The effect of autoantibodies on G-protein coupled receptors is a generally accepted cause for the pathogenesis of a number of diseases, especially in the heart and vascular system. Among these, dilated cardiomyopathy (DCM) is the most intensively investigated pathological situation. Autoantibodies against the β_1-adrenoceptor and the muscarinic M_2-receptor have been found in high percentage of investigated patients in DCM. Immunoadsorption for autoantibody removal has shown a long-term beneficial therapeutic effect. As an alternative, a neutralizing aptamer of autoantibodies against G-protein-coupled receptors has been discovered.[149] The binding and neutralizing effect has been investigated using a bioassay of spontaneously beating neonatal rat cardiomyocytes and enzyme-linked immunosorbent assay (ELISA). It demonstrated broad spectrum neutralization of pathogenic autoantibodies against G-protein-coupled receptors and removal of serum autoantibodies. This data suggests that the aptamer against G-protein coupled receptors might be an appropriate therapeutic candidate in G-protein-coupled receptor autoantibody induced diseases.

6.12.2.3.2.2 Agnostic aptamers

Conventionally, most aptamers are developed to antagonize target function for therapeutic applications. Agnostic aptamers are the contrary concept of antagonistic aptamers. Their function is to activate the function of targets. The new concept of agonistic aptamers has been developed mainly as immunomodulators. The targets of developed agonistic aptamers include 4-1BB, OX-40, CD28, and CD40 for immunological modulation in cancer immunotherapy.[150] In these studies, a monomeric aptamer acts singly as an antagonist, but interestingly, with dimerization converts into an agonistic aptamer that activates immune cells, because receptor signaling requires the ligand-induced oligomerization. Agonistic aptamers have been developed as an alternative to antibody based therapeutics, which can cause severe side effects. Systemic administration of immunomodulatory antibodies has been associated with autoimmune pathologies, conceivably reflecting also the activation of resident autoreactive T-cells. In clinical trials, the antibodies also showed high toxicity. Immunomodulatory aptamers are less toxic and immunogenic options. Also, it is noteworthy that the agonistic immunomodulatory aptamers are as effective as antibodies in in vivo assays.

Agonistic aptamers have also been developed for neurodegenerative disorders and metabolic diseases. Agonistic aptamers against the neurotrophin receptor TrkB selectively activates TrkB in an in vivo model of neurodegenerative disease.[151] The study showed neuroprotective effects of the aptamers in cultured cortical neurons and activation of TrkB upon infusion into the hippocampus in mice; systemic administration of the agonistic TrkB aptamers potentiated kainic acid-induced seizure development.

In metabolic disease, an agonistic aptamer against the insulin receptor promotes glucose uptake through preferential stimulation of Y1150 phosphorylation, both in vitro and in vivo.[152] Even though the insulin agonistic aptamer stimulates autophosphorylation, similar to insulin, it not only binds to an allosteric site distinct from the insulin binding site, but also preferentially induces Y1150 phosphorylation in the IR kinase domain.

6.12.2.3.2.3 Aptamer-targeted oligonucleotide therapeutics

The therapeutic oligonucleotides have remarkable potential for treating human diseases. However, difficulties in specific delivery of nucleic acid based therapeutics to target organs still remain a major impediment in clinical application. Aptamers have emerged as effective delivery vehicles for therapeutic oligonucleotides, including siRNAs, saRNA, miRNAs, anti-miRs, and ASOs. Cell-internalizing aptamers have demonstrated the ability to deliver therapeutic oligonucleotides to target cells. The first aptamer-targeted siRNA drug, designed to target a cytotoxic, cancer-specific siRNA to prostate cancer cells, was described in 2006.[153] Since then, many groups have expanded on this approach to develop aptamer-siRNA chimeras with the ability to specifically target different diseases. These studies highlight the flexibility and broad clinical potential of the aptamer-siRNA chimera platform. By changing the aptamer, the aptamer-siRNA chimera redirects delivery of the applicable RNAi-based therapy to many diseases, including cancer and infectious diseases. This approach is rapidly expanding, as target cell specific delivery, aptamer-siRNA chimera technology has been applied to target molecules such as Her2, PSMA, BAFF-R, gp120, TLR9, MUC1, Nucleolin, CD4, CD8, EpCAM, CCR5, and pancreatic cancer markers.[154]

It is worth noting that a different approach to constructing chimeras that covalently links the aptamer to a cytotoxic siRNA, has been applied against STAT3 transcripts in lymphoma[155] or to deliver small activating RNA to C/EBPα in pancreatic cancer.[154c] Even though outstanding preclinical studies have demonstrated the potential of exploiting aptamers as delivery cargo for RNAi-based therapeutics, the aptamer-based delivery of oligonucleotides have yet to be evaluated in clinical trials.

6.12.2.3.2.4 Delivery of chemotherapeutics

Aptamer mediated delivery of therapeutics is very powerful for targeted therapeutics. Aptamers selected to cell surface membrane components provide an important route for targeted chemotherapeutics. Here, we discuss aptamer drug conjugates for targeted therapeutics. Poor efficacy and off-target systemic toxicity are major problems associated with current chemotherapeutics to treat cancer. Potentially efficacious drugs which would otherwise have limited use in clinical settings due to general toxicity are good candidates for aptamer-targeted delivery.

Epirubicin (Epi), an anthracycline drug, is limited in clinical use because of its cardiotoxicity. Specific delivery of epirubicin has employed polyvalant aptamers, MUC1 and nucleolin (AS1411) aptamers.[156] Epirubicin binds preferably to sequences containing CG. The AS1411 aptamer and its complimentary strand have poly G/C double-stranded areas and MUC1 as a targeting aptamer. The Epi-aptamer conjugate significantly enhances the cellular uptake of Epi and increases its cytotoxicity in target cells (MCF7) as compared with nontargeted cells (CHO).

Cisplatin is a platinum-based chemotherapy drug that is used to treat a variety of cancers. However, its responsiveness is less than 15%, when it is given alone. To improve the efficacy and tolerability of cisplatin, EGFR-targeted albumin-cisplatin nanoparticles (NPs) have been constructed.[157] The cisplatin NPs have been conjugated with EGFR aptamer, which internalized to HeLa cells specifically by receptor mediated endocytosis. The EGFR aptamer functionalized NPs enhance in vitro antitumor effects and markedly improve its tolerability and in vivo efficacy when compared with free cisplatin and other single treatments. Furthermore, reduced systemic and nephrotoxicity was also observed in vivo.

Doxorubicin (DOX) is a widely used chemotherapeutic agent but exhibits cardiotoxicity as a serious adverse side effect in cancer patients. F binds preferably to CG sequences. The MUC1 aptamer can be combined with a DNA tetrahedron (Td) that carries doxorubicin (Dox) within its DNA structure. The complex thus formed (Apt-Td) preferentially binds toMUC1-positive MCF-7 breast cancer cells, similar to the MUC1 aptamer alone. Each Apt-Td complex carries approximately 25 Dox molecules. Moreover, Aptamer-Td selectively delivers Dox into MUC1-positive breast cancer cells but reduces Dox uptake by the MUC1-negative control cells. Dox-loaded Apt-Td induces a significantly higher cytotoxicity to the MUC1-positive cancer cells versus the MUC1-negative control cells.

Gemcitabine (GEM), a nucleoside analogue, is used as the first line of chemotherapy. However, it possesses some drawbacks, such as poor biological half-life resulting from rapid metabolism and the induction of resistance, leading to its restricted therapeutic potential. To increase the efficacy of gemcitabine, GEM-loaded nucleolin aptamer (AS1411) surface-decorated polyethylene glycol-poly nanopolymersome (Apt-GEM-NP) was constructed to target nucleolin-overexpressing nonsmall cell lung cancer (NSCLC).[158] The Apt-GEM-NP exhibited sustained release of drug in physiological conditions and greatly improved the chemotherapeutic efficiency. It clearly showed an enhanced cell proliferation inhibitory effect of AS1411-conjugated NP NSCLC. The great advantages of targeted delivery of anticancer drugs by aptamers are much reduced side effects and improved therapeutic efficacy.

6.12.2.3.2.5 Theragnostics

Theragnostics is a treatment strategy that combines therapeutics with diagnostics. It associates both a diagnostic test and targeted drug therapy, including molecular imaging to develop efficient new targeted therapies.

As molecular imaging and theragnostic tools, aptamers are considered to be promising next-generation ligands. Aptamers are synthetic nucleic acids that can be held together with complementary sequences by base-pair hybridization. Using these characteristics, the complementary oligonucleotide (cODN) hybridization-based aptamer conjugation platform was developed to use

aptamers as the molecular imaging agent.[159] The ^{18}F prelabeled cODN was hybridized with a matched sequence containing nucleolin (AS1411) aptamer. The cODN platform-hybridized aptamers exhibited good serum stability and specific binding affinity towards target cancer cells both in vitro and in vivo. In small-animal PET-CT scan and image analysis, ^{18}F-hybridized aptamers (^{18}F-hybridized AS1411) showed target cancer cell specific localization comparing scrambled aptamer. However, high uptake was observed in the kidneys, intestines, and liver for both in biodistribution.

The human Matrix MetalloProtease-9 (hMMP-9), a marker of malignant tumor, is overexpressed in tumors where it contributes to tumor metastasis. Fully nuclease-resistant hMMP-9 aptamers have been developed as probes for imaging tumors.[160] The hMMP9 aptamer was labeled with S-acetylmercaptoacetyltriglycine (MAG) and DOTA. Tumor uptake was significantly higher for 111In-DOTA-aptamer than for the 111In-DOTA-control oligonucleotide. In a biodistribution study, following IV injection of 111In-DOTA-aptamer, high levels of radioactivity were observed in kidneys and bladder but digestive tract uptake was very limited.

Protein tyrosine kinase-7 (PTK7), a member of receptor tyrosine kinase superfamily initially identified as colon carcinoma kinase-4, is highly expressed in various human malignancies. Its expression is correlated with aggressive biologic behaviors such as increased cell proliferation, invasiveness, and migration. A 41-oligonucleotide DNA aptamer that targets PTK7 was labeled with ^{18}F[161] and evaluated in vivo. In vivo PET imaging clearly visualized specific accumulation of ^{18}F-aptamer in tumor-bearing mice. In biodistribution studies, the labeled aptamer was rapidly cleared from the blood through the kidneys and bladder.

These results consistently showed aptamer-mediated theragnostics are rapidly cleared, but more importantly, strong tumor homing and tumor specific accumulation, suggesting that the aptamer-based platform offers great potential as molecular imaging agents.

6.12.2.3.3 Aptamers in clinical development

Since the first aptamer drug (Macugen) was approved by the FDA, a number of aptamer-based drugs have been developed and reached advanced clinical trials (Table 3). For example, Pegnivacogin, a 2′-F RNA aptamer against coagulation factor IXa coupled to an 40 kDa branched molecule of methoxypoly ethylene glycol (mPEG) to increase half-life in plasma, has finished a phase IIb clinical study by Regado. Unfortunately, acute coronary syndrome and allergic reactions occurred within minutes of a first dose in 3 of 640 patients.[162] Two events met criteria for anaphylaxis and one event a dermal reactions; each event is serious and life-threatening; this lead to early termination of the trial. A broader investigation of these three events, found no other serious allergic reactions to pegnivacogin. In addition, there was no evidence that pegnivacogin caused an inflammatory response, histamine release, or complement activation. However, an association between high levels of antibody to polyethylene glycol (PEG) and the first exposure allergic reactions was identified in more than half of the patients.

Currently, PEGylation of recombinant proteins and antibodies is become the golden standard of the technology due to increased solubility, stability, masking humoral and cellular immunogenicity, protease protection, controlled release, reduced absorption, and reduced injection volume.[163] Since the approval of PEG-adenosine deaminase for severe combined immunodeficiency syndrome in 1990s, at least 12 therapeutic PEGylated agents, including three blockbusters have been approved, with several more in development.[164] In contrast to the accepted general assumption that polyethylene glycol (PEG) is nonimmunogenic and nonantigenic, animal studies clearly showed that some other PEGylated agents can elicit antibody formation against PEG (anti-PEG). In the clinical trials by Regado, it also clearly showed that preexisting antipolyethylene glycol antibody induce severe allergic reactions.

Table 3 Aptamers in clinical trials or marketed

Intervention	*Company*	*Target*	*Indication*	*Phase*	*Status*	*Clinical trial ID*
Macugen	Eyetech/Pfizer	VEGF	Age-related macular degeneration		Approved	
Fovista	Ophthotech	PDGF	Age-related macular degeneration	III	Recruiting	NCT01944839
				III	Recruiting	NCT01940887
				III	Active	NCT01940900
Zimura	Ophthotech	C5	Geographic atrophy Macular degeneration	II/III	Recruiting	NCT02686658
			Idiopathic polypoidal choroidal vasculopathy	II	Completed	NCT02397954
REG1	Regado	Factor Ixa	Coronary artery disease	II	Completed	NCT00715455
				II	Completed	NCT00932100
ARC1779	Archemix	vWF	Purpura, thrombotic thrombocytopenic Von Willebrand disease type-2b	II	Completed	NCT00632242
NOX-A12	NOXXON	CXCL12	Chronic lymphocytic leukemia	II	Active	NCT01486797
			Multiple myeloma	II	Completed	NCT01521533
NOX-H94	NOXXON	Hepcidin	Anemia of chronic disease	II	Completed	NCT01691040
NOX-E36	NOXXON	MCP-1/CCL2	Type 2 diabetes mellitus Albuminuria	II	Completed	NCT01547897

Listed clinical studies are found in clinicaltrials.gov. Most advanced clinical studies for each aptamer are listed.

6.12.2.3.4 Challenges and future perspectives

As a therapeutic molecule, aptamers have been utilized in a variety of fields. Even though aptamers have very attractive features of low immunogenicity and high specificity, the main drawback with the use of aptamers therapeutics is rapid clearance in vivo. The major challenge of aptamer-based therapeutics thus remains longer lasting pharmacokinetics in systemic application. To increase retention time and serum stability in vivo, PEGylation of aptamers has been widely utilized to improve pharmacokinetics. Unfortunately, PEGylation has induced severe allergic reactions which are associated with preexisting antibodies to PEG in clinical trials[162]; however, aptamers have demonstrated efficacy in clinical trials. Alternative formulations to PEGylation need to be developed for aptamer-based therapies. Capping the 3′ and 5′ ends of aptamers, or incorporating modified nucleotides to generate highly nuclease-resistance aptamers during the SELEX are promising avenues of exploration. Currently, to incorporate modified nucleotides, sugar modified nucleotides such as 2′-F or 2′-amino (2′-NH_2) groups on the pyrimidine residues are available for enzymatic synthesis. Inclusion of other modified nucleotides will require the development of new enzymes.

6.12.3 Biochemically Produced RNAs

While synthetic small nucleic acid therapeutics have a variety of potential medical applications, some diseases and conditions may benefit from long-term gene therapy regimens. Engineering disease-susceptible cells to express small RNA therapeutics can fill this need. For instance, the development of an HIV-resistant T cell population using gene therapy remains an important aspect of research geared to developing an HIV cure.[165] The challenges of HIV-1 treatment are based on the high viral mutation rate resulting in the rapid production of escape mutants, coupled with the difficulties in eradication of latently infected cells.[166] Consequently, most anti-HIV gene therapeutic strategies employ a combinatorial approach. These include multiple RNA and/or protein modalities and targeting different stages of the viral replication cycle as well as endogenous cellular proteins. This topic has been covered in depth in other reviews,[167] but for our purposes HIV-1 gene therapy can serve to illustrate general principles in the application of small RNA therapeutic designs.

A number of factors are considered when choosing the most appropriately expressed small RNA modality for a given application. The most crucial include the type of small RNA therapeutic, the expression format or platform, the promoter type, and the ultimate delivery method. These are highly interrelated issues and decisions on the best approach are dependent on the context of the biology of the disease.

U1 interference, ribozymes, aptamers, and RNA interference triggers are some of the major categories of self-contained small RNA therapeutics (in contrast to CRISPR-based strategies, which depend on Cas9 protein a well, see below and **Fig. 5**). The development of therapeutic U1 interference is still in a relatively early stage, but shows promise.[168] RNA enzymes or ribozymes, have been a major focus of RNA therapeutics. Ribozymes have the theoretical advantage of multiple turnover kinetics. Also, as they do not depend on any known cellular pathways, ribozymes are less likely to interfere with critical endogenous processes. However, this latter characteristic also underlies much of the difficulties in developing ribozymes that work efficiently in vivo, where the absence of a protein machinery to enhance ribozyme/target association and compensate for target site inaccessibility compromises target binding and catalysis. As a consequence, ribozyme research has shifted somewhat away from therapeutic applications; nonetheless, progress continues towards a better understanding of ribozyme catalysis[169] which may prove the basis for next generation ribozyme therapeutics.

This discussion will therefore be devoted to recent research that informs the design of expressed RNAi triggers. Our goal is to introduce the reader to different expression platforms and the factors to consider in developing applications of expressed small RNA therapeutics. Additional information and viewpoints can be found in recent reviews.[170]

6.12.3.1 RNAi Triggers

RNAi-based gene therapy strategies may employ either siRNAs (that are fully complementary to the target) or microRNA triggers (see above and **Fig. 2**) of RNA interference. The former is more commonly used for expressed therapeutics as siRNAs typically mediate higher levels of mRNA knockdown through Ago2 cleavage. Both types of triggers can be expressed in contexts or formats that require both Drosha and Dicer, either complex alone, or neither to process the trigger. We will discuss the various formats of expressed RNAi triggers in order of their processing requirements, with an emphasis on more recent research.

6.12.3.1.1 Pri-miRNA mimics

Shortly after the discovery of microRNA genes,[171] the Cullen group showed that it was possible to reprogram human pri-miR30 by replacing the mature miR30 region with sequences complementary to alternate mRNA targets, generating so-called pri-miRNA mimics. However, initial replacement strategies remain unreliable, generating low-potency RNAi triggers,[172] which can still be a problem.[173] Nonetheless, a number of laboratories successfully developed microRNA mimics, based on endogenous single or clustered pri-microRNAs. This approach has markedly improved with greater understanding of the miRNA biogenesis pathway and the features that distinguish effective pri-microRNA substrates.

Several pri-miRNA structural characteristics required for efficient processing emerged from early comparative studies of endogenous pri-microRNAs coupled with mutational analysis. These delineated the basic structural features of the pri-microRNA stem/loop and surrounding context. First, the pri-microRNA stem consists of approximately three helical turns (with some bulges and small loops)

and has a preference for at least 8 bp at the base of the stem.[174] In addition, the cleavage site at position 11 must be double stranded, i.e., not be in a bulge or loop.[175] Also, the flanking regions of the stem/loop are largely single stranded or nonstructured[176] as is the apical loop of at least 10 nt.[174]

Some sequence biases also became apparent.[177] There is also a strong preference for uridine at the 5′ end (5′U) of the mature microRNA.[178] Argonaute loading of the mature miRNA favors loading the 5′ end of the strand of the mature miRNA with the weaker pairing. In the pri-miRNA, for instance, this corresponds to bases 14–16 when the 5′, or 5p side of the hairpin will ultimately become the guide strand; this region should also be fully base-paired.[179] In contrast, a 5′ guanosine on the mature microRNA is disfavored.[178c,180]

The general structural features of pri-microRNAs are well-conserved in the animal kingdom; however, while necessary, they are not sufficient. For instance, *C. elegans* pri-miRs are inefficiently processed in human cells. Based on this observation, the Bartel group devised a high-throughput process to determine structural and sequence motifs that characterize efficient substrates (refer to summary in **Fig. 4**). They constructed large pri-miRNA variant pools of the basal stem (below the Drosha cleavage site) and flanking regions of four human pri-miRNAs and conducted in vitro cleavage reactions in microprocessor lysates. Purified cleaved variants were deep sequenced and analyzed for enriched structural and sequence motifs. Potential candidates were validated independently in microprocessor assays.[181] Two important structural features emerged: an 11 bp (one helical turn) basal stem, flanked by at least nine unstructured nucleotides. However strong primary sequence preferences were also revealed: first, a U/G at positions $-1/+1$ straddling the basal 5′ flanking sequence/stem transition (conserved in many chordate pri-miRNAs); second an apical UGU motif at the 5′ stem/loop transition; and third, a CNNC motif, typically 17–18 nt downstream of the Drosha cleavage site. The SRp20 protein, thought to be involved in splicing regulation, mRNA export and translation initiation, binds the CNNC motif and enhances processing.

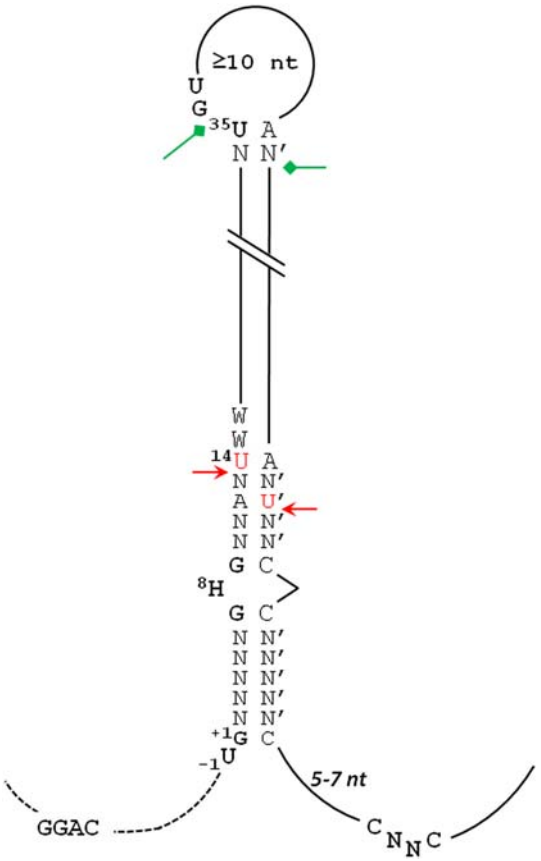

Fig. 4 Pri-miRNA scaffold motifs. Numbering convention is after Fang and Bartel.[182] The stem is fully base paired starting at $+1$, except for base 8. Note that the upper portion is not to scale *(discontinuity marks)*. Shown with optimal basal region of 11 bp below 5′ DROSHA cleavage site, and 24 bp apical region for total stem length of 35 bp. The flanking regions for at least 10 nt on either side and the loop are unstructured. *Red arrows*, microprocessor cleavage sites; *red bases* preferred by DROSHA. *Green arrows*, Dicer cleavage sites. Sequence motifs implicated in enhancing microprocessor activity are shown in *bold*. Motifs in the stem: UG at $-1/+1$; GHG at 7–9; apical UGU. UWW sequence preferred at the end of the guide strand for best siRNA strand selectivity, here shown for the 5p arm. Flanking motifs: METTL3 motif GGAC, variable position likely within 100 nt of the stem; CNNC motif, 16–18 nucleotides downstream of the 3′ DROSHA cleavage site or 5–7 nt from the base of the stem. H, any nucleotide except G; W, either U or A.

Subsequently, the Bartel group performed the complementary analysis on the entire stem region of three pri-miRNAs, using a sophisticated sliding window randomization procedure.[182] Their methodology varied not only the sequence but also generated all possible bulge sequences of 0 (none) 1, and 2 nucleotides. There was strong selection for a narrow window of stem length: 35 ± 1 bp, subsequently confirmed by other researchers.[173] Note that Drosha processing of the pri-miRNA with this stem length generates a pre-miRNA with two helical turns, the preferred length for Dicer processing.[183] In addition, there was a clear preference for stem pairing (both Watson-Crick and noncanonical wobbles) over nonpairing, particularly at the base and the apical three base pairs (33–35), with one exception; position 8. Moreover, this unpaired base is part of a larger sequence motif, GHG (where H is any nucleotide except G) for basal stem nucleotides 7–9.

With these new motifs, the authors were able to successfully implement de novo design of artificial pri-miRNAs favoring 5p selection. All were processed more efficiently than a miR-1 standard in vitro and in vivo. Though initial designs contained fully complementary stems (with the exception of base 8), up to 4 wobble bp and 3 single bp mismatches were as efficiently processed as their fully paired counterparts. This is fortunate, as some wobbles and/or mismatches are likely to enhance genomic stability and facilitate cloning. Also encouraging, from a design viewpoint, is that removal of a single motif had only minor detrimental effects.

Research continues to reveal additional sequence motifs that aid pri-miRNA processing.[173,184] For instance a METTL3 (Methyltransferase-like 3) motif within pri-miRNA flanking regions at various positions is associated with enhanced processing.[173,185] Active areas of interest include the tolerance of pri-miRNA scaffolds to omissions of motifs, the effects of flanking sequences, and the interplay between scaffold and exogenous sequences.[173,180b,182]

As with synthetic siRNAs, off-target effects are a major concern, but additional mechanisms come into play with expressed RNAi triggers. A single pri-miRNA can produce a group of related mature miRNA variants or isomiRs, which are due in part to pri-miRNA cleavage at multiple sites. Endogenous pri-miRNAs vary widely in their propensity to generate isomiRs, which can function to fine-tune regulatory networks.[186] 3′-Terminal miRNA heterogeneity is common; 5′ heterogeneity is less frequent, but more consequential as it changes in the seed sequence of the mature miRNA. Both types of heterogeneity can affect strand selectivity. For these reasons, isomiR production is generally undesirable for designed miRNA mimics. IsomiRs can be due to imprecise microprocessor processing, Dicer processing, or both. Interpreting the contributions of each effect to determine design rules presents challenges. Happily, efficiency and precision determinants can overlap, as when optimized substrate stem length results in both high efficiency and precision,[182,187] but maximal precision may sometimes require compromised efficiency.[180b]

One approach determined pri-miRNA features contributing to processing precision by analyzing sequences surrounding cleavage sites in cellular pri-miRNAs that are homogenously processed, relative to those producing isomiRs.[188] Precision pri-miRS show preferences in the 5′ arm Drosha cut site for a $+14$ position for U over and above the known Ago loading bias[189]. There is also a preference against G in the same position. Dicer also prefers cutting after a uridine on the 5′ arm, while Drosha and Dicer are both biased against cutting before a guanine. Other intriguing observations reveal that the endogenous pri-miRNA scaffolds influence mimic processing efficiency and precision, while structural features within the exogenous sequences affect precision.[173,177,180b]

Liu et al.[190] have begun studies on the possibility of regulating individual endogenous pri-miRNAs with conventional small molecule therapeutics. To identify targets for drug development, they analyzed human pri-miRNAs to see if it was possible to identify unique small structural motifs such as stem bulges, internal loops, and apical loops. They zeroed in on the regions of Drosha and Dicer processing sites, hypothesizing that drug binding to these areas would be more likely to have an effect on miRNA production, and were able to generate a database of motifs specific to individual pri-miRNAs. Ultimately, these motifs also could potentially be incorporated into microRNA mimic scaffolds to regulate expression.

6.12.3.1.2 shRNA triggers

One of the earliest and most extensively used forms of expressed RNAi trigger, as well as the simplest, is the hairpin or shRNA (sometimes referred to as a pre-miRNA), which bypasses Drosha processing. After transcription shRNAs are directly exported to the cytoplasm via exportin 5. There, Dicer cleaves the shRNA into the mature siRNA (**Fig. 3**). ShRNA design is covered elsewhere in detail.[170b,191] Online tools are available to assist shRNA design, and there are a number of commercial vectors that facilitate cloning and expression of shRNAs.

Typically, shRNAs are designed with fully complementary 21–23 base pairs stems using Watson-Crick base pairing, although wobble pairing may be used to optimize thermodynamic properties for optimal strand selection bias in the siRNA product. As discussed above, Dicer cleavage precision is governed by a number of factors. A helpful general guide is the loop-counting rule, which states that Dicer cleaves precisely two nucleotides away from a single-stranded apical loop or internal bulge.[183b]

6.12.3.1.3 Ago2shRNAs

An intriguing approach was recently developed that utilizes Drosha but bypasses Dicer processing. This methodology is based on observations of the unusual processing pathway of the highly conserved miR-451. Processing of pri- to the pre-miR-451 occurs using canonical Drosha processing; however, the resulting pre-miR-451 has an atypically short stem that makes it a poor Dicer substrate.[192] Instead, pre-miR-451 is cleaved by Ago2 to generate a 30 nt guide strand that is subsequently trimmed by Poly(A)-Specific Ribonuclease (PARN).[193] Human pri-miR-451 can be reprogrammed to silence other RNA targets using a standard microRNA mimic approach, maintaining the contexts of the parental pri- and pre-miR-451 precursors.[192a]

A logical extension of this approach is to use the pre-miR-451 structure to design shRNAs that bypass both DROSHA and Dicer processing. These are referred to as AgoshRNAs to emphasize their dependence on Ago2 cleavage and to distinguish them from standard Dicer-dependent shRNAs.[194] AgoshRNA and standard shRNA designs differ in important ways. Typical shRNAs use

a passenger-loop-guide sequence order and have a 21–23 bp stem which is processed by Dicer at two staggered cleavage sites to yield a double-stranded siRNA. In contrast, AgoshRNAs use a guide-loop-passenger format with an optimal stem of 18 bp[193,195] which Ago2 cleaves only once approximately half-way into the 3′ side of the stem, ultimately yielding only one stable single-stranded guide sequence. Ago2 cleavage of tested precursors is precise, but sensitive to mispairing at the cleavage site.[193] With small, 3–5 nt apical loops, this yields a 5′ product containing the guide sequence of about 30–33 nt (depending on the exact size of the loop) and a 3′ product too short to program RISC, theoretically eliminating passenger strand off-target effects.

6.12.3.1.4 Biochemically produced RNAi in clinical development

Gene therapy for HIV-1 continues to be explored due to the persistence of latent HIV-1 reservoirs and the propensity to evolve resistance to conventional drug therapies, which also have considerable side effects. The current approach is to create a resistant immune system by introducing vectors carrying anti-HIV-1 gene therapeutics into hematopoetic stem cells ex vivo followed by reintroduction into the patient.[167a,196] Lentiviral and adeno-associated virus (AAV) vectors are commonly employed to delivery expressed RNA therapeutics with the former the vector of choice for HIV-1 therapeutic applications. Both in silico analyses[197] and empirical results indicate that a minimum of three gene therapeutic HIV-1 antivirals are required to control HIV-1 replication; consequently, multiplexing or combinatorial approaches are common in HIV-1 gene therapy.

As an example, we have developed a lentiviral vector expressing three anti-HIV-1 therapeutic cassettes: a U6-*tat*/*rev* shRNA, a U6 TAR aptamer decoy (in a U16 backbone), and a CCR5 ribozyme under the adenovirus VA promoter. A phase 0 safety and feasibility clinical trial showed that introduction of this vector into hematopoietic stem cells ex vivo, as part of an autologous bone marrow transplant for treatment of AIDS-related lymphoma, was well tolerated in four patients.[198] We then developed a next generation lentiviral therapeutic that expresses three anti-HIV RNAs using the endogenous miR-106b microRNA cluster within an intron of the MCM7 (minichromosome maintenance complex component-7) gene as a platform.[199] The MCM7 cluster was expressed using the constitutive CMV Pol II promoter. Various combinations of miRNA mimics, ribozymes and aptamers mediated efficient knockdown. Moreover, it was possible to add a fourth shRNA directed against the CCR5 HIV-1 cellular coreceptor, expressed from a $tRNA^{Ser}$ promoter, within the cluster. We achieved effective inhibition with this system despite production of much lower amounts of RNAi triggers from the miRNA mimics compared to U6-expressed counterparts.[200] Moreover, the MCM7 platform is compact enough to permit addition of independent expression cassettes in lentiviral vectors; for instance, a U6-aptamer for interaction with abundant substrates. Other anti-HIV combinatorial approaches in development also include anti-HIV proteins.[201] It is clear that the diversity of RNA therapeutic modalities, expression platforms and promoters comprise an impressive set of tools that can be used to treat a number of diseases and conditions.

6.12.3.1.5 Challenges and future perspectives

The exact choice of RNAi trigger format ultimately depends on factors unique to the ultimate therapeutic application, but we mention some general considerations here. The first is ease of design, where shRNA/pre-miR and AgoshRNAs have a clear advantage over pri-miRNA mimics. There is a large body of work addressing construction of traditional shRNAs, while AgoshRNAs are a relatively new technology.

The second major issue relates to toxicity. A common cause of toxicity with both synthetic and expressed RNA triggers are off-target effects due to shared complementarity between the intended target and other cellular RNAs. Best practices to avoid this problem include verifying the phenotype of knockdown with two different RNA triggers whenever possible. Another is poor selectivity of the guide strand (passenger strand effects). We note that passenger strand effects are minimized with AgoshRNA triggers as the 3′ product of cleavage is too small to enter the RNAi pathway.

Problems more common to expressed RNAi triggers include poor processing precision, creating multiple guide strands, and increasing the likelihood of off-target effects; in this regard, pri-miRNA mimics are more difficult to design than shRNAs. Off-target effects tend to increase with expression level as well. Deep sequencing to analyze expressed small RNA products in the cell type of interest is very useful for optimizing expressed therapeutic triggers.

Toxicity can also arise from saturation of the RNAi pathway components, resulting in perturbation of endogenous microRNA production or function. Levels of RNAi pathway proteins can differ widely in different tissues and disease states; the use of the appropriate trigger format can bypass limiting components. The level of trigger expression is also a factor, particularly when multiple siRNAs are required, and can depend on the intrinsic nature of the trigger in conjunction with the promoter (see below).[202] Typically the highest amount of trigger expression is mediated with U6 or H1 promoters of shRNAs. At the other end of the range are Drosha-dependent miRNA mimics under Pol II promoters. It is worth noting that AgoshRNAs produce lower amounts of guide than their cognate shRNAs, even when using Pol III promoters.[195b]

One example of saturation toxicity was reported in which a U6-shRNA therapeutic expressed in mouse liver was fatal. Use of the H1 promoter, which has about half the expression level of U6, was tolerated.[203] Further investigation revealed that when exogenous shRNAs are expressed above a threshold of 12% of total murine liver microRNAs, the resulting fatalities are directly associated with loss of a single isoform of miR-122.[204]

The human promoters of snRNAs U6 and H1 are used extensively to express small RNA therapeutics. Unlike RNA polymerase II promoters, which drive transcripts including extraneous sequences that can interfere with the structure and function of small RNA therapeutics, U6 and H1 promoters utilize RNA polymerase III (Pol III). Pol III promoters have a well-defined start site, and a small, poly U termination signal encoded by a run of at least five thymidines.[205] These features are critical for correct processing of both AgoshRNAs and Dicer-dependent shRNAs/pre-miRNAs, as both enzymes measure from the 5′ end of the transcript, which must

initiate with a G for U6, and preferably a purine for H1. Moreover, these promoters are relatively small allowing them to be easily multiplexed in vectors with size limitations. U6 and H1 mediate very high levels of basal expression (although H1 less than U6), an asset when expressing aptamers which have a stoichiometric mode of action, but a potential disadvantage for RNAi triggers. We developed tRNA promoters that express RNAi triggers as a pre-tRNA-shRNA chimeras, which are processed by endogenous tRNAseZ to release the shRNA moieties. This promoter system produces shRNAs with 5′ terminal mono-phosphates, rather than the 5′ triphosphates found on U6 and H1 transcripts, which at high levels have been linked to activation of cellular immunity. Moreover, we developed tRNA promoter variants that produce lower levels of siRNA triggers than the wild-type tRNA, a possible aid in avoiding toxicity due to overexpression.[206]

Another downside of Pol III promoters is that conditional expression is limited to tetracycline responsive versions of U6 and H1; these are useful for research purposes, but are not likely to be used in actual therapeutic applications.[207] Either constitutive or regulated Pol II promoters can be used to express pri-miRNA mimics, although the resulting cassettes are larger when using Pol III promoters, and other design factors need to be considered.

6.12.3.2 CRISPR/Cas9

The clustered, regularly interspaced, short repeat (CRISPR and CRISPR associated protein system (aka CRISPR/Cas system)) was originally discovered as an adoptive immune system in bacteria against foreign genes.[208] Following the demonstration in 2012, where the CRISPR/Cas9 system was shown to be an RNA-guided DNA endonuclease that uses the RNA to direct a double-stranded break (DSB) of target DNA,[209] CRISPR/Cas9 system has emerged as the most attractive and promising gene-editing tool to transform biology. Among three CRISPR/Cas systems (I, II and III),[210] the type II system has been most commonly used in biological applications because it relies on a single multifunctional protein, Cas9, whereas other types consist of multiple protein complex.[211] In bacteria, the CRISPR system incorporates invading foreign DNA into the CRISPR array encoded in the host genome.[212] The CRISPR arrays are then transcribed into CRISPR RNAs (crRNAs) bearing sequences from the invading DNA (protospacer) and part of CRISPR repeat sequences. The crRNAs hybridize with the transactivating CRISPR RNA (tracrRNA), and the resulting complexes are associated with the Cas9 nuclease (**Fig. 5**). The protospacer sequences guide the crRNA-tracrRNA:Cas9 complex to cause DSBs of the invading DNA that harbors complementary sequences to the protospacer sequence. This sequence recognition system is somewhat restricted by the protospacer adjacent motif (PAM) sequence, a three consecutive nucleotide sequence that must exist adjacent to the 20-nt target sequence. While the original CRISPR/Cas9 complex consists of three components, the simple two-component system which consists of Cas9 and a single guide RNA (sgRNA) is currently most widely adopted. The sgRNA is a fusion of crRNA and tracrRNA (**Fig. 5**), thus playing both roles in the DSB process.[209] An attractive feature of this system is that unlike other genome engineering technology such as zinc-finger nucleases (ZFNs) and transcription activator like effector nucleases (TALENs), which require considerable protein engineering for each target, the CRISPR/Cas9 system only requires a change in protospacer sequence of the sgRNA for each target. There are at least two DSB repairing pathways catalyzed by cellular machinery: nonhomologous end joining (NHEJ) and homology-directed repair (HDR) (**Fig. 5**). NJEJ is the most active and rapid repair pathway that gives various length of insertion or deletion in the DSB site. This random repairing results in translational disruption of reading frame by creating deletions, insertions, or frameshift mutations. On the other hand, HDR can be used to introduce specific nucleotides or sequences by homologous sequence based recombination on the target site. While the efficiency of HDR is generally low ($<10\%$) and usually taken over by NHEJ pathway, it gives precise editing of genomic sequences (**Fig. 5**).[213]

6.12.3.2.1 Potential therapeutic applications of CRISPR/Cas9

This simple but powerful platform of genome editing has rapidly spread and become widely adopted by many researchers. The development of this technology is breathtakingly fast and a number of applications have been reported over the past few years. Nowadays, the use of CRISPR/Cas9 system is available not only for genome editing but also for gene expression regulation, epigenetic modulation, and genome imaging. Exploring therapeutics based on this technology has also been in progress. These include, for example, correction of defective genetic mutations, immunotherapy for cancers, and treating infectious diseases by targeting virus or blocking infectious pathways. Here we will discuss some examples of potential therapeutic applications of CRISPR/Cas9 technology.

As described above, frameshift mutations in the dystrophin gene (*Dmd*) impair myofiber integrity, resulting in functional deterioration of muscle in DMD. Correction of the gene mutation using CRISPR/Cas9 system has been attempted by several groups. Long et al. designed a sgRNA to target a mutation site in dmd exon 23 and a HDR oligonucleotide template, which were injected with Cas9 mRNA to zygotes from mdx DMD model mice that carry a nonsense mutation in exon 23 of *Dmd* gene which disrupts dystrophin expression.[214] The genome editing produced genetically mosaic mice containing 2–100% correction of the *Dmd* gene. In vivo gene correction of Dmd gene was performed separately by three different groups around the same time.[215] In these studies, components of gene editing, including Cas9 and gRNAs that were designed to target exon 23 of the Dmd gene, were systemically delivered using AAV to mxd mice. Deletion of exon 23 by CRISPR/Cas9 mediated genome editing restored dystrophin protein expression in cardiac muscle and skeletal myofibers, enhancing muscle function. These studies indicated that CRISPR/Cas9 mediated genome editing was a potential therapy to treat DMD.

Viral infections have also been shown as potential targets of CRISPR/Cas9 system. Several groups have demonstrated potential use of CRISPR/Cas9 system in targeting viral infections such as human immunodeficiency virus-1 (HIV-1),[216] hepatitis B,[217] Epstein–Barr virus,[218] and human papillomavirus.[219] The most advanced therapeutic genome editing to date is ex vivo ZFN

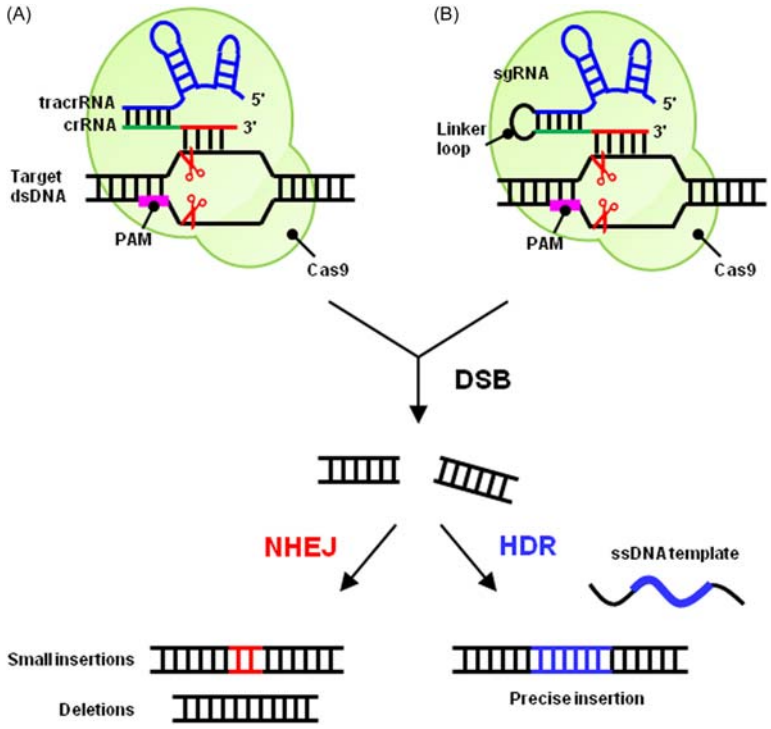

Fig. 5 Schematic of CRISPR/Cas9 mediated genome editing. (A) Naturally occurring CRISPR/Cas9 complex consisting of a pair of crRNA and tracrRNA, and the Cas9 nuclease. (B) Engineered CRISPR/Cas9 complex consisting of single guide RNA which mimics both crRNA and tracrRNA with Cas9 nuclease. These complexes recognize target DNA that is complementary to the 20 nt from 5′ end of sgRNA lying next to a PAM sequence, and cause double-strand breaks (DSBs), which can be repaired by endogenous DNA repair machinery; nonhomologous end joining (NHEJ) or homology-directed repair (HDR). NHEJ repair DSBs generating small insertions or deletions, while HDR introduces desired sequence insertion by recombination of the DSB locus with single-stranded DNA templates.

mediated gene modification of CCR5 gene to prevent HIV-1 infection. The cell surface chemokine receptor CCR5 is the macrophage-tropic HIV-1 coreceptor, which dominates in early stages of HIV-1 infection. Inhibition of CCR5 could lead to disruption of viral entry to host cells. Autologous T-cells, modified by CCR5-ZFN and expanded ex vivo, are being tested in a series of clinical trials in HIV-1 positive patients. Encouraged by this successful example with ZFNs, several CRISPR/Cas9 mediated genome editing approaches against CCR5 have also been developed and tested in various cell types including CD4 + T cells,[216a,d] CD34 + HSCs,[216c] and iPSCs.[216b] For example, Wang et al. used lentiviral vectors expressing Cas9 and CCR5 sgRNAs which were subjected to a single round transduction into HIV-1 susceptible human CD4+ cells.[216a] High frequencies of CCR5 gene disruption was observed without measurable detection of potential off-target modification of the genomic site containing highly homologous sequences to the CCR5 sgRNAs. Since CCR5 gene is highly homologous to CCR2 gene,[216c] when targeting CCR5 with CRISPR/Cas9 system, one should carefully design sgRNAs to avoid potential off-target events. Directly targeting viral genes is also one of potential anti-viral genome editing strategies. Complete excision of the integrated HIV-1 proviral DNA fragment using CRISPR/Cas9 was achieved by targeting the U3 region of HIV-1 long terminal repeat flanking the viral genome.[216e,f] These studies demonstrated the potency of the CRISPR/Cas9 system for preventing viral infection/replication as well as eradication of viral latency which is a major hurdle for achieving a sterilizing HIV cure.

In recent years, T-cell immunotherapy has been gaining widespread attention for its great promise in cancer treatment. In particular, one technology with the most potential is the use of modified T cells that express synthetic receptors known as chimeric antigen receptors, or CARs that recognize cancer-specific cell surface antigens.[220] Such CAR T-cells have shown their potency in treating B-cell lymphoma by targeting cell surface CD19.[221] However, the binding of checkpoint inhibitors on cancer cell surface to PD-1 receptors on T cells blocks antitumor function of T-cells and induce apoptosis and exhaustion. Su et al. successfully demonstrated the gene knockout of PD-1 using CRISPR/Cas9 system in human primary CD4+ T-cells.[222] The disruption of PD-1 expression enhanced cytotoxicity of the T-cells against PD-1 ligand, or PD-L1 expressing M14 melanoma cells. Thus, knockout of checkpoint inhibitors may be a critical strategy to facilitate T-cell immunotherapy for cancer treatment.

Applications of CRISPR/Cas9 technology are not limited to genome editing. Another potential use of the technology involves regulation of gene expression using catalytically inactive "dead Cas9 (dCas9)." A dCas9/sgRNA complex can bind target genomic DNA thereby sterically inhibiting binding or elongation of RNA polymerase. The technology is now known as CRISPR interference (CRISPRi).[223] In a proof-of-concept study by Gilbert et al., transcriptional silencing efficiency of CRISPRi was successfully improved by fusing dCas9 to a repressive chromatin modifier domain, KRAB (Krüppel-associated box) domain of Kox1, which

achieved 5–15-fold repression of target gene expression whereas an unfused dCas9 showed only ~2-fold repression.[223] Specificity of CRISPRi was assessed by using high-throughput screening.[224] The authors found that maximum repression can be achieved when targeting a window of DNA from −50 to +100 bp relative to the transcription starting site. The analysis also showed that CRISPRi activity is highly sensitive to mismatches between the sgRNA and target DNA, suggesting properly designed CRISPRi systems are highly specific.

The dCas9 protein fused to transcription activators such as VP64 (a tetramer of the minimal VP16 domain), p65 (RelA), and p300 has been shown to upregulate transcription in mammalian cells.[225] This approach is known as CRISPR activation (CRISPRa). For example, Saayman et al. demonstrated sgRNA-guided dCas9-VP64 system targeted atLTR promoter region of HIV-1 induced potent transcriptional activation of latent HIV-1 infection in human T cells.[226] Similarly, Limsirichai et al. demonstrated activation of latent HIV-1 expression by two distinct CRISPRa systems.[227] Compared to dCas9-VP64, more robust transcriptional activation was observed when using the synergistic activation mediator (SAM) complex which consists of dCas9-VP64 and an accessory trans-activation domain designed to recruit a complementary suite of transcription and chromatin remodeling factors. Together, CRISPRi and CRISPRa have been shown as powerful tools for systematically manipulating transcription of endogenous genes in human cells. The use of CRISPRi and CRISPRa for gene regulation may offer an alternative to RNAi or RNAa for therapeutics as well as a tool for better understanding gene function.

6.12.3.2.2 Challenges and future perspectives

While CRISPR/Cas9 system has been showing its power and potency of genome editing, a number of challenges still remain to be solved including efficiency, specificity, and delivery of the genome editing components. Several groups have addressed off-target activities of Cas9.[228] Studies showed that mismatches at the 5′ end of target sequences are generally tolerated while mismatches at the 3′-end are not, suggesting that the 3′ terminal sequence is crucial for sgRNA recognition of the target. Pattanayak et al. performed off-target profiling of CRISPR/Cas9 mediated DSB using in vitro selection and high-throughput sequencing. Preselected DNA libraries which contain $>10^{12}$ potential off-target sequences were treated with Cas9/sgRNA complexes of interest which were then subjected to high-throughput sequencing.[228c] The sequencing analysis revealed that a shorter, less-active guide RNA is more specific than a longer, more-active guide RNA. They also found that higher concentrations of Cas9/sgRNA complex can decrease DNA-cleaving specificity, and that potential off-target sites that contain four mutations relative to the on-target site can be modified. A number of approaches to improve the specificity of CRISPR/Cas9 system have been proposed by many researchers. Computational algorithms may be useful to predict proper sgRNA sequences. Indeed, several groups have developed algorithmic tools that help to design sequences of sgRNA with minimized off-target effect. It could also be avoided by delivering purified recombinant Cas9 protein and guide RNA complex[229] or truncation of sgRNAs to reduce binding affinity.[230]

An engineered Cas9 protein that cleaves one strand of the target DNA, known as Cas9 nickase has also been shown to increase specificity.[231] Cas9 nickase contains a point mutation at either the RuvC1 or HNH-like nuclease domain that disrupts cleavage function at either complementary or noncomplementary DNA target strands. Using a pair of Cas9 nickases that require independent binding to target DNA, can generate highly site specific DSB, compared to Cas9 mediated DSB that requires binding at only one site. The Cas9 nickase has also been shown as an useful tool to introduce site specific HDR.

The efficient delivery of CRISPR/Cas9 to the targeted cells is another great challenge.[232] Possible delivery approaches include AAV, adenovirus, lentiviruses, and nonviral physical methods. Due to its low immunogenicity, AAV is currently most widely used for in vivo delivery of CRISPR/Cas9 gene. However, the use of AAV is somewhat limited because of the small packaging capacity of the virus (about 4.9 kb). The size of SpCas9 cDNA is about 4.2 kb long which leaves only 0.7 kb for other regulatory elements necessary for gene expression. Thus, sgRNAs (~100 bp) are usually delivered in separate AAV particles. Recently smaller Cas9 orthologs such as *Staphylococcus aureus* Cas9 which is ~1 kb smaller than SpCas9 have been established which may allow "all-in-one" AAV vectors. Adenovirus and lentivirus have larger packaging capacities that permit inclusion of all CRISPR/Cas9 components. The use of adenovirus is limited because of its serious immunogenicity. Lentiviral vectors, which are based in HIV-1, have LTRs that facilitate host genome integration. However, as CRISPR/Cas9 gene editing requires transient expression of the Cas9 nuclease to limit off-target events, the use of integrase-defective lentiviruses (IDLV) is preferable. Potent nonviral delivery methods for systemic delivery of CRISPR/Cas9 have also been demonstrated. Yin et al. combined lipid nanoparticle-mediated delivery of Cas9 mRNA, AAVs encoding a sgRNA, and induced repair of fumarylacetoacetate hydrolase (Fah) splicing mutations in adult mice.[233]

Furthermore, little is known about the immunogenicity of bacteria originated Cas9 protein in humans so far. Potential toxicity caused by the immunogenicity of the Cas9 protein should be addressed before its application in clinical trials.

Finally, along with its development, this cost-effective and easy-to-use genome editing technology raises ethical concerns that need to be addressed. For example, any genomic changes in the human germline can be potentially passed down to future generations, introducing those changes into the human population. Rules and a regulatory framework that address human germline genome editing should be established in a timely manner in order to avoid inhibiting research and development.

Since the initial discovery that Cas9 is an RNA-programmable DNA endonuclease was published in 2012, an explosive increase in the number of research publications has been seen in PubMed using a keyword "CRISPR": 282 papers in 2013, 606 in 2014, and 1251 in 2015. Recently a research team at the University of Pennsylvania has received permission from US National Institutes of Health (NIH) panel for the first study that proposes using CRISPR/Cas9 genome editing technology in humans to treat cancer. The study proposal is a phase I trial of autologous CAR-T cells expressing NY-ESO-1 TCR in which TCR and PD-1 gene expression is eliminated by genome editing. If approved by the FDA, it will be the first-in-human trial of CRISPR/Cas9 technology. Despite

a number of challenges that remain to be addressed, significant progress has already been made in CRISPR/Cas9 technology and these advances will undoubtedly lead this technology toward understanding and treating a variety of human diseases.

6.12.4 Conclusions

Since the first nucleic acid based drug, fomivirsen, was approved for clinical use more than one and half decades ago, only two agents, macugen and mipomersen have reached the market. Major challenges in therapeutic development that most nucleic acid based therapeutics face include delivery methods, target specificity, effectiveness, immunogenicity, toxicity, and cost of synthesis. These challenges have been addressed by a number of studies and achieved significant improvement. For example, stability and immunogenicity of nucleic acids can be improved by chemical modifications. In addition, some chemical modifications, especially the PS modification, offer drug-like PK/PD properties. Therefore, the majority of currently clinically tested nucleic acid therapeutics are chemically modified. On top of these challenges, targeted delivery remains the major hurdle in clinical development of nucleic acid based therapeutics. The issue has been addressed by developing delivery tools including lipid nano particles, conjugation of target cell-specific ligands and cell-specific aptamers, some of which have already shown clinical significance in advanced phase clinical studies. Gaining a better understanding of the function of targets, PK/PD properties, and functional pathway of the agents will facilitate approaches to improve these challenges, thus enhance clinical development of nucleic acid based therapeutics.

Along with the emergence of CRISPR/Cas9 system, a new nucleic acid based technology, nucleic acid based therapeutics become more important and attractive. One of the advantages of nucleic acid based therapeutics is that, in theory, they can target virtually any genes. Thus, many of nucleic acid based therapeutics currently being tested in clinical trials target rare but life-threatening severe diseases that are difficult to treat by current small molecule based drugs or monoclonal antibodies. Thus, we believe that some of these nucleic acid based therapeutics will soon become available for treatment of those diseases.

PREFACE

Previous editions of *Comprehensive Medicinal Chemistry*, published in 1990 and 2006, provided an integrated reference source that encompassed all major aspects of drug discovery research. The third edition follows this tradition and considerably expands its scope and content.

The trailblazing scientific discoveries of the 21st century have brought new opportunities for drug discovery research. The discipline of medicinal chemistry continues to evolve as it adapts to these new opportunities and strives to solve new challenges. Covered in the new edition are not only the breakthrough therapies of the past decade in cancer, hepatitis C, heart failure, dyslipidemia, cystic fibrosis, multiple sclerosis, HIV, etc., but also extensive discussion of new business models in drug discovery research, shifting industry demographics, emerging technologies, *in silico* drug discovery tools, experimental ADME and toxicology, and biologics medicine. The tone of this edition is prospective in which contributors identify outstanding issues and paths forward in their area of expertise. The aim is to provide drug discovery scientists in industry, government, academia, and research organizations with a contemporary global perspective on the field that includes a look ahead in selected areas.

The eight individual volumes fulfill these objectives and include extensive discussion of biomolecular therapeutics, drug targeting and delivery, development of chemical biology tools, data collection and analysis, *in silico* models as predictors for biological properties, identification/validation of new targets, approaches to quantify target engagement, new methods for synthesis of drug candidates such as green chemistry, development of novel scaffolds for drug discovery, and the role of regulatory agencies in drug discovery.

The individual volume editors have done an outstanding job to identify topics and contributors to meet these goals and we thank them for their hardwork and diligence. In volume 1, Ana Martinez and Carmen Gil recruited an international group of contributors who provide chapters on the emerging role of organizations other than traditional pharmaceutical companies in drug discovery, the evolving science of chemical biology, and new organic chemistry contributions to the discipline. In volume 2, Helmut Buschmann, Norbert Handler, and Andrea Wolkerstorfer have accomplished a seemingly impossible task and attracted world-leading experts across the wide field of drug discovery enabling technologies, covering contemporary thinking in a wide range of key disciplines that enable modern medicinal chemistry and drug discovery and development. The computational enabling technologies are the focus of volume 3, in which Andy Davis and Colin Edge have assembled chapters covering both ligand-based and protein structure–based advances as well as exciting new methodologies and case studies exploiting these. Alan Wilson identified experts in the fields of pharmacokinetics and toxicology who describe a wide range of contemporary advances in prediction and analysis of pharmaceutical properties and drug safety in volume 4. In volume 5, Ian Collins, Louis Lombardo, and Will Watkins have assembled leading experts to discuss high impact drug discovery accomplishments over the past decade in cancer chemotherapeutics, immunology and inflammation, and infectious diseases therapeutic areas. Ved Srivastava edited volume 6 on biologic medicines, a significant and rapidly evolving area where medicinal chemistry plays an important role. The chapters in this volume provide timely information on not only protein-based drugs, such as monoclonal antibodies and therapeutic proteins, but also peptides and nucleic acid–based therapeutics. Volume 7, edited by Adrian Hall, Santhosh Neelamkavil, and Rob Jones, presents a detailed account of the major advances in CNS, metabolic, and cardiovascular fields over the past decade and the promising new opportunities. Joerg Holenz edited volume 8 that presents case histories of successful drug discovery and strategic differentiation that have resulted in commercialized drugs and candidates in advanced clinical trials.

We are truly grateful to the publishing team at Elsevier that includes Gemma Tomalin, Rachel Gerlis, Marise Willis, and Sean Simms for their assistance and support throughout the process. With their expertise, this project became what we believe is a noteworthy and valuable resource for the discipline of medicinal chemistry. We look forward to the response and feedback of our colleagues who will use this information in their own work.

Samuel Chackalamannil, David P. Rotella, and Simon E. Ward

EDITORS-IN-CHIEF: BIOGRAPHIES

Dr. Samuel Chackalamannil

Dr. Chackalamannil obtained his PhD in chemistry from Yale University in 1984 and subsequently worked in drug discovery research at Schering-Plough Corporation and Merck Research Laboratories, where he was a distinguished fellow when he left in 2011. Since then, he has been teaching at Ernest Mario School of Pharmacy, Rutgers University, New Jersey.

Dr. Chackalamannil has significant accomplishments in the discovery of new medicines. He led the discovery of vorapaxar (Zontivity®), an FDA-approved antiplatelet drug for the prevention of heart attack and stroke. His group also discovered a PDE-5 inhibitor clinical candidate dasantafil and an adenosine A2a antagonist clinical candidate for the treatment of Parkinson's disease. Altogether, he was responsible for the discovery of nine development candidates in cardiovascular, central nervous system, and metabolic disease areas.

Dr. Chackalamannil is a coinventor of 62 allowed US patents and numerous patent applications worldwide. He has published 81 peer-reviewed articles and has coauthored a book. He has also given numerous lectures at international meetings and academic institutions.

Dr. Chackalamannil is a two-time recipient of the Thomas Alva Edison Award for Emerging Technology Patent and a two-time recipient of the Presidential Award for Discovery at Schering-Plough Research Institute. He has chaired several sessions at American Chemical Society national meetings and Gordon Research Conference on Medicinal Chemistry and was an organizer for Chemistry as a Life Science Symposium.

Dr. David Rotella

Dr. Rotella earned a PhD in medicinal chemistry from The Ohio State University and carried out postdoctoral research in organic chemistry at Penn State University. He joined the faculty at Montclair State University in July 2011 as the Margaret and Herman Sokol Professor of medicinal chemistry after a successful career in the pharmaceutical industry. He is an expert in the discovery and optimization of small molecule drug candidates for use in metabolic, cardiovascular, cancer, and central nervous system diseases. His current research is focused on discovering new lead compounds for use in parasitic and central nervous system diseases. He has coedited the seventh edition of *Burger's Medicinal Chemistry* and is a senior editor for the Royal Society of Chemistry's Drug Discovery book series. He has authored over 40 peer-reviewed articles, is an inventor on 8 issued US patents, and has contributed 10 book chapters.

Simon E. Ward

Simon Ward has an MA in natural sciences and PhD in synthetic organic chemistry from Cambridge University, UK. He has a wide-ranging experience of drug discovery in both large and small companies (GlaxoSmithKline, Knoll Pharmaceuticals, Vernalis, Chiroscience, BioCrea) and specialist experience of discovering and developing drugs for central nervous system indications. He has led multidisciplinary project teams and medicinal chemistry groups from target identification through to early clinical studies, delivering multiple clinical development candidates across indications. He is a fellow of the Royal Society of Chemistry. He is currently a professor of medicinal chemistry at the University of Sussex, UK, and the director of the Sussex Drug Discovery Centre, which he established within the University of Sussex in 2010.

An Introduction to the CNS Section of Volume 7: Recent Approvals and Advances in CNS Drug Discovery

Adrian Hall, UCB, Chemin du Foriest, Braine l'Alleud, Belgium

© 2017 Elsevier Ltd. All rights reserved.

The current CNS section of *Comprehensive Medicinal Chemistry III* aims to cover some of the most prominent areas of CNS research in the last decade. These include disease areas such as epilepsy (Chapter 7.01. Recent Advances and Future Directions in the Treatment of Epilepsy), molecular targets that have received major research effort, e.g., CGRP antagonists (Chapter 7.05. CGRP Antagonists for the Treatment of Migraine), AMPA modulators (Chapter 7.11. Modulating AMPA Receptors for the Treatment of CNS Disorders), γ-secretase modulators (Chapter 7.07. Targeting Gamma Secretase for the Treatment of Alzheimer's Disease), β-secretase/BACE inhibitors (Chapter 7.08. Targeting β-Secretase (BACE) for the Treatment of Alzheimer's Disease), target classes that have received significant and sustained research interest, e.g., PDE inhibitors (Chapter 7.02. Progress and Challenges in the Development if PET Ligands to Aid CNS Drug Discovery), voltage-gated calcium channel blockers (Chapter 7.03. Progress in the Discovery of the Ca Channel Blockers for the Treatment of Pain), voltage-gated sodium channel blockers (Chapter 7.04. Sodium Channel Blockers for the Treatment of Pain), and kinase inhibitors for CNS indications (Chapter 7.10. Inhibiting Kinases in the CNS). In addition, one of the major challenges in CNS drug discovery is the incorporation of biomarkers. To this end, the use of positron emission tomography (PET) is one of the major technologies that is employed to show target engagement or track temporal functional or biomarker changes and greatly enables CNS drug discovery. Thus, a chapter on the progress and challenges in PET discovery (Chapter 7.02. Progress and Challenges in the Development if PET Ligands to Aid CNS Drug Discovery) is a must. Each chapter has been written by experts with deep knowledge of the area, and the authors have been sourced from around the globe (Belgium, China, Denmark, Japan, the United Kingdom, and the United States) and include those from both industry and academia.

CNS drug is often highlighted to have a high rate of attrition, and several companies[1] such as GSK,[2] AZ,[3] BMS,[4,5] and Novartis[6] have reduced or halted neuroscience research in recent years. However, many companies and academic research groups are focused on oncology, which actually has the highest rate of attrition of all disease areas, in terms of likelihood of approval from PhI or probability of PhIII success.[7] Furthermore, while huge advances have been made in the oncology field, many of the newly approved medicines do not offer a cure, but a period of remission, which although can provide a huge improvement for patients there is still room for improvement.

In addition to highlighting some of the areas that are discussed in this section, the introduction also offers an opportunity to review the approvals of CNS drugs over the last decade or so since the publication of the last edition of *Comprehensive Medicinal Chemistry*, to assess the productivity and ingenuity of research in the area. Furthermore, it is possible to look back at the trials and tribulations in the field and see what we can learn from the failures and to highlight the prospective medicines that could impact the lives of many patients.

Although seemingly easy, it is first important to clarify the definition of a CNS drug. For instance, a CNS drug could be labeled as such as it is administered to treat a disease, which is generally associated with a CNS or neurodegenerative disease. However, some CNS diseases can have peripheral components, or the symptoms can be treated by a peripherally active agent. Also, there are not always data to demonstrate that the drug in question penetrates the CNS or acts there. Hence, for the purposes of this overview, a CNS drug is classified as one for which the site of action is believed to be in the CNS, and not one which is simply used to treat a neurological disease.

To this end, information was collected on CNS drug approvals that were launched in any country by year, i.e., not just FDA approvals, from 2005 to 2016 and is summarized in **Table 1**. The information was gathered from Annual Reports in Medicinal Chemistry and Medicinal Chemistry Reviews from the American Chemical Society.[8–18]

As highlighted in **Table 1** and **Fig. 1**, CNS research has provided a steady stream of new drug approvals over this period of time, ranging from two to six per year. It can sometimes be difficult to discern whether a compound represents a new mechanism of action, as for some compounds this is not always clearly defined, or multiple pharmacologies may contribute to its efficacy. For example, over the years there have been many antipsychotic NCEs, which vary to some degree in the aminergic GPCRs they interact with, for example, paliperidone (2007), lurasidone (2010), vilazodone (2011), aripiprazole lauroxil (2015), brexpiprazole (2015), cariprazine (2015), **Table 2**. However, compounds such as flibanserin (2015), which also bears an arylpiperazine moiety, similar to the antipsychotics, has been noted as a first-in-class compound by the FDA as its pharmacology is attributed to $5HT_{1A}$ and D_4 partial agonism in combination with $5HT_{2A}$ antagonism. There are also several compounds, such as lisdexamfetamine (2007), desvenlafaxine (2008), dapoxetine (2009), and vilazodone (2011), which inhibit, to different extents, the aminergic transporters, serotonin (SERT), norepinephrine/noradrenaline (NET), and dopamine (DAT).

Although there have been many compounds with similar pharmacologies, it is noteworthy that multiple first-in-class compounds have been launched in recent years, including ramelteon, an $MT_{1/2}$ agonist for insomnia; ziconotide, an N-type Ca^{2+} channel blocker for pain; rimonabant, a CB_1 antagonist for obesity (now withdrawn); varenicline, an $\alpha_4\beta_2$ agonist for smoking

Table 1 Listing of number of approvals in any country by year

Year	*NMEs*	*NCEs*	*CNS*
2005	24	21	4
2006	27	21	3
2007	20	19	3
2008	24	20	4
2009	28	23	5
2010	24	21	3
2011	26	21	3
2012	30	27	2
2013	27	25	2
2014	47	37	4
2015	38	29	6

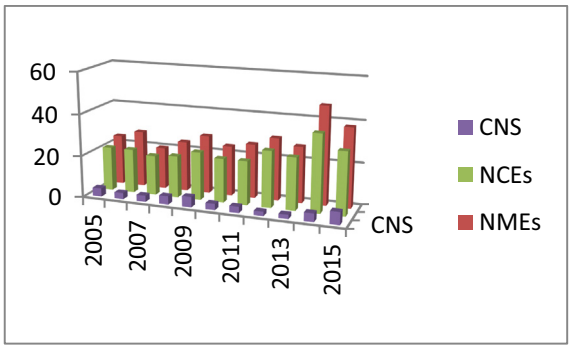

Figure 1 Depiction of the number of CNS drug approvals by year versus the number of NCE and NME approvals.

cessation; fosaprepitant (the first of three NK_1 antagonists to be launched) for emesis; fingolimod, an $S1P_1$ agonist for MS; retigabine, a KCNQ2–5 (K_v7.2–7.5) PAM/channel opener for epilepsy (soon to be withdrawn)[20]; lorcaserin, a $5HT_{2C}$ agonist for obesity; perampanel, an AMPA antagonist for epilepsy; istradefylline, an adenosine A_{2A} antagonist for PD; alectinib, an ALK inhibitor for non–small-cell lung cancer (NSCLC) and associated leptomeningeal metastases; and suvorexant, an $OX_{1/2}$ antagonist for sleep disorders. This steady flow of exciting new medicines highlights that CNS research is still very much alive and can still deliver a huge impact for many patients in the future.

Despite the highlights mentioned above, there have been a number of areas of disappointment in CNS drug discovery in recent years, which highlights the challenges on the field. In terms of Alzheimer's disease, there have been a number of notable failures. Firstly, the γ-secretase inhibitor field (GSIs), where many companies had invested significant resource, and several, such as Lilly with semagacestat and BMS with avagacestat (BMS-708163), progressed compounds to late-stage clinical trials. Compounds from this class failed to impact cognitive decline, actually worsening cognition and having mechanism-based side effects. For example, semagacestat worsened cognition[21] and was associated with increased adverse events such as skin cancers and infections.[22] Avagacestat achieved only 10–15% reductions in CSF amyloid levels, did not impact cognition and produced GI effects[23] as well as basal cell carcinoma (BCC) and squamous cell carcinoma (SCC).[24] Following closely behind, with the promise of overcoming mechanistic side effects were the γ-secretase modulators (GSMs), reviewed in this section (Chapter 7.07. Targeting Gamma Secretase for the Treatment of Alzheimer's Disease). Early compounds such as Flurizan were the subject of much hype,[25] despite the failure to show an effect on amyloid biomarkers.[26] The failure of Flurizan was predicted by many, based on its extremely weak GSM activity, its low CNS penetration and its lack of effect on amyloid levels.[27] Despite significant effort by a range of groups, it appears that none of the more recent GSMs have progressed beyond PhI clinical trials, see Chapter 7.07. Targeting Gamma Secretase for the Treatment of Alzheimer's Disease. This appears to be due to a combination of weak activity and side effects. Hence, it appears that progressing compounds beyond PhI represents a considerable challenge, which may be insurmountable.

In addition to disease-modifying approaches, the field of cognitive enhancers or palliative AD therapeutics has experienced significant attrition. Notable areas include H_3 antagonists, where most pharmaceutical companies had invested research efforts, GSK, with GSK189254[28] and GSK239512,[29,30] and Merck, with MK-0249,[31] were early leaders in the field. However, despite much promise, no improvements in cognition were recorded. Despite this, one of the first H_3 antagonists, pitolisant (Wakix®)[32]

Table 2 List of CNS drug approvals by year, including disease treated, MoA, structure, and name

Year of launch	*Name*	*Structure*	*MoA*	*Use*	*Note*
2005	Eszopiclone (Lunesta™)		$GABA_A$ PAM	Hypnotic	Single enantiomer of zopiclone
2005	Ramelteon (Rozerem™)		$MT_{1/2}$ agonist	Insomnia	
2005	Rasagiline (Azilect™)		MAO-B inhibitor	Parkinson's disease	
2005	Ziconotide (Prialt™)	Peptide	N-type Ca^{2+} channel blocker	Severe chronic pain	Intrathecal administration
2006	Rimonabant (Acomplia™)		CB_1 antagonist	Obesity	Withdrawn
2006	Rotigotine (Neupro™)		D_2 agonist with D_1 and D_3 agonism, D_4 and D_5 partial agonist	Parkinson's disease	Administered via patch
2006	Varenicline (Chantix™)		$\alpha_4\beta_2$ nAChR agonist	Smoking cessation	
2007	Lisdexamfetamine (Vyvanse™)		Elevates extracellular dopamine levels via various mechanisms including DAT inhibition	ADHD	L-lysine prodrug of D-amphetamine
2007	Paliperidone (Invega™)		D2, $5HT_{2A}$ antagonist, with affinity for other aminergic receptors such as D_3, $5HT_7$, $5HT_{1D}$, H_1, α_{1A}, α_{2A}, α_{2C}, α_{2B}, and $5HT_{2C}$	Antipsychotic	Metabolite of risperidone
2007	Rufinamide (Inovelon™)		Unknown, thought to be Na channel blocker (prolongation of inactive state)	Anticonvulsant/ Lennox–Gastaut syndrome	
2008	Blonanserin (Lonasen™)		D2, $5HT_{2A}$ antagonist with affinity for other aminergic receptors such as $5HT_6$ and D_3	Antipsychotic	

(Continued)

Table 2 List of CNS drug approvals by year, including disease treated, MoA, structure, and name—cont'd

Year of launch	*Name*	*Structure*	*MoA*	*Use*	*Note*
2008	Desvenlafaxine (Pristiq™)		SNRI (SERT, NET inhibitor)	Antidepressant	Metabolite of venlafaxine
2008	Fosaprepitant (Emend™)		NK_1 antagonist	Antiemetic	Phosphate prodrug
2008	Lacosamide (Vimpat™)		Unknown, potentially via enhancing slow inactivation of voltage-gated Na channels or via CRMP-2	Anticonvulsant	
2009	Armodafinil (Nuvigil™)		Unknown. Potentially via α1 agonism or DAT inhibition.	Treatment of excessive daytime sleepiness	Single enantiomer of modafinil
2009	Asenapine (Saphris™)		D2, $5HT_{2A}$ antagonist, with similar or higher affinity for $5HT_{2C}$, $5HT_{2A}$, $5HT_{2B}$, $5HT_{7}$, $5HT_{6}$, α_{2B}, D_3, and affinity for other aminergic receptors such as $5HT_{1A}$, $5HT_{1B}$, $5HT_5$, D_1, D_4, H_1, H_2, α_{2A}, α_{2C}, α_1	Antipsychotic	
2009	Dapoxetine (Priligy™)		SERT inhibitor (short acting)	Premature ejaculation	
2009	Eslicarbazepine (Zebinix™)		Voltage-gated Na channel blocker	Antiepileptic	Acetate prodrug of 10-hydroxycarbazepine (carbazepine metabolite)
2009	Tapentadol (Nucynta™)		μ-Opioid (MOR) agonist and NET inhibitor	Pain	
2010	Dalfampridine (Ampyra™)		K channel blocker	Multiple sclerosis	
2010	Fingolimod (Gilenya™)		$S1P_1$ agonist	Multiple sclerosis	

Table 2 List of CNS drug approvals by year, including disease treated, MoA, structure, and name—cont'd

Year of launch	*Name*	*Structure*	*MoA*	*Use*	*Note*
2010	Lurasidone (Latuda™)		D_2, $5HT_{2A}$, $5HT_7$ antagonist, $5HT_{1A}$ partial agonist with weaker activity at α_{2C} and α_{2A}	Antipsychotic	
2011	Gabapentin enacarbil (Horizant™)		Modulator of N-type Ca^{2+} channel α_2-δ subunit	Restless leg syndrome	Prodrug of gabapentin
2011	Retigabine (Trobalt™, Potiga™)		KCNQ2-5 (K_v7.2–7.5) PAM/opener	Anticonvulsant	
2011	Vilazodone (Viibryd™)		SERT inhibitor and $5HT_{1A}$ partial agonist	Antidepressant	
2012	Lorcaserin (Belviq™)		$5HT_{2C}$ agonist, with antagonism of $5TH_{2A}$ & $5HT_{2B}$	Obesity	
2012	Perampanel (Fycompa™)		AMPA antagonist	Anticonvulsant	
2013	Istradefylline (Nouriast™)		A_{2A} antagonist	Parkinson's disease	
2013	Vortioxetine (Brintellix™)		SERT inhibitor, $5HT_{1A}$ and $5HT_{1B}$ partial agonist, and $5HT_3$ and $5HT_7$ antagonist with weaker affinity for $5HT_{1D}$ and NET	Antidepressant	
2014	Alectinib (Alecensa™)		ALK inhibitor	Non–small-cell lung cancer	Demonstrated to penetrate the brain effectively treat leptomeningeal metastases.[19]
2014	Netupitant (Akynzeo™)		NK_1 antagonist	Emesis	

(Continued)

Table 2 List of CNS drug approvals by year, including disease treated, MoA, structure, and name—cont'd

Year of launch	*Name*	*Structure*	*MoA*	*Use*	*Note*
2014	Suvorexant (Belsomra™)		Orexin $OX_{1/2}$ antagonist	Sleep disorders	
2014	Tasimelteon (Hetlioz™)		$MT_{1/2}$ agonist	Sleep disorders	
2015	Aripiprazole lauroxil (Aristada™)		D_2, D_3, $5HT_{1A}$ partial agonist, $5HT_{2A}$ antagonist, with affinity for $5HT_{2B}$, $5HT_7$	Antipsychotic	Prodrug
2015	Brexpiprazole (Rexulti™)		D_2 partial agonist/ antagonist, D_3, $5HT_{1A}$ partial agonist, $5HT_{2A}$ antagonist, with affinity for $5HT_{2B}$, $5HT_7$, α_{1B}, α_{2C}, α_{1A}, H_1, and weak partial agonism at $5HT_{2C}$	Antidepressant, antipsychotic	
2015	Cariprazine (Vraylar™)		D_3, D_2 antagonist/partial agonist, $5HT_{1A}$ partial agonist $5HT_{2A}$ and $5HT_{2B}$ antagonist with affinity for H_1, $5HT_7$, $5HT_{2C}$, α_{1A}, α_{1D}, σ_1	Antipsychotic	
2015	Flibanserin (Addyi™)		$5HT_{1A}$ partial agonist, $5HT_{2A}$ antagonist and D_4 weak partial agonist	Female sexual dysfunction	
2015	Rolapitant (Varubi™)		NK_1 antagonist	Emesis	
2015	Safinamide (Xadago™)		MAO-B inhibitor and Na and Ca channel activity	Parkinson's disease	

2011 does not include Tafamidis (Vyndaqel™), transthyretin (TTR) stabilizer for the treatment of neurodegeneration. 2012 does not include Teriflunomide (Aubagio), dihydroorotate dehydrogenase (DHODH) inhibitor for the treatment of multiple sclerosis, MoA believed to be dampening of immune system via lymphocytes. 2013 does not include dimethyl fumarate (Tecfidera™), thought to be an Nrf2 pathway activator, for the treatment of multiple sclerosis. 2013 does not include ^{18}F-flutemetamol (Vizamyl™) for the diagnosis of AD, Aβ PET ligand.

