic research realm? Certainly, one of the most useful strategies for promoting biomedical research in any given area, and one within reach of even relatively small organizations, is the development and dissemination of disease-specific research tools, such as antibodies, animal models, or human tissues.

Many of the recently formed RDFs focus on genetically based disorders, in which transgenic animal models play a key role in basic mechanisms of disease research. These animal models are also critical for translational elaboration of any findings made during the course of basic research, and they are essential for preclinical validation of potential therapeutic strategies. Transgenic mice are one of the most common model systems for the study of disease, offering an entry level mammalian model. The technology for creating knockout, knock-in, and other forms of transgenics is well established and cost-effective, though it should be noted that creating a transgenic mouse model for a given disease is often the easiest step in the process. Characterizing the resulting model systems is often more difficult, but at least as important, since animal phenotypes rarely match human phenotypes precisely.[14]

Phenotypic characterization of transgenic animal models can be especially challenging when a major transition in specialization is required. For example, fragile X was known as a developmental disorder with X-linked inheritance; when the FMR1 gene was discovered, the field was dominated by geneticists and molecular biologists. When the knockout mouse model of fragile X was created by some of the same scientists who first discovered the gene, these research groups had little experience with in vivo mouse research or even general neuroscience. Formation of collaborations and recruitment of neuroscientists took many years to bring about adequate characterization of reliable phenotypes in this model system.

Some degree of interdisciplinary transition must necessarily occur in virtually any field. The acknowledged experts in a particular RD (assuming it is genetically based) prior to the discovery of its genetic basis will typically be geneticists and clinical specialists involved in routine treatment of the condition. While molecular biologists may make quick work of developing a knockout mouse for a single gene, loss of function mutation, using this model system to understand the underlying pathophysiology of the disease will require a very different set of experts, scientists with experience studying the organ systems affected by the mutation (the full extent of which may take many years to appreciate). Thus, RDFs will often convene meetings to introduce new scientists to the field, and disseminate information as quickly as possible.

Recent advances have made many species viable as animal models for genetically based disease. Transgenic rats are now in common use, and offer the advantage of greater intelligence, more "human-like" physiology, and more complex social interaction, though at a greater cost than mice for acquisition and housing.[15] Drosophila mutants can be excellent models for the study of human disease, offering low cost, ease of genetic manipulation, and short generation times.[16] However, their genome is greatly simplified compared to humans, and their nonmammalian brains and metabolism can vary significantly from those of humans. Increasingly, patient-derived induced pluripotent stem cells are seen as important model systems for future research. Here RDFs can make an enormous contribution by organizing tissue donation and banking; in a similar fashion, surgical and postmortem tissue samples from patients with RDs are difficult for most scientists to obtain unless RDFs take the lead in making these tissues available for the study.

Biomedical research is a complex undertaking, but even the most complex systems usually have bottlenecks or rate-limiting steps. The crucial task of an effective RDF is to identify these bottlenecks and relieve them as quickly and efficiently as possible. If no mouse model exists, or if specific antibodies are unavailable, RDFs can fund academic labs to make these, or pay a Contract Research Organization (CRO) to make them.[14] While it is perhaps more traditional for nonprofit RDFs to fund research at nonprofit universities, while for-profit pharma companies are more likely to outsource research to for-profit CROs, cost inflation in the university system has made CROs competitive with academic labs at many levels. This alternative pathway may be especially productive when providing research resources to a burgeoning field. CROs can make antibodies, transgenic animals, or novel reagents quickly

and without intellectual property claims which might hinder their later use in the field. Likewise, the RDF may then distribute these without encumbrance to all interested parties (including, ultimately, industry partners). In comparison, an academic lab may be able to produce an antibody or generate a knockout mouse rather quickly, but standard academic etiquette would allow the lab (absent specific prior contracts) to retain exclusive use of these until their work is published, a process which can delay dissemination for several years.

Leverage Potential: Direct funding by RDFs can serve as seed money to obtain much larger grants from governmental agencies or larger, endowed private funding sources. Basic disease mechanisms for a number of conditions may also intersect, revealing common research interests and other sources of funding. For example, fragile X and other monogenic causes of autism cause impairments in signaling pathways regulating synaptically driven protein translation; thus fragile X researchers have had success in obtaining grants from autism foundations. Many smaller RDFs limit the duration of funding to avoid long-term dependence of academic labs on their relatively meager resources, and to encourage applications to other funding organizations. This can be seen as an attempt to maximize leverage.

1.22.7.2 Translational Research

While this category often defies precise definition (indeed, the term "translational research" is sometimes used more generally to refer to the entire development process), translational research can be seen as the attempt to use the information gained from basic science discoveries to develop new treatment targets.[17] This is a relatively new concept and one with broad appeal. In the context of RD research, translational research is a critical step in the development of new therapies. While true translational research may be hard to come by, this is one area in which RDFs can have a major impact and can hope to drive the drug discovery process.

Typically, translational research begins when basic scientists make a significant finding concerning disease mechanisms. For example, research on a genetic disease may reveal that a mutant protein product results in abnormal intracellular signaling in a specific pathway. The question for the research field is then, how much of the disease is caused by this one abnormality? Is this a valid treatment target, or only one small facet of a much larger disorder? With the emergence of powerful animal transgenic technologies, one straightforward way to answer this question is to attempt genetic rescue of the identified pathway. Expression of individual elements of involved pathways can be increased or decreased, and this can now be done with a reasonable degree of spatial and temporal specificity using inducible systems (eg, Cre-Lox).[18] This allows scientists to isolate the effects of specific alterations in protein expression and to validate potential therapeutic targets (other than the affected gene/gene product, of course).

Generally speaking, small molecule therapies are more effective in inhibiting biological processes than in replacing them, but most genetic diseases result in loss of function (loss or mutation of a protein). This is the essential quandary faced by anyone attempting to develop treatments for genetic disorders from the ground up. It is very difficult to replace the function of a complex biological molecule (a protein) with a simple small molecule (a drug), but it is relatively easy to find small molecules which inhibit the function(s) of virtually any protein. Occasional exceptions, such as channel openers or receptor agonists, are the rare exceptions which only reinforce this general principle. One challenge in translational research, therefore, is to find a useful "double negative" — a process which can be inhibited to compensate for the loss of function caused by the disease mutation. Clearly, significant understanding of basic pathophysiology is required to make this approach work, and often the studies required to enable translational research are quite specific. In this situation, RDFs can play an important role by plugging gaps in research — recruiting scientists to look at specific questions which are holding a particular field back, using "double knockout" rescue models of disease (and making them available), and generally studying aspects of the disease which may not be considered of general intellectual interest, but of great interest to patients suffering from that particular condition.

1.22.7.3 Genetic Rescue Versus Rational Approach

Another approach to RDs, especially genetic disorders whose disease mechanisms are not well understood, is to simply attempt "genetic rescue" of patients. Newer technologies offer the promise of gene therapy, gene repair, gene editing, gene knockdown, gene reactivation, and these possibilities have brought great excitement to the RDF world. This is a (conceptually) simple way of bypassing all the trouble and expense of understanding disease mechanisms by fixing the problem at its source — the defective gene. Unfortunately, this promise has been largely unfulfilled, and most of these techniques have been far more difficult to implement in humans than in animal models. It is encouraging that more and more biotechnology industry funding has flowed into these new technologies, and this may help speed the maturation of this field. However, for most RDs (and even for most common ones) the idea of genetic rescue remains more science fiction than near-term reality.[19,20]

For an understanding of the technical difficulties inherent in these approaches, one need only look to the surprisingly sluggish development of protein replacement therapies. There would seem to be few problems as simple as a single missing protein, and few solutions as simple as replacing that protein. Indeed, for some diseases, like diabetes or hemophilia, this simple and straightforward approach works quite well. Once the protein is produced and purified, replacement results in an excellent therapeutic effect. However, this represents a best case scenario. Most proteins are not secreted; many are involved in complex regulatory functions, where precise spatial and temporal control of concentration is required and dosage is critical. Simply dumping these proteins into the circulatory system in an uncontrolled fashion can be toxic in many cases.[21] Likewise, global reactivation of a silenced gene may result simultaneously in therapeutic effects in target organs and toxic effects in unanticipated locations. It seems likely that for each

new technology, some "low hanging fruit" will be picked — conditions which are especially amenable to this new intervention. However, the vast body of RDs will invariably encounter technical difficulties.

Leverage Potential: Simply by offering grant funding to identify and validate therapeutic targets for a given RD, an RDF can incentivize this type of treatment-oriented translational research. In many cases, especially for RDs, this kind of research might not otherwise take place. Many larger governmental and private funding organizations have expressed interest in funding translational research, but this type of work is often perceived as particularly risky. This makes pilot funding of early translational studies especially important, and a particularly good candidate for leveraging RDF funding.

1.22.7.4 Preclinical Research

RDFs can play an important role in preclinical research leading to new therapeutics; that role is characterized by two main strategies: *derisking* and *repurposing*.[22] If basic research in a specific disease area has revealed possible disease mechanisms, and translational follow-up has identified specific therapeutic targets, the field may be ready to move on to preclinical research.

The point of preclinical research is to learn as much as possible about any proposed treatment strategy from model systems before moving into the next (very expensive) stage of clinical trials. The value of models systems can vary quite a bit, depending on the model and the disease condition being studied; the high rate of failure in transitioning from preclinical research, through clinical trials and into marketing, has led many critics to question the value of preclinical validation in animal models.[23] Clearly, mice are not humans; indeed, even human cells are not humans. No model system can replicate the complexity of a live human being, so the predictive value of any preclinical research must be kept in perspective. Nevertheless, clinical trials are so expensive that any groundwork which can be done to enhance their chances of success is quite valuable.[24] Derisking is perhaps in the eye of the beholder, but if an RDF can show particularly good effects of a therapeutic strategy in relevant model systems, that strategy can be deemed "derisked." An accumulation of data can convince potential industry partners (not to mention governmental agencies and larger healthcare foundations) that investment in therapeutic development for this indication is less risky.

One of the greatest challenges faced by RDFs operating primarily in the academic arena (funding university labs) is that many academic scientists are reluctant to conduct experiments which are essentially following up another academic scientist's work. Such studies are not considered especially innovative, and may be considered a breach of etiquette in some cases. Funding may be difficult to obtain. Preclinical validation of potential therapeutics also usually involves a major transition in experimental methods compared to translational research. For example, basic research may have implicated a particular signaling pathway in the pathogenesis of a genetically based developmental disorder using electrophysiological methods in hippocampal slices from a transgenic mouse model. Translational research may have shown that a class of small molecules can rescue this disease-related phenotype by inhibiting one element of the pathway; this might be demonstrated by adding a research reagent to the bath surrounding the slice of brain tissue. Preclinical validation of this therapeutic strategy might require administration of an actual drug candidate (whether an available drug or one in development) to a live animal model; this requires a completely different skill set and equipment which may not be available to the same researchers. If they are unable to form collaborations (via meetings and research networks), progress on this treatment strategy could easily stall at this point.

A potential method that RDFs can employ to overcome this common obstacle is to develop contract lab facilities to conduct vital translational and preclinical studies as needed. Certainly, there are many commercial CROs which can conduct preclinical validation studies quickly and cost-effectively. While these facilities are not inexpensive, their rapid turnaround time compared to academic labs can be a distinct advantage; in addition, the sponsoring RDF will usually retain all intellectual property rights from these studies, simplifying further development. An alternative to the usual commercial CRO is a specialized academic lab functioning as a "nonprofit CRO." This could be an academic lab with experience in the field which is willing to do this kind of work on a contract basis, or a dedicated university-based facility.[19] Studies of this kind could be seen as a radical departure from typical academic research, in that the academic contractor is being asked to work at the behest of the RDF, rather than pursuing independent intellectual interests. However, university-based labs are increasingly willing and eager to take on this kind of project, especially at times when traditional funding is harder to find, making this an attractive option for RDFs with more advanced research programs facing a preclinical validation bottleneck. For example, when researchers discovered a promising new drug target (mGluR5) for rescuing synaptic plasticity in fragile X syndrome,[25] most lab groups in the field lacked the animal model resources to conduct preclinical validation studies of mGluR5 antagonists. FRAXA Research Foundation contracted with the Columbia University laboratory run by Robert Bauchwitz, a transgenic animal expert, to test this drug class in the fragile X knockout mouse model. This resulted in the first validation of the "mGluR Theory of Fragile X"[26] and supported development of this drug class for a fragile X indication. Subsequently, increasing demand for preclinical validation of promising therapeutic candidates has led FRAXA to establish a long-running Drug Validation Initiative at the University of Chile and Frauenhofer-Chile Research Institute,[27] which maintains animal models of fragile X and conducts validation studies utilizing standardized methods for any interested industry partner.

Repurposing strategies may also begin in earnest at this point. If the goal is to bring innovative new treatments into clinical use, and translational research has uncovered drugs in development which may be of use, then it is much quicker and less expensive to repurpose an existing drug than to attempt development from scratch. Obviously, available drugs which are on the market may be validated with no permission required, and this type of "off-the-shelf" treatment is everyone's first choice. However, this is not always possible, given the relatively limited repertoire of available drugs. Pharmaceutical companies have developed vast numbers of investigational new drugs (INDs) over the past 50 years, the great majority of which have never found an approvable use. This great age of drug discovery was, unfortunately, not accompanied by the requisite "disease discovery," so huge numbers of

compounds, characterized to varying degrees, languish in pharma vaults, waiting to be paired with the ideal indication. For any RDF, this is the great promise of repurposing.[28]

While it is possible to do some preclinical validation with class prototype drugs, it is still most desirable to validate the same compounds available for repurposing from pharma partners[29]; however, this requires establishment of relationships between scientists, RDFs, and pharmaceutical partners. This process faces several obstacles. Long-dormant drugs-in-development may be considered safe to restart for a new indication, but drugs in active development may not be viewed this way at all. The conventional wisdom is that development for an orphan/niche indication could jeopardize development for a mainstream indication, especially if previously unseen toxicity is encountered during preclinical or clinical studies. Thus, timing is critical, and often the ideal time for repurposing comes when the blockbuster indication begins to falter.

Another major problem in negotiating Material Transfer Agreements (MTAs) for compounds in development is that universities, especially in the United States, have become increasingly aggressive in asserting intellectual property rights. This poses a significant problem for any industry collaborator, in that MTAs can be very difficult and time-consuming to negotiate, and academic institutions may be unwilling to waive potential intellectual property (IP) claims. The prospect of competing IP interests can cause significant distrust between industry and academia, but an RDF can often be seen as an honest third party to facilitate these collaborations. An attractive option for RDFs at this stage can also be found in contracting with foreign labs, a form of nonprofit off-shoring. A great many high-quality academic labs in Asia and Latin America are available to perform contract studies in an environment which can be more pharma-friendly. Indeed, universities outside of the United States and Western Europe are significantly less aggressive in pursuing potential IP claims.

Leverage Potential: RDFs can use contract labs of various types (commercial CRO vs. academic contractor) in various locations (potentially offshore) to achieve quicker and more cost-effective preclinical validation. Derisking and repurposing can make a rare or neglected disease indication much more attractive to industry partners, and can attract funding for clinical trials which would otherwise be unavailable to most RDFs.

1.22.7.5 Clinical Trials

Traditionally, RDFs and other patient organizations have played a role in clinical trials by assisting with recruitment of subjects. Patient associations are in an ideal position to do this if they have a patient registry or even an extensive database.[22] As noted previously, modern web-based communications make the dissemination of clinical trial information easy, efficient, and inexpensive. However, RDFs are increasingly taking a more direct approach in funding and even organizing clinical trials.

Derisking strategies can encourage pharmaceutical companies to pursue an indication for a target disease. However, the market for any given RD therapeutic may not appear attractive enough. RDFs may, at this stage, opt to organize and/or fund studies via investigator-initiated IND studies.[30] RDF-funded clinical trials will necessarily be smaller than most industry-sponsored studies, even in the RD field, where all clinical trials are relatively small. This is not necessarily a problem, however, in that clinical trial methodology usually must be developed for each new indication, and most rare and neglected disorders do not have a well-worn path for drug development. Many of the elements of clinical trials methodology, such as outcome measures, must be tailored to the target disorder in an iterative validation process. For instance, in the case of outcome measures, specific rating scales may be designed to capture the prominent features of the RD; these outcome measures may be validated in disease populations to document interrater and test–retest reliability. However, until these disease-specific outcome measures can be shown to capture not just disease symptoms, but also treatment response, they cannot be considered fully validated. This iterative process may require several cycles.[13] Early, smaller, RDF-funded trials can help to pave the way for larger industry-sponsored clinical trials. This can be considered an important form of derisking, and illustrates the usefulness of early clinical trials of available agents to facilitate the development of proper trials methodology in a given field.

It is important to recognize that while the specifics will vary with each disease indication, some variant of this iterative process is always required to develop adequate clinical trial methods. Even the best preclinical validation simply cannot predict human therapeutic effects with precision, and even the best-designed outcome measures for a new indication will themselves require repeated validation in their own development cycle.

Leverage Potential: Ultimately, the most effective leveraging strategy for RDFs is to use the previous development stages to convince industry or governmental agencies to fund larger clinical trials. Larger trials are required for approval of new chemical entities, or even to establish efficacy of available drugs for a new RD indication. By organizing and funding smaller early-stage trials, improving clinical trial methodology through the necessary iterative process, RDFs can derisk this process substantially. Those fortunate RDFs with sufficient funding may even engage in full partnerships with pharmaceutical companies; perhaps the best-known and most successful example is the partnership between Vertex Pharmaceuticals (http://www.vrtx.com) and the Cystic Fibrosis Foundation (http://www.cff.org). The exceptionally well-funded CF Foundation invested more than $150 million in Vertex, beginning in the late 1990s, with the express goal of developing a new class of drugs to treat a subset of CF patients. This eventually led to the approval of Kalydeco (ivacaftor), which increases chloride transport via cystic fibrosis transmembrane conductance regulator, the protein impaired in cystic fibrosis.[31] Royalties to the CF Foundation from this deal are now estimated to exceed $3 billion, and will likely fund the Foundation's operations for many years. However, the ethics and incentives of this partnership have caused concern in many circles,[32] in part because of the astronomical cost of the drug. Clearly, this type of collaboration is reserved for the wealthiest of RDFs, but other groups, such as the SMA Foundation, have embraced this direct funding partnership model.[33]

1.22.7.6 Limitations of This Approach — and Possible Solutions

1.22.7.6.1 Biomedical research is expensive

Just as tuition at universities in the western world has increased at a rate far higher than the background rate of inflation, the cost of conducting research at these institutions has also skyrocketed. Average college tuition in the United States increased by 498.49% versus only 114.85% increase in the overall Consumer Price Index (the official figure for price inflation in the United States) between 1985 and 2011.[34] This university price inflation has made academic research much more expensive over the past 30 years. Likewise, rapidly increasing healthcare costs have driven inflation of pharmaceutical research costs, with players competing for limited research resources in an effort to exploit increasingly lucrative markets. Outsourcing some of this work to more cost-effective areas may be a solution for RDFs, especially in earlier phases of research, where regulatory requirements are not a major concern. For example, a custom synthesis firm in India may be able to produce an essential reagent for significantly less than a US firm. For example, during FRAXA's partnership with the UK-based startup Neuropharm to develop fenobam (an mGluR5 antagonist) for fragile X, it was necessary to synthesize large quantities of the compound. Bids for a (several kilogram) Good Manufacturing Practices (GMP) synthesis of fenobam were obtained from multiple US firms and a well-known Indian pharmaceutical manufacturer; the cost of the GMP fenobam from the Indian source was approximately one-fourth the cost of the lowest US firm. It is unlikely that the development project could have proceeded at the higher cost, given the limited resources of this small company.

1.22.7.6.2 University-based research can be inefficient

Academic labs do not always share the same culture of accountability as industry research facilities, and many RDFs are unaccustomed to enforcing strict accountability. They are, after all, charities, not businesses. Add to this different incentive structure the increasing pressure from ever larger numbers of RDFs seeking high-quality research, and we can see an emerging problem: competition within the conventional university-based research paradigm limits the ability of RDFs to demand accountability from academic labs, since successful research groups may have many options for funding. Nonetheless, many RDFs have adopted policies which can increase the efficiency and accountability of its grantees. For example, an RDF may limit funding of any given research group to a 2- or 3-year time span, to reduce dependence on RDF funding and encourage scientists to seek out other funding sources. Most importantly, the issue of accountability must be considered from the start of the grant-making process. Expectations must be specified and enumerated in grant contracts, and monitoring mechanisms should be accepted by all parties. Likewise, intellectual property issues must be decided in advance and specified in any grant contract. For example, if a disease foundation would like a transgenic mouse model produced for the benefit of the research community, and it has elected to pursue a nonprofit/academic route, it should issue a request for proposals (RFPs) for this model. It should have some guidelines for the funding available, and the timeline required. The foundation should also specify in its RFP any requirements for sharing of the mouse model, the mechanism for distribution, and the ownership of intellectual property. These issues will all be critical for future work, but they are very difficult to negotiate after the fact. Consideration of these issues in advance can make academic research more efficient, and move this model closer to the CRO model, while still allowing for the utilization of the often unique expertise of academic labs.

1.22.7.6.3 The drug discovery process is very risky

Pharmaceutical industry researchers are well aware of the risks of developing new drugs. However, the influence of RDFs and other nonprofit funding sources may actually introduce new perils into the process. Repurposing, in particular, has one potentially fatal flaw: drugs are typically developed for an initial indication, with a particular dose range in mind. In most cases, the drug's mechanism of action is not directly related to the disease mechanism. For example, most patients with hypertension do not have excess angiotensin converting enzyme activity, but angiotensin converting enzyme (ACE) inhibitors will still lower their blood pressure. The preclinical toxicology package for the drug's indication often reflects the anticipated use, and this may not align with the requirements of the RD indication. Consider a case where research into the mechanism of a RD has shown excessive enzyme activity, perhaps as a result of the disease's genetic mutation. If a drug class in development is known to inhibit this enzyme quite potently and specifically, it might appear to be a perfect candidate for repurposing. However, we might reasonably anticipate that the effective dose in the RD patient population could actually be much higher than the dose for the original indication in the general population, since the RD group is known to have higher baseline, constitutive activity of this enzyme. Indeed the RD patients may be able to tolerate higher doses without significant adverse effects. However, repurposing may be heavily constrained by the preclinical toxicology already done on this class of compounds, originally targeted at the general population. While preclinical toxicology could be repeated for the RD, with the higher dosage in mind, this greatly decreases the attraction of repurposing, increasing the time and expense involved in pursuing the rare/orphan indication.

1.22.7.6.4 Impatient patients — everything takes too long

Curing disease is no easy task. When one considers that most of the effective treatments we have in modern medicine today were essentially discovered serendipitously, the prospect of developing a specific treatment for a particular disease from the ground up seems even more daunting. Even when everything goes right in the drug discovery process, many years are still required to develop a new treatment. Clearly, those embarking on this kind of project must be prepared for a long and arduous journey. Not surprisingly, many patients and families are losing patience with the current RDF model and starting their own biotech and pharma companies:

Tracy and Benjamin Seckler in 2011 helped found a startup, now known as Akashi Therapeutics Inc., in Cambridge, Mass., after growing frustrated that some compounds their foundation supported for Duchenne muscular dystrophy weren't moving forward in development. Their son, Charley, 14, has the fatal condition.

Jill Wood of Brooklyn, N.Y., cofounded Phoenix Nest Inc. to seek treatments for Sanfilippo syndrome, a fatal genetic condition affecting her son Jonah, 6. She and her husband also have a nonprofit, but she says she realized "I can't nickel and dime my friends and family forever."

The for-profit approach is a harder slog than many anticipate, says Harvey Lodish, a Massachusetts Institute of Technology molecular biologist who advises parents wanting to start companies to develop drugs for their children. He was an original scientific adviser to Genzyme, now Sanofi unit, which has developed drugs for Gaucher disease, a rare disorder that can swell internal organs and weaken bones. He later discovered it affects his grandson Andrew, 12.[35]

Anyone entering the RDF world should be prepared for a long haul, yet the impatience of RD patients and families to find improved treatment can itself be a major driving force. RDFs have shown great potential for motivating drug discovery, and these patient-driven organizations have certainly helped to accelerate the pace of drug discovery in many ways.[13] Though actual progress in biomedical research is often frustratingly gradual, this trend shows no signs of abating, and RDFs will likely continue to play a growing role in the future of drug discovery.

1.22.8 Conclusions

As medical technology has progressed, our perceptions of medicine and disease have changed. As we have seen once incurable scourges of modern societies like TB and polio become preventable, treatable, and even eradicable, our expectations have changed significantly. Economic expansion and advances in telecommunications have allowed newly affluent people around the world to coalesce around the causes that are most important to them. Thus, small groups of people affected by even the rarest conditions now feel empowered to change the course of diseases. Vast numbers of RDFs have formed in recent years, and while their specific missions vary, most aim to promote biomedical research into the mechanisms of their diseases, with the goal of expediting the development of improved medical treatment. Some of these patient associations have successfully navigated the long and complex drug discovery process, and found ways to improve the long odds facing any new treatment strategy. A greater understanding of how nonprofits can participate in the drug discovery process benefits both patient-run, disease-focused groups and their potential partners in industry.

From the perspective of a patient association, drug discovery entails basic research to elucidate disease mechanisms, translational research to identify treatment targets, preclinical research to evaluate the effectiveness of potential treatments, and clinical trials to test new therapeutics in patients. RDFs and other patient-run groups can contribute at every stage of this process, though the means employed will necessarily be determined by the resources available. Most importantly, the personal commitment and added motivation of patient associations can be an important factor in overcoming the significant obstacles posed by drug development in the modern era and promoting medical advances for otherwise neglected conditions.

1.23.1 Introduction

While there are many successful medicines now in use, there is abundant evidence of the many financial, scientific, and societal challenges for today's drug discovery and pharma industry, including:

- Patients are still in need of more effective drugs for many diseases.
- Payers are increasingly only prepared to pay for innovative rather than derivative drugs.
- Investors often believe they can get a better return on investment elsewhere, especially when a short-term view is taken.
- Legislators demand that only the very safest possible drugs are licensed.
- Researchers are frustrated that despite all our accumulated knowledge and the continued introduction of new technologies, the challenge of successfully navigating the scientific, administrative, and regulatory hurdles to find novel, effective medicines seems to get harder rather than easier and with high rates of attrition.

One consequence of these and related considerations is that the average cost of developing a new drug once all the failures are accounted for is now $1.8 billion.[1]

Drug discovery is so challenging in part because of the multitude of factors that need to be delivered successfully, across many different scientific, clinical, and business areas as summarized in the "equation" shown in Fig. 1. A "miss" on any one of these factors can lead to overall failure.

In this article, we will focus primarily on the "molecule" component, with an emphasis on small molecule therapeutics. Prompted by the challenges outlined earlier, and in part as a response to the perceived failure of combinatorial chemistry and high-throughput screening in the 1990s, the drug discovery and medicinal chemistry communities subsequently tried to understand the drivers for success or failure. We will review some of the discoveries and learnings (and in some cases, rediscoveries and relearnings) from these studies and analyses. At the same time, we will endeavor to indicate future challenges and opportunities and so provide the reader with a practical and pragmatic toolbox to help with the challenging yet rewarding task of finding effective and safe new medicines.

1.23.2 Molecular Properties, Drug-Like Chemical Space, and "Rules"

The notion of drug-like chemical space has evolved over the last 20 years both as a concept and as a practical tool to improve the probability that molecules being designed and synthesized in pharmaceutical research have the potential to deliver useful medicines. Just as overall success in drug discovery is dependent on a multiplicative array of components (molecule, target, study, etc., see Fig. 1), so for the molecule itself it is necessary to achieve, in a single entity, a multitude of properties that together confer the efficacy, safety, absorption, distribution, metabolism, excretion, and toxicology (ADMET), physicochemical, physical form, synthetic accessibility,

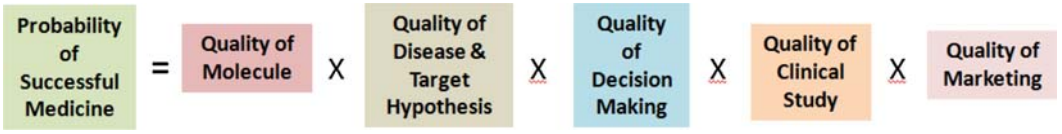

Fig. 1 The overall probability of success in making an impactful new medicine is dependent on many components.

and other properties that are required to enable the successful delivery of a medicine to patients. A perennial challenge in drug discovery, and one that will be a constant theme throughout this article, concerns the need for methods to assess and predict complex properties of molecules using simple in vitro measurements and in silico methods. Of course, it might be considered that trying to represent complex pharmacokinetic, pharmacodynamic, and toxicological phenomena using simple molecular properties is a fool's errand. Nevertheless, as we will endeavor to show, there have been some successes in moving toward this objective. It is very important however to recognize that in many cases, these properties and parameters are only indirectly related to the true molecular phenomena of interest. Another consideration, and one that has caused much debate, is that many of these studies have expressed these characteristics in the form of "rules." Some practitioners have chosen to interpret and apply these in a very rigid way. However, if the approach adopted is "rules are for the obedience of fools and the guidance of wise men," then there is a strong case to support their role in drug discovery, as we will try to show using our own drug discovery experiences.

The most frequently (and first) quoted "rule" of drug space was defined by Chris Lipinski, whose rule of fives (Ro5) refers to the probability that a compound will be orally bioavailable in humans.[2] The Ro5 states that if a compound has more than one violation of the following four criteria, then it is unlikely to be orally bioavailable: (1) greater than 5 hydrogen bond donors (defined as the total number of hydrogens directly bonded to O or N), (2) greater than 10 hydrogen bond acceptors (defined by all N or O atoms in the molecule), (3) a molecular weight greater than 500, and (4) a calculated octanol–water partition coefficient log *P* greater than 5. The Ro5 refers to only one aspect (i.e., oral absorption) of the overall ADMET profile of a compound, and it has frequently and erroneously been misquoted as "the" rule of drug-like space, no doubt helped by its simple formulation and it being the first major study of its type. This common conflation of Ro5 with drug space is probably due to the fact that most drug discovery projects do aspire to achieve oral bioavailability. However, while this may be desirable it is certainly not sufficient. To more fully define a drug-like space, we need guidance on parameters such as solubility, permeability, dose, toxicity, metabolism, etc. In part inspired by Lipinski, over the past 5–10 years, many analyses of data sets from the literature and from internal Pharma company projects have been published that aim in whole or in part to extend Lipinski's work. These studies typically involve comparisons between compounds that successfully progress through a particular test or milestone (e.g., candidate selection, animal safety testing, or a clinical phase) and compounds that do not, with the goal of finding a few simple properties that can account for the observed differences. The work of Wenlock and colleagues is a good example of this type of analysis; they concluded that the properties with the strongest influence on the successful passage of a candidate drug through the different stages of development are molecular weight and lipophilicity.[3] This and other analyses are summarized in **Table 1**.

It should be noted that lipophilicity is the most common parameter in **Table 1**. The importance of controlling lipophilicity is not new and was integral to the conclusions described in particular by Corwin Hansch et al. in the early days of quantitative structure activity relationships (QSAR) where the emphasis was more on properties such as absorption. In today's target-based approach to drug discovery, the role of lipophilicity as a key parameter in modulating target potency has also become an important consideration. The challenge here is to avoid an excess of lipophilicity driven interactions in a drive for improved potency. This phenomenon has been described by Hann as molecular obesity, in recognition of the similarities with medical obesity.[12] Some of the more common drivers for increased lipophilicity are summarized in **Table 2**.

The "rules" summarized in **Table 1** are all reported using hard cut-offs. While simple to articulate and incorporate into computational filters there are well-known dangers of expressing conclusions in this way. First, rules such as these do not reflect effectively the complete spectrum of molecules that are medicines. Second, they do not reflect the inherent uncertainties in the experimental measurements (or indeed, in computed properties). The third drawback comes from the potential for misuse, insofar as all compounds that "pass" a rule are deemed acceptable and all that "fail" are unacceptable. To take an extreme case, there is no real difference between two compounds, one of which may fail the Lipinski rule because of a calculated log *P* of 5.1 versus a closely

Table 1 Guidance "rules of thumb" for physchem property influence on ADMET outcomes[4]

Drug-like property considered	*Guidance*	*References*
Lipinski/Pfizer Ro5 for oral bioavailability	Violating two or more of MW < 500, log *P* < 5, HBD < 5, and HBA < 10 results in poor oral bioavailability	2
AZ receptor promiscuity	Maximize LLE = pIC50–log *P* to reduce promiscuity	5
Pfizer 3/75 rule for toxicity	Keep c log *P* < 3 and PSA > 75 to minimize toxicity	6
GSK 4/400 rule for general ADMET	Keep c log *P* < 4 and MW < 400 for generally favorable ADMET properties	7
AZ permeability model	Larger "small molecules" need more lipophilicity to penetrate membranes	8
GSK PFI model for general drug-like properties (including solubility)	Favored space from property forecast index (PFI) when PFI = mChromLogD7.4 + Number of aromatic rings < 6. But note that permeability max is PFI = 6–8	9
Pfizer dosage guidance for reducing toxicity	Keep predicted human efficacious dosage of < 250 nM (total drug) and < 40 nM (free drug)	10
GSK developability classification system DCS based on permeability, dose, and solubility	Compounds with DCS classification I, IIa, or III are much easier to develop	11

Table 2 Reasons for molecular obesity and mitigating strategies[4]

Reason for lipophilicity increase	*How to avoid or alleviate*	*References*
Potency is easily driven by nondirectional lipophilic interactions and which are therefore easier to make	Ensure maximum potency is initially achieved through polar (enthalpic) interactions	13,14
Permeability sweet spot is often found by indiscriminate use of lipophilicity—particularly for larger molecules	Use lipophilic ligand efficiency metric LLE to control lipophilicity driven membrane effects	5,15
Organic synthesis favors purification of lipophilic compounds	Design synthesis, work up, and purification schemas which can cope with more polar molecules	16

related compound from the same series with a corresponding value of 4.9. To counter this particular limitation, Bickerton et al. introduced the concept of desirability which they termed the quantitative estimate of drug likeness (QED) that can reflect more effectively the underlying distribution of molecular properties.[17]

Clearly there are effective oral drugs that lie outside drug space, as defined by Lipinski's Ro5 or indeed one or more of the other rules listed earlier. Equally, there are many compounds that meet the Ro5 but which for any of a whole variety of reasons will never be an effective medicine. What can we learn from drugs that fall outside the Ro5? In a recent study, Doak et al. identified 226 clinical or preclinical candidate drugs which have a MW greater than 500 Da. The set includes macrolides, peptides, rifamycins, HSV NS3/4A and NS5A inhibitors, HIV protease inhibitors, azole antifungals, cyclosporins, taxanes, cardiac glycosides, etc.[18] They use this set to define a "beyond rule of 5" (bRo5) space, although it should be pointed out that the criterion for inclusion in the set is a violation of one or more of the Lipinski criteria, whereas the original Lipinski publication required two violations to be excluded. Furthermore, as we noted earlier, Lipinski was focused on oral absorption rather than "drug likeness." The bRo5 set represents approximately 10% of the total number of oral clinical and preclinical agents. This may seem quite a significant percentage but it should be noted that many of the compounds in the bRo5 set are from a limited set of chemotypes based on natural products, and there is a preponderance of antiinfective therapies. These compounds have likely benefitted from significant evolutionary pressures, often against the infective agents or related pathogens for which they are primarily prescribed.

There is thus an apparent discrepancy between the numbers and structural diversity of oral drugs that conform broadly to the Lipinski guidelines and the smaller numbers in the bRo5 space that represent a much more limited set of chemotypes. Can we identify possible explanations for this? Has the medicinal chemistry community been too dismissive of bRo5 compounds because they do not conform to what a "typical" drug molecule "looks like"? One viewpoint is to consider this problem from the perspective of the distribution of drugs within chemical space. It is estimated that there are of the order of 10^{30} compounds with MW < 500 Da that could in principle exist. From this, there are ca. 2×10^3 drugs, giving a hit rate of $1{:}10^{27}$. There are $\sim 10^{78}$ possible compounds with 500 Da < MW < 1000 Da, which has so far yielded 0.1×10^3 drugs, equivalent to a hit rate of $1{:}10^{76}$. In other words, if drug-like molecules are equally distributed throughout chemical space (a big assumption, granted), then it will be much more difficult to find them in the bRo5 region than in the Lipinski space. This simple argument, albeit based on very approximate statistics, suggests that the probability of success is likely to be higher in the Ro5 space and so it is incumbent on teams to ensure that they have fully explored the options here before venturing into the more challenging arena of bRo5. This perspective is supported by Ritchie and Macdonald who used the QED drug likeness score on a set of 771 clinical drugs to compare the top scoring compounds with the worst scoring compounds and they clearly show that it is the absorption and bioavailability characteristics of the different subsets that are the most striking differences and these characteristics are much better understood and predictable in drug-like space.[19]

How can an organization or a team practically apply the myriad rules and guidelines now available in the literature? At GSK, our increased understanding of compound attributes that can influence successful candidate drug progression has resulted in documented guidance to project teams designed to improve the probability of success of oral candidates. Our compound quality criteria have been created by combining three measures which can variously be predicted or measured as the project progresses: property forecast index (PFI, a composite measure of lipophilicity and aromaticity), solubility, and dose. For each of these three properties benchmarked guidelines are provided, based on the distributions of marketed oral small molecule drugs.[20] It is important to highlight that these are intended as guidelines; teams are not prohibited from progressing or selecting molecules outside the defined regions. Compounds that are far outside the guideline regions are nevertheless considered to have a higher risk that may warrant performing certain preclinical studies earlier in the progression cascade. The guidelines are also intended to ensure that teams thoroughly explore drug-like space before moving far from it. Also of note is the inclusion in our criteria of solubility and dose which are tangible experimental quantities rather than the more abstract property counts used in the Lipinski-type guidance.

Just as important as the actual guidelines have been the communication, educational, and support mechanisms. These have focused on providing access to the underlying data together with practical and pragmatic insights into the rationale for selecting the particular properties and their guideline values. For example, the developability classification scheme (DCS) is a straightforward yet highly effective way to assess the solubility and permeability properties required in a potential drug to enable absorption in the gastrointestinal (GI) tract.[11] The *X*-axis in the DCS plot is the ratio of dose and solubility, which may appear at first sight a somewhat abstract concept but has physical meaning as the volume required to dissolve the intended dose. The logarithmic scale along the *X*-axis corresponds to values ranging from a tea-spoon to a small swimming pool. Volumes exceeding approximately 1 L (i.e., the

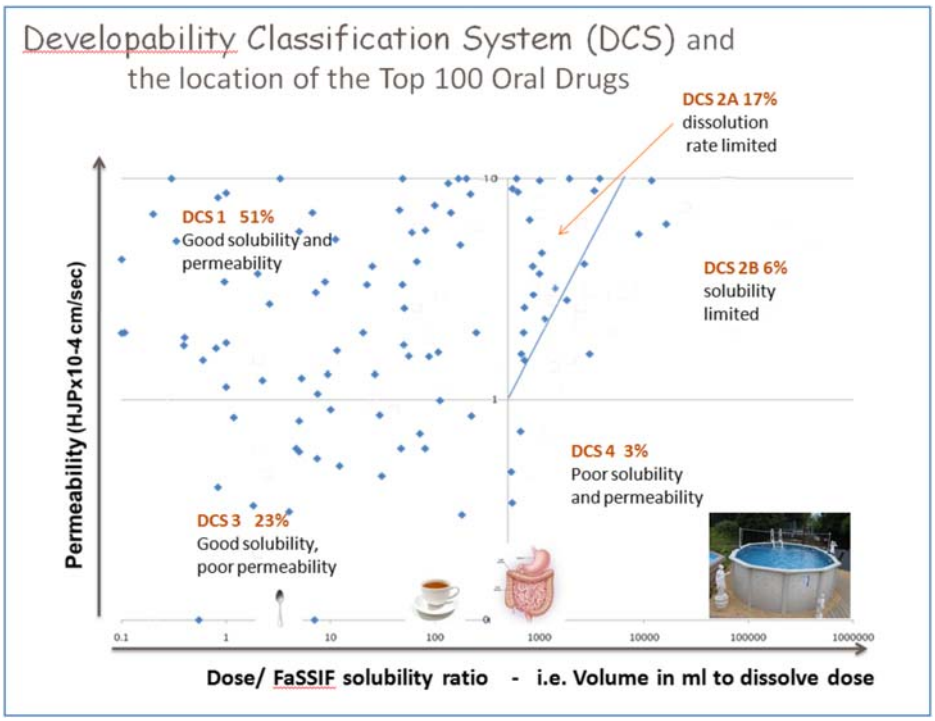

Fig. 2 Distribution of top 100 oral drugs[22] in developability classification system (DCS) space and visualization of volumes needed to dissolve intended dose. Drawn with the help of Anthony Taylor, GSK Stevenage.

approximate volume of the gut in its fed state) can be problematic as there is insufficient volume to dissolve the intended dose again emphasizing the influence physicochemical properties such as solubility on dissolution of drugs in the GI tract[21] (see Fig. 2).

The picture emerging thus far is one where appropriate monitoring of key physicochemical properties is important in the early phases of drug discovery, with well-understood risks of being in the wrong space (though as always there are successful medicines that lie outside the norms). Lipophilicity is a key molecular property where inadequate monitoring or control can have undesirable consequences. In some cases, there is a direct link and/or molecular rationale between too high or too low a lipophilicity value and the undesired property. In other cases such as off-target toxicity, the link may be less clear but there is ample circumstantial evidence in support. However, as a recent pan-Pharma analysis suggested,[23] simple physicochemical properties will not be sufficient to solve all of the challenges. We concur; at GSK we consider our physicochemical property-based guidelines as just the first phase of a series of tools and techniques designed to address attrition across the entire portfolio and through all phases. Clearly the discovery and development of molecules which have the greatest likelihood of success requires a combined evaluation of *all* the contributing factors during the lead optimization phase including lipophilicity, protein binding, solubility, in vitro and in vivo clearance, and exposure. Moreover, it is important to take a broad perspective. We therefore need to find a new language to capture some of the more complex processes involved in the later preclinical and clinical phases of drug discovery and development. The challenge then is to identify effective and cost-efficient ways to incorporate any learning's into our Discovery programs.

In a series of publications, scientists at Pfizer and Astra Zeneca sought to understand some of the more fundamental reasons why projects progress or fail. The first of these studies was from the Pfizer group who examined the underlying reasons for success or failure at the critical transition from Phase II to Phase III—Fig. 3A summarizes the findings from the retrospective analysis of information available at the time that the Phase II trial was initiated.[24] Key to successful progression were the following three critical requirements (termed the "three Pillars of survival"): (1) Does the molecule get to the site of action? (2) Does it engage the target effectively? (3) Does the target engagement elicit a pharmacological response? In a subsequent publication a fourth pillar was added: (4) Does this translate into therapeutic benefit)?[25] The importance of getting firm evidence for each pillar is emphasized in the temple diagram shown in Fig. 3B. We similarly believe that these concepts are critical for the delivery of a successful medicine and will expand on each of these concepts in the subsequent sections of this article. It should be noted that these do not obviate the need for a quality molecule and in particular for the therapeutic index to be sufficiently high to enable a clinically effective dose to be delivered.

Another useful set of considerations for successful drug discovery has come from a longitudinal review of AstraZeneca's small molecule drug projects from 2005 to 2010 which identified the most important technical determinants of project success and drug pipeline quality.[26] These criteria have been termed the 6Rs: the right target, the right patient, the right tissue, the right safety, the right culture, and the right commercial potential. They thus mirror to some extent the components in Fig. 1; the need is for effective integration of knowledge and data throughout the lifecycle of a project to ensure a thorough understanding of the

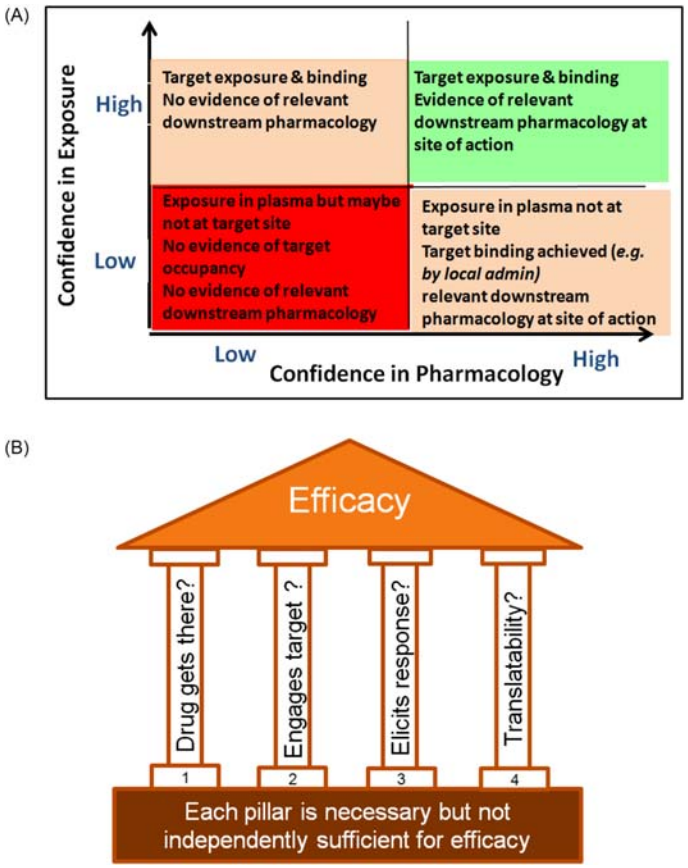

Fig. 3 (A) Causes of high/low confidence in exposure and pharmacology for Phase II Survival (adapted from Morgan, P.; Van Der Graaf, P. H.; Arrowsmith, J.; Feltner, D. E.; Drummond, K. S.; Wegner, C. D.; Street, S. D. A. *Drug Discov. Today* **2012**, *17*, 419–424); (B) iconic representation of the necessity of having each pillar in place to guarantee efficacy.

relationships between systemic exposure, target engagement, efficacy, and safety potential of any asset progressed to the clinic. Of these six criteria, the right culture is perhaps the hardest of all to measure as it is far more subjective than the other criteria but is critically important for enabling high-quality decision making based on the data relevant to the remaining 5Rs. Organizational aspects have also been the subject of analyses of medicinal chemistry strategies, for instance in how different companies appear to have embraced the challenge of dealing with excess lipophilicity.[27]

The Pfizer and Astra Zeneca reviews, together with other publications and in-house analysis at GSK, provide us with useful indicators for the challenges and issues that the next generation of attrition tools will need to address. In the following sections, we consider a number of these topics: understanding drug concentrations distribution and concentrations; monitoring the binding interactions between drug and target (and drug/off-targets); pharmacokinetic and pharmacodynamic analysis and modeling and how this relates to accurate human dose prediction.

1.23.3 Drug at Target

Clearly, a medicine cannot be effective if it does not get to the target location at a sufficient concentration to enable a molecular interaction. In those cases where there is clear and definitive evidence that the compound is demonstrating the required effects in vitro and in vivo, then it is highly likely that it is present at the target. However, as with many aspects of drug discovery, the lack of such an observation can be due to a number of factors of which only one is an insufficient amount of drug at the target over the required time period. Further, it is rarely possible to work backward from an observed phenotypic effect and/or target engagement study to understand precisely how much compound really is present and available to bind to the target. Even when such calculations can be done, it is useful to be able to measure directly compound disposition both total and free. This can also help understand the location of compound that is not contributing to the desired activity.

Important data come from tissue distribution studies using radiolabeled development compounds. An example of such a dataset is that from an analysis of ca. 200 quantitative whole body autoradiography (QWBA) studies conducted at GSK over a number of years.[28] The results show that in vivo distribution to compartments (Fig. 4) is strongly influenced by lipophilicity and ionization state

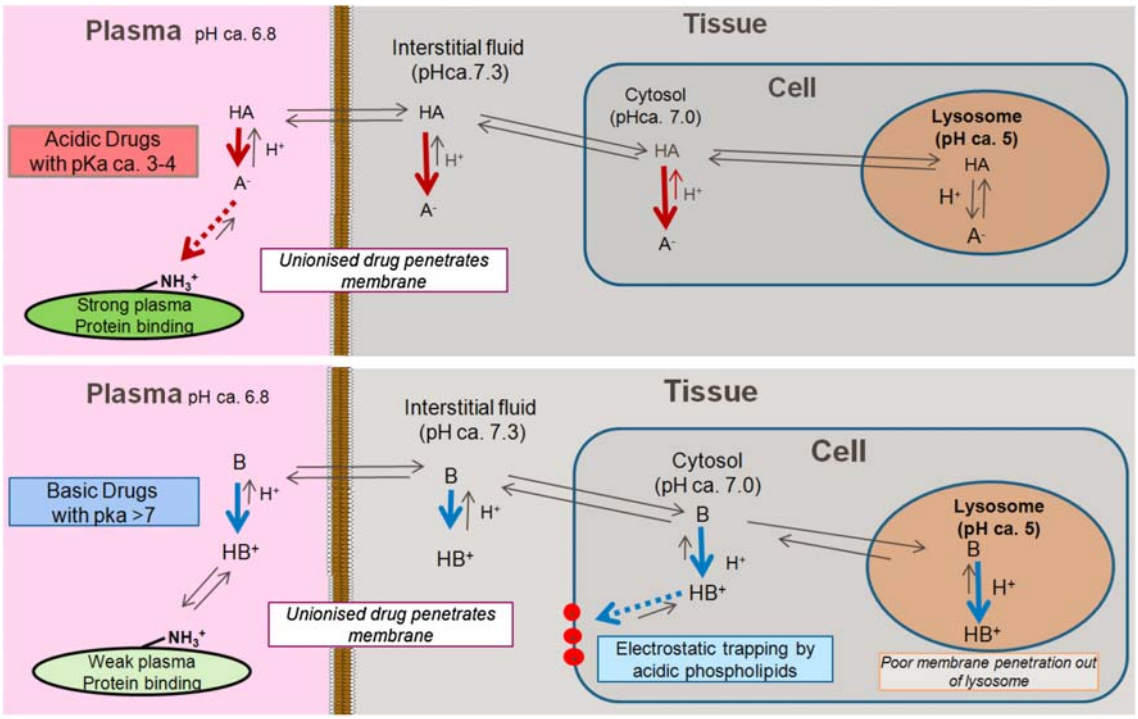

Fig. 4 The effect of pH and pK_a on the distribution of molecules between plasma, tissues, cells, and subcellular organelles. Drawn with help from Andy Harrell, GSK Ware.

as a consequence of their role in determining phospholipid and plasma protein binding. Basic and neutral molecules are more effectively distributed due to weaker plasma protein and stronger phospholipid binding. By contrast, the poor distribution of acidic drugs into tissues is due to high plasma protein and weak phospholipid binding. However, anionic uptake transporters in liver and kidney can favor the uptake of several anionic drugs into these organs. From these studies it is clear that for many molecules the role of drug binding to endogenous macromolecules heavily influences the distribution of total drug. Reducing lipophilicity decreases the effect of nonspecific binding on drug distribution in tissues, confirming again the critical role that this parameter has in drug disposition.

Studies in the discovery phase are traditionally limited to nonradiolabeled compounds due to the costs, complexities, and timescales associated with radiolabeling experiments. An alternative is to use mass spectrometric methods which are widely used to determine levels of total or free drug (and/or known metabolites) in plasma and other compartments such as Cerebrospinal fluid (CSF) or in tissue homogenates. The advent of spatially resolved mass spectrometric methods such as Matrix Assisted Laser Desorption/Ionization (MALDI) and secondary ion mass spectrometry (SIMS) offer exciting new opportunities to observe the distribution of compounds at resolutions below the subcellular, as we will discuss shortly. The more traditional approach is to perform in vivo (or in vitro) measurements in plasma and then apply the free drug hypothesis. This states that at equilibrium, the free drug concentration is the same on both sides of a biomembrane and that at the site of action, it is the free drug concentration that drives target engagement.[29] However, Smith et al. have argued that over reliance on the free drug hypothesis is dangerous due to the number of implicit assumptions.[29] This is particularly true for compounds of low passive permeability or when there is low blood flow to the tissue or cells, or when efflux or influx of the drug is mediated by active transporters. Other causes of the breakdown of the free drug hypothesis occur when there is irreversible inactivation of the target, or when in vitro assays are used for which the therapeutic target concentration of drug differs from that in the in vivo environment.

A situation commonly encountered occurs when the target of interest is intracellular, where the free intracellular concentration of drug is important for driving target engagement.[30] Use and application of the free drug hypothesis can be particularly problematic here. A typical example of such an issue is shown in **Fig. 5** where the potency of a series of compounds assayed for syk inhibition in a biochemical assay (full-length syk in HTRF format) is plotted against their cellular potency (as measured by Erk phosphorylation in a B-cell assay that identifies inhibitors of activation mediated by B-cell receptor signaling events including syk).[31]

This cellular assay is typical of those used prior to in vivo studies as part of a lead optimization screening cascade. It is clear that there is a degree of correlation between the two measurements, but also a pronounced deviation from the line of unity. The main explanation for this is presumed to be due to varying levels of free compound in the cells due to compound binding to cell membranes, lipid binding proteins, and other macromolecules. This variability was first studied by Corwin Hansch and colleagues in their QSAR studies.[32,33] Invariably it was found that lipophilicity (as measured by the octanol–water partition log P or calculated as the equivalent c log P) was a key parameter in relating cellular, tissue, or whole animal activity to target-based biochemical activity and this was well understood in the era where drug discovery usually started with a cellular or tissue assay.

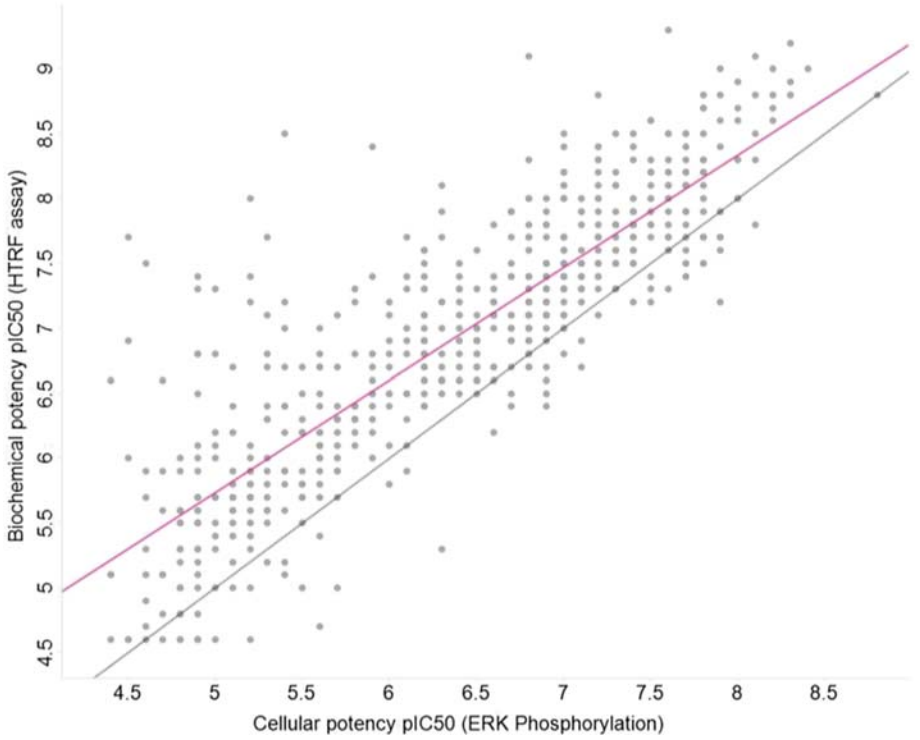

Fig. 5 Plot of biochemical potency (pIC50) versus cellular potency (pEC50) across multiple chemotypes studied as syk inhibitors at GSK. *Black line* represents 1:1 correspondence; *red line* represents correlation line of best fit ($r^2 = 0.7$).

With the advent of contemporary screening cascades where achieving potency in biochemical assays is often the starting norm, it is clear that understanding how much compound is actually available at the site of action in a subsequent cellular assay is a key consideration in lead optimization. Without this information it is difficult to determine how much of the total dose is available for effective target engagement rather than being lost through metabolism and excretion, or distribution to nonproductive compartments, potentially leading to unwanted interactions with off-targets, causing side effects.

This balance between potency and compound concentration at the site of action has always been a key consideration in medicinal chemistry. Recently, a simple mathematical formalism has been introduced that expresses this in a succinct manner. Drug efficiency (D_{eff}) is defined as the fraction of the dose (usually oral) that is available, that is, free, in the compartment of interest (traditionally the plasma). D_{eff} (sometimes also referred to as Kpu) is thus a useful measure of the free bioavailability of the drug.[34] Montanari et al. subsequently defined the drug efficiency index (DEI) as the sum of $\log D_{\text{eff}}$ and the measured potency of the drug at its target (expressed as pIC50 or pK_a). DEI can be considered as a potency corrected for the amount of drug at the site of action.[35] If the D_{eff} equals 1%, then $\log D_{\text{eff}}$ is zero and the DEI equals the intrinsic potency. If D_{eff} is greater than 1% (which is true only for some drugs), then DEI is greater than the intrinsic potency. Conversely, if D_{eff} is less than 1% (a situation not uncommon with known drugs), the intrinsic potency is less than the target potency, and becomes increasingly lower as D_{eff} gets smaller. As discussed in the article, DEI also relates to the likely receptor occupancy that can be achieved, another key parameter that needs to be understood in lead optimization studies. DEI thus provides a convenient way to monitor the balance between potency and compound availability. Further, this simple index was found to be a very good predictor of dose—compounds with a higher DEI (>7) show a corresponding reduction in the efficacious dose. An additional benefit of the DEI is that it helps to emphasize that low intrinsic potency is not as essential a requirement for a good drug as is often perceived. Indeed, it is worth pointing out that the average potency of drugs at their molecular site of action (when known) is only 50 nM (equivalent to pK 7.8).[36]

D_{eff} is an experimentally determined parameter that relies on in vivo experiments to determine the plasma free concentration. This typically requires animal studies and significant compound requirements. An in vitro alternative that may be more suitable for lead optimization where only a few milligrams may be available was developed by Valko et al. using biomimetic partition coefficient data for compounds of known D_{eff}, giving an expression for an in vitro $D_{\text{eff max}}$[37]:

$$D_{\text{eff max}} = 100/10(0.23 \times \log K \text{ HSA} + 0.43 \times \log K \text{ IAM} - 0.72)$$

HSA and IAM refer to human serum albumin (HSA) and immobilized artificial membrane (IAM), respectively. It should be noted that this model should be considered the best case scenario as it assumes that a compound's bioavailability is 100%, and no active transport and/or permeability barriers impact the free biophase concentration.

The equation shows that low drug efficiency is related to high protein binding (the HSA term) and high lipid binding (K_{IAM}). $D_{\text{eff max}}$ can also be understood in more classical terms through its link to the volume of distribution. A high volume is often

considered to give an extended drug half-life, but likely to give a low free drug concentration.[38] As in silico predictions of HSA and IAM binding can be made, it is also possible to make predictions of in vitro $D_{\text{eff max}}$ in advance of synthesis, thus enabling a much more predictive approach to drug design.

Mateus et al. have described a platform for the routine and comparative analysis of total and free drug in cells routinely used in drug discovery programs such as HeLa, HEK293, or even primary cells.[39] This is achieved by incubating cells with compound and then after a rapid wash, the cells are ruptured and the total concentration of cell-associated compound is measured by LC/MS. In a separate experiment, they use cell homogenates and equilibrium dialysis to estimate the free intracellular concentration of compound. At GSK, an assay similar to this has been automated with the aid of a Rapidfire LC/MS platform to provide routine and robust data sets for use in early lead optimization.[40] **Fig. 6** shows a plot of the total compound in the cells expressed as a concentration against the free concentration. The plot shows compounds color coded by their lipophilicity using PFI values and confirms the expectation that as the compounds become more lipophilic the free concentration is not greatly affected while the total concentration associated with the cell rises. Note that for the most lipophilic compounds (*red* and *yellow*), the total concentrations can be up to two orders of magnitude higher than the applied concentration of 20 μM, while the free concentration is typically below 20 μM, the maximum expected from the free drug hypothesis. This shows that as compounds become more lipophilic, they are increasingly bound to lipid and protein and that there is no parallel increase of free drug concentration. This is also fully consistent with the bell-shaped curves of biological response with log *P* that Corwin Hansch first pointed out ca. 50 years ago and is highlighted by Yvonne Martin in her review of his many contributions to QSAR.[33]

While increasing the free concentration of a drug at the site of action is generally considered a good strategy during lead optimization, it should also be born in mind that a high free concentration means that the compound is also free to interact with off-targets, which may in turn result in a lack of specificity and potential toxicity. Wenlock has suggested that a value of over 100 nM (free concentration in plasma) is likely to be associated with adverse effects.[41] This is only slightly higher than the value of $\leq$40 nM as free drug concentration (or $\leq$250 nM (total drug)) which was suggested in a study by Pfizer scientists as an acceptable concentration to avoid toxicity problems.[10] It is interesting to note that a concentration of 250 nM for a 500 Da molecule is equivalent to 10 mg dissolved in 80 L (i.e., the approximate size of an average adult); a daily dose of 10 mg has been proposed as the threshold below which idiosyncratic toxicity is less likely to occur.[42] We can thus see, through the key property of administered dose, some convergence of the desired values of these more complex properties, similar to the situation for lipophilicity.

Earlier, we discussed the insights gained from QWBA on tissue distribution for radiolabeled compounds. Unfortunately such studies are often limited to very few compounds and are rarely performed in lead optimization. More suitable for lead optimization studies are the mass spectrometry imaging (MSI) methods that have become available in the last 15 years due to improvements in MS sensitivity and ionization methods. The most widely used approach is the MALDI MSI approach in which a tissue slice from a drug treated animal is sprayed with MALDI matrix and then raster imaged using a laser beam to produce ions which are analyzed

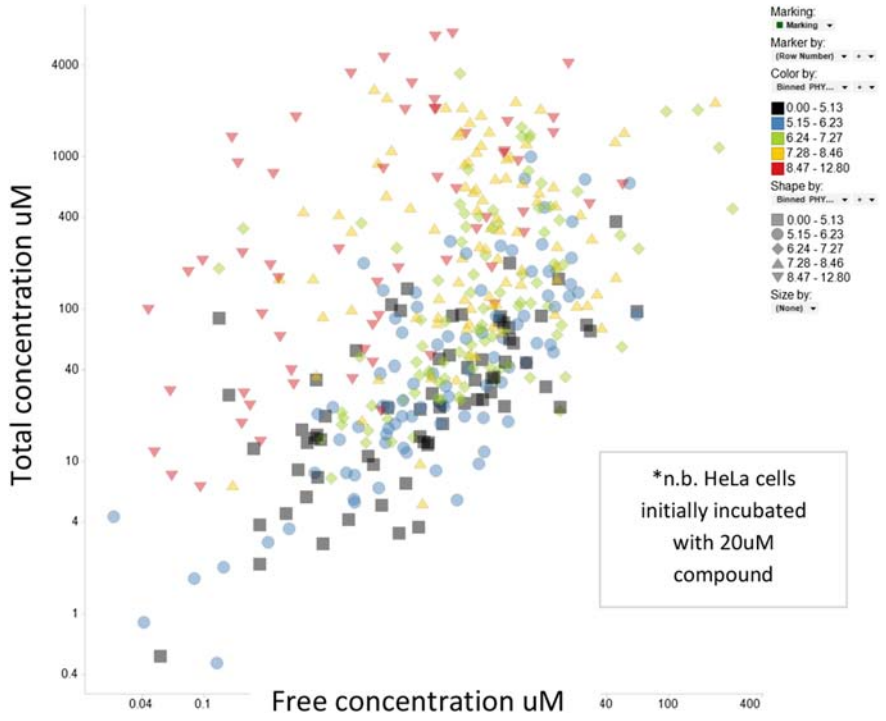

Fig. 6 Plot of total versus free concentration of compounds of multiple chemotypes in the GSK HeLa cell concentration assay.

in either TOF, TOF–TOF, or Fourier Transform Ion Cyclotron Resonance (FTICR) MS instruments.[43] This enables specific ion detection at increasingly high-mass resolution to provide spatial mapping of drugs, metabolites, and endogenous molecules (see **Fig. 7**).

While MS sensitivity continues to improve thus lowering the limits of detection, ion suppression by endogenous compounds (particularly lipids) remains a problem.[44] The alternative ionization method of desorption electrospray ionization is also being developed for MSI of tissue slices.[45] Relying on charged droplets for the ionization process, the spatial resolution is currently limited by droplet size production to around 50 μm. The spatial resolution of MALDI MSI is limited to around 5–10 μm by the size of the matrix crystals formed and lateral diffusion of compounds into them, thus limiting resolution to approximately cellular resolution. While this is at least as good as QWBA, neither method is able to achieve cellular or subcellular resolution. To address this limitation, SIMS imaging methods are being developed for application to biological samples (both tissue slices[46] and single cells[47]), allowing spatial resolution down to 100 nm. Moreover, 3D images can be generated by etching through the sample with ion beams. The next generation of SIMS instruments will undoubtedly reveal new insights into the spatial distribution of compounds within cells, hopefully down to suborganelle resolution.

A different approach to understanding compound disposition at high resolution has been the use of optical imaging methods. Intrinsically fluorescent compounds can be tracked by fluorescence microscopy at sub-micron resolution. However, most drug molecules are not fluorescent. For proteins the addition of a fluorescent tag can be considered to have minimal effect on its properties, enabling, for example, super resolution microscopy to track protein–protein interactions (PPIs) in real time.[48] However, the challenge of faithfully tracking small drug-like molecules is far greater because addition of even a small fluorescent ligand such as Bodipy adds a significant amount of chemical material to the drug, thus altering its likely distribution and other properties. An alternative approach, termed biorthogonal chemistry by Sletten and Bertozzi,[49] is to incorporate an even smaller moiety on the drug molecule which can subsequently be chemically linked within cells to a separately introduced fluorescent tag using, for example, the tetrazine and *trans*-cyclooctene Cu-free click reactions.[50] However, even this elegant approach cannot guarantee that the distribution of the unlabeled and labeled drug molecule is the same. Competition experiments with unlabeled drug can however be used to help in the correct interpretation of such experiments.[51] With some types of microscopy, the change in the fluorescence life time or correlation time on ligand binding to macromolecule can be deconvoluted and studies using unlabeled drug to compete with labeled ligand give a better indication of compound disposition and even target engagement.[52] Raman spectroscopy methods are capable of imaging unlabeled compounds provided there is a functional group in the drug which is Raman active at a frequency distinct from those found in endogenous compounds. Groups such as nitriles, alkynes, halo, or deutero are possible moieties of interest. One of the major challenges with Raman is an intrinsic lack of sensitivity, but multiphoton enhancement techniques such as coherent anti-Stokes Raman spectroscopy show promise for tracking species at high concentrations such as lipids. The related stimulated Raman spectroscopy method does have greater sensitivity but still fails to reach the micro- and submicro-molar concentration of drugs that will be required to be truly transformational as a technique.[53]

The discussion in this section has so far considered drug disposition from the perspective of the free drug hypothesis, which is generally considered to be reliant on passive diffusion, without reference to the contribution that transporters play in moving drugs across membranes in either direction. It has been understood for many years that drugs can be facilitated in their movements into and out of cells by channel and carrier proteins which can be important determinants governing ultimate drug absorption into target organs and their excretion. Alterations in these transporter functions, either due to genetic polymorphisms, drug–drug interactions (DDIs), or external factors (e.g., diet), can result in unexpected toxicity or lack of efficacy.[54] This may be due to the interplay between uptake and efflux transporters leading to pronounced in vivo variability in drug disposition of certain drugs between

individuals. Thus it is important to understand as early as possible in drug discovery if these problems exist; many drug discovery projects have had to be terminated or seriously delayed by issues related to lack of understanding or resolution of the role of transporters in a compound's ADMET profile. With the advent of technologies for creating transporter knockouts or by the use of inhibitors it has become easier to identify issues with compounds using for instance Caco-2 or Madin Darby canine kidney (MDCK) cell-based intestinal permeability assay. However the challenge of recognizing issues in lead optimization still suffers from a limited range of suitable tools and reagents for use in these early stages of discovery. There are also conflicting opinions about the importance of transporters in drug disposition which will require further rigorous experimentation on cell lines with specific transporter knockouts.[55,56] Drugs that rely on transporters for access to the site of action as opposed to passive diffusion are not only subject to the vagaries of genetic differences, DDIs, and dietary effects, but there is the added challenge that for antiinfectives (and likely oncology drugs) mutations may lead to resistance. A recent review of how antimalarial drugs reach their intracellular targets highlights the importance of this and how passive diffusion across a minimum of three membranes is actually achieved by most antimalarials.[57]

Barton and Riley have attempted to incorporate the effects of transporters into a decision tree to understand the compound risk.[58] They do so by introducing the effects of polar surface area into the widely-cited lipophilic ligand efficiency index of Leeson and Springthorpe.[5] As can be seen from the flowchart in Fig. 8, this results in another efficiency index termed the ADMET efficiency index (AEI) which is defined as $AEI = (pActivity - \log P) \times 100/PSA$ and is in effect LLE normalized by polar surface area which is introduced to characterize the effects of transporters. The flow chart in Fig. 8 enables potential issues with a compound (or series of compounds) to be flagged in early lead optimization so that any risks identified can be mitigated by appropriate follow-up experiments.

The challenges of dealing with both the upsides and downsides of transporters have led the International Transporter Consortium, a collective of academic, industrial, and regulatory scientists, which aims to provide guidance on current thinking on drug transporters with a particular focus on clinical relevance. This guidance is similarly based on decision trees which can be used to assess the potential risks of drug interactions. While generic decision trees such as these can help, it is clear that a customized strategy must be built for each clinical drug candidate to mitigate the risks. There is also a clear need for such understanding to be brought earlier into drug discovery where it is easier to change the molecule for an improved candidate.[59]

1.23.4 Target and Off-Target Engagement

Having obtained evidence that a candidate drug molecule is present at or in the vicinity of the target, the second pillar requires evidence of target engagement. It is also important to consider the potential for off-target engagement which may lead to toxicity. Evidence that

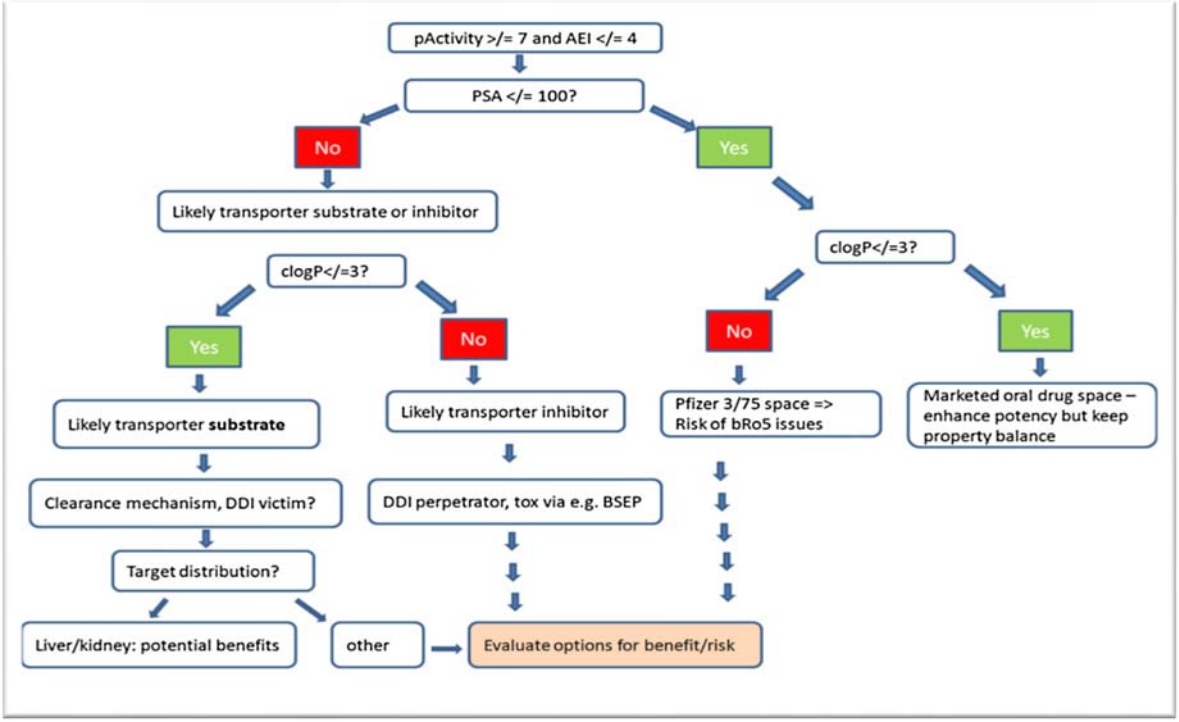

Fig. 8 Decision tree for use of ADMET efficiency index (AEI) in alerting to potential transporter issues. Based on Barton, P.; Riley, R. J. *Drug Discov. Today* **2016**, *21*, 72–81.

the compound binds to the required target in cell free, biochemical, or biophysical assays will most likely have been used as part of the initial compound or compound series selection and subsequent potency optimization. However, demonstrating that the compound effectively engages the target in cells and then in vivo, firstly in animals and then in clinical studies, can be difficult. This is especially an issue if there is an unexpected drop or total loss of activity. Provided the compound has been shown to be present at the target, then the most obvious explanation must be that the target protein is somehow different to that which was used for biochemical studies (e.g., due to posttranslational modification—PTM) or there are differences in the concentration of cofactors or reactants (e.g., ATP). Bunnage et al. have cataloged both target and compound related issues relevant to this pillar as summarized here.[60]

Target related issues

- Subcellular distribution of target may be different to that anticipated from transcriptomic or proteomic studies due to translocation or compartmentalization into organelles.
- Target exists as isoforms, splice variants, or PTMs which may also differ in different species or tissues.
- Endogenous ligand concentration or interaction in disease state may be different to that in healthy tissue.
- The target protein may be part of a larger complex in vivo which modulates its behavior in a different way to how the protein expressed for biochemical experiments behaves.
- The pharmacodynamic effect of a covalent or degradation promoting drug will be influenced by the resynthesis rate of the target and this rate may be variable in different situations.
- Target abundance data derived from transcriptomic and proteomic data can be very different.
- Closely related off-target proteins may be key determinants of selectivity.

Compound related issues

- What targets and off-targets does the compound bind to and what efficacy or toxicity consequence does each have?
- Understanding required target occupancy sets expectations about potency and likely efficacious drug concentration required.
- Characterization of binding kinetics can aid in understanding of pharmacodynamics.

Early signs of off-target engagement can be recognized by profiling compounds of interest in a panel of in vitro safety-related drug attrition assays. Such methods for in vitro pharmacological profiling have recently been reviewed using experiences from four major pharmaceutical companies (AstraZeneca, GlaxoSmithKline, Novartis, and Pfizer) with the conclusion that the use of a minimal core panel of <60 targets can reduce safety-related attrition of drug molecules during drug discovery.[61] Assays focussed on whole cell or organism phenotypic assays can also be used, but these will likely need target deconvolution to determine the specific off-targets. Traditionally, this has been a challenging task, but a number of significant new technologies have been recently introduced which can help to deconvolute the results from phenotypic assays and provide evidence of target engagement (for both "on" targets and "off" targets) through direct observation rather than relying on downstream intrinsic or engineered pharmacology readouts. Phenotypic screening has seen a resurgence of interest in recent years, prompted in part by the analysis of Swinney and Anthony which showed that first in class drugs have historically been discovered more often through phenotypic screening than through target-based approaches.[62] This conclusion has been challenged by more recent work from Eder et al. which takes into account the lag time in drug discovery whereby the impact of target-based approaches is only recently being seen.[63] With this current renewed interest in using phenotypic screening to source new points of effective intervention in pathways and molecules that can affect this, it is vital that appropriate cell-based assays are set up. Useful guidance on the value of getting the right stimulus, cell/tissue type, and readout to ensure the most faithful reproduction of the disease situation has been provided by Vincent et al.[64] Designing assays with an endogenous stimulus using relevant human disease cells/tissue without over engineering the readout so that the assay is still fit for purpose in high-throughput screening is considered the pinnacle of design.

Techniques that are now routinely used to deconvolute points of intervention on biological pathways include pull-down experiments where compounds of interest are immobilized on solid support (e.g., with kinobeads[65]) and used to identify proteins from lysates. Stable Isotope Labelleing with Amino acids in Culture (SILAC)[66] or isobaric Tags for Relative and Absolute Quantification. (iTRAQ)[67] enhanced mass spectrometry methods enable such studies to be performed at a proteome-wide scale. Such approaches are even more powerful when combined with whole genome sequencing[68] and functional genomics.[69] The ever-increasing sensitivity of modern mass spectrometry now enables unbiased open proteomics[70] and similar technical advances in genomic sequencing down to, for example, single molecule and single cell levels,[71] continue to enhance capabilities in these areas for target deconvolution. The complementary use of shRNA-based gene knock out, suppression, or overexpression techniques is also now being widely used to confirm the significance of the deconvoluted targets. The advent of gene editing methods such as Zinc fingers, Talens, and CRISPR-Cas9 continues to bring increasingly powerful and specific tools to the armory for target engagement and identification studies.[72]

For situations where the target is known and confirmation of effective target engagement is required, a number of recently introduced protocols may help. These rely on compound-induced stabilization of the target protein inside living cells. Such compound-induced stabilization protects the protein from aggregation; the stabilization is detected by having preengineered the protein to provide a readout of the amount of protein remaining in solution. Two such methods are fragment complementation using β-galactosidase (InCell Hunter technology) or time-resolved fluorescence resonance energy transfer using affinity-tagged proteins (NanoLuc technology) and they have both been effectively used to show target engagement in bromodomain studies.[73,74]

A more recent approach to the problem of demonstrating target engagement in cellular or in vivo systems is the cellular thermal shift assay (CETSA) pioneered by Nordlund's group[75] (see **Fig. 9**). Again, this relies on ligand-induced stabilization against thermal

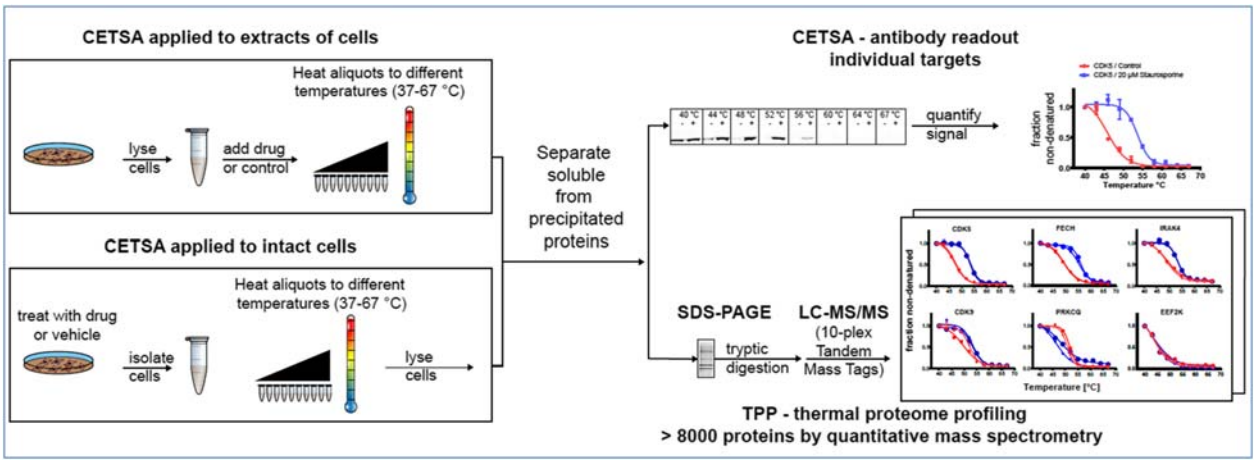

Fig. 9 Cellular thermal shift assay (CETSA) and thermal proteome profiling (TPP) modalities. Figure courtesy of Friedrich Reinhard, GSK Cellzome, Heidelberg.

denaturation but does not require protein engineering to introduce a label onto the target protein of interest. Instead the stabilized protein that remains in solution at different temperatures is monitored with a western blot readout, so all that is required is a high affinity and specific antibody for the protein of interest to enable a readout of the melting temperature (T_m) of the protein. Such assays can either be run at several temperatures and constant ligand concentration or at a selected elevated temperature with increasing ligand concentration so as to get a more classical dose response curve. However, as with all T_m-based assays, the experiment is performed on systems that are not at equilibrium and thus it is not easy to get a true binding affinity.

The use of the antibody readout for CETSA limits the experiment to a specific predefined protein, but this limitation can be addressed through the use of mass spectrometry-based proteomic studies and the thermal proteome profiling (TPP)[76] approach. In TPP, no cell engineering is required and thermal profiles for up to 7000 proteins in their native cellular environment can be performed to identify the direct targets of compounds in cells or homogenates, as well as downstream effectors. Huber et al. used the TPP method to profile targets of the drugs methotrexate and (*S*)-crizotinib and the metabolite 2′3′-cGAMP; in the latter case, they identified the 2′3′-cGAMP cognate transmembrane receptor STING which is involved in immune signaling.[77] The power of the method for identifying off-target engagement is illustrated in a study by Klaeger et al. which revealed ferrochelatase as a common off-target of kinase inhibitors.[78] The main limitation of the CETSA and TPP approaches is that not all interacting ligands cause stabilization (or destabilization, which can also be detected) so there will likely be false negatives in these unbiased/open proteomic studies. This may be ameliorated if downstream stabilization of a protein in a biological pathway occurs, so indicating that the compound engages somewhere in the pathway. A current limitation is that membrane-bound proteins, and possibly those in larger complexes, are often difficult to study as the method relies on aggregation of unstabilized protein followed by subsequent detection of that remaining. This may not occur in membrane systems, which serve to keep the protein folded in the first place. This limitation is likely to be overcome by further development of the protocols for handling membrane-bound targets.[79]

1.23.5 Pharmacokinetics and Pharmacodynamics

The third pillar focuses on the lack of efficacy which is all too often the cause of failure in Phase II trials. While historically, drug metabolism and pharmacokinetic properties have been cited as the reasons that oral compounds fail and have been the subject of several reviews,[80–82] more recent studies have shown that the survival of new molecular entities is now more significantly impacted by insufficient or lack of clinical efficacy in Phases II and III.[83] These authors also indicated that the attrition due to lack of efficacy in Phase II was higher in the 2011–12 analysis verses a previous analysis in 2008–10. A lack of biological efficacy continues to be a root cause of attrition in Phase II as highlighted in the publications by Hay et al.[84] as well as the studies from the Pfizer and AstraZeneca groups already summarized earlier.

Human dose prediction has been recognized as an important parameter in molecule selection.[85] The consequent recent emphasis on earlier effective dose prediction prior to selecting a candidate molecule has prompted an improved understanding of the balance of a molecule's intrinsic potency, pharmacokinetic, pharmacodynamic, and toxicological properties and how such properties can be predicted.

A great deal of effort has been focused on accurate methods for predicting human pharmacokinetic parameters including clearance and scaling from animal exposure data, with varying levels of accuracy.[86] These methods can be described as:

1. allometry-related methods and include simple allometric scaling in a single species such as rat, dog, and or monkey or in multiple species, scaling corrected by various factors such as life span, intrinsic clearance, and/or plasma protein binding;

2. methods that focus on in vitro hepatic clearance, for example, the well-stirred model; and
3. physiologically based pharmacokinetic (PBPK) prediction methods using both in vitro and in vivo data.

These methods have been the subject of review articles and regulatory guidance. The FDA guidance on first human dose does not explicitly mention pharmacokinetic prediction but recommends a human dose estimation method which is consistent with single species allometry and assumes the same bioavailability between human and the nonhuman species. Allometry, a method that has been used routinely for many years for human pharmacokinetic prediction, has been explored retrospectively using 50 compounds for which it was shown that using a single species approach was as accurate or more accurate than using multi-species allometry.[87] However, work from Goteti et al. evaluating 45 different compounds contradicted this finding, suggesting that two species scaling is useful for prediction purposes and that the prediction of clearance from three species was far more accurate than two species scaling.[88] Yet others have indicated that the prediction from allometry suffers from a lack of predictive power.[89] In practice, since monkey data are now not routinely generated for small molecule compounds, only two species are usually available for prediction, which makes the allometry approach challenging.

More mechanistic methods, such as PBPK, have been suggested to perform no better than allometry in accurately predicting human pharmacokinetics.[90] PBPK estimate the dose required at the target tissue by taking into account the rate of absorption into the body, the distribution and retention in tissues, the metabolism and excretion of the compound based on the relationship between physiological, physicochemical, and biochemical parameters and is required to provide insights to PK and pharmacokinetic and pharmacodynamics modeling (PKPD) when a target is located in a tissue. The application in drug discovery has been reviewed.[91] The use of PKPB in regulatory submissions to support dose selections has also been explored[92,93] and in addition the value of PBPK in designing clinical studies has been reviewed.[91] However, these pharmacokinetic-based methods do not take into account the pharmacology of the compound when determining the initial dose, which is an essential consideration when progressing to the clinic. More recently human dose prediction has been recognized as an important parameter in molecule selection in the early stages of drug discovery.[85] These authors validated a method to predict human dose and free C_{max} for a number of molecules using in vitro data and predicted parameters which were incorporated into a pharmacokinetic model. The authors further developed the work of McGinty et al. who were able to predict clinical doses taking into account all parameters contributing to human pharmacokinetics; clearance, volume of distribution, protein binding (fraction unbound), bioavailability, and dosing interval assuming that efficacy would be observed if unbound plasma concentrations exceed an in vitro measure of potency.[94] This work relies on the use of in vitro intrinsic clearance data produced in vitro using human tissue and has been supported by other workers.[87,95,96] However, the work of McGinty et al. includes the use of in vivo preclinical data. Page et al. enhanced and developed the dose prediction methodology of McGinty et al. without the use of in vivo data so that it could be reliably used in the early stages of drug discovery to select compounds for progression earlier.[85] These authors were able to produce a reliable human dose prediction across a wide range of chemistry with the use of in vitro data and QSAR-predicted parameters. One of the challenges of the approach of Page and colleagues is the use of human tissues. A recent survey highlighted a number of challenges to a wider uptake, including regulatory barriers, supply issues, practical, and scientific barriers.[97] However to aid in chemical design and influence early drug discovery, the use of in vitro approaches will be key. In addition these in vitro approaches have limits when exploring low clearance compounds which will require further work.[98] Nevertheless, the approaches defined by McGinty and Page represent significant progress. The science of human pharmacokinetic predictions has continued to develop but at times has been limited by the fact that we are unable to discriminate between closely related compounds, that additional preclinical data adds no further value to the prediction, and that the quest for potency associated with novel targets pushes the physicochemical properties to a challenging space where human pharmacokinetic properties are difficult to assess. These challenges make prediction of human parameters open to challenge and to address these challenges alternative strategies such as microdosing using subpharmacological doses can be considered.

The term microdosing refers to a pharmacokinetic study where the dose is administered at a subpharmacological level and where the focus is predominately on analysis of pharmacokinetic parameters.[99] This approach requires a dose of either 1/100th of the known active dose or < 100 μg total dose and therefore requires a reduced toxicology package comprising a single dose in the rodent via the clinical route of administration for progression. If the total dose is < 500 μg, then a 7-day rodent study is required administering the dose via the clinical route. The requirements for these exploratory clinical studies are detailed in the International Conference on Harmonisation (ICH) guidance documentation.[100] A key advantage of microdosing studies is that they enable early evaluation of candidate molecules when the preclinical data in animal species is conflicting, leading to wide variability in human pharmacokinetic predictions and therefore the best approach is to understand the outcome in human. Additional advantages include less animal use, less drug requirements, and less time to acquire human data. The endpoints following an intravenous dose are clearance, volume, and half-life and following an oral dose the absolute bioavailability can be determined when combined with intravenous dosing. However, when to use this approach has attracted some discussion as the key assumption of microdosing is that the pharmacokinetic parameters determined using the microdosing approach are predictive of the pharmacokinetics of the efficacious dose.[101] Work by Rowland indicates that the number of microdose studies has increased significantly between 2002 and 2011, the rationale for this being the lack of success of approaches such as allometry and PBPK to predict human pharmacokinetics from preclinical and in vitro data.[102] There has also been some debate on the additional cost and time required to complete the microdose studies before completing the full regulatory package for a first time in human study. Furthermore, data from Bosgra et al. showed that nonlinear kinetics between an efficacious dose and a microdose could be anticipated from preclinical data. These authors also presented a strategy that could be utilized in the decision to progress with a microdose study as part of the development

of a drug candidate.[101] The improvement in analytical technologies such as liquid chromatography coupled with tandem mass spectrometry (LC MS-MS) and accelerated mass spectrometry (AMS) may provide the tools which could enhance the use of microdosing although the AMS approach would require the use of trace amounts of a ^{14}C radio isotope-labeled compound.[103]

The need to improve our understanding of the drivers of efficacy has been highlighted as key to advancing drug discovery. PKPD and simulation is an important tool in understanding the efficacy of a molecule earlier within the drug discovery process.[104] PKPD analysis quantitatively interrelates drug behavior and its effects on the biological systems using mathematical functions. Mechanism-based PKPD modeling allows the quantitative analysis of identified species differences in factors such as pharmacokinetics or in vivo efficacy studies, enabling the relationship of concentration to a pharmacodynamic effect from often variable in vivo preclinical efficacy data. Recently, there have been several examples published outlining the use of PKPD analysis to translate findings in preclinical experiments to the human situation.[105–108] Ultimately the development of PKPD models enables integration of all available data to develop a prospective simulation. As described previously, the early assessment of pharmacokinetics has been shown to reduce attrition due to poor or in appropriate pharmacokinetics[80–82] an improved understanding of drug effect using preclinical PKPD analysis offers an important tool to potentially reduce attrition due to a lack of efficacy.[23,25] Schuck et al. completed a survey of the pharmaceutical industry members of the International Consortium for Quality and Innovation in Pharmaceutical development and showed that the majority of pharma companies in the group used preclinical PKPD in all therapy areas and an important goal was the selection and optimization of doses and dose regimens including the prediction of efficacious human doses.[104] These authors highlighted oncology as one therapeutic area where PKPD had a major impact; most companies had observed an impact of the preclinical PKPD analysis; and preclinical PKPD analysis was increasingly used in regulatory submissions. The authors also reported that there was an opportunity for PKPD modeling to impact future drug discovery and development. Furthermore, an opportunity exists to incorporate the consistent use of systems pharmacology and physiologically based PK models with PKPD modeling.

An additional strategy to the approaches to reduce late-stage efficacy failures outlined earlier is to consider the impact of biomarkers of both efficacy and safety. The strategy is to identify a biomarker or biomarkers that can be objectively measured and evaluated as an indicator of a change in a biological process in response to a drug intervention. A biomarker is defined as "a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention."[109] Once validated, a biomarker can play a key role in disease diagnosis, the prediction of disease progression, and the monitoring of a response following drug intervention. The use of biomarkers is recommended by regulators in the development of a chemical entity and is also a key focus of the Strategic Research agenda for the European Union Innovative Medicine Initiative. The use of biomarkers has been the subject of an extensive review.[110] Further work to assess the next generation of biomarkers has been described by Caberlotto and Lauria.[111] These authors suggest that biomarkers and companion diagnostics will require technologies that are able to integrate the advances in high-throughput biology in the field of –omic technologies such as genomics, proteomics, metabolomics, and transcriptomics. This approach will help to further reduce failure and enhance access to personalized medicine for patients.

1.23.6 Target Choices

Target choice is fundamental to the likely outcome of a drug discovery program. The prospect of improved understanding of the translatability of a hypothesis into a drug is being driven by the deeper understanding of genetic linkage of diseases to targets and pathways, and this can be referred to as improved biological tractability of a target.[112] However this is not sufficient to guarantee success, because the ligandability of the target is equally important. Ligandability is the likelihood that a drug-like molecule can be found to effectively engage with the target to illicit the biological response needed. Both chemical and biological tractability of a target are therefore essential.

Historically, many drugs have been targeted at proteins that can be accessed extracellularly and when their 3D structures are examined it is often found that the binding sites are amenable to small, Lipinski-compliant Ro5 small molecules. As the history of drug discovery has shown, this region of chemical space is also compatible with the properties required for traditional once or twice a day oral delivery. Clearly there are many effective nonoral drugs, though a high proportion of these are for extracellular targets. However, there is increased interest in intracellular proteins as potential targets and in particular those involved in PPIs. Many PPIs are considered to have low chemical tractability because they are intractable to traditional Lipinski-compliant small molecules. Doak et al., using X-ray structural information, have analyzed the properties of complexes to understand more about the nature of binding sites for bRo5 molecules compared to Ro5 compliant molecules.[113] Not surprisingly, larger molecules (e.g., macrocycles) have lower local curvature and thus will have higher contact area which allows them to bind to flat sites. Analyses by the Morelli[114] and Blundell[115] groups have confirmed these types of findings from PPI inhibitor databases (e.g., 2P2I, TIMBAL) which include a wider range of nonclinical molecules. PPI-disrupting interacting small molecules (where they can be found) are generally larger, have more sp3 character, and are more lipophilic than non-PPI-interacting compounds.

The challenge of finding drug-like ligands for difficult targets raises the question of whether such targets should be considered ligandable and ultimately "druggable" in the first place. The genomic revolution is leading to a rapidly growing body of biological and disease knowledge, but some of the best biologically and genetically validated targets (e.g., PCSK9) are proving intractable to small molecule intervention. In the case of PCSK9, of course, whose binding to the Low Density Lipoprotein (LDL) receptor is an extracellular event, then intervention by injected antibodies is proving an effective strategy.[116] Understanding as early as possible the

likely tractability of an intracellular target to small molecule intervention can be used to help reduce attrition due to failure in hit generation. Methods for assessing the ligandability of a target by either experimental methods such as fragment screening[117] or in silico[118] analysis are important tools for carrying out such assessments.

With such a high level of attrition prevalent in drug discovery, it can often appear that there is a significant amount of luck associated with the small proportion of projects that are ultimately successful in bringing a new drug to patients. While serendipity often does play a role, it is also true that "chance favors the prepared mind." Put another way, improving the odds of success by exploring fully the most statistically likely approaches first is surely the most fruitful approach to adopt for improving return on investment in the pharmaceutical industry. However, the desire for novelty in new therapeutics and technologies, almost by definition, drives us to the unknown regions of science where low probability of success is unfortunately intrinsically too often the norm until sufficient experience is gained. However while new biology opportunities continue to unfold, it is essential that quality and rigorous methods of drug discovery are applied if low probabilities of success are going to deliver anything. We hope that this article has helped to ensure that the learnings of the recent years continue to be valued and applied as we enter into an era of renewed hope in turning the advances in basic biology and understanding into, efficacious and affordable new drugs.

Acknowledgments

We would like to thank the many GSK and other pharma and academic colleagues who have contributed to the ideas that we have set out to express in this article. In particular we thank Peter Marshall, Andy West, Andy Harrell, Friedrich Reinhard, Valeriu Damian, and Anthony Taylor for help with diagrams and thoughtful input.

1.24.1 Relevance of Carbohydrates

This article will describe how carbohydrates in their different forms (glycans, glycoconjugates, or glycomimetics) can be considered as very interesting tools in chemical biology and medicinal chemistry and the perspectives of their use in drug development with emphasis on those examples already approved for use or under clinical trials. This article does not intend to be an exhaustive collection of all potential carbohydrate drug candidates, but a compilation of significant and illustrative examples of those carbohydrate-based compounds that represent novel structures with promising activity to be considered as potential drug candidates in the future.

Carbohydrates are a very important class of biomolecules present at the surface of most of eukaryotic cells as glycoconjugates (glycolipids and glycoproteins) as well as in the extracellular space.[1] Among other important functions, they are responsible for cellular communication and protein folding. They have key roles in many biological processes such as inflammation, angiogenesis, pathogen infection, immune modulation, cell development, fertilization and embryogenesis, tumor progression, and metastasis.[1] In fact, some of these glycan structures have been selected as specific biomarkers for diseases such as congenital disorders and cancer and other pathological processes. For this reason, carbohydrates, involved in many human diseases and disorders (depicted in Fig. 1), can be considered as potential targets for drug development.[2]

The term glycome (similarly to proteome and genome) has been recently coined to describe the whole glycans within a biological system. Nowadays, a new "omics" comes on the scene, glycomics, which describes the structures and functions of glycans in a biological system (Fig. 1).[3] Glycans encode a large amount of molecular information that is decoded by lectins, proteins able to read out this information through their interaction with these glycans. The complexity of the glycan structures present in nature, their heterogeneity, and the difficulty to synthesize them in amounts enough to study the structure–activity relationships have delayed the boom of the glycoscience.[4] The direct consequence of this is a deficient development of carbohydrate-based therapeutics over the last years. Advances in both analytic techniques and the synthetic methods (in solution, enzymatic, or in solid phase, manual or automatic) have finally allowed access to pure complex carbohydrates that facilitated the understanding of carbohydrate function and their activity in nature. This has opened new avenues of remarkable interest in chemical biology and medicinal chemistry for the development of carbohydrate-based therapeutics and diagnostics.

Glycans are biomolecules with very interesting properties from the point of view of drug development such as low toxicity and poor immunogenicity; however, the chemical and physical properties of carbohydrates (specially, their polarity and their instability against degradation by glycosidases) have limited, in some cases, their use as drugs. Also, carbohydrates frequently interact with their receptors with weak affinities that are compensated in nature by multivalent interactions through the presence of multiple copies (multivalency) of both ligands (carbohydrates) and receptors (lectins). All these points lead to consider these molecules as poor candidates for drug development by the pharmaceutical industry. In fact, the percentage that represents carbohydrate-based drugs in the pharmaceutical market is still very small. In spite of all the drawbacks concerning the use of carbohydrates as drugs and the reticence that medicinal chemists have to work with these polar molecules, there are some remarkable examples in the market that demonstrate that this kind of molecules can be used effectively. As reviewed recently, more than 130 natural carbohydrate drugs are present in four pharmacopeias (the United States, China, Japan, and EU) as drugs or as excipients.[2] These

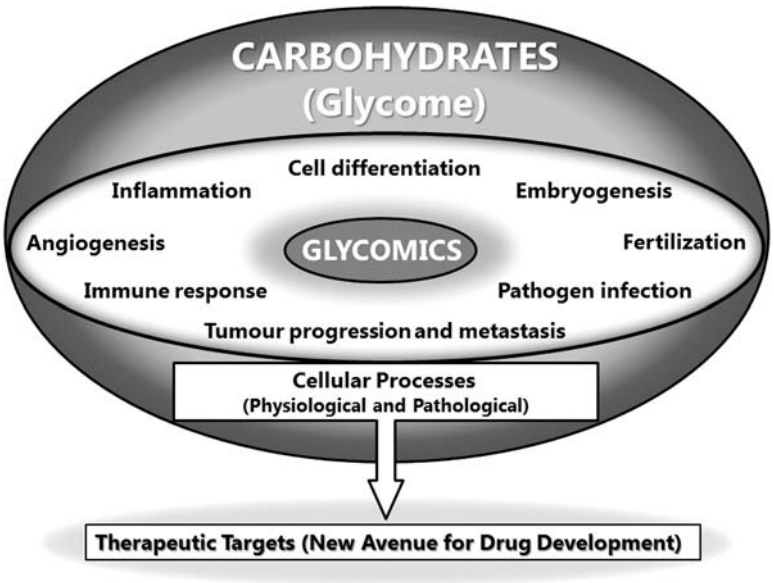

Fig. 1 The carbohydrate world as a source for the development of therapeutics.

drugs include natural compounds from simple monosaccharides as glucose to complex polysaccharides as heparin. In some cases, the biological target is not known, although the carbohydrate drug is active against a particular disease. Therefore, a deep understanding at molecular level of the carbohydrate role in biological processes and the mechanism of action of these natural ligands should lead to new synthetic promising compounds to increase, in following years, the arsenal of therapeutics against a large variety of diseases.

1.24.2 Current Uses of Carbohydrates in Drug Discovery

A large variety of carbohydrates and glycomimetics are available as drugs or are in clinical phases as promising candidates. This pool of carbohydrate-based candidates shows very different structures, from simple monosaccharide derivatives to complex polymers. The different structures of these compounds, the biological targets, and the diseases where they can be used are so complex and diverse that many different classifications are possible. In this section, the organization is based on biological targets of the carbohydrate drugs, with the exception of the glycosaminoglycan (GAG) derivatives, which represent a large family of drugs with different targets and in some cases without well-defined ones.

Heparin, one of the first glycans with medical applications, is a very popular drug. This oligosaccharide, a highly sulfated GAG clinically used since the 1930s to treat thrombosis in humans, is a classic natural carbohydrate-based drug that is still commonly used.[5] Heparin and derivatives are carbohydrate-based drugs that do not have, strictly speaking, a target enzyme, but modulate the activity of an enzyme through an interaction with one of its inhibitors. The mechanism of action of heparin is based on its binding to the enzyme inhibitor antithrombin III,[6] causing a conformational change that results in its activation. The activated antithrombin then inactivates thrombin and other enzymes that promote coagulation, most notably factor Xa.[7] This glycan is in fact a heterogeneous mixture of complex structures obtained from natural sources. The main source of heparin is porcine mucosa, although relevant advances have been performed in the last decade to prepare synthetic heparin[8] as well as low-molecular-weight heparin (LMWH) derivatives from simple precursors.[9] In 2008, contaminated batches of heparin and LMWH led to an international health crisis, emphasizing the need of a reliable method for generating well-defined (homogeneous) heparin therapeutics.[10] In this context, a series of low-molecular-weight carbohydrate-based drugs have been developed and clinically approved as alternative antithrombotic agents (Table 1 and Fig. 2). A relevant example is fondaparinux (Arixtra, **1**; Fig. 2),[11] the first synthetically well-defined small-molecule heparin derivative, on the market since 2002. Fondaparinux (**1**) is a pentasaccharide widely used for the treatment of deep vein thrombosis. Its chemical structure is almost identical to the antithrombin-binding pentasaccharide sequence found in natural heparin and heparan sulfate. It is noteworthy that some low-molecular-weight derivatives present additional advantages, such as quality control manufacturing, enhanced potency, and reduced risk of thrombocytopenia, which makes them more selective and reduces adverse events.

Apart from heparin, other common GAGs with applications in the pharmaceutical industry are hyaluronic acid (HA, also known as hyaluronan), chondroitin sulfate, dermatan sulfate, and keratan sulfate. In nature, GAGs are often covalently linked to a protein forming proteoglycans, which are located in the membranes of all animal tissues, on the surface of cells, or in the extracellular matrix, where they perform a variety of biological functions.[18]

Table 1 LMWH-based drugs with antithrombotic and anticoagulant activity currently on the market

Hyaluronic acid repeating unit (**5**)

Fig. 3 Chemical structure of HA (**5**).

Some of the biological roles of GAGs have been exploited for the preparation of drugs with applications in tissue engineering and repair. For instance, HA has been used therapeutically for several years. HA is a nonsulfated, high-molecular-weight GAG made of repeating units of disaccharides composed of glucuronic acid and *N*-acetyl-glucosamine linked by a glucuronidic β(1 → 3) bond (**5**; Fig. 3).[19] It is naturally produced by hyaluronan synthases and is degraded by a category of enzymes called hyaluronidases. HA can be found both in the skin, where it plays a major role in tissue repair, and in cartilage and connective tissues, where it works as a lubricant and as a constituent of the extracellular matrix.

In this particular context, Anika Therapeutics has launched several drugs based on HA to the market (mainly in Europe), with many others in the pipeline (Table 2).[20] Anika Therapeutics uses naturally sourced HA, which is properly manufactured in order to obtain a purified, high-quality, and medical grade HA. The company offers therapeutic products in orthobiologics, dermatology, surgery, ophthalmology, and veterinary. One of the most successful products is Orthovisc, employed for the treatment of osteoarthritis. The mechanism of action is complex and most likely involves both the viscoelastic properties of the polymer and effects on synovial cells in the joint capsule. In addition, HA has been proved to suppress cartilage degeneration, act as a lubricant, and reduce pain perception.

Finally, it is important to remark the growing use of HA in popular beauty treatments such as soft tissue augmentation or as fillers for the "treatment" of the aging face.[21]

Table 2 Some examples of HA-based drugs developed by Anika Therapeutics[20]

Trade name	*Application*	*Description*	*Clinical status*
Orthovisc	Orthobiologics. Treatment of joint pain caused by osteoarthritis	High-molecular-weight injectable HA	Approved worldwide
Monovisc	Orthobiologics. Treatment of joint pain caused by osteoarthritis	HA single-injection treatment. Delivers the maximum dose of HA currently available in any single-injection treatment	Approved worldwide
Hyalofast	Orthobiologics. Treatment of lesions in the knee and ankle	HA-based implant for cartilage regeneration. It supports mesenchymal stem cell attachment, proliferation, and differentiation	CE-marked
Hyaloglide	Orthobiologics. Prevention or reduction of adhesions or fibrosis after surgical procedures	Auto-cross-linked HA gel that creates an antiadhesion barrier that keeps the adjacent tissues separated while repair occurs after surgery	CE-marked
Hyalomatrix/ Hyalomatrix PA	Dermal. Suited for a range of wounds that include pressure ulcers, diabetic foot ulcers, and deep second-degree burns	Pad composed of a wound contact layer made of a derivative of HA with an outer layer composed of a semipermeable silicone membrane. The wound contact layer acts as a 3-D scaffold for cellular invasion and capillary growth	Approved worldwide
Hyalofill-R	Dermal. Treatment of deep exuding wounds, sinuses, and fistulae	Absorbent and soft fibrous rope composed of an ester of HA. In contact with wound, it turns into a gel that keeps a wet environment, promotes wound healing, and allows a painless removal of the dressing	FDA-cleared and CE-marked
Elevess/Hydrelle	Dermal. Correction of facial lines and wrinkles	Injectable dermal filler made of cross-linked HA that contains the anesthetic lidocaine	Approved worldwide
Anikavisc	Ophthalmology	Viscoelastic for use in eye surgery	Approved worldwide
Hyaloss matrix	Dental surgery. Promotes bone graft application in the bone defect	Matrix constituted by bundles of fibers entirely made of a solid derivative of HA	CE-marked
Hyvisc	Veterinary. Treatment of noninfectious synovitis associated with equine osteoarthritis	HA-based viscous fluid	FDA-approved
Cingal	Orthobiologics. Treatment of pain caused by osteoarthritis of the knee	Palliative treatment	About to be launched

1.24.2.1 Modulation of Enzymes

Glycoconjugates (glycolipids and glycoproteins) are posttranslational modifications of lipids and proteins, respectively, mediated by specific enzymes, the so-called glycosyltransferases. The improper operation of these enzymes leads to aberrant glycosylation patterns, one of the most significant marks of several pathologies such as cancer, congenital disorders, and autoimmune diseases. Glycomimetics able to interact and interfere with the activity of these enzymes have been developed as therapeutics to be applied in the treatment of these pathologies. Representative examples of drugs marketed or under clinical studies will be highlighted in the succeeding text.