DAT, dopamine transporter; *MOR*, μ opioid receptor; *NAT*, noradrenaline transporter; *NET*, norepinephrine transporter; *SERT*, serotonin transporter; *SSRI*, selective serotonin reuptake inhibitor.

was recently granted marketing access approval (MAA) in the EU for the treatment of narcolepsy.[33] While this is very positive news, the initial hope of improving cognition was not realized and the return on investment is significantly lower than initially anticipated. $5HT_6$ antagonists have also received a lot of attention, with many companies progressing compounds to clinical trials. Despite promise, early compounds such as SB-742457 from GSK failed to offer sufficient benefit for GSK to progress the compound to PhIII trials. This compound, now known as intepirdine (RVT-101), has recently been acquired by Axovant and is currently undergoing PhIII trials in mild-to-moderate AD.[34] Despite showing promising effects in a PhII 24-week trial in moderate AD when given on top of donepezil,[35] Lu AE58054 from Lundbeck, now known as idalopirdine, initial results from the first (STARSHINE) of three PhIII clinical trials have failed to show efficacy.[36] However, two further PhIII trials (STARBEAM and STARBRIGHT) are ongoing.[36] Another aminergic target for cognitive enhancement, $5HT_4$ agonism/partial agonism also met with disappointment. In addition to enhancing cognition this target was also proposed to modulate amyloid levels,[37,38] although the latter effect appears very weak.[39] Compounds, such as PF-04995724, failed to deliver the anticipated clinical efficacy. Pfizer also experienced further set back when they licensed the mixed aminergic antagonist (including $5HT_7$ and $5HT_6$),[40] dimebon (latrepirdine) showed initial promise in a PhII trial where it apparently improved cognition,[41] only to fail to recapitulate the data in subsequent trials.[42,43] The α7 nicotinic acetyl choline receptor (nAChR) has been the subject of considerable interest due to its potential role in cognition.[44] Thus, many groups have invested resources into the identification of α7 agonists and positive allosteric modulators (PAMs). Disappointingly, two of the most advanced compounds, TC-5619[45] developed by Targacept in conjunction with AZ, and EVP-6124 (encenicline)[46] from EnVivo/Forum, yielded disappointing results,[47] despite initial promise.[48]

Finally, the centrally active CB_1 antagonist rimonabant showed great promise with the demonstration of efficacy in terms of weight loss. Many other companies had also invested effort into what appeared to a very attractive mechanism, and further clinical development compounds were identified, such as Otenabant (Pfizer) and Taranabant (Merck), only for mechanism-based psychiatric side effects, such as depression and anxiety, to lead to the withdrawal of rimonabant.

There was also disappointment with GlyT1 inhibitors, where RG1678 (bitopertin) showed initial promise in proof of concept trials,[49] but failed to reproduce the data in subsequent trials.[50,51]

Negative allosteric modulation (NAM) of the metabotropic glutamate receptor, mGlu5, has received significant medicinal chemistry research over the years.[52,53] There have been numerous development compounds identified and progressed to clinical studies, with dose selection aided by PET studies. However, despite these efforts, the trials have failed to yield positive data, with prominent compounds such as Basimglurant (RO4917523/RG7090)[54,55] and Mavoglurant (AFQ056)[56] failing proof of concept studies in PD,[57,58] depression,[59] fragile X syndrome,[60,61] and other indications.[62]

Thus there have been many notable failures. However, looking back some compounds were perhaps advanced more in hope than on data. For example, early GSIs and GSMs did not clearly demonstrate modulation of amyloid levels in the clinic. In terms of cognition enhancers, perhaps target validation could have been better and it is clear that relying on animal models of cognition is not a viable strategy. As a number of projects did employ PET imaging, it at least permits the mechanism of action to be disproven. However, the major factor for the attrition of most of the mechanisms can be attributed to target validation, hence improving the link between target and disease, ideally via genetics, should be an area of focus going forward.

Despite these numerous disappointments, there have also been numerous major successes as can be seen from the steady stream of drugs reaching the marketplace in the last decade, **Table 2**, including many first-in-class drugs, as listed above. In addition to therapeutic drugs, there have been significant advances in the PET field, as discussed by Mercier and Provins in Chapter 7.02. Progress and Challenges in the Development if PET Ligands to Aid CNS Drug Discovery. This chapter highlights the utility of PET to enhance the success rate of CNS drug discovery and highlights the progress in identifying PET ligands for different biological target classes. The chapter also highlights the fact that PET ligands have not only been used to measure target engagement in the CNS, but there are several examples of PET ligands being used for patient diagnosis/stratification and also in longitudinal studies to measure disease progression, for example, amyloid PET ligands such as PiB, etc. Although lagging somewhat behind, there have been significant recent advances in the tau PET ligand area and this may be an area for future review.

There are also several major areas for hope in the field of CNS research. Notable areas are AD, where BACE inhibitors (reviewed in Chapter 7.08. Targeting β-Secretase (BACE) for the Treatment of Alzheimer's Disease) have made exceptional progress and demonstrated pronounced reductions in CNS amyloid levels. BACE inhibitors from a number of companies are now in late-stage clinical trials and offer the potential to test the amyloid hypothesis in AD. Hall and Gijsen review the fruit of a sustained industry-wide assault on BACE, which is now poised to test the amyloid hypothesis after many years. In a similar vein, Hall and Velter review GSMs (Chapter 7.07. Targeting Gamma Secretase for the Treatment of Alzheimer's Disease), which at one point appeared to be a more promising approach than BACE inhibition to tackle amyloid. Despite significant effort, few compounds have reached clinical trials, apparently hampered by target and compound toxicologies, and those that have reached clinical trials appear to display moderate efficacy at best.

In Chapter 7.05. CGRP Antagonists for the Treatment of Migraine, Dubowchik and Bell chart the progress and status of CGRP antagonists for the treatment of migraine. The mechanism holds great potential due to its novel mechanism, which would block the CGRP-mediated vasodilation, instead of actively inducing vasoconstriction as the triptans, which are $5HT_{1B/1D}$ agonists. Due to the potential advantage, CGRP antagonism promised to allow a prophylactic migraine treatment, which sparked huge interest from the pharmaceutical industry. Despite many years of sustained research and the fact that four compounds have demonstrated clinical efficacy, no CGRP antagonist has yet been launched. The chapter highlights the numerous challenges that researchers have

overcome to identify potent, orally bioavailable antagonists for this family B GPCR. Despite overcoming these challenges, other issues have been encountered, such as elevation of liver enzymes, which have hampered development and perhaps tampered the potential to deliver a prophylactic treatment. Perhaps based on this, Merck recently agreed to license their CGRP programme to Allergan.[63] Hopefully deals like this will ultimately lead to the approval of a CGRP antagonist.

Antagonism of central orexin receptors has been of interest due to their potential role in sleep, addiction, stress, and anxiety. In Chapter 7.06. Orexin Receptor Antagonists for the Treatment of Sleep, Shireman and Letavic review the substantial body of work that has been conducted to identify antagonists for the OX1 and OX2 GPCRs. Several companies have committed effort to this field, and despite rapid early progress and positive clinical data, compound-specific issues were encountered, which prevented further development. Merck have identified numerous development candidates, and their effort has recently been rewarded with the approval of Suvorexant in 2014, **Table 2**. In addition, the area has recently seen some licensing activity with Janssen collaborating on the development of their clinical compound JNJ-42847922 (now also known as MIN-202) to Minerva[64] and Eisai entering a worldwide collaboration on E2006/Lemborexant to Purdue Pharma.[65] Deals such as these may conceivably facilitate future orexin antagonist approvals.

In Chapter 7.09. Targeting phophodiesterases in the CNS, Kehler summarizes the phosphodiesterase (PDE) research in the CNS field. This area has seen sustained research on several family members, with some research groups, e.g., Pfizer actually employing a platform approach to the area. Family members are discussed in turn with reference made to selectivity and structural biology as well as clinical development candidates. Despite much promise, there has been some disappointment within this class, including the PDE9 inhibitor PF-4447943, which failed to improve cognition despite showing target engagement in CSF. Despite this, other research groups are actively pursuing PDE9 inhibitors, although the main area of interest remains PDE10.

Epilepsy is the only specific disease area covered in this section as there has been a diverse array of drug discovery approaches, and in some cases the molecular pharmacology of drugs has not always been elucidated with certainty. Thus in the epilepsy chapter, Kurokawa et al. provide an overview of antiepileptic drugs (AEDs) before covering the approaches employed to identify new compounds and targets. They then comment on some of the more recent AED approvals and next-generation therapeutics in development, then conclude with some recent advances.

Reuillon et al. cover AMPA receptor modulators (Chapter 7.11. Modulating AMPA Receptors for the Treatment of CNS Disorders), focusing on PAMs and highlighting development compounds from several groups. The chapter also comments on notable advances in the antagonist field, namely the advancement to late-stage trails of several antagonists and the approval of perampanel for epilepsy. In addition, some very recent and new advances in targeting TARPs, AMPA regulatory proteins that have selective regional brain distribution, and therefore offers the potential to identify compounds that can antagonize the AMPA receptor without inducing the undesirable side effects is also discussed.

The two chapters in this section that cover the sodium (Witty et al., Chapter 7.04. Sodium Channel Blockers for the Treatment of Pain) and calcium (Beswick, Chapter 7.03. Progress in the Discovery of the Ca Channel Blockers for the Treatment of Pain) ion channels review huge bodies of work. Approaches to both targets face similar challenges in navigating subtype selectivity, measuring target engagement, and also the potential that more than one subtype may contribute to efficacy. In this respect the authors do a fantastic job to cover a huge amount of literature and succinctly while highlighting the numerous clinical development compounds that have been identified by multiple groups.

While it was initially thought of as infeasible to identify and develop CNS penetrant kinase inhibitors due to the molecular properties of ATP-competitive inhibitors, the field has progressed significantly in recent years and has made excellent progress, initially in the oncology field, e.g., alectinib (currently approved for NSCLC) and AZD3759, but also now for a range of CNS diseases, as reviewed in Chapter 7.10. Inhibiting kinases in the CNS.

Inevitably not all areas of CNS research are reviewed in this section. Some promising areas have not been reviewed as they are still too early, or the approaches are somewhat fragmented. For example, there has been a significant and ongoing effort to tackle tau in AD; however, the approaches have been desperate, tackling posttranslational modifications (mainly phosphorylation) and aggregation. Similarly, while there is research targeting α-synuclein, there is insufficient for a comprehensive review article.

7.01.1 Introduction

7.01.1.1 General Introduction to Epilepsy

Epilepsy is a common neurological condition in the world. The estimated median prevalence of active epilepsy is 4.9 out of 1000 people in developed countries and 12.7 out of 1000 people in rural areas of developing countries.[1] Epilepsy is one of the oldest recognized conditions. The first description of an epileptic seizure was written in 2000 BC in the Akkadian language, which was spoken in the ancient region of Mesopotamia.[2] The word "epilepsy" is derived from the Greek verb, *epilambanem*, which means "to take hold of" or "to seize."

Epilepsy is simply defined as the predisposition to generate recurrent seizures. Epileptic seizures are sudden, brief episodes of involuntary body movement, and are also accompanied by loss of consciousness depending on the type of epilepsy. Epileptic seizures result from abnormal electrical discharges within the brain; therefore, depending on the part of the brain where the electrical discharges originate, these seizures can vary from an instantaneous lapse of attention or series of muscle spasms to more severe, prolonged convulsions. A single seizure does not necessarily indicate that someone has epilepsy, and up to 10% of all people experience one unproven seizure in their lifetime.[3] The International League Against Epilepsy currently defines epilepsy as a disease of the brain defined by any of the following conditions: (1) at least two unprovoked seizures occurring greater than 24 h apart; (2) one unprovoked seizure and a probability of further seizures similar to the general recurrence risk after two unprovoked seizures, occurring over the next 10 years; or (3) diagnosis of an epilepsy syndrome.[4]

7.01.1.2 Classification of Epilepsy

With advance in the diagnosis of epilepsy and genetic biotechnology, the classification of epilepsies has been revised several times. The modern epilepsy classification was first introduced in 1970 by the International League Against Epilepsy, and it was revised in 1981 to include the relationship between seizure type and electroencephalogram finding.[5] In 1989, it was again revised to provide a classification of epilepsies and epileptic syndromes that took account of seizure type and etiology.[6] Although a number of risk factors for the development of epilepsy, such as age, head injury, stroke, central nervous system infections, and developmental and genetic factors,[7] have been identified, the causes for more than 50% of cases of epilepsy remain unknown due to the heterogeneous nature of the condition.[8] Therefore, the classification does not cover the full spectrum of epileptic conditions; however, it is helpful for providing a clinical overview of the condition. Recently, the International League Against Epilepsy recommended an update to the classification, introducing new terms and concepts; they recommended replacing the etiologic categories of *idiopathic*, *symptomatic*, and *cryptogenic* with categories of *genetic*, *structural-metabolic*, and *unknown*.[9] The general classification of epilepsy is shown in Fig. 1.

7.01.1.3 Management of Epilepsy

Despite advances in surgical procedures for treating epilepsy, pharmacotherapy remains the primary therapeutic means of management. In the past three decades, more than 20 antiepileptic drugs (AEDs) have been developed and approved. The successful management of epilepsy relies on accurate diagnosis and the proper selection and utilization of pharmacotherapy. Approximately 70% of patients with newly diagnosed epilepsy remain seizure-free after starting on the currently available AEDs.[10] However, since these medications fail to control seizures in 30% of patients, there remains a considerable medical need for more efficacious drugs for the management of epilepsy.

7.01.2 Anti-Epileptic Drugs[11,12]

7.01.2.1 First-Generation AEDs (— 1970s)

Potassium bromide was the first effective AED to be popularized when, in 1857, Sir Charles Locock commented in the *Lancet* on his use of potassium bromide in 15 cases of "hysterical epilepsy" in young women.[13] Since then and until the early 1970s, AEDs were generally developed only after a chance discovery that a compound had anti-convulsant properties. One well-known example of a drug developed using this approach is the still commonly used medication phenobarbital, which was serendipitously found to have anti-convulsant properties by Alfred Hauptmann in 1912.

Epilepsy is a result of excessive abnormal activity of the cortical neurons in the brain, and the current pharmacological era of AED therapy began with the discovery of the antiepileptic effects of anesthetics and hypnotics. In 1937, Tracy Putnam and Houston

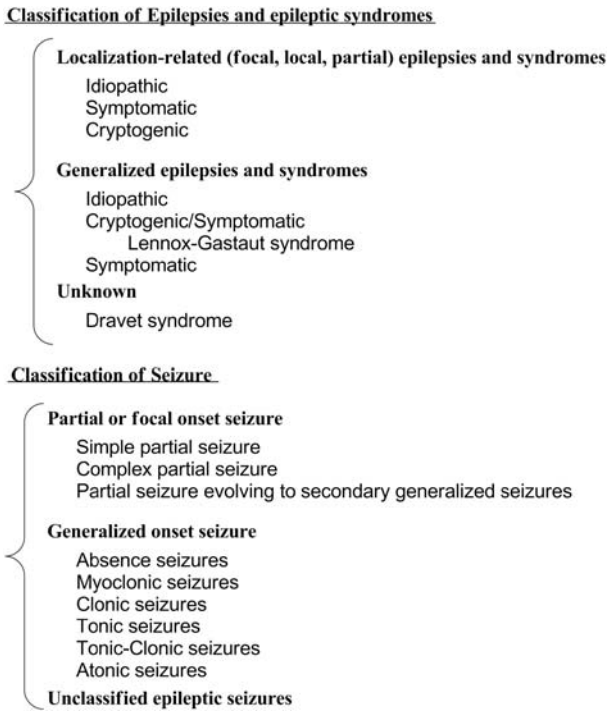

Fig. 1 General classification of epilepsy.

Merritt discovered the strong anti-convulsant properties of phenytoin in electroshock-induced seizure animal models, making phenytoin the first AED discovered by means of animal experimentation. The next AEDs to be developed were primidone, ethosuximide, the benzodiazepines, carbamazepine, and valproic acid. Although the anti-convulsant properties of valproic acid, which remains a first-line choice for the prevention of generalized seizures, was discovered serendipitously, carbamazepine, which is also still a widely used first-line AED, was developed empirically. Current clinically approved AEDs are summarized in Table 1 and Fig. 2.

7.01.2.2 Second-Generation AEDs (1980s–1990s)

At the end of the 1970s, large AED screening programs such as the Anticonvulsant Screening Program (ASP) of the National Institute of Neurological Disorders and Stroke (NINDS) of the US National Institutes of Health (NIH) began screening new chemical entities to encourage and facilitate the discovery and development of new therapeutic agents for the symptomatic treatment of epilepsy. By using a random screening approach with simple rodent models of seizures such as the maximal electroshock (MES) and pentylenetetrazole (PTZ)-induced seizure models, these programs identified many promising lead compounds. Although these animal models of acute seizures do not fully reflect the "true epilepsy" that occurs in epileptic brains, they are technically simple to perform and permit high throughput, and by the end of the 20th century this approach had afforded a range of novel AEDs, including lamotrigine, gabapentin, and topiramate. Although these AEDs have good efficacy and a broad spectrum of activities against different types of seizure, they also have strong central nervous system side effects such as sedation and motor impairment because they act mainly via Na^+ channel blockade and gamma-aminobutyric acid (GABA) potentiation. Therefore, although random screening using simple models of acute seizures is suitable for obtaining broad-spectrum AEDs, it might not be suitable for obtaining AEDs that are effective against drug-refractory seizures or that can prevent or modify the condition. Although many promising novel AEDs were discovered during this period, it was also realized that the broad-spectrum approach would need to be adjusted if drugs with efficacy against drug-resistant seizures were to be developed.

7.01.2.3 Third-Generation AEDs (2000s)

Since 2000, a number of novel AEDs identified by using chronic seizure animal models such as kindling and GAERS, or non-conventional acute seizure models such as 6 Hz model, in tandem with older animal models of acute seizures, have started to be launched. Through this kind of approach, several promising anti-epileptic drug candidates for the treatment of drug-resistant epilepsy were identified. In addition, some AEDs with different mechanisms of actions from conventional ones such as Na^+ channel blockade, GABA potentiation or Ca^{2+} channel blockade, have been placed on the market, like levetiracetam with SV2A binding, retigabine with K^+ channel activator or perampanel with AMPA antagonist. And also in clinical, several novel AEDs have shown highly efficacy, such as stiripentol in Dravet syndrome, vigabatrin in West syndrome, and rufinamide in Lennox–Gastaut syndrome. It may be argued that broad spectrum concept is not suitable to identify AEDs with higher efficacy in refractory epilepsy. Since many epilepsy patients have suffered from pharmacoresistant epilepsy, AED research has shifted from a broad-spectrum approach to a more target-based approach with prevention and modification of epilepsy as the targets for the next generation of AEDs.

7.01.3 Preclinical Strategies for the Development of AEDs

7.01.3.1 Overview of Common Preclinical Strategies

Historically, AEDs have been developed using one of three preclinical strategies: (1) random in vivo phenotypic screening; (2) structural modification of a known antiepileptic; or (3) hypothesis-driven, target-based approach.[12] Since each approach has its own pros and cons (see Table 3), it is likely that the development of the next generation of AEDs will require complementary hybridization of these approaches.

7.01.3.1.1 Random in vivo phenotypic screening

Until recently, most AED development programs followed a random phenotypic screening approach using animal models of seizures. This approach has afforded a range of useful lead compounds and has contributed greatly to the development of many of the clinically effective AEDs currently available. The screening campaign of the US NIH is one such example of this approach, and this program was instrumental in the development of several currently available AEDs (eg, felbamate [Felbatol]; topiramate [Topamax]; lacosamide [Vimpat]; retigabine [Potiga]; and rufinamide [Banzel, Inovelon]).[14]

Rodent models of seizures are the most commonly used means of screening for compounds with antiepileptic activity (Table 2). In these models, susceptibility to generate seizures is induced via electrical or chemical stimuli or genetic modification. Several experimental models have been developed for the various epilepsies and epileptic syndromes, including pharmacoresistant epilepsy, and each model offers, to some extent, a means of differentiating an exploratory AED from existing AEDs. Therefore, historically, the development of novel animal models of seizures is closely related to the discovery of new AEDs.

The success of random in vivo phenotypic screening can be attributed to the translatability of the animal models in the clinical development of AEDs. Animal models with a similarly high predictive value do not exist for other central nervous system disorders, such as bipolar disorder and migraine.[15] Further advantages of using animal models are that they are sensitive to the anticonvulsant

Table 1 Current clinically approved antiepileptic drugs[12]

Antiepileptic drug	*Year of approval*[a]	*Mechanism of action*	*Approved indications*	*Marketing company*
Potassium bromide	1857	GABA potentiation(hypothesized mechanism of action)	Primary generalized tonic–clonic seizures, myoclonic seizures	Dow
Phenobarbital	1912	GABA potentiation	Partial and generalized convulsive seizures, status epileptus, sedation, anxiety disorders, sleep disorders	Bayer
Phenytoin	1938	Na^+ channel blockade	Partial and generalized convulsive seizures, focal seizures, status epilepticus, trigeminal neuralgia	Parke-Davis/Pfizer
Trimethadione	1946	T-type Ca^{2+} channel blockade	Absence seizures	Abbott
Primidone	1954	GABA potentiation	Partial onset seizures, primary generalized tonic–clonic seizures, focal seizures, myoclonic seizures	Imperial Chemical Industries
Ethosuximide	1958	T-type Ca^{2+} channel blockade	Absence seizures	Parke-Davis/Pfizer
Diazepam	1963	GABA potentiation (GABA A receptor benzodiazepine site)	Convulsive disorders, status epilepticus, anxiety disorder, alcohol withdrawal	Roche
Carbamazepine	1964	Na^+ channel blockade	Partial onset seizures, primary generalized tonic–clonic seizures, trigeminal neuralgia, bipolar disorder	Novartis
Valproic acid	1967	Multiple (GABA potentiation, Na^+ channel blockade, T-type Ca^{2+} channel blockade or NMDA receptor inhibition, etc.)	Partial onset seizures, absence seizures, migraine prophylaxis, bipolar disorder	Sanofi/Abbott
Clonazepam	1968	GABA potentiation (GABA A receptor benzodiazepine site)	Lennox–Gastaut syndrome, akinetic seizures, mycolonic seizures, absence seizures, panic disorders	Roche
Clobazam	1975	GABA potentiation (GABA A receptor benzodiazepine site)	Adjunctive therapy for Lennox–Gastaut syndrome, anxiety disorders	Hoechst Roussel/Lundbeck/Sanofi
Progabide	1985	GABA potentiation	Primary generalized tonic–clonic seizures, Lennox–Gastaut syndrome, mycolonic seizures, muscle hypertonia	Synthelado
Vigabatrin	1989	GABA potentiation (GABA aminotransferase inhibition)	Infantile spasms, adjunctive therapy for refractory complex partial seizures	Sanofi/Lundbeck
Lamotrigine	1990	Na^+ channel blockade, glutamate transporter inhibition	Partial onset seizures, adjunctive therapy for primary generalized tonic–clonic seizures and Lennox–Gastaut syndrome, bipolar disorder	GlaxoSmithKline
Oxcarbazepine	1990	Na^+ channel blockade	Partial onset seizures	Novartis
Felbamate	1993	Multiple (GABA potentiation, Na^+ channel blockade, Ca^{2+} channel blockade or NMDA receptor inhibition, etc.)	Partial onset seizures, adjunctive therapy for Lennox–Gastaut syndrome	Carter-Wallance/MedPointe Pharmaceuticals
Gabapentin	1993	Ca^{2+} channel blockade ($\alpha 2\delta$ subunit)	Partial onset seizures, postherpetic neuralgia	Parke-Davis/Pfizer
Topiramate	1995	Multiple (GABA potentiation, Na^+ channel blockade, Ca^{2+} channel blockade, AMPA receptor inhibition, kainate receptor inhibition or carbonic anhydrate II inhibition, etc.)	Partial onset seizures, primary generalized tonic–clonic seizures, adjunctive therapy for Lennox–Gastaut syndrome	Janssen/Johnson & Johnson
Tiagabine	1996	GABA potentiation (GABA reuptake inhibition)	Adjunctive therapy for partial onset seizures	Novo Nordisk

Levetiracetam	2000	SV2A modulation, high-voltage-activated N-type Ca^{2+} channel blockade	Partial onset seizures, myoclonic seizures, primary generalized tonic–clonic seizures	UCB Pharma
Zonisamide	2000	Na^{+} channel blockade, T-type Ca^{2+} channel blockade	Partial seizures	Elan
Stiripentol	2002	GABA potentiation (GABA aminotransferase inhibition, GABA reuptake inhibition), Na^{+} channel blockade, lactate dehydrogenase inhibition	Dravet syndrome	Biocodex
Pregabalin	2004	Ca^{2+} channel blockade ($\alpha 2\delta$ subunit), L-type Ca^{2+} channel blockade	Adjunctive therapy for partial onset seizures, neuropathic pain, anxiety disorder, fibromyalgia	Pfizer
Rufinamide	2004	Na^{+} channel blockade	Adjunctive therapy for Lennox–Gastaut syndrome	Eisai
Lacosamide	2008	Enhanced slow inactivation of voltage-gated Na^{+} channels, NMDA receptor antagonism (glycine site)	Partial onset seizures	UCB Pharma
Eslicarbazepine acetate	2009	Na^{+} channel blockade	Partial onset seizures	Bial/Eisai
Retigabine	2011	K^{+} channel activation, GABA aminotransferase inhibition	Adjunctive therapy for partial onset seizures	GlaxoSmithKline
Perampanel	2012	AMPA receptor antagonism	Adjunctive therapy for partial onset seizures and primary generalized tonic–clonic seizures	Eisai

[a]Year in which the drug was first approved or marketed in the United States or Europe.

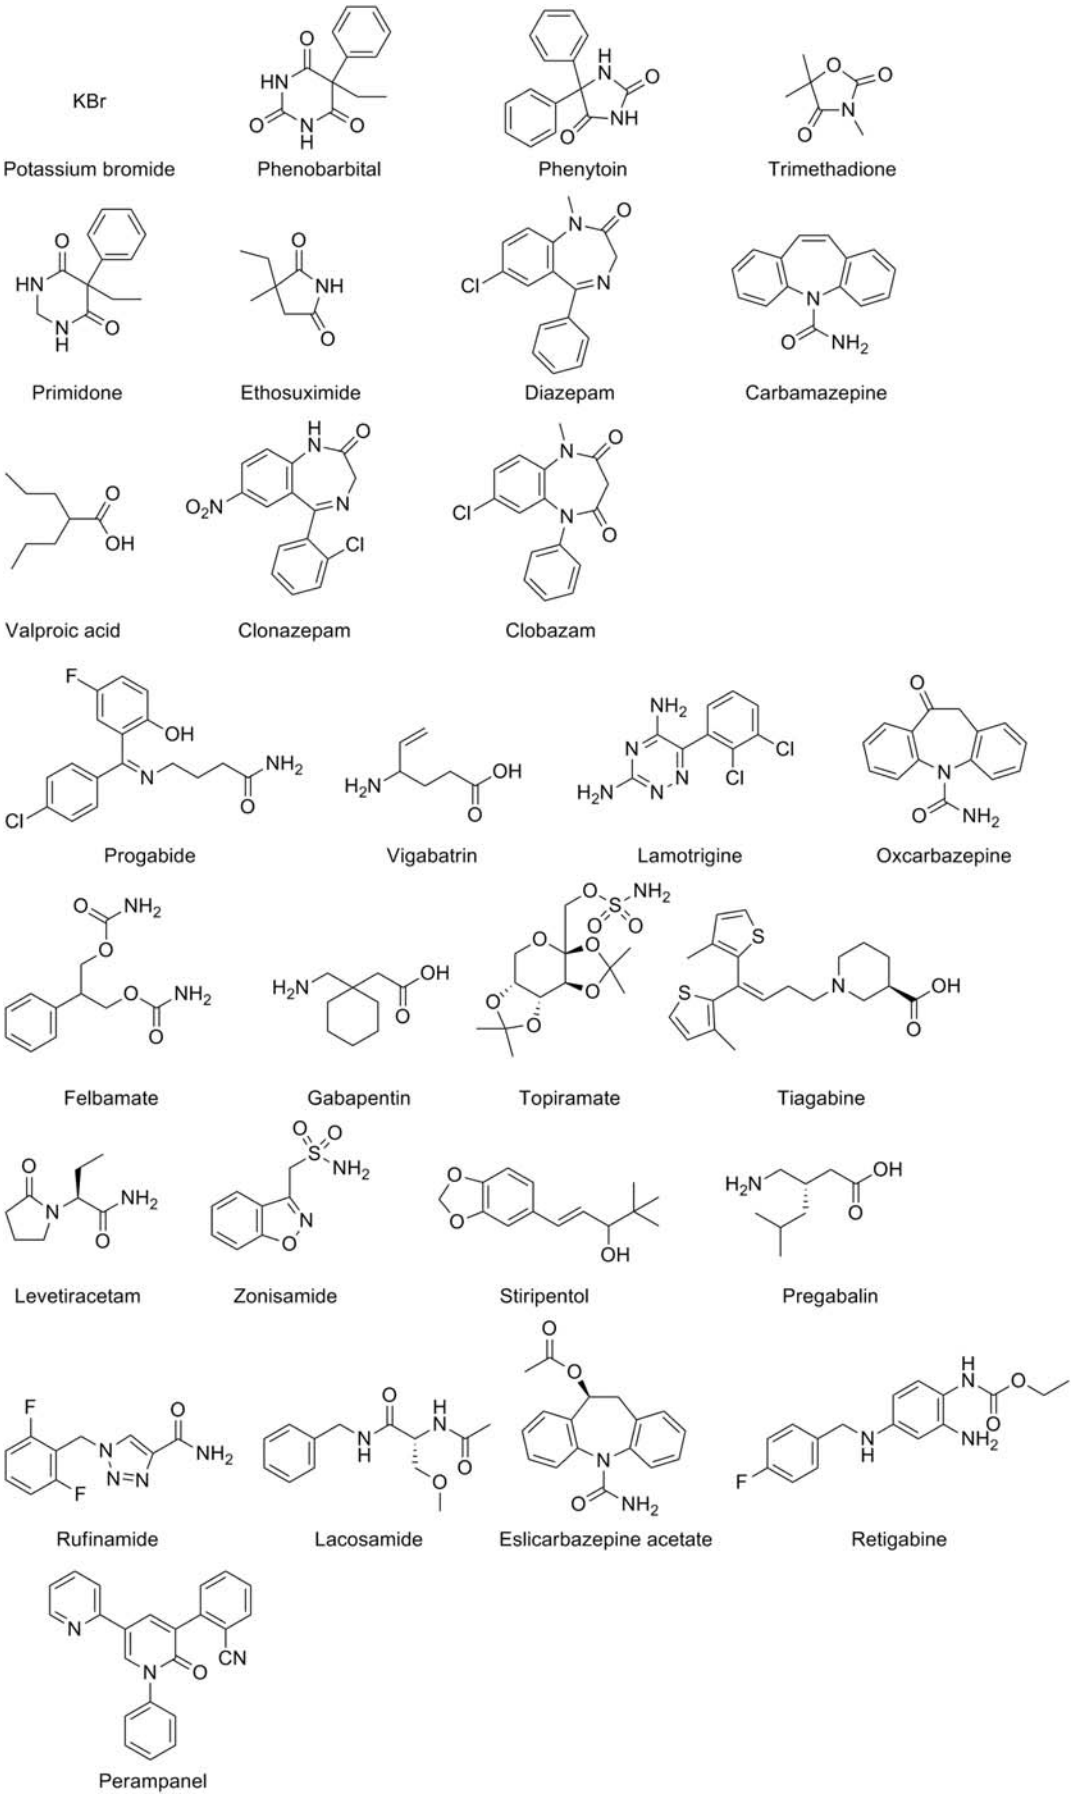

Fig. 2 Structures of the clinically approved antiepileptic drugs shown in **Table 1**.

Table 2 Representative animal models of seizures[12,16–18]

Seizure model	*Seizure modelled*	*Description*
Acute seizure models		
Maximal electroshock (MES)	Generalized tonic–clonic seizure	In the MES test, rodents receive a brief (0.2 s) 50- or 60-Hz electrical stimulus to induce maximal seizures of their hind limbs, with tonic extension as the endpoint of the test. This test is a gold standard for the early detection of anticonvulsant activity
Subcutaneous pentylenetetrazole (scPTZ)	Absence or myoclonic seizure	In the scPTZ test, a convulsive dose of PTZ is subcutaneously administered and rodents are observed, usually for 30 min, for the occurrence of a threshold seizure. This test is a gold standard for the early detection of anticonvulsant activity
6 Hz psychomotor	Therapy-resistant epilepsy (depending on current intensity)	Electrical stimulation via low-frequency (6 Hz) rectangular pulses of 0.2-ms duration is delivered through corneal electrodes for a total of 3 s to induce seizures that are reminiscent of the psychomotor seizures occurring in human limbic epilepsy. At high currents (eg, 44 mA), most antiepileptic drugs loose efficacy, suggesting that this may be a useful model of therapy-resistant limbic seizures
Audiogenic seizure	Generalized seizures	High-frequency sound is used to induce seizures in the rodent. This model has high sensitivity for detecting anticonvulsant effects. Regardless of mechanism of action, most current antiepileptic drugs show an effect in this model
Chronic seizure models		
Kindling	Partial seizures	Chronic model that is currently used by most antiepileptic drug discovery programs and is thought to adequately predict anticonvulsant activity against partial seizures in the clinic. Repeated application of electrical stimuli via a depth electrode in the limbic system (amygdala or hippocampus) of rats induces seizures that are permanently enhanced in severity and duration. Modified kindling models, such as the phenytoin-resistant kindled rat and the lamotrigine-resistant kindled rat, have been developed as pharmacoresistant epilepsy models. The corneal kindled mouse model is a simple modified kindling model that enables high-throughput screening
GAERS (genetic absence epileptic rat from Strasbourg)	Generalized absence seizures	GAERS is a genetic model of generalized absence seizures. All GAERS rats develop spike-wave electrographic seizures. A homozygous, missense, single mutation in the gene encoding Cav3.2 T-type Ca^{2+} channel has been reported in the GAERS rat
Others		
Status epilepticus	Status epilepticus	Status epilepticus is a life-threatening condition in humans that is characterized by continuous seizure or multiple seizures with loss of consciousness. Experimental rodent models represent the continuous seizure state, which can be induced by kainic acid, pilocarpine, lithium-pilocarpine, or electrical stimulation

Table 3 Pros and cons of common approaches to the preclinical development of antiepileptic drugs

Preclinical approach	*Pros*	*Cons*
Random in vivo phenotypic screening	Direct detection of in vivo efficacy Novel mechanisms of action found serendipiously	Difficult to understand structure-activity relationship Labor-intensive screening Identification of mechanism of action
Structural modification of a known antiepileptic	Clear starting point for medicinal chemistry Established assay system	Differentiation from previously developed antiepileptic drugs
Hypothesis-driven, target-based approach	Clear rationale Compound optimization	Drug target validation

effects of a compound regardless of its mechanism of action, and this offers the opportunity to find compounds with novel mechanisms of action. On the other hand, this approach more often than not yields lead compounds with multiple or unclear mechanisms of action, which generally makes it difficult to develop the compound into a marketable drug.

7.01.3.1.2 Structural modification of a known antiepileptic

New drug discovery from analogs of known drugs is a widely used approach in medicinal chemistry. Without exception in AED development, more than 10 new AEDs that are structural analogs of existing AEDs have been developed, and most have advantageous profiles in term of pharmacokinetics, toxicity, tolerability, and reduced potential for drug interactions compared with their parent compound. These AEDs are regarded as second-generation compounds to former AEDs such as carbamazepine. An advantage of this approach over in vivo phenotypic screening lies in compound optimization. Furthermore, this would enable a less costly operation because there is no need to establish an assay or seed-finding campaign, if the differentiation strategy is established.

7.01.3.1.3 Hypothesis-driven, target-based approach

Few AEDs have been developed by means of hypothesis-driven, target-based strategies targeted at mechanisms of action related to seizure generation such as imbalances in GABAergic inhibition/glutamatergic excitation. Although the heterogeneous nature of epilepsy makes this approach difficult, advances in our understanding of the mechanisms of epilepsy have supported drug discovery via hypothesis-driven strategies. Hypothesis-driven, target-based drug development has advantages over in vivo phenotypic screening in terms of compound optimization; however, in hypothesis-driven, target-based drug development it is often difficult to validate the biological target.

7.01.3.2 Development of Levetiracetam, Brivaracetam, and Seletracetam[19–22]

Levetiracetam and its analogs, carbamazepine and its analogs, and perampanel are examples of AEDs that were developed by means of the three preclinical development approaches of (1) random in vivo phenotypic screening; (2) structural modification of a known antiepileptic; and (3) hypothesis-driven, target-based approach.

7.01.3.2.1 Levetiracetam

Levetiracetam was originally synthesized as a structural analog of the nootropic piracetam (2-oxo-1-pyrrolidine acetamide), which itself is used clinically to enhance the seizure protection conferred by carbamazepine in epileptic patients.[23] Nootropic drugs, which are used clinically as cognition-enhancing agents in the elderly, have shown anti-convulsant effects in models of various seizures; however, by themselves they have only weak anti-convulsant effects.[24–26] The antiepileptic properties of levetiracetam were identified by means of random in vivo phenotypic screening using a mouse model of audiogenic seizures. Discovery of levetiracetam and its related compounds is shown in Fig. 3.

Photo-affinity labeling studies using [^{3}H]ucb 30889, a radioactive ligand of levetiracetam, have shown that the target protein of levetiracetam is synaptic vesicle protein SV2 isoform A, which is present in all neurons.[27,28] SV2A is the most widely distributed isoform of SV2 that is ubiquitously expressed in the brain and in edocrine cells. SV2A is thought to be involved in neuronal excitability, neurotransmitter exocytosis, and vesicle fusion modulation.[28–34] In animal models of epilepsy, there was a strong correlation between the binding affinities for SV2A of levetiracetam and its close analogs and the anti-seizure activities of these compounds.[28] However, the precise mechanism of how the binding of levetiracetam to SV2A is involved in its anti-seizure effects is not yet fully understood. There are reports that levetiracetam selectively inhibits high-voltage-activated N-type Ca^{2+} channels[35–37] or presynptic voltage-dependent Ca^{2+} channels,[38] and SV2A binding may be a key component of this Ca^{2+} channel blockade.

Levetiracetam has a unique anti-seizure profile compared to first-generation AEDs. It does not have efficacy in the MES and PTZ-induced seizure models, but it does have substantial antiepileptic effects in absence seizure and kindling models with a very high safety margin (Table 4).[21,39,40] Levetiracetam is currently indicated for the treatment of partial onset seizures, myoclonic seizures, and primary generalized tonic–clonic seizures.

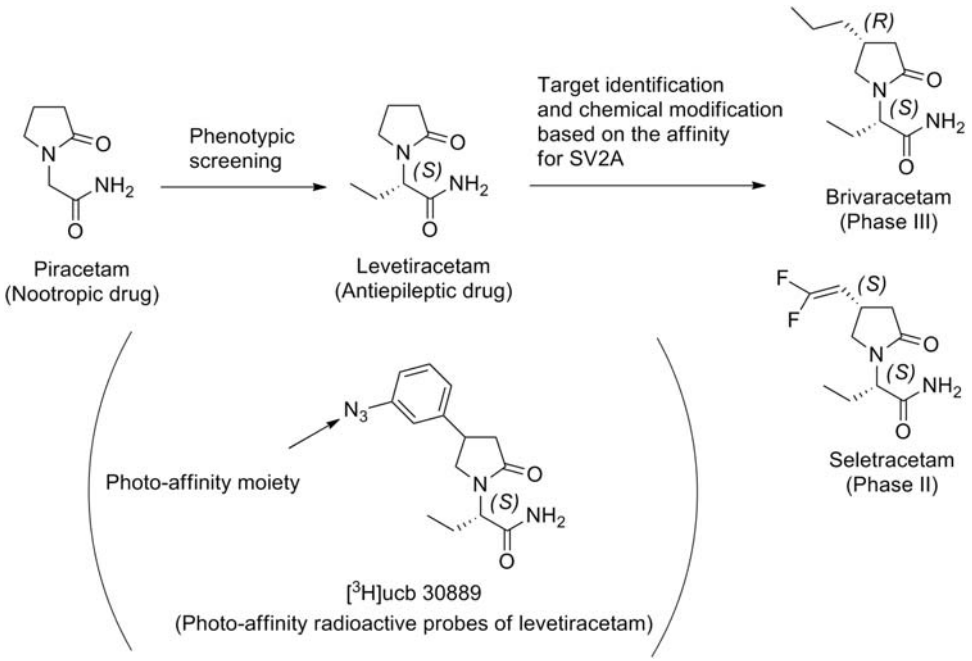

Fig. 3 Discovery of levetiracetam and its related compounds.

Table 4 In vivo activities of levetiracetam, brivaracetam, and selectracetam[19]

Model	*Levetiracetam*	*Brivaracetam*	*Seletracetam*
Binding affinity for SV2A (pIC_{50})	6.1	7.1	7.1
Mouse MES	ineffective	113 (i.p.)	ineffective
Mouse PTZ (s.c.)	ineffective	30 (i.p.)	ineffective
Mouse 6 Hz (44 mA)	19.4 (i.p.)	4.4 (i.p.)	–
Rat GEARS	>170 (i.p.)	67.9 (i.p.)	0.15 (i.p.)
Mouse corneal kindling	7.3 (i.p.)	1.2 (i.p.)	0.31 (i.p.)
Protective index (mouse corneal kindling[a], TD_{50}/ED_{50})	148	46	1048

[a]Protective index is the ratio of TD_{50} (rotarod test) to ED_{50} (seizure protection) in corneal kindled mice.

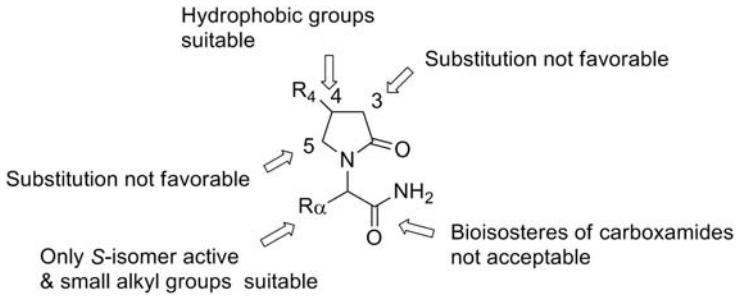

Fig. 4 Structure–activity relationship of levetiracetam and its analogs based on binding affinity.

7.01.3.2.2 Development of second-generation compounds of levetiracetam

Structure–activity relationship studies of levetiracetam were systematically conducted to identify analogs with higher binding affinities for SV2A than levetiracetam.[22] During this screening, compounds were tested both in a binding assay with [^{3}H]ucb 30889 and in a mouse model of audiogenic seizures, and the binding affinity for SV2A and anti-seizure effect of the compounds were found to be well correlated.[28] The structure–activity relationships of analogs of 2-oxopyrrolidine acetamide based on their affinity for SV2A is summarized in Fig. 4.

The carboxamide moiety of levetiracetam was found to be play an important role in the binding affinity, and other bioisosteres of carboxamide, such as carboxylic acid, ethyl ester, thioamide, and amidine, were not acceptable. Substitution of various side chains at the α-position of the carboxamide of levetiracetam was also examined; however, none of the compounds examined exceeded levetiracetam in terms of SV2A binding affinity. The *S*-enantiomers of side-chain analogs had higher binding affinity than the *R*-enantiomers. Although substitution at the 3- and/or 5-position of the 2-pyrrolidine ring did not produce compounds with improved binding affinity, the addition of hydrophobic groups at the 4-position did. Through the exploration of substitution at the 4-position, brivaracetam (propyl moiety at the 4-position of levetiracetam) and seletracetam (2,2-difluorovinyl moiety at the 4-position of levetiracetam) were discovered as second-generation antiepileptics of levetiracetam.

Brivaracetam has 10-fold higher binding affinity for SV2A and superior efficacy than levetiracetam in various animal models of epilepsy.[41,42] Unlike levetiracetam, brivaracetam has anti-seizure effects in the MES and PTZ-induced seizure models, possibly due to its inhibition of voltage-dependent Na^+ channels.[43] Brivaracetam has a linear pharmacokinetic profile in humans, 100% oral bioavailability, and dose-dependent efficacy. Four phase III trials have been completed, and several long-term, open-label, follow-up trials of brivaracetam as adjunctive treatment are on-going.[44]

Seletracetam also has 10-fold higher binding affinity for SV2A and greater in vivo efficacy in many animal models than levetiracetam. In particular, it has a higher protective index (1048) than has levetiracetam in corneal kindled mice.[45] Unlike brivaracetam, selectracetam does not decrease MES and PTZ-induced seizures in mice because it has no effect on voltage-dependent Na^+ channels.[46] The phase II clinical trials of seletracetam seem to be on hold.

7.01.3.2.3 Summary

The successful development of brivaracetam and selectacetam shows a viable approach for the development of next-generation antiepileptic drugs. Brivaracetam and selectacetam were discovered through target-based in vitro high-throughput screening developed after the mechanism of action of levetiracetam had been identified. A large proportion of antiepileptic compounds have been discovered via phenotypic screening, and further elucidation of their mechanisms of action might be a shortcut to producing next-generation compounds with superior efficacy compared with the parent compounds. Compounds obtained by chemical structural modification do not necessary have the exact same pharmacological, toxicological, and pharmacokinetic profiles as the parent compound. Small changes in the chemical structure of a molecule can cause marked changes in compound's potency, range of anti-convulsant activities, or safety margin, and brivaracetam and selectacetam are examples where this has been harnessed to provide improved AEDs.

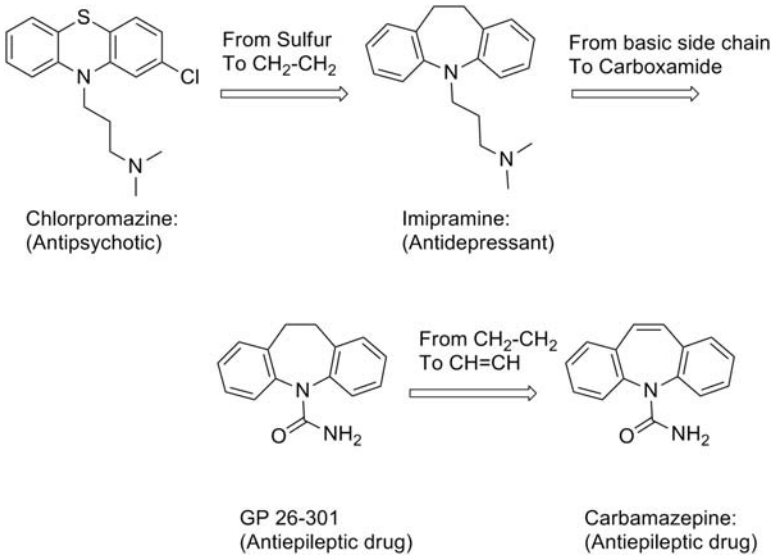

Fig. 5 Discovery of carbamazepine.

7.01.3.3 Development of Carbamazepine, Oxcarbazepine, and Eslicarbazepine Acetate

7.01.3.3.1 Carbamazepine

The antiepileptic effects of carbamazepine derivatives were discovered by chance in the 1950s when tricyclic derivatives of the antipsychotic chlorpromazine were synthesized.[47] One of these tricyclic derivatives, imipramine, in which the sulfur in the central moiety of chlorpromazine is replaced with CH_2–CH_2, was discovered to have antidepressant rather than antipsychotic effects. Next, GP 26–301, in which the basic side chain of imipramine is substituted for a carbamoyl group, was found to have potent anticonvulsant activity in an MES model. Further optimization by replacing CH_2–CH_2 in the central moiety of GP 26–301 with CH=CH produced the anticonvulsant carbamazepine (Fig. 5).

Carbamazepine is currently one of the most widely used first-line AEDs for the prevention of partial and generalized tonic–clonic seizures, but it is ineffective against absence or myoclonic seizures. Carbamazepine is also used to treat neuropathic pain and some psychiatric disorders. Although carbamazepine has multiple targets, it is widely accepted that the main mechanism of action is inhibition of voltage-gated sodium channels.[47,48]

The most frequently observed adverse effects associated with carbamazepine are dizziness, drowsiness, unsteadiness, nausea, and vomiting, which generally occur at the start of therapy. These neurotoxic adverse effects are dose-related and reversible in most patients. Idiosyncratic reactions in the hemopoietic system, skin, liver, and cardiovascular system have been also reported.[49] The mechanisms of toxicity are unclear; however, 10,11-epoxide, an active metabolite of carbamazepine, is likely responsible for at least some of the adverse effects (Fig. 6).[50] Moreover, it is well known that carbamazepine and 10,11-epoxide are potent inducers of CYP3A4; therefore, carbamazepine has high potential for interacting with other drugs.

7.01.3.3.2 Oxcarbazepine

Since carbamazepine is not effective in several types of patients and is associated with several adverse effects, a number of derivatives were synthesized and examined preclinically with the hope of finding a compound with an improved efficacy and safety profile. Of these derivatives, oxcarbazepine had the most promising profile and was selected for further development.[51] In preclinical and clinical studies, oxcarbazepine was shown to have anticonvulsant efficacy comparable to that of carbamazepine.

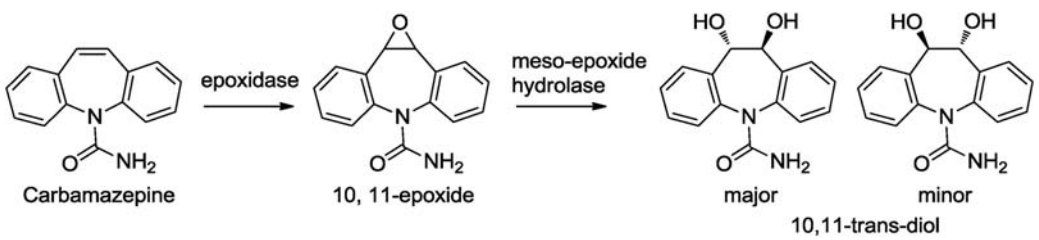

Fig. 6 Metabolism of carbamazepine.

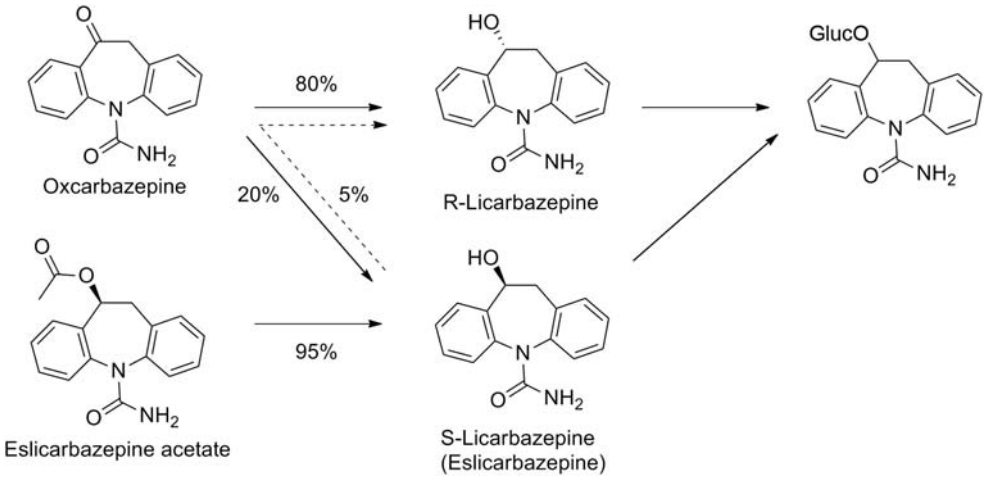

Fig. 7 Metabolism of oxcarbazepine and eslicarbazepine acetate.

The adverse effect profiles of oxcarbazepine and carbamazepine are also similar, although the adverse effects associated with oxcarbazepine are less frequent and less severe than those associated with carbamazepine.[52] In addition, there is no auto-induction of CYP mediated metabolism, and there are fewer interactions of oxcarbazepine with other drugs compared with carbamazepine. The major difference between oxcarbazepine and carbamazepine is in their metabolism. Oxcarbazepine has a 10-ketone group, and is almost completely metabolized to the biologically active compound licarbazepine in humans (Fig. 7).[53] Licarbazepine has an (*S*)/(*R*) ratio of approximately 80/20.[11] Licarbazepine is then conjugated to a glucuronide and excreted by the kidneys. Unlike carbamazepine, oxcarbazepine is not oxidatively metabolized to 10,11-epoxide, which is probably one reason why oxcarbazepine is associated with fewer allergic reactions, less enzyme induction, and fewer side effects. Oxcarbazepine is currently indicated as monotherapy or adjunctive therapy for the treatment of partial onset seizures in adults and children.

7.01.3.3.3 Eslicarbazepine acetate

Since oxcarbazepine is an achiral prodrug that is metabolically transformed into a mixture of two active enantiomers, its corresponding esters are also potential prodrugs. A number of esters of licarbazepine were synthesized and tested in a MES model using gastric tube administration,[54] and from these esters, eslicarbazepine acetate was found to be as potent anticonvulsant as carbamazepine, and more potent than both oxcarbazepine and (*R*)-licarbazepine acetate (Table 5). Interestingly, in another MES model using intraperitoneal administration, eslicarbazepine acetate was nearly threefold more potent than eslicarbazepine and had a wider protective index.[54]

In humans, eslicarbazepine acetate is metabolized mainly to (*S*)-licarbazepine. Less than 5% of (*S*)-licarbazepine is then converted to (*R*)-licarbazepine via oxidation to oxcarbazepine (Fig. 7).[11,55] As a result, the area under the curve for (*S*)-licarbazepine is 16% greater than that for the equivalent dose of oxcarbazepine. Indeed, patients in a phase III clinical trial who were treated with carbamazepine benefited in reduction in seizure frequency from the addition of concomitant eslicarbazepine acetate. In addition, eslicarbazepine acetate significantly improved quality of life during long-term (1-year), open-label studies conducted after the phase III studies.[56] Eslicarbazepine is currently approved as adjunctive therapy in adults with partial-onset seizures with or without secondary generalization.

7.01.3.4 Development of Perampanel[57–59]

7.01.3.4.1 Background

Glutamate is an excitatory neurotransmitter in the human brain that has principal roles in a variety of physiological functions. Glutamate receptors are classified based on their mode of signal transduction as either metabotropic glutamate receptors or ionotropic glutamate receptors. Metabotropic glutamate receptors are coupled with G-protein and they modulate synaptic transmission

Table 5 In vivo activity of carbamazepine, oxcarbazepine, (*R*)-licarbazepine acetate, and eslicarbazepine acetate[54]

Parameter	*Carbamazepine*	*Oxcarbazepine*	*(R)-licarbazepine acetate*	*Eslicarbazepine acetate*
T_{max} (h)	2	2	8	2
Rat maximal electroshock seizure model ED_{50} (mg/kg)	5.4 ± 0.8	10 ± 1.9	10.9 ± 2.3	4.7 ± 0.9
Rotarod TD_{50} (mg/kg)	251 ± 9.8	>1000	>1000	358.7 ± 17.2
Protective index (TD_{50}/ED_{50})	46.5	>100	>91.7	76.3

via a second messenger. Ionotropic glutamate receptors possess a ligand-gated ion channel and therefore mediate fast synaptic transmissions. Ionotropic glutamate receptors are further differentiated into three types by the appearance of their selective antagonists (ie, α-amino-3-hydroxy-5-methyl-4-isoxazolepropanoic acid—AMPA; kainite, and *N*-methyl-D-aspartic acid—NMDA). Since abnormal increases in glutamate concentration in the brain trigger seizure activity,[60] epilepsy and some epileptic syndromes are thought to be linked to over-activity of ionotropic glutamate receptors, and the AMPA ionotropic glutamate receptors is most critical for the generation of epileptic discharges.[61] Furthermore, the AMPA receptor is a crucial mediator of seizure propagation.[62] Thus, antagonism of the AMPA receptor is a promising target for AED development. Representative AMPA receptor antagonists are shown in Fig. 8.[63,64]

The first selective AMPA receptor antagonists were quinoxalinedione derivatives such as NBQX; however, this series of compounds has poor blood–brain barrier penetration and poor solubility under neutral conditions. A polar moiety was introduced in an attempt to improve the compound's solubility; however, this resulted in less blood–brain barrier penetration. Other competitive AMPA receptor antagonists, fanapanel and tezampanel, have not yet advanced to clinical trial. Selurampanel, a quinazolinedione sulfonamide, is being tested in a phase II study for the treatment of epilepsy, migraine, and tinnitus.

The exploration of novel AMPA receptor antagonists has now expanded to include a variety of non-competitive antagonists. These compounds have the functional advantage that they exert their antagonist activity even when the level of glutamate is elevated. The 2,3-benzodiazepine-type compounds, which include talampanel, drove early research into AMPA antagonism. Talampanel demonstrated modest in vitro inhibitory efficacy but better in vivo efficacy, indicating blood–brain barrier penetration. However, it was also found to have a short-half life.[19] Talampanel was assessed in clinical trials for the treatment of various disease conditions, including epilepsy and amyotrophic lateral sclerosis, but it is yet to reach the market. Therefore, perampanel is the first selective AMPA receptor antagonist that was approved for the treatment of epilepsy.

7.01.3.4.2 Discovery of perampanel, a novel non-competitive AMPA receptor antagonist

To identify a starting compound for medicinal chemistry, two high-throughput screening campaigns were conducted using a rat cortical neuron AMPA-induced cell-death assay and a tritium-labeled AMPA binding assay to detect compounds with competitive AMPA receptor antagonist activity. Hit compounds were further screened by using an AMPA-induced Ca^{2+} influx assay to evaluate inhibitory potency and exclude false-positives. Through these assays, 2,4-diphenyl-4*H*-[1,3,4]oxadiazin-5-one, which is a commercially available compound, was selected for further development (AMPA-induced Ca^{2+} influx assay, $IC_{50} = 9.17$ μM; Fig. 9). The selection of this compound was based not only on its potential for chemical modification but also on its structural uniqueness compared with previously reported AMPA antagonists.[57]

The initial structure–activity relationship study for 2,4-diphenyl-4*H*-[1,3,4]oxadiazin-5-one focused on replacement of the two side-chains attached to the central oxadiazinone core. Introduction of an aliphatic substituent such as a benzyl or cyclohexyl group instead of the phenyl group resulted in a marked decrease in receptor inhibitory activity, indicating that conjugated aromaticity is necessary for AMPA inhibitory activity in oxadiazinone derivatives.[57] Next, the central ring structure was altered to try and produce a compound with improved AMPA receptor inhibitory activity and metabolic stability. Keeping the carbonyl group and the two phenyl substituents on the central ring structure, several chemical modifications were examined (Fig. 9). Introduction of diazinone ($IC_{50} = 28.10$ μM) or converting the central core to a pyridone derivative ($IC_{50} = 69.54$ μM, 57.72 μM) diminished but still

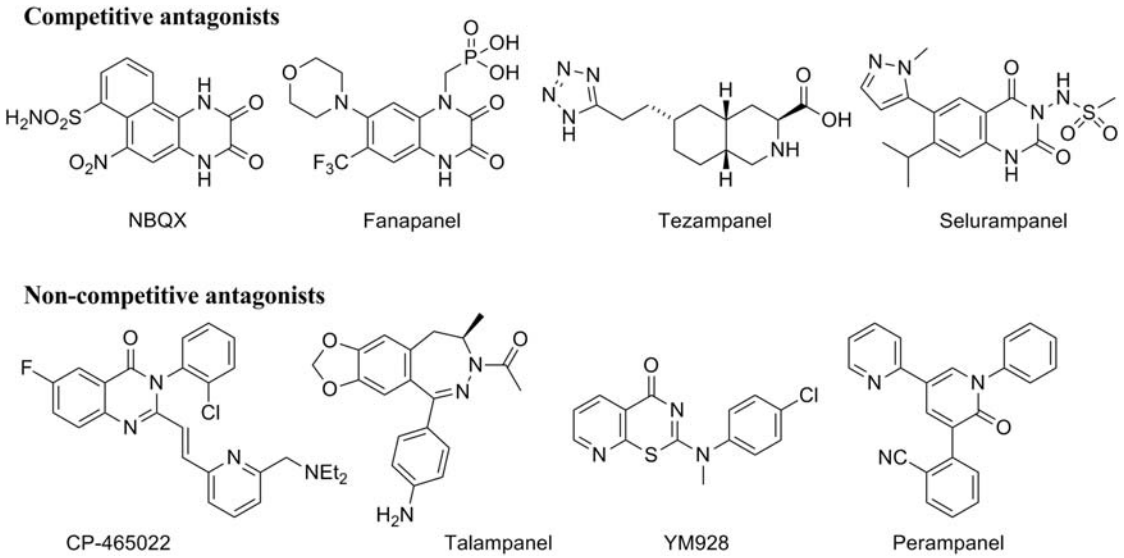

Fig. 8 AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropanoic acid) antagonists.

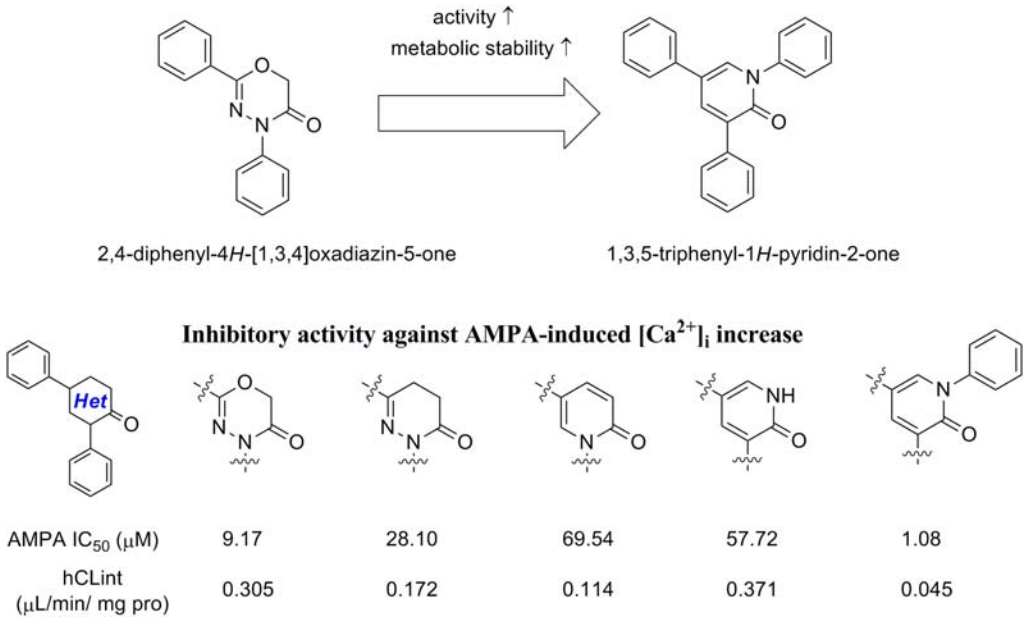

Fig. 9 Exploration of the central oxadiazinone core of 2,4-diphenyl-4*H*-[1,3,4]oxadiazin-5-one.

maintained in vitro inhibitory activity of the compound. A comparison of the two pyridone isomers suggested that acidic hydrogen affected metabolic stability in humans, and the presence of acidic hydrogen is also known to generally hamper blood–brain barrier penetration. Therefore, addition of one more phenyl group to the pyridone central core to mask the acidic hydrogen produced 1,3,5-triphenyl-1*H*-pyridin-2-one, which showed dramatically improved AMPA inhibitory activity ($IC_{50} = 1.08$ μM) and intrinsic clearance in humans in a microsome stability assay. The identification of 1,3,5-triphenyl-1*H*-pyridin-2-one was a major milestone in the drug discovery history of perampanel.

Next, a systematic series of structure–activity relationship studies using the 1,3,5-triphenyl-1*H*-pyridin-2-one template were conducted by focusing on optimization of the individual aromatic rings located at the 1, 3, and 5-positions of the central pyridone ring (Fig. 10). At the 5-position, 2-pyridine was found to be the optimal substituent in terms of receptor inhibitory activity.

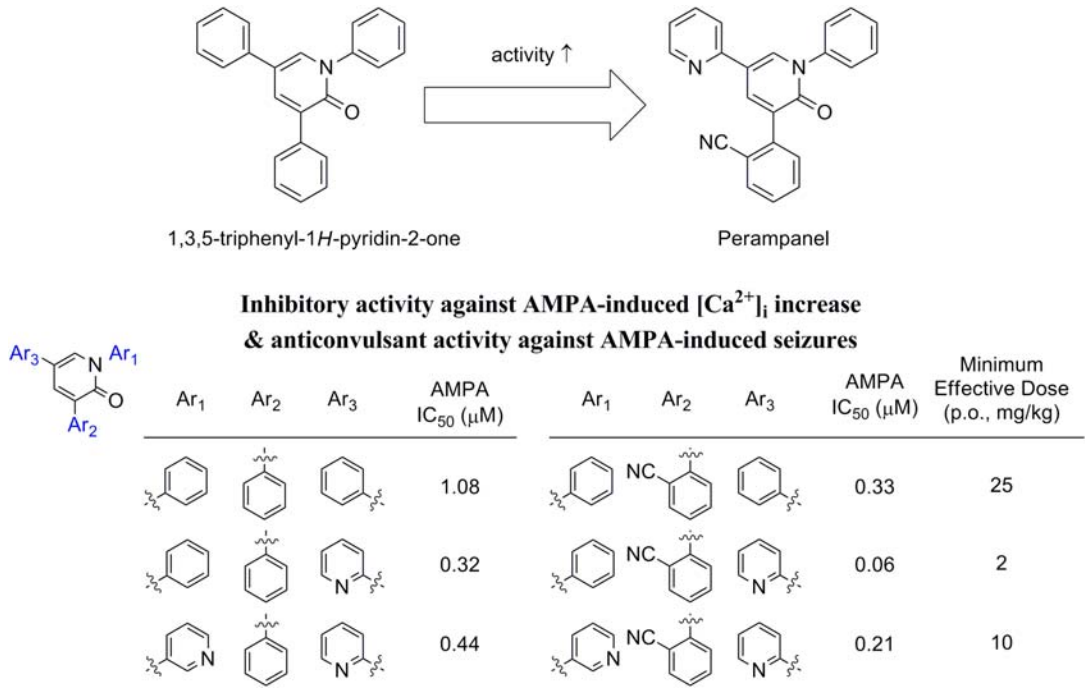

Fig. 10 Optimization of the individual aromatic rings of 1,3,5-triphenyl-1*H*-pyridin-2-one.

The replacement of phenyl with 2-pyridyl improved the receptor inhibitory activity at the submicromolar level. Substitutions at the 3-position were also found to increase receptor inhibitory activity. 2-cyanophenyl was the most active, by comparison with the compounds with a cyano moiety at the *ortho*, *meta*, or *para* positions. The effects of cyano, halogen (F or Cl), alkyl, or alkoxy substituents at the *ortho* position were also examined. A cyano substitution was found to have the greatest impact on receptor inhibitory activity.[57] Both the electron-withdrawing properties and the bulkiness of a cyano substituent on the phenyl group, which induces a twist angle between the central pyridone core and the 3-aryl ring, were found to be essential for improving receptor inhibitory activity. At the 1-position, a wide range of substituents produced AMPA receptor inhibitory activity, but the optimization indicated that nonsubstituted phenyl produced the best activity in vitro.

The most potent compounds from the structure–activity relationship studies were further evaluated in vivo using a mouse AMPA-induced seizure model (**Fig. 10**) and the data indicated that 2-(2-oxo-1-phenyl-5-pyridin-2-yl-1,2-dihydropyridin-3-yl) benzonitrile (perampanel) was the most promising compound, leading to its selection for clinical development.

7.01.3.4.3 Preclinical profile of perampanel

Perampanel is a novel pyridone derivative that has extremely high receptor inhibitory activity in vitro and in vivo ($IC_{50} = 60$ nM in an AMPA-induced Ca^{2+} influx assay; minimum effective dose = 2 mg/kg, per os in an AMPA-induced seizure model) and a favorable pharmacokinetic profile for clinical use in that it has good metabolic stability in humans (intrinsic clearance = 0.009 μL/min/mg protein) and good blood–brain barrier penetration (cerebrospinal fluid-to-unbound plasma concentration ratio in mice = 1.14).[57] A binding assay[58] indicated that perampanel binds at a similar binding site on the AMPA receptor as other non-competitive AMPA antagonists. Furthermore, perampanel is highly selective for the AMPA receptor against 63 physiologically relevant enzymes, ion channels, and neurotransmitter transporters, including NMDA and kainate receptors.[57]

The in vivo potency of perampanel was confirmed in several animal models of seizures. Perampanel demonstrated antiseizure activity in both the MES and subcutaneous PTZ (scPTZ) models of acute seizures (MES test, $ED_{50} = 1.6$ mg/kg p.o.; scPTZ test, $ED_{50} = 0.94$ mg/kg p.o.).[58] These ED_{50} values are much lower than those for carbamazepine ($ED_{50} = 21$ mg/kg p.o. and > 100 mg/kg p.o., respectively) and sodium valproate ($ED_{50} = 460$ mg/kg p.o. and 350 mg/kg p.o., respectively). In addition, perampanel prevents 6-Hz seizure (at 44 mA) ($ED_{50} = 2.8$ mg/kg, p.o.).[59]

Perampanel was proven to be efficacious in a rat amygdala kindling model of chronic seizures.[58] However, it was inactive at doses of 1, 3, and 10 mg/kg p.o. in a GAERS (Generic Absence Epilepsy Rat from Strasbourg) model.[58] A similar trend has been observed with other non-competitive AMPA receptor antagonists.[65]

In a lithium–pilocarpine rat model of status epilepticus, 8 mg/kg of perampanel administered intravenously prevented further seizures when administered at 10, 30, or 60 min after seizure onset, and its efficacy was observed in all individual animals tested.[59] In contrast, 20 mg/kg diazepam administered intravenously terminated the seizure only when administered at 10 min after seizure onset in some of the animals tested.

The effect of co-administration of perampanel with other AEDs was also examined in animal models of seizures.[59] Enhanced seizure protection was observed in the 6-Hz seizure test with combinations of perampanel with carbamazepine, phenytoin, or valproic acid. In a rat amygdala kindling model, at least additive and in some cases a synergistic effect, was observed when perampanel was combined with levetiracetam, lamotorigine, carbamazepine, or valproic acid.

In a phase III study,[66–70] adjunctive perampanel reduced the frequencies of primary generalized tonic–clonic seizures as well as the one of partial-onset seizures, compared with placebo. Consequently, perampanel is now approved for the treatment of partial-onset seizure in over 45 countries, including European Union, United States, and Canada, and in 2015 the indications were expanded in the United States and European Union to include primary generalized tonic–clonic seizures.

7.01.4 Future Perspectives

7.01.4.1 Overview

Many AEDs have been developed since the first reported use of potassium bromide, and more than 20 AEDs are currently available. However, approximately 30% of patients with epilepsy still suffer from recurrent seizures.[10] Adverse events such as dizziness, somnolence, and fatigue are also still frequently reported.[71] Although some of the more recently launched AEDs have improved efficacy and safety profiles, more efficacious and better-tolerated AEDs are needed.

The AEDs currently available have been developed primarily for their effects in suppressing epileptic seizures, that is, they have been developed as anti-seizure drugs. A target for developing AEDs would be shifted to next stage. A drugs that prevent progression to epilepsy once a patient develops or is exposed to a risk factor, that is, drugs that are antiepileptogenic, may become a game-changer in epilepsy treatment.

Epileptic disorders have a heterogeneous pathological background, and pharmacoresistance can arise from multifactorial causes such as reduction of drug-target sensitivity and overexpression of multidrug transporters in the epileptic brain.[72] Therefore, the heterogeneous nature of epilepsy makes it difficult to treat. Further study of the genetic basis of epilepsy and of its etiologies, as well as of the mechanisms involved in AED resistance and the development to epileptic condition, will be indispensable in the development of next-generation AEDs.

7.01.4.2 Next-Generation AEDs Currently Undergoing Clinical Development

Some of the AEDs currently undergoing clinical investigation have novel chemical structures and mechanisms of action. Selected next-generation AEDs are summarized in Table 6 and Fig. 11.

Ganaxolone is a synthetic analog of the endogenous neurosteroid allopregnanolone, a metabolite of progesterone, that is currently undergoing phase III clinical trials in adults with partial seizures. YKP-3089 is an orally active small compound currently undergoing phase II clinical trials. YKP-3089 selectively inhibits the inactivated state of Na^+ channels and preferentially blocks persistent sodium current. It also increases inhibitory synaptic transmission by modulating presynaptic GABA release.[44] Naluzotan is a 5-hydroxytrytamine 1A receptor agonist currently undergoing phase II clinical trials for the treatment of epilepsy. 4-Chlorokynurenine is an NMDA gycine B receptor antagonist currently undergoing phase II clinical trials for the treatment of major depressive disorder and phase I clinical trials for the treatment of epilepsy, Parkinson's disease, and neuropathic pain. Tonabersat is a neuronal gap junction modulator currently undergoing phase I clinical development for the treatment of epilepsy.

7.01.4.3 Recent Advances in AED Development

7.01.4.3.1 Animal models and random phenotypic in vivo screening

Animal models of seizures have made a crucial contribution to the development of effective AEDs. Along with advances in genomics, certain genetic mutations that result in the development of epileptic disorders have been elucidated. These findings have led to new genetic variant-induced seizure models that are expected to more accurately reflect epilepsy in humans.[11] For example, changes in Na^+ channel pharmacosensitivity are associated with downregulation of the β1 and β2 subunits of Na^+ channels. Therefore, a transgenic model with a mutation in the β1 subunit gene (SCNB1) would potentially be one tool to tackle phamacoresistant epilepsy. As for antieplileptogenic drug, its discovery would require the adequate experimental models and also the diagnosis method for developing epileptic condition.

The basis of phenotypic screening for AED discovery is the exposure of the central nervous system to a series of test compounds. Along with the development of chemoinformatics, some favorable property to blood–brain barrier penetration have been proposed.[73] Various strategies to access biologically relevant areas in chemical space have been developed (eg, diversity-oriented synthesis, biology-oriented synthesis). These methodologies should help us to construct an adequate central nervous system-oriented library of compounds. Novel animal models and advances in medicinal chemistry will support AED discovery.

Table 6 Selected antiepileptic drugs currently undergoing clinical development

Antiepileptic drug	*Development phase*[a]	*Hypothesized mechanism of action*	*Targeted condition*	*Developing company*
Ganaxolone	Phase III	GABA A receptor modulation	Epilepsy, fragile X syndrome, anxiety, post-traumatic stress disorder	CoCensys, Marinus Pharmaceuticals
YKP-3089 (structure not disclosed)	Phase II	Selective blockade of the inactivated state of Na^+ channels and facilitation of presynaptic GABA release	Epilepsy	SK Biopharmaceuticals
Naluzotan	Phase II	5-HT1A receptor agonism, signal transduction modulation	Epilepsy	Epi Pharmaceuticals, Proximagen
4-Chlorokynurenine	Phase I	NMDA glycine B receptor antagonism, signal transduction modulation	Epilepsy, major depressive disorder, Parkinson's disease, neuropathic pain	VistaGen/Sanofi
Tonabersat	Phase I	Gap junction modulation	Epilepsy	Upsher–Smith, Proximagen

[a]Highest clinical study phase for epilepsy.

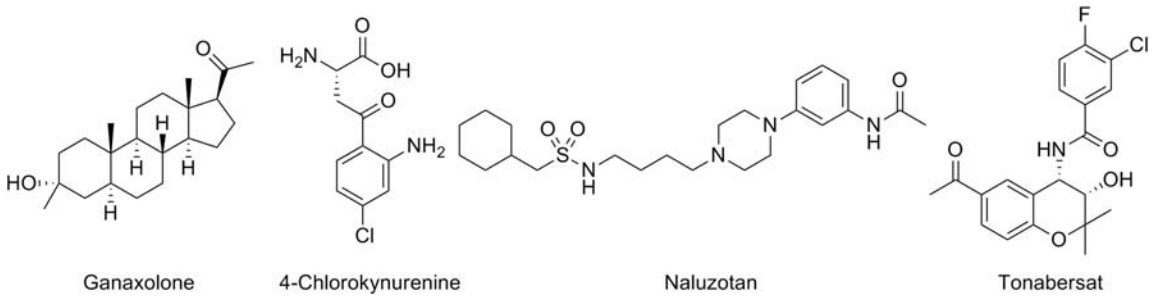

Fig. 11 Structures of the antiepileptic drugs currently undergoing clinical development shown in Table 6.

7.01.4.3.2 Potential drug targets for AEDs[12]

The majority of AEDs have been developed preclinically by means of in vivo phenotypic screening using animal models of seizures, which has meant that the mechanisms of action have only been identified after the compound was found to have antiepileptic effects. However, recent advances in our understanding of the cellular and molecular events involved in epilepsy has led to a shift towards hypothesis-driven, target-based approaches for the development of more efficacious and better-tolerated AEDs and antiepileptogenic drugs. In particular, systems biology incorporating functional genomics, transcriptomics, proteomics, epigenetics, and metabolomics, coupled with high-throughput technologies, is a powerful tool for identifying the causal pathways of ictogenesis and epileptogenesis, which can then be used to define new candidate targets.[74] Many existing AEDs exert their anti-seizure effects via voltage-gated sodium channel blockade and GABA potentiation, and reduced sensitivity of these targets is thought to be involved in the development of AED-resistant chronic epilepsy in humans and other species.[72,75] Therefore, novel AEDs acting through molecular targets that are not desensitized in the epileptic condition could offer promise for future AED discovery. Potential targets include inflammatory pathways, cation–chloride co-transporters, monoaminergic systems, and genetic and epigenetic targets.

7.01.4.3.2.1 Inflammatory pathways

Evidence indicating the strong involvement of inflammatory pathways in both ictogenesis and epileptogenesis is being rapidly accumulated.[76–78] Clinical evidence suggests that steroids and other anti-inflammatory drugs have anti-convulsant effects in some drug-resistant epilepsy syndromes.[77] Many preclinical studies have shown that interleukin-1β, toll-like receptor 4, and very late antigen-4 (also known as α4β1 integrin) have key roles in the inflammatory pathways involved in icogenesis and epileptogenesis. Belnacasan (Fig. 12), an interleukin-1β-converting enzyme, reduces acute and pharmacoresistant chronic seizures in mice.[79] It was examined in phase II clinical trials for the treatment of partial epilepsy; however, these clinical studies were stopped due to a business-related decision.[80] Toll-like receptor 4 is a key factor involved in innate immunity. The activation of interleukin-1 receptor/toll-like receptor signaling in neurons and glia (microglia and astrocytes) is considered to be a crucial step in the inflammatory brain response following seizures and epileptogenic brain insults.[81] Toll-like receptor 4 antagonists are reported to delay seizure precipitation and reduce acute and chronic seizure activity in rodents.[82]

7.01.4.3.2.2 Cation–chloride co-transporters

The shift from inhibitory to excitatory GABA-mediated transmission in neurons may contribute to the chronic hyperexcitability of epileptic neurons. This shift is attributed to the alternation in the intracellular chloride concentration caused by dramatic changes in expression of cation–chloride co-transporters such as bumetanide-sensitive sodium-potassium-chloride co-transporter 1 (NKCC1; also known as SLC12A2) and electroneutral potassium chloride co-transporter 2 (KCC2; also known as SLC12A5).[83] Therefore, these cation–chloride co-transporters could be a potential target for the treatment of refractory epilepsy and epileptogenesis. The NKCC1 inhibitor bumetanide (Fig. 12) is reported to block neonatal seizures in rodents.[84]

7.01.4.3.2.3 Monoaminergic systems

Patients with epilepsy suffer not only from seizures but also from considerable cognitive impairment and psychiatric comorbidities.[85] The monoaminergic system is heavily involved in psychiatric diseases such as anxiety, depression, bipolar disorders, and sleep disorders, but it also contributes to the regulation of the seizure threshold as well.[86–88] Therefore, molecules engaged in serotonergic, noradrenergic, or dopaminergic neurotransmission may be suitable targets for novel epilepsy treatments that attenuate the neurological comorbidities associated with epilepsy as well as control the generation of seizures. Naluzotan (Fig. 11), a selective 5-hydroxytryptamine 1A receptor agonist, is currently undergoing phase II clinical studies for the treatment of epilepsy. Approaches targeting a single mechanism that is involved in both seizures and the associated neurological comorbidities may be a promising means of discovering novel AEDs.

7.01.4.3.2.4 Genetic and epigenetic targets

In models of acquired epilepsy, gene expression appears to change in a time-dependent manner, and various events that occur simultaneously may be closely linked to epileptogenesis. Therefore, attractive novel targets for antiepileptogenesis could be found in the genetic and epigenetic alternations found in epilepsy.[89]

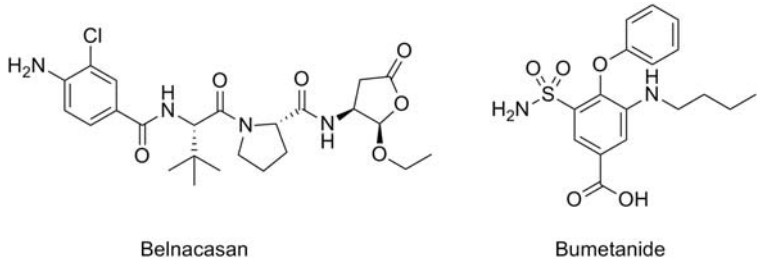

Fig. 12 Chemical structures of belnacasan and bumetanide.

7.01.5 Conclusion

Many patients with epilepsy still experience uncontrollable epileptic seizures despite the range of currently available AEDs, indicating that there are treatment targets that remain unidentified. Further elucidation of the molecular and genetic basis of the various seizure types and mechanisms of epileptogenesis will produce new avenues for the discovery of novel drug targets, which will lead to the development of novel epilepsy therapies. A target-based approach is the most direct means of obtaining more efficacious and better-tolerated AEDs and antiepileptogenetic drugs. However, despite recent technological innovations in this area and advances in our understanding of the cellular and molecular events leading to epilepsy, this approach remains difficult. One of the reasons for this is the complex intertwining of the many factors and molecules that are involved in the epileptic condition. Therefore, to move towards the ultimate goal in epilepsy treatment, which is a "permanent cure," we must utilize the full range of approaches to preclinical development that are available to us.

7.02.1 Introduction

7.02.1.1 What Is PET Imaging

Positron emission tomography (PET) is a quantitative molecular imaging technology based on radiotracers. Those are labeled with short-lived positron-emitting isotopes of atoms commonly available in small-molecule drug candidates, typically ^{11}C and ^{18}F. The short half-life of these positron-emitting isotopes (respectively, 20 and 110 min) and their specific decay into coincident and highly tissue-penetrant γ-rays allows relatively noninvasive in vivo imaging with good spatial resolution and very high sensitivity. PET radiotracers can therefore provide quantitation of biochemical processes within a living human being, including within the central nervous system (CNS) (Fig. 1).

These characteristics confer to PET imaging the potential to assess neurological processes in healthy human subjects and those in various disease states. When combined with the increasing availability of μPET cameras allowing performing preclinical studies in small animals, PET imaging becomes a powerful translational tool to support drug discovery.

*These authors contributed equally to the work.

7.02.1.2 How PET Imaging Can Aid CNS Drug Discovery

Despite many efforts over the last 15 years to decrease the attrition in drug development, there is still less than a 10% chance that a drug entering clinical trials will reach the market. Attrition is the highest for oncology and CNS drug development, in particular with novel targets with limited understanding of the biology.[2] In order to reduce drug attrition in clinical trials and to continue to attract investment, the pharmaceutical industry must develop reliable translational evaluation tools that will enable faster and better decisions.[3]

Due to the inaccessibility of the brain in living humans, the development of translational tools to support CNS drug discovery has to rely on noninvasive techniques like in vivo imaging. Over the last years, a few imaging technologies have been increasingly used to support drug discovery. They include the use of radioisotope-based techniques, mainly PET and to a lesser extent single-photon emission computed tomography (SPECT), magnetic resonance imaging (MRI), and more particularly functional MRI.[4]

Among the radioisotope-based imaging techniques that can aid CNS drug discovery, PET is particularly well suited as it relies on the incorporation of radioisotopes that are already present in most small-molecule drug candidates. It can provide quantitative information to support the decision-making process at different stages of preclinical and clinical drug development (**Fig. 2**).[5,6]

First, PET imaging can provide brain PK information in living subjects. Through the direct radiolabeling of a drug candidate, information regarding the blood–brain barrier (BBB) penetration in both healthy and diseased subjects can be obtained. Taking advantage of the microdosing concept, such studies can even be performed while the drug candidate is still at a preclinical development stage, providing a quick read-out before the first administration in humans at pharmacological doses. However, this straightforward approach raises first a radiochemistry challenge. Indeed, the direct labeling of a drug candidate may be synthetically challenging, and the development of new labeling methodologies to expand the radiochemist's toolbox would be very beneficial to this approach. This challenge will be briefly addressed in the concluding remarks of this article.

Secondly, the development of a validated PET ligand for the protein targeted by the drug development program provides the opportunity to assess, through blocking studies, the target occupancy of a drug candidate. These studies provide critical information such as the relationship between target occupancy and administered dose as well as the target occupancy kinetics. When obtained in phase I of clinical development, such information is decision-making to select the most appropriate dose range and regimen for

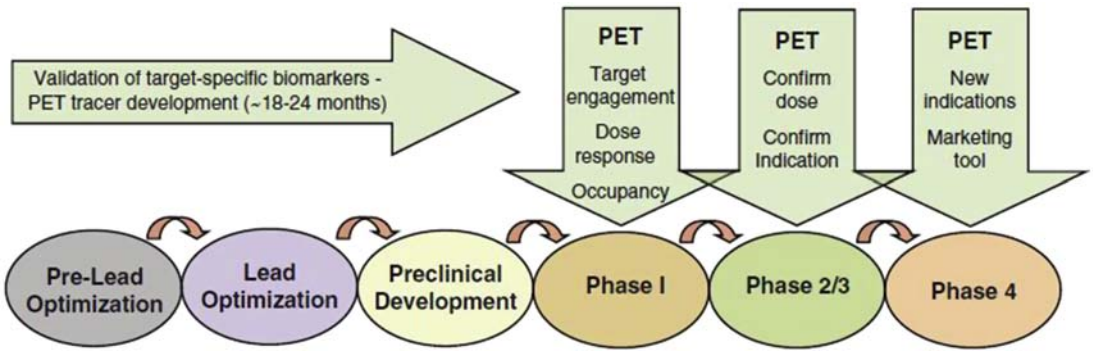

Fig. 2 Potential impact of PET imaging in the drug discovery process. Adapted from Grachev, I. D.; Hargreaves, R. J. Integrative Processes: Neuroscience Clinical Imaging Biomarkers. In *Imaging in CNS Drug Discovery and Development: Implications for Disease and Therapy*; Springer Science+-Business Media, LLC, 2010; pp 363–379.

phase II POC studies. As discussed in the next section, the design, synthesis, and validation of a tracer for a specific target is a challenging journey and may take several years. This is the major challenge of this approach.

Thirdly, PET imaging studies can also be performed with known physiology or pathophysiology biomarkers labeled with a positron emitter. Such studies can provide some insight into the mechanism of action of a drug candidate and can allow patient stratification, monitoring of disease progression, or be used for proof of pharmacology or as objective endpoints in phase II POC. The identification and validation of such pharmacodynamic imaging biomarkers is still an unmet need for most drug development programs in neurological diseases. However, they could drastically speed-up the clinical development by providing surrogate molecular endpoints of behavioral changes for POC studies.

This article will provide an overview of the available PET tracers for clinical studies and of the recent advances in the identification of novel PET tracers for specific protein targets in neurosciences. It is not intended to be an exhaustive review of all PET tracers available but will rather focus on targets that have either been recently investigated in clinical trials or been addressed preclinically for the first time. This article will also discuss some of the current and future challenges and limits to develop new PET tracers and will eventually suggest future areas of interest in the field.

7.02.2 Recent PET Imaging Tracers in Neurosciences

7.02.2.1 Introduction

Designing PET tracers requires the targeting of compounds with specific properties that are not necessarily aligned with the properties of drug candidates. Many reviews[7–10] have discussed the ideal properties of a tracer for brain imaging and these can be summarized as follows:

- high affinity (usually expressed as $B_{max}/K_D > 10$) and specificity to achieve sufficient signal (bound specifically at the target) to background (nonspecifically bound) ratio;
- moderate log P ($1.5 < \log P < 3$) in order to highly penetrate the BBB without resulting in excessive nonspecific binding (NSB);
- moderate to high clearance from a reference tissue of the target of interest;
- no brain-penetrant radiolabeled metabolite to ensure that the measured radioactivity represents only the amount of parent tracer in the tissue of interest;
- not a P-gP substrate;
- late-stage incorporation of a suitable radionuclide (typically ^{11}C or ^{18}F);
- high-specific activity to stay in tracer conditions, especially for targets with low densities;
- simple automated synthetic procedure, compliant with the good manufacturing practices, for reliable production in clinical use.

Although these properties do not necessarily align with the ones of drug candidates, the multiparameter optimization (MPO) challenge to design a good PET imaging tracer is conceptually very similar to developing a new drug. Therefore, medicinal chemists and PET imaging scientists have made several attempts to develop metrics, indices, and models[11] aimed at predicting the probability of success of a molecule to become a suitable tracer. Considering that NSB is a frequent cause of failure for candidate PET tracers, most of these approaches are actually aimed at better predicting the NSB risk. Zhang et al. analyzed 62 successful PET ligands and proposed a CNS PET MPO score based on both in silico and experimental physicochemical design parameters predictive of reduced NSB risk.[9] Alternatively, other groups have reported various computational[12] or experimental methods, mostly relying on surrogate measurements of the lipophilicity and of the interaction of the candidate tracer molecule with artificial membrane systems.[8,13,14]

Due to these challenging requirements, many compounds produced by the pharmaceutical industry in the last decade for multiple target proteins did not translate into numerous new imaging agents in clinical use. Indeed, only about 40 have been successfully developed for imaging in humans.[10,15] The next sections will briefly review these successful tracers according to their target class and discuss the most recent developments and areas of interest.

7.02.2.2 PET Tracers Targeting G Protein-Coupled Receptors

About 30% of marketed drugs are targeting G Protein-Coupled receptors (GPCRs). These are involved in numerous pathophysiological processes, including in the CNS. Neuroreceptors such as dopaminergic or serotoninergic receptors were historically the targets of choice for the development of the first PET tracers for CNS use. One might have thought a couple of years ago that GPCRs were drug targets of the past. However, recent scientific and technological breakthroughs simply demonstrated the contrary.

In the last 5 years, the crystallization of transmembrane proteins has started to become a routine drug discovery tool, as demonstrated by the dramatic increase in the number of GPCRs structures solved in the last 2 years. The emergence and development of novel areas of interest in drug design such as allosterism, other complex ligand–receptor interactions, the importance of residence time, or the number of receptors of physiological importance still to be deorphanized have also contributed to a sort of "rebirth" of the target class, as illustrated by an exponential growth in the number of papers, reviews, conferences, and new drug candidates targeting GPCRs.

As a consequence, the development of PET tracers targeting GPCRs is still of critical importance. Various challenges such as the design of tracers that bind allosterically to the receptors, the development of agonist tracers, or simply the identification of PET ligands of novel orphan receptors remain a hot topic that will be discussed in this section.

7.02.2.2.1 Tracers in clinical use

See Table 1.

7.02.2.2.2 Recent developments

7.02.2.2.2.1 Dopaminergic receptors[25,26,60,61]

7.02.2.2.2.1.1 D1 receptors (Table 1, Scheme 1)

D1 receptors play an important role in several pathologies such as schizophrenia, cognitive disorders, and Parkinson's disease (PD). [^{11}C]NNC112 and [^{11}C]SCH23390 have been available for decades and have become valuable tools to investigate and understand those diseases in vivo. These are still currently widely used in clinical studies.[23,24,62–64]

Both tracers were developed as selective D1 orthosteric antagonists but suffer from a relative lack of D1 specific binding due to high affinity for the 5HT2A receptor.[65] Other closely related and more selective ligands, such as [^{11}C]SCH39166 and [^{11}C]NNC756, were developed but their evaluation was plagued by low specificity or tracer kinetics issues. Given the renewed interest for noncatechol selective D1 orthosteric agonists or allosteric modulators,[66,67] there is a strong need for selective D1 radiotracers for human use either to support the development of drug candidates or to delineate D1 receptor roles in pathologies of interest.

7.02.2.2.2.1.2 D2/D3 receptors (Table 1, Scheme 2)

D2 and D3 receptors are involved in numerous neurological or neuropsychiatric disorders such as PD, schizophrenia, anxiety, or drug addiction. The first PET tracers that were developed, [^{11}C]Raclopride, [^{11}C]FLB 457, and [^{18}F]Fallypride, are D2/D3

nonselective antagonists. Limitations to their use are due to their lack of preference for high-affinity G-protein-coupled states of the receptors, therefore rendering them less suited for the imaging of synaptic neurotransmission. This has been overcome by the development of agonist tracers such as [^{11}C]MNPA, [^{11}C]NPA, or [^{11}C](+)PHNO which display higher affinities for receptor G-protein complexes allowing to study or diagnose disorders linked to the relative abundance of these receptor states.

Recent developments are focused on the discovery of [^{18}F]-labeled agonist tracers which could potentially offer several advantages thanks to the longer-lived [^{18}F] compared to [^{11}C]. [^{18}F]MCL-524[68] was recently identified and validated in cynomolgus monkeys. It displays high affinity for the D2 receptor in its high-affinity state, favorable specific D2/D3 binding, and suitable kinetic properties. It has not been reported to be used in humans yet. Other [^{18}F] D2/D3 potential tracers have also been recently reported but still suffer from suboptimal properties, in particular nonspecific binding.[69]

Over the last couple of years, there has been a considerable interest in the development of selective D2 or D3 receptor ligands, and in the differentiation of their respective functional roles in humans. In particular, the more restricted localization and distribution of D3 receptors in brain areas such as nucleus accumbens suggests a specific role in drug abuse pathologies or as a potential target for antipsychotics with reduced side effects, such as extrapyramidal motor symptoms, compared with D2 antagonists. Most available radiotracers are nonselective D2/D3 antagonists or agonists and cannot distinguish between those two receptors in humans. It has nevertheless been recently demonstrated that [^{11}C](+)PHNO preferentially binds to the D3 receptor subtype in vivo with about 20-fold selectivity. Several studies in healthy volunteers or Parkinson's patients have suggested the suitability of [^{11}C](+)PHNO as a D3-preferring probe in humans despite a suboptimal brain distribution in D3-specific areas.[70–73] Several groups have also reported efforts toward the identification of suitable selective [^{18}F]-labeled tracers,[74,75] but none of the potential radiotracers are suitable yet for brain imaging, mainly due to high nonspecific binding, despite subnanomolar affinities and promising selectivity for dopamine and serotonin receptor subtypes.

Selective D2 radiotracers are also of high interest. Promising high-affinity ligands, such as [^{11}C]Cyclopropyl-FLB 457, for the selective imaging D2 receptors in extrastriatal low-density regions in cynomolgus monkey brains or in postmortem human autoradiography have been reported.[76] [^{11}C]Cyclopropyl-FLB 457 is characterized by picomolar D2 in vitro affinity, about 100-fold selectivity versus D3 receptor, high-specific binding in low-density D2 regions, and high brain uptake in monkeys.

7.02.2.2.2.1.3 D4 receptors (**Scheme 3**)

D4 is the third subtype of the D2-like family of receptors. Despite having been cloned in 1991, its pathophysiological functions, localization, and brain distribution remain unclear and matter of controversy. A D4-selective radiotracer would therefore allow a better understanding of the role of D4 in living brains. There have been several attempts to develop [^{11}C] or [^{18}F]-labeled D4 PET ligands but none of them have proved to be successful as of today. Considerable challenges have been reported over the past few years and are associated with the difficulty to combine very high affinity for the D4 receptor, which is characterized by a low B_{max} value, high selectivity for other dopamine receptor subtypes, and low nonspecific binding.[77–80]

7.02.2.2.2.2 Histaminergic receptors

PET ligands for the selective brain imaging of histamine receptors subtypes have been recently reviewed.[81] PET radiotracers have been developed for human use in the case of H1 and H3 receptors.

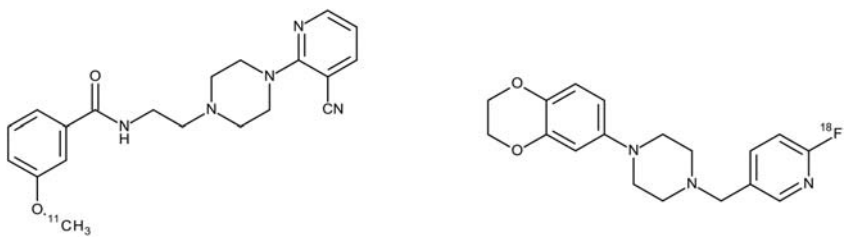
7.02.2.2.2.2.1 H1 receptors (**Table 1**, **Scheme 4**)

[^{11}C]Pyrilamine and [^{11}C]Doxepin have been developed as selective H1R radiotracers and extensively used to study H1R binding in vivo in several species including humans. [^{11}C]-Doxepin is the most widely used and the most suitable ligand because of a higher metabolic stability and higher contrast in brain images. Numerous studies were performed in humans in order to investigate cognitive and sedative side effects of H1 antagonists and have demonstrated a correlation of sleepiness with brain receptor occupancies. [^{11}C]Doxepin is still used today as part of the evaluation of H1 receptor occupancy of novel drug candidates.[28]

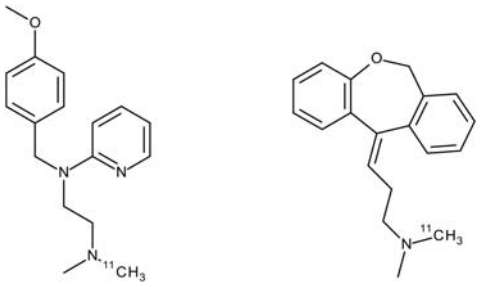
7.02.2.2.2.2.2 H3 receptors (**Table 1**, **Scheme 5**)

Several selective H3R radiotracers have been developed over the last decade, mainly to support the numerous drug candidates that have progressed toward clinical development and proof-of-concept studies.

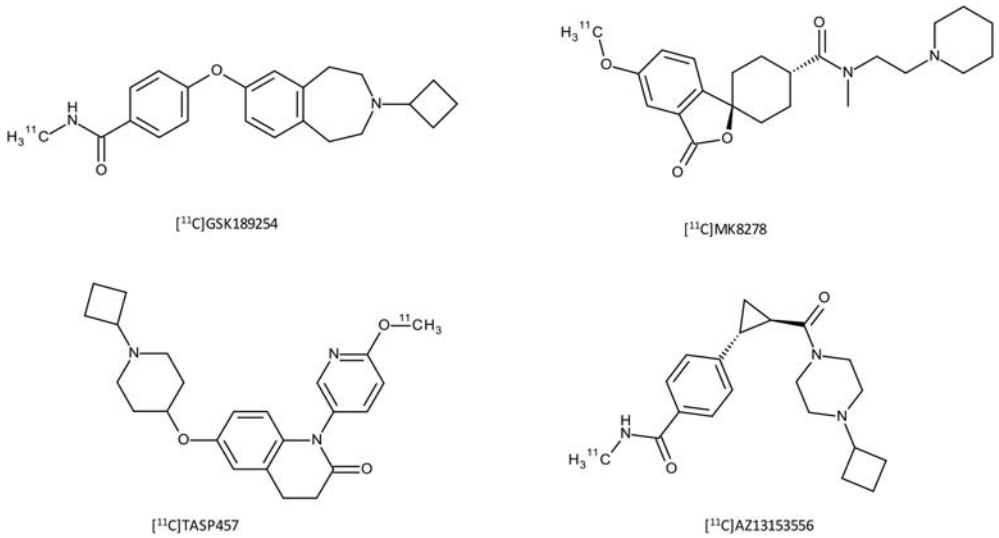
[^{11}C]GSK189254[29] and [^{11}C]MK8278[30] were developed and used in humans to measure H3R occupancy of several H3 inverse agonist drug candidates developed for the treatment of cognitive or sleep disorders, in particular GSK189254,[29] GSK239512,[82] AZD5213,[83] MK0249, and MK3134. However, it has been reported that [^{11}C]GSK189254 suffers from a very low K_D and slow kinetics in the brain, in particular in high density regions such as the striatum of globus pallidus, limiting the precision of PET quantification, while [^{11}C]MK8278 displayed large test–retest variability.



Scheme 3 Selected D4 receptor PET tracers.



Scheme 4 Selected H1 receptor PET tracers.



Scheme 5 Selected H3 receptor PET tracers.

More recently, several groups have reported efforts to overcome the limitations of the available ligands for human use. In particular, [^{11}C]TASP457 was identified as a suitable ligand with faster kinetics than [^{11}C]GSK189254 and higher brain penetration than [^{11}C]MK8278. Promising human data have been obtained, demonstrating that [^{11}C]TASP457 is suitable for the investigation of H3 receptor density in human.[84,85] Similarly, [^{11}C]AZ13153556 was also recently reported to display improved preclinical properties, in particular lower affinity in vitro in rat and nonhuman primate tissue homogenates and in autoradiography using brain sections from rats and human as well as in vivo through PET measurements in mice and nonhuman primates. Faster kinetics in a head-to-head comparison study with [^{11}C]GSK189254 were also confirmed, offering some potential for improved properties in human.[86] [^{18}F]FMH3 was also tested in humans as the first [^{18}F]-labeled H3 PET tracer.[31]

*7.02.2.2.2.3 H4 receptors (**Scheme 6**)*

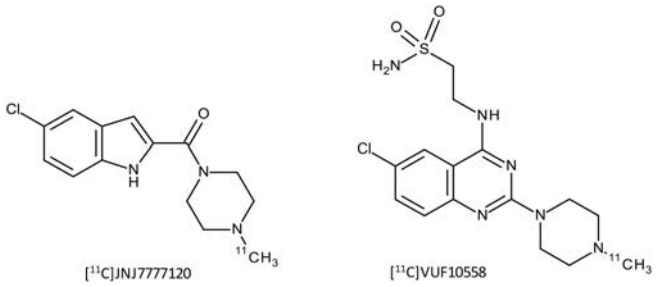
The development of selective H4R radiotracers is still in its infancy with few reports of [^{11}C] radiolabeled analogs of the prototypical antagonists JNJ7777120[87] and VUF10558.[88] The field is nevertheless evolving thanks to the identification of other selective high-affinity ligands as potential starting points for the discovery of PET ligands.[81]

7.02.2.2.2.3 Muscarinic receptors[89]

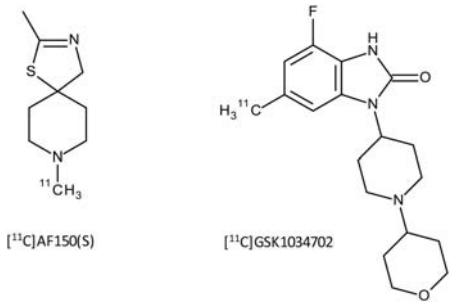
*7.02.2.2.2.3.1 M1 receptors (**Table 1**, **Scheme 7**)*

Among the five muscarinic acetylcholine receptor (mACh-R) subtypes, M1 is the most prevalent in the central nervous system. It is mainly localized in forebrain regions such as the basal ganglia, hippocampus, and cortical areas and is thought to play a role in cognition and motor control. Initial tracers such as [^{11}C]-MPB or [^{11}C]QNB are unselective muscarinic antagonists displaying slow kinetics. These tracers are unable to distinguish between muscarinic receptor subtypes and, as antagonists, between high- and low-affinity states of the receptors.

[^{11}C]AF150(S) was discovered and designed from cevimeline (AF102B), a rigidified analog of acetylcholine acting as an orthosteric agonist. It displays modest M1 functional selectivity versus the peripherally restricted M3 receptor subtype and is selective over



Scheme 6 Selected H4 receptor PET tracers.



Scheme 7 Selected M1 receptor PET tracers.

M2, M4, and M5 subtypes. [^{11}C]AF150(S) displays rapid and high brain uptake in rats and binding in M1-R rich brain areas was demonstrated with autoradiography. Its potential for human use remains to be demonstrated.[90,91] The only selective M1-R radiotracer tested in humans is [^{11}C]GSK1034702 which is obtained by direct labeling of GSK1034702, a novel M1 positive allosteric modulator (PAM), and was used to quantify the brain penetration of its drug candidate analog in order to derisk its progression into clinical trials. Thus, PET scans were performed in baboons and healthy human volunteers. Good brain uptake was demonstrated as well as BBB passage mainly through passive diffusion or active influx.[43]

7.02.2.2.2.4 Serotoninergic receptors[92]

*7.02.2.2.2.4.1 5HT1A receptors (**Table 1**, **Scheme 8**)*

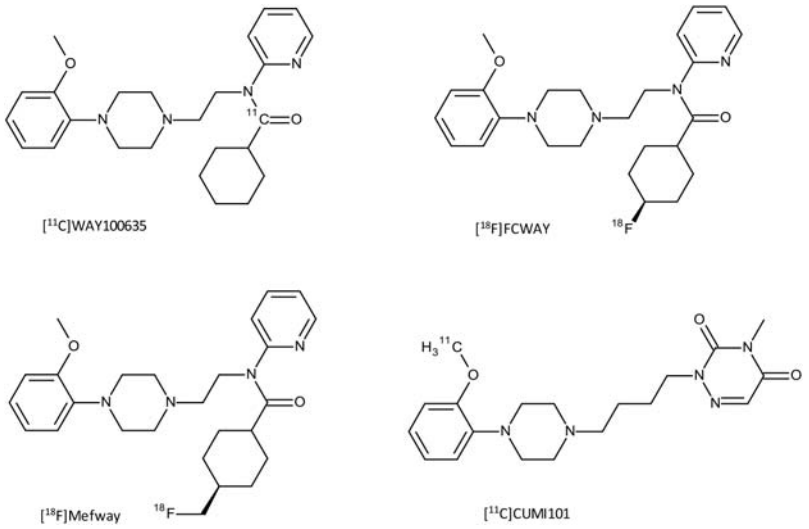
Several [^{11}C] and [^{18}F] selective 5HT1A antagonist radioligands have been developed over the last decade. Some of them are being used in human subjects but still suffer from [^{11}C]-driven short half-life ([^{11}C]WAY100635 and analogs), high level of in vivo defluorination ([^{18}F]FCWAY), or P-gp efflux ([^{18}F]-MPPF, [^{18}F]FCWAY).[32] Defluorination might be circumvented through concomitant use of disulfiram (1,1′,1″,1‴-[disulfanediylbis(carbonothioylnitrilo)]tetraethane) but its potential neurotoxicity hampers a more widespread use. Current trends are therefore focused on the identification of suitable [^{18}F] tracers which are better able to resist defluorination, such as [^{18}F]Mefway.[35,93] One selective 5HT1A agonist, [^{11}C]CUMI-101, selectively binds to the G-protein coupled state of the 5HT1A receptor and has been developed. It is available for human use.[33,94,95] Its [^{18}F]-labeled analog has been reported as [^{18}F]FECUMI-101.[96]

*7.02.2.2.2.4.2 5HT2 receptors (**Table 1**, **Scheme 9**)*

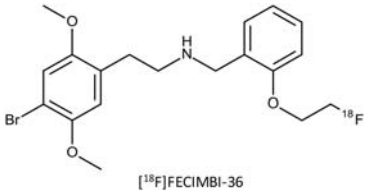
5HT2 receptors have three subtypes 5HT2A, 2B, and 2C, of which the 5HT2A is the most abundant receptor in the human brain. Several antagonist radioligands are available but none of them is able to discriminate between high- and low-affinity binding states. Current efforts therefore focus on the discovery of 5HT2A agonist tracers such as [^{18}F]FECIMBI-36 allowing the quantification of binding to G-protein bound forms.[97]

*7.02.2.2.2.4.3 5HT4 receptors (**Table 1**, **Scheme 10**)*

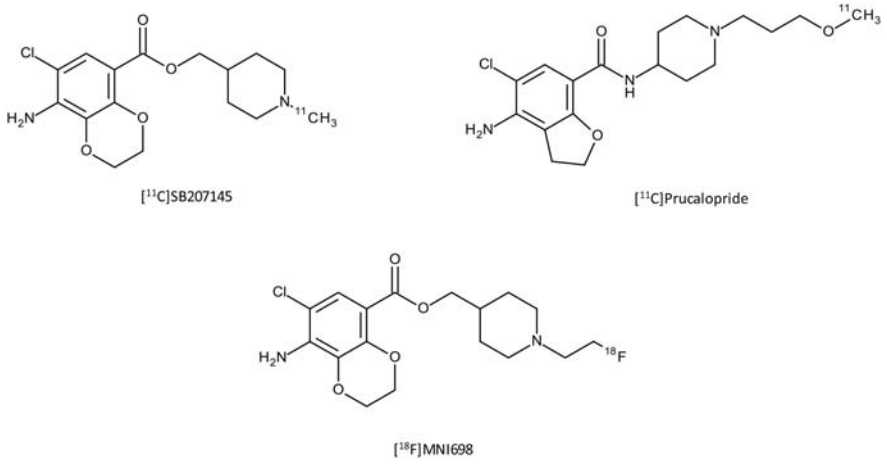
High densities of 5HT4R are detected in several brain regions (basal ganglia, limbic structures) and are potentially involved in several pathologies such as depression, ADHD, obesity/anorexia and possibly Alzheimer's disease (AD), and Huntington disease. Selective antagonist radiotracers have been developed and [^{11}C]SB207145 has been evaluated in human volunteers.[41,98] Current research efforts mainly focus on the identification of either suitable [^{18}F]-based tracers or selective agonist radioligands such as [^{18}F]MNI698[99] or [^{11}C]-Prucalopride,[100] respectively, but none of them has yet been evaluated in human.



Scheme 8 Selected 5HT1A receptor PET tracers.



Scheme 9 Selected 5HT2 receptor PET tracers.

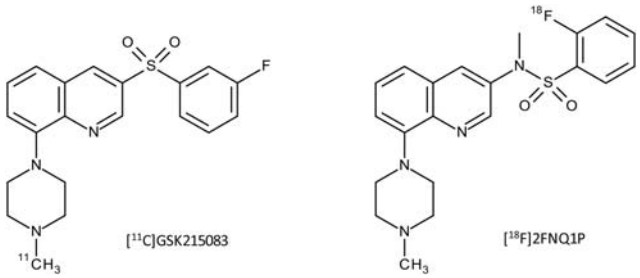


Scheme 10 Selected 5HT4 receptor PET tracers.

*7.02.2.2.2.4.4 5HT6 receptors (**Table 1**, **Scheme 11**)*

5HT6 receptor antagonists are currently in clinical development for the symptomatic treatment of cognitive disorders associated with AD. [^{11}C]GSK215083, however, characterized by a modest approximately fivefold 5HT6/5HT2A selectivity, has recently been evaluated in human subjects in order to better understand the mechanism of action of the 5HT6/5HT2A antagonist SB742457, currently in phase II. The PET studies aimed to delineate its receptor occupancies and the respective contribution of each target in the cognitive enhancing properties of the candidate at the active doses.

Data obtained with [^{11}C]GSK215083 support its use as a suitable 5HT6 imaging marker in human. Saturation of 5HT6 receptors at all doses of SB742457 and a dose-dependent engagement of 5HT2A receptors were observed, suggesting that the blockade of both targets was required to ensure therapeutic efficacy in patients.[42]



Scheme 11 Selected 5HT6 receptor PET tracers.

More selective [^{18}F]-5HT6 radiotracers are also currently being developed but none of them has yet reached clinical trials.[101] [^{18}F]2FNQ1P was recently discovered and evaluated in rats, cats, and macaques and displays encouraging results in terms of specific in vivo 5HT6 binding.[102]

*7.02.2.2.2.4.5 5HT7 receptors (**Scheme 12**)*

5HT7 selective PET imaging probes have not demonstrated applicability in human yet. Several groups have reported their design efforts as well as some biological characterization.[103,104] The most promising selective radioligand so far is [^{11}C]Cimbi-717 characterized by a specific binding in accordance with 5-HT7R distribution, adequate tracer kinetics, and a dose-dependent decline in cerebral binding after receptor blockade by the widely used prototypical selective 5HT7 antagonist SB-269970.[105]

7.02.2.2.2.5 Metabotropic glutamate receptors[106]

Metabotropic glutamate receptors are classified into three groups: group I (mGLUR1 and mGLUR5), group II (mGLUR2 and mGLUR3), and group III (mGLUR4, mGLUR6, mGLUR7, and mGLUR8). Attempts have been made to develop PET ligands for several receptors, covering all three groups.

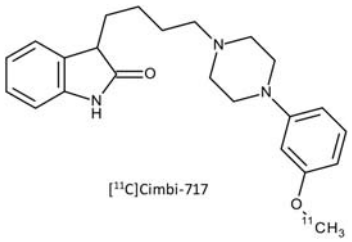
*7.02.2.2.2.5.1 mGLU1 receptors (**Table 1**, **Scheme 13**)*

mGLU1 receptors belong to group I, together with mGLUR5 which is closely related both structurally and functionally but very distinct in terms of brain distribution. mGLUR1 is highly expressed in the cerebellum and implicated in anxiety, mood disorders, stroke, PD, Huntington disease, pain, and schizophrenia.

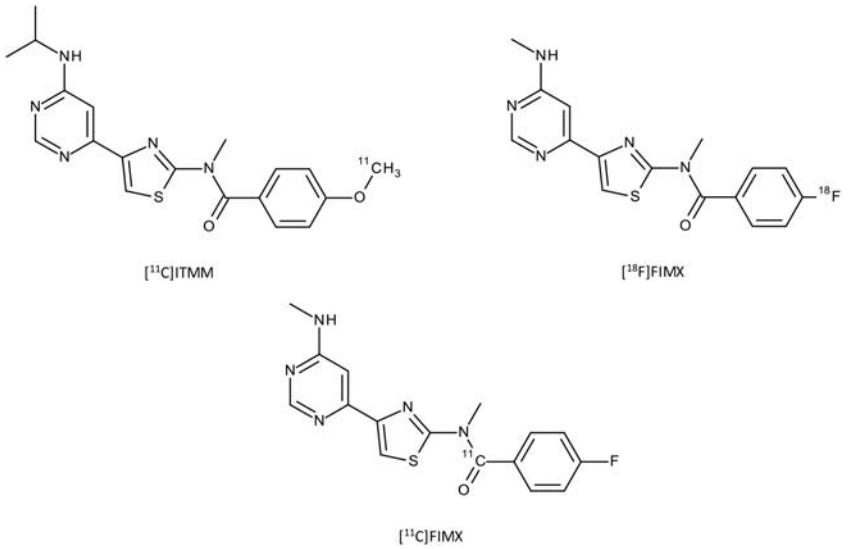
Selective mGLUR1 radioligands have been reported, and as of today, two of them have been validated in human: [^{11}C]ITMM[44,45] and [^{18}F]FIMX.[107,108] The former is, however, characterized by slow kinetics and moderate brain uptake. Dosimetry of [^{18}F]FIMX limits its use to a low number of daily radioligand injections in humans. The development of the [^{11}C] analog was initiated to overcome this limitation and to allow multiple scans per day in the same subject. The overall properties observed in monkeys suggest superiority to [^{11}C]ITMM and a similar profile compared to its [^{18}F]-labeled analog.[109]

*7.02.2.2.2.5.2 mGLU2 receptors (**Scheme 14**)*

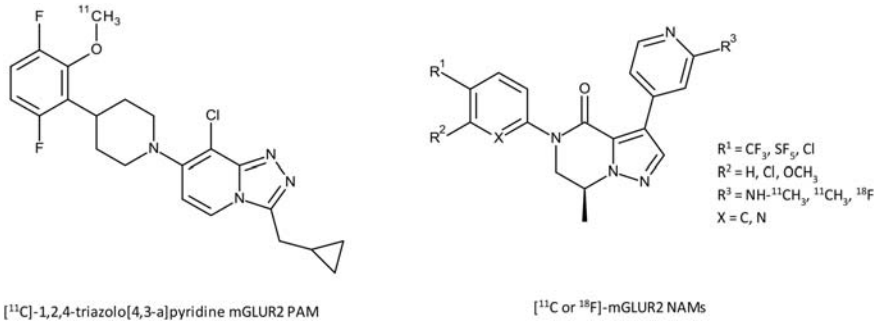
mGLU2 receptors belong to group II and are mainly expressed on presynaptic terminals. mGLU2 stimulation with orthosteric agonists or PAMs reduces excessive synaptic glutamate levels and is therefore a very attractive target to treat positive and negative symptoms in schizophrenia patients.[110] The concept has been validated in patients with LY2140023, an orthosteric dual mGLUR2/3 agonist.[111] Current efforts focus on the discovery and development of PAMs with improved selectivity, a lower tendency to receptor desensitization and only acting "on-demand," in presence of the endogenous glutamate. There are few reports disclosing selective mGLUR2 tracers based upon PAMs.[112] One major challenge is the ability to radiolabel potent and selective cold PAMs to image their specific allosteric binding site. Promising [^{11}C]-labeled PET candidates based on a series of 1,2,4-triazolo[4,3a]pyridine PAMs with adequate potency and selectivity, brain penetration, and biodistribution have been reported.[113] Modulation of mGLUR2



Scheme 12 Selected 5HT7 receptor PET tracers.



Scheme 13 Selected mGLU1 receptor PET tracers.



Scheme 14 Selected mGLU2 receptor PET tracers.

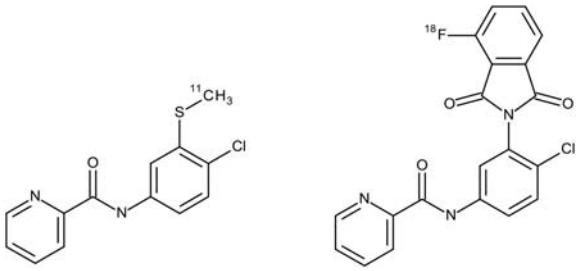
with orthosteric antagonists or negative allosteric modulators offers promise in the treatment of mood and cognitive disorders or autism. [^{18}F] and [^{11}C]-labeled compounds have recently been disclosed.[114]

*7.02.2.2.2.5.3 mGLU4 receptors (**Scheme 15**)*

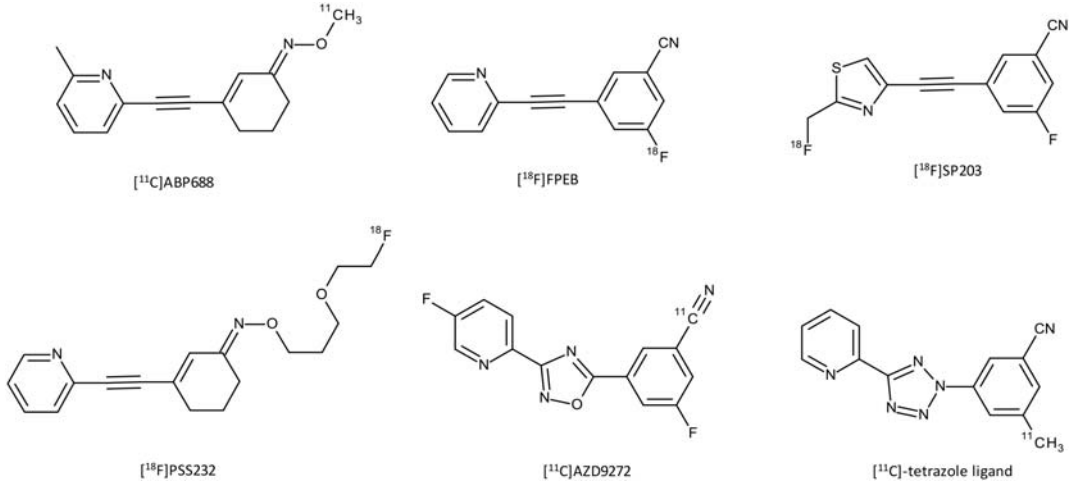
mGLU4 receptors belong to group III and are mainly expressed presynaptically in the striatum, hippocampus, thalamus, and cerebellum. Their activation with either orthosteric agonists or PAMs could have potential benefits in neurological disorders such as PD.[115,116] Numerous mGLUR4 PAMs have been reported triggering the need for the identification of suitable selective radiotracers[117–119] with adequate properties in rats but no PET ligand was found suitable yet for clinical studies.

*7.02.2.2.2.5.4 mGLU5 receptors (**Table 1**, **Scheme 16**)*

mGLU5 receptors (group I) are highly expressed in cerebrum and involved in several neuropsychiatric, neurodevelopmental, and neurological disorders among which Fragile X or Down's syndrome, schizophrenia, PD, Pick's disease, psychosis, or AD are the most recognized. Reviews summarizing state-of-the-art knowledge around mGLUR5 and the development of selective radioligands have been published.[120,121] mGLUR5 is an attractive target for drug development and neuroimaging and provides an interesting mean to study and understand the pathophysiology of multiple glutamate-related CNS disorders, to measure mGLUR5 receptor occupancy of drug candidates, and to aid dose selection. Selective tracers have been developed and tested in humans. [^{11}C]ABP688,[46,122] [^{18}F]FPEB,[47] and [^{18}F]SP203[123] are the most widely used and are characterized by suitable tracer kinetics and dosimetry but test–retest studies have been reported to be poorly reproducible for [^{11}C]ABP688.[124] Individual differences due to glutathione trapping of the alkyne moiety might explain the variability. Nonalkyne tracers such as [^{11}C]AZD9272,[48] which have been evaluated in human volunteers, have been disclosed. In addition, further lead optimization has allowed the identification of tetrazole ligands with promising properties including reliable test–retest studies.[124] Promising [^{18}F]-labeled tracers such as [^{18}F]PSS232[125] have also been reported but display significant defluorination in vivo. All of the PET tracers reported to date behave as mGLUR5 negative allosteric modulators, thus no studies have reported the development of mGLUR5 PAM tracers.



Scheme 15 Selected mGLU4 receptor PET tracers.



Scheme 16 Selected mGLU5 receptor PET tracers.

7.02.2.2.2.6 Adenosine receptors

An exhaustive overview of adenosine receptor PET tracers was published in 2007.[126] PET tracers for human use are only available for A1 and A2a receptor subtypes.[127]

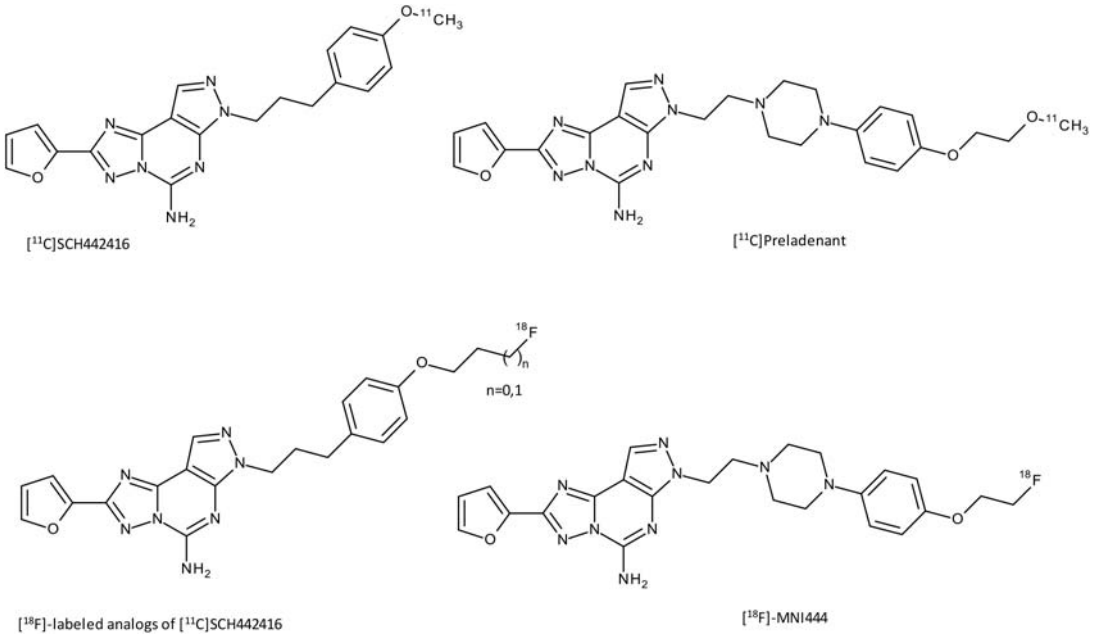
*7.02.2.2.2.6.1 A2a receptors (**Table 1**, **Scheme 17**)*

Initial xanthine-based [^{11}C] tracers were characterized by a low signal-to-noise ratio, high level of nonspecific binding, and multiple and undefined binding sites, causing retention of radioactivity. Nonxanthine ligands usually display superior properties and [^{11}C] SCH442416 was the first nonxanthine PET tracer suitable for A2a receptor mapping.[18] Direct [^{11}C]-labeling of preladenant, a drug candidate recently terminated in phase III due to lack of differentiation, has also been reported but has only been evaluated in rats.[128] More recently, several research efforts have focused on the development of longer half-life [^{18}F]-based selective A2a radiotracers,[129] which potentially offer better regional distribution (striatum vs. cerebellum) and higher brain uptake than [^{11}C] SCH442416, as well as lower nonspecific binding. Similarly, [^{18}F]MNI444 was recently characterized in humans based upon preliminary evaluation in nonhuman primates.[19,130] A study in human volunteers demonstrated its suitability as an imaging A2a radiotracer in human brain thanks to superior kinetic properties and brain distribution, consistent with A2a densities, and allowing cerebellum as a reference region.

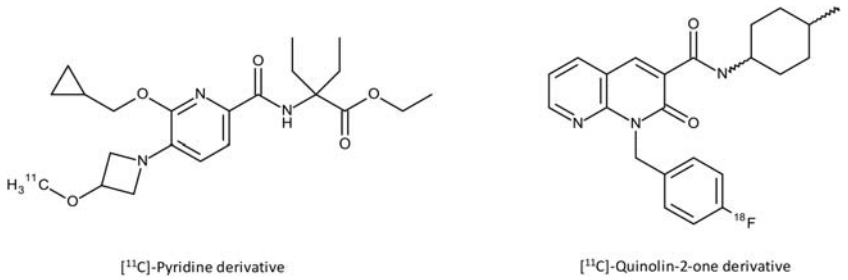
7.02.2.2.2.7 Cannabinoid receptors

*7.02.2.2.2.7.1 Cannabinoid type 2 (CB2) receptors (**Table 1**, **Scheme 18**)*

While CB1 PET tracers are well known and used in clinical development for the imaging of CB1 receptors in several pathologies such as substance abuse disorders or obesity,[21] selective CB2 radiotracers are still in their early days. CB2 receptors, while mainly expressed in immune cells, are also present in the brain, though at lower expression levels, and constitute a promising target for AD[131] or amyotrophic lateral sclerosis (ALS).[132] Numerous publications have reported the discovery of [^{11}C] or [^{18}F]-labeled PET tracers over the last 5 years, such as those shown in **Scheme 18**, and one clinical study has recently been reported with [^{11}C]GW842166.[22,133,134]



Scheme 17 Selected A2a receptor PET tracers.



Scheme 18 Selected CB2 receptor PET tracers.

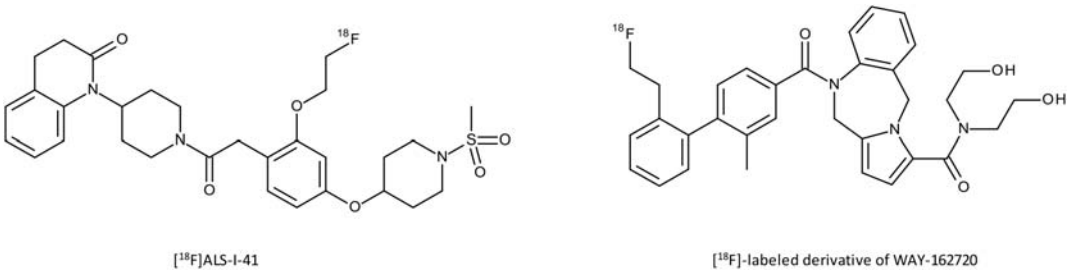
7.02.2.2.2.8 Other receptors

*7.02.2.2.2.8.1 Oxytocin receptor (**Scheme 19**)*

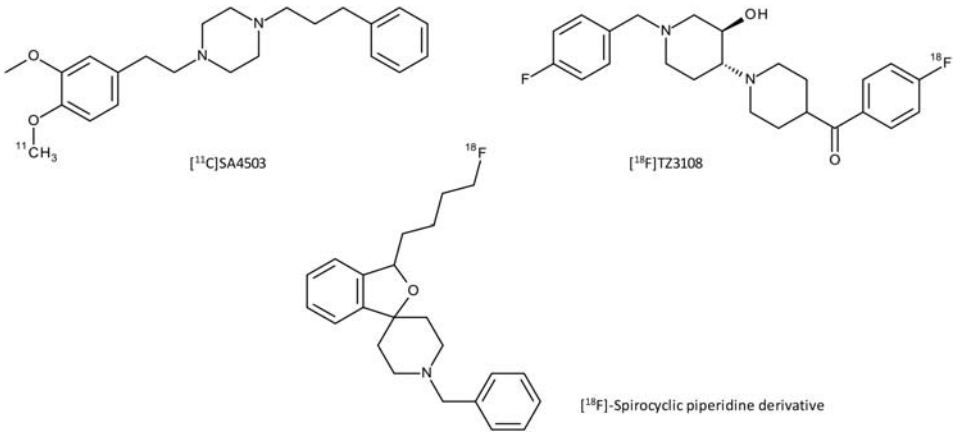
The oxytocin receptors (OXTR or OTR) are neuroendocrine receptors involved in modulating human social behaviors and relationships including cognition in psychiatric or neurological disorders. Neuroimaging of OXTR is of growing importance and could allow the in vivo quantification and precise localization of the receptors in the brain. Only a few papers have reported attempts to identify suitable tracers. [^{18}F] and [^{11}C]-labeled compounds such as [^{18}F]ALS-I-41 or labeled derivatives of WAY-162720 have been identified but none of them was able to display adequate brain penetrance although studies in marmoset have shown that some compounds do seem to cross the BBB, however further investigations are needed to ensure signal specificity.[135–137]

*7.02.2.2.2.8.2 Sigma-1 receptors (**Table 1**, **Scheme 20**)*

Although sigma-1 receptors are not GPCRs but are rather unique integral membrane chaperone proteins with no homology to other receptors, it was felt important to mention them given their important role in several neuropsychiatric and neurodegenerative diseases. Indeed, sigma-1 agonists have shown efficacy in animal models of AD, depression, and schizophrenia, while antagonists display some potential as antinociceptive agents. [^{11}C]SA4503 is the first and only sigma-1 radiotracer approved and evaluated in humans[58,59] and used to quantify sigma-1 receptor density. It displays a widespread distribution in all brain regions of healthy subjects but decreased distribution in brain areas of early AD patients, demonstrating a reduced cerebral and cerebellar sigma-1 receptor density in the early stage of the disease. The absence of a reference region, sigma-1 receptor being expressed in all brain areas, renders its use rather complex for early AD diagnosis, given the need for arterial blood sampling. Although interesting results have been obtained with [^{11}C]SA4503, several groups have recently reported their efforts in the design of [^{18}F]-labeled tracers with longer half-life compared to [^{11}C]-derivatives and displaying better selectivities versus sigma-2 receptor and the vesicular acetylcholine transporter. The testing of a [^{18}F]-fluorobutyl spirocyclic derivative[138] or of [^{18}F]-TZ3108[139] in rats or nonhuman primates has



Scheme 19 Selected OXT receptor PET tracers.



Scheme 20 Selected sigma-1 receptor PET tracers.

shown promising profiles, characterized by specific brain uptake, high selectivity, and non-brain-penetrant radiometabolites. However, no further development has been reported.

7.02.2.3 PET Tracers Targeting Enzymes

Although historically focus was placed on the imaging and detection of neuroreceptors such as GPCRs, probing enzymes and enzymatic processes in the brain is of utmost importance. However, the development of PET tracers has proven to be much more challenging than expected since enzymes are often characterized by too low catalytic rate for the production of enzymatic products within the time limits of PET detection. Progress in the discovery of suitable high-affinity inhibitors as potential tracers has permitted scientists to monitor several key processes in the brain such as protein or neurotransmitter synthesis or metabolism, cell proliferation or to study intracellular systems.[140]

The following section will focus on some recent developments in the field, and particularly on the imaging of selected kinases and phosphodiesterase subtypes.

7.02.2.3.1 Tracers in clinical use

See Table 2.

7.02.2.3.2 Recent developments

7.02.2.3.2.1 Phosphodiesterase inhibitors

Phosphodiesterases (PDE) are a class of enzymes which catalyze the hydrolysis of phosphodiester bonds of 3′,5′-cyclic adenosine monophosphate (cAMP) and/or cyclic guanosine monophosphate (cGMP), two key secondary messengers involved in numerous intracellular downstream signaling pathways from GPCRs. About 50 different PDE isoforms have been grouped into 11 subfamilies (PDE1-11) according to their amino acid sequence, kinetic properties, or substrate. PDE4 and PDE7 display cAMP-selectivity, PDE5, 6, and 9 are cGMP-specific, while PDE1, 2, 3, 10, and 11 are able to hydrolyze both types of cyclic nucleotides with similar affinity.[155] The development of selective PDE1-11 inhibitors has been the subject of intense research efforts over the last decades and several suitable PET radiotracers of PDE enzymes have been identified and were recently reviewed.[156] In particular, and given the importance of PDE2,[157] 7, and 10 in several brain diseases, those specific radiotracers will be briefly discussed hereafter.

Table 2 CNS radiotracers used in human studies for enzymes

Molecular target	*^{11}C-labeled ligand*	*^{18}F-labeled ligand*	*Selected references*

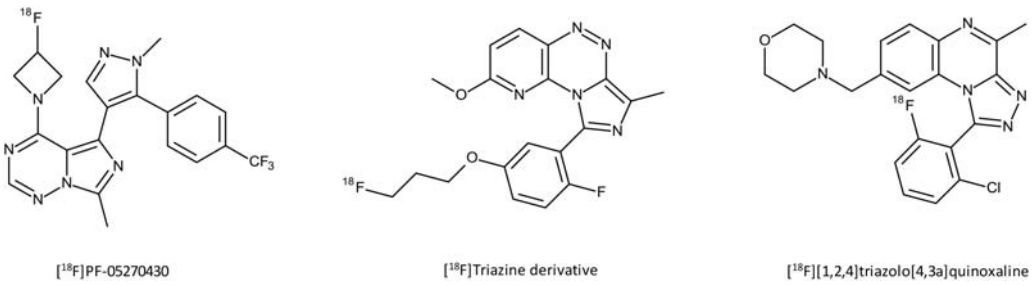
*7.02.2.3.2.1.1 PDE2A (**Table 2**, **Scheme 21**)*

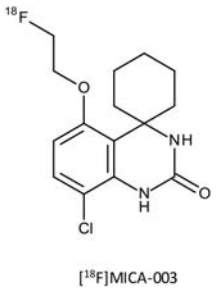
PDE2A is mainly expressed in limbic area and basal ganglia. Increased levels of cyclic nucleotides in these regions, through selective PDE2A inhibition, could be of importance for cognitive processes. Only a few reports deal with the identification of selective PDE2A PET ligands. [^{18}F]-Triazine derivatives[158] were recently disclosed but are not suitable for in vivo imaging purposes due to the formation of brain-penetrant radiometabolites accumulating in reference regions such as the cerebellum. Imidazo[5,1f]-[1,2,4] triazines,[159] among which [^{18}F]-PF05270430 was tested in cynomolgus monkeys and recently in humans, were also reported.[150] Consistent with reported PDE2A distribution, high uptake of [^{18}F]-PF05270430 was observed in striatum and low uptake in cerebellum and no defluorination was detected. The signal in striatum was dose-dependently blocked by a reference PDE2A inhibitor. Low-binding potential in humans is nevertheless observed. [1,2,4]Triazolo[4,3a]quinoxalines[160] were also reported in a patent application but are lacking selectivity and also bind to PDE10A with high affinity.

*7.02.2.3.2.1.2 PDE7 (**Scheme 22**)*

PDE7 is, together with PDE4, a cAMP-specific PDE subtype. PDE7 inhibitors might therefore advantageously replace PDE4 inhibitors which are characterized by proemetic properties limiting their clinical use. Beyond the well-known potential in inflammatory and T-cell driven diseases, selective PDE7 inhibitors have been shown to improve motor function and induce some level of



Scheme 21 Selected PDE2 PET tracers.



Scheme 22 Selected PDE7 PET tracer.

neuroprotection in animal models of PD.[161] Additional potential benefits in drug or alcohol-addiction disorders have raised the interest in PDE7 and triggered the need to identify a suitable PET tracer in order to quantify PDE7 in the brain, to delineate the role of PDE7 in neurological disorders, and to support the development of selective inhibitors. Only one group has reported the design and synthesis of a [^{18}F]-labeled tracer, [^{18}F]MICA-003, based on a spiroquinazolinone scaffold. Despite favorable kinetics and homogenous distribution in the brain, in vivo evaluation in mice nevertheless indicated the presence of [^{18}F]-fluoroethanol as a major brain-penetrant radiometabolite, therefore impairing PDE7 quantification and further development.[162]

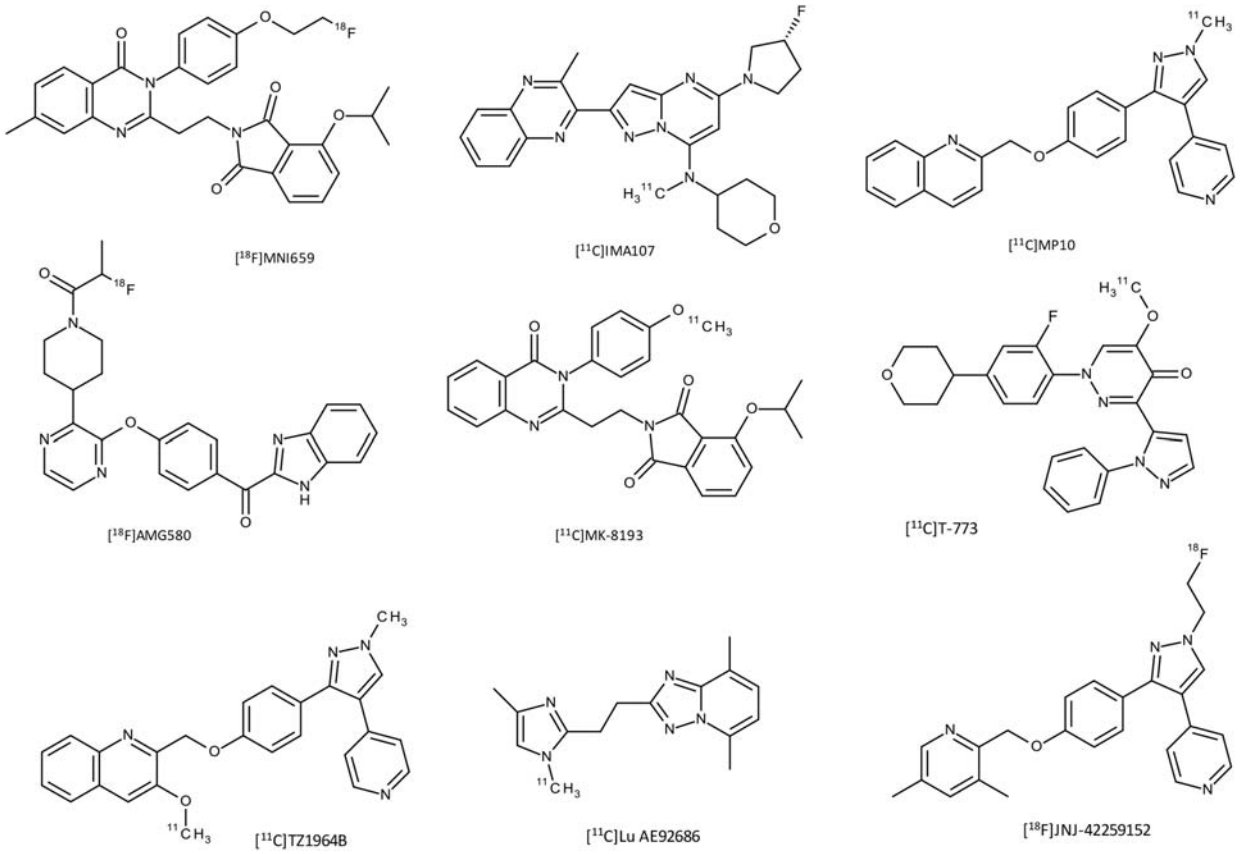
*7.02.2.3.2.1.3 PDE10A (**Table 2**, **Scheme 23**)*

PDE10A is a dual cAMP/cGMP hydrolyzing enzyme which has triggered considerable interest over the last few years thanks to its high expression in the brain and in particular in the striatal medium spiny neurons in conjunction with its relatively low expression in periphery. Selective PDE10A inhibitors could therefore play a major role in several pathophysiologies such as schizophrenia, Huntington's disease, or addiction.[163–166] A high therapeutic potential combined with an optimal target density and restricted distribution in the brain, facilitating strong PET signals, has triggered a lot of interest from pharmaceutical companies and academic groups.

Several PET tracers are currently used in clinical development. Recently, [^{18}F]MNI659 demonstrated that a PDE10A radiotracer could be a useful biomarker of striatal neurodegeneration in patients with early Huntington disease.[152] [^{11}C]IMA107 was also reported to be particularly promising after first-in-human studies based upon direct comparison with [^{11}C]MP10[167,168] in baboons.[153] [^{11}C]IMA107 was recently evaluated in patients with chronic schizophrenia in order to assess PDE10A brain expression in comparison with healthy subjects. Results did not show any significant correlation between [^{11}C]IMA107 binding potential and the severity of the psychotic symptoms and no alteration of PDE10A in schizophrenic patients was found.[154] [^{18}F]AMG580 was discovered by scientists at Amgen and hold promises for human use.[169,170] [^{11}C]MK-8193,[171,172] [^{11}C]T-773,[173,174] [^{11}C]TZ1964B,[175] [^{11}C]Lu AE92686,[176] [^{18}F]JNJ-42259152, and [^{18}F]JNJ-42071965[177–179] were also reported as promising ligands.

7.02.2.3.2.2 Kinase inhibitors

While the development of PET ligands to support the development of kinase inhibitors and to monitor enzymes densities in oncology is a fast-growing field with several clinical studies ongoing, in vivo PET imaging in neurology and neuro-oncology appears much more complex to tackle. In addition to the usual requirements needed for successful PET ligand design, subnano- or



Scheme 23 Selected PDE10 PET tracers.

picomolar affinity for the kinase target is needed, representing a particular challenge in the case of ATP-competitive kinase inhibitors with low $K_{M,ATP}$ values. Furthermore, the use of kinase PET radiotracers beyond tumor imaging or biodistribution studies might be limited and challenging to interpret since most kinase inhibitors lack sufficient selectivity for a large part of the kinome. Brain penetration is another key element to consider, knowing that numerous kinase inhibitors are characterized by suboptimal physicochemical properties such as polar surface area, or lipophilicity and/or interactions with ABC transporters (e.g., P-glycoprotein) which impair BBB penetration and foster nonspecific binding. Finally, huge variations in $K_{M,ATP}$ values between ATP-competitive kinases, differences between Type 1 and Type 2 inhibitors, in terms either of residence time and selectivity or binding mode and interactions with the DFG motif and the associated requirement for polar groups, render the development of PET tracers quite challenging. Advances in the field of kinase imaging have been reviewed recently.[180] Several examples are described, in particular in the case of tyrosine kinase (e.g., Trk inhibitors)[181–183] and serine/threonine kinase inhibitors which are further detailed hereafter.

*7.02.2.3.2.2.1 Glycogen synthase kinase 3 (GSK-3) (**Scheme 24**)*

GSK-3 is a serine/threonine kinase family member. It has two isoforms (α and β) and is involved in glycogen metabolism. Interest in the development of selective GSK-3 inhibitors was triggered by its high abundance in the brain and its implication in the pathogenesis of several neurological and neurodegenerative diseases. It is indeed known to phosphorylate Tau which has been liked to AD and is therefore associated with the progression of tauopathies. There is an important need for suitable in vivo quantification and an early diagnostic tool to allow the measurement of target engagement of novel GSK-3 inhibitors, to help their development.[184] The first reported potential PET tracers, [^{11}C]AR-A014418[185] and [^{11}C]PyrATP-1,[186] were not able to cross the BBB according to autoradiography experiments in rats, despite apparent favorable in vitro properties. Two recent papers have disclosed the identification and preclinical characterization in rodents and nonhuman primates of two promising brain-penetrant ATP-competitive GSK-3 PET tracers, [^{11}C]SB-216763[187] and [^{11}C]PF-367.[188,189] Both display single-digit nanomolar GSK-3 affinity, high selectivity, and uniform brain distribution, consistent with the ubiquitous enzyme distribution throughout all brain areas. However, no human studies have been reported to date.