One common approach toward the preparation of novel carbohydrate-based therapeutics is the rational design of low-molecular-weight compounds able to mimic (glycomimetics) the bioactive conformation of the native functional carbohydrate ligand in its target binding site.[2,22] Probably, the most well-known examples are the glycomimetic inhibitors of the influenza virus neuraminidase enzyme (NA).[23] The antiviral drugs oseltamivir phosphate (Tamiflu, Hoffman La Roche, **6**; Fig. 4)[24] and zanamivir (Relenza, GlaxoSmithKline, **7**; Fig. 4)[25] perfectly illustrate the rational design of potent and effective glycomimetic drugs. These drugs are indicated for the treatment of both influenza A and B (flu) in adults and children. Their mechanism of action is based on mimicking the high-affinity transition state of the sialic acid substrate before being cleaved by the influenza NA, rendering the influenza virus unable to escape its host cell and infect others.

Carbohydrate analogs that target α-glucosidases, intestinal enzymes that release glucose from larger polysaccharides, have also been developed for the treatment of diabetes. Examples of these drugs are miglitol (Glyset, Bayer, **8**; Fig. 5),[26] voglibose (Glustat, Takedo/Abbott, **9**; Fig. 5),[27] and acarbose (Glucobay, Bayer, **10**; Fig. 5).[28] Voglibose (**9**; Fig. 5) was first launched in 1994 and is an α-glucosidase inhibitor used for lowering postprandial blood glucose levels in people with diabetes mellitus. Acarbose (**10**; Fig. 5) is a modified tetrasaccharide of microbial origin that acts as a reversible α-glucosidase inhibitor, specifically of those enzymes in the brush border of the small intestine and pancreatic α-amylase.

Similarly, phosphomannopentaose sulfate (PI-88, Progen/Medigen Biotechnology Corporation, **11**; Fig. 6)[29] inhibits the enzyme endo-β-D-glucuronidase heparanase, thereby interfering with the heparanase-mediated degradation of heparan sulfate proteoglycans in extracellular matrices, an important step in the metastatic process. Heparanase expression has been directly correlated with the metastatic spread of various tumors.[30] PI-88 (**11**; Fig. 6) is a mixture of oligosaccharides mimicking heparan sulfate that exhibited antirecurrence and antimetastatic activity to hepatocellular carcinoma in preliminary clinical trials.[31] Phase I and II clinical studies have demonstrated good safety profiles and promising efficacy in the treatment of liver cancer,[32] while phase III clinical trials are currently being carried out.

Acarbose (*Glucobay*) **10**

Fig. 5 Chemical structures of α-glucosidase inhibitors employed in the treatment of diabetes.

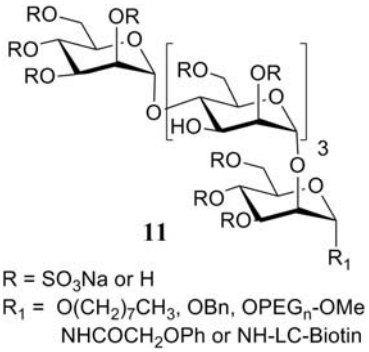

Fig. 6 Chemical structure of phosphomannopentaose sulfate (PI-88, **11**).

Another relevant glycomimetic that also inhibits carbohydrate biosynthesis is miglustat (Zavesca, Actelion Pharmaceuticals, **12**; Fig. 7), used to treat Gaucher disease and type C Niemann–Pick disease (NP-C). Zavesca was approved in Europe in 2002 and by the US Food and Drug Administration (FDA) in 2003 to treat adults with mild to moderate type I Gaucher disease for whom enzyme replacement therapy is unsuitable.[33] It is also approved for the treatment of NP-C disease in 45 countries, including the European Union since 2009. Miglustat reduces the biosynthesis of glucosylceramide from ceramide through the inhibition of the enzyme glucosylceramide synthase, thus reducing the production of glycosphingolipids in cells. This is expected to slow down or prevent the development of the symptoms of type 1 Gaucher disease and to reduce the symptoms of NP-C disease in adult and pediatric patients.[34]

Finally, another significant carbohydrate-based drug on the market is topiramate (Topamax, Johnson & Johnson, **13**; Fig. 7), employed as an antiepileptic medicine and to prevent migraine headaches.[35] The precise mechanism of action of topiramate is relatively complex and is not completely understood. However, preclinical studies have revealed some properties that may contribute to topiramate's efficacy: this drug blocks voltage-dependent Na^+ channels, increases activity of the neurotransmitter γ-aminobutyrate (GABA) at some subtypes of the GABA-A receptor, antagonizes the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate subtype of the glutamate receptor, and inhibits carbonic anhydrase.

Another vast family of enzyme-modulating carbohydrate-based drugs is composed of natural products that possess glycan components. This group includes chemotherapeutic drugs, antibiotics, and compounds to treat cardiovascular diseases (Fig. 8). Some of these drugs, described in the next paragraphs, are contained within the World Health Organization List of Essential Medicines, which compiles the most important medications needed in a basic health system.

Doxorubicin (**14**) and daunorubicin (**15**) are cytotoxic drugs in the anthracycline family (Fig. 8). These drugs are potent neoplastic agents that bind to nucleic acids, apparently by specific intercalation of the planar anthracycline nucleus with the DNA double helix. This intercalation inhibits nucleotide replication and action of DNA and RNA polymerases. Topoisomerase II-mediated DNA damage is followed by cell death.[36]

Streptomycin (**16**) and erythromycin (**17**) are examples of antibiotics of natural origin for which their sugar moiety is an essential component (Fig. 8).[37] Removal of this carbohydrate residue typically leads to elimination of the drug's therapeutic properties. Streptomycin inhibits both Gram-positive and Gram-negative bacteria and is therefore a useful broad-spectrum antibiotic. It is a bacterial protein synthesis inhibitor and was the first efficient treatment for tuberculosis.[38] In a similar way, erythromycin, an antibiotic of microbial origin used for several infections, hampers the production of functional proteins in bacteria. It induces peptidyl transferase activity and interferes with translocation of amino acids during translation and assembly of proteins. Several semisynthetic antibiotics derived from erythromycin—dirithromycin, clarithromycin (Biaxin, Abbott), and azithromycin (Zithromax, Pfizer)—are currently on the market.[39]

Digoxin (**18**; Fig. 8) is a glycoside used in the treatment of various heart disorders, namely, atrial fibrillation, atrial flutter, and sometimes heart failure that cannot be controlled by other medication.[40] Digoxin's mechanism of action involves inhibition of the Na^+/K^+ ATPase, mainly in the myocardium, which eventually leads to a decrease in heart rate and smooth muscle contraction and vasoconstriction.

1.24.2.2 Lectin Inhibitors

Lectins were first discovered at the end of the nineteenth century as plant proteins capable to agglutinate erythrocytes, a process that later was demonstrated to occur through the specific recognition of the carbohydrates present at the surface of these blood cells. Since then, many members of this family have been identified, isolated, and characterized in a broad range of different species (lectins occur ubiquitously in nature), and nowadays lectins are very useful tools in chemical biology.[41] These proteins received little attention until the discovery of animal lectins implicated in many relevant biological processes. Based on this fact, lectins are considered as very important therapeutic targets for the development of carbohydrate-based drugs. Some of these lectins, selectins, galectins, and C-type lectins, such as dendritic cell-specific intercellular adhesion molecule 3-grabbing nonintegrin (DC-SIGN) among others, have attracted the interest of scientists to develop new drugs. The progress in this field is summarized in the next sections.

1.24.2.2.1 Inhibition of selectins

Selectins mediate the initial attachment of leukocytes to endothelial cells at sites of inflammation.[42] Selectins were discovered in the late 1980s and probably are one of the best known carbohydrate-binding proteins. The selectin family is composed of three members: E-selectin (expressed on endothelial cells), P-selectin (expressed on activated platelets and stored in endothelial cells), and L-selectin (expressed by most leukocytes). L-selectin plays a major role in the trafficking of lymphocytes through the blood and lymphatic system. The L-selectins regulate the attraction of leukocytes to sites of inflammation through the binding of their carbohydrate domains to sialyl Lewis^x (SLe^x) and sialyl Lewis^a (SLe^a) oligosaccharides present on the cell surface.[43] Remarkably, these carbohydrate sequences were originally discovered as cancer-associated antigens and are prognostic indicators of metastatic

diseases.[44] Apart from cancer, selectins take part in many other inflammatory diseases such as rheumatoid arthritis, psoriasis, asthma, transplant rejection, inflammatory bowel disease, and multiple sclerosis (MS), among others.[45] Therefore, selectins are considered very appealing therapeutic targets in oncology and other medical fields.

Initially, strong efforts were made to synthesize small mimetics of SLe^x to inhibit the selectins (Fig. 9). The first selectin antagonist was cylexin (CY-1503, **19**; Fig. 9),[46] developed by the company Cytel, although clinical results were not satisfactory mainly due to a poor oral availability and lack of potency. Structural modifications have been made in order to prepare synthetically simpler structures,[47] like the fucosylated mimetics of SLe^x bimosiamose (TBC-1269, Revotar, **20**; Fig. 9) and rivipansel (GMI-1070, GlycoMimetics/Pfizer, **21**; Fig. 9). Bimosiamose showed promising results in the treatment of asthma, but was discontinued after phase II clinical trials.[48] Rivipansel is about to start a phase III clinical trial to assess its efficacy and safety for the treatment of vaso-occlusive crisis in patients with sickle cell disease.[49]

Interestingly, E-selectins have also been reported to play an important role in the dissemination of hematologic cancers and the homing of leukemic stem cells to the bone marrow. In this context, GlycoMimetics has also launched a small-molecule E-selectin antagonist (GMI-1271), which is currently being evaluated in phase I/II trials in combination with chemotherapy for the treatment of acute myeloid leukemia.

1.24.2.2.2 Inhibition of galectins

Galectins are a family of lectins characterized by a galactose-specific carbohydrate-binding domain that interacts with galactose moieties located on glycoproteins.[50] These lectins are known to be involved in a plethora of biological processes, such as inflammation, immune response regulation, and tumor progression and metastasis.[51] They can be found in cellular compartments or in the extracellular space where they interact with cell surface and extracellular glycoproteins.

To date, 15 different galectins have been identified. Among them, galectin-1 and galectin-3 are the two galectins most frequently involved in pathological processes. In addition, these galectins are overexpressed in several diseases including inflammation and fibrosis and several types of cancer.[52] As a consequence, targeting and blocking galectins may have an efficacious therapeutic effect on some of these diseases. To this end, several strategies have been reported to obtain natural[53] or synthetic derivatives[54] that could behave as effective and safe pharmacological inhibitors.

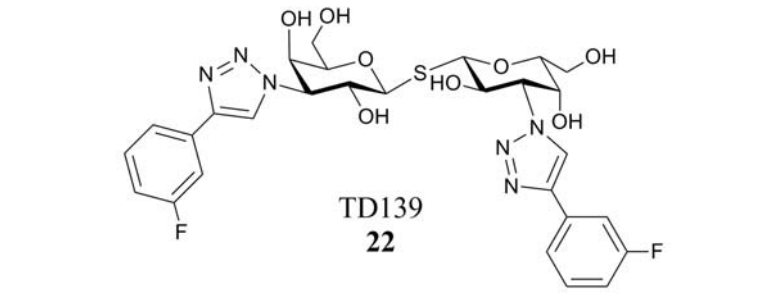
One of the most successful examples is the potent galectin-3 inhibitor (TD139, **22**; **Fig. 10**) developed by Galecto Biotech,[55] which specifically blocks the binding of galectin-3 to carbohydrate structures inhibiting various biological actions like modulation of immune processes and profibrotic activity. TD139 is a small glycan derived from thiodigalactoside that has shown very promising results in clinical trials for the treatment of patients with idiopathic pulmonary fibrosis, an irreversible and fatal lung disease with no effective treatments. According to the studies, TD139 interferes with signaling from receptors for the cytokine *transforming growth factor* (TGFβ), a potent inducer of lung fibrosis, ultimately showing strong antifibrotic potential.[56] In 2015, the US FDA has approved an Investigational New Drug application for the treatment of patients with idiopathic pulmonary fibrosis, and TD130 has entered in phase Ib/IIa trials.

In a complementary approach, Galectin Therapeutics uses naturally occurring carbohydrate polymers to prepare well-defined, pharmaceutical grade polysaccharides that serve as galectin ligands and interfere with their function. This company has developed GM-CT-01 (also known as Davanat, **23**; **Fig. 10**) and GR-MD-02 (galactoarabino-rhamnogalacturonate) as promising galectin inhibitors for the treatment of liver fibrosis, fatty liver disease, diabetic kidney disease, and metastatic melanoma.[57] Davanat is the galactomannan isolated from seeds of *Cyamopsis tetragonoloba*, or guar gum, and subjected to a controlled partial chemical degradation. It was the first polymeric carbohydrate-based drug candidate proved to be an effective ligand for galectin-1.[58]

Due to the interest on targeting galectins and their implication in several diseases as mentioned in the preceding text, nowadays, there is a strong activity in the search of new therapeutics based on galactose derivatives looking for more efficient and selective drugs.

1.24.2.2.3 Inhibition of bacterial lectins: adhesins and toxins

Bacteria express on their surfaces many glycan-binding proteins or lectins (often called adhesins) that show strong and specific binding for carbohydrates expressed on human cells. Such interactions constitute an essential part of the infection pathway, as their primary function is to facilitate attachment or adherence of bacteria to host cells, a prerequisite for bacterial colonization and infection.



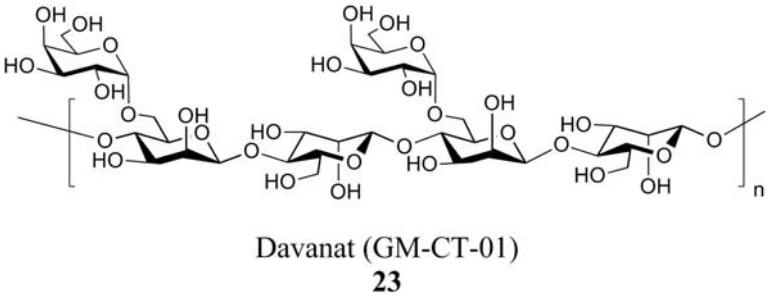


Fig. 10 Chemical structure of the galectin-3 inhibitors TD139 (**22**) and GM-CT-01 (Davanat, **23**).

Bacteria also produce toxins, whose actions often depend on carbohydrate-binding subunits that allow the toxin to combine with host membranes and deliver the active toxic subunit across the plasma. For instance, the family of the AB_5 toxins, important virulence factors for several major bacterial pathogens,[59] are so termed because they comprise a catalytic A subunit (or disease-causing component), which is responsible for disruption of essential host functions, and a pentameric B subunit that binds to specific glycan ligands on the target cell surface.[60] Toxins producing diseases such as cholera or hemolytic uremic syndrome (HUS) can be found within this family. Cholera, still a life-threatening disease in many parts of the world, is caused by the cholera toxin (CT) produced by *Vibrio cholerae*, while *Shigella dysenteriae* and *Shiga toxigenic Escherichia coli* generate shiga toxins (Stx), whose the associated symptoms include diarrhea and hemorrhagic colitis, but it could also result in life-threatening HUS.[61]

In addition to the cytotoxicity of bacterial lectins, it has been suggested that many of them contribute to the formation of bacterial microcolonies and biofilms,[62] thereby promoting colonization of host tissues and being one of the key factors responsible for the virulence and antibiotic resistance of pathogens.

To prevent or suppress infection, soluble forms of human cell surface oligosaccharides or glycomimetics are being investigated to block the initial attachment of microbes and toxins to the cell surfaces. Development of such potential antiadhesive drugs against bacterial infection[63] is emerging as a relevant strategy due to the increasing antibiotic resistance of several bacterium strains.[64] It has also been postulated that, since antiinfective agents rely on disrupting carbohydrate–lectin interactions, any mutation that provides the bacteria with resistance to the antiinfective carbohydrate agents should also render on bacteria unable to bind the host's carbohydrates.[2]

To this end, some monosaccharides have been tested to limit bacterial infection through competition, for example, with LecA (or PA-IL) and LecB (or PA-IIL), main lectins of *Pseudomonas aeruginosa*, an opportunistic pathogen involved not only in a large number of diseases[65] such as septicemia and urinary tract infections but also in lung infections in immunocompromised and cystic fibrosis patients.[66] It was demonstrated that solutions of galactose and fucose, LecA and LecB ligands, respectively, were active against the spread of infection of *P. aeruginosa* in mice models[67] and cystic fibrosis patients,[66] particularly in combination with antibiotics.[68] Adhesion of *P. aeruginosa* to human respiratory epithelial cells was also significantly prevented by human milk oligosaccharides.[69] In addition, other LecA and LecB ligands such as plant- and microbial-derived polysaccharides were identified as candidates with potential applications in gastrointestinal and external infections.[70]

However, difficulties with carbohydrate-based antiadhesion therapies still remain, not only making necessary the development of more potent inhibitors through rational design[71] but also overcoming the low affinity of free carbohydrates for microbial lectins, which may be afforded with optimized multivalent carrier carbohydrates conjugates.[63]

Although reaching submicromolar affinity with monovalent ligands has proved to be a rather complicated task, the use of rational drug design and several medicinal chemistry strategies can strongly improve the affinity of these saccharides in comparison with the natural ligands, providing efficient antiadhesive strategies against bacteria. In this context, hydrophobic aglycon modification is a commonly used approach because hydrophobic interactions are usually possible in the surroundings of the lectin's binding site.[72] For instance, some modified monovalent ligands of FimH lectin from uropathogenic *E. coli* were identified as improved ligands for the bacterial lectin in terms of affinity.[73] This rational design led to one of the best FimH inhibitors to date ($EC_{>90} = 10$ nM), which additionally inhibited the biofilm formation with an IC_{50} value of 43 nM (**24**; **Fig. 11**).[74] A monoamide derivative of the previous inhibitor was also synthesized (**25**; **Fig. 11**) and, although the inhibitory properties were slightly decreased ($IC_{50} = 62$ nM) in comparison with the 3,5-diamide (**24**; **Fig. 11**), such compound appears as a promising candidate after successful in vivo assays.[75]

Another strategy in rational design is introduction on the aglycon derivative of relevant protein's recognition motifs such as those of the serum amyloid P (SAP) protein, an endogenous protein that plays an important role in the clearance of several pathogens.[76] The conjugation of a CT ligand with a proline group (an SAP recognition motif) on the aglycon derivative provided a bifunctional construct that allowed the preorganization of such ligand with the CT B subunits (CTB) and the SAP protein in a ternary complex. This noncovalent and multivalent preorganization enhanced the potency against CTB from an IC_{50} in the high micromolar range, without preorganizing SAP, to submicromolar IC_{50} when noncovalently bound to SAP. It was demonstrated that this increase was promoted by the formation of the CTB/bifunctional ligand/SAP ternary complex in solution.[76] The latter approach was also employed in the optimization of the so-called STARFISH (**26**; **Fig. 12**) and DAISY (**27**; **Fig. 12**) glycodendrimers,[77] the landmark studies in the Stx inhibitor field.

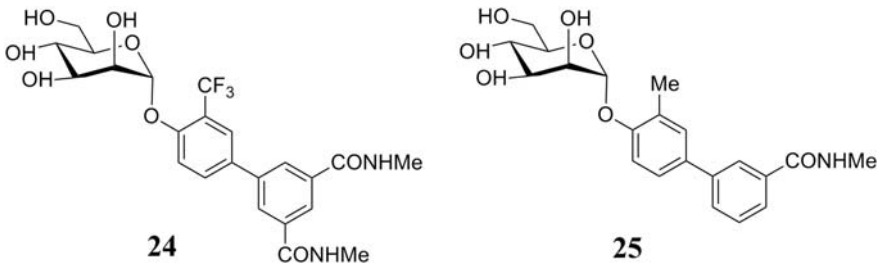

Fig. 11 Lead monovalent inhibitors of FimH.

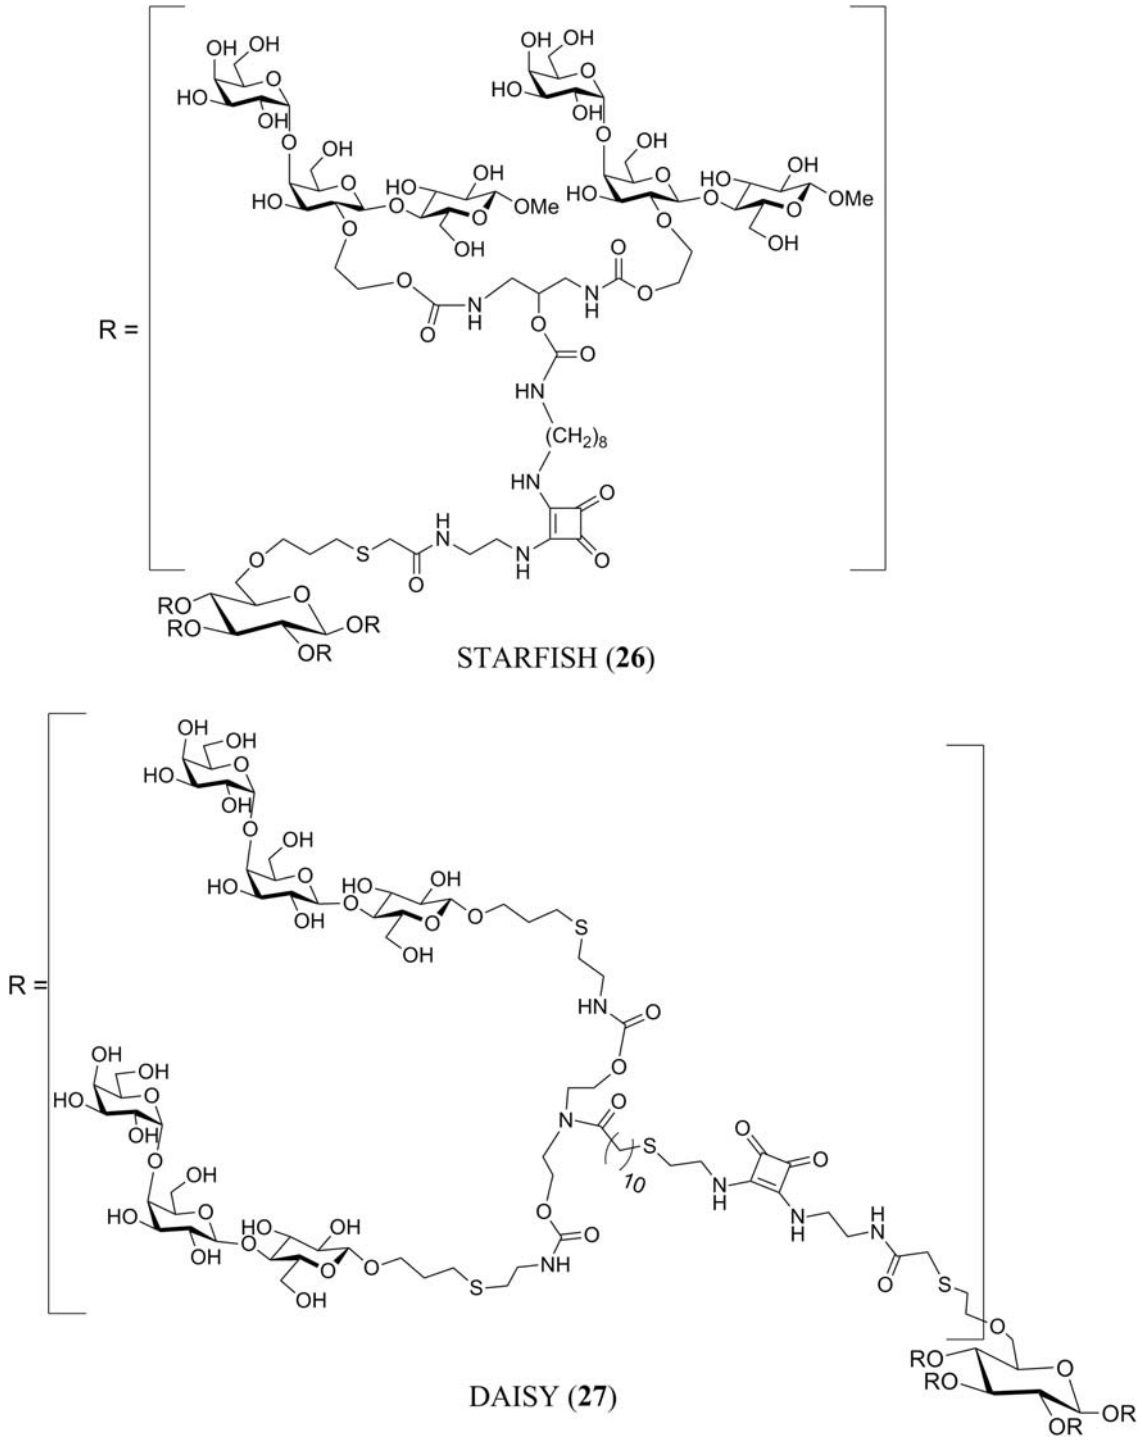

Fig. 12 STARFISH (**26**) and DAISY (**27**) inhibitors of Stx.

STARFISH dendrimer (**26**; Fig. 12) utilized a central pentavalent glucose core functionalized with 10 trisaccharide epitopes (Galα(1,4)Galβ(1,4)Glc or P^k glycan) and displayed IC_{50} values in the subnanomolar range against Stx1 (8.75×10^6-fold more potent when compared with the natural ligand). Unfortunately, this system did not show the biological activity expected in mice infection models.[78] DAISY (**27**; Fig. 12), a refined structure of STARFISH (where the trisaccharide was conjugated to the scaffold through the anomeric position of the glucose at the reducing end), was also tested in in vivo experiments demonstrating protection from both Stx1 and Stx2.[78]

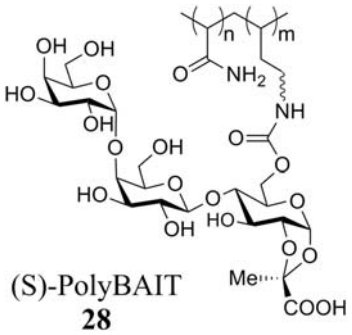

Fig. 13 Glycopolymer (S)-PolyBAIT (**28**).

The STARFISH inhibitor was improved by creating the glycopolymer (S)-PolyBAIT (**28**; **Fig. 13**), composed of a monomer containing the P^k glycan with a cyclic pyruvate ketal (CP),[79] a known binder of serum amyloid P (SAP) component.[79] An intravenous injection of this polymer protected 100% of mice that were subcutaneously inoculated with a lethal dose of Stx1. Interestingly, mice treated with a copolymer, in which P^k and CP were randomly distributed, developed severe signs of shigatoxemia. These results highlight the importance of the ligand placement on a polymeric scaffold in recruiting the necessary protein components for toxin clearance and drug efficacy.

Such important adhesin inhibitor rational design has also been conducted to the development of lead candidates in the antimicrobial drug field based on structure–activity relationship studies. Guided by the structural knowledge at the molecular level, divalent LecA ligands against *P. aeruginosa* infection were designed,[80] providing the best ligand to date (**29**; **Fig. 14**) with an $IC_{50} = 2.7$ nM (over 7500-fold stronger than the relevant reference compound) and a K_d value of 28 nM toward LecA (close to 800-fold more potent than the monovalent probe).[81] The study focused on the design of a rigid spacer based on the alternation of a different number of glucose moieties linked at 1 and 4 positions by a 1,2,3-triazole unit via "click chemistry." Docking studies revealed that the two terminal galactose units of the divalent ligand match in a "perfect" chelate-binding mode in the adjacent binding sites of a single LecA tetramer.[81]

Structure–activity relationship studies have also demonstrated the need for multivalency to achieve strong inhibitory activities, since ligand–lectin recognition processes usually go through multivalent interactions. A plethora of multivalent glycoconjugates have been investigated, displaying high affinities toward many bacterial lectins[73,82] with some of them applied in studying biofilm dispersion.[83] Scaffolds like proteins, peptides, fullerenes, calixarenes, and gold nanoparticles (GNPs), with different valencies (number of ligands), linkers, and spatial organization, have been used to multimerize carbohydrates and to enhance affinity of the monomers toward their respective targets.[73,82,84] Among these molecules, the 1,3-alternate conformer of calix[4]arene (**30**; **Fig. 15**) demonstrated the most efficient and dramatic increase in affinity to LecA from *P. aeruginosa*. A chelate-binding mode in which two galactose residues interact with two neighboring binding sites in a single LecA could be confirmed by atomic force microscopy.[85] The study of its inhibitory properties on *P. aeruginosa* aggregation, biofilm formation, adhesion on epithelial cells, and destruction of alveolar tissues was performed, and antiadhesive properties were evaluated through several in vitro bioassays. The use of this compound in in vivo mouse models of lung infection demonstrated an almost complete protection against *P. aeruginosa* infection. Such multivalent ligands now appear as promising drug candidates for the treatment of bacterial infections.[86]

Multivalent scaffolds have also been used to obtain inhibitors with nanomolar[87] to picomolar[88] activities against bacterial toxins. The combination of "click chemistry" with chemoenzymatic synthesis enabled the assembly of multivalent versions of the GM1os glycan (natural ligand of CT)[89] into glycodendrimers.[90] The octavalent version glycodendrimer (**31**; **Fig. 16**), with an $IC_{50} = 50$ pM, was 380,000-fold more potent compared with the GM1os natural ligand.[90,91]

GNPs have also reached very high affinities toward Stx.[92] P^k-functionalized GNPs, decorated with around 2000 copies of this ligand, showed binding constants in the picomolar range ($IC_{50} = 1.14$ pM and $K_i = 0.254$ pM), providing the highest relative

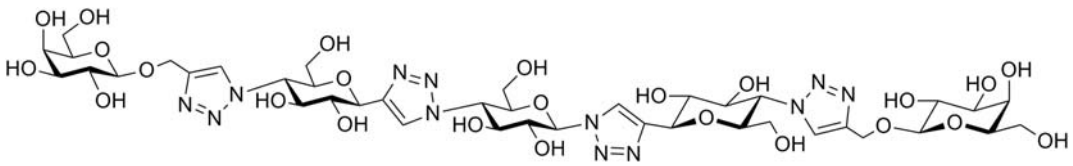

Fig. 14 Chemical structure of the best inhibitor for LecA lectin (**29**).

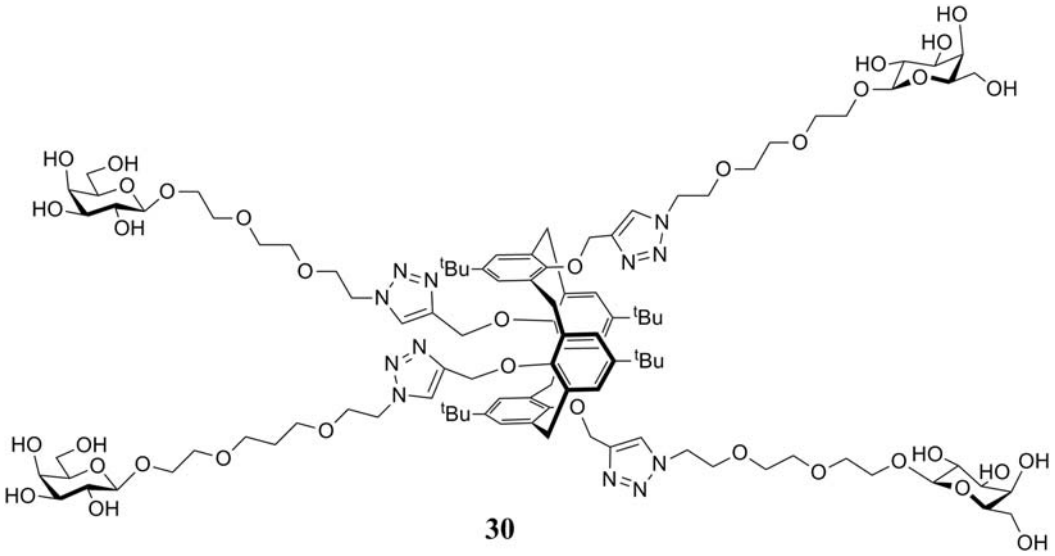

Fig. 15 Galactosyl calix[4]arene (**30**).

potency (β) to date when compared with the natural monovalent ligand Gb3.[93] Such hyperavidity has been applied to the purification of Stx from bacterial extracts.

Clinical trials up to phase III have been performed using multivalent systems of Gb3 or other epitopes.[94] The company Synsorb Biotech has developed two antiinfective agents that consisted of insoluble powders bearing carbohydrates that mimic the natural cell-bound carbohydrate targets of two bacterial toxins, namely, Synsorb Pk (**32**; **Fig. 17**) and Synsorb Cd. Synsorb Pk targets the Stx-producing *E. coli* enterohemorrhagic infections, and Synsorb Cd has demonstrated to be effective against *Clostridium difficile*-associated diarrhea. Both compounds underwent phase III clinical trials, but, unfortunately, these studies have now been discontinued as in vivo experimentation seems to be highly challenging in this field.[2]

Multivalent glycoconjugates have also proved higher affinities toward bacterial lectins with just one binding site. That is the case of fimbrial adhesin FimH, a protein located on the tip of type 1 pili (or fimbriae) from uropathogenic *E. coli*.[95] Since only one α-mannoside fits in the FimH binding site, the observed multivalency effects[96] cannot be explained on the basis of the structure of mannose-specific lectin FimH. Nevertheless, avidity effects have frequently been demonstrated with a variety of multivalent mannose-containing glycomimetics.[73] Interestingly, adhesion on multivalent glycomaterials can be utilized for aggregating *E. coli* and removing them from solution with the use of appropriate filters. For instance, glyconanodiamonds decorated with mannose (**33**; **Fig. 18**) have been shown to be able to clean bacteria-polluted water.[97]

1.24.2.2.4 Targeting DC-SIGN lectin

DC-SIGN is a C-type lectin mainly expressed at the surface of macrophages and immature dendritic cells (DCs). This lectin plays a critical role in the recognition of viruses (e.g., HIV, Ebola, dengue, and cytomegalovirus) and other pathogens (e.g., *Leishmania*, *Candida albicans*, *Mycobacterium tuberculosis*, *Streptococcus pneumoniae*, and *Aspergillus fumigatus*).[98] DC-SIGN is naturally expressed at the surface of DCs as a homotetramer presenting four carbohydrate recognition domains,[99] which binds glycoconjugates containing mannose or fucose in a multivalent and calcium-dependent manner.[100] The main natural ligands recognized by DC-SIGN are the high-mannose glycan, $(Man)_9(GlcNAc)_2$ or Man_9 (**34**; **Fig. 19**) and a group of fucosylated oligosaccharides bearing Lewis-type epitopes such as Lewis X (Le^x) or Lewis Y (Le^y) (**35**; **Fig. 19**).[101] This lectin is substantially involved in innate immunity internalizing highly glycosylated antigens into DCs to be processed and presented to T lymphocytes, activating and tailoring adaptive immune responses against different pathogens. Because of its crucial relevance in the immunological system, DC-SIGN has been extensively targeted with the aim of interfering with pathogenic processes through the development of not only new antiviral drugs but also immune modulators (see Section "**Carbohydrates as immune modulators**").[102] In this section, we will focus on the former application, highlighting the most relevant discoveries in the design and development of DC-SIGN inhibitors against viral infections, such as those of HIV or Ebola.

The design of DC-SIGN high-affinity ligands can be performed through glycomimetics of the high-mannose glycan (Man_9), which mimic the two or three terminal mannose residues (**34**; **Fig. 19**),[103] through structural analogs of the Le^x trisaccharide (Galβ(1,4)[Fucα(1,3)]GlcNAc) (**35a**; **Fig. 19**)[104] or through the construction of highly glycosylated polyvalent compounds.[73,82] Although most of the work concerns with mannose or mannose analogs,[105] fucose-based antagonists have been reported as well[106] providing moderately potent DC-SIGN ligands (similar to, or slightly better than, the natural ligand Le^x).

In 2008, a nonavalent mannose glycodendron that displayed nanomolar IC_{50} values toward DC-SIGN (10^6-fold more potent than mannose) was developed, inhibiting the binding of the HIV envelope glycoprotein gp120 to anti-HIV antibodies and

Fig. 18 Mannosylated nanodiamonds (**33**).

a recombinant dimeric DC-SIGN.[107] Since then, several examples have shown the importance of carbohydrate multivalency in the design and development of viral inhibitors (Fig. 20).[73,82] For instance, the conjugation of a trimannoside analog[105] to a tetravalent scaffold resulted in a glycocluster displaying improved binding properties and also better inhibition of DC-SIGN-mediated HIV infection.[108] The same linear trimannoside analog was conjugated to a Boltorn H30 dendrimer,[109] yielding a glycodendrimer functionalized with 30–32 copies of the synthetic epitope (**36**; Fig. 20).[110] While related mannosylated glycodendrimers were active against Ebola or HIV viral infections in the micromolar range,[111] this glycomimetic construct inhibited the Ebola virus infection in the nanomolar range.[110]

In order to mimic the cluster presentation of high mannose-type glycans on the HIV envelope, GNPs functionalized with gp120 oligomannosides (**37**; Fig. 20) have been prepared and tested as anti-HIV agents.[112] DC-SIGN/gp120 binding was inhibited by these manno-GNPs at nanomolar concentrations, a remarkable improved activity compared with those of monovalent oligomannosides (in the millimolar range).[112] Furthermore, it was demonstrated that manno-GNPs were uptaken by DCs,[113] thus explaining the inhibition observed for the DC-SIGN-mediated HIV transinfection of human activated peripheral blood mononuclear cells.[114]

In another attempt to prepare virus-like particles as potential inhibitors, fullerenes seemed to emerge as great scaffolds for a multivalent presentation of carbohydrates. In this regard, hexakis adducts of C60 fullerene are useful building blocks because they maintain a globular shape and, at the same time, allow the control over the size and multivalency. New glycodendritic compounds displaying a wide variety of valencies and spatial presentations of carbohydrate ligands have been prepared using a C60 fullerene as a central core.[115] Glycofullerenes decorated with 120 peripheral mannoses, the so-called superballs (**38**; Fig. 20), appeared as potent inhibitors of cell infection by using an artificial Ebola virus with IC_{50} in the subnanomolar range.[116]

Proteins have also been used as platforms in the development of multivalent antiviral inhibitors. A methodology in which glycodendrimers were attached to multiple sites of a protein producing highly valent glycodendriproteins was recently described.[117] This technology was employed in the conjugation of mannose dendrimers to the bacteriophage Qβ capsid. The resulting glycodendrinanoparticles (**39**; Fig. 20) are the highest multivalent glycodendrimeric constructs described to date, bearing up to 1620 glycan units, and were obtained as pure and well-defined entities with diameters of up to 32 nm. This kind of glycodendrinanoparticles are capable of mimicking pathogens both in size and in their highly glycosylated surfaces. Through this mimicry, they were able to inhibit the Ebola infection of DCs by blocking viral binding to DC-SIGN in the nanomolar to picomolar range.[118]

All these examples represent interesting multivalent strategies to afford the development of successful and potent carbohydrate-based antiviral drugs that inhibit the cell entry by an antiadhesive effect. Although the in vitro results are very promising, up to now, none of these carbohydrate multivalent systems have been tested in vivo. These studies will be necessary in the future to confirm the application of these systems as therapeutics.

1.24.2.3 Carbohydrates in Vaccine Development

The development of an effective and successful vaccine involves the induction of protective immune responses. These types of responses are best achieved by the generation of long-term protection through a precise integration between innate and adaptive (antigen-specific) immunities.

The innate immune cells, mainly antigen-presenting cells (APCs), detect pathogen-associated molecular patterns (PAMPs) through their surface pattern recognition receptors (PRRs), including the Toll-like receptor (TLR) family and the C-type lectins such as DC-SIGN. APCs, in particular DCs, provide an essential link between innate and adaptive immune systems. PRR stimulation leads to antigen uptake, full maturation of DCs, and intracellular processing of antigens. Antigen presentation to *naive* T cells at the lymph nodes triggers a specific adaptive response (mediated by T and/or B lymphocytes), depending on the antigen exposed on the DC surface. The long-term immunity requires the persistence of vaccine-induced antibodies (or immunoglobulins (Ig)) and/or the generation of immune memory cells. As T lymphocytes are essential to the induction of high-affinity antibodies and immune

memory, triggering T cell-dependent responses should be the foremost aim on the designing and development of novel vaccine candidates.

In this context, pathogen oligosaccharides, as one of the major PAMPs recognized by host immune cells, can be exploited as the basis for the design of carbohydrate vaccines.[119] As well as specific pathogenic carbohydrates, *tumor-associated carbohydrate antigens* (TACAs) can be recognized by the host immune system, thus employed as cancer vaccine epitopes. Most of the human cancers are characterized by aberrant glycosylation, expressing abnormal oligosaccharides (TACAs) that are not produced by normal tissues or at least in a quantitative or qualitative different form.[120] However, two main problems are related to the use of TACAs as epitopes: their poor immunogenicity and that they sometimes are regarded as "self-antigens." These TACAs have been generally classified into four main groups: *gangliosides* (such as GM2, GM3, GD2, GD3, and fucosyl-GM1, compounds **40–43**), overexpressed in melanoma, and colon, and prostate cancers; *blood group determinants* (SLe^x, SLe^a, Le^y, and KH-1 antigens, compounds **44–47**), implicated in tumor invasion and metastasis; *glycophorins* (including Tn, STn, and TF antigens, compounds **48–50**), typically associated with mucin proteins implicated in epithelial cancers such as breast, prostate, and ovarian; and the *globo series* (globo H and Gb3 oligosaccharides, compounds **51–52**) (Fig. 21).[121] It is important to notice that, whereas classical pathogen vaccines have generally a prophylactic preventing action against future infections, cancer vaccines are intended to induce an immune response against an already existing disease.[121]

Carbohydrates have been widely explored in the design and development of vaccines relying on two main approaches: (a) using antigenic carbohydrates as immunogens to trigger responses against the related pathogenic oligosaccharides (*carbohydrate-based vaccines*) and (b) employing the sugar moiety as an "adjuvant" or immune modulator to target several PPRs, thus improving the immune profiles for a more effective response against other antigens such as peptides (*carbohydrates as immune modulators*). In some cases, both roles are synergistically overlapped.

1.24.2.3.1 Carbohydrates as immune modulators

It has been postulated that, since peptide and protein mannosylations facilitate their uptake by APCs through interaction with some receptors at their surfaces (such as DC-SIGN or mannose receptor (MR)),[122] carbohydrate constructs can be used in the design and

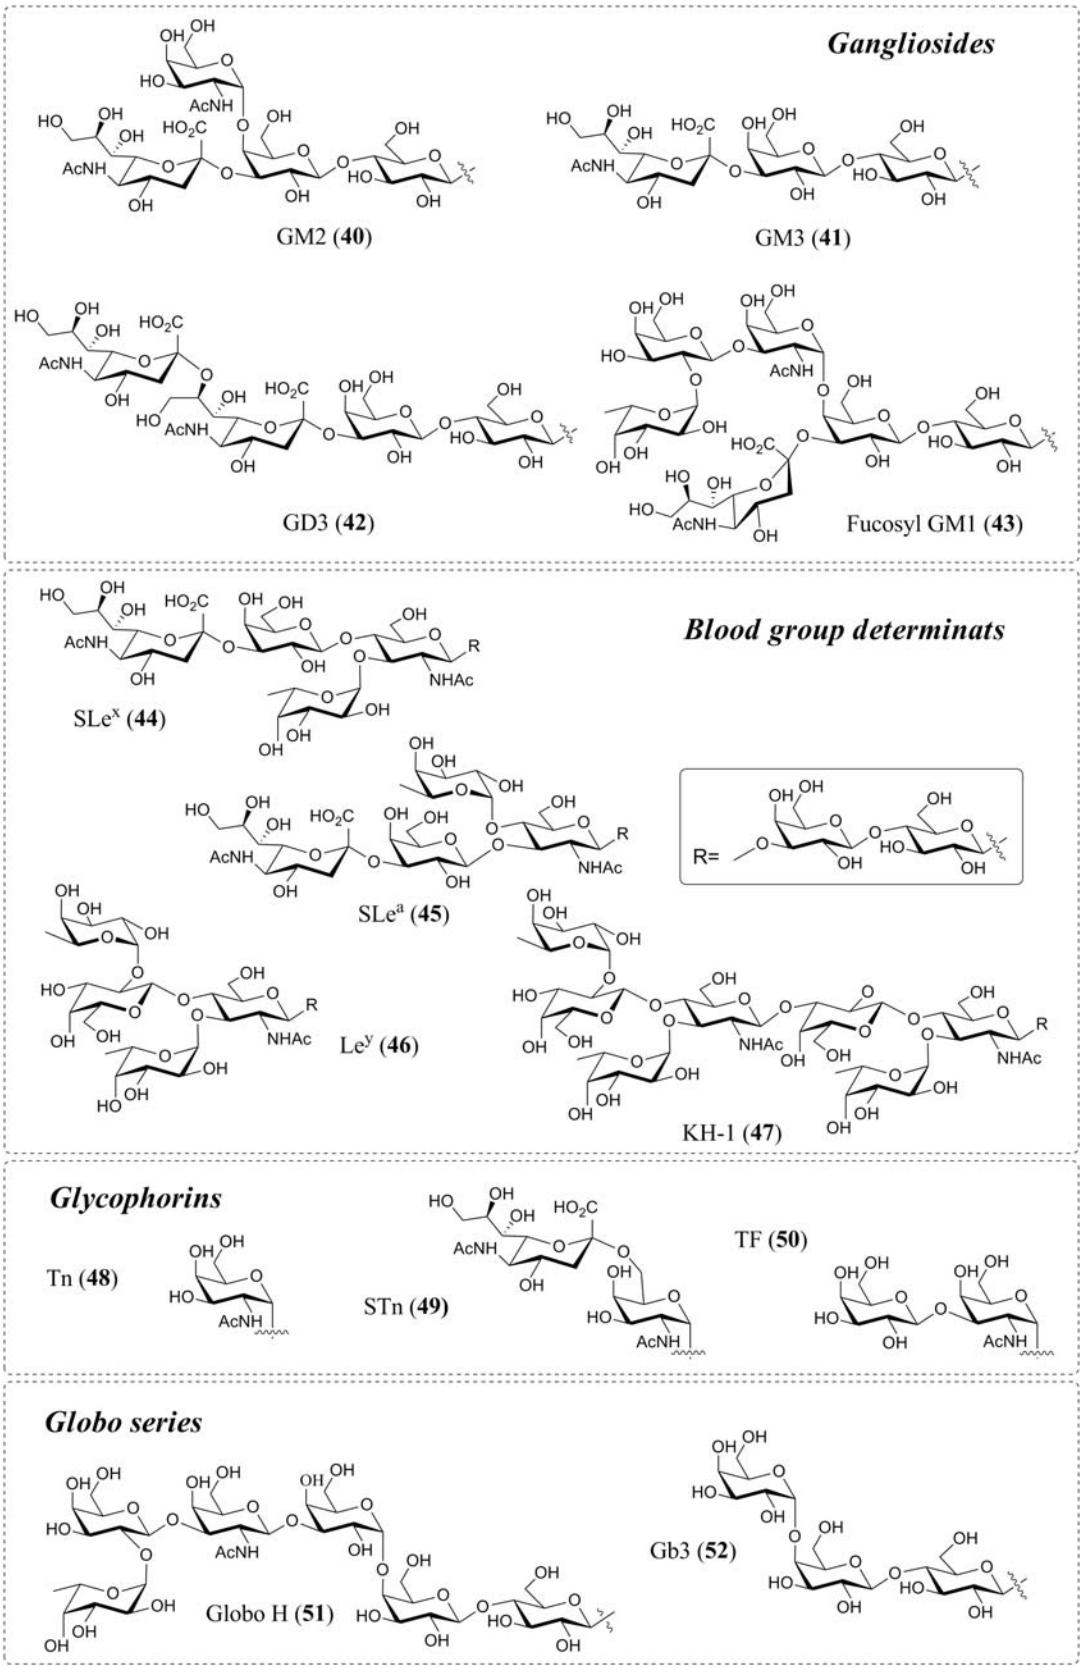

Fig. 21 Selected tumor-associated carbohydrate antigens (TACAs).

development of vaccines with the aim of improving the peptidic epitope delivery and/or initiating DC-mediated signaling, which should result in a better immune response against the mentioned epitopes. Based on this hypothesis, several groups have employed their multivalent glycoconstructs not only to inhibit lectin–carbohydrate-mediated infections but also to develop synthetic vaccine candidates.[123] For instance, ovalbumin (OVA) protein was modified with a DC-SIGN targeting multivalent glycan construct. This structure consisted on poly(amidoamine) dendrimers conjugated with the Le^b tetrasaccharide.[124] The glycan modification enhanced both CD4 + and CD8 + T-cell responses compared with the unmodified OVA, through DC-SIGN interaction in transgenic DCs. In a latter work, it was demonstrated that the use of an OVA peptide, instead of the full entire protein, produced stronger DC activation and subsequent T-cell stimulation.[125] In another attempt to develop a new synthetic vaccine against *influenza A virus*, hybrid constructs named glycodendropeptides (GDPs) and constituted by both peptide- and carbohydrate-functionalized dendrons were designed.[126] Recently, in vitro assays were carried out, demonstrating that these GDPs were recognized by the immunological system inducing DC maturation and CD8 T-lymphocyte proliferation.[127] All these works highlight the observation that APC targeting via PPR interaction might be an important strategy to improve vaccine design.

In the context of vaccine formulation, synthetic carbohydrates are also useful tools for the development of immunoadjuvants (Fig. 22).[2c,128] In this sense, TLR carbohydrate agonist, mainly palmitoylated TLR2 ligands (e.g., Pam_3CysSK_4, **53**; Fig. 22), can be

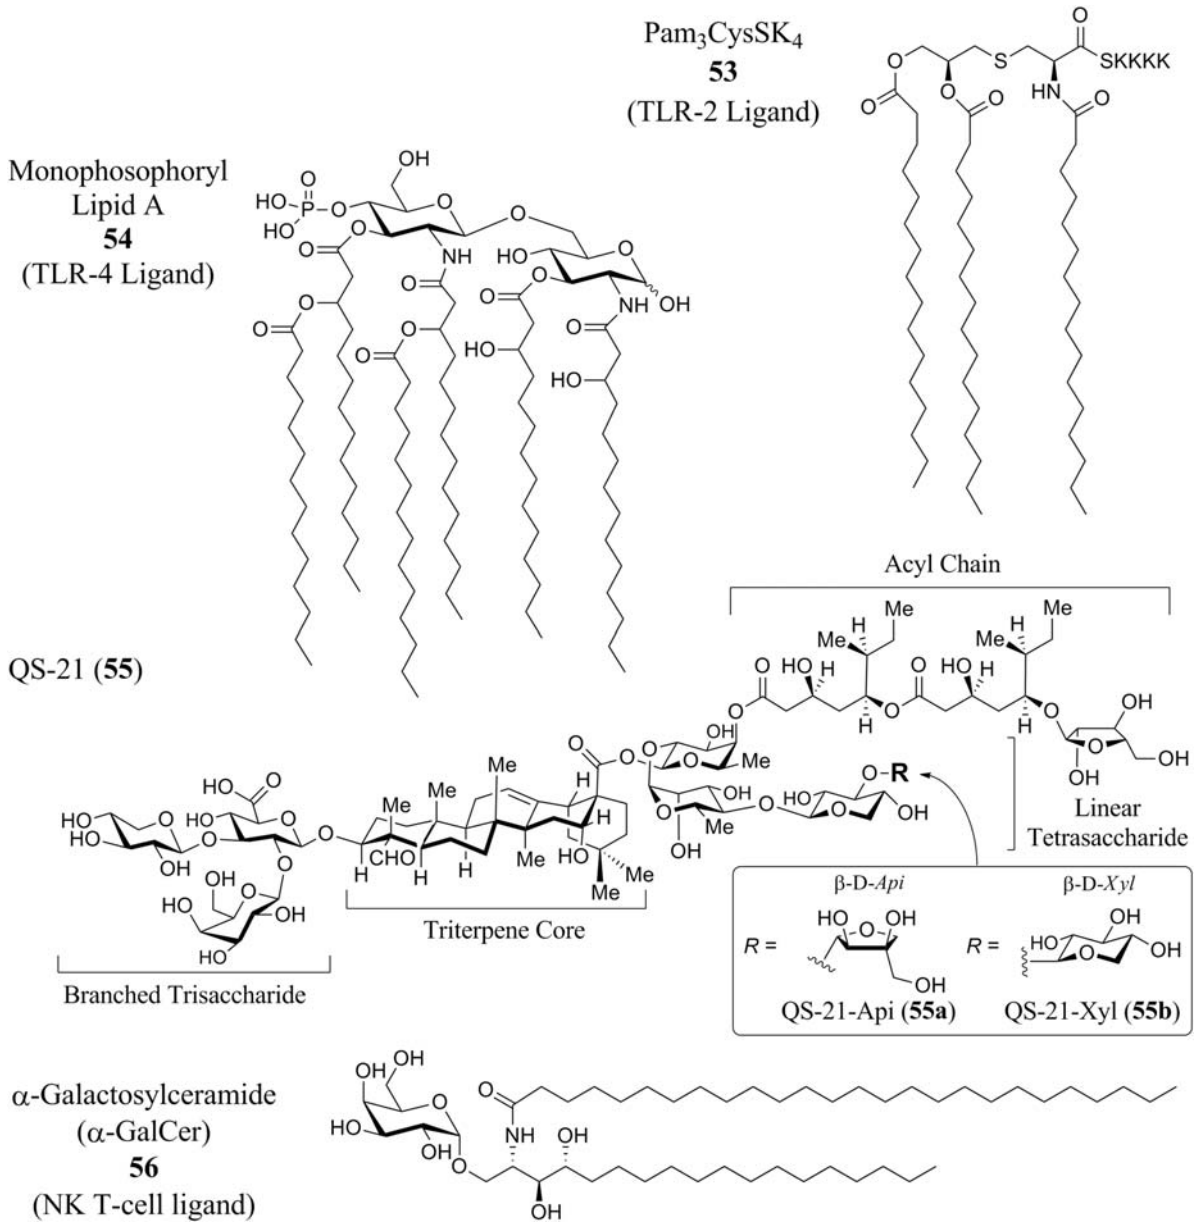

Fig. 22 Carbohydrate adjuvant molecules: Pam_3CysSK_4 (**53**), monophosphoryl lipid A (**54**), QS-21 (**55**), and α-GalCer (**56**).

included in synthetic molecules to improve their immunological responses. Lipopolysaccharides,[82] as TLR4 ligands, can be chemically modified to be conjugated to synthetic vaccines as adjuvant (e.g., the synthetic monophosphoryl lipid A,[129] **54**; Fig. 22). The oligosaccharide-containing natural product saponin QS-21 (**55**; Fig. 22), from the *Quillaja saponaria* tree, is one of the most investigated adjuvants. Two QS-21 active components, QS-21-Api (**55a**; Fig. 22) and QS-21-Xyl (**55b**; Fig. 22), were synthesized, and adjuvant activity was demonstrated by immunological assays.[130] Subsequently, structure–activity relationship studies led to several carbohydrate-truncated Q-21 versions with improved activity–toxicity profiles.[131] Synthetic phosphatidylinositol mannosides from *M. tuberculosis* also exhibit adjuvant activity.[132] Another carbohydrate-based immunoadjuvant is the α-galactosyl ceramide (α-GalCer, **56**; Fig. 22), a natural killer (NK) T-cell ligand. This lead compound, in particular their synthetic analogs, have demonstrated to highly stimulate NK cells in animal models in a range of diseases such as malaria and melanoma.[133] For instance, a capsular polysaccharide antigen covalently linked to α-GalCer induced protection in mice against *S. pneumoniae* by eliciting potent carbohydrate-specific humoral responses.[134] Zwitterionic polysaccharides (ZPSs) have also been employed as immune stimulators as they are able to elicit MHC-II-mediated T-cell responses in the absence of carrier proteins.[135] In an example, a ZPS extracted from *Bacteroides fragilis* was chemoselective conjugated to the GalNAc tumor Tn epitope, with the aim of developing an entirely carbohydrate-based cancer vaccine.[136] The in vivo assays in Tn-ZPS-conjugated immunized mice demonstrated that carbohydrate-specific IgG3 antibodies were produced. These immunoglobulins were able to both bind and recognize human tumor cells displaying the Tn hapten.[137]

1.24.2.3.2 Carbohydrate-based vaccines

The use of carbohydrate antigens as potential vaccines was firstly demonstrated in 1930, when a bacterial capsular polysaccharide could elicit antibody responses against *Streptococcus pneumoniae*.[138] The first polysaccharide-based vaccine, Pneumovax, was commercially launched by Merck in 1983. The current version of this vaccine is composed by an unconjugated capsular polysaccharide isolated from 23 out of around 90 known pneumonia serotypes.[139] Although this vaccine resulted in good protective immune responses in healthy adults, polysaccharide-based vaccines are generally poorly immunogenic with no induced protection in infants, elderly, and immunocompromised patients.[140] This is mainly due to the fact that usually carbohydrate-associated antigens just trigger B-cell responses by cross-linking the B-cell receptor, and they cannot be processed by APCs (an exception is represented by the previously mentioned zwitterionic polysaccharides A from *B. fragilis*). This results in T cell-independent immunity without any MHC-II CD4+ interaction, which is the major obstacle associated with the development of carbohydrate-based vaccines.[141] These T cell-independent responses are less robust and primarily consist of short-lived low-affinity IgM antibody-mediated reactions. *Conjugate vaccines*,[142] consisting of a carbohydrate antigen and an immunogenic T-cell epitope protein (protein carriers like keyhole limpet hemocyanin (KLH), OVA, holo-acyl (HA), and tetanus toxoid (TT)), have proved to overcome this problem, promoting an antibody class switching from IgM to carbohydrate-specific long-term antibodies (IgG) and memory responses. When polysaccharides are covalently linked to proteins, after binding to the carbohydrate B-cell receptor, the protein portion is digested by proteases in the B-cell endosomes. The released peptide epitopes are exposed on the surface of B cells in association with MHC-II and presented to CD4+ T cells. Peptide/MHC-II-activated T cells produce cytokines to stimulate B-cell maturation to memory cells and induce the mentioned immunoglobulin class switch from IgM to IgG.

Many currently commercialized vaccines are based on this glycoconjugated vaccine approach and have proved to be very efficient in preventing a range of human diseases. Among them, vaccines as Menactra (against *Neisseria meningitidis*), Typhim VI (*Salmonella typhi*), Prevnar (*S. pneumoniae*), and Hib Comvax (*Haemophilus influenzae* type b, Hib) can be selected as examples.[2f,143] However, polysaccharide antigens used in these constructs are derived from natural sources, a challenging task that is not always readily available.

In general, polysaccharides obtained from natural sources are heterogeneous mixtures that might imply hard isolation and purification processes, difficulty in the characterization, unavailability of enough amounts of material, loss of activity, and not always safety profiles. Consequently, strategies on the development of new carbohydrate-based vaccines are focusing on the use of more defined fully synthetic oligosaccharides as antigens. A breakthrough in this regard was the Cuban Hib vaccine developed in 2004, which consisted of a synthetic carbohydrate epitope covalently linked to the TT.[144] This first clinically approved fully synthetic carbohydrate vaccine is based on the structure of the capsular polysaccharide antigen from Hib (Fig. 23), and it can be produced in scales large enough to be incorporated into Cuba's current routine vaccination system. Other synthetic glycan epitopes from several pathogens have been attached to carrier proteins, many of them conferring protection against their respective pathologies in animal models.[121,145] Among them can be mentioned those against *Staphylococcus aureus*, *S. pneumoniae*, *Leishmania*,[146] *Plasmodium falciparum*-caused malaria,[147] and even surface spores of *Bacillus anthracis* (anthrax)[148] (Fig. 23). The carrier protein selection is of acute importance in the design of cancer vaccines due to the poor immunogenicity of TACAs. For instance, Theratope (Biomira), a promising candidate vaccine that consisted of an STn-KLH conjugate, failed in the phase III clinical trial because of its low efficiency against breast and metastatic colon cancers.[149]

Despite the conjugation to carrier proteins having demonstrated to be a good approach, preexisting immunity to the protein may suppress the immune response to the conjugated carbohydrate antigen.[150] This phenomenon, known as *carrier-induced epitope suppression*, is particularly problematic when "self-antigens" such as TACAs are employed for the vaccine construct.[151] Using peptidic epitopes instead of the full-length protein has been deeply studied to overcome this matter. This, in combination with the covalent link of immunoadjuvants, may improve the immune response against the pathogenic carbohydrate epitopes, especially for those poor immunogenics as TACAs.[152] Such adjuvants include TLR2 agonist (Pam_2CysSK_4 or Pam_3CysSK_4),[153] saponin QS-21, and α-GalCer.

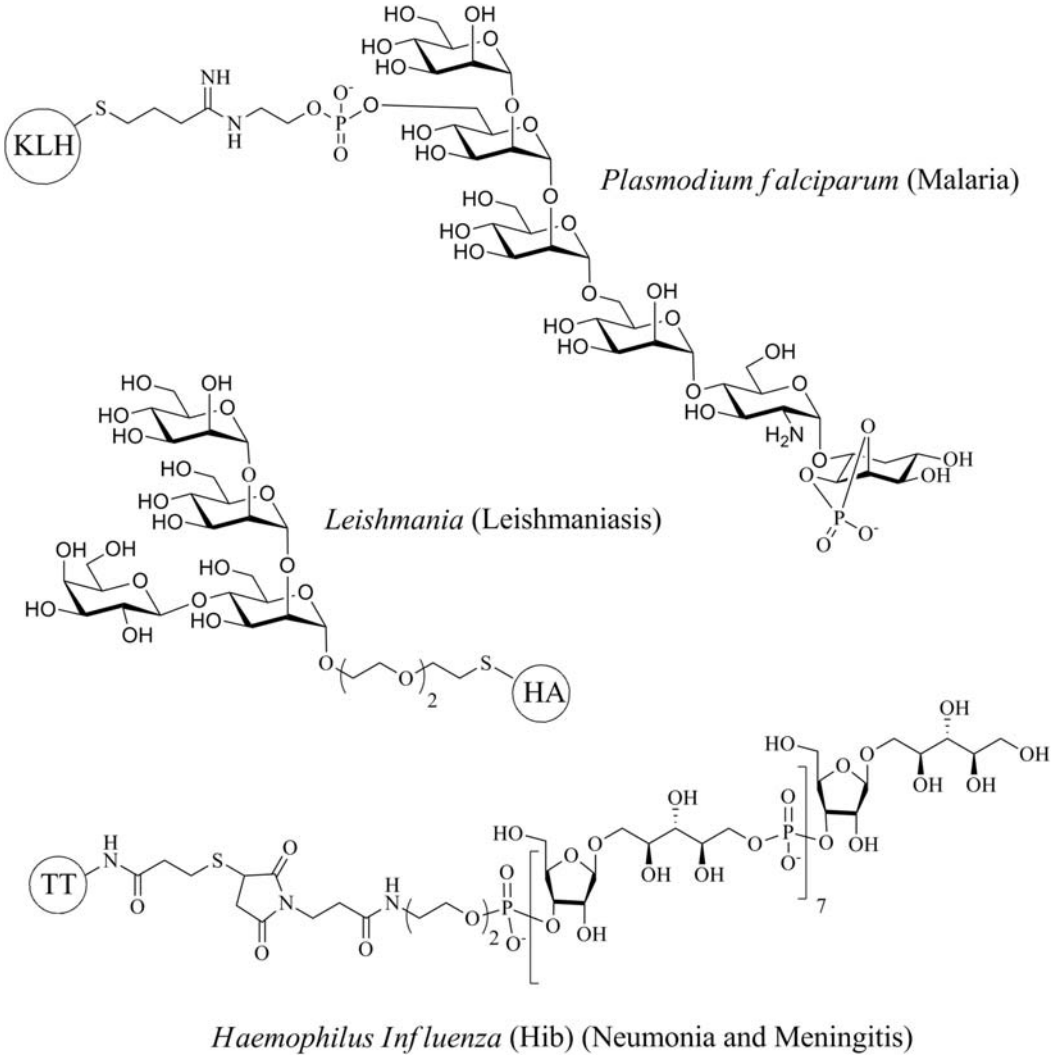

Fig. 23 Synthetic carbohydrate-based vaccines against several microbial pathogens: *H. influenzae type b* (Hib), *Leishmania*, and *P. falciparum*.

With the aim of overcoming the immune tolerance against TACAs, multicomponent self-adjuvanting approaches have been employed to develop totally synthetic vaccines that incorporate the carbohydrate antigen (B-cell epitope), a synthetic adjuvant and/or a selected T-cell peptide. A representative example of this strategy is the design of a tricomponent vaccine candidate composed of a tumor-associated glycopeptide (Tn-MUC1), a T-helper peptide epitope derived from poliovirus ($PV_{103–115}$), and a TLR2 ligand (Pam_2CysSK_4 or Pam_3CysSK_4) (Fig. 24). This all-in-one construct was able to induce high titers of anti-MUC1 IgG antibodies against the Tn antigen of human cancer cells.[154] More recently, those multicomponent self-adjuvant constructs proved to elicit both cellular and humoral immunity, leading to a therapeutic IgG production in a mouse model of breast cancer.[155]

Carbohydrate-based compounds also represent a promising strategy for the development of an effective HIV vaccine, in order to stimulate neutralizing antibodies that bind oligosaccharide high mannose (Man_9) and glycopeptide epitopes from the gp120 envelope protein. Among these antibodies, the most highly studied variant is the 2G12, which neutralizes HIV infection by slowing down the entry of the virus into cells and inhibiting replication after passive transfer into patients.[156] Accordingly, early efforts to elicit an immune response against the high-mannose epitope of gp120 focused on the design and synthesis of multivalent glycoconjugate vaccines on a variety of carrier proteins such as bovine serum albumin. Unfortunately, while these conjugates were able to elicit anticarbohydrate antibodies in animal models, the resulting antibodies were not capable to bind the native gp120 *N*-glycans or neutralize the virus.[157] In a further attempt to prompt protective immunity, synthetic analogs were used instead of mannose to create more immunogenic nonself epitopes. Conjugation of this carbohydrate mimic onto the viruslike particle Qβ resulted in a compound able to bind to the antibody 2G12 with high affinity and elicited a greater antibody response than vaccines constructed with only mannose. However, they failed to bind the native gp120 and did not exhibit HIV-neutralizing activity.[158] In a representative example, the synthesis of several glycopeptides containing the epitope for another HIV-neutralizing antibody (PG9) has been described.[159] The synthetic constructs containing the two closely spaced high-mannose glycans at the amino acids Asn160

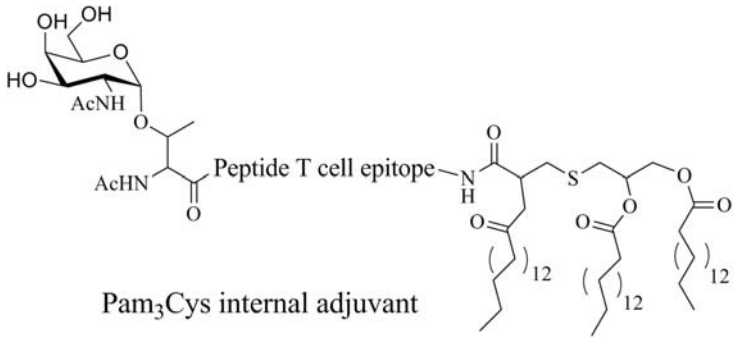

Fig. 24 Tricomponent synthetic vaccine construct composed of the Tn antigen, a T-helper peptide epitope, and a TLR2 ligand (Pam_3CysSK_4).

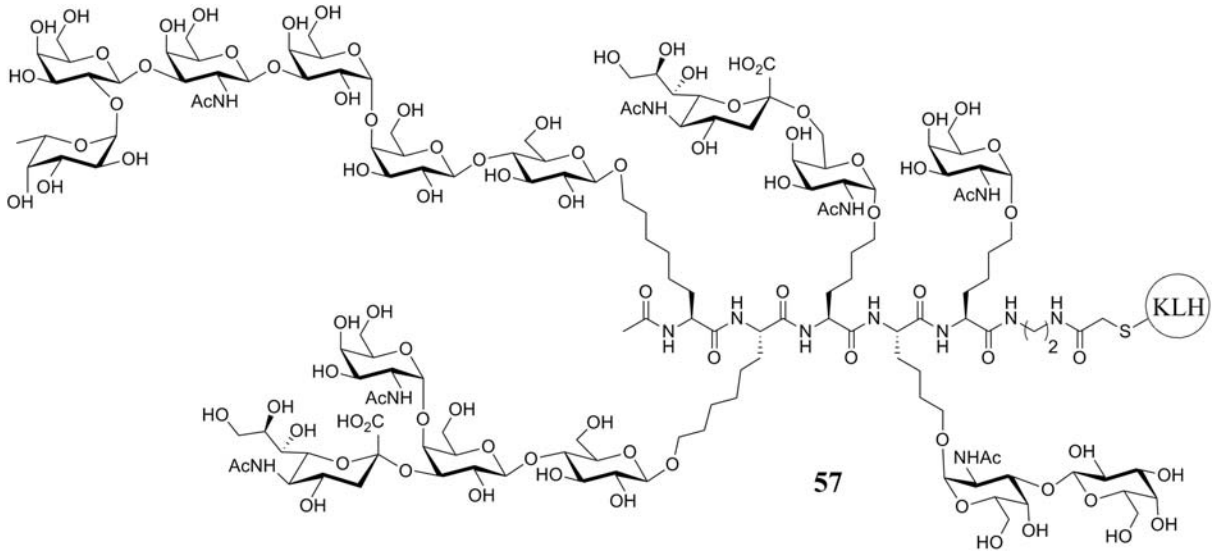

Fig. 25 A peptidic construct containing the antigens globo H, GM2, STn, TF, and Tn (**57**).

and Asn156 of gp120 could bind with high affinity to the PG9 antibody, while the glycans alone were not good ligands. Promising experiments are currently in progress to evaluate their immunogenicity and HIV protection in animal models.

The multivalent presentation of sugar antigens has also been exploited to enhance the immunogenicity of conjugate vaccines against cancer. With the goal of mimicking more closely the heterogeneity of tumor cell surface, trimeric clusters of one carbohydrate antigen[160] and, subsequently, a broader combination of several prostate and breast cancer-associated carbohydrate antigens were developed. This latter construct containing globo H, GM2, STn, TF, and Tn antigens on a single peptide backbone was conjugated to the KLH carrier protein (**57**; Fig. 25).[161] This extraordinary synthetic molecule, in combination with the QS-21 immunoadjuvant, elicited a successful antibody response in mice and is currently in clinical trials against ovarian cancer.

As a summary, the considerations generally applicable to the design of carbohydrate-based conjugate vaccines can be englobed in the good choice of the antigen source, the protein/peptidic carrier, the conjugation method, the adjuvant, and, sometimes, the required multivalency.

1.24.3 Carbohydrate-Mediated Drug and Gene Delivery

Many efforts of the biopharmaceutical industry have been focused on the development of targeted drug delivery in order to improve the efficacy and reduce the side effects of medicaments. A drug delivery system (DDS) is defined as a formulation or a device that enables a therapeutic substance to selectively reach its site of action without reaching the nontarget cells, organs, or tissues. The term therapeutic substance refers not only to a prodrug (a pharmacologically inert substance that undergoes to an active drug in vivo by either chemical or enzymatic reactions) but also to agents such as those for gene therapy. Besides other tools, receptor-mediated endocytosis has been commonly used to deliver drugs to specific types of cells or tissues, and it is particularly applicable to cytotoxic therapy for cancer and gene therapy.

A number of carrier systems and devices have been developed for targeted delivery, like monoclonal antibodies, resealed erythrocytes, and nanocarriers such as nanoparticles, polymers, micelles, carbon-based materials, liposomes, and gels. The early-stage nanocarriers were mostly built up from inorganic materials[162] or artificial polymers.[163] However, mainly due to hydrophobic interactions, most of these nanocarriers adsorb proteins on their surfaces in a process known as *opsonization*.[164] This opsonization can result in a fast nanocarrier clearance from the bloodstream through MPS (*mononuclear phagocyte system*) phagocytosis, turning any in vivo application into a challenge.[164] Enhanced blood circulation times have been usually achieved by the attachment of polyethylene glycol (PEG) moieties to the surface of the carriers, which increases the hydrophilicity and the steric repulsion to proteins,[165] thus resulting in a decreased protein adsorption.[162] Despite the PEG benefits, it is not biodegradable, and several drawbacks might be associated to its use.[158]

In this context, the development of safer and biocompatible nanocarriers, such as those functionalized or performed with mono-, oligo-, or polysaccharides, is currently discussed as alternatives for the traditional ones.[166] Moreover, specific recognition processes mediated by carbohydrate ligands and their respective cell receptors resulted in useful applications for targeting drug or gene delivery.[2f,167] Besides their biodegradation and their active biological function to interact with certain proteins/cell surfaces, their inherent hydrophilicity and their low unspecific protein adsorption make them attractive candidates in the design of DDS for biomedical applications.[165] It has been reported that the polysaccharide hydroxyethyl starch,[168] a synthetically modified starch derivative, dextrin[169], or other saccharides[170] can reduce or even suppress the unspecific uptake of nanocarriers, prolonging their circulation half-life times in the bloodstream.

With the aim of targeting several pathogenic processes such as cancer, infection, or metabolic diseases, many studies have been carried out in the drug delivery field, showing that carbohydrate-functionalized nanodevices (such as liposomes, microspheres, and nanoparticles) or saccharide constructs are excellent tools to target specific cells, tissues, or organs.[171] For example, lactosylated microspheres, micelles, liposomes, or polymers with high specificity for the asialoglycoprotein receptor found on mammalian hepatocytes have been created for liver-specific delivery of drugs and genes.[172] Furthermore, some of these studies have verified that the saccharide shells can be cleaved under a reductive environment that mimics the cell's interior.[173] Mannose-modified liposomes, selectively targeting their MRs, have also been developed as efficient alveolar macrophage selective drug carriers.[174]

Cyclodextrins (CDs), as they are composed of a hydrophilic outside surface and a hydrophobic internal cavity, have been successfully exploited to form inclusion complexes with various hydrophobic drugs to intensely improve their water solubility (**58**; **Fig. 26**).[177] Additionally, these cyclodextrin scaffold glycotransporters have also been widely studied for gene delivery (**59**; **Fig. 26**).[178]

Besides these examples, chitosan and HA have been deeply investigated as novel materials for drug delivery due to their unique biomedical properties.[179] Chitosan is a linear cationic polysaccharide composed of *N*-acetyl-D-glucosamine and glucosamine. The positive charge plays a very important role in mucoadhesion of chitosan DDSs. Also, due to these cationic charges, chitosan can be electrostatically anchored onto the surface of negatively charged polymers or particles. For instance, chitosan-coated particles showed significantly increased uptake by the breast cancer MCF-7 cell line compared with the unmodified nanoparticles. Furthermore, the proapoptotic effect of chitosan proved synergistic with the chemotherapy drug docetaxel.[171] Additionally, multilayered polysaccharide vesicles have been generated from starch as the core and HA as the shell, resulting in self-assembled nanoparticles with a hollow inner core. The enzymatic degradation of the HA shell by hyaluronidase enzyme contributed to accelerate the release of the payload.[180] Antibacterial nanodevices have also been developed by using HA nanocapsules containing the antimicrobial agent polyhexanide. They could be specifically cleaved in the presence of bacterial hyaluronidases, "spreading factors" of pathogens such as *Staphylococcus aureus* and *E. coli*.[181]

A novel strategy named *lectin-directed enzyme-activated prodrug therapy* (LEAPT) has been developed for a regioselective drug release into specific cells that display lectins (**Fig. 27**). LEAPT has been designed as a two-component delivery system that employs a nonmammalian glycosylated enzyme (e.g., α-L-rhamnosidase from *Penicillium decumbens*) and a sugar-bearing prodrug, which is itself the substrate for the enzyme.[182] Through specific carbohydrate–lectin interactions, both the enzyme and the prodrug are internalized into the target cell. Colocalization of both components allows the selective drug release at the target cell, as it only occurs within the vicinity of the enzyme. In this way, by modifying the carbohydrate attached to the glycosidase enzyme, different cell types can be targeted for the release of a given drug.

In the context of lectin-mediated therapies, a class of cell surface receptors expressed in hematopoietic cells and known as siglecs (from *sialic acid-binding immunoglobulin-like lectins*) have been considered attractive targets, not only for carbohydrate-directed therapy for leukemia, lymphomas, and immune cell-mediated diseases but also for carbohydrate recognition-based drug delivery.[183] A number of multivalent sialoside siglec ligands have been successfully applied to direct drug-loaded liposomal nanoparticles to lymphoma cells expressing these lectins.[184] These approaches provide new targets in gene delivery and anticancer therapies.[183] In a sophisticated study, doxorubicin-loaded liposomal nanoparticles were decorated with a high-affinity ligand of the CD22 siglec lectin. These devices were evaluated for targeting B-lymphoma cells, and it was demonstrated that these constructs were actively bound and endocytosed by B cells and able to kill primary malignant B cells from patients with hairy leukemia. Moreover, these CD22-targeted liposomes significantly extended survival in a xenograft model of disseminated Daudi human B-cell lymphoma.[184]

In summary, carbohydrate-based nanocarriers have shown several advantageous properties, such as biodegradability, specific targeting to different cell types, protection and decreased toxicity of the payload, controlled release of the drug by specific protein interaction, and prolonged in vivo plasma half-life times due to reduced protein adsorption. Such behavior makes these sugar constructs highly potential platforms for developing targeted drug devices against many pathogenic processes.

1.24.4 Carbohydrate-Based Diagnostics

In the last decades, several methods have been established to study the interactions of carbohydrates with other relevant biomolecules. Among them, carbohydrate[185] and lectin microarrays[186] have emerged as new tools for glycan analysis and diagnosis purposes. Carbohydrate microarrays were independently developed by several groups in 2002 with the aim of obtaining fast and reliable information about the interactions between glycans and antibodies or other carbohydrate-recognizing proteins. Carbohydrate microarrays are composed of diverse glycans densely and orderly attached to a solid surface. One advantage of this microarray-based technology is that it permits the simultaneous evaluation of many glycan–protein interactions using small amounts of samples. More importantly, another relevant hallmark of microarrays is that the glycans anchored on the solid surface are presented in a multivalent fashion, allowing the formation of multivalent complexes with glycan-binding proteins. As a result, proteins that weakly interact with monovalent glycans in solution can strongly bind to carbohydrates on the microarrays (cluster effect).

Apart from the rapid detection of glycan–protein interactions, carbohydrate microarrays have also been employed to study binding properties of several viruses' strains, which has cleared up the differences in binding specificities of pandemic strains and seasonal ones. Similarly, the knowledge gained from the multiple microarray analyses of the interactions related to the HIV infection has been essential for the design of carbohydrate-based HIV vaccine candidates.[187] Other examples, like the screening of human sera to correlate the presence of specific antibodies with resistance to malaria[147] or to identify markers for Crohn's disease,[188] highlight the relevance of carbohydrate microarrays in the diagnostics field.

Overexpression of certain glycoproteins or the alteration in glycan expression can be a hallmark of severe pathologies, including cancer and autoimmune diseases. Accordingly, many efforts have been devoted to the identification of molecular targets that allow the early detection of diseases and the evaluation of the effects of therapy.

The discovery of 2-fluorodeoxy-D-glucose (^{18}FDG)[189] was a huge boost for the routine application of positron emission tomography as a screening tool in oncology, neurology, and cardiology.[190] The employment of FDG in this noninvasive imaging technology relies on its increased concentration in tumor cells or diseased tissues, as they are more glucose-demanding than other cell types.[191]

More recently, the so-called metabolic oligosaccharide engineering (MOE; Fig. 28) was developed to achieve molecular imaging of glycans in living organisms. In a pioneering approach, cell surface carbohydrates were modified with unnatural sugars that

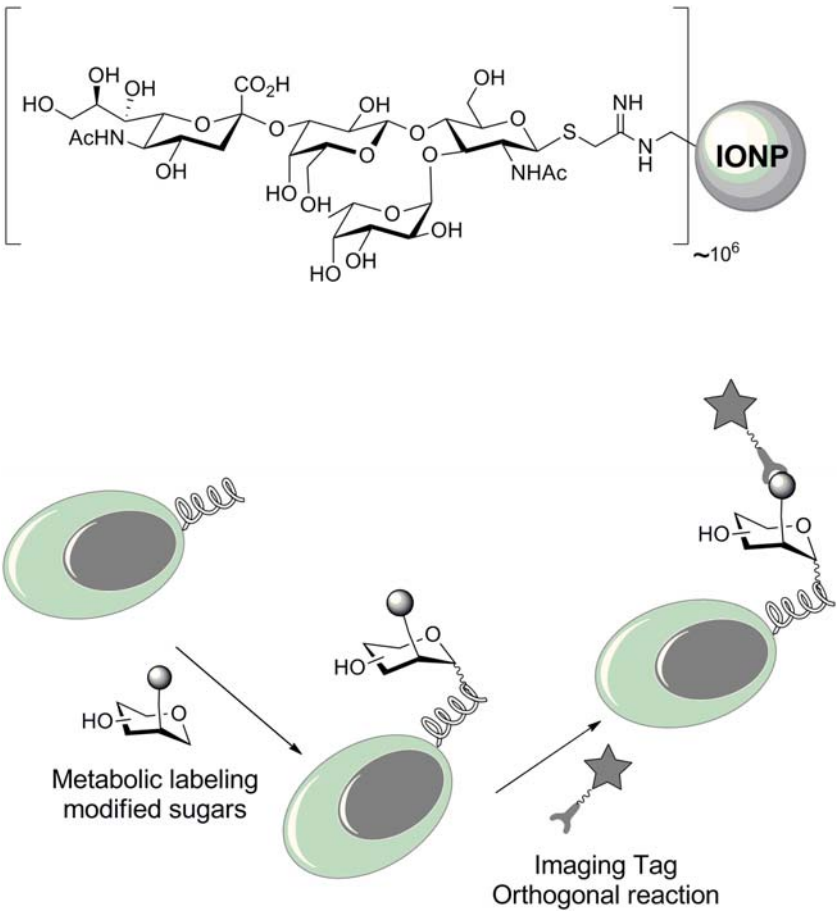

Fig. 28 Schematic representation of SLe^x glyconanoparticles (*above*) and MOE (*below*).

subsequently underwent bioorthogonal reaction with imaging probes. Considering that cancer cells are more metabolically active, this technique should allow discrimination of altered tissues from normal ones using noninvasive detection by magnetic resonance imaging of the preferentially tagged glycans. More broadly, this chemical imaging platform paves the road to the diagnosis of several pathologies related to changes in glycosylation.[192]

Iron oxide nanoparticles (Fig. 28) functionalized with an impressive number of SLe^x have been used to detect presymptomatic brain diseases. The strategy exploited the affinity of the multivalent SLe^x glyconanoparticles toward E- and P-selectins to selectively target and image cerebral inflammation in animal models of MS and stroke.

1.24.5 Glycoengineering in Therapeutics

Most protein-based drugs (antibodies, hormones, enzymes, etc.) are glycoproteins.[193] The glycan part of these molecules modulates the chemical and physical properties as well as the stability, immunogenicity, serum half-life, and clearance from serum. Therefore, control of glycans present in the glycoproteins is essential to maintain their therapeutic properties. An additional problem is the presence of several glycoforms, structural variations in the glycan moieties, frequently found in natural glycoproteins, that complicates the quality control of the therapeutics and the isolation of homogeneous samples.

The development of glycoscience has facilitated the understanding of the glycan role in glycoconjugates, the importance of glycan structures, the definition of their biological targets, and the identification of the glycosyltransferases involved in their biosynthesis. With all this information and the current tools of molecular biology, now it is possible to address the large-scale production of recombinant glycoprotein therapeutics in high quality and purity with a reasonable cost. Moreover, control of the protein glycosylation process in a tailor-made fashion can provide the way to obtain neoglycoproteins with improved therapeutic properties, an emerging field of remarkable interest in particular for the biotechnology industry. There are already some notable examples of glycoprotein therapeutics in the market (Table 3).

To address the preparation of these glycoprotein-based therapeutics, different strategies are described such as modification of the glycosyl pattern of native proteins (entries 1, 2, and 3; Table 3), proteins chemically modified (entry 4; Table 3), engineered fusion proteins (entries 5 and 11; Table 3), antibodies (entries 6, 7, and 8; Table 3), cytokines (entries 9 and 10; Table 3), and recombinant enzymes (entry 12; Table 3).

A very well-known example is erythropoietin, also known as EPO, a glycoprotein hormone that controls erythropoiesis, or red blood cell production, and therefore prescribed for the treatment of anemia. This drug is very popular due to its use by athletes to increase aerobic capacity by maximizing the uptake of O_2 in order to enhance its transport to the muscles. Erythropoietin is considered a performance-enhancing drug and a doping agent by various athletic governing bodies. EPO plays other important roles in the brain's response to neuronal injury and is also involved in the wound healing process. Exogenous erythropoietin is produced by recombinant DNA technology in cell culture. Several different pharmaceutical agents are available with a variety of glycosylation patterns and are collectively called erythropoiesis-stimulating agents such as epoetin alfa (Procrit, Johnson & Johnson, or Epogen, Amgen) and, a second generation based on a different glycosylation pattern with improved therapeutic properties, darbepoetin alfa (Aranesp, Amgen).[194] A different strategy to improve the therapeutic activity of EPO derivatives is the chemical modification of the glycoprotein introducing a polyethylene glycol (PEG). Methoxy PEG-epoetin beta (Mircera, Roche) is a continuous erythropoietin receptor activator. It is indicated for patients with anemia associated with chronic kidney disease. This molecule is based on erythropoietin where methoxy polyethylene glycol butanoic acid is conjugated to the N-terminal amino group or to the ε-amino group of any lysine present in the protein.[195]

Imiglucerase (Cerezyme and Genzyme) is an enzyme-based glycoprotein for the treatment of Gaucher disease. This disorder is characterized by the accumulation of glucosylceramide in cells of certain organs due to the lack of glucocerebrosidase enzyme activity. The treatment of patients by direct injection of the native glucocerebrosidase is not efficient due to the fast clearance of

Table 3 Glycoprotein-based drugs approved for their use

Entry	*Compound (trade name)*	*Indication*	*Company*
1	Epoetin alfa (*Procrit*, *Epogen*)	Anemia	Johnson & Johnson, Amgen
2	Darbepoetin alfa (*Aranesp*)	Anemia	Amgen
3	Imiglucerase (*Cerezyme*)	Gauche disease	Genzyme
4	Methoxy polyethylene glycol-epoetin beta (*Mircera*)	Anemia	Roche
5	Rilonacept (*Arcalyst*)	Cryopyrin-associated periodic syndromes (CAPS)	Regeneron Pharmaceuticals
6	Bevacizumab (*Avastin*)	Metastatic colorectal cancer	Genentech
7	Cetuximab (*Erbitux*)	Colorectal cancer	Eli Lilly, BMS
8	Trastuzumab (*Herceptin*)	Breast cancer	Roche
9	Interferon alpha (*Wellferon*)	Chronic hepatitis B	Wellcome
10	Interferon beta-1a (Avonex)	Multiple sclerosis	Biogen
11	Etanercept (Enbrel)	Rheumatoid arthritis	Pfizer, Amgen
12	Idursulfase (*Elaprase*)	Hunter syndrome (mucopolysaccharidosis II)	Shire Pharmaceuticals

the enzyme by the liver. Imiglucerase is based on modified glycans in which the native sialic acid residues have been removed, thereby allowing exposure of mannose sugar residues that notably reduces its clearance by the liver, enhancing its therapeutic effects.[196]

Rilonacept (Arcalyst, Regeneron) is an engineered dimeric fusion protein consisting of the ligand-binding domains of the extracellular portions of the human interleukin-1 receptor component and interleukin-1 (IL-1) receptor accessory protein linked to the Fc region of human immunoglobulin IgG1. This protein binds and neutralizes IL-1. The drug is used for the treatment of cryopyrin-associated periodic syndrome (CAPS).[197] Another example of the fusion protein strategy is etanercept (Enbrel, Amgen). This fusion protein is indicated for the treatment of active rheumatoid arthritis. The protein is produced by recombinant DNA and contains the tumor necrosis factor (TNF) receptor fused with the constant end of the IgG1. Its mechanism of action is based on the interaction with TNF inhibiting the pro-inflammatory effects caused by TNF.[198]

Probably, one of the more active research fields in the glycoengineering area is the production of antibodies due to their high selectivity and efficiency to interact with target molecules. Bevacizumab (Avastin, Genentech) is a recombinant humanized monoclonal antibody that interacts with the vascular endothelial growth factor A and inhibits angiogenesis. This molecule is indicated for colorectal cancer.[199] Cetuximab (Erbitux, Eli Lilly) is a monoclonal antibody that specifically blocks the epidermal growth factor receptor (EGFR) overexpressed in colorectal cancer cells. This receptor is related with the tumor progression. The inhibition of EGFR will induce the downregulation of this receptor and will modulate the cell division.[200] Another example is trastuzumab (Herceptin, Roche), a humanized monoclonal antibody that interferes with a receptor of the EGFR family, the HER2 receptor, overexpressed in breast cancer.[201]

Two examples of interferon cytokines are commercialized to treat different diseases. Interferon alpha-n1 (Wellferon, Wellcome) is a natural glycosylated human interferon alpha produced from a lymphoid cell line and consists of multiple subtypes. This interferon presents antiviral, immunomodulatory, and antiproliferative properties and is indicated for the treatment of chronic viral hepatitis B.[202] Interferon beta-1a (Avonex, Biogen) is another cytokine of the interferon family used to treat MS reducing neuron inflammation. The mechanism of action is complex and probably comprises several pathways.[203]

A final example comprises the use of an enzyme, idursulfase (Elaprase, Shire), a recombinant enzyme used in enzyme replacement therapy to treat mucopolysaccharidosis type II (Hunter syndrome). MPS is a lysosomal storage disease characterized by a deficiency of iduronate-2-sulfatase, an enzyme responsible for cleavage of O-linked sulfate from GAGs dermatan sulfate and heparan sulfate.[204]

1.24.6 Conclusions and Perspectives

The understanding of the role that carbohydrates play in many relevant biological processes and the progress of glycoscience have boosted the development of carbohydrate-based drugs. Modern analytic tools and the application of glycoarrays have facilitated the identification and characterization of glycan structures involved in defining physiological and pathological processes as well as the identification of new therapeutic targets. The development of efficient synthetic strategies has provided the tools to access to complex carbohydrate structures in the pure forms and quantities required for carbohydrate-based drug developments. The high selectivity of carbohydrate–protein interactions involved in these biological events and the huge possibilities that carbohydrate scaffolds offer to design new drugs based on them, improving their drug-like properties, their affinity, and even the selectivity, are important items to be taken into account. For this reason, the search for new carbohydrate-based drugs can be considered as a hot topic in medicinal chemistry.

Several examples described in the preceding text, where the typical heat to lead the medicinal chemistry process has been applied, show how this strategy can be successful for the development of new therapeutics based on carbohydrates. There is still plenty of room to improve the current available carbohydrate-based drug candidates and for the discovery of new ones. Up to now, some important contributions to the pharmaceutical arsenal came from the glycomimetics. Probably, one of the most recent remarkable and very popular examples is the well-known drug oseltamivir (Tamiflu), which was in high demand when the avian influenza (bird flu) pandemic by the strain H5N1 caused a world health crisis in 2005.

Today, new avenues are envisaged with the development of carbohydrate multivalent systems to be applied in many biological processes where carbohydrate participates through the interaction with lectins. A priori, these high-molecular-weight molecules do not seem adequate to be considered as drugs; however, these compounds have attracted the attention of medicinal chemists due to their potential therapeutic applications.

Glycoengineering and the development of tools in molecular biology pave the way to create de novo glycoproteins as therapeutics (biotherapeutics) with remarkable selectivities and efficiencies for their targets. The reduction of the production cost and the improvement of the bioengineering processes to generate large-scale glycoproteins are fundamental issues to the progress of this field. More recently, the application of carbohydrates in the development of synthetic vaccines represented a landmark in the area, although a large road waits until the role that carbohydrates play in immune modulation and immunogenicity can be fully understood.

A very promising future is ahead for the carbohydrate field in the area of medicinal chemistry. The development of new carbohydrate-based drugs and the progress in the glycoscience field should go hand in hand to face persistent, chronic, and new diseases, for which new medications are demanded, a challenge to be certainly achieved with the participation of glycoscientists.

PREFACE

Previous editions of *Comprehensive Medicinal Chemistry*, published in 1990 and 2006, provided an integrated reference source that encompassed all major aspects of drug discovery research. The third edition follows this tradition and considerably expands its scope and content.

The trailblazing scientific discoveries of the 21st century have brought new opportunities for drug discovery research. The discipline of medicinal chemistry continues to evolve as it adapts to these new opportunities and strives to solve new challenges. Covered in the new edition are not only the breakthrough therapies of the past decade in cancer, hepatitis C, heart failure, dyslipidemia, cystic fibrosis, multiple sclerosis, HIV, etc., but also extensive discussion of new business models in drug discovery research, shifting industry demographics, emerging technologies, *in silico* drug discovery tools, experimental ADME and toxicology, and biologics medicine. The tone of this edition is prospective in which contributors identify outstanding issues and paths forward in their area of expertise. The aim is to provide drug discovery scientists in industry, government, academia, and research organizations with a contemporary global perspective on the field that includes a look ahead in selected areas.

The eight individual volumes fulfill these objectives and include extensive discussion of biomolecular therapeutics, drug targeting and delivery, development of chemical biology tools, data collection and analysis, *in silico* models as predictors for biological properties, identification/validation of new targets, approaches to quantify target engagement, new methods for synthesis of drug candidates such as green chemistry, development of novel scaffolds for drug discovery, and the role of regulatory agencies in drug discovery.

The individual volume editors have done an outstanding job to identify topics and contributors to meet these goals and we thank them for their hardwork and diligence. In volume 1, Ana Martinez and Carmen Gil recruited an international group of contributors who provide chapters on the emerging role of organizations other than traditional pharmaceutical companies in drug discovery, the evolving science of chemical biology, and new organic chemistry contributions to the discipline. In volume 2, Helmut Buschmann, Norbert Handler, and Andrea Wolkerstorfer have accomplished a seemingly impossible task and attracted world-leading experts across the wide field of drug discovery enabling technologies, covering contemporary thinking in a wide range of key disciplines that enable modern medicinal chemistry and drug discovery and development. The computational enabling technologies are the focus of volume 3, in which Andy Davis and Colin Edge have assembled chapters covering both ligand-based and protein structure–based advances as well as exciting new methodologies and case studies exploiting these. Alan Wilson identified experts in the fields of pharmacokinetics and toxicology who describe a wide range of contemporary advances in prediction and analysis of pharmaceutical properties and drug safety in volume 4. In volume 5, Ian Collins, Louis Lombardo, and Will Watkins have assembled leading experts to discuss high impact drug discovery accomplishments over the past decade in cancer chemotherapeutics, immunology and inflammation, and infectious diseases therapeutic areas. Ved Srivastava edited volume 6 on biologic medicines, a significant and rapidly evolving area where medicinal chemistry plays an important role. The chapters in this volume provide timely information on not only protein-based drugs, such as monoclonal antibodies and therapeutic proteins, but also peptides and nucleic acid–based therapeutics. Volume 7, edited by Adrian Hall, Santhosh Neelamkavil, and Rob Jones, presents a detailed account of the major advances in CNS, metabolic, and cardiovascular fields over the past decade and the promising new opportunities. Joerg Holenz edited volume 8 that presents case histories of successful drug discovery and strategic differentiation that have resulted in commercialized drugs and candidates in advanced clinical trials.

We are truly grateful to the publishing team at Elsevier that includes Gemma Tomalin, Rachel Gerlis, Marise Willis, and Sean Simms for their assistance and support throughout the process. With their expertise, this project became what we believe is a noteworthy and valuable resource for the discipline of medicinal chemistry. We look forward to the response and feedback of our colleagues who will use this information in their own work.

Samuel Chackalamannil, David P. Rotella, and Simon E. Ward

EDITORS-IN-CHIEF: BIOGRAPHIES

Dr. Samuel Chackalamannil

Dr. Chackalamannil obtained his PhD in chemistry from Yale University in 1984 and subsequently worked in drug discovery research at Schering-Plough Corporation and Merck Research Laboratories, where he was a distinguished fellow when he left in 2011. Since then, he has been teaching at Ernest Mario School of Pharmacy, Rutgers University, New Jersey.

Dr. Chackalamannil has significant accomplishments in the discovery of new medicines. He led the discovery of vorapaxar (Zontivity®), an FDA-approved antiplatelet drug for the prevention of heart attack and stroke. His group also discovered a PDE-5 inhibitor clinical candidate dasantafil and an adenosine A2a antagonist clinical candidate for the treatment of Parkinson's disease. Altogether, he was responsible for the discovery of nine development candidates in cardiovascular, central nervous system, and metabolic disease areas.

Dr. Chackalamannil is a coinventor of 62 allowed US patents and numerous patent applications worldwide. He has published 81 peer-reviewed articles and has coauthored a book. He has also given numerous lectures at international meetings and academic institutions.

Dr. Chackalamannil is a two-time recipient of the Thomas Alva Edison Award for Emerging Technology Patent and a two-time recipient of the Presidential Award for Discovery at Schering-Plough Research Institute. He has chaired several sessions at American Chemical Society national meetings and Gordon Research Conference on Medicinal Chemistry and was an organizer for Chemistry as a Life Science Symposium.

Dr. David Rotella

Dr. Rotella earned a PhD in medicinal chemistry from The Ohio State University and carried out postdoctoral research in organic chemistry at Penn State University. He joined the faculty at Montclair State University in July 2011 as the Margaret and Herman Sokol Professor of medicinal chemistry after a successful career in the pharmaceutical industry. He is an expert in the discovery and optimization of small molecule drug candidates for use in metabolic, cardiovascular, cancer, and central nervous system diseases. His current research is focused on discovering new lead compounds for use in parasitic and central nervous system diseases. He has coedited the seventh edition of *Burger's Medicinal Chemistry* and is a senior editor for the Royal Society of Chemistry's Drug Discovery book series. He has authored over 40 peer-reviewed articles, is an inventor on 8 issued US patents, and has contributed 10 book chapters.

Simon E. Ward

Simon Ward has an MA in natural sciences and PhD in synthetic organic chemistry from Cambridge University, UK. He has a wide-ranging experience of drug discovery in both large and small companies (GlaxoSmithKline, Knoll Pharmaceuticals, Vernalis, Chiroscience, BioCrea) and specialist experience of discovering and developing drugs for central nervous system indications. He has led multidisciplinary project teams and medicinal chemistry groups from target identification through to early clinical studies, delivering multiple clinical development candidates across indications. He is a fellow of the Royal Society of Chemistry. He is currently a professor of medicinal chemistry at the University of Sussex, UK, and the director of the Sussex Drug Discovery Centre, which he established within the University of Sussex in 2010.

2.01.1 Introduction

Since the early days of human civilization, humankind has searched for medicinal remedies to treat disease. The earliest medicines were derived from plant or herbal extracts discovered through pure empiricism—either by experiencing their effects after human consumption or through observing their impact on animals that consumed them. These discoveries led to the compendium of folk medicines used in Ancient Rome, China, Egypt, and Greece.[1] The practice of medicine became considerably more refined during the Renaissance, which laid the foundation for applying the scientific method to understanding disease and to developing medical practices and treatments.[1] The development of synthetic organic chemistry was transformative in allowing structural analogues to be prepared and tested for superior properties and led to the emergence of the pharmaceutical industry in the early 20th Century. The introduction of molecular biology and decoding of the human genome led to a revolution in the pharmaceutical industry, wherein drug discovery could be translated from a purely phenotypic screening approach to a target-based strategy that begins with a molecular hypothesis impacting the disease state. Modern drug discovery captures elements from each of these periods: empirical observations leading to new indications for existing medicines, use of natural products as leads for drug discovery programs, application of phenotypic screening to identify novel targets for disease intervention, and target-based approaches leveraging genome-wide association studies that implicate a target in disease.

Despite these advances, drug discovery remains perhaps the most challenging applied science—largely due to the complexity of human biology, the vastness of chemical space, the discontinuous impact of functional group changes on molecular properties, and the inability to optimize a single variable (potency, selectivity, permeability, metabolic stability, solubility) without having simultaneous and sometimes detrimental effects on other critical parameters. For these reasons, a successful drug discovery campaign often emerges after investigating dozens of pharmacological targets, with each one requiring thousands of chemical hits to be triaged and hundreds of close-in synthetic analogues to be evaluated. A recent 2016 publication based on 106 new drugs from 10 pharmaceutical firms estimated that the overall investment in discovery and clinical development approaches $2.6 billion for each successful launch.[2] Prior studies, dated 2003–12, have given estimates ranging from $0.8 billion to $2.2 billion, and although the numbers are hotly debated, there is a clear trend for increasing costs in recent years.[2] Technologies that enable more effective selection of productive biomolecular targets, provide novel ways to engage targets, or appropriately guide design to the most effective regions of chemical space will lead to transformative improvements in drug discovery efficiency.

The complexity of human biology contributes most directly to the challenge of drug discovery, as a flawed biological hypothesis will lead to certain failure no matter how elegantly the screening and medicinal chemistry components of the process are devised. There are an estimated 25,000 protein encoding genes in the human genome.[3,4] These genes are regulated by processes that govern the transcription, splicing variation, translation and post-translational modification of the resulting proteins. Many of these proteins interact as part of larger intracellular signaling systems or multiprotein complexes with different functions. Chronic diseases such as cancer, diabetes, Alzheimer's disease, and rheumatoid arthritis likely have their origins in several dysregulated proteins or pathways, making it very difficult to identify single targets that will lead to efficacious and durable therapies in a broad patient population. Advances in genome-wide association studies to identify polymorphisms associated with disease, coupled with gene editing and

molecular biology tools to probe specific proteins and pathways, will lead to more informed drug target selection with greater confidence in translational pharmacology.

Another major challenge for drug discovery is the vastness of chemical space. It is estimated that there are $>10^{40}$ possible structures in the universe of drug-like small molecules—more than the total number of atoms in the universe.[5] Typical compound collections within the pharmaceutical industry range between 10^6 real compounds and 10^{20} virtual compounds and are limited by the practicality of chemical synthesis and screening of real compounds along with computing power needed for virtual screening. Regardless of the methodology used for hit identification, either figure is dwarfed by the breadth of drug-like chemical space. The fact that any drug discovery efforts are successful is believed to result from the finite number of protein folds and similarity of binding pockets across targets within a gene family that, over time, have focused pharmaceutical company collections on biological hotspots in chemical space. In order to further expand the diversity of corporate collections, companies have broadened their chemical equity to include products of Diversity-Oriented Synthesis (DOS),[6–8] DNA-encoded massively parallel libraries,[9,10] and fragments for fragment-based drug discovery (FBDD).[11–14] Additionally, companies are broadening their definition of drug-like chemical space to extend beyond the boundaries contemplated by applying the Lipinski Rule of Five—to include cyclic peptides and natural product derivatives.

In order for a drug to demonstrate efficacy, it must reach the target tissue and safely attain sustained concentrations to deliver the appropriate degree of pharmacological modulation over the course of the dosing interval.[15] While this statement sounds intrinsically simple, optimizing for biopharmaceutic, pharmacokinetic, and safety properties can be extraordinarily difficult while retaining potency, selectivity, and the desired mechanism of action (antagonism, agonism, or allosteric modulation) on the primary pharmacological target. All drugs must persist for a reasonable period of time after administration, which is a function of their absorption rate, distribution into tissues, metabolism, and excretion. Absorption and tissue distribution occurs as a function of passive permeability together with transporter-mediated uptake and efflux. In addition, distribution is also a function of plasma and tissue protein binding. Metabolism can occur through oxidative processes mediated by enzymes such as CYPs (Cytochrome p450 family enzymes, of which there are 57 isoforms[16]), amine oxygenases, and aldehyde oxidase. Alternatively, conjugative processes, such as glucuronidation and sulfation, modify polar functional groups such as acids and alcohols. Finally, excretion can occur through biliary transporters, active renal transport or passive renal excretion without reabsorption. While there are widely known medicinal chemistry principles for modulating many of these pharmacokinetic parameters, their application is often challenged by limited flexibility of the biomolecular target to allow appropriate modification of the pharmacophore.