*7.02.2.3.2.2.2 Rho-kinase (**Scheme 25**)*

Rho-kinase is another serine–threonine protein kinase. In addition to considerable interest in many peripheral disorders, it may also be involved in the pathogenesis of several neurological diseases such as AD, stroke, and ischemia–reperfusion injury. *N*-[^{11}C]methyl-hydroxyfasudil was designed based on hydroxyfasudil, a major active metabolite of fasudil, a known ATP-competitive Rho-kinase inhibitor developed for the treatment of ischemic stroke. It showed widespread distribution but low-level radioactivity in mouse brain. Data in a mouse cold brain injury model suggest that it binds to the active form of Rho-kinase. Insufficient binding affinity and low lipophilicity, hence the low brain penetrance of *N*-[^{11}C]methyl-hydroxyfasudil, impair its use for human purposes and further efforts are required to identify suitable Rho-kinase PET tracers.[190,191]

*7.02.2.3.2.3 Transglutaminase (TG2) inhibitors (**Scheme 26**)*

TG2 is an ubiquitously expressed calcium-dependent transglutaminase. It is involved in the formation of toxic protein aggregates through inter- and intramolecular crosslinking and potentially in several neurodegenerative disorders such as Parkinson's disease,

[^{11}C]-TG2 inhibitor

Scheme 26 Selected TG2 PET tracer.

Huntington's disease, and AD.[192,193] The first example of a selective [^{11}C]-radiolabeled TG2 inhibitor was recently reported.[194] However, the brain uptake was nevertheless very low in rats, impairing further CNS use.

7.02.2.4 PET Tracers Targeting Ion Channels

Ion channels are membrane proteins which control the flow of ions through the cell membrane in almost all living species. Despite the fact that a large number of ion channels are known, only a few have been thoroughly studied and even less have seen the development of successful PET tracers for clinical application, namely only the γ-aminobutyric acid–benzodiazepine receptor (GABA-A) and the nicotinic acetylcholine receptor (nAChR), both of which are ligand-gated.[195] Therefore, PET imaging of neuronal ion channel-linked receptors should be a developing area of preclinical and clinical research in the coming years.

The following section will briefly review the most recent clinical application of GABA-A and nAChR PET tracers and will discuss some of the challenges faced to develop a successful PET tracer of a third important class of ion channel receptor, namely the *N*-methyl-D-aspartate (NMDA) receptor. P2X7, another ion channel recently investigated for PET imaging, will be discussed in the neuroinflammation section.

7.02.2.4.1 Tracers in clinical use

See **Table 3**.

7.02.2.4.2 Recent developments

7.02.2.4.2.1 Neuronal nAChR

*7.02.2.4.2.1.1 α4β2-nAChR[197205] (**Table 3**, **Scheme 27**)*

Neuronal nAChRs are involved in many neurological processes and have been implicated in several neurodegenerative diseases, including AD, PD, and multiple system atrophy (MSA), as well as in epilepsy, depression, schizophrenia, and dementia.

Five PET radiotracers, one ^{11}C-labeled, [^{11}C]nicotine, and four ^{18}F-labeled, [^{18}F]2-FA, [^{18}F]6-FA, [^{18}F]Flubatine, and [^{18}F]AZAN have been used for imaging the α4β2 subtype in human. Although an ideal PET ligand for this receptor subtype has not yet been definitively established, [^{18}F]2-FA has been extensively used in recent years for clinical studies in AD, PD, and schizophrenia.[196,206] More recently, two novel α4β2 selective PET tracers, [^{18}F]Flubatine and [^{18}F]AZAN, have been developed and validated in human.[198,199,207] The first data in human suggest that they display very favorable characteristics, including better kinetics than [^{18}F]2-FA, warranting further investigation with these novel tracers. More recently, [^{18}F]Nifene and [^{18}F]Niofene, two analogs of [^{18}F]2-FA, have demonstrated improved kinetics over [^{18}F]2-FA in preclinical studies.[208,209] However, these tracers have not yet been assessed in clinical studies but their improved kinetic profile may bring benefit compared to [^{18}F]2-FA.

*7.02.2.4.2.1.2 α7-nAChR (**Table 3**, **Scheme 28**)*

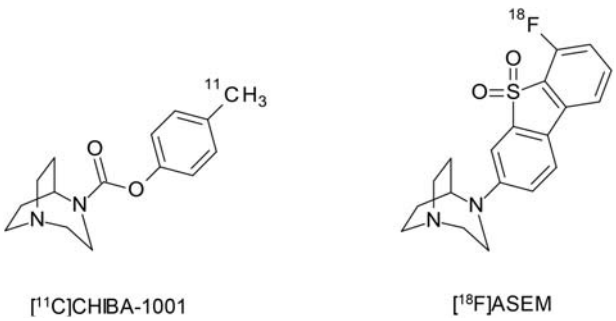
Agonists of the α7-nAChR have been developed as potential therapeutic drugs for diseases such as schizophrenia disease and AD. Therefore, an α7-nAChR selective PET tracer to measure receptor occupancy in the living human brain is of high interest for the pharmaceutical industry. Although much effort has been devoted to create specific PET radioligands for the α7-nAChR, only [^{11}C]CHIBA-1001 and [^{18}F]ASEM are currently available for clinical studies.

Although [^{11}C]CHIBA-1001 has a high level of nonspecific binding in the human brain, it has been used to measure the target occupancy of two antagonist drug candidates;[200] however, a novel tracer with lower nonspecific binding would be required for more accurate occupancy measurements. More promising preclinical and clinical human brain imaging data have been reported recently with [^{18}F]ASEM which may be the first highly specific α7-nAChR radioligand available for human PET imaging.[201,202]

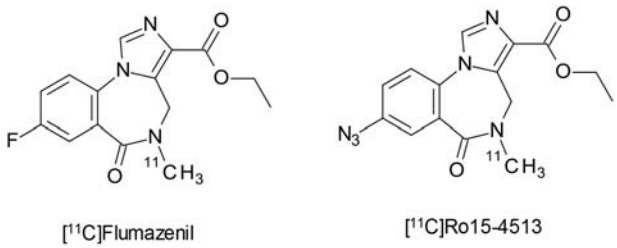
*7.02.2.4.2.2 γ-aminobutyric acid A–benzodiazepine receptor (GABA-A—BZR)[203] (**Table 3**, **Scheme 29**)*

GABA-A is a ligand-gated ion channel found on most neurons in the brain. The GABA-A ion channel has been reported to be a potential marker of various pathological conditions, such as PD, Huntington's chorea, AD, and epilepsy. The benzodiazepine binding site is an allosteric modulatory site on the GABA-A ion channel. Many different chemotypes can bind to this allosteric site and this is the binding site of all GABA-A PET tracers used to date. There are six subtypes of the GABA-A ion channel and, except for the tracer [^{11}C]Ro15-4513, which exhibits some selectivity for the α5 subtype, all available other tracers are nonselective.[203]

Currently, the most widely used GABA-A PET tracer is still [^{11}C]Flumazenil, despite its radiolabeling with ^{11}C. In particular, it has been used recently to quantify the GABA-A ion channel in the brain of Fragile X patients.[204] By contrast to Flumazenil which is not selective for the various subtypes of GABA-A, [^{11}C]Ro15-4513 has a higher affinity for the α5 subtype. The first human PET data indicated that [^{11}C]Ro15-4513 can be used to explore the functional role of this subtype in humans.[210,211]



Scheme 28 Structures of the only two α7 tracers used in clinics.



Scheme 29 Structures of some flumazenil-based GABA-A PET tracers used in clinics.

Although [^{11}C]Flumazenil is broadly available for PET studies, its radiolabeling with ^{11}C still requires access to a cyclotron for production of ^{11}C. An ^{18}F-labeled tracer would allow a much broader application. ^{18}F-labeling of Flumazenil itself has long been considered unachievable due to the inactivated aromatic ring to perform an aromatic nucleophilic substitution. Therefore, [^{18}F]Fluoroethylflumazenil has been developed to circumvent the radiochemistry issue. Unfortunately, this tracer has lower affinity and faster metabolism than Flumazenil, which limit its use.[203] As discussed in the section addressing radiosynthesis methods, there have been considerable efforts in the last few years to explore novel F-18 labeling methodologies to broaden the chemical space of substrates that can be radiolabeled. The use of diaryl iodonium salts as labeling precursors has allowed chemists to perform aromatic nucleophilic substitution on unactivated aryl rings. This methodology has been successfully applied to the radiosynthesis of [^{18}F]Flumazenil, thus providing much broader access to this tracer (**Scheme 30**).[212]

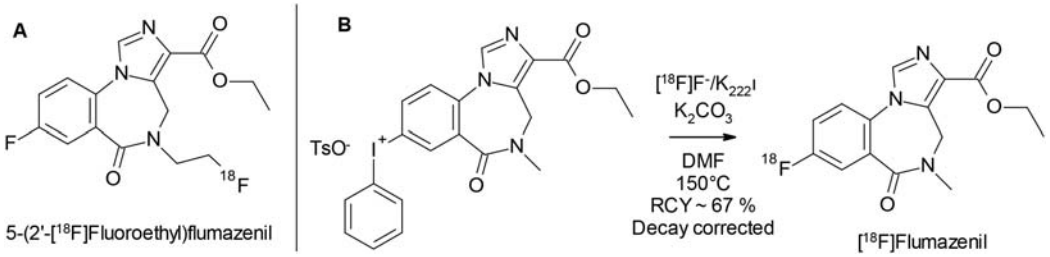
7.02.2.4.2.3 NMDA receptor[213]

Among the ionotropic glutamate receptors, the NMDA subtype plays a key role in processes involving excitatory neurotransmission, including learning, memory, and synaptic plasticity. It has been extensively investigated by many research groups in order to develop a suitable PET tracer for human use. Efforts have been mostly devoted to compounds binding to the channel blocker site, also named phencyclidine (PCP) binding site, as well as to the NR2B-specific allosteric site, often named the ifenprodil-binding site. These efforts have been recently reviewed in several papers.[195,213] Unfortunately, to date, no suitable PET tracer for human PET imaging of the NMDA receptor has been identified, thus further improvements are necessary before a satisfactory PET radiotracer is developed. Low brain penetration has been a significant challenge for most tracer candidates developed for the PCP-binding site while lack of selectivity, especially over the sigma-1 receptor, has been a recurrent issue for compounds targeting the ifenprodil-binding site.

7.02.2.5 PET Tracers Targeting Transporters

In the past two decades, due to their implication in a broad range of neurological and neuropsychiatric conditions, transporters of neurotransmitters have been extensively investigated as targets for the developments of PET imaging tracers. In order to develop suitable PET tracers for human use for most of these transporters, several recurrent challenges had to be solved. A prominent challenge has been selectivity and to some extent is still an issue, for example, for dopamine transporter (DAT) tracers. Due to the high affinity required for these PET tracers, achieving a suitable kinetic profile (i.e., achieving equilibrium in timeframe compatible with the half-life of PET radioisotopes) has also been a significant challenge. Finally, as described later, researchers are still struggling to develop an ^{18}F-labeled version of some of the early tracers developed using ^{11}C and further work may still be required to identify suitable ^{18}F tracers for these transporters.

The following section will review the challenges and advances during the last 5 years in order to make available specific ^{18}F-labeled PET tracers of neurotransmitter transporters for broad clinical use.



Scheme 30 (A) Structure of [^{18}F]Fluoroethylflumazenil; (B) recent improvement of the synthesis of [^{18}F]Flumazenil.

7.02.2.5.1 Tracers in clinical use

See Table 4.

7.02.2.5.2 Recent developments

7.02.2.5.2.1 Dopamine transporter (DAT) (Table 4, Schemes 31 and 32)

Imaging of the presynaptic DAT has been widely used in PD patients over the last 2 decades and has been mainly performed using SPECT.[233] Although SPECT imaging is slightly less sensitive and provides lower spatial resolution in human than PET imaging, it has the advantage of being much cheaper and uses longer half-life radioisotopes. Indeed, slow equilibration kinetics has been a major property of early imaging tracers such as β-CIT, preventing the use of the shorter half-life PET radioisotopes (typically ^{11}C and ^{18}F) to perform imaging studies at equilibrium. The most widely used SPECT tracer for DAT imaging is [^{123}I]FP- CIT or [^{123}I]Ioflupane, which has been approved by the FDA in 2011 for clinical imaging of DAT and is commercialized under the brand-name DaTscan™.

Besides the slow equilibration kinetics, the lack of selectivity versus the serotonin transporter (SERT) of early DAT tracers has also been a significant issue. The most widely used tracers to date are not selective and SERT binding may be a confounding factor for image analysis outside of the striatum or in patients receiving selective serotonin reuptake inhibitor (SSRI) medication. Therefore, some research groups have developed and validated new tracers during the last decade in order to fix both the slow kinetics and selectivity issues and some of these tracers have been radiolabeled with PET radioisotopes. Among the most characterized new tracers are [^{18}F]FE-PE2I and [^{18}F]FECNT (Scheme 32).

Both tracers have been tested in healthy human volunteers and in PD patients.[214–217] Both compounds have suitable kinetics allowing accurate quantification using a reference tissue model and are both more selective versus SERT. In particular, [^{18}F]FE-PE2I has excellent selectivity in vivo[234] which should allow its use for DAT quantification in both striatum and substantia nigra,[215] by contrast to the current gold standard [^{123}I]Ioflupane which allows only DAT quantification in striatum.

7.02.2.5.2.2 Norepinephrine transporter (Table 4, Schemes 33 and 34)

PET imaging of the norepinephrine transporter (NET) has a wide range of possible applications in neurology and psychiatry, including diseases such as AD, depression, and attention deficit hyperactivity disorder. A few PET tracers have been developed in the last decade based on the reboxetine template. Among these tracers, [^{11}C]MeNER (or [^{11}C]MRB) and [^{18}F]FMeNER-d2 (Scheme 33) have progressed to human studies and allowed the first in vivo quantification of NET in human as well as the first occupancy

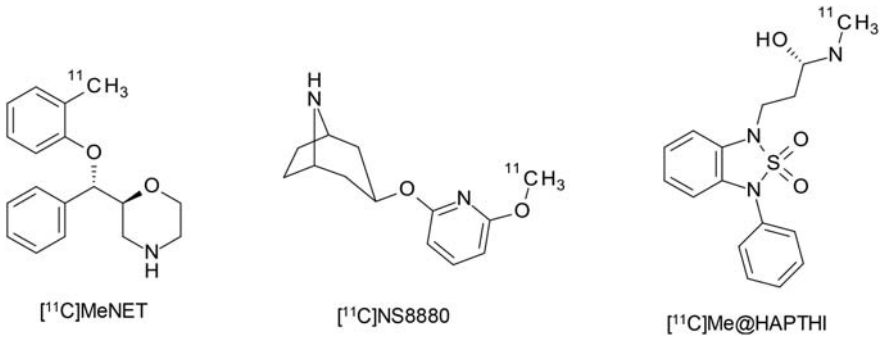


Scheme 34 Novel NET PET tracers.

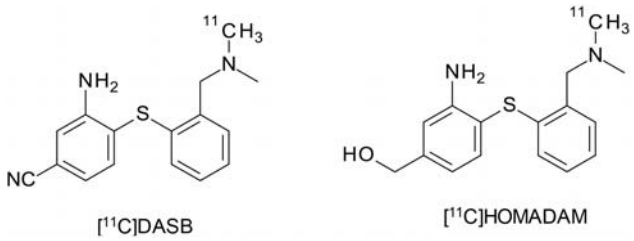
study with methylphenidate.[222,223] However, these tracers suffer from slow kinetics and a quite low specific-to-non-specific binding ratio which leads to suboptimal imaging properties.

These limitations have triggered additional efforts to identify improved NET PET tracers. A few new candidate molecules [^{11}C]MeNET, [^{11}C]NS8880, and [^{11}C]Me@HAPTHI have been reported recently (**Scheme 34**).

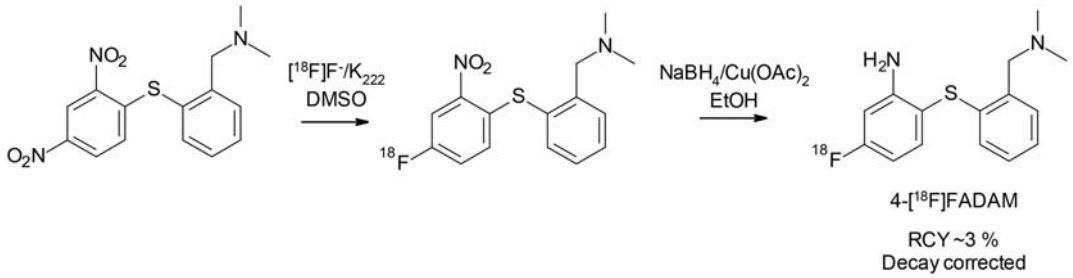
[^{11}C]MeNET is the only one so far to have been tested in humans. It shares the same chemotype as the previous tracers and, although it is reported to have a slightly improved kinetic profile, it has a very similar, low, specific-to-non-specific binding ratio as its previous analogs.[224] By contrast, [^{11}C]NS8880 and [^{11}C]Me@HAPTHI have been developed from novel chemotypes and may therefore bring a different profile. Initial preclinical studies with [^{11}C]NS8880 suggest that it may have an improved kinetic profile but it still has low specific-to-non-specific binding ratio.[235] [^{11}C]Me@HAPTHI has only been characterized in vitro so far and will require more data before any conclusion can be drawn. However, if its pharmacokinetic profile turns out to be suitable, its subnanomolar affinity for NET may eventually lead to an improved specific-to-non-specific binding ratio in vivo.[236]

*7.02.2.5.2.3 Serotonin transporter (SERT) (**Table 4**, **Schemes 35–37**)*

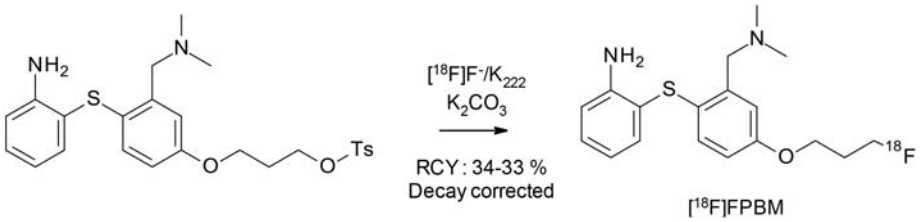
Alterations of the SERT have been implicated mainly in neuropsychiatric disorders such as depression, anxiety, and suicide. SERT is also the target of the SSRI antidepressant drugs. Therefore, SERT PET imaging would enable the measurement of SERT density in these psychiatric disorders[238] and also target occupancy of SSRIs.[239]



Scheme 35 Most widely used SERT tracer [^{11}C]DASB and its analog [^{11}C]HOMADAM.



Scheme 36 Low-yield two-step radiosynthesis of 4-[^{18}F]FADAM.



Scheme 37 Efficient radiosynthesis of [^{18}F]FPBM recently reported.[237]

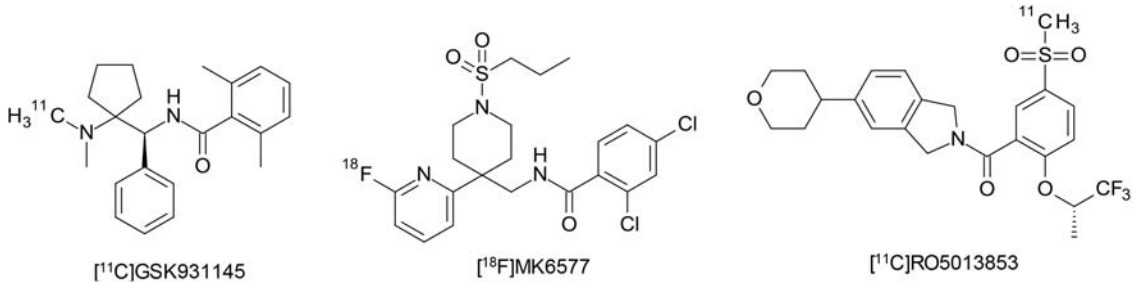
Several successful PET tracers have been developed from the so-called diaryl sulfide chemotype.[225] Among those PET tracers [^{11}C]DASB and [^{11}C]HOMADAM (**Scheme 35**) have been compared in monkey and tested in human and both provide suitable properties to image SERT. The most widely used tracer, [^{11}C]DASB, has excellent selectivity, kinetic profile, and reproducibility allowing accurate quantification. However, its widespread clinical use is limited by the short half-life of its radioisotope.

Therefore, significant efforts have been made more recently to develop an ^{18}F-labeled SERT PET tracer that could facilitate commercial delivery. The only successful ^{18}F-labeled SERT PET tracer reported to date in human is 4-[^{18}F]FADAM.[240] 4-[^{18}F]FADAM showed high-specific binding and a suitable kinetic profile suggesting that it could be used to image SERT in human. However, its radiosynthesis provides very low and unreliable radiochemical yields preventing its widespread clinical use (**Scheme 36**). 4-[^{18}F]FADAM is a typical example of an ^{18}F-labeled PET tracer that would benefit from the development of novel radiolabeling methods as discussed in the section addressing radiosynthesis methods.

[^{18}F]FPBM has been suggested as an alternative ^{18}F-labeled SERT PET tracer and very promising data have been recently reported in cynomolgus monkey, suggesting a high-specific binding and faster kinetics than 4-[^{18}F]FADAM.[237] In addition, an efficient one-step radiosynthesis of [^{18}F]FPBM has been developed that should facilitate its possible translation to human studies (**Scheme 37**).

*7.02.2.5.2.4 Glycine transporter Type 1 (GlyT-1) (**Table 4**, **Scheme 38**)*

The glycine transporter type (GlyT-1) is expressed at glutamatergic synapses throughout the mammalian brain and has therefore been implicated in diseases such as schizophrenia. The current interest by the pharmaceutical industry in developing GlyT-1 inhibitors has led to the demand for a GlyT-1 PET tracer. Such a PET tracer would be useful to support drug development and, in particular, to drive the dose selection for human efficacy studies. Indeed, as efficacy in animal models of schizophrenia has been reported to show an inverted-U shape response dose response curve,[241] adopting a maximum tolerated dose paradigm in a proof-of-concept study may result in GlyT-1 inhibition outside of the efficacious range. Therefore, the support of a suitable PET tracer to measure GlyT-1 occupancy in human and its relationship with the administered dose may be critical for the success of GlyT-1 inhibitors in clinical development.



Scheme 38 Structure of the three GlyT-1 PET tracers used in clinical studies.

Three GlyT-1 PET tracers have recently been developed and characterized in human. While they are all reported to be suitable for target occupancy measurements,[218–220] the test–retest variability of [^{11}C]GSK931145 is much higher and precludes its use for measuring interpopulation GlyT1 differences. Both [^{11}C]RO5013853 and [^{18}F]MK6577 provide lower variability. The better profile of [^{18}F]MK6577 has also been confirmed in a head-to-head comparative study between with [^{11}C]GSK931145 in the same monkey.[221]

*7.02.2.5.2.5 Vesicular monoamine transporter type 2 (VMAT2) (**Table 4**, **Scheme 39**)*

The vesicular monoamine transporter type 2 (VMAT2) is involved in the transport of monoamines from cytosol to presynaptic vesicles of monoaminergic neurons. VMAT2 density is linearly correlated with the integrity of the dopaminergic neurons in the substantia nigra.[242] While at the early stage of PD, other imaging modalities such as aromatic L-amino acid decarboxylase (AADC) and DAT imaging can be affected by compensatory mechanisms, it is reported that VMAT2 availability is less affected by compensatory regulation.[243,244] Therefore, VMAT2 PET imaging may be a better biomarker for the quantification of the presynaptic dopaminergic neurons.

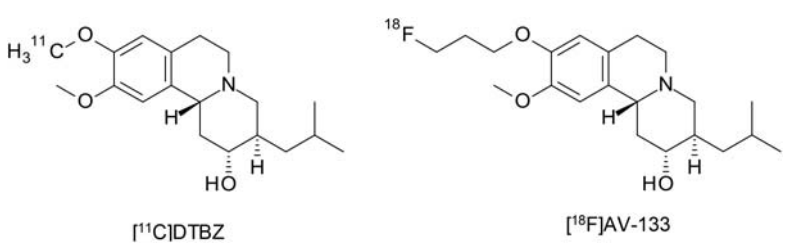
[^{11}C]Dihydrotetrabenazine ([^{11}C]DTBZ) has been reported as a suitable PET tracer for the accurate quantification of the nigrostriatal integrity.[245,246] However, the short half-life of ^{11}C prevents its widespread clinical use. Therefore, [^{18}F]-9-fluoropropyl-(1)-dihydrotetrabenzazine ([^{18}F]FP-DTBZ/[^{18}F]florbenazine/[^{18}F]AV-133) has been recently developed to allow a potential broader commercial use. [^{18}F]AV-133 has high affinity and selectivity for VMAT2, and preclinical and human clinical studies have demonstrated its suitability for quantification of VMAT2 density.[230–232] [^{18}F]AV-133 is currently in phase II clinical development as a potential diagnostic biomarker of PD and PD progression.

*7.02.2.5.2.6 Synaptic vesicle proteins 2 (SV2) (**Table 4**, **Scheme 40**)*

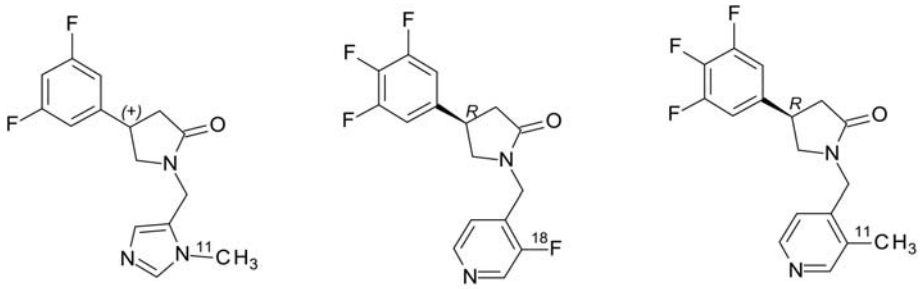
The synaptic vesicle glycoprotein 2A (SV2A) is a 12-transmembrane glycoprotein expressed ubiquitously in synaptic vesicles in all brain areas.[247,248] SV2A is critical for synaptic function, but the exact role of SV2A in neurotransmitter release is still unclear. Mice deficient in SV2A develop seizures and die within 3 weeks of birth, indicating the role of SV2A in epilepsy. To this end, SV2A is the molecular target for the antiepileptic drug levetiracetam (LEV).[249,250] In addition, SV2A dysfunction has been implicated in other neurological disorders such as AD.[251,252]

PET imaging can be used to measure changes in the density of a molecular target in various disease conditions. Therefore, PET imaging of SV2A could be used to measure brain levels of SV2A in patients with epilepsy, AD, or other neurological conditions where SV2A may play a role, and potentially as a biomarker of synaptic density in neurodegenerative disorders. PET tracers can also be used to measure a drug's binding to a target, and so PET imaging of SV2A could be used to characterize binding of SV2A-targeting drugs.

Direct radiolabeling of LEV has been reported[253]; however, its low affinity and slow brain penetration hamper its ability to perform well as a PET tracer. Hence, several high-affinity SV2A ligands that penetrate the brain rapidly have been developed over the last years: UCB-A, UCB-H, and UCB-J.[226]



Scheme 39 Structure of the two most widely used VMAT2 PET tracers.



Scheme 40 CNS radiotracers that have developed for the SV2A protein.

UCB-A has been radiolabeled with C-11 and tested in mini-pigs and rhesus monkeys. Although the tracer shows slow kinetics, preclinical data suggest that it can be used to quantify SV2A expression and to study target occupancy.[254] Further testing in human is required to confirm these preclinical data. UCB-H was radiolabeled with F-18 and displayed good kinetics in rats[227] and nonhuman primates, and acceptable dosimetry in humans.[255] However, its multistep radiosynthesis has proven challenging and will require improvement to broaden its use as tracer. Finally, the most recent ligand, [^{11}C]UCB-J, has been reported as the best-in-class SV2A tracer in nonhuman primates.[228] The first-in-human data were recently reported and confirm the excellent behavior of [^{11}C]UCB-J in healthy volunteers[229] as well as its potential to quantify SV2A density in the human brain.

Quantification of synaptic density is typically performed using immunohistochemical approaches with antibodies that target key proteins located in the proximity to the synapse, such as synaptophysin (SYN) which is present in the membrane of presynaptic vesicles.[256] These methods are, however, limited to in vitro experiments and there is still a need for an in vivo synapse quantification technique. PET imaging in combination with a suitable radioligand for SV2A may allow this goal to be achieved. Synaptic vesicle protein-2 (SV2) is present in all vertebrates and located in the presynaptic vesicle membranes, like SYN. SV2 consists of three isoforms SV2A, SV2B, and SV2AC, with SV2A being the only isoform ubiquitously and homogeneously located in synaptic vesicles across the brain.[247] Thus, PET quantification of the SV2A signal may provide an excellent in vivo surrogate measurement of synaptic density. Thus SV2A PET has the potential to find broad application as a biomarker for research, clinical diagnosis, and therapeutic monitoring purposes in neurodegenerative and psychiatric diseases.[229]

By contrast to SV2A, the SV2C isoform has quite limited distribution and is found primarily in regions such as the basal ganglia and the brainstem but is undetectable in the cerebral cortex and the hippocampus.[257] Two recent studies suggest that SV2C could play a role in the pathogenesis of PD and that SV2C expression might be a useful marker to positively impact on personalized prevention and treatment strategies in PD.[258–260] A recent attempt to develop a PET tracer selective for the SV2C isoform [^{18}F]UCB-F was reported in 2013.[261] Despite the fact that the tracer did not work in vivo due to limited brain penetration and rapid metabolism, the close match between the ex vivo autoradiography binding of [^{18}F]UCB-F and the reported distribution of SV2C suggests that further optimization may lead to a selective SV2C PET tracer.

7.02.2.6 PET Tracers Targeting Aggregated Proteins

Abnormally aggregated proteins, such as β-amyloid, hyperphosphorylated tau, and α-synuclein, are now well recognized to play a major role in the pathology of neurodegenerative disorders such as AD, progressive supranuclear palsy and PD, etc. Therefore, over the past 5 years, they have become the hottest targets for developing novel molecular neuroimaging tracers as well as disease-modifying treatments.

7.02.2.6.1 Tracers in clinical use

See **Table 5**.

7.02.2.6.2 Recent developments

*7.02.2.6.2.1 β-amyloid (**Table 5**, **Scheme 41**)*

Early work with [^{11}C]PIB has demonstrated that β-amyloid imaging strongly correlates with the histopathology of β-amyloid deposits.[262] As a consequence, many efforts have been devoted to develop several β-amyloid PET tracers and over the last years, three of which ([^{18}F]Florbetapir, [^{18}F]Flutemetamol, and [^{18}F]Florbetaben) have obtained approval from the US Food and Drug Administration (FDA) to measure the density of β-amyloid plaques in adults with cognitive impairment who are being evaluated for AD and other causes of cognitive decline.

These tracers are used in the evaluation of AD and dementia, only in combination with other diagnostic tests. Indeed, a positive scan does not establish a diagnosis of AD, but simply means that there is a higher amount of amyloid in the brain compared with an

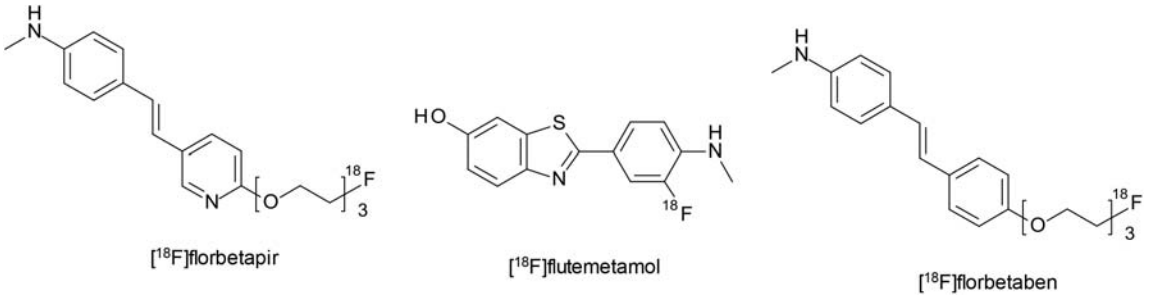

Scheme 41 CNS radiotracers that have used in human studies for aggregated proteins.

age-matched healthy control. A negative scan with these tracers means that there is little or no β-amyloid accumulation in the brain. Consequently, it could be concluded that the cause of the cognitive decline is probably not due to AD, when the β-amyloid PET scan is negative.

Importantly for neuroscience drug discovery, two recent studies have demonstrated that β-amyloid imaging can be applied to enhance patient selection for clinical trials and the monitoring of therapeutic interventions.[263,272] In these two small phase II and phase IB studies with anti-β-amyloid monoclonal antibodies, a positive baseline β-amyloid PET scan was a required entry criterion in order to select appropriate patients. A follow-up scan performed after a few months of treatment demonstrated significant reduction in β-amyloid plaques in the brain of treated patients compared with placebo (**Fig. 3**). These two studies demonstrate the potential of PET imaging to inform the drug development process beyond the historical use of target occupancy assessment. They pave the way for more studies and with novel tracers, therefore enabling better and faster decisions.

*7.02.2.6.2.2 Tau (**Table 5**, **Schemes 42** and **43**)*

More recently, literature evidence has suggested that tau protein aggregates might be more closely related to cognitive decline in AD than β-amyloid deposits.[273–275] Therefore, it is believed that antitau treatments may delay the progression of AD as well as other tau-mediated neurodegenerative diseases. As demonstrated recently, it is expected that tau imaging would promote the establishment of such disease-modifying antitau therapies. This has led to numerous discovery programs aimed at developing a PET tracer that binds selectively to tau aggregates.

Compared with β-amyloid, developing a selective tau tracer is associated with more challenges. First, tau is an intracellular protein, therefore the radiotracer must be able not only to cross the BBB, but also the plasma membrane. Furthermore, due to the heterogeneity of tau (multiple isoforms and posttranslational modifications) in different tauopathies, it is important that the radiotracer can at least bind to both 3R and 4R isoforms in order to be useful to detect tau in several disorders. Another challenge is the secondary β-sheet structure that tau shares with β-amyloid and α-synuclein aggregates. Most tracers reported so far for aggregated proteins are flat, poly-aromatic compounds that are likely to bind to the highly similar core of the β-sheet structure.[276] As a consequence, early tracers such as 2-(1-{6-[(2-[^{18}F]Fluoroethyl)(methyl)amino]-2-naphthyl}ethylidene) malononitrile ([^{18}F]FDDNP) (**Scheme 42**) are reported to bind undistinguishably to β-amyloid and tau aggregates. [^{18}F]FDDNP was proposed as a PET tracer to allow the visualization of tau aggregates in the human brain, but it binds with equal affinities to both senile plaques and neurofibrillary tangles, showing a lack of selectivity for tau over β-amyloid.

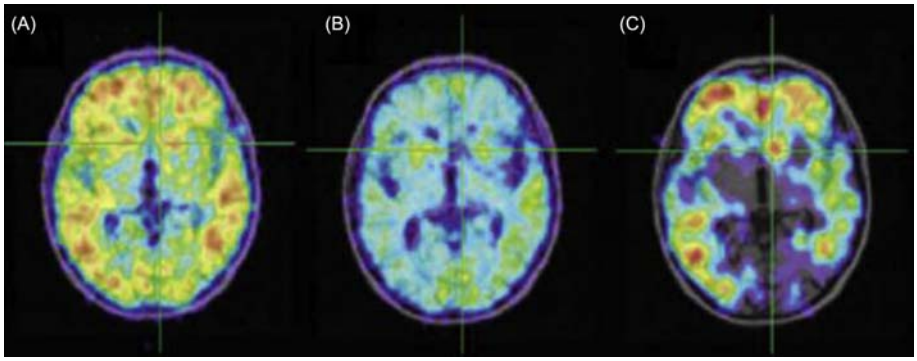

Fig. 3 Overall [^{11}C]PIB SUVR decrease observed in a patient treated with 2 × 200 mg of Gantenerumab. Baseline scan (A), posttreatment scan (B), and difference map (C). Mechanism of Amyloid Removal in Patients With Alzheimer Disease Treated With Gantenerumab. *Arch. Neurol.* **2012**, *69* (2), 198–207.

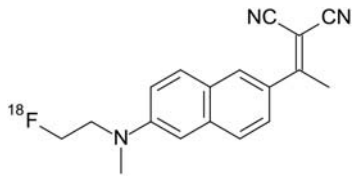
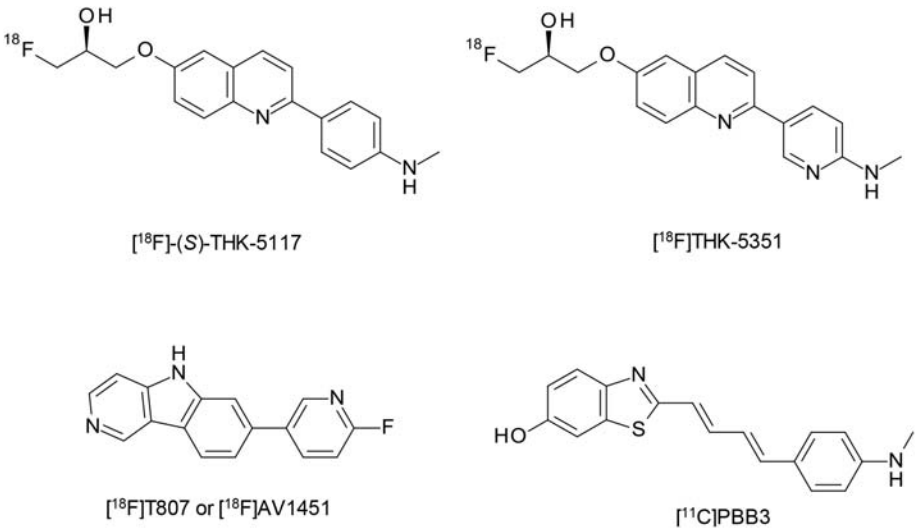


Scheme 42 Chemical structure of the nonselective amyloid tracer [^{18}F]FDDNP.



Scheme 43 Chemical structures of the most advanced known selective tau tracer in clinical development.

Many research groups have focused on developing a tau-selective PET tracer and these efforts have been recently reviewed by several authors.[265–268] Several of these novel tracers (**Scheme 43**) have now entered clinical development and are progressing toward larger phase II studies.

Among the first selective radiotracers that have been tested in AD patients is [^{18}F]T807, now known as [^{18}F]AV1451. This tricyclic pyrido-indole derivative was initially selected for its ability to selectively bind to tau over β-amyloid plaques, its rapid uptake and washout, and low off-target binding to other common central nervous system targets.[277] With several clinical studies in AD and other tauopathies successfully completed,[278,279] it is now progressing in phase II clinical development in AD. However, the binding of this tracer to Tau in other tauopathies is still controversial[269] and some possible off-target binding has been reported, such as binding to the monoamine oxidase (MAO) enzymes[280] and to neuromelanin containing neurons.[281]

Taking into consideration these possible limitations of [^{18}F]AV1451, novel tracers like [^{18}F]GTP-1[282] and [^{18}F]RO6958948[283,284] have recently been characterized in human. The chemical structure of these tracers is still unknown, and the reported data, although encouraging, are still very limited. Additional studies will be required to understand whether these novel tracers may bring any significant benefit compared with AV-1451.

7.02.2.6.3 Future developments

Besides β-amyloid and tau, other proteins are known to form aggregates such as α-synuclein, TDP43, or Huntingtin, and have been implicated in neurodegenerative disorders such as PD, ALS and Huntington's diseases, respectively. To date, no selective PET tracers for these proteins have been reported and would be highly desireable in order to support the accurate diagnosis of these diseases as well the development of disease-modifying therapies.

Fostered by the very high unmet need[285,286] and the support of the Michael J. Fox Foundation,[287] the most active area of research is currently the identification of a selective α-synuclein PET tracer. Many research groups are currently investigating the development of such a tracer, however, only limited data have been reported so far.

The most advanced tracer characterized so far is BF227 (**Table 5**, **Scheme 44**). This tracer has been reported to bind to α-synuclein with low nanomolar affinity[270] and has been tested in a clinical study involving patients suffering from MSA.[271] The published data demonstrated higher distribution volumes in the subcortical white matter, globus pallidus, substantia nigra, and other regions of the brain of MSA subjects compared with controls. However, BF227 is not a selective α-synuclein PET tracer and binds to β-amyloid with very high affinity as well. Therefore, these clinical data should be treated with caution as a significant uptake due to binding to β-amyloid may be a confounding factor.

A recent paper reported [^{125}I]SIL23 (**Scheme 45**) as a novel α-synuclein radioligand with moderate affinity.[288] The molecule binds to α-synuclein aggregates in postmortem brain tissue from PD patients. The density of binding sites of SIL23 correlated with the level of aggregated α-synuclein in PD brain tissue and should be high enough to enable in vivo imaging provided a higher affinity ligand than SIL23 can be identified. Furthermore, high nonspecific binding, likely due to the high lipophilicity, appears to be a limiting factor in the use of SIL23 in autoradiography experiments.

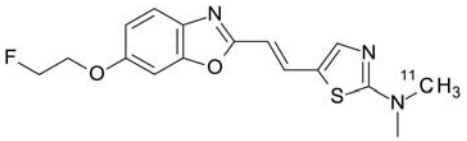
Despite this recent progress and the interest from many research groups, no selective α-synuclein PET tracer has been reported yet and it will be a major challenge for the next few years in order to meet the needs and timelines of therapeutic molecules already in clinical development.[289,290]

7.02.3 Some Present and Future Challenges of PET Imaging

7.02.3.1 Improved Radiosynthesis Methods

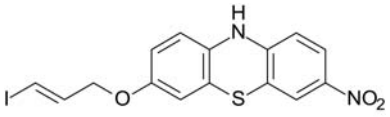
As described in the introduction section, meeting all the medicinal chemistry requirements that make a PET tracer successful is already very challenging and yet PET radiotracer development suffers the additional burden of a limited scope of molecules for which isotope labeling is possible, particularly with ^{18}F.[291–293]

Well-established ^{18}F fluorination methods, now classified as conventional processes, typically rely on thermal activation or the use of highly reactive reagents (e.g., [^{18}F]F_2) for ^{18}F-C bond construction. These fundamental reactions, for example, S_N2, S_NAr, and S_EAr have transformed PET imaging and enable the routine production of the most commonly used tracers in the clinic. [^{18}F]-Fluorodeoxyglucose (FDG) is currently produced by nucleophilic substitution of a triflate leaving group with ^{18}F-fluoride and ^{18}F-DOPA by electrophilic fluoro-destannylation with [^{18}F]F_2. On the other hand, with the increasing demand for new ^{18}F-labeled molecules to improve diagnosis, to progress personalized medicine, and as a tool to facilitate drug discovery, radiochemists are currently facing



[^{11}C]BF227

Scheme 44 Chemical structure of the nonselective α-synuclein tracer [^{11}C]BF227.



[^{125}I]SIL23

Scheme 45 Chemical structure of the a-synuclein radioligand [^{125}I]SIL23.

the challenge of labeling molecules that are not easily within reach using well-established methods for ^{18}F incorporation. This limitation typically leads researchers to design new radiotracers based on what can be labeled, rather than what should be labeled. Fundamentally new fluorination chemistry that is suitable for ^{18}F-fluorination could expand the accessible chemical space for labeling and open the door to new chemical entities for use in PET research, radiotracer discovery, and ultimately clinical imaging.

A first option to contribute to radiotracer structural diversity is to consider the large number of reactions requiring F^+ reagents for C–F bond formation and to develop these pathways for ^{18}F labeling. This strategy presents numerous challenges, not least the production of ^{18}F-labeled F^+ reagents, produced in high-specific activity (**Scheme 46**). The design of innovative chemistry that could transform ^{18}F fluoride into F^+ reagents is an exciting, but notoriously complex, problem that has met today only with limited success.[294]

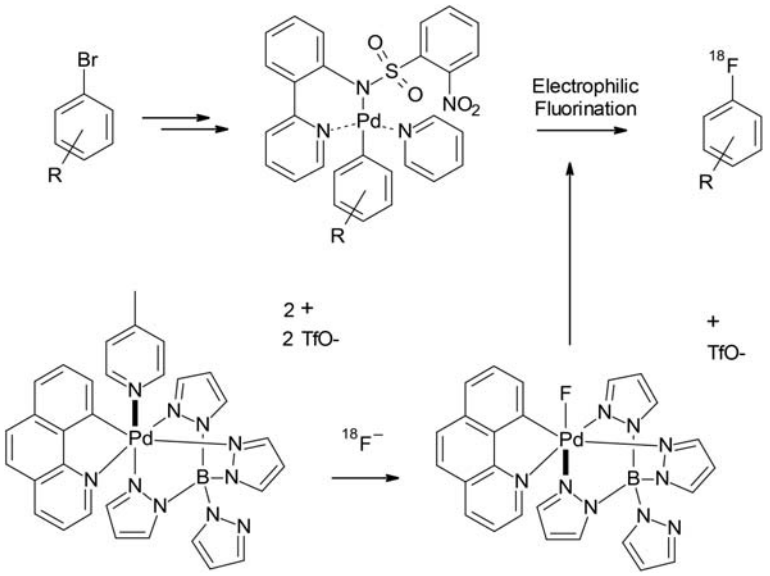
A second option is to expand the substrate scope for the conventional S_NAr using ^{18}F fluoride, in particular toward heteroaromatics and electron-rich aromatics. Recent breakthroughs have emerged with metal activation as a new manifold to induce ^{18}F-C bond formation. Since 2010, a range of metals (Ag, Pd, Ir, Ni, Co, Cu, Mn) have been used to induce ^{18}F incorporation on sp2-hybridized carbons (**Scheme 47**).[295–298] This new era opens the door to a myriad of possibilities considering the number of metal-mediated processes one could consider for ^{18}F-labeling.

The majority of the advances in ^{18}F radiochemistry occurred in recent years have not progressed far beyond fundamental research and the path toward clinical use is still not clear. As an unfortunate consequence, it is therefore difficult to measure the value of these new radiofluorination methods and it will probably not be possible for several more years.

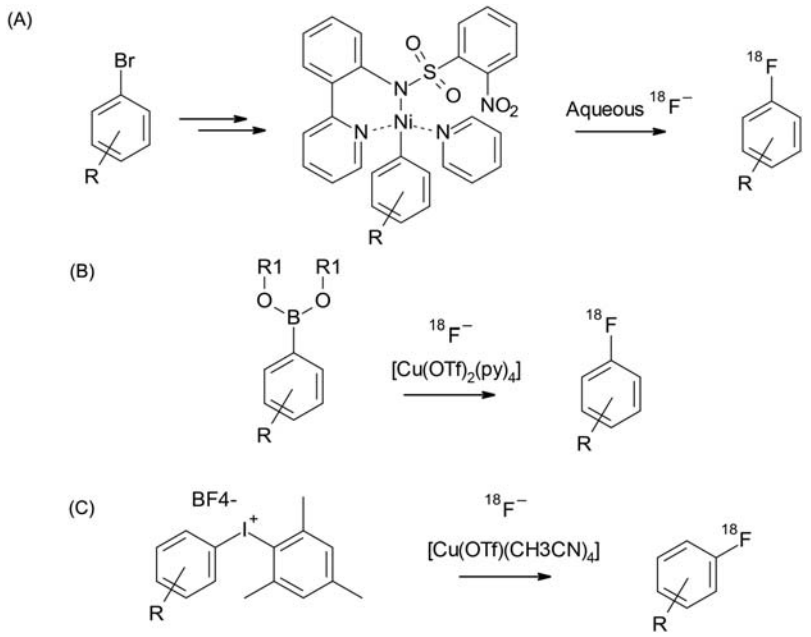
7.02.3.2 Immuno-PET in Neurosciences

In the past decade, antibodies have clearly demonstrated their utility as therapeutics.[299] They provide highly selective and effective drugs to treat a variety of diseases such as oncology, immunology, and autoimmunity. The success of antibody therapeutics validates their ability to find and engage their targets in vivo. More recently, triggered by the huge unmet need for therapeutic options for neurodegenerative disorders, the development of immunotherapeutic approaches targeting β-amyloid, tau, and α-synuclein has received considerable attention.[300,301] However, the antibodies targeting neurodegenerative processes will have to enter the brain in order to achieve the adequate engagement of their target. This is of course a considerable challenge to achieve for an antibody, but it is also a similar challenge to measure the target engagement of the antibody within the brain. Thus, it is not surprising that there is a renewed interest in the utility of imaging agents based on antibodies.

The antibodies have the ability to engage their target with nanomolar or picomolar affinity. The large size of antibodies also allows the conjugation with a variety of cargoes bearing suitable functional groups for molecular nuclear imaging applications, without perturbing their innate specificity and affinity. These properties provide a strong foundation to develop highly sensitive imaging agents. Similar to therapeutic antibodies, these immuno-PET tracers will have to cross the BBB in order to be taken up in sufficient quantity to bind to their target protein and provide good imaging contrast. This will represent the most important challenge to overcome in order to apply immune-PET imaging in neurosciences. The second significant challenge of using monoclonal antibodies as molecular templates for developing PET imaging tracers is their slow kinetics of distribution. Due to their large size, molecular weight, and their high hydrophilicity, monoclonal antibodies have very low volume of distribution leading to slow distribution to tissue, not compatible with short half-life emitting radioisotopes.[302] Monoclonal antibodies have therefore mostly been



Scheme 46 Pd-mediated electrophilic fluorination starting from ^{18}F fluoride.



Scheme 47 (A) Ni-mediated S_NAr of electron-rich aromatics; (B) Cu-mediated S_NAr of electron-rich aromatics from boronic derivatives; (C) Cu-mediated S_NAr of electron-rich aromatics from iodonium salts.

radiolabeled using coordinating positron-emitting radiometals with longer decay half-lives such as ^{64}Cu ($T_{1/2}=12.7$ h), ^{86}Y ($T_{1/2}=14.7$ h), and ^{89}Zr ($T_{1/2}=78.5$ h) allowing to measure antibody uptake in the target tissue up to several days postadministration. However, a major drawback of using these radiometals is a drastic increase of the radiation burden incurred by the subjects. According to the US Code of Federal Regulations Title 21 (21CFR361.1), the whole body radiation dose is limited to 30 mSv for single administration and to 50 mSv for total annual commitment. The typical whole body radiation dose for patients receiving 74 MBq ^{89}Zr is about 40 mSv, which is high and clearly limits the field of possible applications.[303]

In order to meet these important challenges, advanced antibody engineering using either antibody fragments, such as scFv or nanobodies, or bi-specific antibodies bearing an epitope allowing receptor-mediated transcytosis may be required to increase the kinetics and the extent of the distribution in tissue. These approaches have been reviewed by Freise and Wu[304] and Schirrmacher et al.,[305] and the first preclinical experiments recently reported are encouraging (Fig. 4).[306–308] Finally, a pretargeted immuno-PET approach using the bioorthogonal reaction between transcyclooctene and tetrazine has also recently been successfully reported to overcome these challenges.[309,310]

7.02.3.3 Neuroinflammation Imaging Beyond Translocator Protein

Interactions between the brain and the immune system, and their role in the pathophysiology of neurologic diseases, are an area of increased interest to drug developers. Genetic, epidemiologic, clinical, postmortem, and animal model data indicate that interactions between the brain and the immune system modulate the pathophysiology of a range of neurological diseases. In order to advance this area of medicine, imaging tools to measure immune activity in the brain of living humans are needed.

This article focuses exclusively on radioisotope-based imaging; however, it is important to point out that magnetic resonance (MR)-based methods to image neuroinflammation are very important. For instance, gadolinium-based MR can detect BBB breakdown, while MR using labeled iron oxide particles is being developed to detect myeloperoxidase activity, free radicals, metalloproteinases, and endothelial adhesion molecules, and to track immune cell entry into the brain.[311,312]

PET with ^{18}F-fluorodeoxyglucose (FDG) can image inflammation (which is characterized by high metabolism) in peripheral tissues that otherwise have low baseline metabolism, for example, atherosclerosis, vasculitis, and rheumatoid arthritis,[313] but FDG cannot be used to detect inflammation in tissues with high baseline metabolism such as the myocardium and the brain.[314]

See Table 6.

7.02.3.3.2 Recent developments

*7.02.3.3.2.1 Translocator Protein (**Table 6**, **Scheme 48**)*

Currently, the cornerstone of neuroinflammation PET imaging are tracers that bind to the translocator protein (TSPO), a mitochondrial protein that is upregulated in activated microglia and reactive astrocytes. The first-generation tracer ^{11}C-PK11195 is limited by

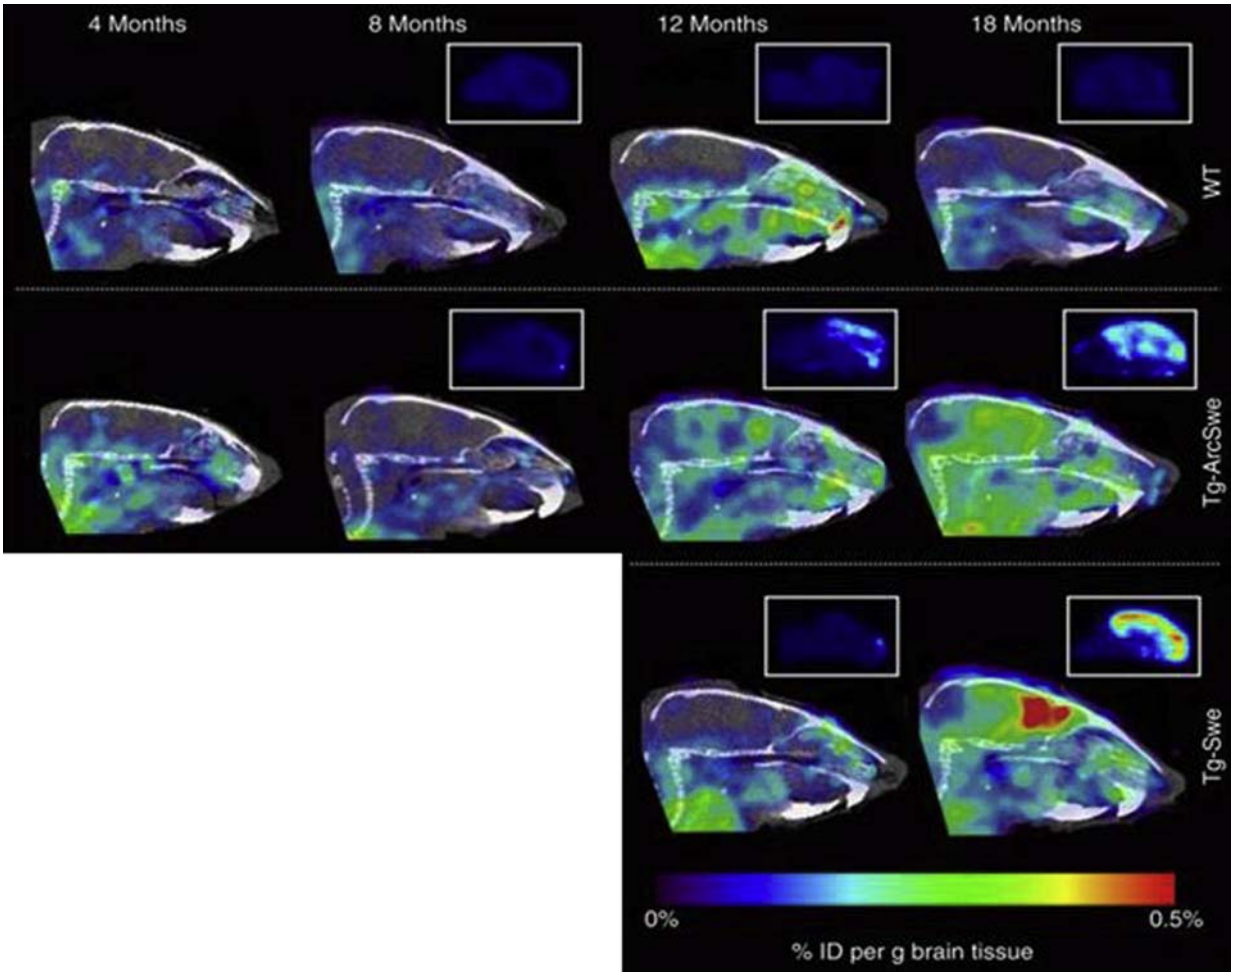

Fig. 4 Comparison of PET images postinjection of [^{124}I]8D3-F(ab0)2-h158 from WT, tg-ArcSwe, and tg-Swe mice of different ages demonstrating progression of Ab pathology.[306] Sehlin, D.; Fang, X.; Cato, L.; Antoni, G.; Lannfelt, L.; Syvänen, S. a low signal-to-noise ratio, but several second-generation TSPO tracers have been developed and validated in humans in the last decade.[315] These new TSPO tracers have greatly improved sensitivity, but, unlike ^{11}C-PK11195, their affinity for TSPO is modulated by a polymorphism in the TSPO gene.[328] Fortunately, this polymorphism can be easily genotyped and taken into account in the image analysis. It has been suggested that the quantification of TSPO binding may be complicated by the existence of a vascular compartment[329]; however, this idea remains controversial.

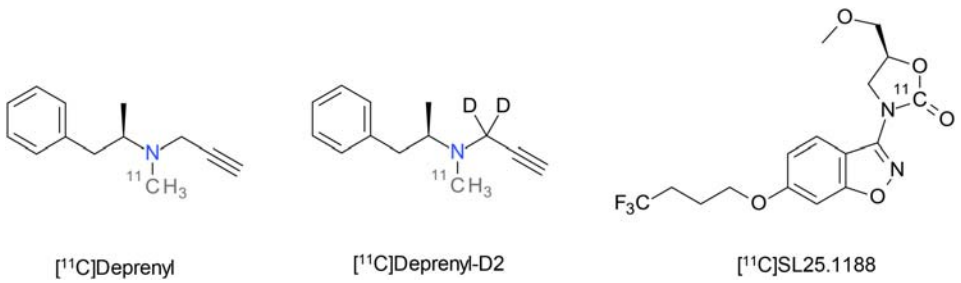
The main limitation of TSPO PET imaging is that it does not distinguish between microglia and astrocytes and probably not between various microglial phenotypes (e.g., M1 vs. M2). In other words, TSPO PET imaging is a gross measure of neuroinflammation that does not provide much information about the underlying molecular processes. New tracers that target more specific activities or cellular markers would be beneficial to further our understanding of immune–brain interactions.

*7.02.3.3.2.2 MAO-B (**Table 6**, **Schemes 49** and **50**)*

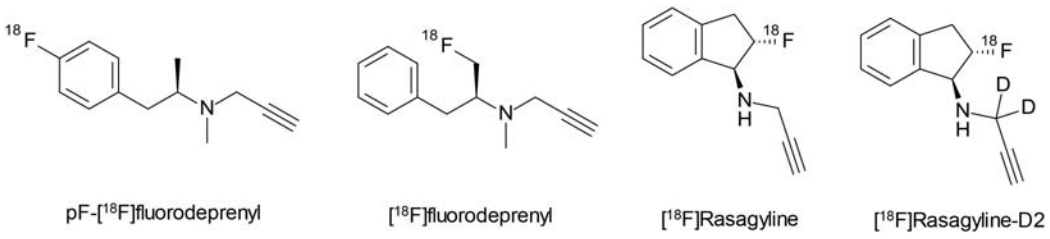
The monoamine oxidase B enzyme (MAO-B) is located in serotoninergic neurons and on the outer mitochondrial membrane of astrocytes. In particular, it has been reported that MAO-B expression is highly abundant in astrocytes with upregulated activity in sites of neuroinflammation.[330] As a consequence, MAO-B has been suggested as a potential PET imaging biomarker of neuroinflammation in neurodegenerative disorders.

Several PET tracers, both reversible and irreversible binders, have been developed to image MAO-B but only two have been validated in human, that is, [^{11}C]deprenyl and [^{11}C]deprenyl-D2 (**Scheme 49**).[331,332]

Deuteration of [^{11}C]deprenyl is required in order to overcome the issue of blood flow delivery dependence of the tracer in brain areas where MAO-B is highly abundant and thus, to achieve a better quantification of this tracer.[333] Another limitation of deprenyl is the ^{11}C-labeling which hampers its availability for large multisite clinical studies in various patient populations. Consequently, some groups have developed ^{18}F-labeled MAO-B PET tracers (**Scheme 50**).[334,335] Some promising results in nonhuman primates have been reported with [^{18}F]rasagiline-D2, but further studies will be required to achieve validation in humans.[336]



Scheme 49 Selected irreversible (Deprenyl) and reversible (SL25.118) MAO-B PET tracers.



Scheme 50 Selected irreversible ^{18}F-labeled MAO-B PET tracers under investigation.

7.02.3.3.2.3 CB2 (see also Section "Cannabinoid receptors") (Tables 1 and 6)

Cannabinoid Type 2 receptor (CB2) agonists have also been investigated as markers of neuroinflammation, including ^{11}C-A836339[316,337] and ^{11}C-RS-016,[317] which, unlike the older ^{11}C-methoxy-Sch225336,[338] have good brain penetration. CB2 PET appears to be a good marker for microglial activation; however, it has the same main limitation as TSPO, that is, it does not provide much information about the underlying molecular processes.

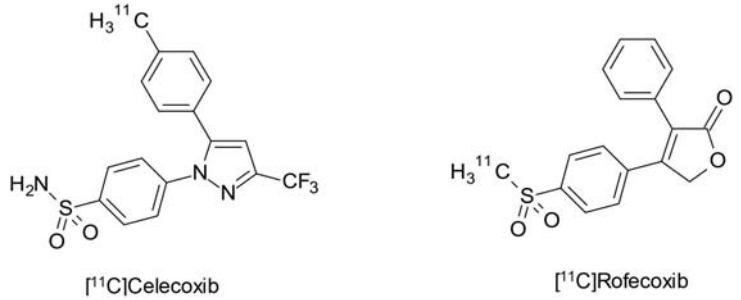
7.02.3.3.2.4 Arachidonic acid turnover (Table 6, Scheme 51)

Cyclooxygenase-2 (COX-2; aka prostaglandin-endoperoxide synthase 2) converts arachidonic acid (AA) to prostaglandins, which are essential mediators of inflammation. Several PET tracers to measure COX-2 activity have been developed (reviewed by Tietz et al.[318]) over the last years; however, so far none of these tracers has suitable imaging properties to allow in vivo studies of COX-2 activity emphasizing again that developing an imaging tracer does not simply involve the introduction of a radiolabeled isotope into a drug molecule.

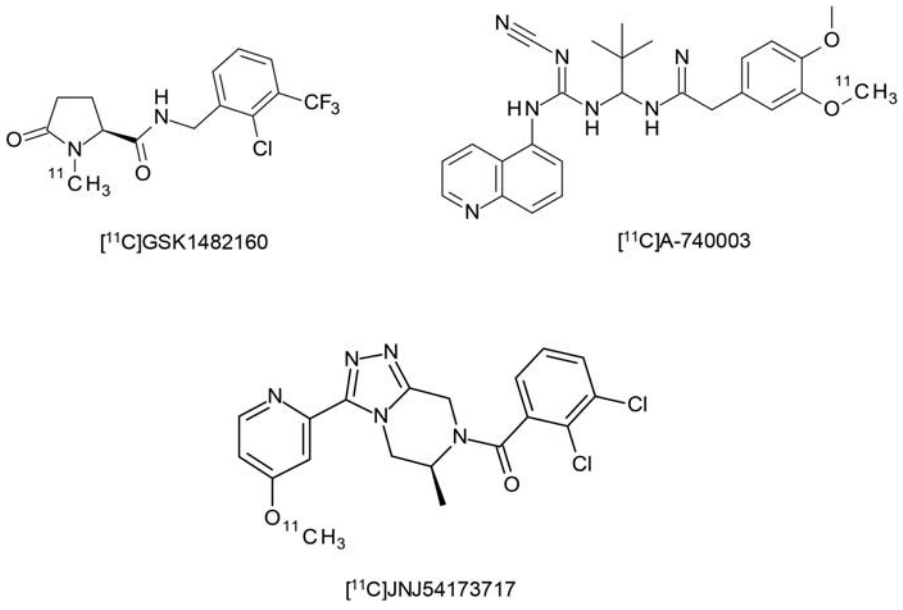
The enzyme monoacylglycerol lipase converts 2-arachidonoylglycerol to AA, which provides a further source for prostaglandin E2 synthesis. A suitable PET tracer for monoacylglycerol lipase, ^{11}C-SAR127303, was recently characterized preclinically.[319] PET tracers that measure AA turnover, for example, 1-[^{11}C]-AA[320] and [^{18}F]-FAA[321] may be useful in understanding changes in AA turnover and its role in inflammation.

7.02.3.3.2.5 P2X7 (Table 6, Scheme 52)

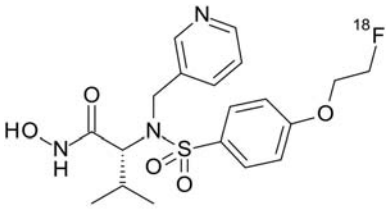
P2X7, which is a member of the ATP-gated ion channel family, plays an important role in inflammation[339] and in neurological disorders associated with inflammation such as PD and AD.[340] Recently, three novel PET tracers have been developed for P2X7. No biological data are reported yet on [^{11}C]-GSK1482160[322] and [^{11}C]-A-740003[323] has very low brain uptake, which prevents analyses of their utility. However, [^{11}C]JNJ-54173717 displays favorable characteristics for in vivo evaluation and will be evaluated in a clinical study in a near future.[341]



Scheme 51 Examples of COX-2 inhibitors unsuitable for PET imaging.



Scheme 52 Recent examples of P2X7 candidate PET tracers.



[18F]fluoro-CGS27023A

Scheme 53 Preliminary attempt to develop a MMP-3 PET tracer.

*7.02.3.3.2.6 MMPs (**Table 6**, **Scheme 53**)*

Matrix metalloproteinases (MMPs) are expressed as a result of inflammation or injury and have been implicated in the pathophysiology of AD[342] and stroke.[343] The MMP-3 inhibitor CGS 27023A has been radiolabeled with ^{18}F for PET and ^{123}I for SPECT imaging,[324,344] but this is still exploratory work and no information yet is available about its performance in the human brain.

*7.02.3.3.2.7 VCAM-1 and α4β1 integrin (**Table 6**)*

Vascular cell adhesion molecule 1 (VCAM-1 or CD106) is expressed in endothelial cells in response to cytokines (e.g., TNFα and IL-1β) and mediates adhesion of leukocytes including lymphocytes and monocytes. The leukocyte ligand for VCAM-1 is α4β1 integrin (also known as Very Late Antigen 4). Together with the β2-integrins αLβ2 and αMβ2, α4β1 is an important mediator of leukocyte trafficking, including entry of neutrophils in the brain.[345] PET tracers have been developed both for α4β1 integrin[325] and VCAM-1.[326] Such tracers could provide important information about the recruitment of blood leukocytes during brain diseases; however, as these are peptides, they are unlikely to penetrate the brain.

*7.02.3.3.2.8 Alternate options (**Table 6**, **Scheme 54**)*

PET imaging of oxidative stress may also be possible with ^{18}F-5-fluoro-L-aminosuberic acid ([^{18}F]FASu), which is taken up by the cystine/glutamate transporter xCT. This transporter is upregulated when cells experience oxidative stress[327] because cystine uptake is necessary to maintain levels of glutathione, an essential antioxidant.[346] However, [^{18}F]FASu, like the other reported xCT PET tracers,[327] is an amino acid derivative that does not cross the BBB and therefore imaging neuroinflammation via xCT would require the design of novel, non-amino acid-based, PET tracers.

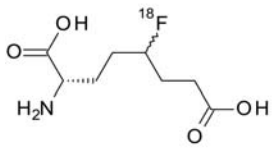
Activated microglia release β-glucuronidase and the PET tracer [^{18}F]FEAnGA has been developed to measure β-glucuronidase activity. Despite relatively low brain uptake, [^{18}F]FEAnGA was able to detect an increased release of β-glucuronidase in a preclinical model of neuroinflammation.[347] It remains to be seen if this will become an important method of measuring microglial activation.

7.02.3.3.3 Possible future developments

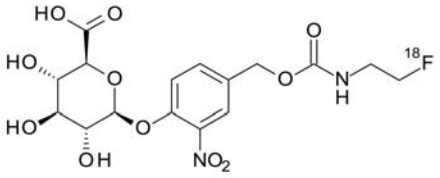
One area that has not been developed is PET tracers to detect microglia activated to an M2 phenotype. Potential M2 markers include arginase-1, interleukin-4 (IL-4), IL-10, and IL-13. Another M2 marker is TGFβ. ^{89}Zr-fresolimumab, a large molecule tracer, has been developed and used to image TGFβ in gliomas,[348] but whether this tracer can cross the BBB in the absence of a glioma is not yet known.

7.02.3.4 Reimbursement of Approved Diagnostic PET Agents

Molecular imaging techniques hold the potential to provide important information to clinicians in order to better understand the onset and time course of many diseases as well as their response to drugs and therapies. They could be used to personalize treatments on a molecular phenotypic basis which could be established at the time of diagnosis and monitored throughout the course of therapy. This is particularly true for diseases that are localized in areas of the body where it is not practical or safe to obtain tissue samples for analysis, such as the brain.[349] Neuroscience is at the dawn of a new era, now focusing mostly on disease-modifying



[^{18}F]FASu



[^{18}F]FEAnGA

Scheme 54 PET tracers for xCT and β-glucuronidase imaging.

approaches to treat neurodegenerative disorders and molecular imaging will be a key technique to allow clinicians and drug researchers to characterize and monitor therapies noninvasively over time.

However, these techniques, in particular PET imaging, are expensive and ensuring the clinical viability of new PET imaging tracers will require not only regulatory approval by the Food and Drug Administration (FDA) or the European Medicines Agency (EMA) but, above all, reimbursement from health insurance carriers and national authorities such as the Center for Medicare and Medicaid Services (CMS) in the United States.[349,350] Indeed, marketing approval does not necessarily lead to insurance coverage as recently exemplified by the recent CMS decision regarding the β-amyloid PET tracers,[351] whereby CMS decided there was insufficient evidence to conclude that PET amyloid imaging is reasonable and necessary for the diagnosis or treatment of patients with dementia or neurodegenerative disease. The need to show improved health outcomes was central in this decision. The CMS decision not to cover amyloid PET imaging agents has been an important disappointment in the nuclear medicine community. However, it gives a signal about the type of evidence that will be required for insurance coverage of future diagnostic radiopharmaceuticals. Clinical studies designed to demonstrate combined diagnostic accuracy and improved health outcomes may be required to obtain both marketing and insurance approval of new radiopharmaceuticals and such clinical studies may only be possible once viable therapeutic options have been discovered.

7.02.4 Concluding Remarks

The development of a novel PET tracer for clinical use is not a trivial process and it may take several years from early research until tracer validation in human. Still, the use of PET imaging to support CNS drug development has tremendously increased in the last decade. Although some targets are still resistant to the development of PET imaging agents, many new tracers have been made available for human use in the recent years as a result of increased collaboration between the pharmaceutical industry and the PET experts. In the case where several tracers are available for the same target or receptor, it is often challenging to identify which one may be the best tracer to use as there are very few head-to-head comparisons reported in the literature. More studies like the one performed by the Yale group with the GlyT-1 tracers [^{11}C]GSK931145 and [^{18}F]MK-6577[221] may be needed in the future to help researchers identify which tracer will best suits their needs.

Undoubtedly, the most active area of research in the last 5 years has been and is still the development of novel PET tracers aimed at imaging the neurodegenerative process. In this context, the identification of molecules binding selectively to the various aggregated proteins involved in neurodegeneration still represents a considerable challenge for the field. However, considering the prohibitive cost of large phase III clinical studies aimed at demonstrating a disease-modifying effect, this challenge has to be met by the PET field in order to support the selection/stratification of patients entering these clinical trials and to monitor the therapeutic intervention over time on an individualized basis.

Finally, development of novel PET tracers is not possible without efficient radiolabeling methodologies. There have been some efforts in recent years to broaden the scope of the existing methods and to develop fundamentally new methods to enlarge the accessible chemical space for radiolabeling. Considering the high MPO challenge that developing a novel PET tracer is, removing radiochemistry from the critical path in order to allow the medicinal chemists to select the best molecules rather than the ones that can be radiolabeled may lead to significant advances in the future.

7.03.1 Introduction

In the last decade there has been a large increase in drug discovery projects focussed on voltage-gated ion channel targets fuelled by a combination of factors including the development of new technologies which allow rapid screening.[1–3] The discovery of highly potent and selective peptide toxins, which have allowed improved target validation both preclinically and in certain cases

clinically[4,5] and through advances in genetics which have provided further target validation. The identification of channelopathies not only serves as excellent target validation but also offers the potential of a personalized medicine approach to the treatment of disease.[6] All of these advances have enabled successful drug discovery programs in the voltage-gated calcium channel field, and there is now a highly selective and efficacious agent in clinical use which acts through inhibition of Cav2.2 channels and is derived from a snail toxin.[7] Additionally a number of small-molecule inhibitors have entered clinical stages of development (Section "Compounds Under Clinical Evaluation") which have added to a class of older drugs, gabapentin and pregabalin, which were previously thought to act via another target but in recent years have been shown to be ligands of voltage-gated calcium channels.

In recent years there have been many excellent reviews covering the medicinal chemistry,[8–13] biology,[14–19] structure,[20,21] patents,[22] and clinical efficacy of calcium channel blockers.[23–26] This article will focus on medicinal chemistry advances in the field over the last 10 years.

Voltage-gated calcium channels are expressed predominantly on nerve and muscle cells, the channels as their name suggests, react to changes in the potential of the cell membrane allowing calcium ions to enter the cells. This results in an increase of the calcium concentration in the cytoplasm initiating a number of key biochemical processes which include hormone secretion, neurotransmitter release, and gene transcription.[27] Due to the key role in facilitating calcium entry into cells the voltage-gated calcium channel family has a rich pharmacology, and for certain channels there is strong disease association and consequently been the focus of drug discovery groups for many years. Recent genetic data[28–31] has both reinforced existing disease association and highlighted new potential therapeutic indications and current interest in this family of proteins is therefore very high. It is important to note that the genetic studies highlight changes in calcium channel function in a number of disorders many of which are not pain indications. For the Medicinal Chemist voltage-gated calcium channels have proved to be highly tractable to small-molecule drug discovery with a number of agents in widespread clinical use and others at various stages of clinical development. Marketed agents are currently used to treat a number of important clinical indications including hypertension, pain, and epilepsy. Disease association studies reported to date highlight the potential in a broad spectrum of disorders. This article will focus only on progress in the area of pain including migraine but will not cover progress in other therapeutic areas.

7.03.2 Voltage-Gated Calcium Channels—Structure and Function

7.03.2.1 Channel Subtypes

Voltage-Gated calcium channels were originally classified in terms of the voltage required to activate them, and two distinct classes were described, namely, low voltage activated (now known as T-type channels) and high voltage activated (L, P/Q-, N-, and R-type channels).[32] Subsequently with the identification of small-molecule ligands the pharmacology was investigated resulting in the further classification of channel subtypes.[33] The first selective pharmacological agents identified were those which targeted the L-type family which was given the name due to the large conductance observed when the channel is open. The discovery of peptide natural products largely derived from cone snail and spider toxins allowed the current classification of the channel family to be established with the identification of peptide ligands which were selective for channel subtypes.[4] Current nomenclature classifies voltage-gated calcium channels according to the subunits which form the pore of the channel of the so-called Cavα1 subunits. Currently 10 distinct channels have been identified. The L-type family comprises four subtypes (Cav1.1–Cav1.4); the T-type family comprises three (Cav3.1–Cav3.3); and for the P/Q (Cav2.1), N- (Cav2.2), and R-type (Cav2.3) families there is currently only one member known.[18] Each Cavα1 subunit is encoded by a distinct gene CACNA1A-S.

7.03.2.2 Channel Structure

All of the channels possess the same general structure,[18,34] each consisting of a pore forming unit (α1) and in some cases combinations of regulatory or auxiliary units (β and α2δ). The α1 unit determines the general functional characteristics of the channel, including pharmacology, voltage dependence, and conductivity; the auxiliary units can play a role in these too and additionally affect other processes such as trafficking. Functional channels are classified according to their α1 subunit of which currently 10 are known, each one being encoded by a distinct CACNA1 gene. Additionally the α2δ subunits are encoded by four distinct genes CACNA2D1-4. To date a number of distinct binding sites for different classes of drugs have been identified both on the α1 subunits and on the α2δ unit.[35–37] For the currently known subtypes each channel has a different expression profile and function which is described in the following section. Specific sites on the channels which bind different classes of drugs have been identified (Fig. 1). Most bind to sites on the α1 subunit although one class of drug has been shown to bind to the α2δ subunit.[37] Voltage-gated calcium channel structures have been known and publically available to medicinal chemists for a number of years but as yet there are no reports of ligands that have been designed using the available structural information. Channel structure has been thoroughly reviewed in recent articles[18,34] and will not be covered in detail in this article.

7.03.2.3 Channel Distribution and Function

Voltage-gated channels are widely distributed throughout the central nervous system and peripheral tissues and play a diverse array of physiological roles (Table 1). Nine of the 10 voltage-gated calcium channels subtypes are highly expressed either in the brain or

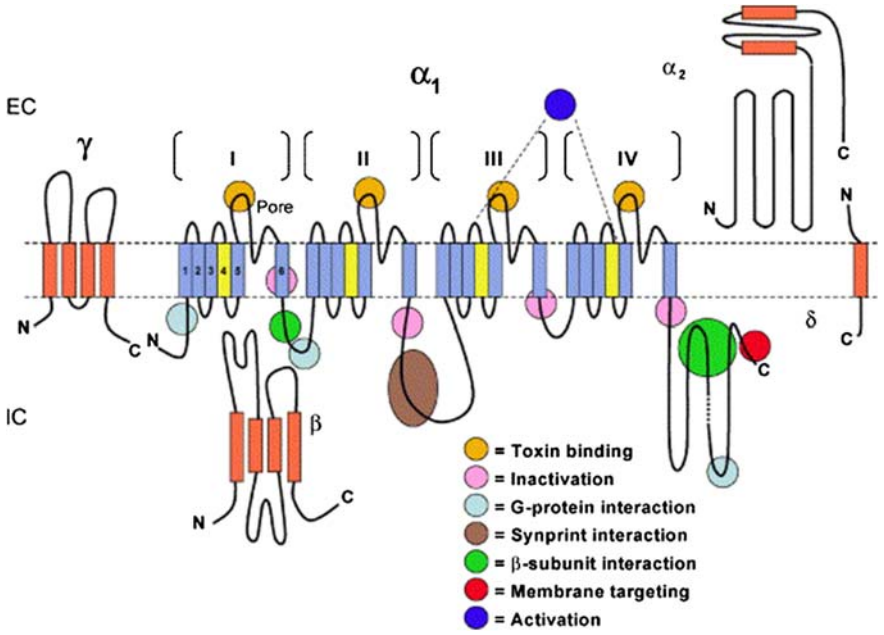

Fig. 1 Structure of voltage-gated calcium channels.

Table 1 Tissue distribution of voltage-gated calcium channels

Channel family	*Channel subtype*	*Gene*	*Tissue distribution*
L type	Cav1.1	CACNA1S	Skeletal muscle (high) Brain (low)
	Cav1.2	CACNA1C	Heart (ventricular muscle), smooth muscle, brain, and secretory cells
	Cav1.3	CACNA1D	Heart (sino atrial node) Ear (inner hair cells)
	Cav1.4	CACNA1F	Retina
P/Q type	Cav2.1	CACNA1A	Brain (high in cerebellum) and presynaptic nerve terminals
N type	Cav2.2	CACNA1B	Central and peripheral nervous system
R type	Cav2.3	CACNA1E	Brain
T type	Cav3.1	CACNA1G	Cardiac muscle, skeletal muscle, and neurons
	Cav3.2	CACNA1H	Cardiac muscle, neurons
	Cav3.3	CACNA1I	Neurons

on the neuronal tissue and with the exception of some members of the L-type family all are involved in sensory processing and are therefore potential targets for the development of new analgesic agents.

P/Q-type channels are best characterized for their role in migraine[31] and less so in other types of pain signaling. P/Q channels are widely expressed on presynaptic nerve terminal in the CNS where they have been shown to regulate neurotransmitter release. Their role in pain signaling associated with migraine comes from studies which provide strong evidence that activation of P/Q channels is a key process in neurotransmitter release, particularly glutamate in cortical and trigeminal neurons during certain migraine attacks.[38] N-type channels are highly expressed on presynaptic nerve terminals, when activated they trigger the release of key neurotransmitters which are well-characterized mediators of pain signaling including calcitonin gene-related peptide (CGRP), substance P and glutamate.[39] It has also been well characterized that opiate analgesics exert their effect on neurotransmitter release through indirectly blocking N-type calcium channel activity on stimulation of presynaptic opiate receptors.[40] R-type channels are perhaps the least well-understood member of the family, particularly regarding how their function is implicated in pain signaling. Their biophysical profile is the closest to that of the T-type family, suggesting a role in neuroexcitability. R-type channels have been shown to be expressed in Dorsal Root Ganglion (DRG) neurons and to control the release of neurotransmitters which strongly implicates them in pain signaling.[41]

T-type channels have very different biophysical characteristics compared to other family members, they are activated at lower voltages which positions them in the ideal range to regulate neuronal excitability which is supported by studies that have implicated them in processes linked to epilepsy. Neuronal excitability is also closely associated with pain signaling particularly in individuals with neuropathic pain conditions. Cav3.2 channels have also been shown to be expressed on primary afferent nerves further supporting the role of T-type channels in pain signaling.[42]

All of the channel subtypes have an associated α2δ subunit. These subunits play a role on modulating channel function. The mechanism of this modulation has been the subject of debate for many years and has only recently been established.[43] The mechanism is discussed in Section "Alpha 2 Delta Ligands."

7.03.3 Target Validation

Voltage-gated calcium channels are perhaps among the most highly validated pain targets. For certain channel subtypes there is either direct clinical target validation or strong genetic association. Table 2 summarizes the clinical and genetic target validation data currently available. For all families, with the exception of L-type channels, strong preclinical target validation packages are published. These have been enabled in many cases by the availability of highly potent and selective channel ligands isolated from animal toxins. It is important to note that the validity of preclinical validation for pain targets has in recent years been called into question largely due to the high failure rate of compounds in clinical trials which had previously demonstrated encouraging data in preclinical models. Table 2 summarizes preclinical target validation data currently available.

The most highly validated channel subtype is Cav2.2 for which there is a peptide channel blocker ziconotide, currently on the market.[7] The success of ziconotide prompted huge interest among the drug discovery community and has resulted in a large number of structurally diverse small-molecule blockers being identified, some of which are currently under clinical investigation.[8] It is also worth noting that opiate analgesics indirectly inhibit Cav2.2 function through stimulation of opiate receptors on presynaptic nerve terminals thus adding strength to the direct target validation data.[40]

Of some concern however is that one small-molecule Cav2.2 blocker Z160 has recently been reported to have failed to show any analgesic efficacy in two phase 2 studies; one in patients with diabetic neuropathy and a second in patients with lumbosacral radiculopathy (LSR)[14] where ziconotide has been reported to show excellent analgesic efficacy in a number of clinical studies.[7] This recent observation potentially asks a question about the exact nature of channel inhibition required for optimal analgesic efficacy, and it will be interesting to see how compounds currently in clinical evaluation perform in similar studies (Section "Compounds Under Clinical Evaluation").

Cav2.1 is strongly implicated in the pathology of migraine in particular a rare condition known as familial hemiplegic migraine 1 (FHM1) which is associated with gain of function mutations of the CACNA1A gene.[44] The genetic evidence is further supported by the fact that a number of drugs which show clinical efficacy in patients with FHM1 such as flunarizine[45] and verapamil[47] also have activity at Cav2.1 channels; however it is important to note that the clinical agents tested are not selective. It has also been shown that the extracts from medicinal plants such as feverfew or butterbur which show efficacy in treating various forms of migraine contain compounds which inhibit the Cav2.1 channel. However similar to the drugs which have demonstrated clinical efficacy, these compounds are not selective.[48] In contrast to the high level of target validation in migraine the same is not true for other pain modalities where validation is limited to preclinical studies.

Cav2.3 remains largely unexplored compared with other voltage-gated channel family members, and any target validation reported is limited to preclinical studies with a selective peptide ligand.

The T-type family has some limited and also confusing human genetic data which has recently been published.[46] A single patient was reported to have a loss of function mutation of the CACNA1H gene which resulted in a phenotype characterized by chronic pain and absence seizures. This observation is in contrast to preclinical knockout studies which result in reduced sensitivity.[49] Before any firm conclusions can be reached it is important to identify further individuals with altered Cav3.2 function. In addition to the genetic data a recent failed clinical study with a small-molecule Cav3.2 blocker ABT-639 failed to produce efficacy.[50,51]

In addition to selective modulation of specific channel subtypes it is important to highlight that agents which bind to the α2δ subunit also show clinical efficacy particularly in neuropathic pain. Gabapentin and pregabalin are both currently marketed for the treatment of neuropathic pain and exert their effect through this site.[52,53]

The genetic and clinical target validation is further supported by preclinical data in rodents which have either been genetically modified or have pain phenotypes modified by treatment with selective tool compounds.[12] The availability of selective tool compounds isolated from animal toxins has enabled many of these studies.[4] The validity of animal pain models has been called into question recently,[54–56] given the poor translation of preclinical data into the clinical setting and given the high level of clinical

Table 2 Clinical and genetic target validation data

Channel family	*Channel subtype*	*Gene*	*Validation*	*Observation*	*Reference*
P/Q type	Cav2.1	CACNA1A	Genetic association	Gain on function mutation linked to Familial Hemiplegic Migraine	44
			Clinical data	Agents with Cav21.1 inhibitory activity have shown clinical efficacy	45
N type	Cav2.2	CACNA1B	Clinical data with Ziconotide	Efficacy demonstrated in multiple pain states including those intractable to opiate therapy	7
T type	Cav3.2	CACNA1H	Genetic association	Single person identified with a CACNA1H mutation leading to a chronic pain phenotype	46

target validation for this target family preclinical data will not be discussed. It should be noted that despite the high level of target validation small molecules which inhibit voltage-gated calcium channel function have recently failed to show efficacy in clinical trials.[14,50,51] Reports of the discovery of these molecules suggest that the compounds were designed with a heavy reliance on animal model data (Sections "Neuromed compounds" and "ABT639 and related compounds"), and no other translational studies were performed. Encouragingly there are recent reports of more recent molecules that have been identified with potentially more robust translational packages which include in vivo electrophysiology studies and measurement of the compounds effect on neurotransmitter release. It will be interesting to follow the progression of these compounds into clinical evaluation.

7.03.4 Mechanism of Action

Peptide blockers such as ziconotide have to be administered intrathecally to avoid severe adverse effects on the cardiovascular system resulting in a dramatic fall in blood pressure,[57] yet small-molecule Cav2.2 blockers developed recently retain the analgesic efficacy of ziconotide in preclinical testing yet do not affect the cardiovascular system. The reason the small molecules have an improved safety profile is that they are so-called state-dependent blockers which are able to spare functions, such as neurotransmitter release, that are required for normal central processing and peripheral sympathetic control of cardiac and smooth muscle function yet block sensory neurons involved in pain processing. The small molecules have a higher affinity for a state of the channel which occurs to a higher degree in situations where cells are operating under nonresting, typically high frequency conditions.[58] Voltage-gated ion channels can exist in a number of different states, and some blockers can exert their action selectively through a single state or a subset of states and such compounds are referred to as state-dependent blockers. Once channels enter the inactivated state, a characteristic interval must pass before the channel can be reactivated. Fig. 2A represents a model of the different states. Voltage-gated calcium channels exist in open and closed (or resting) states and various inactivated states together with various intermediate closed states. It has been suggested that a channel entering an inactivated state is comparable with receptor desensitization, wherein the continued influence of an activating stimulus, in this case depolarizing transmembrane voltage sufficient to cause channel opening, loses its ability to sustain the channel in the open state. The inactivated state is believed to represent a different protein conformation distinct from both the open and closed states.

There are many theories describing how channels can enter inactivated states. One widely accepted model which fits with observations of channels on sensory neurons and the effects of certain drugs is so-called closed state inactivation proposed by Winquist.[58] Channels are able to access an inactivated state through an intermediate closed state (the so-called closed state inactivation or CSI). Intermediate closed states occur at potentials which are below the threshold required for channel opening. This explains the concept of use-dependent block (Fig. 2B), whereby channels which undergo rapid cycling through different intermediate states, for example, when exposed to rapid high frequency stimulations are preferentially blocked compared to those cycling at lower frequencies. This phenomenon explains physiological observation, whereby compounds are able to inhibit calcium channels operating at high frequencies such as those on sensory neurons fitting aberrantly in pain states but have little or no effect on channels functioning under low-frequency conditions such as in the heart.

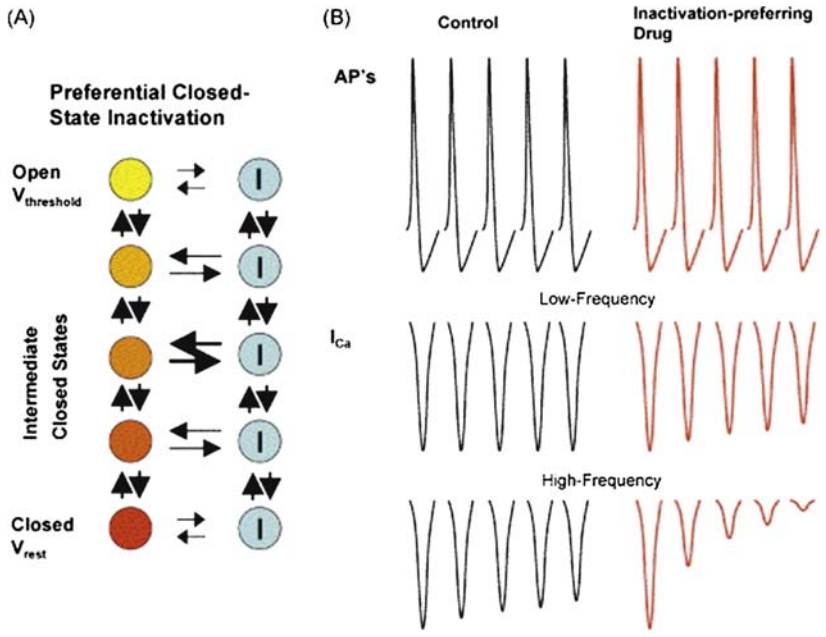

Fig. 2 State-dependent inhibition.

Drugs such as ziconotide, for example, do not selectively bind to a single state of the channel and have different pharmacology to state-dependent blockers which are typically small molecules although state-dependent peptides have been reported.[59] State-dependent inhibition therefore offers an opportunity to achieve a therapeutic window between analgesic effects and target-driven side effects. All drug discovery efforts based on voltage-gated calcium channels have targeted state dependence and have identified molecules with excellent therapeutic indices preclinically and which are safe and well tolerated where tested in humans. However while only a very small number of molecules have been tested, a state-dependent inhibitor of a voltage-gated calcium channel has yet to demonstrate robust clinical efficacy, and it will be interesting to observe the results of clinical studies in the near future to see if the situation changes.

7.03.5 Inhibitors of Voltage-Gated Calcium Channels

The literature is confusing as different authors use different nomenclature when referring to channels and channel subtypes. For clarity and consistency in this article channels will be referred to using the α1 subunit nomenclature, for example, Cav2.1, Cav2.1, etc., with the exception of Section "Alpha 2 Delta Ligands" which covers molecules which act through binding to the α2δ subunit.

There has been an explosion in terms of publications covering voltage-gated calcium channel inhibitors in recent years. This is largely due to advances in technology which have allowed the development of screening assays with sufficient throughput to support drug discovery projects.[1–3] Current technology allows assays to be run to support ongoing chemistry projects and also high-throughput screening campaigns for voltage-gated ion channels. Early drug discovery programs were hampered by the low throughput of conventional electrophysiological techniques and achieved only limited success. Recently through the application of diversity screening techniques a wide variety of molecular scaffolds have been identified which inhibit calcium channels, particularly inhibitors of the Cav2.2 and Cav3 channel families. The majority of compounds covered by patents and journal articles which have published to date cover compounds described as either selective Cav2.2 or Cav3 inhibitors. There has been little if any work in the field of Cav2.1 and Cav2.3 channels. The exact reason for this bias is unclear; it is possible that the Cav2.2 and Cav3 family are more tractable from a small-molecule perspective or linked to the higher level of target validation currently reported for these channels. Additionally there has been some work focussed on the identification of molecules which bind to the α2δ subunit both based around the gabapentin and pregabalin scaffolds and some based on hits identified through screening approaches.

7.03.5.1 Compounds Under Clinical Evaluation

Several compounds have reached clinical trials and are shown in Table 3.

7.03.5.1.1 Z160

The first Cav2.2 inhibitor to enter clinical evaluation was Z160 (1) (previously known as NP118809, NMED 160, and MK6721), most recently developed by Epirus following the merger with Zalicus. The compound was originally identified by Neuromed (Section "Neuromed compounds") and for a brief period jointly developed in partnership with Merck Development was terminated in 2013 after the compound failed to show efficacy in two clinical studies. Z160 did not meet the primary endpoint in either of two phase 2 clinical studies in patients with LSR[60] and postherpetic neuralgia.[61] It is encouraging that in both studies the drug was reported to be well tolerated. No reason has been given to explain the failures, and in a statement on the company website Zalicus commented that they had conducted a review of both studies and adequate exposures had been achieved.

It is important to note that the physical properties of the compound were not optimal for a CNS drug due to very high lipophilicity and caused possible problems during development as indicated by a press release in 2007 after a collaboration between Merck and Neuromed was terminated following a decision to abandon an earlier clinical study due to the compound failing "to demonstrate the ideal pharmaceutical characteristics necessary to advance the compound further into development." The reasons for withdrawal were likely to be due to poor physical properties as evidenced by a patent which presents data showing that the bioavailability can be enhanced by dosing after a high fat meal[62] which is later followed by a number of formulation patents.[63,64]

7.03.5.1.2 CNV2197944

A second Cav2.2 blocker with an unknown structure CNV2197944 being developed by Calchan Pharmaceuticals following its discovery by scientists at GlaxoSmithKline is currently in phase 2 trials. Following the decision by GSK to exit neuroscience focussed research in 2011 the development of a number of pain assets was continued through the formation of a spin-out company; Convergence Pharmaceuticals. Convergence progressed CNV2197944 into phase 1 studies where it was shown to be well tolerated and a have a pharmacokinetic profile suitable for progression [Source Convergence website]. In 2013 Convergence announced the start of two phase 2 studies in two different patient groups, one in patients with PHN[65] and a second in patients with peripheral diabetic neuropathy.[66] Both studies have now completed but as yet no results have been released. Early in 2015 Convergence was acquired by Biogen who continued to work on certain assets which did not include CNV2197944. Currently CNV2197944 is being developed by Calchan pharmaceuticals a second spin-out company formed by former Convergence management. To date no data from any of the human studies with CNV2197944 have been published.

Table 3 Voltage-gated calcium channel inhibitors under clinical evaluation

Compound	*Structure*	*Target channel*	*Status*
Z160	 (1)	Cav2.2	Terminated–failed phase 2
CNV2197944	Unknown	Cav2.2	Phase 2
ABT639	 (2)	Cav3	Terminated–failed phase 2
Z944	 (3)	Ca3	Phase 2
Ethosuximide	 (4)	Cav3	Proof of concept
Microgabalin	 (5)	α2δ	Phase 3

7.03.5.1.3 ABT-639

A similar picture emerges for T-type channels with one compound ABT-639 (2) having recently failed in a clinical study in patients with diabetic neuropathy.[50] In the trial patients were given 100 mg ABT-639 twice daily for a period of 6 weeks. When assessing the mean changes from baseline in patient-recorded pain scores at the end of week 6, there was no significant difference observed for ABT-639 compared with placebo. Pregabalin treatment resulted in a transient improvement in pain compared with placebo, which did not persist throughout the study. In a parallel[51] study which used a technique called microneurography to examine effects on spontaneous C fiber activity, patients were given a 100 mg single dose of ABT-639. Results showed that the drug behaved no differently to placebo although interestingly lidocaine also showed no difference to placebo. In addition it also failed to show an effect in an experimental medicine study which looked at intradermal capsaicin experimental pain model in healthy adults.[67] In a phase 1 study ABT-639 was well tolerated and demonstrated a pharmacokinetic profile supportive of progression.[68] The reason for the failure in the clinical studies is again not clear. ABT-639 is described as being peripherally restricted in preclinical pharmacokinetic studies,[69] and it is possible that a centrally penetrant molecule could have had a better chance of success.

7.03.5.1.4 Z944

Z944 (3) is a selective Cav3 blocker, originally identified by Zalicus scientists. Following the acquisition of Zalicus by Epirus Biopharmaceutical, its development has continued and Epirus are currently evaluating Z944 in a phase 2 study. The compound was safe and well tolerated in a phase 1 study, and in a subsequent phase 1b study Z944 is reported to have shown efficacy in experimental medicine studies of both neuropathic and inflammatory pain.[70] Volunteers were given four administrations of Z944, 20, 40, or 80 mg or placebo every 2 h, and laser-evoked potentials (LEPs) from skin were measured following either topical administration of capsaicin (to model neuropathic pain) or a UV burn (to model inflammatory pain). Z944 reduced peak-to-peak amplitudes of the LEPs and also pain scores from the volunteers determined using a visual analogue scale. Epirus also state that the study results prompted work to look for controlled release formulations for future studies.

Currently there is no other development reported, but with the large volume of patents covering compounds that inhibit Cav2.2 and the T-type family it is reasonable to expect that new compounds will enter early development shortly, indeed there maybe molecules in early development as this information is not often made publically available by companies.

The following sections will describe in detail the structures of known inhibitors of voltage-gated calcium channels that have been published to date together with structure–activity relationships and, where appropriate, pharmacokinetic data and the in vivo efficacy results.

7.03.5.1.5 Ethosuximide

Ethosuximide (4) is an existing drug used to treat epilepsy and is currently under clinical evaluation for its potential to treat neuropathic pain.[71] The compound has been shown to inhibit Cav3 channels; however it also has activity at other targets.[72]

7.03.5.1.6 Mirogabalin

Daiichi Sankyo is developing a compound, mirogabalin (5, DS-5565) which is reported in the patent literature to be a potent α2δ ligand (binding $IC_{50} = 14$ nM). The medicinal chemistry relating to the identification of this compound has not been disclosed, but the company has reported clinical data from two phase 2 studies in patients with diabetic neuropathy which demonstrated positive effects at doses of 15, 20, and 30 mg per day.[73,74] Studies in patients with fibromyalgia on currently ongoing[75] and the company is currently recruiting patients to begin phase 3 studies.

There are other agents which have calcium channel blocking activity which are currently being developed for nonpain indication such as epilepsy and insomnia. As these conditions are beyond the scope of this article the compounds will not be discussed in detail, but ongoing studies will be highlighted in the following sections.

7.03.5.2 Cav2.1 Inhibitors

Currently there are no selective small-molecule inhibitors of Cav2.1 reported, and this is in some ways surprising given the strong genetic association with familial hemiplegic migraine,[31,44] a fact that has been highlighted by several authors who have expressed the need for such a compound.[76,77] The only truly selective Cav2.1 inhibitors that are currently available are peptides such as ω-agatoxin 1VA[78] which has been used for target validation studies.[79] Small-molecule inhibitors are reported but are all nonselective; these are natural products, marketed drugs, or compounds designed as inhibitors of related channels which have showed activity at Cav2.1 (Section "**Compounds known to inhibit Cav2.1**"). It has been suggested that selectivity may not be possible to achieve as that while there is clear evidence that a gain of function mutation of Cav2.1 leads to Familial Hemiplegic Migraine[44] the gain of function is dependent on the particular splice background in which the mutation is present.[80]

7.03.5.2.1 Nomenclature

Cav2.1 channels are also known as P/Q channels, the reason for the nomenclature is historic as P-type current were first identified in Purkinje neurons of the cerebellum and are distinct from Q-type current identified in cerebellar granule neurons, both being characterized by sensitivity to the toxin ω-agatoxin-IVA and are generated by ion channels encoded by the gene CACNA1A.[81] As the exact distinction is unclear, the channels are commonly referred to as P/Q channels. The channels have an expression profile similar to the related Cav2.2 channels, the distinction being that Cav2.1 channels show a greater bias toward neuronal expression in the CNS.[82]

7.03.5.2.2 Target validation

To date a number of mutations of the CACNA1A1 gene which encodes the pore forming unit of the Cav2.1 channel have been identified. Mutations which lead to a gain of function of the channel are associated with migraine, most commonly FHM1,[44] conversely loss of function mutations are associated with Episodic Ataxia type 2.[83] The biochemical and physiological consequences of the mutations have been extensively studied and are consistent with the linkage to a migraine phenotype with both cells and neuronal tissues expressing a channel that has a shift in the voltage required to activate them resulting in enhanced neurotransmitter release and neuroexcitability.[23] Mice expressing a mutant form of the channel associated with FHM possess a phenotype consistent with the disease which can be reversed by treatment with ω-agatoxin 1VA.[84] It is important to consider that loss of function mutations of Cav2.1 has also been identified which are linked to ataxia (Episodic Ataxia type 1), thus suggesting that direct inhibition of the channel would not be appropriate as a treatment for migraine. A state-dependent inhibitor which binds to the inactivated state of the channel however has the potential to restore normal function and provide a safe effective therapy. Preclinical

target validation for Cav2.1 inhibition to be a treatment for migraine in general has also been described.[79] Agatoxin application is able to reverse the hyperexcitibility of the trigeminal nerve in a mouse model of general migraine. Finally as described in the following section certain agents in current clinical use have shown activity in migraine clinical studies. This data should be treated with some caution as none of the agents are selective Cav2.1 blockers.

7.03.5.2.3 Compounds known to inhibit Cav2.1

Currently available agents which have activity at Cav2.1 channels fall into three groups: peptide toxins, existing drugs shown to have Cav2.1 inhibitory activity in addition to activity at other targets, and small molecules which were originally designed as ligands for other targets but have been found to be Cav2.1 inhibitors as part of selectivity screening studies.[76] Reference[76] contains a thorough review of currently known agents which have been shown to interact with Cav2.1 channels and are summarized in the following paragraphs.

There are many toxins that have been reported to be potent blockers of Cav2.1 channels; however most are nonselective. Currently only toxins are reported to be selective, ω-agatoxin-IVA and ω-agatoxin-IVB. Both are reported to have inhibitory activity in the nanomolar range and to produce complete channel block at sub-nanomolar concentrations. ω-Agatoxin-IVA has been shown to bind to the outside of the pore forming α1 subunit where other toxins studied have been demonstrated to bind in the pore itself. It has been suggested that the different binding mode of ω-agatoxin-IVA may explain its selectivity compared to other known peptide inhibitors.

Many known drugs have been reported to have activity at Cav2.1 channels (**Fig. 3**). Virtually all members of the calcium channel blocker class of antihypertensives, including the structurally diverse compounds verapamil (6), diltiazem (7), and amlodipine (8), where tested have activity at Cav2.1. While potency varies from compound to compound this class of drug shows little selectivity across the Cav 1.2, Cav2.1, and Cav2.2 family members; verapamil is reported to inhibit Cav2.1 channels with an IC_{50} of 62 μM, Cav1.2 channels with an IC_{50} of 4 μM and produces full inhibition of Cav2.2 at 40 μM. Amlodipine appears generally more potent and less selective inhibiting Cav2.1 with IC_{50} values ranging from 3 to 11.5 μM, inhibiting Cav1.2 with an IC_{50} ranging from 1.2 to 4.2 μM and Cav2.2 in the range of 0.14–7.9 μM. Interestingly there are several reports of migraine being successfully treated with amlodipine and other drugs of this class[85,86]; however it is difficult to draw any conclusions as to which channel if any is responsible for the beneficial effect. Cav2.1 activity is not limited to the antihypertensive class of compounds. Drugs such as fluspirilene (11), gabapentin (12), isoproterenol (13), lamotrigine (14), and levetiracetam (15) have also demonstrated activity. All of the compounds in **Fig. 4** are reported to inhibit Cav2.1 channels in the micromolar range, but none of the compounds show any significant selectivity for Cav2.1. It is also important to note as highlighted in a recent review[76] that all of the Cav2.1 inhibitory data published on these compounds has been generated in different laboratories often using different protocols and care should be exercised when making comparisons.

Additional nonselective Cav2.1 inhibitors have recently been published by groups engaged in projects focussed on the identification of selective Cav2.2 inhibitors,[76] and examples are shown in **Fig. 4**. The molecules will be described in more detail in Section "**Merck compounds**." As they were not identified through a targeted search for a selective Cav2.1 blocker, little information has been published regarding SAR at Cav2.1 channels or functional activity associated with this activity. Z160 (1) was the first small molecule rationally designed Cav2.1 inhibitor to enter clinical studies. The compound displays some selectivity for Cav2.2 channels (IC_{50} 0.04–0.2 μM) but is still a relatively potent inhibitor of Cav2.1 channels (IC_{50} 0.12–0.65 μM) and Cav1.2 channels (IC_{50} 0.3–0.5 μM). While detailed SAR for activity at Cav2.2 and Cav1.2 channels is reported, little data describing selectivity over Cav2.1 channels has been described. A-1048400 (16) is a related compound identified by Abbott, and it has a similar profile regarding selectivity inhibiting Cav2.1 channels with an IC_{50} of 1.3 μM and Cav2.2 channels with an IC_{50} of 0.8 μM when in the inactivated state and shows some evidence of state dependence inhibiting Cav2.1 and Cav2.2 with IC_{50}s of 16.1 and 4.1 μM, respectively, when in the closed state.

LY393615 (17) was described by the Lilly group and was derived from a high-throughput screening hit which was optimized to be a nonselective agent for the treatment of ischemia. It is reported to block Cav2.1, 2.2, and 2.3 currents with IC_{50} values of 4.1, 19, and 5.2 μM, respectively. In addition to inhibiting calcium channel function the compound is also reported to be a sodium channel blocker.

TROX-1 (18) is a compound identified by the Merck group as part of their Cav2.2 blocker program and was profiled extensively but terminated due to poor selectivity over Cav2.1 and Cav2.3 channels. The compound is described as a nonselective blocker of Cav2 channels, and data is presented in two assay formats TROX-1 having depolarized IC_{50} values of 0.19, 0.29, and 0.28 μM at Cav2.1, 2.2, and 2.3, respectively, in a manual electrophysiology assay and using matched conditions in a calcium influx assay IC_{50} of 1.8, 0.69, and 1.1 μM were observed. Merck reports that the compound was extensively profiled in vivo with no serious adverse effects being observed.

In addition to marketed drugs and compounds identified with Cav2.1 activity, projects focussed on other channel subtypes. A third group of molecules has been published that possess Cav2.1 inhibitory activity, namely, natural products of the petassin (19) family and eudesmol isomers (20) (**Fig. 5**). Of particular interest is that these compounds have been shown to be present in extracts of medicinal plants which have demonstrated clinical efficacy in treating migraine.[87] Both petassin A (19) and α eudesmol (20) have been shown to demonstrate strong use-dependent block of Cav2.1 channels at concentration of 3–10 μM.[87] In summary no selective small-molecule inhibitors of Cav2.1 channels are currently reported; however many structurally diverse compounds do nonselectively inhibit channel function, suggesting that this channel is a chemically tractable target for drug discovery. Given recent genetic findings it is reasonable to expect that selective agents will be reported in the near future.

7.03.5.3 Cav2.2 Inhibitors

In contrast to Cav2.1 there are many reports describing focussed efforts to discover agents which act through inhibition of the Cav2.2 channel. The majority of these highlight pain as the primary indication; however some early work centered on agents to treat ischemia. The reason for the high level of interest can be attributed to the success of ziconotide,[23–25] the selective peptide Cav2.2 inhibitor currently licensed for the treatment of neuropathic pain and which shows excellent clinical efficacy. The ziconotide data makes the Cav2.2 channel a rare and highly sought after clinically validated target and hence the high level of interest which continues today. As described in Section "**Compounds Under Clinical Evaluation**" following the success of the ziconotide small-molecule, state-dependent, Cav2.2 blockers have been identified, some of which have progressed to clinical studies (**Table 3**). Given the large volume of patent filings in the area it can be expected that further agents will enter clinical evaluation in the coming years. The fact that one of the small molecules failed to show clinical efficacy raises an important question as to what is the optimal profile for an efficacious yet safe Cav2.2 blocking agent to treat pain? As previously described ziconotide is efficacious yet has to be administered directly into the spinal cord as systemic delivery leads to severe, mechanism-driven cardiovascular adverse effects. Side effects arise as the peptide blocks all states of the channel and therefore blocks all channel function. State-dependent compounds have since been identified which can be administered systemically without causing the adverse effects seen with ziconotide in clinical studies and also demonstrate preclinical analgesic efficacy in a variety of models, however as yet are still to demonstrate clinical efficacy. The reasons for the failure of Z160 are not yet understood, and these observations prompt the question as to whether the biophysical profile of the compound possibly suboptimal, and if so what profile should a safe and efficacious compound possess? One possible explanation is that in some cases compounds are not screened adequately as they are progressed

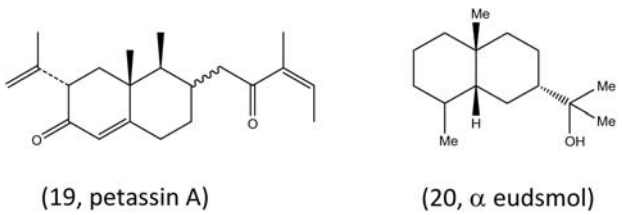

Fig. 5 Natural products from medicinal plants used to treat migraine with inhibitory activity at Cav2.1 channels.

from electrophysiological profiling to pharmacokinetic studies and then once the target profile has been achieved advanced to animal testing. Given the number of recent reports which question the translatability of preclinical pain models more confidence is needed that a compound will be efficacious in clinical testing. Encouragingly workers are starting to do this, the Janssen group recently reported studies with one of their Cav2.2 molecules which showed the compound was able to inhibit neurotransmitter release from spinal cord slices in a similar manner to ziconotide,[88] thus allowing a more in depth comparison and also providing a potential translational biomarker with which to measure target engagement in early clinical studies.

A number of different strategies have been used to identify small-molecule Cav2.2 blockers including structure-based design based on selective peptide ligands, modification of known compounds which nonselectively inhibit Cav2.2 and high-throughput screening. While there are a large number of medicinal chemistry publications which describe in detail the discovery of various Cav2.2 inhibitor templates there are many more novel structures only described in the patent literature publishing very little data, hence like many areas of active medicinal chemistry it is not possible to understand the full picture at any moment in time. An additional complication which makes comparing compound profiles difficult is that frequently different groups use different assay formats or report data in different ways therefore allowing only meaningful comparisons to be made with data from the same laboratory.

7.03.5.3.1 Early inhibitors

Early reports of Cav2.2 inhibitors focused on compounds for the treatment of both pain and ischemia. These have been thoroughly reviewed[89–92] and will only be briefly summarized in this article. Compounds include SB-206284A (21), PD 151307 (23), PD 175069 (24), NS 649 (28), and E2050 (29) and are shown in Fig. 6.

The medicinal chemistry behind the discovery of SB-206284A (21) has not been published, but comparing the right-hand side aryl groups and the relative position of the basic center in each compound one can speculate that they might bind in a similar region of the protein. The biological profile has been published,[93] and the compound inhibits calcium channels in a DRG preparation with an IC_{50} of 5.6 μM. The Parke-Davis group has described the discovery of PD175069 (24) derived from a screening hit PD151307 (23), which was a potent Cav2.2 blocker ($IC_{50}=0.32$ μM, in human IMR32 neuroblastoma cells) but had poor physicochemical properties, in particular poor aqueous solubility and stability.[94] The ester could be replaced with an amide to give as compound with similar activity. Further modification of the urea gave the tertiary amine PD175069 (24). In a subsequent article[95] Parke-Davis described the preparation of conformationaly restrained analogues in which the left-hand acyclic amine is cyclized to form a piperidine with retention of activity. Subsequently Parke-Davis has described a number of other analogs[96–99] together with structurally distinct compounds designed using the structure of conotoxin peptides (see Section "Small-molecule blockers based on peptide toxin structures").

One of the earliest examples of Cav2.2 blockers being described specifically for the treatment of pain is the quinolone (22) which appears in a 2002 patent.[100] The detailed medicinal chemistry behind the discovery of this compound has not been published.

Ono has also described the discovery of amino acid-derived inhibitors arising from screening hits. Compound (25) was a hit chosen for investigation and reported to have $IC_{50}=3.4$ μM (IMR calcium flux assay and $IC_{50}=34$ μM IMR electrophysiology assay) with significant activity at Cav1.2 (selectivity 4.4-fold). The corresponding enantiomer had a similar profile in terms of both potency and selectivity.[101] Encouraged by the profile of (25) it was studied in vivo in the formalin model of analgesia[102] where it showed modest activity after *intrathecal* injection (34% reversal of effect, 3 mmol kg^{-1}). Following a detailed SAR investigation (26) was identified[103] which is a more potent Cav2.2 blocker in the calcium assay ($IC_{50}=0.17$ μM) but with a similar profile in electrophysiology ($IC_{50}=25$ μM) and with slightly improved selectivity over Cav1.2 (12-fold). This compound however failed to demonstrate any analgesic efficacy in two pain models following oral dosing. The lack of efficacy may have been due to poor solubility which is reported by Ono. Further work showed that the left-hand ring of the diphenyl ether group present in (26) could be replaced with a piperidine (27) giving a compound with a similar biological profile ($IC_{50}=0.33$ μM in the IMR calcium assay) and 15-fold selectivity of Cav1.2, but more potent in electrophysiology (76% inhibition at 3 μM, compared with 25% for (26)). Compound (27) was subsequently tested in two pain models where, unlike (26), it showed activity having minimum effective doses of 10 and 30 mg kg^{-1} in the rat formalin and CCI models,[104] respectively, following oral dosing.

No SAR has been published for NS-649 (28), but its synthesis and biological profile have been described.[105] Similarly little has been described relating to the discovery of E2050 (29).

7.03.5.3.2 Small-molecule blockers based on peptide toxin structures

Using the structure of the highly active and selective conotoxin peptides, one of which has demonstrated clinical efficacy is a potentially attractive starting point for small-molecule design; however it is an area which has significant challenges. A number of groups have taken this approach and have identified inhibitors with activities in the low micromolar region. Most of the work published to date has been based on the structures of ω-conotoxin MVIIA and ω-conotoxin GVIA.

The first group to report work in this area was Parke-Davis. They used the ^1H NMR structure of ω-conotoxin MVIIA in combination with the knowledge that key residues, namely, Lys2, Arg10, Leu11, Tyr13, and Arg21 were key for binding to the Cav2.2 channel to design a scaffold in which three of the residues Arg10, Leu11, Tyr13 were incorporated in a spacial orientation close to that observed in the peptide structure. The initial design[106] was not successful giving a compound (30) which showed only 19% inhibition at 10 μM in an IMR32 assay.[107] Further optimization of the scaffold through molecular modeling gave (31) a 2.7 μM inhibitor, a compound which more closely resembles the conformation of the peptide. A subsequent publication[108] describes compounds in which a quinolone moiety is introduced by formation of a ring through cyclization from one of the central

phenyl rings onto the chain which links the Tyr13 mimetic. No biological data is reported for these latter compounds. The compounds in Fig. 7 are the only ones reported to be designed using ω-conotoxin MVIIA as the template. Most workers have focused on the more selective ω-conotoxin GVIA.

Fig. 8 shows the initial compounds published using this strategy from a group at Monash University. The scaffolds were again designed using a knowledge of the ^{1}H NMR structure of the peptide in combination with the knowledge that Lys2 and Tyr13 residues were crucial for potency and that Arg17, Tyr22, and Lys24 were also needed but were less important. The group decided that three residues should be incorporated into the peptidomimetic and that Lys2 and Tyr13 should be two of them and used computational chemistry to aid the selection of Arg17 as the third. Once the residues were chosen they were combined with a series of scaffolds designed to mimic the natural peptide conformation and hold the key residues in the optimal space to interact with the channel.[109] The benzthiazole (33) and antharanilamide (34) derivatives showed activities of 98 and 68 μM, respectively, when tested in a rat vas deferens assay and with binding affinities in the single figure micromolar range.[110,111] Extensive SAR studies have been reported around these scaffolds[112] which have focused on variation of the groups postulated to mimic Lys 2 and Arg 17. A variety of basic groups are tolerated in combination with various chain lengths; however none of the modifications led to a significant increase in potency. The nature of the Tyr13 mimetic has also been investigated; results showed that the hydroxyl group could be removed with little effect on activity and a slight increase in potency when replaced with a fluorine atom. In addition to investigating the chain length of the linker, the nature of the linkage to the aromatic core was investigated and data demonstrated that the ether linkage in (34) could be effectively replaced by an amide with no effect on potency. Despite very thorough SAR investigation around these scaffolds workers have not been able to achieve submicromolar activity within this series. It was reported that for some compounds there was some evidence of selectivity with (33) being reported to be 30-fold selective over Cav2.2. In

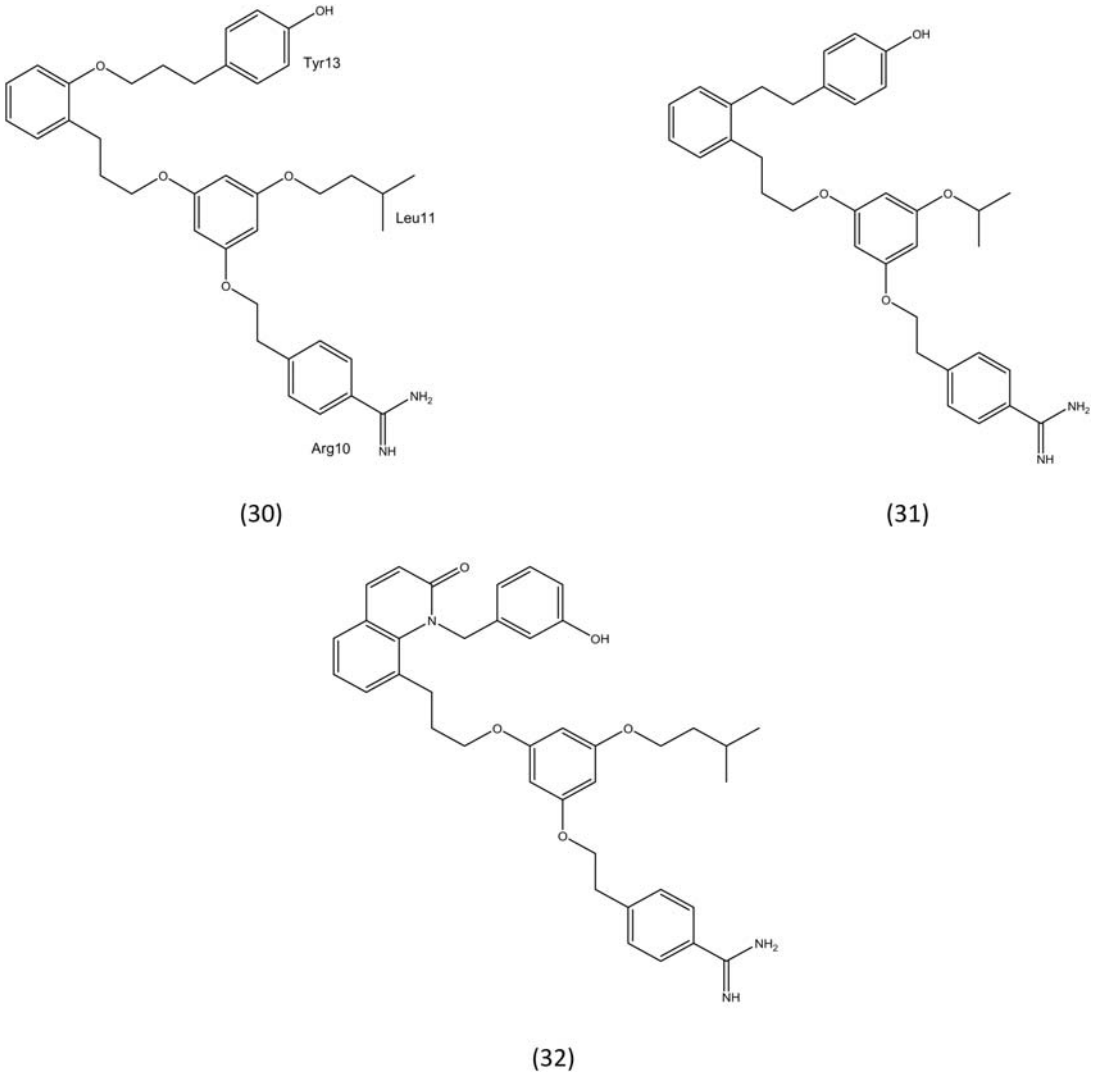

Fig. 7 Peptidomimetics designed from the structure of ω-conotoxin MVIIA.

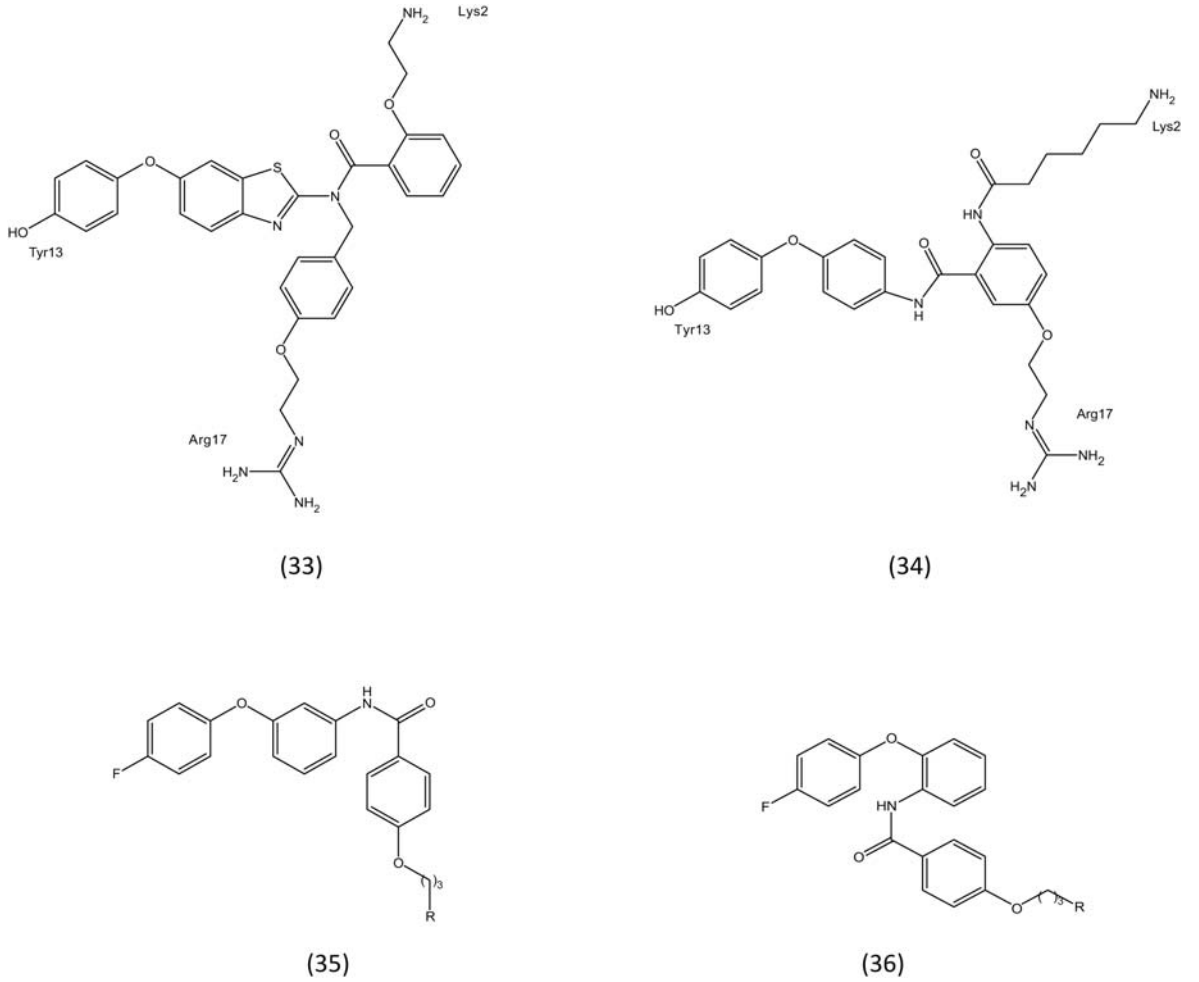

Fig. 8 Peptidomimetics designed from the structure of ω-conotoxin GVIA.

a recent article[113] truncated derivatives were reported (35 and 36) in which one of the side-chain mimetics was deleted with the aim of improving the physical properties. It was found that it was possible to retain activity in these truncated molecules but the nature of the side-chain mimetic which could be deleted was determined by the isomer of the central phenoxy aniline. Deleting either chain in the original para isomeric series resulted in a significant drop in activity ($IC_{50} > 700$ μM in functional assays). Changing to the meta phenoxy anilide (35) removal of the Arg17 mimetic side chain is preferred (R = NH_2 $IC_{50} = 35$ μM, R = guanidine $IC_{50} = 185$ μM) in the ortho series (36) the reverse was found to be the case (R = NH_2 $IC_{50} = 124$ μM, R = guanidine $IC_{50} = 46$ μM).

7.03.5.3.2.1 Hybrid compounds

Recently hybrid molecules have been reported[114] which incorporate common pharmacophoric features of another structurally distinct class of small-molecule Cav2.2 blockers into the phenoxy anilide template (Fig. 9). The authors noted that a number of reported small-molecule Cav2.2 blockers such as Z160 (1) and A-1048400 (16) contain a diphenylmethylpiperazine group and investigated the potential of replacing the phenoxy anilide group in the anilide series (37) with the substituted piperazine. They also highlighted that this should avoid any potential toxicity which may be caused by a phenoxy anilide. Four hybrid compounds were reported which showed activity in both binding and functional assays but was not improved over previous peptidomimentics. The analogues with highest binding affinity were guanidines (R2 = guanidine, R1 = H ($IC_{50} = 12$ μM), F ($IC_{50} = 16$ μM)), where R2 was a primary amine the fluoro derivative was the more potent compound (R1 = F, $IC_{50} = 65$ μM, R1 = H $IC_{50} = 214$ μM). All of the compounds however showed weak activity ($IC_{50} = > 100$ μM) in two functional assay formats.

7.03.5.3.3 Arylthiazolidinediones

7.03.5.3.3.1 Ionix compounds

Ionix has published data on a series of 2-Arylthiazolidinediones in 2007 (Fig. 10).[115] The series was identified through a screening campaign, the original hits identified were (38, $IC_{50} = 1.68$ μM, 5.6-fold selective over Cav1.2 (IMR32 fluorescence-based assay)) and (39, $IC_{50} = 0.66$ μM, 12.8-fold selective over Cav1.2). Preliminary SAR investigation showed that (39) was more amenable

to modification, and the Ionix group focused on this template. Overall none of the modifications described gave large changes in either potency or selectivity, but a few interesting observations were highlighted. A variety of alkyl replacements for the sec butyl group were tolerated, as was changing the position of the nitrogen in the pyridine ring and the nature of the lipophilic group on the phenyl ring. The pyridyl isomer present in (39) was generally preferred. Separation of the enantiomers produced the largest difference in activity and selectivity as illustrated by compounds (40) and (41), (40) was a relatively weak blocker of Cav2.2 channels ($IC_{50}=4.44\ \mu M$) and nonselective over Cav1.2 (2.9-fold), whereas the enantiomer (41) was more potent ($IC_{50}=0.73\ \mu M$) and showed selectivity over Cav1.2 (31.8-fold). No additional data on these compounds has been reported. The compounds described in the Ionix paper are covered by two patents.[116,117]

7.03.5.3.3.2 Arylthiazolidinediones published in the patent literature

In addition to the publications from Ionix, two patents, a Chinese research institute, published in 2010[118] covering (42) and 2013[119] covering (43) describe series of related molecules (Fig. 11). No data is given in the filings.

7.03.5.3.4 Dihydropyridines

The 1,4-dihydropyridine class of drugs is one of the best characterized class of voltage-gated calcium channel blockers. They exert their antihypertensive action largely through inhibition of Cav1 channels. In recent years a number of these compounds have been shown to have activity at other voltage-gated calcium channels, clinidipine (44), $R=O(CH_2)_2OMe$), for example, is reported to inhibit both Cav1.2 and Cav2.2 channels. Ajinomoto has reported studies around the clinidipine template to enhance selectivity for Cav2.2 (Fig. 12). Studies focused on APJ2708 (44), R = H) which they report to be an equipotent blocker of Cav1.2 and

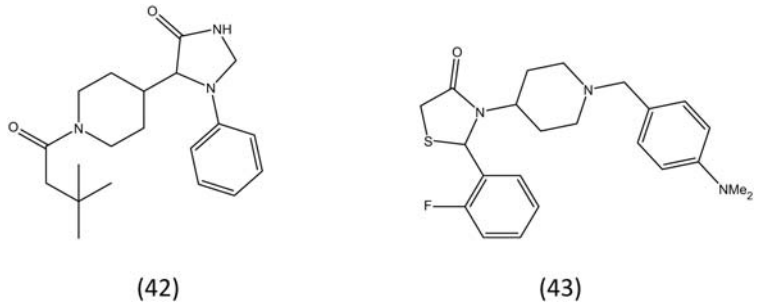

Fig. 11 Arylthiazolidinediones published in the patent literature.

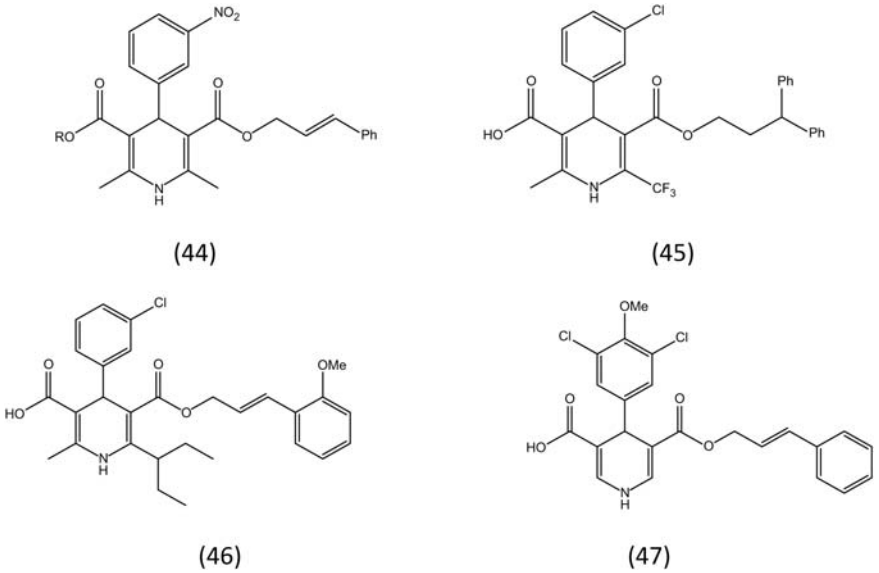

Fig. 12 Dihydropyridines published by Ajinomoto.

Cav2.2. Modulation of the lipophilic side chain produced (45), a compound selective for Cav2.2 channels (Cav2.2 $IC_{50} = 1.7$ μM, Cav2.2 $IC_{50} = 1.8$ μM). The assay formats used are different and have different sensitivities (IMR-32 calcium flux assays to determine Cav2.2 activity and a rat aortic ring (magus) assay for Cav1.2). The IMR-32 assay is reported to be approximately 1000-fold more sensitive than the magus assay, thus confusing data interpretation. Ajinomoto claims that (45) is 1600-fold selective for Cav2.2 over Cav1.2. Compound (45) was progressed to the rat formalin pain model where it demonstrated similar efficacy to clinidipine when dosed orally at 30 mg kg^{-1}. However, (45) was not progressed further due to poor solubility, reported to be 3.5 mg mL^{-1}, with a log *D* reported to be 3.5.[120] Further modification produced (46) a compound with reduced lipophilicity (log $D = 1.29$) and with similar activity and selectivity to (45) (Cav2.2 $IC_{50} = 2.5$ μM, Cav2.2 $IC_{50} = 5.9$ μM), combined with a slight improvement in solubility (10.2 mg mL^{-1}).[121] In a recent article (47) is reported,[122] the (+) isomer of which shows a slight increase in potency compared with previous compounds and improved selectivity (Cav2.2 $IC_{50} = 0.72$ μM, Cav2.2 $IC_{50} = 40$ μM) and when dosed orally at 3 mg kg^{-1} demonstrated similar efficacy to Gabapentin (100 mg kg^{-1}) in the rat formalin model. No patents have published covering these compounds nor has any development been reported.

7.03.5.3.5 Diarylmethylpiperazines

This class of compound is one that has received much attention in recent years and has led to the identification of compounds which have entered clinical evaluation, most notable being Z160 (1). The starting point for work in this area was two known drugs flunarizine (48) and lomerizine (49) (Fig. 13). Both compounds were shown to possess significant Cav2.2 inhibitory activity but were not selective. As both compounds contain a diarylmethylpiperazine group, it was originally suggested that this is a key contributor to the Cav2.2 blocking activity of these molecules.

7.03.5.3.5.1 Early molecules

A number of groups published Cav2.2 blockers containing the diphenylmethyl group, and the first reports came from the Parke-Davis group who reported that (50, Fig. 14) possessed Cav2.2 blocking activity[123]; however the compound is also reported to

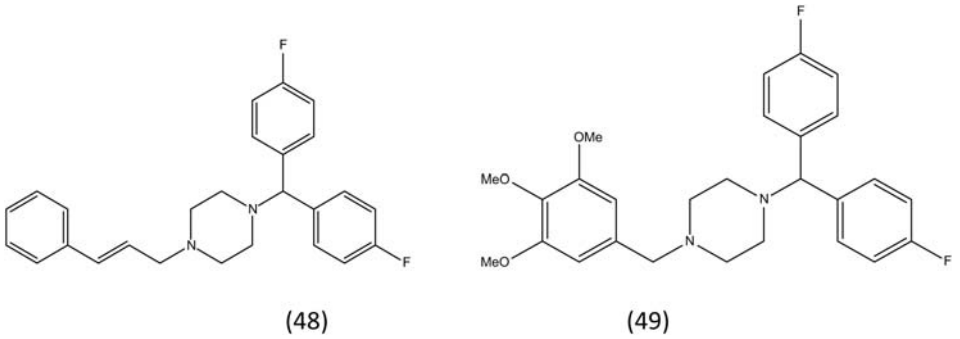

Fig. 13 Flunarizine (48) and Lomerizine (49).

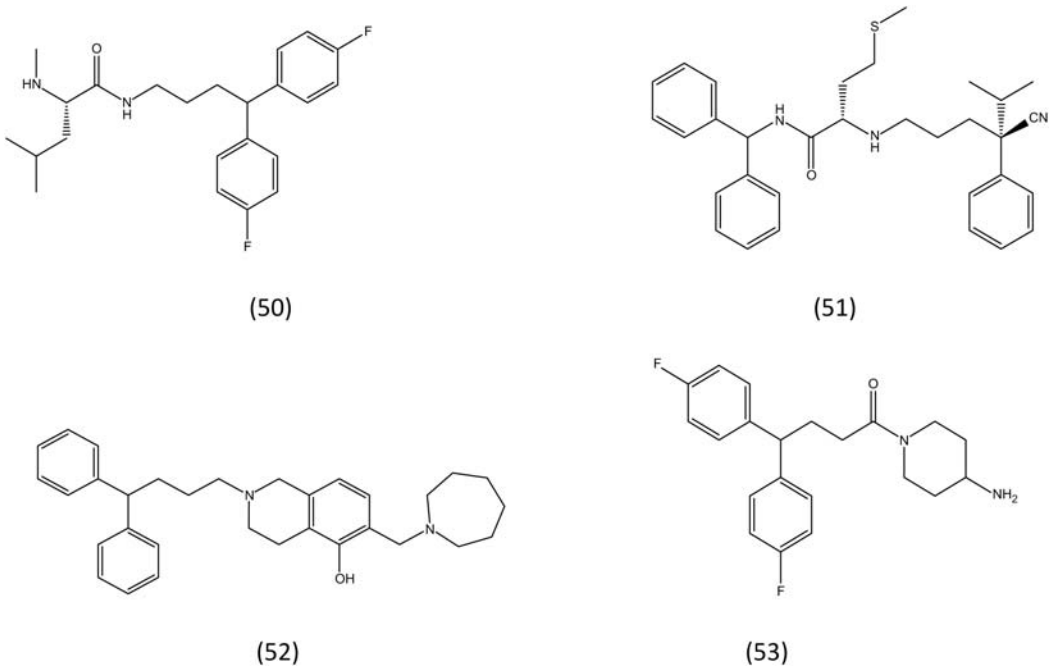

Fig. 14 Prototype Cav2.2 blockers containing a diphenylmethyl group.

be a Cav1.2 blockers as well as having activities at neuronal sodium and potassium channels. In a second article[124] Parke-Davis reported (52) which was a compound resulting from the optimisation of a screening hit that contained the hydroxyl tetrahydroisoquinoline grouping and possessed only weak potency ($IC_{50} = 35$ μM in a IMR32 assay), appending the diphenylmethyl group produced a compound with significantly increased potency ($IC_{50} = 1.1$ μM). Compound (51) appears in an early patent from Lilly,[125] however, is not reported outside the patent literature. The first report of the design of a molecule containing the diphenylmethyl moiety comes from the University of Florence[126] where they describe the discovery of (53), and their interest in designing Cav2.2 blocker came from earlier work focused on Cav1.2 blockers.

7.03.5.3.5.2 Neuromed compounds

Neuromed, who was subsequently known as Zalicus and more recently Epirus, drove the initial work in this area which led to the identification of the clinical candidate Z160 (1) (previously known as NP118809, NMED 160, and MK-6721). The initial working hypothesis was that while the diarylmethylpiperazine group was primarily responsible for the Cav2.2 blocking activity the cinnamyl groups of flunarizine (48) and the benzyl group of lomerizine (49) were contributing to the off target activities in particular Cav1.2 inhibition.[127] In the Neuromed electrophysiology assays neither compound had any selectivity; flunarizine having an estimated IC_{50} of 0.08 and 0.3 μM at Cav2.2 and Cav1.2, respectively, and lomerizine having a similar profile with IC_{50} values of 0.09 and 0.15 μM at Cav2.2 and Cav1.2. Initial investigations focused on compounds in which a second diphenylmethyl group was introduced in place of the substituents postulated to be responsible for the off target activity (Fig. 15). The diphenylmethyl group was attached to the piperazine through a variety of different linkers (54). When the linker was a simple alkyl chain ($X = CH_2$) all of

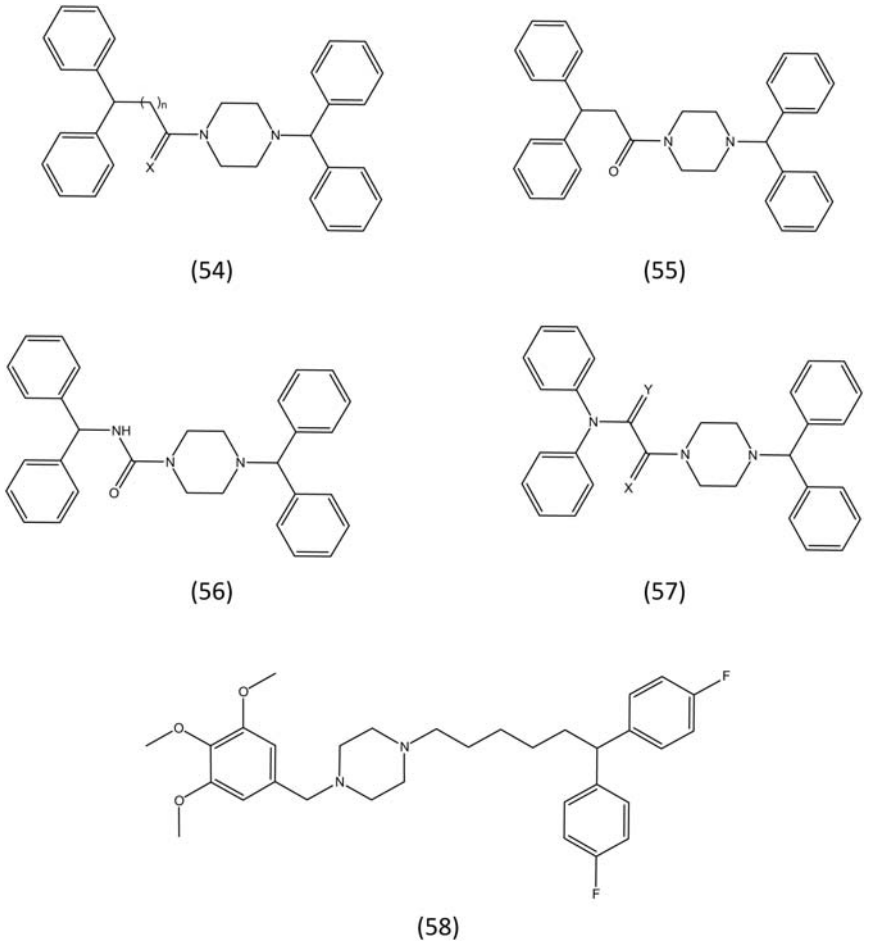

Fig. 15 Compounds reported by Neuromed derived from flunarizine and lomerizine.

the compounds were less active than the known drugs, the most potent compound having an $IC_{50} = 5$ μM ($n = 1$). The introduction of a carbonyl linker (X = O) resulted in an active compound with improved selectivity and interesting SAR. Compound (55) had an $IC_{50} = 0.11$ μM and a selectivity of 111-fold over Cav1.2; however small changes to the length of the linker resulted in significant loss of activity, with only one other compound reported to be active (54, $n = 2$) has an $IC_{50} = 23$ μM. Further investigation of linker modifications showed that nitrogen atoms could be incorporated with retention of potency but a loss in selectivity (56) having an $IC_{50} = 0.15$ μM at Cav2.2 channels but with a reduced selectivity of 12-fold. Moving the nitrogen to the benzylic position (57) resulted in compounds with different activities dependent on the position of the carbonyl group. When the carbonyl group was attached to the piperazine (57; X = O, Y = H_2) a loss in potency was observed Cav2.2 $IC_{50} = 6.6$ μM, with the isomeric compound (57; X = H_2, Y = O) retaining activity. Selectivity was not reported on the latter two compounds. Compound (55) is identified by the authors as NP118809 early in the publication.

In a parallel investigation the effect of increasing the chain length in lomerizine is reported, little SAR is reported but the profile of NP078585 (58) is described, the compound is equipotent with NP118809 but much less selective (12-fold).

The detailed profiles of NP118809 (55) and NP078585 (58) are described. Both molecules showed acceptable pharmacokinetic profiles in the rat. NP078585 was relatively quickly absorbed ($T_{max} = 1$ h), with a good half-life (4.5 h) and an oral bioavailability of 20%. NP118809 was more slowly absorbed ($T_{max} = 2.3$ h) with a half-life of 2.1 h and a bioavailability of 30%.

Both compounds are active in the rat formalin model of neuropathic pain when dosed at 25 mg kg^{-1} (*ip*). When profiled against the hERG channel NP118809 was found to be a weak blocker ($IC_{50} = 7.4$ μM), in contrast NP078585 was a highly potent blocker (98.7% inhibition at 1 μM).

This publication is the first report of NP118809 (Z160) which became the first small-molecule Cav2.2 blocker to enter clinical evaluation. The compound is covered by a number of patents[128,129] including previously described formulation patents, but other than these very little else has been reported on this compound to date.

Two subsequent publications from Neuromed describe further optimisation of NP118809[130] and NP078585.[131] The work on NP118809 focuses on demonstration of additional SAR with a strong emphasis on improving aqueous solubility.[130] Initial studies focused on the investigation of substitution of the benzhydryl group (Fig. 16, 59) focusing on introduction of small lipophilic

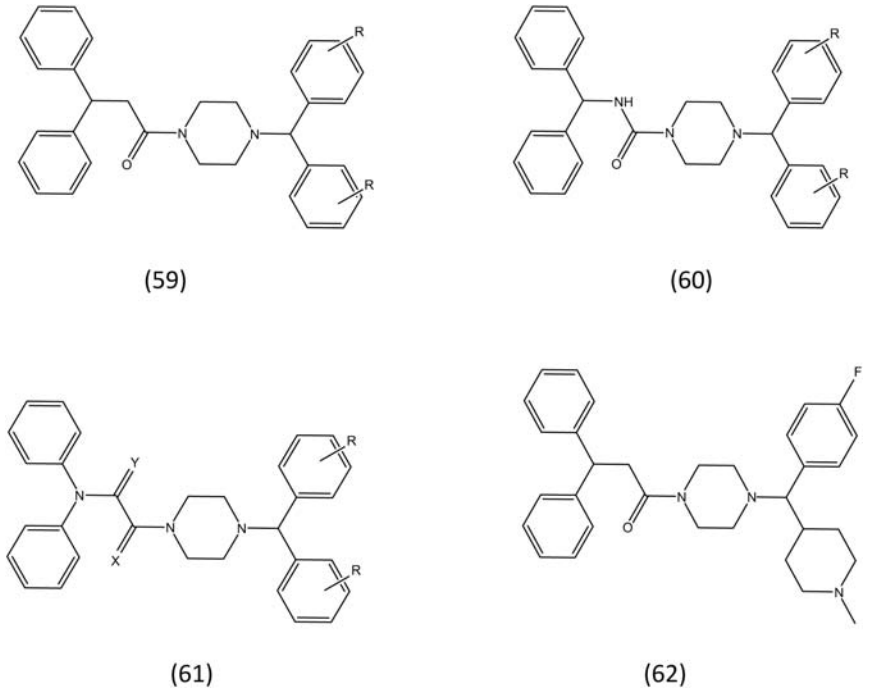

Fig. 16 Compounds prepared by Neuromed during the optimisation of NP118809.

groups which differed in their electronic nature. For mono substitution a wide variety of groups are tolerated with a slight preference for electron withdrawing groups. Optimal potency and selectivity was seen with R = 2-chloro which produced a compound with Cav2.2 $IC_{50} = 0.09$ μM and selectivity > 1000-fold over Cav1.2. A second study investigated the effects of a similar range of lipophilic substituents when introduced into analogues of (60) and (61). The results were similar to those seen with (59) and unsurprisingly all of the analogues had poor aqueous solubility and was never greater than that of NP118809 (0.52 μg mL^{-1}). Replacing one of the aromatic rings of the diphenylmethyl group with a piperidine however did enhance solubility and importantly retain both potency and selectivity. Compound (62) was a potent Cav2.2 blocker ($IC_{50} = 0.1$ μM) with similar selectivity to NP118809 (110-fold) and an aqueous solubility of 72.7 μg mL^{-1}; however when tested in a rat model of neuropathic pain [spinal nerve ligation (SNL) model], it failed to show analgesic efficacy. No pharmacokinetic data on the compound is given, so the reason for lack of efficacy is not clear.