Moreover, safety is a multiparametric property that depends on the intrinsic effects of modulating the primary pharmacological target, absence of detrimental off-target pharmacology, absence of intrinsically reactive functionality, and negligible propensity to form reactive metabolites that induce indiscriminate covalent protein modification. While most compounds possess one or more of these effects at some level, it is often a question of efficacious dose and whether the off-target effects can be minimized or tolerated at low enough doses where repair and clearance mechanisms can effectively handle insults. For example, the generation of reactive metabolites can sometimes be managed by glutathione trapping in the cytosol, provided doses are low enough to prevent persistence of electrophilic species that could covalently modify proteins.[17] Likewise, the heterogeneity of protein-binding pockets will lead to a narrowing of secondary targets that are modulated as exposure decreases, provided that the compound possesses some modicum of selectivity.

To address these challenges, medicinal chemists utilize a wide array of technologies to better understand how lead compounds interact with their targets, address off target pharmacology through understanding selectivity at a molecular level, develop design strategies to reduce metabolism or alter clearance pathways, and optimize distribution to specific tissue compartments. This chapter will provide a broad overview of established technologies and will emphasize advances in enabling technologies that have occurred in the last ten years. Our emphasis will be on technologies that enable quality drug design: identifying quality starting points for drug discovery, determining their molecular mode of action, and understanding their pharmacokinetic properties. The equally important areas of enabling technologies in chemical synthesis and formulations will not be covered owing to limitations of space.

2.01.2 New Modalities for Target Modulation and Validation

Classical drug discovery was largely driven by phenotypic assays due to a limited understanding of the biomolecular basis of disease, and many therapeutic agents were advanced to clinical practice with only a limited understanding of their molecular mode of action. Major advances in genetics and molecular biology, coupled with the decoding of the human genome, drove a target-centric approach to drug discovery and unleashed a broad array of tools to associate specific genetic targets to disease. Despite these advances, the pharmaceutical industry continues to struggle with clinical candidate attrition, which in many cases is due to insufficient efficacy or differentiation. This attrition has been ascribed in part to insufficient validation of drug targets, prompting investment in chemical biology and genetic methods to increase confidence in targets and the molecular basis for their modulation by drug candidates.[18,19]

2.01.2.1 Gene Editing and Gene therapy

Throughout the late 1990s, target validation studies were conducted in vivo using embryonic or conditional gene knockouts to understand the impact of target inhibition on the disease state. These transgenic organisms are created through the generation of engineered embryonic stem cells, using plasmids that encompass part of the gene target and exploiting homologous recombination

to introduce a nonfunctional sequence into the target gene. These methods provide valuable information on the physiological role of the protein target but are complicated by the potential for embryonic lethality of the genetic knockout in cases where the target gene is critical for organismal development, making phenotypic study of the knockout impossible. Additionally, developmental compensation through altered expression of other genes has the potential to ameliorate the impact of the target knockout. Finally, these studies are time-consuming and expensive. Over the past few years, a variety of molecular genetic tools have emerged that make these studies more efficient, enable temporal alterations in gene function, and can be conducted in fully developed cells or organisms. Moreover, gene-editing tools can in principle enable the study of target modulation through genetic manipulation as opposed to simple target inhibition through genetic knockout. With greater access to human patient-derived tissues, these gene-editing techniques are now routinely used to create isogenic cell lines in which specific disease-related mutations are induced or corrected to enable holistic interrogations of cellular alterations in normal vs disease state.[20]

Discovery of the CRISPR-Cas9 (Clustered Regularly Interspersed Palindromic Repeats—CRISPR-associated protein 9) system has revolutionized genetic manipulation in cells and whole organisms. In comparison to earlier gene-editing technologies such as ZFNs (zinc finger nucleases) and TALENs (Transcription activator-like effector nucleases), the CRIPSR system is much simplified leading to an increased ability to test for the most efficient design, increased speed of model creation, reduced cost of reagents, and a higher editing activity. While we focus primarily on the concept of the CRISPR system here due to its broad availability and widespread application, there may still be merit to using TALENs and ZFNs to give greater specificity when targeting genes with very homologous family members.[21,22] The native CRISPR-Cas system functions as a bacterial innate immune system, which protects against bacteriophage replication by cleaving phage DNA at specific points. The cleavage sites are defined by portions of bacteriophage DNA from prior infections that become incorporated into the bacterial genome and are contained between the palindromic repeats in a larger CRISPR array.[23] This CRISPR array begins with a leader sequence that promotes its transcription and subsequent processing into small CRISPR RNAs. These RNAs function as a prokaryotic analogue to shRNA in eukaryotic cells and guide the Cas endonuclease complex to cleave complementary sequence from the DNA of the new invading bacteriophage. This system was adapted to function in eukaryotic cells using the *S. pyogenes* Cas9 system, which requires two short RNAs for specificity—the CRISPR RNA and the noncoding transactivating crRNA (tracrRNA), which are combined into a single-chimeric guide RNA (sgRNA).[24] Endonuclease cleavage produces a specific double-stranded DNA break only when the targeted site is located immediately downstream from a PAM (protospacer adjacent motif) nucleotide triplet. The cleaved DNA is then repaired through nonhomologous end joining that introduces frameshift insertion/deletion (indel) mutations, rendering the targeted gene nonfunctional. By using two guide RNAs directed at multiple sites in the target gene, complete deletion of the intervening sequence can be achieved (see **Fig. 1**).

One liability of the early CRISPR-Cas9 technology was incomplete specificity resulting from cleavage at partially mismatched sites relative to the guide RNA. Mutant Cas9 proteins (Cas9 D10A) have been developed to effect only single-strand cleavage of the target DNA sequence, precluding the nonhomologous end joining repair mechanism.[25] Through delivering two such guide RNAs directed at proximal sequences on both strands of DNA within the target gene, two single-strand breaks will occur in close proximity, triggering nonhomologous end joining with increased specificity. The Cas9 D10A mutant also enables the introduction of new genetic sequences through homology-directed repair, wherein a coexpressed exon serves as a homology-directed repair donor and is inserted into the target sequence. This technique offers the possibility of genetic knock in using the CRISPR-Cas9 editing system.

In addition to its editing capabilities, the CRISPR-Cas9 system offers exciting potential for genetic and epigenetic regulation to further dissect gene function and linkage to disease. Mutation of the two nuclease domains of Cas9 to create a nuclease-deactivated Cas9 (dCas9) followed by subsequent fusion to a transcriptional activator (CRISPRa) or repressor (CRISPRi) converts this system into an easily programmable transcription factor when paired with its target specific sgRNA.[26] Additionally, fusion of dCas9 with a histone acetyltransferase was shown to create a platform capable of manipulating the epigenome.[27]

The extension of this technology to pooled genetic screening has enabled the interrogation of many genes at once, and all three versions of the CRISPR-Cas system described earlier have been used for mammalian cell screening.[28] In 2014, multiple reports were almost simultaneously published describing pooled screens that used the wild-type humanized Cas9 system.[29–32] Cells were transduced with lentiviral vectors containing the guide RNA libraries and then positively selected for resistance to toxin-mediated death. Most guide RNAs do not confer resistance and therefore "drop out" in the subsequent selection process, whereas those that do confer resistance become enriched.[29–32] CRIPSRa and CRIPSRi screens have also been described[33,34] and together with CRIPSR knockout screens provide complementary systems. Genes that are highly enriched with CRISPRa are likely to "drop out" of

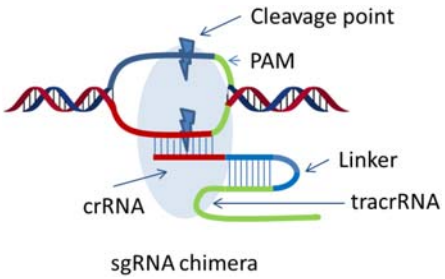

Fig. 1 Illustration of targeted DNA cleavage by CRISPR single-guide RNA.

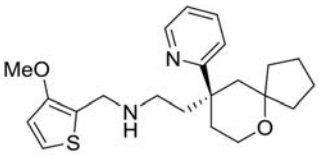
a CRISPRi or knockout screen and vice versa. Since there is less sensitivity and more noise in the guide RNAs that drop out of a screen, upregulation and downregulation may offer complementary sensitivities.[26]

One of the most significant challenges associated with the CRISPR-Cas9 system is efficient delivery of the Cas9 nuclease DNA and guide RNA to the target cells. This delivery can be accomplished through liposomal-mediated transfection or electroporation.[35] However, these systems are not suitable for in vivo delivery of the CRISPR-Cas9 machinery, which would be necessary for in vivo target validation studies or adaptation of the CRISPR-Cas9 system for gene therapy. Adenoviral delivery of Cas9 and sgRNA is attractive in principle due to the low immunogenicity and oncogenic risk from incorporation into the host genome. However, adenoviral vectors are limited with respect to their genetic payload size (c.4.5 kb), which is insufficient to carry the commonly used *S. pyogenes* Cas9 DNA alongside its sgRNA in the same vector. A systematic screen of smaller Cas9 orthologues revealed that the *S. aureus* Cas9 protein possesses properties conducive to efficient, selective gene editing with a sequence small enough for adenoviral delivery (1053 amino acids vs. 1368 amino acids for *S. pyogenes* Cas9).[36] To demonstrate proof of concept, a U6-driven sgRNA encoding either the ApoB or PCSK9 gene and a cytomegalovirus-driven or thyroxine-binding globulin-driven *S. aureus* Cas9 expression vector were delivered in a single adenoviral vector to C57BL/6 mice.[36] Genetic and phenotypic evidence of selective target knockdown was demonstrated in each case. The ApoB-transfected animals demonstrated 5% indel incorporation and increased hepatic lipid levels, and the PCSK9-transfected animals showed 40% indel incorporation and lowered PCSK9 and LDL cholesterol levels as expected for this mechanism.

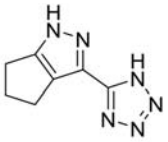
2.01.2.2 Biased Receptor Signaling

The concept of using sensors to measure physiological changes within cellular systems has been a mainstay of cell-based high-throughput screening since the 1980s. This strategy has ranged from the use of molecular indicators, such as the calcium-responsive dyes (Fura-2, Fluo-3, Fluo-4, etc.) to genetically encoded reporters such as luciferase. As scientific advances continue to reveal the increasing complexity of the cellular milieu, genetically encoded biosensors are being refined and applied to further dissect signaling cascades and understand the protein interactome. Fluorescence/bioluminescence resonance energy transfer techniques (FRET/BRET) have been applied to measure conformational changes within a single protein or to monitor protein–protein interactions and are well reviewed by Lohse et al.[37] Panels of FRET/BRET biosensors have been developed to interrogate all the nodes of the GPCR signaling cascade, and as the understanding that these pathways can be modulated independently has emerged, these biosensors have been leveraged to guide the design of biased ligands that preferentially signal through specific pathways in order to tease apart therapeutic benefits from unwanted adverse effects. This approach has formed the premise for the development of TRV130 (**1**, currently in Phase 2 clinical trials), a potent analgesic at the μ-opioid receptor that has reduced β-arrestin recruitment and receptor internalization and is reported to show less gastrointestinal dysfunction and respiratory suppression than morphine at equianalgesic doses.[38] The physiological importance of functional bias at GPCRs has also been demonstrated through the beneficial cardiac effects displayed by angiotensin-1 receptor (AT1R) ligands that selectively activate β-arrestin and not G-proteins [TRV027, **2**, Phase 2b].[39,40] Moreover, the G-protein-biased GPR109A agonist MK0354 (**3**) that does not activate β-arrestin and ERK reduces triglyceride levels without promoting the unwanted cutaneous flushing caused by nicotinic acid.[41]



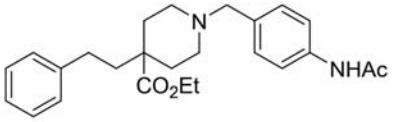
1

2



3

FRET technologies have also been exploited to investigate receptor heteromers which are defined as macromolecular complexes formed of at least two functional receptor units with biochemical properties different from their individual counterparts.[42] A screen for δ-opioid-μ-opioid heteromer ligands led to the identification of CYM51010 (**4**), which exhibited antinociceptive activity similar to morphine with lower levels of tolerance and provides an alternate potential path to analgesics with reduced side effects.[43] While there is still some controversy around the existence and physiological relevance of GPCR heteromers in native tissues, a number of examples including A2A-D2R, MT1-MT2, α_{1A}AR-CXCR4, and α_{1B}AR-CXCR4 have been described.[42] The biased ligand and GPCR heteromer approaches to modulating intracellular signaling cascades represent evolving tactics for the design of GPCR-directed therapeutics, which currently comprise almost 30% of marketed drugs.



4

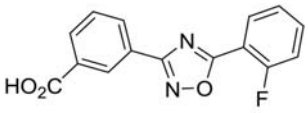
One caveat of the FRET/BRET biosensor systems is that they are frequently generated as stably transfected cell lines in which the receptor of interest is overexpressed. The drive to improve translation into the clinic calls for more physiologically relevant systems early in screening cascades, and thus emphasis is shifting to the expression of biosensors in primary[44] and stem cell[45] derived systems.

2.01.2.3 Modulators of Protein Transcription, Translation, and Translocation

The vast majority of small molecule and nonvaccine biological agents in the human pharmacopeia exert their pharmacology through direct modulation of their protein target—either through orthosteric or allosteric receptor modulation, or via competitive, noncompetitive or uncompetitive modulation of enzyme activity. As the proverbial "low hanging" fruit of therapeutic targets are successfully modulated with these specific ligands, we are observing an expansion of innovative therapeutic approaches. These approaches aim to fine tune efficacy and reduce adverse effects, to provide differentiation from available therapies or to overcome hurdles posed by difficult targets with strong links to disease. Some examples include: undruggable proteins (with large or shallow binding pockets or highly conserved active sites), complex protein–protein interactions, and mutant or misfolded proteins that may initiate cellular damage *per se* or may be unrecognizable to the cell's trafficking machinery and become misrouted to incorrect subcellular locations. Therapeutic modulators of gene expression, including read-through compounds, RNA splicing modulators, epigenetic regulators, pharmacological chaperones, and proteostasis regulators, have all received attention. This section will briefly touch on all these mechanisms of action, using some key disease and therapeutic examples to provide context.

Cystic fibrosis (CF), the most common fatal genetic disorder affecting 1 of 3000 live newborns in Caucasian populations, is caused by mutations in the gene encoding the cAMP-regulated CF transmembrane conductance regulator (CFTR) chloride channel. The loss of CFTR function/expression at the apical membrane in bronchial epithelia impairs ion homeostasis and mucociliary clearance, leading to obstruction, infection, and inflammation. More than 2000 CFTR mutations have been identified and categorized by their alteration of CFTR function and/or expression and phenotypic consequences.[46] Class I mutations cause nonsense, frameshift or mRNA splicing mutations, resulting in the absence of CFTR synthesis. In general, class II mutations lead to defective protein maturation and premature degradation. Class III and IV mutations are responsible for gating defects and lower conductance respectively, while class V mutations lead to reduced CFTR protein due to alternative splicing of CFTR mRNA. Class VI mutations cause a decreased stability of CFTR protein at plasma membranes.

In about 5–10% of CF patients, at least one allele is affected with a nonsense (class I) mutation that creates a PTC (premature termination codon) in the mRNA open reading frame. This mutation leads to truncation and almost total absence of full-length protein. In trying to identify compounds that enable read-through of these premature, nonsense stop signs, PTC Therapeutics has developed Translarna™ (ataluren, PTC124 (**5**)), a nonaminoglycoside compound for oral administration. Ataluren is believed to interact with the ribosome to enable production of a full-length functional CFTR protein. Unfortunately, outcome measures were insufficient to provide a clinical benefit in CF patients, and in the meantime, ataluren has been conditionally approved for the treatment of Duchenne muscular dystrophy which can be linked to a similar premature termination codon etiology.



5

The process of pre-mRNA splicing, that is the precise ligation of exons and removal of introns, is essential for the correct expression and regulation of the majority of human genes. The splicing process is highly complex, requiring an array of *cis*-elements embedded in the mRNA and *trans*-factors that bind to them. Perhaps not surprisingly, this process is susceptible to derangement, and numerous diseases are attributable to mutations that alter splicing. Mutations in *cis* elements cause missplicing of genes, thereby altering gene function and contributing to disease pathology. Mutations of core spliceosomal factors are associated with hematolymphoid neoplasias, retinitis pigmentosa, and microcephalic osteodysplastic primordial dwarfism type 1 (MOPD1). Mutations in the *trans*-regulatory factors that control alternative splicing are associated with autism spectrum disorder, amyotrophic lateral sclerosis (ALS), and various cancers. A good review of the outcomes of these mutations together with references to a comprehensive list of splicing-associated diseases can be found in Singh and Cooper, 2012.[47] In addition to the use of antisense oligonucleotides (such as ISIS-SMNRx; ISIS Pharmaceuticals/Biogen), therapeutic advances have been made in the identification of small molecules to control splicing rearrangements. For example, various antitumor drugs have been reported to inhibit splicing: isoginkgetin (**6**), pladienolide B (**7**), herboxidiene (**8**,GEX1A), and spliceostatin A (**9**).[47,48] Three small molecule candidate therapeutics are currently in development for the correction of SMN2 splicing in spinal muscular atrophy (SMA). SMA is an inherited, automsomal recessive, motor neuron disease that affects 1 in 6,000 to 1 in 10,000 live births. It is characterized by loss of function of the survival of motorneuron 1, telomeric (SMN1) gene which leads to degeneration of motor neurons in the spinal cord and to muscle atrophy. The paralogous gene in humans, SMN2, contains a silent mutation in exon 7 that leads to exon skipping and a truncated, unstable SMN protein that does not compensate for the loss of SMN1. Paratek Pharmaceuticals identified PTK-SMA1 (**10**), a tetracycline derivative that promoted exon 7 inclusion.[49,50] A partnership between PTC Therapeutics, Roche, and the SMA Foundation has RG7800 currently

in phase 1b/2a clinical trials (see PTC website for status updates).[49] Independently, Novartis identified another orally active small molecule (**11**) that modulates splicing of SMN2 to increase levels of SMA protein.[49,51]

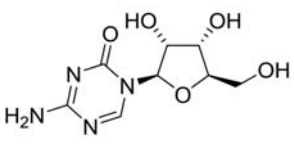
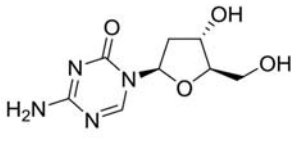
Regulating of gene expression through manipulating epigenetic factors has accrued some credence as a therapeutic approach as an increased understanding of the role of epigenetics in various diseases has emerged. Epigenetics relates genetics to a varied phenotypic outcome as a result of external or environmental factors that influence *how* genes are read as opposed to being caused by changes in the DNA sequence. At the molecular level this process refers to chemical modifications of chromatin through DNA modifications, histone modifications, histone variants, noncoding RNAs, and nucleosome remodeling.

DNA methylation is controlled by DNA methyltransferase enzymes and plays a crucial role in cell development and physiology. DNA methylation at CpG islands represses gene expression. For example, SMN2 is silenced by DNA methylation specifically at CpG islands within or in close proximity of the SMN2 promoter.[49] However, deregulation of methylation can lead to silencing of tumor-suppressor genes and the subsequent onset of cancer. Azacytidine (**12**) and its deoxy derivative, decitabine (**13**), are two nucleoside inhibitors, originally synthesized as potential chemotherapeutics that have FDA approval for the treatment of myelodysplasia. These compounds are believed to act in part through DNA methyltransferase inhibiton, causing hypomethylation of DNA, in addition to having a direct cytotoxic effect on abnormal hematopoietic cells. Despite their early promise as potential therapeutic targets in cancer, DNA methyltransferase inhibitors have not demonstrated single agent efficacy in other cancers, and reported compounds are generally low in potency and have poor metabolic or chemical stability.[52]



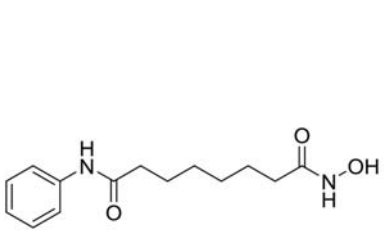
12



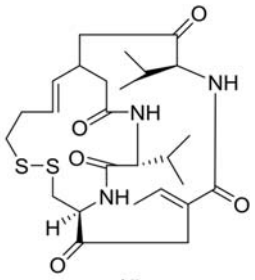
13

A causal role for epigenetic modifications of histone proteins in disease has also attracted the awareness of the research community to targets previously considered merely "packaging proteins." Multiple lysine residues can be acetylated in histone proteins, and numerous enzymes can write (histone acetyltransferases) or erase (histone deacetylases, HDACs) these modifications. HDACs

suppress transcriptionally active genes, and in 2001 the HDAC inhibitor sodium butyrate was shown to increase SMN levels in patient-derived cells and in mouse models of mild SMA.[53] Two HDAC inhibitors (vorinostat (**14**) and romidepsin (**15**)) have FDA approval for the treatment of refractory cutaneous T-cell lymphoma, although in a similar vein to the DNA methyltransferase inhibitors, there is some skepticism on the value of HDAC inhibitors for single agent therapy in general oncology. Histone methylation provides higher contextual environments than DNA methylation or histone acetylation. Histone proteins may be methylated on lysine residues (mono-, di-, or tri-), and on arginine residues (mono- or di-), and the position of methylation may vary. Each of these modifications may attract a different complex of reader proteins and have different cellular effects, for example: gene expression or gene repression.[54] Activating mutations in the histone methyltransferase, EZH2, which is responsible for trimethylating Lys27 of histone H3 (H3K27), have been reported to contribute to B-cell non-Hodgkin lymphomas. EZH2 inhibitors still retain promise as effective chemotherapeutic agents.[55] In addition to being methylated and acetylated, histone proteins can also be (de) phosphorylated, (de) ubiquitinated, and (de) SUMOylated leading to a complex intricacy of potential regulatory signals. Reader proteins recognize these chromatin modifications and activate the appropriate intracellular pathways, for example, BRD4, which contains a BET domain that binds to acetyl-lysine in histone proteins. There is hope that inhibitors of BRD4 will prove clinically useful in the treatment of midline carcinomas and acute myeloid leukemia.[54] While oncology remains the key area of focus for epigenetic therapies, interest is spreading to other areas such as autoimmune disorders and diabetes. Much work is needed, however, to deliver a second generation of epigenetic therapies that have greater efficacy and tolerability than seen in currently developed compounds.



14



15

The potential to arrest protein translation by stalling a translating ribosome on its nascent peptide has recently emerged as a potential therapeutic opportunity to reduce the synthesis of mutant proteins that contribute to a disease phenotype. During protein translation the ribosome polymerizes amino acid building blocks into the elongating nascent polypeptide chain by forming a new peptide bond at the peptidlytransferase center. The rate of this nucleophilic attack varies with each amino acid, and specific amino acids or combinations of amino acids can slow or even stop translation in a *cis* fashion, stalling the self-synthesizing ribosome. In eukaryotes for example, stretches of positively charged amino acids (such as lysine or arginine) and motifs of three or more consecutive proline residues have all been shown to induce stalling.[56] Stalling during translation of the upstream open reading frames of arginine attenuator peptide (AAP), cytomegalovirus (CMV), and S-adenosyl-methionine decarboxylase (SAM-DC) prevents further ribosomal scanning and represses expression of the downstream genes.[56] Most of the sequences that pause translation, the so-called arrest peptides, are active only in the presence of specific environmental cues and modulate the cell's downstream response. For example, in bacteria, exposure to antibiotics causes ribosomal stalling to induce an upregulation of downstream antibiotic-resistance genes. High-resolution cryo-EM structures demonstrated that erythromycin, either through direct contact with an upstream open reading frame or through limiting its conformation, induces interactions between the peptide and the ribosome that render the peptidlytransferase center inactive and stall the ribosome on the uORF.[57,58] This stalled ribosome induces an alternative conformation that exposes a new ribosomal binding site and enables translation of the downstream rRNA methyltransferase, ErmC. This enzyme dimethylates ribosomes at the erythromycin binding site, conferring antibiotic resistance.[56,59] Regulation of translation in response to a small molecule has been demonstrated in additional systems. For example, stalling of the bacterial TnaC arrest peptide occurs in response to L-tryptophan,[56] however, only recently has it been conceived that this could be a potential therapeutic mechanism, and should this activity be translated into the clinical setting, this modality will open the doors for greater therapeutic impetus in this area.

Mutations in receptors, ion channels, and enzymes frequently interfere with the tertiary folded protein structure alerting the cellular quality control system and leading to protein retention in the endoplasmic reticulum (ER) or other misrouting. These outcomes result in loss of function at the normal site of biological activity. A pharmacological chaperone (or pharmacoperone, from "protein chaperone") is a small molecule that serves as molecular scaffolding to induce the correct folding and trafficking of mutant proteins within the cell, bypassing the quality control systems, and thereby ameliorating disease symptoms. Candidate diseases that may be susceptible to such treatments include neurodegenerative diseases, such as: Alzheimer's, Parkinson's, and Huntington's diseases, diabetes, inherited cataracts and cystic fibrosis.[60] In 2013 Michael Conn and coworkers demonstrated the ability of pharmacoperone, IN3, to rescue the plasma membrane localization of mutant gonadotropin-releasing hormone receptor (GnRHR) in a knock-in mouse model that mirrors the mutation causing human hypogonadotropic hypogonadism (failed puberty).[61] Restoration of plasma membrane localization was associated with renewed responsiveness to the endogenous ligand, gonadotropin-releasing hormone, and a mutant-specific agonist. Moreover, pharmacoperone treatment in the mice improved testis function (restored spermatogenesis and testosterone production) and restored fertility.

The prototype class II mutation in CF is a deletion of the phenylalanine in position 508 (F508del-CFTR). This mutation is found in 90% of CF alleles and impairs the protein folding leading to protein retention in the endoplasmic reticulum (ER) and degradation by the proteasomal pathway. VX-809 (Iumacaftor (**16**), Vertex Pharmaceuticals) was the most promising of the first generation of pharmacological chaperones or correctors for CFTR restoring about 15% of normal CFTR function in human epithelial airway cells. Unfortunately, in phase IIa clinical studies a number of patient outcome parameters were not improved, and therefore polypharmacology approaches combining additional mechanisms of action with these corrector compounds is expected to be necessary for effective protein repair. A potentiator compound (e.g., VX-770 (**17**)) increases the cAMP-regulated chloride channel gating of the CFTR channel and is most likely to have positive impact on Class III and IV mutations. Successful phase III trials were reported for patients with gating deficiency mutations, but monotherapy in F508del-CFTR patients failed due to limited CFTR expression at the plasma membrane. VX-809 and a second-generation chaperone, VX-661 (**18**), have both been combined with VX-770 for clinical testing.

2.01.2.4 Modulating Proteostasis and Protein Degradation

An alternate approach to treating protein misfolding disorders is to address the proteostasis network, the cellular machinery that controls protein homeostasis.[62,63] Cystic fibrosis serves yet again as a good context for this approach, with multiple examples being reported that increase pathway capacity, modulate intracellular signaling, or affect protein degradation.[46] Silencing expression of the heat shock protein 90 co-chaperone, Aha1, partially restores folding, trafficking and chloride conductance of F508del-CFTR. Additionally, the decrease of ubiquitinated F508del-CFTR via overexpression of ubiquitin protease 10 leads to increased expression at plasma membranes in human epithelial airway cells. Transglutaminase 2 inhibitors have been tested in an attempt to correct defective autophagy. Nivalis Therapeutics is working to increase intracellular concentrations of GSNO (s-nitrosoglutathione) to prevent CFTR degradation, and Bayer is testing Riociguat (FDA approved for pulmonary arterial hypertension and chronic thromboembolic pulmonary hypertension) for stimulation of CFTR activity via elevation of intracellular cGMP levels. Accordingly, phosphodiesterase type 5 inhibitors (PDE5), which also enhance cGMP accumulation, have also been studied for potential therapeutic benefit in CF.

Targeted protein degradation strategies exploit the ubiquitin-proteasome system to achieve selective destruction of a target protein.[64] Ubiquitin is a small regulatory protein that is expressed in almost all human tissues. Its attachment to target proteins by ubiquitin ligases can result in several outcomes, one of which is altered subcellular localization and protein destruction by the 26S proteasome. The latter outcome is typically signaled by polyubiquitination of a target protein at lysine. Protein ubiquitination is reversible, the forward reaction being catalyzed by ubiquitin ligases, and the reverse reaction being effected by deubiquitinases. Ubiquitin ligases are modular proteins, comprised of an E3 substrate recognition domain, an E1 ubiquitin-activating enzyme, and an E2 ubiquitin-conjugating enzyme. Of these three modules, the E3 ubiquitin ligase is the most heterogeneous, and it is estimated that there are over 600 different E3 ligases in the human genome.[65] The targeted protein degradation strategy relies on reprogramming the E3 ligase to operate on a neomorphic substrate through the use of a chimeric ligand possessing a moiety that binds to the target protein and another subunit that binds to the E3 ligase being exploited for target destruction (see **Fig. 2**).

Four ligases have been exploited for targeted protein degradation: VHL, Cereblon, MDM2, and cIAP2.[64] In addition, a hydrophobic tagging strategy has been devised to exploit the general ubiquitination and destruction of proteins with exposed hydrophobic cores, a hallmark of misfolded proteins. Because these protein degraders must simultaneously bind to the E3 ligase and the target protein in order to be effective, their design typically involves two elaborated ligands for each protein (with affinities between 1 nM and 1 μM) and a flexible linker. The resulting physicochemical property space poses challenges for cellular permeability and oral absorption. However, unlike typical enzyme inhibition and receptor antagonism approaches which are stoichiometric in ligand, targeted protein degradation is catalytic and irreversible.[64] This unique mechanistic property should dramatically reduce the intracellular concentration of chimeric ligand needed to suppress target protein function relative to conventional approaches. Additionally, the protein degrader approach requires that one identify a ligand that binds to the desired target; it

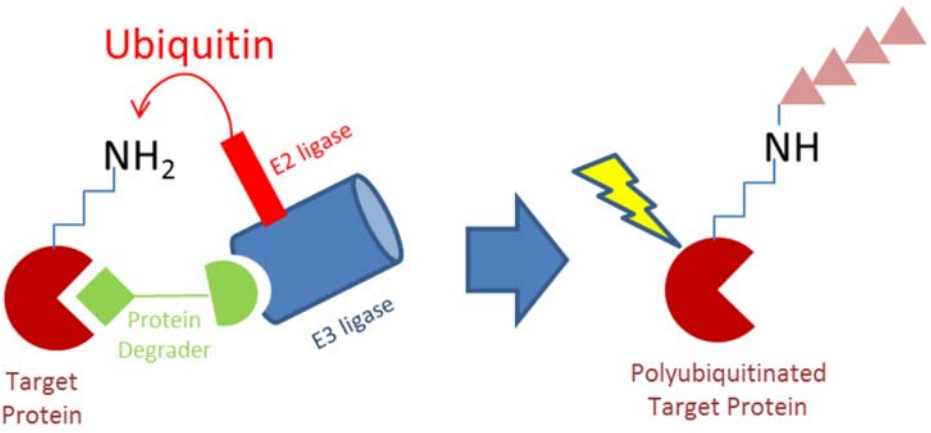

Fig. 2 Targeted protein degradation through the recruitment of ubiquitin ligases by a bispecific ligand.

does not need to possess intrinsic functional activity. Therefore, protein degrader strategies theoretically expand the number of useful binding sites on the target protein, enabling selection of the most drugable pocket for chimera design.

The first E3 ligase hijacked for protein degradation is cIAP1, which interacts with other protein targets through its BIR3 (Baculoviral IAP Repeat) domain.[66] Small-molecule ligands like methyl bestatin were shown to bind the BIR3 domain and induce autoubiquitination; therefore, methyl bestatin was selected as a target binder for further study. Early proof of concept was demonstrated with chimeric degraders (SNIPERS) of CRABP I and CRABP II (Cellular Retinoic Acid Binding Protein).[66] Bestatin-based protein degraders were found to induce autoubiquitination and degradation of the cIAP1 protein, which could lead to reduced efficacy over time due to depletion of the E3 ligase. While methyl bestatin (**19**) is known to induce this autodegradation, as are ester-based SNIPERs, the corresponding N-methyl amide of bestatin **20** does not despite its tight binding to the BIR3 domain. Therefore, the amide-based SNIPER **21** was designed.[67,68] This compound demonstrates nearly complete degradation of CRABP II after 6 h of treatment at 3 μM, whereas no degradation of cIAP1, cIAP2, or XIAP was observed over the entire concentration range (up to 30 μM) for 48 h. The earlier SNIPER **22** demonstrated nearly complete loss of cIAP from 6-24 h under these conditions. Other proteins that have been successfully degraded by cIAP1-based degraders include the retinoic acid receptor (RAR), the estrogen receptor (ER), and the androgen receptor (AR).[69]

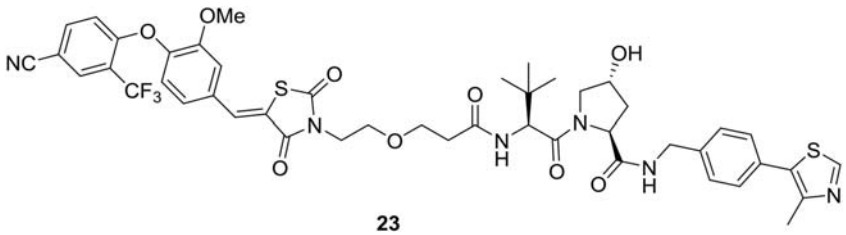
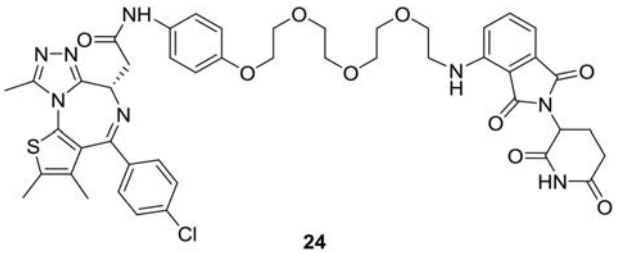
21 X = O, n = 2
22 X = NH, n = 2

The Von Hippel Lindau ligase (VHL) has been repeatedly exploited for targeted protein degradation in vitro and in vivo. The VHL protein is an E3 ligase that is responsible for degrading Hypoxia Inducible Factor (HIF), a protein that regulates erythropoiesis under hypoxic conditions. Under normoxic conditions, P402/564 is hydroxylated by HIF prolyl hydroxylase. The VHL ligase recognizes the hydroxylated proline residue, catalyzing ubiquitination of the protein as a negative feedback mechanism. The unique recognition of hydroxyproline was exploited in the design of VHL targeting ligands for protein degrader chimeras—for example, the ERRα degrader **23**. These chimeras typically possess a tripeptide-based VHL ligand featuring 4-hydroxyproline as the central residue. Targeted protein degradation has been accomplished for the Estrogen Receptor,[70,71] Androgen Receptor, FKBP,[70] TrkA,[72] ErbB2/ErbB3,[72] RIPK2,[71] BCR-ABL,[73] and BET[74] using VHL chimeras.



23

Cereblon is an E3 ligase that binds to damaged DNA-binding protein 1 (DDB1), cullin 4A, and regulator of cullins 1.[75] It is the biomolecular target of thalidomide, pomalidomide, and lenalidomide, which associate with its substrate binding site and alter substrate specificity for the protein, inducing ubiquitination of neomorphic substrates and preventing modification of its endogenous substrate.[76] It is this mechanism of action that is postulated to result in the teratogenic effects of these agents. Because these ligands are small, drug-like compounds, they have been exploited for targeted protein degradation through linkage to target-binding compounds through the phthalimide ring—for example, the BRD4 degrader **24**. Cereblon-containing protein degraders have successfully been designed for Androgen Receptor, Estrogen Receptor, BRD4,[77,78] FKBP,[77,78] and TBK1.



24

While targeted protein degradation is a promising new modality for target inhibition or antagonism, the technology has primarily been demonstrated in vitro, with few reports describing in vivo efficacy after subcutaneous administration.[71,78] Moreover, given the requirement for simultaneous binding of the protein target and the E3 ligase in a manner that allows positioning of a surface lysine residue near the E2 ubiquitin thioester bond, it can be challenging to design effective degraders for a given protein target. Design principles for effective protein degrader design have yet to be described but will need to consider: (1) the physicochemical properties required for effective cell penetration; (2) linker group properties such as length, polarity, and flexibility to allow formation of an effective ternary complex; and (3) optimum affinity for the target and ligase-binding moieties to generate that complex under physiologically relevant concentrations of the chimera. The lack of published design strategies is to be expected for a technology in its nascent stage, and further advances promise to yield effective target inhibition strategies for proteins that are otherwise challenging to pursue.

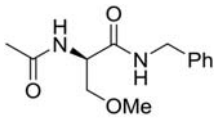
2.01.3 Hit Identification Methods

Advances in the molecular understanding of enzymes and receptors throughout the 20th century[79,80] together with the revelation of the human genomic sequence[81] and the concepts of drugability[3] heralded an era of molecular target-based drug discovery in the 1990s and the early 2000s. Modern drug discovery strategies now typically begin from the hypothesis that modulating a single biomolecular target or pathway is expected to deliver a beneficial effect on the disease state. Early confidence in rationale is established using genetic analysis, bioinformatics and pathway mining, molecular biology tools, and chemical probes. Upon determination that the target merits pursuing a drug discovery campaign, efforts begin toward the identification of lead matter to initiate medicinal chemistry optimization. Early screening strategies can encompass high-throughput, target-based, biochemical, functional assays; binding assays; or cell-based screens to identify chemical starting points. There is a wide array of well-established screening technologies for this purpose, and this section will focus on alternate philosophies and newer methods that have emerged or matured over the last 10 years.

2.01.3.1 Phenotypic Screening

Recent commentaries on the productivity crisis in the pharmaceutical industry have pointed to the highly reductionist approach applied in target selection and target-centric campaigns as contributing to poor clinical translation, and hence there has been a resurgence of interest in phenotypic screening as a mechanism to identify new drug targets and molecular mechanisms for treating disease.[82,83] Phenotypic screening potentially offers several advantages over target-based approaches.[84] Its inherent lack of target bias opens the possibility of targeting any biomolecular entity in its cellular context. In principle, this property enables discovering new targets for modulating cellular pathways and disease states. Because many drug targets reside within the cell, an attractive aspect of phenotypic screening is that it generally selects for compounds with favorable molecular properties for cellular penetration. It also selects for compounds that can attain intracellular concentrations sufficient to modulate their target in the presence of physiologically relevant concentrations of cofactors that might be competitive with compound binding. Finally, a phenotypic approach allows for discovering new molecular modes of action that might not be found in an isolated target-based assay with a defined molecular endpoint that could limit the number functional mechanisms that can be detected for modulating target activity. For example, a phenotypic screen using live bacteria led to Linezolid, a member of a novel antibiotic class that blocks the initiation of protein translation.[85] Similarly, the antiepileptic Lacosamide (**25**) was identified through testing in an in vivo rat model of epilepsy; following its FDA approval, it was documented to promote slow inactivation of voltage-gated sodium channels rather than blocking them directly.[86,87] The essence of the phenotypic movement proposes that the value of a phenotypic screen lies in

its ability to predict the successful translation of a compound or molecular mechanism of action to patients. As a result the greatest success is anticipated from an assay that uses a cellular system with a clear link to disease (e.g., patient-derived primary cells), a physiologically relevant stimulus (e.g., an intrinsic disease stimulus already provided in patient-derived cells), and a proximal and/or clinically relevant readout (e.g., a functional manifestation of disease).[88]



25

Technological advances have helped in the generation of more physiologically relevant systems in which to screen. Greater access to patient tissues and cells together with advances in the ability to induce pluripotency and to subsequently differentiate these iPS cells (IPSCs, induced pluripotent stem cells) in culture to a cell type of interest enables the development of a system using relevant cells that are compromised and demonstrate a disease phenotype in vivo. The genomic editing techniques described above are frequently applied to generate isogenic "normal or corrected" cells in diseases where a specific genetic mutation is being investigated. This practice allows for the comparison of normal and disease cell populations that can be tested for recapitulating a disease phenotype in vitro. If this phenotype can be established and quantitatively measured, then the identification of compounds that can correct/modify the phenotype comes with an increased confidence of clinical translation. Likewise, it is easy to understand the appeal of iPSC-derived hepatocytes to the drug metabolism and pharmacokinetics discipline that has traditionally been limited to working with labor intensive, high cost, and variable primary human hepatocytes for an understanding of clearance mechanisms. A key challenge with the use of iPSCs has been the inability to generate mature differentiated phenotypes that accurately mimic the expression profiles of the gold standard: primary human tissue. As a result, more complex coculture, three-dimensional (3D) culture, and microphysiological systems are emerging that are anticipated to provide the appropriate signals and growth factors for greater cell maturity and physiological relevance.

Spatial control is one of the fundamental premises of 3D cell culture, allowing for patterning of multiple cell types in a way that more faithfully represents the organization of tissues and organs. Four major platforms are typically used for the generation of 3D cultures: spheroids or cellular aggregates, synthetic scaffolds, naturally derived matrices, and hydrogels. Multiple reports have revealed significant changes in gene expression profiles of 3D vs. 2D cultured cells.[89] Many physiological processes take place under flow conditions, for example, blood flowing through vasculature and cancer cells circulating through the body. High-throughput microfluidic systems can be used to mimic these conditions, creating a physiologically relevant shear profile, and these systems have advantages in the design of assays to interrogate processes such as cell or platelet adhesion, rolling velocity, or transmigration.[90] Such cellular models may still be relatively simple from the context of one cell type flowing across a simple immortalized cell monolayer. In contrast, simple in vitro models of kidney function for efficacy, safety, and ADME testing have been challenging to develop for a variety of reasons.[91] The functional filtering unit of the kidney, the nephron, is composed of several cell types with multiple interactions and a specific architecture. There are apical and basal surfaces displaying unique protein expression profiles that drive transport of endogenous substrates and xenobiotics. Isolated primary kidney cells in the absence of 3D cues lose these properties when extracted from the body; moreover, these cells are limited in supply. Immortalized cells derived from the kidney similarly often retain only a subset of renal properties in two-dimensional (2D) cell cultures. The expression of relevant solute transporters has been documented to increase in proximal kidney tubule cells cultured under flow conditions, and a growing body of evidence suggests that extrinsic cues such as appropriate architecture and fluid flow are necessary to establish polarity and promote functional maturation of in vitro kidney cells.[92–94] Enter microphysiological systems, cellular and organ microsystems which have a multicellular architecture representing the characteristics and functions of the tissue of origin and demonstrate a reproducible and viable operation under physiological conditions over a long culture period. These systems, which are often referred to as organs-on-a-chip or tissues-on-a-chip, integrate advances in microfabrication and microfluidics to present highly controlled extracellular cues to cultured cells in a physiologically relevant context. Fluid flow and tissue deformation can be controlled, and the design enables the formation of independent channels with their own fluid access for co-culture systems in order to mimic typical barriers found in the human body. Microphysiological systems have been described for a variety of tissues including the liver, heart, lung, intestine, kidney, brain, vasculature, and bone. The competitive landscape is rapidly evolving although to date most testing has been low-throughput evaluations of efficacy or toxicity.[95]

One significant drawback of running phenotypic screens, even in physiologically relevant systems, is uncertainty of the molecular mechanism of compound action. Anticipation of this challenge and the desire of many chemists to ultimately deconvolute phenotypic hits to their specific protein target for lead optimization often engenders careful consideration of the chemical equity tested in the primary screen. The creation of well-annotated compound collections that are selected based on biological activity against key pathway targets is a typical approach with the hope being that specific cohorts of hits, known to demonstrate activity at the same target or at targets in the same pathway, might lead to a hypothesis for modulating the phenotypic outcome measured. The libraries are generally designed to cover broad areas of pharmacological space and frequently take into account primary target potency, selectivity, and cellular data, or at least physicochemical properties to ensure cell penetration. Compounds that have good lead-like properties and are cell permeable are favorable for phenotypic screens, and clearly compounds with clinical or patient data

can provide invaluable mechanistic hypotheses in addition to fast routes to in vivo testing if they show activity. Compounds that have demonstrated in vivo toxicity are also frequently well annotated within Pharma compound collections and can serve as learning tools within the context of a phenotypic project through indentifying key safety liabilities as well as providing substrate for tool compounds or SAR. Genetic screens such as the CRISPR-Cas9 described previously, or siRNA/shRNA screens provide a complementary approach to small molecule phenotypic screening. Using an arrayed format targeting one gene per well, a very similar approach to small-molecule screening can be taken, often with the very same assay format. These approaches rely on the identification or reversal of the endpoint in question after knockdown of a specific gene, and they are essentially target or pathway identification efforts that can subsequently be converted to target-centric projects. Combining hits from a small-molecule screening campaign with specific genes that impact the phenotype in question can provide a key to unlocking disease physiology.

Recent advances in genetic and proteomic analysis have enabled more rigorous and efficient determination of the target and molecular mode of action for phenotypic screening hits. Activity-based proteomic profiling (ABPP) enables the identification of specific enzyme targets for inhibitors using proteomic technology.[96] This technology relies on the development of mechanistic probes that covalently modify the catalytically active residue of enzymes within a specific gene family. These probes possess molecular features that enable their general activation and covalent labeling only of proteins within that gene family. Activity-based probes generally have fluorescent labels or cell capture tags (typically biotin) attached to them, enabling fluorescent analysis after gel electrophoresis or mass spectral identification after capture on streptavidin-coated beads.[97] The typical ABPP workflow involves incubating drug-treated cell lysates with the fluorescently labeled activity-based probe, quenching the reaction and separating the proteins by gel electrophoresis. Proteins for which compounds compete with the probe produce a reduced fluorescent signal in the compound-treated lysates relative to the untreated controls. The bands corresponding to these differentially labeled proteins can be excised from the gel, digested with trypsin and analyzed by mass spectrometry to identify the protein target from its tryptic peptides. Alternatively, SILAC (Stable Isotope Labeling by Amino Acids in Cell Culture) labeling can be used to produce differentially labeled cells that can be used for the compound treated and control lysates for subsequent treatment by a biotin-labeled activity-based probe.[98,99] Streptavidin capture of the labeled proteins, followed by digestion and mass spectral analysis, allows identification of target proteins by virtue of different quantities of tryptic peptides captured in the compound treated vs. control samples.

Activity-based probes exist for the ATP-site of protein kinases, serine hydrolases, and glucosidases.[100] ATP-based acylphosphonate probes (e.g., **26**) enable general labeling of the catalytic lysine in over 75% of all protein kinases, providing a general method for kinome selectivity profiling and identifying kinase targets for phenotypic screening hits. Probes for serine hydrolases are typically based on fluorophosphonates (e.g., **27**) owing to their broad reactivity with this enzyme family. The requirement for enzyme activity is elegantly demonstrated by the lack of reactivity with serine hydrolase zymogens.[97] Glucosidases contain a nucleophilic aspartate or glutamate residue that is covalently labeled by cyclophellitol. Activity-based probes containing an analogous epoxide or aziridine function (e.g., **28**) as activity-based probes against this enzyme family and can also modify nucleophilic acidic residues in related enzymes.[100] Additionally, general covalent probes for nucleophilic cysteines enable covalent tagging of the reactive cysteinome. These electrophilic compounds can be used to interrogate the differential reactivity of cysteines, which has important implications for understanding their function as potential nucleophiles or as sites for oxidation as a potential regulatory mechanism for protein function.[100–103] Compounds that bind proximally to a site of cysteine alkylation by these electrophiles produce a reduction in reactivity that can be detected by differential fluorimetric or mass spectrometric analysis.

2.01.3.2 New Technologies for Target-Based Screening

Affinity selection mass spectrometry (ASMS) is a high-throughput technology for the unbiased identification of target binders.[104,105] It enables massive parallel screening of compound libraries that can be compressed to >100 compounds per well, provided that each has a unique molecular weight for structural identification by mass spectrometry. In ASMS, the target protein is incubated with a set of potential binders and is then subjected to a separation step that discards unbound compounds (see **Fig. 3**). This separation step is critical for the success of the technique, and several methods have been employed including size exclusion chromatography and ultrafiltration.[106] Size exclusion methods are unique in that they are nonequilibrium methods owing to retention of the unbound compounds relative to rapid elution of the target protein. As a result, this separation method selects for compounds that have a low dissociation rate relative to the elution time of the protein. By contrast, centrifugal ultrafiltration techniques are more likely to select binders based on affinity due to the equilibrium that is established with each washing step. Once the target

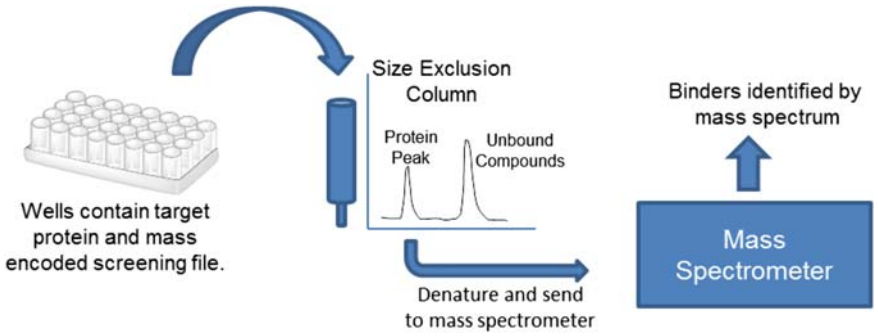

Fig. 3 Schematic representation of the process of affinity selection mass spectrometry used for identification of target binders.

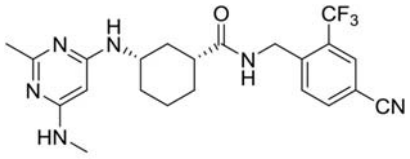
protein is eluted, it is denatured or precipitated, and bound compounds are analyzed by mass spectrometry. Binders are identified by comparing the molecular weights of the bound compounds with a mass table that contains the structures and unique molecular weights of the compounds present in the incubation mixture.

Affinity selection mass spectrometry offers advantages of speed and a low false positive rate once the separation step is optimized. It is also relatively immune to artifacts, provided that the buffers used do not interfere with mass spectrometric analysis through ion suppression. One downside of the technique is that it can require large amounts of the target protein due to sensitivity limitations of the mass spectral readout. It is also impossible to infer the extent of target binding based on signal strength, as each compound has a different ionization efficiency that can vary by orders of magnitude. However, it is possible to determine affinity constants by conducting the ASMS experiment across a range of ligand concentrations and fitting the ASMS response as a function of ligand concentration to a saturation-binding curve.[107] Competition experiments with ligands of known affinity can also be used to estimate K_d for mixtures of compounds.[108] Because ASMS identifies target binders without regard for functional activity, subsequent validation steps are needed to characterize whether and how hits modulate the target. These validation steps typically consist of an orthogonal biophysical technique to validate binding and characterize the binding site, along with a functional assay to determine whether the hit compound inhibits, activates or has no effect on the target protein's activity. Through adding high concentrations of agents that are known to occupy one binding site on the target, it is possible to select for noncompetitive binders or to characterize whether hits identified in an unbiased screen bind at a particular site.[107]

DNA-encoded libraries take the compound compression that can be achieved through ASMS to another level, screening over 100 billion compounds in a single experiment.[109] Once again this is, at its foundation, an affinity-based approach; however, DNA-encoded libraries can dwarf conventional small-molecule libraries and offer a complementary approach for finding structures that bind to novel or challenging targets based on the diversity of chemical space covered just from sheer numbers. DNA-encoded libraries can be synthesized in several different ways, but the largest libraries (including GSK's which comprises 1×10^{12} compounds) tend to be built using a DNA-recording approach. A chemical building block is synthesized and tagged with a unique DNA barcode. A new building block is added to create a small molecule, and subsequently the DNA tag is lengthened to represent the new addition. Through a split and pool chemistry approach, the number of potential combinations is enormous. The protein target of interest is engineered with a purification tag, and then the library and target are combined and passed through a purification column. Binders are identified through sequencing the DNA tag, and an advantage over ASMS appears to be the revelation of a full structure–activity matrix including weaker binders. Clinical candidates are beginning to emerge from DNA-encoded library hits with the most advanced being the soluble epoxide hydrolase inhibitor, GSK2256294 (**29**), which is currently in phase 1.[110,111] This approach is not without its caveats. The DNA tag can sometimes interfere with target binding, and some library members can bind to the purification column causing false positives. The next wave of developments looks to move beyond soluble targets to membrane-bound proteins, and multiple large pharma are investing in collaborations or internal libraries for hit identification.[109]



29

Fragment-based drug discovery (see Fig. 4) is a lead identification technique that has matured considerably over the last decade.[11–14] This strategy also relies on biophysical techniques to detect binders—typically using surface plasmon resonance, NMR-binding assays, or X-ray crystallography. Fragment screens are focused on identifying compounds with low molecular weight (<250) that incompletely occupy a binding site on the target protein.[112,113] Due to their limited binding surface, these compounds usually possess low affinity (sometimes approaching 1 mM), placing a higher hurdle on subsequent medicinal chemistry

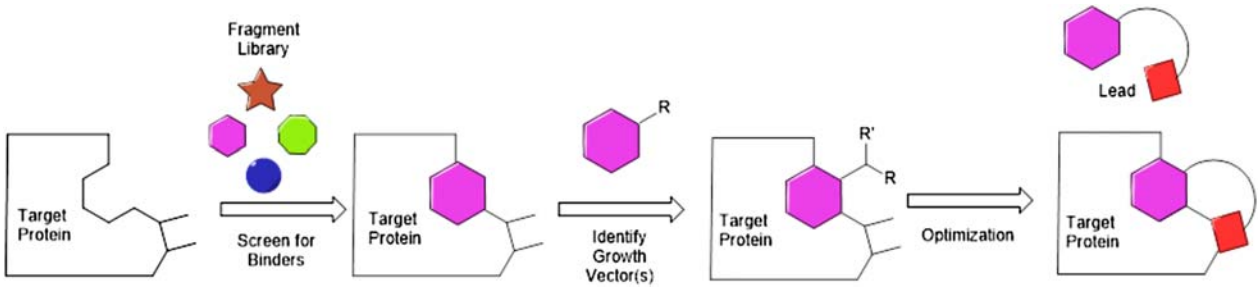


Fig. 4 Schematic representation of fragment-based drug discovery.

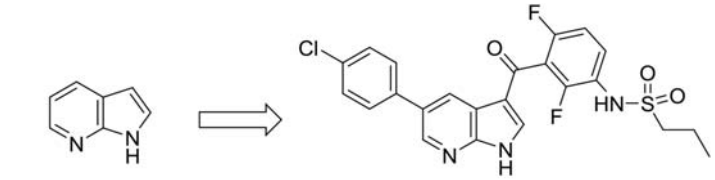
optimization for potency. Structure-guided optimization allows growth of the fragment to yield compounds with lead-like potency. Because the chemical starting points are small, chemical space is significantly more limited in the universe of fragments, making it possible upon fragment growth to penetrate regions of chemical space that are not covered in a corporate compound collection. Therefore, fragment screening offers the potential to identify or create diverse leads for protein targets that would not otherwise deliver compelling hits from a traditional functional high-throughput assay.

As with ASMS, the biophysical techniques that identify fragment hits will only select for target binders. It is not uncommon for functional activity to be undetectable due to the limited dynamic range of functional biological assays. Therefore, early optimization efforts are sometimes undertaken with the belief that increasing affinity will lead to measurable functional activity. Also, it is typical for hit optimization efforts to rely on crystallographic information that guides structure-based optimization of potency and selectivity.

Fragment screening approaches claimed early success with kinases, demonstrating regular propensity to identify compounds that bind at their ATP-binding site. However, corporate collections readily yield elaborated leads that are potent inhibitors binding to these sites. Some early examples of fragment-linking strategies, wherein fragments that bind adjacent sites are attached by a chemical linker to deliver a compound with dramatically improved potency, yielded high-molecular-weight compounds with poor drug-like properties. For these reasons, fragment-based drug discovery took a while before being broadly embraced across the pharmaceutical industry. The emergence of compelling leads from fragment approaches toward difficult targets like beta-secretase (BACE),[114] coupled with the recent approval of vemurafenib (**30**), a fragment-derived drug that targets the BRAF mutant kinase V600E,[115–117] have contributed to wider acceptance of fragment-based drug design as a viable approach for drug discovery.



Original Fragment Hit **30**

2.01.4 Hit Characterization Using Computational Approaches and Biophysical Assays

In any screening campaign (target centric or phenotypic) the first round of hit identification approaches will ideally yield multiple series of compounds that reproducibly demonstrate activity in a dose-dependent manner in the identifying assay/technology. Subsequently, multiple techniques are employed to confirm the validity of these hits, to demonstrate target binding and pharmacological modulation following a target centric screen and, in the case of phenotypic screens, to further deconvolute the biological mechanism of activity.

Computational expertise can frequently be applied immediately to weed out likely false positives based on the wealth of data that already exists in a corporate database and literature examples.[118] For example, some hit compounds may be promiscuous binders, or the so-called frequent hitters. In a recent study, colleagues of ours surveyed 96 high-throughput screening campaigns (HTS) run within Pfizer (82 different targets, 66 gene families, ~300 million data points), and characterized the common features among frequent hitters.[119] The topology and physical attributes of these compounds were analyzed and compared with random sets of compounds generating a fingerprint-based Bayesian model to predict frequent hitters and potentially reduce the time and cost of HTS triage and chemistry follow-up during hit-to-lead optimization. Currently, this model is used as part of Pfizer's tool box for HTS triage and hit follow-up. Multiple groups have published on the nonspecific inhibition of enzymes by compounds that form organic small-molecule aggregates, and more recently, Brian Shoichet's lab have attempted to describe the mechanism of action of aggregate-based promiscuous inhibitors as a partial protein unfolding.[120] Historically, fluorescent compounds were often false

positives in fluorescence-based assays and were triaged out of hit lists or passed through nonfluorescence-based assays for confirmation. Newer generations of fluorescent probes and fluorescent technologies, together with improved compound file characteristics however, have reduced the impact of these compounds on screening campaigns.

Computational expertise is also highly valuable in determining a biological fingerprint of activities to enable the expansion of an initial hit list or build hypothesis around mode of action. Similarity searches based on chemocentric attributes have long been standard approaches for hit expansion and the defining of Structure–Activity Relationships (SAR) using the computational toolbox. Additionally, mining large biological datasets across multiple screens or cell lines enables the clustering of compounds based on their biological similarity. In 2005, Anton Fliri and Pfizer colleagues used percent activities of over 1500 compounds against 92 targets to demonstrate that comparing biological profiles of molecules provides an unbiased quantitative relationship between chemical structure and broad biological effects.[121–123] More recently Novartis identified bioactivity relationships using 195 biochemical- and cell-based assays, highlighting value for virtual screening, scaffold hopping, and designing new subsets.[124] The authors also found that their HTS-fingerprint clustering enriched the gene ontology categories in each cluster, illustrating that compounds in a cluster may not share the same chemical structure, nor target the same proteins, yet they participate in related cellular processes. Hence, biological fingerprint analysis (within a screen and across preexisting datasets) can be a valuable way to characterize hits from a phenotypic screen. Building on this concept, platforms of cell-based assays and informatics models are becoming available to profile compounds in a focused manner. Primary human cells cultured in systems representative of vascular, immune, and inflammatory biology and of sites of human exposure (skin and lung) have been used to classify novel agents according to mechanism of action and to provide insight into clinical phenomena.[125] Similarly a so-called cell painting assay in immortalized cell lines (U2OS) utilizes six stains to profile seven different cellular compartments (nucleus, nucleoli, golgi, plasma membrane, endoplasmic reticulum, mitochondria, and F-actin), and this assay has been shown to similarly cluster compounds with like actions.[126] What is needed now is a way to bring together physiological models and higher-throughput capacities at lower cost to enable disease relevant molecular profiling at scale in the earliest stages of lead identification and optimization. Hypotheses that are generated for the mechanism of action of hits at the conclusion of phenotypic campaigns, for example, from an annotated compound subset with known activities or from biological fingerprint clustering, can be validated through targeted siRNA/shRNA experiments designed to modulate the targets or pathways in question in an attempt to phenocopy the compound activity.

In addition to being biologically validated, hits identified from target-centric high-throughput screening need to have their target-binding properties characterized in order to have confidence in their suitability for lead optimization efforts. This process involves using an orthogonal technology, typically a biophysical or biochemical assay that is complimentary to that used in primary screening so that binding kinetics and thermodynamics can be characterized alongside functional activity. Well-designed studies provide information on molecular mode of action in addition to triaging compounds that emerge as false positives due to undesired mechanisms of target modulation.

Surface plasmon resonance is a general technique for characterizing binding affinity, association rate, and dissociation rate. This technique measures subtle refractive index fluctuations that occur when effective target mass changes upon ligand binding. Flow-based systems are commonly used for this purpose, as they enable direct measurement of binding kinetics. The target protein is immobilized—typically through biotinylation of surface lysine residues and capture on a streptavidin chip. The protein-treated chip is then exposed to a running buffer across a control and treatment channel. Upon addition of compound to the running buffer on the treated channel, a difference in refractive index is captured as a function of time, enabling association rate to be quantified. After equilibration, the treated channel is washed with running buffer, enabling the measurement of dissociation kinetics. Saturation binding can be measured by treating the chip with different concentrations of the test compound. As such, it is possible to measure binding kinetics and affinity in a single experiment. Because this technique requires immobilized protein, it is important to ensure that the immobilization process does not alter the structural properties of the target-binding site. The observation of similar control compound affinity as measured by SPR and solution techniques gives confidence in the structural relevance of the immobilized protein. It is also possible for the protein to bind test compounds so tightly that regeneration of the unbound protein is impossible or occurs very slowly upon treatment with the running buffer. In these cases, the utility of SPR is compromised by the expense and limited lifetime of the protein-treated chip.

Microscale thermophoresis (MST) is a related technique that allows direct measurement of binding affinity. It is an optical technique that requires a fluorescent tag to be attached to the protein; alternatively, label-free MST can be used, provided there is sufficient fluorescent signal from tryptophan residues in the protein.[127] This technique relies on compound-induced thermophoretic mobility shifts, which result from differences in solvation entropy, size, or charge of the bound vs. unbound protein.[128] In MST, the protein sample is introduced into a capillary on a thermally controlled stage. Local heating by an IR laser induces changes in the fluorophore's fluorescence due to conformational alterations in its local environment. These rapid changes are followed by a slower, diffusion-controlled depletion of protein concentration in the local field of heating due to thermophoresis. Upon termination of the IR-laser-induced heating, the fluorophore's environment changes again due to local cooling, resulting in a rapid reversion to the initial intrinsic fluorescence of the protein complex. This event is followed by diffusion-controlled re-equilibration of the concentration gradient through thermophoresis. The fluorescent signal changes produced from each of these properties can, in principle, be influenced by compound binding.

Microscale thermophoresis offers the advantages of studying proteins in solution, and with the use of a suitable fluorescent tag, proteins can be studied in mixtures or even cell lysates provided the target protein can be selectively observed. Furthermore, by titrating test compound in the presence of cofactors or other binding partners, it is possible to determine the molecular mode of action (competitive or noncompetitive) relative to the other agents.[127] As examples of its utility, MST was used to characterize

the binding affinity of several protein–protein interactions, such as the binding of TEM-1 β-lactamase to the β-lactamase inhibitory protein BLIP.[127] The binding affinity of the Grb2 homodimer was studied by titrating fluorescently tagged Grb2 with untagged protein.[127] Here, the technique demonstrates superiority to isothermal calorimetry due to the relative insensitivity of that technique, limiting its use in studying high-affinity protein dimerization events. The MST technique was also successfully used to characterize the interaction of caffeine, theophylline, and amiloride with the adenosine A2a receptor, where results concurred well with radiolabeled ligand affinity studies.[127]

Isothermal titration calorimetry is a technique by which binding free energy, enthalpy, and entropy can be determined.[129] It directly measures heat evolution from the incubation chamber, which is held at constant temperature while the test compound is introduced. Its sensitivity is directly dependent on the amount of enthalpy generated by binding of the analyte ligand to the protein target. Free energy of binding can be calculated from the K_d, which can be derived from titrating the test sample and looking for saturation of the binding enthalpy curve. Binding entropy is then calculated using the Gibbs free energy equation, given that the free energy and enthalpy of binding are directly determined from the experiment. While the technique is generally useful for determining binding thermodynamics, conventional ITC requires a relatively large amount of pure protein. Moreover, the energetics of binding can be significantly influenced by experimental conditions such as buffer composition. Recent reviews of drug discovery campaigns have suggested that binding thermodynamics are characteristic of lead quality, with enthalpically driven binding events being regarded as highly beneficial relative to entropically driven affinity.[130] During lead optimization, it is common to see entropy–enthalpy compensation, a process by which increasing enthalpic interactions drives a corresponding decrease in the favorability of the entropy term in the Gibbs free energy equation. This phenomenon can be understood chemically from the observation that increasing binding enthalpy through improving H-bonding, van der Waals, and pi-stacking interactions generally rigidifies the protein–ligand complex, resulting in lower entropy upon binding.

The ability to monitor target engagement directly within cells or tissue was provided by the development of the cellular thermal shift assay (CETSA).[131] In this procedure, cell lysates, intact cells, or live animals can be dosed with compound. For in vivo experiments, frozen organs are homogenized, lysed, and then cleared of lipids and cell debris. Small aliquots of lysates or intact cells are heated to different predetermined temperatures for short period of time (~3 min) and then cooled at room temperature (~3 min). Intact cells are lysed at this stage, and subsequently soluble protein is isolated (typically by filtration or centrifugation) and quantitated (by western, ELISA, antibody, mass spectrometry, etc).[132] In the first proof-of-principle study, all samples were centrifuged to separate soluble fractions from precipitates, and the supernatants were separated by SDS-PAGE and quantitated by Western blotting. Plotting amount of soluble protein against temperature yields the CETSA melting curve, and subsequent addition of a ligand results in a shift of this melting curve. For a range of drug concentrations measured at constant temperature, the isothermal dose–response curve generated is used as a fingerprint of target engagement along the drug concentration range. Absolute binding affinities cannot be derived, since the protein precipitation on unfolding is not reversible, and the system is clearly not in equilibrium. However, at high concentrations of compound the aggregation temperature approximates the melting temperature and can be used to relatively rank affinities. Although CETSA data are highly related to the data achieved with pure protein (such as in isothermal calorimetry), the melting curves in cells and lysates are more dispersed than in purified proteins, and this phenomenon has been suggested to reflect the presence of multiple forms of protein in the cell. Combining pulsed temperature denaturation with enzyme fragmentation complementation technology[133] is proposed to generate a facile HTS-compatible protocol with a sensitive and quantitative readout. In this refinement, the target of interest is tagged with a label that can be detected by its complimentary binding partner, thus creating the signal readout. A differential signal post-heating therefore identifies a stabilized target bound by compound. Using quantitative mass spectrometry as the CETSA detection method enables parallel binding experiments in proteome-wide studies, and the identification of downstream thermal shifts representing altered signaling changes provides an exciting opportunity for MS-CETSA to play a role in phenotypic deconvolution and discovering mechanistic biomarkers.[132]

Back-scattering interferometry provides another label-free, binding detection methodology which is performed in solution, is matrix-tolerant and has low sample requirements. Sample contained within a microfluidic channel on a chip is placed in the beam from a He-Ne laser. Combinations of reflection and refraction at the air-chip and fluid-chip interfaces create constructive and destructive interference fringe patterns, which can be detected in the direction of the back-scattered light. The fringe patterns are collected by a mirror and directed to a CCD array. When molecules combine, the refractive index in the detection zone changes, creating a phase shift pattern at the fringes. This phenomenon allows for quantitative equilibrium K_d measurements to be performed even in complex biological or chemical matrices. Both positive and negative changes in the refractive index can be detected by back-scattering interferometry relating, respectively, to an increase and a decrease in the molecular footprint (solvent addressable surface area and mean radius of gyration). A publication from AstraZeneca demonstrates the use of back-scattering interferometry in a recent effort to assess whether GPR39 agonists might enhance β-cell function in type 2 diabetes, leading to improved insulin release and glucose control.[134] Three compounds identified in a high-throughput screen were assessed for their ability to bind GPR39 in the presence of Zn^{2+}, which is known to modulate GPR39 function. Compound binding affinities were calculated using a one site model, and, interestingly, the technique also allowed the detection of Zn^{2+} binding to GPR39 at both high- and low-affinity sites.

Second-harmonic generation can also be used to detect structural and conformational changes of proteins. It is an optical technique in which two photons of equal energy are combined by a nonlinear molecule or material to generate one photon with twice the energy. The protein of interest is labeled with proprietary dyes conjugated to either amines or thiols and tethered to a lipid bilayer surface via a His-tag. Upon stimulation by a femtosecond laser, the dyes generate second harmonic light, and the intensity of the signal is highly sensitive to the average angular orientation of the dye. Even sub-Ångström shifts in orientation cause a detectable signal change that is not affected by mass or structure, and so is amenable to proteins of varying molecular weight and ligands

ranging from small fragments to protein complexes, including antibody-antigen interactions. Moree et al. recently used second-generation harmonics to identify hits from a fragment library that can modulate the confirmation of α-synuclein and reduce protein aggregation in cells.[135]

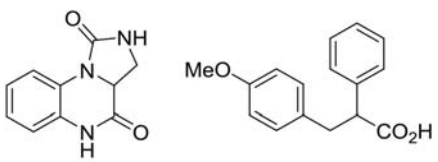
X-ray fluorescence is analogous to optical fluorescence but uses X-ray photons rather than optical or ultraviolet wavelengths for excitation. Each excited element emits X-rays at a unique frequency dependent on its atomic number, and analysis of a frequency spectrum can reveal the elements present in a sample. Since all elements with atomic number greater than 12 can be assessed, this approach could prove valuable as an orthogonal technique for transporter or ion channel assays to measure flux of monovalent and divalent cations, to track halogens, first-row transition metals, and small molecules.[136]

Nuclear Magnetic Resonance (NMR) provides a powerful set of methods for screening fragment collections to identify binders, characterizing protein–ligand interactions, studying the dynamics of protein motion, and determining functional inhibition of enzyme action. As such, it is a commonly used biophysical technique for both primary screening and hit characterization. NMR methods offer the advantage of good sensitivity, enabling the study of weak protein–ligand interactions that are typically found with fragments used as starting points for fragment-based drug discovery. Moreover, protein NMR spectroscopy offers the possibility of determining the precise binding site and molecular mode of action for hits, delivering mechanistic information that can be difficult to obtain using other techniques. With the evolution of 1.7 mm cryoprobes, protein requirements have diminished considerably due to the threefold sensitivity improvement and reduced material requirements relative to earlier 5 mm cryoprobes.

Saturation Transfer Difference NMR spectroscopy is commonly used as a screening technique for fragments and other weakly binding compounds. The basic principle of STD spectroscopy involves the transfer of energy from irradiated methyl groups on the protein to bound small molecules.[137] Upon dissociation of the small molecule from the protein, some of this transferred energy is retained and can be detected in the 1D NMR spectrum. Compounds that do not bind to the protein will receive no transferred energy and therefore will not present signals in an STD NMR experiment. A related method for detecting protein binders is Water-LOGSY.[138] Like STD spectroscopy, this technique relies on the transfer of energy across interacting molecules—in this case from water to the protein–ligand complex and then to the bound ligand. These techniques are more sensitive to weak binders and are preferred for screening fragments or for confirming the binding of compounds that are identified via other methods.

The protein requirements for NMR screening can be dramatically reduced by adapting these screening methods to a flow-based system, wherein the target protein is immobilized on a solid support. Target Immobilized NMR Screening (TINS) relies on the principle that transverse relaxation times increase for ligands that are bound to an immobilized protein, resulting in a loss of their resonances from a proton NMR spectrum due to line broadening.[139] By examining difference spectra between the initial mixture of test compounds in solution and in the presence of immobilized protein in a flow NMR probe, one can determine the identity of compounds that bind to the target protein. The TINS technique is quite sensitive, being able to detect compounds with affinities as low as 1 mM. Because the technique does not rely on magnetization transfer, it is more sensitive to compounds that bind tightly to the target protein. Targets are typically biotinylated and immobilized on a streptavidin-containing sepharose support.

Protein NMR spectroscopy can also be used to characterize the binding site for small-molecule ligands by observing ligand-induced changes in TROSY (transverse relaxation-optimized spectroscopy) spectra.[140] TROSY spectroscopy reduces the multiplicity of peaks in an HSQC spectrum by exploiting relaxation mechanisms that cancel out the different relaxation components of multiplet peaks, enabling the study of large molecule spectra. This technique is most powerful where spectral peak assignments have been made on the target protein, but it is still useful for comparing the likely molecular mode of action between different ligands even in the absence of peak assignments. Selective isotope labeling of one amino acid type with ^{15}N and ^{13}C atoms (Phe, for example), dramatically simplifies the HSQC spectrum by restricting observations to only that subset of residues. Single residue assignments can be made through site-directed mutagenesis and noting the absence of that particular residue in the TROSY spectrum of the labeled protein. Upon ligand binding, local changes in the environment of the ligand's binding pocket result in chemical shift changes for adjacent amino acid residues. These chemical shift changes feature prominently in the TROSY spectrum, allowing definitive placement of the ligand by assignment of the perturbed resonances.[140] While it is possible to see long-range chemical shift perturbations induced by compound-induced protein motions, the largest changes are typically observed for the ^{15}N-^{13}C correlations that correspond to backbone amide groups closest to the compound's binding site. This technique is quite reliable for determining the similarity or uniqueness of the molecular mode of action for a series of protein ligands. For example, TROSY spectroscopy was used to characterize the binding site of PDK inhibitors by observing the similarity of chemical shift perturbation fingerprints for test compounds relative to spectra collected for a known ATP-site binder (staurosporine) or a substrate analogue.[140] Thus, fragment screening hit **31** was determined to bind to the ATP site based on similar chemical shift perturbations relative to staurosporine, whereas fragment hit **32** was determined to bind at the allosteric PIF pocket by virtue of similar chemical shift perturbations to a short peptide PIF-site binder.[140]



31 **32**

Spin labeling is another method, wherein compounds can be localized within a protein.[141,142] This technique relies on paramagnetic acceleration of relaxation rates for nuclei that are proximal to a spin label that has been introduced on a specific site of the protein. Compounds that are bound within 20 Ångström of the spin label experience accelerated relaxation rates, leading to further line broadening and signal reduction.

While NMR spectroscopy has demonstrated significant utility for directly assessing compound binding and determining molecular mode of action, it is also useful for studying functional modulation of enzyme action. Like mass spectrometry, NMR has been used to follow the course of enzymatic reactions and thereby characterize small molecule potency and function. In principle, NMR-based functional activity screening offers significant specificity advantages over optical methods for following the course of an enzymatic reaction. It is insensitive to optical artifacts induced by compound fluorescence or absorption in regions of the visible spectrum that are used to detect enzymatic reactions. Therefore, studies can be conducted at high concentrations of test compounds, enabling the characterization of weak binders such as fragments. The practicality of this method depends on the ability to detect substrate and product resonances without interference from compound signals. A strategy for reducing interference is to use fluorinated substrates and track the ^{19}F NMR signal, taking advantage of its broad chemical shift dispersion and high NMR sensitivity. Incorporation of a trifluoromethyl group was used to create functional peptide probes for the AKT1 Ser/Thr kinase and for trypsin as a model protease.[143] This technique was dubbed 3-FABS (Three Fluorine Atoms for Biochemical Screening). Because the 3-FABS technique is insensitive to interference from compounds lacking fluorine, it is possible to screen in the presence of human serum albumin to enable estimation of plasma protein binding.

One limitation of the 3-FABS approach is its requirement for a trifluoromethyl group, which in some cases may not be tolerated on the protein substrate or cofactor. Proton-decoupled NMR data collection enables use of a single fluorine atom, which is a more conservative substitution. This approach was successfully extended to the study of fluorinated ATP analogues as substrates for ATP-dependent enzymes, including kinases, hydrolases, and ligases.[144] A survey of two fluorinated ATP derivatives revealed that 2′-Fluoro ATP (**33**) is a substrate for some ATP-dependent enzymes, including the kinase PDK1 and the bacterial ligase MurC. However, it was not a functional substrate for the bacterial enzyme NadE. The related substrate 2-fluoro-ATP is a functional substrate for nine different enzymes, including NadE, PDK1, the bacterial thymidylate kinase TMK, adenylate kinase, hexokinase, pyruvate kinase, myosin ATPase, creatinine kinase, and RNA polymerase. This broad substrate compatibility suggests that 2-fluoro-ATP (**34**) could serve as a general tool for developing NMR-based functional assays across a wide array of ATP-dependent enzymes. The conversion of ATP to ADP and AMP can be monitored for either substrate by monitoring the ^{19}F NMR resonances near 24 ppm (2-fluoro ATP) or −127 ppm (2′-fluoro-ATP) using this technique. The broad chemical shift dispersion associated with fluorine led to very little interference from fluorine-containing test compounds.

2.01.5 Lead Optimization

It is rare for a lead compound to possess all of the attributes required of a clinical candidate suitable for development. The lead optimization process requires careful medicinal chemistry design to optimize protein–ligand interactions, which have a direct bearing on potency and selectivity, while paying careful attention to physicochemical properties that are conducive to favorable pharmacokinetic, biopharmaceutic and safety properties, and avoiding functional groups that are associated with toxicity. The complexity of this process results from interplay of these variables, the number of parameters requiring optimization, and the frequent concomitant deterioration of some of these properties during attempts to optimize others. The flow of design ideas occurs more rapidly than the pace of synthetic chemistry, placing a premium on technologies that enable selection of those design hypotheses with the greatest probability of success. Despite the power of technologies that will be highlighted in this section, it is sometimes prudent to challenge models that are used to drive design by occasionally preparing and testing compounds that are orthogonal to the direction that they suggest. Doing so enables model refinement and builds confidence in the tools being used to drive drug design.

The optimization of binding affinity, selectivity, and functional activity is greatly enhanced through structure-based drug design using protein–ligand structures or homology models. The field of structural biology has undergone a renaissance in recent years with breakthrough advances in membrane protein crystallography, cryo-electron microscopy of multiprotein complexes, and new techniques for ultrafast crystallographic data collection that have broadly expanded the structural genome. These technology achievements have opened new frontiers in understanding the molecular basis of receptor and ion channel function, RNA splicing, ribosomal protein synthesis, epigenetic regulation of gene expression and transporter function, to name a few.

The G-Protein-Coupled Receptor family has been an extraordinarily productive hunting ground for drug targets, in part because of the pivotal role these receptors play in cellular signal transduction, but also because a number of them have very drug-like endogenous ligands. The human genome encodes for over 390 nonolfactory GPCRs, and approximately 150 drugs in the human pharmacopeia have at least one GPCR as their primary target. However, there remains a lot of opportunity for drug discovery within this gene family. Despite the number of drugs developed for GPCR proteins, roughly 80% of this gene family remains without a marketed drug agent. Recent advances in understanding GPCR pharmacology have also opened new opportunities for differentiated therapeutics directed at GPCRs that are already targeted by a marketed drug agent. GPCR's signal through two second messenger systems G-proteins and β-arrestin. It is possible to bias this signaling toward one of these two pathways through structural modification of orthosteric agonists or through allosteric modulation. As such, it is conceivable to dissociate some of the adverse effects or tachyphalaxis from therapeutic effects in certain diseases as described earlier.

Integral membrane proteins are significantly challenging targets for structural biology. Their membrane localization results in extensively exposed hydrophobic surface that often leads to poor expression and aggregation in aqueous buffers used for purification and crystallization. The seven transmembrane helical domain of GPCRs generally lacks polar surface residues that are important for forming crystal contacts. Finally, G-protein-coupled receptors and transporters tend to be very dynamic proteins, creating particularly high entropic barriers to crystallization in an ordered lattice. As such, stabilizing mutations, fusion proteins, antibodies, or tightly binding ligands must be used to stabilize these proteins for crystallization.[145] Finally, crystals from these protein targets can exhibit significant instability to radiation, requiring merging of datasets across several crystals or X-ray free-electron laser technology to collect a complete data set from one crystal.

Many of these challenges have been addressed through technology advances that enable more facile protein purification and crystallization. Issues of protein instability and the absence of adequate polar contacts for crystallization can be addressed through introducing stabilized mutations (STaR technology), designing fusion constructs with BRIL or T4-lysozyme proteins, or complexation with Fab antibody fragments. The StaR approach involves scanning mutagenesis of transmembrane residues to identify point mutations that increase thermal melting temperature of the protein, which is an indicator of its stability. Mutations conferring this property are analyzed for their effect on protein expression and ligand pharmacology to ensure the mutant receptor retains function and that protein can be produced in adequate quantities for structural studies. Fusion protein constructs aim to introduce polar crystal contacts and reduce protein aggregation through introduction of a highly crystalline protein fragment in one of the intracellular or extracellular loops. A similar, noncovalent strategy involves the use of antibody Fab fragments or nanobodies raised to conformational epitopes of the GPCR to stabilize the receptor and enable its crystallization. Crystallization of the protein is typically accomplished in lipidic cubic phases, which enable the protein to crystallize in an environment resembling its native membrane. The membrane protein is typically purified in an aqueous mixture with detergents and is then homogenized with monoacylglycerol, which forms a cubic phase in which the aqueous and bilayer components are continuous in all three dimensions. Addition of a precipitant then forces crystallization of the protein in an environment enriched in one of the lipidic cubic-phase components, which form lamellar sheets onto which the regular ordered array of protein molecules assembles.

The first nonrhodopsin GPCR to deliver a high-resolution crystal structure was the β2-adrenergic receptor, the structure of which was reported in 2007. Since then, structures from each major class of GPCRs have appeared in the literature.[146] Many of the first GPCR structures were delivered with antagonists bound to the orthosteric site. Subsequent structures with bound agonists and allosteric modulators have dramatically expanded our understanding of the molecular basis for GPCR pharmacology.[147] Specifically, agonist structures of the β2-adrenergic receptor with Gs-heterotrimer protein[148] or of rhodopsin complexed with β-arrestin[149] have given insights into interactions that are critical for binding these partner proteins and affecting signaling through their cognate pathways.[150]

The ion channels constitute an important family of signaling proteins and drug targets. These proteins regulate the passage of calcium, sodium, potassium, chloride, and other ions through the plasma membrane and are responsible for regulating a number of physiological processes, such as muscle contraction and synaptic transmission. There are over 200 ion channels encoded by the human genome, reflecting the diversity of signaling pathways which they regulate. Ion channels are able to respond to many extracellular stimuli, such as temperature, pH and membrane potential, and their activity can be regulated by a variety of small-molecule ligands that bind to the pore domain or to various allosteric sensor domains. Many drugs have been discovered which modulate ion channels, including (1) the benzodiazepines, which modulate GABA channels and are important anxiolytics; (2) topical anesthetics, which modulate voltage-gated ion channels; (3) calcium channel blockers, which function as antihypertensives; and (4) GABA analogs, such as gabapentin, which regulate voltage-gated calcium channels and are effective agents for treating neuropathic pain and epilepsy.[151] Despite the discovery of many therapeutic agents that target ion channels, there remains considerable untapped opportunity for discovering new agents given the number of family members with no known ligands, or for which only weakly active, nonselective ligands are known. Recent advances in ion channel structural biology have provided insights into the diverse mechanisms of their regulation and promise to enable more efficient optimization of potency and selectivity through structure-based drug design.

Ion channels are transmembrane proteins which function through gating of a central pore that passes ions across the membrane. This gating event typically involves stimulus-induced molecular movements in the pore domain which alter its size and can occur based on ligand binding or gradients of voltage, temperature, or pH.[152,153] Most ion channels are highly selective for the ions that they transport. This selectivity is driven by a region known as the selectivity filter, which adopts dimensions closely aligned with the ion that the channel transports. Ion conduction is facilitated by an array of backbone carbonyls or polar side chains that line the pore and enable transport of ions in either their hydrated or partially dehydrated form through a polar channel of defined size. Ion

channel antagonists function by blocking the pore at either its extracellular or intracellular face or through allosteric modulation of the protein.

For over 50 years, protein crystallography has been the preferred technique for studying protein structure at high resolution. Advances in crystallization techniques, the evolution of microfocused synchrotron beamlines, development of highly sensitive detectors, and the introduction of novel phasing methods have made protein crystallography almost a routine practice, enabling structure-based drug design for a wide range of protein targets. Furthermore, the range of biomolecules able to be studied by X-ray crystallography spans crambin at the lower end of molecular weight to the 70S ribosome. Despite this progress, the requirement for protein crystals makes X-ray crystallography a demanding technique for studying large biomolecules or multiprotein complexes. Cryo-electron microscopy (CryoEM) offers a complementary method for studying these systems based on its ability to image single particles in a 2-dimensional array and its greater effectiveness with larger proteins.[154,155] The Cryo-EM technique uses transmission electron microscopy to deliver a 2-dimensional projection-image of the protein. These 2-dimensional projections can be reconstructed into a 3-dimensional model, yielding structural information with near-atomic resolution.

Recent advances in technology have overcome some of the key hurdles impeding high-resolution cryoEM studies of protein assemblies.[154,155] One of the challenges with sample preparation for electron microscopy is dehydration of the protein sample in the vacuum environment required for EM studies. Through plunging the hydrated sample into a cryogen, the protein becomes trapped in a layer of vitrified ice, which obviates this issue. The lack of heavy atoms in biological specimens limits the extent of electron scattering. The radiation sensitivity of many protein specimens requires low electron doses to preserve sample integrity. This fact, coupled with the lack of heavy atoms in biological specimens which limits the extent of electron scattering, leads to low signal-to-noise ratio. The low signal-to-noise ratio for protein cryoEM can be managed through aligning and averaging across thousands of 2D projection images. This strategy requires the protein sample to be very pure so as to not complicate analysis with the presence of interfering contaminant particles. Likewise, the need to align across many projections requires easily identifiable features on the molecule being studied, which is more likely with larger samples or protein assemblies bearing symmetry. The introduction of direct electron detection (DED) cameras addresses one of the principal barriers to obtaining high-resolution structures: the movement of the protein molecule upon collision with the electron beam. This motion results in blurring of the 2D image, limiting resolution. The DED camera allows image collection in movie mode, which enables tracking beam-induced motion of the protein and its surroundings. Relatively few protein structures have been solved at high resolution by cryoEM, but several noteworthy recent examples include the gamma secretase complex[156,157] and the TRPV1[158,159] and TRPA1[160] ion channels. These examples illustrate the promise of cryoEM in enabling structural studies of targets that would be difficult address with protein crystallography and as an addition to the armamentarium of techniques supporting structure-based drug design.

Experimentally determined structural information forms the basis for computational modeling of protein–ligand interactions that lead to new hypotheses on how to design for increased potency and selectivity of lead compounds. The era of structure-based drug design was ushered in with the discovery of the angiotensin-converting enzyme (ACE) inhibitor captopril, which used homology modeling of the related zinc peptidase, carboxypeptidase A, to design succinyl amino acid-based ligands bearing a thiol-based zinc chelator.[161–163] Since that discovery, computational modeling of crystal structures has become a central feature of many successful drug discovery programs targeting kinases, proteases, and hydrolases.[164] Early techniques employed in structure-based drug design used manual assessment of ligand-based functional group replacements based on their compatibility with neighboring residues in the protein–ligand complex. The accurate prediction of binding energetics is critical to the success of modern structure-based drug design and relies on having a high-performance potential energy function and molecular dynamics simulations to estimate the conformational space of both the ligand- and the protein-binding pocket. Significant effort has been devoted to the development of force fields that estimate the energetics of protein–ligand binding interactions. Newer force fields, such as OPLS2.1 (Optimized Potentials for Liquid Simulations—Schrodinger, New York, 2014), which is trained on thousands of organic compounds that are representative of small molecule drug space, promise to deliver more accurate estimation of torsional energies and nonbonded interactions that are critical for computing binding free energy.[165] In order to reduce the number of protein residues that are required for sampling the conformational space of the ligand-binding pocket, REST (Replica Exchange with Solvent Tempering) is employed to determine the regions of the protein and ligand that are subjected to simulated annealing. While it is computationally challenging to conduct accurate absolute free energy prediction, the use of free energy perturbation (FEP) analysis to compare the impact of minor structural changes on binding energy is more feasible and useful in potency optimization. The combined FEP/REST approach involves the collection of a series of structurally related molecules that are sorted by similarity, and free energy perturbation cycles are then created between a limited number of related compounds.[165] Free energy perturbation calculations then generate a series of $\Delta\Delta G$ values between each structural member of a given free energy cycle, leading to potency predictions for every molecule in the set. A study of eight different protein targets comprising 330 free energy perturbations demonstrated that the FEP/REST method employing the OPLS2.1 force field delivered accuracy to within RMSE of 1 kcal/mol across the data set.[165] Furthermore, this method was accurate in predicting the direction and magnitude of affinity change resulting from ligand pairs emphasizing differences in electrostatic interactions, hydrophobic interactions, ionic interactions and ability to expel unfavorable water molecules from the ligand-binding pocket.[165]

An important component of binding free energy for a protein–ligand interaction is derived from displacement of water molecules upon binding a ligand with functional groups that complement residues in the ligand-binding pocket.[166] Displacing these water molecules is often entropically favorable due to the protein-inducing constraints on their motion relative to bulk solution. Moreover, water molecules enclosed within a largely hydrophobic protein pocket suffer from unfavorable enthalpy due to an incomplete complement of hydrogen bonds relative to their completely solvated state. It is now possible to estimate the binding

energy, entropy, and enthalpy of water molecules in the ligand-binding site using explicit solvent models such as Watermap®. In the Watermap® application, solvent sites are defined by conducting a short molecular dynamics simulation on an explicitly solvated binding pocket and defining bound waters through examination of solvent clusters (density peaks) relative to a uniform solvation model.[166,167] The chemical potential of the bound state of each water molecule is then computed. Inhomogeneous solvent theory is used to calculate the average system interaction energy of each water molecule in the bound state relative to bulk solvent, which delivers an estimate of the water molecule's binding enthalpy. The system interaction energy is defined as the average interaction energy of a given water molecule with the rest of the system (protein residues, backbone atoms, and other solvent molecules). Likewise, the excess entropy resulting from the bound state of the water molecule defines its binding entropy. This information delivers more accurate estimates of ligand-binding energy and potency prediction across a series of compounds but also provides useful physical insight that is applicable to drug design. Specifically, this information is helpful in estimating whether a design strategy should target displacement of a given structural water molecule or building in functional groups to form productive hydrogen-bonding interactions with it. Water molecules that are predicted to have favorable binding energies driven through strong enthalpic interactions become appropriate for targeting hydrogen-bonding interactions with the inhibitor, whereas those with unfavorable entropy that is not offset by highly favorable enthalpic interactions become targets for displacement strategies.

Applications of the WaterMap approach include improving the performance of docking and scoring calculations using implicit solvent models (MM-GB/SA) to orient the ligand in the protein, followed by replacing the GB/SA component with the explicit solvent model from WaterMap to calculate interaction energies. This combination was shown to be better than GLIDE XP, Watermap, or MM-GB/SA alone for predicting binding affinities within congeneric series for inhibitors of CDK2 and Factor Xa.[168] The use of WaterMap alone for predicting binding affinity needs to be treated with caution. While desolvation of a protein-binding pocket accounts for the majority of binding energy in most cases, WaterMap does not consider ligand strain energy, ligand desolvation, conformational entropy penalties, protein–ligand electrostatic interactions, or protein strain energies. As an example, WaterMap performance in predicting the binding energies of a series of SRC inhibitors was only qualitative; although it successfully clustered highly potent and less active compounds across a 4 kcal/mol energy range, it performed poorly in predicting potency trends for compounds with intermediate affinity.[169] WaterMap was used to analyze complexes of tofacitinib with JAK family members (JAK1, JAK2, JAK3, and Tyk2), ascribing a tentative role for tofacitinib's nitrile group in displacing a highly unfavorable water molecule near the glycine-rich loop of the kinase. The role of this nitrile group in imparting exquisite potency to tofacitinib is otherwise unapparent from protein crystal structures.[170] Watermap also successfully explained structure–activity relationships for a congeneric series of spiropiperidine BACE inhibitors based on the propensity of groups binding to the S1 and S1a pockets to displace energetically unfavorable water molecules.[171] Applying WaterMap to a series of matriptase inhibitors revealed unstable water molecules in the S1′ pocket that when displaced by compounds bearing larger groups projecting into the S1′ region led to a 100x improvement in binding affinity.[172] Solvent modeling using WaterMap combined with a related protocol SZMAP was able to rationalize differences in off rate of a series of adenosine 2a receptor binders.[173] While this combination afforded reasonable prediction of binding affinity when used in conjunction with MMSA, it did not perform as well as a combined GRID search using water and a CRY probe for lipophilicity in conjunction with MMSA. Finally, WaterMap analysis has been used to understand the relative binding thermodynamics of core fragments and auxiliary binding groups in fragment to lead optimization and to develop principles for protein druggability analysis based on the association of fragment hotspots with clusters of energetically unfavorable water molecules.[174]

2.01.5.1 Expanding drug-like chemical space: Rational design of covalent inhibitors

Medicinal chemistry strategies for improving potency and selectivity typically involve optimizing nonbonded interactions between the drug molecule and its target protein. This reversible, noncovalent target modulation strategy enables understanding PK/PD relationships in terms of equilibrium binding affinity relative to steady-state plasma concentrations and reduces the risk of idiosyncratic toxicity due to immunogenic reactions against modified proteins. However, there are instances where a covalent inhibition strategy might be preferred: for instance, when highly homologous binding sites exist between a desired target and close family members for which selectivity is desired. In cases where the target resynthesis rate is slow, covalent target modulation strategies also capitalize on prolonged pharmacodynamic effects long after dissipation of free drug concentrations in plasma. These advantages have led to a recent resurgence of interest in covalent target modulation strategies.[175,176] However, these advantages come with two principal risks: the generation of immunogenic responses to haptens created by irreversible covalent modulation of a drug target and the potential for reduced selectivity in cases where the functional group forming the covalent bond is too reactive. Recent advances in proteomic technology, coupled with a better understanding of the capacity of physiological mechanisms to manage low doses of reactive species, have led to a better appreciation of how to quantify and manage these risks.[17,177]

The question of covalent inhibitor selectivity can be elegantly addressed using recent advances in proteomic technology. In cases where the covalent inhibitor binds to the active site of a kinase or serine hydrolase target, the aforementioned competitive activity-based proteomic profiling (ABPP) technique can be used to interrogate selectivity within the target protein gene family.[97,178] In a basic implementation of this technique, a broadly reactive activity-based probe is used to interrogate the proteome with which it reacts. Competition experiments utilizing the test compound deliver a selectivity profile through comparing the treated and untreated cell lysates for differences in signal generated by the activity-based probe. This technique can use fluorescently tagged activity-based probes for in-gel analysis or biotinylated probes to allow capture of labeled proteins, followed by mass spectral analysis. One important limitation of this technique is that selectivity across the broader proteome must be inferred from the inhibition profile within the target gene family that was interrogated. A more thorough technique involves generating an activity-based probe

using the covalent inhibitor itself, wherein a clickable handle is introduced at a position that is tolerated for target binding.[177] After incubating either cells (or cell lysates) with the covalent probe, the resultant cell lysate is subjected to click chemistry with either a fluorescent tag or a biotinylated tag to allow direct visualization or capture of the labeled proteins. Because some level of indiscriminate labeling occurs, usually as a function of protein abundance, a competition experiment is needed to delineate the selectivity profile of the actual test compound. It is also important to conduct these experiments across a range of probe concentrations, as it was observed with EGFR- and BTK-based probes that indiscriminate labeling surmounting compound competition occurs at probe concentrations above 1 μM. Comparing the test compound treated and untreated samples yields the selectivity profile of the original inhibitor. This technique assumes that the activity-based probe binds to every target that the test compound binds; the presence of a small clickable handle (usually a tethered terminal alkyne, with which an azide-containing tag reacts to form a 1,2, 3-triazole under copper catalysis) offers minimal perturbation of binding interactions or physical properties related to cellular permeability.

The resurgence of covalent inhibitors has also been aided by an increased appreciation of the relationship between dose and toxicity for reactive compounds. Idiosyncratic toxicity is believed to occur when a reactive species (either the compound itself or a metabolite thereof which bears an electrophilic group) forms a covalently modified protein to which an immunogenic response is mounted. These toxicities are difficult to predict through preclinical toxicology studies and have resulted in several withdrawals of marketed drug compounds or late-stage clinical candidates. The extent of covalent labeling associated with a test compound can be assessed through the use of radiolabeled derivatives and quantitating the residual reactivity upon incubation with liver microsomes. It has been proposed that an in vivo covalent labeling threshold of 50 pmol/mg of protein should be used to reduce the probability of toxicity based on a safety margin of 20× relative to levels of covalent labeling typically associated with liver toxicity in animal studies of prototypic hepatotoxins.[179] It has also been observed that thresholds of total daily dose can be used to define the probability of drug-induced toxicity for compounds that form reactive species—either due to reduced cell stress or the induction of immune tolerance at low doses.[180] The combination of dose, propensity to covalently modify proteins and percentage of metabolism that results in reactive species has been proposed as a predictive measure for the propensity of reactive compounds to cause toxicity (as defined by the presence of a black box label or withdrawal from the market).[17,181] These guidelines are based on retrospective studies of the safety of clinical compounds that are known to form reactive species.

The design of targeted covalent inhibitors is assisted by methods to quantify and predict the reactivity of electrophilic functional groups. The intrinsic activity of a covalent inhibitor is best defined by k_{inact}/K_i, the second-order rate constant for reaction of the protein with the inhibitor. Maximizing selectivity, therefore, depends on optimizing this parameter for the target protein relative to secondary targets. The k_{inact} parameter is defined by the intrinsic reactivity of both the nucleophile and the electrophile, along with the unique arrangement of residues that can minimize the transition state energy for forming the covalent bond between the protein and the inhibitor. Compounds that possess a highly electrophilic group have the potential for eroded selectivity with nucleophilic residues on other proteins, coupled with a greater propensity for reaction with endogenous nucleophiles (such as glutathione), which result in high clearance. Therefore, a sensible design strategy is to minimize the intrinsic reactivity of the electrophilic species while maximizing nonbonding interactions that enhance inhibitor affinity. As such, several groups have compiled tables of pseudo first-order rate constants for the reaction of electrophilic groups with biologically relevant nucleophiles.[182–185] These tools, coupled with computational transition state modeling, allow medicinal chemists to incorporate these parameters into design of more selective covalent inhibitors.

2.01.5.2 Expanding drug-like chemical space: Designing permeable compounds beyond the Lipinski Rule of Five

There have been numerous attempts to codify design principles that maximize drug-likeness, often defined by the molecular properties that correlate with oral absorption. One of the most commonly used guidelines is the Lipinski Rule of Five, which defines property boundaries for molecular weight, number of hydrogen bond donors, number of N and O atoms, and *C*log *P*.[186] Intuitively, this heuristic set of guidelines is aimed at maximizing solubility without compromising permeability by a large number of polar groups that must be desolvated prior to passing through the lipid bilayer of the cell membrane. While small molecule drug discovery efforts are typically focused in chemical space that aligns with the Rule of Five, there are several examples of targets for which Rule of Five compliant chemical matter is unlikely to deliver the level of potency required for a successful drug candidate. Examples include proteases, peptide GPCRs, and direct modulation of protein–protein interactions, where it is often necessary to explore chemical space that pushes beyond the Rule of Five boundaries for molecular weight, polar functional group and lipophilicity. As such, there has been a resurgence of effort in the past several years to define molecular properties associated with reasonable permeability and metabolic stability for such compounds, particularly small peptides.

The cyclic peptide cyclosporine is an orally administered immunosuppressant that binds to cyclophilin. It has a remarkably high oral bioavailability of 29% given its structure. Cyclosporine is known to adopt multiple conformations in solution and is endowed with chameleon-like properties. It can display its polar backbone functionality to confer adequate solubility in an aqueous environment, while adopting an alternative conformation in apolar solvents where lipophilic groups project to the exterior of the molecule and polar groups are engaged in intramolecular hydrogen bonds on its interior. These structural preferences were observed in X-ray structural studies of cyclosporine crystallized from both water and chloroform (which mimics the interior environment of the apolar lipid bilayer), along with solution NMR studies in $CDCl_3$.[187] Another factor assisting the membrane permeability of cyclosporine is the extensive N-methylation of its peptide backbone, which removes several hydrogen bond donors that would exist in the native cyclic peptide. The importance of intramolecular hydrogen bonding in elevating passive permeability of cyclic peptides

was also shown in a study of synthetic cyclic peptides bearing no backbone nitrogen methylation.[188] A systematic evaluation of permeability as a function of stereochemistry at individual amino acid residues showed the importance of peptides being able to adopt conformations favoring intramolecular H-bonding for conferring good permeability. This same scaffold was subjected to electrophilic methylation conditions on solid support to probe the accessibility of exposed N-H groups, which should be reflective of lesser engagement in transannular intramolecular hydrogen bonding. Methylation of exposed peptide backbone NH groups led to a reduction in H-D exchange (reflecting extensive intramolecular hydrogen bonding of the remaining backbone amide NH groups) and improved permeability.[189] The extent of methylation could be varied based on the polarity of the reaction solvent, reflecting altered conformational dynamics in apolar vs. polar solvents. A more extensive assessment of permeability for 1152 cyclic hexapeptide stereoisomers and N-methylated variants prepared from this same scaffold found that sterically masking polar functionality by subtle effects of side-chain orientation, in addition to intramolecular hydrogen bonding, had profound effects on permeability.[190] Likewise, an evaluation of 39 cyclic peptide natural products illustrated the importance of backbone alkylation and intramolecular hydrogen bonding in improving the membrane permeability of these high-molecular-weight compounds.[191] It was noted that many natural products and synthetic peptides that exhibit good cellular permeability possess nonproteinogenic amino acids or functionality, which contributes to conformational flexibility and shielding of polar groups.[192]

A physics-based model was developed to guide design toward maximizing permeability for cyclic peptides.[189] The physics-based model offers advantages over statistical models in that it does not rely on a training set to bootstrap calculations. This model assesses multiple conformational states in aqueous solution, while presuming membrane permeability is conferred by a single low energy conformation in the apolar cell membrane. This low dielectric conformation is selected from the ensemble of states in aqueous solution, and membrane flux is modeled by calculating the free energy of transitioning the low dielectric conformation from water to the low dielectric environment. The observed free energies showed good correlation to PAMPA permeability ($\log P_e$). This model was improved by incorporating terms for the energy of neutralizing ionizable centers, diffusion across the membrane, and thickness of the membrane.[193,194] The physics-based model showed good correlation across six datasets with experimental PAMPA values and eight datasets with cell-based permeability values.[194]

The experimental assessment of hydrogen bonding has been assessed using a variety of methods for compounds outside Rule of Five chemical space. The most common techniques involve evaluation of the temperature dependence of NMR chemical shift changes for exchangeable protons, hydrogen-deuterium exchange rates, delta log *P* and chromatographic assays. Variable temperature NMR chemical shift changes were used to characterize intramolecular hydrogen-bonding patterns for cyclosporine and atazanavir.[187] Hydrogen–Deuterium exchange was used to characterize intramolecular hydrogen bonding in a series of cyclic peptide analogues.[189] The assessment of log *P* differences between octanol–water and toluene–water systems leads to some inference into intramolecular hydrogen-bonding propensity, as compounds with extensive intramolecular hydrogen bonding are expected to show smaller differences in log *P* across octanol (which has hydrogen-bonding capability) and toluene (which does not).[195] None of these methods provides a high-throughput experimental assessment of hydrogen-bonding capability. Chromatographic methods have been established to evaluate molecular polarity and intramolecular hydrogen bonding. Critical to their success is the use of nonpolar supercritical fluid eluents that maximize propensity for compounds to form intramolecular hydrogen bonds. The exposed polarity (termed EPSA) method utilizes supercritical CO_2 supplemented with methanol as a mobile phase with a Chirex 3014 stationary phase that possesses lipophilic and polar attributes and is able to separate compounds across a wide range of polarity differences.[196,197] In a set of cyclic peptides evaluated by the EPSA method, only compounds with EPSA values less than 80 were shown to have appreciable permeability in RRCK assays.[197] Moreover, small molecules with the capability of forming intramolecular H-bonds demonstrated significantly lower EPSA values than corresponding isomers lacking the ability to form an intramolecular hydrogen bond.[196]

2.01.5.3 Developing Design Principles for Asymmetric Tissue Distribution

In order for drugs to demonstrate efficacy, they must distribute to the tissue where the pharmacological target governing their activity resides. The efficacy of most permeable small molecule drugs is governed by the free drug hypothesis, which states that only the unbound concentration of a drug is available for binding to its pharmacological target. This unbound concentration generally reaches equilibrium across different tissues such that at steady state the unbound concentration in tissue equals the unbound concentration in plasma. Under these circumstances, total tissue levels can vary significantly relative to total plasma concentrations due to differences in affinity for plasma or tissue proteins. An important exception to this free drug equilibrium between plasma and tissues occurs where there are active transport systems that are involved in uptake or efflux of the drug. These processes have the potential to create very different free drug concentrations within certain tissues, which have important implications for efficacy and safety. Where active transport leads to higher concentrations in a target tissue of interest, lower plasma free drug concentrations will be required for efficacy. Likewise, efflux mechanisms that actively pump drug out of a tissue compartment will raise the plasma free drug levels required to achieve sufficient concentrations needed for efficacy in that tissue.