A second publication[131] describes work focused on NP078585, where the focus is on reduction of the hERG inhibition previously reported to be an issue with this compound. Initially the work investigated introducing amide linkers between the side chains and the central piperazine in combination with varying the substituents (R) on the left-hand phenyl ring (63, Fig. 17). This initial work resulted in (64) which had a dramatic improvement in overall profile compared with NP078585, having Cav2.2 $IC_{50} = 0.09$ μM, selectivity of 900-fold over Cav1.2 and hERG $IC_{50} = 9.0$ μM. Trifluormethyl and methyl groups were also investigated as alternatives to tert-butyl but lost potency at Cav2.2. Following the initial success neuromed went on to investigate modifications of the central piperazine ring. Initially they investigated the effect of adding a simple methyl group and found that this was able to increase Cav2.2 potency and selectivity over hERG, but the selectivity profile of the compound was highly dependent on the position and isomeric nature of the methyl group as illustrated by (65) and (66). Both compounds were very potent Cav2.2 blockers ((65) $IC_{50} = 0.01$ μM and (66) $IC_{50} = 0.04$ μM) but had different hERG profiles ((65) $IC_{50} = 0.9$ μM and (66) $IC_{50} = 4.9$ μM).

In addition to substitution of the piperazine ring, replacements were also investigated in the form of 3-amino pyrrolidines (67), and while encouraging profiles were obtained, the compounds were generally inferior to the corresponding piperazines. Compounds (64) and (65) were selected for study in two different pain models. Both showed good efficacy when dosed at 30 mg kg^{-1} (*ip*) in the formalin model and when tested at the same dose but by oral administration in the Chung model of neuropathic pain[132] both (64) and (65) were able to significantly reverse thermal hyperalgesia but only (65) was efficacious at reversing mechanical hyperalgesia. The medicinal chemistry article of this second series is also accompanied by a second publication which focuses on the synthesis on the chiral piperazine derivatives.[133]

The compounds described in Neuromed's publications are covered by a number of patent applications[134–136]; however no development has been reported for Cav2.2 blockers other than Z160.

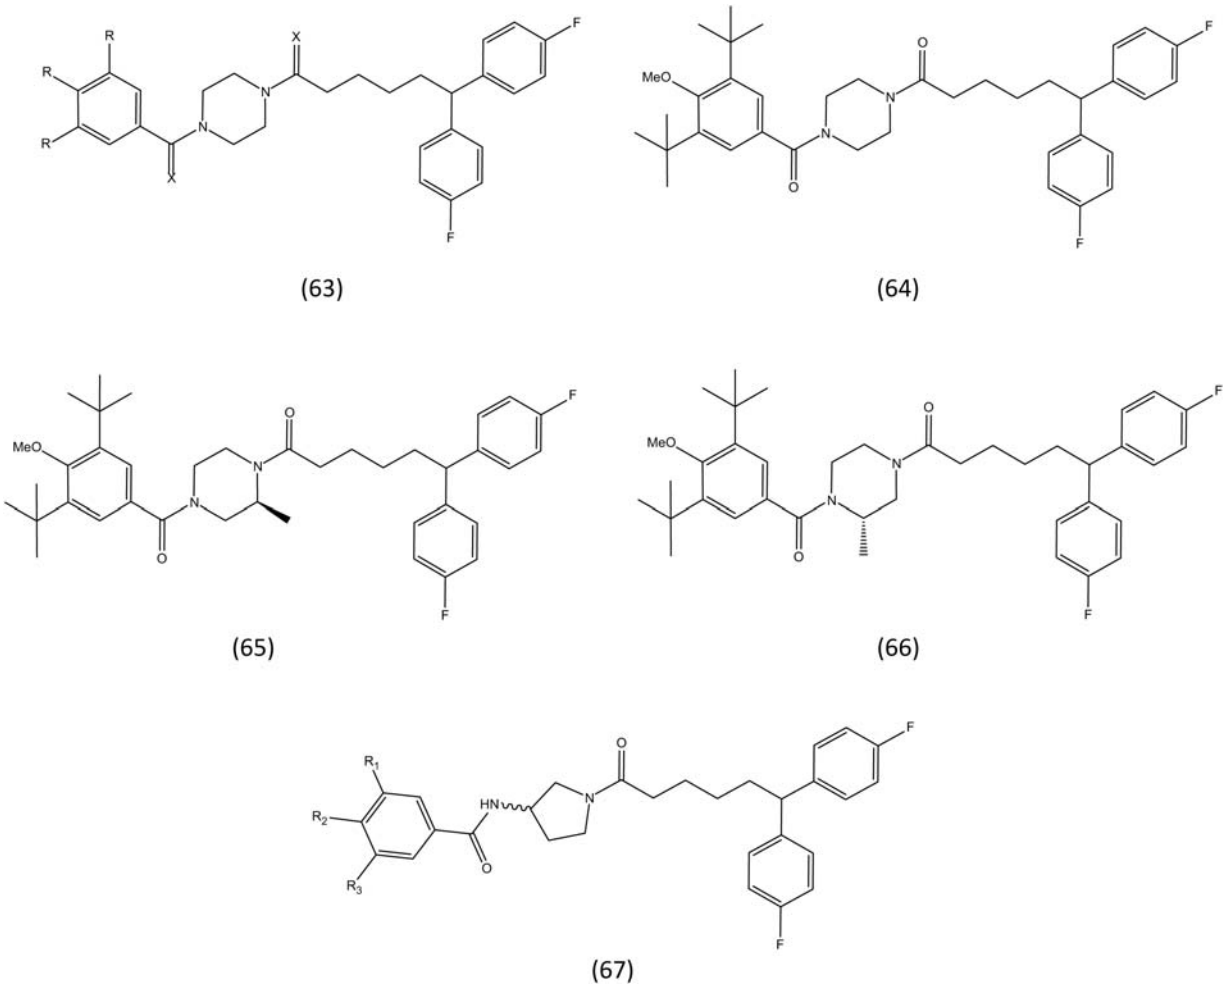

Fig. 17 Compounds prepared by Neuromed during the optimisation of NP078585.

7.03.5.3.5.3 Abbott compounds

Abbott has described the identification of a series of diphenyl lactams in which the diphenylmethyl group is incorporated into the lactam ring[137] (**Fig. 18**). The work led to two advanced compounds A-686085 (69) and A-1048400 (16) whose detailed profiles have been described in a subsequent publication.[138] The series was identified through high-throughput screening with the original hit being trimethoxy compound (68). Comparing the structure of the hit with the compounds published by the Neuromed group led to the proposal that the diphenyl lactam might be acting as an isostere for the diphenylmethylpiperazine. To test their proposal Abbott prepared several small sets of compounds based on the general structure (70). Initially both 5- and 6-membered ring lactams were synthesized and analogues prepared in which a piperazine ring substituted with either a benzhydryl group (70, R = phenyl, D = N) or benzyl group (70, R = H, D = N) was attached through an acetamide linker. The initial set of compounds tested was benzyhydryl derivatives, and all compounds were tested in a FLIPR assay. Promising activity was seen in both 5- and 6-membered lactam analogues with a set of benzhydryl groups which were either unsubstituted or had a halogen (chlorine or fluorine) in the 4 position of each benzene ring. pIC_{50} values ranged from 5.4 to 6.4. Work was quickly stopped as all compounds suffered from poor aqueous solubility (< 25 μM, neutral pH) largely due to the high lipophilicity (cLogP > 6 in most cases). The exercise was repeated with benzyl substituents (70, R = H) which reduced the overall log *P* of the compounds and improved solubility but resulted in a small drop in potency, typically 0.5 log unit compared to the corresponding benzhydryl analogue. Finally replacements for the piperazine were investigated focusing mainly on piperazines (70 R = Ph, D = CH). The replacement was tolerated in terms of potency but increased the lipophilicity of the compounds resulting in poor drug like properties. All compounds described were active with pIC_{50} values in the range of 5.5–6.0. Finally selected compounds were profiled in in vitro DMPK assays and in in vivo DMPK and efficacy assays with (16) having the optimal profile. The full profile of both (16) and (70, A-686085) was described in a subsequent publication[138] which is summarized in **Tables 4** and **5**.

The two compounds were profiled together initially in selectivity assays and in an in vivo study which examined the effects of the compounds on cardiovascular parameters. Neither compound showed appreciable selectivity over the Cav3 channels but differed in their effects on Cav1.2 channels as determined in a rat aortic ring assay. The original lead A-686085 (70) potently relaxed the tissue with an $IC_{50} = 0.6\ \mu M$, whereas A-1048400 (16) produced only weak inhibition. When profiled in vivo A-686085 caused a marked decrease in mean arterial pressure (MAP) at a concentration of $0.7\ \mu g\ mL^{-1}$ in contrast to A-1048400 which showed no effects on MAP up to and including a concentration of $4.9 \mu g\ mL^{-1}$. Based on the data in **Table 4** A-1048400 was selected for detailed profiling along, and the data is shown in **Table 5**.

When tested in electrophysiology assays A-1048400 was shown to be a potent and state-dependent inhibitor of Cav2.2 channels. Interestingly it showed little or no selectivity for Ca2.1 and Cav3.2 channels. In terms of general selectivity the compound had an excellent profile, only having appreciable binding affinity at the neuropeptide Y2 receptor.

The molecule had a pharmacokinetic profile suitable for testing via oral administration with acceptable bioavailability and reasonable half-life in the rat. The brain to blood ratio was rather low and perhaps surprising given the quite high volume of distribution, suggesting the compound maybe a transporter substrate, although this is not mentioned in the publications. Encouragingly when tested in a battery of pain models A-1048400 showed activity in all modalities being active in models of inflammatory pain—the mono-iodoacetic acid (MIA) model of osteoarthritis pain[139] and the complete Freunds adjuvant (CFA) inflammatory pain model [140] together with models of neuropathic pain, the sciatic nerve ligation model and the chronic constriction injury model. Finally and also encouragingly there appeared to be low potential for CNS side effects as no adverse effects on motor coordination were detected in the rotorod test.[141]

A-1048400 is covered by a single patent[142] and does not appear to have entered development based on currently available information.

A second and possibly related series was later described by the Abbott group[143] which contains a dicyclohexylmethyl group rather than the more common diphenylmethyl (**Fig. 19**). These compounds were also identified through a high-throughput screen. A series of bicyclic compounds were identified as micromolar Cav2.2 blockers in a FLIPR assay (e.g., (71), **Fig. 19**, $IC_{50} = 4.67\ \mu M$) which importantly were devoid of Cav1.2 activity ($IC_{50} > 30\ \mu M$). Initial work focused on studies using racemic material and examined two areas of the molecule (a) introduction of substitution on the benzyl group where it was found that addition of lipophilic groups gave rise to a modest increase in potency but did not affect selectivity over Cav1.2, for example, (72) was shown to have a Cav2.2 $IC_{50} = 1.3\ \mu M$ and Cav1.2 $IC_{50} > 30\ \mu M$. (b) Variation of the amide moiety and a variety of amide substituents were tolerated in dialkylmethyl groups and monoalkylmethyl groups, analysis of the data showed that the dicyclohexyl was optimal both for potency and selectivity of Cav1.2.

Resolution of (72) into separate enantiomers showed (73) to have the superior profile (Cav2.2 $IC_{50} = 0.46\ \mu M$; Cav1.2 $IC_{50} = > 30\ \mu M$) with (74) being slightly less potent (Cav2.2 $IC_{50} = 1.4\ \mu M$; Cav1.2 $IC_{50} = > 30\ \mu M$). Based on this data (73) was selected for further study (**Table 6**).

Compound (73) was shown to be a highly potent state-dependent Cav2.2 blocker which was selective over Cav1.2 channels as demonstrated in the rat aortic ring assay and consequently had no effect on cardiovascular parameters up to a concentration of

Rotorod	No significant effects up to and including 30 mg kg	

17 μg mL^{-1} in vivo. Abbott stated that the compound is highly lipophilic (data not given) and that as a consequence the compound was poorly soluble and unstable in both rat and human microsomes ($<5\%$ parent remaining after 30 min incubation). Due to the poor solubility and metabolic instability, its pharmacokinetic profile was evaluated via ip administration and shown to be suitable for efficacy and safety profiling. In a variety of pain models (73) demonstrated efficacy and showed no sign of CNS side effects in the rotorod model. The compounds are covered by two patents[144,145]; however, to date there is no evidence that any of these compounds entered development.

7.03.5.3.5.4 Diphenylmethylpiperazines and related structures published only in the patent literature

A number of companies have patented novel Cav2.2 blockers containing diphenylmethyl groups linked to a saturated nitrogen containing heterocyclic ring. These are summarized in Fig. 20. The majority of compounds have been identified by Shionogi or

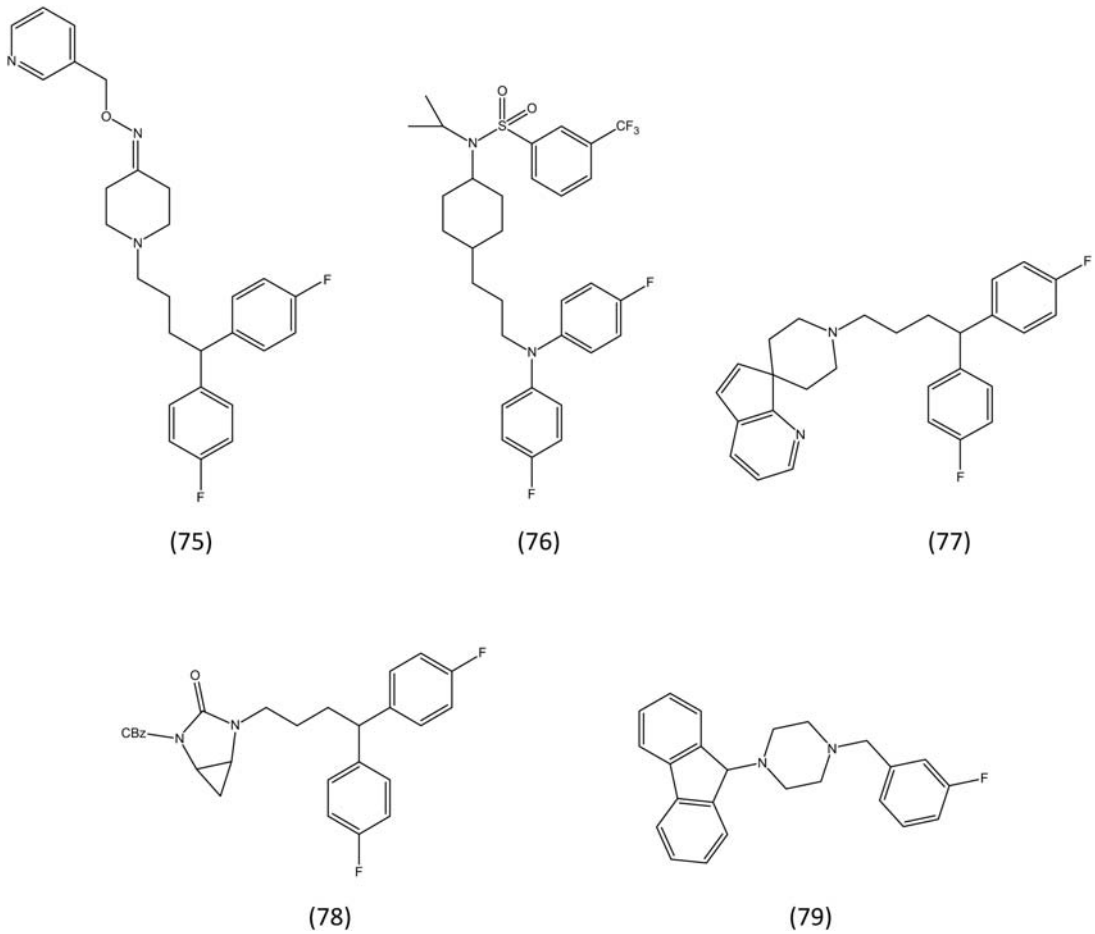

Fig. 20 Diphenylmethylpiperazines published in the patent literature.

Shionogi/Euro-Celtique who have published four patent filings covering compounds containing this template or related structures. The only patent which contains screening data describes a series of oximes with (75) reported to have an IC_{50} of 6.6 μM in a Cav2.2 FLIPR assays.[146] Other filings cover a range of different group including aminocyclohexylsulfonamides (76),[147] spiro indanes (77),[148] and cyclic ureas (78).[149] A recent filing from Institute of Pharmacology and Toxicology, Academy of Military Medical Sciences, PLA, Peoples Republic of China covers a series in which the diphenylmethyl group is fused producing a tricyclic system (79).[150] No data is provided.

7.03.5.3.6 Sulfones and sulfonamides

7.03.5.3.6.1 Merck compounds

Another template which has been reported by a number of groups is that based on a core structure of a saturated cyclic amine capped with a sulfonamide or the corresponding sulfone. Many examples of this template have appeared in the patent literature during recent years but as yet relatively few scientific articles have been published. Merck has published the details of one series of compounds.[151,152] Sulfonamide (80, Fig. 21) was identified by high-throughput screening and showed promising activity in a FLIPR assay (Cav2.2 $IC_{50} = 0.12$ μM), the compound however displayed poor selectivity over Cav1.2 ($IC_{50} = 0.12$ μM) and hERG (91% inhibition (1 μM). Additionally (80) had a poor pharmacokinetic profile when tested in the rat having a clearance in excess of liver blood flow ($Clp = 169$ mL $min^{-1} kg^{-1}$). Initial modification of the propyl group on the sulfonamide gave (81) which showed increased Cav2.2 potency ($IC_{50} = 0.06$ μM) but retained similar activity at hERG (70% inhibition (1 μM)), and this template was selected for further SAR investigation. Modification of the left-hand phenyl ring (phenyl ring of the benzyl group) substituents revealed that (a) a wide range of lipophilic groups were tolerated but retained the profile of the original hit; (b) polar, hydrogen bond donor groups reduced potency at Cav2.2; and (c) introduction of a sulfonyl group at the 2-position improved both potency and selectivity (82). Several compounds were selected for further profiling of which (82) is described in the most detail (Table 7).

Compound (82) has slightly reduced activity at Cav2.2 in the FLIPR assay but an improved selectivity profile both against Cav2.1 and hERG. The compound had an excellent pharmacokinetic profile in the rat and showed efficacy in models of both inflammatory and neuropathic pain. Unfortunately the in vivo efficacy results were rendered equivocal with the finding that a metabolite which circulated in appreciable concentrations (83) showed efficacy in both pain models but was devoid of Cav2.2 activity, hence the compound was not progressed further. It also inhibited cytochrome P450 3A4 ($IC_{50} = 5.1$ μM) and showed the potential to induce

the same enzyme through its activity at the PXR receptor ($EC_{50} = 0.43$ μM). These results did however initiate further chemistry studies[152] to identify related compounds with similar Cav2.2 activity but which did not produce the same metabolite.

Efforts initially focused on two areas (a) further modification of the left-hand phenyl ring substituents and (b) replacement of the central piperidine with alternative saturated heterocycles. While many of the modifications resulted in potent Cav2.2 blockers, where tested compounds retained cytochrome P450 inhibitory and induction together with producing (83) when incubated with liver microsomes. The successful strategy which ultimately prevented formation of the undesired metabolite was to replace the nitrogen of the sulfonamide with a tertiary carbon atom thus creating a sulfone and avoiding a potential metabolic pathway involving initial hydroxylation of the carbon atom to which the nitrogen atom of the sulfonamide is attached. The profiles of two compounds (84) and (85) resulting from the work are described. Both compounds retained potent Cav2.2 activity in the FLIPR assay and good selectivity over Ca1.2 and hERG. Compound (84) showed a slight improvement in PXR activity and (85) had a much better profile. Both compounds had moderate clearance in the rat with (85) having higher bioavailability compared to (84); no reason is suggested for this difference. Both compounds demonstrate modest efficacy in the FCA inflammatory pain model. Compound (85) is reported to be a substrate for the transporter P glycoprotein (P-gp, efflux ratio 4.2) compared to (84) which is reported to have an efflux ration of 1.8. Neither compound was considered to be suitable for further progression. The compounds are covered by two patent filings.[153,154]

7.03.5.3.6.2 Janssen compounds

Janssen has also described a structurally distinct series of sulfonamides[155] derived from hits identified by high-throughput screening (**Fig. 22**). A series of diphenyl pyrazoles were identified from the screen which showed excellent potency in a functional calcium indicator dye assay (FDSS), ((86) $IC_{50} = 97$ nM) but demonstrated poor in vitro metabolic stability (14% remaining after 10 min incubation with rat liver microsomes). Additionally the hits were not chemically novel. In an attempt to achieve novelty and improved metabolic stability a series of substituted piperidines (87) were synthesized. A number of alkyl sulfonamides all demonstrated promising activity in the FDSS assay ($IC_{50} < 100$ nM). The compound (87, $R = MeSO_2$) was selected for full profiling (**Table 8**). The compound is a potent Cav2.2 blocker in both the FDSS and automated patch clamp assays; in the latter the compound showed evidence of frequency-dependent inhibition unlike ω conotoxin. Additionally selectivity of Cav1.2 is reported. What is interesting about Janssen's approach is they report data in a biochemical functional assay where (87) potently inhibits CGRP release from rat spinal cord slices evoked by potassium chloride treatment. Compound (87) is much more stable in liver microsomes compared to the original hit and when tested in the rat demonstrated had an encouraging pharmacokinetic profile. Surprisingly given the encouraging bioavailability (87) was subsequently profiled in two pain studies via ip administration where it showed efficacy in models of both inflammatory and neuropathic pain. SAR investigation around both of the benzene rings is reported and additionally the replacement of the chlorophenyl group with either saturated or heterocyclic systems. Limited studies around the methoxyphenyl group suggest that hydrophobic groups are preferred, and that the relative position of the chlorine on the other ring is important. However insufficient compounds are reported to draw strong conclusions. A similar trend regarding

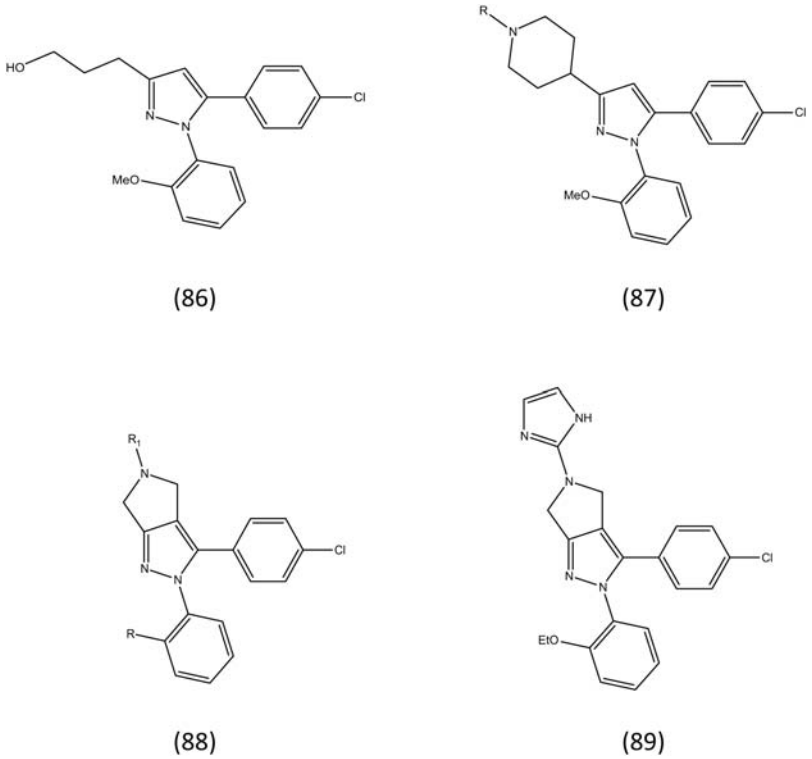

Fig. 22 Sulfonamides and related compounds published by Janssen.

a preference for hydrophobic groups is observed with the chlorophenyl ring. Attempts to replace the chlorophenyl group with fully saturated rings resulted in a small loss of potency which could be restored through introduction of a double bond. Heterocycles also appear to be tolerated although only a few examples are reported.

In two subsequent publications[88,156] Janssen described further studies based around optimization of (86). An alternative strategy to that previously described was to fuse a saturated nitrogen containing heterocycle onto the core pyrazole (88). Initial studies investigated a variety of phenyl substituents (R) in combination with nitrogen substituents (R1). Sulfonamides and sulfamides in combination with R as methoxy were optimal for both potency but did not afford stability in microsomes, for example, the methylsulfonamide derivative (R = OMe, R1 = SO_2Me) is reported to have Cav2.2 $IC_{50} = 21$ nM (FDSS assay) but following 10 min incubation with human liver microsomes only 3% compound remained. An extensive investigation of different sulfonamides in combination with different phenyl substituents produced a number of active compounds but failed to solve the metabolic stability issue in microsomes. The only way to achieve both potency and in vitro stability was to replace the sulfonamide

group within this series, the optimal compound being the imidazole derivative (89). It should be highlighted that in their article Janssen does not specify which imidazole isomer was prepared however from the perspectives of both chemical stability and bioisosterism the isomer depicted by (89) is the most likely. Compound (89) is reported to have Cav2.2 activity ($IC_{50}=38$ nM, FDFSS assay), was active in the QPatch assay (13% inhibition at low frequency and 29% at high frequency when tested at 0.1 μM), inhibited CGRP release from rat spinal cord slices (21%@ 1 μM), and was stable in rat liver microsomes (81% remaining after 10 min incubation). No further scientific articles have been published by the Janssen group; however a number of patents have published covering structures related to those described. Compound (87) does not appear to have been covered by any patent filing; however bicyclic sulfonyl derivatives (88) are covered by a 2014 patent.[157] A number of related nonsulfonyl compounds are covered by patent filings but not covered by scientific publications and are briefly described in the following section.

7.03.5.3.6.2.1 Related compounds described in the patent literature

In addition to the sulfonamides and related structures that have been described in the scientific literature a number of closely related nonsulfonamide structures have been the subject of patent filings (**Fig. 23**). Three patents cover pyrazoles[158–160] with a cyclic oxygen containing substituent which is directly linked (90), fused as part of a cyclic ketal (91), or attached through a linker (92). In a more recent filing imidazole analogues (93) are also described.[161]

7.03.5.3.6.3 Sulfones and sulfonamides only published in the patent literature

The sulfonyl class of channel blocker is by far the most common in terms of publications, and while some templates have been described in detail in the scientific literature, many more are covered by patent filings. A summary of patents published in the last 10 years is shown in **Table 9**. A wide variety of sulfonamides have been patented which typically, but not exclusively, have an aryl sulfonyl group attached to a saturated ring which can bear a wide variety of functionality, suggesting that the phenyl sulfonyl moiety is in some way a privileged fragment. In many cases little or no data is given so drawing conclusions regarding SAR or the preferred compound in the patent is difficult.

Zalicus has filed one patent covering diaryl sufonyl derivatives, and compound (94) is reported to have an $IC_{50}=320$ nM in a FLIPR assay.[162] Shionogi has filed a total of eight patents all covering arylsufonamides some of which are filed by Shionogi and Euro-Celtique. Euro-Celtique SA acts as a patent holding agent for various companies. Four patents cover phenyl sulfonyl piperidines and vary in the nature of the group appended to the 4-position of the piperidine, which may be a vinyl amide, for example, (95) with the compound reported to have $IC_{50}=550$ nM (FLIPR assay).[163] *N*-acyl hydroxyamines (96),[164] oxycarbamates (97, $IC_{50}=240$ nM),[165] as well as glycine amides (98, $IC_{50}=440$ nM)[166] are claimed. The remaining four filings cover 4-piperidine sulfonamides (99, 100, and 101)[147,167–169] or 3-piperidine sulfonamides (102)[149] with the ring nitrogen capped by either acyl, sulfonyl, or alkyl groups. Compound (102) is reported to have $IC_{50}=130$ nM (FLIPR).

Convergence has filed a number of patents covering different sulfonamides. Five related patents cover piperazine sulfonamides (103–107). The first three patents[170–172] cover simple piperazine sulfonamides (103–105) capped with an amide and differ that in one case the piperazine is substituted with an alkyl group.[171] A further case covers similar structures, but the piperazine is capped

with a urea (106),[173] and in a fifth case the capping group is fused to the piperazine ring to form a tricyclic structure (107).[174] Three further cases cover piperidine sulfonamides (108–110) with an additional ring either attached as a spiro system at the 3-position[175] or 4-position[176] or appended directly to the 3-position of the piperidine.[177] In each case limited data is given, but the compounds shown are all described as being use-dependent blockers ($pUID_{30} > 5$) with at least 10-fold selectivity over the resting state of the channel tonic inhibition ($pIC_{50} < 4.5$ in an ionworks assay). No scientific publications have yet emerged from GSK or Convergence describing the discovery of these compounds, and the structure and biological profile of the clinical development candidate CNV2197944 still remains unknown.

Pfizer has filed a single patent[178] covering various saturated heterocyclic sulfonamides, and the morpholine (111) is reported to have $IC_{50} = 70$ nM (NTCC assay). Recently Grunenthal has filed two applications covering phenylsulfones with a tetrahydrofuran (112)[179] or tetrahydropyran (113) core[180]; both (112) and (113) are reported to inhibit Cav2.2 by >95% when tested at 3 μM (FLIPR). Ono has filed one patent covering benzenesulfonamides[181] with (114) reported to inhibit Cav2.2 by 82% (1 μM (FLIPR). Vernalis has filed a single patent[182] covering acyclic sulfonamides (115), no data is given. And Ionix has filed a patent[183] covering piperidine sulfonamides (116) with most compounds inhibiting Cav2.2 in the single-digit micromolar range (FLIPR).

7.03.5.3.7 Indole-derived structures

7.03.5.3.7.1 Merck compounds

Merck has published the profiles of several structurally diverse compounds with an indole ring as the core structure. The oxindole (18, TROX-1) is described in two biology publications[184,185] which detail the compounds pharmacological profile in detail. No medicinal chemistry around this template has been described to date, but the compound and analogues are covered by two patent filings.[186,187] It is also unclear exactly how TROX-1 was identified, but an assay development paper[188] published at a similar time to the biology papers suggest it might have been identified by screening. TROX-1 is a state-dependent Cav2.2 blocker (**Table 10**) and shows encouraging activity in several assay formats. It is selective over a wide range of targets, but poorly selective among the subtypes of the Cav2 family, particularly when tested in the depolarized state where it is an equipotent blocker of Cav2.1, Cav2.2, and Cav2.3 channels. The compound has an encouraging pharmacokinetic profile in the rat with high bioavailability a good plasma half-life and a brain to plasma ratio of unity. When tested in a range of pain models at 30 mg kg^{-1} the compound shows similar analgesic effects to standard marketed compounds such as pregabalin. In the rotorod assay while the compound did show the potential for CNS side effects at 100 mg kg^{-1}, no adverse effects were seen at lower doses suggesting the potential for an acceptable therapeutic index. When tested in a dog cardiovascular model, dose-related effects on heart rate and MAP were seen at doses of 3 and 10 mg kg^{-1}. The authors suggest that the effects are Cav2 mechanism related and that potentially the state

dependency is not optimal. It was felt that the profile was not suitable for progression largely due to the lack of selectivity among Cav2 family members.

TROX-1 and related analogues are covered by two patent filings.[186,187] Ref.[186] covers TROX-1 and a close set of analogues[187] covers structurally related compounds but with either no nitrogen substituent or those containing a methylene linker between the oxindole core and the nitrogen substituent, for example, (117). Little data is given in the patents hence it is difficult to have an idea of detailed SAR, but general trends can be observed.

In a related publication[189] Merck described the discovery of a series of indoles (118–121, **Fig. 24**). The series was identified through a screening campaign with the original hit being (118) having Cav2.2 $IC_{50} = 0.88$ μM (FLIPR) and encouraging selectivity over Cav1.2 and sodium channels (Nav1.5 channels). Preliminary SAR studies led to the identification of (119) which retained the potency and selectivity of the original hit. The initial focus was to simplify the structure, and Merck hypothesized that the C3 substituent might not be required for activity which was indeed the case. Focus then turned to SAR at the 5-position with compounds unsubstituted at C3. It was found that the gem dimethyl group was required for activity and that the bicyclic amide could be simplified to a *t*-butyl group which gave lead structure (120), having a very similar profile to (118) (Cav2.2 $IC_{50} = 0.88$ μM, similar selectivity). Further optimization showed that *t*-butyl acetamides at both N1 and C5 were optimal for potency, and isosteric replacements resulted in loss of activity. When tested, compounds with the 3,5 diphenyl group at C2 were unstable in both rat and human liver microsomes. Modifying the substituents on the phenyl ring afforded improved stability (for (121), 20% compound

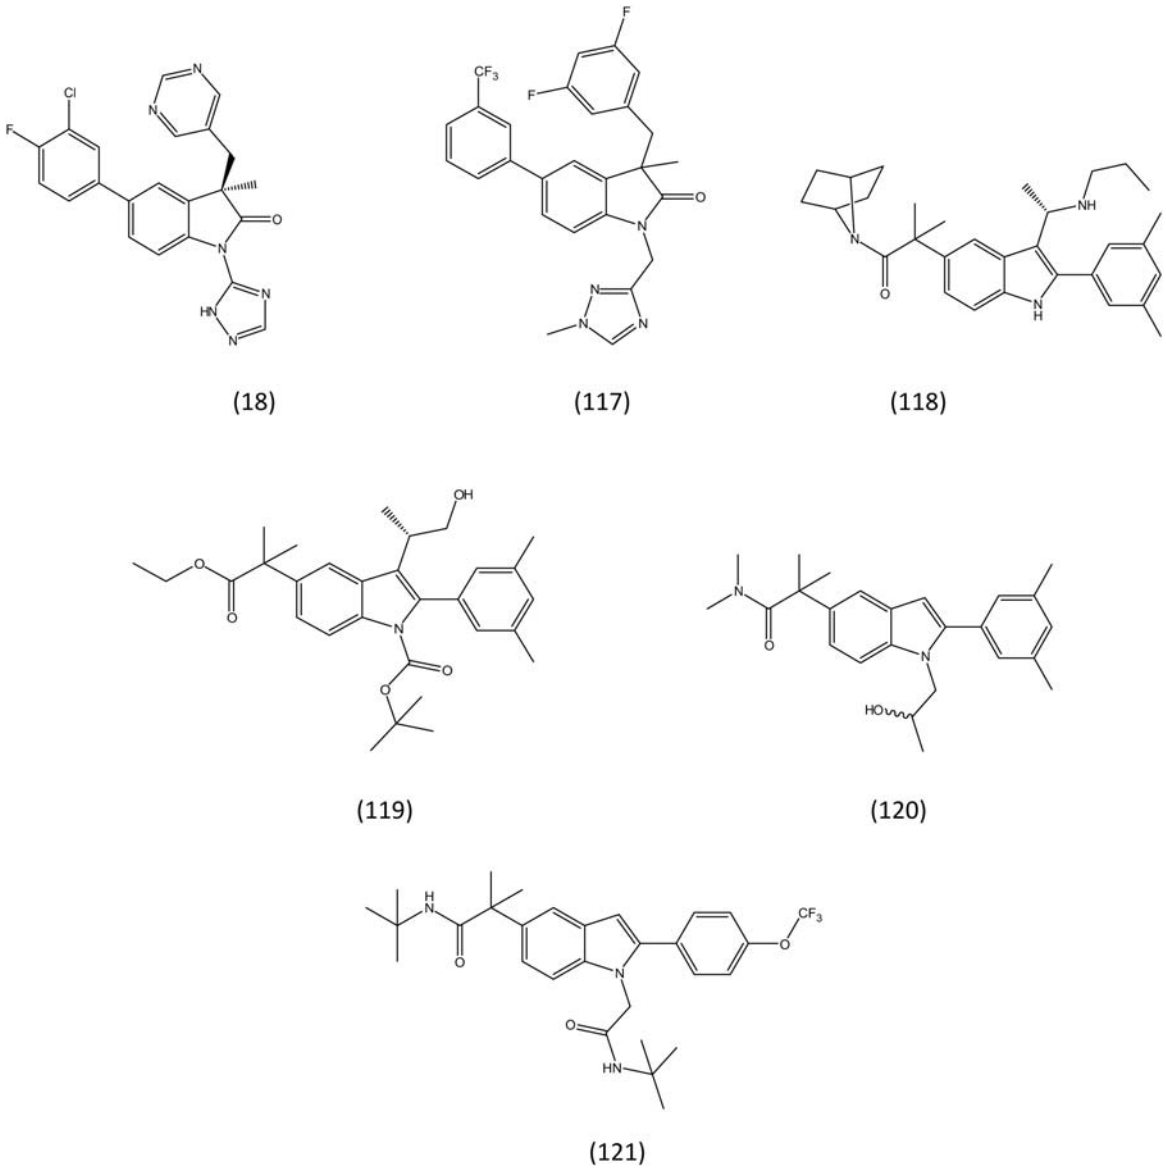

Fig. 24 Indole based compounds published by Merck.

remaining after 60 min incubation with both rat and human liver microsomes). The 2-trifluoromethoxy analogue of B was more stable in microsomal assays, but in vivo (121) had the better bioavailability and was chosen for further study. The indole derivative (121) was a potent Cav2.2 inhibitor in the FLIPR assay ($IC_{50}=0.15$ μM) with modest selectivity over Cav1.2 ($IC_{50}=0.91$ μM). It has a pharmacokinetic profile in the rat suitable for profiling in pain models (high clearance (64 mL $min^{-1}kg^{-1}$), $T_{1/2}=1.4$ h and 68% bioavailable). When profiled in models of both inflammatory and neuropathic pain it demonstrated robust efficacy at a dose of 30 mg kg^{-1} (*po*). However when dosed to dogs it showed effects on both heart rate and MAP at doses between 1 and 10 mg kg^{-1}. Plasma levels from the experiments suggest that the effects are consistent with the poor selectivity over Cav1.2. No further studies have been reported with this class of compounds. The indole compounds are covered by a single patent filing.[190]

7.03.5.3.7.2 Structures only disclosed in patents

Merck filed a patent[191] covering the tetrahydroisoquinoline derivatives (**Fig. 25**, (122) and (123)). The compounds are not indoles specifically, but given their structural similarity to TROX-1 (16) it is appropriate that they are included in this section. Compounds containing the mono and dioxo core are covered. They differ from TROX-1 in that no compounds are claimed with a pendant heterocycle corresponding to the triazole in (18). The compounds are potent Cav2.2 blockers with (122) and (123) have IC_{50} values of 023 and 0.02 μM, respectively. Preferred compounds are also described as having activity at Cav3 channels although no data is given. Lectus has filed two patents[192,193] covering indoles with a glyoxamide at the 3-position. The compounds are claimed to act by blocking interaction between the channels α1 and β subunits. The patent[192] covers simple oxamide derivatives, and compound (124) is reported to inhibit Cav2.2 activity by 44% at 1 μM in a rat DRG electrophysiology assay. The second patent[193] covers aminoacetic acid derivatives (125). Little data is given although (125) is described at inhibiting Cav2.2 currents in a rat DRG assay when applied at 50 μM.

7.03.5.3.8 Miscellaneous templates

7.03.5.3.8.1 Miscellaneous structures disclosed in the scientific literature

The 2-bromofuran ZC88 (126, **Fig. 26**) is reported to be a potent Cav2.2 blocker ($IC_{50}=0.45$ μM in oocytes) with high selectivity over Cav1.2 and Cav2.1 channels[194]; however it is also reported to be a hERG blocker.[195] The compound has been profiled in pain models where it demonstrates encouraging efficacy.[196] However, the presence of a 2-bromofuran moiety raises the question to the stability of the compound and its utility as a tool. The triazine T4 (127) has recently been reported by Abbvie scientists as a highly state-dependent blocker.[197] No patents have been published covering either of these compounds.

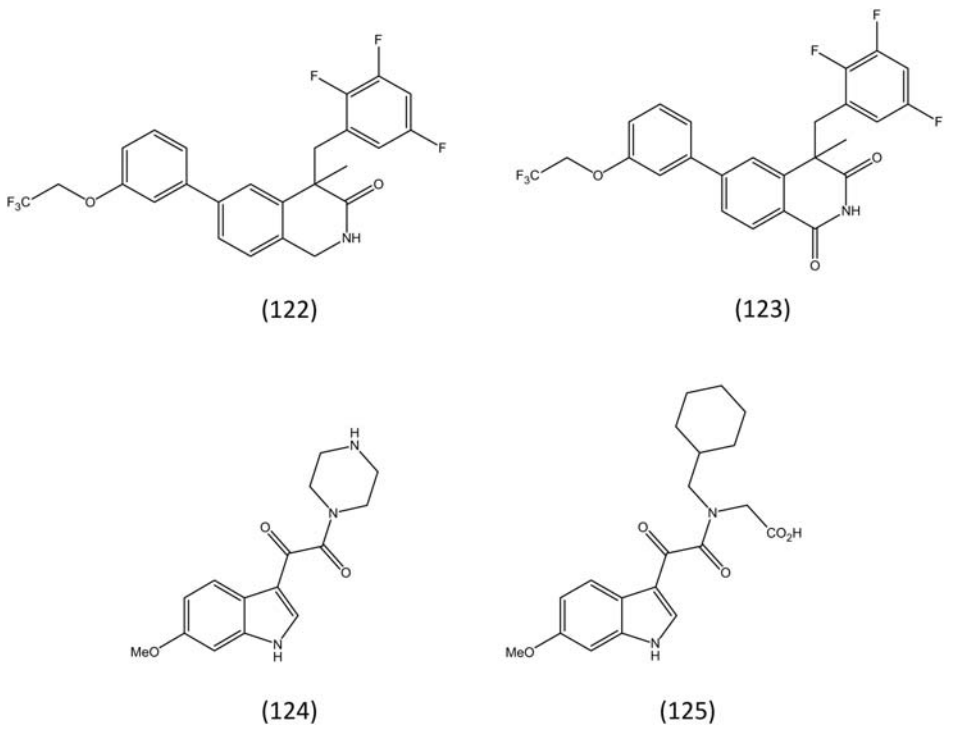

Fig. 25 Indole based scaffolds only disclosed in the patent literature.

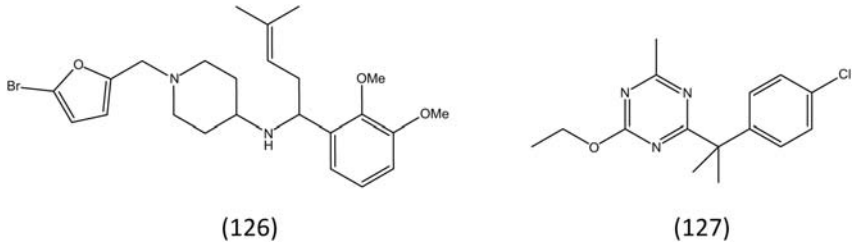

Fig. 26 Miscellaneous structures disclosed in the scientific literature.

7.03.5.3.8.2 Miscellaneous structures disclosed in the patent literature

A number of patent filings cover compounds not disclosed in the scientific literature and which do not belong to classes reported by other organizations (Fig. 27). Astellas has a single filing[198] which covers tetrahydroisoquinolines (128), and the compound is reported to actively block calcium influx into IMR 2 cells when tested at 1 μM, and when tested in the formalin pain model at 100 mg kg^{-1} produced a 52% reversal of response. Vertex has filed a patent covering quinazolines (129), but no data is given.[199] Neuromed has filed a patent[200] covering amino acid derivatives (130) distinct from other templates they have disclosed. GSK/Convergence has filed one patent[201] which covers structurally distinct compounds from the sulfonamides around which their other patents are based. This case covers phenyltetrazoles (131), similar to the other cases compounds are reported to be use-dependent blockers and not display any tonic inhibition ($IC_{50} < 4.5$) in an ionworks assay. Grunenthal has filed four patents[202–204,306] covering pyrrole derivative (132).

7.03.5.4 Cav2.3 Blockers

There have been recent reports which suggest that Cav2.3 plays a role in pain signaling and that this channel might also be a pain target.[14] Validation data comes from studies with the tarantula toxin SNX-482 demonstrating efficacy in preclinical pain models.[205] It important to highlight that while SNX-482 selectively blocks Cav2.3 channels it does have some activity at Cav1 channels. Mice lacking the Cav2.3 gene demonstrate reduced sensitivity to pain,[206] and clinically it has been suggested that polymorphisms of the gene may be responsible for different responses to fentanyl in patients undergoing surgery.[14] Currently no selective small-molecule

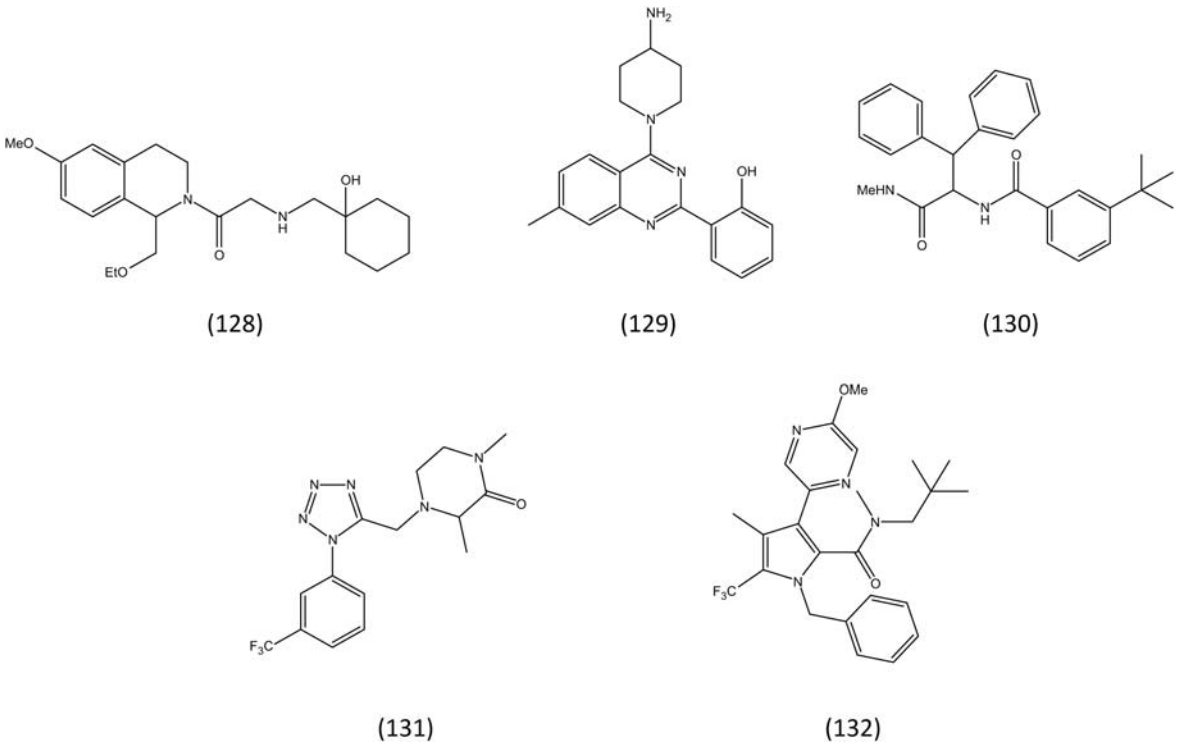

Fig. 27 Miscellaneous structures disclosed in the patent literature.

Cav2.3 inhibitors have been reported. There are publications showing that drugs such as lamotrigine and topiramate block Cav2.3 in addition to other channels.[14]

7.03.5.5 Cav3 Blockers

The Cav3 or T-type family has received much attention and is alongside Cav2.2 with respect to the level of interest based on volume of publications. Unlike Cav2.2 the T-type family has three well-characterized subtypes, Cav3.1, Ca3.2, and Ca3.3 all of which are validated pain targets. Most workers have focused on the identification of nonselective Cav3 blockers rather than subtype selective agents, and all three will be covered together in this section and molecules which have demonstrated selectivity will be highlighted. Unlike the Cav2.2 there are relatively few toxins reported to be potent and selective inhibitors of Cav3 channels. A number of agents have been reported that block Cav3 channel but are also potent blockers of other channels. The only toxin reported to date with any genuine selectivity is PsPTx3, a peptide isolated from Theraphosidae tarantula that has apparent selectivity for Cav3.2 calcium channels.[207] The preferred tools for Cav3 block in electrophysioloigical characterization studies are metal ions such as nickel. Thus there has been no small-molecule inhibitors designed using peptides as starting points. It should be pointed out that there is strong target validation for the role of Cav3 channel in neurological disorders other than pain, including epilepsy, Parkinson's disease, hypertension, and regulation of arousal state.[11,208–210] As a result many of the compounds reported have been profiled in models of several indications. While the therapeutic potential of Cav3 blockers in other indications is well validated a detailed discussion is beyond the scope of this article and discussion will be limited to pain studies where available.

7.03.5.5.1 Early molecules

A number of early compounds which are currently in clinical use for non-pain indications have been reported to have activity at the Cav3 family (Fig. 28). One of the first small-molecule Cav3 blockers reported was amiloride (133) which has multiple other activities has been shown to block Cav3.2 channels with about 10-fold selectivity over Cav3.1 and 3.3. Ethosuximide (4) has been shown to be a weak, nonselective, state-dependent Cav3 blocker[72] and is currently used clinically as a treatment for epilepsy. Recently a study commenced to investigate the clinical potential of ethosuximide to treat neuropathic pain.[71] It has previously demonstrated efficacy in a number of preclinical pain models. The first compound which emerged which was claimed to be a potent and selective blocker of Cav3 channels was Mibefradil (134). The compound was marketed for the treatment of hypertension in 1997, however withdrawn a year later due to an issue with drug–drug interactions mediated by cytochrome P450 inhibition.[211] Mibefradil has subsequently been shown to be a nonselective Cav channel inhibitor with activity at most family members. NMP7 (135) has been reported to be a Cav3 blocker and demonstrates activity in a number of animal pain models however also possesses activity at cannabinoid receptors thus making data difficult to interpret.[212]

The most advanced compounds have been identified by Abbott and Epirus who both currently have compounds undergoing clinical studies ABT-639 (2) and Z944 (3), respectively. The Epirus compound is derived from a previously reported series of Cav2.2 blockers. The Abbott molecule represents a new structural class of calcium channel blocker.

7.03.5.5.2 Sulfonamides

7.03.5.5.2.1 ABT-639 and related compounds

The discovery and ADME optimization which led to ABT639 has been published[69] together with the detailed biological profile.[213] ABT-639 (2) is derived from screening hits (136) and (137) (Fig. 29). The hits were identified from a high-throughput screen using

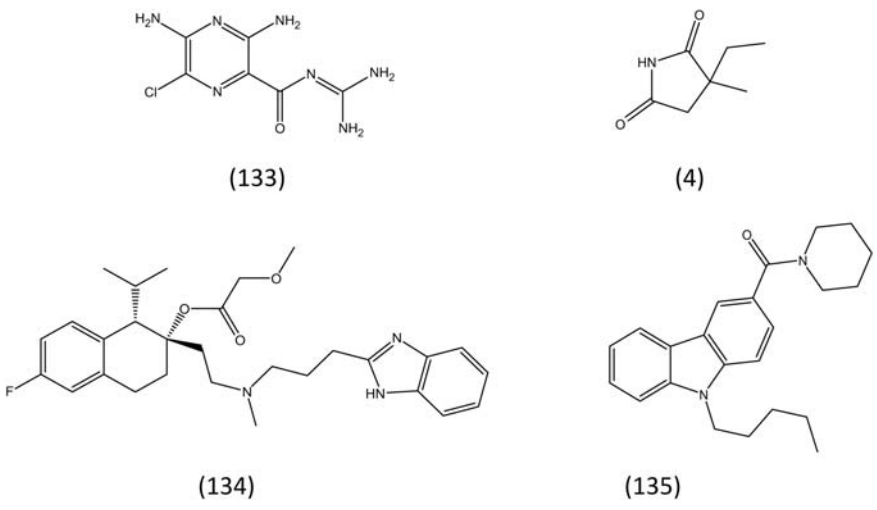

Fig. 28 Early small-molecule Cav3 blockers.

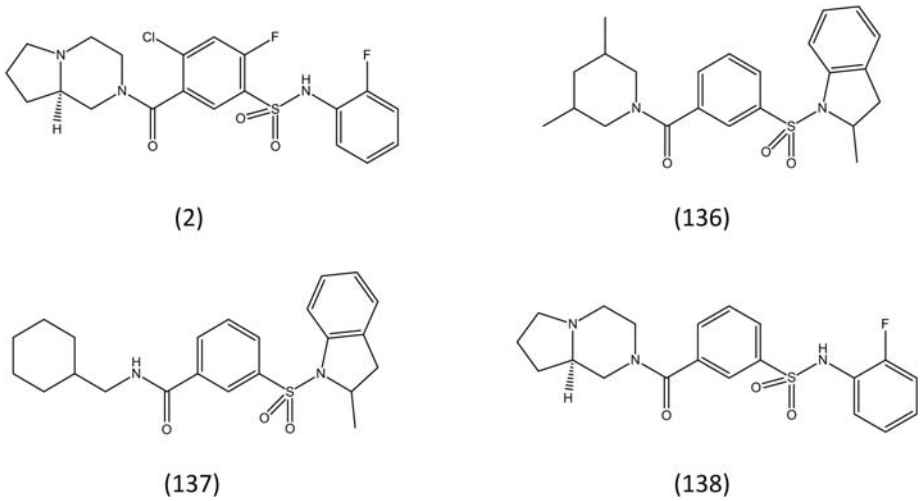

Fig. 29 ABT-639 and key molecules which led to its identification.

a FLIPR assay and a cell line expressing Cav3.2 and had IC_{50} values in the micromolar range (136, $IC_{50}=3$ μM ; 137, $IC_{50}=5$ μM); the compounds were however very unstable in rat liver microsomes (0.5% and 0.1% remaining, respectively, after 30 min incubation). Both compounds were also highly lipophilic (136, cLogP = 4.4; 137 cLogP = 5.3), and it was suggested that this was responsible for the metabolic instability. Following an exercise to reduce lipophilicity through changes to both the left- and right-hand sides of the molecule (138) was identified which had reduced lipophilicity (cLogP = 2.8) and an improved DMPK profile (68% compound remaining after 30 min incubation in rat liver microsomes) and when tested in vivo (rat) had acceptable bioavailability (35%) but was still highly cleared ($1.79\ L\ h^{-1}\ kg^{-1}$). The paper focuses on optimization of the ADME profile, and no Cav3.2 SAR is reported. Investigation of the relative clearance (138) and its enantiomer together with several other enantiomeric pairs showed the R enantiomers to be more stable than the corresponding S isomers, thus (138) was the preferred isomer from an ADME perspective. Further improvement in stability was achieved by substitution of the central aromatic core to give the final compound ABT-639.

The detailed biological profile of ABT-639 was published in a separate article[213] and is shown in **Table 11**. The compound is a selective state-dependent blocker of Cav3.2 channels with a pharmacokinetic profile in the rat suitable of supporting efficacy

Table 11 Biological profile of ABT-639

studies, and it is peripherally restricted. When tested in rat pain models it was highly efficacious in models on neuropathic pain but poorly effective in models of inflammatory pain. In vivo electrophysiology studies supported these results as an iv infusion of ABT-639 (3 mg kg^{-1}) had no effect on spinal cord neuron firing in FCA-treated rats when stimulated with Von Frey hairs yet attenuated neuron firing in rats with spinal nerve ligation (SNL model). The compound had an encouraging safety profile when investigated for the potential to cause CNS-mediated effects and cardiovascular adverse effects. As discussed in Section "**Compounds Under Clinical Evaluation**" ABT-639 has recently failed to show efficacy in a clinical study for reason which are not clear, maybe central penetration could have been an advantage or possible selective inhibition of a single Cav3 subtype is not optimal. The compound is covered by two patent filings.[214,215]

7.03.5.5.2.2 Sulfonamides reported by Bristol Myers Squibb

Bristol Myers Squibb has reported a structurally distinct series of Cav3.2 blocker (139, **Fig. 30**) designed by computational methods using the structure of known antihypertensives which have been demonstrated to act via Cav3 blockade.[216] The compound has $IC_{50} = 110$ nM (patch clamp). Both the pharmacological profile and the compounds physicochemical properties do not lend it to being an analgesic agent however and the full profile will not be discussed.

7.03.5.5.2.3 Sulfonamides, sulfones, and related structures only reported in the patent literature

In addition to the detailed description of the discovery of ABT-639 in the scientific literature there are also a number of related templates that have been disclosed in the patent literature in recent years (**Fig. 31**). In a 2015 patent[217] Korea Institute of Science and Technology described a series of pyrazole containing sulfonamides with (140) being an example disclosed with relatively weak activity (61.42% of inhibition at 10 μM). A second patent[218] from the same group describes amide derivatives (141) with a similar right hand side, suggesting that the sulfonamide is not essential for activity (141) and are reported to have similar activity to (140). In a 2010 patent[219] Zalicus claims a series of sulfones a specific example being (143) which has micromolar activity at Cav3.1 ($IC_{50} = 2.79$ μM) and Cav3.2 ($IC_{50} = 4.66$ μM). Only limited in vitro data is given for key compounds.

7.03.5.5.3 Piperidine- and piperazine-based structures

A number of groups have reported a diverse range of structures containing a piperidine or piperazine ring as a core structure. In each case the core ring is flanked on either side by a hydrophobic group commonly linked by an amide function. The most advanced example of a compound from this series is Z944 (3) currently being developed by Epirus.

7.03.5.5.3.1 Z944 and related compounds

The discovery of Z944 (3) and a related compound Z941 (143) has recently been described[220] (**Fig. 32**). Both compounds were originally identified as treatments for epilepsy for which there is much precedent[208]; however it appears that currently the major clinical focus on Z944 is for its potential as an analgesic agent. Epirus described the chemistry strategy which initiated from Z160 (1) thus maintaining the beneficial properties of the compound, namely, lack of off target activity, potential for a good pharmacokinetic profile, particularly high central penetration, and ease of synthesis while optimizing Cav3.2 activity and enhancing solubility. The steps taken during the optimization are described in the publication, but no data is provided for the intermediates. The detailed profile of Z944 (3) is shown in **Table 12**. A less complete data package has been published on Z941 (1) and is therefore not included in the table although the reported Cav3.2 IC_{50} (inactivated state) is 150 nM. Both compounds are potent inhibitors of Cav3 channels with selectivity for the inactivated state. Z944 (3) shows selectivity for Cav2.2 and Cav1.2 channels. No pharmacokinetic information is given for either compound. Z944 (3) was profiled in a number of pain models[221] where it showed significant reversal of effects in the CFA model, the formalin test and in a butyric acid model of visceral pain. In a recent study Z944 (3) reversed

thermal hyperalgesia in the rat CCI model and encouragingly reduced neuronal firing when examined in an in vivo electrophysiology study.[222] Z944 (3) has also been profiled extensively in epilepsy models where it demonstrates an encouraging profile.[223] Both compounds were originally covered by a 2009 Neuromed patent.[224]

7.03.5.5.3.2 Merck TTA derivatives

Merck has reported the discovery of a number of structurally distinct series of Cav3 blockers all prefixed TTA which were all developed from hits identified by high-throughput screening using a FLIPR assay.[225] The first series of compounds (Fig. 33) is structurally related to Z941 and Z944, the most advanced compounds being TTA-P2 (147) and TTA-P1 (148). Details of two hit compounds arising from screening hits (144) and (145) have been published.[226,227] Compounds were tested in a membrane potential assay at two different holding potentials −20 mV (representative of the depolarized state and −60 mV (representative of the hyperpolarized state) in a cell line expressing Cav3.3 channels. Both hits had encouraging potency (144, $IC_{50}=185$ nM (−60 mV), $IC_{50}=215$ nM (−20 mV); 145, $IC_{50}=342$ nM (−60 mV), $IC_{50}=373$ nM (−20 mV)) but were not selective over hERG or Cav1.2. Initial SAR studies revealed that the optimal combination of substituents for potency at Cav3.3 and selectivity were those in (146) (Cav3.3 $IC_{50}=98$ nM (−60 mV), $IC_{50}=61$ nM, hERG $IC_{50}=1930$ nM, Cav1.2 $IC_{50}=1190$ nM); however when (146) was tested against a panel of GPCRs and other ion channels, it demonstrated a poor overall profile inhibiting eight other targets by more than 50% at 10 μM. Merck hypothesized that the strongly basic center might be responsible for the selectivity

issue and investigated potential substituents which had the potential to modulate basicity. Introduction of a fluorine at the 4-position of the piperidine proved successful and following further SAR studies led to (147) and (148) whose profiles are shown in Table 13. Both compounds are potent CaV3 blockers with little selectivity for Cav3 subtypes. The compounds show some activity at hERG and Cav1.2 although a true comparison is not possible as different assay formats are used in the two papers describing the profile of each compound. Compound (147), also known as TTA-P2, was well tolerated and without issue when tested in a dog cardiovascular study having no effect on ECG, heart rate, or MAP, where (148, also known as TTA-P1) produced no changes in ECG but did cause mild bradycardia, suggesting that it does not have the desired level of functional selectivity over Cav1.2. Both compounds had good pharmacokinetics in all species tested. Compounds were evaluated in models of epilepsy where they demonstrated encouraging effects. TTA-P2 (A) has been profiled in models of neuropathic pain. *i.p.* injections of 5 or 7.5 mg kg^{-1} TTA-P2 reduced pain responses in mice in phases 1 and 2 of the formalin test. Furthermore, TTA-P2, at 10 mg kg^{-1} *i.p.*, selectively and completely reversed thermal hyperalgesia in diabetic rats treated with streptozocin but had no effect on the nociceptive response of healthy animals. The antihyperalgesic effects of TTA-P2 in diabetic rats were completely abolished by administration of oligonucleotide antisense for Cav3.2 isoform of T channels. The compounds are covered by patents.[228,229] No development has been reported for the compounds reported from this series.

7.03.5.5.3.3 Piperidines reported by Astra Zeneca

Astra Zeneca has reported a series of piperidines[307] closely related to TTA-P2 (147) in terms of structure (Fig. 34); however these compounds are tonic Cav3.2 blockers rather than state-dependent and thus produce strong reductions in heart rate and blood pressure and were prepared with a cardiovascular indication in mind. Given their different therapeutic indication a detailed discussion is beyond the scope of this article. The lead compound (150) was derived from a screening hit (149). It is not clear from the publications which structural features are responsible for driving the different mechanisms of action, but the structural

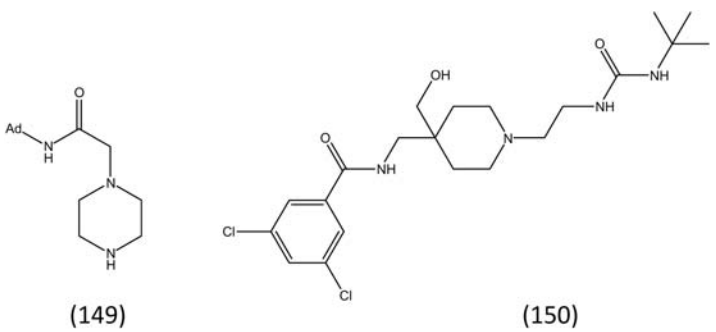

Fig. 34 Cav3.2 blockers reported by Astra Zeneca with strong cardiovascular effects.

similarities between TTA-P2 (147) and (150) indicate that subtle modifications can result dramatic changes in electrophysiological profile.

7.03.5.5.3.4 Piperidine amide templates reported in the patent literature

Toa Eiyo Ltd., Japan, has filed one patent[230] covering tropane derivatives (151) related to the compounds described by Zalicus, and Merck is reported to have $IC_{50} = 68$ nM (FLIPR), although it is not clear which Cav3 subtype was used in the screen (Fig. 35).

7.03.5.5.3.5 Hybrid compounds

The University of Calgary has identified a series of carbazole derivative (152, 153) which were derived from hybrids of NMP7 (135) and TTA-P2 (Fig. 36).[231] The rationale was that the hybrid structures would potentially enhance the Cav3 blocking activity of NMP7 and remove or reduce the activity at cannabinoid receptors. Preliminary work demonstrated that attaching a cyclic amine via an aliphatic chain to the amide group of NMP7 increased activity at Cav3.2 channels. Further optimization produced two compounds which were potent Cav3.2 blockers (152) and (153) but while being structurally similar had very different selectivity profiles when tested at cannabinoid receptors. Compounds (152) and (153) inhibited Cav3.2 channels with IC_{50} values of 1.48 and 3.68 μM, respectively. In addition (153), when tested in a radioligand binding assay (152) showed no affinity for either the CB1 or CB2 receptor ($K_i > 5$ μM), where (153) showed high affinity for CB1 ($pK_i = 15$ nM) and weaker, but measurable affinity for CB2 receptors ($pK_i = 1.9$ μM). The authors present SAR data to show that the chain length between the amide and the basic center is the key driver for selectivity over cannabinoid receptors. Compound (152) was tested for selectivity at other Cav3 channels using a single concentration of 3 μM where it blocked Cav3.1 by 44% and Cav3.3 by 42.5% and Cav3.2 by 69%. Finally (152) was profiled

in vivo where it showed positive effects in a mouse formalin test inhibiting both early and late stage responses when dosed at 1–10 μg (*it*) and 10–100 mg kg^{-1} (*ip*) the response being slightly greater following *it* administration. Encouragingly none of the animals dosed *ip* showed any disturbance in locomotor activity. Compound (152) was also efficacious in a mouse peripheral nerve injury model of neuropathic pain when dosed at 30 mg kg^{-1} (*ip*) producing significant reversal of mechanical hyperalgesia for greater than 3 h.

7.03.5.5.3.6 Piperidines reported by The Korea Institute of Science and Technology

The Korea Institute of Science and Technology has also reported the discovery of a series of piperidines and tetrahydropydinedines.[232] The compounds (**Fig. 37**) originate from early work which identified micromolar Cav3.2 inhibitors, for example, (154, Cav3.2 $IC_{50} = 1$ μM). These compounds were based on Cav3 blockers reported in the early 2000s with a strategy of introducing an amide isostere to produce more stable compounds. Recently following the reports of other piperidine based blockers such as TTA-P1 and TTA-P2examination of the model showed that proposed targets (155) and (156) mapped well with a five point pharmacophore having three hydrophobic regions, one positively ionized center and a H bond acceptor. TTA-P1 also mapped well with the model. Synthesis of a set of analogues containing either a piperidine or a tetrahydropiperidine core with diverse substituents on the phenyl ring and the isoxazole showed (155) and (156) to have optimal activity. The full profiles are shown in **Table 14**.

Both (155) and (156) inhibit Cav3.1 and Cav3.2 channel in a whole cell patch clamp assay with micromolar potency although no information regarding state dependency is given. Both compounds are also potent inhibitors of hERG. Interestingly the

Table 14 Profiles of piperidines published by the Korea Institute of Science and Technology

tetrahydropyrine has a better pharmacokinetic profile in the rat. Both compounds were profiled in the sciatic nerve ligation model of neuropathic pain (Chung model) at 100 mg kg^{-1} orally. Both showed similar efficacy in reversing both cold and mechanical allodynia which was comparable with gabapentin (100 mg kg^{-1}) for cold allodynia but slightly weaker for mechanical allodynia. The compounds are covered by two Korean patents.[233,234] No further development of these compounds is reported.

7.03.5.5.3.7 Spiro piperidine derivatives

Icagen has reported a series of spiro piperidine derivatives by (157) identified initially by phamacophore modeling using a similar strategy to that described the scientists at The Korea Institute of Science and Technology[235] (Fig. 38). The modeling led to the spiro scaffold present in (157). Investigations around the scaffold showed that all of the pharmacophoric elements present were needed for optimal potency (157; 58% inhibition Cav3.2 (30 nM) and 31% inhibition Cav1.2 (100 nM)). In particular removal of the diphenylmethyl group or the carbonyl function results in loss of activity.

7.03.5.5.3.8 Fused piperidines

A group from the Vanderbilt Centre for Neuroscience Drug Discovery has reported the identification of a series of fused piperidine derivatives (Fig. 39)[236] represented by ML218 (160). The compound is derived from a screening hit (158, Cav3.2 $IC_{50} = 810$ nM, FLIPR assay). The Vanderbilt scientists used scaffold hopping techniques in the process to remove the undesirable oxadiazole ring and increase potency. Initial efforts focused on piperdines (159) and resulted in similar potency. Further optimization through the use of a phamacophore led to ML218 which had slightly improved potency (Cav3.2 $IC_{50} = 120$ nM (FLIPR)). Activity was confirmed in electrophysiology studies where the compounds had Cav3.2 $IC_{50} = 310$ nM and Cav3.3 $IC_{50} = 274$ nM. When tested in a rat pharmacokinetic study the compound had moderate clearance (56 mL min^{-1} kg^{-1}) and a long-terminal half-life (7 h). When tested in a panel of 68 different molecular targets ML218 was highly selective including against other calcium channels thus rendering it a highly attractive chemical probe for studying the pharmacology and role of Cav3 channels in different disease indications. ML218 was made available to the research community for such purposes.

7.03.5.5.3.9 Related compounds disclosed in the patent literature

In addition to the filings from the Korea Institute of Science and Technology around this template other groups have also filed patents on similar chemotypes. Pfizer has published a patent[237] covering molecules related to (161) which is described as having $IC_{50} = 19$ nM at Cav3, however it is not clear from the patent how selective the compounds are over Cav2 and Cav1 channels (Fig. 40).

7.03.5.5.4 Piperazines and homopiperazines

7.03.5.5.4.1 Homopiperazines

A series of studies from the Korea Institute of Science and Technology describe the discovery of a series of homopiperazines (Fig. 41) represented by lead compound (164). Initial work generated a pharmacophore from available data and structures of Cav3 blockers published at the time.[238] This led to the preparation of a library of phthalimides (163). Screening of the library identified two lead compounds (R = Me, Cav3.2 IC_{50} = 0.96 μM, R = H, Cav3.2 IC_{50} = 0.96 μM). Further refinement of the pharmacophore led to the generation of a series of homopiperazines[239] with a pendant benzimidazole of which (163) had the optimal profile from the set of compounds prepared (Cav3.2 IC_{50} = 1.23 μM, Cav2.2 IC_{50} = 28.7 μM, hERG IC_{50} = 3.9 μM). Compound (163) was also profiled in DMPK studies (F = 43%, $T_{1/2}$ = 5.7 h, brain/plasma ratio = 0.43). The group next focused on increasing Cav3.2 potency and reexamination of the pharmacophore suggested that increasing the hydrophobicity of the left-hand side was the preferred option. A library of different bicyclic and monocyclic heterocycles was prepared[240] from which (164) emerged with the highest potency (IC_{50} = 0.2 μM). No further reports describing more detailed profiles of these compounds have been published. The compounds are covered by patent filings.[241]

7.03.5.5.4.2 Homopiperazine and piperazine disclosed in the patent literature

In addition to the compounds described in the scientific literature Korea Institute of Science and Technology has filed a large number of patents covering this area. Representative structures (168–167, Fig. 42) and corresponding patents are shown below.[242–244]

7.03.5.5.5 Pyridyl amides

Merck has also reported[245] the identification of a series of pyridyl amides (Fig. 43), the most advanced of which is (171, TTA-A2), which was derived from screening hit (168) having encouraging activity at Cav3.3 in a FLIPR assay (IP* = 235 nM, When describing the TTA-A series Merck change the format in which the primary assay data is reported and quote IP (inflection point) values rather than IC_{50} values for the FLIPR assay. The infection point[245] is defined as the point of the concentration response curve where the curvature changes direction, for compounds producing a traditional sigmoidal concentration response this value is close to the

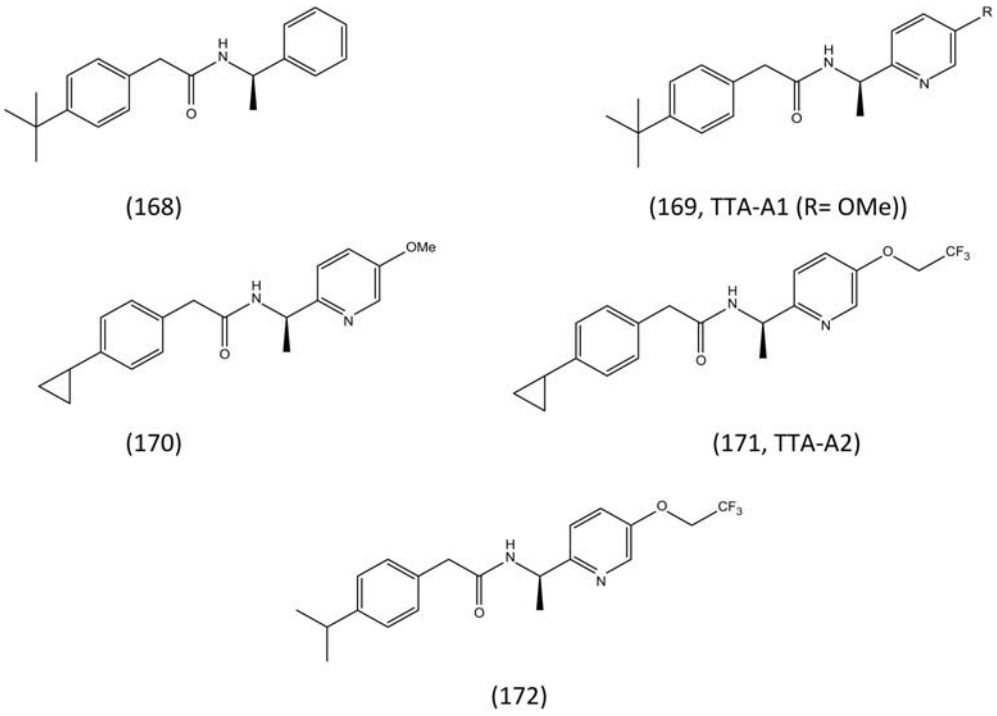

Fig. 43 Pyridyl amide compounds reported by Merck.