There are over 400 membrane transporters encoded in the human genome.[198] However, only a handful of these transporters have been implicated in the absorption, excretion, or asymmetric tissue distribution of most small-molecule drugs.[199200] Aside from cancerous tumors, the principal organs where asymmetric tissue distribution is most often noted include the liver, brain/CNS, and kidney. Common transporters affecting drug uptake in the intestinal lumen include members of the organic anion transporters (OATP2B1) and peptide transporters (PEPT1).[199] Efflux pumps limiting oral bioavailability include the multidrug resistance proteins MDR1 and BCRP along with P-glycoprotein P-gp.[199] The latter protein is often implicated in limiting brain and CNS

exposure of drugs as well as biliary excretion. Hepatic uptake transporters include members of the OAT family, such as OATP1B1, OATP1B3, and OATP2B1, along with the organic cation transporter OCT1.[199] Biliary elimination is facilitated by members of the MDR and MRP families of transporters (MDR1, MDR3, MRP2 and BCRP) as well as bile salt efflux pumps (BSEP). Several transporters are implicated in active renal excretion, which requires carrier-mediated transport at both the basolateral and apical sides of the tubule cell.[198] Basolateral transporters that accept drug substrates from the blood include OAT1, OAT3, OCT2 and OATP4C1.[198] Apical transporters include the multidrug resistance proteins MDR1, BCRP, MRP2 and MRP4, along with multidrug and toxin extrusion proteins MATE1 and MATE2/2 K.[198] There are several challenges associated with incorporating active transport approaches in drug discovery. Variations in cross-species transporter expression and tissue localization create potential translational pharmacology problems. Likewise, the potential to saturate the function of a transporter creates the potential for drug–drug interactions with other substrates of the same transporter or safety issues in the event that physiological transport processes are interrupted.[201]

The diversity of transporters implies that selective asymmetric tissue distribution strategies could be developed provided knowledge of structure–activity relationships for exploiting different transporters. In practice this is quite challenging due to conflicting recognition motifs for designed transporter uptake relative to activity against the desired pharmacological target. An additional limitation is the lack of structural information for many of these transporters owing to the difficulty associated with crystallizing membrane proteins. Finally, genetic polymorphisms that impact transporter expression and function have the potential to introduce variability in tissue exposure across diverse patient populations.[202,203] Despite these factors, transport strategies have been devised for achieving hepatoselective drug delivery for several metabolic disease targets.[204]

For many drug discovery programs, achieving high CNS concentrations is challenging due to the tight junctions present at the blood–brain barrier, coupled with high expression of several efflux transporters. These challenges have typically restricted CNS drug discovery programs to pursuing lipophilic amines, which traditionally have achieved high central concentrations. However, these physicochemical properties are commonly associated with toxicity and are not compatible with several protein families that are implicated in neurological disorders. Recent efforts to evaluate CNS penetration across large sets of small molecules revealed significantly expanded chemical space for CNS penetration. These studies have led to the development of a CNS MPO (multiparameter optimization) algorithm that incorporates *C* log *P*, *C* log *D*, MW, TPSA, HBD number and pK_a based on physicochemical properties of 119 CNS drugs and 108 clinical candidates.[205–207] These physicochemical properties were chosen based on their association with common ADME and safety endpoints, and for each a combination of linear functions was used to derive a desirability score of 0–1 based on their individual association with favorable ADME and safety properties.[206] A composite CNS MPO score is derived through combining the individual property scores. Statistical analysis showed that CNS drugs typically were associated with a higher CNS MPO score than CNS candidates (some of which experienced safety or ADME attrition), reflecting the need to shift molecular properties to more drug-like space. Since implementation of the CNS MPO algorithm at Pfizer, neuroscience drug candidates display higher *C* log *D*, lower median basic pKa, higher TPSA, and higher molecular weight compared to either the drug or candidate component of the original test set.[208] The higher *C* log *D* value was derived from significantly lower mean basicity (pK_a 4.1 vs. 8.0 in the drug or candidate test set). The higher TPSA value was intentionally designed to avoid safety issues associated with compounds having *C* log $P > 3$ and TPSA < 75. The fact that these post-MPO CNS candidates occupy very different property space from either the pre-MPO CNS candidate or drug test sets speaks to the effectiveness of the MPO algorithm in expanding property space for CNS penetrant compounds by considering multiple combinations of physicochemical properties that achieve high passive permeability and avoid efflux.[208]

Conversely, it is sometimes desirable to restrict CNS exposure in order to avoid safety issues associated with modulation of a target that is expressed both centrally and peripherally, but where modulation of central activity produces a harmful effect. One effective strategy to restrict compounds to peripheral tissues is to combine low-moderate passive permeability with structural features that impart efflux by pumps at the blood–brain barrier.[203] While some of these efflux transporters are also present in the GI lumen, they can be surmounted by high local concentrations of drug in the GI tract, provided sufficient aqueous solubility exists to effect saturation of the efflux transporter. In this way, central restriction can be achieved without adversely impacting oral bioavailability.

2.01.5.4 Screening Technologies for ADME and Safety Optimization

In the 1990s poor PK and biopharmaceutical properties caused a high percentage of clinical candidate attrition.[209–212] Safety has also been, and continues to be, a key attrition factor, though as mechanistic toxicity and adverse drug reactions (ADR's) become better understood, it is possible to proactively avoid some recognized issues.[213,214] Unfortunately, since we do not fully understand the mechanisms contributing to PK or safety profiles, it is unlikely that attrition due to these factors will ever be totally eliminated, particularly since, as described in this volume, experimental strategies to treat disease constantly evolve and diversify. However, in spite of this complexity, significant progress has been made to increase success in these areas over the last two decades. A key strategic approach has been to measure significant properties that define the PK profile and eliminate known safety liabilities early in discovery while the opportunity remains to influence candidate design and selection. This strategy has led to plate-based measurements of physical properties and to in vitro absorption, distribution, metabolism, and elimination (ADME) assays and safety assays run at a throughput that matches discovery chemistry output. As a result, profiling of multiple series and property optimization in large numbers of compounds can occur in parallel with efforts to improve potency. Moreover, as data from these assays have been accumulated, powerful in silico tools have been built that can help to avoid liabilities or to optimize desirable profiles at the concept

stage of the drug design process.[215–217] Optimizing ADME properties early in lead molecules has additional positive impact, over and above directly reducing attrition from poor PK, for example, by enabling lower compound doses, thus avoiding solubility challenges that may occur at higher levels.[211,218,219]

Realizing the ability to conduct ADME profiling on a high-throughput scale has required several unique scientific and technical advancements.[211] Perhaps one of the key scientific advancements was the establishment of a relationship between ADME properties and the PK profile. Indeed, much work has been done building relationship models correlating in vivo (whole organism), in situ (organ), in vitro (cell and tissue models), physical properties, and in silico predicted properties. Consequently, the in vivo to in vitro correlation (IVIVC) is now well understood for many properties and mechanisms with varying degrees of sophistication from binning to accurate prediction. Pharmaceutical research organizations have amassed well-annotated compound sets that can be used to establish quantitative or semiquantitative translation from experimental models to potential clinical outcomes. Keeping pace with parallel medicinal chemistry capabilities has required in vitro ADME models that can be tested rapidly on plate-based scales with minimal amounts of compound. The widespread establishment of cell culture models (e.g., Caco-2, MDCK) and readily available reagents (e.g., human liver microsomes and hepatocytes) has provided key tools for in vitro ADME assay development. These systems are amenable to miniaturization, and given their ease of use a high number of studies can be performed per design cycle. Complementary technological advances in workflow and sample analysis have also had significant impact on the early discovery cycle. Typically, the endpoint measured in ADME profiling is the compound of interest itself, rather than a downstream physiological consequence as is the case in pharmacology and safety assays. This change presented four major challenges to be overcome.[218] First, an ability to rapidly generate analytical methods was needed, given the thousands of compounds requiring analysis. The solution involved creating automated methods development, applicable on the microtiter plate scale together with informatics capabilities to manage compound details and the resulting analytical conditions specific to each test compound.[220–222] A second challenge was that miniaturized assays using small amounts of compound required highly sensitive instruments for sample analysis. In this case, the utilization of mass spectrometry (MS) technology played a powerful role by providing the necessary sensitivity to quantify samples in the nanomolar to micromolar ranges. The third major challenge was a requirement for high analytical throughput and capacity since multiple assays, each yielding many sets of samples, are commonly performed per given compound. One approach to overcoming this challenge was the creation of high-throughput autosamplers to take samples from plates and introduce them to the mass spectrometer. These autosamplers are capable of handling many samples per minute, and plates per hour.[221,222] Examples include the RapidFire® system from Agilent and the Apricot Designs Dual-Arm Autosampler. The former integrates a fast autosampler and automated micro-scale solid-phase extraction enabling a cycle time of 5–10 s/sample, and the latter achieves its speed (also under 10 s/sample in trap and elute mode) with two robotic arms each equipped with a needle and up to four injection ports. Tandem mass spectrometry (MS/MS) played a significant role in increasing sample throughput by creating a rapid and highly specific analytical method that can be utilized by multiple instruments and reducing the need to perform chromatographic separations for reliable analysis. A final challenge required the ability to manipulate large volumes of data in rapid fashion for reviewing each sample analysis and summarizing endpoints from multiple samples. Automated approaches to each problem have been created and typically involve laboratory information systems. The establishment of this high-throughput analytical platform represents a major step forward in enabling early ADME profiling both from the standpoint of meeting capacity and demand, along with being universally applicable as an approach to measure samples across a wide variety of ADME endpoints.

A compound's PK profile is a reflection of: (1) its bioavailability and distribution, or ability to reach the target site following an acceptable dosing route (typically oral); (2) residence time in the body required to yield efficacy (described by half-life and elimination, expressed as clearance); and (3) the potential for drug–drug interactions (DDI). In depth discussions of these areas will occur in subsequent chapters, so here we will highlight mechanistic elements of bioavailability, distribution, clearance and DDI, and provide some example systems that are used for profiling. Since most drugs are dosed orally, a prerequisite to attaining their site of action (unless they target the gut wall) is absorption from the gut lumen into blood. This factor is determined by a balance of solubility and permeability characteristics, which are attributable to physical properties such as lipophilicity, hydrogen-bonding abilities (to donate and to accept), polar surface area and molecular size as described by Lipinski's rule of 5.[223,224] These properties can be calculated or computationally derived values, but lipophilicity may also be experimentally measured, often using octanol–water shake-flask methods, immobilized artificial membrane, or chromatographic approaches.[225,226] Measures of solubility and permeability are typically assessed in an ADME suite of assays. For solubility determinations, UV detection, nephelometry, turbidity, or mass spectrometry are typically employed to kinetically assess the dissolved concentration of a compound as it equilibrates in an appropriate buffer system.[227,228] Intestinal permeability can be measured using artificial or tissue culture models, where the ability of a compound to partition into and to diffuse across a membrane is determined by using bicameral systems with donor and acceptor chambers. The parallel artificial membrane permeability assay (PAMPA) utilizes common lipids (such as dodecane and phosphatidylcholine) or extracts (such as soy lecithin) to form the membrane.[229,230] Advantages of this approach include the ease of reagent generation and optimization, whereas disadvantages include challenges of translation to true tissue permeability. Tissue culture models such as Caco-2 and MDCK, which spontaneously differentiate into polarized epithelium under normal culture conditions, have been widely utilized.[231–233] Both models allow for a multimechanistic study of transport processes across intestinal epithelium, though both require labor-intensive cell culture efforts.

Subsequent to absorption, permeability will also govern a compound's distribution within the body and its access to the required site of action. This is particularly relevant for brain-localized targets, where the blood–brain barrier (BBB) poses a significant hurdle. Unfortunately, models of the BBB have been challenging to develop, and consequently focus has shifted to understanding

that role that membrane transporters play in tissue distribution. Many of the ABC transporters, notably P-glycoprotein (P-gp), Breast Cancer Resistance Protein (BCRP), and Multidrug-Related Protein (MRP), can efflux a wide spectrum of drugs and exist in barrier tissues throughout the body. It is thought that these transporters serve a protective role to limit exposure of these pharmacological sanctuaries to foreign compounds. Assays to profile efflux potential have tended to utilize Caco-2 cells (P-gp and BCRP), or transfected MDCK cells (P-gp, BCRP, MRP) and to determine transport polarity via comparing absorptive transport (apical to basolateral) vs. secretory transport (basolateral to apical).[234,235] Another key factor involved in distribution is protein binding, notably plasma protein binding. While this parameter is routinely profiled for establishing the free drug concentration, which is necessary for PK predictions, it plays no role in drug action and should not be used in compound design optimization.[211] Commonly used methods to measure protein binding in high-throughput formats include ultrafiltration and equilibrium dialysis.[236–238]

Residence time in the body is an important factor in governing therapeutic efficacy, and that rate at which a compound is eliminated is commonly expressed as the flow parameter clearance, which is dependent on metabolic stability (metabolic clearance is typically observed for more lipophilic compounds), and biliary and renal excretion. The liver is the major drug metabolizing organ, and reagents used to gauge metabolic stability are typically derived from liver tissue, for example, human liver microsomes, and hepatocytes. Microsomes have been used successfully to profile Phase I, or oxidative, metabolism where polarity is imparted to the parent compound.[239] Hepatocytes provide an intact whole-cell system that can be used to assess both phase I and II metabolism. Phase II metabolism imparts hydrophilicity to the compound and includes synthesis and conjugation reactions such as glucuronidation and sulfation. Reports have shown that data generated using these assays can be used to inform PK predictions when metabolism is the rate-limiting event that determines clearance.[240] The amenability of these reagents to high-throughput approaches, translation to clinical outcomes and applicability to a large majority of drug-like chemical space has led to them being placed on the front lines of ADME profiling. The emerging importance of biliary and renal excretion as major pathways of clearance for metabolically stable compounds has led to greater focus on their characterization. These processes involve passive and/or active transport from blood into bile and urine, respectively, and when they have been important contributors to overall clearance, active transport mediated by transporters has often played a significant role. Whole-cell systems such as sandwich-cultured human hepatocytes have been used to determine biliary elimination,[241,242] and cell lines expressing a suite of key transporters such OATP, OAT and OCT isoforms are becoming more prevalent.[243,244]

A compound's PK profile can be significantly shifted through biochemical interactions with enzymes, transporters, other proteins and even other drugs. Hence, it is important to assess this interaction potential to reveal any variability that may be displayed in the patient population with particular focus on identifying any key safety liabilities. Numerous clinical reports have revealed CYP-mediated DDI,[245] and therefore routine high-throughput profiling of the major Cytochrome P450 enzymes, CYP1A2, CYP2C8/9/19, CYP2B6, CYP2D6 and CYP3A4 using either recombinant CYP enzymes or microsomes together with marker substrates is typically performed early in discovery. Some CYP isoforms are important to profile due to the large variety of substrates metabolized (e.g., CYP3A4), while others are important to profile due to the existence of polymorphisms within the population (e.g., CYP2D6). CYP-mediated DDI experiments evaluate competitive inhibition, time/mechanism-based inhibition, and induction. Induction experiments may study perpetrator propensity to bind and activate the nuclear receptors, PXR and CAR, or profile changes in CYP expression in whole-cell models such as primary hepatocytes.[246] These data are typically included in regulatory submissions; therefore, the degree of rigor of the assays typically increases as a candidate compound progresses from discovery into development. Once again, transporters are emerging as important factors in this space. Interactions between P-gp and digoxin have been seen clinically, and assays have been developed to profile these events.[247,248] It is likely that as more candidates, for which transporters play a major ADME role, reach the clinic, a greater need to profile transporter-mediated DDI will emerge.

The advances in parallel medicinal chemistry and high-throughput profiling of compounds in plate-based pharmacology and ADME studies, combined with the reduced amounts of compound being synthesized in these chemistry methodologies, required a consequential evolution of safety strategies that previously called for large amounts of compounds and significant resources in the planning and use of animals. These studies were typically conducted in the later stages of discovery when reoptimization of lead compounds becomes more challenging. Today, in vitro assays for safety profiling are taking their place alongside potency and ADME assays for use during lead identification and optimization. The strategic approach here often biases toward allowing false negatives rather than false positives to avoid the risk of deselecting potentially useful compounds and therefore relies on downstream techniques to ultimately identify unsafe compounds.[249] The Ames assay, which addresses a compound's potential to cause genotoxicity, is the most widely utilized assay and is a prerequisite to dosing in humans.[249] Scaled down versions of the Ames test and surrogates, including the in vitro micronucleus assay, have been developed for high-throughput profiling.[250,251] Recently, a high-throughput assay using transformed human liver epithelial (THLE) cells and monitoring ATP depletion was shown to successfully predict cytotoxicity,[252,253] and a glucose/galactose assay is frequently used in early discovery as a surrogate for mitochondrial toxicity.[254]

High-content screening attempts to assess numerous endpoints and to define an overall toxic profile for compounds. The human hepatocellular liver carcinoma (HepG2) cell line has been used in a high-content format to profile cell number, nuclear area, calcium content and mitochondrial membrane potential.[255] A commercially available assay with primary human hepatocytes is offered by CellCiphr that includes markers for oxidative stress, organelle function, stress pathway activation, cytoskeletal integrity, cell cycle, and DNA damage. Luxcel Biosciences has developed assays that can profile mitochondrial toxicity using soluble phosphorescence and fluorescence-based sensors for extracellular oxygen consumption. These assays can be adapted to the system of interest, for example, isolated mitochondria, organisms or tissues.[256–258] Genomic-based technologies have led to the creation of micorarrays that probe expression changes in specific pathways including oxidative stress, mitochondrial

dysfunction, differentiation, inflammation and apoptosis pathways allowing a targeted profiling of these outcomes.[249] These efforts require informatics support to map profiles against a database providing a greater understanding of translation to clinical outcomes and to guide decisions on next steps to eliminate safety risks. Furthermore, in order to become a more main stream early discovery profiling technology microarrays will require increases in capacity and reductions in cost.

In addition to profiling markers of general toxicity, some safety studies are directed toward specific pharmacological interactions. Profiling against the heterologously expressed, human voltage-gated potassium channel subfamily H member (hERG) is required for regulatory submission due to the association of compounds that block this channel with potentially fatal arrhythmia (Torsades de Pointe).[214] Typically, profiling includes a binding assay using astemizole or dofetilide, followed by patch-clamp assays.[259,260] The technologies utilized for in vitro safety pharmacology profiling are very much the same as those used in plate-based primary pharmacology, and include ligand-binding approaches and functional approaches performed in single-concentration and dose–response formats to obtain an effect profile. A recent publication from Bowes et al.[214] compares the collective safety experiences of four major pharmaceutical companies and suggests a strategic approach together with a baseline set of targets, including receptors, ion channels, enzymes and transporters against which to profile using in vitro models.[214]

2.01.6 Perspective and Future Direction

Advances in drug discovery technology over the last 15 years have created tremendous opportunity to accelerate the discovery and development of novel therapeutic agents to treat devastating human diseases. These advances have touched nearly every area of the drug discovery process and leave us poised on a threshold of innovation. We have the opportunity to assimilate big data sets from large patient cohorts and combine this information with genome-wide association studies to correlate genotype and phenotype. The decoding of the human genome, coupled with advances in our understanding of processes regulating transcription, translation, and the role of posttranslational modification have expanded the number of compelling drug targets, increased confidence in their association with disease and introduced new modalities for modulating their function. Rapid and precise genomic editing capabilities can be applied to build systems of greater physiological relevance and disease significance. Additionally we have greater access to the specific cell types impacted by disease using primary patient cells, stem cell-derived models, 3D organoids and tissue models. The expansion of accessible chemical space—through diversity oriented synthetic libraries, DNA-encoded library technology, fragment screening, newer high-throughput screening technologies and an increased appreciation for the merits of covalent drug discovery have enabled drug discovery targets once considered inaccessible for small molecule therapeutic development to be pursued with higher quality leads. Moreover, the landscape of chemical space believed to be privileged for oral absorption or access to restricted tissue compartments (such as the central nervous system) is changing with the introduction of multiparameter optimization techniques and design principles to access uptake transporters and avoid efflux. Phenotypic screening, the mainstay of classical drug discovery efforts briefly set aside in favor of hypothesis-driven, target-directed approaches, is undergoing a resurgence given the development of tools enabling scientists to confidently determine mechanism of action. These same technologies are also finding application for developing target engagement probes used to guide preclinical and clinical efficacy studies. Finally, our ability to predict pharmacokinetics and safety—even to the extent of once challenging areas such as transporter-mediated clearance, aldehyde oxidase-driven metabolism, and hepatic safety, are improving thanks to new screening technologies and an understanding of the capacity of physiological detoxification mechanisms.

Despite these advances, there are still gaps that impede swift progress from medical need to candidate molecule identification. The leap from genetic association data to a therapeutically relevant drug target is still a daunting one, requiring the demonstration of causality, determining directionality for target modulation, further target validation, and demonstrating drugability. Complex multifactorial diseases such as Alzheimer's and diabetes markedly demonstrate these challenges. While newer screening technologies such as ASMS and DNA-encoded libraries may require less assay development time and can be relatively quick to execute, these techniques are not routinely successful with membrane proteins and complex targets. Disease models, on the other hand, while more physiologically relevant are also more costly, labor intensive and time-consuming. Moreover, the heterogeneity and lower reproducibility in stem cell and 3D model systems present new challenges to the standard approaches of traditional biochemical or cellular screens. A phenotpypic screening campaign yielding small molecule hits is still just the beginning of a long haul to identify mechanisms of action for the hits, deconvolute them to targets and understand safety properties.

Improving drug discovery productivity in the next decade will require generating physiologically relevant disease models for major therapeutic areas, including robust and reproducible stem-cell differentiation protocols for a broad range of target tissues. It will be necessary to run high-throughput, small-molecule screens with a clinically relevant stimulus and endpoints to generate phenotypic hits and, in parallel, to probe these endpoints with genomic perturbagens such as siRNA, shRNA, CRISPRa and CRISPRi for new target identification. Currently, pooled genomic screens are best suited to oncology (using synthetic lethal or dropout approaches) or to cell surface markers that can be monitored at the single cell level by high-throughput flow cytometry. Innovative technologies such as microfluidics will be necessary to capture the advantage of pooled genomic screens and apply them more broadly across other therapeutic areas. We also need to see a step change in the efficiency of phenotypic deconvolution and target identification in order to rapidly assess multiple hit series and effectively triage the most valuable active compounds from a screen.

As drug discovery efforts venture into more complex modalities, such as interfering with protein–protein interactions, modulating peptidergic GPCRs and influencing complex intracellular multiprotein assemblies, medicinal chemists will be challenged to think beyond traditional small-molecule drug discovery paradigms. Emerging technologies such as targeted protein degraders

(PROTACs) bring challenges associated with poor cellular permeability that limits their effectiveness. Despite advances in understanding permeability of cyclic peptides and other macrocyclic compounds, it is still difficult to combine potency, permeability and metabolic stability into the same molecular entity for programs reliant on this type of chemical matter. Finally, newer modalities such as targeted inhibition of protein translation and RNA splicing modulators have yet to be proven as general strategies for addressing challenging drug targets. Progress in each of these areas will further expand options for drug discovery scientists in pursuing challenging targets of the future.

Medicinal chemistry was once considered to be a discipline integrating organic synthesis and bioorganic chemistry. That narrow focus is now changing with the breadth of these new technologies impacting the entire drug discovery process and the intimate involvement of chemistry as a central science in their development and implementation. The ever expanding landscape of new technology makes it more important than ever for medicinal chemists, analytical chemists, structural biologists, screening biologists, and computational scientists to integrate their efforts into fluid cross-disciplinary collaborations and to become more familiar with the challenges and new science occurring in these respective areas. Often it is the creative advances in the application of new science in a seemingly unrelated area that provokes transformative change in how drug discovery is practiced, ultimately enabling scientists to surmount challenges once presumed to be extremely difficult or impossible to overcome. This creativity requires scientists to expand their interests beyond the immediate problem at hand in a drug discovery program and ask how new science might be more broadly applied to address obstacles encountered in other programs. We have attempted to provide a high level overview of the most impactful advances in drug discovery technologies over the past decade. Subsequent chapters in this volume will treat these topics in greater detail and hopefully inspire new applications that will enable further advances in medicinal chemistry and drug discovery approaches.

2.02.1 Introduction

How does one best identify a pharmacologically active compound? This important milestone in every low molecular weight (MW) drug discovery endeavor can be a starting point for further optimization (hit/lead) or already a drug from past preclinical and clinical development. The need for efficient hit and lead discovery has not changed over the past century—it is only the approach that has changed, and the technologies involved have progressed significantly. Analog- or chemocentric-based starting points still play an important role in medicinal chemistry, especially for systems-based target-agnostic approaches, but are of limited use for novel unprecedented targets. Hundreds of thousands of primary hits are now almost routinely identified using functional, biophysical, or even phenotypic high-throughput screens (HTS). Here the challenge has matured to the efficient identification of validated hits as starting points worth investing chemistry resources on. The characterization of confirmed and validated hits is discussed, as well as the paradigm shift from screening ever-increasingly large number of compounds to smaller targeted, and often well annotated, libraries. Among the approved new molecular entities, biologics (eg, antibodies) have an increasing role in addressing unmet medical needs. Since 2009, approximately 50% of the approved drugs are biologics. The recent advances in new biological entities (NBEs) and their success highlight the fact that the often proclaimed productivity and innovation drought in pharmaceutical industry are not due to a lack of new therapeutic concepts or druggable targets. Since biologics still have to face the cellular membrane barrier it is estimated that 10–20% of the target space will be addressable by antibodies, and the remaining 80–90% will be reserved for creative medicinal chemists and their teams.[1]

2.02.2 The Major Approaches for Hit and Lead Discovery

There are basically three major routes toward hit and lead discovery, the analog-based "chemocentric" approach, "de-novo" structure-based design, and the screening approach. The analog-based and screening approach can be pursued in a systems-based, target-agnostic, manner or in a target-based manner. Depending on the feasibility, technical availability, and priority setting these routes are often explored in parallel, thereby benefiting from the mutual synergies between the hit-finding approaches.

2.02.2.1 Analog-Based Drug Discovery

The analog-based approach considers lead structures that have well-defined medicinal properties, such as natural products, substrate or product derivatives, or other drugs. Camille Wermuth differentiates between three categories of analogs based on chemical and pharmacological similarity;[2] however, agreeing on what defines these similarities renders this classification difficult.[3] For simplicity, drugs, which did not require a screen or upfront structural research investment as a starting point for their drug discovery,

were labeled as originating from an analog-based approach. In 1988, Kurt Freter noted that all new drugs that had been approved by the Food and Drug Administration (FDA) in 1985 appeared to be the result of analog-based approaches.[4] The number of exploited lead structures was relatively small; in 1996, Walter Sneader categorized 244 drug prototypes, fewer than 140 of which would be considered drug-like as currently defined.[5] Until about 1980, information on drug targets at the molecular level was scarce, and drug discovery was mostly driven by data obtained from testing a limited number of compounds in animal models or microorganism cultures.[6–9] One of the most spectacular examples of such analog-based drug discovery approaches was the discovery of Warfarin. Warfarin, a coumarin derivative that acts as a vitamin K antagonist, was approved by the FDA in 1952 as a rat poison.[10] When a US soldier survived a suicide attempt with Warfarin unharmed, the idea for the pharmacological use of this approved rodenticide as an anticoagulant in humans was born.[10] In 1954, Warfarin's use as medication in humans was approved by the FDA, and other close coumarin analogs, such as acenocoumarol and phenprocoumon, followed in due course. The mode of action of these coumarins was only later discovered in 1978.[11]

Interestingly, even in the third millennium, more than half of the approved drugs (new chemical entities, NCEs) still originated from analog-based approaches (**Fig. 1**). There have been exciting and important discoveries highlighting the fact that analog-based approaches deliver first-in-class medicines (**Table 1**). Innovative analog-based drugs include, for example, the thalidomide analogs pomalidomide[12] and lenalidomide,[12] which were approved by the FDA for the treatment of mantel cell lymphoma in 2013, and apremilast,[13] which was approved in 2014 for the treatment of psoriatic arthritis. Thalidomide was first marketed in 1957 under the trade name Contergan. It was primarily prescribed as a sedative, but was also, unfortunately, prescribed to pregnant women to alleviate morning sickness. Due to its high teratogenicity, its use was discontinued in the early 1960s. Observations of the immunomodulatory and antiangiogenic effects of the withdrawn sedative thalidomide led to its investigation as a treatment for multiple myeloma. Phenotypic optimization of analogs in turn led to the discovery of lenalidomide. This drug was found to be 50,000-fold more potent in downregulating tumor necrosis factor production while having reduced sedative and neuropathic adverse effects compared to thalidomide.[12] The identification of a primary target of thalidomide teratogenicity lead to the identification of CRBN E3 ubiquitin ligase as the target of the "lidomides,"[14] and opened up a new approach for targeted therapies.[15] Another example for innovative analog-based drug discovery is afatinib, as a first-in-class irreversible dual specificity EGFR/HER2 inhibitor derived from anilinoquinazoline chemical series that was designed to covalently bind to Cys 797 of EGFR and Cys 805 of HER2.[16] Although the anilinoquinazoline chemical series was well known from gefitinib and erlotinib,[17] the addition of the functional Michael acceptor was an innovative step for increased efficacy in the treatment of EGFR-mutated lung cancers.[18]

2.02.2.2 "De-novo" Structure-Based Design

Advances in molecular biology provided access to many potential drug targets as pure or overexpressed proteins, and made them available for molecular or cellular assays as well as for structural biology.[7] These advances led to a paradigm shift in drug discovery from "phenotypic" to a target-based approach that relies on a profound understanding, on the molecular level, of the target under investigation. In the 1970s, structural biology started to have an ever-increasing role in drug discovery.[19] Detailed knowledge about protein–ligand interactions allowed a more rational design of new drugs, and X-ray structures of natural ligand–protein complexes offered new starting points for hit and lead identification. As the advances in technology are covered in another chapter in this article we concentrate on the key examples of marketed drugs that originated from "de-novo" structure-based drug design. Of course, structure-based design has a very important role beyond hit and lead selection in the lead optimization phase. Lead optimization

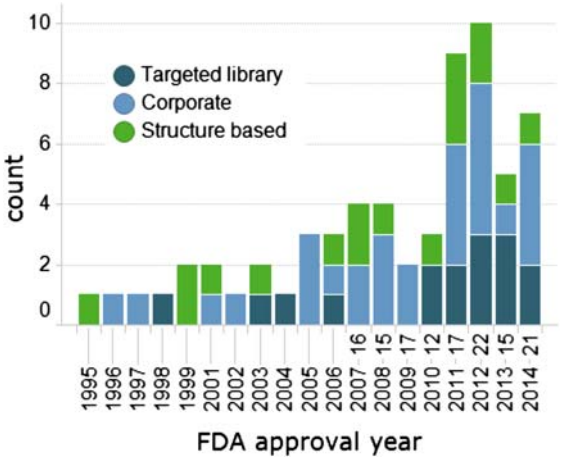

Fig. 1 Number of marketed drugs (*bars*) that emerged from screening (*blue*) or from structure-based design leads (*green*), summarized by their respective FDA approval date.[47] The number under the bars indicate the total number of novel NCEs approved between 2007 and 2014 including those originating from analog-based approaches.

Table 1 Representative examples for analog-based and "de-novo" structure-based design hit and lead discovery approaches

Drug	*Approach*	*Unmet medical need*	*Origin*
Warfarin[10] 	Analog	High: New use for pharmacological active compound	Warfarin used as rodenticide
Phenprocoumon[11] 	Analog	Low (me-too/me-better)	Warfarin
Pomalidomide[12] 	Analog	High: New use of old drug	Thalidomide[12] Afatinib[16,18] 	Analog	High: First-in-class irreversible dual specificity EGFR/HER2 inhibitor	Gefitinib[17]: First-in-class EGFR family inhibitor from screening Erelotinib[17] 	Analog	Low (me-too/me-better)	Gefitinb
Saquinavir[20] 	"De-novo" structure-based design	High: First-in-class HIV-protease inhibitor	Peptides containing reduced amide and hydroxyethylamine transition state mimetics
Oseltamivir[21] 	"De-novo" structure-based design	High: First-in-class oral neuraminidase inhibitor	2,3-Didehydro-2-deoxy-*N*-acetyl neuraminic acid 
is significantly accelerated when X-ray structure determination is enabled for the hit and lead candidate. These success stories have been extensively reviewed[19] and are not covered here.

Table 2 lists the 17 marketed drugs that were approved by the FDA between 1996 and 2014, where a literature review suggests that they had been derived from structure-based "de-novo" design starting points. It is interesting to note that there are quite a number of protease inhibitors where a peptidomimetic starting point has been used. Some protease inhibitors were designed to mimic the transition state of the protease's actual substrates. For example, for aspartyl proteases an –NH–CO– peptide linkage is replaced by an hydroxyethylene group (–CH_2–CH(OH)–, the "statin" moiety), which cannot be cleaved by the protease.

Table 2 Drugs derived from "de-novo" structure-based design leads

Drug	*Target-based actions*	*FDA approved*
Saquinavir[20]	HIV-1 protease inhibitor	1995
Oseltamivir[21]	Neuraminidase inhibitor	1999
Zanamivir[22]	Neuraminidase inhibitor	1999
Imatinib[23]	Protein-tyrosine kinase	2001
Bortezomib[24]	Proteasome inhibitor	2003
Darunavir[25]	HIV-1 protease inhibitor	2006
Aliskiren[26]	Renin inhibitor	2007
Nilotinib[27]	Protein-tyrosine kinase	2007
Dabigatran[28]	Factor IIa antagonist	2010
Boceprevir[29]	Hepatitis C virus NS3 protease inhibitor	2011
Rilpivirine[30]	Nonnucleoside reverse transcriptase inhibitor	2011
Telaprevir[31]	Hepatitis C virus NS3 protease inhibitor	2011
Carfilzomib[32]	Proteasome inhibitor	2012
Ponatinib[33]	Protein-tyrosine kinase	2012
Alogliptin[34]	Dipeptidyl peptidase IV inhibitor	2013
Apremilast[13]	PDE 4 inhibitor	2014

Substrate competitive HIV-protease inhibitors were rationally designed utilizing knowledge of the aspartyl protease's mode of action. The most promising transition state mimic was hydroxyethylamine that led to the discovery of the first protease inhibitor; saquinavir.[20] Following this discovery, another HIV-protease inhibitor (darunavir) was designed using the same principle.[25]

2.02.2.3 Screening

Over the years, various screening strategies have been applied to the identification of drug and lead candidates. The screening of natural product extracts for bioactivity, followed by the isolation of the active principle or principles, has been a successful source of initial leads for drug discovery. The identification of cyclosporin A as an effective immunosuppressive drug is illustrative for this process.[35] Screening of a fungal extract for antimicrobial activity led to the isolation of a number of cyclosporins that were subsequently found to possess immunosuppressive properties. The molecular target mediating the pharmacological activity was only identified several years after market approval was obtained for the drug.[36] The microtubulin inhibitor eribulin mesylate[37] and fingolimod,[38] a novel immunosuppressive, are further examples of marketed drugs that originate from natural products. Natural products have been the most productive source of leads for new drugs in the past: 36 out of 114 first-in-class low molecular drugs approved between 1999 and 2013 originate from natural products (see **Table 6**). Interestingly, they are currently out of fashion with the pharmaceutical industry,[39] and many pharmaceutical companies stopped the screening of extracts and the labor-intensive isolation of the active principle. Given the past contributions of natural products to drug discovery, it seems surprising that natural product-based drug discovery is no longer routinely used by the pharmaceutical industry. Some of the reasons behind this shift relate to the difficulties in accessing natural products in ways that are compatible with target-based HTS. Natural products are often synthesized in small quantities or are present as mixtures in extracts, which require labor-intensive and time-consuming purification procedures. Obtaining further quantities for lead optimization or preclinical development requires large-scale reacquisition or fermentation, resulting in a substantial impact on the development timeline. Furthermore, the rediscovery of known compounds is a major problem when screening natural product libraries. The time-consuming processes of dereplication and purification are not compatible with the present regime of HTS campaigns. From a medicinal chemist point of view, natural products are often structurally complex and modification of complex natural products using synthetic organic chemistry is often challenging.[40] Finally, a mixture of natural compounds in a natural extract can be required for activity and this concerted activity of various compounds against several targets is an additional challenge for target-based drug discovery.

Screening of discrete synthetic compounds in vivo or in vitro for a targeted pharmacological or phenotypic effect constitutes the second approach. This approach was employed by Ehrlich in the early part of the last century to identify arsphenarnine, an important early antiinfective drug.[5] From the 1950s, the National Cancer Institute screened many thousands of samples per year in vivo and in vitro,[41] and identified anticancer agents such as hydroxyurea[42] and the lead structure for carmustine[43] using this approach. The access to many potential drug targets as pure or overexpressed proteins has made them more readily available for biochemical or cellular assays.[7] The feasibility of probing the mode of action at the target level has triggered further advancements in assay technologies, automation, and miniaturization—and the era of HTS was born.[44]

2.02.2.3.1 Screening and its impact in drug discovery

Testing against isolated targets in a high-throughput manner to identify novel lead structures was previously limited by the relatively small numbers of synthetic compounds available for screening. Improved automation and informatics have provided tools for the organization of screening libraries and the collection and interpretation of the large quantities of data generated by screening

campaigns. Finally, combinatorial chemistry and high-throughput synthesis methods have provided large collections of compounds to fuel the screening process. The combined application of these new technologies has enabled an HTS approach to lead identification, and large numbers of discrete small molecules can now be assessed for activity against a well-defined biological target within a relatively short period of time. The widespread adoption of HTS, and associated technologies for lead identification, has led to the expectation that an increased number of drug candidates would progress through the clinic. Indeed, in 2006, a study involving 58 HTS laboratories and 34 suppliers revealed a twofold increase in HTS-derived leads having progressed to clinical trials from 2000 to 2004.[45] As the success of any drug discovery technology has to be evaluated based on the final product, the marketed drug, the origin of the marketed small-molecule drugs approved by the FDA between 1996 and 2014 was investigated. John Proudfoot found that from 2005 onward a significant number of approved small-molecule drugs have emerged from screening leads.[46] Between 2007 and 2014, 98 NBEs and 270 NCEs have been approved by the FDA (see relevant websites). The 270 NCEs can be further split into: 97 (36%) new formulations/indications for approved drugs, 38 (14%) fixed combinations, and 135 (50%) active substances that have never before been approved for the market in any form in the United States. As shown in **Fig. 1** and **Table 3**, the positive trend for approved drugs emerging from screening derived leads has continued. "De-novo" structure-based design leads also contribute to new therapies, but to a lesser extent when compared to screening. Until 2004, only one new drug per year originated from any screening approach, while in 2012 seven such drugs were granted approval by the FDA. The average timeline of approximately 12 years from the new therapeutic concept discovery to the approved drug explains the time lag from the start of the HTS era mid-1990s to its positive impact. However, the time required to develop processes that effectively leverage the application of these new technologies to lead identification has contributed to this delay. The drop in the number of approvals in 2009 (**Fig. 1**), for instance, might reflect the learning phase in the early days of combinatorial chemistry. Chris Lipinski et al. noted in 1997 that HTS campaigns tended to produce relatively large, lipophilic lead molecules.[77,78] Since it is common during LO (lead optimization) to enhance potency through the addition of lipophilic substituents, many discovery campaigns based on screening leads provided large, poorly soluble, lipophilic drug-candidate molecules that were difficult to progress successfully through the clinic.[79]

Since the compound collections screened are not always disclosed by the respective authors and also come in many flavors, the available information was summarized as follows: When the corporate compound collection was screened in an HTS format, the screening library is designated "corporate." "Targeted library" summarizes all customized libraries (eg, lead-like, fragments, natural products, in silico preselected libraries) of a smaller size. Interestingly, among the drugs emerging from screening leads there is a general trend toward targeted libraries from 2010 onward. This trend likely relates to the observation made in 1997 that HTS campaigns tended to produce relatively large and lipophilic leads with a high failure rate in subsequent drug development.[77,78] PLX4720, the predecessor of the first-in-class B-Raf protein kinase inhibitor vemurafenib, was discovered by screening a targeted library of 20,000 compounds ranging in molecular mass from 150 to 350 Da at a concentration of 200 μM through three divergent but structurally characterized kinases.[58] A total of 238 hits were subjected to cocrystallographic analysis in at least one of these three kinases. The combination of screening a set of lead-like molecules at high concentration with large-scale X-ray structure analysis can be seen as the first successful example of fragment-based drug discovery (FBDD).

2.02.2.3.2 Chemical space considerations

The advances in HTS technologies in terms of quality, throughput, and efficiency have resulted in an ever-increasing importance of the nature (lead-likeness) of the compounds in the screening collection. Corporate screening collections often exceed one million compounds, combining the output from NCE projects, combinatorial chemistry efforts, and purchases from commercial vendors.[80] These libraries are often complemented by DNA-encoded libraries[81] and dynamic combinatorial libraries (DCLs)[82] that require customized screening processes. DNA-encoded chemical libraries represent a relatively new and inexpensive tool for the fast and efficient identification of ligands to target proteins of choice by affinity capture at subpicomolar concentrations. Such libraries consist of mixtures of millions of organic molecules, covalently linked to a unique DNA tag serving as an amplifiable identification bar code. The implementation of next-generation high-throughput sequencing has enabled the rapid identification of binding molecules. Dynamic combinatorial chemistry (also known as dynamic covalent chemistry) is a method for the generation of new molecules formed by the reversible reaction of simple building blocks under thermodynamic control. The library of these reversibly interconverting building blocks is called a DCL. When a DCL is exposed to an external influence (such as proteins or nucleic acids), the equilibrium shifts and those components that interact with the external influence are stabilized and amplified, allowing more of the active compound to be formed.

Compounds produced by early combinatorial chemistry methods were designed based on synthetic accessibility and diversity of structure, and tended to be high MW, lipophilic structures of questionable purity. The current emphasis on the quality of compounds produced by high-throughput synthesis, rather than on the sheer numbers, has led to libraries where drug-like properties[78] are considered before synthesis is initiated, and where the design is often focused on providing leads against particular targets or target classes.

As the building and maintenance of large libraries is expensive, there are constant debates as to the optimal size. Suggestions range from two to three million compounds being sufficient to deliver multiple starting points from any given screen[83] to an estimate that up to 24 million compounds would be needed to ensure potent hits for all targets.[84] Interestingly, in recent years some pharmaceutical companies started to open up their vaults to share their collections, in order to increase the chemical space and therefore the chance of finding suitable hit molecules.[80] The recent open sharing of compound collection property information also highlights the progress made with respect to the quality of the compound collections. The analysis of the European lead factory

Table 3 Drugs derived from screening leads

Drug	*Target-based actions*	*FDA approved*	*Screening library*
Nevirapine[46]	Nonnucleoside reverse transcriptase inhibitor	1996	Corporate
Delavirdine[46]	Nonnucleoside reverse transcriptase inhibitor	1997	Corporate
Tirofiban[46]	GP IIb IIIa antagonist	1998	Targeted library
Bosentan[46]	Endothelin antagonist	2001	Corporate
Efavirenz[46]	Nonnucleoside reverse transcriptase inhibitor	2002	Corporate
Gefitinib[46]	EGFR family tyrosine kinase receptor inhibitor	2003	Targeted library
Cinacalcet[46]	Parathyroid hormone ligand inhibitor	2004	Targeted library
Conivaptan[46]	Vasopressin antagonist	2005	Corporate
Sorafenib[46]	Tyrosine kinase inhibitor	2005	Corporate
Tipranavir[46]	HIV-1 protease inhibitor	2005	Corporate
Dasatinib[46]	Tyrosine kinase inhibitor	2006	Targeted library
Ditagliptin[46]	Dipeptidyl peptidase IV inhibitor	2006	Corporate
Ambrisentan[46]	Endothelin ET-A antagonist	2007	Corporate
Maraviroc[46]	CCR5 chemokine antagonist	2007	Corporate
Eltrombopag[48]	Thrombopoietin receptor agonist	2008	Corporate
Etravirine[49]	Nonnucleoside reverse transcriptase inhibitor	2008	Corporate
Plerixafor[50]	CXCR4 chemokine antagonist	2008	Corporate
Mozavaptan[51]	Vasopressin V2 antagonist	2009	Corporate
Tolvaptan[52]	Vasopressin V2 antagonist	2009	Corporate
Eribulin mesylate[37]	Microtubule inhibitor	2010	Targeted library
Fingolimod[38]	Sphingosine-1-phosphate receptor-1 modulator	2010	Targeted library
Crizotinib[53]	Protein kinase inhibitor	2011	Corporate
Linagliptin[54]	Dipeptidyl peptidase IV inhibitor	2011	Corporate
Rivaroxaban[55]	Factor Xa antagonist	2011	Corporate
Roflumilast[56]	PDE 4 inhibitor	2011	Targeted library
Sunitinib[57]	Tyrosine kinase inhibitor	2011	Corporate
Vemurafenib[58]	B-Raf protein kinase inhibitor	2011	Targeted library
Apixaban[59]	Factor Xa antagonist	2012	Targeted library
Bedaquiline[60]	ATP synthase inhibitor	2012	Corporate
Bosutinib[61]	Abl tyrosine kinase inhibitor	2012	Targeted library
Ivacaftor[62]	CFTR stimulator	2012	Targeted library
Lomitapide[63]	Microsomal triglyceride transfer protein inhibitor	2012	Corporate
Perampanel[64]	AMPA receptor antagonist	2012	Corporate
Tofacitinib[65]	JAK tyrosine kinase inhibitor	2012	Corporate
Vismodegib[66]	Smoothened receptor antagonist	2012	Corporate
Dabrafenib[67]	Raf B protein kinase inhibitor	2013	Targeted library
Ibrutinib[68]	Btk tyrosine kinase inhibitor	2013	Targeted library
Luliconazole[69]	Fungicide	2013	Targeted library
Trametinib[70]	MEK protein kinase inhibitor	2013	Corporate
Ceritinib[71]	Protein kinase inhibitor	2014	Targeted library
Eliglustat[72]	Glucosylceramide synthase inhibitor	2014	Corporate
Olaparib[73]	PARP inhibitor	2014	Corporate
Olodaterol[74]	Beta 2 adrenoceptor agonist	2014	Targeted library
Ombitasvir[75]	Hepatitis C virus NS5A inhibitor	2014	Corporate
Suvorexant[76]	Orexin receptor antagonist	2014	Corporate

The lead source "corporate" was shown when the corporate compound collection was screened in HTS format. "Targeted library" summarizes all customized libraries (eg, lead-like, fragments, natural products, virtual screening libraries) of a smaller size.

compound collection (seven pharmaceutical companies collaborated to generate a pooled resource) shows good quality with respect to lead-like properties with a MW centered around 350 Da, a log *P* of 2–3, and diversity based on Tanimoto similarity (the most popular similarity measure for comparing chemical structures). Two structures are usually considered similar if $T > 0.85$ (for daylight fingerprints, **Fig. 2**).[85] The progression of leads into drugs tends to increase the MW (Δ69 Da), lipophilicity [ΔLogD(pH 7.4) = 1], and complexity, therefore it seems obvious that lead structures should be relatively simple, of low MW and not too lipophilic.[86]

In addition to keeping the focus on heavy atom count (HAC), MW, Log *P*, and topological polar surface area (TPSA) in the lead-like and drug-like space to avoid false positives,[87] structural elements that frequently result in assay artifacts are now well recognized. Many of these molecules—pan-assay interference compounds, or PAINS—have defined structures and cover several structural classes (**Table 4**). Most PAINS act as reactive chemicals rather than discriminating drugs, and contain, for example, alkylating, acylating, and redox active groups, as well as aggregating and chelating moieties.[88] Although software tools can easily filter

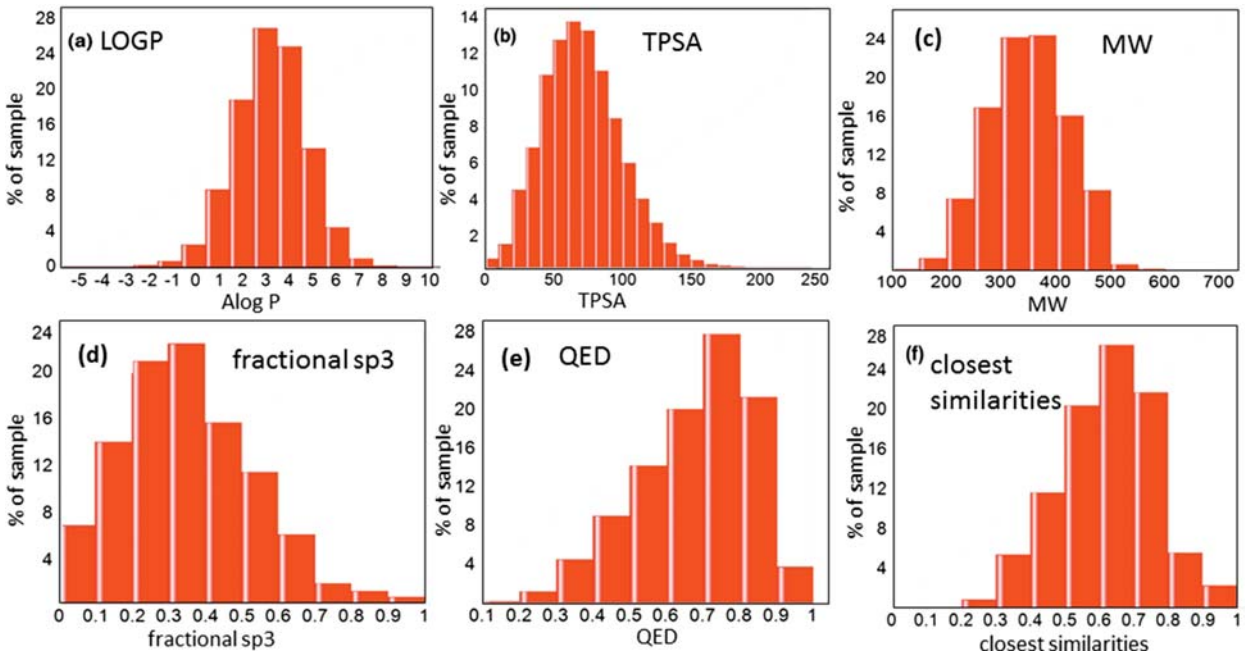

Fig. 2 Key physicochemical parameters and diversity of the Joint European Compound Library (JECL). The key physicochemical parameters of (A) log *P*, (B) topological polar surface area (TPSA), (C) molecular weight (MW), (D) fraction sp^3 carbon atoms, and (E) the quantitative estimate of drug-likeness (QED) desirability score, are typical of a lead-like library and centered on a MW of 350 Da and a log *P* of 2–3. The fraction of sp^3-hybridized carbon atoms indicates a broad spread of 3-dimensionality. (F) The nearest-neighbor diversity of the collection using Tanimoto similarity with extended connectivity fingerprint (ECFP6). Reproduced from Besnard, J.; Jones, P.S.; Hopkins, A.L.; Pannifer, A.D. The Joint European Compound Library: Boosting Precompetitive Research. Drug Discov. Today **2015**, *20*, 181–186.

PAINS from screening libraries, not all PAINS can be identified by structural features. False-positive hits may occur due to synthesis-related impurities that might not be noticed in liquid chromatography/mass spectrometry (LC/MS) or nuclear magnetic resonance (NMR) quality control checks. These include metal ions and long-term storage condition-dependent decomposition products.[89] It proved extremely valuable to check (database or literature search) if the hits interacted with unrelated proteins or had been implicated in nondrug-like mechanisms. The Boehringer-Ingelheim (BI) corporate and a collaborator library were recently screened against 10 protein–protein interaction (PPI) assays using the Alpha Screen® technology. Analysis of the 91,000 primary hits for the presence of PAINS structural elements, and unrelated targets where the compound was also found as a primary hit (frequent hitter (FH) score) revealed that there is merely a trend indicating that FHs contain a higher percentage of PAINS structural elements (Fig. 3). Interestingly, only the bin with an FH score of 1–2 and no PAIN structural alerts contained validated hits (see next section on the definition) against several PPIs. Significant resources and profiling time were saved by restricting further triaging of the primary hits to PAIN-free compounds (43,500, 48%). At BI, for future Alpha Screens® hits a FH score of ≤ 2 will be applied, that in a retrospective analysis would have disqualified a further 14,000 (32%) primary Alpha Screen hits from further profiling.

In addition, or as an alternative to screening increasingly large numbers of complex molecules, many pharmaceutical companies utilize much smaller but well-designed and characterized sets of low MW compounds for fragment-based screening (FBS). A fragment is commonly defined by the Astex Rule of 3 in which the MW is ≤ 300 and the number of hydrogen-bond acceptors, donors, and rotatable bonds is ≤ 3 in each case.[90] The HAC (already well-established for ligand efficiency (LE) calculation) was found to be a better descriptor for lead-likeness than MW since halogen atoms have a higher impact on the MW gain than on the volume of a molecule. Therefore at BI, a heavy atom (HA) range was defined from 10 to 22, as the preferred compound space for hit finding (Hit Zone). Hits from this zone should permit effective hit-to-lead optimization toward the Oral Drug Zone [HAC 14–34 and pIC50-cLogP (lipophilic ligand efficiency, LLE) >2.4].

Screening in the Hit Zone, however, comes at the price of lower binding affinity/potency, requiring higher screening concentrations, and a special focus on sufficiently high solubility. LE is defined as the free binding energy per ligand atom to its binding partner. Mathematically, LE is defined as $LE = (\Delta G)/N = -RT\ln K_i/N$ where N is the number of HAs in a ligand.[91] LE is not only an excellent tool for ranking hits coming from any screening campaign; it also helps to relate the molecular size of the screening compound to the expected potency or binding affinity (Fig. 4). While an HTS hit with $LE = 0.3$ can be found when screening at 10 μM, a fragment with the same LE can require millimolar screening concentrations. To enable screening concentrations in the mM range, aqueous solubility data were measured experimentally and only fragments that passed this threshold were included in the fragment library.

Table 4 Frequent pan-assay interference compounds (PAINS): These, and related compounds, should set off alarm bells if found as hits in functional screens

Toxoflavin	*Redox cycler: can produce hydrogen peroxide which can activate or inactivate different proteins*	Isothiazolone	Covalent modifier: reacts chemically with proteins in nonspecific, nondrug-like ways	Curcumin	Covalent modifier, membrane disruptor: muddles response of membrane receptors	Hydroxyphenyl hydrazones	Covalent modifier, metal complexer: sequesters metal ions that inactivate proteins	Ene-rhodanine	Covalent modifier, metal complexer	Phenol-sulphonamides	Redox cycler, covalent modifier, unstable compound: breaks down into molecules that give false signals	Enones	Covalent modifier	Quinones and catechols	Redox cycler, metal complexer, covalent modifier	
Reactive parts are colored *red* (reproduced from Baell, J.; Walters, M.A. Chemistry: Chemical Con Artists Foil Drug Discovery. Nature **2014**, *513*, 481–483).

Since some compound-related pan-assay interferences properties like aggregation, quenching of fluorescent readouts, or the impact of sample impurities are more critical at higher concentrations, it is not recommended that biochemical assays are used for screening at concentrations $\geq 200\ \mu M$, unless the tolerability of the assay principle at such high concentrations has been demonstrated. The optimal screening technology for a given concentration is shown in Fig. 4. Ligand-based NMR studies are most sensitive and can reliably pick binders with mM Kd values. Target-based NMR Heteronuclear Single-Quantum Coherence Spectroscopy (HSQC), isothermal calorimeter (ITC), microscale thermophoresis (MST), and surface plasmon resonance (SPR) all have the advantage of detecting the specific and saturable interaction of the ligand with its target protein, and thereby discriminate between true binders and aggregators.

2.02.2.3.3 Virtual screening

Hit-finding campaigns are increasingly supported or even driven by smart computational techniques,[92] and virtual screening (VS) has matured into an invaluable approach that can significantly save time and costs (eg, screening a smartly selected small subset of

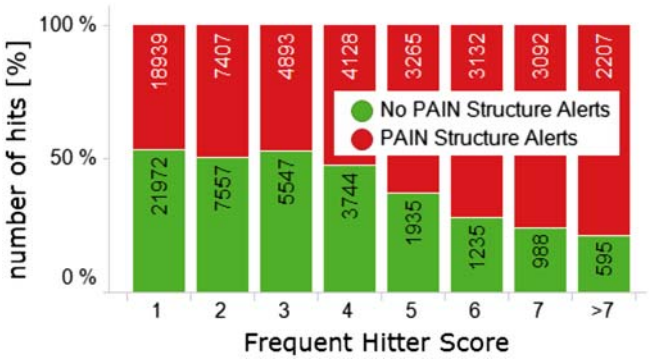

Fig. 3 Histogram representation of the number of hits without (*green*) or with (*red*) structural pain alerts versus the number of unrelated targets where the compound was found as a hit (frequent hitter score) in 10 PPI assays using the AlphaScreen® technology.

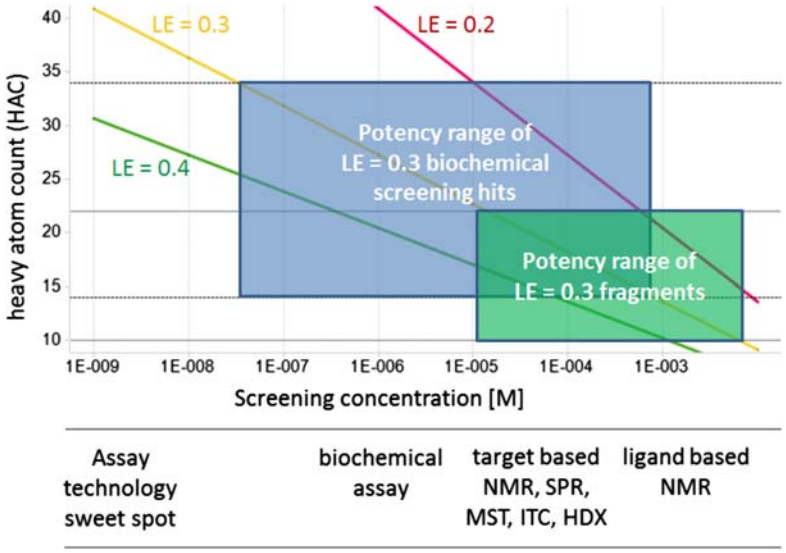

Fig. 4 Relationship between heavy atom count (size) and required screening concentration to find hits within an LE range of 0.2–0.4. The potency range for LE = 0.3 biochemical screening hits (HA = 24 ± 10) is shown in *green* and the potency range for LE = 0.3 fragments ($10 \leq HA \leq 22$) is shown in *blue*. The best-suited assay technology (sweet spot) for a screening concentration range is listed here.

a corporate library instead of running an HTS). It has also been clearly shown that VS has contributed to the discovery of compounds that ultimately reached the market.[93]

VS, or in silico screening,[94] is a general term for a broad range of computational methods for selecting compounds from a database that are likely to bind and exhibit activity against a target of interest. VS approaches are driven by various types of additional knowledge concerning the target or active compounds, which are available prior to executing a VS campaign. Depending upon the type of information that is utilized and embraced in the concept of a VS method, VS methods are designated as ligand-based VS (LBVS) methods and structure-based VS (SBVS).

2.02.2.3.3.1 Ligand-based VS (LBVS)

The starting point for LBVS is the chemical structures of known active compounds, without using any 3D-structural information of their target protein. In situations where abundant structural information of active and inactive compounds is available, machine learning tools such as, for example, Bayesian classifiers, supper vector machines, neural networks, decision trees, and random forests, can be applied for generating activity prediction models to be used in VS. Here, we focus on methods that can be applied if only one or few active compounds are known. For an overview and applications of machine learning in LBVS, we refer the reader to the recent review by Lavecchia.[95]

Most of the chemoinformatics-based LBVS[96] methods are based upon the similar property principle, that is, the fundamental hypothesis that similar compounds have similar properties,[97] as in a compound that is similar to an active molecule is also likely active. LBVS is the search for molecules in a database that are similar to known active compounds, referred to as template (also query or seed) structures. However, there is no absolute measure of similarity, and different similarity metrics result in different sets of

similar compounds. Since the advent of chemoinformatics, a huge multitude of similarity search methods has been established, each with its particular purpose representing a certain aspect of chemical similarity. Molecular fingerprints (FPs) have now been used for a long time in analogging and VS, and still remain amongst the most commonly applied LBVS methods.[98] A recent advancement of FP-based VS is turbo similarity searching,[99] an approach that uses the results of a similarity search as the query molecules in a subsequent second similarity search step. The idea of using successive similarity searches has been extended to using bioisosteric enumerations and combining different similarity methods in multistep searches.[100]

While FPs encode the composition of molecules in terms of certain features that are present or absent in a molecule, other methods work with abstractions of molecules, thereby aiming to represent certain physicochemical characteristics in a way that allows fast comparisons by computer algorithms. Feature trees and pharmacophore graphs condense atom groups that embody, for example, donors, acceptors, aromatic moieties, as the nodes of a tree. Such trees can be considered as generic 2D pharmacophores, and graph-theory based methods enable rapid comparison of template (query) structure trees with trees that are calculated from large compound databases.[101]

More physics-based descriptions of molecules accrue if the 3D-shape and electrostatic potential is used. Contrary to the 2D methods described above, which depend only upon the connectivity tables of the molecule, shape-based search methods depend upon reasonable 3D conformations of the query molecules. Knowledge or at least a sound hypothesis of the bioactive conformation of the query molecules is clearly advantageous. The use of such computationally more demanding 3D methods such as ShaEP(Molecular Overlay Based on Shape and Electrostatic Potential),[102] ROCS (Software from OpenEye),[103] or BLAZE (Software from Cresset)[104] against large databases is nowadays easily viable on multicore computers or clusters, and often leads to high-quality hits.

The development of methods that use more physics-based descriptions of molecules suggests, at a first glance, that such methods should be superior to simpler and less physics-aware methods, rendering many of the initially developed methods such as FPs obsolete for LBVS. However, evidence has been provided that it is difficult to gauge a priori which VS method is best suited to a particular project situation, and there is consensus that the success of VS is extremely hard to predict.[94]

On the other hand, it has been suspected for a long time that the parallel use of various VS approaches promises a higher rate of success.[105] This notion is strongly supported by a number of studies that systematically assess the assumption that multiple searches truly increase the likelihood of finding more active compounds, see for example the study by Holliday et al.[106] This is not surprising given that different molecular descriptors describe different aspects of molecular structure, and hence, different methods probe a compound's neighborhood in chemical space in different ways.[107] A key task when using multiple methods is the stringent aggregation of the individual results, the systematic approach to do so is referred to as data fusion. According to Willet, data fusion is the name given to a body of techniques that combine multiple sources of data into a single source, with the expectation that the resulting fused source will be more informative than the individual input sources.[108] A number of advanced data fusion approaches for aggregating multisearch results have been developed, including theoretically derived fusion rules[109] and a method based upon belief theory.[110]

2.02.2.3.3.2 Structure-based VS

SBVS relies on the 3D structure of a protein with a suitable binding site of interest that can accommodate compounds of interest. In essence, SBVS is the automated positioning (docking) of compounds in a database into such a binding site, whereupon generating different 3D conformations (poses) that should represent likely binding modes of the compound. This procedure is driven or complemented by a scoring scheme that aims to rank the compounds by their likelihood of binding.

The challenges, limitations, and successes of SBVS have been extensively discussed and reviewed. In this article, we only outline some of the key issues, in particular the treatment of the target protein and its binding site in the docking process, and the handling of the poses. For further details we refer the reader to the literature and recommend, for example, the following recent reviews by Spyrakis.[111]

Binding site: The specification of what can be considered a suitable binding site for docking is by no means a trivial task. In most cases, the relevant area on the protein surface is known, but cavity detection methods[112] can be applied if this is not the case. The preparation of the protein prior to docking, as in the correct protonation and specification of, for example, Asn/Gln side chain flip status, is of utmost importance. The latter aspect points to the much more general issue of protein flexibility. While some docking programs consider side chain flexibility, as an example for small structural change, in their pose generation method to a certain level, and are hence apt to adapting different ligands that can trigger side chain flips, the more general dynamic behavior of a binding site cannot be easily treated in this way. Rather, multiple conformations, for example, from different X-ray crystal structures with slightly different binding site arrangements can be used. Furthermore, snapshots from molecular dynamics simulations have also successfully been used. Such approaches are commonly termed ensemble docking. While their success in comparison to docking against one single structure is a priori not predictable, it is commonly accepted that ensemble docking normally outperforms docking into a single structure.[113] Various approaches for handling protein flexibility in docking have been reviewed recently,[114] and include docking to an ensemble of structures (ensemble docking). Recently, basic guidelines for selecting the best binding site for docking from an ensemble of X-ray structures have also been published.[115]

Another crucial aspect of protein–ligand binding is the involvement of water molecules. Water molecules can bind tightly to the protein surface and, as conserved water molecules that are localized across a number of X-ray crystal structures in the same position, considered to be part of the binding pocket. Other water molecules can mediate protein–ligand contact in some complex structures of a target, and not in others. Hence, the involvement of water molecules in protein–ligand binding is extremely heterogenous, and highly depends upon the targets and the ligand binding to it. Docking programs generally allow the specification of the water

molecules that are part of the pocket. In the FlexX docking program,[116] a particle placement concept has been pioneered that allows the placement of energetically favorable water molecules on-the-fly during the docking process, similar mechanisms have been implemented in other docking tools, such as GOLD (Genetic Optimisation for Ligand Docking) and Glide.[117] These few examples show that an in-depth analysis of the available structural information of a target, its dynamics and hydration behavior, and the selection and preparation of proteins with the most promising binding sites for docking, is of great importance for conducting successful SBVS campaigns.

In the absence of suitable 3D X-ray crystal structures, homology models can also be used as structures for docking. The usefulness of such models in SBVS has been a topic of controversial discussions, but their value has been demonstrated in a number of studies,[118] see also examples in a recent review on homology modeling in drug discovery.[119] Interestingly, the quality of hits identified using individual or ensembles of homology models can be even higher than for hits identified by docking into X-ray structures. This underpins that the success of SBVS campaigns is intimately linked to adequate treatment of binding site flexibility, and in particular the adaptation of the ligand binding cavity to bound ligands, which can have a more significant impact on docking success than the intrinsic methodical errors of homology modeling. Nevertheless, as for experimental structures, the selection of the most suitable model for docking from a pool of generated models remains a problem.

2.02.2.3.3.3 Scoring

The fundamental physical principles of protein–ligand binding are essentially formulated by the theory of statistical thermodynamics. However, it only recently became possible to approximate the free binding energy ΔG of a ligand binding to a protein with an accuracy that is even worthwhile discussing. Such approaches still have their limitations and are computationally extremely demanding, and will clearly not be applicable to SBVS with large compound sets for the foreseeable future. Since the advent of SBVS, major attempts have been made to develop different types of scoring functions that would, ideally, approximate ΔG with reasonable accuracy to enable the selection of poses that are most likely to represent true binders. At the same time, such functions need to be fast enough to allow calculations for very large data sets. Unfortunately, the correlation between ΔG and typical scoring functions is very low, which can most likely be attributed to the fact that ΔG cannot, principally, be decomposed into a sum of its components.[120] Nevertheless, scoring functions serve an important purpose as a rough first filter. As a result of these failures, various pose postprocessing methods have been established as a crucial step for successful SBVS campaigns showing a reasonable enrichment. A typical way of filtering poses is by applying constraints, for example, by enforcing the presence of certain hydrogen bonds or other protein-ligand interactions in the pose. The downside of such an approach is clearly that novel and unprecedented binding modes, and hence relevant new chemical matter, could be missed. A common postprocessing method is consensus scoring, that is, the rescoring of poses with different scoring functions. The principle of consensus scoring is the same as for data fusion, as outlined in the LBVS section, using the combination of information from different sources. In spite of all these efforts, careful visual inspection of the remaining top ranked poses by an experienced computational chemist is still often the best filtering method for distinguishing meaningful poses from artifacts.

2.02.2.3.3.4 Conclusion

The compilation of some key aspects of both LBVS and SBVS in this article demonstrates that devising a promising VS strategy for a target in a particular project situation requires detailed analysis of the available knowledge that operates the VS campaign. Obviously, for well-known pharmaceutical targets there is often a wealth of structural and ligand information available that allows precise SBVS and LBVS screening campaigns to be set up in parallel, including machine learning techniques. Knowledge of active chemical matter enables an a priori estimation of the success rates to be expected. The rescue or retrieval of known active compounds from a set of inactive compounds can be simulated and exploited for adjusting and optimizing the VS protocols before use in the actual campaign. Moreover, in such situations LBVS and SBVS can complement each other such that ligand-based methods can guide the specification of the SBVS protocol, thus exploiting the best of both worlds.[121] However, in projects on new targets, the knowledge base on protein structure and chemical matter is often small, and such estimations prior to the VS campaign can be difficult or impossible. Although a high level of automation in the VS search procedures is key to drug discovery projects, the composition of the most suitable VS approach still depends highly upon experience.

A common approach for fast follow-up of hits obtained by the first round of screening is hit expansion (HE). Validated hit structures and relevant structures obtained from data-mining procedures can be employed for defining small compound decks using in silico compound selection methods. The compound decks are then used in subsequent rounds of screening. HE can serve multiple purposes, depending on the outcome of the primary screen and the aim of a hit-finding project. It can consolidate and expand knowledge about active regions in chemical space by scaffold hopping and by finding derivatives of active scaffolds, hence establishing or broadening SAR information. Alternative naming conventions include structure activity relationship (SAR) expansion and hit-directed nearest-neighbor searching. HE is intended to strengthen the knowledge base for direct use in hit-to-lead campaigns.

2.02.2.3.4 Assay technology advances for functional screens

The increasing number of compounds available for testing and a growing number of molecular targets triggered parallel advances in assay technologies and automation, achieving adequate throughput. Suitable assay technologies had to be easily automated and robust. This led to the development of new homogeneous assay techniques without separation, washing, or transfer steps. Another driving factor for technology development was cost pressure, which brought forth the miniaturization of plates, to 384-well and

1536-well formats. While medicinal chemists rarely setup and run functional screens, it is of utmost importance that the medicinal chemist understands the scope and limitation of a given screening system.

One of the earliest homogeneous assay technologies was the scintillation proximity assay (SPA),[122] which consists of microspheres with embedded scintillant coated with acceptor molecules. The energy of β-particles from ^{3}H decay is absorbed in assay buffer and only stimulates light emission of the scintillant if it is in close proximity to the bead. The adaption of radioimmunoassays to SPA technology made them amenable to HTS. The great convenience of this format is that no tag is required, which could affect binding affinities. However, its downside is radioactivity and radioactive waste.

As a result, fluorescence and luminescence became established as the most widely applied assay principles. There are a whole range of fluorescent technologies available, the simplest being direct measurement of fluorescence intensity including fluorescence quenching. Fluorescence polarization (FP) exploits the size-dependent rotation rate of molecules, which is reflected by the extent of polarization of the fluorescently labeled molecule when excited by polarized light.[123,124] This allows binding of small molecules like DNA, RNA, or peptides to proteins to be monitored. Since the assay window is dependent on the difference of the fraction of tracer bound, a high saturation of tracer is needed. Depending on the Kd of the binding partners, this can require very high concentrations of protein and test compounds. Furthermore, a careful design of the fluorescent labeling is important to avoid a propeller effect and steric hindrance. FRET (Förster or fluorescence resonance energy transfer)[125] uses dipole coupling of donor–acceptor pairs (eg, 5-((2-Aminoethyl)amino)naphthalene-1-sulfonic acid (EDANS) and 4-(dimethylaminoazo)benzene-4-carboxylic acid (DABCYL))) to quantify binding events. The strong distance dependence of the energy transfer limits the detection range of binding events to 5–10 nm. All fluorescent assays are prone to artifacts due to debris and compound fluorescence, which can be reduced by using a red-shifted fluorescent label.[126] The possibility of a ratiometric measurement of FRET offers some improvement in this regard. A further improvement is obtained by time-resolved FRET, which uses long-lived lanthanide cryptate or chelate donor fluorophores with a large Stokes shift. A time delay between excitation and measurement of emission reduces background, debris, and compound fluorescence.[127] Unlike fluorescence, chemiluminescence is the result of an exothermic chemical reaction and not light absorption.[128] The light intensities of chemiluminescent assays are usually below those of fluorescent assays, but their great advantage is an extremely low background and a smaller fraction of interfering compounds in compound collections. Bioluminescence is the reaction of luciferase with its substrate luciferin resulting in a very efficient photon emission due to the enzymatic amplification.[129] It is used in cellular assay systems to quantify changes in Adenosine triphosphate (ATP) levels or modulation of gene transcription in cases where luciferase has been introduced into the cells as reporter gene. Aequorin, a calcium-sensitive photoprotein, allows intracellular calcium levels to be measured. Bioluminescent resonance energy transfer (BRET) is a bioluminescent assay format for measuring PPIs in cells. It is composed of luciferase or another bioluminescent donor fused to the protein of interest and a fluorescent receptor linked to the binding partner.[130] The quantification of ATP levels can also be used to quantify kinase activity in biochemical assays. The application of modified versions of enzyme or substrate extends the application of this assay principle to various other enzyme activities (eg, proteases, Monoamine oxidase (MOA), P450) in biochemical assays.[131] One source of interference in bioluminescent assays is the tested compounds, which affect the luciferase activity.[132] In biochemical assays, this effect can be minimized by using high luciferase concentrations. Another very important chemiluminescent assay technology is AlphaScreen[133] (amplified luminescent proximity homogeneous assay), which is based on a donor–acceptor bead pair. The partners interact directly or indirectly via tags, antibodies, or biotin-SA coupled to each of the two types of beads. Excitation at 680 nm of the photosensitizer in the donor bead converts triplet oxygen to singlet oxygen, which induces chemiluminescence and subsequent light emission at 520–620 nm at the acceptor bead if close to it. The short half-life of the singlet oxygen limits the detectable distance between the beads to 200 nm, which is significantly above the range which is covered by FRET and Time-Resolved Fluorescence Resonance Energy Transfer (TR-FRET), and thus enables monitoring of larger interacting molecules. This assay technology has a very low background and a very high sensitivity, which makes it amenable to miniaturization down to a 1536-well format. It can also be used in cellular assays to identify modification of target molecules for which antibodies are available (eg, Surefire). As with all homogeneous assay technologies, where the compounds remain in the assay, this one is also prone to interferences, in particular, singlet oxygen quenchers, such as NaN_3, divalent ions, and blue-colored compounds.

Compound-dependent assay interference leads to artifacts and these must be excluded to identify the true hits modulating the biological activity of interest. Chemoinformatic filters have been described to rule out assay technology-specific FHs.[134,135] Although these filters allow a proportion of these compounds to be eliminated the prediction is not very reliable. Tags can also be targets of compound interference. In addition to spectroscopic artifacts, chemical artifacts can occur as a result of aggregate formation.[136] Experience has shown that confirmation of biological activity should necessarily include testing in an orthogonal assay technology.[137] In 2003, FP and TR-FRET were ranked as the most suitable HTS assay technologies followed by AlphaScreen.[138] The analysis of a large set of historical data at AstraZeneca identified luminescence and FRET technologies as more successful than the average. Future directions might be the use of more complex and multiplexed assay systems. Two attractive assay principles are direct quantification via mass spectroscopy (MS) and quantification of gene expression using real-time quantitative reverse transcription polymerase chain reaction (RT-qPCR). In spite of significant technological advancement in terms of automated sampling and miniaturization, these technologies still suffer from limited throughput.[139]

2.02.2.3.5 Fragment-based drug discovery

FBDD is a complementary approach for finding new leads that during the past 15 years has increasingly been adopted by research groups in the pharmaceutical industry. The goal of FBDD is to identify small organic molecules (MW <300 Da), "fragments" of

lead-like molecular entities, that bind to a functional pocket of the target protein, and to further optimize them into potent leads using strategies that are similar to the traditional structure-based design approaches used for hits derived from HTS. Since the introduction of this concept in the mid-1990s through a seminal work by a group from Abbott,[140] the field has rapidly matured. A great variety of success stories have been published[141], which are good show cases for the efficiency and versatility of the approach. To date, there are numerous FBDD-derived clinical compounds and with vemurafenib (PLX4032)[58] the first representative has reached the market.

The great conceptual appeal of FBDD is based on considerations of sampling efficiency and of the optimal physicochemical or drug-like properties of lead compounds. Since the chemical space of organic molecules with drug-like properties is vast [estimations indicate that there are approximately 10^{50} molecules with [HAC of 15–35]; screening of corporate libraries of up to 10^{7} compounds with limited structural diversity will not get anywhere close to a representative sampling of the chemical space of potential lead structures. In contrast, screening a set of 10^{3}–10^{4} structurally diverse fragments with HAC between 10 and 22 will sample the corresponding chemical space of approximately 10^{20} molecules more efficiently.[142] In addition, due to the lower complexity of the screened compounds, hit rates are much higher.[143] Due to the small size and fewer options of forming interactions with the target receptor, fragment hits are weak binders. Therefore, in order to detect the binding event, fragments need to be screened at high compound concentrations, which in turn necessitate the selection of polar and highly water soluble specimens in the design of a fragment screening library. While this may seem a restriction at first glance, it in fact yields the advantage that such fragment hits have better physicochemical properties than typical HTS-derived hits and are thus usually better starting points for a chemical optimization effort.

The typical workflow of FBDD starts with a biophysics and structural biology dominated FBS process followed by a round of hit analogging and a fragment-hit-to-lead/drug (FHTL) phase in which synthetic medicinal chemistry activities need to be resourced.

FBS typically comprises a primary screening step in which various biophysical methods are employed to screen for the weak binding events between target and fragment. The most commonly utilized technologies are ligand- or protein-detecting NMR spectroscopy, SPR, differential scanning fluorimetry (DSF), and MST. Fluorescence displacement assays or mass spectrometry (MS) or calorimetry-based technologies are reported, but less frequently used. The selection of technologies is based on throughput and sensitivity. Throughput must be such that a library of a few thousand compounds can be screened in a (semi)-automated fashion in a timeframe of a few days or weeks. An ideal fragment screening technology should be sensitive enough to measure high micro- to millimolar interactions without any interference due to unspecific binding events. In reality, all existing technologies have liabilities that lead to false-negative and false-positive screening results. Therefore, strategies need to be devised to extract the most reliable hit set. This can be done for instance by using a triaging scheme that employs multiple screening technologies consecutively or in parallel.[144] In almost all published cases of FBDD, the identification of the primary FBS hit set is followed by a second process step in which X-ray crystallography is used to elucidate the binding site and the details of the protein–ligand interaction. Cocrystallography thereby not only provides another orthogonal proof of binding, but, more importantly, enables the structurally informed design of optimization strategies of selected fragment hits.

In the ensuing process step, selected fragment hits with suitable binding affinity and binding mode are further validated using analogging approaches in which hypotheses about determining factors for binding affinity are probed with close structural analogs of the hits. Ideally, initial fragment structure–activity relationships can be derived, the binding mode of the fragment and its analogs is found to be preserved, and promising growth vectors are identified in the process. Improving the affinity of fragments can be achieved through various avenues, most prominently fragment growing, merging, and linking.[145] In the first examples of industrial FBS, the SAR-by-NMR approach pioneered by Abbott,[140] fragment linking was used and emphasis was put on the profound effect on the resulting affinity when covalently linking two weakly binding fragments. In retrospect, fragment linking has been used relatively rarely compared to fragment growing strategies, which elaborate leads by stepwise and structure-guided growing of the starting fragment hit (Fig. 5).

There are numerous biotech companies that specialize in FBDD, and for these enterprises FBDD is typically the only accessible hit generation technology. Major pharmaceutical companies, in contrast, have built FBS units that operate in parallel to HTS units.

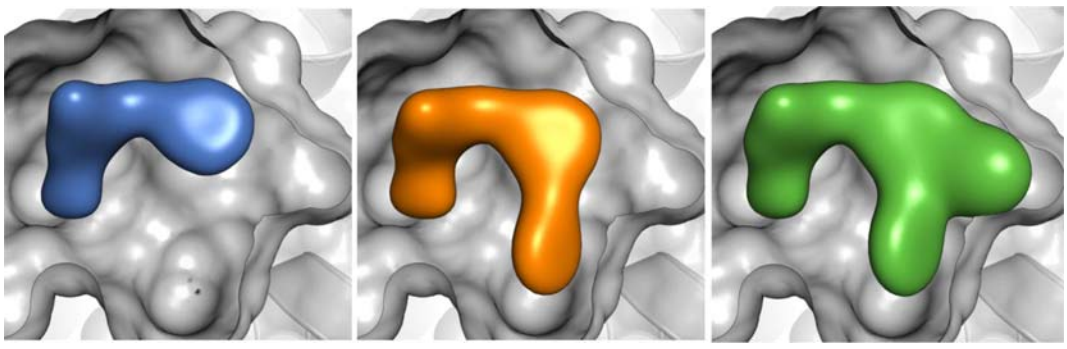

Fig. 5 Fragment-based drug discovery: Structure-guided fragment growing leads to high affinity lead candidates.

Thus, typical hit generation strategies in major pharmaceutical companies employ various approaches simultaneously. In such a scenario, FBS, HTS, and VS all produce hit sets that yield complementary information at the end of the hit-finding phase. A decision point is then reached at which the most suitable chemical starting points to be prosecuted are selected. At the start, and along the course of compound optimization, information derived from the original FBS campaign is of great use, even if the original fragment hits are not directly used as optimization starting points. In the literature, this opportunity is referred to as "fragment assisted" drug discovery.[142] For example, an HTS hit with some "functional" activity in a biochemical assay can be decorated with a substituent or merged/hybridized with a moiety that was identified in a parallel FBS. The particular way in which decoration or hybridization is done is informed by the available high resolution structural information. In literature, examples documenting merging or linking approaches spectacular improvements in potency were achieved in a single round of medicinal chemistry optimization.[146] This mix-and-match strategy can also be employed to modulate physicochemical properties of compounds, for example, by replacing a hydrophobic substituent in an HTS-derived lead by a more polar fragment, leading to an improved LLE of the resulting structural class.[147]

Synergy between the concepts of FBS and HTS can be further used to setup a separate biochemical screening scenario, in which the fragment subset of the corporate screening deck is screened in a high-concentration screening (HiCoS) regime and yields yet another functionally active fragment hit set that can be prosecuted in a similar fashion to biophysically derived hit sets (Fig. 6).

Notwithstanding the details of FBDD implementation it has become clear that this relatively new hit generation paradigm in pharmaceutical research represents a highly useful resource and time efficient approach that in a short period of time has become an integral part of drug discovery in the industry.

Future areas of development and expansion of FBDD will encompass (1) technology improvements leading to higher throughput and data quality and, in turn, to faster access to a higher quality fragment hit set, (2) enhancements in data-mining capabilities that will lead to improved fragment selection and optimization strategies, and, finally, (3) work on difficult target classes such as oligonucleotides, PPI targets, and integral membrane proteins such as G-Protein-Coupled Receptors (GPCRs).

2.02.2.3.6 Phenotypic screening

As the technology advance are covered in this paragraph concentrates on the past and future role of phenotypic screening in drug discovery. Among the factors contributing to the growing interest in phenotypic screening in drug discovery in general is the perception that, by avoiding oversimplified reductionist assumptions regarding molecular targets and instead focusing on functional effects, compounds that are discovered in phenotypic assays may be more likely to show clinical efficacy.

We would like to define "phenotypic screening" as the testing of a large number of—in most cases randomly selected—compounds in a systems-based assays. This should not be confused with systems-based chemocentric approaches. The latter typically includes an active ingredient from a plant or microbial extract with known pharmacological activity (eg, aspirin) or the derivation of a pharmacologically active natural substance (eg, prostaglandins, steroids, nucleosides, amino acids, and biogenic amines) or a synthetic compound, often based on serendipitous findings made decades before. In addition, optimization of such analogs using phenotypic assays does not classify them as phenotypic screening leads. The term "phenotypic screening" in particular appears to be used rather loosely and with different meanings. In a recent and frequently cited analysis,[148] focusing on first-in-class drugs,[149] phenotypic screening was considered to encompass all nontarget based approaches to drug discovery.

Indeed, there are highly encouraging recent examples of approved first-in-class drugs derived from phenotypic screening. However, between 1999 and 2014, only eight of the approved drugs were discovered through phenotypic screening. Fingolimod, sirolimus, and plerixafor are immunomodulatory drugs; daptomycin, artemether-lumefantrine, and bedaquiline are antibacterial/antiparasitic drugs;

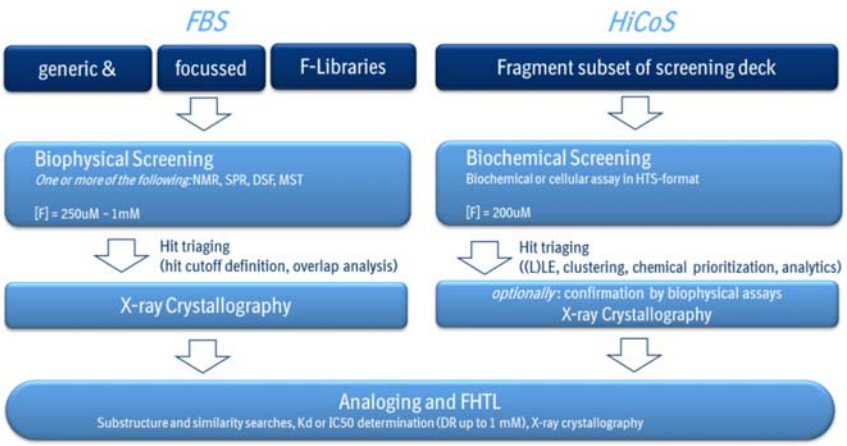

Fig. 6 Parallel prosecution of biophysical FBS and biochemical high-concentration screening (HiCoS) merging into the same downstream pipeline of FHTL activities.

and eribulin and trametinib are anticancer drugs[150] (Table 5). The fascinating case study of the discovery of fingolimod[38] illustrates nicely why developing a phenotypic screening hit can be a lengthy and twisted process (Fig. 7).

Myriocin (ISP-1), a natural product first characterized in 1972,[151] was rediscovered as an immunosuppressive metabolite in 1990[152] using MLR (mouse allogeneic mixed lymphocyte reaction). The phenotypic screening hit was subsequently assessed for prolongation of allograft survival in a rat skin allogeneic transplantation model and found to be efficacious but also toxic. Simplified derivatives were prepared with the objective of identifying ISP-1 derivatives with reduced toxicity. Out of the in-vivo characterized 2-alkyl-2-amino-propane-1,3-diols derivatives, ISP-I55 was found to be more efficacious than ISP-1 in the rat skin transplantation model but no longer inhibited MLR.[153] The different in-vitro profile compared to Cyclosporine A (CsA) and ISP-1 at that time was already pointing toward a mode of action switch. Based on ISP-I55 further conformationally constrained derivatives were prepared and the importance of correct position of the phenyl ring for the in-vivo efficacy noted. The first patent containing FTY-720 was filed in 1993 and the SAR published in 1995.[154] Only in 2002, it was disclosed that FTY-720 actually gets enantioselectively phosphorylated by sphingosine kinase and that (S)FT720-P is the active principle.[155] The obvious similarity of FTY-720P to sphingosine phosphate further stimulated research in this area and the binding of FTY-720P to the very recently discovered S1P receptor family was published.[156] At the same time, the utility of this prodrug for the treatment of multiple sclerosis was discovered and development of fingolimod was focused toward a first-in-class multiple sclerosis therapeutic with a novel mechanism of action (MoA).[157] In contrast to CsA, FTY-720 and its active principle FTY-720P do not inhibit Il-2 production and lymphocyte proliferation. Fingolimod sequesters circulating mature lymphocytes into peripheral and mesenteric lymph nodes and thereby reduces the number of lymphocytes in peripheral blood. There was a lot of speculation and uncertainty how FTY720P accomplishes this in the presence of exceeding amounts of the natural ligand of S1PR, sphingosine-1-phosphate, until Brinkmann et al. published in 2009 that FTY-720P causes long lasting internalization of the S1P receptors and thereby acts as a functional antagonist.[158]

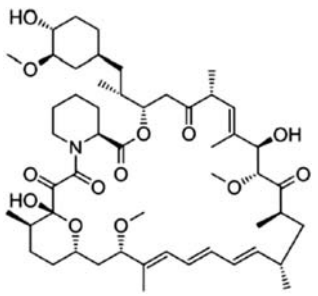
One of the many challenges of phenotypic screening is the selection of a few interesting compounds from a list of typically thousands of hits. These hit lists are often heavily dominated by unselective or toxic compounds, substances with already known unwanted MoA or false positives. Usually, potency is the sole criterion by which such hit lists are sorted and compounds selected for further studies, but this criterion might be inappropriate for identifying the best chemotypes. Usually these hits are progressed to more physiological cellular assays, but it is important to understand that new methodologies and approaches are required to increase the success rate of phenotypic screens. Validation strategies like recently established for target-based screens are not easily translatable for phenotypic screens.

Another challenge is the definition of the correct phenotype to mimic the disease in the patient. For example, phenotypic screening for the induction of cell death in cancer cell lines has frequently yielded the same "low-hanging fruit" in terms of mode of actions (MoA)—such as targeting microtubule dynamics and DNA modifications—and has thus made relatively little contribution to the identification of drugs with novel MoAs.[150] Many diseases today are still difficult to faithfully mirror in test plates and model organisms, and the use of stem cell technology or whole-organism screens might enable the establishment of more physiological assay systems that better reflect the actual disease. Reporter gene assays are a specific category of phenotypic screens, although they are somewhat artificial and have limitations.[159,160] Many reporter gene assays have been run in pharmaceutical companies and academic institutions over the past 20 years, with a peak in the mid to late 1990s, apparently with little success in terms of delivering drug candidates. To our knowledge, there is not yet an example of a first-in-class drug originating from such a screen. Progress here will certainly increase the likelihood of finding disease-relevant pathways, but it may not enable a more effective selection of interesting compounds, and so more innovation is required.

A third challenge poses the target identification for a phenotypic lead or drug.[161] Traditionally, the follow-up work of target identification and elucidating the MoA of hits from phenotypic screens have been slow and at times fruitless. Knowledge of the efficacy target, the protein through which the drug elicits the phenotype of interest via direct binding and modulation is not necessarily an absolute requirement during initial development stages. However, the definition of the on- and off-target space remains a crucial step toward full development for a drug candidate; it facilitates the definition of a patient selection biomarker, the optimization of potency within a lead scaffold, and the translation from a simplified cellular model to in vivo models. Progress has been made with respect to the identification of intracellular binding partners of the hit by affinity-based approaches like small-molecule affinity proteomics and proteomic target stability profiling.[162] Chemoproteomics approaches interrogate proteins directly in cell lysates or live cells. Despite the ever-increasing sensitivity of detection methods, the differences in cellular abundance of putative interactors that are being interrogated in parallel still pose a challenge (protein levels span 10 orders of magnitude). In addition, most of these methods do not differentiate between direct and indirect binding. A popular version of chemoproteomics combines small-molecule affinity chromatography with MS-based proteomics.[163] For unbiased target deconvolution, the compound of interest is immobilized on solid support via a functionalized linker introduced at a permissive site so that the resulting affinity probe retains cellular activity. Like in every screening process, the challenge is in the follow-up work with the identified potential targets and their functional characterization. Alternatively, genetic suppression or potentiation of compound mechanism has been achieved in human cells by combining compound treatment with cDNA overexpression[164] as well as with Ribonucleic Acid Interference (RNAi), reviewed in Palchaudhuri et al.,[165] in genome-wide screens. Small Interfering RNA (siRNA) and pooled Small hairpin RNA (shRNA) screens are amenable to unbiased, genome-wide compound-sensitization experiments. As an example, successful target ID was achieved for STF118804, a compound that reduced viability of most B-ALL cell lines, using a genome-wide pooled shRNA screen, where the direct target, nicotinamide phosphoribosyltransferase, was the most statistically significant gene conferring drug sensitivity.[166] Finally, knowledge-based approaches for target ID are the fastest, making them the first approaches

Table 5 Low molecular weight first-in-class drugs approved between 1999 and 2014 originating from phenotypic screening

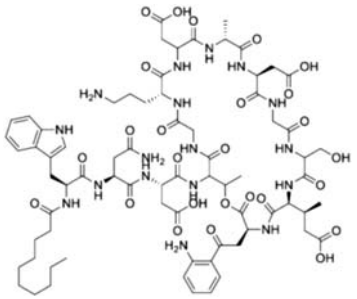
Sirolimus (transplantation, coronary stent coating)



Natural product (derived) MoA: mTOR (in complex with FKBP12), kinase inhibitor

Sirolimus was isolated from a streptomycetes and found to have antifungal activity (1975). It was later found to be immunosuppressive (1978), and its utility for allograph rejection was published in 1989. Its mechanism of action was only later elucidated (1991). FDA approval was granted in 1999

Daptomycin (antibacterial)

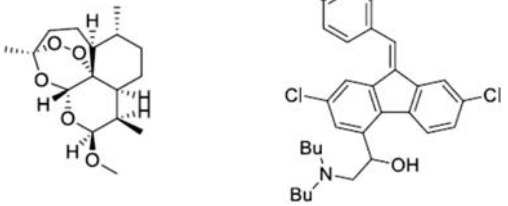


Natural product (derived) MoA: Antibacterial

The drug is a lipopeptide which binds to the bacterial cell membrane and causes rapid polarization

1980, the chemotype with indication was discovered in a cellular in vitro phenotypic screen. The final molecule was published in 1986, FDA approval was granted in 2003

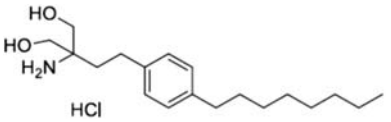
Artemether-lumefantrine (malaria)



Combination of a natural product derivative (artemether) and a l.m.w. synthetic compound (lumefantrine) Target/MoA unknown

Discovered in 1972 by testing various traditional Chinese medicines in a rodent model of malaria (artemisinin). Little has been published about the discovery since this project was regarded secret by the Chinese military. Lumefantrine was also discovered in the same project

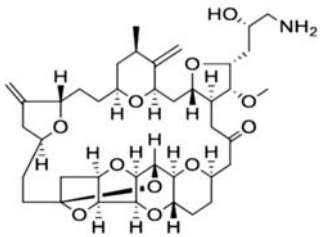
Fingolimod (multiple sclerosis)



Natural product (derived) MoA: Sphingosine 1-phosphate receptor modulator

The chemotype was discovered through a phenotypic screen for novel immunosuppressive natural products using a cellular assay (mixed lymphocyte reaction). Subsequent chemical optimization using in vitro and in vivo models serendipitously changed the mechanism of action which later was established to be sphingosine 1-phosphate receptor modulation

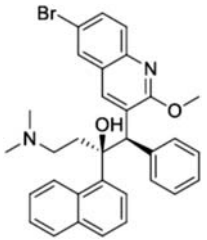
Eribulin [cancer (breast cancer)]



Natural product (derived) MoA: Microtubule inhibitor

Studying active substances of marine organisms, halichondrin B was isolated (1985) and shown to have antitumor activity in a cellular assay. The final molecule was synthesized as a structurally simplified, fully synthetic analog (2001). The mechanism of action was established subsequently in 2005

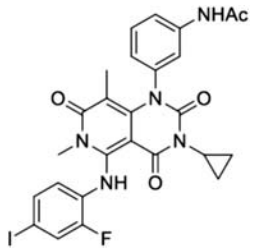
Bedaquiline (tuberculosis)



Synthetic molecule *MoA: Mycobacterium tuberculosis* ATP synthase, enzyme inhibitor

The final molecule was discovered at least 7 years prior to the first publication in 2007. The chemotype was found by high-throughput screening using *M. smegmatis* cultures. The target was subsequently identified through the characterization of resistant mutants

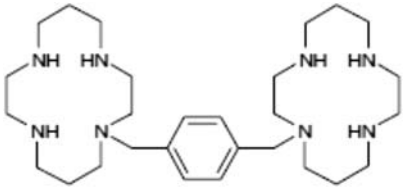
Trametinib (melanoma)



Synthetic molecule MoA: MEK1 and MEK2, allosteric kinase inhibitor

The chemotype was discovered using a cellular screen for inducers of p15INK4B and p27Kip1/CDKN1B (2007) and subsequently shown to be a specific, allosteric MEK1/MEK2 inhibitor (2011)

Plerixafor (immunostimulant)



Synthetic molecule CXCR4 antagonist

The chemotype was discovered as a chemical impurity in a whole cell screen searching for compounds that prevent HIV infection (1995). In 1998, it was characterized as an inhibitor of HIV-1 entry via the CXCR4 co-receptor. Development as an anti-HIV agent was redirected toward stem cell-mobilizing agent in 2002

Adapted from Eder, J.; Sedrani, R.; Wiesmann, C. The Discovery of First-in-Class Drugs: Origins and Evolution. Nat. Rev. Drug Discov. **2014**, *13*, 577–586.

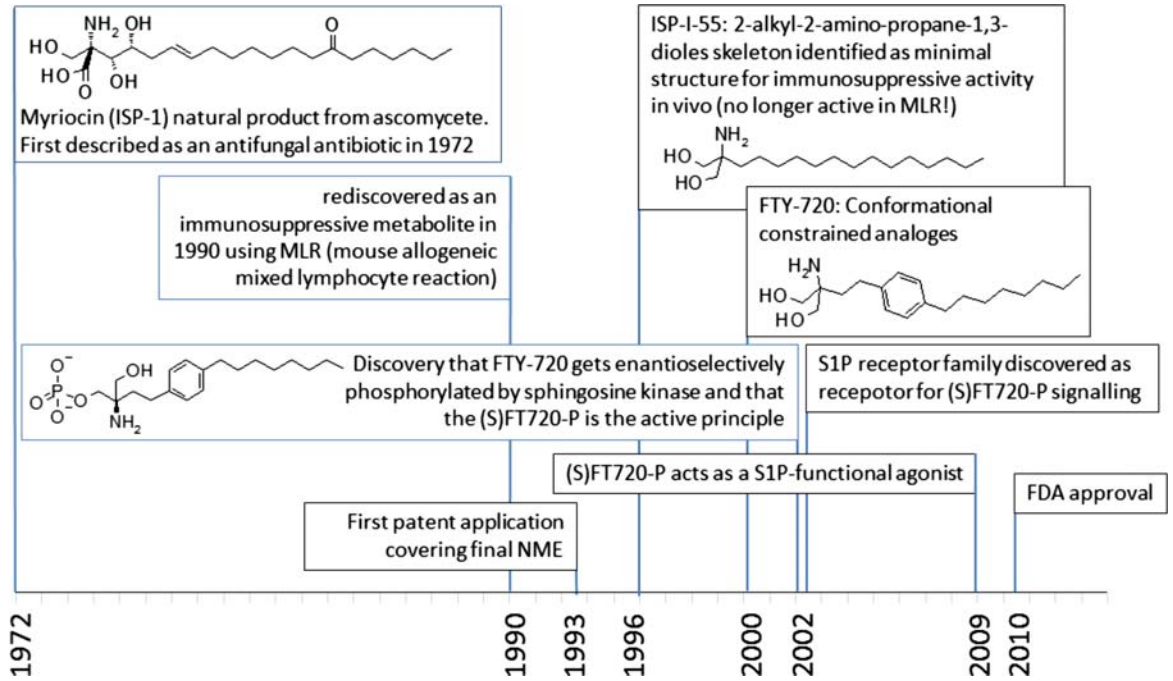


Fig. 7 The long and twisted journey of Fingolimod from the natural product phenotypic screening hit Myriocin to the first-in-class drug approved by the FDA.

implemented for deconvoluting phenotypic screening hits. However, like all approaches relying on correlation to reference compounds, they are limited in their breadth of targets that can be predicted, and ultimately depend on experimental validation of efficacy targets. Knowledge-based approaches, at their core, rely on exploitation of integrated compound–target associations gleaned from bioactivity data.

Consequently, in order for phenotypic screening to be successful, it will be important to recognize it as a new discipline that needs new technologies and methods, and for which lessons must be learnt to avoid frustration from unrealistic expectations and premature conclusions if the current investments do not yield quick returns. Now, with an increased chemical space, the time might be right to further broaden the target space and open up new avenues. This could well be achieved by investing in phenotypic screening using the compound libraries and the many tools that have been established in the context of target-based approaches, but it also requires further technological advancements. The choice should not be between phenotypic screening and target-based discovery, as both approaches can complement each other and are interconnected they should be run in parallel. Therefore, the goal will be to screen phenotypically in an efficient and effective manner and to combine phenotypic screening sensibly and productively with target-based drug discovery.

2.02.2.4 How to Best Identify Valid Hits?

In any target-based screening campaign involving a large number of samples, it is likely that a hundred to several thousand samples can be identified that display activity above a statistical significant threshold. While there is hardly a screen with any hits, a hit rate in the single digit percent range is more concerning than reassuring. A large number of primary hits always translate to big work packages to identify those hits that show specific, drug-like interaction between molecule and protein. Validated (true) hits inhibit or activate a protein by fitting into a binding site on the protein. Saturable interaction of the ligand with its target protein is best shown with biophysical assays[167] like resonant waveguide (RWG), Thermal Shift Assay (TSA) DSF, SPR, MST, or ITC. The specificity of binding is ideally deduced from the cocrystal structure, 2D (HSQC) NMR techniques, or HDX exchange studies. Covalent inhibitors can be validated by proving the specific covalent labeling of the target protein and ideally the target epitope by chemoproteomics. All these biophysical methods need to be carefully validated using validated binders, like natural substrates or validated hits from another screen, for example, an FBS campaign, before being applied in triaging schemes for inhibitors out of a functional assay. Not all methods are suitable for all targets, and not all have the same information content. As most of the biophysical methods are more resource intensive, and of slower throughput than the functional screening assay the primary hits must be smartly triaged down to a number that is compatible with the profiling assays.

This triaging process of the primary hits to validated hits is often underestimated or seen as part of the hit-to-lead process. The latter is especially unfortunate since synthetic chemistry on assay artifacts is probably the biggest waste of resources in preclinical drug discovery. Retrospective analysis of the timelines for the 10 PPI screens done with a collaborator revealed that the initial screen

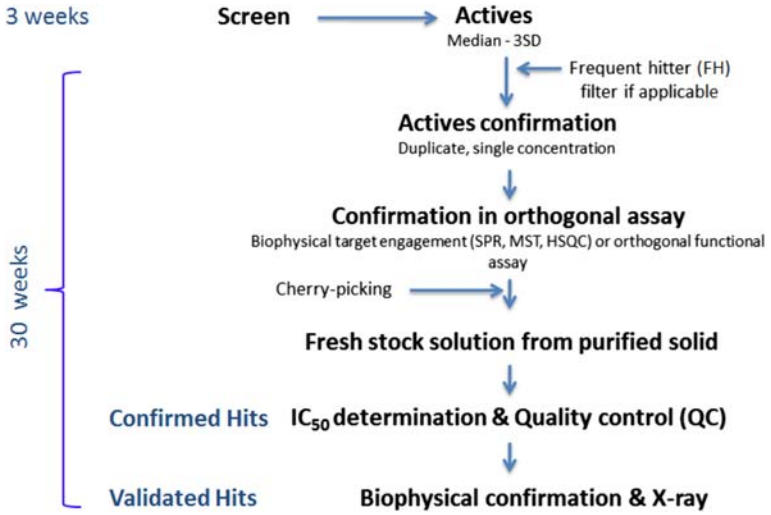

Fig. 8 Generic triaging process for functional screens.

of 1,700,000 samples took only 3 weeks, while the triaging process to validated hits needed on average 30 weeks. In terms of efficiency, much more is gained from designing a smarter triaging scheme than to further increase the throughput of the primary screen. The triaging scheme should also be geared toward the rapid identification of some validated hits with the anticipated risk of not finding all validated hits in the deck. As much time can be lost rescuing presumed "false negatives" as submitting "false positive" to the next profiling round.

Based on our experience we suggest a generic hit triaging process as outlined in Fig. 8. The primary actives from a large (>200,000) biochemical or cellular assay are submitted for confirmation in the identical assay. Those that display activity above a statistically significant threshold (confirmed actives) are ideally tested for binding to the target by a biophysical method with sufficient throughput like RWG, DSF, or SPR. At this stage, a single concentration thermal shift value or a SPR sensogram for the target protein as well as a control protein is likely to be more efficient than a full Kd determination. If a biophysical assay is not feasible, we recommend retesting the confirmed actives in an orthogonal assay utilizing a different technology than the primary screening assay. We and others[88] find this "active in both assays" flag much more efficient than the typical assay technology and compound property specific counter screens, where each potential liability needs to be addressed in a separate experiment. Those confirmed actives are then assessed for dose-responsive inhibition (or activation) and those that pass are cherry picked for retesting from a freshly prepared stock solution, ideally from purified solid. As not all confirmed hits will be readily available as solids, cherry picking based on cluster representatives at this stage will be required. Those that confirm in the primary screening assay (confirmed hits) are submitted to Kd determination using suitable biophysical assays. If saturable and sufficiently potent binding (LE $\geq$ 0.3) to the target protein can be obtained, then the sample is prioritized for elucidation of the binding site information by X-ray cocrystallography or HSQC.

2.02.3 Hit-to-Lead Process

The process usually referred to as "hit-to lead" is geared toward the identification of lead series around validated hits with satisfactory molecular potency, and a more detailed assessment of the liabilities and opportunities with respect to selectivity, patentability, and ADME properties (absorption, distribution, metabolism, and excretion). In the hit-to-lead phase, systematic and sometimes quite intensive SAR investigations are performed on several core structures in parallel. Experience shows that it is important to pursue several structurally diverse series in parallel to balance the risk of dead ends due to incompatible pharmacokinetics/pharmacodynamics (PK)/PD.

It is now common to demonstrate that an appropriate PK or pharmacological profile can be achieved for selected compounds.[168] Obstacles to a targeted PK profile, for example, poor permeability or rapid metabolism, can now be readily identified through well-established in vitro surrogates such as permeability in a Caco-2 assay or by in vitro metabolism as measured in microsomal or hepatocyte preparations. Off-target liabilities such as human ether-a-go-go-related gene (hERG) (life-threatening long QT syndrome (long interval between Q and T wave in the hearts electric cycle) due to block of the hERG channel) or Cytochrom P450 (CYP) inhibition[169,170] or phospho-lipidoses[171] should also be identified at this early stage—it is not necessary to fix all the issues that are identified, but the data should indicate that there is a path forward during LO (Fig. 9). These assays are now fairly high throughput and allow the characterization of a large number of hit derivatives. However, sometimes the throughput is achieved by making compromises on the predictability of the surrogate assay. High-throughput microsomal stability assays have less

Fig. 9 Medicinal Chemists face many challenges. Reproduced from Bleicher, K.H.; Böhm, H.-J.; Müller, K.; Alanine, A.I. A Guide to Drug Discovery: Hit and Lead Generation: Beyond High-Throughput Screening. Nat. Rev. Drug Discov. **2003**, *2*, 369–378.

predictability than more labor-intensive hepatocyte preparations.[172] Many companies also prefer the more labor-intensive functional patch-clamp assay to a radiometric or fluorescence-based hERG binding assay for an early risk assessment of hERG channel blockage.

2.02.3.1 Chemical Probes for Novel Therapeutic Concepts

The recent years witnessed an increased acceptance of the usefulness of high-quality chemical probes for improved understanding of human biology. Especially for novel, unprecedented targets the detailed understanding of their role in disease is potentially of greater importance than ADME properties in line with oral dosage. Classical hit-to-lead work and the development of chemical probes both require validated hits as starting points; however, the objectives of these processes can be significantly different. So what is a chemical probe and why should it be different from a lead for a drug discovery campaign targeting an unmet medical need? (Fig. 10). A chemical probe is simply a reagent—a selective small-molecule modulator of a protein's

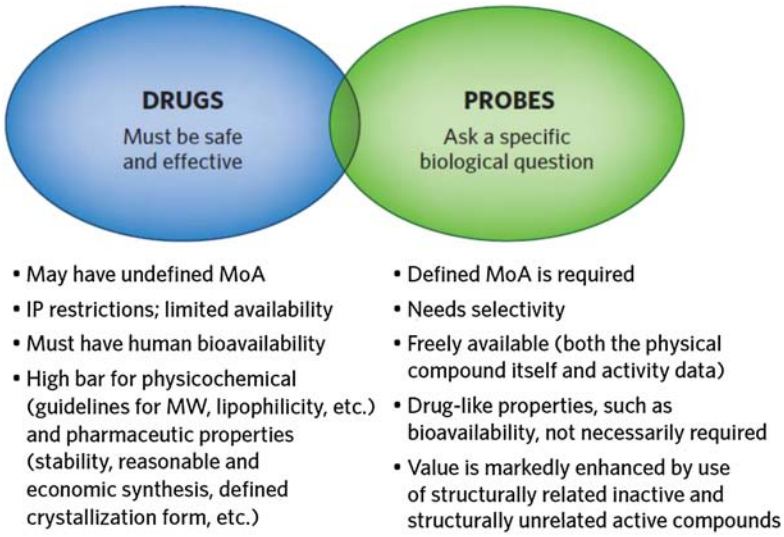

Fig. 10 Different purposes and requirements for chemical probes and drugs. Reproduced from Arrowsmith, C.H.; Audia, J. E.; Austin, C.; Baell, J.; Bennett, J.; Blagg, J.; Bountra, C., et.al. The Promise and Peril of Chemical Probes. Nat. Chem. Biol. **2015**, *8*, 536-541.

function that allows the user to ask mechanistic and phenotypic questions about its molecular target in biochemical, cell-based, or animal studies. Chemical probes do not need to meet the same requirements as a successful medicine, such as good PDs and oral bioavailability, but they must exhibit high potency, selectivity, and proven intracellular target engagement to be useful probes of biological questions. The prime objective of a chemical probe will always be to interrogate system biology. Making such a probe publicly available can significantly increase the learning curve and therefore enable an earlier understanding about the validity of a novel therapeutic concept. A lead compound is almost always kept secret until the patent application is filed and published.

Chemical probes have proven to be very impactful not only because they are complementary to genetic approaches, such as CRISPR (Clustered Regularly Interspaced Short Palindromic Repeat) and RNAi,[173] but also because they have unique advantages. They can rapidly and reversibly inhibit a protein or a protein domain in cells or animals, be used in almost any cell type and reveal temporal features of target inhibition. They allow the interrogation the catalytic versus scaffolding functions of an enzyme. A target family restricted polypharmacology can be an additional upside potential compared to RNAi studies. Finally, and importantly, the results obtained with chemical probes are more relevant for translational studies as they are more likely to mimic the pharmacology realized when a therapeutic small-molecule drug is used.

The difference in IP restriction between a lead for a drug (keep secret) and a chemical probe (share with the community to learn more about the biology) make such approaches attractive for private–public partnerships. About a decade ago, academia substantially increased its efforts in chemical biology and drug discovery. These efforts arose in part because of the availability of large numbers of uncharacterized potential drug targets emerging from genome sequencing efforts, from the development and commoditization of new screening technologies and from the possibility of inventing new medicines. In the context of public–private partnerships for chemical probes, the Structure Genomics Consortium (SGC; http://www.thesgc.org/) is the leading example for a large collaboration of academic and industry scientists.[174] SGC probes for epigenetic targets require minimally to have in vitro potency at the target protein of <100 nM (ideally by biophysical assays), possess >30-fold selectivity relative to other sequence-related proteins of the same target family, be profiled against an "industry standard" selection of pharmacologically relevant off-targets and against large protein families of relevance to drug discovery and, finally, have demonstrated target engagement in cells at <1 μM. In addition the consortium now also requires that the chemical probe be accompanied by an inactive close analog of the compound (eg, for chiral probes the distomer) to serve as a negative control.

By mid-2015, more than 30 chemical probes have been made publicly available by the SGC and over 6000 samples of SGC probes have been used in various experiments proving the validity of the open access approach.[174] Early successes of open access inhibitors have been driven by bromodomain and, in particular, Bromodomain and extraterminal domain family (BET) inhibitors, but as more probes become available, insights into other target areas and therapeutic potentials are emerging (**Fig. 11**). Importantly, in less than 5 years after the publication of the first BRD4 chemical probe, inhibitors of the BET family have entered clinical trials enabled, in part, through a solid new therapeutic concept validation by the scientific community.

2.02.4 Origin of First-in-Class Drugs: Past and Future Outlook

In 1997, Drews and Ryser[175] published their seminal analysis on escalating research and development (R&D) costs in the pharmaceutical industry. Many additional studies and perspectives have been published since then on the trends, metrics, and measures that drive R&D productivity and the potential causes for the productivity and innovation draught. Groundbreaking scientific discoveries and technological advances like the modern molecular biology method toolbox, fragment, and HTS advances, structure-based drug design, combinatorial and parallel chemistry, and the sequencing of the human genome have allowed a rational, target- and hypothesis-driven approach to drug discovery. They were implemented with the promise of greatly enhancing the productivity of R&D; however, so far there has been little apparent impact of these advances on the number of drug approvals by the US FDA. So was this paradigm shift from the "phenotypic" systems-based drug discovery approach to the target-based the wrong decision for drug discovery? Has the pharmaceutical industry invested trillions in the wrong technologies for almost three decades?

Eder et al.[150] address this worrisome question with the analysis of the origin of first-in-class drugs approved by the FDA between 1999 and 2013. Drugs were designated as first-in-class drugs based on their modulation of—until then— an unprecedented target or biological pathway. This was considered to be independent of the mechanism of modulation, so if for the same target several drugs with different mode of action (eg, reversible and irreversible or competitive and allosteric) exist, only the drug that was approved first was included in the analysis. Using these stringent criteria the drugs were categorized if they emerged from a systems-based approach (target-agnostic approach that is based on a phenotypic change in vitro or in vivo) or target-based approaches (aims to manipulate a biological system by pharmacologically modulating a specific component or target). According to this analysis, of the 114 first-in-class drugs, 34 (30%) were discovered through systems-based approaches and more than double (78, 70%) were discovered from target-based approaches (**Fig. 12A**). While there is no statistically significant trend over the 15-year period that would indicate a clear superiority of one approach over the other, there is a positive trend for an increasing number of newly approved target-based first-in-class drugs (**Fig. 12A** and **Table 6**).

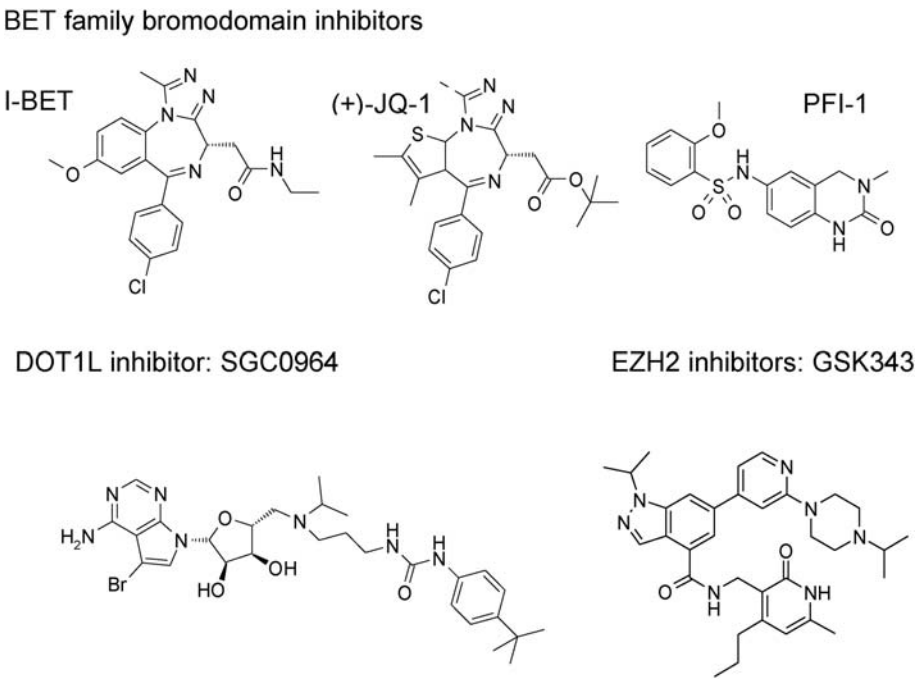

Fig. 11 SGC chemical probes that enabled new therapeutic concept validation and subsequent start of clinical trials (not necessarily with the same compound).

Confirming that the increased investment in target-based approaches translates into more first-in-class drugs, we wondered if the investment in high-throughput and FBS technologies as well as in structural research and improved compound collections in the last decades translates into increased number of first-in-class drugs. Out of the 114 drugs, 34 are biologics and were excluded from further analysis since the finding approaches for antibodies and biologics in general differ significantly from low MW drug discovery. From the remaining 80 first-in-class low molecular drugs, 49 are natural product derived or from existing drugs, 26 drugs originated from screening campaigns, and 5 drugs were derived by de-novo structure-based design (**Fig. 12B**). Although there is a trend for more first-in-class drugs originating from screening leads even in the second decade of the new millennium, the majority of first-in-class drugs did not require sophisticated screening technology or early structural research investments to be discovered. This puzzling finding needs closer examination. Upon additional inspection it becomes clear that approximately half of the first-in-class drugs (26) that originated from analogs were discovered using a systems-based approach. This is different to the screening and "de-novo" structure-based design derived lead-derived drugs where only eight originate from a phenotypic screen. So how have these starting points for analog-based drug discovery been discovered? Thirty-one (63%) of these 49 analogs are actually natural product derived and only 18 (37%) are from former synthetic leads or drugs (see **Table 7** for examples approved in 2013). Looking at patent filing dates for these drugs one has to note that interestingly, all but four, systems-based drugs have their beginnings before 1985. So, the finding that a considerable number of systems-based drugs have been approved over the past 10 years is likely to be due in part to the length of time these projects took. Low MW first-in-class drugs that originated from target-based screening or de-novo structure-based design (taking 8 years) took only half the time as the systems-based approaches (taking 16 years). The data also suggest that target-based drug discovery might have helped reduce the median time for drug discovery and development. However, this does not change the fact that technology driven target-based approaches failed to live up the high expectations put into them. Based on the previously described analysis, systems-based, target-agnostic, approaches seem to be a productive source for first-in-class drugs addressing unmet medical needs. There are principally two major shortcomings for systems-based low MW drug discovery: (1) The shortage of existing chemotypes. Natural products have been a successful source in this respect, but fall out of fashion with the move to target-based approaches. (2) The long time it needs to bring a systems-based drug to the market.

In this context, phenotypic screening could be an important contribution as it offers the potential to provide important new pharmacological tools to study new biology at a faster pace than classical chemocentric systems-based approaches. Phenotypic screening as a new discipline holds the promise to uncover new therapeutic principles and molecular pathways of currently untreatable diseases (see section on Cellular imaging in drug discovery: biomolecular imaging and informatics). In order for phenotypic screening to be successful, it will be important to recognize it as a new discipline that needs new technologies and

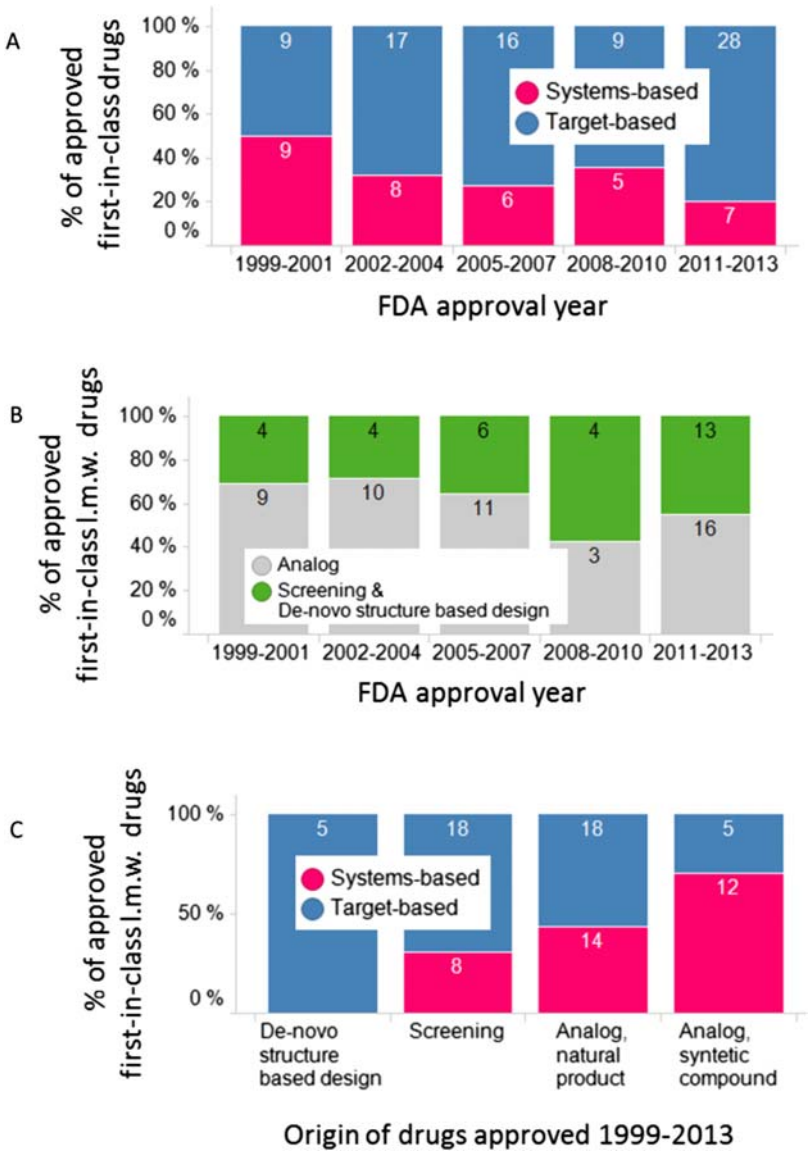

Fig. 12 (A) Percentage of 114 first-in-class drugs that were discovered through systems-based approaches (*red*) and target-based approaches (*blue*) by FDA approval date. Numbers in the bars reflect the discreet number of approved drugs in this category. (B) Percentage of first-in-class drugs that originated from a screening lead or "de-novo" structure-based design (*green*) and an analog-based approach (*gray*) by FDA approval date. Numbers in the bars reflect the discrete numbers of approved drugs in this category. (C) Origin of low molecular weight drugs approved by the FDA between 1999 and 2013.

methods, and for which lessons must be learnt to avoid frustration from unrealistic expectations and premature conclusions if the current investments do not yield quick returns. We therefore consider phenotypic screening not as a neoclassical approach that reverts to a supposedly more successful systems-based method of the past, but instead as a logical evolution of the current target-based activities in drug discovery. Moreover, phenotypic screening is not just dependent on the use of many tools that have been established for target-based approaches; it also requires further technological advancements. The choice should not be between phenotypic screening or target-based discovery, as both approaches can complement each other, are interconnected, and should be run in parallel. Although target or pathway discovery for chemotypes identified from phenotypic screens is not necessarily required for further drug development, it could be an advantage in order to discover additional pathway nodes for target-based therapeutic intervention or to enable the discovery of follow-on drugs. Therefore, the goal will be to screen phenotypically in an efficient and effective manner and to combine phenotypic screening sensibly and productively with target-based drug discovery.

Table 6 One hundred and fourteen first-in-class low molecular drugs approved between 1999 and 2013: Approach and origin of lead structure

Name	*Approach*	*Origin of lead*	*Indication*	*FDA approval*	*Years*[a]
Sofosbuvir	Target-based	Analog, natural product	Hepatitis C viral infection	2013	6
Ibrutinib	Target-based	Screening	Mantle cell lymphoma	2013	6
Riociguat	Target-based	Analog, synthetic compound	Pulmonary arterial hypertension and chronic thromboembolic pulmonary	2013	10
Trametinib	Systems-based	Screening	Melanoma	2013	8
Canagliflozin	Target-based	Analog, natural product	Type 2 diabetes	2013	8
Dimethyl fumarate	Systems-based	Analog, natural product	Multiple sclerosis	2013	16
Mipomersen sodium	Target-based	Analog, natural product	Homozygous familial hypercholesterolemia	2013	10
Crofelemer	Systems-based	Analog, natural product	Diarrhea	2012	6
Bedaquiline	Systems-based	Screening	Tuberculosis	2012	8
Lomitapide	Target-based	Screening	Familial hypercholesterolemia	2012	17
Teduglutide	Target-based	Analog, natural product	Short bowel syndrome	2012	16
Tofacitinib	Target-based	Screening	Rheumatoid arthritis	2012	10
Omacetaxine	Systems-based	Analog, natural product	Cancer (chronic myeloid leukemia)	2012	35
Perampanel	Target-based	Screening	Epilepsy	2012	11
Linaclotide	Target-based	Analog, natural product	Chronic idiopathic constipation, irritable bowel syndrome with constipation	2012	9
Mirabegron	Target-based	Analog, synthetic compound	Overactive bladder	2012	14
Lucinactant	Target-based	Analog, natural product	Respiratory distress syndrome	2012	15
Ivacaftor	Target-based	Screening	Cystic fibrosis	2012	7
Vismodegib	Target-based	Screening	Cancer (basal cell carcinoma)	2012	6
Ingenol mebutate	Systems-based	Analog, natural product	Cancer (actinic keratosis)	2012	11
Ruxolitinib	Target-based	Analog, synthetic compound	Cancer (intermediate or high-risk myelofibrosis)	2011	5
Crizotinib	Target-based	Screening	Cancer (ALK-positive nonsmall cell lung cancers)	2011	6
Icatibant	Target-based	Analog, natural product	Hereditary angioedema	2011	22
Vemurafenib	Target-based	Screening	Cancer (melanoma)	2011	5
Rivaroxaban	Target-based	Screening	Thrombosis	2011	9
Ezogabine	Systems-based	Analog, synthetic compound	Epilepsy	2011	19
Boceprevir	Target-based	De-novo structure-based design	Hepatitis C viral infection	2011	10
Abiraterone	Target-based	Analog, natural product	Cancer (prostate)	2011	18
Roflumilast	Target-based	Screening	Chronic obstructive pulmonary disease	2011	17
Eribulin	Systems-based	Screening	Cancer (breast cancer)	2010	11
Tesamorelin	Target-based	Analog, natural product	Lipodystrophy associated with HIV infection	2010	14
Fingolimod	Systems-based	Screening	Multiple sclerosis	2010	17
Carglumic acid	Target-based	Analog, natural product	Hyperammonemia	2010	44
Artemether-lumefantrine	Systems-based	Screening	Malaria	2009	22
Plerixafor	Systems-based	Screening	Immunostimulant	2008	18
Rufinamide	Systems-based	Analog, synthetic compound	Seizures, epilepsy, Lennox-Gastaut syndrome	2008	23
Tetrahydro-biopterin	Target-based	Analog, natural product	Phenylketonuria	2007	23
Raltegravir	Target-based	Analog, synthetic compound	HIV infection	2007	5
Maraviroc	Target-based	Screening	HIV infection	2007	6
Aliskiren	Target-based	De-novo structure-based design	Hypertension	2007	12
Sinecatechins	Systems-based	Analog, natural product	Genital and perianal warts (antiviral; topical)	2006	11
Sitagliptin	Target-based	Screening	Diabetes type-2	2006	4
Vorinostat	Systems-based	Analog, synthetic compound	Cutaneous T-cell lymphoma (hematologic and solid tumors)	2006	14
Varenicline	Systems-based	Analog, natural product	Smoking cessation	2006	5
Lubiprostone	Systems-based	Analog, natural product	Irritable bowel syndrome and chronic constipation	2006	15

Table 6 One hundred and fourteen first-in-class low molecular drugs approved between 1999 and 2013: Approach and origin of lead structure—cont'd

Name	*Approach*	*Origin of lead*	*Indication*	*FDA approval*	*Years*[a]
Ranolazine	Systems-based	Analog, synthetic compound	Chronic angina pectoris	2006	22
Sunitinib	Target-based	Screening	Cancer (renal cell carcinoma and gastrointestinal stromal tumor)	2006	5
Conivaptan	Target-based	Screening	Hyponatremia	2005	11
Sorafenib	Target-based	Screening	Cancer (renal, liver)	2005	6
Nelarabine	Systems-based	Analog, natural product	Cancer (T-cell acute lymphoblastic leukemia and T-cell lymphoblastic)	2005	17
Ramelteon	Target-based	Analog, natural product	Insomnia	2005	8
Exenatide	Target-based	Analog, natural product	Diabetes type 2	2005	8
Pramlintide	Target-based	Analog, natural product	Diabetes types 1 and 2	2005	12
Ziconotide	Systems-based	Analog, natural product	Severe chronic pain (intrathecal injection)	2004	14
Acamprosate	Target-based	Analog, natural product	Alcohol dependence	2004	7
Azacitidine	Systems-based	Analog, natural product	Myelodysplastic syndromes (cancer)	2004	43
Cinacalcet	Target-based	Screening	Secondary hyperparathyroidism and hypercalcemia in patients with parathyroid carcinoma	2004	8
Memantine	Systems-based	Analog, synthetic compound	Alzheimer's disease	2003	32
Daptomycin	Systems-based	Screening	Antibacterial	2003	18
Miglustat	Systems-based	Analog, natural product	Gaucher disease	2003	26
Bortezomib	Target-based	De-novo structure-based design	Cancer (multiple myeloma, mantle cell lymphoma)	2003	8
Gefitinib	Target-based	Screening	Cancer (breast, lung, others)	2003	7
Aprepitant	Target-based	Analog, synthetic compound	Chemotherapy induced nausea and vomiting	2003	8
Enfuvirtide	Target-based	Analog, natural product	HIV infection	2003	9
Nitazoxanide	Systems-based	Analog, synthetic compound	Antiparasitic (*Cryptosporidium* and *Giardia* infections)	2002	28
Ezetimibe	Systems-based	Analog, synthetic compound	Cardiovascular, LDL cholesterol lowering	2002	10
Nitisinone	Systems-based	Analog, natural product	Hereditary tyrosinemia type 1	2002	16
Bosentan	Target-based	Screening	Pulmonary arterial hypertension	2001	9
Imatinib	Target-based	De-novo structure-based design	Cancer (chronic myelogenous leukemia, gastrointestinal stromal tumors)	2001	8
Caspofungin	Systems-based	Analog, natural product	Fungal infections	2001	7
Mifepristone	Target-based	Analog, natural product	Termination of intrauterine pregnancies	2000	20
Docosanol	Systems-based	Analog, synthetic compound	Herpes simplex virus (topical treatment)	2000	9
Zonisamide	Systems-based	Analog, synthetic compound	Epilepsy	2000	23
Aminolevulinic acid	Systems-based	Analog, natural product	Actinic keratosis	1999	14
Levetiracetam	Systems-based	Analog, synthetic compound	Epilepsy	1999	15
Pemirolast	Systems-based	Analog, synthetic compound	Itch associated with allergic conjunctivitis	1999	22
Sirolimus	Systems-based	Screening	Transplantation, coronary stent coating	1999	26
Zanamivir	Target-based	De-novo structure-based design	Influenza viral infection	1999	8
Orlistat	Target-based	Analog, natural product	Obesity	1999	15
Cilostazol	Systems-based	Analog, synthetic compound	Intermittent claudication in peripheral vascular disease (inhibits platelet)	1999	20

[a]Timespan from first patent filing date to FDA approval.

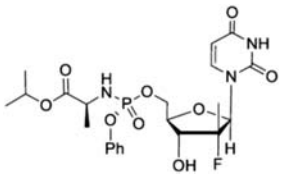
Table 7 Examples of first-in-class drugs approved in 2013

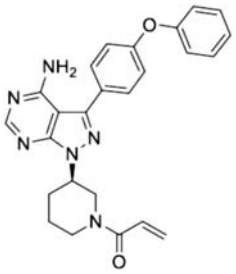
Sofosbuvir (hepatitis C viral infection)



Approach: Target-based | Origin of lead: Analog, natural product | MoA: HCV NS5B polymerase, enzyme inhibitor

Rational design, the molecule is a cytidine analog (prodrug) optimized for selectivity and pharmacokinetic properties

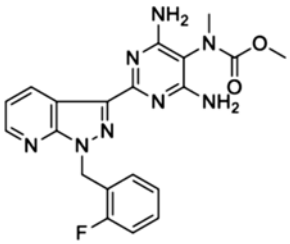
Ibrutinib (mantle cell lymphoma)



Approach: Target-based | Origin of lead: Screening | MoA: Bruton's tyrosine kinase inhibitor

The fundamental target biology was discovered in 1993. Pyrrolo[2,3-*d*]pyrimidines have been identified as tyrosine kinase inhibitors by screening various compound collections using biochemical kinase assays. The final molecule was rationally designed by introducing an electrophilic group capable of irreversibly inactivating the target. The lymphoma "melting" effect in patients was not predicted by preclinical models

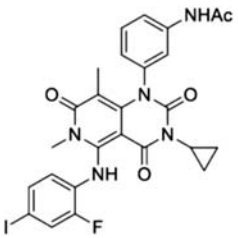
Riociguat (pulmonary arterial hypertension)



Approach: Target-based | Origin of lead: Analog, synthetic compound | MoA: Stimulator of soluble guanylate cyclase, enzyme

The target rationale was established in the late 1970s. The chemotype was discovered by a systems-based approach in 1994 and later used as a chemical starting point in a target-based drug discovery effort using the recombinant enzyme

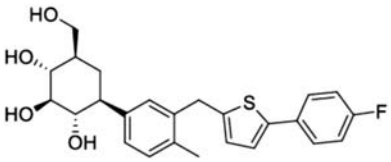
Trametinib (melanoma)



Approach: Systems-based | Origin of lead: Phenotypic screening | MoA: MEK1 and MEK2, allosteric kinase inhibitor

The chemotype was discovered using a cellular screen for inducers of p15INK4B and p27Kip1/CDKN1B and subsequently shown to be a specific, allosteric MEK1/MEK2 inhibitor

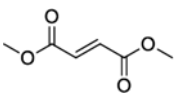
Canagliflozin (type 2 diabetes)



Approach: Target-based | Origin of lead: Analog, natural product | MoA: Sodium-glucose transport protein subtype 2 (SGLT2), enzyme inhibitor

The transporter was cloned in 1992 (Wells et al.). Cloning of a human kidney cDNA with similarity to the sodium-glucose cotransporter and characterized in 1994. The chemotype, inspired by the natural product phlorizin, was optimized to selectively inhibit SGLT2 using a cellular assay with an exogenously overexpressed transporter

Dimethyl fumarate (multiple sclerosis)



Approach: Systems-based | Origin of lead: Analog, natural product | MoA: Unclear

Serendipitous finding assuming that psoriasis might be caused by a metabolic disturbance involving the citrate cycle. Schweckendiek, who suffered from psoriasis, was working on C4 compounds of the citrate cycle and was taking fumaric acid in a self-experiment. The final molecule was approved for treatment of psoriasis in Germany in 1994 and it was found later that two psoriasis patients who also suffered from multiple sclerosis improved in both diseases. This triggered further clinical trials in multiple sclerosis

https://www.centerwatch.com/drug-information/fda-approved-drugs. The above link is to a database containing a listing of drugs (NMEs) approved by the Food and Drug Administration (FDA) for sale in the United States. Drug information typically includes the drug name, approval status, indication of use, and clinical trial results. A New Molecular Entity (NME) is defined by the FDA as a medication containing an active substance that has never before been approved for marketing in any form in the United States. The database also includes some recombinant proteins and biologics that were approved by the FDA's Center for Drug Evaluation and Research (CDER).

2.03.1 Introduction

The pharmaceutical industry has undergone dramatic changes over recent decades, adapting to an ever evolving understanding of how to target human diseases. This has resulted in the incorporation of additional assays, technologies and management practices into the drug discovery process.[1] It has invariably led to the earlier assessment of preclinical compounds using in vitro and animal models for efficacy, safety, and pharmacokinetics. The increased number of new targets under investigation, and the increasing front loading in the preclinical phase have led to a dramatic increase in research and development (R&D) costs.[2,3] Nevertheless, it has been predicted that without a considerable increase in productivity, or the adoption of new approaches and practices, that drug discovery will become unsustainable in the future.[3–5]

Recent analyses of marketed drugs showed that the mean development cost per drug molecule was approximately 1.8 billion US dollars (USD), with 32% of the cost coming from the preclinical phase and 63% in the clinical phase.[5,6] However, analysis of the total cost throughout development, both on projects that resulted in drugs, and those that were prematurely terminated, has shown that the total costs in clinical and preclinical development were similar. The two most cost intensive phases identified were lead optimization and phase III.[5,6] Yet > 90% of all drug candidates identified in the preclinical phase fail in clinical development, with in vivo safety and efficacy being the primary scientific causes for termination.[5,7,8] This would suggest that the predictive value of the preclinical scientific process is in need of improvement.[9–11]

Mergers and the widespread downsizing observed in the pharmaceutical industry are an unsurprising reaction to the high costs and the low predictive performance of the preclinical phases. This has forced the industry to cut R&D by moving to lower cost regions[5] as well as reorganize internally into smaller units.[12,13] The benefit of the latter approach is that dogmatic practices that can develop within large organizations are less likely to take hold, including standardized progression paths and milestones, which have the potential to limit true scientific innovation.[10,14,15]

The typical medicinal chemist follows a reasonable well defined process starting with target selection, hit identification and the subsequent lead optimization.[16] Target selection is often based on clinically unvalidated disease or systems-biology data; hit selection using simple, robust biochemical or cellular assays; lead optimization aided by in vitro and in vivo data on animals.[17] The sophistication of the models employed in this process is without question, yet the integration of this data to identify the best

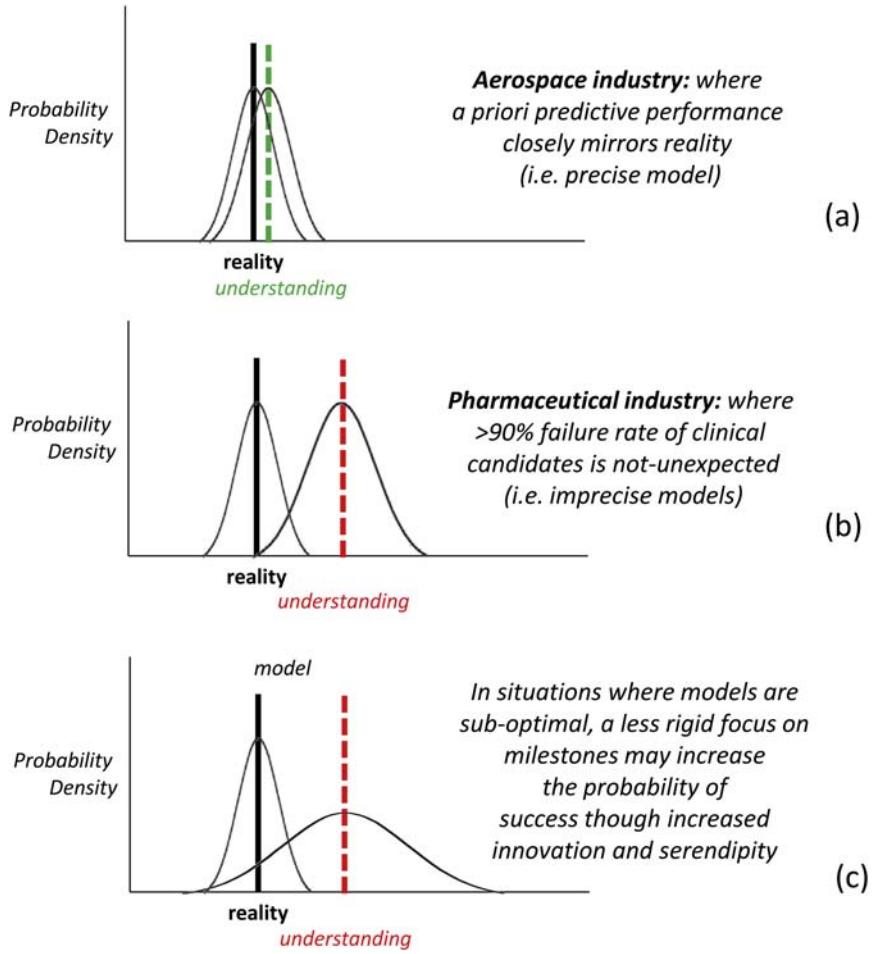

Fig. 1 Some models are of more utility than others: (A) the aerospace and (B) pharmaceutical industry. In the case of (C), models with more limited predictive capability can also be effectively used, however in such cases additional flexibility in the solutions should be considered to identify or include serendipitous and innovative discoveries.

possible compounds to test the disease-target hypothesis is perhaps not. The development statistics discussed above highlight that there is considerable potential to improve the discovery process: How and when we collect data and how it is integrated together in a multiobjective fashion.

In this chapter we consider whether the use of the term "process" in conjunction with drug discovery is perhaps optimistic, since it is difficult to define a rigid flow-chart process for something that is not fully understood or difficult to model.[18–22] Contrast the pharmaceutical and aerospace industries. The process of designing new aircraft, which also utilizes theoretical and physical models, is found to be considerable more predictive (Fig. 1). In the latter case, focusing development efforts on models that show good agreement with reality results in a design that translate well.[14] In contrast, when models show weaker agreement with reality, focusing rigidly to these will probably not result in translatable designs. In such a situation a more effective approach would be to incorporate information from these models, yet acknowledge the limitations of the methods, and in doing so, undertake parallel approaches to maximize the probability of success though true innovation and/or serendipity.[15,23]

We discuss issues regarding the drug-target hypothesizes, pharmacokinetics & dynamics (PK/PD), toxicity and physical properties, and whether they are fully accounted for in a systematic fashion during the translational process.

2.03.1.1 Multiobjective Optimization in Drug Discovery

The retrospective analysis of drug discovery data is a valuable means to gain insight into the phenomenally complex process that is drug discovery. Unfortunately, the available data generated on clinical candidates and drug molecules to date is insufficient, or not of sufficient quality or diversity, to fully understand or define with any accuracy, a universal concept of "drug-like" properties. Indeed, at present drug-likeness is more often framed in terms of the physical property space occupied by oral drugs rather than being a definition of a precise location in biological/pharmacological space. Nevertheless, analysis of the available data generated in drug discovery can still shed light on the challenges we face and how we can adapt to them.

Morgan et al.[8] reported an insightful retrospective analysis of phase II compounds from Pfizer. Forty four compounds for which progression decisions were made were analyzed in terms of the underlying causes of success and failure. They defined 3 criteria, the 3 pillars of survival, to assess the outcome of the phase II trials:

(1) exposure time profile at the target site of action,
(2) binding to the pharmacological target and receptor engagement,
(3) confidence in the validity of the target and the pharmacological outcome.

It was found that just 14 (33%) of the compounds that had successfully exited preclinical research, and progressed through phase I trials, achieved a positive proof of concept by meeting all 3 of the criteria.[8] Efficacy (ie, 1&2) was the principal cause of failures (27%), while exposure issues (2&3) led to a further 13%. The final 27% of compound failed to meet any of the criteria. The authors stated that a back to basic approach to better integrate pharmacology and PK is needed to improve the chances of success.

Scientists from AstraZeneca reported a retrospective analysis of 142 small molecule projects between 2005–10 to understand the causes of project failure and to identify the features associated with successful outcomes.[10] Phase II failures were identified as being the greatest issue, with safety and efficacy being the main causes of attrition. It was found that unacceptable safety was the most important reason for failure overall, accounting for more than half of all project closures. The majority of these failures occurred before clinical testing and in phase I. Safety related failures remained an important reason for project closure in later development with approximately 30% of projects failing due to safety issues in Phase II. The other highest cause of project closure overall was a lack of efficacy in the chosen disease indication. Overall, 65% of projects failed owing to efficacy issues in Phase II. Failures due to exposure were lower than that reported by Morgan et al. at Pfizer,[8] which is potentially due to the definitions used and the level of detail in which project failures were analyzed. The authors came up with recommendations to target the main causes of failure by suggesting a careful consideration of the most appropriate parameters needed from the outset:

(1) Right target
(2) Right tissue
(3) Right safety
(4) Right patients
(5) Right commercial potential
(6) Right culture

AstraZeneca, Eli Lilly, GlaxoSmithKline, and Pfizer joined together to analyze their development failures in terms of the role of physicochemical properties.[7] This collaboration was driven by the fact that no individual company has sufficient numbers of compounds, or the chemical diversity, to determine statistically reliable trends. The authors found that toxicology and safety issues were the principal causes of failures, with portfolio rationalization also being a major issue. In phase II, efficacy, followed by clinical safety were the dominant reasons for termination. Failures due to exposure were low. The authors also noted the importance of physicochemical properties in controlling absorption, distribution, metabolism, excretion, and toxicity (ADMET) but that beyond a certain point (ie, after preclinical optimization is complete), the effect of such factors become negligible.[7]

2.03.1.2 Defining the Project Target Requirements

Target selection and the definition of a desired pharmacokinetic profile are critical steps in a discovery project. This will fundamentally influence the nature of the compounds selected in hit identification and their subsequent optimization.[10,24] It has been demonstrated that the success of a project is predicated on the strength of the target validation available and the types of assays used to identify and optimize compounds.[5,7,10,25] Recent reports have highlighted the problems associated with target validation, with one study from Novartis noting that only 23% of 70 published claims in the literature could be verified.[18] Additionally, Amgen scientists were able to reproduce just 6 out of 53 landmark studies in the oncology area,[26] highlighting the need for increased rigor in target validation.[19,27]

Target based approaches have dominated the drug discovery process due to the benefits of selectively modulating a single target that is relevant to the disease pathway.[28] Network pharmacology studies have suggested that disease-target pathways are highly complex and having compounds which have polypharmacology, but are not promiscuous,[29] may in fact be desirable. The question is how we can identify the required pharmacological profile, from a target based or phenotypic based screening. Swinney et al.[30,31] reported that projects that have employed phenotypic assays either as the primary assay, or a secondary assay, were identified as having a greater probability of success than those that used target based approaches.[31,32] It is presumed that a further benefit of the phenotypic approach is that permeability and solubility are concomitantly optimized along with the pharmacologically relevant target interaction. However, Eder et al.[33] suggest the success of the phenotypic approach has been overstated and the full effect of target based approaches has yet to be observed. Furthermore, a limitation of the phenotypic approach is the difficulty in identifying the precise target,[34,35] and/or the precise mode of action.[36]

Castoreno and Eggert[37] stated that in vitro assays based on purified proteins, while extremely useful to identify potent and selective compounds, have limits including: (i) they primarily target very specific and measurable functions of a protein or complex of proteins, either particular enzymatic activities or particular functional interactions between defined proteins; (ii) potent and selective in vitro activity is not necessarily predictive of actual activity in cells, for example, due to poor cell permeability; and (iii) the

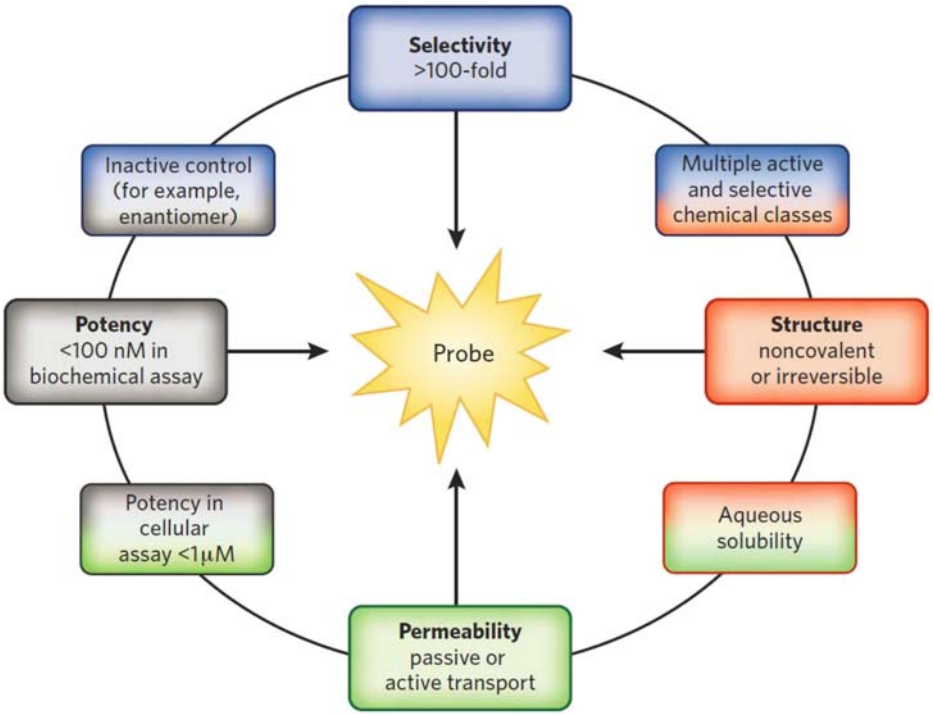

Fig. 2 Important criteria for designing and creating effective chemical probes. Selectivity against close-family-member biological targets, chemical structure and mode of inhibition, cell permeability, and biochemical activity are four essential considerations in designing successful chemical probes. Additional considerations may include aqueous solubility and potency in cellular assays, the value of building a chemical tool kit that includes probes from orthogonal active and selective chemical classes and the importance of having structurally related inactive controls. Figure reproduced with permission from reference Bunnage, M.E.; Chekler, E.L.P.; Jones, L.H., Target Validation Using Chemical Probes. *Nat. Chem. Biol.* **2013**, 9(4), 195–199.

scope of off-target cellular effects due to, for example, similarities between related proteins, eg, kinases, as well as toxicity is not readily discernible.

It has been suggested that project teams can sometimes place too much confidence in the early disease-target hypothesis and that without due-diligence to validate that link, the project risks wasting time and resource before failing in later development.[38] Indeed, this is consistent with the large failure rates due to efficacy in phase II trials and suggests greater effort should be made to produce selective chemical probes to validate the hypothesis prior to late stage development.[2,39] In practice, the requirements for a probe are not so far from those of a clinical candidate (Fig. 2). Both require good solubility and permeability, potency <100 nM and selectivity of >100-fold. Obtaining the required selectivity can be challenging as the screening panels used to assess compounds are not necessarily sufficient to meet this criteria completely, meaning a positive or negative response may still have a degree of uncertainty.[40,41] Validation in preclinical cellular or animal models using both active and inactive variants of a chemotype at the suggested target offers a means to confirm the role of the target in the disease.[2,39] In addition, detailed preclinical studies in models of diseased[17] and healthy tissue are not necessarily performed early in the life of a project. However their deployment towards the start of the project have been suggested to help confirm target engagement and the expected pharmacology.[42]

Covalent binding compounds are often avoided due to increased safety risk, however, given the large number of drugs that function via this mechanism, there are some who argue that this neglected mechanism offers great potential.[43,44] Indeed the blocker buster drug omeprazole, as well as penicillins, act in a covalent fashion, indicating their potential.[45] The known limitation with this approach is that the reactive functionality employed in such molecules have the potential to cause unintended off-target pharmacological effects.[22] The majority of these drugs were identified by serendipity, but more recently a number of compounds in clinical development have been specifically developed to target such a mechanism.[44]

2.03.1.2.1 Target potency and selectivity requirements

It is necessary to consider the expression levels of the target in question and how it is distributed, and what level of activity and exposure will be needed to modulate it. As is common with any multidimensional problem, focus at the early stage typically turns to those variables that are more easily controllable. Compounds are assessed for potency as measured in an in vitro assay system as the primary filter. Potency is typically expressed as $pXC_{50} = -\text{Log}XC_{50}$, where XC_{50} is the concentration of a substance that results in

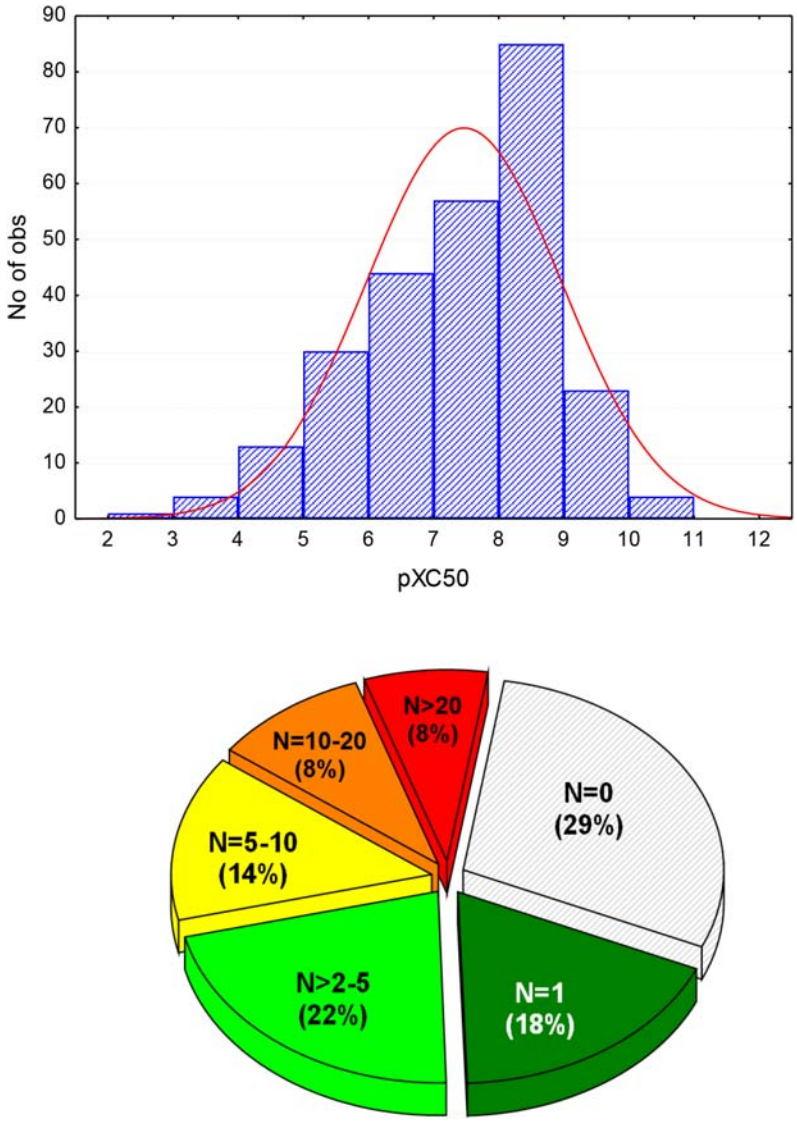

Fig. 3 The reported (A) therapeutically relevant pXC_{50}s values for 261 oral drugs has a mean value of 63 μM. (B) Promiscuity of oral drugs where *N* is the number of reported hits in target based assays in ChEMBL with an XC50 $\leq$ 1 μM. Adapted with permission from reference Gleeson, M.P.; Hersey, A.; Montanari, D.; Overington, J., Probing the Links Between in vitro Potency, ADMET and Physicochemical Parameters. *Nat. Rev. Drug Discov.* **2011**, 10, 197–208.

a 50% biological effect at the therapeutic target. It is common to aim for $<$ 100 nM, yet many projects extol the benefits of even greater potency ($\sim$1 nM) as can be appreciated from the perusal of articles in the medicinal chemistry literature.

Analysis of the biological activities of a set of drugs would appear to suggest these are somewhat arbitrary cut-offs. Overington et al.[46] extracted the reported on and off-target potencies of drug molecules and found that the median XC_{50} was approximately 16 nM. Later, Gleeson et al.[47] extracted and analyzed the mean target potencies of 261 oral drugs, finding a median value of approximately 50 nM. Irrespective of the precise median value, the XC_{50} distribution in Fig. 3A suggests that a large percentage of molecules have XC_{50} at or around 1 μM.[47]

The distribution presented Fig. 3A suggests that potency cut-offs should be taken as approximate given the need to balance a wide range of biological parameters in the eventual candidate molecule, as well as the uncertainty or relevance of the assay system being used. It could be argued that benefit should exist in probing lower potency compounds in certain circumstances. Moreover, setting an arbitrary cut-off of 0.1 μM for compounds to progress to a secondary screening assay may have the unintended consequence of excluding compounds with more optimal characteristics (ie, solubility & permeability) that might allow improved efficacy.

Drug selectivity can also be assessed from data reported in the literature (Fig. 3B). The data associated with 291 oral drugs shows that a large number of these compounds hit multiple targets at or below 1 μM and suggests they are not totally selective.[46]

This data can be considered in the context of the current discussions around designing in specific target selectivity to a molecule,[34,48–50] as well as the desire to avoid high promiscuity, particularly at known antitargets such as the potassium channel encoded by the human ether a go-go related gene (hERG) and cytochrome P450 enzymes (CYP).[40] Reports on anticancer compounds show that while avoiding particular pathways is desirable, the complexity of the disease means that poly pharmacology approaches are highly attractive.[51,52] This is consistent with a move away from the traditional "1 disease—1 target" hypothesis,[34,48–50] which has been accompanied by an increased interest in target nonspecific, phenotypic screening methods.[17,28,32,35,36,53]

2.03.1.3 Physical Properties

The physical properties of legacy oral drugs are found to cluster into a relatively tight area of chemical space. The earliest, and most notable observation was provided by Lipinski et al who noted that oral drugs and late stage development compounds were found to have no more than 1 parameter outside of the following: molecular weight (MWT) $\leq$ 500, lipophilicity (logP) $\leq$ 5, hydrogen bond donors (HBD) $\leq$ 10 and hydrogen bond acceptors (HBA) $\leq$ 5.[54] The so called "Lipinski rule of 5" was general considered to represent a property range in which good solubility and permeability, which are important for oral exposure, was more likely.

Teague et al. subsequently introduced the distinction between lead-like and drug-like molecules, noting that the low potency leads obtained from high throughput screening (HTS) were often optimized beyond drug-like space in an effort to obtain potency.[55] They defined medicinal chemistry "lead-like space," wherein lead-like structures are, on the average, less complex.[56] Libraries consisting of molecules with MWT between 100–350 and calculated logP (clogP) between 1 and 3 were therefore proposed to be superior to ones consisting of drug-like compounds.[55,57] Later Oprea et al. were to show that it was also possible to define a literature publication-like (pub-like, or data reported in the peer reviewed literature) chemical space which lay beyond lead or drug-like space.[58] They proposed that these highly optimized, typically potent compounds derived from failed drug discovery or academic projects, therefore had higher mean MWT and logP.[58] This effect can be seen from a comparison of ChEMBL compounds (pub-like) to oral drugs (Fig. 4). The ChEMBL dataset is made up of 112,586 unique compounds while the oral drug dataset consists of approximately 2000.[59] As can be seen from the density contours, the area occupied by pub-like compounds is dramatically larger, and shifted upwards in terms of the MWT and logP of oral drugs.

Wenlock et al.[60] considered how parameters such as MWT and logP affected the progression of compounds though the different phases of development. The properties showing the clearest influence on the successful passage of a candidate drug through the different stages of development are MWT and logP. Statistical analysis shows that the mean MWT of orally administered drugs in development decreases on passing through each of the different clinical phases and gradually converges toward the mean MWT of marketed oral drugs. A more recent analysis of attrition also noted a link between these two physicochemical properties and clinical failure due to safety issues, and that the parameters identified in the former analysis should be restrained, though only up to a point (ie, no absolute guarantee of success).[7]

Proudfoot analyzed the variation in physical properties of oral drugs over the period 1937–97 and found that the most notable change in molecular properties was a steady increase in MWT.[59] In contrast, the logP was found not to have changed. In addition, fewer than 5% of oral marketed drugs have more than 4 H-bond donors and a small number exceed both the MWT $\leq$ 500 and HBD $\leq$ 5 rules suggesting that Lipinski's rule is a relatively generous definition of legacy drug-like space (as it was designed to be). Nonetheless, drug molecules that violate the rule of 5 are not negligible ($\sim$12%) and there is some concern that restricting physical properties to those of legacy drugs might stifle our ability to target less druggable targets. While target classes do show differences in terms of the molecular properties of their ligands, these differences do not appear to justify searching beyond drug-like space.[24,61]

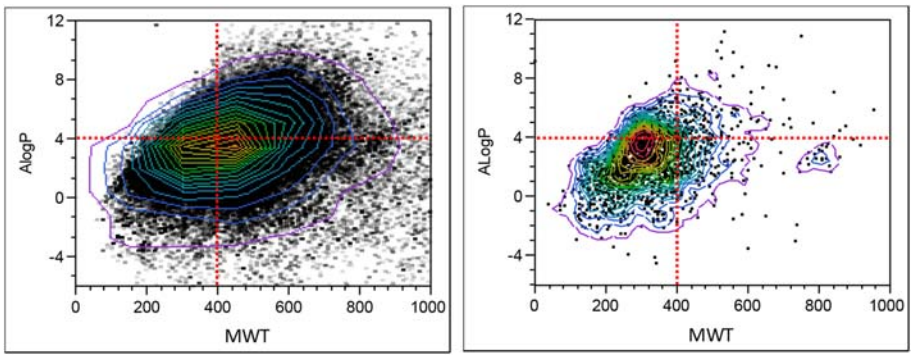

Fig. 4 Plot of MWT against calculated logP (ALogP) for ChEMBL database pub-like compounds (N=112,586) and oral drugs (N=1791). Red contours represent area of maximum density while blue represent lowest. Drug Discov.* **2011**, 10, 197–208.

2.03.2 Multiobjective Optimization and the Role of Physical Properties

The job of identifying a molecule that meets the project requirements (ie, can safely modulate a therapeutic target in human with minimal side effects) is a massively complex undertaking with many unknowns. The medicinal chemist lies at the center of this endeavor and is tasked with distilling the information from disparate disciplines in the discovery effort to synthesize and deliver a suitable candidate.[62–65] This process involves a degree of subjective decision making to select and iterative modify a lead series to achieve the desired criteria. The decisions made by an individual are based on a unique combination of their unique expertise, educational background, past project experiences and organizational culture.

The process of drug discovery involves trying to standardize the decision making such that we try to tackle known issues (ie, commonly experienced) in drug discovery. Yet it is clear that our current understanding represents the tip of the iceberg, with many "known-unknowns" and "unknown-unknowns." Thus, the definition of rigid progression path and milestones, may act to restrict the choices open to the medicinal chemist, thereby stifling the opportunity for progress achieved through trial and error, serendipity, and innovative thinking. The drug discovery scientist must be given sufficient leeway to think outside of the box, without fear of re-percussions should it fail. This requires a less rigid process with better and more flexible management oversight less driven by metrics.[10]

The challenge for the medicinal chemist, and indeed their partners in drug discovery, is to know when to think outside of the box and when to follow convention. This is a challenge in the serial drug discovery process as the decisions made early in the project will invariably lead the project team down a restrictive path that offers little room for maneuver. Yet, there is now an acknowledgment that a parallel process, where the aim is to assess many compounds rapidly, and fail them rapidly, may be a more effective way to perform drug discovery.[5,14]

2.03.2.1 Drug-Like Property Space

Despite Lipinski's et al.'s seminal paper[54] being close to 2 decades old, the restraining of physicochemical parameters to an area of drug-like space is still somewhat controversial.[66,67] Analyses have shown that moving outside drug-like space leads to poorer ADMET parameters and increased promiscuity, yet there are many who see these constraints potentially hamper the search for drugs for less druggable targets.[68] Focusing on the exceptions to the rule can be desirable for reasons of diversity, but only up to a point as the probability of success is expected to drop accordingly. The consensus opinion is that properties should be restrained within drug-like space unless there are clear reasons to move beyond them. [47,54,67,69–71]

Drug discovery must be pursued with a view to maximizing the chances of success and all data to date suggest that drug-like space is a confined area of parameter space where it is probabilistically more likely to obtain a molecule with a good balance of properties. Should a project team feel it was pertinent to spend a percentage of medicinal chemistry resource to explore this region, for the purpose of generating structure activity relationships (SAR), then that could certainly be justified so as to not restrict innovation or serendipity. [64,72] However, it would be prudent for organizations to look at their preclinical drug discovery efforts as a whole and ensure that the overall molecular properties of the compounds they are working on can be justified given the range of target classes and due to the apparent benefits of remaining within legacy drug-like space.

2.03.2.2 DMPK, Safety, and Physical Properties

Lipinski et al.[54] reported that marketed drugs and drugs in clinical development had distinctive molecular property distributions. Over approximately two decades since this analysis, numerous researchers have worked to improve our understanding of link between ADMET parameters and physicochemical properties.[47,72–78]

The role of some key physicochemical parameters (MWT, logP, and ionization state) were demonstrated quite clearly using 10,000 s of proprietary GSK data on commonly measured ADMET parameters (**Table 1**).[79]

Table 1 List of the ADMET assays evaluated in references[79,80]

Assay type	*Description*
Solubility	Phosphate buffer pH 7.4
Permeability	Permeability assay pH 7.4
Oral bioavailability	Rat—in vivo PK studies
Volume of distribution	Rat—in vivo PK studies
Plasma protein binding	Rat plasma—equilibrium dialysis
CNS penetration	Rat—in vivo PK studies
P-gp substrate efflux	MDCK assay with and without a P-gp inhibitor
Brain tissue binding	Rat brain homogenate—equilibrium dialysis
In vivo clearance	Rat—*in vivo* PK studies
hERG inhibition	[^{3}H] dofetilide assay
CYP inhibition	Fluorescence based assay

Analyses demonstrated the underlying intercorrelation between common physicochemical properties and a range of measured ADMET parameters (Table 2). This allowed for a direct comparison between the physicochemical parameters having a simultaneous impact on multiple ADMET endpoints. The effects observed using proprietary GSK compounds[79] can also be demonstrated using open access ChEMBL data.[47] This data consisted of diverse compounds from a range of assays including solubility, bioavailability, plasma protein binding and P450 3A4 inhibition (Fig. 5). It is apparent there is an overall detrimental effect of increasing logP and MWT on average within these diverse sets. Furthermore, the results are in agreement with SAR observations on smaller congeneric series.[79]

Due to the fact the datasets are highly diverse in nature, the trends observed are relatively weak compared to those often observed within a congeneric series. However, the results demonstrate that the probability of obtaining favorable ADMET across all assays is probabilistically less likely with increased logP and MWT. It also offers a quick method of assessing what ADMET properties might be modulated for a given series to give rise to the desired property change. For example, a basic compound with significant P450 2D6 inhibition would generally be expected to improve by reducing lipophilicity, as well as removing any basic center, assuming it was tolerated by the target pharmacophore. Alternatively, one could add an acidic center, yet this would also likely to lead to a drop in permeability (Table 3).

Safety represents an altogether more challenging endpoint to predict as the causes can be both target specific and nonspecific in nature. Unlike many ADME endpoints, relatively little bulk property SAR exists (excluding hERG and P450s) for the multitude of known toxicity pathways. The following represent the key causes of safety related issues:

(1) due to primary pharmacology of the molecule,
(2) secondary pharmacology of the molecule,
(3) due to a structural fragment or toxicophore in the molecule,
(4) the overall physicochemical properties of the molecule.

The progression of a molecule through development rarely occurs in the absence of some form of toxicity, thus it is necessary that this risk be mitigated using the predicted safety margins and the therapeutic exposure level required to modulate the target. Prediction of the therapeutic index is a nontrivial process that according to Muller and Milton requires more effective approaches to systematically and quantitatively compare the in vitro and in vivo data and to apply this knowledge more effectively.[82]

Some toxicity endpoints have been shown to correlate to some degree with physicochemical parameters. Unintended off-target activity is often a source of side effects and a number of studies have shown that making molecules larger (not necessarily more complex) and more lipophilic is likely to increase this effect.[47,74,75,83] Basicity has also been shown to be a factor that increases the probability of off-target effects.[83] It has been clearly demonstrated that strong hERG inhibition correlates with the presence of a basic center and higher lipophilicity.[79,84,85]

Nevertheless, molecular properties can get you only so far, as revealed by Leach et al.[86] The authors showed sizeable differences in certain ADMET parameters (ie, solubility, intrinsic clearance and volume of distribution) for different enantiomeric pairs. The large differences could not be explained by properties alone which is in line with reports from clinical attrition data that while important, molecular properties will get you only so far.[7]

2.03.2.3 Target Activity and Physical Properties

The identification of a therapeutic target allows for the instigation of assay development, and medicinal chemistry efforts can subsequently start. HTS is the primary source of hits at this early stage.[87,88] HTS has a reported success rate $>60\%$[88] for identifying tractable leads, however doubt regarding its effectiveness remain.[89] The origin of this doubt relates to the suitability of the compounds in terms of their molecular properties.

Over two decades ago a survey of the tightest binding compounds for a variety of protein targets showed that the free energy of binding increases with the number of nonhydrogen atoms. For ligands with more than 15 nonhydrogen atoms, the free energy of binding plateaus, increasing very little with additional MWT.[90] This and other analyses[91] inferred that potency can be built into compounds by increasing the number of Van der Waals interactions and overall hydrophobicity. These fundamental observations, rather than being an effective way to quickly increase the potency of a molecular series, could potentially be a distraction in the generation of molecules with balanced biological and physical properties. A more recent analysis by Hajduk et al. showed that an optimal 64 Da increase in MWT was needed per 1 log unit increase in activity.[92]

To demonstrate the correlation between MWT, logP and target activity, we have analyzed six target specific sets[93] containing a single chemotype and a diverse set of molecules with activities at a variety of receptors (Figs. 6 and 7).[47] Analysis of variance (ANOVA) was used to show the relationship between the molecular properties, which are binned, and the target activity. A diverse dataset of 205,582 unique target-compound activities (112,586 unique compounds) derived from the ChEMBL database shows a statistically significant relationship (Fig. 7). It can be seen that the higher MWT and logP compounds have higher potencies on average. It is also apparent that a 100 Da increase in MWT appears to have a stronger effect on the mean affinity than a 1 log unit increase in logP. Broken down by specific target-molecular series pairs also reveals similar relationships (Fig. 6). The effect of increasing MWT was found to be statistically significant for 4 out of 5 chemotypes, while the effect for logP was observed for 2 (logP and MWT show some degree of intercorrelation). This indicates these two properties do play a role in defining the level of potency of a series. As we will show, restraint needs to be exercised in the pursuit of potency so that project teams focus on specific enthalpic gains through new interactions rather than though nonspecific effects.

Table 2 An indication of how changes in key molecular properties will affect a range of ADMET parameters. Green indicates, better, orange neutral, and red poorer values of the ADMET parameter in question (relative to the mean of the distribution). MWT and logP (calculated logP) cut-offs of 400 and 4 respectively are used

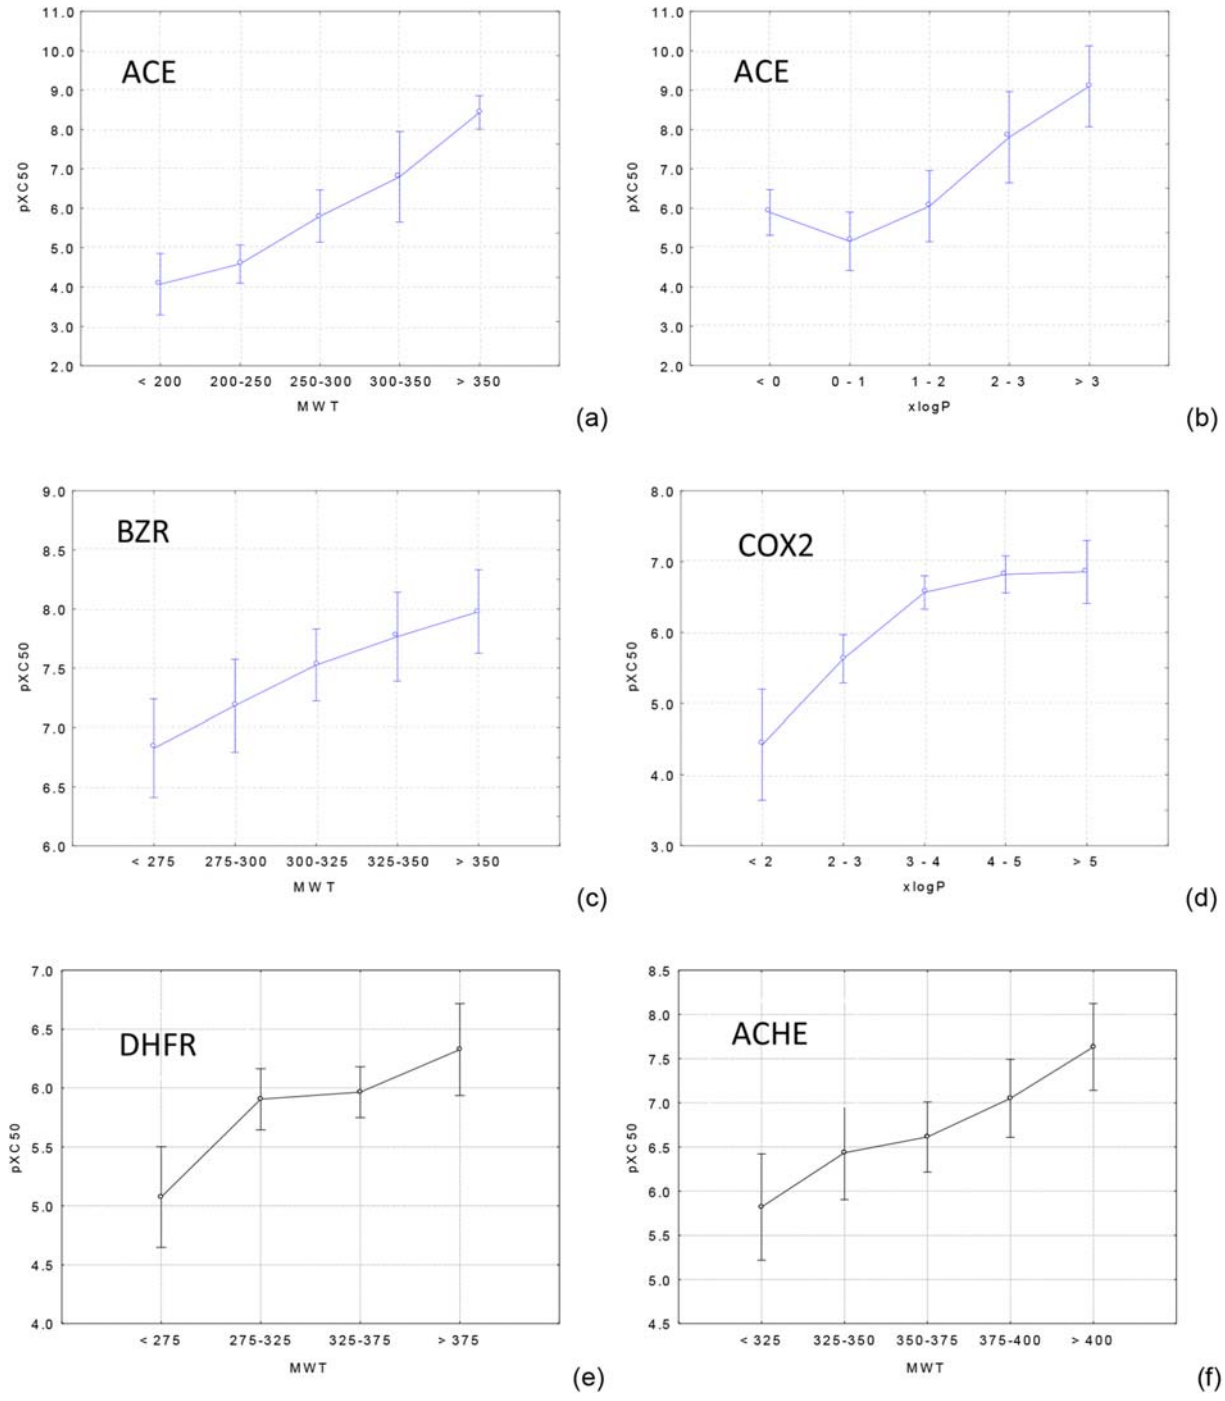

Fig. 6 The relationship between the in vitro potency, MWT and calculated logP for 5 different chemotypes (specific structural scaffold/class of compound), each acting at a single target.[94] Adapted with permission from reference Gleeson, M.P.; Hersey, A.; Montanari, D.; Overington, J., Probing the Links Between in vitro Potency, ADMET and Physicochemical Parameters. *Nat. Rev. Drug Discov.* **2011**, 10, 197–208.

Increasing logP and MWT will also affect compound selectivity. The theoretical analyses of Harper et al. demonstrated that as the complexity of a molecule increased the probability of inhibiting multiple different targets decreases.[95] While nominally larger molecules might be considered more complex, due to increased lipophilicity/bulk that may not be the case. The addition of substituents that can form van der Waals (VDW) interactions in essentially nonspecific binding pockets, i.e. the addition of "grease," which drives the entropic partitioning of the molecule from solution (hydrophobic effect). Thus, while an approach to increase potency though increases in size and logP may work in the short term, the probability of having off-target activity increases accordingly. Experimental evidence for this comes from the work of Leeson et al. analyzed a dataset of approximately 2000 compound screened

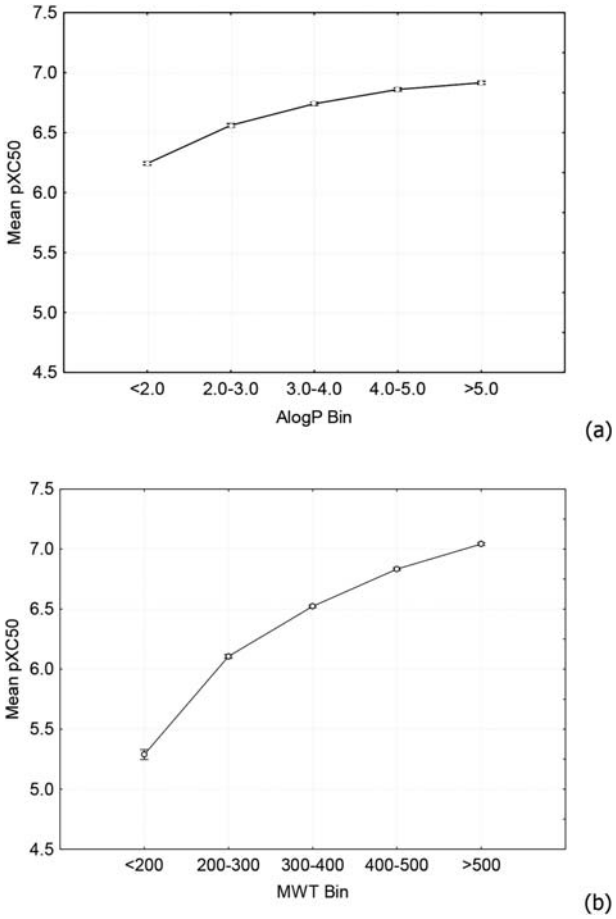

Fig. 7 The relationship between the mean reported in vitro potency (pXC_{50}), MWT and calculated logP for 201,355 compounds with reported activity measurements in the ChEMBL. Drug Discov.* **2011**, 10, 197–208.

in the Bioprint® database which had % inhibition data at approximately 140 targets. They noted a significant relationship between increasing promiscuity with increasing clogP and to a lesser extent MWT.[75] A subsequent analysis of pXC_{50} values of oral drugs derived from ChEMBL by Gleeson et al.[47] also demonstrated the negative effect of logP and also MWT on selectivity. Additionally, Peters et al. analyzed an updated Bioprint® dataset and identified lipophilicity and the basic pKa as key drivers for promiscuity.[83]

2.03.2.3.1 Ligand efficiency

It would appear that the availability of relatively cheap, high throughput purified protein and recombinant cellular assays at the inception of the project, and the relative ease with which SAR can be established, may represent a key strategic problem due to the effect this may have on physicochemical properties, and thus impact the overall balanced biological profile.[76]

Ligand efficiency represents a surprisingly simple and effective way of meeting one of the key challenges in drug discovery, namely restraining compounds within drug-like space (at least logP and MWT) by indirectly minimizing the focus on nonspecific potency gains.[96] This parameter may also have the unintended effect of helping to increase the probability that the ADMET parameters associated with the series in question will therefore be more acceptable (since logP and MWT are restrained).[97]

A range of different ligand efficiency metrics have been proposed in the literature, which has led to criticism by some.[98,99] The key feature of all of these metrics is to focus on potency gains per unit mass, atom or lipophilicity (Eqs. 1, 2).[69] The two principle parameters are obtained by dividing the pXC_{50} by the heavy atom count (or MWT):

$$\text{Ligand efficiency (LE)} = pXC_{50} \times 1.37/\text{Heavy atom count}^{96} \quad (1)$$

$$\text{Lipophilic ligand efficiency (LLE or LiPE)} = pXC_{50} - \text{LogP(or LogD)}^{75} \quad (2)$$

Ligand efficiency metrics are useful for placing the potency gains within a series into perspective. Issues include the nonlinearity of LE after approximately 25 heavy atoms (HA) and the use of predicted clogP values in the equation for LLE.[100]

A retrospective analysis of marketed oral drugs by Hopkins et al.[69] showed that they frequently have highly optimized ligand efficiency values for their target. They propose (a) replacing carbon atoms with oxygen or nitrogen atoms (especially converting phenyl rings to heteroaromatic rings), (b) adding polar substitutions/functional groups where possible, (c) removing or replacing lipophilic substituents and templates, and (d) controlling growth of heavy atom count. The authors conclude that optimizing on combined LE and LLE measures have the potential to reverse the molecular inflation that pervades current practice in medicinal chemistry, and to increase the developability of drug candidates. Perola et al. describe suggested guidelines for utilizing the different efficiency parameters to increase the overall potency of a lead by carefully controlling the changes in logP and MWT. They noted that 90% of leads have LE values over 12.4, whereas 90% of drugs have binding efficiencies over 14.7.[101]

2.03.3 Multiobjective Optimization of PK/PD Parameters

The integration challenge in drug discovery is how to achieve a dosing regimen and concentration time profile in the body which attains an appropriate balance between drug efficacy and potential adverse drug reactions (ADRs).[102] It has been reported that about 75% of ADRs are dose dependent and can be predicted by the exposure of a given tissue to the drug and on the basis of the pharmacological profile, primary and secondary effects, of the candidates compound.[103–105] Under an exposure centered approach, a thorough characterization of the lead compounds aimed at the identification of the inherent pharmacokinetic and safety liabilities includes, but it is not restricted to, an early generation of quantitative pharmacokinetic-pharmacodynamics (PK/PD) relationship, linking in vitro and in vivo pharmacology to target exposure and efficacy in animal studies, and therapeutic window, which is a quantitative relationship between the exposure level at the chosen safety end point and the exposure level at the chosen efficacy end point. As the extent of efficacy and safety data increases as a candidate drug progresses from in vitro to animal to human studies, the understanding of both PK/PD and therapeutic window increases.

It is important to emphasize that there is a continuum of information, which must be refined and have to be put into context during the process, and that there is no fixed tiered screening tree that can guarantee success. Project teams may decide to adopt a classical approach based on:

(1) potency and selectivity in biochemical and cellular assays,
(2) physicochemical properties (ie, drug-likeness parameters, solubility, and permeability) to eliminate unwanted compounds,
(3) ADME, drug–drug interaction (DDI) and safety in vitro profile (ie, intrinsic metabolic clearance, permeability, cytochrome P450 (CYP) inhibition and induction, panel of secondary pharmacological targets, hepatotoxicity and genotoxicity assays),
(4) in vivo pharmacokinetic (PK) profile in rodent and pharmacodymanic (PD) species,
(5) preliminary in vivo PD experiments,
(6) in vivo non rodent PK (ie, dog and monkey), and
(7) exploratory in vivo toxicity studies.

However, whatever the screening tree adopted, it is the relationship between PK, PD and safety that needs to be rigorously understood to define the drivers for robust in vivo efficacy, desired human PK and for the prediction of human therapeutic dose and safety margins. After more than a decade since drug metabolism and pharmacokinetic (DMPK) representatives have become part of discovery project teams, and helped in the reduction of the PK related attrition to ca. 10% today,[11,106–108] it is now time that discovery toxicologists also become part of discovery project teams to actively influence decision making.[109,110] Despite the availability of toxicology assays and models in early phases, safety related attrition is still high (~30% of all new drugs) and there is the need for an integrated in vitro, ex vivo and in vivo strategy to steer away safety hazards.[111–117]

It is worth noting that DMPK is increasingly being seen as a problem that is no longer a significant issue in drug discovery. At a simplistic level this appears to be true, yet is becoming increasingly clear that our understanding of the DMPK concept is evolving, and its role in failures due to efficacy.[8] It is also worth noting that 10 years ago it was common for discovery to optimize protein binding to maximize free fraction (not concentration) yet now it is accepted that the effect of the free fraction on the free concentration is generally negated by the simultaneous effects on increased clearance.[118] Furthermore, the desire for increased efficacy though increased receptor off-rates[119,120] have been brought into question due to the confounding effects of PK/PD. The receptor off rates can only have a significant effect on efficacy if the off rates are longer than the plasma elimination rate.[119] Data extracted by Dahl and Akerud[119] for several drugs and development compounds indicate that they have a slower elimination compared with dissociation. These observations greatly reduce the usability of drug-target residence times for estimating the duration of effect of a drug in vivo. It appears that consensus is still to be found in terms of what parameters should be optimized to achieve the required plasma concentration and target binding necessary for efficacy and once a day dosing.

2.03.3.1 Assessment of PK/PD Properties of Development Compounds

The identification of tractable chemical series that modulates the target means the hit to lead phase can start. Many properties of the hit series are assessed and the most promising are progressed for further characterization. The decision regarding which series to promote is based on a variety of data usually generated from both cheminformatics based searches, using scientific literature and/or available public databases, followed by high-content screening assays, such as lipophilicity, permeability, solubility, target affinity, potency in relevant cellular assay, metabolic stability, CYP450 inhibition, initial exposure data, cytotoxicity, hERG, and

genotoxicity (Table 3). Other information regarding the patentability, synthetic feasibility are also considered. The purpose of the characterization at this stage is not necessarily to prevent progression of a compound series but rather to flag potential issues that might indicate a significant liability in an individual chemical series. This would allow a project team to take an informed decision based on an assessment of risk.[121–123]

The aim of the project team during the lead optimization phase is to explore whether an appropriate balance of properties can be achieved in a single compound, and ideally a number of diverse backups. Many structural features and properties can change dramatically meaning extensive characterization of relevant physicochemical, pharmacological, DMPK, and exploratory toxicology in vitro and in vivo assays is needed to define, confirm and derive a working hypothesis and understand the SAR (Table 1).[118,124,125]

It is widely accepted that while the optimization of a single endpoint is often doable, achieving the desired balanced profile and the understanding of what makes that specific compound a disease-modifying drug is difficult, requiring a sound understanding of the relationship between the primary and off-target pharmacology, pharmacokinetic and toxicological properties. It is important to evaluate, with quantitative and reliable data, whether structural modifications, introduced to improve one property, do not lead to other liabilities negatively affecting the overall developability profile. Among the most important processes characterized during lead optimization are the classical processes: absorption, distribution, metabolism, and excretion, collectively referred to as ADME. These processes are described in vivo by the conventional pharmacokinetic parameters (ie, bioavailability, clearance, distribution volumes, half-life) as well as using in vitro data (ie, plasma and target tissue binding, transporters efflux ratios, and permeability). An incorrect assumption is that each individual ADME parameter is somehow independent and can be separately "optimized" one by one. This may drive scientists to adopt unsuitable practices by trying to establish SAR and optimize individual properties but neglecting other factors that will also change concomitantly (ie, PK/PD and therapeutic dose). The reality is that there is interdependency between different PK/PD phenomena, including acting in correlated or inversely correlated manner. The search for the best drug candidate is almost always a search for the molecule with the most balanced properties. The decision making strategy will therefore be heavily affected by the availability of data at a given time in the project which will have implications for product profile.[79,126,127]

Prior to the first-in-human (FIH) study, a number of preclinical in vivo and in vitro experiments are performed on a drug candidate to understand the PK/PD/safety and efficacy. Typically, the preclinical species are mouse, rat, and dog. The relationship between dose, kinetics of the unbound drug concentration, target engagement, functional response (MoA) and in vivo efficacy must be understood in the animal disease model. Then, translation of these parameters to predict PK/PD/safety outcomes in a human population is required. The process can be summarized as follow:

1. Human PK prediction
2. Human therapeutic exposure (dose) prediction
3. Estimation of therapeutic window

There are several approaches currently used to predict human PK.[128–130] These approaches could be broadly divided into three areas: allometry, in vitro–in vivo extrapolation (IVIVE), and physiologically based pharmacokinetics (PBPK).

Allometry, involving scaling to humans PK data in test animals (often rat and dog and nonhuman primate), relates in vivo derived parameters across species as a function of differences in body weight and is the mainstay approach by industry. Allometry tends to be successful in the prediction of volume of distribution and flow dependent pathways such as renal clearance, but has limited predictive capacity for hepatic clearance compounds (most often oral drugs), since it does not take into consideration species differences in metabolism.

IVIVE, which may be regarded as a subcomponent of PBPK, has been applied to predict hepatic metabolic clearance based on animal and human-derived tissues or expression systems. It aims to address particularly the known species differences in enzymatic and/or active processes.[131] A PBPK model consists of anatomically and physiologically meaningful compartments connected by flow rates that relate to circulating blood and the lymph system. It integrates physiological parameters and in vitro and in vivo DMPK data and represents a quantitative framework for mechanistic translation across species.

PBPK is highly mechanistic and can be employed upstream by linking processes to physicochemical and structure properties and hence guide in the design of more optimal compounds. In addition, it has the potential to explain the observed in vivo behavior of drugs, and can be used beyond dose selection in FIH studies, by helping to guide various aspects of clinical development, such as prediction of the impact of DDIs, age, and disease. However, PBPK is inherently mathematically complex and many underlying assumptions are difficult to verify. Animal data are not inherently required in PBPK prediction of human PK, although development and verification of the methodology are often undertaken in animals. It has been reported that although some prediction methods are definitely better than others, there is currently no universally outstanding method and that the prediction of human pharmacokinetic parameters following intravenous administration is much better than the prediction of events following oral administration due to the complex physiology of the gastrointestinal tract and the complex processes occurring during the absorption phase.[140] Despite its limitations, allometry is likely to remain a key approach by industry for prediction of human PK in lead optimization. However, as the refinement and commercialization of PBPK methodologies, together with the understanding of processes controlling both PK and PD, improves, the adoption of more mechanistic PBPK approach will become essential for drug discovery.[142]

The effective unbound concentration time profile for both plasma and the effect compartment, as determined in animal disease models, provides the corresponding target concentration time profile as required for efficacy in human. The estimation of the pharmacologically active therapeutic exposure should be based on a set of dedicated PK/PD studies with quantitative data analysis in

relevant PD and/or efficacy models, and with different doses and dosing schedules. For targets residing in the body's periphery, it is important to characterize and describe the blood—target site equilibrium according to the free drug hypothesis and evaluate if the unbound plasma concentration fully represents the unbound concentration at the target site.[132,133] For CNS drugs, the target site is located behind the blood–brain barrier (BBB) and additional data, such as interaction with efflux transporters P-glycoprotein (P-gp/MDR1/ABCB1), are needed to translate unbound plasma concentration into relevant brain concentration.[134]

The human therapeutic dose is estimated by considering the human PK prediction and the pharmacologically active therapeutic exposure. The prediction of the human therapeutic dose reflects all the uncertainties of the available data and therefore often results in a range of predictions originating from different assumptions and scenarios.[135] The amount of safety and efficacy data increases as the front running compound progresses along the discovery process, from in vitro to animal PK, PD, and toxicology studies. Off-target pharmacology interactions that are often the cause of ADRs in animal models or clinical studies, and the evaluation of the potential DDI risks are needed to carefully characterize compounds at the early stages of the process.[136,137]

In vitro pharmacological and DDI profiling involves the screening of compounds against a broad range of targets distinct for the primary therapeutic targets to identify specific molecular interactions that may cause safety hazards in human, and the characterization of the potential for CYP inhibition, CYP induction and transporter protein interactions, respectively. Good laboratory practice (GLP) safety pharmacology and toxicology studies are conducted according to regulatory guidelines, candidate drugs are evaluated in project and compound specific non-GLP pilot studies, such as 2-week toxicology studies in relevant preclinical species, usually rat and dog. The data generated from these studies constitute the basis for the initial estimate of the therapeutic window. Safety margins, which are ratios derived from concentration data (IC_{50}) from in vitro safety and efficacy studies, and therapeutic indices, ratios derived from concentration data from animal and human in vivo safety and in vivo efficacy studies, are calculated to put the target product profile into context.[82]

2.03.3.2 Achieving a Balanced PK/PD Profile

As stated above, for a drug to achieve a therapeutic effect it should have the ability to access the effective compartment at the "right" time and concentration. The selection of high quality drug candidates is a complex and multidimensional exercise where project teams must integrate data from various in vitro and in vivo assays in order to ensure a sound understanding of the PK/PD/safety relationships. Indeed, in **Fig. 8**, the relationship between the dose and in vitro potency at the therapeutic target is found to be relatively poor. Potency is a key driver of efficacy yet it is obvious from the poor correlation that other factors are at play.[47]

To that end a number of issues and misconceptions need to be considered:

- From a technical perspective, there are limitations to the validity of some in vitro pharmacological, toxicological, and DMPK assays. These assays are often validated in very static conditions (ie, time of incubation, reagent concentrations, protein content etc.) and therefore may not be totally representative of the in vivo situation.
- Measuring and understanding the pharmacokinetics of the unbound drug is critical, as it is the unbound drug that is able to interact with the target and elicit the effect. This can be problematic for some nonperipheral targets (ie, CNS). For these targets, understanding the mechanisms involved in uptake into and efflux from the effective and plasma compartments is essential to describe the drug effect.

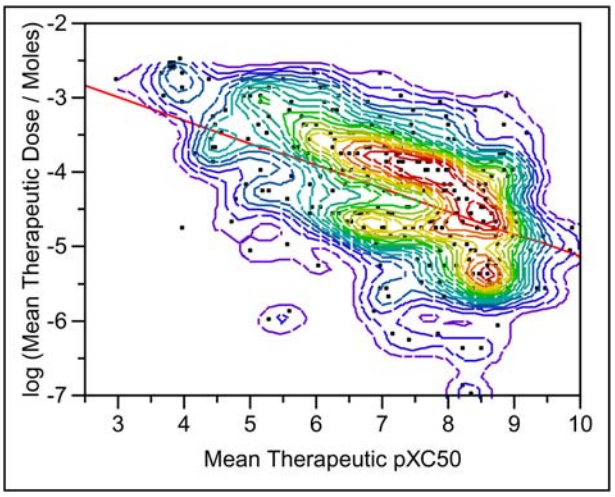

Fig. 8 The relationship between the reported mean therapeutic dose and the mean therapeutically relevant pXC_{50} reported for a set of 261 oral drugs. Adapted from reference Gleeson, M.P.; Hersey, A.; Montanari, D.; Overington, J., Probing the Links Between in vitro Potency, ADMET and Physicochemical Parameters. *Nat. Rev. Drug Discov.* **2011**, 10, 197–208.

- A reduction in plasma protein binding has occasionally been attempted to improve the systemic exposure of new compounds in a chemical series. However, it has now become clear that for compounds that are cleared predominantly by hepatic clearance, the protein binding has no impact on plasma levels.[118]
- It is necessary to consider drug-receptor theory for quantifying the efficacy of drugs and minimize the therapeutic dose. It is the optimal balance of properties (ie, physicochemical properties, target affinity and unbound concentration in the effect compartment, and not their absolute values that dictates the quality and potential of drug molecules.
- One challenging scientific problem is the need for better understanding of the biological mechanism and the underlying PK/PD relationships. The lack of appropriate disease models and the complexity and, sometimes, impossibility of testing pharmacological outcomes in preclinical species limit the confidence a project can have in the validity of the biological hypothesis. Project teams may not be able to ask the right questions if they do not have the right tools to test the hypothesis.
- Some biological and physiological systems operate in different ways under different conditions. Understanding the drug effect under a variety of circumstances important. Innovative experimental procedures are needed to uncover the factors that govern the PK/PD relationship. The dynamic regulation of context related mechanisms contribute to the variability in drug effect. Hence, heterogeneity in species, gender, genetic background, tissue, age, diet, disease condition etc., must be considered for the prediction of human response.[138]
- Sophisticated mathematical modeling techniques are needed to reveal complex PK/PD relationships and extrapolate pharmacokinetic parameters. These techniques (ie, PBPK modeling) are complex and many underlying assumptions are difficult to verify experimentally.

2.03.3.3 Drug Efficiency and the Free Drug Hypothesis

The free drug hypothesis is extensively applied in drug discovery and development to select and design new chemical entities, to support and establish the design and interpretation of PK/PD studies, to predict the therapeutic relevant dose and to monitor drug concentration in clinical studies. According to the free drug hypothesis, it is the time profile of the unbound drug concentration in the effect compartment which is responsible for receptor occupancy (RO%) and hence the in vivo efficacy. The assessment of a compound's exposure profile allows us to generate a hypothesis as to how best elicit the required pharmacological response. This facilitates the identification of compounds that are likely to maximize target exposure per unit of dose which should be a central strategy for any discovery project.

The establishment of solid PK/PD relationships is a fundamental as it allows the building of a rational basis for the prediction of human therapeutic dose and dose regimens, and for the estimation of the therapeutic window in human. This is to allow us to understand the in vivo target RO% (drug action), how it translates to the expected MOA, and the in vivo efficacy of the disease model.[139] To this end, theoretical models which use in vitro potency data and in vivo experimental determinations of the RO% are required. This requires an estimation of the therapeutic effect as early as possible in order to effectively guide the selection of optimal drug candidate. The level of RO% can be assessed using Eq. 3, with K_d being the in vitro potency and $C_{u,e}$ the unbound concentration in the effect compartment.

$$RO\% = C_{u,e} \times 100/(C_{u,e} + K_d) \tag{3}$$

Once the level of RO% needed for efficacy in vivo, and the relevance of C_u in the effect compartment has been established, the information must be related to the dose and peripheral PK using appropriate PK/PD models.

Targeting low therapeutic dose by maximizing efficacy in vivo is essential to reduce the risk of attrition. It has been estimated that ~75% of all ADRs are dose related and can be predicted from either the pharmacology (target and/or off-target) or the structure of the of the candidate compound.[104,140] Maximizing target RO% per unit of dose is therefore a valuable strategy to do this. There are two ways to improve a series: either by increasing target affinity and by improving the concentration unbound in the effective compartment. It is, therefore, the optimal balance of these properties, and not their absolute values that dictates the potential of a compound to achieve a low in vivo efficacious dose.

According to the free drug hypothesis, at steady state, drugs that have a high rate of membrane permeation must therefore have unbound drug concentration that are the same on both sides of the biomembrane (intracellular, extracellular, and cerebrospinal).[118] The free drug hypothesis can be represented by Eq. 4.

$$C_{u,p} = C_{u,e} \tag{4}$$

Here $C_{u,p}$ is the unbound plasma concentration and $C_{u,e}$ is the unbound effect compartment concentration. Exceptions to the free drug hypothesis mainly refer to when a drug has low passive permeability, when influx or efflux of the drug occurs from the tissue of the therapeutic target by active transporters and when the drug encounters tissues with low discontinuous blood flow. After oral dosing, the unbound plasma concentration of compounds that are cleared predominantly by hepatic clearance is affected by the dose, the fraction of a dose absorbed, intrinsic clearance and the dose interval according to the following Eq. 5 where $C_{u,av}$ is the average unbound plasma concentration, Fa is the fraction of a dose absorbed, Clint is intrinsic clearance and T is the dose interval.

$$C_{u,av} = (Fa \times dose) \div (Clint \times T) \tag{5}$$

The assumption that there is an absence of barriers between the different physiological compartments (unbound levels would be identical) holds true for most peripheral tissues, however, for other tissues, such as CNS, which is separated from the plasma by the BBB, the unbound concentration in plasma and tissue (effect compartment) will differ by a factor equivalent to $K_{p,uu,e}$ (the ratio of the unbound concentration in the effect compartment and the unbound plasma concentration) (Eq. 6) if either active transport is involved or if there is a significant gradient between the diffusion rate from blood to tissue.

$$K_{p,uu,e} = C_{u,e}/C_{u,p} \tag{6}$$

Eqs. 5, 6 can therefore be generalized as follows:

$$C_{u,e} = (Fa \times dose) \times K_{p,uu,e} \div (Clint \times T) \tag{7}$$

Strategies to increase the unbound concentration in the effect compartment ($C_{u,e}$) for oral drugs that are cleared predominantly by hepatic clearance, and which are consistent with Eq. 7, require the following:

1. Reducing intrinsic clearance (Clint) in liver microsomes and or hepatocytes.
2. Increasing the fraction of dose absorbed (Fa): which can be achieved by
   - increasing the solubility of the compound.
   - increasing intestinal permeability.
3. Minimizing interactions with active transporters (ie, P-glycoprotein).

2.03.3.3.1 Definition of DRUG efficiency

The drug efficiency (DRUGeff) measure relates the estimate of the compound potency to the free concentration of the administered dose.[141–144] DRUGeff is a straightforward parameter that takes into account the factors influencing the concentration of a given compound at the site of action and can be used, in combination with in vitro potency, in the selection of the compounds with optimized in vivo potency to be progressed for further characterization.

In contrast to in vitro testing, where almost all the dose is available to interact with the target, in the in vivo situation only a small portion of the dose effectively reaches the effective compartment, the biophase, and is available to interact with the desired biological target as a consequence of all ADME processes occurring after administration. DRUGeff is estimated through the Eq. 8:

$$DRUGeff(\%) = C_{u,e} \times 100/Dose \tag{8}$$

In Eq. 8, the $C_{u,e}$ is expressed in μg/mL and the dose is expressed in mg/kg, (with the assumption that 1 L is equivalent to 1 kg as done for tissues to blood calculations). Thus the DRUGeff can be considered as a percentage. For compounds that are cleared predominantly by hepatic clearance can be generalized as follows:

$$DRUGeff(\%) = Fa \times K_{p,uu,e} \times 100/(Clint \times T) \tag{9}$$

The assessment of the exposure profile, required to elicit the pharmacological response and the identification of compounds that are likely to maximize DRUGeff are essential for any discovery project working toward a low dose drug. One of the key benefits of the DRUGeff parameter is that it takes an integrated view on the pharmacokinetic profile and helps correct the ranking of compounds for further progression.

The impact of DRUGeff on discovery project strategy is shown in **Table 4**. A series of analogs targeting a peripheral receptor for which the biophase has been defined to be the plasma unbound concentration is considered. All candidates show an acceptable profile based on the classical PK parameters and therefore the selection of the compound for progression into further assessment would probably be driven mainly by the target affinity (Drug C). When DRUGeff values are calculated it becomes apparent that

Table 4 In vitro and In vivo pharmacokinetic parameters of a series of potential candidates. In vitro target affinity (pKi), in vitro permeability (Papp), in vitro plasma protein binding (F_u plasma), in vitro metabolic stability (clint), in vivo volume of distribution (Vd_{ss}), in vivo blood clearance (CLb), in vivo half-life ($t_{1/2}$), in vivo oral bioavailability (F), and drug efficiency (DRUGeff)

Parameter	*DRUG A*	*DRUG B*	*DRUG C*	*DRUG D*
pKi	6.9	7.0	7.5	7.4
Papp (nm/s)	85	90	122	143
F_u plasma (%)	5.4	2.4	1.5	2.4
Clint (ng/min/g)	0.5	0.6	0.5	0.7
Vd_{ss} (L/Kg)	0.4	0.4	2.3	2.1
CLb (mL/min/Kg)	3.0	2.0	18	42
$t_{1/2}$ (hr)	1.5	2.3	1.5	0.6
F (%)	60	80	67	50
DRUGeff (%)	1.8	2.7	0.25	0.12

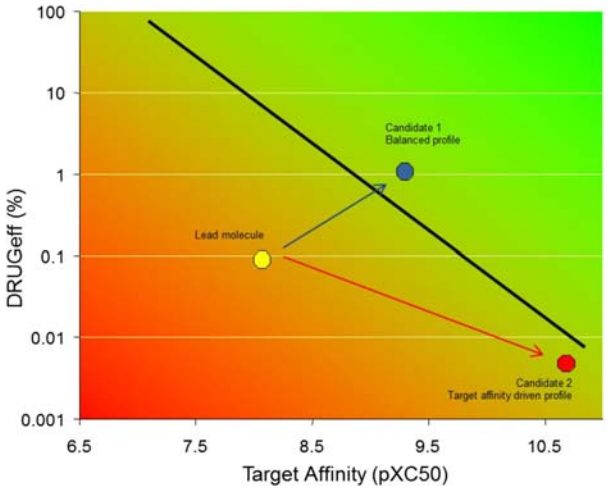

Fig. 9 DRUGeff versus target affinity (pXC_{50}) analysis. The solid black line represent the level of combined DRUGeff and affinity required to reach the PK/PD target of 90% of RO%, at the dose of 1 mg/kg. Figure adapted from reference Braggio, S.; Montanari, D.; Rossi, T.; Ratti, E., Drug Efficiency: A New Concept to Guide Lead Optimization Programs Towards the Selection of Better Clinical Candidates. *Expert Opin. Drug Discovery* **2010**, 5, (7), 609–618. www.tandfonline.com

Drugs A and B have a significantly higher efficiency with 15–20-fold higher biophase concentrations compared to Drugs C and D. Considering both DRUGeff and in vitro affinity, Drug B appears to be the one with the more balanced profile and higher potential for in vivo potency assessment (ie, lowest dose).

The prioritization of compounds using DRUGeff is summarized in Fig. 9, which shows a plot of DRUGeff versus target affinity. The solid black line represents the level of DRUGeff and affinity that is required to reach the PK/PD target of 90% RO% at the dose of 1 mg/kg. The same efficacious dose can be achieved with a compound having a high affinity and low DRUGeff or vice versa. Compounds with DRUGeff versus target affinity combinations in the upper right-hand region of the plot (*green*) will have lower efficacious doses. Compounds with DRUGeff versus target affinity combinations in the lower-left hand region (*red*) will have higher efficacious doses. The direction taken from the lead to the candidate illustrate the impact of using a "balanced" approach (*blue* arrow) rather than selecting on target affinity alone (*red arrow*).

The utility of the DRUGeff parameter can be further illustrated from a consideration of 215 oral drugs compiled from a variety of literature sources (see below). The therapeutically relevant potency, the daily dose, as well as plasma concentration and protein binding were collated and analyzed. The mean DRUGeff(%) for this set of oral drugs is 9.0. About 5% of the 215 oral drugs have DRUGeff(%) <0.1 and $\sim$30% have DRUGeff(%) <1 meaning that very few marketed drugs have poor DRUGeff.

If the target affinity (XC_{50}) is also considered (Fig. 10), $\sim$8% of the 215 oral drugs have a DRUGeff(%) <1 and a reported $XC_{50}>0.1$ uM, while $\sim$37% have a DRUGeff(%) >1 and a reported $XC_{50}<0.1$ uM. This suggests that the majority of the oral drugs ($\sim$55%) are either biased toward high DRUGeff or high target affinity, with a preference for the former. If the therapeutic dose is considered, there is a clear trend suggesting that achieving low therapeutic dose is often the result of a compromise between DRUGeff and target affinity. In fact about 82% of low therapeutic dose drugs lie to towards the top right of the plot.

2.03.3.3.2 Drug efficiency index

Fig. 10 clearly shows that DRUGeff can be used to enhance the chances of achieving a balance of affinity and ADMET properties and low therapeutic dose. This observation has been rationalized by considering classical receptor theory, which states that, at equilibrium, receptor-ligand interactions must obey the law of mass action that follows the basic laws of thermodynamics (Eq. 10). A theoretical estimation of the target RO% can be obtained as a function of the biophase concentration, the unbound concentration in the effect compartment $C_{u,\,e}$ (Eq. 11), where K_d (or K_i) is the in vitro estimation of the drug affinity (binding) to the specific receptor.

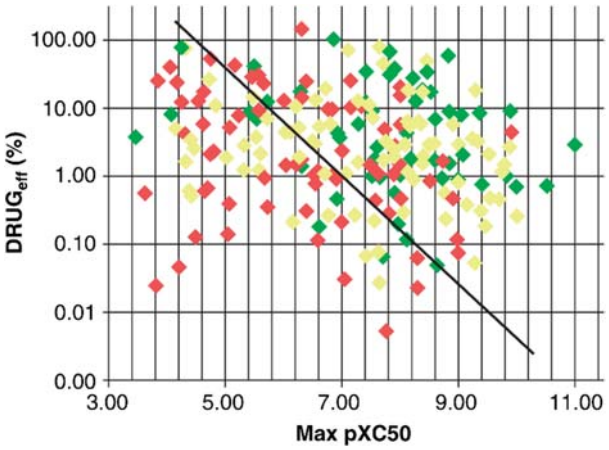

Fig. 10 The relations between the calculated DRUGeff and the reported in vitro pXC_{50} color-coded by therapeutic dose for oral drugs ($N=215$). Green spots represent therapeutic dose $<=$ 10 mg/day, orange spots represent therapeutic dose in the range 10–100 mg/day, *red spots* represent therapeutic dose $>=100$ mg/Day. Solid black line represents 50% RO% achieved at a therapeutic dose of 10 mg/day. Figure adapted from reference Braggio, S.; Montanari, D.; Rossi, T.; Ratti, E., Drug Efficiency: A New Concept to Guide Lead Optimization Programs Towards the Selection of Better Clinical Candidates. *Expert Opin. Drug Discovery* **2010**, 5, (7), 609–618. www.tandfonline.com

$$\text{Receptor} + \text{Ligand} \leftrightarrow \text{Receptor} - \text{Ligand} \tag{10}$$

$$\text{RO\%} = C_{u,e} \times 100/\left(K_d + C_{u,e}\right) \tag{11}$$

By inserting $C_{u,e}$ from Eq. 8 into Eq. 11, the result is that the sum of the DRUGeff and in vitro efficacy, defined as drug efficiency index (DEI) is directly proportional to the RO% and inversely proportional to the Dose.

$$\text{Log}[\text{DRUGeff}(\%)] + pK_d = \text{Log}[\text{RO\%}/(100 - \text{RO\%})] - \text{Log}(\text{Dose}) + 2 \tag{12}$$

The right-hand side of Eq. 12 is found to increase with increasing RO%. Thus the left-hand side term $\text{Log}(\text{DRUGeff}) + pK_d$ should be larger for drugs with larger RO%. Thus, the DEI can be defined by Eq. 13 with larger values leading to lower dose drugs. This can be achieved by either increasing the affinity of the compound to target receptor (smaller K_d), or through a larger value DRUGeff(%). DRUGeff positively adds to DEI if the DRUGeff $>1\%$. In this case lower in vitro potency results in the same RO%. Higher DEI values predict lower doses, thus lower risk of attrition.

$$\text{Log}[\text{DRUGeff}(\%)] + pK_d = \text{DEI} \tag{13}$$

The relation between DEI and therapeutic dose for the set of 215 oral drugs is shown in **Table 5**. DEI, which can be seen as a correction of the in vitro target affinity by the in vivo pharmacokinetic potential (DRUGeff), increases from 6.7 to 8.4 for high (>100 mg/day) dose to low (<10 mg/day) therapeutic dose regimens. It is worth noting that high DRUGeff appears to be the main driver in achieving low (<10 mg/day) therapeutic dose. A high therapeutic dose appears to be the result of profiles where a low target affinity is not sufficiently compensated by the DRUGeff.

In **Fig. 11** the pXC_{50} values for marketed oral drugs (**Table 6**) are plotted against the DEI parameter. The diagonal line corresponds to DRUGeff $=1\%$, ie, to $pXC_{50}=$DEI. Note that most of the marketed drugs lie below the diagonal line as they possess DRUGeff $>1\%$. For the highlighted drug, the in vitro pXC_{50} of 8 corresponds to a DEI above 9. This difference of 1 unit between the DEI and the target affinity reflects a 10-fold lower therapeutic dose required for a given receptor engagement.