Table 15 Biological profile of TTA-A2 (171)

FLIPR	IP (nM)

Clp (mL $min^{-1}kg^{-1}$)	6	

IC_{50}.). Early investigations showed that the S-enantiomer as depicted was the preferred isomer with the R-isomer and the gem dimethyl analogues showing little activity. Exploration of the SAR around the right-hand aromatic ring showed that potency could be increased by replacing the phenyl group with a 2-pyridyl having a lipophilic 5-substituent ((169); R = Cl, Cav3.3 IP = 30 nM, R = OMe, Cav3.3 IP = 22 nM). The methoxy derivative (169, TTA-A1) was profiled further but revealed to be a potent PXR activator (87% rifampicin response at 10 μM). Molecular modeling studies suggested that changing the tert-butyl group to a less lipophilic substituent would reduce the PXR liability. Extensive studies revealed that introduction of polar groups reduced the PXR liability but also reduced calcium channel activity of the compounds. Ultimately it was shown that a slight reduction in the size of the lipophilic group was able to remove the CYP induction potential (170, Cav3.3 IP = 70 nM, 22% PXR activation relative to rifampacin (10 μM)). A further gain in potency was achieved by modification of the ether on the pyridyl ring to give (171, TTA-A2).

The full biological profile of TTA-A2[246,247] is summarized in Table 15. The compound is a highly potent, and nonselective state-dependent blocker of Cav3 channels. Binding data suggests it is selective over Cav1.2 and hERG channels. Compared with close analogues TTA-A2 is a weak activator of the PXR receptor and when tested in a permeability assay it showed no potential to be a P-gp substrate. The compound has an excellent pharmacokinetic profile in rats being highly bioavailable with low clearance and a long half-life. When tested in an in vivo model of epilepsy at 10 mg kg (*po*) TTA-A2 showed a robust response with a 87% reduction in seizures over 4 h. Like other TTA compounds, Merck investigated the effect of TTA-A2 on sleep patterns in mice, where significant changes were observed. A reduction in active wake was observed soon after dosing with a concurrent increase in delta sleep and decrease in REM sleep, the effects lasted for 4 hours. Similar effects have also been reported for other TTA compounds suggesting that Cav3 channels are involved. TTA-A2 has also been profiled in a number of different in vivo pain models where it shows efficacy.[154] Merck has recently reported progressing a Cav3 blocker MK-8998 into clinical studies for schizophrenia.[248] The exact structure of the compound has not been published by the company, but a compound of that name is available from a number of chemical suppliers; however the precise nature of the structure is still confusing, particularly the chirality which varies from supplier to supplier. Based on published SAR the structure of MK-8998 is believed to be (172). Little data is available but the compound is a potent Cav3 blocker (Cav3.3 IP = 5 nM) and a modest PXR activator (30% rifampicin response at 10 μM). When tested in acutely psychotic patients with schizophrenia at doses of 6–8 mg twice a day MK-8998 showed no difference to placebo on all primary outcome measures and had a similar side effect profile to olanzapine (5–15 mg twice daily).[248] These compounds are covered by a single patent.[249]

7.03.5.5.6 Quinazoline derivatives

The quinazoline series is another structurally distinct series of Cav3 blocker reported by Merck arising from high-throughput screening.[250] The original hit was (173) which demonstrated encouraging activity in a FLIPR assay (IC_{50} = 2174 nM, hyperpolarized state, and 847 nM, depolarized state). Resolution of enantiomers quickly showed that the activity lay mainly in the isomer depicted in Fig. 44. Initial profiling of compounds with an unsubstituted pendant phenyl ring revealed an encouraging profile but a tendency for time dependent cytochrome P450 inhibition which was resolved by the introduction of an electron withdrawing group in the 4-position. A trifluoroethyl group at the 3-position was reported to be optimal both for potency and metabolic stability. The initial chemistry led to a number of highly potent compounds of which (174, TTA-Q3) and (175, TTA-Q6) are examples which were extensively profiled (Table 15). Further SAR investigation produced further compounds of which (176) was the most extensively profiled. Their second publication focused on this template.[251] Merck has reported that replacement of the pendant phenyl resulted in a drop in potency, as did substitution of the N1 atom of the quinazoline ring with few exceptions and that enhancement of metabolic stability can be achieved through fluorination of the aliphatic C4 substituent. Profiles of the most advanced compounds are shown in Table 16.

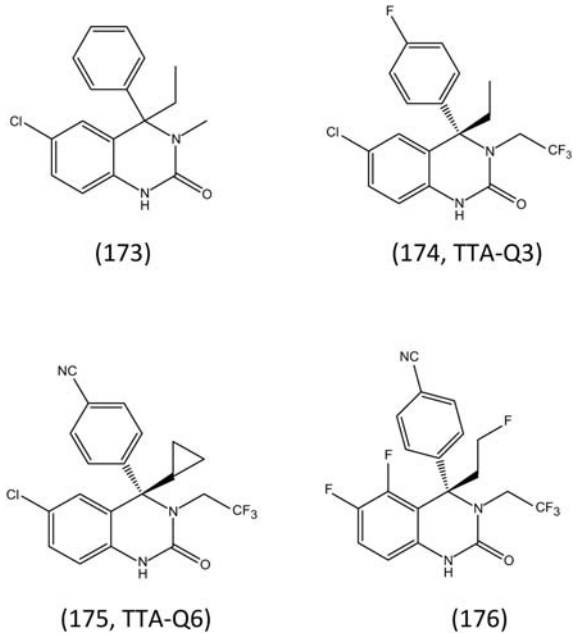

Fig. 44 Quinazolines reported by Merck.

Both TTA-Q3 (174) and TTA-Q6 (175) are potent blockers of Cav3.3 with evidence of state dependence as shown by the FLIPR data and are selective over Cav1.2 and Cav2.2. Compound (176) is a potent Cav3.3 blocker when tested in a FLIPR assay with channels in the depolarized state; it is also state dependent as evidenced by the reported whole cell patch clamp data. When tested at holding potentials of −100 mV and −80 mV (176) blocked Cav3.3 current with IC_{50} values of 190 and 31 nM, respectively. No selectivity data is given for this compound. None of the compounds were Pgp substrate but did have a cytochrome P450 induction liability. TTA-Q3 (174) and TTA-Q6 (175) had the better rat pharmacokinetic profiles both being low clearance compounds with good bioavailability and encouraging half-lives. All three compounds were tested in the WAG/Rij epilepsy model where they showed robust efficacy in reversing seizures (174) and (175) at 3 mg kg^{-1} and (176) at 10 mg kg^{-1}. When tested in sleep models they displayed similar profiles to other compounds reported by Merck. The quinazoline compounds are covered by two patent applications.[251,252]

In a follow-up article[225] Merck has compared the properties of all of their identified Cav3 blockers. Of interest is a series of binding experiments performed with labeled TTA-A1 (169) where they show that all of the compounds binding competitively with this ligand as do literature standards including mibefradil and flunarizine. The only exception being the quinazoline series which are not competitive and suggesting they bind at an allosteric site.

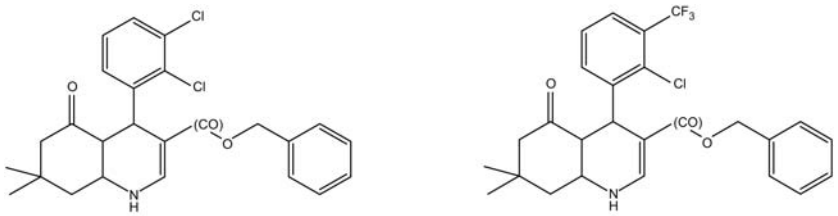

Fig. 45 Dihydropyridines reported by the University of Calgary.

7.03.5.5.7 Dihydropyridine derivatives

A group from the University of Calgary, some of whom had been previously associated with Neuromed and subsequent companies has recently described a series of dihyropyridine ester (Fig. 45) which show some selectivity over Ca1 channels and are active in neuropathic pain models.[253,254] In the initial publication a series of compounds are described with a saturated ring fused onto the dihydropyridine ring. Compounds (178) and (179) were shown to have optimal in vitro profiles, potently inhibiting Cav3.2 (178, $IC_{50}=257$ nM, 179, $IC_{50}=177$ nM) when tested in an electrophysiology assay and showing selectivity over Cav1.2 (179, 40% inhibition @ 10 μM). The key groups which enhance potency at Cav3.2 are described as being the gem dimethyl group on the saturated ring, and their position is critical for potency as moving them to the alpha position results in an approximate 10-fold loss in Cav3.2 potency. Compound (179) was profiled in a pain model (formalin test) using Cav3.2 null mice where it showed no activity, but when profiled in wild-type animals at 10 mg kg^{-1} (*ip*) it produced almost complete reversal of both initial and late phase responses and importantly showed no effects on locomotor function in wild-type mice at the same dose. When tested in a sciatic nerve ligation model of neuropathic pain in mice, (179) produced near maximal reversal of mechanical hyperalgesia at 10 mg kg^{-1} (*ip*) when tested 1 h post dose with 50% reversal when tested at 3 h. The more recent article[254] has investigated potential structural explanations for the SAR reported by the Calgary group and proposed further studies which might add confidence to the hypothesis.

7.03.5.5.8 Indoles

In addition to the three structurally diverse series of Cav3 blockers which have been extensively profiled, Merck has also reported a further compound (Fig. 46), the indole derivative TTA-I1 (180). Little data is given for this compound except that it was identified through high-throughput screening.[255]

7.03.5.5.9 Dihydroquinazolines

A group from the Korean institute of science and Technology was the first to pioneer work in the area of Cav3 blockers and have published work on a number of different templates. The first template explored was the dihydroquinazolines from which they identified a number of interesting compounds (Fig. 47). Early examples are KYS05044 (181, R=H) and KYS05050 (182, R=H)

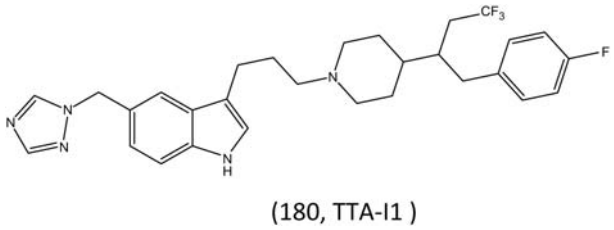

Fig. 46 TTA-I1 Recently described by Merck.

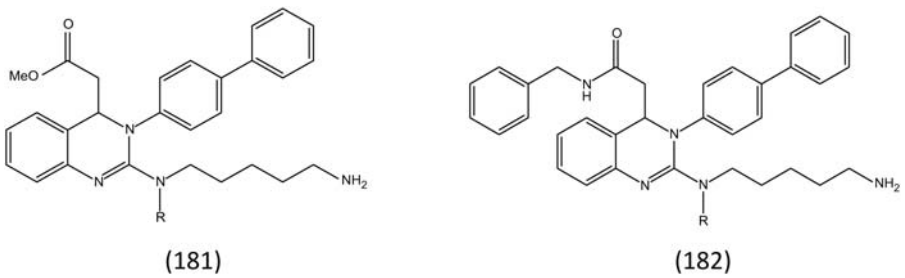

Fig. 47 KYS05044 and KYS05050.

reported to be equipotent with mibefradil but more selective. Published data shows KYS05044 to have Cav3.2 $IC_{50} = 0.56$ μM when tested in a whole cell manual patch clamp assay with >100-fold selectivity over Cav2.2 and KYS05050 Cav3.2 $IC_{50} = 0.13$ μM and 10-fold selectivity over Cav2.2. Extensive SAR investigations have been published, and ultimately KYS05090 (182, R = Me) was identified with Cav3.2 $IC_{50} = 0.04$ μM and 119-fold selectivity over Cav2.2. Interestingly N-methylation of (181) has little effect on potency and selectivity of the parent compound. The authors state that the series did not progress further due to not being able to achieve the desired pharmaceutical properties.[256] This area will not be reviewed in detail given that the chemistry was performed more than 10 years ago but for completeness it is included given a recent report describing the in vivo profile of KYS05090. In a recent study KYS05090 has been profiled in mouse models of acute and neuropathic pain. KYS-05090S (10 μg/10 μL delivered intrathecally) significantly reduced acute pain induced by formalin in both the tonic and inflammatory phases. Its antinociceptive effect was not observed when delivered to Cav3.2 null mice revealing a Cav3.2-dependent mechanism. KYS-05090S also reduced neuropathic pain in a model of partial sciatic nerve injury.[257] However caution should be applied when interpreting results with these compounds as KYS-05090S has also recently be shown to be a highly potent TRPV1 antagonist.[258]

7.03.5.5.10 Miscellaneous chemotypes disclosed only in the patent literature

In addition to the diverse array of chemotypes reported in the scientific literature a similar number of equally diverse templates have been disclosed in the recent patent literature (Table 17).

Astellas has filed two patents covering benzyltriazole (183) and benzylpyrazole amides (184).[259,260] The compounds shown are potent Cav3.2 blockers (FLIPR assay) having IC_{50} values of 21 nM (183) and 14 nM (184). Nissan Chemical Industries have filed three patents covering triazinone structures.[261–263] Cav3.2 data is reported (FLIPR assay) with the compounds becoming increasingly potent (185, $IC_{50} = 220$ nM; 186 $IC_{50} = 67$ nM; and 187, $IC_{50} = 4.7$ nM). A number of bicyclic heterocyclic structures have been published. Kyowa Hakko Kirin has published two patents[264,265] covering imidazopyridines (188) and (189); however little data is given on the compounds. Compound (189) is described as having a Cav3.2 $IC_{50} < 100$ nM (FLIPR). Merck has described a series of simple indole structures represented by (190), no data is given in the patent.[266] Two similar structural types have been patented by the University of Naples (191)[267] and the Japanese company Toa Eiyo Ltd.[268]; neither organization has published activity data on the molecules disclosed. Zalicus has published a patent[269] covering more complex structures with a bicyclic pyrimidione core (193) again little data is given. VM Therapeutics has published a patent[270] claiming the bicyclic compound pirenperone (194) as a Cav3 blocker and present in vivo data in the FCA model of inflammatory pain where the compound shows efficacy superior to Naproxen when dosed orally at 30 mg kg^{-1}. The value of this claim is questionable as pirenperone also has activity at 5HT and dopaminergic receptors which could be responsible for the effects in the pain model. Kinki University in Japan has filed a patent claiming T type calcium channel blockers containing flavanones[271] and highlight the natural product 6-prenylnaringenin (195) as an example. Little data is provided. Finally the University of Virginia has filed a patent[272] covering a series of pyrrolidines (196) for the treatment of conditions mediated by splice variants of Cav3.1.

7.03.5.6 Alpha 2 Delta Ligands

Two drugs which bind to the α2δ subunit of voltage-gated calcium channel are currently licensed for the treatment of neuropathic pain and are widely used, namely, gabapentin and pregabalin[273] (Fig. 48). The compounds were not originally designed to target calcium channels nor as analgesic agents. Gabapentin was initially prepared as a more lipophilic analogue of γ aminobutyric acid (GABA) to treat epilepsy and was launched onto the market in 1994 as an adjunct therapy to existing treatments.[274] While it was in clinical use as an anticonvulsant its potential as an analgesic agent was realized. Pregabalin was identified later through a similar chemical approach and has a very similar profile to gabapentin both clinically and preclinically. For many years the mechanism of action of these compounds was not understood and there are many reports of investigations into exactly how they illicit their analgesic effects. It was only recently that the now accepted mechanistic explanation was published. Arising from investigations in rats a group at University College London showed that in rats that had undergone SNL, on the side of the ligation, α2δ expression was increased in various structures. Chronic pregabalin treatment of SNL animals, at a dose that alleviated allodynia, markedly reduced the elevation of α2δ in the spinal cord and ascending axon tracts in vitro, pregabalin reduced plasma membrane expression of α2δ proteinwithout affecting endocytosis. They concluded that the antiallodynic effect of pregabalin in vivo was associated with impaired trafficking of α2δ, resulting in its decrease in presynaptic terminals, which would reduce neurotransmitter release and spinal sensitization, an important factor in the maintenance of neuropathic pain.[275] The discovery of gabapentin and pregabalin and early analogues has been well and extensively reviewed.[273] This section will focus on developments in the last decade. A number of close analogues of gabapentin and pregabalin have been identified and also progressed to clinical development including imagabalin (199, PD-0332334) which advanced as far as phase 3 studies for generalized anxiety disorder,[276] and atagabalin (200, PD-0200390) which entered clinical evaluation for insomnia (Section "Alpha 2 Delta Ligands") but was not progressed into later studies due to unsatisfactory data from initial studies.[277]

7.03.5.6.1 Amino acid-derived structures

The majority of the work has been based around modifications of the GABA skeleton producing compounds related to gabapentin and pregabalin but with different pharmacological properties. Daiichi Sankyo and Pfizer have led the way in this area. The focus of all of the studies has been to identify molecules which are both more potent and more efficacious than the two marketed

compounds. Gabapentin and pregabalin are reported by Pfizer to have binding affinities for the α2δ protein of 140 and 80 nM, respectively. Both Daiichi Sankyo and Pfizer have identified molecules with increased potency that have progressed to the clinic. Daiichi Sankyo currently has a compound microgabalin (5, DS-5565) which has shown positive analgesic effects in phase 2 studies and is reported to be entering phase 3 (Section "**Compounds Under Clinical Evaluation**"). Pfizer has progressed two compounds to clinical testing but not for pain indications. Imagabalin (199, PD-0332334) was studied for its potential to treat anxiety and atagabalin (200, PD-0200390) for insomonia. The structures of the two Pfizer molecules are shown in **Fig. 48**, and the Daiichi Sankyo compound is a bicyclic compound (**Fig. 51**) related to a class of compound termed by Pfizer (who also worked in this area) as gababutins (Section "**Alpha 2 Delta Ligands**").

7.03.5.6.1.1 Proline derivatives

A series of proline derivatives has been reported by Pfizer (**Fig. 49**) the most advanced of which is (204) which was evaluated in early clinical studies.[278–280,308] The starting point for the chemistry program was (202, R = H) which is reported to have a binding affinity of 5.4 μM.[278] Preliminary SAR studies showed that potency could be improved through introduction of lipophilic groups on the

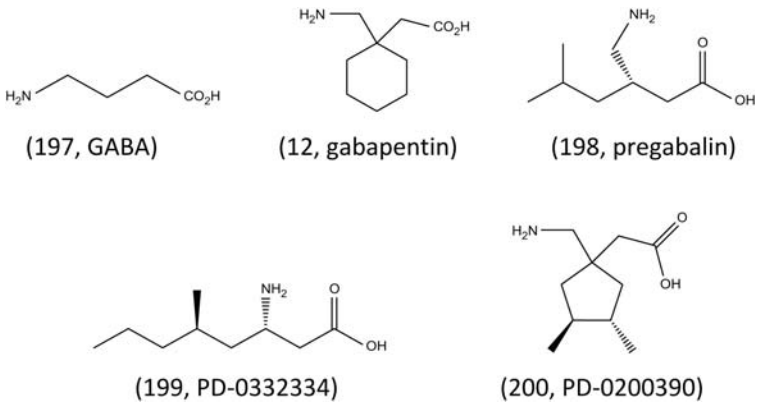

Fig. 48 GABA, gabapentin, and early compounds that have entered clinical development.

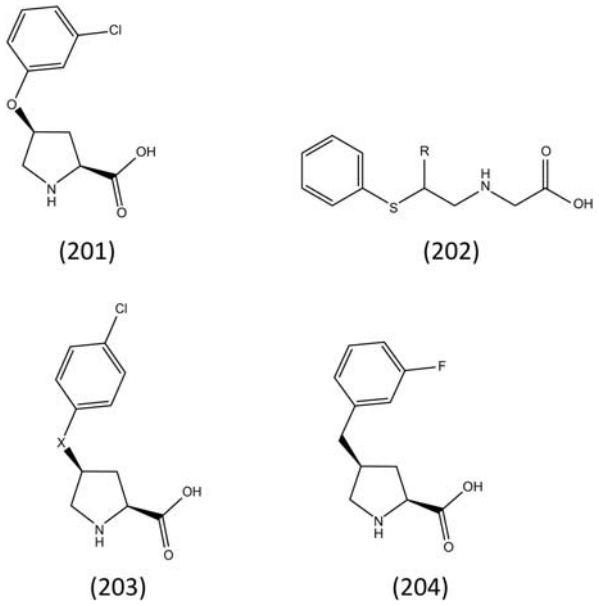

Fig. 49 Proline derivatives reported by Pfizer.

aromatic ring and by adding small lipophilic groups adjacent to the sulfur atom (e.g., (202) R = Me). A sulfur linker was preferred but could be replaced with oxygen with potency being increased through modulation of the chain substituent (R). The naphthyl analogue of (202, R = H) has a binding affinity of 22 nM. The compounds from the initial exploration were highly potent but generally had poor physicochemical properties due to the requirement for lipophilic groups for optimal potency. Conformational restraint of the open chain glycine derivatives was then tried[279] as an approach to enhance potency. The proline derivatives (203, X = O, S) were prepared, and both showed increased potency (203, X = O IC_{50} = 32 nM, X = S IC_{50} = 72 nM) compared to the open chain analogues (ether analogues of (202)—IC_{50} = 523 nM, X = S IC_{50} = 195 nM—both analogues having a methyl alpha to the heteroatom). The activity resided with the isomer of (203) as shown (2*S*, 4*S*). The corresponding (2*R*, 4*R*) isomer was devoid of activity (X = O). Moving the chlorine atom around the phenyl ring gave three isomers all with binding affinities $<$100 nM, the most potent being (201, IC_{50} = 4 nM). When profiled in preclinical species (201) had a relatively short half-life [0.4 h (rat), 1.5 h (dog)] and an unbound clearance higher than glomerular filtration rate. In human studies the compound also had a short half-life (2.3 h), suggesting that it was being renally cleared. Due to the short half-life (201) was not progressed further. Further exploration focussed on the linker atom and a series of benzylprolines were prepared.[280] SAR was similar to that seen with the heteroatom linked series; however these compound were not substrates for the neutral amino acid transporter (believed to be responsible for the active renal excretion) unlike their heteroatom linked analogues. The difference is proposed to be due to the difference in pK_a of the proline nitrogen between the series. The clearance of (204) in the dog is reported to be 0.4 mL $min^{-1} kg^{-1}$, significantly lower than glomerular filtration rate. Compound (204) was reported to have been evaluated in a human pharmacokinetic study[280] but to date the full results have not been published.

7.03.5.6.2 Gabapentins

A second series reported by Pfizer are the gabapentins (Fig. 50), compounds initially derived from studies focused on the gabapentin and pregabalin templates with added conformational constraint. The original compound (205) was weakly active (IC_{50} = 450 nM). The objective was to identify compounds with both increased binding affinity and efficacy. Initial studies[281] focused on the cyclopentane derivatives, and early studies showed that the two isomers (206) and (207) had increased binding affinity (206, IC_{50} = 30 nM, 207, IC_{50} = 71 nM). Both compounds showed similar efficacy to the standard molecules when tested in models of pain and anxiety. Addition of a second methyl group led to the identification of atabagalin (200)[282] which has a similar potency to the monomethyl compounds (IC_{50} = 22 nM); the opposite stereoisomer was also prepared and was weakly active (IC_{50} = 882 nM). The diethyl analogues interestingly showed a dramatic fall in potency (IC_{50} = 1.1 μM). Compound (200) was profiled in the carrageenan model of inflammatory pain where it showed encouraging efficacy and an effect similar to pregabalin producing full reversal of hyperalgesia at a dose of 30 mg kg^{-1}. The pharmacokinetic profile of (200) was investigated in the rat, and it had high bioavailability (Table 18) and a short half-life. The compound was found to be rapidly renally cleared but considered worthy of progression. In humans it had an acceptable half-life and was rapidly absorbed. To date atagabalin has been investigated in three human studies focusing on its potential to treat insomnia.[283–285] No results from these studies have yet been published.

Further investigations identified a series of bicyclic compounds of which (208, IC_{50} = 38 nM) and (209, IC_{50} = 46 nM) had the optimal profiles.[286] Similar to other compounds of this class both compounds had high bioavailabilities and short half-lives. When

T_{max} (h)	1.3

tested in the CCI model of neuropathic pain both were more efficacious than gabapentin. No further studies on these compounds have been reported. The compounds described above are covered by a number of patent filings.[309,310]

Daiichi Sankyo is developing a related molecule mirogabalin (DS-5565) (5, Fig. 51) which is reported in the patent literature[287] to be a potent α2δ ligand (binding IC50 = 14 nM) the medicinal chemistry relating to the identification of this compound has not been disclosed, but Daiichi Sankyo has reported clinical data from two phase 2 studies in patients with diabetic neuropathy where it demonstrated positive effects at doses of 15, 20, and 30 mg per day.[288,289] Studies in patients with fibromyalgia are currently ongoing.[73,75] The company is currently recruiting patients to begin phase 3 studies.

7.03.5.6.2.1 Acid bioisosteres

Pfizer has also reported a study into bioisosteres of gabapentin.[290] Oxadiazazolone (210, Fig. 52) and tetrazole derivatives were synthesized and found to have similar affinity to the parent acids to α2δ (IC_{50} = 210 nM). The consequence of modifying the acid was that (210) was no longer a substrate for the transporter which actively uptakes gabapentin into the brain and as a result

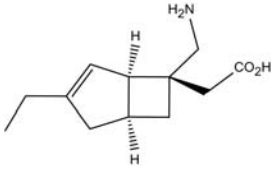

Fig. 51 Mirogabalin (DS-5565).

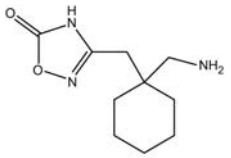


(210)

Fig. 52 Acid bioisotere gabapentin analogue reported by Pfizer.

achieved much lower brain levels when dosed to rats (brain/plasma ration = 0.05). The compound was tested in a number of neuropathic pain models where it showed no efficacy due to poor CNS penetration. It did show efficacy however in a model of osteoarthritis. The compounds are covered by a patent filing.[291]

7.03.5.6.2.2 Silicon containing derivatives

A recent report[292] from a group at Research Foundation ITSUU in Japan has described some silicon containing analogues of pregabalin (Fig. 53). Compounds have excellent pharmacokinetic profiles and show efficacy in models of neuropathic pain at low oral doses yet appear to have only weak affinity for the α2δ protein. When tested in a binding assay (211) and (212) displaced radiolabelled gabapentin with IC_{50} of 1.35 and 2.4 μM, respectively. Given the surprising levels of efficacy compared with the weak binding affinity it is not clear if the analgesia observed is mediated by the α2δ mechanism.

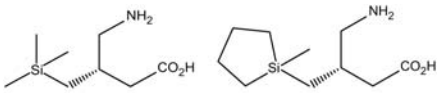
7.03.5.6.2.3 Amino acid derivatives in the patent literature

In addition to the templates described in the previous sections a number of related compounds have been disclosed in patent filings but not in the scientific literature. Few data are disclosed except for binding activity on selected compounds. Key structures are shown in Fig. 54. Daiichi Sankyo has patented[293] a series of β-alanine derivatives (213, $IC_{50} = 25$ nM). Novassay SA has recently filed a patent[294] covering compounds related to microgabalin which contain acid bioisosteres, for example, (214, $IC_{50} = 19$ nM). The Canadian company Bellus Health Inc. has patented[295] a series of low molecular weight amino acid derivatives, for example, (215) but no data is given.

7.03.5.6.3 Nonamino acid structures

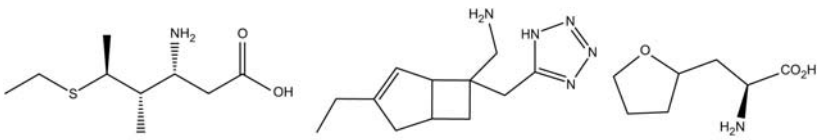
7.03.5.6.3.1 Merck compounds

Merck has published a series of structures (Fig. 55) which are reported to bind potency to membranes expressing α2δ which arose from a high-throughput screen. Compound (216) was identified from the screen and bound potently to rat α2δ membranes displacing ^3H with $IC_{50} = 180$ nM. Initial optimization efforts[296] focused on addressing potential issues regarding the functional groups present and attempting to replace the ethoxy group and the methyl groups on the bicycle. Efforts to move or replace the ethoxy group failed as changing its position on the ring or even slight modifications (methoxy or isopropxy) resulted in a large drop in binding affinity. Changing the phenyl ring to pyridine or diazaheterocycles was also unsuccessful. Introduction of an additional alkoxy or alkyl group (218, R1) did produce an increase in activity with (218, R1 = OMe) being the most potent ($IC_{50} = 4$ nM). Modification of one of the methyl groups on the 6-membered ring of the bicycle (217) was also more successful. Introduction of larger alkyl, cycloalkyl, or aryl groups retained activity but produced molecules with inferior physical properties.



(211) (212)

Fig. 53 Silicon containing pregabalin derivatives.



(213) (214) (215)

Fig. 54 Amino acid-derived α2δ ligands reported in the patent literature.

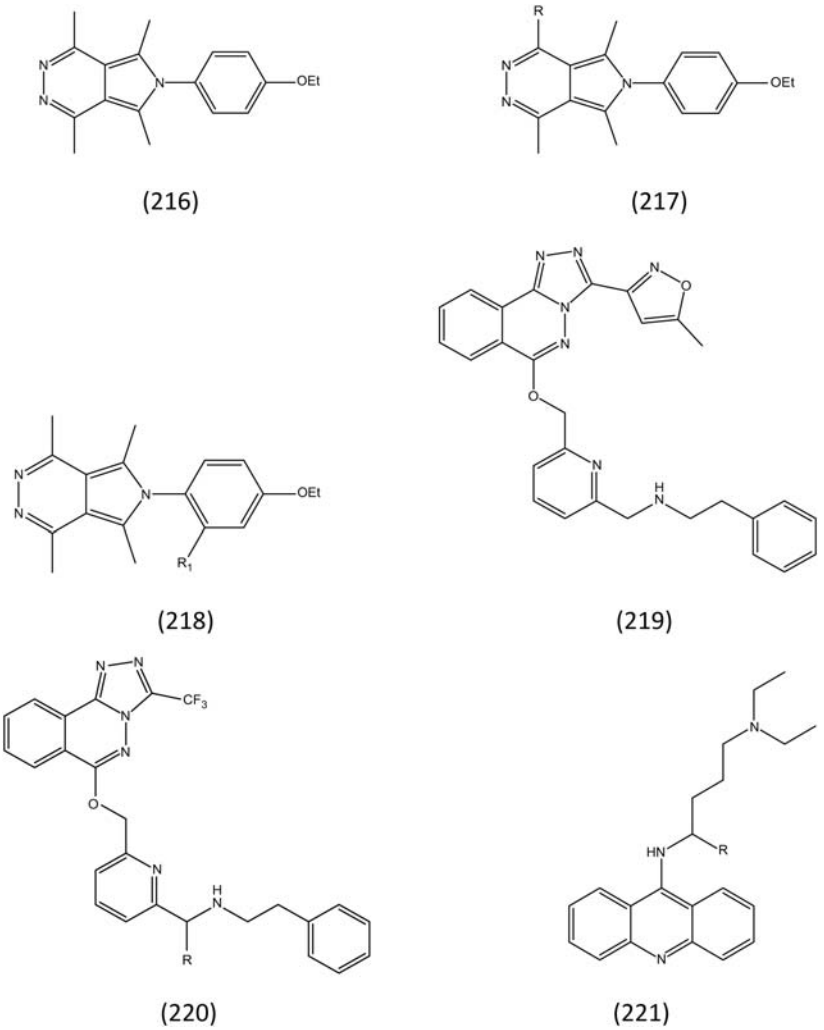


Fig. 55 Nonamino acid α2δ ligands reported by Merck.

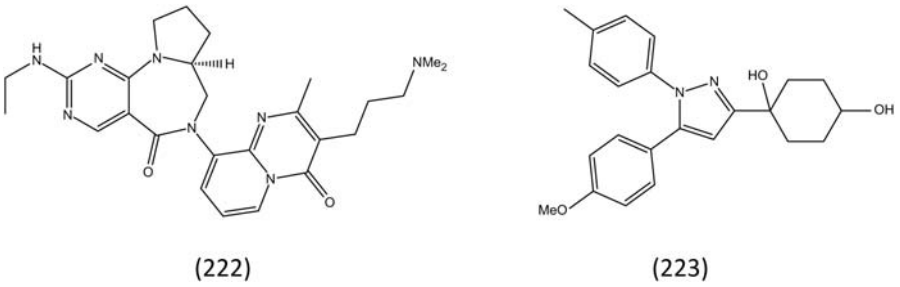
Introducing alkoxy groups resulted in a loss of activity. Amino groups were tolerated with (217, R = MeNH) (IC_{50} = 40 nM) and (217, R = PhNH) (IC_{50} = 70 nM) being the most potent.[297]

Compound (216) was progressed to a rat pharmacokinetic study where it showed an encouraging profile (81% bioavailable, half-life 4.5 h) but was slowly absorbed (T_{max} = 2.8 h), and when tested in the Chung model (*ip*) it had a similar response (ID_{50} = 9.4 mg kg^{-1}, ip) to gabapentin (ID_{50} = 39 mg kg^{-1}, *ip*). The compounds are covered by a patent application.[298]

A second hit identified by the Merck screen was the tricyclic compound (219 IC_{50} = 220 nM).[299] Unsurprisingly the compound is described as having poor physical properties, and chemistry focused on attempts to prepare compounds with improved solubility. Replacement of the isoxazole failed to give active compounds with improved profiles, and the trifluoromethyl derivative which had a similar profile to the lead (220 R = H, IC_{50} = 75 nM) was the most potent compound prepared and chosen as the template for further studies. Introduction of an α alkyl group (R) on the benzylic position of the pyridylmethylamine was well tolerated with an α methyl group being optimal, the racemic compound showing increased potency (IC_{50} = 36 nM). Separation of the isomers revealed that the activity largely lay in the (S) enantiomer (IC_{50} = 30 nM) with the (R) enantiomer having only weak affinity (IC_{50} = 10,000 nM). The compounds are covered by a patent filing.[300] There are no reports of further studies with this series of compounds.

A third series identified by screening was represented by amino acridine (221).[301] The original hit was a racemic compound (221, R = Me, IC_{50} = 220 nM). Separation of the enantiomers revealed that much of the activity came from the (S) enantiomer (IC_{50} = 110 nM) with the (R) isomer having very weak affinity (IC_{50} = 11,000 nM). Working with the (S) enantiomers SAR studies revealed that a small increase in size produced a dramatic increase in binding affinity (221, R = (*S*) *n*-propyl, IC_{50} = 9 nM), larger groups such as phenyl were poorly tolerated. The diethylamine appeared to be optimal as all modifications reported produced a large drop in affinity. Saturation on one or both of the carbocyclic rings on the acridine was tolerated but did not improve affinity.



(222) (223)

Fig. 56 Nonamino acid-derived α2δ ligands reported in the patent literature.

No further studies with this series of compounds are reported. The compounds are covered by a patent filing.[302] None of the hits described by Merck appears to have been developed further.

7.03.5.6.3.2 Nonamino acid derivatives in the patent literature

The structures reported by Merck suggest that the α2δ protein is able to accommodate a structurally diverse range of ligands. This is further supported by patent filing covering further structurally distinct templates (**Fig. 56**). Two Japanese companies have filed patents covering new α2δ templates. Kyowa Hakko Kirin Co has filed two patents[303,304] covering pyrimido-diazepinones (e.g., 222, $IC_{50} = 700$ nM), and Toray Industries has filed a single patent describing the diphenyl pyrazole (223),[305] no data is given.

7.03.6 Conclusion

There has been a large volume of work in the area of voltage-gated calcium channels during the last decade as evidenced by the large number of scientific publications and patent filings as well as new chemical entities entering development. This ion channel family represents a highly validated target class with three compounds on the market which are approved for the treatment of pain. These compounds have been on the market for a number of years, and their clinical efficacy and safety profiles are well established. Focus has centered on two areas; the identification of small-molecule state-dependent calcium channel blockers which retain the efficacy of ziconotide yet have an improved safety profile that permits oral administration and α2δ ligands with improved efficacy compared with gabapentin and pregabalin. Unfortunately to date compounds with the desired clinical profiles have not been identified. The results of recent clinical studies with small-molecule inhibitors of Cav2.2 and Cav3 channels are disappointing, and the results of compounds currently undergoing proof of concept studies are eagerly awaited. If the results from studies with CNV2197944 and Z944 are also negative then it will be important to understand fully why the compounds have failed in order to inform any future programs. It would be unadvisable to progress any similar compounds into development unless they are clearly differentiated from the early compounds. Many of these compounds were identified through traditional strategies which relied heavily on the validity of animal pain models to predict clinical efficacy. This is a strategy which is clearly flawed as so many compounds which work in these models have in recent years failed to show efficacy in the clinic. It is therefore encouraging to see the climate changing slightly and groups using in vivo electrophysiology techniques to measure target engagement in preclinical models as Zalicus did in the profiling of Z944. Similarly the studies reported by Janssen which examined their Cav2.2 blockers ability to inhibit neurotransmitter release from spinal cord slices are also a very positive step. Particularly as the effects of ziconotide in similar assays as well as in vivo have also been reported and can be linked to efficacious drug concentrations. Compounds that bind to the α2δ channel subunit with higher affinity than gabapentin or pregabalin have been identified but the increased binding affinity has not translated into increased clinical efficacy.

Another important point to consider is that targeting state-dependent calcium channel blockers clearly produces an excellent safety profile compared with tonic blockers such as ziconotide; however a state-dependent calcium channel blocker has yet to demonstrate clinical efficacy. This poses an important question: is it possible to achieve clinical efficacy with a state-dependent calcium channel blocker? And if so what is the optimal profile?

In future programs, workers should be encouraged to fully determine selectivity across all members of the voltage-gated calcium channel family. This is highlighted by recent reports of compounds such as TROX1 from Merck which was believed to be a selective Ca2.2 blocker, but later shown to inhibit Cav2.1 and Cav2.3 channels with similar potency to Cav2.2. From what has been reported groups only screen against a limited number of family members, and it would be interesting to see how selective many agents really are, if they were to be fully profiled across a full panel of channels.

When reading articles describing the profiles of calcium channel blockers caution should be exercised if trying to compare results from one group with those of another unless identical screening protocols have been used. Potencies and selectivities can vary widely from one assay format to another, thus rendering comparisons very difficult.

From a chemistry perspective the voltage-gated calcium channel family is clearly highly tractable as demonstrated by the diversity of structures that have been published. There also appears to be certain motifs which confer calcium channel activity on a molecule such as the diphenylmethyl group and phenylsulfonyl moiety.

The voltage-gated calcium channel family has a huge potential to deliver future effective and safe pain medicines. To date the potential has not been fully realized with a small molecule that has been designed for the purpose. For future projects there is a huge volume of data now available which has been published during the last decade; data which should be carefully analyzed and the results used to inform the design of the next-generation compounds which will have a higher chance of success.

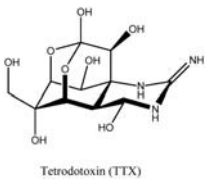
7.04.1 Introduction

Voltage-gated sodium channels[1] (Na_Vs) are ubiquitous proteins found in all known classes of organisms indicating their essential role in the basic functions of life. In multicellular organisms, they are critical mediators of intracellular information transfer along neurons and play a pivotal role in neuronal networks. There is a long history of sodium channel blockers showing utility in the treatment of human diseases, for example, carbamazepine was introduced for the treatment of epilepsy and trigeminal neuralgia in the 1960s,[2] and lamotrigine for epilepsy and bipolar disorder in the 1990s.[3] More recently, driven by discoveries in human sodium channel genetics, there has been a resurgence of effort aimed at discovering novel, subtype selective sodium channel blockers for the treatment of pain.[4]

Sodium channels are transmembrane proteins consisting of a large tetrameric pore-forming α-subunit and smaller auxiliary β-subunits. There are ten known subtypes designated by their respective α-subunits, $Na_V1.1$–1.9 and Na_x, which arise from genes SCN1A to SCN11A (**Table 1**).[6] Sodium channels at resting membrane potential are closed to sodium ion transport but respond to external stimuli by detecting small changes in membrane potential. This triggers activation of the channel via a conformational change, resulting in transient channel opening permitting selective cellular influx of sodium. This leads to further depolarization resulting in neuronal activation and excitation. Channels remain in the open state for a short period before entering an inactivated state that is nonconducting and resistant to activation. An increase in membrane potential known as hyperpolarization causes the channel to return to the resting state. In order to intervene pharmacologically it is preferable to stabilize the inactivated state rather than blocking the open state, which has important roles in homeostasis[7] (*vide infra*).

Table 1 Identification of Na_V channels and inhibition profile with Tetrodotoxin[5]

Channel	*Gene*	*TTX IC_{50} (nM)*	*Occurrence*
Na_V 1.1	SCN1A	6	CNS
Na_V 1.2	SCN2A	13	CNS
Na_V 1.3	SCN3A	4	Embryonic CNS
Na_V 1.4	SCN4A	5	Skeletal muscle
Na_V 1.5	SCN5A	2000	Cardiac
Na_V 1.6	SCN8A	3	CNS, glia, DRG
Na_V 1.7	SCN9A	4	DRG, CNS
Na_V 1.8	SCN10A	31,000	DRG
Na_V 1.9	SCN11A	1500	DRG
Na_X	SCN6(7)A	–	Heart, uterus, lung, DRG, glia, circumventricular organs



Tetrodotoxin (TTX)

The distribution and function of sodium channels are well characterized.[8] In summary, sodium channels are expressed principally in the central nervous system (CNS) and peripheral nervous system (PNS) on neurons and glial cells. However subtypes $Na_V1.4$ and $Na_V1.5$ are expressed mainly in skeletal and cardiac myocytes. More specifically $Na_V1.1$, 1.2, and 1.3, known as brain sodium channels, are highly expressed in the CNS and are highly sequence homologous. $Na_V1.1$ is also expressed in the dorsal root ganglia (DRG) and is responsible for propagating nociceptive signals from the periphery to the CNS via the dorsal horn of the spinal cord. $Na_V1.2$ is abundant in adult brain whereas $Na_V1.3$ appears to be the dominant brain isoform in the embryonic CNS but is downregulated after birth. $Na_V1.6$ is expressed in the CNS, PNS, and glial cells. $Na_V1.7$ is notable for its high levels of expression in the PNS, particularly in DRG nociceptive neurons, indicating a potential role in pain pathways. $Na_V1.8$ is not expressed in the CNS and occurs mainly in nociceptive neurones in the DRG. $Na_V1.9$ is particularly localized in small DRG neurons and not in the CNS. Hence multiple Na_V channels are associated with cellular locations and cell types that are important for the processing of pain signals and therefore sodium channels are attractive targets for therapeutic intervention in conditions that cause pain.

Human genetic studies[9] have identified a number of mutations that result in interesting pain phenotypes. Certain mutations in the SCN9A gene, which codes for the $Na_V1.7$ channel, result in a rare inherited condition known as erythromelalgia (EM).[10] Patients with EM suffer swelling and painful burning sensations in the extremities, often in the toes but also the ears and face. Electrophysiology studies have demonstrated that mutated $Na_V1.7$ channels from EM patients are constitutively hyperexcited. In addition these mutations cause the voltage sensitivity of inactivation to change resulting in channels that are open for a longer period of time, producing a more prolonged change in membrane potential. Inherited EM became the first neuropathic pain condition with a causal link to genetic mutations. Subsequently other conditions have been genetically linked to SCN9A: paroxysmal extreme pain disorder in which mutant $Na_V1.7$ channels have a disrupted inactivation pathway that prevents channel closure and results in persistent pain; and Congenital Insensitivity to Pain (CIP), a rare condition in which patients experience no pain due to a mutated nonfunctional $Na_V1.7$ channel.

Further genetic linkages to sodium channels[11] have been discovered, including mutations to the SCN10A ($Na_V1.8$ encoding) gene that results in hyperexcitability and decreased pain thresholds in small fiber neuropathy patients, and SCN11A ($Na_V1.9$) mutations, which produce gain-of-function effects in painful peripheral neuropathy and familial episodic pain. Although further genetic studies are warranted in other well-defined human pain populations, it is already evident that mutations in sodium channels can result in either gain-of-function effects or complete loss of pain sensitivity. Evidently multiple channel subtypes are involved in processing pathogenic pain signaling. The specific role of certain subtypes has been defined (e.g., evidence suggests that $Na_V1.7$ acts as a threshold channel which, when activated above a certain membrane voltage, undergoes a slow transition into the inactivated state). However, specific roles of other channels in different cellular population types require further elucidation. Notwithstanding this complexity of subtypes, targeting sodium channels continues to be a focus for pharmacologic and therapeutic intervention in the treatment of human pain conditions.[4]

A considerable number of studies have characterized the effect of sodium channel blockers in animal models of pain. Both nonselective[12] and subtype selective $Na_V1.7$[13,14]and $Na_V1.8$[14,15] molecules have shown efficacy in a range of preclinical pain models, providing further support for these sodium channels as targets for therapeutic intervention.

The last decade has seen major progress in the design of selective sodium channel blockers targeting channel subtypes with a genetic linkage to pain.[11] This progress has been driven by the emergence of an understanding of the structure and function of voltage-gated ion channels, through both detailed electrophysiology studies of particular channels[16] and the solving of the first X-ray crystal structures of sodium channels.[17]

Clinically there have been a number of human studies investigating the efficacy of sodium channel blockers in neuropathic pain. Local anesthetics such as lidocaine are non-selective sodium channel blockers. The analgesic activity of local anesthetics is clinically well characterized although the therapeutic index is low limiting use to local administration. Lamotrigine was developed as a sodium channel blocker with a much improved therapeutic index due to its use- or state-dependency, subsequently shown to be associated with its selective targeting of the inactivated state of the channel. Lamotrigine is effective in reducing pain in patients with diabetic neuropathy at oral doses of 200 mg and above.[18] However it causes a rare life-threatening rash (Stevens–Johnson syndrome), which has limited its use to more severe clinical indications. Recently a new state-dependent small molecule, CNV1014802, has been reported to show efficacy in two Phase II clinical studies in lumbosacral radiculopathy (lower back pain/sciatica) patients and patients suffering from trigeminal neuralgia, a debilitating and excruciatingly painful condition associated with entrapment of the trigeminal nerve in the face.[19] CNV1014802 is reported to be entering Phase III studies in 2016 (*vide infra*).

It is the purpose of this chapter to identify and profile novel classes of sodium channel blockers directed at pain indications. The work comprehensively reviews patent filings and publications from 2012 to 2015 and references all compound classes reported since 2010. Papers describing compounds in which sodium channel blockade is one of a number of polypharmacologic modes of action are not exhaustively covered. The reader is directed to several recent reviews, which also discuss aspects of sodium channel drug discovery.[20]

In addition to small molecule research, modified toxin and antibody approaches are examined. This review will also discuss recently reported clinical findings.

7.04.2 Sodium Channel Structure and Function

7.04.2.1 Voltage-Gated Sodium Channels

Mammalian voltage-gated sodium channels have been characterized by their sensitivity to interaction with tetrodotoxin (**Table 1**) as well as subtype and location. A review of diseases and clinical indications for voltage-gated sodium channels as well as the use of

toxins to characterize channel responses has recently been published.[21] The channels most frequently associated with pain sensation pathways are $Na_V1.2$, 1.3, 1.6, 1.7, 1.8, and 1.9. Much work has been undertaken to discover small molecules with selectivity over the $Na_V1.5$ channel, which is important for cardiac function. Many of the papers and patents discussed report $Na_V1.7/Na_V1.5$ selectivity as a key parameter in drug design. As certain channel subtypes are predominantly found in either peripheral or central locations, designing compounds for a particular compartment has often been a factor in designing blockers for a particular function. For example researchers have reported the design of compounds with low central penetrance as a mechanism by which selective blockade of peripheral sodium channels can be obtained. It is a matter of debate as to whether effective systemic. Sodium channel analgesic agents can be designed without the need to modulate central activity to achieve clinical efficacy.[22]

7.04.2.2 Ligand-Gated Sodium Channels

In contrast to their voltage-gated counterparts, ligand-gated sodium channels are activated by the binding of a ligand rather than a change in membrane potential and have rarely been a target for pain research. However the epithelial sodium channel (ENAC/degenerin family) is known to be ligand gated and has been reported to be associated with pain sensation, but it is also involved with mechanosensation, blood pressure control, and the expression of fear. This channel is predominantly located in the lung, kidney, and colon where it effects transepithelial Na^+ ion transport. It is modulated by the mineral corticosteroid aldosterone and has been shown to be blocked by triamterene or amiloride. The main therapeutic use of these agents is as diuretics and, despite the association, there has been no report of ENAC channel blockers being targeted specifically for pain indications.[23]

7.04.2.3 Mechanisms of Ion Channel Modulation

Both site-directed mutagenesis studies and ligand competition experiments indicate that channel blocking compounds can bind at many differing sites within the ion channel assembly.[24] Certain compounds, such as Tetrodotoxin, block the outer pore which is wide enough to accommodate hydrated sodium ions. Several drugs, such as lidocaine, bind at the "local anesthetic" site on the inside of the pore; this is a broad cavity accessible to small molecules capable of penetrating the cell membrane. Generally there is high sequence homology between channel subtypes in this region but recent structural biology studies using the bacterial sodium channel have indicated that there are fenestrations in the side of the protein assembly that offer a path through which lipophilic molecules can enter and interact with the pore domain.[25] It may be that the shape characteristics of these different openings in the pseudosymmetric assembly of differing channels, and the states of these channels, offer the opportunity of selective binding. In addition it has been established that selective binding to remote voltage sensor and extracellular loop regions, which differ significantly in amino acid sequence between channel subtypes, can be effective at stabilizing particular states of the channel, and hence are accessible drug targets. The differentiated extracellular ion channel surface also provides a potential target for the design of ion channel-specific antibodies, and is the binding site of several toxins and designed peptidic agents (*vide infra*) (**Fig. 1**).

An alternative approach to achieving both specificity and safety with ion channel blockers is to target particular states of the ion channel. Selective stabilization of the inactivated state may reduce the propensity for channel opening in response to high frequency firing. This is important to pain function as pain is typically associated with a high frequency of nerve pulses—often in the hundred hertz region—whereas many other physiological functions, such as heartbeat, also modulated by sodium channel action, are associated with much lower frequency activity. Measurement in the change in conduction after a rapid sequence of action potentials indicates the "use-dependence" of an agent, which blocks the inactivated state of the channel (**Fig. 2**).

An alternative app). The state selectivity of channel blockers and their effect on inhibition of firing frequency is a complex function of compound affinity, binding site location, and binding kinetics; so use-dependency and state selectivity do not always correspond.

By controlling the voltage across a channel within a cell using electrophysiology techniques, it is possible to change the proportion of channels in open, closed, and inactivated states. Therefore testing channel inhibition at differing biasing voltages can also give a measure of the state selectivity of blockers. However, as differing conformations will be present at intermediate voltages and, as channels are necessarily in equilibrium, absolute inhibition constants for specific states are very difficult to establish. Inhibition constants for specific voltages are therefore more typically quoted, but the experimental details may not be disclosed. Furthermore, changes in instrumentation, buffer, cell line, and protocols can have a marked effect on measured values. IC_{50} values are generated by a wide range of techniques from electrophysiological measures in automated or manual patch studies to ion flux assays based on dye concentrations. Consequently, channel inhibition measurements from different experimental groups are not easily compared and this should be borne in mind when assessing inhibition data presented in the rest of this chapter.

7.04.3 Voltage-Gated Sodium Channel Blocking Agents

7.04.3.1 Toxins and Peptides

Several toxins are known to block voltage sodium channels and typically do so in a non-state-selective manner. The best characterized of these agents is tetrodotoxin, a polyhydroxylated bridged alicyclic compound present in the liver of the puffer fish (*Tetraodontidae*), which acts by occupying part of the extracellular end of the channel in an area normally occupied by sodium ions and water. Despite the evident toxicity (deaths are caused each year by ingestion of the tetrodotoxin in specific seafood), research is underway to formulate this agent for treating certain pain conditions.[26,27] The channel selectivity of different toxins has been widely reviewed.[28]

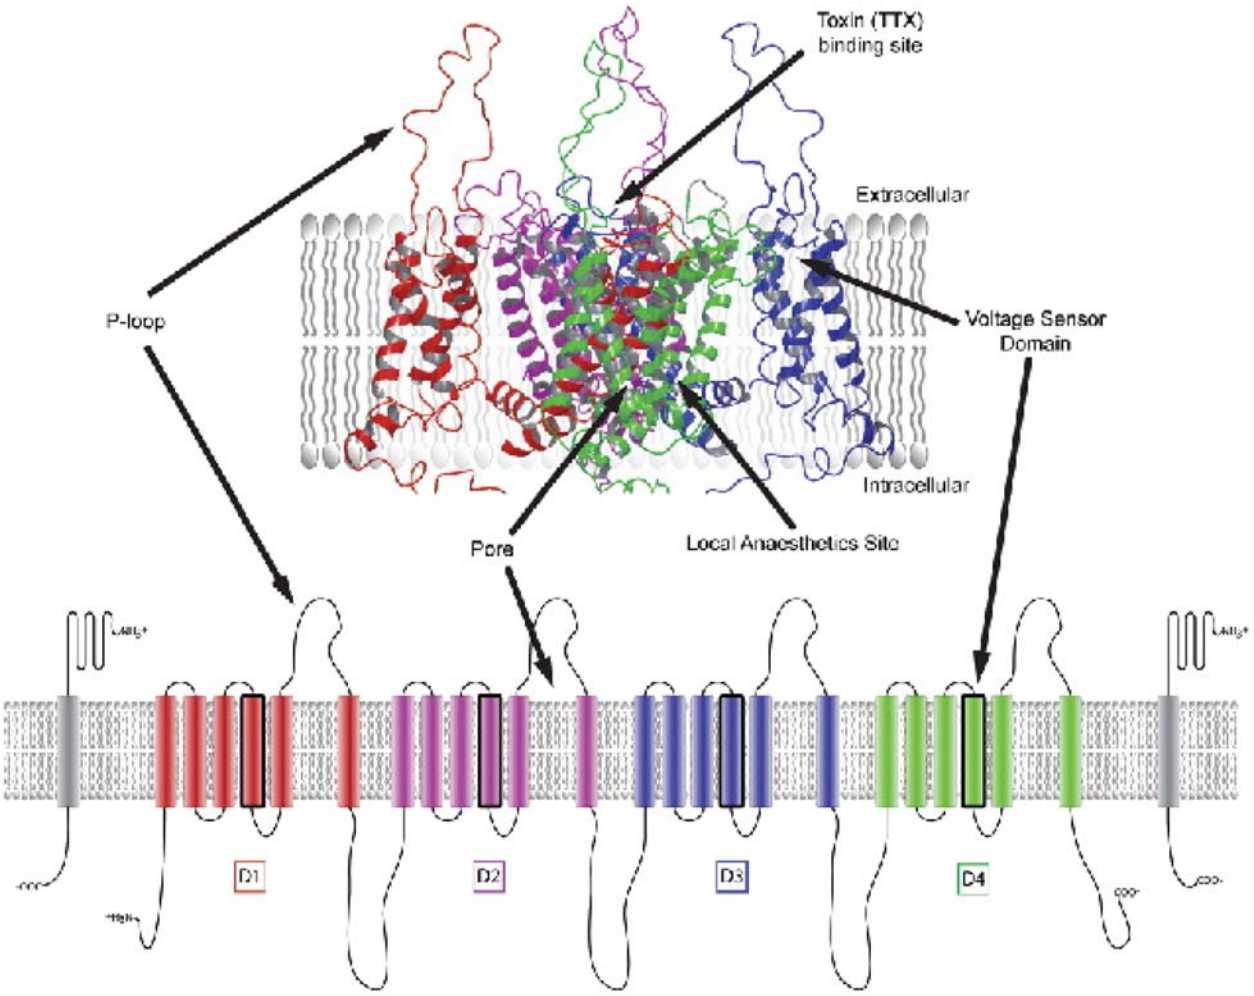


Fig. 1 Na_V channel structural topology, highlighting common ligand binding sites and significant structural features. Domains D1-D4 are represented in different colors while β-subunits are shown in gray.[4] [Reproduced with permission from Taylor and Francis © 2015].

Reproduced with permission from Rugiero F, Derjean D, Morisset V, Owen DE, Giblin GMP, Davis JB, Gunn K, Palmer J, and Tate S (2012) CNV1014802, A Novel, Potent Nav 1.7 Selective State-Dependent Sodium Channel Blocker With Broad Preclinical Antihyperalgesic Efficacy. *14th World Congress on Pain (IASP)*, (Milan, Italy).

Other well-characterized isolated small molecule toxins include saxitoxin and neosaxitoxin, members of a related group of compounds isolated from paralytic shellfish toxin which, like tetrodotoxin, bind to an extracellular site on the channel.[29] These agents have been proposed as local anesthetic agents, but not systemic analgesics. Peptidic sodium channel blockers are present in venom produced by a number of invertebrates including cone snails, tarantula spiders, and certain scorpion species.[30] These are typically characterized by their tertiary structure which contains a number of specific disulfide bonds, however these agents also inhibit a range of other ion channels and because of their polypharmacology have not been developed themselves for drug use as sodium channel blocking agents. Other toxins known to bind to specific sites on the sodium channel include α-scorpion toxin, sea-anemone toxin (reported to slow sodium channel inactivation), β-scorpion toxin, brevetoxin, and ciguatoxin.[31] Despite their value as laboratory agents and standards for channel characterization,[32] none of these latter toxins are reported to be developed directly for therapeutic use.

However, peptides from modified toxins have been extensively researched as potential drugs. Amgen in particular has invested significant effort in designing inhibitors utilizing features of the domain II binding peptide present in the tarantula toxin GpTx-1.[33] In a major undertaking, the Amgen team chemically synthesized the toxin and undertook modifications with a range of alterative (including some unnatural) amino acids at all non-cysteine positions on the peptide chain, characterizing the binding site and, through modification, achieving highly selective and potent agents. For example, while the parent toxin has a 10 nM IC_{50} for $Na_V1.7$ and a 20-fold selectivity for $Na_V1.4$, a peptide analogue [Ala5,Phe6,Leu26,Arg28]-GpTx-1 is a 1.6-nM inhibitor with over 10,000-fold selectivity for $Na_V1.7$ over $Na_V1.4$. Aspects of this work are the subject of a patent application.[34]

Janssen has adopted a similar approach in developing selective toxin analogues. Their researchers have designed compounds based on the Peruvian green velvet tarantula venom protoxin-II. Peptides with IC_{50}s for $Na_V1.7$ in the range 2 nM–400 nM have been developed with no measurable activity against $Na_V1.5$.[35] Another set of patent applications describes an approach to variants of huwentoxin-IV from the Chinese bird spider.[36] These disclose effects in a pain model of paw pressure in the rat at low nM concentrations. The spider toxin has also been shown to specifically bind to the voltage sensor β-subunit of the sodium channel, in conjunction with extensive *in silico* docking studies.[37]

Purdue has also engaged in extensive studies on protoxin-II using an approach of making chimeric molecules between protoxin-I and II to modulate channel specificity.[38] This work led to the identification of more potent $Na_V1.7$ blockers, including a methylamino derivative with a 42 pM IC_{50}. The research is associated with a number of patent applications[39] targeting $Na_V1.7$ for pain.

Continuing the theme, researchers at the University of Utah prepared conopeptides from the cone snails *Conus geographus* to act as $Na_V1.7$ blockers.[40] As a class these are known to interact with both sodium and calcium channels and their patent application suggests that novel analogues may have preferred selectivity properties.

The University of Arizona has patented peptides, which have the effect of modulating sodium channels but using an entirely different mechanism, namely inhibiting the trafficking of $Na_V1.7$ ion channels[41] by interacting with the collapsing response mediator protein 2, and affecting the SUMOylation cycle. A patent describes dye studies indicating that a specific peptide can effectively inhibit $Na_V1.7$ currents and claims that spinal delivery of 10 μg of this peptide at a 5 μl dose resulted in a significant long-lasting reversal of both thermal and mechanical hypersensitivity in a rat model.

Saxitoxin has also been a subject of medicinal chemistry optimization for potential therapeutic use, this time by Stanford Junior University in conjunction with SiteOne Therapeutics. The researchers found ester derivatives such as **1** (Fig. 3), which were potent at both $Na_V1.4$ and $Na_V1.7$ while being selective over $Na_V1.5$; however no detailed inhibition data was provided.[42] This work builds on a long-standing interest in modified saxitoxins for treating pain.[43] Another study with this toxin this time at Stanford University involved the preparation of modified forms bearing a cysteine-reactive maleimide group.[44] These were demonstrated to be irreversible inhibitors of sodium conductance.

7.04.3.2 Antibodies

A $Na_V1.7$ blocking antibody has long been mooted as a potential pain therapeutic agent and has attracted both academic and commercial research interest. There has been an expectation that the peripheral distribution of the $Na_V1.7$ channel would be particularly suited to the parenteral route of administration required for antibody delivery, but whether an antibody would be effective against myelinated nerve fibres was unknown. The first academic report of a selective $Na_V1.7$ blocking antibody came from the group of Lee et al. at Duke University in 2014.[45] The Duke team created an antibody that binds to the voltage sensor paddle region of $Na_V1.7$. Their molecule showed between 2 and 3 orders of magnitude selectivity for $Na_V1.7$ over seven other voltage-gated

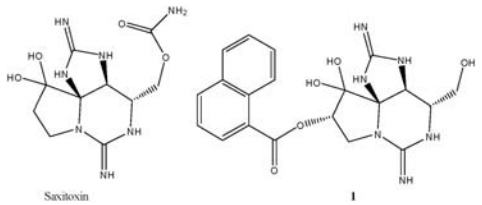

Fig. 3 Small molecule toxin-derived Na_V inhibition.

sodium channels, an IC_{50} of 30 nM, and maximal inhibition of 87%. Efficacy was reported against itch-related synaptic transmission in mouse lamina IIo neurons and this anti-itch activity was borne out in a mouse model. In a model of acute inflammatory pain—formalin induced writhing in mice—only intrathecal activity was recorded, demonstrating a previously unreported central mechanism of $Na_V1.7$ in pain inhibition, and efficacy against myelinated nerve fibres. The activity of the agent was relatively weak compared with other analgesic antibody agents such as the anti-NGF antibody Tanezumab. Interest in an antibody approach has been demonstrated in patent applications filed by UCB,[46] Argen-X,[47] Harvard University,[48] Duke University,[49] and Regeneron.[50] UCB published the earliest claim in 2011 on $Na_V1.7$ monoclonal antibodies. This indicated that the antibodies inhibited evoked action potentials in isolated DRG cells. Argen-X reported that they used a DNA immunization technique to create antibodies that were selective for affinity to the $Na_V1.7$ extracellular loop and these were shown to inhibit inward current in whole-cell voltage-clamp experiments. Regeneron created antibodies that bind to at least one extracellular loop or to the paddle region by immunizing a humanized "VELOCIMMUNE" mouse and generating hybridoma cell lines or isolating anti-$Na_V1.7$ antibodies directly from antigen-positive B cells from immunized animals. The Harvard team described a single-domain antibody that specifically binds both to $Na_V1.7$ and an ion channel toxin in order to have maximal efficacy and selectivity for $Na_V1.7$.

$Na_V1.9$ antibodies have also been the subject of a number of claims from of the CNRS group in France, but the current status of any agents is not clear.[51]

7.04.3.3 Small Molecules

7.04.3.3.1 Clinical compounds with a sodium channel mode of action

Various small molecule agents originating from phenotypic discovery programs aimed at other indications have been discovered that show analgesic effects. Though several act as Na_V blockers, very few have been designed to act specifically by a sodium channel mechanism. It is therefore worth briefly reviewing some therapeutic agents (in addition to lamotrigine and local anesthetics) presently marketed or used in the treatment of pain conditions that are known to act, at least partially, through sodium channel blockade or modulation. An understanding of the properties and deficiencies of these agents has helped inform the design of newer classes of drugs.

Carbamazepine (Tegretol™) and oxcarbazepine (Trieptal™) (Fig. 4) are tricyclic agents developed some 50 years ago as antiepileptics but also with efficacy against neuropathic pain. Their mode of action is likely to be due to a combination of activities, but including sodium channel blockade. Carbamazepine stabilizes the inactivated state of Na_Vs but is also a GABA receptor antagonist and has effects on serotonin release and uptake. Carbamazepine's polypharmacology is compounded by the fact that it interacts strongly with cytochrome P450 enzymes which makes this a difficult agent to use in combination therapies. It also suffers from the potential to induce certain severe skin conditions and anemias, and commonly shows central effects including motor coordination impairment. The structurally related oxcarbazepine has a similar activity but a better metabolic profile and lower propensity to induce anemias, but still with significant central side effects. It is a prodrug of the active component in which the keto carbonyl is reduced to a hydroxyl group *in vivo* ($t_{1/2}=2$ h) but this material, eslicarbazepine, also has a lower half life than carbamazepine.[52]

Lacosamide (Vimpat™) is an anticonvulsant sodium channel blocker marketed by UCB that is approved for the adjunctive treatment of partial onset seizures and neuropathic pain (though it does not presently have FDA approval for the latter indication). It works by enhancing the slow inactivation of Na_Vs without affecting the fast inactivation mechanism. This inactivation prevents the channel from opening, helping to reduce the action potential. However lacosamide has a second mechanism of action as it modulates collapsing response mediator protein 2, preventing the formation of abnormal connections in the brain. For pain, it has been shown to have efficacy in an 18-week Phase III clinical study in diabetic neuropathy compared with placebo. However, it shows significant central and other side effects in at least 10% of patients and has to be titrated to maximal dose over a period of weeks.[53]

7.04.3.3.2 Multi-channel, partially selective and $Na_V1.7$ selective sodium channel blockers

In consideration of the issues presented by the polypharmacology of marketed compounds, the focus of sodium channel drug discovery efforts in pain during the past 5 years has therefore been on discovering sodium channel-specific and subtype selective

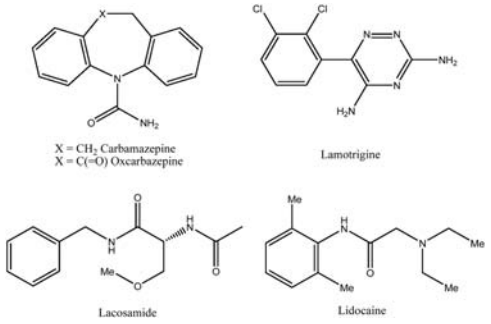

Fig. 4 Some marketed Na_V blockers.

blockers. The majority of research has focused on $Na_V1.7$, and to a lesser extent Na_Vs 1.8 and 1.9. Once thought to be challenging,[54] given the homology in the pore region of sodium channel isoforms, recent studies have shown that it is possible to design small molecules with high levels of channel selectivity as well as specificity for binding to different states of the ion channel.[55] The diversity of Na_V blockers reported, especially in the patent literature, points to multiple targetable binding sites; at least eight have been suggested.[56] However, many Na_V blocking compounds disclosed in the literature cannot readily be allocated to a specific known pharmacophore and there is some evidence that even compounds from well-defined inhibitor classes can have more than one mode of action. Thus the analysis of medicinal chemistry approaches to Na_V inhibition is complex. Furthermore, to date there have been few papers published describing the Structure Activity Relationships (SARs) found in lead optimizing Na_V inhibitor campaigns. In this review we have therefore sought to categorize compounds, predominantly from the patent literature, into agents targeted at particular channels and compare them, where appropriate, in pharmacophoric groups.

The case for $Na_V1.7$ subtype selective inhibitors as therapeutics is very strong, founded on the observation that inherited human familial mutations are known, which render this ion channel inactive and individuals with the phenotype experience no pain,[57] although $Na_V1.7$-independent pain mechanisms are known.[58] Consequently, much research has focused on the design of $Na_V1.7$ blockers, but selectivity is often not reported, especially in the patent literature. Additionally early screens in lead optimization campaigns have often been performed with surrogate ion channels, even though $Na_V1.7$ is the eventual target. This section of the review therefore covers together both $Na_V1.7$ and Na_V blockers of unspecified selectivity, though noting when activity at specific or multiple channels is disclosed or developed as the target profile. The discussion also includes pan-sodium channel blocking agents with selectivity over channels known to be associated with central or peripheral side effects, by virtue of their state- or use-dependency.

7.04.3.3.2.1 Aryl-linked aminoamides

The pharmacophore for a local anesthetic agent such as lidocaine can be described by an aromatic group linked to an amide with a pendant amine, and this has been a starting point for the design of some classes of systemic analgesic agents (Fig. 5), for example by Astellas and EWHA (*vide infra*). However, Convergence has demonstrated that it is possible to obtain state-selective and isoform-selective compounds from a variant of the pharmacophore in which the amino and amide groups are reversed. This aryl-linked aminoamide pharmacophore has been utilized by a number of companies (Fig. 5) and elaborated in different ways. Analogues have been designed to be either brain penetrant or peripherally restricted.

There is significant subtlety in functional group disposition and substitution patterns, which determines the level of state-dependence, inhibition potency, or subtype selective blockade within this pharmacophore. Certain compounds of this class have been reported as showing strong state-dependent selectivity for the $Na_V1.7$ or particular selectivity for the $Na_V1.8$ channel. This first section will therefore discuss both $Na_V1.7$ blockers and unspecified Na_V blockers that related to a particular

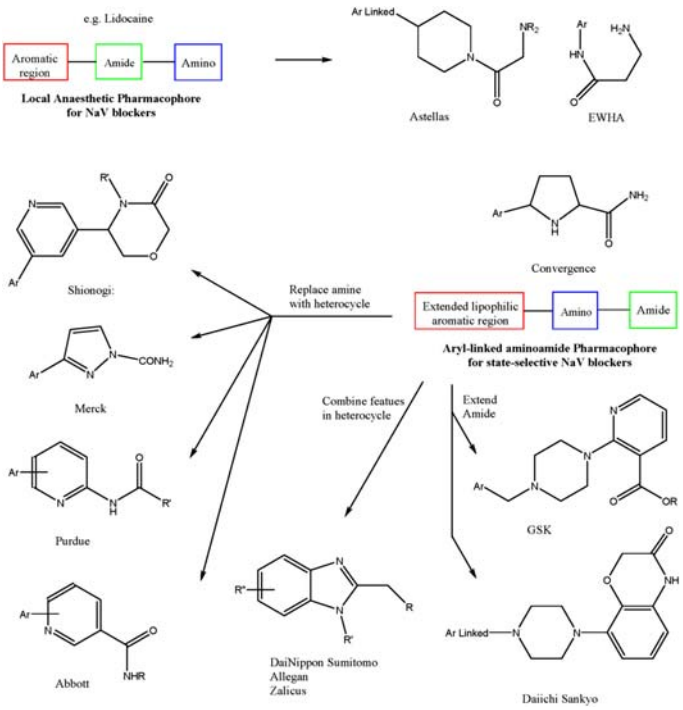

Fig. 5 Compound classes linked to aryl-linked aminoamide and local anesthetic pharmacophores.

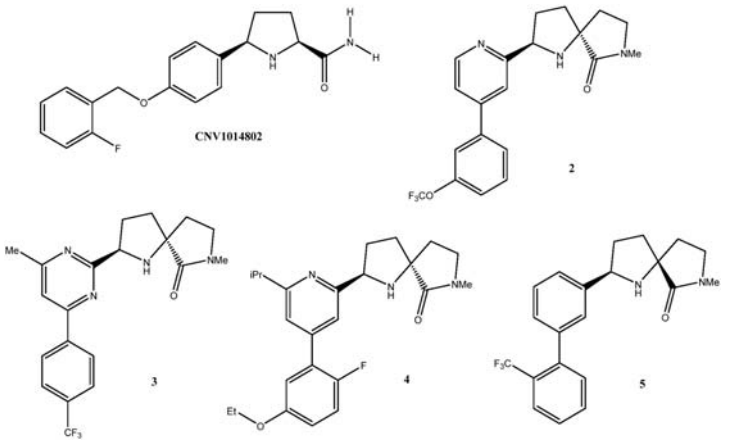

Fig. 6 Convergence Na_V blockers.

pharmacophore. In some cases the scaffold has morphed into other classes of Na_V blocker. In particular, compounds from Purdue Pharma, which have features of two classes, are discussed with triazines (*vide infra*).

CNV1014802 (Fig. 6) is being developed by Convergence Pharmaceuticals for pain and is also discussed under clinical studies as it has recently demonstrated a successful Proof of Concept in Phase II clinical studies for pain (*vide infra*). It shows significant state-dependent selectivity for Na_V 1.7.[59] The compound shows good aqueous solubility, an excellent pharmacokinetic profile, and a low potential for drug–drug interactions.[60]

More recent work has indicated a focus on conformationally restricted spirocyclic aryl-linked aminoamides and this time bearing a biaryl or heterobiaryl feature. A 2014 review[4] noted compounds **2** and **3** as examples from recent Convergence patent applications. Compounds **4** and **5**, which possess differing relative ring stereochemistries, are exemplified as potent $Na_V1.7$ state-dependent blockers with sub-micromolar IC_{50}s against $Na_V1.7$ at V_{half} potential.[61]

One class of Na_V blocker investigated extensively at Merck Sharp and Dohme (MSD) is related to the aryl-linked aminoamide series, but with the basic amino group replaced with a heterocyclic moiety. Three successive publications in 2010 summarized this work, highlighted in Fig. 7.[62] These papers describe the discovery of the three ring class as a development from the semicarbazone sodium channel blocker V102862.[63] A tricyclic aromatic class of Na_V blocker was formed by the replacement of the semicarbazone with a heterocycle-generic structure **9**. Analogues based on the heterocycles **6**, **7**, or **8** were then shown to be able to provide low micromolar or better IC_{50s} for blockade of $Na_V1.7$ in a fluorescence resonance energy transfer (FRET) assay, with compound **8** showing a $Na_V1.7$ IC_{50} of 228 nM. It is interesting to note that the meta-disposition of the three rings was important for activity. The most potent analogue emerging from this work was **10**, a sub-micromolar blocker of $Na_V1.7$ with a good in vitro PK profile and efficacy comparable to gabapentin in the Chung spinal nerve ligation (SNL) model at 30 mg/kg. However, this series suffered from a potential hydrolytic liability, and the final paper in the trio indicated how this was resolved through changing the substitution

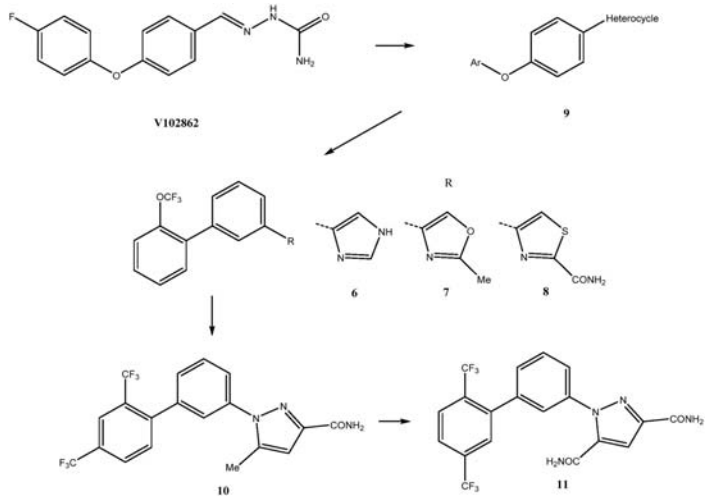

Fig. 7 Evolution of MSD aryl-linked aminoamide Na_V blockers.

pattern on the terminal aromatic ring and introducing a second amide substituent on the heterocycle. This led to the discovery of **11**, a stable molecule which possessed a good *in vitro* PK profile, activity in the SNL model, and which showed 50% reversal of mechanical hyperalgesia in an FCA model of neuropathic pain on oral dosing at 30 mg/kg. The compound also showed little effect on motor function in the mouse at doses of 100 mg/kg.