The DEI is a simple descriptor which is directly connected to efficacy and therapeutic dose and has the potential to help us understand the balance between in vitro affinity and ADME properties. To illustrate how DEI can prove advantageous to select molecules we highlight the situation for three lead and candidate pairs for different CNS indications (**Table 7**) Drug pair 1 represents a balanced example of a lead optimization strategy: the increase in DEI values from lead to candidate is achieved by increasing both affinity and DRUGeff. An Eight-fold increase in affinity combined to a 220-fold increase in DRUGeff leads to a dramatic

Table 5 Therapeutic dose, in vitro pXC_{50}, DRUGeff, and DEI for oral drugs ($N=215$)

Therapeutic dose (mg/day)	*Mean pXC_{50} (SEM)*	*Mean DRUGeff% (SEM)*	*Mean DEI (SEM)*
≤ 10 ($n=53$)	7.8 (0.2)	13.0 (2.8)	8.4 (0.2)
10–100 ($n=89$)	7.3 (0.2)	7.8 (1.6)	7.6 (0.2)
>100 ($n=73$)	6.4 (0.2)	7.7 (1.3)	6.7 (0.2)

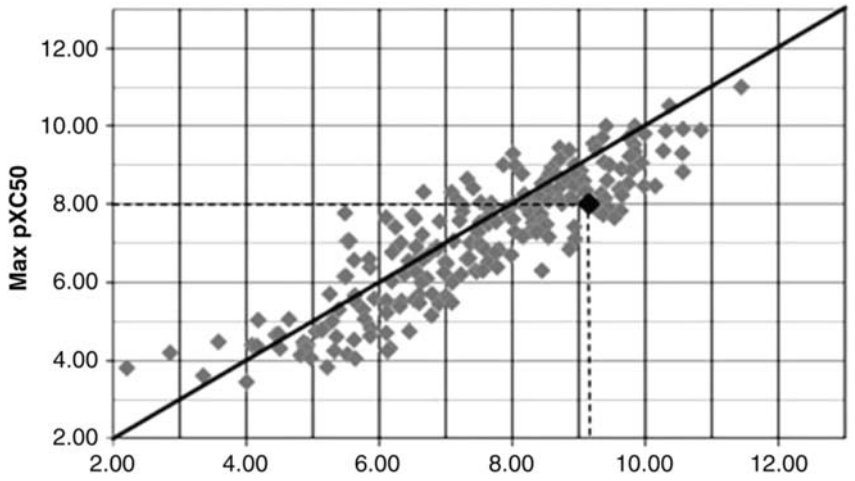

Fig. 11 The relation between the reported in vitro pXC_{50} and DEI for oral drugs ($N=215$). Dark spot is marketed drug with reported in vitro pXC_{50} of 8 and DEI above 9. Table 7 The relation between target affinity, DRUGeff, and DEI for 3 CNS lead-candidate pairs

	MWT (Da)	*clogP*	*pKi*	*DRUGeff (%)*	*DEI*
Pair 1					
Lead	415.5	3.3	7.1	0.025	4.6
Candidate	363.5	3.5	8.0	5.49	6.4
Pair 2					
Lead	545	6.4	9.4	0.001	6.4
Candidate	615	5.6	10	0.017	8.24
Pair 3					
Lead	363.5	2.9	6.4	0.1	5.4
Candidate	472	4.9	7.9	0.08	6.8

increase in DEI and the corresponding in vivo efficacy potential. Drug pair 2 represents an example of profile biased toward in vitro affinity as DRUGeff is very low. The optimized candidate shows slight improvements in both in vitro affinity and DRUGeff; however this molecule has very high MWT and logP leading to suboptimal ADMET properties. In drug pair 3, the increase in DEI value for the candidate with respect to the lead drug is achieved mainly by increasing the in vitro potency, as DRUGeff remains constant. In this case the directions taken by the project team involved chasing target affinity.

2.03.4 Effect of Systematic Biases in Drug Discovery

The systematic, multivariate optimization of disparate biological measurements obtained from in vitro and in vivo models of efficacy, safety and PK is a relatively new and evolving area of pharmaceutical research.[145] Our ability to identify and understand the reasons for compound attrition points to a renewed need to consider how we rank order preclinical compounds using the data generated in drug discovery. Ranking compounds using data from 10–100 s of different assay systems is complicated by the fact that each assay has a different relative importance to efficacy and safety, can have linear or nonlinear relationship with the probability of success. Each parameter will have an intrinsically different relevance/accuracy to the endpoint they are supposed to model.[28,37,146] The ability to effectively manage a large number of parameters, some of which can be orthogonal, correlated or inversely correlated, is absolutely critical in lead optimization, yet it remains one of the key challenges.[147,148]

Many of the highly complex decisions that must be made over the course of a discovery project will be heavily influenced by the personal backgrounds and experience of the individual(s) involved, or the organization where the research is undertaken. It is important to acknowledge that when decisions are made on complex problems a reductionist approach is required. A situation may arise where the solutions obtained by taking the reductionist step may involve a project team following the same path, rather than exploring diverse solutions. Indeed, concepts such as lean sigma are increasingly being proposed to improve the efficiency and streamline processes in R&D, and can be beneficial unless they somehow limit scientific innovation in the pursuit of standardization and data reproducibility.[149,150]

A concern is that the causes of undesirable, systematic biases in decision making may limit creativity and reduce the diversity of the solutions investigated to probe a given problem. This is important since the goal of the discovery process is to probe a problem with a set of diverse solutions that are probabilistically more likely to work, or at least answer a question that may help influence the future direction of the project, or indeed close it.

2.03.4.1 The Effect of Personal and Organization Biases

Management, metrics, and the culture of an organization contribute significantly to the decision making and thus output of a drug discovery project. A number of groups have noted how an industry-wide pressure existed for increased number of hits, leads and candidates, rather than a focus on quality science.[10,63] Furthermore, Leeson et al. have shown that the physicochemical properties from AstraZeneca, GlaxoSmithKline, Merck, and Pfizer showed marked intercompany differences even on the same target class, driven by different corporate cultures.[75] A subsequent more extensive patent based analysis on a wider set of companies demonstrated similar findings and suggested that differences in physical properties between the organization's compounds are not influenced very much by the targets or target classes pursued, but more by the different strategies and tactics followed.[10,61]

Personal biases will invariable affect lead optimization where a quantitative balance of a range of diverse parameters must be developed in the lead series. Unlike a binary classification of good or bad, the search for optimal pharmacokinetics, dynamics and safety involves considering an array of assay parameters that constitutes a multidimensional hypersurface that is not easily navigated using the human brain. A further complication is that not all parameters are as meaningful as others, yet selection bias may mean some parameters take greater precedence over others. Once an apparently desirable solution has been achieved there may also be a reticence on the part of the team to stray too far from this solution when searching for a backup molecule. This can sometimes mean that the backup series contains the same fundamental safety issues or mode of action issue as the molecule that preceded it.[151]

Lajiness et al.[152] demonstrated the bias displayed by individuals by asking different chemists to assess the suitability of 2000 compounds based on their "attractiveness" and/or synthetic feasibility as a basis for launching a drug discovery campaign. Intriguingly, they found that medicinal chemists were not even internally consistent when reviewing compounds as it was shown that the review of the same compounds a second time but in a different set, saw the rejection of the same compounds only about 50% of the time. It is therefore no surprise that the average agreement between a pair of chemists was approximately 28%. These findings were given additional support by an exercise to separate a set of approximately 4000 fragments into lead-like and non lead-like sets which was reported by Kutchukian et al.[153] It was found that the 19 chemists involved adopted a simplified selection strategy, taking into account no more than 2–3 parameters, with ring topology and functional groups being the key factors. In addition, the chemists involved were often unaware of the parameters they had instinctively used (such as size), and overestimated the number of overall parameters they employed.

The difficultly in identifying molecules with the required balance in properties might explain why project teams frequently synthesize more molecules than are needed.[151] This finding was echoed by Bennani[154] who found that between 20–30% of effort within a project was spent "over fitting" the molecular series to fit the disease model. The over synthesis of compounds must be viewed in the context of (a) the approximate nature of the biological profile at the start of a project, and (b) the approximate nature of the in vitro and in vivo models used to meet the profile.

Suggested Guidelines for Project Progression:

- Aim to meet the proposed biological profile set by the project team as best as possible with the series(s) under investigation.
  - However, avoid a box ticking exercise with parameters. Assess the relevance and meaning of the assumptions and try to validate.
- Acknowledge that the biological profile is an estimate and adjust
  - Remain conscious that it may not be necessary to meet the required profile defined at the outset given the limited understanding at that particular time.
- Acknowledge that the in vitro and in vivo assays used to prioritize compounds at each stage are reductionist. Values are approximate, and discordance with in vivo models can be sizeable.
  - Perfect agreement with the model(s) is not expected.
- Be aware that meeting one criterion typically leads to deterioration in others, often due to their conflicting physicochemical dependences.

2.03.4.2 Overcoming Systematic Biases

Cognitive biases can also affect the integration of data that is critical in defining a clinical candidate (Table 8). Types of biases that can arise include (a) overconfidence in the project rationale leading to a lack of due-diligence in the mode of action studies (MOA), (b) insufficient understanding of the reliability of individual parameters leading to poor decisions being made,[155] (c) over focusing on one's own experience and neglecting probabilistically important lessons, and (d) focus on parameters under ones control and neglecting more relevant parameters which are harder to understand or influence. Such biases could in theory lead to the progression of less lead-like molecules should potency considerations dominate decision making,[47,156] or allow the progression of compounds that should have failed in earlier development.

The use of arbitrary cut-offs or the overreliance on certain individual parameters out of the many generated increases the risk of biased solutions emerging from a drug discovery project. Consider a case where we have two equally important parameters (ie, the free concentration vs. the potency), a large number of equally acceptable solutions will exist in terms of the Pareto ranking[155,157] yet often it is the most potent molecules that are taken forward (ie, seldom above 0.1 uM) before even considering the free concentration in vivo. This essentially limits the coverage of parameter space and will bias the solutions in ways that might not be easily rationalized a priori (Fig. 12). This is despite the fact that the relevance of in vitro potency has been questioned in the past,[28,29,37,156] and that it is known that a focus on absolute potency values can lead to the inflation of MWT and logP.[47,96,156] This of course means that lower logP and MWT compounds, which traditionally have better overall ADMET parameters,[54,79,80] including (exposure, clearance, and protein binding) are more likely to be excluded earlier on in the process.

Table 8 Cognitive biases discussed in this paper, their potential implications for drug discovery decision-making[147]

	Bias	*Implications*
a	Overconfidence: reluctance and/or inability to "prove a negative" and instigate premature closure	Projects failed too late. Insufficiently wide search before choosing a lead series or candidate
b	Poor calibration of judgements on estimating and forecasting reliability	Inappropriate weight given to results from early screening methods, or rules of thumb, that might too often reject drugs that should have survived
c	"Availability" bias: over-attention to the vivid and recent, with neglect of prior information	Failure to apply and learn from the "big picture" of industry project successes and failures
d	Excess focus on certainty when considering whether to accept one or more sources of residual risk	Inefficient use of resources when screening across multiple risk factors or possible indications

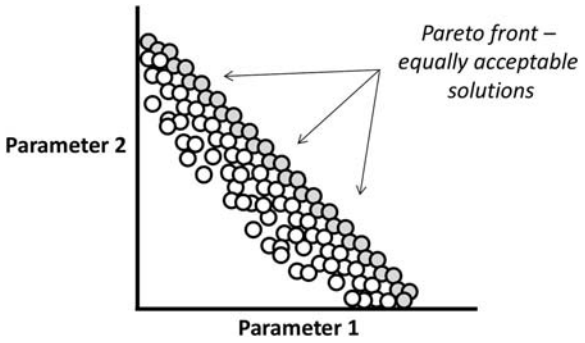

Fig. 12 An example of a Pareto front[155,157] obtained from two equally weighted variables. A large number of equally acceptable solutions are obtained (*gray circles*).

2.03.5 Conclusions

Achieving a molecule with balanced PK/PD and safety properties, that meets or exceeds the project goals, is a very difficult undertaking. This is especially true for projects associated with novel targets where little historical validation data is available. The current rates of attrition point to failures in utilizing the current battery of assays in preclinical and early clinical development to weed out problematic compounds. Moreover, it suggests further scientific effort is needed to rectify the situation, including the development and validation of more predictive toxicity assays to help reduce the large numbers of failures due to safety, as well as earlier proof of concept studies to tackle failures due to efficacy. A process that can identify and fail problematic compounds faster and more cheaply is a key goal.[5]

Despite Lipinski's seminal paper[54] being close to 2 decades old, the restraining of physicochemical parameters to an area of drug-like space is still somewhat controversial.[66,67] It could be argued that physical properties should be restrained within drug-like space unless there are justifiable reasons to move beyond them. We also question whether we take enough risks with lower potency compounds, given this is a major cause of property inflation. Justification for this is clear given that oral drugs display mean XC_{50} of ~0.1 μM (ie, 50% of compounds have XC_{50}s below this cut-off)[46,47]. Medicinal chemistry teams are highly effective at optimizing compounds against these high throughput assays, yet the relevance of them towards efficacy is often not always clear,[28] especially since efficacy is the single largest failure of compounds in clinical development.[158] A more effective strategy may be for the drug discovery project to work towards developing 2–3 distinctly novel chemical series to target the most optimal areas of physical property space, thereby maximizing the probability of obtaining an a balanced PK/PD and safety profile.

From a PK/PD perspective a more effective translational approach is to target low therapeutic doses by maximizing target affinity and the free drug concentration. This has the potential to reduce the risk of attrition related to drug burden and direct organ toxicity. This strategy sees the maximization of the target RO% per unit of dose which can be achieved in two ways: either by increasing the target affinity and/or by improving the unbound concentration in the relevant compartment. It is the optimal balance of these properties, and not their absolute values per se that dictates the potential to achieve a low in vivo efficacious dose. This forms the basis of the DEI, a method that allows the comparison of leads and candidates in terms of their RO% per unit of dose.

List of Recommendations:

- Take a probabilistic approach to drug discovery; there are clearly unknowns so following a standard strategy that results in a 96% failure rate is not practical.
- Focus initially on ideal area of property space—but don't be afraid to make undesirable compounds for reasons of diversity
- Aim for backup molecules with truly different structures and properties (PK/PD and physicochemical properties)
- There will be a need to compromise on certain parameters—avoid the desire to maintain potency over other parameters as this is typically a refined protein or recombinant assays which by their very nature have questionable disease/phenotype relevance.[28]
- Follow best practice in target activity/selectivity, PK/PD, and molecular properties, but do not be afraid to "break from the model" to test a hypothesis.

2.04.1 Introduction

2.04.1.1 Why Drugs Fail

The probability of successfully launching a new small-molecule drug is very small,[1,2] with the likelihood of progressing from phase I clinical trial to FDA approval being in the region of 10%.[3] An analysis of reasons for late-stage (phase II and phase III) failure identified lack of efficacy as the major contributor in >50% of cases between 2007 and 2012,[4] suggesting that investing in target validation might have the greatest impact on attrition. Arrowsmith and Miller[4] identified that the next largest cause of late-stage failure, accounting for 19–35%, is safety. It is notable that this is a rather different picture from that in 1991 when the pharmacokinetics and bioavailability of compounds were by far the largest challenge to success, accounting for around 40% of failures.[5] By 2000, the implementation of early *in vitro* absorption, distribution, metabolism, and excretion (ADME) assays early in the drug discovery process and utilizing *in vitro* intestinal permeability and hepatic metabolism assays alongside physiochemical understanding, had reduced this to ~10%, and this figure remains low. Here, we discuss key *in vitro* technologies that can make early predictions of drug safety, offering the opportunity for significant improvement on the probability of success in drug discovery and development.

2.04.1.2 The Proportionality and Predictability of Adverse Drug Reactions

Around 75% of adverse drug reactions (ADRs) in hospitalized patients (those admitted to the hospital due to an ADR or those experiencing an ADR while undergoing hospitalized treatment)[6] have been classified[7] as "type A" ADRs: those that are dose-dependent,

those that are related to a pharmacological action of the drug, and (perhaps most importantly) those that are predictable. This suggests that, with early characterization of the pharmacological properties of candidate molecules, there is an opportunity to eliminate a large proportion of the undesired effects of molecules selected to enter the development phase.

Given the immensely complex nature of normal physiology, the key question is where to focus in implementing early testing, detection, and elimination strategies. Redfern and colleagues[8] provide a meta-analysis identifying the proportional contribution of key organ systems to adverse events or causes of attrition broken down by phase. For example, genetic toxicity accounts for 5% of attrition in nonclinical phases of drug discovery.[8] Importantly, genetic toxicity does not feature as a cause of any attrition during clinical development or postmarketing: The decision-enabling data are generated in the nonclinical phase and appropriate decisions are made to avoid progression of genetically toxic molecules. In order to assess potential metabolites of the tested compounds that may be generated *in vivo*, genetic toxicity tests employ an *in vitro* metabolic activation system (normally the so-called S9 mix from rat liver). Interestingly, cardiovascular toxicology accounts for 27% of attrition in the nonclinical phase but only 9% of ADRs reported during phase I clinical trials. However, 45% of postmarketing drug withdrawals are due to cardiovascular ADRs. This suggests that nonclinical data enable selection of molecules that are relatively safe in populations of (often healthy) volunteers in phase I trials, whereas in larger patient populations, where the disease state may compromise the cardiovascular system and chronic treatment is not limited by the set period of clinical trials, ADRs occur, which were not predicted by nonclinical models, presumably because such models are based on the normal healthy physiological state.

2.04.1.3 Regulatory Context

In addition to the economic drivers demanding improvement in attrition, there are of course ethical requirements for safe medicines that are embodied in guidelines issued by the International Council for Harmonization of Technical Requirements for Pharmaceuticals for Human Use (ICH). The "S" series guidance contains descriptions of both recommended and required nonclinical tests for assessment of the safety of candidate molecules (http://www.ich.org/products/guidelines/safety/article/safety-guidelines.html). Three of the 10 guidelines explicitly encourage *in vitro* testing: S2 for genetic toxicology, S7A/B for safety and secondary pharmacology and specifically prolongation of the QT interval of the surface electrocardiogram, and S10 for photosafety. ICH guidance S2 is quite explicit in requiring assessment of genetic toxicologic potential in bacterial reverse gene mutation (Ames) tests in addition to *in vivo* tests. ICH guidance S10 recommends characterization of UV–visible absorption spectra as an initial experiment to determine whether further testing is required, and the initial toxicity testing involves a test in 3T3 fibroblasts *in vitro*. Although ICH S7A does not specify methodologies for secondary pharmacology, many in the industry have chosen to use *in vitro* biochemical and pharmacological assays as a means to assess off-target activity.[9,10] ICH S7B recommends *in vitro* electrophysiological assays for the activity of compounds at cardiac ion channels as part of an integrated risk assessment of cardiovascular safety. Thus, it is clear that a major aspect of the ICH S guidelines involves the results of *in vivo* tests for candidate drugs. This leaves a wide opportunity to develop rapid, cost-effective, and predictive medium- and high-throughput *in vitro* methodologies to enable selection of the best molecules to move forward into *in vivo* testing without the constraints of the regulatory environment.

2.04.1.4 3Rs

Notwithstanding a regulatory requirement for animal testing prior to first human testing of new chemical entities, there has been a strong movement to "refine, reduce, and replace" animal studies in toxicologic testing, based on the framework proposed by Russell and Burch.[11] In part, this reduction in some *in vivo* testing is driven by the understanding that models or tests should provide useful information on which to base decisions to design and select drug-like molecules and that some *in vitro* systems can be more predictive of human effects than some animal tests. For example, in 2001, the LD_{50} Draize test (a test that determines the acute oral dose at which 50% of animals tested are killed) was abolished by the Organization for Economic Co-operation and Development (OECD) with the realization that the test did not provide particularly useful information for specific understanding of toxicity. Such examples are simplistic and rare; much stronger, current drivers for the pharmaceutical industry to implement more *in vitro* and *in silico* toxicity and safety testing are the need to improve predictivity, throughput, and quality while minimizing sample requirement and cost.

One approach to reducing the need for testing is in the application of a "read-across" process. This is the concept that compounds with defined structures and toxicologic end points (source compounds) may be grouped into categories. The aim would be to use the known end points to predict the toxicologic effect of an untested compound (target compound).[12] While perhaps more commonly applied in areas such as environmental toxicology or cosmetics, read-across has been successfully applied in the pharmaceutical development, for example, in generating alerts for structures associated with the potential for causing hepatotoxicity,[13] offering the opportunity to evaluate *in silico* before synthesis or testing.

2.04.1.5 What Are We Trying to Predict?

The search for new medicines that are both efficacious and safe in humans requires the ability to make predictions based on data from nonclinical models to likely effects in humans. However, given a regulatory requirement for *in vivo* safety testing prior to first human testing, it may also be appropriate to generate *in silico* or *in vitro* models that are predictive of effects obtained from preclinical species. The use of drug combinations is becoming more common, particularly in the areas of oncology and infectious disease.

The ability to predict whether administration of drug combinations affects the toxicologic profile, through synergistic effects on off-target pathways, effects on bioavailability, or changes in metabolism, is becoming an important component of predictive toxicology and may be amenable to *in silico* system informatics approaches.[14]

The selection of appropriate end points is also of interest: some models may provide specific molecular detail and understanding related to a well-defined physiological end point. Perhaps the most common example of this is the electrophysiological assessment of block of the delayed rectifier potassium current IKr carried by the human ether-à-go-go (hERG) potassium channel. It is now well established that block of the hERG channel is linked to lengthening of the QT interval of the surface electrocardiogram, which in a small number of cases is associated with life-threatening cardiac arrhythmias including torsades de pointes (TdP).[15] While it is possible to build a chain of ever more integrative models in order to assess the risk of arrhythmia in humans, with models ranging from electrophysiological recordings of recombinant ion channels[16] or Purkinje fibers,[17] isolated cardiomyocyte action potential duration recording,[18] ventricular wedge preparations,[19] isolated heart,[20,21] to conscious telemetered dogs,[22] it may not be efficient or desirable to utilize all of the available models. At present, the most conservative approach is mandated by regulatory authorities, based on hERG channel inhibition measured in recombinant channels expressed in immortalized cells by manual patch clamp, followed by nonrodent telemetry. This approach is open to criticism, as arrhythmogenesis in the heart is the result of integrated effects of the modulation of ion channel kinetics and other pharmacological factors. Importantly, the mode of inhibition of the hERG channel might differentiate in the translation to arrhythmia.[15] The comprehensive *in vitro* proarrhythmia assay initiative (http://cipaproject.org/) is a coordinated effort between regulatory authorities, industry, and academia, to address these questions and provide suite of mechanistically based *in vitro* assays coupled to *in silico* reconstructions of cellular cardiac electrophysiological activity that could integrate the various components of chronotropy. A body of evidence can be generated to provide an integrated risk assessment of the likelihood of the occurrence of specific functional end points.

At the other end of the scale, some end points such as manifestation of phospholipidosis may be reasonably well defined,[23] and *in vitro* black-box assays are available to predict the effects;[24] however, the underlying molecular mechanisms driving the effect either *in vitro* or *in vivo* are less clear. In these cases, using an appropriately characterized set of compounds to evaluate the *in vitro* model allows calculation of sensitivity, specificity, and predictive value of an assay.[25]

It is also important to have an understanding of the predictive value of animal models themselves. Ultimately an integrated risk assessment involving the understanding of toxicologic findings and their underlying mechanisms is required to determine the safety profile relevant to human use. In a recent example, ticagrelor, a reversible $P2Y_{12}$ receptor antagonist for the treatment of acute coronary syndrome, was found to affect the incidence of uterine and mammary tumor in a 2-year rat carcinogenicity study,[26] which was performed to meet the requirement of ICH guidance S1. At face value, it may appear that ticagrelor would pose a carcinogenic risk for human patients. However, mechanistic investigations using *in vitro* biochemical and pharmacological assays to understand the off-target profile (secondary pharmacology) revealed that ticagrelor inhibits the function of the dopamine transporter, increasing dopaminergic signaling so modulating prolactin release from the anterior pituitary.[27] Understanding the fundamental differences in rat and human physiology, specifically that prolactin is eutrophic in rats but not in humans,[28] allows an integrated assessment, combining the *in vitro* off-target activity, *in vitro* genotoxicity, and *in vivo* data. Taken together, these findings do not indicate a patient safety risk, based on qualitative species differences between rat and human.[26] The learning from this example is that for a chain of different models from *in vitro* to *in vivo* to the clinic, it is essential to understand both the predictivity of each model to the next and the relevance of every model to the clinical setting.

2.04.1.6 Assessment of Predictivity

A key element in the assessment of predictivity is the availability of well-characterized reference compounds. While the dynamic range of a model may be explored with pharmacological tool compounds, the ability to correctly classify the activity or lack of activity of compounds whose effects have previously been characterized in humans is essential to gain an understanding of the predictive value of a safety or toxicologic model. Selection of drugs for model validation requires evidence of effect or lack of effect on the desired end point, an understanding of the prevalence of the end point in the human population, an understanding of the population in which the end point was studied (eg, healthy volunteers versus patient), characterization of the exposure (AUC and free C_{max}) at which the effect occurred/did not occur, and understanding whether there are active metabolites with a similar or diverse pharmacological profile to the parent relevant to the measured end point.

Cooper et al.[25] describe a contingency matrix (**Table 1**) that clearly defines terms to describe the characteristics of an assay. Of greatest interest are sensitivity—the finding of true-positive outcomes as a proportion of both true-positive and false-negative outcomes—and specificity—the finding of true-negative outcomes as a proportion of both true-negative and false-positive outcomes. The definition of a true outcome is in the hands of the assay developer, and the characterization of the test is dependent on this definition; thus, the selection of appropriate reference compounds, as discussed in the preceding text, is critical in assay development. The balance of sensitivity and specificity required of an early *in vitro* safety assay will depend on the severity of the adverse event that the assay is attempting to predict, the context of when the assay will be used in the discovery process, and the availability of additional confirmatory assays. It may be that for very early, higher throughput safety assays, specificity is the most important parameter in order to avoid discarding compounds too early in the discovery process. It is worth noting that in the selection of reference compounds for characterization of an assay, there should be a good balance of both positive and negative compounds; if the training set is heavily weighted to either positive or negative compounds, the assessment of sensitivity and specificity will be biased.

Table 1 Terms used to characterize *in vitro* assays[25]

		Reference compound annotation	
		Toxic	*Nontoxic*
In vitro assay outcome	Positive	True positive (TP)	False positive (FP)
	Negative	False negative (FN)	True negative (TN)

(from Cooper, J.A.; Saracci, R.; Cole, P. Describing the Validity of Carcinogen Screening Tests. *Br. J. Cancer* **1979**, *39*(1), 87–89). Reference compounds are grouped according to defined criteria as either toxic or nontoxic (eg, based on clinical finding), and the outcome of the assay under evaluation is shown as either positive or negative. Sensitivity = TP/(TP + FN). Specificity = TN/(TN + FP)

2.04.2 Model Systems for Toxicology

2.04.2.1 Individual Target Screening

In vitro pharmacological profiling, using simple biochemical, enzymological, and pharmacological assays to assess the interaction of test molecules with individual molecular targets from a broad range of target classes typically including G protein-coupled receptors (GPCRs), enzymes, kinases, nuclear hormone receptors, ion channels, and transporters, is now well established in the pharma industry as a preferred method of assessing secondary pharmacodynamics early in the discovery process.[9,10] These techniques offer rapid, cost-effective methods with low sample requirement to generate an understanding of off-target activity. Often, assays are grouped into panels ranging from a handful to hundreds of targets, and testing may be performed at single concentration or over a range of concentrations, with assays being readily available at several contract research organizations (CROs). Typically, a small number of targets with key links to safety end points are screened early, with broader coverage of targets employed for more advanced compounds. Since there is little regulatory guidance on the appropriate selection of targets for *in vitro* profiling,[29] a minimum panel of 44 targets has been proposed based on the shared experience of four large pharma companies.[9]

Selection of appropriate targets for *in vitro* pharmacology screening has to be considered at two levels: (1) identification of targets that are associated with a known hazard when affected by drugs or modulated by genetic modifications and (2) selection of targets from the collection identified at level 1 for screening and profiling *in vitro* and also *in silico*. The composition of the second level is largely dependent on the indication, therapeutic targets, preferred chemical structure, and availability of high-quality assays. It is important to maintain a broad focus in panel design: in a mapping on "pharmacological space," Paolini and colleagues[30] demonstrated that many compounds bind to more than one target and that the promiscuity is not limited to like-target classes; in other words, if the primary target is a kinase, it is not sufficient to screen only kinases as off-targets.

Some understanding of the physiological role of a target is usually obtained in a number of different sources, including extensive literature surveys, cataloging data from human genetics (OMIM http://www.ncbi.nlm.nih.gov/omim provides a useful resource), knockout animal studies (although of course the long-term absence of a target is not necessarily the same as pharmacological antagonism), clinical trial data (databases such as PharmaPendium provide helpful curation of compound, exposure, and ADR reports), and pharmacological studies using previously characterized and reference compounds.

It should be remembered that adverse events may be driven by primary drug targets, for example, skin rash caused by EGFR inhibitors,[31] or opiate analgesics associated with abdominal distension, pain, constipation, nausea, and vomiting,[32] and this can provide valuable evidence linking target to effect. However, the use of reference compounds can be challenging in that certainty of the mechanism of action (MOA) can be difficult to demonstrate. For example, CGP 71683A has been described as a selective neuropeptide NPY Y_5 antagonist that reduces food intake in rats. Indeed, Criscione and colleagues[33] showed >1000-fold selectivity of the compound for the NPY_5 subtype over Y_1, Y_2, Y_4 receptors in *in vitro* radioligand binding assays. However, this study did not examine the effects of CGP 71683A at targets outside the immediate receptor family, and Della Zuna[34] subsequently found high affinity for muscarinic receptors and serotonin reuptake sites (presumably the 5-HT transporter) within approximately threefold of the affinity for the NPY Y_5 receptor. A number of hypotheses can be generated to relate these off-target activities with modulation of food intake in addition to the action at NPY Y_5 receptors[34]; thus, the hypothesis that NPY Y_5 receptors affect food intake is not conclusively supported by data from studies using CGP 71683A as a reference compound.

Interpretation of the off-target profile on a target-by-target basis involves some assessment of the potency in the *in vitro* assay relative to free plasma concentrations (free C_{max}, for reasons reviewed in[35]): those likely to be achieved in humans for efficacy and those achieved in preclinical species as part of an integrated risk assessment. Typically, a 100-fold difference between free C_{max} and *in vitro* potency is taken as likely to be of little concern (**Fig. 1**). For the shortlist of targets where separation between *in vitro* potency and (likely) *in vivo* plasma exposure is <100-fold, it may be appropriate to assess safety margins on an individual target basis. For example, Smith[36] has shown that for a range of GPCR antagonists, there is a strong correlation between the clinical free C_{max} required for efficacy and 3x the *in vitro* affinity for the receptor (K_i); therefore, for the specific subgroup of GPCR antagonist hits, it may be that >3x separation between *in vitro* affinity and free C_{max} would be accepted as low risk. For other targets, individual assessments can be made by comparing the exposures for known drug/ADR pairs at a given target to determine a safety margin unique to the target.[37] A comprehensive review of the therapeutic index, the relationship of exposure data to a variety of assay and clinical data, is provided by Muller and Milton.[38]

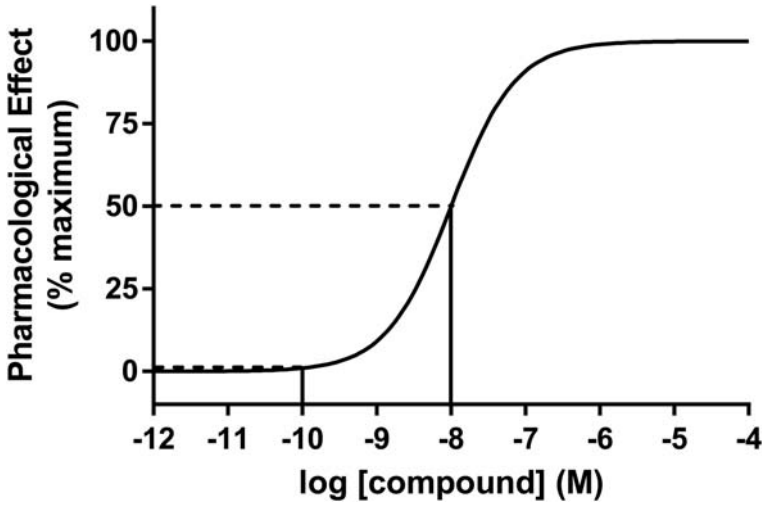

Fig. 1 A standardized pharmacological concentration–response curve using the Hill–Langmuir equation to relate increasing concentrations of the compound of interest to increasing effect. The curve is described by a lower asymptote of 0% and an upper asymptote of 100%, a slope of unity, and a midpoint of 10 nM. It can be seen that at a concentration of drug 100x lower (0.1 nM) than the midpoint of the curve, the pharmacological effect is approximately 1%.

Examining the profiles for known compounds can give confidence that *in vitro* profiling is able to detect target interactions that are relevant to drug discovery. For example, in Fig. 2, the *in vitro* target profile of three generations of antidepressants is shown grouped with the oldest generation at the top of the table. While most of the compounds have strong interactions with the 5-hydroxytryptamine (5-HT) transporter, it can be seen that the newer generations of compounds are less promiscuous, especially among muscarinic, histaminergic, and adrenergic receptors, which appears to correlate with fewer ADRs. A second example is shown in Fig. 3 where the *in vitro* activity at phosphodiesterase 3 (PDE3) was found to translate to both histopathologic and functional changes in rat heart for a number of tyrosine kinase inhibitors. The link between PDE3 and myocardial toxicity has been described for both milrinone, for which the primary target is assumed to be PDE3, and other kinase inhibitors for which PDE3 is a secondary target.[39]

The overall promiscuity of a drug in the context of likelihood of success may also be considered. An analysis of marketed and withdrawn drugs shows that a higher proportion of withdrawn drugs are promiscuous than those that remain on the market (see Fig. 2 in[9]). Typically, promiscuity is expressed as the proportion of targets at which a compound has a defined activity (eg, $IC_{50} < 10$ μM or shows >50% effect at a given test concentration); however, to our knowledge, there is no validated scaling factor that would encompass, in a single summary value, both the number of hits and the potency at each of the targets.

Fig. 2 *In vitro* secondary target profile for selected antidepressants with the first-generation compounds at the top of the table. Values are *in vitro* A_{50} in μM. Color-coded red <1 μM; orange 1–10 μM; yellow 10–30 μM; white >30 μM. Data from Novartis in house screening.

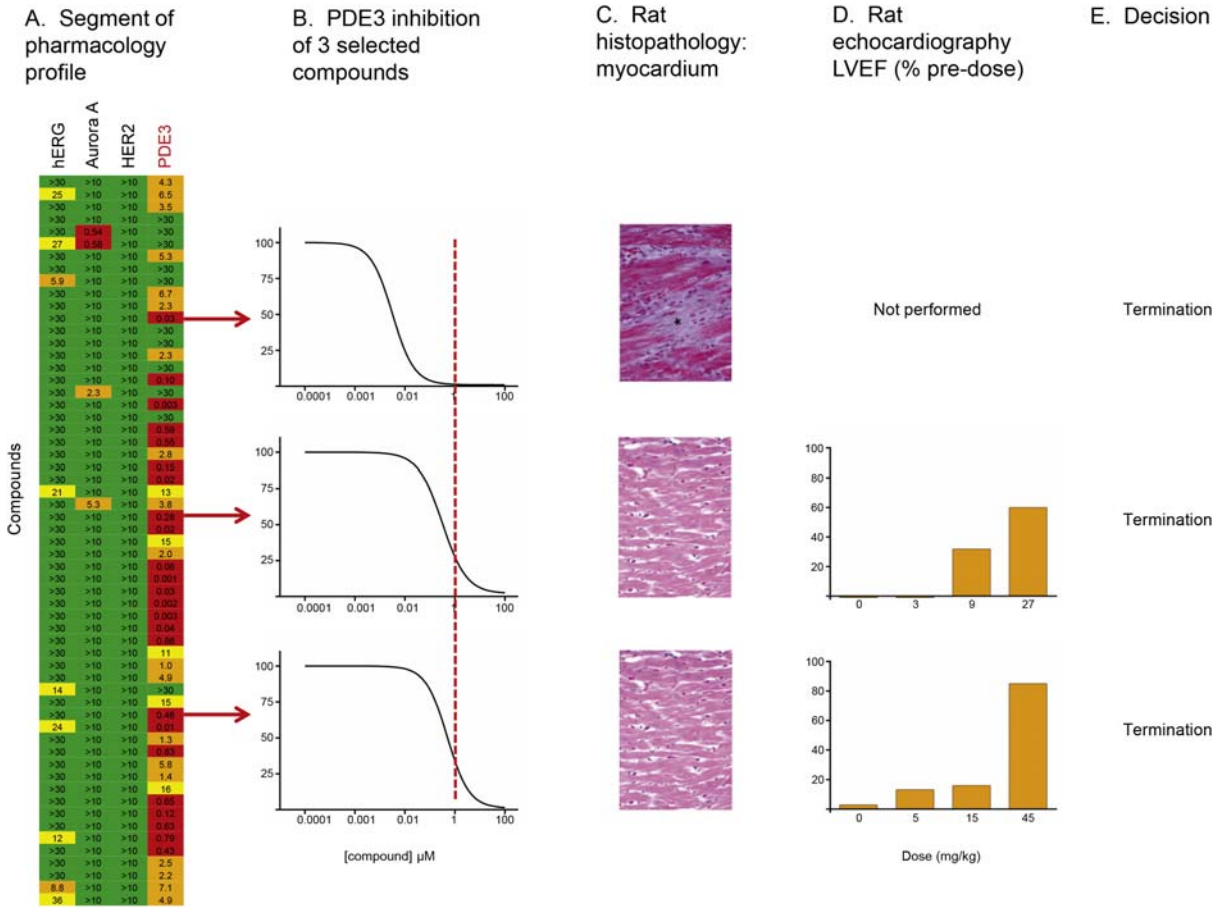

Fig. 3 Translation of PDE3 from *in vitro* to *in vivo* effects. (A) Excerpt of *in vitro* secondary pharmacology profile for a range of compounds from a tyrosine kinase inhibitor project. Each row represents a single compound, each column the result of an *in vitro* target assay; red high activity; yellow moderate activity; green low activity. (B) Concentration–response curves showing inhibition of PDE3 by 3 example compounds from panel A. Dashed red line indicates approximate free plasma concentration achieved in *in vivo* rat studies (panels C and D). (C) Histopathologic effects of 3 example compounds in rat myocardium from free plasma exposures around 1 μM. Compound 1 shows necrosis. (D) Evaluation of compounds 2 and 3 in rat using echocardiography, measured 1 h post dose. Percentage increase in left ventricular ejection fraction for control and 3 increasing doses. Maximum free plasma exposure at high dose for all 3 compounds was approximately 1 μM. (E) Integrating 4 preceding data sets to make a decision on compound progression.

One of the appeals of individual target screening is the ability to access specific molecular-level information about the activity of a compound; often, this is useful in reverse pharmacology: understanding the underlying mechanisms of *in vivo* or clinical observations. One of the most common examples of reverse pharmacology is the relationship between agonism of the 5-HT_{2B} receptor and cardiac valvulopathy, which has been found to be caused by norfenfluramine, pergolide, methysergide and cabergoline.[40] The original finding of valve disease caused by fenfluramine's metabolite, norfenfluramine, showed striking similarities to valvulopathies caused by serotonin-releasing tumors[41] that pointed toward the involvement of 5-HT receptors. Specific association between agonism of the 5-HT_{2B} receptor and valvulopathy was demonstrated by Rothman and colleagues[42] by screening both positive (compounds known or suspected of causing cardiac valvular damage) and negative controls for activity at 11 cloned 5-HT receptors in radioligand binding and functional assays in a classic example of *in vitro* secondary pharmacology. The underlying mechanism appears to relate to the role of 5-HT_{2B} receptors in valve fibroblasts, with overstimulation causing upregulation of mitogenesis and induction of differentiation into myofibroblasts that overproduce interstitial collagen affecting the function of the valve (extensively reviewed in[43–45]).

Scaling of individual target screening using traditional biochemical assays is dependent on the ability to source appropriate reagents, develop an appropriate assay, and synthesize an appropriate quantity of test compound. Catalogs of major CROs offer in the 100s to low 1000s of individual assays. However, this represents only a fraction of the ~19,000 proteins that are encoded by the human genome,[46] and an increasing number of different assays and reagents pose a logistic challenge to perform. Grouping targets into shared technology assays may be one way of addressing this challenge. For example, GPCRs may be "force-coupled" to the same G protein, thereby allowing a single functional platform, often a calcium-based technology[47,48]; circular dielectric spectroscopy may also be appropriate for GPCR functional measures.[49] Cell microarray technology may offer an alternate approach

to measurement of direct ligand–receptor interaction, although at the present time, this requires labeling of the test compound with, for example, radioactive isotope and luminescent or antigenic tags, and is limited to targets expressed on the cell surface. This technology, which uses ink jet printing technology to transfect discrete groups of cells within a monolayer cultured on glass slides, each with a vector encoding a unique protein, was successfully used to identify the human endothelial protein C receptor as a key target in *Plasmodium falciparum*-induced malaria from an array of 2505 cell surface proteins.[50]

2.04.2.2 Simple Cellular Models

Simple cellular models fall into two categories: First, those addressing individual molecular targets in a whole cell (eg, cell-based kinase assays, whole-cell GPCR functional assays, and reporter gene assays) may be grouped into the preceding category of *in vitro* pharmacological profiling by single-target screening. The second category of simple cellular models uses whole cells as models of functional or pathway end points where the action of a test compound may be mediated by a number of different mechanisms that may not be readily distinguished. In essence, a toxicologic end point is defined for which it is intended that the effects of test compounds in single cells will reflect the effect in whole tissue or organism. One of the common applications of simple cellular models is the prediction of hepatic toxicity since drug-induced liver injury manifests in a range of different phenotypes with a number of different potential underlying mechanisms.[51] Isolated primary hepatocytes have been used for many years as the gold standard *in vitro* test for hepatotoxicity.[52] Typically, some measure of cytotoxicity is used as an end point, for example, membrane permeability by DNA stain or depletion of metabolites such as ATP after exposure of test compound for 24–48 h. However, isolated primary hepatocytes cultured in monolayers experience changes in morphology and gene expression toward a more dedifferentiated phenotype, which change intracellular metabolism, cell–cell interactions, and cell integrity.[53] These changes may underlie some of the limitations in the ability of these assays to detect some hepatotoxins.[54] The challenges of obtaining and culturing primary cells, coupled with low sensitivity of cytotoxicity assays (even though specificity is generally very good, $>80\%$[54]), have encouraged exploration of immortalized cell lines. Human hepatocellular carcinoma-derived cell lines such as HepG2 and HepaRG are cheaper and easier to culture. However, their liver-like morphology and function are more removed from the whole organ than primary cells, and these cell lines also show very limited sensitivity: one study reported 6–13%,[55] although again specificity is generally good. Hepatotoxicity is a good example of a multifactorial end point for which very simple models are insufficient to provide reliable prediction of the *in vivo* toxicity.

For some cardiovascular risk assessments, single-cell analyses show promise. For example, human-induced pluripotent stem cell-derived cardiomyocytes (iPS-CM) provide a model for arrhythmia and QT interval prolongation. Guo and colleagues[56] defined sensitivity and specificity of $>80\%$ for both of these end points using cellular impedance to quantitate the effects of 88 reference compounds on beat rate and rhythm. Despite this success, it must be noted that iPS-CM are not perfect replicas of adult cardiomyocytes, with perhaps the most noticeable difference being spontaneous beating in iPS-CM not found in isolated adult cardiomyocytes.[57]

2.04.2.3 Complex Cellular Models

One of the key limitations of simple cellular models is the lack of physiologically relevant cell–cell interaction. Culturing one or more cell types together in 3-D, rather than as monolayers, offers opportunities to explore more complex biology. Perhaps the simplest of the 3-D models is the culture of cells together as spheroids in which cells aggregate into small (up to $\sim 600\ \mu M$) spherical clusters. These spheroids, which are long-established tumor models useful in drug discovery, provide a microenvironment of self-secreted extracellular matrix and generate inherent metabolic and proliferative gradients (see[58] for review). Ramaiahgari and colleagues[59] have successfully cultured HepG2 cells in spheroids that appear to differentiate to develop hepatic phenotypes including storage of glycogen, transport of bile salts, and the formation of structures resembling bile canaliculi and increased expression of albumin, urea, and xenobiotic transcription factors. This differentiated state can last for up to 28 days and has been shown to be sensitive to a small number of known hepatotoxins. Similarly, primary human hepatocytes in 3-D culture are more sensitive to acetaminophen than 2-D monolayers,[60] although a thorough evaluation of the sensitivity and specificity of these cultures as a model of hepatotoxicity is yet to be published.

Further physiological approximation of an *in vivo* functionality can be achieved for some systems by coculturing different cell types. For example, a liver model with microscale architecture and optimal stromal interactions (micropatterned cocultures [MPCCs]) has displayed phenotypic stability for several weeks *in vitro* as assessed by major liver-specific functions, and gene expression has been developed.[61,62] In MPCCs, primary hepatocytes are patterned onto extracellular matrix domains of optimized dimensions and then surrounded by 3T3-J2 murine embryonic fibroblasts. This model was found to be somewhat more sensitive than monoculture of primary hepatocytes in predicting hepatotoxicity with a sensitivity of around 50% at a specificity of 90%.[63]

A different take on complex cell systems has been described by Plavec and colleagues[64] who developed a test and data analysis system termed biologically multiplexed activity profiling (BioMAP). This system, originally described as a method for analyzing biological processes associated with endothelial cell responses to inflammatory stimuli, involves the culture of primary human endothelial cells under a number of different conditions with a select set of stimuli (cytokines such as TNF-α and IL-1β) and with select overexpression of genes in pathways of interest (eg, TNF receptors, MEK1 kinase, RAF, and PI3K). The response of the cell systems to stimulus and/or test compound is measured by ELISA, detecting changes in the expression level of specific proteins in the pathways of interest (eg, VCAM-1, E-selectin, and CXCL8). Using this system, relationships between pathways

and responses were built, for example, in endothelial cells expressing constitutively active *MEK1* or *MEK2*, the protein expression profiles were similar in cells treated with IL-1β and TNFα but different from those stimulated with INFγ or unstimulated cells. Berg and colleagues[65–67] have since expanded the range of cells and biological pathways that are able to be interrogated to include human primary cells from the endothelial system, bronchial cells, smooth muscle cells, fibroblasts, and others. Most recently, this system has been used to screen 776 diverse environmental and industrial chemicals as part of the US Environmental Protection Agency's ToxCast program.[68] Using a combination of 8 primary cell lines and 87 measurements per test compound concentration, a detailed fingerprint of the effects of test chemicals has been built in the BioMAP system with end points potentially relating to cardiovascular and respiratory diseases, inflammation, dermatitis, and oncology, among others. Initial success has been reported both in clustering compounds by fingerprint and known mechanism, such as mitochondrial toxins, and in identifying known and suspected activities such as the association between MAP kinase inhibitors and skin rash. The future value of such a data set is dependent on the quality of annotation that can be associated with each compound: clustering by bioassay fingerprint allows association of novel compound to already screened compounds; if these latter compounds share known toxicologic effects, then predictions may be made about the potential toxicity of the novel compound.

2.04.2.4 Organ Chips

The current cutting edge of cell-based models is in the generation of complex multicellular 3-D structures with integrated microscale structure and microfluidics, "organs-on-chips" (so called because the microengineering technology involved in the construction of the structures is analogous to that used in generating computer microchips). Models of bone, brain, breast, eye, gut, liver, lung, and kidney tissues have been generated (reviewed in[69]). These microengineered models generate the opportunity to explore multicell interactions in the context of organ-relevant spatial and structural constraints and in the presence of mechanical stresses. For example, in a "lung-on-a-chip" model,[70] human alveolar epithelial cells and human pulmonary microvascular endothelial cells were cultured on opposite sides of a porous, flexible membrane made of poly(dimethylsiloxane) (PDMS) contained in a microengineered structure able to be stretched to mimic inspiration and with microchannels able to deliver air or liquid to each face of the membrane. Beyond confirming basic functional interactions formed between the alveolar epithelial and endothelial cells, Huh and colleagues[70] showed that the "organ" was able to respond to the presence of a bacterial pathogen, *Escherichia coli*, introduced to the alveolar face, by recruitment of neutrophils circulating in the endothelial channel that migrated to the alveolar channel and engulfed the pathogen.

While the organ-on-a-chip technology is still in its early stages, many of the systems are being characterized to support toxicologic studies. One example of this is the generation of a biomimetic of the human kidney proximal tubule.[71] Jang and colleagues generated two microfluidic channels separated by a PDMS membrane on which human kidney proximal tubule epithelial cells were seeded. An apical channel allowed flow of culture medium to provide shear stress analogous to the lumen of the proximal tubule, while the opposing channel was filled with culture medium to mimic the interstitial space. The resulting organ model was sensitive to the known nephrotoxin cisplatin (reviewed in[72]) as measured by LDL release and by apoptosis, and this toxicity was antagonized by cimetidine, an inhibitor of the OCT-2 transporter by which cisplatin is taken up by proximal tubule cells.

Connection of multiple organs-on-chips has already been achieved, giving the opportunity to study ADME of drugs across different organ systems. Such linkage is also relevant to toxicology in detecting effects of metabolites or the active parts of prodrugs. In one example, Viravaidya and colleagues[73] connected liver and lung chips and administered naphthalene that was converted by the liver compartment to its reactive metabolites, 1,2-naphthalenediol and 1,2-naphthoquinone. These metabolites circulated to the lung compartment where it was possible to detect a reduction in glutathione levels as a measure of toxicity.

2.04.2.5 Isolated Tissues and Organs

Isolated perfused organs have long been used as pharmacological tools to investigate the MOA of drugs (see[74] for review), and many different organs have been successfully isolated and maintained in perfusate allowing measurements of function to be made. In toxicology, one of the more common isolates is the heart, isolated and maintained by a technique pioneered by Langendorff (reviewed in[75]). Many functional end points relevant to safety pharmacological evaluation of drug effects may be measured including left ventricular pressure, contractility, perfusion pressure, electrograms delivering the equivalent to standard surface ECG wave form (PR, QRS, and QT intervals), and monophasic action potential. One particularly successful application of the isolated rabbit heart by Hondeghem[21] was validated in two studies of clinically characterized drugs and correctly classified arrhythmogenic and nonarrhythmogenic compounds in 14 of 14[76] and 49 of 52[77] cases.

Working with isolated tissues is not a high-throughput screening methodology; the key advantage is the rich detail of conserved physiology available when testing compounds for effects on an organ or tissue. The closest to the "whole human" one may reasonably expect to achieve is by using isolated human tissues. This offers a species-relevant model, overcoming many concerns of differential sensitivity between species, but can present a challenge in trying to assure that the tissue donor is a reasonable representative of a desired population (eg, healthy versus diseased state), the tissue is in a representative condition, and there is no contamination of drugs. Sources are typically organs residual from surgery (diagnostic or cosmetic procedures), unused organs from transplant surgery, or tissues retrieved post-mortem. It should be noted that in many countries, acquisition, storage, and use of human tissues for research are very highly regulated (eg, Human Tissue Act 2004, the United Kingdom; Code of Federal Regulations Title 21 Part 1271, the United States).

2.04.2.6 Animal Models: How Good Are They?

The translatability of animal models to human outcome has been the subject of detailed scrutiny with particular focus on animal models of disease used to test the efficacy of candidate drugs and in the field of nuclear medicine.[78–81] Successful translation rates appear to vary from abject failure of 0% for prediction of vaccination development against acquired immunodeficiency syndrome by nonhuman primates,[80] to low 5% for oncology models to 20% for cardiovascular disease.[79] Martic-Kehl and colleagues[78,79] suggest that some of the reasons for low success rates of translation may be in the design, execution, and analysis of animal experiments, rather than inherent issues of species difference or inappropriate biology.

One of the key studies addressing the predictivity of animal models for human toxicology (as opposed to efficacy of candidate drugs) is presented by Olson and colleagues[82]: a summary of data shared by multinational pharmaceutical companies and the output of an International Life Sciences Institute (ILSI) meeting in 1999. This study concludes that for 150 compounds and 221 human toxicities, the true-positive concordance rate was 71% across rodent and nonrodent species, which at first may suggest that animal models are a reasonable predictor of human toxicity and have a success rate far in excess of animal models of disease. However, the study was unable to analyze a full matrix of true- and false-positive and negative data (refer to **Table 1** for definitions): only compounds that were found to be toxic in humans were considered and compared with preclinical animal data. No compounds were assessed that had been shown to be nontoxic for a given end point in humans; thus, the ability to detect false-negative and true-negative compounds was not assessed. This and other studies have been heavily criticized by Shanks et al. in a paper published in 2009,[83] questioning the statistical methods employed, inclusion criteria for data, and the retrospective approach. In the absence of a definitive analysis, it is very unlikely that regulatory authorities will abandon the requirement for *in vivo* preclinical testing of candidate drugs, especially for the assessment of general (whole-body) toxicologic effects. However, as more *in vitro* systems are validated against clinical data for specific end points, the predictive power of integrated preclinical risk assessments will increase.

2.04.3 OMICS Technologies

2.04.3.1 Genomics

The concept that changes in gene expression may be correlated with toxicologic events induced by xenobiotics was recognized in the 1990s,[84,85] and the profiling of gene transcription in toxicology is termed toxicogenomics.

The technology underpinning the advent of toxicogenomics is the DNA microarray: substrates typically of silica, plastic, or glass onto which thousands of DNA probes are anchored, representing either a set of genes of specific interest or a sample of genes across the whole genome. Total RNA is extracted from the sample and used in reverse transcription as a template to synthesize cDNA. Either the cDNA is labeled with fluorophore and hybridized to the microarray chip or the cDNA is used to synthesize cRNA including biotinylated nucleotides to label the cRNA that is subsequently hybridized to the chip. After hybridization, the chip is washed to remove unbound molecules and visualized in a scanner to detect the bound nucleotide. The intensity of the signal is related to the extent of gene expression. Detailed technical descriptions are beyond the scope of this article and the reader is referred to existing publications.[86,87] Expression of genes is determined either in relation to other genes in the same experiment (one-channel analysis) or relative to control or reference samples (two-channel analysis).[88,89]

The majority of toxicogenomics studies are conducted using the rat as the most common laboratory small species with complete genome annotation. Studies typically use homogeneous tissues (eg, heart and liver) as these are most consistent in their transcriptome and so give more robust and reliable detection of expression changes; more heterogeneous tissues (eg, brain) with different cell types and different transcriptomes depending on regional location give greater challenges in resolving changes in signal.[90] While cultured cell systems offer homogeneity and simplicity and have been successfully used as model systems in toxicogenomics (eg,[91,92]), the advantage is also the limitation: the lack of interaction with the whole tissue or whole organism provides a major challenge in detecting specific toxicogenomics effects.

In common with the preceding discussion of molecular and cell-based technologies, the application of toxicogenomics has typically been to either characterize organ-specific toxicities (hepatotoxins, cardiotoxins, and nephrotoxins) or identify molecular mechanisms or pathways underlying a specific toxicity. For example, Waring et al.[93] have shown that global gene expression analysis could distinguish groups of hepatotoxins in both rat and cultured rat hepatocytes based on their MOA. Interestingly, Hamadeh et al.[94] found that for methapyrilene, gene expression changes correlated with histopathologic changes and preceded the observation of overt toxicity suggesting the potential to use shorter term studies with the same or increased sensitivity compared with traditional toxicology.

Using a set of 64 known nephrotoxic and nonnephrotoxic drugs, an expression profile of 35 genes was identified by Fielden and colleagues[95] as a signature of renal tubular degeneration in rats. This signature was validated with 21 test compounds: 7 of 9 nephrotoxins were correctly identified (2 false negatives) and 9 of 12 nonnephrotoxins (3 false positives). What makes the toxicogenomics approach unique in this application is that the change in gene expression was detected in samples from only three rats in each treatment group on day 5 of a 28-day repeat-dose study at which point no significant histopathologic evidence of renal tubular degeneration was found; traditional toxicologic end points were informative only after the 4 weeks of dosing.

Similarly, Thukral and colleagues[96] used a set of 4 known nephrotoxins to evaluate renal gene expression profiles in rats after 1, 3, and 7 days of dosing. The gene expression profiles were clustered by both the severity and the type of tubular degeneration found

pathologically. The profiles were used to generate a predictive model that was tested against the expression profiles of 28 compounds and found 82% sensitivity. The study also identified individual genes for which the expression profile changed in a time- and dose-dependent manner aligned to the progression of proximal tubular toxicity. Perhaps unsurprisingly several of these genes are transporters (*Slc21a2*, *Slc15*, and *Slc34a2*) that can offer potential biomarkers for renal toxicology.

Key to the utilization of predictive toxicogenomics is the development of reference databases of gene expression profiles: often, it is the changes in expression profiles of a number of genes together that represent modulation of toxicologically relevant pathways, rather than the expression profile of a single gene. However, the vast array of patterns that may result from treatment with a xenobiotic must be placed in an appropriate context: it is necessary to separate the expression changes relevant to the toxicity from those that are adaptive, compensatory, or unrelated to the toxicity. For example, decreased food consumption is a common adverse reaction to xenobiotic treatment and may have wide-ranging effects on standard toxicologic end points,[97] yet it may be secondary to a specific end point of interest. Generation of such databases requires not only reference compound profiles but also sufficient annotation of technological and biological information to appropriately contextualize the data sets. Several public and commercial toxicogenomics databases exist, such as those of Gene Logic, the Toxicogenomics Project–Genomics Assisted Toxicity Evaluation (TG-GATE) system (http://toxico.nibiohn.go.jp/english/),[98] Drug Matrix (https://ntp.niehs.nih.gov/drugmatrix/index.html),[99] the EU PredTox 6 initiative outcome (http://www.ebi.ac.uk/bioinvindex/browse_studies.seam),[100] and the IMI eTOX initiative (http://www.e-tox.net/).[101]

In 2005, the FDA issued a Guidance for Industry: Pharmacogenomics Data Submissions that described in broad terms how and when pharmacogenomics data should be submitted including the concept of a Voluntary Genomic Data Submission system, which is intended to enhance the learning of both sponsors and regulators in the exploration of this new technology.[102] Importantly, the guidance provides reassurance to sponsors that early/exploratory toxicogenomics studies would not result in negative regulatory consequences, thus providing a motivation to apply this technology and drive the field forward. There are opportunities to improve the sensitivity of toxicologic studies and to refine some current studies, particularly long-term carcinogenicity studies.[103]

2.04.3.2 Proteomics

Proteomics, as originally described by Wilkins et al. in 1996,[104] is the study of the protein complement of the genome, and of course, toxicoproteomics is the term now used to describe the study of the response of the proteome to toxicants.

Although a detailed technical description is beyond the scope of this article, the key technologies underlying toxicoproteomics are electrophoresis, chromatography, and mass spectrometry (MS) (see[105,106] for reviews). In essence, to study the proteome, total protein must be isolated from a donor cell, tissue, biological fluid, or organism. The proteins of interest must be solubilized in standard chemicals including urea, guanidine hydrochloride, detergents such as Triton X-100, and sodium dodecyl sulfate (SDS). Certain groups of proteins have differential solubility and so lend themselves to studies of subgroups by type, for example, cytosolic, membrane, or glycoproteins. Some very abundant proteins may be selectively removed from the sample by immunodepletion, that is, using antibodies to remove very abundant proteins (such as albumin, IgG, and IgA present in plasma), which might otherwise mask signal from proteins of lower abundance. The sample of soluble proteins is separated by 2-D electrophoresis, first by isoelectric focus and then by polyacrylamide gel electrophoresis. This results in a 2-D separation of proteins into spots that may be stained and visualized with, for example, Coomassie, silver, or fluorescent dyes. Typically, a control sample is compared against a treatment sample to identify patterns of spots that change in intensity. Identification of the protein constituents of the spots of interest is performed using MS of fragments of the proteins that have been digested with endoproteases such as trypsin. Comparison of the fragmented sequences against protein sequence databases allows identification of the original protein. Alternatively, proteins may be digested to peptides and then separated by liquid chromatography (LC), rather than gel electrophoresis, directly coupled to a mass spectrometer. Major advances in the throughput of MS and in data handling have facilitated the development of proteomics.[107]

In essence, toxicoproteomics and toxicogenomics share principles and aims in either studying broad responses to challenge or identifying biomarkers of toxicity and are very complementary approaches. For example, it is suggested that around 50% of the measured changes in mRNA correspond to changes in expressed protein[108–110] such that proteomics may provide a level of filtration of findings from genomic studies. Toxicoproteomics also shares with toxicogenomics the requirement to filter out "background" or "nonspecific" responses. For example, Wang and colleagues[111] identified a list of 44 proteins for which a change in expression is generally detected regardless of species or experimental objective and a list of 28 protein families commonly detected in different studies. These appear to be generally related to stress response, protein stabilization, and homoeostatic control.

Specific application of toxicoproteomics has tended to focus on common organ-level toxicities such as liver, kidney, and heart in an effort to characterize the response of the proteome to a small number of specific toxins to identify markers of toxicities in these organs and understand underlying mechanisms. Success has been modest thus far; for example, Van Summeren and colleagues[112] identified 86 proteins differentially expressed in HepG2 cells in response to the known hepatotoxin cyclosporin A. However, the pattern of change was unable to distinguish two other hepatotoxins, amiodarone and acetaminophen, from the control sample, though it is unclear whether this is a limitation of the technique or the choice of HepG2 cells as a model.

Proteomic assessment of the whole liver from mice treated with acetaminophen identified 35 proteins changed by treatment with this hepatotoxicant[113] including proteins known to interact with the metabolite n-acetyl-p-benzoquinoneimine. Similarly, 33 protein targets of bromobenzene were identified as targets of this compound,[114] indicating that proteomics can identify changes in the proteome relevant to specific toxicities.

In one of the few proteomic studies to use a relatively large number of compounds, Yamanaka et al.[115] measured changes in the proteome of rat livers after 28 days of dosing with 63 carcinogenic and noncarcinogenic compounds, identifying a set of 30 changes that showed >70% concordance in classification of the reference compound set, offering the potential to create predictive analyses of carcinogenicity based on proteomic measurements. Similar proteomic studies of a large number of reference compounds of known effect/no effect in order to generate predictive tools are currently lacking.

2.04.3.3 Metabolomics

In a broad sense, metabolites are endogenous chemical entities other than DNA, RNA, proteins, and polymeric saccharides, and the measurement of such molecules has come to be termed metabolomics, although other terms including metabonomics and metabolic profiling have also been used.[116,117] Typical metabolites inspected by metabolomics are small molecules including nucleic acids, amino acids, small peptides, lipids, and sterols. The analytic tools in the metabolomics fields are naturally those that are effective in small-molecule analysis. Since metabolomics studies metabolite modulation in one or a few pathways, if not on the system level, an ideal analytic strategy should permit accurate identification and quantification of multiple interesting metabolites from biological matrices including cells, tissues, and blood.

Metabolomics studied by nuclear magnetic resonance (NMR)[118] is typically more stable and has smaller variability across samples and labs than MS. While NMR is a versatile and powerful tool, the sensitivity of NMR can be orders of magnitude lower than MS.[119] MS can be used by itself in some metabolomics applications, as in the direct infusion method for lipidomics[120]; but more often, MS is coupled online to separation methods, such as gas chromatography, LC, and capillary electrophoresis, thanks to the advance in interfacing technologies such as electrospray.[121] Separation delineates the mixture of metabolites along the time axis and reduces the complexity of the copresent metabolites at any time point. This reduces the possibility of ion suppression, which in many applications is essential to improve the sensitivity of detection and quality of quantification for MS quantification.[122] In addition, under the same chromatographic method, a metabolite of the same molecular structure is eluted at the same retention time (RT); thus, RT can be used as an orthogonal matrix for metabolite identification.[123] A so-called untargeted MS-based strategy scans and measures the entire range of molecular weight accurately.[124] Metabolites are identified by searching the measured molecular weight against metabolite database. Because the identification is solely based on molecular weight, isomeric metabolites or, in practice, those of similar molecular weights cannot be differentiated. To increase the reliability of metabolite identification, fragmentation patterns may be obtained by additional LC/MS experiment and compared with standard spectra generated previously. An alternative approach, the so-called targeted method,[125] does not look for a comprehensive coverage of metabolite space, but rather is focused on a subset of metabolites for which standards are available. Using metabolite standards, knowledge such as molecular fragmentation pattern and RT can be obtained experimentally. The sensitivity of detection and the reliability of identification of metabolites can be improved by incorporating this knowledge to build analytic methods. For these reasons, although limited to a subset of metabolites, targeted metabolomics has enjoyed great success in recent years.[126–129]

Small molecular metabolites can be indicators of disease progression, and discovery of disease-relevant biomarkers is always one of the top applications for metabolomics. As examples, the concentration of creatinine has been used to indicate renal dysfunction,[130] and a panel of metabolites in plasma is used for rare disease diagnostics for newborns.[131] Since metabolites are the end products of biochemical reactions, they reflect the working status of protein machinery. The functionality of protein machinery depends not only on the protein sequence, expression level, and posttranslational modification, traditional topics for proteomic studies, but also on factors such as the folding and binding partners, which can be extremely difficult to measure at the system level. Thus, the change in the metabolome may be most indicative of a phenotypic change, and metabolomics is well positioned to study the efficacy and side effects of drug treatment. In this regard, metabolomics in toxicology and the so-called pharmacometabolomics[132,133] have coincided,[134] with the latter focusing more on the efficacy but not excluding side effects.

While change in the metabolome is indicative of phenotypic change, the understanding of MOA often cannot be derived from metabolomics alone. The technical challenge is that no method can measure the entire metabolome accurately. In addition, intricate knowledge of how a metabolite interacts with the biological system is needed to link the change of metabolite level to MOA. A metabolite may stand at the intersection of several pathways, its production or transportation may be modulated by other proteins or other metabolites, it may inhibit or activate enzymes, and it may bind to translational factors to modulate several pathways at the same time. Databases such as KEGG (Kyoto Encyclopedia of Genes and Genomes)[135] capture knowledge of how metabolites interact with enzymes; however, our knowledge about metabolites and metabolism is far from complete, as has been demonstrated in many publications in the active field of cancer metabolism[136,137] and immunometabolism.[138,139]

Despite these challenges, metabolomics, in combination with other technologies, has been used successfully to elucidate MOA. In a metabolomics study of prostate cancer, sarcosine was found to be an important metabolic intermediary of prostate cancer progress.[140,141] Using metabolomics profiling, elevated adenosine was found in the blood of humans with sickle cell disease, inducing 2,3-diphosphoglycerate, an erythrocyte-specific metabolite that decreases the oxygen-binding affinity of hemoglobin.[142] In another study, the previously unidentified mechanism of GMX1778 antitumor activity was found to be due to inhibition of NAD+ biosynthesis.[143] In a recent study, metabolomics was used with transcriptomics to uncover significant alterations in the nucleotide metabolism networks of pink1 mutant flies, which leads to the conclusion that mitochondrial dysfunction and neurodegeneration of Parkinson's disease may be protected against by enhancing nucleotide metabolism.[144]

There are also a few examples where metabolomics has been applied to elucidate a toxicologic MOA. Ethylene glycol monomethyl ether was revealed to induce toxicity by inhibiting the flavoprotein dehydrogenase enzyme family.[145] The source of

drug-induced acute kidney injury was found via the interaction with the microbiota.[146] In another study, *in vitro* and *in vivo* models were used to evaluate epigenetic toxicity of trichloroethylene at the genetic, transcriptomic, metabolomics, and signaling levels.[147] Irinotecan (CPT-11), a first-line anti-colon cancer drug, was found to suppress IL-10 expression by causing metabolic changes in the composition of bile acids.[148]

As with other omics techniques, in order to generate predictive tools applicable to toxicology, the key to success is the generation of an annotated reference database relating known compounds, toxicologic end points, and metabolomics profiles. Two notable attempts have been made: the Consortium for Metabonomic Toxicology (COMET)[149] generated NMR profiles of the urine and blood serum of rats used in acute toxicity studies dosed with 147 compounds, with particular focus on liver and kidney toxicants of interest to pharmaceutical development. The database was annotated with histopathologic data as the reference for toxicity. Lindon reported that, using a subset of the compounds as a test set, the database identified the main organ of toxicity "in over 50% of cases" and that in 5% of cases, an incorrect prediction was made.[149] Subsequently Ebbels and colleagues[150] reported a model built on this database with sensitivities of 67% and 41% and specificities of 77% and 100% for hepatic and renal toxicity, respectively.

BASF have generated a database, MetaMapTox®, of the effects of over 500 reference compounds (chemicals, agrochemicals, and drugs) in 28-day rat toxicology studies including metabolomics profiles generated by MS and claim to be able to distinguish metabolomics profiles associated with different target organ toxicities.[151–153] Although no broad assessment of the predictivity of the database is provided, case studies are available in which the database correctly predicts the presence/absence of renal toxicity for 5 agents.[154]

Some nontoxicologic signatures can be found in metabolomics. For example, Saito and colleagues[155] describe that differential lipid profiles in rats discriminated by food intake and as described for both genomics and proteomics may relate to nontoxicologic effects.[60] Similarly, age, diet, diurnal, and estrus cycles all give measurable changes in metabolic profiles in urine.[156–158] A list of "usual suspects," that is, metabolites frequently found to change in response to toxicant administration, regardless of class, is given by Robertson,[116] analogous to the changes in 44 proteins found to occur frequently in proteomic analyses, described by Wang et al.[111] It is important to be able to distinguish and suspend where necessary these potentially distracting signatures in order to focus on the most predictive data sets, although it must be remembered there is no indication that these effects are artifactual.

2.04.4 Predictive Genetic Toxicology

Genotoxicity assessment provides mechanistic evidence for a major pathway of cancer induction, that is, by genomic alterations that lead to oncogene activation or tumor suppressor gene inactivation. Genotoxicity assessment is an interesting example of predictive toxicology where two tiers of assays are employed. While a thorough assessment of potential for genotoxicity is prescribed in regulatory guidance (ie, assays to predict effects in humans), low throughput and expense have driven the evolution of simpler, higher throughput assays employed earlier in the drug development process that are well correlated with the regulatory assays.

A scientific and regulatory framework for genotoxicity testing in the development of pharmaceutically active ingredients for human drugs is well established. ICH guidance S2[159] focuses on two fundamental areas of genotoxicity testing: the identification of a standard set of suitable and predictive assays to be performed to support clinical trials and drug registration and guidance for result interpretation (eg, extent of confirmatory experimentation). The purpose of the document is to recommend an optimized standard genetic toxicology battery for the prediction of a potential human risk and to provide guidance on the interpretation of results, with the ultimate goal of improving risk characterization for carcinogenic effects that have their basis in changes in the genetic material.

However, testing for genotoxicity extends to many other chemical areas (cosmetics and industrial or environmental chemicals), and a broader set of important guidelines include the OECD technical guidelines for the testing of chemicals, which describe the specific tests that are used routinely, such as OECD TG 471, Bacterial Reverse Mutation Test[160]; TG487, *In Vitro* Mammalian Cell Micronucleus Test[161]; TG474, Mammalian Erythrocyte Micronucleus Test[162]; and TG 489, *In Vivo* Mammalian Alkaline Comet Assay.[163]

Genotoxicity testing may comprise regulatory testing, exploratory testing, screening, and special strategies for batch/impurity/metabolite qualification. Here, we will focus on screening approaches to predict the regulatory assays as covered by ICH guidance S2.

2.04.4.1 The Standard Genotoxicity Testing Battery

According to ICH S2, the standard test battery of regulatory assays consists of the assessment of mutagenicity in a bacterial reverse gene mutation test (Ames test) and the evaluation of genotoxicity in mammalian cells *in vitro* and/or *in vivo* as covered by two options: a cytogenetics test for chromosomal damage (chromosome aberration test, micronucleus test, or a mouse lymphoma TK test) and an *in vivo* test for chromosomal damage in rodent hematopoietic cells (usually the micronucleus test in bone marrow or peripheral blood cells). Alternatively, leaving aside the mammalian *in vitro* option, an *in vivo* assessment of genotoxicity using two different assays can be conducted. Usually, this would include a micronucleus test in rodent hematopoietic cells and a second *in vivo* assay addressing DNA damage in a relevant organ: either the single-cell gel electrophoresis ("comet") assay or, more generally, an alkaline elution assay or the *in vivo* transgenic mouse mutation assay.

A common testing strategy for pharmaceutical products is the conduction of an Ames test and an *in vitro* micronucleus test, later to be complemented by an *in vivo* micronucleus test following option 1 of the ICH S2 guidance, with oncology compounds

addressed slightly differently (reduced genotoxicity testing for lifesaving indications, based on a risk–benefit approach). A requirement is that all tests conducted to support clinical testing or marketing authorization adhere to the principles of good laboratory practice (GLP).

The standard test battery may consist of an Ames test in 5 strains of *Salmonella typhimurium* (TA97a, TA98, TA100, TA102, and TA1535). The objective of the Ames assay is to evaluate the mutagenic potential of a test item by measuring its effect on the histidine-requiring bacterial strains to revert to histidine proficiency, which is a reliable method for characterizing compounds with regard to induction of mutagenic activity at the nucleotide level (such as point mutations, frameshifts, and small deletions). The micronucleus test in primary human lymphocytes or TK6 cells serves as an *in vitro* test for the assessment of chromosomal damage, which is an essential part in the characterization of the genotoxic potential of a test compound. For this purpose, the induction of micronuclei in cultured cells has shown to be a sensitive and reliable alternative to the time-consuming metaphase analysis.[164] Micronuclei are generated upon cell division, from parts of chromosomes or whole chromosomes that are lost from the nucleus during mitosis, and they can be specifically detected as extranuclear particles. As a measure for numerical and structural chromosome aberrations, the micronucleus test consists of determining the frequency of micronucleated cells in a representative fraction of cells, which is indicative for a clastogenic and/or aneugenic effect of the test item *in vitro* and *in vivo*. In order to cover potential metabolites of the tested compounds, in all *in vitro* tests, a modification using a metabolic activation system (normally the so-called S9 mix from rat liver) is included.

The micronucleus test in the bone marrow or in the peripheral blood of rats from a 4-week general toxicology study, analyzed by flow cytometry, provides the necessary information *in vivo*.[165]

Besides the well-established micronucleus test in rodent bone marrow that has been an integral part of industrial genotoxicity testing for many years,[166] the comet assay *in vivo* has emerged as the second *in vivo* test to further elucidate potentially clastogenic mechanisms by measuring DNA strand breaks in isolated cells (DNA migration in an electric field).[167] Before the revision of ICH S2(R1), the comet assay was mainly used as a mechanistic assay to follow up on *in vitro* and/or *in vivo* positives. Now, option 2 recommends the assay as a second *in vivo* genotoxicity test, for example, to follow up on *in vitro* positive genotoxicity results (option 1) or as a second *in vivo* test parallel to the *in vivo* micronucleus test (option 2).

The *in vivo* alkaline comet assay is especially suitable to assess genotoxic hazard in different organs because the assay can be conducted in any organ or cell type from which a single-cell suspension can be obtained. Usually, the liver as a metabolically active organ, areas of the gastrointestinal tract such as the jejunum and duodenum as site-of-contact tissues, and blood for systemic exposure are considered as standard organs. However, other target organs can be evaluated as well.

2.04.4.2 The Two-Strain Ames Screen

A genotoxicity testing strategy that integrates screening to predict the outcome of the regulatory assays (as outlined in the preceding text) can consist of an Ames screen and an *in vitro* micronucleus test, either in primary lymphocytes or in a cell line. For the Ames screen, designed to predict the 5-strain GLP version of the Ames test, often only the two strains TA98 and TA100 are used.[168] This strategy has also been adopted by Novartis where data show that all mutagenic compounds were identified by just using TA98 and TA100. We have found that a positive result in any of the other three strains only occurs for around 20% of synthesis intermediates showing structural alerts [unpublished Novartis internal data]. In order to further minimize test compound consumption, a miniaturized 6-well format was introduced, with which Novartis has accumulated a large database confirming the ability to detect genetically active compounds of most chemical classes with 100% sensitivity while minimizing the amount of test compound and increasing the throughput.

2.04.4.3 The Micronucleus Test *In Vitro*

Similar to the 2-strain Ames screen, the *in vitro* micronucleus test using adherent or suspension cells, designed to predict the GLP version in human lymphocytes, has evolved to include fully automated liquid handlers, flow cytometry, and image analysis.

Immortalized cell lines such as V79, CHO, and TK6 cells have been used routinely in many laboratories for conducting chromosomal aberration studies *in vitro* for many years. They have been found to be genetically stable and easy to handle and thus well suited for large-scale routine screening, with an excellent correlation between *in vitro* chromosomal aberration and *in vitro* micronucleus data in various cell lines.[169] Automated sample analysis[170] further helped to establish a simple and reliable screen for genotoxic effects, more than doubling the compound screening throughput. In order to reduce the number of positive results due to the oversensitivity of rodent cell lines such as V79, CHO, and mouse lymphoma L5178Y, when compared with the results of chromosome aberration tests in human lymphocytes, we have found that the use of the human p53-proficient TK6 cell line provides sensitivity and specificity for predicting chromosome aberration or micronucleus test in human lymphocytes of $>80\%$ [Novartis, unpublished data].

2.04.5 Physicochemical Properties Link With Drug Promiscuity and *In Vivo* Toxicologic Outcomes

Pharmaceutical companies require drug candidates to have a favorable balance of pharmacological, pharmacokinetic, and physicochemical properties. Undesirable physicochemical properties can lead to the drug having a "promiscuous" profile, which refers

to activity against multiple targets for a single molecule including nontherapeutic "off-targets."[171,172] Of course, it must be remembered that not all promiscuity is "bad"; many central nervous system (CNS) disorders such as depression, schizophrenia, and bipolar disorder present with complex pharmacology, and treatment is achieved through polypharmacological drugs such as clozapine, risperidone, and haloperidol (see[173] for a review). However, outside of the CNS, promiscuity is a major safety concern, and there is a drive within the pharmaceutical industry to detect an unfavorable profile as early as possible in the drug discovery process as it has been recognized that undesirable off-target activity profiles can prevent the development of drug compounds and even in some cases lead to market withdrawal when discovered after the drug has been approved.[9] Gaining a much better perspective and understanding of the potential safety profile at an earlier stage in the drug discovery process is essential. Physicochemical properties such as lipophilicity, size, and polarity are routinely examined in relation to drug disposition and ADME characteristics; these parameters should also be studied closely with a view on potential drug promiscuity and inherent toxicologic liabilities. Insight into property–promiscuity relationships can lead to an early recognition of potential toxic liabilities in a series and can be extremely useful in the optimization stage.

We will focus on the physicochemical parameters lipophilicity and ionization state and demonstrate how these factors combined aid in a better prediction of drug promiscuity. We will also introduce the concept of combining in one methodology the ability to rank order potential drug promiscuity by phospholipid affinity, which is a combination of both lipophilic and electrostatic interactions, and describe how this correlates with drug promiscuity.

2.04.5.1 Lipophilicity and Promiscuity

Lipophilicity is generally recognized as an important parameter of potential promiscuity, and many published property–promiscuity analyses report that drug promiscuity increases with lipophilicity. Both Hopkins et al. and Peters et al.[174,175] found that maximum promiscuity is observed for compounds when cLogP hits a threshold higher than 2.5–3. This trend can be a concern as increasing the lipophilicity of a molecule can often increase the potency of the molecule at the primary target; however, this may be offset with an increase in off-target promiscuity. Waring and Johnstone[176] concluded that the overall trend for increasing hERG potency is also driven by lipophilicity. Inhibition of the hERG potassium channel can cause delayed cardiac repolarization, which, in a very small percentage of people, is associated with a potentially fatal cardiac arrhythmia, TdP. This has resulted in a number of drugs being withdrawn from the market and represents a significant regulatory hurdle for new molecular entities in development.[177] A review of the physical properties of compounds interacting with this channel has shown that there is a low probability of lipophilic bases achieving an acceptable hERG potency.[176]

2.04.5.2 Basicity and Promiscuity

For a given lipophilicity, basic compounds tend to be more promiscuous.[178] An example of increasing basicity, while maintaining similar lipophilicity, can be found in the gentamicin series of aminoglycoside antibiotics. Increasing nephrotoxicity is seen with an increasing number of basic groups in the aminoglycoside molecule. This is due to increased binding of the drug to the anionic phospholipids on the brush border of the proximal tubular cells of the kidney and subsequent accumulation in secondary lysosomes. These cells become necrotic after repeated dosing as the time required for the tissue concentration to decrease after treatment termination is 5–6 days.[179] This is an example where increasing basicity while maintaining lipophilicity is associated with risk of compound accumulation in tissues.

When the analyses of a large data set of promiscuous molecules are further reviewed, it becomes clearer that the majority of promiscuous compounds are strong bases and bear a positive charge at pH7.[171] This research correlates well with an analysis by Peters et al.[175] and also a study by Lounkine et al. of promiscuity of 656 marketed drugs that concluded that promiscuous drugs are often both hydrophobic and cationic.[180] The link between increasing adverse *in vivo* outcomes and increasing lipophilicity and pKa for basic molecules was also recently published.[181] There is clear evidence that compounds with a cLogP > 3 and containing a basic center with a $pK_a > 8$ have physicochemical properties that can lead to phospholipidosis,[181] where intracellular accumulation of phospholipids and vacuole formation occur. A strategy to move drug design away from the physicochemical property space of these phospholipidosis potentiators is exemplified by disobutamide, a dibasic lipophilic molecule modified to reduce the risk of vacuole formation.[182]

2.04.5.3 Phospholipid Affinity: Incorporating Both Lipophilic and Ionic Interactions

Accumulation of drug in the cell membrane can be undesirable, not only reducing the ability of the drug to reach its intended target but also resulting in toxicologic consequences such as phospholipidosis or nonspecific modification of the function of membrane proteins. Cationic amphiphilic compounds are known to sequester into cell membranes, and some phospholipogenics cause liver toxicity in preclinical species such as rats[183–187] and dogs.[187] It has been documented previously that the phospholipogenic potential of drugs can be predicted by chromatographic methods including the phosphatidylcholine affinity retention factor.[188] The chance of a phospholipidotic response increases with increasing affinity for phospholipid. A statistical correlation has been found between the measured chromatographic retention factors of 36 drugs and their phospholipidosis-inducing potential.[187] It has also been demonstrated that the extent of nonspecific tissue binding of ligands used for positron emission tomography can be predicted by the retention factor in phospholipid affinity chromatographic methods,[188] which is additional information to suggest that higher

phospholipid affinity may correlate with increased risk of drug promiscuity. Finally, an in-house study at Novartis was compiled for a large data set (550) of marketed drugs and candidate drug molecules. Here, the HPLC phospholipid affinity was determined by an immobilized artificial membrane (IAM) assay, a method that incorporates not only lipophilic but also ionic contributions of test compounds.[189] In this study, there was much stronger correlation with promiscuity than lipophilicity alone as shown in Fig. 4. High values of chromatographic hydrophobicity index using IAM (CHI $IAM_{7.4}$) (>60) serve as a cautionary flag for compound promiscuity.

Physicochemical properties in small-molecule drug discovery programs are controllable by medicinal chemistry methods, and some measure of these properties can be calculated before chemical synthesis. In drug discovery, early lead generation approaches often start with small, more hydrophilic molecules but frequently expand to larger more hydrophobic and basic molecules to drive potency at the primary target. The suboptimal physicochemical properties that can arise during this stage need to be taken into account when balancing improvement in potency with promiscuity and potential toxic liabilities. Lipophilicity and ionization state of the molecule are important parameters that can be adjusted to reduce drug promiscuity and the associated safety risk. It has been demonstrated that a simple IAM HPLC phospholipid affinity measurement can incorporate the ionic and lipophilic interactions between drugs and tissue and is an efficient experimental method to rank order molecules in respect to nonspecific binding to tissue, drug phospholipidosis, and drug promiscuity potential.[188]

2.04.6 *In Silico* Approaches to Predictive Toxicology

Traditional predictive toxicology has used molecular structure information collected by experts to build knowledge-based rules or toxicophores to alert for possible toxicity end point. This approach is represented by systems like DEREK.[190] Here, we focused on computational algorithms that use 2-D or 3-D structural information along with biological activity data to generate statistical models for risk assessment, implemented with tools such as MultiCASE, MDL, BioEpisteme, and Leadscope.[191]

Consistent with the experimental tools for drug candidate risk assessment described in this article, available *in silico* predictive tools range from single- or multiple-target models to system biology approaches, from cell-based toxicity end points to whole system organ models.

For specific target models, it is appropriate to start with analyzing hERG, which is a well-recognized safety target linked to a cardiac arrhythmia called TdP. hERG blockade has been modeled using a variety of different techniques and continues to serve as a good example of how different modeling approaches can complement each other.

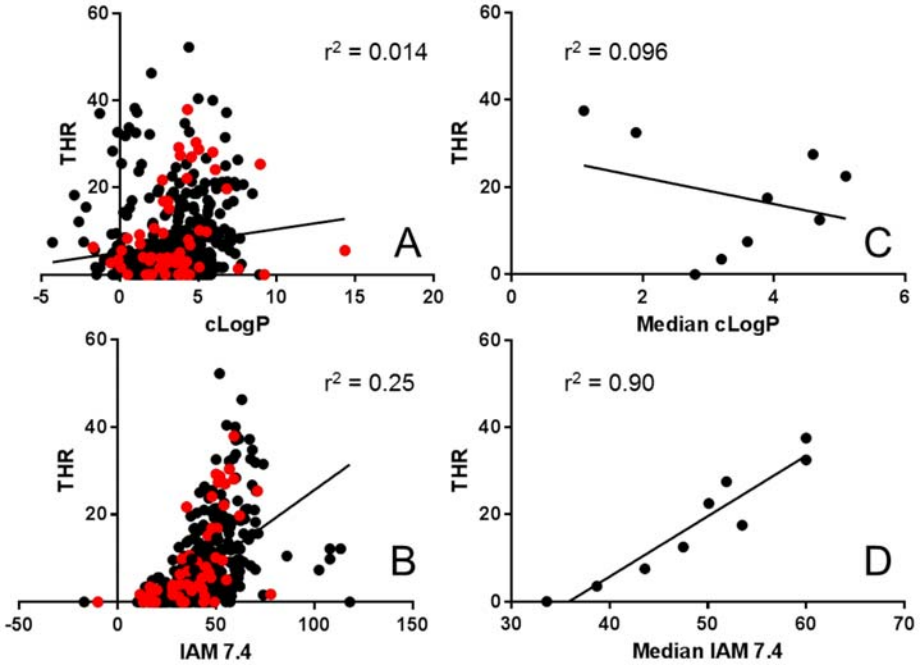

Fig. 4 Phosphatidylcholine affinity (IAM) is superior to lipophilicity alone (cLogP) to predict drug promiscuity. Promiscuity index (target hit rate (THR)) compared with cLogP (A) and chromatographic hydrophobicity index using immobilized artificial membrane (IAM) (B) for 57 marketed drugs (red) and 493 research compounds (black); the same data are shown in (C) and (D), but the THR has been binned into 9 groups, and the median cLogP (C) and median IAM (D) for each THR bin have been plotted. The THR is defined as the percentage of targets giving greater than 50% inhibition at 10 μM from a panel of at least 50 targets; higher values represent increased promiscuity.

Several pharmacophore models for hERG binding have been developed since the discovery of this ion channel linkage to LQT and TdP. The early pharmacophore model contained a tertiary or quaternary amine along with two or three aromatic rings.[192–194] Further examination of known hERG modulators shows that not all pharmacophore features are necessary and molecules with two (in case of clofilium) or three (in case of dofetilide) features can bind hERG with high affinity. The classical hERG pharmacophore model was later augmented by a possibility to have an aliphatic tail attached to a positively charged amine group to describe additional hERG blockers (C10-TEA).[195]

To provide additional insight into how hERG blockers interact with residues within the ion channel pore, Farid et al.[196] performed a number of induced-fit docking studies. The hERG homology model was built as a tetramer using MthK and KvAP structures, and six ligands known to be strong hERG binders were computationally docked into the hERG model. All six molecules demonstrate multiple ring stacking and hydrophobic interactions with the Tyr652 and Phe656 side chains of each subunit (**Fig. 5**), thus suggesting that the promiscuity of the channel is in part due to the possibilities for interactions of aromatic or hydrophobic side chains of a ligand with eight aromatic residues of the hERG tetramer.

While pharmacophore and docking modules provide chemists with visual and qualitative assessment of potential hERG binders, QSAR models can provide a quantitative assessment of the risk. The available hERG QSAR models range from those establishing a regression model between cLogP and hERG activity for a specific chemical series[176] to more complex multivariate type models using neural networks or support vector machines.[197,198] The application of QSAR models in ligand-based virtual screening is not limited to ion channels: Luo and colleagues[199] have shown the strength of such models in predicting binding affinity at a number of G protein-coupled receptors.

While blockade of the hERG ion channel remains the main focus for cardiosafety risk assessment during lead optimization, it becomes increasingly clear that modulation or perturbation of multiple cardiac ion channels can affect QT prolongation and result in life-threatening arrhythmias. This interplay of multiple targets was a subject of an integrated system-based computer model of the heart study.[200]

Recent years have seen increased attention to off-target polypharmacology, whether by design or adversely modulating many safety-related antitargets. Although chemistry optimization around several safety target liabilities is a daunting task, attempts have been made to build computational models to help with that. One example is the use of the *in vitro* secondary pharmacology profiling that involves screening lead candidates across a panel of binding and functional assays including a diverse set of GPCRs, nuclear hormone receptors, transporters, enzymes, and ion channels—all linked with documented clinical ADRs.[201] Promiscuous molecules that hit many targets in this secondary pharmacology profiling panel carry various ADR liabilities that need to be addressed earlier during lead optimization. As a result, a simple scoring model was built to classify promiscuity and selectivity.[202] As expected, the authors observed a strong correlation between a higher model score (low promiscuity) for marketed drugs than for compounds in early clinical development or compounds that failed in the clinic. This also demonstrates the relevance of a low promiscuity in the *in vitro* secondary pharmacology panel and therefore the benefit of using the promiscuity predictive model during early lead optimization.

The development of more extensive computational models came with the emergence of large public and internal databases amenable to computational modeling. These so-called chemogenomics data sets have computer-readable chemical structures, well-annotated biological targets (eg, Entrez gene ID), and activity values (eg, IC_{50}, EC_{50}, and K_d). Once these data are available, it can be used to predict potential targets based on a chemical structure. These predictions rely on chemical similarity search, using

Fig. 5 Positions of Y652 and F656 predicted from KvAP-based hERG homology model. Y652 and F656 side chains are shown in magenta. Molecular surfaces drawn amino acid side chains in contact with terfenadine (rendered in spheres). The view direction is from intracellular hERG domain to extracellular. Courtesy of R. Pearlstein.

a tool such as SciFinder. Alternatively, statistical Bayesian models were built using extended connectivity fingerprints for each target or target class in the chemogenomics database, thus resulting in predictions for activities of multiple targets based on chemical structure.[201]

The utility of these multitarget predictions becomes clear in cases of reverse pharmacology, when generating hypotheses for an observed *in vivo* toxicity can help in designing experiments to determine the mechanism of that toxicity.[180] Combining multiple data sources (eg, biochemical activities, chemical proteomics, chemical genetics, and toxicogenomics) with known biological pathway data can further enhance predictive power for possible mechanisms of toxicities[203] and help reduce liabilities in backup compounds.

So far, the main focus of this section has been on chemical modulation of safety pharmacology targets. Apart from that, there has been significant effort on predicting direct safety end points, without focusing on specific pharmacological mechanisms. Examples include the use of chemical structural alerts[190] and QSAR models for drug-induced phototoxicity,[204] to name a few.

In summary, predictive computational models can be used either prospectively during chemical lead optimization or retrospectively when toxicity is already observed in animals or clinical trial. These powerful predictive tools can help design better compounds with reduced safety liabilities or help understand mechanisms of toxicities for clinical candidates and estimate safety margins necessary to enable risk-based decision for further clinical development.

2.04.7 Summary

It is an exciting time for early predictive toxicology. A wide range of methods are available to support filtration of drug candidates to those most likely to succeed in the clinic. It seems unlikely that established tools such as *in vitro* pharmacological profiling will be entirely replaced in the near future; focus will be more on ensuring that the selected set of targets tested[9] is an appropriate subset of the whole[46] or drug-able[174,205] genome and will consider nontraditional modes of action such as disruption of protein–protein interactions.[206] Integrated *in vitro* toxicologic models will offer the opportunity to explore organ-level toxicology in a specific manner[69] and perhaps explore species-specific effects in greater detail than ever before. The opportunity exists to blur the boundary between phenotypic screening and targeted mechanistic toxicology,[66] and the curation of toxicologic reference databases will enable the development of powerful *in silico* predictive tools.

One of the key hurdles in developing new platforms, particularly those with low throughput, is to screen a sufficient number of reference compounds to enable a broad characterization of the system. The omics technologies, for example, may at this time be best suited to identifying novel biomarkers of toxic effects for which simpler, higher throughput assays could be developed, rather than being screening technologies in themselves. Underlying all *in vitro* toxicology assay development is the need for well-annotated reference compounds—those whose characteristics are well understood, with safety and toxicologic end points clearly related not only to dose but also to exposure in humans. Of necessity, this set is limited in size and the challenge is frequently to be able to find and access robust data.

Selection of techniques depends on the phase of drug discovery and development: medium- and high-throughput methods are required in early phases to triage a large number of compounds; sensitive and highly predictive methods to characterize in detail the safety profiles of candidate molecules are employed later in development. The challenge is always to be able to perform these studies quickly, accurately, and with as little cost as possible while at the same time understanding the translational value.

In an age of increasing regulatory risk awareness, there is also an enthusiasm to explore new technologies to improve our predictive ability.

2.05.1 Introduction

2.05.1.1 The Concept of a Privileged Structure

When is a chemical structure a privileged structure? The definition adopted in this article is that of Evans[1] who stated that: "privileged structures are capable of providing useful ligands for more than one receptor." The privileged structures discussed in this article (Fig. 1) with two exceptions (prostanoic acid and morphine) generally have a molecular weight (MW) between 75 and 250 Da (with a median of 160 Da) and a cLog*P* (calculated partition solubility) −3 to +3 (with a median of +1.8). The topological polar surface area (tPSA) ranges from 0 to 110.4 Å with a median of 27 Å. This falls well within certain aspects of the rule of three (Ro3),[2] and therefore, privileged structures can be viewed as preferred fragments.[3,4] Biological targets are unconcerned with the minutia of chemical structures, but the overall size and charge are important factors. Privileged scaffolds, as we will discuss, are structures with favorable starting properties for drug discovery (such as obeying characteristics of Ro3) but importantly allow for the addition of multiple vectors to interact with the generic biological target via the addition of suitable functional groups. Importantly, this suggests most low MW (and as we will find almost exclusively nitrogen-containing) scaffolds have the potential to become privileged if sufficient biological data against a range of targets are obtained for multiple compounds containing that particular scaffold. We will also discuss examples that push the limits of the privileged argument that interact with nearly every biological target they are screened against (chelators, rhodanines, and reactive species, e.g., Michael acceptors). There is a panoply of privileged structures currently available, which have had significant impacts on medicinal chemistry, being a good starting point on discovery programs (the caveat to this is intellectual property (IP) considerations). We discuss outstanding examples of this and in Section "**Natural Products as Lead Structures**" look to the future in terms of the as yet not privileged but potentially so lead-like scaffold synthesis and what this may hold for medicinal chemists in the ever-changing world of drug discovery.

The conundrum that we have to contend with here is does ease of synthesis of certain scaffolds influence what we consider privileged scaffolds; for example, there is a panoply of low-cost methods to synthesis the indole skeleton, while there are more limited and expensive methods to prepare more elaborate heterocycles. Although the pharmaceutical industry has moved away from the preparation of large numbers (the quantity approach, e.g., 100–100,000 s) of new compounds (with potentially less structural diversity), the combinatorial chemistry approach to preparing "quality" compounds (with potentially more structural diversity

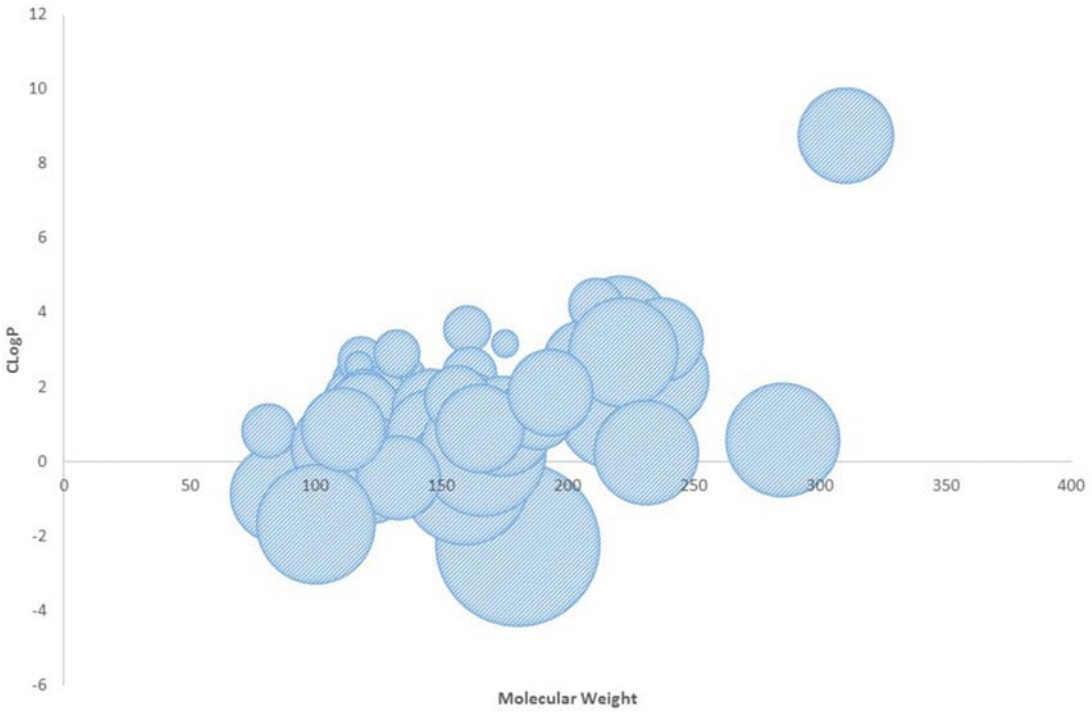

Fig. 1 Evaluation of the broad properties of the privileged structures discussed in this article (Size of the circle relates to tPSA).

but in smaller numbers) that interrogate less explored areas of chemical/biological space has more recently taken precedence. The literature explored in this article 2007–16 will undoubtedly have remnants of the quantity over quality structural approach. However, it is not the purpose of this article to question the validity of these alternate approaches, but to make the reader aware of the trends in chemical synthesis that when performed on an industrial scale whether in companies, research institutes or hybrid academic research models can artificially bias the compounds available to explore the privileged scaffold concept. Hot topics, trends, and even the general popularity of certain research areas within universities, companies, and the academe influence the pots of money and the resulting compounds prepared. High-risk fundamental synthetic work can go unnoticed (and unfunded) and research that builds on a narrow window of previous knowledge may be considered less risky and more fundable, perpetuating the cycle of looking narrowly for new biological activity. Certain research funders now appear to be bucking this trend with their pioneer awards. Of pertinence to this is a recent paper by Grzybowski's group[5] that has shone light onto the myriad of chemical networks and synthetic strategies employed by chemists during synthetic campaigns. Although we may believe that chemical synthesis by the multitude of research groups over the world is inherently random and free-spirited based on intuition and imagination, statistical analysis has shown this not to be the case, it is evolution of popular motifs through chemical decoration that wins out. With the assumption that there may be many other "privileged structures" languishing in research labs or yet to be isolated natural products or as the American politician, Donald Rumsfeld, aptly put it in his infamous quote "unknown unknowns," let us concentrate on the "known knowns" privileged structures that, can and often do, yield bioactive compounds.

With this caveat, we, the synthetic chemistry/medicinal chemistry community, have not systematically explored chemical space, iteratively building out from known scaffolds to new and as yet unprepared scaffolds examining the minutiae of functional group interconversions and testing the resulting materials for all possible bioactivity. Firstly, the costs would be prohibitive, and the number of small organic molecules (even at <500 Da) that can be possibly prepared, estimated at 166 billion structures (consisting of up to 17 atoms of C, N, O, S, and halogens),[6] is more than all the organic chemical matter available in the universe. Clearly this is impossible and coupled with an unsystematic exploration of chemical space and the presumption that analogs that are more tractable have been prepared in abundance (including the privileged scaffolds), we can still reach the following conclusion: there are privileged scaffolds. Certain scaffolds do tend to show biological activity to multiple different targets (discussed in Section "**Privileged Scaffolds for Library Design and Drug Discovery**"), possibly due to evolutionary recognition. Yet, these multitarget privileged scaffolds can branch over into the area of "frequent hitters/promiscuous inhibitors,"[7–10] and we will discuss the pros and cons of the privileged scaffold approach through a discussion of the famous class of rhodanine-like privileged scaffolds. These are examples of a chemotype that is prevalent in company and academic screening collections, which satisfies the maximal vector exploration needed in a privileged scaffold but has received a mixed response from the medicinal chemistry community. A caveat to identifying promiscuous compounds is that they are almost always well-established chemotypes identified from historical screening data where there is an abundance of cross target screening data. Understandably, analog design and synthesis of "promiscuous" chemotypes would only occur after detection of a protein–ligand response; this in turn would validate whether a chemotype is promiscuous.

As medicinal chemists, we cannot ignore this information at least as a starting point for developing new compounds. Herein lies a second consideration encountered with privileged scaffolds, the space to operate, for patent considerations, which may ultimately limit this approach with certain targets. Some privileged structures will also possess undesired off-target activity that needs to be dialed out early on in a campaign.

So with all these issues with the concept of "privileged structures," why do we still pursue it? Based on the current evidence, the strategy does appear to work and work well to deliver new clinical candidates, chemical tools, and drugs for patient benefit. Herein, the purpose of all our research to advance the field and contribute to scientific understanding can be more readily achieved using synthetically tractable routes to privileged scaffolds to design, develop, and optimize new inhibitors for patient benefit. Even if the privileged structure approach is proved wrong at a later point in the years to come, the privileged structure approach has led to the successful development of multiple small molecules described in the following sections. Having a rationale and increasing the often dire success rate of drug development can only be a good thing both for patients and companies and for the morale of the scientists in the lab. It should also be noted that the term "privileged structure" finds use in a number of disciplines, which complicates matters, but even within synthetic and medicinal chemistry, the term is often applied without much forethought to the spirit of the original definition.

Bringing the privileged structure approach up-to-date with modern advancements *in silico* developments, the approach of scaffold hopping[11] may be a particularly helpful addition to the drug discovery process when combined with privileged leads. Brown[11] has eloquently stated the drug discovery challenge as a "multiobjective optimization process" that ultimately satisfies the objectives of safety and efficacy. The process is reliant on (i) identifying a molecular scaffold and (ii) optimizing that scaffold through decoration or scaffold hopping improving efficacy, safety, and IP considerations. The privileged structure may therefore find intense use in the discovery and lead-optimization stages. In particular, the privileged scaffold, and it is often the case, acts as a *functional scaffold* interacting with the target and to a lesser extent as a *structural scaffold*, providing a framework for decoration that ultimately interacts with the target. Importantly, the privileged scaffold decoration pattern allows it to have significantly different functional engagements with targets. Langdon, Brown, and Blagg[12] have also analyzed the scaffold diversity of seven reported commercial compound libraries, demonstrating that the majority of compounds contain only a small number of well-represented scaffolds and the need to diversify these screening collections. Coupled with these limitations, the privileged scaffold has found extensive use in lead generation since the inception of the concept in 1988 and has become integrated into a variety of drug development platforms not purely as a standalone strategy. Zhao and Dietrich[13] have highlighted the strategic value of employing the privileged scaffold concept in both the mass production of compounds for high-throughput screening (HTS) and in the design of highly selective warhead-based ligands. The use of *privileged structures* has changed since its original inception and has allowed for the accelerated discovery of bioactive ligands for most currently investigated targets, with high levels of selectivity for the desired target or target space.

Kim and coworkers have coined the term *efficient chemical* "navigators" *of biological space* to get to new areas of bioactive chemical space[14] to explain the use of privileged structures as *activity beacons*. When coupled to diversity-oriented synthesis (DOS), the use of privileged substructure-based DOS results in compounds that can be used toward discovering bioactivity in traditionally "undruggable" targets. Collins and Jones[15] have recently reviewed the diversity-oriented landscape to preparing and discovering new molecular scaffolds, often incorporating privileged scaffold elements, to anticancer compounds. The privileged structure approach is compatible with the original tenets of chemical diversity-driven DOS.[16] At the extreme of the spectrum of limitations on skeletal diversity that may be considered, this approach becomes analogous to the privileged structure strategy familiar to medicinal chemists,[17] which typically involves substituent decoration of single scaffolds selected for their propensity to show particular bioactivities. In this context, it is interesting to note that minimal changes to the privileged scaffold may result in quite profound changes in biological activity despite high apparent similarity in the structural framework.

The reader is directed to these reviews (Nelson and coworkers[18] have reviewed natural product-inspired DOS. Waldmann and coworkers[19] have reviewed natural products as inspiration for the design of bioactive compounds. DeSimone and coworkers[20] have reviewed the many applications of privileged structures in drug discovery) and chapters and sections in the accompanying volumes in this compendium for further in-depth discussion of these concepts as they arise.

The most comprehensive definition of the types of scaffold that meet the criteria of a *privileged structure* since Evans (1988) first definition was by Stockwell and coworkers in 2010.[21] In this review, for the first time, a strategy for grouping and sorting privileged structures was offered and has served as inspiration for this article. The reader is directed to this article for its comprehensive coverage of the privileged structure landscape as of 2010.

The privileged structure approach also fits well with newer approaches to drug discovery, such as fragment-based drug discovery.[22] Chen and coworkers[23] have critically reviewed the evolution of fragment-based drug design and the deconstruction–reconstruction strategy of using privileged fragments from previously reported ligands. If we look at O'Donnell and colleagues comprehensive synthetic approaches, reviews to the new drugs of each year 2009–13[16-20,24-28] demonstrate the prevalence of the privileged structure in drugs launched each year. For instance, in 2009,[24] pazopanib hydrochloride, a multitargeted receptor tyrosine kinase of VEGFR-1, VEGFR-2, VEGFR-3, PDGFR-α/β, and c-Kit, contains the diaminopyrimidine privileged scaffold. In 2010,[25] bazedoxifene acetate, an estrogen receptor (ER) modulator for the treatment of osteoporosis in postmenopausal women, contains a central indole core. In 2011,[26] bilastine, a selective histamine H_2 antagonist for the treatment of rhinoconjunctivitis and urticarial, contains a benzimidazole privileged motif. In 2012,[27] bosutinib hydrate, a dual Src/Abl kinase inhibitor for the treatment of chronic myeloid leukemia, contains a central anilinoquinoline privileged hinge-binding motif. In 2013,[28] afatinib dimaleate containing the privileged quinazoline 6,6-ring system was approved for the treatment of nonsmall-cell lung cancer (NSCLC), highlighting some of the successes with incorporating the privileged scaffold approach.

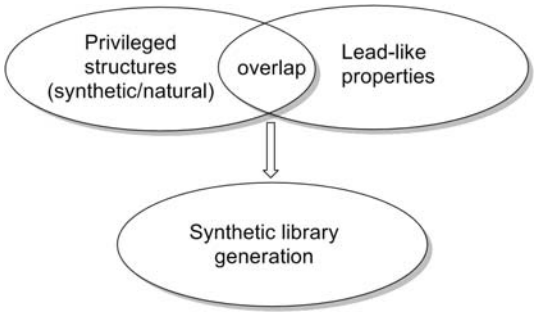

Fig. 2 Overlap between the main concepts described in this Chapter.

The structure of this article (Fig. 2) will first introduce and focus on (i) the most commonly encountered classes of privileged structures, directing the reader to seminal articles and comprehensive reviews within the field and (ii) the incorporation of privileged scaffolds into library design displaying examples of discovering bioactivity different to the scaffold source (or its known bioactivity). Next, we look at a potential source for discovering privileged scaffolds, natural products, and how they can be incorporated into library design. In the penultimate section, we look at the current trend of "lead-like" compounds by focusing on exemplar library synthesis and application to bioactive molecule discovery. Finally, we consider the outlook for privileged scaffold-based drug discovery and, in the changeable world of drug discovery, for instance, public-private partnerships (PPP) initiatives such as the European Lead Factory from IMI that also has and will identify new privileged structure scaffolds.[29]

Drugs on the market and a natural product that contains some of the privileged structures: Indomethacin **1** is a nonsteroidal antiinflammatory drug; tamoxifen **2** is an antiestrogen therapy for hormone receptor-positive breast cancer; camptothecin **3** is a cytotoxic quinoline containing alkaloid that inhibits topoisomerase I; gefitinib (Iressa) **4** is an epidermal growth factor receptor inhibitor used to treat, among others; NSCLC are shown in Fig. 3.

Chan and colleagues[30] have mined the protein data bank for chemical fragments that bind to the four most common side-chain residues: Asp, Glu, Arg, and His. Analysis of 8000 protein–ligand interactions revealed 2038 unique ligands containing a recurring 462 fragments. This work shows that certain fragments (or privileged structures) have a higher propensity for interaction with these key residues, and further global mapping of pharmacological space[31] may reveal other networks of privileged structure interactions. Related to this, Stahl and coworkers[32] have written an excellent perspective piece on molecular interactions between the ligand (which may be privileged) and the biological target from a medicinal chemist's viewpoint.

To give a flavor of this article, four articles have been selected to highlight examples of different privileged approaches. For instance, Kim and coworkers[33] have described the discovery and structure–activity relationships (SARs) of privileged pyrazolodiazepine scaffolds as the first reported agonists of the *Drosophila sex* peptide receptor (also known as *D. melanogaster* (DrmSPR)). DrmSPR is an important G-protein-coupled receptor (GPCR) involved in postmating responses such as egg laying, and the receptor is modulated by a natural peptide agonist (the sex peptide). A library of pyrazolodiazepines was screened against this target, and a weak agonistic effect was observed. A SAR was determined leading to the synthesis of variously substituted pyrazolodiazepines. Two examples bearing a pendant 6-benzyl moiety exhibited EC_{50} values of 3–4 μM, and they were also the first small molecules to achieve this effect.

Sun and coworkers[34] have developed an expedient synthesis of oxa-, thio-, and selenohydantoin-fused tetrahydrozaepino[4,5-*b*]indoles. These privileged scaffolds were inspired from the seven-membered azepino[4,5-*b*]indole ring found in the *iboga* class of naturally occurring alkaloids.

Che and Marshall have reviewed privileged scaffolds that target reverse-turn and helix recognition.[35] Disrupting protein–protein interactions through small-molecule inhibition is one of the key challenges of drug discovery at the time of writing, and the

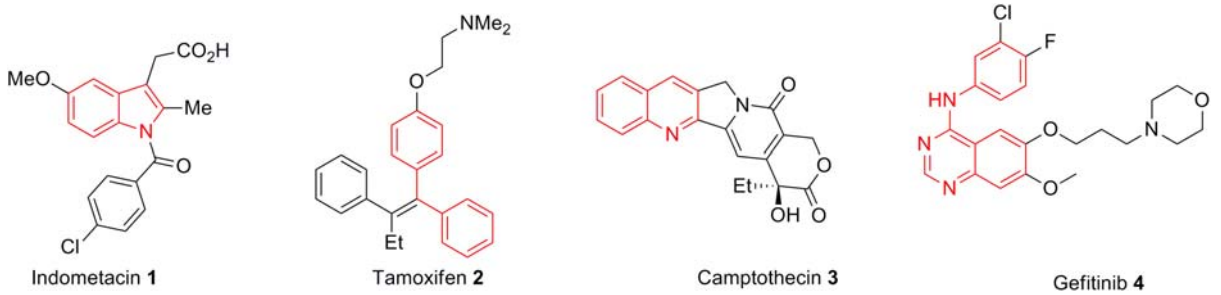

Fig. 3 Examples of drugs and natural products that contain privileged structures (indomethacin **1**, indole; tamoxifen **2**, diphenylmethane; camptothecin **3**, quinoline; and gefitinib **4**, anilinoquinazoline).

application of privileged scaffolds is advocated and finding new uses. For example, privileged structures that target reverse turns include the benzodiazepine scaffold, and α-helical recognition include trispyridylamides. Arkin, Tang, and Wells have written an excellent review of progress toward small-molecule inhibitors of protein–protein interaction.[36] The reader is directed to this article for further information on this rapidly evolving area. However, for the purpose of this article, it is of note that several research inhibitors contain privileged elements. For example, TL-32711 (birinapant) contains a bisindole motif, (+)-JQ1 contains the thienodiazepine scaffold as a BRD4 inhibitor, and BCL family inhibitors contain the aryl and benzylpiperazine scaffolds, for instance, in ABT-263 (navitoclax). These and others will be used to exemplify the privileged structure, development of privileged syntheses, and ultimately the use of privileged scaffolds in medicinal chemistry.

2.05.2 Privileged Scaffolds for Library Design and Drug Discovery

2.05.2.1 Classes of Privileged Structure

We have grouped Chapter 2 around general and repeating functional scaffolds that show bioactivity in more than one target depending on the substitution pattern. The potential for privileged scaffolds to become *promiscuous* is also highlighted. Han and coworkers[37] have studied the drug-likeness of bicyclic privileged structures (such as 6,5-, 6,6-, and 6,7-ring systems represented by purine, chromone, and benzodiazepine in the following sections) with the purpose of designing new bicyclic privileged structure combinatorial libraries. In particular, they focused on the physicochemical properties (such as MW, Log *P*, and tPSA) and noted a significant difference between the drug-likeness range of privileged bicyclic scaffolds compared with nonprivileged scaffolds. A 76% prediction accuracy for designing improved drug-like privileged scaffolds was obtained.

2.05.2.1.1 Privileged 6,6 heterocyclic ring systems

Examples of the privileged unsaturated 6,6 heterocyclic ring system are provided in Fig. 4.

There is a wealth of examples (Fig. 4) and reviews in this area. Bolognesi and coworkers have reported the privileged structure-guided synthesis of quinazolines as trypanothione reductase inhibitors[38] and quinolones as a privileged structure in antimicrobial drugs[39]; the 8-hydroxyquinoline scaffold (as a strong metal ion chelator) acts as an anticancer agent, anti-HIV properties, antifungal, chelator of metalloproteins, inhibitor of 2OG-dependent enzymes, antileishmanial, antischistosomal, *Mycobacterium tuberculosis* inhibitor, and botulinum neurotoxin inhibitor, among others.[40] Solomon and Lee have reviewed the application of the 6,6-ring system and quinoline in drug discovery.[41] Shiro and coworkers[42] have reviewed the privileged quinolinone-containing heterocyclic scaffold from both a synthetic and biological viewpoint. Quinolones are shown to act as antiinflammatory, antitumor, antidiabetic, and antipsychotic agents.

Ross and coworkers[43] have prepared ciprofloxacin dimers to explore atypical chemical space with bacterial permeability properties. Fluoroquinolones, such as ciprofloxacin, are well-known antibiotics; the dimer prepared showed enhanced inhibition of the intracellular target (DNA gyrase) and general antibacterial activity in whole cells, which in turn is governed by its cellular permeation and physicochemical properties. Principal component analysis showed that the privileged dimers occupied a unique region of chemical space most similar to macrolides.

Nakamura and coworkers[44] have evaluated 46 in-house synthesized 2,3-substituted quinoxalines as antileishmanial and antitrypanosomal drugs with inhibition levels of *T. cruzi* promastigotes and epimastigotes between $IC_{50} = 100–800$ nM for the most potent analogs.

Similarly, a collection of 2,3-substituted quinoxalin-6-amine analogs was evaluated by Natarajan and coworkers[45] for cancer cell line activity. A urea-containing analog showed cancer cell line growth inhibition at 20 μM with concomitant caspase-3/7 activation, PARP cleavage, and Mcl-1-dependent apoptosis.

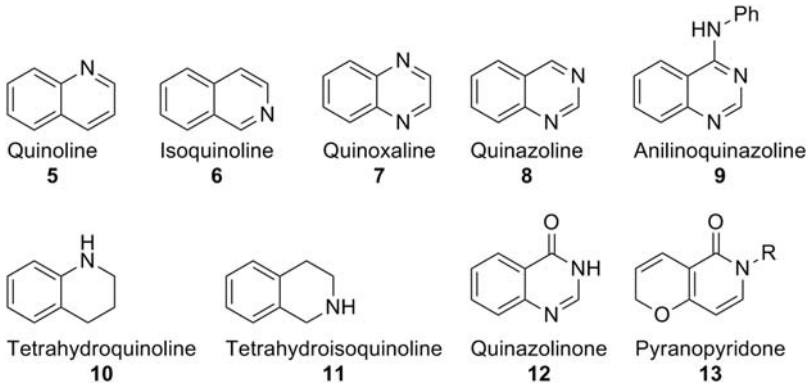

Fig. 4 Examples of privileged 6,6 heterocyclic ring systems **5–13** (saturated/unsaturated).

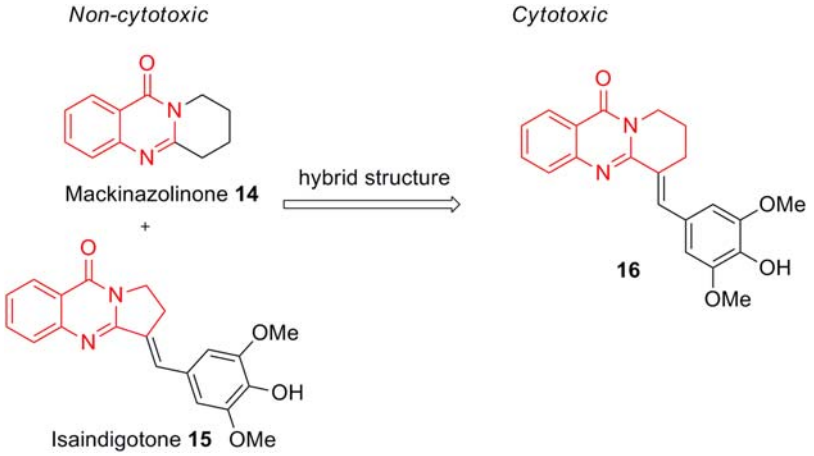

Fig. 5 Natural product hybridization strategy to privileged cytotoxic scaffolds.

The group of Liu and coworkers has reported[46] a focused library containing a privileged quinazolinone natural product motif (Fig. 5). Using a strategy of hybridizing the structures of two known natural products, mackinazolinone **14** and isaindigotone **15**, a library of natural product-related compounds was rapidly prepared. Prior to the synthesis campaign, a virtual library of 900 analogs was assembled using the ArQule software from a 30×30 collection of anthranilic acids and benzaldehydes. Using the diversity paradigm, 67 analogs were synthesized. Importantly, it should also be noted that neither parent natural product mackinazolinone **14** nor isaindigotone **15** is reported to exhibit cytotoxic activity. Screening of the 67-member library using an (3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium) (MTS) cell proliferation assay (five cancer cell lines, NCI-H460, A549, DU-145, MDA-MB-231, and SF-268 and one primary cell culture Human Mammary Epithelial Cells (HMEC)) identified compounds such as the cytotoxic hybrid **16** (shown in Fig. 5) as a cytotoxic, an unexpected feature based on the structures the molecule was hybridized from. Particularly active analogs of the hybrid were further evaluated in a phosphohistone H3 (pH3) assay to demonstrate whether their inhibition of cell proliferation resulted from mitotic arrest. A dose-dependent response with pH3 EC_{50}'s from 0.3 to 11 μM gave support to this argument. The antimitotic agents were further evaluated in a tubulin polymerization assay; the inhibition observed suggests these compounds act through destabilization of tubulin polymerization. Taken together, the authors suggest that the cytotoxic hybrid may also be a new privileged structure for further development.

Liu and coworkers[47] applied a biased privileged structure-enriched library approach to the screening and identification of new hepatitis C virus (HCV) inhibitors. A quinoxalin-2(*1H*)-one derivative **17** (Fig. 6) showed potent HCV inhibition *in vitro* from the screening library; further synthesis identified key SARs leading to five advanced compounds with increased antiviral potency, EC_{50} range of 1–2 μM, while concomitantly reducing cytotoxic effects inherent to the hit compound, although the underlying mechanism of action was unclear at this stage.

The synthesis of derivatives of the hit compound was accomplished as follows: treatment of a difluoro dinitro benzene with methyl glycine afforded the first of two S_NAr products; the second fluoro group was displaced by a secondary amine, in this case, *N*-methyl cyclohexane. The quinoxalin-2(1*H*)-one ring system was formed via hydrogenation of both remaining nitro groups using hydrogen over palladium on carbon. A spontaneous cyclization of the ortho-amine to the glycine carbonyl atom effected this transformation. Finally, the remaining amino group was reacted with a benzoyl isothiocyanate to install the carbamothioylbenzamide functionality.

Manfroni and coworkers[48] have reevaluated their previously reported antibacterial- and antiviral-privileged 6-aminoquinolone scaffold as potent inhibitors of NS5B polymerase, a target for the development of HCV inhibitors. In particular, the 6-amino-7-[4-(2-pyridinyl)-1-piperazinyl]quinolone derivative possessed an IC_{50} value of 69 nM against NS5B polymerase and selective antiviral effect ($EC_{50} = 3.03$ μM) with no detectable cytostatic effects in the high micromolar range measured by MTS in Huh 9–13 cells; demonstrating the repurposability of privileged scaffolds to interact with other biological targets. We discuss this later in a secondary context in Section "**Arylated piperidine/piperazine ring systems**."

Kandi and coworkers[49] have noted the prevalence of the privileged scaffolds, curcumin, and 4-aminoquinolines that are often found in ligands that can modulate diseases such as cancer and malaria. Hybridization of these two privileged scaffolds with a triazole linker was postulated to give a dual privileged scaffold ligand with potentially improved anticancer activity. Evaluation of these new ligands in a diverse set of 60 human cancer cell lines revealed examples that showed nanomolar growth inhibition. Mechanistically, this was due to the privileged-linked compounds acting in an apoptotic-inducing manner.

D'hooghe and Vandekerckhove have reviewed[50] quinoline-derived antimalarial hybrid compounds. Joseph and coworkers[51] have reported a ketene-initiated domino reaction to the privileged quinolizidine class of molecules with multiple stereogenic centers and high diastereoselectivities. These quinolizidines are constrained mimetics of the privileged H-bonded conformation of (−)-Lobeline.

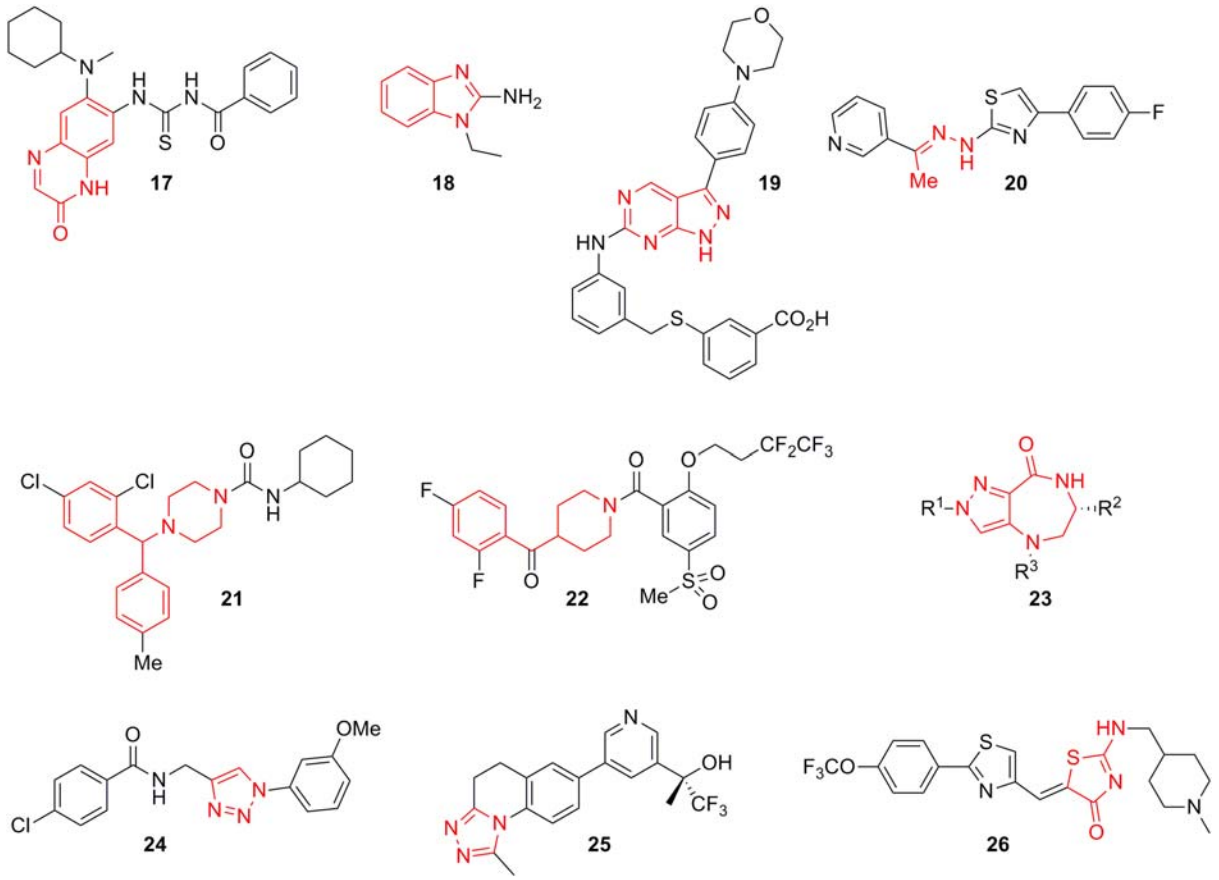

Fig. 6 Examples of singleton-privileged hit scaffolds discussed in this article **17–26**.

2.05.2.1.1.1 A special subset: kinase inhibitors

Gray and coworkers[52] have made a compelling argument for the extension of the privileged structure approach to the development of type II binding mode kinase inhibitors. In kinases, the Adenosine triphosphate (ATP) active site is conformationally flexible on its account of its ability to accept a range of small-molecule inhibitors. In turn, the conformation of the kinase, the activation segment, controls access to the substrate-binding pocket. This large conformational change leads to a DFG-in (active state) and a DFG-out (inactive state) (where DFG means D = aspartic acid, F = phenylalanine, and G = glycine). Type II kinase inhibitors typically bind to the DFG-out conformation of the kinase (while type I inhibitors bind to the DFG-in conformation). Gray and colleagues have reviewed the large number of reported type II kinase inhibitors and undertaken a crystallographic analysis of their previously determined binding modes. Using a small collection of type II inhibitors, over 200 kinases can be inhibited, suggesting they are not only less selective than type I inhibitors but also privileged to be able to modulate a range of kinases. Zhang and coworkers[53] have investigated the privileged pharmacophore elements of type II kinase inhibitors that target the v-RAF murine sarcoma viral oncogene homologue B1 (BRAF). BRAF is a protein kinase that is frequently mutated in cancer to BRAF V600E. In turn, this activates the RAS/RAF/MEK/ERK pathway (RAS = p21/RAS protein, RAF = RAF proto-oncogene serine/threonine-protein kinase, MEK = Mitogen-activated protein kinase kinase, ERK = extracellular signal–regulated kinase) and is therefore a validated target. Using two privileged pharmacophores in kinase inhibitor design, anilinopyrimidine and an unsymmetrical diaryl-substituted urea, a series of hybridized structures were prepared. The lead compound from the series is a selective inhibitor of BRAF and its oncogenic BRAF V600E and was demonstrated to possess antitumor efficacy in an A549 human NSCLC xenograft model through a once-daily po dosing regime. Furthermore, molecular docking studies showed that these privileged structure motifs might act in a type II kinase inhibition mode with the DFG-out conformation of BRAF.

Hoelder and coworkers[54] have updated the literature on the privileged-fused pyrimidine core, ubiquitous in kinase inhibitor scaffolds. In particular, they have developed a route to the underrepresented 2-amino-pyrido[3,4-*d*]-pyrimidine scaffold, a potential privileged scaffold of the future. As all privileged scaffolds are dependent on tractable syntheses, this work makes this scaffold more likely to be developed and explored in future medicinal chemistry campaigns. Furthermore, their effects in a checkpoint kinase 2 (CHK2) assay were evaluated and showed nanomolar inhibition. This work demonstrates that privileged scaffolds can be used as potential predictors of future privileged scaffolds that may be currently untractable but with effort and imagination can be overcome.

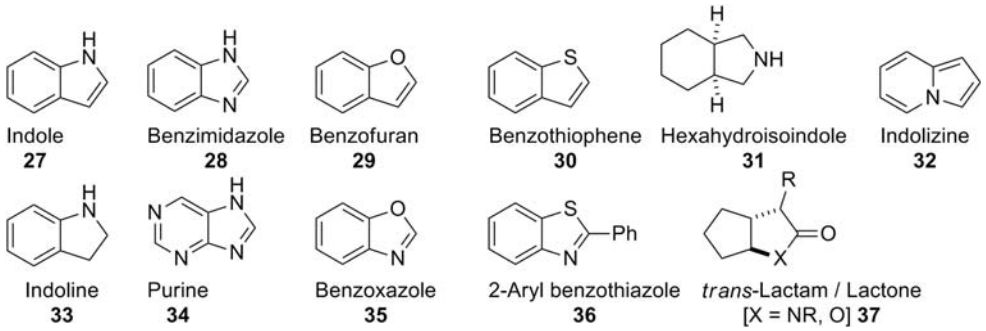

Fig. 7 Privileged 6,5 heterocyclic ring systems (saturated/unsaturated) **27–37**.

Zhan and coworkers[55] have reported anticancer dual c-Met and VEGFR-2 inhibitors derived from the privileged anilinopyrimidine scaffold. Two novel synthetic routes allowed for rapid library preparation and SAR interrogation of the privileged scaffold. At the enzyme level, nanomolar potency was detected. In a cellular environment, low micromolar antiproliferative effects against c-Met-dependent cell lines were found. The binding mode of the privileged anilinopyrimidine scaffold with c-Met was conclusively determined with a cocrystal determination.

Zhao and coworkers[56] have analyzed the chemical space coverage of reported kinase inhibitors. Deconstruction of 26,668 kinase inhibitors into their constituent fragments revealed that half of the 10,302 fragments are not commercially available and 5861 ring-containing fragments were capable of hinge-binding. This is only 1% of all the known ring systems (~75,000) capable of forming a bidentate hinge-binding interaction, leading to the conclusion "current kinase inhibitors cover a tiny fraction of fragment space."

2.05.2.1.2 Privileged 6,5 heterocyclic ring systems

The privileged 6,5 heterocyclic ring systems can be viewed as a subset of the privileged 6,6 heterocyclic ring systems in Section "**Privileged 6,6 heterocyclic ring systems**" but due to the panoply of examples reported is individually discussed here.

There is a wealth of examples (**Fig. 7**) and reviews in this area: Xiang and coworkers have extensively reviewed the synthetic routes to the indoline privileged scaffold,[57] and Fang and coworkers have reviewed the development of indole-containing antiviral agents.[58] Fraga and coworkers[59] have reviewed the indole as a privileged drug discovery motif, again from a natural product inspiration perspective. Zhang and coworkers[58] have reviewed recent strides in the development of the privileged indole-containing antiviral compounds from compounds on the market, clinical trials, and research in development. Likewise, Sonsona[60] has highlighted some of the methods to the synthesis and diversification of privileged indole-containing natural products and bioactive molecules. Keri and coworkers[61] have extensively reviewed the benzimidazole privileged structure, highlighting examples of antibacterial, antifungal, antiinflammatory, antioxidant, anticonvulsant, and antitubercular activities, among others. Lim and coworkers[62] have reviewed 1,3,5-triazine-derived analogs of purines not only as isosteres of the privileged purine class but also as privileged structures in their own right. Purines are one of the most prevalent heterocycles in biology, and through isosteric replacement with other *N*-containing heterocycles, seven purine isosteres can be determined. This range of privileged isosteres and their associated bioactivities such as inhibitors of kinases, phosphodiesterases, xanthine oxidases, and thymidine phosphorylases is reviewed. Zhang and coworkers[16] have reported a library of privileged heterocycles, including indoles, from an Ugi four-component reaction, which may also be considered a privileged reaction. Paul and colleagues[63] have reviewed the synthetic approaches and derivatization methods of the privileged imidazo[1,2-*a*]pyrimidine scaffold. Xiao and coworkers[64] have reviewed synthetic methods to and biological activities of privileged pyrroloquinazolines.

Bunders and colleagues[65] have investigated desformylflustrabromine (dFBr) analogs (**Fig. 8**) as an indole-derived privileged template for the discovery of novel inhibitors of the indole-signaling network in *Escherichia coli* and *Staphylococcus aureus*. The indole-signaling network is an important pathway in the bacterial kingdom. Using this privileged starting point for derivatives of dFBr, 10–1000-fold more potent analogs than indole were discovered demonstrating the value of the flustramine natural product family as a starting point for the design of bioactive small molecules. Analog, **38**, was a nonmicrobiocidal inhibitor of biofilm formation; mechanistic studies in wild-type (wt) and knockout *E. coli* strains showed a temperature-dependent mode of action. It was further suggested based on the indole template from flustramine that **38** may achieve its potency via modulation of indole-based signaling pathways. Furthermore, due to the activity of **38** against indole-positive and indole-negative bacteria and the putative role of indole-signaling in nature, the privileged structure-containing molecule, **38** and **39** will also be employed as chemical probes.

Pedersen and coworkers[66] have used the privileged 2-phenylindole scaffold to develop for the first time selective allosteric antagonists of the G-protein-coupled receptor (GPRC6A). GPCRs are an important biological target for drug development, and class C GPCRs are new drug targets. Using a fluorescence resonance energy transfer (FRET) FRET-based inositol monophosphate assay, three privileged 2-phenylindoles were identified as antagonists at the GPRC6A receptor in the low micromolar range, and two of these compounds displayed a greater than ninefold selectivity for the GPRC6A receptor over related GPCRs. This makes this privileged scaffold the most potent and selective inhibitor of GPRC6A reported to date.

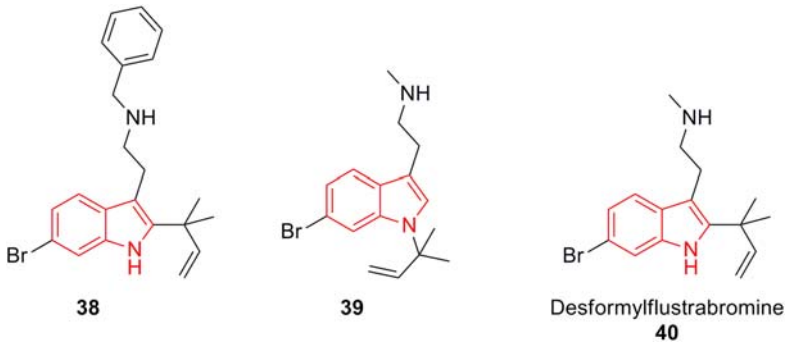

Fig. 8 Privileged bioactive desformylflustrabromine analogs **38** and **39**.

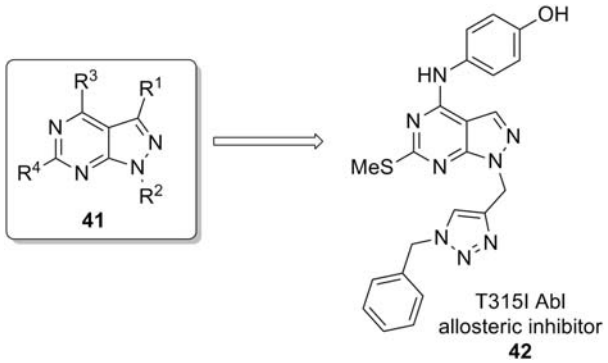

Fig. 9 Evolution of a hit privileged scaffold into a T315I Abl allosteric inhibitor **42**.

Vignaroli and coworkers[67] used a privileged pyrazolo[3,4-*d*]pyrimidine scaffold **41** (isosteric to purine) coupled with a diversification strategy to generate a library, using synthetic sequences to functionalize the C3, C4, C6, and N1 positions (Fig. 9). Screening the library prepared against enzymatic targets revealed several inhibitors of the Src and Abl kinases (including wt and T315I-mutated forms) with comparable levels of activities to known inhibitors. This area of kinase inhibitor discovery is often explored successfully using a target-oriented approach; therefore, a diversity-oriented approval is a novel update in this field. Of interest, a member of the library was demonstrated to be an allosteric inhibitor of the T315I form of Abl (**42**), opening up a new avenue of noncompetitive inhibition.

Using a fragment-based Nuclear Magnetic Resonance (NMR) spectroscopy screening platform, Miller and coworkers[68] discovered a series of privileged structures, such as benzothiazoles and benzoimidazoles, as in **18** (Fig. 6) that bind to the plant homeodomain (PHD)–the BCL9 HD1 domain interface, blocking protein–protein interactions. The chromatin reading Pygo–BCL9 complex is a novel and emerging target in oncology that anchors the histone H3 tail methylated at lysine 4 (H3K4me).

X-ray crystallography of the newly discovered privileged fragments revealed that, despite their small size, they bind to a cleft on the PHD–HD1 interface, displacing the native H3K4me peptide from the PHD finger. This demonstrated that the Pygo–BCL9 complex can be inhibited using a privileged fragment approach.

De La Cruz, Kapoor, and coworkers[69] utilized a purine privileged structure template in their discovery program of small-molecule probes (such as **19**, Fig. 6) of nonclass II myosins. Myosins are motor proteins that translate across the actin cytoskeleton, important for muscle contraction among other biological motions. There are now 18 classes of myosins, with small-molecule probes for class II myosins only. Intriguingly, purine derivatives are more commonly encountered as kinase inhibitors; therefore, this may be viewed as a scaffold hop to a kinase-like inhibitor that now targets a GTPase-fold protein. Iterative SAR afforded a selective myosin V inhibitor that does not interfere directly with nucleotide binding.

Wang and coworkers[70] have investigated novel thieno[2,3-*b*]pyridine analogs and their resulting SAR as HCV inhibitors. From an initial hit compound (from a larger privileged small-molecule library) containing a thienopyridine core, in cell-based screening, several noncytotoxic analogs with low micromolar EC_{50} were uncovered. Although a mechanism of action was not elucidated, this privileged scaffold showed potential as an anti-HCV agent.

2.05.2.1.3 Privileged 5,5 heterocyclic ring systems

A subset of the 6,5-ring systems are the ring-contracted 5,5-ring systems. Romagnoli and coworkers[71] have designed heterobivalent antiproliferative hybrids based on the privileged imidazo[2,1-*b*][1,3,4]thiadiazole and imidazo[2,1-*b*][1,3]thiazole structures. Using

a strategy of selecting two different pharmacophores that bind to different biological targets or indeed separate sites on the same molecular target, the two privileged scaffolds were selected for investigation. The scaffolds were fused at their respective C6 positions by a *meta*-(bromoacryloylamido)phenyl motif. Most of the prepared biprivileged hybrids showed antiproliferative activity against a wide panel of cancer cell lines with up to submicromolar IC_{50}. Selected promising candidates induced apoptosis via the release of cytochrome c and cleavage of a variety of caspases. Despite overexpression of Bcl-2 in the tested cell lines, this did not appear to confer protection from cell death from the biprivileged hybrids tested.

Sztanke and coworkers[72] have explored a novel class of thiophene bioisosteres based on the privileged 7,8-dihydroimidazo[2,1-*c*][1,2,4]triazin-4(6*H*)-one moiety for antiproliferative effects in cancer cell lines. Using the reaction of 1-aryl-2-hydrazonoimidazolidine hydroiodides with ethyl 2-oxo-2-(2-thienyl)acetate, a range of analogs were prepared in good overall yield. Upon testing in vitro in human tumor cell lines (A549, HeLa, T47D, and TOV112D), the compounds showed good levels of antiproliferation and were found to be in most cell lines more cytotoxic than pemetrexed. In normal cell lines, this cytotoxic effect was limited, demonstrating a potential window for further development. A bioassay using double fluorochrome staining provided some insight into how these privileged scaffolds gave rise to an anticancer effect in the tumor cell lines described.

2.05.2.1.4 Coumarin-/chromone-/pyran-derived privileged structures

Although the coumarin/chromone class is another example of the 6,6-ring system, particular bioactivity exclusively associated with this class merits its own section.

There is a wealth of examples (Fig. 10) in this area: Grover and Jachak have reviewed the coumarin privileged scaffold as a starting point in antiinflammatory drug discovery [73]; Keri and colleagues have extensively reviewed the chromone scaffold as a general privileged class,[74] which possesses a range of biological activity (e.g., anticancer, anti-HIV, wound healing, and antiinflammatory). Gaspar and colleagues[75] have extensively reviewed the properties of the chromone scaffold detailing the many and varied biological effects of this simple privileged structure.

Park and coworkers have developed a branching DOS library inspired by natural products containing the privileged benzopyran ring system.[76,77] The DOS strategy involved balancing two seeming opposites: biased incorporation of privileged structures and unbiased diversity. In total, 22 unique core structures were prepared with limited appendage diversity; this enabled the side-by-side evaluation of core structural diversity. From a 3- or 4-(pseudo)halo-substituted benzopyran, three key reactions were performed to generate the diastereo-enriched library: Diels–Alder cycloaddition, click chemistry, and palladium-catalyzed cross coupling. In particular, Stille cross coupling followed by endo-favored Diels–Alder cycloaddition generated steroid-like tetracycles (Fig. 11). Three-dimensional structures were generated by hydrogenation, while dichlorodicyanoquinone (DDQ)-mediated oxidation gave flat aromatic systems. Comparison of examples **52** and **53** highlighted the power of three-dimensional architectures to provide differential biological activity: a viability assay in A549 lung carcinoma cells demonstrated the cytotoxicity of **52** (1.0 μM) versus **53**(63.9 μM). Using a cell-based reporter assay in LNCaP human prostate adenocarcinoma cells, screening of a 2000-member benzopyran DOS library followed by focused screening of 19 second-round derivatives identified P01F01 (**54**) as an antagonist of the androgen receptor.[77,78] The compound was also shown to inhibit transcription mediated by androgen receptor mutants that are resistant to inhibition with conventional antagonists such as bicalutamide.

Gaspar and coworkers[79] have employed the chromone privileged scaffold to develop two new series of monoamine oxidase (MAO) inhibitors. SAR studies showed preference for MAO-B inhibition that could be enhanced via 3-position substitution, while identical 2-position substitution ablated activity. The optimal compound showed an MAO-B IC_{50} of 63 nM with a 1000-fold selectivity window over MAO-A inhibition, thus validating the chromone privileged scaffold as a MAO inhibition template. Massari and coworkers[80] have investigated both the irreversible and reversible small-molecule inhibition of monoamine B (MAO-B) using a range of biophysical techniques. MAO-B is an important target (involved in the metabolism of dopamine) for diseases and disorders associated with a decrease in dopaminergic neurotransmission, such as Parkinson's disease. Isothermal titration calorimetry and thermal shift approaches were used to identify interesting scaffolds to further investigate from a binding mode direction (reversible or irreversible) and also thermodynamically privileged chemical scaffolds for MAO-B inhibition. Due to the mechanism-based difference in the thermal shift assay from the MAO-B inhibitors, reversible and irreversible inhibitors were easily identified. Coupled with screening of privileged scaffolds, these biophysical approaches may help shed light on the next generation of MAO-B inhibitors. Ortuso and coworkers[81] have also probed the development of monoamine oxidase-B (MAO-B) inhibitors based on a known privileged 3-acetyl-2-dichlorophenyl-5-aryl-2,3-dihydro-1,3,4-oxadiazole scaffold for this target. Applying molecular interaction field analysis, several compounds were developed that displayed potent in vitro activity (IC_{50} medium to low nanomolar range).

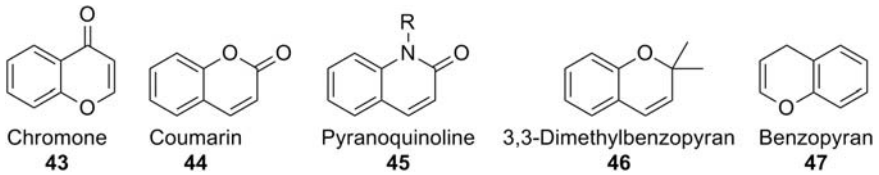

Fig. 10 Privileged coumarin/chromones/pyrans **43–44**.

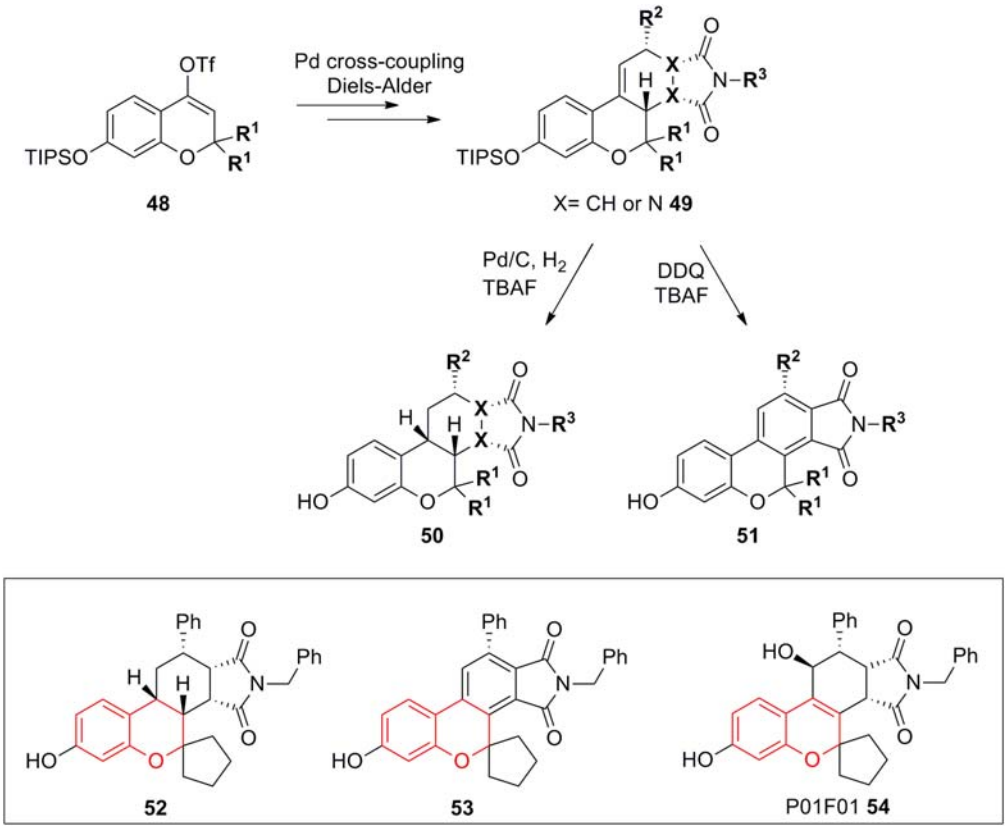

Fig. 11 DOS of privileged benzopyran-containing polycycles and identification of an androgen receptor antagonist **54**.

The enantiomers of the most promising compounds were separated, and the (*R*) enantiomer was found to be more active. Khan and coworkers[82] have also investigated triazolothiadiazole and triazolothiadiazine scaffolds as cholinesterase and MAO inhibitors.

2.05.2.1.5 Miscellanea

Unfortunately, not all scaffolds fall into a clustering system, due to either limited examples reported or the lack of investigations. Thus, in this section, examples from small scaffolds to steroids are represented.

There is a wealth of examples (Fig. 12) in this area that are mainly singletons rather than clusters of hit scaffolds, as in the previous sections.

2.05.2.1.5.1 N-Acylhydrazones and related diazo structures

Fraga and coworkers have reviewed the patent literature on the acylhydrazone privileged functional group.[83] For instance, the drug dantrolene contains this privileged motif and is used to treat malignant hyperthermia. The acylhydrazone core is used in research studies for pain, inflammation, cancer, and cardiovascular targets. Fraga and coworkers[84] have combined a rational design approach using molecular modeling studies with the acylhydrazone privileged template to generate a novel IKK-β inhibitor (*E*)-*N*-(4-nitrobenzylidene)-2-naphthohydrazide. Incorporation of two lipophilic motifs around the central privileged template led to a scaffold with increased selectivity over IKK-α and CHK2. Furthermore, the privileged compound was shown to suppress arachidonic acid-induced edema formation in vivo, demonstrating an antiinflammatory mode of action.

Barreiro and coworkers[85] have designed a new class of cyclohexyl-*N*-acylhydrazones using the prototype compound, LASSBio-294 with the aim of preparing analogs with analgesic and antiinflammatory properties. The *N*-acylhydrazone motif is considered a privileged scaffold with pluripotent biological activities. Most analogs demonstrated some antiinflammatory and/or analgesic activity, and one example showed remarkable activity in a chronic neuropathic pain model.

Secci and coworkers[86] synthesized a library of (4-substituted-thiazol-2-yl)hydrazines (such as **20**, Fig. 6) as potential reversible and selective in vitro inhibitors of human monoamine oxidase B (*h*MAO-B) with nanomolar potency and up to 58,820-fold selectivity over *h*MAO-A. These compounds show marked similarity to the privileged *N*-acyl hydrazine class and may be viewed as pseudoprivileged motifs, mimicking portions of a more understood pharmacophore. SAR revealed that substitution on the α-carbon to the N1 nitrogen atom had marked effects on potency and *h*MAO-B selectivity. Substitution of the 4-position of the thiazole with aryl ring systems, such as in **20**, has demonstrated further interactions with the well-documented aromatic cage in *h*MAOs. Prior to this work, arylalkylhydrazines were irreversible, nonselective *h*MAO inhibitors and show that privileged structures are not a panacea in

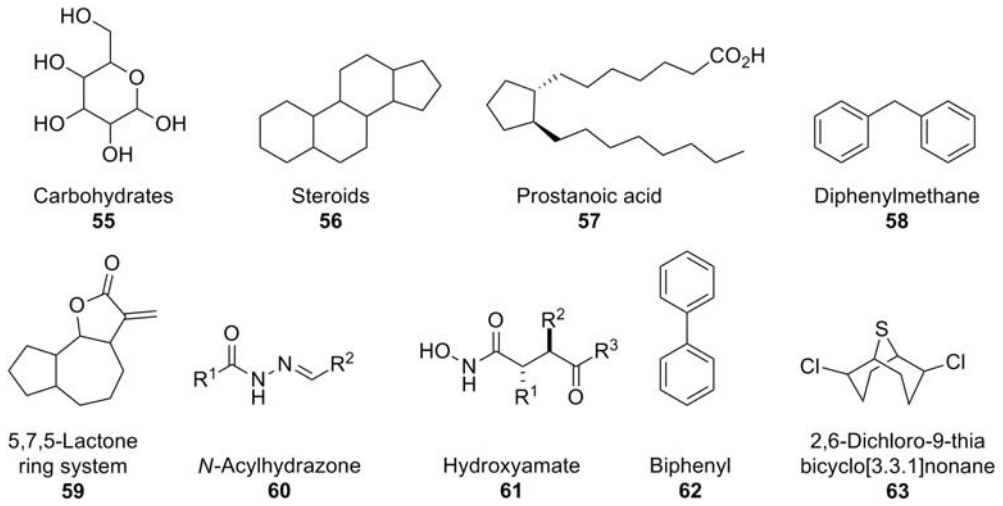

Fig. 12 Miscellaneous privileged structures **55–63**.

themselves but through SAR work, therapeutically relevant inhibitors can be derived. Abou-Gharbia and colleagues have also investigated the 2-aminothiazole scaffold[87] as methicillin-resistant Staphylococcus aureus (MRSA) antimicrobials.

2.05.2.1.5.2 Bispidines, tetralones, diphenyls, and related scaffolds

Haridas and coworkers[88] searched for new compounds to inhibit Japanese encephalitis virus (JEV) and the related West Nile virus (Fig. 13). Using the backbone of the natural product, sparteine, as a privileged scaffold template that mimics protein secondary structure, they identified and synthesized a collection of 3,7-diazabicyclo[3.3.1]nonanes based on the naturally occurring lupin alkaloid, sparteine, or more commonly known as bispidine analogs **65** that showed antiviral effects. These bispidine derivatives are rigid structures with a hydrophobic surface area that orients the R groups in defined geometries, ideal for mimicking protein–protein interactions. In particular, the decoration of the core structure with hydrophobic amino acids, such as tryptophan, showed a 100-fold improvement in inhibition of JEV infection in neuroblastoma cells at a concentration of 5 mM. The location of viral inhibition was postulated to be at the RNA replication stage, post-entry, and prior to protein translation. The same privileged scaffold demonstrated inhibition of similar viruses, West Nile virus and Chandipura virus, in the same concentration range.

Carro and coworkers[89] synthesized and evaluated a series of aminoalkyl-tetralones and tetralols as dual dopamine/serotonin ligands. The privileged molecules were evaluated to obtain their binding affinities for the 5-HT_{2A} and D_2 receptors (D_2Rs), with the goal of determining how the substitution pattern of the aromatic ring affects selectivity and affinity for these important targets for antischizophrenia drug development. Competitive antagonists with $pK_i > 8.3$ were obtained for 5-HT_{2A} and D_2 and may serve as a promising approach to developing dual inhibitors using a privileged structure approach.

Endo and coworkers[90] have developed SAR around the privileged diphenylamine scaffold as ER antagonists. The diphenylamine skeleton was selected as an improvement over the previously used diphenylmethane scaffold (another privileged moiety). Furthermore, incorporating basic alkylamino side chains on one of the phenyl groups was used to probe the ER antagonist effect. Cyclic alkylamine-containing derivatives were more potent ER antagonists in the MCF-7 cell proliferation assay. Indeed, the most potent antiestrogenic activity ($IC_{50} = 130$ nM) is more potent than tamoxifen.

Zhang and coworkers[91] have reported the synthesis of privileged pyrazole-based structures using a divergent cascade method. These enantio-enriched pyrazoles were in turn derived from easily accessible chiral pyrazole tetrahydropyran acetals. From these pluripotent acetals, a variety of reactions can be performed including Michael–aldol, reduction, lactonization, α-hydroxylation–acetalization–oxidation, Wittig–aldol, and Wittig–oxa-Michael synthetic cascades. From six simple starting materials, five molecular scaffolds could be accessed. Representative examples were screened and revealed potent anticancer activities.

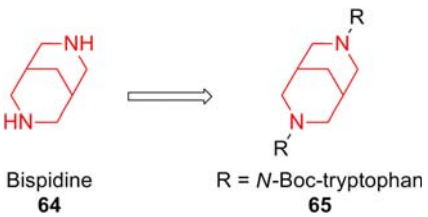

Fig. 13 Bispidine **64**-inspired privileged Japanese encephalitis virus inhibitor **65**.

2.05.2.1.5.3 Peptide and peptidomimetics

Assimon and coworkers[92] were inspired by the promising antibiotic properties of the natural product spergualin that is a privileged scaffold (amino acid-based). However, it is difficult to synthesize, and this had limited analog synthesis in an attempt to find compounds with broad-spectrum antibiotic activity. Using the recurring Ugi multicomponent reaction (MCR) (a privileged reaction), spergualin-inspired analogs were rapidly assembled. Testing the 43 novel compounds prepared in four Gram-negative and two Gram-positive strains revealed the most potent analog to have a MIC of 4–32 μg mL^{-1} against the six strains, which is comparable to spergualin (Minimum inhibitory concentration (MIC) 6.25–50 μg mL^{-1}).

Neubauer and coworkers[93] have investigated the selective targeting of the αvβ3 integrin subtype without targeting the structurally similar receptor α5β1 using a peptidomimetic approach. Peptidomimetic approaches may incorporate privileged heterocycles, but peptides themselves may also be viewed as privileged units. They report Arg-Gly-Asp (RGD) peptidomimetics for αvβ3 integrin with selectivity against α5β1. The incorporation of a privileged methoxypyridine unit into the peptidomimetic scaffold led to subnanomolar αvβ3-antagonistic activity. Docking studies helped elucidate the binding mode, and this privileged approach coupled with remarkable affinity and selectivity may help in the identification of personalized integrin-based medicines. Diederich and coworkers[94] have used the privileged structure C_2-symmetrical 3,4-disubstituted pyrrolidines as nonpeptidic human T-cell leukemia virus 1 protease (HTLV-1 PR) inhibitors, which may be a new avenue to explore HTLV-1. The scaffold selected had previously been designed and evaluated to inhibit the related HIV-1 protease, and therefore, it was logical to explore the related protease. This privileged scaffold exhibited nanomolar affinity and may be one of the most potent nonpeptidic inhibitors of HTLV-1 PR reported. X-ray data gave further insight into this small-molecule mode of interaction. Vilaivan[95] has reviewed using pyrrolidinyl peptide nucleic acid (PNA) with an α/β-dipeptide backbone, among others, as a possible new privileged avenue for the design of oligonucleotide mimics.

2.05.2.1.5.4 Steroidal scaffolds

Blanco-Ania and coworkers[96] have reported an unusual pressure-facilitated extension of the privileged steroid scaffold. Mohamed and coworkers[97] have utilized a Cu(I)-catalyzed alkyne–azide 1,3-dipolar cycloaddition reaction to synthesize privileged 17a-[1-(substituted phenyl)-1,2,3-triazol-4-yl]-19-nortestosterone-17b-yl acetates. These steroidal analogs were investigated for progestational and antiproliferative activities. Synthetic steroidal agonist can be optimized for progestational potency by placing large chemical moieties at the 17a-position of the steroid scaffold. Several analogs showed low nanomolar modification to the rat uterus using histopathologic endpoints. At up to 40 mg kg^{-1} dosage, the tested compounds were nontoxic. From an anticancer perspective, the privileged steroidal analogs showed 46–57% growth inhibition in the central nervous system (CNS) cancer SNB-75, renal cancer A498, and prostate cancer PC-3 cell lines mediated by cell cycle arrest.

2.05.2.1.5.5 Epoxy compounds

Tan and coworkers[98] have investigated the antibacterial activity of a range of epoxypyrrolidinones prepared by epoxidation of carboxamide-activated bicyclic lactams against *S. aureus* and *E. coli*. These scaffolds may be viewed as mimics of the natural products pramanicin and epolactaene. Lin and Tan have written an excellent review on the cross kingdom action of phytohormones,[99] naturally occurring molecules (such as the gibberellins, salicylic, and jasmonic acids) that act as a functional privileged scaffold. These molecules show a variety of bioactivities such as antitumour, antiviral, and immunomodulatory activity that justify their title as privileged scaffolds. Although phytohormones are outside the scope of this work, there may be many more complex, natural, privileged structures yet to be discovered and investigated.

2.05.2.1.6 Arylated piperidine/piperazine ring systems

We next consider the single unsaturated six-membered nitrogen-containing heterocycles joined to an aromatic ring system (**Fig. 14**).

Rutjes and coworkers have extensively reviewed the synthetic approaches to the 3-hydroxypiperidine privileged scaffold[100] that is prevalent in bioactive natural products. Kim and coworkers[101] have developed an efficient synthesis of 140 diversity-driven tetrasubstituted Δ^5-2-oxopiperazine privileged structures that mimics the β-turn structural motif of proteins without the loss of stereochemical purity using a fluorous tag approach. The claim that these privileged scaffolds mimicked β-turns was demonstrated via an in silico study that involved conformational overlapping with β-turns and distance measurements.

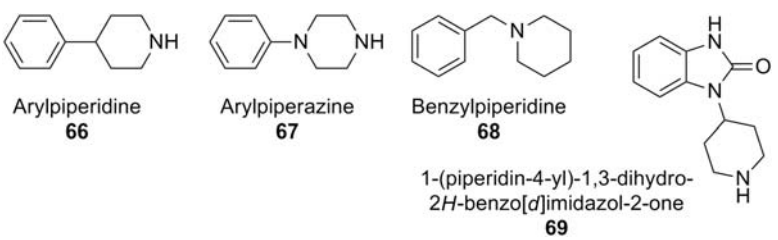

Fig. 14 Piperidine/piperazine ring systems linked to an aryl core **66**–**69**.

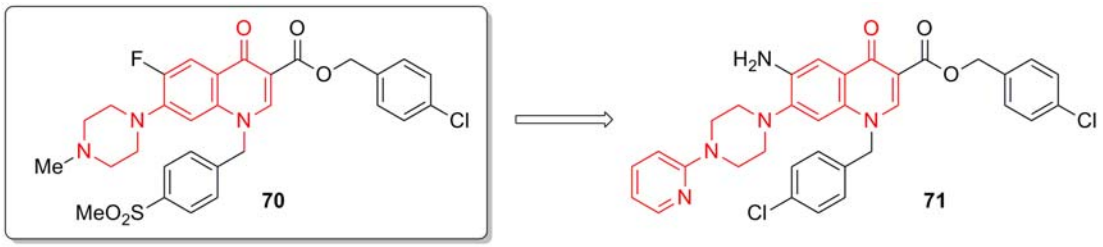

Fig. 15 The 6-aminoquinolone scaffold **70–71**.

Manfroni and coworkers[48] used their previously reported 6-aminoquinolone privileged scaffold **70** to prepare new antibacterial and antiviral agents (Fig. 15). In particular, they demonstrated inhibition of NS5B polymerase as a potential new therapeutic intervention for HCV. The most potent compound **71** prepared demonstrated inhibition of NS5B polymerase ($IC_{50} = 6.9$ nM), a selective antiviral effect ($EC_{50} = 3.03$ μM), and no cytostatic effect up to $CC_{50} > 163$ μM in Huh 9–13 cells by MTS assay. Key to the success was the early introduction of a further privileged motif at the C7 position, an arylpiperazine motif. The synthesis began with an acrylate that was reacted with 4-chlorobenzylamine, followed by base-mediated thermal S_NAr to form the core 6-aminoquinolone scaffold. Acid-mediated hydrolysis of the ethyl ester under microwave irradiation afforded the carboxylic acid to install the 4-chlorobenzyl ester. Finally, an S_NAr reaction with pyridyl piperazine followed by reduction revealed the amino functionality in the active compound.

Meng and coworkers[102] developed novel CB_1 receptor modulatory agents, using a privileged structure-based approach derived from the benzhydryl piperazine scaffold, as a strategy to investigate the control obesity. Structural modification to the original four hit compounds led to a lead series by iterative fragment A, B, C, and D SAR studies. In particular, compound **21** (shown in Fig. 6) had a >2000-fold selectivity profile for hCB_1 ($K_i = 0.15$ nM (hCB_1) versus 329 nM (hCB_2)). In diet-induced obese Sprague–Dawley rats, **5** was shown to reduce body weight for the first time for this scaffold.

Capuano and coworkers[103] investigated a privileged structure approach to dopamine D_2R ligands as an approach to the potentially therapeutically valuable biased agonism of GPCRs as antipsychotics (Fig. 16). By using three distinct privileged structures and varying changes to the linker and heterocycle cores, the relative activity and selectivity as a D_2R ligand were probed. Privileged structure-containing compounds prepared were profiled for biased agonism at the D_2R in Cyclic adenosine monophosphate (cAMP) and pERK1/2 signaling assays. It was found that substitution of the phenylpiperazine privileged structures affected agonism bias when the thienopyridine was removed. However, addition of the thienopyridine overruled the effect of phenylpiperazine substitution. This was rationalized by the proposed extended-binding mode present for this compound with the second heterocycle (thienopyridine) interacting with a secondary binding pocket. This is an unusual case where one privileged structure can overrule another privileged structure. **72** is the first example of a selection rule for an inhibitor containing multiple privileged structures.

The linker between the privileged structures (phenylpiperazine and thienopyridine) was another determinant of affinity. In particular, linker length (3–5 carbon atoms) gave rise to partial agonism at the D_2R. It was proposed that compounds containing one heterocycle plus the linker bind to the D_2R in a different orientation to the larger multipocket binding structure. It was found that simple substitution around the privileged heterocycle terminal groups led to similar affinity of D_2R ligands, as in aripiprazole, but has dramatically different bias profiles.

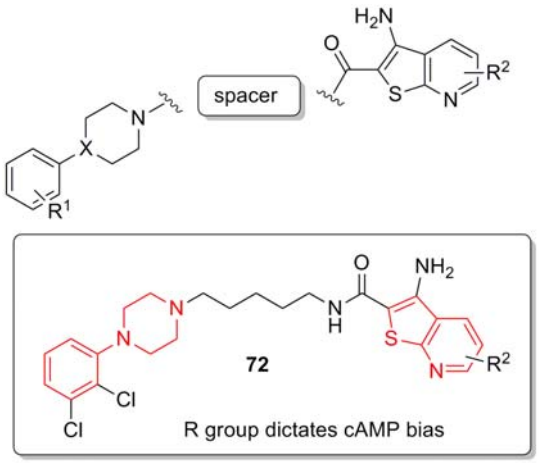

Fig. 16 A privileged approach to D_2R ligands.

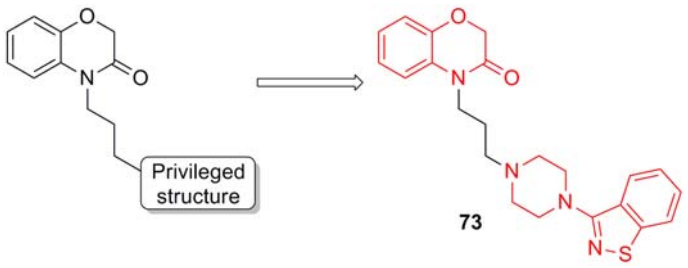

Fig. 17 A privileged structure approach to new antipsychotics.

Capuano and coworkers[104] have also recently shown that SB269652 interacts with one protomer of the dopamine D_2R and, via a dual mode of action, allosterically inhibits the binding of dopamine at the other protomer. To probe the structural cause of this allosteric action, various head groups were exchanged. For instance, the tetrahydroisoquinoline head group could be replaced with other D^2R "privileged structures" to generate orthosteric antagonists. Another privileged element, the indole NH, acting as a hydrogen-bond donor, was found to be crucial to maintaining the allosteric interaction. However, other related privileged structures such as the azaindole conferred a 30-fold increase in affinity while maintaining negative cooperativity. These privileged structure replacements were found to provide new SAR data on a class of bitopic ligands that are negative allosteric modulators of the D_2R.

Szabo and coworkers[105] used privileged structures found in clinically prescribed antipsychotics to develop new ligands (Fig. 17). Interaction with multiple targets is a useful drug design approach to treat the variety of symptoms of schizophrenia. For instance, the M_1AChR is a useful target for cognitive issues prevalent in many CNS disorders, and D_2 and 5-HT_{2A} receptors are useful targets to engage antipsychotic activity. A hybridization strategy of an M_1 scaffold (benzoxazinone) and a D_2 scaffold (substituted piperazine) was employed. Using this approach of hybridizing two known but separately engaging privileged structures, **73** was prepared that not only retained activity against M_1AChR and D_2R but also engaged 5-$HT_{2A}R$. This approach of "designing in" multiple pharmacologies is a new and enabling approach that is reliant on the privileged structures and their inherent effects against the multiple targets selected.

Liu and coworkers[106] developed a new series of 4-benzoylpiperidine derivatives as regulators of glycine transporter 1 (GlyT1) activity, a potential strategy in the management of schizophrenia. Bioisosteric replacement of the pyridine ring in RG1678 and modification of the piperazine ring based on incorporating extra heteroatoms and the need to compensate for the loss of binding energy resulted in potent ($\sim IC_{50} = 30$ nM) examples. Furthermore, based on the privileged structure template coupled with rigidification of the terminal acyl phenol to a benzo[*d*]isoxazole resulted in blood–brain barrier penetrant examples, such as **22** (Fig. 6), with good selectivity for GlyT1 over GlyT2, $D_{1/2/3}$, and 5-$HT_{1A/2A}$ receptors. Crucially, the most potent examples were effective on the Phencyclidine (PCP) treated schizophrenia-like behavioral model at 40 mg kg^{-1}. A rationale for the relatively high dose is explained by the poor pharmacokinetics of the compound.

Spadoni and coworkers[107] have developed 5-HT_7 ligands by combining the privileged serotonin-like and arylpiperazine scaffolds. Although these molecules are supposed to bind to the same pocket on the receptor, Spadoni has postulated that these two molecules can bind to the same target but in different binding pockets. Using 5-hydroxyindol-3-ylethyl (or a bioisostere such as 3-hydroxyanilinoalkyl) and a 1-arylpiperazine moieties connected by a short linker, the prepared compounds were tested for their effects on the human 5-HT_7 serotonin receptor. Examples of potent antagonist ligands of the 5-HT_7 receptor were uncovered but with limited selectivity. Molecular modeling studies showed that the 5-HT_7 receptor can accept both privileged scaffolds in the hybridized (or fragment-linked) mode. The serotonin-like scaffold exists in the orthosteric site, and the arylpiperazine exists in an accessory pocket. This work demonstrates that it may be possible to develop new 5-HT_7 ligands by merging multiple privileged structures into a larger hybrid molecule.

Liu and coworkers[108] adopted the strategy of privileged fragment hybridization to prepare a novel collection of 4-aminopiperidinyl-linked 3,5-disubstituted-1,2-6-thiadiazine-1,1-dione analogs. These compounds were evaluated in vitro for anti-HIV activity in MT-4 cells, and although only weak inhibition was observed against wild-type HIV1, a mode of action was determined using the HIV-1 RT inhibitory assay with micromolar activity.

2.05.2.1.7 Benzodiazepine and related seven-membered ring systems

A commonly encountered privileged scaffold is the seven-membered ring system, usually fused to cyclic ring systems, represented by the benzodiazepine class.

For a recent review of the biological significance of the 1,4-benzodiazepine scaffold, see[109] Fig. 18. Benzothiazepines[110] are another class of privileged structure that have reported bioactivities as antimicrobials, antifungals, Ca^{2+} antagonists, and CNS depressant, among others. The reader is directed to this review for a comprehensive evaluation of synthetic routes to this core scaffold. Lee and coworkers[111] were inspired by the first examples of "privileged structures," namely, 1,4-benzodiazepin-2-ones, which show a wide range of binding affinities to multiple drug targets. Analysis of the benzodiazepine core shows they conformationally mimic beta turns. Using the same strategy of attempting to mimic beta turns, the pyrazolodiazepine scaffold is advocated as a new

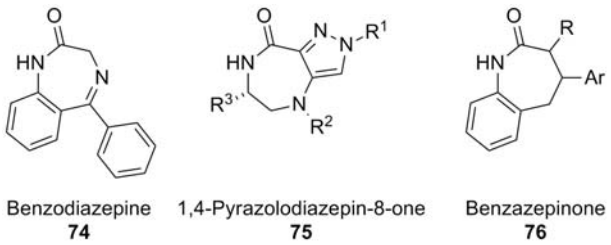

Fig. 18 Examples of the seven-membered privileged scaffolds **74–76**.

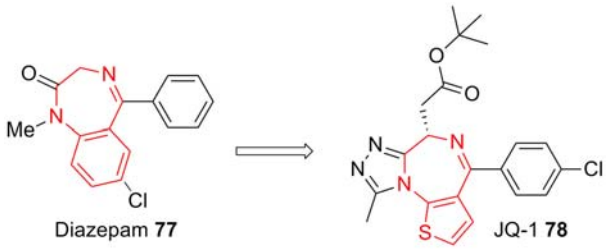

Fig. 19 Bromodomain inhibitors inspired by the privileged diazepam core.

privileged structure. One hundred and forty six examples of tetrahydro-1,4-pyrazolodiazepin-8(2*H*)-ones, such as **23** (Fig. 6), were prepared with three decoration points. Assessment of their bioactivity was through $P2X_7R$, BACE-1, and MC4R targets. It was found that examples from the collection showed activity against these targets based on the functional group decoration. Therefore, based on the conformation displayed, a variety of new and differing bioactivities were discovered derived from a privileged template.

Smith, Sanchez, and Zhou[112] have recently reviewed new applications of the privileged diazepine structure as bromodomain inhibitors. JQ-1 (**78**), for instance, (Fig. 19) based on a pseudodiazepam core is a potent inhibitor of acetyllysine binding activity and an important target for the gene transcriptional activity in inflammation and cancer, demonstrating new uses in the epigenetic age for the privileged structure methodology. In particular, an excellent commentary on the unique topological features of diazepine, which make it a versatile scaffold in drug discovery and chemical biology, is detailed, and the reader is directed to this article for further information outside the scope of this article. Medina-Franco and coworkers[113] have updated the chemoinformatics world with a take on the chemical space that is relevant to epigenetics, in particular, DNA methyltransferase (DNMTs) inhibition. DNA methylation is regulated on the epigenetics level by proteins, termed DNMTs. In turn, the covalent modification of DNA by the addition of a methyl group, if misregulated, is common in cancer and other diseases. Medina-Franco et al. have curated the blossoming collection of known inhibitors and revealed the structural diversity and chemical space coverage of this emerging field, showing the presence of privileged scaffolds within this new branch of chemical biology and drug discovery.

Galli and coworkers[114] have also exploited the privileged features of the 1,4-benzodiazepin-2-one core to prepare a novel class of *cis*-locked combretastatins (Fig. 20) that show similar cytotoxic and antitubulin activity in neuroblastoma cells compared with the natural product it is derived from, combretastatin A-4 (CA-4), together with an improved pharmacokinetic profile. CA-4 was in clinical trials; however, concerns relating to isomerism, half-life, and metabolism prompted the current research into conformationally

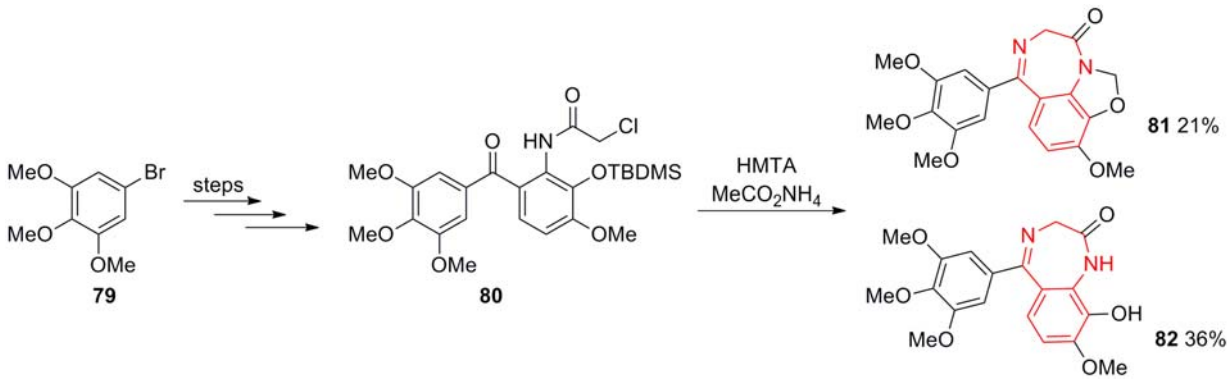

Fig. 20 A synthetic route to privileged *cis*-locked benzophenones **81–82** inspired by the combretastatin class.

locked analogs, which also contain a new privileged element. Compound **82** had a longer half-life than CA-4 in human liver microsomes (HLMs). It was found that the introduction of the 1,4-benzodiazepin-2-one not only retained activity but also prevented double-bond isomerization, O-demethylation, and aromatic hydroxylation metabolic pathways. Taken together, this privileged motif via the prevention of these pathways also mitigated the formation of glutathione conjugates, a previous disadvantage of CA-4.

The combretabenzodiazepine scaffold was prepared in five synthetic steps from the reaction of a 2-nitrobenzaldehyde (with *tert*-butyl dimethylsilane (TBDMS) protection of the phenolic oxygen) with an in situ prepared trimethoxyphenyl Grignard reagent in a 61% yield. Pyridinium dichromate (PDC) mediated oxidation of the newly formed racemic secondary alcohol afforded the diphenylketone scaffold (84%). Reduction of the ortho-nitro group with hydrogen over palladium on carbon smoothly afforded the ortho-amine functionality (78%). Treatment of the newly formed amine with 2-chloroacylchloride afforded the amide in 76% yield. Finally, treatment with ammonium acetate and hexamethylenetetramine (HMTA) mediated the formation of the imine and completed the ring closure with concomitant TBDMS group deprotection in a 36% yield. Intriguingly, it was also found that 6,7,5-ring system **81** was formed in a 21% yield, presumably from thermal decomposition of HMTA to yield formaldehyde to react with the OH and NH functionality. Viviano and colleagues[115] have developed a continuous flow process for synthesizing the privileged scaffold 1,4-benzodiazepin-5-one.

2.05.2.1.8 Single-cycle ring systems

Monocyclic scaffold can also possess privileged biological activity, often in combination with an extended network of ring decorations.

Palasz and Ciez[116] have reviewed the privileged scaffold uracil and related fused uracils from both a synthetic and biological activity viewpoint. Uracils (Fig. 21) are privileged motifs, with a panoply of bioactivities including antiviral and antitumor, herbicidal, insecticidal, and bactericidal properties. Ruvo and colleagues[117] note that 1,2,3 triazoles are privileged pharmacophores for inhibition of specific serine proteases, in particular the Acylamino-acid-releasing enzyme (APEH) enzyme inhibitor, opening a new therapeutic avenue.

Bai and coworkers[118] have used a privileged phenyltriazole core scaffold to prepare new inhibitors (such as **24**, shown in Fig. 6) of firefly luciferase. Firefly luciferase is one of the most widely applied and studied bioluminescent systems for the development of small-molecule probes through to imaging techniques. These compounds showed comparable activity to the widely studied inhibitor resveratrol but intriguingly were found to exhibit a novel inhibition mechanism based on kinetic studies. Kinetic studies showed a mixed noncompetitive response for the substrate amino-luciferin and were ATP-noncompetitive.

Hoyt and coworkers[119] discovered during a hit-to-lead campaign, a privileged structure-containing molecule, **25** (see Fig. 6) as a potent CYP11B2 inhibitor possessing selectivity over related cytochrome P450s (CYPs). Inhibition of CYP11B2, also known as aldosterone synthase, is validated in the clinic to lower blood pressure for treating hypertension. Coupled with good pharmacokinetics in rat and rhesus monkeys and lead-like properties, the privileged structure triazole-containing **25** has been considered for further drug development.

Cantley and coworkers[120] screened 9517 compounds (Fig. 22), pre-selected for their lead-like properties from a larger subset of 3,372,615 compounds against a dexamethasone-resistant T-cell acute lymphoblastic leukemia (T-ALL). One of the more potent examples found was the privileged structure-containing **90**; further SARs were determined leading to **91** and **92**. These compounds restored sensitivity to the current treatment, glucocorticoids, through upregulation of the self-named receptor. Further mechanistic experiments demonstrated the dependence on the expression of glucocorticoid receptor.

Terracciano and coworkers[121] have used structure-based techniques from the crystal structure of prostaglandin E_2 synthase 1 (mPGES-1) in complex with a known ligand to optimize the dihydropyrimidin-2-one, a privileged structure-containing scaffold.

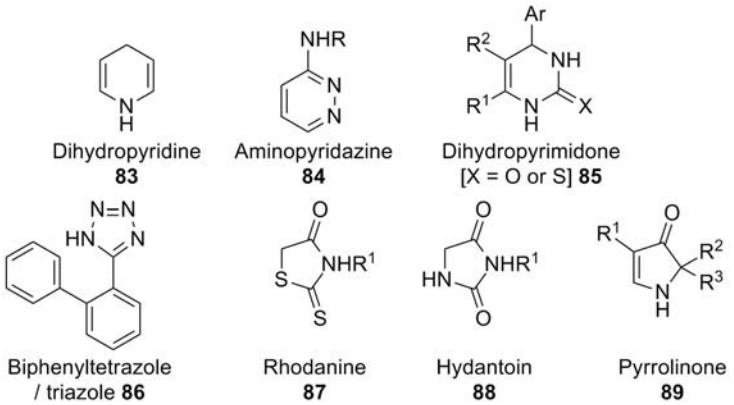

Fig. 21 Examples of the monocyclic scaffolds considered in this section **83–89**.

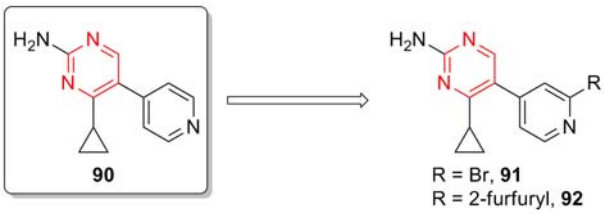

Fig. 22 Privileged hit and potent analogs for T-cell acute lymphoblastic leukemia.

A 10-fold improvement in mPGES-1 IC_{50} was obtained. Computational modeling suggested further dihydropyrimidine privileged scaffolds that may interact with mPGES-1.

Wermuth has recommended the pyridazine[122] scaffold as a possible new contender for a privileged structure due to their affinity to a variety of receptor proteins. From a physicochemical perspective, changing a phenyl ring to a pyridazine ring results in a two-logarithmic unit decrease in lipophilicity and concomitant increase in aqueous solubility, among other, changes in overall absorption, distribution, metabolism, and excretion (ADME) and toxicity improvements.

Gerona-Navarro and coworkers[123] have investigated a solid-phase synthesis of a library of amphipathic hydantoins. Hydantoins are another class of five-membered heterocycles that can be considered privileged due to the panoply of bioactivities associated with them, for example, antituberculosis and antiproliferative effects, among others. The library design consisted of attaching a privileged hydantoin molecule to a biologically diverse functional group, in this case guanidine-containing molecules. The library was prepared using parallel solid-phase synthesis upon an orthogonally protected Lys–Lys skeleton attached to the resin. The key synthetic step upon the Lys–Lys skeleton was the construction of the central hydantoin ring, which was accomplished via reaction of the terminal amino group with *N,N*-disuccinimidyl carbonate, and then, under basic conditions, the cyclization was completed. Removal of the alloc protecting group allowed the attachment of the guanidine-containing functional group to the C-terminal Lys side chain. In total, 112 amphipathic hydantoins were prepared from eight diverse guanidine functional groups and 14 different acyl terminal groups for the amino hydantoin alkyl linker. Screening of this library resulted in the discovery of novel TRPV1 ion channel blockers, in particular through blockage of capsaicin-induced Ca^{2+} influx. Particularly active hydantoins contained highly lipophilic fatty-type acyl substituents and substituted guanidines on the C-terminal chain. The thio-analogs of hydantoin, rhodanine, and related scaffolds pose a unique question of the privileged structure approach, which is worthy of further discussion in Section "**Single-cycle ring systems**."

2.05.2.1.9 Rhodanines (and related) as a special class of potentially privileged scaffolds

Mendgen and coworkers[124] have posed the following question regarding the rhodanine (and related) scaffold: *privileged structure or promiscuous binders?* Rhodanines are historically regarded as promiscuous binders by medicinal chemists. To probe whether the intuition of medicinal chemists toward this chemotype was indeed valid, a total of 163 rhodanines, hydantoins, thiohydantoins, and thiazolidinediones were tested against multiple biological targets in a focused and controlled campaign. Their behavior, including electrophilic reactivity and aggregation ability, was probed. A further comparison with binding mode behavior from published crystallography studies of these rhodanine-like structures was evaluated. Although promiscuous behavior can be identified at "screening concentration" levels, it is not sufficiently serious as to merit exclusion as a general criteria. It was found that the exocyclic double-bonded sulfur atom in some rhodanine-like structures is a critically important, high-density, binding site for both polar interactions and hydrogen bonding to the biological target. Intriguingly, the Michael acceptor capacity of the exocyclic alkene was found to be insignificant, and only 2 out of 163 examples demonstrated potential aggregation problems through particle size measurement (dynamic light scattering). The α-carbon attachment decoration proved key to selectivity of the rhodanine-like structures and limiting promiscuous effects.

As with any concept, there are limitations and rule breakers, for instance, examples of promiscuous inhibitors.[125–132] The rhodanine class, which meets some requirements of being privileged (showing activity in multiple assays) yet as often as they are shown to be a true hit, if proper precautions are not followed, turns out to aggregate and cause inhibition through less clear mechanisms. This warrants caution when interpreting biological results, leading to the policy of many academic and industrial labs to treat rhodanines as "guilty, until proved innocent" with regard to their promiscuous behavior.

Ge and coworkers[125] have reported the use of a catechol–rhodanine privileged scaffold for target and antitarget fishing experiments for NAD(P)(H) dehydrogenase-binding proteins. Using this chemical proteomics-based drug design strategy, they have reversed the common lead drug design strategy and identified NAD(P)(H)-binding proteins using privileged scaffolds to discover potential targets in *M. tuberculosis* and/or antitargets in the human liver.

Similarly, the thiazolidinedione-based drugs, rosiglitazone and pioglitazone, have been investigated by Hoffmann and coworkers[126] using a chemical proteomics approach to assess potential cardiotoxicity issues. Both drugs contain a common glitazone privileged core scaffold and, via a suitable linker, are attached to a resin. Although peroxisome proliferator-activated receptor γ (PPARγ) inhibition is well known with these drugs, they were further investigated to determine off-target binding events in the rat heart to rationalize reported cardiovascular risk factors associated with the drug molecules. Their results suggest that the glitazone

privileged scaffold has affinity for dehydrogenases, ion channels (such as voltage-dependent L-type calcium channels), and modulators.

Martinez and coworkers[127] have explored the SAR and 3-D-QSAR of a collection of thiadiazolidinone derivatives, with a view to identifying the structural features necessary for glycogen synthase kinase 3 (GSK-3) inhibition. In particular, the 2,4-substituted thiadiazolidinones were found to be the first ATP-noncompetitive GSK-3 inhibitors. Through a study of individual changes in the thiadiazolidinone heterocyclic ring, a molecular interaction network was identified with the approximate contribution of each heteroatom in the densely functionalized five-membered privileged ring system. Comparison with other five-membered heterocycles such as hydantoins, dithiazolidindiones, rhodanines, maleimides, and triazoles suggested the thiadiazolidinone core to be privileged for GSK-3 inhibition. Mapping studies have shown that the thiadiazolidinone core has two different binding modes with GSK-3, suggesting possible mechanistic differences in the GSK-3 inhibitory activity, for follow-up studies.

Raghubir and coworkers[128] have reinvestigated the thiazolidin-4-one privileged scaffold as a replacement for the alternative privileged thiazolidine-2,4-dione scaffold found in PPARγ agonists such as pioglitazone and rosiglitazone for neuroprotective effects in cerebral ischemia/reperfusion injury. Three of the 20 novel thiazolidin-4-one analogs of the generic glitazone scaffold were found to have significantly improved neuroprotection compared with rosiglitazone at the same dose, enhancing GLT-1 glutamate uptake and showing a 6 h postdose curative effect.

Zhou and coworkers[132] have designed and synthesized privileged 2-thioxo-4-thiazolidinone derivatives as PPAR-gamma-binding modulators. Two compounds were found to potently interact with peroxisome proliferator-activated receptor g (PPARg) with K_i values of between 12.15 and 14.46 nmol L^{-1}. SARs obtained with these privileged scaffolds were molecularly mapped on to the approved drug rosiglitazone (a PPARγ ligand-binding domain) to design new analogs and demonstrate the privileged scaffold approach.

If we look to the patent literature, we can find further examples of the employment of a privileged structure approach. Using a privileged structure as the starting hit, in a hit-to-lead campaign, a class of rhodanine-containing compounds (including **26**) was prepared by the Russell group at the University of Oxford.[133] These compounds displayed therapeutically relevant inhibition of proviral integration site for the Moloney murine leukemia virus kinase.

Zhao and coworkers[134] used a fragment-based drug discovery approach to the identification and optimization of a novel class of privileged 2-thiazolidinones as BET bromodomain, BRD4, inhibitors (**Fig. 23**). Several bromodomain inhibitors are potent anticancer agents, and some have reached clinical trials. Bromodomains act as a recognition site for signal transduction of acetylated lysines on the histone tail. The fragment-based approach adopted by the group was informed by crystal structure analysis, in particular the reversing of the direction of a sulfonamide group, which in turn led to the identification of a new binding mode. The most potent BRD4 inhibitors prepared had an $IC_{50} = 50–100$ nM measured via a fluorescence polarization assay and a $GI_{50} = 100–300$ nM in a cellular environment. Interrogation of the downstream c-Myc protein of BRD4 with the scaffold, alongside stability assays, reaffirmed the lead-like properties of this privileged fragment-derived series.

2.05.2.1.10 Spirocyclic structures

The reader is directed to this article for further background in this area (**Fig. 24**). The spirocyclic scaffold is an example of a 3-D-enriched scaffold, which can often exhibit privileged biological activity.

The privileged spirooxindole ring system was used as inspiration for a DOS library by the research groups of Zhang and Shi.[135] The 1,3-dipolar cycloaddition reaction between a range of electron-deficient alkynes and isatin-derived azomethine ylides afforded 36 spirooxindole-based 2,5-dihydropyrrole compounds in good to excellent yield (**Fig. 25**). Several compounds exhibited modest cytotoxic effects in vitro in MCF-7 cells (up to 28% inhibition at 100 μg mL^{-1}). The possible mechanism of the cytotoxicity of this compound was investigated using Hoechst 33 324 staining to determine whether the cytotoxic effects were related to cell apoptosis. A dose-dependent response was found by flow cytometry studies indicating that the observed cytotoxicity was due to cell apoptosis. To elucidate the mechanism of apoptosis, the levels of the signaling kinases ERK1/2, p38, and JNK and their respective phosphorylation states were measured. Levels of p38 and pJNK increased after 30 min, followed by pERK1/2 after 1 h, and remained high for 8 h post-treatment. Separate pretreatment of MCF-7 cells with a MEK1, an ERK1/2, or a c-Jun *N*-terminal kinase (JNK) inhibitor, respectively, did not affect the apoptotic response, and it was concluded that compound **101** acted on MCF-7 cells through the Mitogen-activated protein kinase (MAPK) pathway.

Mercurio and coworkers[136] have developed potent histone deacetylase (HDAC) inhibitors as anticancer probes using privileged spirochromanes as the key scaffold. In particular, using molecular modeling and biological evaluation feedback loops, their

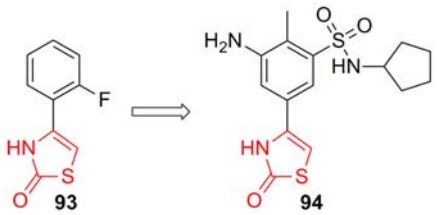

Fig. 23 Novel bromodomain inhibitors incorporating a privileged fragment.

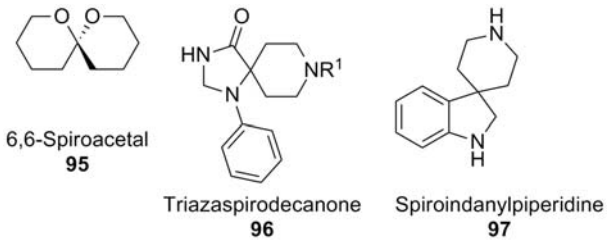

Fig. 24 Examples of spirocyclic structures considered in this section **95–97**.

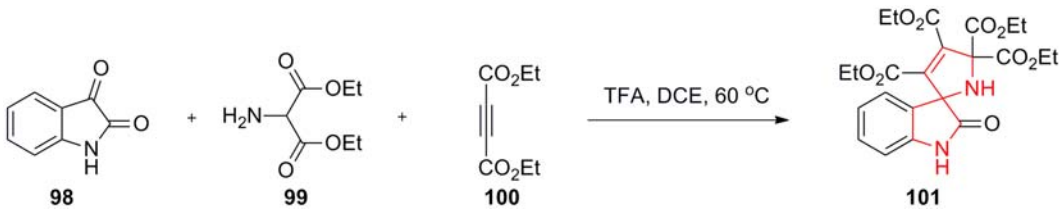

Fig. 25 A three-component reaction to a 2,5-dihydropyrrole spirooxindole-based library.

previously reported spiro[chromane-2,4′-piperidine]hydroxamic acid analogs were optimized via replacement of the piperidine ring with a range of cycloamines. These changes were made in the attempt to retain the potency of the privileged scaffold while improving the ADME profile.

He and coworkers[137] have reported SAR around a class of spiroindane *N*-methyl-1,2,4-triazole privileged structures as melanocortin transmembrane G-protein-coupled receptor subtype 4 (MC4R) agonists for the treatment of obesity. This privileged class of compounds showed subnanomolar *h*MC45 IC_{50} and in early experiments showed antiobesity efficacy in a mouse model; however, this was not reported to be solely due to the MC4R pathway. Further SAR studies revealed that it was possible to design a privileged scaffold that is both effective for in vitro inhibition of MC4R and obtain an MC4R-dependent mode of antiobesity efficacy in a mouse model. Lavieri and coworkers[138] have also reported the use of the 1,3-triazaspiro[4,5]decan-4-one privileged scaffold for isoform-2-selective phospholipase D inhibition.

2.05.3 Privileged Scaffolds to Identify Biologically Active Compounds Through Building Chemical Libraries

2.05.3.1 Natural Product-Inspired Chemical Synthesis

Natural products, often containing evolutionarily conserved privileged elements, can serve as inspiration for new chemical synthesis.

2.05.3.1.1 Benzimidazolinopiperazinones

Ventosa-Andrés and coworkers[139] used a solid-phase-supported route to highly decorated 2,3,10,10a-tetrahydrobenzo[4,5]imidazo[1,2-*a*]pyrazin-4(1*H*)-ones (Fig. 26), possessing a privileged structure element, namely, a benzimidazolinopiperazinone. These elements were incorporated to act as a peptide backbone conformational restraint. Critical to the success of their route was the modularity of their approach, in particular the tandem *N*-acyl-*N*-aryliminium ion cyclization–nucleophilic addition reaction, which proceeded with complete stereointegrity and control of the newly formed stereocentre.

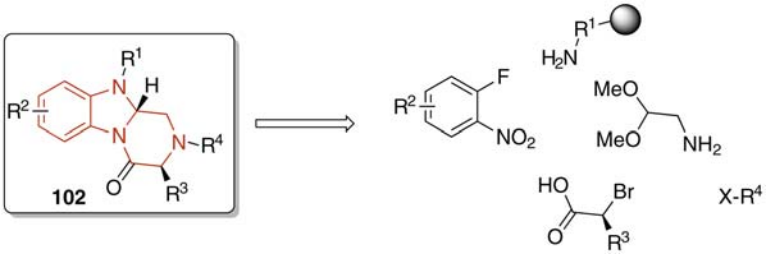

Fig. 26 Deconstruction of a highly decorated privileged structure.

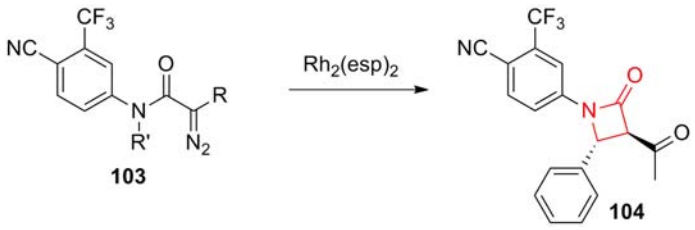

Fig. 27 Example of activity-directed synthesis.

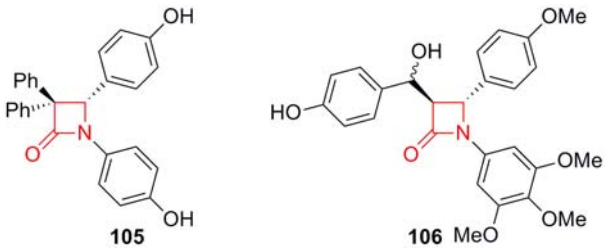

Fig. 28 The privileged β-lactam scaffold as an ER antagonist and tubulin-targeting compound.

2.05.3.1.2 β-Lactams

Karageorgis and coworkers[140] have reported an "activity-directed synthesis" discovery approach to the development of new biologically active small molecules (Fig. 27), in an analogous manner to evolutionary inspired biosynthetic pathways to natural products. As synthetic chemistry reactions have become more robust, medicinal chemistry has followed suit, utilizing these well-known reactions to prepare compounds that possibly are a smaller subset of the many molecular scaffolds that could be prepared. Methods such as DOS[15] and biology-inspired organic synthesis (BIOS) have expanded the collection of molecular scaffolds that have been tested for bioactivity, but there is still space for improvement. In the *activity-directed synthesis* approach advocated, bioactivity of the small-molecule product dictates the evolution of a synthetic strategy. In particular, substrates that could give rise to a wealth of alternative molecular scaffolds via modest changes to the catalyst and reaction conditions were used. After each round of array synthesis, the products formed were tested for androgen receptor agonism and showed dose dependency. Results obtained with round one of the array informed array two and so on, finally revealing after scale-up and purification biologically active ligands. In the current study, nanomolar ligands based on two templates with no previously reported activity androgen receptor were uncovered.

O'Boyle and coworkers[141] have reported a compound derived from the privileged β-lactam scaffold that is the first dual-targeting ER antagonist and tubulin depolymerization (Fig. 28). The majority of breast cancers express ER and treatment with a well-known ER antagonist; tamoxifen has contributed to a dramatic reduction in the lethality of this disease. Twelve analogs were prepared that decorated the core privileged scaffold derived from a Staudinger [2 + 2] cycloaddition to form the key β-lactam motif. In particular, compounds **105** and **106** showed the strongest binding affinity for the ERα form of ER ($IC_{50} = 40$ and 8 nM, respectively) and the ERβ form ($IC_{50} = 19$ and 15 nM, respectively). Compound **105** had the most potent antiproliferative effect in MCF-7 breast cancer cell assay. Of note, **105** led to the accumulation of cells in the G_2/M phase, which indicated mitotic blockade and depolymerization of tubulin in the MCF-7 cells. Compound **106** also induced apoptosis and downregulation of the expression of Bcl-2 and Mcl-1, prosurvival proteins. Despite other β-lactams being ER ligands, the unexpected and beneficial depolymerization of tubulin in MCF-7 cells can be attributed to a privileged starting point.

Waldmann and coworkers[142] have reviewed a powerful method for the construction of the privileged pyrrolidine scaffold, the 1,3-dipolar cycloaddition using azomethine ylides as the dipole. Due to the impressive regio- and stereocontrol, it has found uses in natural product synthesis and BIOS.

Collins and coworkers[143] used the natural product kinase inhibitor indirubin as their inspiration for the development of a lead-like kinase inhibitor screening library (Fig. 29). Using a parallel synthesis strategy, robust routes were developed to the 195 analogs prepared; these new compounds were designed to be consistent with guidelines for lead-like properties (many were also consistent with fragment-like guidelines). Members of their synthetic library consisted of 3-aminopyrazolopyridinones that mimicked the hydrogen-bond donor–acceptor motifs and the substitution vectors of indirubin. Indirubin itself contains the 6,5-ring system privileged scaffold, and the 3-aminopyrazolopyridinones synthesized possess an alternate heteroatom-rich 6,5-ring system with aryl substitution vectors; advantageously, this scaffold is >1000-fold more soluble than indirubin. The library was evaluated against a kinase screening collection, in particular diaryl-substituted compounds possessed submicromolar inhibition of tyrosine kinases with good levels of ligand efficiency. This result translated into the cellular environment and was confirmed via an antiproliferative assay in the MCF-7 breast cancer cell line ($GI_{50} = 40$–60 μM). *In silico* modeling was used to rationalize a probable binding mode to

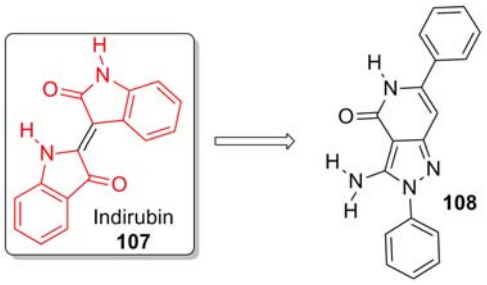

Fig. 29 Natural product-inspired privileged structure construction.

the kinase ATP active site. This research adds to the body of evidence that with careful consideration, natural product (privileged structure-containing)-inspired synthesis generates lead-like molecules with improved physicochemical properties and in this case, good levels of tyrosine kinase inhibition.

2.05.4 Natural Products as Lead Structures

2.05.4.1 Lead-Like Natural Products?

Pascolutti and Quinn have reviewed the concept of using natural products as lead structures.[144] In particular, they focus on controlling MW and the partition coefficient (log *P*) to generate natural product-like libraries that remain lead-like. Quinn and colleagues[145] have eloquently advanced the field of using natural products as drug-like screening candidates. From a survey of 126,140 unique natural products, 60% do not violate Lipinski's rule of five (Ro5), and through further data mining, a collection of 814 chemically diverse natural products with both drug-like and lead-like properties were determined. Similarly, Newman[146] has advocated the use of natural products or natural product-derived/inspired molecules as a source for the next generation of therapeutics. Kombarov and coworkers[147] have discovered an alternate systematic method to locate and describe the many variant of the privileged scaffolds through "BioCores." BioCores was developed through a detailed analysis of known drugs and natural products leading to the identification of privileged saturated and aromatic heterocyclic ring pairs. Medina-Franco and colleagues[148] have investigated a computer-aided discovery approach to natural products as DNMT inhibitors. Tao and coworkers[149] have defined natural product leads of drugs and, via molecular fingerprinting, clustered into discrete drug-productive groups. As a case example, Wezeman and colleagues[150] have reviewed the range of xanthone dimer-containing natural products that are both widespread in nature and, due to the range of reported bioactivities, privileged.

Balsera and coworkers[151] screened a library of natural products for in vitro activity against acetylcholine nicotine receptors (nAChRs) as possible starting points for the development of treatments for cognition disorders, schizophrenia, pain, and inflammation. In particular, their search for positive allosteric modulators of this target revealed privileged chalcone structure-containing molecules. The initial hit compound was isoliquiritigenin; a trihydroxy-substituted chalcone showed moderate positive allosteric modulation of nAChRs. Alteration of the hydroxylation pattern around the hit compound revealed SAR insights, leading to the synthesis of potent compound **110** (Fig. 30). Compound **110** demonstrated an $EC_{50} = 3.3$ mM. Coupled with no discernible cytotoxicity on human embryonic kidney (HEK) cells, primary hippocampal neurons, and no systemic effects on isolated rat organs, the privileged structure-containing **110** may be a viewed as a useful starting point for drug discovery approaches.

Foster and coworkers[152] took inspiration from the natural product canthaimide **111** (Fig. 31) to prepare a general synthesis of cantharimides. Using a [4 + 2] cycloaddition strategy of 3-alkoxyfurans with N-substituted maleimides provided an enabling *endo*-selective approach. The cantharimides prepared show promising lead-like properties for incorporation into medicinal chemistry approaches.

Rosini and coworkers[153] took inspiration from the natural product lipoic acid **115** (a privileged structure-containing natural antioxidant, Fig. 32) and a multiligand compound memoquin **116** and, via a hybridization strategy, prepared compound **117** as a multimodal compound to investigate Alzheimer's disease. Early work ruled out the need to develop a chiral synthesis of lipoic acid, and instead, racemic lipoic acid was coupled with known anticholinesterase agents, such as rivastigmine and memoquin.

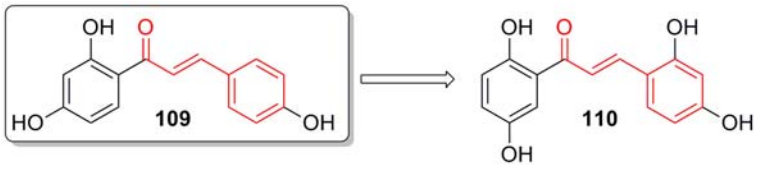

Fig. 30 Privileged natural product optimization.

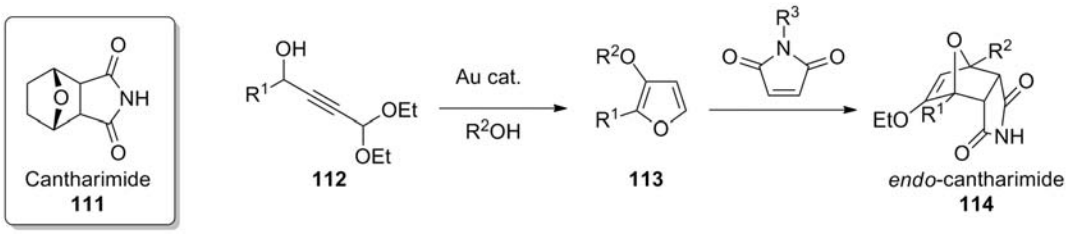

Fig. 31 Development of a lead-like synthesis of cantharimide derivatives.

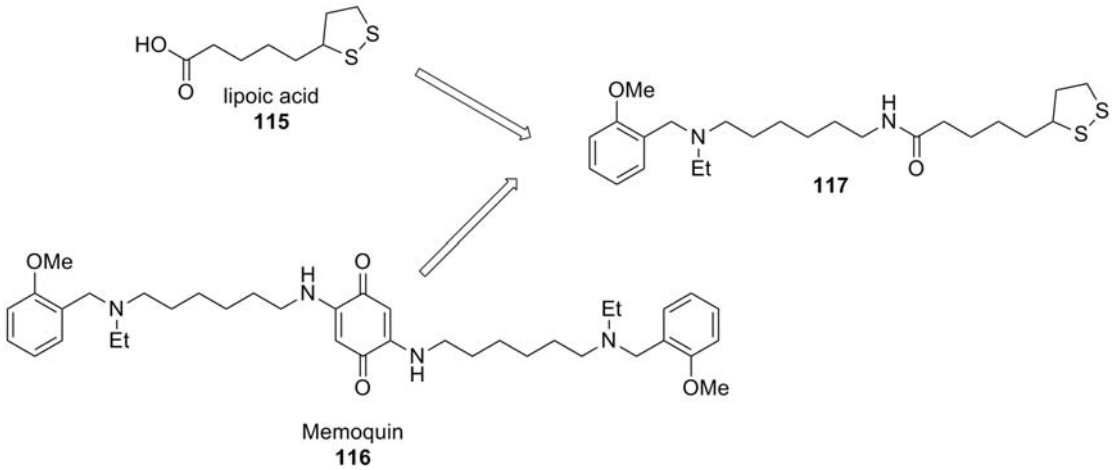

Fig. 32 Privileged multitarget-direct ligand from a hybridization strategy.

Compound **117** is an example of a multitarget-directed ligand (MTDL) that has balanced anticholinesterase and antioxidant capacities, coupled with limited cytotoxicity in neuronal-like cells (SH-SY5Y) at up to 50 mM concentration. This work has demonstrated the importance of using privileged structures to guide MTDL investigations.

Novaes and coworkers[154] investigated a natural product (−)-tarchonanthuslactone **118** (Fig. 33) that contains the privileged α,β-unsaturated lactone motif, but the bioactivity of which is unreported. Molecular simplification led to the synthesis of a collection of dihydropyran-2-ones derived from the natural product, using a strategy of Keck asymmetrical allylation as the key step. Evaluation of the compounds prepared in eight human tumor cell lines in vitro revealed the simplified compound (**119**) as the most cytotoxic and selective compound in six of the eight cancer cell lines analyzed. On one of the cancer cell lines, pancreatic cancer, apoptotic cell death occurs mediated by increased levels of reactive oxygen species. However, care needs to be taken due to the presence of both catechol and two Michael acceptor systems.

Porco and colleagues[155] have designed privileged β-lactone-containing compounds modeled on a natural product. These exhibited in vitro inhibition of the serine hydrolases ABHD10 and ACOT1/2 and the serine peptidases CTSA and SCPEP1, in PC3 cells. Camara and coworkers[156] have developed new privileged β-lactone-containing diverse scaffolds that target serine hydrolases combining aspects of activity-based protein profiling and the cross metathesis method. The β-lactone motif is a well-known scaffold in enzyme inhibitors and chemical probes.

Ononye and coworkers[157] took inspiration from a structurally modest family of natural products, thujaplicins (Fig. 34). In particular, beta-thujaplicin **120** contains a lead-like tropolone motif that is of low MW and has a multitude of diversification sites and of relevance to the intended metalloenzyme target, metal-binding functionality. The well-known anticancer drug target HDAC

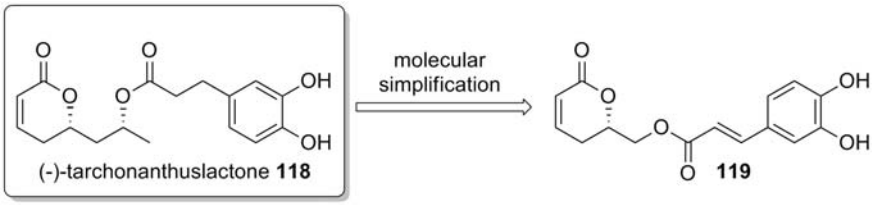

Fig. 33 Simplification as a route to privileged bioactive scaffolds.

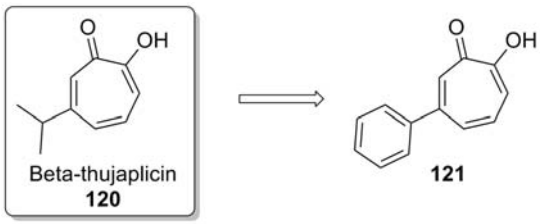

Fig. 34 Natural product-inspired development of thujaplicin analogs **121**.

was selected for biological interrogation. Of note, several tropolone derivatives including **121** displayed HDAC2 selectivity coupled with potent inhibition of T-cell lymphocyte cell lines and may be an underexploited scaffold for drug development.

Sen and coworkers[158] have described a natural product-inspired DOS library development of structurally discrete hybrid systems. Using a privileged pyrroloisoquinoline scaffold prepared via a tandem Pictet–Spengler lactamization reaction, further privileged scaffolds are attached to the core pyrroloisoquinoline unit. The natural product-inspired DOS library was screened for antiplasmodial activity against chloroquine-sensitive 3D7 cells with limited success (20–50 mM).

2.05.5 Chemical Transformations to Create Lead-Like Libraries

2.05.5.1 Lead-Like Library Synthesis Approaches

Bonnet has considered whether synthetic tractability can be computationally predicted for drug-like and lead-like molecules.[159] Intriguingly, the synthetic accessibility was compared via a scoring system between a computer prediction and 11 lab-based medicinal chemists who had to select the compounds. A good correlation (0.7) was obtained and suggests that to avoid missing some useful compounds, collective decisions should be reached on which compounds to synthesize. Oprea and coworkers have considered whether there are substantial differences between lead-like, drug-like, and "pub-like" in the chemical literature.[160] Examination of over 36,000 compounds in the literature (either high- or low-activity scaffolds) is based on MW, molecularly complexity, the number of hydrogen-bond acceptors and hydrogen-bond donors, cLog*P*, intrinsic water solubility (Log *Sw*), and the number of Ro5 violations. From this study, there were no significant differences between leads of known drugs and generally biologically active molecules. Intriguingly, compounds that displayed biological activity were generally less complex, less flexible, and more soluble than drugs and significantly smaller, less complex, and less hydrophobic than high-activity examples. Rishton has written an insightful review on the concept of lead-likeness in biochemical screening[161] with a particular emphasis on moving away from med chem dogma, avoiding the promiscuous inhibitor, frequent hitter, or warhead compounds to obtain meaningful results in biochemical assays. For this section, we will adopt Rishton's summary for the following "lead-likeness": MW = 200–350 Da, cLog*P* < 1.0–3.0, single charge present, and exclusion of chemically reactive functionality. This ordinarily differs from "drug-likeness": MW < 500 Da, cLog*P* < 5, H-bond donors < 5, H-bond acceptors < 10, polar surface area ≤ 140 A^2, and number of rotatable bonds ≤ 10. As the two concepts are interrelated from a lead compound, you would likely add 100–200 Da in weight with concomitant increases in cLog*P*, for instance, during drug development. Doveston and colleagues have described the problem of finding and synthesizing sufficiently large collections of compounds that are within the parameters of being lead-like molecules, using a strategy of lead-oriented synthesis.[162] Conversely, Leeson and colleagues have described the medicinal chemist as "recycling privileged structures"[163] in order to satisfy the concepts of "drug-like" and "lead-like" molecules. However, this biases the chemical profiles of screening collections to known scaffolds (e.g., compounds that we term as being privileged and/or tractable). Leeson proposes that we, although risky, travel the path less worn to new scaffolds. Lipinski[164] has looked back on his Ro5 guide and how it impacts on the next generation of drug-like and tool-like compounds. Jhoti and coworkers[165] have revisited the Ro3 philosophy and its relationship with the advances in fragment-based screening.

Soural and coworkers[166] have reviewed the synthesis of diverse privileged scaffolds using polymer-supported benzene sulfonamides as a general route to bioactive structures.

Tosatti and colleagues have reported a synthetic development in asymmetrical allylic amination[167] using an air-stable iridium catalyst and by employing dimethylsulfoxide (DMSO) as solvent allowed the incorporation of highly polar functionalized amines. The chiral products obtained are sp^3-rich in character and, with suitable physicochemical properties to be considered, valuable lead-like building blocks (**Fig. 35**).

Wang and coworkers[168] have investigated increasing ligand efficiency for the FK506-binding protein 51 through the development of conformational control (**Fig. 36**). Bischoff and coworkers have published the synthesis earlier.[169] In particular, two new classes of bicyclic sulfonamides were developed (a [4.3.1] and a [3.3.1] scaffold) to probe the contribution of conformational energy to ligand efficiency and simultaneously develop lead-like ligands for the protein target. It was found that the [4.3.1] scaffold had higher affinity compared with the [3.3.1] and monocyclic scaffolds, which was attributed to the conformational preorganization of the two key recognition sites. It was also shown that the [4.3.1] scaffold bound to FK506-binding protein 51 (FKBP51) was enthalpically driven and entropically disfavored in comparison with more flexible analogs. Furthermore, a cocrystal structure

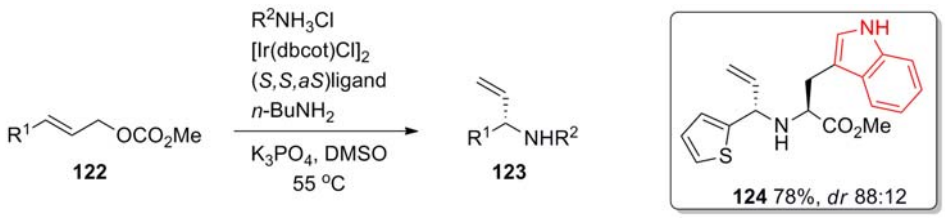

Fig. 35 Asymmetrical allylic amination to lead-like building blocks.

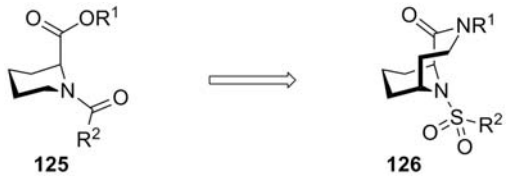

Fig. 36 Chemical transformation to increase conformational control and ligand efficiency in synthesis.

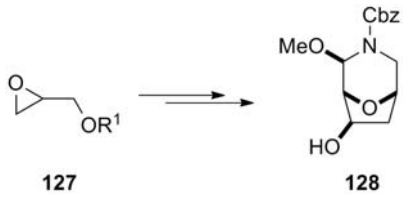

Fig. 37 Development of conformationally locked bicyclic morpholines **128**.

showed that the sulfonamide nitrogen in the bicyclic analogs accepts a hydrogen bond from W113 that mimics the FKBP transition state, giving rise to the first functionally active ligand for FKBP51. Taken together, these findings suggest that lead-like ligand rigidification can enhance affinity; however, it was not due to the expected entropic advantage but instead an enhanced geometric contact mimicking the highly conserved hydrogen bond–dipole contact in FKBP ligands.

Bogacki and coworkers[170] have developed a route to conformationally locked bicyclic morpholines **128** (Fig. 37), reminiscent of the bispidine scaffold (see Fig. 13) from commercially available building blocks. The flexible strategy employed allows for late-stage diversification of these lead-like motifs.

Doveston and coworkers[171] have addressed a challenging aspect of enumerating collections of lead-like compounds for primary screening that could target new lead-like chemical space (Fig. 38). In total, the synthesis of 52 lead-like scaffolds from only 13 chemical precursors was accomplished. Crucial to the success of the strategy was the use of robust, functional group tolerant reactions that were convergent in nature, such as in the preparation of **131**.

Rawling and coworkers[172] have contributed to preparing 3-D space-enriched libraries by developing a six-step method to a sp^3-rich chemical scaffold **134** (Fig. 39). Using a highly regio- and diastereoselective tandem nitrone synthesis followed by intramolecular nitrone–alkene [3 + 2] cycloaddition, 543 lead-like compounds were prepared, inspired by the core skeleton.

Craven and coworkers[173] have designed and developed modular syntheses of six small-molecule libraries inspired by alkaloid natural products (one example is shown in Fig. 40), using strategies such as palladium-catalyzed aminoarylation and/or dipolar cycloadditions. For example, inspired by the structures of nicotine **135** and anisomycin **136**, an elegant Pd-catalyzed

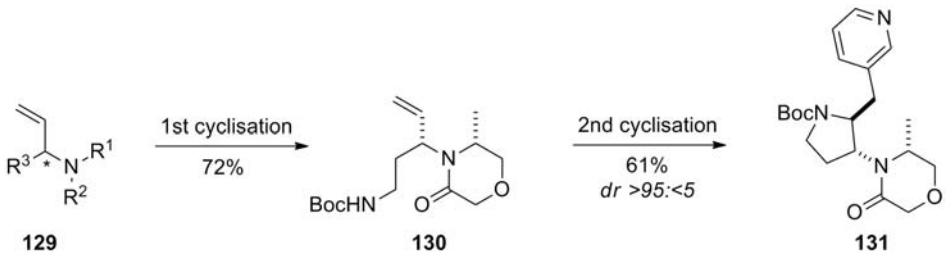

Fig. 38 Two-step route to over 50 diverse lead-like chemical scaffolds.

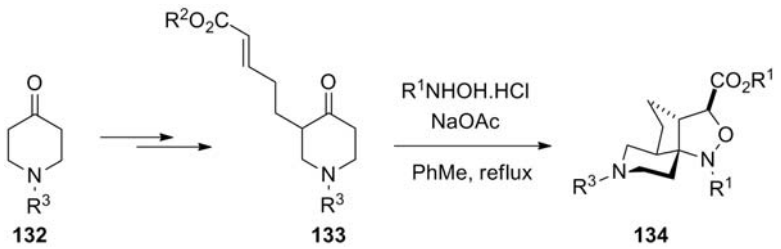

Fig. 39 Synthetic route to sp^3-enriched chemical scaffolds.

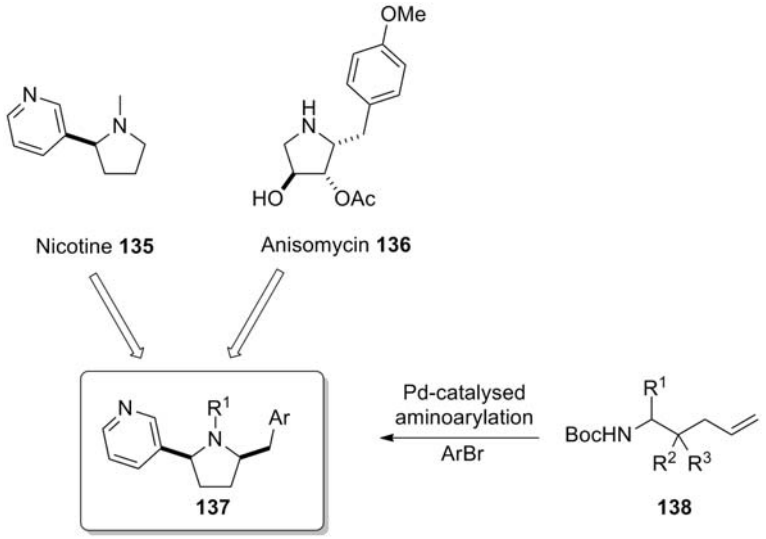

Fig. 40 An example of one of six modular syntheses of natural product-inspired libraries.

aminoarylation with an aryl bromide and a protected aminobutene **138**, a composite structure containing a lead-like privileged element was prepared, **137**. Five of the six libraries were subsequently validated through both scope and limitation studies and predicted molecular properties, leading to the production of over 2500 novel alkaloid-like small molecules for screening. A successful compound synthesis rate of between 58% and 84% was achieved during the library campaign.

Lüthy and coworkers[174] have developed lead-oriented synthetic routes to six 3-D enriched molecular scaffolds containing the privileged piperazine, pyrrolidine, and piperidine cores (representative examples **139–142** are shown in Fig. 41). Using a strategy of N-Boc α-lithiation followed by trapping. On the basis of this chemistry, a virtual library of 190 compounds was assembled, incorporating features from all six scaffolds, and 92 molecules met the lead-like criteria of Log *P*, number of heavy atoms, and tPSA. Furthermore, the 3-D shapes of the enumerated scaffolds were analyzed using normalized principal moments of inertia, giving 46 scaffolds that met both criteria.

Stocks and coworkers[175] have developed a pragmatic method to align the often separated concepts of compound diversity and lead-likeness to enable the scientist to pick with confidence compounds to investigate further from large virtual libraries (Fig. 42). As part of this paradigm shift, Stocks discloses (i) a method for decreasing synthetic attrition through grouping reagents by reaction type, (ii) a predictive method to minimize synthetic effort on compounds that have the potential to exhibit toxicity or less than desirable physicochemical properties, and (iii) a compound selection process that meets the earlier criteria yet also maintains diversity coverage. Taken together, this approach employed at AstraZeneca generated premium quality compounds with increased lead-likeness and novelty. As a case example, a virtual library of 100,299 potential compounds was filtered based on the outlined parameters to yield 12,837 or 12.8% of the compounds that passed these hard cutoffs. A further round of diversity analysis gave a final target size of 518 compounds that covered the complete chemical space of the previous selection. The synthesis of a bisazetidine spirocyclic library (represented by **145**) is one possible outcome.

Nelson and coworkers[176] have identified a paucity of approaches to both fused and C-substituted piperazines scaffolds, and through the development of a modular synthetic approach of the reaction of a cyclic sulfamidate (or hydroxyl sulfonamide) followed by cyclization, the synthesis of substituted piperazine and homologated 1,4-diazepine and 1,5-diazocane scaffolds was prepared (an example of the method to a 1,4-diazepine **148** is shown in the Fig. 43). Using this approach, a large collection of analogs with variations to ring size and substitution pattern of this underrepresented scaffold was achieved. These lead-like molecules were complementary to commercial compound screening collections. Furthermore, a virtual library was assembled using this

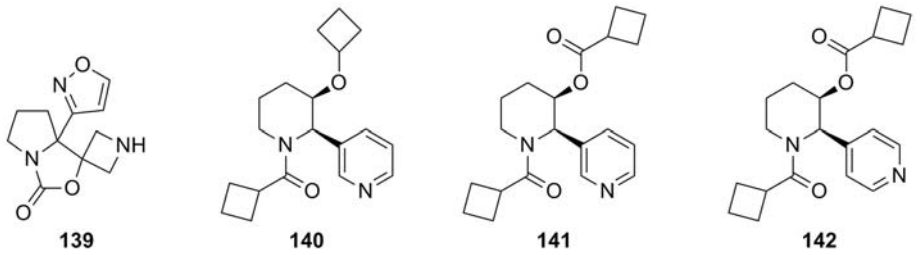

Fig. 41 A lead-oriented synthesis to 3-D-enriched scaffolds **139**–**142**.

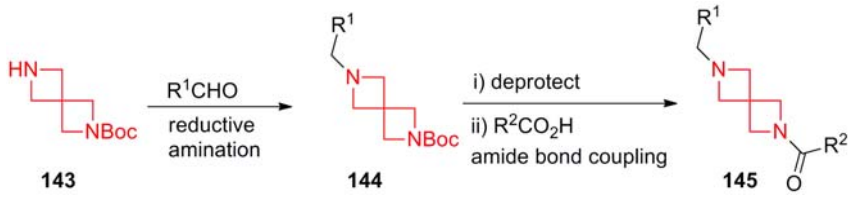

Fig. 42 An approach to align compound diversity and lead-likeness.

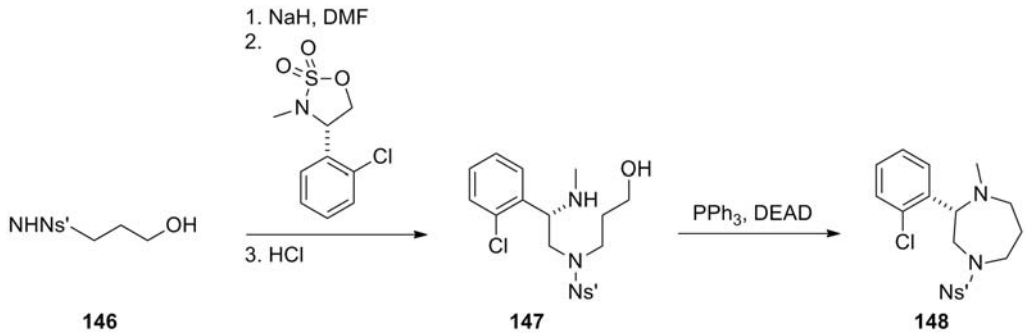

Fig. 43 An approach to C-substituted cyclodiazines, **148**.

synthetic route and followed by deprotection, and approximately one-third of the collection possessed lead-like molecular properties and 3-D shape complementarity properties.

The Wnt proteins are another group of extracellular proteins that initiate signaling cascades that can lead to transcriptional activation and are important in carcinogenesis and cell differentiation. A BIOS-derived library of 91-substituted oxepanes and oxepane-containing frameworks was designed, based on recognition of the oxepane ring as a privileged scaffold embedded in diverse natural products with varying biological activity.[177] Diels–Alder cycloadditions to intermediate 6-vinyl-2,3,4,7-tetrahydrooxepines were used to diversify the core scaffold. The compounds were screened in a cell reporter assay sensitized to detect stimulation of Wnt3a-dependent transcription. Pathway activators that acted synergistically with the presence of the Wnt3a isoform were detected, and subsequent SAR studies identified the activator wntepane 1 (**153**; Fig. 44; ED_{50} 1.8 μM). An affinity probe based on **153** linked to biotin was used to capture potential targets, and reversible binding to the Wnt membrane receptor Vangl1 was demonstrated, the first time a tool molecule targeting this protein was reported.

Also taking a privileged scaffold approach based on indoline alkaloids, Arya and coworkers designed a skeletally diverse DOS screening library that provided inhibitors of focal adhesion kinase (FAK), a protein involved in tumorigenesis and metastasis.[178] N-Alloc-protected 2-formylindolines or homologues were functionalized by addition of allylic or homoallylic Grignard reagents under Felkin–Anh control (Fig. 45). After alcohol protection, the resulting proximal vinyl groups were reacted using ring-closing metathesis (RCM) to afford 6-, 7- and 8-membered rings fused to the indoline scaffold. Compound **157** inhibited FAK activity (30% inhibition at 30 μM), but its mode of action (ATP-competitive or allosteric) was not determined, although docking studies suggested an ATP-site inhibitor. In a cell proliferation assay, **157** had a cytotoxicity of 39 μM and reduced expression of FAK autophosphorylation on pY397. The inhibitor also reduced MDA231-M cell invasion and motility, which may at least in part be due to FAK inhibition.

MacLellan and coworkers[179] have sought to shine a light and bring some redress to the historical unsystematic exploration of chemical space by outlining a new conceptual framework. The proposed framework seeks to "capture, analyze, and plan synthetic

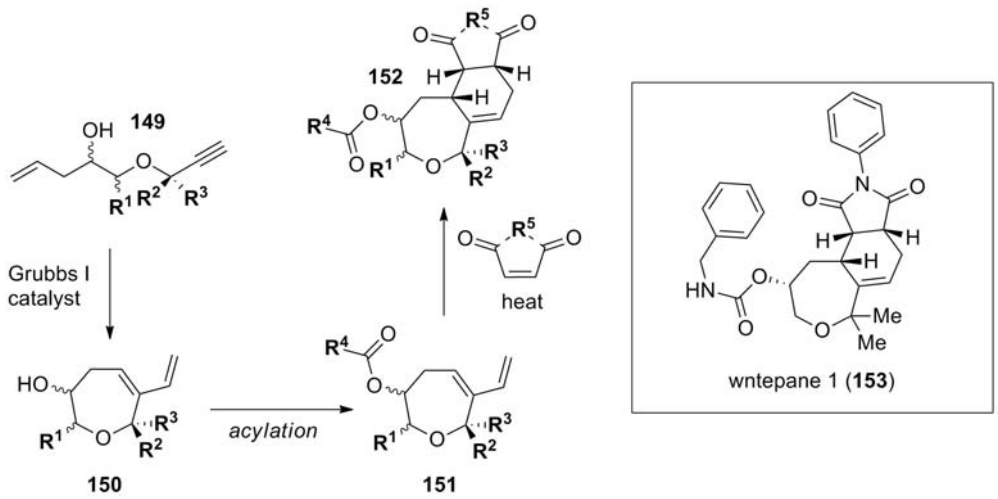

Fig. 44 BIOS and structure of an activator of Wnt signaling.

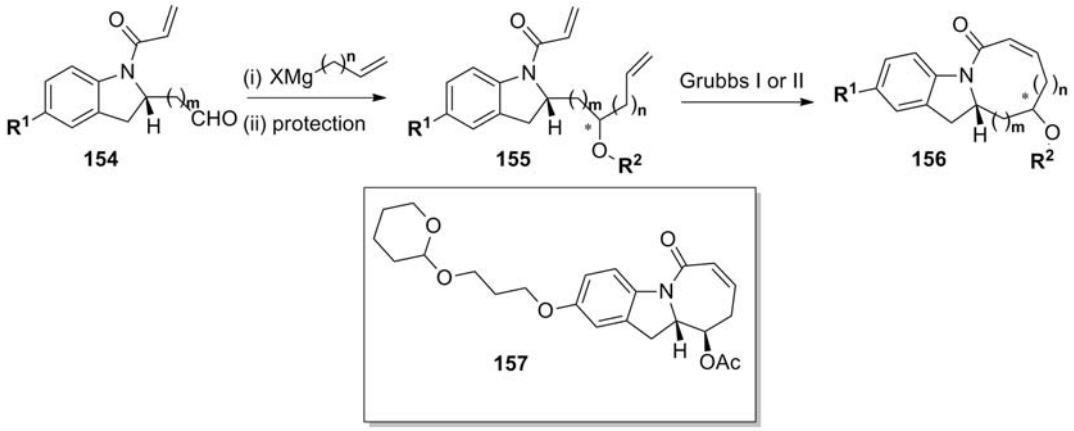

Fig. 45 DOS route to tricyclic indolines.

approaches" to help address this anomaly. An example of a synthetic approach to **160–162**, that is, modular in design to allow for combinatorial variants, is shown in Fig. 46 yet still able to target new expanses of lead-like chemical space. A key distinction to this framework is its ability to prioritize the relative synthetic power of often dissimilar approaches, with complexity generaton the guiding principle. In particular, this was achieved by exploitation of approaches that combine building blocks with greater possible connectivity or enumeration of the building blocks entered into a reaction.

Shaw and coworkers[180] have developed a one-pot, four-component reaction to a structurally diverse, lead-like library of 116 γ-lactams, such as **166** (Fig. 47). The key MCR to access the core scaffold occurred between ammonium acetate, *para*methoxythiophenol, *para*methyoxybenzaldehyde, and maleic anhydride. Through iterative chemical manipulation of the core γ-lactam, for example, amide-bond coupling, thioaryl cleavage, *N*-functionalization, and heterocycle-forming reactions, the complete library was assembled. Post-assembly, computational analysis of the library revealed that the molecular properties and 3-D shape diversity as being suitable for both drug lead discovery and chemical biology probe discovery.

James and coworkers[181] have developed a lead-like synthesis of tetrahydropyrazines (Fig. 48). Using a strategy of propargylic sulfonamide-mediated ring-opening of cyclic sulfamidates afforded intermediates suitable for Au-catalyzed cyclization to the tetrahydropyrazine core scaffold (**170**). Further reaction of the scaffold through chemical manipulation afforded a variety of carbon-substituted tetrahydropyrazine analogs with favorable lead-like properties.

A synthetic route to a new class of privileged tri- and tetracyclic quinazolines containing a medium-sized ring was reported by Hensbergen et al. (Fig. 49).[182] A synthetic route involving nucleophilic aromatic substitution and sequential Niementowski and (benzotriazol-1-yloxy)tris(dimethylamino)phosphonium hexafluorophosphate (BOP)-mediated ring closures afforded a collection of quinazoline-containing analogs (**174**) via the quinazolinone intermediate (**175**, another privileged structure). This application of a tandem cyclization strategy is a new and enabling route to rigidify kinase inhibitor-like quinazolines and has wide-ranging potential in the field of medicinal chemistry.

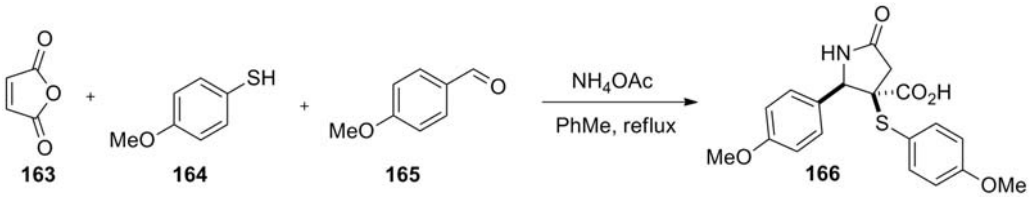

Fig. 47 A one-pot MCR to structurally diverse lead-like scaffolds.

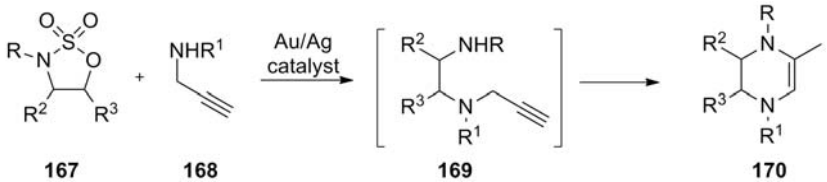

Fig. 48 Lead-like synthesis of tetrahydropyrazines.

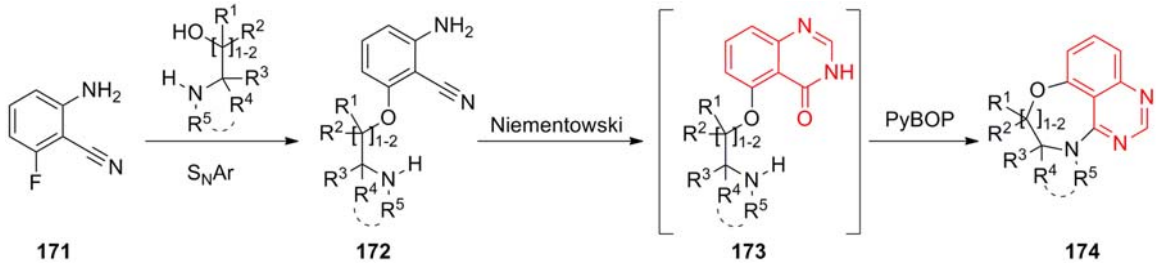

Fig. 49 An expedient synthesis of privileged tri(and tetra)-cyclic quinazolines.

Bull and coworkers[183] have developed an operationally straightforward, high-yielding, copper-catalyzed N-arylation of 2-imidazoles such as **177** (Fig. 50). The reaction is tolerant of a range of electron-rich and electron-poor (hetero)aromatic coupling partners and useful functional groups for late-stage diversification. The imidazole-containing products derived possess lead-like characteristics and are fragment-sized.

Lowe and coworkers[184] have developed a comprehensive synthesis of densely functionalized azetidine ring systems, including fused, bridged, and spirocyclic ring systems **178–184** (Fig. 51). These phenyl azetidine compounds are reminiscent of the phenylethylamine privileged structure (see **185**) prevalent in a variety of synthetic and natural drugs that affect the CNS. Using the solid-supported SynPhase lanterns, a 1976-member library of spirocyclic azetidines was also achieved. Representative examples of all the diverse azetidine families have had their physicochemical and pharmacokinetic properties evaluated in vitro to prioritize the classes

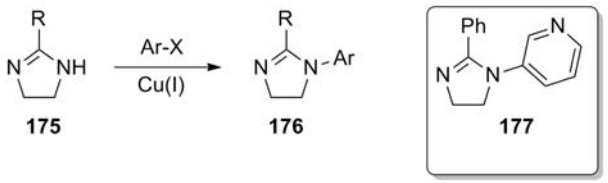

Fig. 50 Fragment- and lead-like synthesis of *N*-aryl imidazoles.

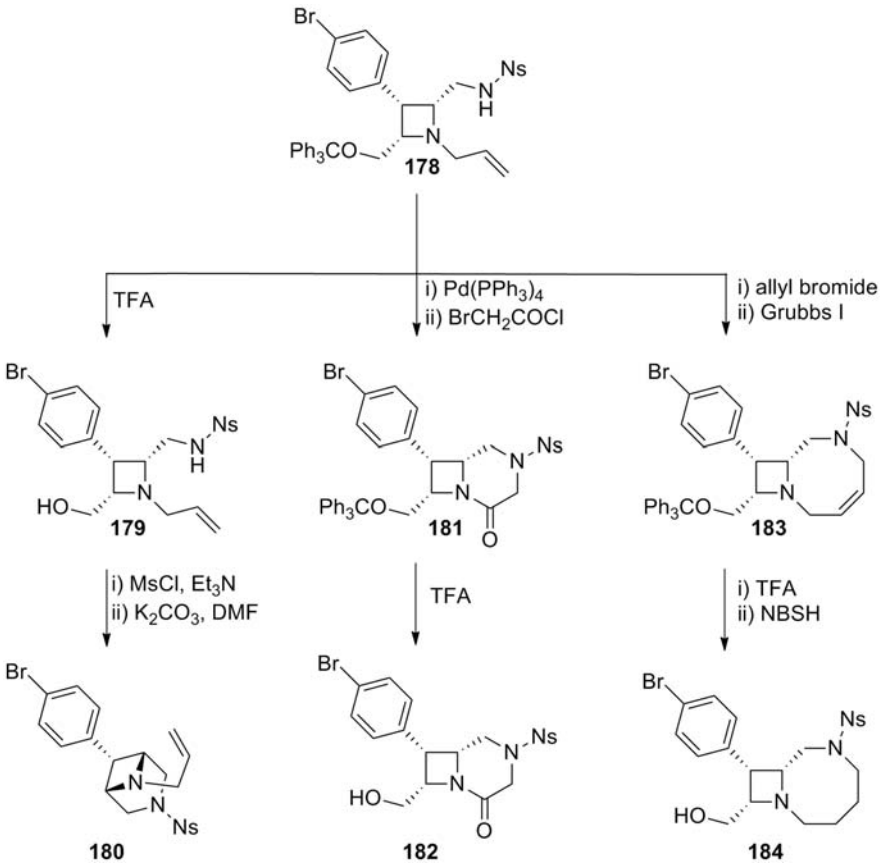

Fig. 51 DOS of densely functionalized azetidines.

to be taken forward for CNS studies. In particular, the *in silico* analysis of the library members showed a good balance of physicochemical properties for CNS application. Optimal compounds showed good ADME profiles in vitro.

The phenylethylamine scaffold has emerged as a versatile privileged motif prevalent in synthetic and natural drug molecules (Fig. 52), such as 3,4-methylenedioxymethamphetamine (MDMA). The area of natural product-inspired drug discovery has been extensively reviewed,[185,186] for instance, alkaloid-inspired libraries[185] and natural and physiologically ligands,[186] which are

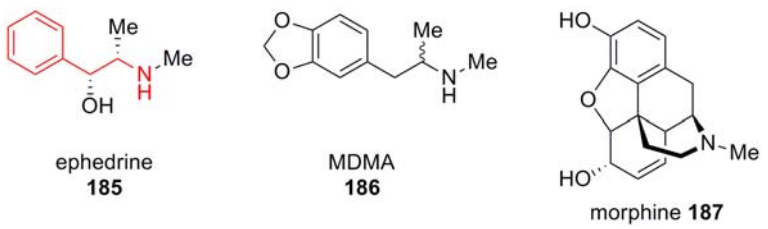

Fig. 52 Phenylethylamine, a privileged structure found in ephedrine **185**, MDMA **186**, morphine **187** (CNS BBB penetrant), and inter alia dopamine.

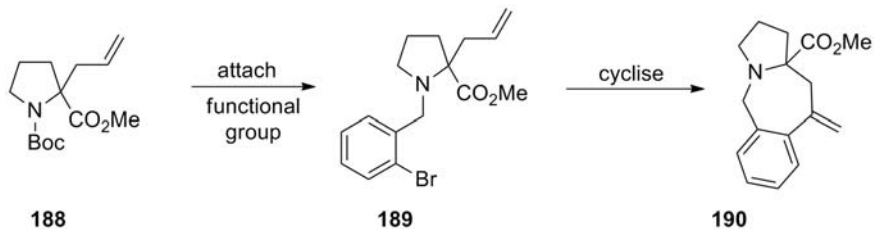

Fig. 53 Lead-oriented synthesis of over 20 new scaffolds.

also highly relevant starting points. Iterative deconstruction of natural product scaffolds can lead to privileged elements such as the indole and phenylethylamine scaffolds we see that are prevalent in the privileged structures discussed in Section "Privileged Scaffolds for Library Design and Drug Discovery."

Foley and coworkers[187] have developed a versatile strategy for lead-oriented synthesis of new scaffolds. As an example of the reaction products prepared, **190** is shown in Fig. 53; in total, 22 novel scaffolds, with the ability to interact with lead-like chemical space, were synthesized from only four alpha-amino acid-based building blocks and six linkage reactions. One aspect of developing new, diverse lead-like libraries is the fraction sp^3 (Fsp^3) challenge. Fsp^3 was first defined by Lovering[188] as a simple measure of the complexity of potential drug molecules. It is a twofold guideline: (1) carbon-bond saturation as defined by Fsp^3 where $Fsp^3 = (\text{number of } sp^3\text{-hybridized carbons/total carbon count})$ and (2) whether a chiral carbon exists in the molecule. The Fsp^3 has been shown to correlate with relative success of a drug candidate. It has been shown that attrition rate of small molecules in screening collections toward becoming drug candidates is correlated with the degree or lack of Fsp^3 present. Inspection of the virtual library showed that Foley's route prepared compounds with Fsp^3 ($m = 0.57$) versus commercial screening collections Fsp^3 ($m = 0.33$).

Ryabukhin and coworkers[189] developed a high-yielding and diastereoselective combinatorial approach to 1,2-disubstituted 5-oxopyrrolidines and 6-oxopiperidine-3-carboxylic acids (such as **193**) using a variant of the Castagnoli condensation of cyclic anhydrides, amines, and aldehydes (Fig. 54). Members of the collection of the compounds prepared meet the strictest criteria of lead-likeness based on their associated physicochemical properties.

Schmitt and coworkers[190] have utilized a lead-like design approach to a library of 2,4-bisheterocyclic-substituted thiophenes. These in turn represent a novel class of nanomolar Dyrk inhibitors with balanced pharmacokinetic properties and high ligand efficiency scores. This lead-like core translated into limited off-target activity against other kinases, namely, a dual Clk/Dyrk inhibition profile.

2.05.6 Conclusions and Outlook

2.05.6.1 Future Directions for Privileged Structure Development

The ubiquitous privileged structure will be with us for many years to come owing to the panoply of interactions with a range of biologically relevant targets and in many cases their ease of synthesis. With an eye on the future, an intriguing feature of some of the privileged structures detailed here is their potential ability to undergo hyperpolarization to enhance selectivity and detection in the NMR or magnetic resonance imaging (MRI) environment. For example, the tuberculosis drugs containing a privileged scaffold such as pyrazinamide and isoniazid have been probed in this manner.[191] For the same target, Ballell and collaborators[192] have described an approach to open-source tuberculosis drug discovery using 177 small-molecule leads. Intriguingly, the eight most promising families from the high-throughput screening (HTS) campaign all contain privileged elements. This demonstrates the potential of collaborative open-source screening, of which the privileged structure will remain a key element. Goldberg and colleagues[193] have made the case for designing novel building blocks as a key strategy to improve compound quality, and this

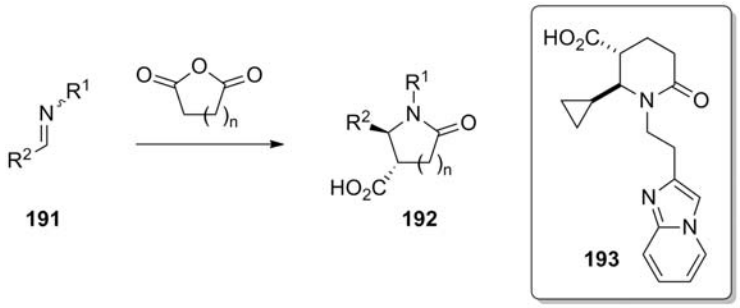

Fig. 54 A diastereoselective combinatorial approach to lead-like scaffolds.

may mean a shift away from the privileged scaffold in time. Open-source, collaborative research, informed with predictive in silico models, and new biophysical techniques will mean the privileged structure will be around until then and beyond.

Software programs and their major applications

AFFIT Program for generating geometrical restraints for small molecules and automatic ligand fitting into electron density
AIMLESS Program for scaling and merging multiple observations of reflections into an average intensity
ARP/wARP Programs for automatic model building and ligand fitting into electron density

autoBUSTER Tools and programs for refining structures against X-ray data
autoPROC Tools and programs to automate the whole range of steps involved in X-ray data processing
BALBES Automatic pipeline for molecular replacement
BLAST or PSI-BLAST Program for finding homologous sequences by (iterative) sequence alignment
eLBOW Program for generating geometrical restraints for small molecules
FoldX Program for quantitatively estimating contributions to protein stability and complex formation
Grade Program for generating geometrical restraints for small molecules
GESAMT Program for structural alignment of macromolecular structures
HHBlits program for finding homologous sequences by iterative comparison of profile hidden Markov models
HKL-2000 Program for processing single crystal X-ray data, scaling and merging of intensities as well as visualization of diffraction images
LABELIT Tools for pre-processing diffraction images, mainly used for indexing single crystal X-ray data
LigandFit Program for automatic ligand fitting into electron density
MOE Integrated drug discovery package
MolProbity Program for validating macromolecular structures
MOLREP Versatile molecular replacement program
MOSFLM Program for processing single crystal X-ray data and visualization of diffraction images
MRage Automatic pipeline for molecular replacement
MrBUMP Automatic pipeline for molecular replacement
PHASER Tools and programs for phasing macromolecular crystal structures, mainly used for molecular replacement and SAD phasing
phenix.ligand_pipeline Automatic pipeline for molecular replacement, refinement and ligand fitting
phenix.refine Program for refining structures against X-ray data
Pipedream Automatic pipeline for processing, molecular replacement, refinement and ligand fitting
Polyphony Tools and methods for the statistical analysis of protein structure ensembles
Protein Ligand interaction Fingerprints application within MOE Application to analyse, categorize and summarize protein–ligand interactions across an ensemble of structures via a fingerprint scheme
PyMOL Program for molecular visualization
REFMAC5 Program for refining structures against X-ray or cryo-EM data
RhoFit Program for automatic ligand fitting into electron density
Robetta Program for building models of protein domains (ab initio or comparative)
Site Finder application within MOE Application for identifying and evaluating binding sites in macromolecular structures
SiteMap Program for identifying and evaluating binding sites in macromolecular structures
TRUNCATE Program for converting intensities into amplitudes and scaling to an approximate absolute scale
WONKA Application to analyse, categorize and summarize protein–ligand interactions, protein conformation and water conservation across an ensemble of structures via a fingerprint scheme
XDS Program for processing single crystal X-ray data
xia2 Tools and programs to automate the whole range of steps involved in X-ray data processing

2.06.1 Introduction

Information on the molecular architecture of important drug targets, the elucidation of their structure–function relationships, and understanding the details of target–ligand interactions have a strong impact on the paths and fates of today's drug discovery projects.

Protein crystallography is the dominant technology that delivers this information. While, in principle, there are also other methods that are able to generate structural information, most notably nuclear magnetic resonance (NMR) spectroscopy which looks at isotopically labeled proteins in solution, structure determination by single crystal X-ray structure determination has turned out to be the most successful, most timely delivering, most broadly applicable, and highest throughput method and has matured to be the "gold standard" technology for structural biology in pharmaceutical research. It is particularly well suited for drug discovery for a number of reasons. It can provide the experimental evidence that a small molecule ligand binds to its target protein and to which functional site it binds. The resolution obtained by X-ray diffraction is high enough to allow for the elucidation of the atomic details of ligand–receptor interactions and the protein conformational changes upon ligand binding. It has no limitations to the size of the studied objects which can be as large as entire ribosomes. It provides a platform for intuitive visualization of drug action and facilitates the understanding of molecular mechanisms of action. And it inspires new hypotheses and experiments to probe the feasibility of small molecule agents to serve as suitable initial scaffolds for lead compounds and to inform the optimization of these initial leads into drug candidate chemical matter.

During the last two decades we have witnessed an explosion both in the number of macromolecular structures as well as of protein complexes with small organic ligands.

This explosion is due to a number of technological developments. Firstly, significant progress has been achieved in methods for recombinant protein production and purification. Secondly, on the level of protein crystallization, the miniaturization and automation, both for initial crystallization screening and crystal hit optimization, lowered the hurdles for entering this process stage and enhanced the probability to obtain high quality crystals diffracting to atomic resolution. For refractive proteins, novel approaches for the optimization of sample preparation such as in situ proteolysis, reductive methylation, or surface entropy reduction have been developed and again improved the probability of crystallization. The mining of the growing body of crystallization data has led to creation of more efficient crystallization cocktail screens. Thirdly, fluorescence-based thermal shift assays and dynamic light scattering are now routinely used for choosing not only the most suitable protein constructs, but also protein buffers or stabilizing ligands prior to crystallization. Further, developments in X-ray data collection protocols, the availability of low noise detectors and sample handling robotics, third-generation synchrotron beamlines, structure phasing approaches using anomalous signal and cryo-crystallography, supported by the concomitant development of associated software have greatly reduced the efforts to collect data and solve, refine, and validate the crystal structures. These technological advances have been spurred for the most part by the initiatives that followed the genome sequencing projects and focused on protein structure and function ("structural proteomics").

As a consequence of these developments, nowadays protein crystallography in drug discovery is operating in a high-throughput mode (high-throughput crystallography—HTX). Enablement of project support is done on time scales aligned with other project time scales, which often means that the three-dimensional structure of the target and a crystal form allowing for fast ligand costructure determinations are available at early stages in the drug discovery process. Therefore, areas of application span the entire project lifetime, starting with structure-based analysis of the "ligandability" of a drug target, supporting the hit validation stage after a biochemical or cellular high-throughput screening (HTS), entertaining fragment-based screening (FBS) activities as well as informing hit selection, and the crucial early stages of the hit-to-lead (HTL) phase. Finally, even for the ever growing area of biologics discovery, protein crystallography has an impact for instance in the definition of the antigen epitope. In the following sections we will discuss first the historical development of industrial protein crystallography and methods applied to achieve high throughput, before focusing on applications in the aforementioned drug discovery project phases.

Despite the tremendous progress made during the last 20 years, there still remain significant challenges and limitations to the technology. These comprise, for example, difficulties in protein crystallization due to protein conformational diversity, limitations in the understanding or preparation of protein chemical heterogeneity such as posttranslational modifications, dealing with intrinsically disordered but functional sections of protein primary structure, as well as limited experience in the work on integral membrane proteins (IMP), an endeavor which still is not routinely used in today's pharmaceutical protein crystallography. All these factors contribute to the failure of our technology in supporting a significant subset of projects. Finally, there remains a significant challenge to exploit the vast body of structural information obtained throughout a project lifetime. Suitable and efficient tools for structural data mining and aggregation of the information of a multitude of ligand costructures are still largely missing and often main conclusions are drawn for inspecting superpositions of just a few individual structures.

Toward the end of this review, we are describing our view on the future development of the field by describing the recent advances in the field of IMP structural biology and the developments in the areas of X-ray free electron lasers (XFELs) as well as cryo-electron microscopy (Cryo-EM) and their expected impact on our field of expertise within drug discovery.

2.06.2 Historical Development

The determination of the three-dimensional structures of myoglobin and hemoglobin around 1960[1,2] heralded the advent of protein structural biology. It showed that protein structures could be determined at atomic resolution and that molecular structures could potentially be useful to unravel the molecular nature of disease processes.

However, it took another 15 years until protein structures were used to guide synthesis of ligands for hemoglobin,[3] to our knowledge the first report to describe the process of design of "compounds … to fit a site of known [protein] structure". In a *Nature* review in 1976, Max Perutz predicted that "knowledge of the three-dimensional structure of these enzymes may open the way to the synthesis of tailor-made inhibitors for the treatment of such diseases" using examples from the serine protease field and their role in blood coagulation and lung disorders.[4]

In the 1960s and 1970s, a number of crystal structures of pharmaceutically relevant protein class representatives were determined, among them members of the trypsin family of serine proteinases, of the aspartyl protease family and influenza virus neuraminidase.[5–9] The structural information was used to understand the molecular details of the function of the proteins, to derive models for the actual drug targets (eg, of the blood clotting enzymes from structures of the homologous chymotrypsin/trypsin) and to describe the topology of the binding sites and their interaction with physiological ligands.

Based on the great potential seen in the application of the technology in pharmaceutical research, in the 1980s the first industrial protein crystallography laboratories were established, often as an experimental section within existing groups of computational chemists.

The pioneers in the pharmaceutical industry had to face a multitude of difficulties: few crystallographic software tools were available, computing power was small, diffraction data collection was done on the first expensive, semiautomated X-ray detectors

mounted on low intensity in-house X-ray generators. All the steps of structure determination had to be done "manually" and throughput was low.

By the mid-1990s all major pharmaceutical companies had invested into protein crystallography units and with the foundation of Agouron and Vertex Pharmaceuticals the first biotech companies had emerged whose business concept relied on the use of structure-based design to develop superior drugs.

At that time, with the boost in computing power and development of improved software tools, the availability of synchrotron beamlines for efficient data collection and advanced structure validation tools, industrial protein crystallography aiming at resolving the structures of pharmacologically important drug targets and their ligand complexes had become much more a routine endeavor and "high-throughput" crystallography—in this context the concept of generating a multitude of protein–ligand costructures in a short period of time—had come within reach. Importantly, in this phase the advances of molecular biology and protein expression and purification technologies had made many drug targets accessible for the crystallography labs.

The sequencing of the human genome[10,11] led to the conception of "structural genomics" in the early 2000s. Many publicly and privately funded consortia across the world started to determine the structures of proteins from a certain species or involved in certain diseases.[12] Industry benefited tremendously from these initiatives because many new structures were determined and new methods were developed along the way. This enabled a further increase in throughput and new concepts like X-ray crystallography-based fragment screening were established.[13,14]

Finally, more recently, structural biology of membrane proteins, invoked in the late 1980s, but for a long time refractive to application in pharma research, has become amenable. This is particularly apparent in the field of G-protein coupled receptors (GPCRs), among the largest families of drug targets, for which an increasing number of representatives are being structurally characterized[15,16] (for an overview on the described timelines see **Fig. 1**).

But how did this technological development impact the output of drug discovery?

The first drug derived from structure-based approaches that came to the market was Captopril in 1981.[17,18] This antihypertensive drug is directed against angiotensin-converting enzyme (ACE). While the structure of ACE was determined in 2003,[19] the design of captopril was based on the then available crystal structure of bovine carboxypeptidase A and information on the mode of substrate binding to this surrogate structural model. In the following years, major contributions to the discovery of new drugs have been made especially for antiviral drugs, for example, nelfinavir,[20] amprenavir,[21] lopinavir,[22] zanamivir,[23] and oseltamivir[24] (**Table 1**). The two latter compounds were developed based on structural information on influenza virus neuraminidase.[8] The key observation leading to zanamivir was the binding mode of sialic acid, the product of the enzymatic reaction.[25,26]

By 2003, >40 compounds discovered by structure-guided approaches entered clinical trials[27] and 7 had become approved and marketed drugs.[17] As of today, this list has to be expanded with numerous kinase, proteinase, phosphodiesterase inhibitors which were discovered and optimized using structural information.[28] Given the lag time of approximately 10–12 years between the discovery of a drug and market approval, the success stories known today have their origin in the 2000–05 time frame. Prospects are such that the majority of drugs approved in the future will have been discovered with the help of knowledge of the structure of the target protein.

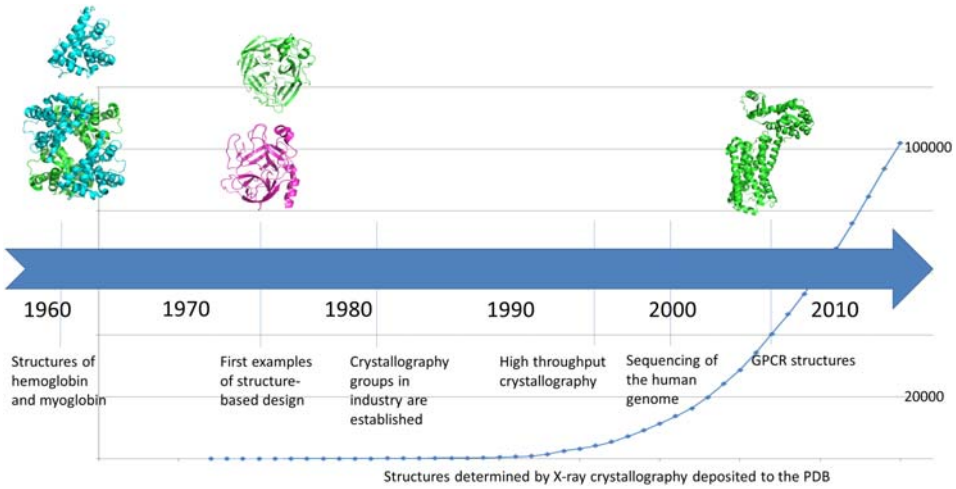

Fig. 1 Key dates and milestone achievements of protein crystallography in drug design. The structures shown are of hemoglobin, myoglobin, trypsin, neuraminidase, and β2-adrenergic receptor. The chart in the background shows the exponential growth in structural information contained in the PDB. Concerning the absolute numbers of structures deposited in the PDB, it is to be noted that the vast majority of protein–ligand complex structures determined in pharmaceutical industry in high-throughput manner is not deposited in the PDB due to both the confidentiality involved and the additional effort to do so.

Table 1 Antiviral drugs discovered with contributions from structure-based design

Trade name	*Generic name*	*Structure*	*Mechanism*
Viracept®	Nelfinavir		HIV protease inhibitor
Agenerase®	Amprenavir		HIV protease inhibitor
Aluviran®	Lopinavir		HIV protease inhibitor
Relenza®	Zanamivir		Neuraminidase inhibitor
Tamilfu®	Oseltamivir		Neuraminidase inhibitor

2.06.3 Methods

Establishing high-throughput processes in structural biology involves the implementation of highly efficient workflows in the entire value chain from protein to 3D structure: protein cloning, expression and purification, protein quality control, crystallization, generation of protein–ligand cocrystals, crystal harvesting, storage and mounting, data collection and evaluation, and structure determination and validation (Fig. 2). We will not cover the issues of generating a relatively high amount of high quality, crystallization grade protein as well as the initial protein crystals in this review. Instead, in the following paragraphs, all steps from the generation of a cocrystal to structure validation are discussed with an emphasis on the establishment of robust high-throughput procedures.

2.06.3.1 Generation of the Complex—Cocrystallisation and Soaking

After obtaining the first crystals of the respective target protein, an essential step is to develop a robust protocol for the reproducible generation of a large number of high quality crystals. A typical goal would be to establish a crystallization protocol delivering tens to hundreds of crystals of constant quality diffracting to 2.5 Å or better from a setup of a few 24- or 96-well crystallization plates. Time invested at that early stage in the optimization of such a crystal system is well spent, since it makes all later process steps much easier. For this purpose screening of crystallization conditions using variations of buffer components and pH as well as other additives turn out to be very helpful.[29–32] For an increase in resolution after crystals have been obtained under optimized conditions crystal dehydration can be applied.[31,33–35]

There are two general methodologies of obtaining complexes between a target protein and a small molecule ligand: cocrystallization and compound soaking. There are pros and cons for each of the methods and the most suitable needs to be selected in a protein and crystal target dependent manner.

2.06.3.1.1 Cocrystallization

In the cocrystallization setting, protein and ligand are mixed prior to the crystallization experiment such that the protein crystals grow in the presence of the ligand. To get a good occupancy of the ligand at the protein binding site as a rule of thumb, the compound concentration should be around 10 times higher than the protein concentration. If the ligand solubility is very low, it is possible to mix protein and ligand at low protein concentration and concentrate the complex to the desired protein concentration prior to crystallization. Introducing the ligand at this stage can have a big positive or negative influence on the outcome

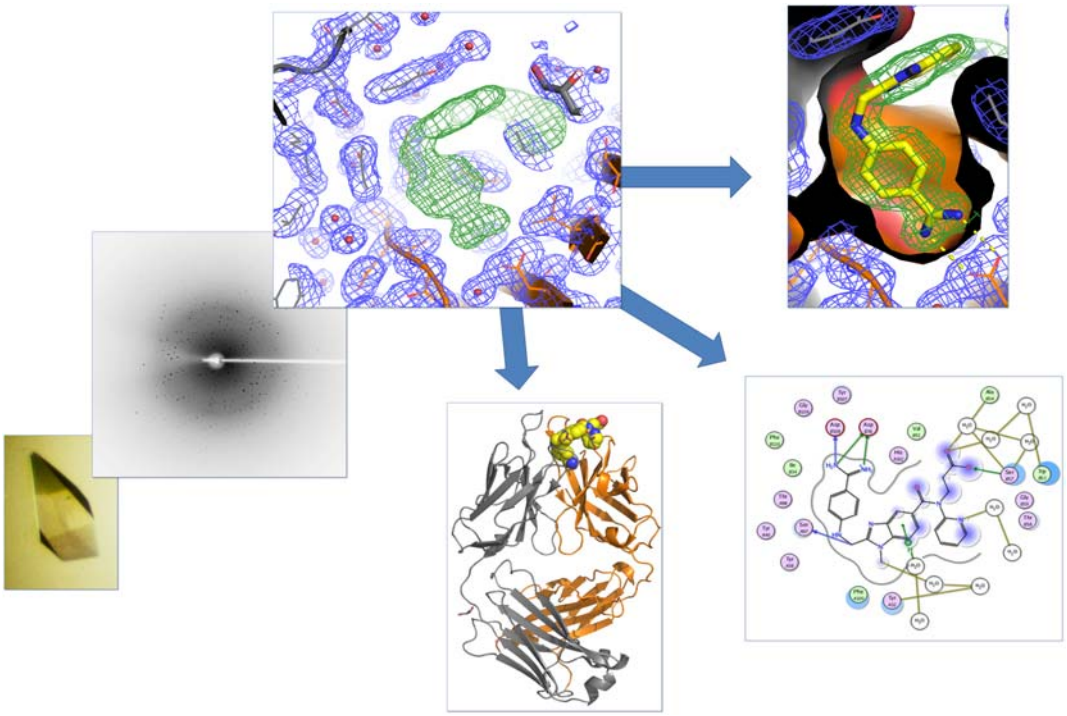

Fig. 2 Workflow in protein structure determination by X-ray crystallography. Depicted are a microscopic image of a protein crystal, an X-ray diffraction pattern, and a representation of the electron density and the protein model. The difference density (in green) clearly indicates the presence of a ligand. Different representations of the structural data are shown on the right. A surface representation of the binding pocket with bound ligand and polar interactions (yellow dashed lines), a ribbon representation of the complete protein:ligand complex, and a 2D representation of the interactions of the ligand (generated with PyMOL and MOE).

of the crystallization experiment. It is quite often observed that the addition of a ligand leads to a stabilization of the protein and thereby facilitates crystallization and improves crystal quality. On the other hand, ligand binding might induce conformational changes in the protein that do not fit the crystal packing arrangement of the unliganded protein. In such a case, for each new ligand a separate crystallization experiment, often even a small crystallization screen needs to be performed, so that the throughput for this method is limited.

2.06.3.1.2 Soaking

Protein crystals have a relatively loose crystal packing and a correspondingly high solvent content. Typical protein crystals have a protein volume content of $<50\%$. Solvent channels have diameters of 5–50 Å. A ligand can therefore quickly diffuse through the channels to the binding site of the target protein provided the respective binding site is freely accessible for the ligand, for instance by facing a solvent channel. The process of generating a protein–ligand complex in situ by letting the ligand diffuse into a preformed crystal of unliganded protein is called "soaking". This is done by addition of ligand to the *mother liquor* (the aqueous buffer within which the crystal has grown) or the *stabilizing solution* (a buffer that will prevent dissolution of the crystals, warrant a long-term stability of the crystals and maintains their diffraction quality) in which the preformed crystals reside. The ligand can be supplied either by dilution of a compound stock solution (eg, in dimethylsulfoxide (DMSO) or aqueous buffers) into the mother liquor or by addition of solid material which subsequently dissolves in the liquor surrounding the crystals. In any case, the concentration of the soaked ligand should exceed the expected dissociation constant of the ligand about 10 to 100 times. For low affinity binders such as fragments, it is often useful to approach the maximally possible concentration by generating a saturated solution of the ligand in the soaking buffer. Once the ligand is supplied to the medium, the ligand concentration gradient between the surrounding mother liquor and the solvent channels inside the crystal induces the onset of diffusion. Diffusion processes in the crystalline environment are relatively fast so that the interior crystal environment equilibrates within a few minutes. Depending on ligand binding kinetics, mass transport limitations and additional factors such as kinetic barriers to complex formation productive incubation times can vary from as short as a few minutes to hours or even a few days.

From the perspective of throughput optimization and process efficiency, crystal soaking is the ideal method to generate protein–ligand cocrystals. In contrast to cocrystallization, many crystals of the empty target protein can be generated using a given crystallization protocol and multiple ligands can be soaked in a highly parallelizable way to generate a multitude of different cocrystals within a few hours.

In the described ways, it is often straightforward to obtain protein–ligand complexes. However, there are cases in which soaking is problematic or even impossible. For instance, sometimes a ligand-free protein cannot be crystallized. If crystallization of a complex of this target protein with a relatively weakly binding tool compound can be achieved, these crystals can be used for soaking if it is possible to generate the ligand-free form of the crystals by diluting out the tool compound or if the added ligand is able to displace the cocrystallized tool compound in situ, a process called "counter-soaking." Other underlying reasons for the failure to establish a successful soaking protocol can be low aqueous ligand solubility or limited solubility in the soaking solution, a soaking buffer pH that is incompatible with the binding event or the partial or full occlusion of the binding site by neighboring protein molecules in the crystal lattice. To overcome the solubility problems solubilizing agents, pH, or temperature changes, exchange of buffers, salts, or precipitants can be explored. Another way to overcome solubility issues is to increase the solubility by added increasing amounts of solubilizing solvents to the aqueous soaking buffer. After suitable stabilization of the crystals, sometimes using crosslinking (see below), the crystals can be transferred into, for example, water/DMSO mixtures with high DMSO content ($>50\%$) in which ligands can be dissolved at much higher concentrations. A similar mechanism is used by Proteros using their "picodropper"-system which titrates DMSO solutions of the ligand onto crystals stabilized in a "free-mounting" system[35] and generates a new crystal saturated with ligand and DMSO.

With regard to occluded binding sites, it is often possible to screen for new crystallization conditions generating crystals with a different crystal packing.[36,37] If the crystals are sensitive to compound addition and significantly lose diffraction quality or even crack or dissolve once ligand is added, chemical stabilization of the crystal by crosslinking reagents, for example, glutaraldehyde can be a method of choice.[38]

At times it is claimed that soaking will not be able to produce an unbiased cocrystal structure, because binding within the solid state and the resulting limitations of protein dynamics will influence the binding mode. However, crystal packing energies for protein crystals are relatively small and proteins are highly dynamic even when fixed in a crystalline environment. Consequently, relatively large protein conformational rearrangement can be tolerated by the crystal lattice. Therefore, in many cases the structures obtained by ligand soaking and ligand cocrystallization are very similar and the numbers of examples in which an artifactual ligand pose was generated by soaking are rare.

2.06.3.2 Crystal Harvesting, Flash-cooling, Storage, and Mounting

After successful crystallization of a protein, the next step is to prepare the crystal for X-ray data collection. The crystal needs to be retrieved from the drop of stabilizing buffer. Nowadays, this is done by seizing the crystal with a small nylon loop mounted on a steel pin.

The crystals need to be flash-cooled in liquid nitrogen for long-term storage, transport, and data collection at a synchrotron light source. The crystallization conditions of proteins are often not suitable for flash-cooling and hence there is a need for finding a suitable cryoprotectant that hinders ordered ice formation. Identification of a good cryoprotectant is a trial and error process for which

a few screens are available.[30,39] Addition of the cryoprotectant to the stabilizing solution generates the *cryo buffer*. In the ideal case the stabilizing solution is already cryogenic. Flash-cooling the crystal is achieved by plunging the crystal into liquid nitrogen.

With this procedure, numerous crystals can be flash-cooled in a short period of time and stored in vials in liquid nitrogen containers. In this flash-cooled state, crystals have an essentially unlimited lifetime. The cryogenic storage provides a convenient way to send samples to a synchrotron light source for data collection. It is of utmost importance that the crystals do not undergo thaw-freeze cycles at any time when transferring the vials between storage and shipment dewars or from storage to the diffractometer. To ensure this, special cryo-tools are available to protect crystals during the transfer (dry mounting). The diffractometer has to be equipped with a cooling device which immerses the crystal in a stream of cool nitrogen gas (usually at 100 K) during data collection. It is also possible to transfer the crystal-pin together with the cap filled with liquid nitrogen in which it was stored to the instrument and quickly remove the cap (wet mounting). This procedure has the advantage to be faster than the dry mounting procedure but can cause turbulence around the crystal which can lead to a warm up of the sample.

Procedures for flash-cooling protein crystals were established in the 1990s and quickly popularized because of the ease of handling and because of the fact that in a flash-cooled state the crystals turned out to be much less sensitive to radiation damage especially when using synchrotron radiation. It should be noted that with the availability of new single pixel counting detectors which enable data collections speeds in the order of hundreds of images per second data collection might become faster than the progress of radiation damage that ultimately destroys the crystal's ability to diffract. This will lead to a renaissance of room temperature data collection for samples for which it is difficult to establish a cryo procedure.

2.06.3.3 Diffraction Experiment, Structure Determination, Ligand Placement, and Refinement

The steps to produce an X-ray crystal structure for a crystallized protein–ligand complex of a protein with a known structure usually are the following:

(i) X-ray data collection resulting in a set of diffraction images (Fig. 3)
(ii) Data processing resulting in a space group, a unit cell and structure factor amplitudes
(iii) Molecular replacement (MR)
(iv) Initial crystallographic refinement of the model
(v) Generating a model of the ligand and a restraints dictionary
(vi) Ligand fitting
(vii) Refinement of the protein–ligand complex
(viii) Model validation, inspection

X-ray data sets are either collected at a synchrotron beamline or using an in-house diffractometer. It includes mounting of a (cooled) crystal onto the goniometer, centring the crystal in the X-ray beam, and collecting a data set using an appropriate strategy. The data collection strategy depends upon the instrumentation and crystal properties such as space group, unit cell dimensions, mosaicity, and sensitivity to radiation damage but also highly on what is to be done with the data. The goal of a suitable data collection strategy for ligand binding studies is to achieve a high resolution and completeness as well as a moderate redundancy of the diffraction data while at the same time achieving a high turnover.[40] Special care has to be taken to avoid radiation damage. Bound ligands might be highly sensitive to radiation damage. Documented cases are cleavage of aromatic carbon–halogen bonds with release of the halogen atom and of sulfonamides.[41] Data processing includes the indexing and the integration of diffraction spots resulting in reflection intensities, the determination of the Laue group and Bravais lattice type, scaling and merging of symmetry equivalent reflections, as well as converting intensities into structure factor amplitudes. Programs widely used in the community

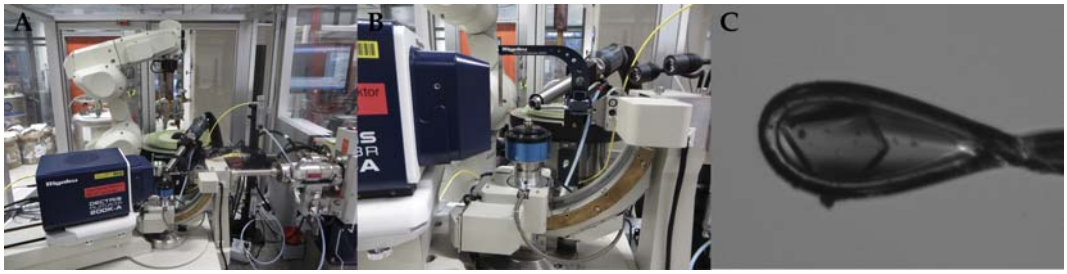

Fig. 3 Setup of an in-house, automated X-ray station. (A) Overall view upon the system. The rotating anode and X-ray optics are on the right. The beam traverses the collimator and hits the crystal, before reflected X-ray beams hit the Dectris Pilatus detector shown on the left (blue box). In the background, an ACTOR robot with its dewar are there to facilitate automated crystal mounting from storage positions inside the dewar. (B) Zoom on the crystal position. Using a mounting onto an automated "microglide" mount instead of a regular goniometer head, the crystal can be automatically centered in the X-ray beam. The crystal is positioned such that it resides in a nitrogen stream of nitrogen gas at 100 K. The nitrogen gas nozzle from an Oxford Cryosystems Cobra instrument protrudes from the upper right corner. (C) A flash-cooled crystal in a nylon loop during an ongoing X-ray diffraction experiment.

are XDS,[42] HKL-2000,[43] MOSFLM,[44] AIMLESS,[45] and TRUNCATE.[46] With autoPROC [47] and xia2,[48] powerful automated expert systems are available. Statistical (precision) indicators to assess quality and to deduce the high-resolution cut-off of the merged data set are Rmeas, CC1/2, Rpim, and mean(I/sig)mrgd. A detailed discussion can be found in Karplus and Diederichs.[49]

The MR step is optional, depending on the actual extent of nonisomorphism of the known structure used as initial model and the structure to be solved. It is run to correct coarse differences in orientation and placement of the initial model or components of the model and to account for a change of the number of molecules within the asymmetric unit. The programs MOLREP[50] and PHASER[51] are widely used for MR. MrBUMP,[52] MRage,[53] or BALBES[54] are all very robust automated MR pipelines allowing the input of a custom set of pdb files as search models. If there are only minor changes the MR step can be replaced by a thorough rigid-body refinement with a sufficient convergence radius.[55]

Refinement is run to improve the parameters of the current working model until a best fit to the experimental data is achieved. A sensible parameterization of the model is highly important since an over-parameterized model will cause overfitting of the data. Usually, only positional coordinates of atoms and B factors are refined. B factors or atomic displacement parameter (ADP), sometimes referred to as the "temperature factor," in theory should reflect the amplitude of atomic movement around an equilibrium position. In reality, B is a capacious parameter, capable of absorbing many other effects, such as static disorder or even experimental errors.[67] During refinement, typically, bond lengths, bond angles (and torsion angles), planar groups, repulsion between nonbonded atoms as well as B factor differences between bonded atoms are restrained to their ideal values. Since isotropic B factors are an oversimplification but anisotropic B factors can only be refined at atomic resolution (due to the sixfold increase in ADPs), the TLS parameterization has been introduced to model the anisotropic movement of sets of atoms (TLS groups[56]). For each TLS group, a pseudo-rigid body, parameters for translation, libration, and screw-rotation displacement are introduced and refined. Occupancies should only be included in the refinement when needed or justified by the quality of the data. To enlarge the convergence radius during early stages of initial refinement it is common to parameterize the model as rigid bodies of molecules or domains. The parameterization as torsion angles during refinement rounds of simulated annealing is also very powerful in terms of escaping local minima. Recently, real-space rotamer correction of amino acid side chains also became available as a routine during refinement further automating the correction of local misfits to the density.[57] If available, noncrystallographic symmetry should be exploited and (local) noncrystallographic symmetry restraints applied.[57–59] If needed, external restraints to a reference structure solved at high resolution can be used to stabilize low resolution refinement.[57–59] Water molecules are handled in different ways. The most common procedure is to either delete all waters or to only keep well defined, conserved water molecules of the starting model. Updating water molecules automatically during refinement is a common practise for high to medium resolution structures. Common programs for these tasks are autoBUSTER (Global Phasing Ltd.), REFMAC5,[58] and phenix.refine.[60]

The preferred starting point for generating a model and a dictionary of refinement restraints (idealized geometric parameters) for the ligand is a format describing connectivity, atom types, and stereochemistry. If there is no information on the latter, all possible stereocentres have to be enumerated. The tautomeric state of the molecule should also be considered as it can have a strong influence on the geometry of its 3D structure. Programs widely used include Grade (Global Phasing Ltd.), eLBOW,[61] and AFFIT.[62] eLBOW and Grade make use of geometry optimization using a quantum chemical method alone or in combination with data mining in small molecule databases. AFFIT uses a molecular mechanics force field to derive model restraints.

Ligand fitting starts with the assessment whether (difference) electron density blobs after refinement justify attempting ligand placement. After blobs of suitable size have been identified, the ligand or set of ligands (stereoisomers, tautomers) can be fit either automatically or manually. There are various programs available that produce excellent results in automatic fitting. Coot (either built-in routine or standalone executable findligand[63]), LigandFit,[64] RhoFit (Global Phasing Ltd.), AFFIT,[62] and ARP/wARP[65] are widely used. Usually, the fit to the density and the binding site are automatically assessed.

After ligand fitting, the protein–ligand complex is refined typically using a similar but less thorough protocol as during initial refinement. The final model needs to be validated and inspected manually. In the past, there have been cases in which a proper validation was not done.[66] In consequence, any published structural information has to be analysed with care prior to use.

2.06.3.4 The Challenge of Automation

To approach or achieve high-throughput hardware and software automation is essential for a structural research (SR) lab in industry. This is true for cloning, protein expression, and purification (not covered here), but even more important for crystallization, data collection, and processing as well as refinement and ligand fitting.

The availability of liquid handling systems and commercial crystallization kits has largely led to a standardization of protein crystallization.[67] Usually, a dedicated crystallization robot for setting up nano-liter sitting drops is used to screen sparse matrix and/or incomplete factorial screens.[68] Automating liquid handling has the benefit of increasing speed and decreasing sample volume. At the same time, it also increases the robustness of the whole process. Once initial crystallization conditions have been found, it may be beneficial to set up optimization trials using larger volumes by hand. Reservoir solutions for this step can conveniently be prepared using general or dedicated liquid handling systems such as the Formulator (Formulatrix, Inc.) or the dragonfly® (TTP Labtech Ltd).

Automated crystal harvesting is needed to bridge the gap between automated crystallization and data collection units and to improve the reliability and reproducibility of the whole process. Several (semi-) automatic procedures are available that demonstrate the feasibility by different methods (eg, microtools, microelectromechanical systems, or laser ablation) but are not yet commonly used.[69,70]

Data collection, either at the home source or at a synchrotron beamline, can be fully automated nowadays. Sample mounts and storage systems are to a great extent standardized. Sample changers are available from commercial suppliers and most synchrotron beamlines and many industrial home lab systems are equipped with automated sample mounting systems which can transfer crystals without user intervention. Software for automatic loop centring is also available.[71–73] If the sample is about the size of the loop and fairly homogeneous, results from this simple approach can be of sufficient quality. For challenging samples diffraction based centring has to be used to define the best diffracting volume of the sample.[74]

The quality of the data and the subsequent crystal structure are strongly affected by an adequate data collection strategy. Therefore a highly reliable, automatic determination of crystal symmetry, unit cell parameters, mosaicity, and radiation sensitivity is a pivotal step to successfully collect good quality data.[75] EDNA MX[76] has been developed for this purpose. The ESRF beamline MASSIF-1[74] is currently the only beamline where sample characterization and data collection is fully automated.

Solving the *n*th crystal structure in a project is unsatisfactory if done manually and a serious waste of time. Most pharmaceutical companies have developed proprietary pipelines to accomplish this task automatically (eg, see Refs.[78,79]). Companies focusing on FBS have published details of their automation process, for example, the Astex "Pyramid" Process[80] or the "FAST" approach at SGX.[81]

At synchrotrons, usually a data processing pipeline is available.[82,83] Recently, a pipeline encompassing all stages starting from integrated and scaled intensities has been implemented in Phenix (phenix.ligand_pipeline[84]). A pipeline named Pipedream that also includes data processing is available from Global Phasing Ltd.

An automation pipeline in industry is best organized on a project and sample orientated level. Information on space groups and unit cell dimensions, initial pdb files, or reference mtz files for a new sample can conveniently be defined by the project setup. Information on the ligand needs to be stored separately for each sample. Maintaining and retrieving this information in/from a laboratory information management system can be highly beneficial. The steps carried out by the pipelines usually are data processing (optional), molecular replacement (optional), initial refinement of the model without the ligand of interest, generating a ligand restraint dictionary, ligand fitting, refinement and validation of the complex.

A custom pipeline can be designed, making use of powerful existing standalone programs (described in **Diffraction Experiment, Structure Determination, Ligand Placement, and Refinement** section). The indexing routine to deduce the crystal lattice needs to be very robust to automatically deal with difficult diffraction patterns. LABELIT[77] is a very good choice for this task. Especially in projects where one has to rely on cocrystallization to generate crystals of the protein–ligand complex, support for multiple crystal systems is important. A robust algorithm needs to be in place to reliably identify the correct crystal system or to trigger processing without using a known crystal system as reference. For data processing, powerful expert systems such as autoPROC[46] or xia2[47] can conveniently be integrated. During refinement robust defaults for the parameterization have to be in place to properly refine structures from different projects and at different resolution. The advantage of a custom pipeline is the possibility to plug in several ligand fitting routines to maximize the success rate.

After refinement of the complex, a thorough validation is important to enable rapid elimination of problems during manual refinement rounds. Results should be accessible via an interface to ease browsing.

2.06.3.5 Validation of the Final Structure

The quality of protein–ligand structures is of high importance for structure-based design since the information is used to guide synthetic strategies aimed at improving protein–ligand interactions.

For all successive steps of the structure-based drug design (SBDD) workflow, therefore, a thorough validation of ligand costructures is essential to ensure that the structural models are correct. Two aspects need to be checked: Does the model fit the electron density (the primary evidence) and is it consistent with basic physics, chemistry, and biology (prior knowledge).[85]

The most important global validation measures indicative of the overall quality of the model are the R-factor and R-free.[86] Both measure the difference between observed and calculated diffraction data. R-free is being used for cross-validation during refinement to avoid overfitting. It is important to note that the resolution only places a limit on the precision of the model. It does not provide any information about its quality.[87] Local measures such as the real-space correlation coefficient, the real-space R,[88] or the recently proposed metrics for local model accuracy and precision, the real-space difference density Z-score, and the real-space observed density Z-score,[89] can be used to judge the local quality of the model in terms of fit to the electron density. (Of course, local measures can also be averaged into global measures.)

Consistency with basic knowledge can, to a great extent, be checked by locating implausible features in stereochemistry, in the chemical environment, or in coordination geometry, often combined with improbable refinement results such as absurdly high or low B factors.[90]

The root mean squared deviation of bond lengths, angles, and planes from their target value are used to assess the stereochemical quality of the model. Deviations from experimental target values are usually expressed in multiples of the standard deviation using statistics such as Z-score.[85] For the parameterization of the protein geometry, a standard set of means and standard deviations is used which was derived from atomic resolution structures of amino acids and peptides.[91] For ligands, Mogul can be used to derive target values and uncertainties from the Cambridge Structural Database and to validate geometry.[92]

Combinations of the main-chain φ and ψ torsion angles as well as side-chain χ torsion angles are a valuable source for validation as they are (still) rarely restrained.[93] Today, the program MolProbity[94] is commonly used to calculate validation statistics for these as

well as for all-atom contacts (physically impossible overlaps). Since hydrogens are usually not modeled explicitly in refinement the latter is a powerful validation tool as well.

2.06.3.6 Communication of Results

The delivery of results to customers, typically project teams consisting of medicinal chemists and computational chemists, is the final step of structure determination of protein–ligand complexes in industry. Since all colleagues that are not well-trained structural biologists will need assistance when looking at and using data from X-ray crystallography, a carefully implemented process to communicate results is essential.

Of course, the basis is a careful evaluation of the structure quality and the analysis of the resulting structure in terms of details of the protein–ligand interactions, the evaluation of the bound conformation of the ligand, and the changes in the protein structure and dynamics upon ligand binding. The resulting information package contains structure validation data and the interpretation of the structural data by the X-ray crystallographer. It is typically provided as a document or slide deck. For validation statistics spider diagrams (as used by POLYGON[95]) or slider representations (as used in the wwPDB validation report[96]) are generally more useful than tables.

Further, the final structure needs to be deposited in a structure repository or file archive. Easy access to structures can be supplied for instance either via PSILO® (Chemical Computing Group Inc.) or Proasis3 (Desert Scientific Software Pty Ltd).

Finally, it is also essential to provide project session files using molecular visualization systems like PyMOL (Schrödinger LLC.). These session files typically contain all structures of relevance for a given project, supplied as superimposed structures, and are used for interactive 3D sessions with the project team or for individual use. The structures can suitably be grouped by ligand classification based on chemistry and by the source of the data (public or in house). Access to electron density maps or at least to scoring via per-atom real-space quality indicators is very important to guide structure-based design. The visualization system has to be flexible enough to include (per-residue) comments and results from other sources such as computational chemistry or screening.

Despite the fact that in many projects a large number of costructures are determined today, only few systems have been developed to provide an aggregated view on information contained in the entire data set. The Protein Ligand Interaction Fingerprints application within MOE (Chemical Computing Group Inc.) can be used to analyse, categorize and summarize protein–ligand interactions across an ensemble of structures via a fingerprint scheme. WONKA[97] extends this kind of analysis to protein conformation and water conservation. Another option that is only infrequently seen in the literature is the analysis of ensembles of crystal structures by principle component analysis,[98–101] Polyphony[102] being a recent and powerful application to accomplish this task. However, despite the availability of these tools, common practice still is to visualize structures alone or as pairwise superpositions and conclusions are drawn from there.

In our experience, it is of paramount importance to entertain face-to-face discussion with project team members as the best form of communication as only in this way it is ensured that no information is lost and a detailed discussion of the implications of the structural data is possible.

2.06.4 Applications

The drug discovery process can be subdivided in a series of project phases that build upon each other, starting with the first idea for a new project and ideally culminating in the handover of a drug candidate molecule to preclinical development (**Fig. 4**).

We will outline in this article why structural biology support in general is a great asset in this process and how knowledge of the three-dimensional structures of protein targets and their ligands—be they endogenous or synthetic—can accelerate and guide drug discovery greatly. We will discuss the various steps using case examples from "real-life" projects conducted at BI.

Historically the focus of SR activities has been in the lead optimization (LO) phase, probably due to the difficulties of obtaining target crystal structures early and the low throughput for protein–ligand costructure determination. It is now commonly accepted that SR enabling should start as early as possible—ideally synchronized with project initiation in other functions—in order to have high-throughput systems for structure determination and biophysics in place once a project enters the lead identification phase.

We will see in the following paragraphs that in this way highest possible project impact is given both through timely validation and quantification of ligand binding, the latter via biophysics, and provision of binding modes of the various possible starting points via X-ray crystallography. Over the lifetime of a typical project nowadays up to 100–300 costructures are generated.

X-ray crystallography is the most widely used technique for protein structure determination in industry, which will be reflected in our choice of examples. Other biophysical technologies can be nicely complementary. In paragraphs "**Hit Validation**" and "**Structure-based Molecular Design**" we will show how these methods are integrated. In the last paragraph ("**Biologics discovery**") of this article we will discuss how X-ray crystallography can leverage the discovery of biological drug molecules (new biological entities, NBEs).

2.06.4.1 Structure-based Target Assessment

The huge amount of structural data that is available in the public domain enables the structural biologist to support the assessment of new target ideas. Typical questions raised in this context concern the nature of known binding pockets of the molecule, the

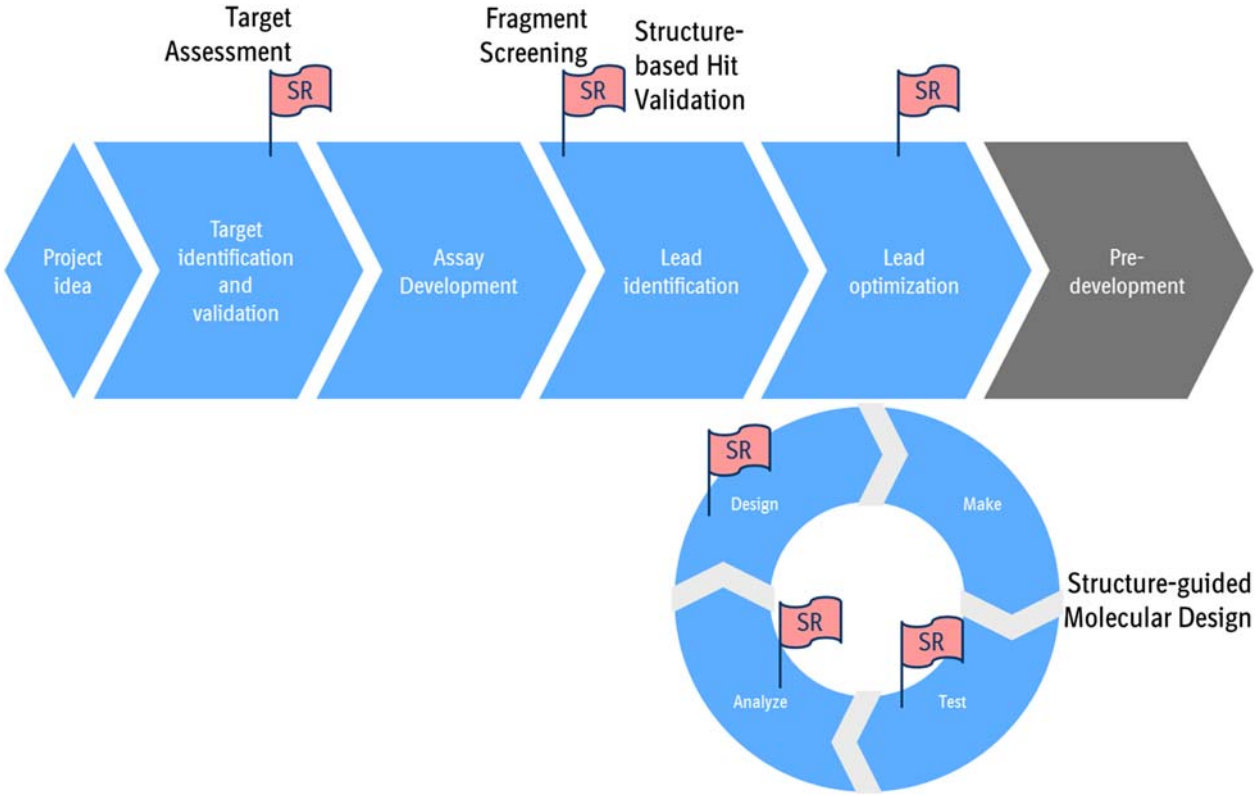

Fig. 4 Applications of structural biology and biophysics technologies in drug discovery. The various phases in the drug discovery process comprise the target identification, development of appropriate assays to test the target function and to screen for chemical starting points, identification of suitable starting points (leads) for medicinal chemistry, and the optimization of these leads toward a desired compound property set. Structural research (SR) can contribute to various phases: a structure-based target assessment, structure-based hit validation after a HTS-based finding activity or fragment-based screening, and supporting structure-based molecular design activities.

possible mechanism of action, or the chance to obtain selectivity against antitargets (see paragraph "**Fragment-based Screening**"). A common workflow usually starts with a query of a sequence database of the protein data bank (PDB) by using BLAST or PSI-BLAST,[103] HHBlits,[104] or a similar sequence search tool. Depending on the chosen cut-off value, one obtains a list of PDB entries of the target protein and proteins similar in sequence. If structural information for the target or a close sequence homolog is available it is possible to search for structurally similar proteins or domains by using the program GESAMT.[105] The structures of interest that are retrieved in these ways need to be superimposed and analysed. If there is prior knowledge about interesting binding sites available (eg, the active site or an effector binding site), these can be analysed with respect to their properties, that is, shape, size, and distribution of charged, polar, or hydrophobic surface patches or metal-ion binding. Taken together, these parameters define the propensity of the respective pocket to bind drug-like molecules, the "ligandability" or "drugability" of the putative functional site. Structures with bound ligands can be used to derive pharmacophore models, to generate a focussed library for screening, for example, and in turn to search the PDB for similar binding sites (eg, from within PSILO®, Chemical Computing Group Inc.). For proteins without known binding sites, pocket detection methods can be applied. These use either geometric algorithms, probe, and/or energy based methods.[106] Some also perform a quantitative drugability prediction of pockets (eg, SiteMap[107] or Site Finder within MOE, Chemical Computing Group Inc.). A limitation of all these methods is that they do not account for pocket flexibility. Using SILCS (Site Identification by Ligand Competitive Saturation) FragMaps[108] to derive information on putative pockets and their properties is a promising recent development to overcome this problem, since it relies on an algorithm employing molecular dynamics simulations that model protein conformational changes and the appearance of transient pockets.

2.06.4.1.1 Protein–Protein Interactions

Assessing protein–protein interactions (PPI) targets remains a challenge. Ideally, structural information is available to deduce the determinants of binding. In general, it is more promising to target an interface that features a pronounced pocket or several clustered smaller pockets (often these are filled by residues of the binding partner) instead of a relatively flat or even convex surface. Clustered hot spots, residues that account for most of the binding energy, are typically targeted when trying to interfere with protein–protein binding. These need to be identified either by experimental alanine-scanning or by in-silico methods. FoldX[109] and Robetta[110] are widely used for the latter.[111] When searching for putative binding pockets, protein flexibility has to be taken into account. This is

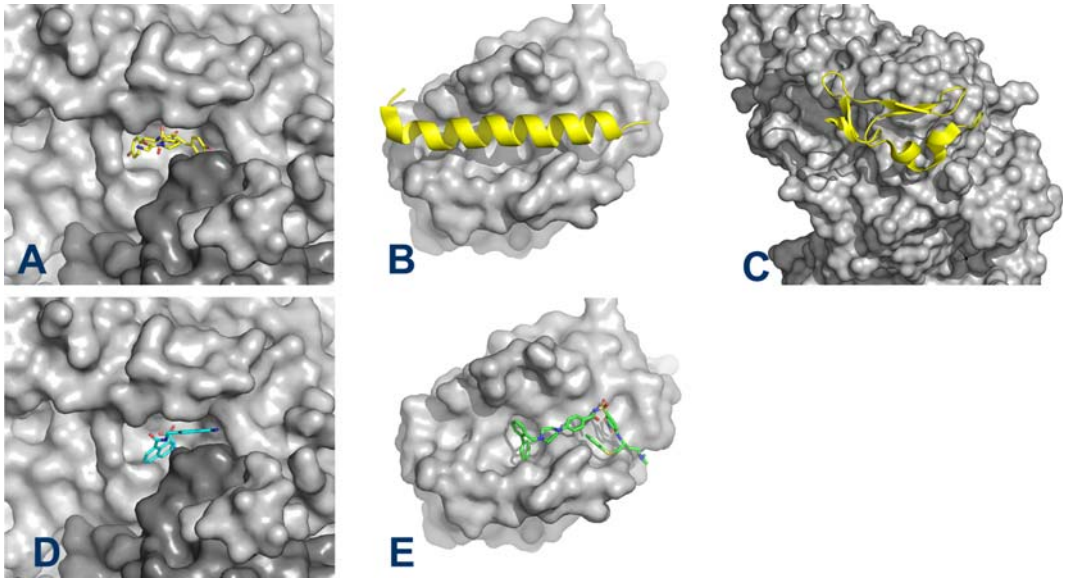

Fig. 5 Protein–protein interactions. The good, the bad, and the ugly PPI. (A and D) Linear epitope, short contiguous peptide sequence binds into relatively deep pocket, main interactions formed by one or few residues (HLGP-GL). The pocket is adressed by fragment or lead-like chemical matter (blue carbon atoms in (D)). (B and E) Linear epitope, contiguous peptide sequence located on a-helix or β-strand/turn, binds into relatively shallow groove, main interactions by few noncontiguous residues (Bcl-Xl-BAK). This binding site is adressed by a large ligand that needs to extend along the groove to pick up multiple interactions for nanomolar affinity (green carbon atom in (E)). (C) 3D epitope, longer noncontiguous peptide sequence binds on flat and convex surface region, main interactions formed by numerous residues (PCSK9–LDLR EGF domain). No small molecule ligand has been identified for this binding site.

especially true if only the structure of the unbound form of a target protein is known. Protein–protein interfaces might be inherently "wobbly,"[112] that is, pockets are transient in nature.

There are a number of possibilities to classify PPIs in groups of targets with low, medium, or high difficulty with respect to the identification of suitable interfering small molecules. For example, Smith and Gestwicki[113] differentiate PPIs according to two parameters: the binding affinity of the two proteins (tight–loose) and the extent of the interaction interface as measured by the surface area occluded from solvent in the complex (narrow–wide). A loose and wide PPI is much harder to target than a narrow and tight PPI. This is conceptually fairly easy to comprehend, since a loose and wide PPI is most probably characterized by a flat interaction surface exhibiting little topological or chemical features to be tackled by a small molecule drug. Here, we would like to introduce a relatively simplistic model to differentiate classes of PPIs (**Fig. 5**). Based on literature known examples of drug discovery projects in which PPIs were successfully or unsuccessfully targeted, we suggest that a PPI is a "good" target, if it consists for at least one of the binding proteins of a sequentially linear epitope, a short contiguous peptide sequence that binds into a relatively deep pocket with main interactions formed by one or just a few residues. Examples for this kind of PPI are the mdm2-p53, IAP BIR3 domain-caspase-9, bromodomain-histone, and HLGP-GL interactions.[112,114,115] For some of these well-known interactions, successful drug discovery efforts have been described that resulted in high affinity and highly ligand efficient drug candidates.

A "bad" PPI would be again a linear epitope on one of the binding proteins with a contiguous peptide sequence located on a secondary structural element, a α-helix or β-strand/turn, which binds into relatively shallow groove with main interactions formed by few noncontiguous residues. Examples for this type of interaction are Bcl-Xl–BAK, gastro-intestinal peptide–GIP receptor, and Nrf2–Keap1.[116,117] This type of PPI is more difficult to address with small molecules. A particularly striking example of a successful drug discovery program is the Abbott program on BCL-Xl which led to the discovery of ABT-199, a promising cancer drug.[118] The compound exhibits an extraordinarily high molecular weight (MW), only moderate ligand efficiency, and it took above-average time and capacity to identify it.

Finally, PPIs that exhibit 3D epitopes made up by longer, noncontiguous peptide sequences on one protein that bind on flat and convex surface regions on the other protein with main interactions formed by numerous residues on both sides would qualify as "ugly" PPIs that are extremely difficult to target. Documented examples are IL4–IL4 receptor and PCSK9–LDLR EGF domain for which no competitively binding small molecule drug has yet been identified.[119,120]

2.06.4.2 Hit Validation

The HTL phase in drug discovery commences after hits have been identified in a finding process that typically measures the ability of compounds to modulate a biochemical or cellular activity in the context of a HTS. The first step in this HTL phase is the "validation"

of the hits. The aim of the validation is to come up with a prioritized set of functionally active compounds that represent the best starting points for follow-on chemistry activities.

A range of criteria are applied to qualify compounds.[121] The screening assay is used to demonstrate reproducibility and concentration responsiveness of the activity. In a second step, employing technology counter screens, assay artifacts relating to an interference of the hits with the assay readout can be assessed and used to remove false positive hits. To test whether the activity is based on a specific mode-of-action on the target or on an undesired unspecific effect due to unwanted compound properties (such as compound aggregation-induced inactivation of the target protein,[122,123] unspecific modulation of an entire target family, or nonspecific cellular toxicity), a number of distinct and target-specific secondary assays are performed. Finally, after computational clustering of hit sets into chemically related hit series, all available project-related and historic assay data are compiled for the hit set and critically scrutinized to search for frequent hitters and initial structure–activity relationships (SAR) within a compound cluster.

At this stage of the process, a confirmation of the hits in orthogonal assays, which are devoid of agents like substrate or readout chemicals but rather measures binding in a binary assay format containing only compound and target, is highly valuable. During the last 15 years, biophysical methods have been increasingly employed to do this job. These methods can be used to either simply prove binding or demonstrate concentration dependence yielding affinity information that can be compared to the effective concentration derived from an activity assay. The biophysical methods are typically chosen and positioned in a screening cascade based on throughput, sensitivity, robustness, cost, and information content. Most prominent technologies in the industry are differential scanning fluorimetry (DSF), microscale thermophoresis (MST), surface plasmon resonance (SPR), NMR, and isothermal titration calorimetry (ITC). SPR and ITC can be used to determine affinities but at the same time characterize the binding kinetics and the thermodynamic profiles of the hits, data that contain valuable information toward the mode-of-action and may be used in prioritization of one hit series over another.[124,125]

Now, if for a given target a medium-high-throughput crystal system is available, the biophysical hit validation can be expanded by a structural component. An X-ray costructure of a ligand–target complex is the gold standard of hit validation, because it not only provides a clear proof of (specific) binding, but at the same time delivers a multitude of additional information. Most importantly at this stage, the binding site of the ligand is unequivocally defined giving immediate access to the mode-of-action of the compounds (eg, orthosteric–allosteric, reversible/noncovalent–irreversible). Further, changes in the target structure become apparent and can be evaluated (eg, larger scale changes such as domain movements, opening of a subpocket in the binding site, changes in protein dynamics upon binding). The details of the ligand–target interaction are revealed and form the basis for the interpretation of the observed SAR in the given hit cluster as well as the structure-guided design of optimization strategies if the particular hit is selected.

Since the crystallographic elucidation of the binding mode will define the main molecular interactions, at this stage the computational or manual classifications into hit clusters can be critically scrutinized at this stage. It may in fact turn out that compounds originally put into the same cluster actually entertain distinct binding modes and should be put into different baskets. Conversely, if compounds with distinct chemical structures initially put into different clusters turn out to form similar interactions, they should be placed in the same bin. Medicinal chemists tend to group and name hit compounds based on the molecular core structure or scaffold, oftentimes an aliphatic or aromatic heterocyclic ring system. This aids both in terms of communication as well as in the early stages of synthetic planning when modifications to the hits are designed. Structural information, however, may show that the scaffold has no direct contact to the target protein merely serving as a spacer that positions the interacting substituents into the right directions. In such a case, the scaffold may be switched without changing the key interactions and may give access to a new core structure that is more easily chemically explored.

While the above might seem trivial at a first glance, the results of this exercise will be extremely helpful during both hit prioritization and the first stages of chemical exploration of a hit cluster.

Since typically not just one hit class representative, but a representative set of hits from all hit clusters are crystallographically characterized, many possible ways to interact with the target protein within its functional sites are discovered, the binding sites are "mapped" by the distinct chemistries of the ligands so that a protein pharmacophore can be elucidated, and information can be extracted how certain moieties/substructures of one ligand class may be transferred to another.

The value and timing of this information cannot be underestimated. If a chemistry program is informed in such a comprehensive way by biophysics and structure at this early stage, even prior to any initiation of synthesis activity, an optimal basis for an informed selection of the ideal starting point as well as for a streamlined optimization process is granted. Therefore early enablement of biophysics and structural biology for all amenable targets is warranted even if this means a heavy capacity frontloading.

2.06.4.2.1 Characterization of the cocrystal structures of a chemically diverse set of CDK1 inhibitors

A historic example from our laboratory that nicely illustrates the above is the case of a CDK1 inhibitor project. At the time, the crystal structure of the target was not available. In order to support the program, we decided to use a previously enabled structural and sequential homolog to CDK1, CDK2, for ligand cocrystallography. An HTS delivered a relatively large hit set. After clustering of hits in groups with identical scaffold, a list of representative compounds was assembled for which the costructures were determined using a soakable high-throughput and high-resolution crystal system of CDK2. The compounds all turned out to be ATP-competitive binders, today classified as Type-I kinase inhibitors (Fig. 6). Superpositioning the entirety of costructures (Fig. 6C) illustrates emerging canonical interaction patterns formed by Type-I kinase inhibitors. The ligands and their distinct substitution patterns result in a broad occupation of the ATP pocket. The binding mode of two hits which exhibit a pyrazolo substructure (Fig. 6D) demonstrate that a distinct tautomer is involved in binding to the kinase, respectively. Finally, a pair of

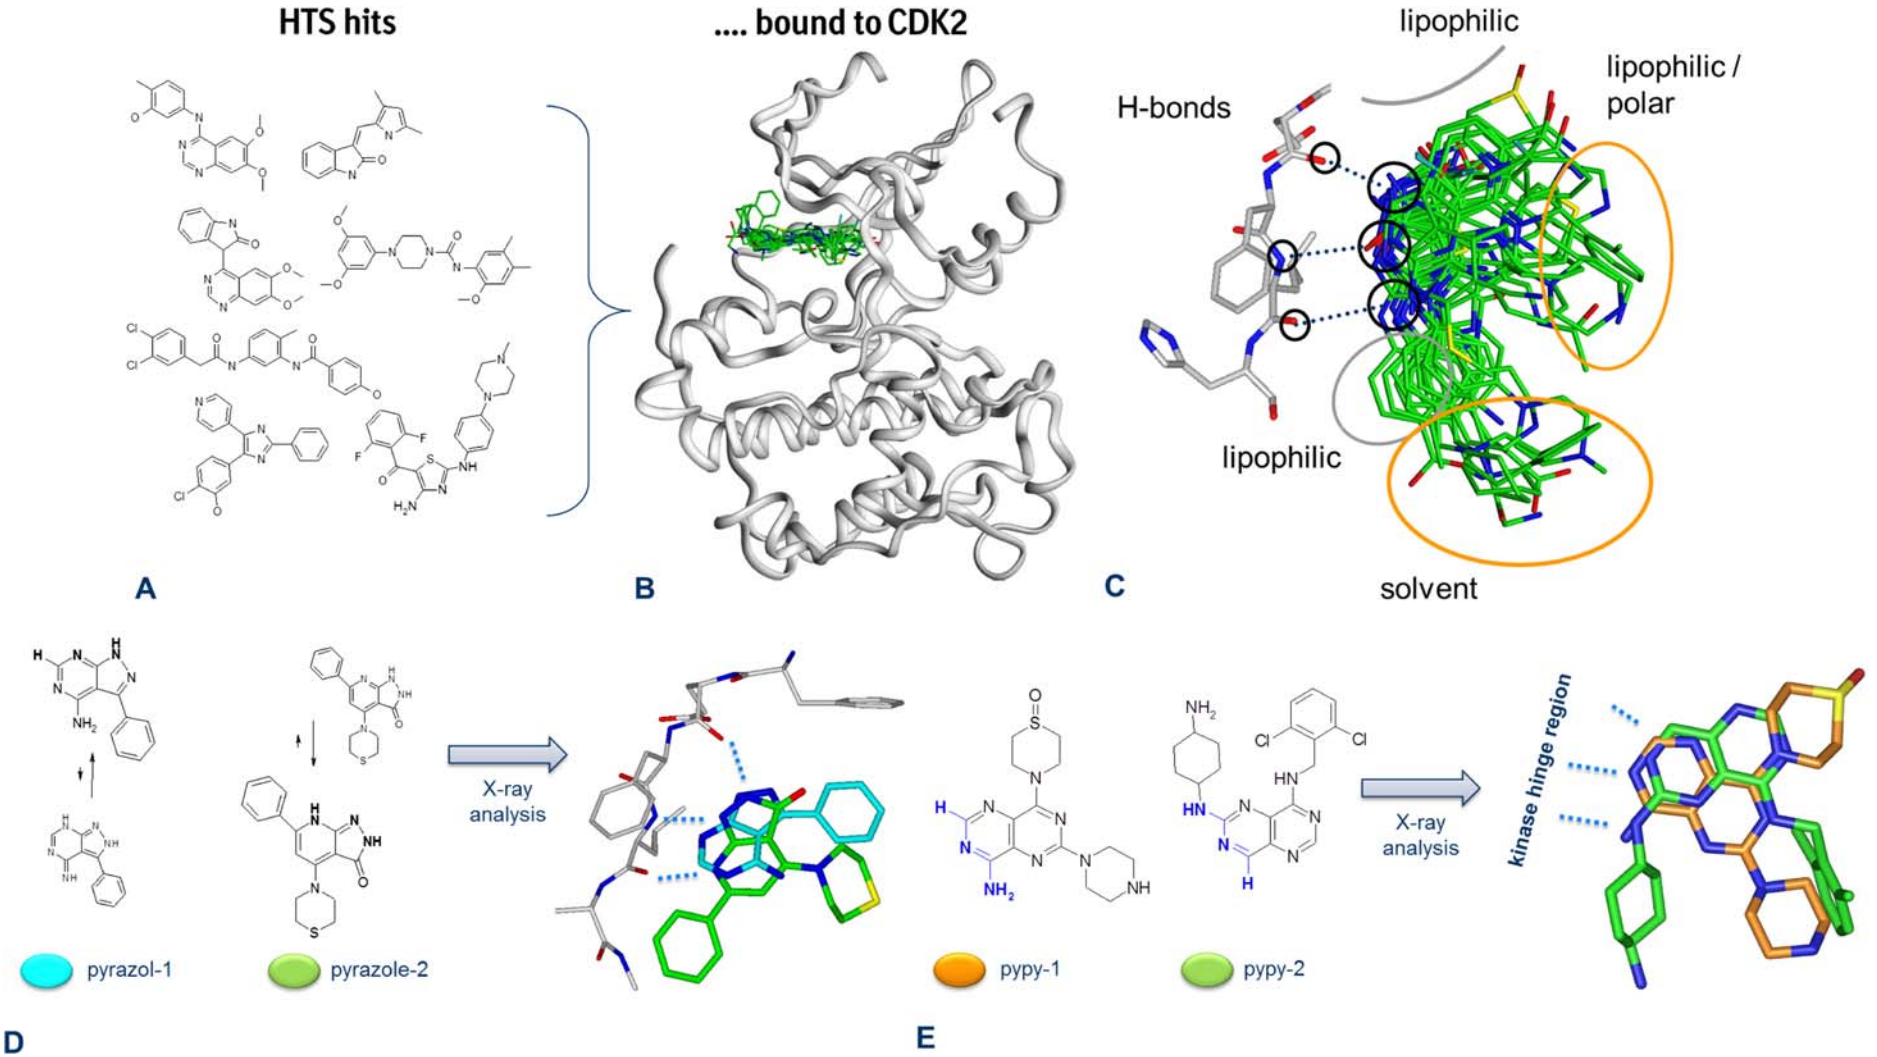

Fig. 6 Structure-based hit validation in the CDK1 project. (A) The chemical structures of a subset of the CDK1 HTS hits are shown. (B) Superposition of the costructures of the hits shown in (A) as bound to the surrogate target CDK2. (C) Interaction details derived from the superposition of a large number of cocrystal structures with chemically diverse hits. Interaction patterns emerge such as the well-known hydrogen bonding interactions with the kinase hinge region, exploration of the hydrophobic parts of the binding site below the glycine rich loop (not shown for clarity). (D) Identification of bound tautomer. The pyrazoles 1 and 2 can exist as different tautomers, with the bound tautomer and hinge-bonding atoms highlighted. A superposition of X-ray structures in complex with CDK2 is shown on the right-hand side. (E) Same scaffold—different binding modes: Variations in the substitution pattern of two pyrimidopyrimidines (left-hand side, with H-bonding atoms highlighted in blue) leads to a swap in binding mode (right-hand side).

pyrimidopyrimidine inhibitors binds in a distinct way to the target due to their different substitution patterns and are to be treated as independent hits despite their identical chemical scaffold (Fig. 6E).

2.06.4.3 Fragment-Based Screening

Fragment-based drug discovery (FBDD) is a complementary approach for finding new leads that during the last 15 years has increasingly been adopted by research groups in the pharmaceutical industry. The goal of FBDD is to identify small organic molecules (MW < 300 Da), "fragments" of lead-like molecular entities, that bind to a functional pocket of the target protein, and to further optimize them into potent leads using strategies that are similar to the traditional structure-based design approaches used for hits derived from HTS. The great conceptual appeal of FBDD is based on considerations of sampling efficiency and of the optimal physicochemical or drug-like properties of lead compounds. Since the chemical space of organic molecules with drug-like properties is vast (estimations indicate that there are approximately 10^{50} molecules with heavy atom count (HAC) of 15 to 35); screening of corporate libraries of up to 10^7 compounds with limited structural diversity will not get anywhere close to a representative sampling of the chemical space of potential lead structures. In contrast, screening a set of 10^3 to 10^4 structurally diverse fragments with HAC between 10 and 22 will sample the corresponding chemical space of approximately 10^{20} molecules more efficiently.[126] In addition, due to the lower complexity of the screened compounds hit rates are much higher.

In a typical FBS campaign, a screening library of a few thousand low MW compound (MW < 280 or HAC < 22) is screened by biophysical screening technologies like ligand- or protein detecting NMR spectroscopy, SPR, DSF, or MST being applied either in parallel or consecutively. The resulting primary FBS hit set (50–150 compounds) is then analyzed by X-ray crystallography.

In addition to validating the binding, the structural information is valuable for the subsequent analoging and optimization process. However, depending on the target it is often observed that only a subset of the hits that have been found in the biophysical prescreening will yield costructures.

This is because the low affinity of the fragments leads to an increase in false positive hit rates in the primary FBS due to the sensitivity of the screening technologies which may fail to differentiate between specific and unspecific binding.

The biophysical prescreen is the standard case in fragment-based lead discovery when larger (2000–15,000 compounds) fragment libraries are used. With smaller libraries, it is also possible to use X-ray analysis as primary screening technology. In the early days of FBS, X-ray crystallography in fact was used as a primary screening technology.[13,14] Recent developments revive the idea of using X-ray crystallography as a primary screening technology. Most prominently, at synchrotron beamlines, services are being set up which focus on the establishment of an efficient process to cocrystallize, perform data collection and structure determination of a fragment library of hundreds of compounds. Secondly, evidence is accumulating that if applied in parallel to biophysical screens, crystallographic screening delivers its own hit set and identifies fragment hits that were missed entirely by other methods.[67]

2.06.4.3.1 Implementation of an X-ray crystallography-based FBS

Both cocrystallization and soaking are used for fragment crystallography. During cocrystallization the small molecule is already present during the crystallization step of the protein and the growing crystals incorporate protein–ligand complexes. The drawback of cocrystallization in this context is that due to the low affinity of the fragments, high concentrations of the ligand are necessary which might hamper crystallization of the protein. The presence of a ligand during crystallization might even lead to a change of the original crystallization requiring new crystallization screens. In general a cocrystallization setting lowers the throughput and is not ideal for fragment-based approaches. The most efficient method in getting crystals that contain protein–ligand complexes is the soaking approach, in which crystals of the target protein that have an empty active site or contain a low affinity ligand are produced in large numbers. These crystals are then incubated in a stabilizing or ideally cryogenic solution with a high (eg, 100 mM) concentration of the fragment. The highest possible concentration of the fragments should be used and corresponds to a saturated solution with remaining solid material of compound in the droplet.

In order to reach high compound concentrations, special requirements in compound logistics are required. DMSO is often the solvent of choice for preparing fragment stock solutions. The concentration of the stocks should be high (100–500 mM), so that a later dilution into the stabilizing solution leads to a high concentration of fragment and a low DMSO content. High concentrations of DMSO can be problematic, for example, in cases where it destroys the crystal lattice or competes with the fragment for a binding site. If it is necessary to use premade DMSO stock solutions of lower concentration it can be an option to evaporate the DMSO. The dried fragment is then resolubilized to a higher concentration in the crystallization or stabilization buffer.[127] It should be noted that fragments can have a low vapor pressure and the fragment might coevaporate with the DMSO.

Depending on the expected hit rate of the target, fragments are pooled into cocktails of 3 to 10. Soaking of mixtures leads to a more efficient process and often reduces the number of datasets that need to be collected but also requires a deconvolution step. Once a cocktail has been found by X-ray analysis to produce significant difference electron density in a binding site, it is often possible to identify the binding fragment based on the shape and form of the electron density. In subsequent experiments the other elements of the cocktail need to be examined to find out whether another component of the mixture is able to bind in the absence of the first hit. Setting up the cocktails using a maximum of structural diversity can help in this deconvolution process.[14] Next to these advantages there are also pitfalls when using cocktails. The compound concentration in cocktail soaks is lower compared to single soaks and this can be critical with low affinity binding fragments. Further, some of the selected compounds might be reactive and lead to unexpected products. The probability of such unwanted reactions is likely to increase with the number of compounds per cocktail[128] (see also Zartler 2014, http://practicalfragments.blogspot.de/).

A nice example that shows that the throughput limitation of protein crystallography in the context of FBS can be overcome are the efforts at the Diamond I04-1 beamline where up to 500 crystals can be soaked and prepared in a day. The subsequent data collection takes about 24 hours (http://www.diamond.ac.uk/Beamlines/Mx/Fragment-Screening.html).

If one drives the fragment idea into extreme one enters the regime of very small fragment screening. Very small fragments (MW < 150 Da) are expected to bind with extremely low affinity (1–50 mM). A costructure with such compounds will only be obtained when the aqueous solubility is very high. In published procedures, soaking of crystals in organic solvents has been performed to address this issue. This technology called multiple solvent crystal structures has been used for locating and characterizing binding sites.[129] While being methodologically very interesting a direct impact on medicinal chemistry programs has not yet been shown.

2.06.4.4 Structure-Based Molecular Design