GlaxoSmithKline (GSK) has pursued inhibition of $Na_V1.7$ and potentially $Na_V1.9$ as a mechanism for suppressing the painful irritation evoking a cough reflex, and have noted that $Na_V1.7$–1.9 are expressed in the vagal sensory neurons that innervate the airways.[64,65] This work has been associated with two patent applications describing series of sodium channel blockers containing 2-piperazinopyridine-3-carboxylates, which fall within an extended amide variant of the aryl-linked aminoamide pharmacophore (**Fig. 5**). In the first,[66] GSK describes over five hundred compounds based on this pharmacophore, with data on compounds which block both $Na_V1.3$ and $Na_V1.7$ to micromolar levels. A representative example **12** is shown in **Fig. 8**.

Compounds in the second application[67] exhibit an extended aromatic region in the pharmacophore and demonstrate higher levels of Na_V blockade, for example, compound **13** which is a sub-micromolar inhibitor of $Na_V1.7$. Detailed ion channel activity data are not recorded in either patent.

Daiichi Sankyo has focused most Na_V patenting activity on the sulfonamide chemotype (*vide infra*); however, in 2015 the company published a summary of work arising from an HTS hit **14** (**Fig. 8**), which was modestly selective for $Na_V1.7$ ($IC_{50} = 3.9$ μM) over $Na_V1.1$ ($IC_{50} > 33$ μM) and $Na_V1.5$ ($IC_{50} = 20$ μM).[68] The initial focus was on replacing the benzoxazinone with a more metabolically stable heterocycle and on reducing the bulk at the right-hand side (as drawn). This work led to the identification of a class of three alternative right-hand side groups, isoindolones, benzamides, and anilides. This latter group was optimized to compound **15**, which is somewhat related to the aryl-linked aminoamide pharmacophore explored by GSK.

Compound **15** continued to show potent human and mouse $Na_V1.7$ inhibitory activities (IC_{50}s of 1.7 and 1.3 μM respectively) with ~10-fold subtype selectivity over $Na_V1.5$, and it successfully demonstrated analgesic efficacy in mice (AcOH-induced writhing $ED_{50} = 19$ mg/kg), comparable to mexiletine, but with an expanded CNS safety margin (5.8-fold) as demonstrated by locomotor activity studies.

Shionogi has filed several related patents targeting blockade of sodium channels with a focus on $Na_V1.7$, which arguably fit the same broad pharmacophore. The first[69] describes a class of over 300 3-oxo-morpholines, linked to a biaryl group—an amide-linked biaryl moiety is a feature seen in various Na_V blockers. Compound **16** (**Fig. 9**) shows blockade of $Na_V1.7$ *in vitro* with an IC_{50} of 1.2 μM. A second patent application[70] provides a similar number of examples based on an imidazoimidazolone core, also typically with IC_{50}s in the micromolar range, for example compound **17** with an IC_{50} of 0.53 μM against $Na_V1.7$.

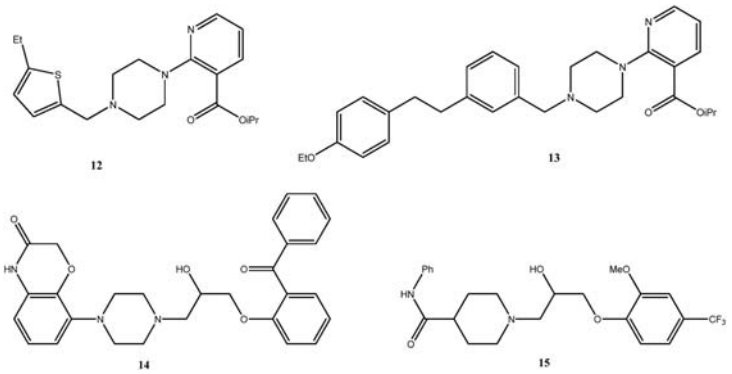

Fig. 8 Extending the aryl-linked amino-amide pharmacophore.

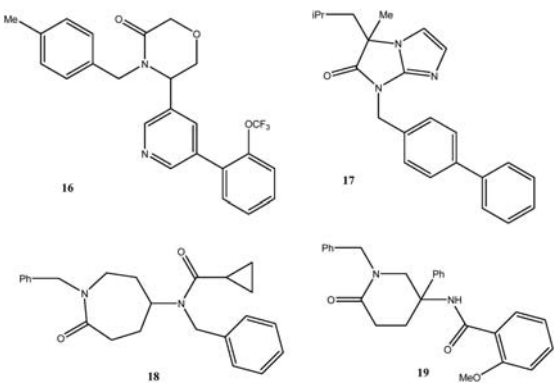

Fig. 9 Extended aryl-linked amino-amide Na_V blockers from Shionogi.

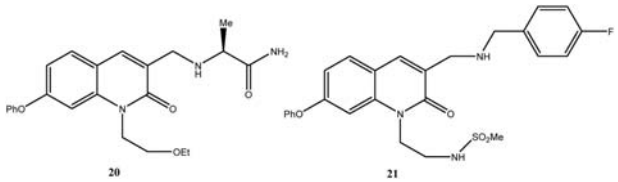

Fig. 10 Quinolone-core Na_V blockers.

A third patent application from this team describes some three hundred more distantly related compounds[71] with a lactam core in either a six- or seven-membered ring, and overall representing a more branched pharmacophore. Compounds **18** and **19** are highlighted as demonstrating potent inhibition of veratridine binding to $Na_V1.7$ with IC_{50}s of 0.58 and 6.3 μM, respectively.

In early studies, DaiNippon Sumitomo had patented a series of quinolone analogues of the aryl-linked aminoamide class bearing a pendant polar side chain (Fig. 10).[72] Such compounds were described as targeting Na_V TTX-resistant channels, rather than identifying the channel by specific subtype. For example, compounds **20** and **21** showed 100% inhibition in the TTX-resistant sodium channel assay at a concentration of 12–13 μM.

More recent work has seen the core shift to a benzimidazole template, replacing the quinolone functionality.[73] The substitution patterns for the 237 exemplified compounds mirror those in the earlier patent with biaryl or aryloxyaryl aromatic portions and a glycine-like amidic region, but the claim is more focused. Table 2 describes examples, which demonstrated 100% inhibition of TTX-sensitive sodium channels expressed in CHO cells at a concentration of 12.5 μM.

Unlike the earlier patent where a wide range of amide and side chain groups are examined, the claims in this patent show an emphasis on fluorinated aromatic substitution patterns which may reflect modulation of developability properties. Notably the benzimidazole compounds contain only one basic group. This, combined with the relatively low molecular weight and low polar surface area of the compounds suggest greater potential for brain penetrance than the quinolone series. Several other companies have also described benzimidazoles as sodium channel blockers (Fig. 11).

Allergan has described benzimidazole sodium channel blockers lacking an aryl substituent. The company has focused patent claims on the target of blocking persistent sodium current. The first case[74] indicates that the compounds may act at a number of ion channels and an emphasis is placed on the *in vivo* studies. These show, for example, that compound **25** (Fig. 12) is effective in a capsaicin model of thermal hyperalgesia in the rat at an oral dose of 10 mg/kg though it was clear that the same compound was much less effective in a spinal nerve ligation model study. This compound, while demonstrating a sub-micromolar IC_{50} in a sodium channel FLIPR assay, was apparently ineffective in an Ionworks electrophysiology study on the same ion channel (either

Table 2 Benzimidazole analogues of aryl-linked aminoamide

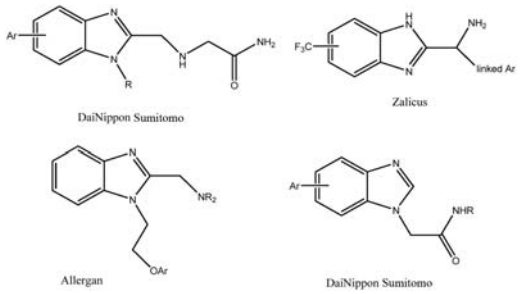

Fig. 11 Classes of benzimidazole-core Na_V blockers.

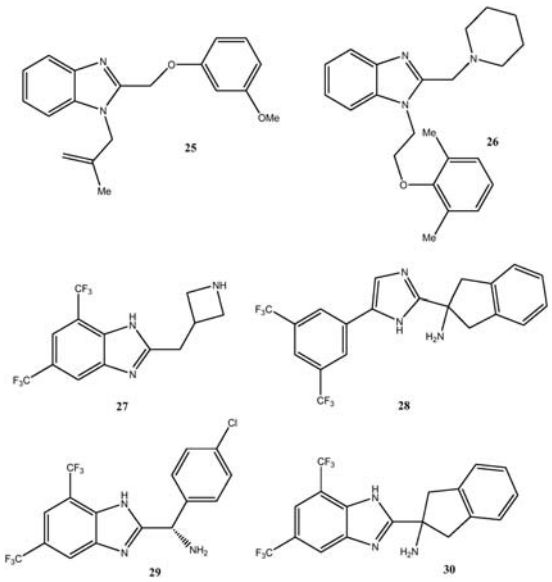

Fig. 12 Substitution patterns of benzimidazole Na_V blockers.

$Na_V1.3$ or $Na_V1.6$). An extension of this series is provided in a second application[75] in which a basic group is included as a benzimidazole substituent. Several compounds are noted as demonstrating significant block of sodium current in either $Na_V1.3$ or $Na_V1.6$ including compound **26,** which inhibited with an IC_{50} of 66 nM in a FLIPR assay. An unspecified close analogue also shows modest efficacy in the capsaicin study.

Zalicus has also worked on the benzimidazole class focused on blocking the slow inactivation process that gives rise to persistent sodium currents as a target for blocking pain. Zalicus filed on a class of ion channel modulators[76] in which inhibitors based on a benzimidazole template are first described. Both amine and amide derivatives are included among 200 examples; however, the only cases which are described as showing activity in pain models were basic. Compound **27** reverses mechanical hyperalgesia in a rat model at 30 mg/kg on oral dosing. Specific ion channel modulatory data is not described for sodium channels on all compounds but some activity at calcium channels is noted, so the compounds may have a mixed mode of action.

The development of this series can be seen in a second patent application[77] where this time the bis-trifluoromethylbenzyl group was not fused with the nitrogen heterocycle. The group investigated hybrid molecules with those of the aryl-linked aminoamide class and other known classes of Na_V blocker. However, in contrast to other patents filed by the group, in this case no data was given describing pain studies and the most potent $Na_V1.7$ modulator of fast inactivation was compound **28** which showed a -19 mV shift in V_{half} for inactivation on exposure at 10 μM. A third application in the series was published in 2014 and while focusing on $Na_V1.7$, emphasized that the compounds may exert their effects by modulation of a broader range of sodium and calcium channels.[78] The same group filed a patent[79] in 2015 covering many of the same compounds with some 90 examples described and data given for the voltage dependence of activation and fast deactivation on human $Na_V1.7$ channels. Zalicus further characterized the compounds by detailed electrophysiology studies indicating which examples were blockers of slow inactivation. Thus compound **29** had an IC_{50} for slow inactivation block of $Na_V1.7$ of 2.9 μM and showed a -27 mV shift in V_{half} for inactivation at 10 μM. In contrast compound **30**, which has much weaker slow activation block and showed a -15 mV shift in V_{half} for inactivation at 10 μM, was reported to show dose-dependent activity in a rat FCA model of pain, with significant activity at 10 mg/kg. The most recent Zalicus Na_V patent application WO 2015130957 starts by exemplifying further compounds from the benzimidazole class but morphs into a disclosure of sulfonamide ion channel modulators and is therefore discussed in that section (Table 4).

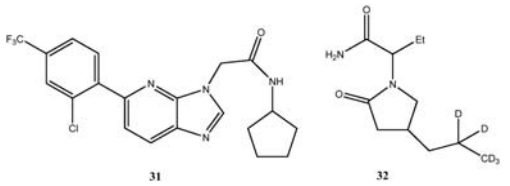

Fig. 13 Recent variations on the aryl-linked amino-amide pharmacophore.

A recent patent filing from DaiNippon Sumitomo[80] also continues to describe work around a benzimidazole template, this time with an N-linked amidic side chain and an emphasis on activity at both $Na_V1.7$ and 1.8. Typical examples include **31** (Fig. 13) with reported Na_V inhibitory activity of 99% at a concentration of 15 μmol/L.

A patent application from Concert Pharmaceuticals suggests that sodium channel blocking activity can be retained in aminoamide derivatives lacking the aryl component.[81] Their examples are also claimed as synaptic vesicle protein 2A (SV2A) ligands and detailed sodium channel activity or selectivity values were not reported. It is interesting to note that their examples included deuterated derivatives such as **32**.

Astellas has published few recent papers on sodium channel blockers; however, the company has disclosed one structure type, arguably most closely related to the local anesthetic pharmacophore.[82] Vinyl piperidines **ASP1120** and **ASP9596** (Fig. 14) are reported to be sodium channel blockers with potent oral analgesic activity in the spinal nerve ligation model in rat ($ED_{50} = 2.1$ and 0.18 mg/kg, for **ASP1120** and **ASP9596**, respectively). Notably the extended aromatic portion extends from the amide rather than from the basic side of the molecule.

Potential inks between the local anesthetic pharmacophore and the aryl-linked amino amide pharmacophore are also indicated in papers published by academic collaborators at several Korean research institutions, including the School of Pharmacy at EWHA Womans University.[83] They indicate that compound **33**, which has been shown to inhibit sodium channels in DRG cells, is also effective in relieving pain in model studies. The compound was effective at reducing both inflammatory and neuropathic pain in the rat on i.p. treatment at 6 mg/kg, while showing no behavioral effects at 60 mg/kg; however, a detailed pharmacological profile of the compound was not given. While demonstrated as inactive at N- and T-type calcium channels, no sodium channel selectivity data was reported. More recently this publication was followed up with a patent filed[84] on sodium channel blockers in which nine further compounds were highlighted and compound **34** was demonstrated to be a 10 μM IC_{50} inhibitor of $Na_V1.7$.

7.04.3.3.2.2 Spirocyclic Na_V blockers

A spirocyclic moiety is a feature of various distinct Na_V blocker series (Fig. 15) and it is interesting to consider why this construct has featured in different compound classes. It is clear that the chiral disposition of different functional groups, fixed by the spirocycles, is critical for aspects of selectivity in at least some of the cases.

A distinct class of spirocyclic indoles is described by Xenon in a series of publications and patent applications, some in collaboration with Genentech and more recently with Teva Pharmaceuticals. Several of these are described as mixed $Na_V1.7$ and $Na_V1.8$ blockers, but for the majority of claims only $Na_V1.7$ data is published. The lead compound XEN402, now TV-45070, is described further in the clinical section. Xenon reported[85] that the series originated from the discovery of oxindole **35** (Fig. 16), which had been identified by high-throughput screening. A series of $Na_V1.7$ blockers was developed by optimization of the oxindole C-3 and N-1 substituents as well as by elimination of metabolically susceptible features. This process led to the simplified analogue **36**, ten times more potent than the original HTS hit.[86] Subsequently a scaffold rigidification strategy gave a number of potential candidate compounds containing the spiro ring including **XEN907 37**, a further 10-fold more potent. A patent application describes the investigation of a several hundred substitution patterns around the phenyl group linked to the spiro center of the oxindole, and it is evident that reducing inhibition of cytochrome 3A4 has been an area of optimization.[87]

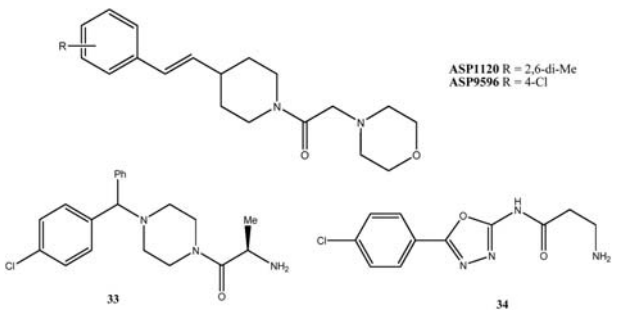

Fig. 14 Systemic Na_V blockers related to the local anesthetic pharmacophore.

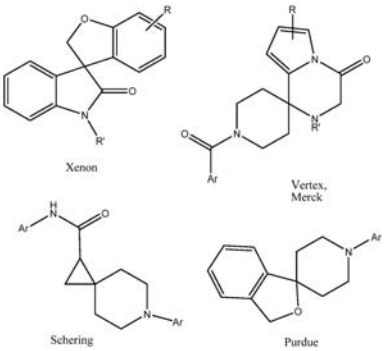

Fig. 15 Spirocycles as sodium channel blockers.

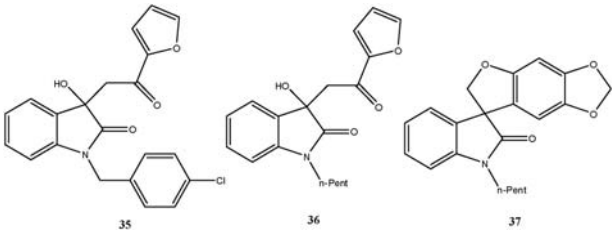

Fig. 16 Discovery of Xenon spirocyclic Na_V blockers.

A selection of spirocyclic indole derivatives from patents filed during the past 5 years by Xenon is described in Table 3. A challenge for this whole class appears to have been the low solubility of the series and formulation has been a significant focus. It is notable that a topical formulation has been developed for their lead compound **XEN402**, identified by Xenon as compound **38**. Significant effort has been applied to developing a bespoke oral formulation.[88] The topical activity of compound **38** in a rat FCA pain model is described as giving a 40% change from baseline in an application with a 4% formulation. Higher dosing levels led to little further change.

The table shows **38** as a single S-enantiomer though the racemate is also claimed in Xenon filings. The preference for the S-enantiomer is described in US 20100331386.[89] Compound **38** is also described in a single compound patent application.[90] *In vitro*, using a guanidinium influx assay, **38** is around 1000 times more potent at blocking the $Na_V1.7$ ion channel than the R-antipode **39**. However a state dependence electrophysiology study suggested that **38** was only fivefold more selective than **39** ($K_i = 0.161$ vs. 0.869 μM) against the inactivated state of $Na_V1.7$, and both compounds had poor affinity for the closed state ($K_i > 10$ μM). A discussion of the atropisomerism of this interesting class has been published.[91]

Further examples illustrate efforts to introduce solubilizing groups into this compound class such as the pyridine containing analogue **40**.[92] In vitro activity was reported based on the block of uptake of C-labeled guanidine in influx assays in cell lines expressing a range of ion channels, and by this means channel selectivity was established, although typically not reported in the patent filings.

The oxindole ring itself could be effectively modified by a further ring fusion, as in **41,** which retained the activity of the parent structure; however, larger ring sizes (**42**) were poorer and incorporation of additional heteroatoms was not tolerated.[93] A range of S-linked imidate variations (such as **43**) is described in WO 2010053998 and while these clearly retain some activity, detailed potency information was not described.[94] Another patent application[95] indicates that attempts were made to introduce solubilizing groups such as pyridines; however, the most potent compounds, including **44**, have only activity range information. It appears that attempts to combine polar features of **40** and **44** in compound **45** led to a lowering of activity. An explicit basic amino group introduced at the end of a chain in **46** lowered the potency in the guanidinium flux assay but actually gave significant potency ($K_i < 300$ nM) in an electrophysiology determination of binding to the inactivated state (of the unspecified channel under test), a contrast to most other examples from the filing.[96]

The Xenon team discussed further aspects of the discovery of the spirocyclic compound class in a paper published in 2013.[97] The group noted that their lead compound at that point, **XEN907** (compound **37** above) while demonstrating high in vitro potency in blocking $Na_V1.7$, showed only moderate bioavailability in the rat, poor solubility in buffer, and only moderate hepatocyte stability across species, with significant inhibition of CYP3A4. This led to efforts to evaluate analogues lacking the methylenedioxy moiety, which was identified as a key liability. A range of analogues was prepared in which this group was replaced with functionality likely to add to stability and solubility, leading to the discovery of **47** (Fig. 17), which was an 8 nM IC_{50} blocker of $Na_V1.7$, but which demonstrated only 29% inhibition of CYP3A4 at 10 μM (c.97% for **37**). This compound also showed around fourfold higher solubility at 25 μg/ml. Increasing the heteroatom incorporation in the aromatic substituent was examined as a next step. Optimization

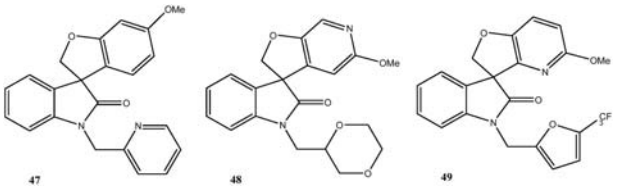

Fig. 17 Xenon spirocycle lead optimization.

of any two of the parameters, $Na_V1.7$ block, solubility, and 3A4 inhibition, was possible, but always at the expense of the other parameter. For example, compound **48** was noted as possessing the best combination of solubility at 67 μg/ml and low CYP3A4 inhibition of 22% at 10 μM, but was a less potent $Na_V1.7$ blocker with an IC_{50} of 0.1 μM. The team went on to demonstrate that, despite poor solubility of less than 5 μM, compound **49**, which was a moderate $Na_V1.7$ blocker with an IC_{50} of 0.13 μM but low CYP3A4 inhibition of 26% at 10 μM, was effective in a Von Frey paw withdrawal rat pain model at 10 mg/kg. However **49** had a relatively short terminal half-life and poor oral bioavailability, and the surprising activity was ascribed to better tissue distribution.

The clinical status and profile of **XEN402 (38)** is described later. The more recent focus of work at Xenon, like many across the industry, has been on compounds of a sulfonamide class and Xenon compounds are described in that section of the review.

Vertex has long had an interest in sodium channel blockers and has patented on a range of chemotypes. In 2011 the company published on a series of spirocycles distinct from those described by Xenon.[98] Variations on the basic template included incorporation of additional nitrogens to form alternative heterocycles in the fused tricyclic ring system, a range of aromatic substituents, and variations in the benzamide portion. The first patent application described several hundred analogues of which about a half fell in the highest activity band disclosed with an IC_{50} of less than or equal to 2.0 μM against $Na_V1.7$, including compound **50** (**Fig. 18**). There is no indication as to which of several screening methodologies was used to generate this figure, only that the ion channels were expressed in HEK cells. A second series[99] retains much of the core structure of the previous case but with a simpler fused heterocycle. Compounds **51** and **52** inhibited the $Na_V1.7$ channel with IC_{50}s of more than 5.0 and less than or equal to 2.0 μM, respectively, using the same assay protocols as earlier. The culmination of this work may be seen in a single compound patent filed in 2014 for solid form formulation of compound **53**, a compound selected from US 20120196869.[100]

Another variant on the same spirocyclic system is described in a case once again representing a simplification on the first described spirocyclic system, and this time with around two hundred examples.[101] Compound **54** (**Fig. 19**) demonstrated an IC_{50} value of less than or equal to 2.0 μM which is typical for most of compounds exemplified. No indication is given as to which

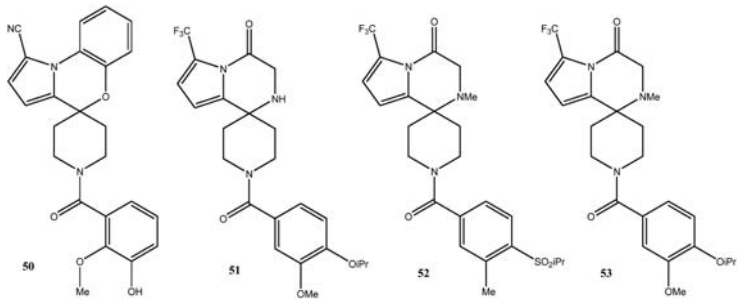

Fig. 18 Vertex spirocyclic Na_V blockers.

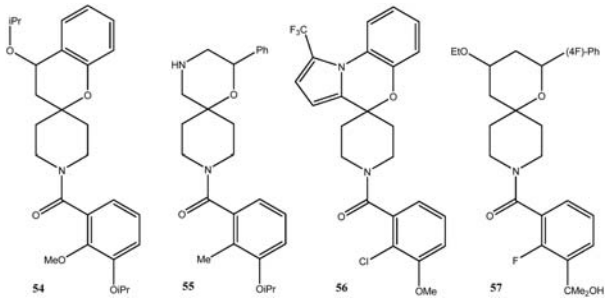

Fig. 19 Evolution of Vertex spirocycle series.

stereochemistry is generally preferred around the spirocyclic system or in aliphatic ring substitution. The same is true of the next patent application in the series[102] in which the morpholine ring at the heart of the spirocycle is not fused with any aromatic. Instead it bears a pendant aromatic substituent, such as phenyl in example **55**. Again, of the approximately three hundred examples, the majority, including **55**, fall into the most active category with an IC_{50} value of less than or equal to 2.0 μM. It is noteworthy that Vertex electrophysiology assays describe a protocol designed to highlight inactivated state block. A further case[103] represents a selection of some eighteen further analogues all in the top potency range and falling under the general description of WO 2011140425 but incorporating a narrow range of substitution patterns, for example, **56**. A later variation replaces the morpholine ring of **55** with a substituted pyran system[104] in which, again, some two hundred examples are claimed, typically with the same preferred substitution patterns represented in analogous series, but perhaps with a greater focus on blocking metabolically vulnerable positions. Compound **57** is typical and like most examples, exhibits the highest reported level of potency with an IC_{50} value of less than or equal to 2.0 μM. The filing discloses that a *cis* arrangement of pyran substituents is significantly favored over the *trans*-form in several examples.

The MSD-Schering merger of 2009 brought together companies actively optimizing different classes of sodium channel blocker. Initial interests in both legacy companies were on constrained amides incorporating conformational restriction through a spiro fusion. These examples are most closely related to the Vertex series. More recent work from MSD has focused on sulfonamide classes.

The first spirocyclic examples are present in a class of compounds described by Schering in patent applications from 2010.[105] These may be considered to be related to the Xenon type of spirocyclic Na_V blocker as they have a similar disposition of features to the parent molecules with no strongly basic center.[106] Compound **58** (**Fig. 20**) is representative, incorporating a conserved fused pyrrole as part of a tricyclic system. Other variations include heterocyclic analogues and changes in substitution pattern around the aromatic amide. Compound **58** is reported as showing an IC_{50} of 13 nM against $Na_V1.7$ in a FLIPR assay. This class was also described in some detail in an MSD publication[107] in which, as well as disclosing the search for selectivity for $Na_V1.7$ over $Na_V1.5$, the authors indicate that compound **59** has oral activity in a rat FCA inflammatory pain model at 100 mg/kg and in a rat spinal nerve ligation neuropathic pain model with an EC_{50} of 75 μM.

Schering also explored blockers based on a linear amidic template, but still incorporating a rigidifying spirocyclic feature, illustrated by compound **60**. In one filing[108] some thirty analogues are claimed with variations in substitution pattern around terminal ring positions, as well as with alternatives to the amide, such as sulfonamides and ureas, e.g., **61**. No detailed activity data is provided, and no indication given of enantiomeric preference, but a focus on $Na_V1.7$ is present in the patent claims.

7.04.3.3.2.3 β-Subunit binding compounds

Between 2005 and 2010 companies started to report compounds containing an aryl sulfonamide feature, typically with a pendant basic side chain, that were reported to be sodium channel blockers. These compounds were later shown to have significant selectivity for the $Na_V1.7$ channel based on the fact that they bound to an entirely different part of the ion channel assembly to the anesthetic binding site that had been the presumed principle binding site for most Na_V blockers hitherto. Recent publications[4] have indicated that the binding site for many molecules of this class is the β-4 subunit, which is known to be quite distinct in sequence between the different voltage-gated sodium channels, thereby providing an explanation for the observed selectivity.[109] A wider range of variants has now been published, though all share a common pharmacophore of an acidic sulfonamide linked through an aryl group to a basic group or pendant heterocycle. Very high levels of $Na_V1.7$ inhibition have been achieved, and it is clear that high levels of channel selectivity are also achievable. Two challenges that medicinal chemistry approaches have sought to overcome have been the relatively poor solubility of this class of, often zwitterionic, compounds, and the tendency for these frequently highly aromatic species to interact with metabolic enzymes and pathways that limit exposure or give rise to significant metabolites.[110] **Table 4** highlights notable or representative compounds described in patent applications from companies active in the area during the past 5 years.

[a]IC_{50}s by electrophysiology.

The majority of reports of the sulfonamide class of Na_V blockers come from the patent literature. A review including the discovery of early examples has been published by Bagal et al.[4] Initial filings do not disclose specific channel inhibition data but several patent applications from 2010 highlight developments. Vertex, long active in the Na_V blocker area, had filed on a series not specifically claimed as targeted at $Na_V1.7$,[111] but included here (e.g., **62**) as indicative of early work in the area. The potencies of their initially disclosed compounds were not in the nM range recorded by other groups, and Vertex's later filings (*vide infra*) suggest a mainly $Na_V1.8$ focused effort. Vertex aside, Pfizer and Icagen together were the main early drivers in the area and in

a sequence of patent applications published between 2010 and 2012, they explored many aspects of the *N*-heterocyclylaminosulfonyl benzamide class. Their earliest patents also do not disclose $Na_V1.7$ activity (e.g., for **63**) but selective compounds are highlighted in the later cases[112] (e.g., for **64**, **73**) and include *N*-heterocyclylamino benzenesulfonamides (e.g., **65**, **66**)[113] and several series of *N*-methanesulfonyl benzamides (**67–72**, **74**).[114] A key pharmacophoric feature, a 4-*O*-linked-5-chloro-2-fluorophenyl group next to the sulfonamide, is adopted in many examples in different Pfizer patent series (e.g., **64**, **66**, **67**, **68**, **70**, **71**, **73**) and has been adopted by other companies working in the field (e.g., **78**, **88**, **95**). Another related patent application describes a heterocycle utilized to introduce rigidity into the core of the molecules while incorporating a flexible side chain (e.g., **72**).[115] Later filings from the Pfizer group revisit the sulfonylurea functionality, but with aliphatic substituents instead of aromatic heterocycles (**73**, **75**). Some of the examples have a reduced affinity for $Na_V1.7$ which may be compensated for by improved developability properties.[116] Several clinical candidates emerged from this work and some indications of the challenges and properties of the class have been presented at conferences.[117] The location of the sulfonamide binding site has been established as the voltage sensor region in the fourth β-subunit of the ion channel; particular characteristics of the compounds include their acidic character, zwitterionic if, like **64**, they contain a basic center. As a whole, the class is peripherally restricted and evidence from formulation studies suggests that solubility may often be low. Pfizer has also reported that the *in vivo* metabolic stability of compounds of this class has presented development challenges and has been a focus behind the choice of heterocyclic component.[117] A key feature of the class is the exquisite potency for $Na_V1.7$ achieved with examples such as **66,** which demonstrate a sub nM IC_{50}. Channel selectivity data is not included in the Pfizer/Icagen patent filings.

Xenon also sought to exploit this class, combining experience of structurally constraining Na_V blockers with utilization of the reported sulfonamide right-hand portions to create $Na_V1.7$ blockers of similar potency to those described by Pfizer, but also disclosing some selectivity data. For example **76** and **77** are five orders of magnitude selective for $Na_V1.7$ over $Na_V1.5$.[118] Pfizer disclosed[119] that several classes of N-heterocyclyl benzene sulfonamides tend to show metabolic susceptibilities and this finding may have influenced Xenon's pursuit of alternative methane sulfonyl benzamides, such as compound **78**.[119] In collaboration with Genentech, Xenon scientists have explored a wider range of heterocycle-containing sulfonamide classes while retaining a preferred ether-linked lipophilic terminal portion (**79–81**).[120] Incorporation of solubilizing groups such as pyridines and piperidines, illustrated for example by **82**, is a feature of other series.[110]

Merck has pursued a tightly focused strategy aimed at optimizing a core pharmacophore incorporating (see examples **83–87**) differently constrained basic features in combination with a relatively conserved heterocyclyl aminosulfonamide group and has developed a number of aromatic spacers and different lipophilic amines to optimize this class. Its researchers have also achieved $Na_V1.7$ block in the nM range and high $Na_V1.5$ selectivity across their series.[121]

Daiichi Sankyo has focused recent patent applications on the *N*-heterocyclyl benzenesulfonamide class with a heterocycle linked to the aryl core via a constrained ether, a pattern first described in the Pfizer-Icagen series. Compound **88** has been selected as a potential development compound based on a selection case. A recent patent filing suggests that later work has also been directed toward series which do not contain a right-hand heterocycle, such as **89**.[122]

Amgen has had a long established interest in Na_V blockers and has recently also investigated the sulfonamide class,[123] homing in on a preferred thiadiazole component in the early cases (e.g., **90**, **91**) before patenting on the simpler methanesulfonyl benzamide class.[124] Early compounds disclosed are also notable for their high lipophilicity and high level of aromaticity (e.g., **91**, **92**), though later compounds such as **93** have fewer ring systems and are more similar to later Xenon and Pfizer examples in containing a methanesulfonamide.

Daewoong has claimed a stake in the sulfonamide class with a single patent filing exhibiting the ortho ether pattern and an N-heterocyclic sulfonamide group, illustrated by example **94**.[125] In contrast Chromocell has focused on designing compounds which bear a range of peptidic linkers potentially providing solubility handles or acting as prodrugs (see example **95**). It is interesting to note that, in these patent application, the company's therapeutic intent appears directed more toward diabetes than pain as an indication.[126]

Novartis has published a single patent application in the sulfonamide area and its series is unique in having fewest conformational degrees of freedom, sporting a tricyclic heterocyclic core as in **96**.[127] In contrast a recent patent filing from Zalicus describes compounds which are clearly related to early Pfizer–Icagen examples such as **65** but, for example in the case of **97**, incorporating a terminal amidic feature rather than a heterocycle or basic group.[128]

Several papers discuss the properties of the sulfonamide Na_V blocker compound class, but few to date have discussed SAR. The detailed electrophysiological profiles of certain lead compounds, which emerged from the early Pfizer–Icagen collaboration, **ICA-121431** (Fig. 21) and **PF-04856264**, have been described in a paper[29] published in 2013, which also describes the factors influencing the binding profile on the voltage sensor region of the ion channel. These two molecules each exhibit exquisite affinity for binding to specific human ion channel subtypes $Na_V1.3/Na_V1.1$ (**ICA-121431**, $IC_{50} = 19$ nM) and $Na_V1.7$ (**PF-04856264** $IC_{50} = 28$ nM).

Although this sulfonamide class of compounds has been unambiguously shown to exert their effect by binding to the voltage sensor region of the ion channel, their mechanism of action may be more subtle in some cases, hinting at a dual mode of action. For example, the behavior of ion channels can be very sensitive to small structure changes to the inhibitor. In a paper published in 2015, **PF-05661014** is shown to selectively inhibit $Na_V1.3$ over $Na_V1.7$ currents by stabilizing the inactivated state of the channel through an interaction with the D4 voltage sensor.[129] **PF-06526290**, which differs from **PF-05661014** by a single methyl group, exhibits a dual effect, greatly slowing inactivation of Na_V channels in a subtype-independent manner. However, upon prolonged depolarization PF-06526290 becomes a Na_V subtype-selective inhibitor similar to PF-05661014. A key finding was that mutation of the D4

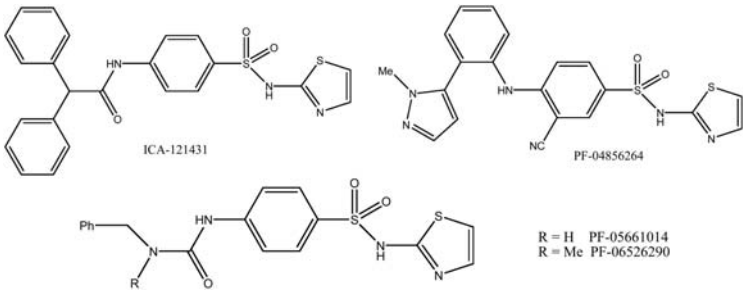

Fig. 21 Evolution of Pfizer sulfonamide Na_V blockers.

region of the ion channel modulates inhibition of $Na_V1.3$ or $Na_V1.7$ by both compounds, but has no effect on the inactivation slowing produced by PF-06526290, suggesting a second mechanism.

The potential for small molecules to bind in different positions in the pseudo-symmetric human ion channel may underlie this behavior and cause the structure sensitivity that has bedevilled attempts to develop clear SAR for small molecule ion channel interactions. Both the site and kinetics of binding will have distinct effects on ion channel behavior, and therefore it is hard to predict physiological effects resulting from channel blockade in vivo.

The Xenon team describe[130] how they explored a class of substituted piperidine methyleneoxy benzenesulfonamides related to the Pfizer compound PF-04856264, typified by compound **98** (Fig. 22). Their starting point was a hybrid compound **99** with the Pfizer right-hand side; however, it was quickly established that substitution on the phenyl ring could give a marked increase in $Na_V1.7$ potency with analogue **100** demonstrating sub nM blockade of $Na_V1.7$ but still high selectivity over $Na_V1.5$. However, the examples proved potent inhibitors of several cytochrome P450 enzymes. The choice of a different right-hand heterocycle could reduce this liability and by selecting the single isomer shown in compound **98,** CYP450 inhibition values of less than 10% across various isoforms at 10 μM were achieved while retaining strong $Na_V1.7$ blockade ($IC_{50} = 11$ nM) and 1000-fold selectivity over $Na_V1.5$.

7.04.3.3.2.4 Aryl triazines and derivatives

The small size of lamotrigine and its activity as a pan-sodium channel blocker has led to the molecule being used a starting point for the development of more selective agents. Some companies have elaborated the core nitrogen containing heterocycle while, in other cases, a triazine structure has been arrived at through lead optimization; analogues are shown in Fig. 23. Optimized compounds may appear unrelated to lamotrigine; however, there are often intermediate structures showing a link to this chemotype. The heterocyclic core has been used to design selective inhibitors of both $Na_V1.7$ and $Na_V1.8$; however, the target profile is not always apparent from the patent literature. Purdue Pharma and Amgen have been most active in exploring this template but it has also been the subject of research by Novartis and various university groups. Abbott and Pfizer have used the template in $Na_V1.8$ blocker design.

Amgen has published a number of patent applications in recent years describing different classes of small molecule sodium channel blockers for the treatment of pain, focused principally on $Na_V1.7$ and in particular on the acyl sulfonamide class also described by Pfizer and others. The earlier patents describe modified toxins, but some publications also include triazines. A patent filing from 2010 describes several hundred compounds including examples with sub-micromolar IC_{50}s in electrophysiology assays.[131] A number of pain model studies are noted including spinal nerve ligation; however, activity data is provided for a small number of compounds including **101,** which showed activity at 10 mg/kg in a rat formalin model of persistent pain when dosed orally. The same molecule gave an IC_{50} against $Na_V1.7$ of 5.0 μM. In contrast, the analgesic activity of the most potent $Na_V1.7$ blocker reported **102** ($IC_{50} = 0.04$ μM) is not recorded. A more detailed description of the discovery and lead optimization of this class is provided in another paper.[132] The origin of this series is revealed to be a high-throughput electrophysiology assay of a compound collection. The authors comment on the need to design compounds based both on $Na_V1.7$ selectivity and state dependence and describe a voltage-dependent protocol for their electrophysiology (E-Phys) assays to enable them to identify compounds, which preferentially bind to the inactivated state of the channel. They reveal that a major hurdle was the need to avoid the hERG blockade and CYP450 liabilities that were identified in their initial lead **103**, which showed an IC_{50} in the partially inactivated state

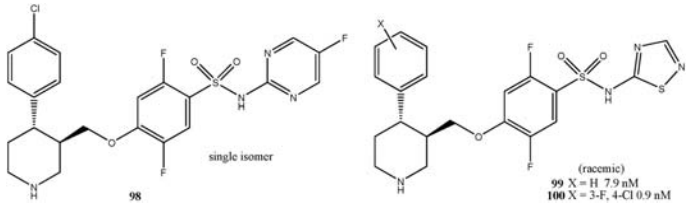

Fig. 22 Optimization of Xenon sulfonamide Na_V blockers.

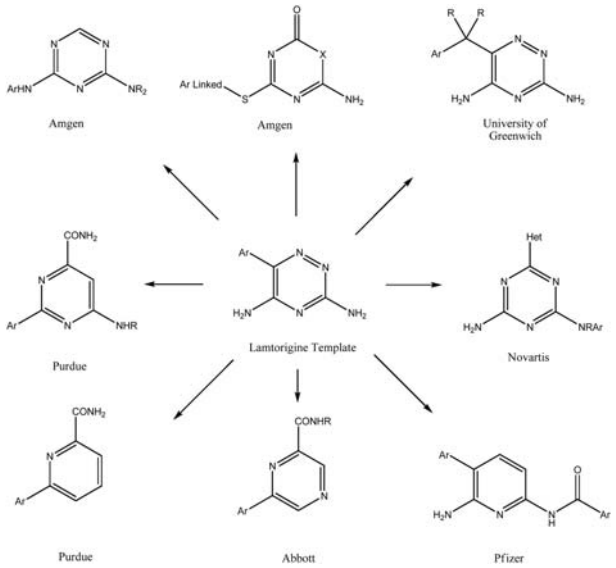

Fig. 23 Relationship of classes of Na_V blockers to Lamotrigine.

E-Phys $Na_V1.7$ assay of 1.9 μM. This issue was overcome by replacement of the tetrahydroisoquinoline with a more flexible and less metabolically susceptible aryl piperidine leading to **104**. This tool compound was between 2- and 12-fold selective for $Na_V1.7$ over other Na_Vs with an IC_{50} of 0.17 μM in a partially inactivated state assay but was much more selective against a wider target class panel. In a rat formalin-induced flinch model, compound **104** showed a dose response with significant efficacy at a minimal oral dose of 10 mg/kg. Interestingly, the group undertook a competition study with tetracaine and batrachotoxin, which suggested that this class of compound does not bind in the Na_V anesthetic binding site (Fig. 24).

In a second related patent application a class of reversed amides was similarly profiled.[133] Among some 300 compounds, example **105** blocked the human $Na_V1.7$ channel with an IC_{50} of 0.52 μM, but no data was given for activity in the pain models described.

Similar compounds have been described in more detail in a series of communications[134] The authors indicated that this series was not specifically modeled on any existing class of sodium channel blocker but was found through an HTS campaign using high-throughput electrophysiology, with a focus on finding state-dependent blockers. The first lead **106** was at least 10-fold selective for the inactivated state over the closed state and showed good developability properties in vitro, but high clearance in vivo. They sought to modify the triazine core to modulate these properties and a pyrazine was found to be suitable as it also gave on average better $Na_V1.5$ selectivity; however, many compounds showed a hERG liability. Further side chain modification led to the discovery of compound **107** with an IC_{50} in a partially inactivated state of 0.24 μM, at least fivefold selectivity over $Na_V1.5$, and IC_{50} against hERG of >30 μM, coupled with low clearance (Fig. 25).

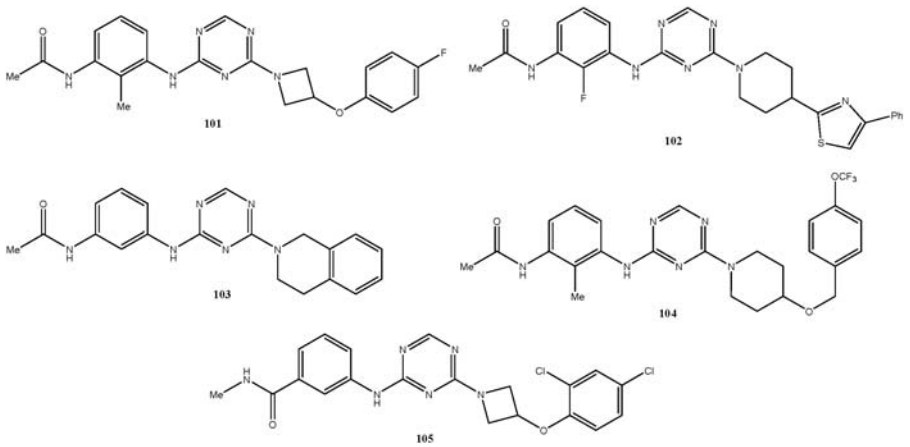

Fig. 24 Amgen Triazine Na_V blockers.

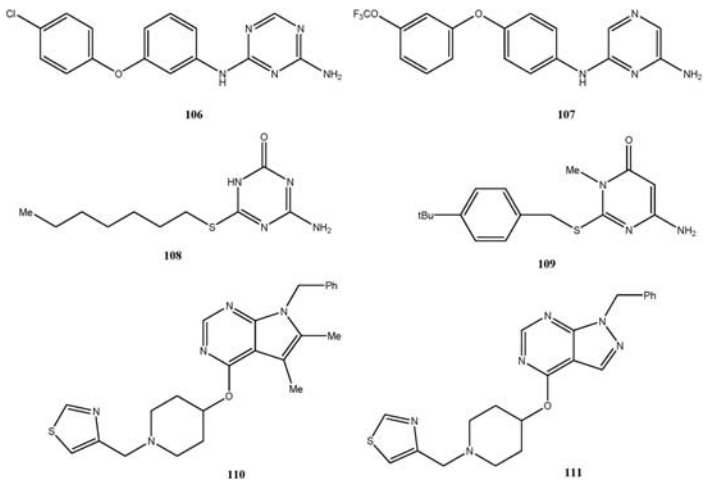

Fig. 25 Evolution of Amgen Na_V blockers.

An even simpler core template has been described in a second paper[135] in which an initial hit **108**, a sub micromolar inhibitor of $Na_V1.7$, was discovered in a screening campaign. It possessed significant activity at $Na_V1.5$ as well, but otherwise possessed a good developability profile. Optimization was effected by varying the thioether side chain and by alkylation on the heterocycle to give an analogue **109**. This showed 10-fold higher potency at $Na_V1.7$ and a low *in vivo* clearance in the rat, though still modest selectivity over $Na_V1.5$. The authors noted that the compound appeared five times more potent under conditions of manual patch testing than when using a Patch Express automated protocol. The clearance had also been reduced fivefold.

Another hit series incorporated a different core heterocycle, replacing the diazine with a pyrrolopyrimidine.[136] A paper describes the lead optimization of a highly potent hit **110** ($Na_V1.7$ $IC_{50} = 0.06$ μM in a partially inactivated state assay) from this class which already showed approximately 100-fold selectivity for this channel over other Na_Vs. This compound had poor stability in human liver microsomes and only modest selectivity over hERG; so these aspects were the focus of the campaign. The methylene thiazole core heterocycle and piperidine linker appeared crucial for activity, and modifications aimed at reducing LogP as a route to lower clearance generally reduced either the potency or selectivity of the series. Aromatic ring substituents offered no advantage. A compromise molecule incorporating a pyrazolopyrimidine (**111**) was therefore selected for further lead optimization based on its better lipophilic efficiency and good microsomal stability despite being a weaker overall inhibitor of $Na_V1.7$ ($IC_{50} = 0.83$ μM).

The patent filings by Purdue illustrate, perhaps better than any other sequence, the links between the aryl-linked aminoamides and triazine Na_V pharmacophores following the evolution of chemotypes through lead optimization in related series. The company has had a long history in sodium channel research and in 2011 published a class of aryl-substituted indoles and azaindoles, which had structural links to the aryl-linked aminoamide class,[137] but included conformational constraint through the indole and biaryl moieties. Compound **112** ($IC_{50} = 0.40$ μM in a $Na_V1.7$ FLIPR assay, Fig. 26) is illustrative. Activity modulation was reported to be

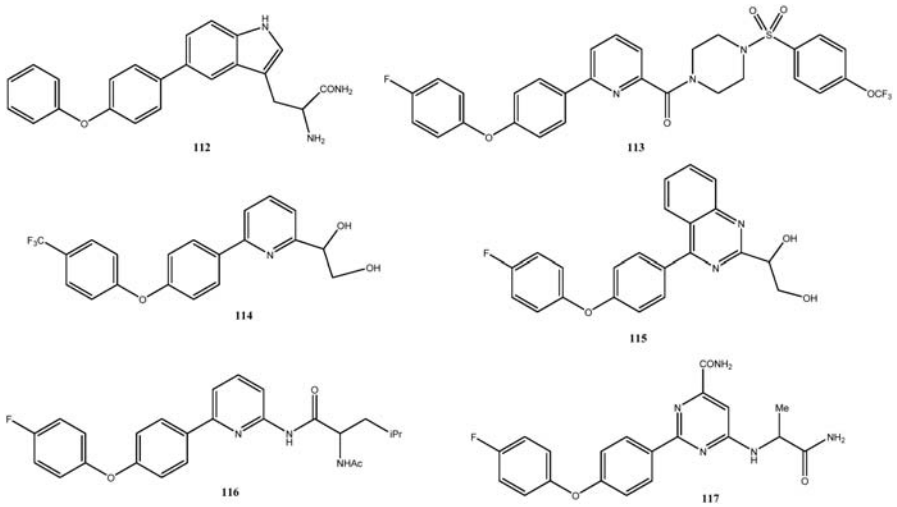

Fig. 26 Early Purdue Na_V blockers.

achieved by either varying the aryl ring substitution pattern or incorporating alkyl or hydroxyl substitutions around the amidic portion. Further patents followed in which the aryl portion was retained while changes were made to the polar amidic region, both by extending (**113** $IC_{50}=0.19$ μM)[138] and contracting (**114** also a micromolar inhibitor) it.[139] The class of compound **114** also included pyrimidines in place of the central pyridine ring and this change is exemplified further with a series of quinazolines highlighted by compound **115**.[140]

Moving from a quinazoline to an amino-pyridine allowed the reincorporation of amidic features, as illustrated by compound **116**, now a potent inhibitor ($IC_{50}=0.042$ μM in FLIPR assay).[141] With the inclusion of a second heteroatom in the pyridine ring **117** ($IC_{50}=0.042$ μM), a link to the lamotrigine chemotype is arguably established, but the similarity to the aryl-linked aminoamide series is also apparent.[142]

Purdue has gone on to explore extensively around these scaffolds, including demonstrating activity with quaternized analogues (Fig. 27) such as **118** ($IC_{50}=0.872$ μM), a feature which would be expected to affect absorption properties.[143] They have also looked to incorporate heteroatoms into the lipophilic aromatic region. For example, compound **119** provides a less amphiphilic molecule ($IC_{50}=0.152$ μM).[144] The significance of incorporating a halogen or CF_3 substituent on the terminal aromatic ring, to both modulate activity and block metabolism, has been demonstrated in other series, which have been subject to patent filings[63] and is a feature in several examples from Purdue including **120** ($IC_{50}=0.098$ μM) another potent $Na_V1.7$ blocker in the FLIPR assay,[145] and **121** ($IC_{50}=0.722$ μM).[146] Triazine carboxamides such as **122** ($IC_{50}=1.8$ μM)[147] are much closer to lamotrigine structurally but still contain the principle aromatic side chain features of the earlier leads; however, they generally appear less potent by the FLIPR assay used throughout this series. Certain compounds incorporate features found in the sulfonamide class of $Na_V1.7$ blockers (such as **123**),[148] but this could be coincidence as sulfonamides are known to bind to a site remote from the pore region believed to be the location where lamotrigine and aryl-linked aminoamide classes are effective.

In a move away from the aromatic dominance of the class and introducing three dimensionality, a more recent series from Purdue incorporated a spiro-linked group through a piperidine substituent **124** with retention of modest $Na_V1.7$ inhibition ($IC_{50}=1.3$ μM).[149] Later filings, however, mostly continue to contain variants on the aryl pyrimidine theme with polar side chains, for example, **125** ($IC_{50}=0.042$ μM) with a glycinamide side chain.[150]

Subsequent patent applications from Purdue have continued the trend of aromatic variation with incorporation of features known to be acceptable in alternative sodium channel pharmacophores (Fig. 28), for example, a benzodiazepine moiety as in **126** ($IC_{50}=0.04$ μM),[151] and indazoles such as **127** ($IC_{50}=0.157$ μM).[152] Compound **128** ($IC_{50}=0.357$ μM) also illustrates attempts within this series to conformationally constrain the aromatic side chain.[153] A further different angled constraint is introduced with a tetrahydroisoquinoline linker in **129** ($IC_{50}=0.428$ μM).[154] It is curious to note that the polar side chain of the original aryl-linked aminoamide series is entirely missing in some of the examples illustrated (such as **126** and **128**) though it is still present

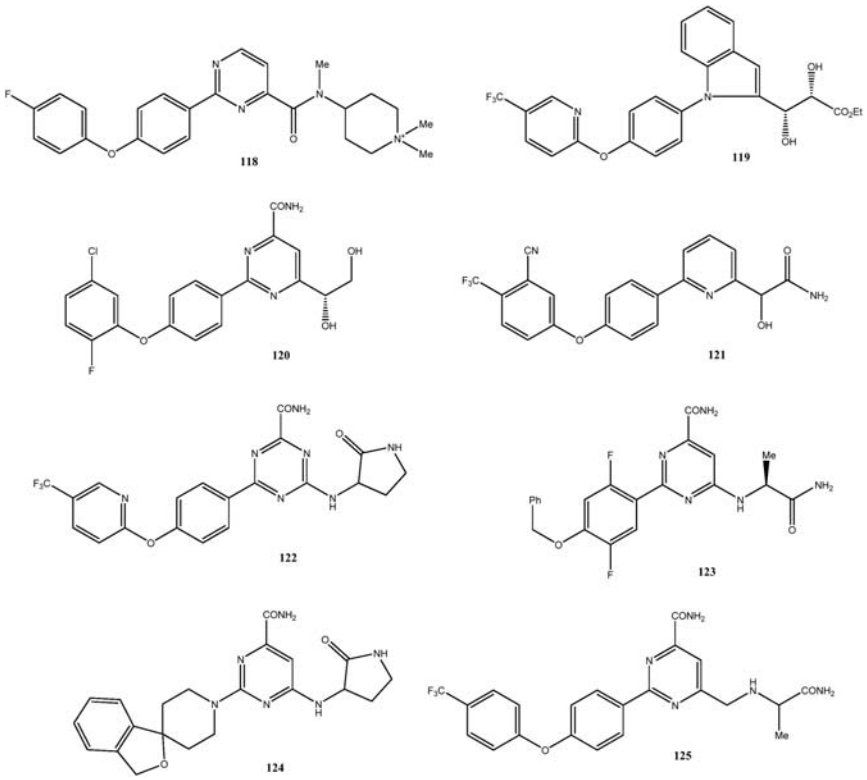

Fig. 27 Diversity of Purdue series.

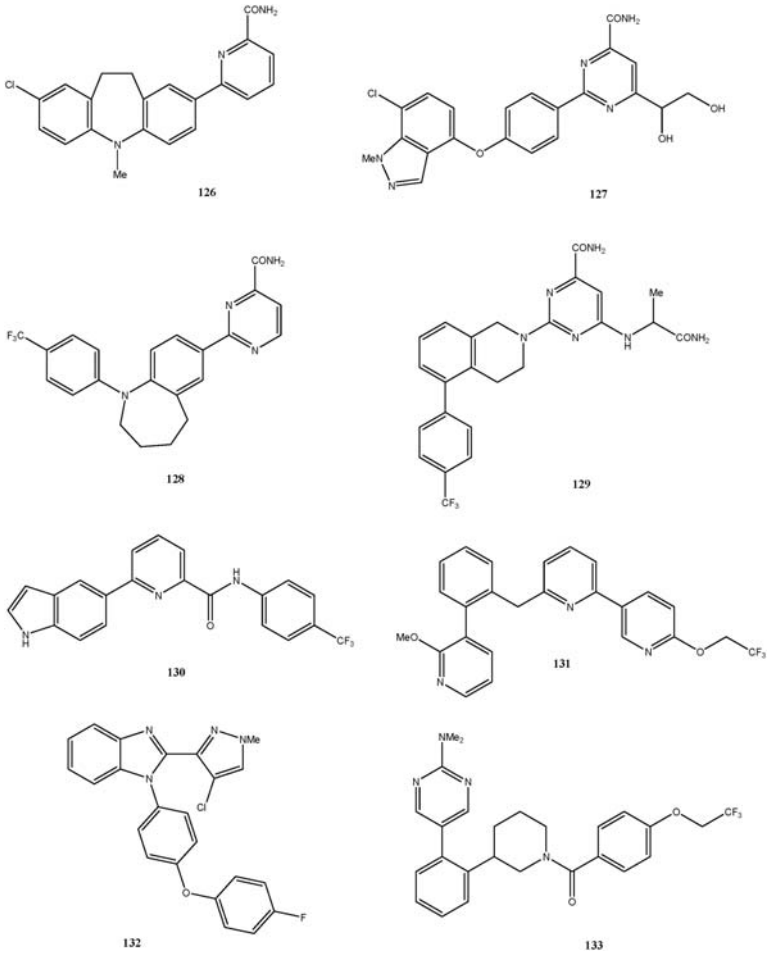

Fig. 28 Combination of Na_V pharmacophores.

within the patent claims, indicating the feature is not by any means essential for Na_V blocking activity. This is perhaps clearest in the most recent patent applications from the group, in which the evolutionary link to the original lead series is scarcely apparent, for example in compound **130** ($IC_{50} = 0.233$ μM)[155] has the glycinamide apparently replaced by anilide, which leads to the question of whether these compounds do bind in the same site as the molecules from which they were derived. Similarly **131**, one of around twenty examples reported as active both in electrophysiological $Na_V1.7$ studies and *in vivo* pain model studies,[156] now just contains four linked aromatic groups and is chemically remote from the original lead series.

Other recent classes of Na_V blockers investigated by Purdue are represented by **132**, a benzimidazole derivative[157] and the piperidine **133**.[158] Compound **132** was reported to have an IC_{50} at $Na_V1.7$ of 0.10 μM and compound **133** 0.096 μM in FLIPR assays. Both represent the most potent of several dozen examples described in their respective patent applications; however, selectivity information was not disclosed.

Purdue has published two papers describing the discovery of certain compound series (Fig. 29). In the first[159] a scaffold hopping strategy takes a previously reported active Na_V blocker **134,** which is close to the aryl-linked aminoamide class, and elaborates it into a series of constrained azepines, illustrated by the generic structure **135**. Some dozen analogues showed potent activity in $Na_V1.7$ electrophysiology assays with IC_{50}s of around 1 μM or less; however, both poor stability in human and rat liver microsomes and low aqueous solubility (~1 μM) made declaration of a lead moot. Compound **136** with a $Na_V1.7$ FLIPR IC_{50} of 1.8 μM was among those highlighted as having the best compromise profile.

The second paper[160] describes a different approach: taking an already identified brain-penetrant sodium channel blocker and rendering it peripherally restricted by modifying the physicochemical profile. The earlier described molecule **134** had previously been elaborated into an azabicyclic derivative **137** (as described above) and the diazepine variant of this moiety was used as a template as the group sought to introduce more polar side chains to limit central penetration. In practice it proved to be a challenge to obtain good gut permeability while limiting brain penetration, but a number of derivatives proved to be substrates for transporters with high MDCK efflux ratios, which potentially offered that prospect. Compound **138**, a sulfonamide with a K_i of 0.23 μM and an efflux ratio of 160, showed high exposure in a rat dosing study and was highlighted as promising, although pharmacodynamic data was not presented nor was evidence of central limitation provided.

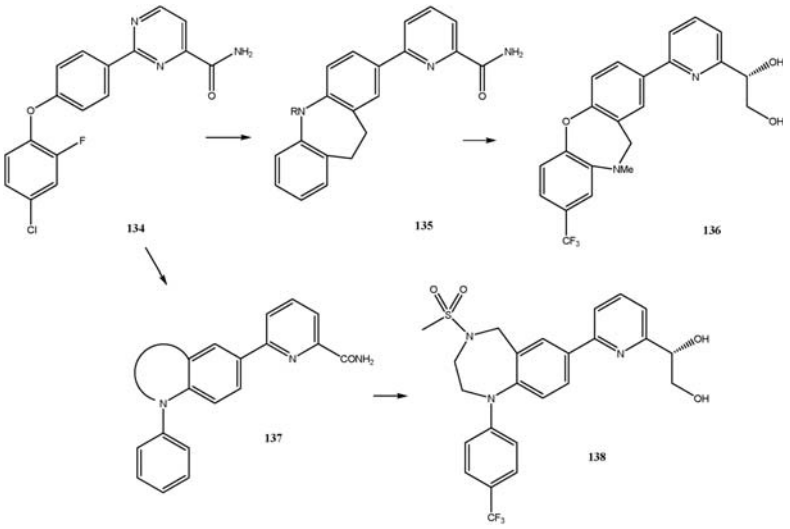

Fig. 29 Optimization of Purdue series.

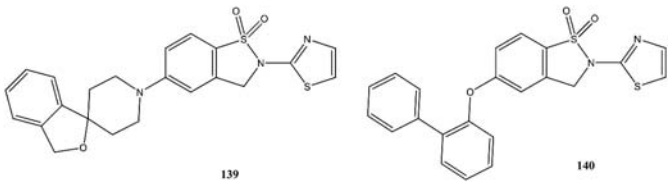

Fig. 30 Cyclic sulfonamides.

Finally, a set of eight cyclic secondary sulfonamides has been described by Purdue.[161] These are, arguably, pharmacophorically more similar to the amidic class of blockers than those sulfonamides that bind to the ion channel allosteric site, as they have neither an acidic proton nor a basic side chain. Several of the compounds claimed do incorporate a spirocyclic feature, including **139** (Fig. 30). Compound **139** is noted as having an IC_{50} of 0.77 μM in a FLIPR assay but no further types of activity data are provided. This spirocycle may provide a link between this class of inhibitor and those discovered by Vertex (e.g., **54**). However, not all compounds have the spirocyclic feature, for example **140** carries a moiety which resembles the β-subunit Na_V binding series; so perhaps this set represents an attempt to marry different pharmacophores.

Novartis has investigated compounds targeted at $Na_V1.7$ based on a triazine template. In a single patent application from 2012 researchers describe some 500 analogues of which compound **141** (Fig. 31) showed the most potent blockade of $Na_V1.7$ at 4 nM, as measured by a patch clamp methodology.[162] Those compounds with the most potency tended to have an extended substituent off the pyridine heterocycle. Data were presented showing that key compounds have a selectivity of at least one order of magnitude over $Na_V1.5$, as measured by high-throughput electrophysiology. The patent disclosed three compounds **142–144,** which were active in a rat FCA model of neuropathic pain and reported unspecified activity between 1 and 3 mg/kg. Notably, this activity does not directly correspond to their measured, blockade, which gave K_is of 110, 560, and 44 nM, respectively.

An interesting twist to the triazine story is seen in compounds which have been the subject of a patent application by the University of Greenwich, UK, who sought to make conformationally restricted lamotrigine derivatives.[163] No characterizing channel

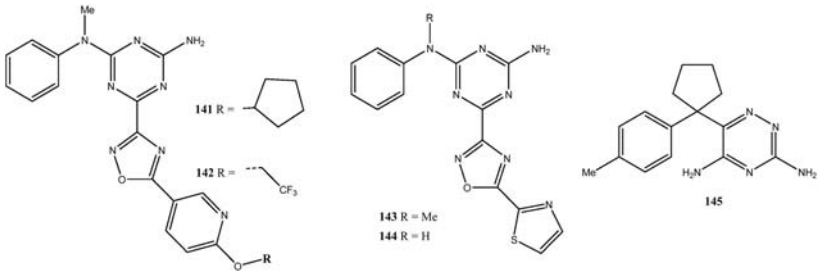

Fig. 31 Novartis triazines and conformationally restricted lamotrigine analogues.

selectivity data was presented and although pain is claimed as an indication, among others, it appears that an objective of this work was a pan-sodium blocker with a better profile than lamotrigine itself. Notable lead compounds included **145,** which exhibited an IC_{50} of less than 0.5 μM in inhibiting the binding of [3H]brevetoxin-B in a sodium channel-blocking assay. An additional claim indicates an interest in the molecule type as antimalarial agents, acting as antifolates, so it is possible that this was their primary interest.

7.04.3.3.2.5 Additional binding classes

RaQualia has identified a class of alkyl-substituted heterocyclic derivatives incorporating an amide side chain, initially described as blockers of both sodium and calcium channels.[164] Their first patent application indicated that around 200 examples out of more than 400 analogues showed IC_{50}s of less than 1 μM in either $Na_V1.7$ or $Na_V1.3$ FRET assays. Most of these compounds, for example **146** (**Fig. 32**), also show T-type calcium channel blocking activity at the same level, and no group of selective compounds is described. Though a wide range of analogues was claimed, a 5-trifluoroethoxy substituent on a 2-substituted pyridine heterocycle is a feature common to most of the claims (e.g., **146**, **149–153**), suggesting a privileged template for their binding site. A wide range of aromatic amides have been incorporated on the right hand side as drawn. Subsequent claims indicated that conformational restriction of the side chain and repositioning of the substitution pattern could focus activity on TTX-sensitive sodium channels and a class of picolinic amides was highlighted, for example, **147**, reported to show TTX blocking with an IC_{50} of less than 0.5 μM.[165] Aromatic groups were also incorporated, linked to the other end of the molecules and described in a patent claiming almost a hundred examples. This application indicates that selectivity over $Na_V1.5$ was being sought but does not provide delineation between $Na_V1.3$ and $Na_V1.7$ inhibitory activity.

A further variation on the constrained aromatic amide theme was highlighted in a third patent application published around the same time.[166] In this case, a substituted piperidine provided the template, usually substituted in the 4-position by an ether-linked aromatic group. The patent indicated that several examples have shown potent but unspecified activity in a FCA-induced thermal hyperalgesia rat model for pain. Compound **148** was highlighted from over 500 examples in showing an IC_{50} of 0.36 μM in a $Na_V1.7$ FRET assay and some 20-fold selectivity over hERG, as measured by dofetilide binding. Another template claimed by RaQualia used piperazine as the amide linker; thus compound **149** is among 40 compounds highlighted from a patent application of some 250 analogues as demonstrating IC_{50}s lower than 3 μM against $Na_V1.7$ and, in this case, some element of selectivity over both $Na_V1.3$ and $Na_V1.5$.[167]

The aryl amide class has proved fertile ground for developing further $Na_V1.7/Na_V1.5$ selective series and two subsequent patent applications indicated a refocus by RaQualia on analogues of **146**.[168] Compounds such as **150** contain a reversed amide, relative to

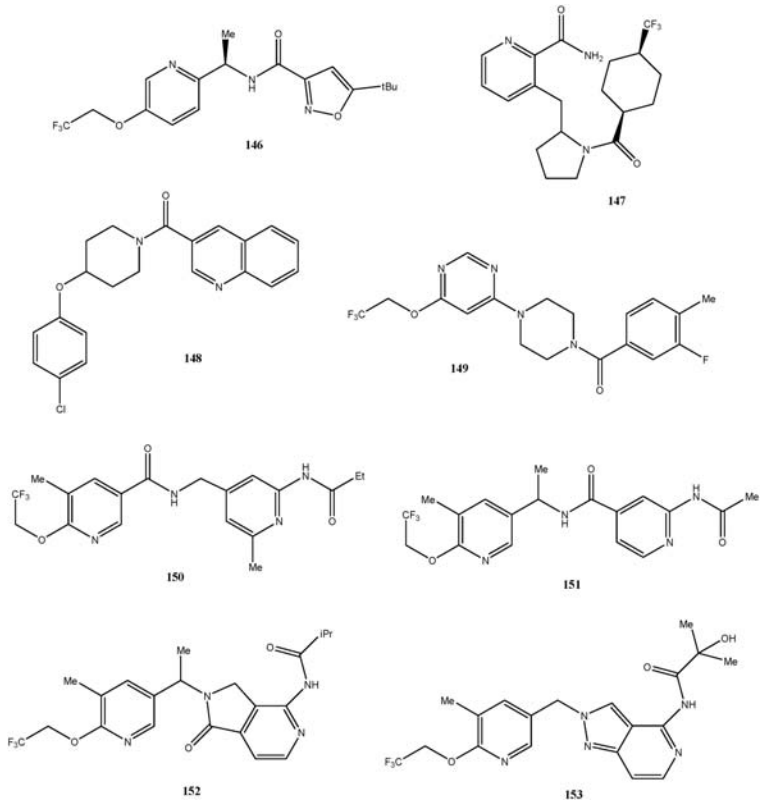

Fig. 32 RaQualia Na_V blockers.

the first series, and a benzylic methyl group is present in most of the example (e.g. **151**, **152**). A wide range of substituents are claimed on the rightmost aromatic right, particularly adjacent to the carbonyl group. Some 350 compounds are exemplified with greater characterization details on just three examples. Compound **150** is highlighted as showing 30-fold selectivity for $Na_V1.7$ ($IC_{50} = 1$ μM) over $Na_V1.5$ in an electrophysiology study while also being an inhibitor of $Na_V1.5$ with an IC_{50} of 0.51 μM in a FRET assay. Likewise in another patent claim[169] over 1000 analogues are described with another amide position varied, typified by **151** which showed K_is of 1.5 μM and 1.3 μM against $Na_V1.3$ and 1.7, respectively in a patch clamp assay based on CHO cells expressing the ion channels. Compound **151** is highlighted in all assay formats and demonstrates activity at 10 mg/kg in a FCA model of static allodynia in the rat.

The two most recent RaQualia patent applications continue the trend but this time with elements of conformational constraint on the right side of the molecule. In the first of these[170] an isoazaindolone forms the basis of the right-hand aromatic portion, exemplified by **152**, one of nearly 700 examples claimed. Again detailed electrophysiology assays are recorded and compound **152** is noted as active in all assay formats including a number of pain models. It is noteworthy that this compound is effective at blocking both $Na_V1.3$ ($K_i = 0.091$ μM) and $Na_V1.7$ ($K_i = 0.014$ μM) in electrophysiology assays on the inactivated state, so a mixed mode of action but state-dependent profile may be the target of RaQualia's research. The most recent filing from this group[171] focuses on a structurally similar chemotype but with a pyrazolopyridine template. Compound **153** was highlighted as showing block of the $Na_V1.3$ and 1.7 inactivated states, but at a lower level than **152** and fewer examples were claimed. *In vivo* activity is claimed in a suite of rat pain models including the formalin-induced nociceptive behavior paradigm, paw incision-induced static allodynia, paclitaxel-induced and FCA-induced weight bearing as well as in established pain models such as chronic constriction injury-induced static allodynia.

An analysis of a series of benzazepinones that had been the subject of earlier Merck patenting activity was published in a paper in 2013.[172] It reports that compound **154** (Fig. 33) achieved good selectivity for $Na_V1.7$ ($IC_{50} = 117$ nM) over other channels ($IC_{50} > 10{,}000$ nM for $Na_V1.5$) and some 10-fold selectivity for blockade of the inactivated state of $Na_V1.7$ compared with $Na_V1.5$, 1.6, and 1.8. In addition oral efficacy in a spinal nerve ligation assay was reported with an ED_{50} of 15 mg/kg. Compound **154** was also reported to have a good selectivity profile across a wide range of assays and to show no significant impairment of motor function at 10-fold higher doses than those shown to be efficacious in the pain model.

UCL filed a patent on a Pan-Na_V blocker for pain including for example compound **155**.[173] However, as the quoted examples showed blockade of $Na_V1.5$ at a level comparable to the other channels, it is not clear on what basis the compounds were expected to be selective for pain indications. The compounds were demonstrated to have some efficacy in an EAE model of relapsing remitting multiple sclerosis (MS); so this may have been the principal target of their investigation.

7.04.3.3.2.6 Dual $Na_V1.7$–1.8 inhibitors

In addition to patenting compounds containing the sulfonamide moiety, which target the voltage sensor region of sodium channels, AbbVie has claimed a class of amidic compounds, with activity at both $Na_V1.7$ and 1.8.[174] The patent application describes over 600 examples based on a quinoline core substituted with an amide-linked ring and an aryl moiety. Most examples were more effective at blocking $Na_V1.7$ than 1.8 in a FRET assay but there were some, such as compound **156** (Fig. 34), with the alternate profile ($Na_V1.7$ $IC_{50} = 0.98$ μM, $Na_V1.8$ $IC_{50} = 0.21$ μM). However, compound **157** ($Na_V1.7$ $IC_{50} = 0.34$ μM, $Na_V1.8$

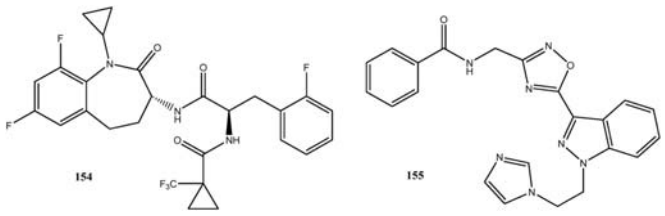

Fig. 33 Alternative Na_V blocker classes.

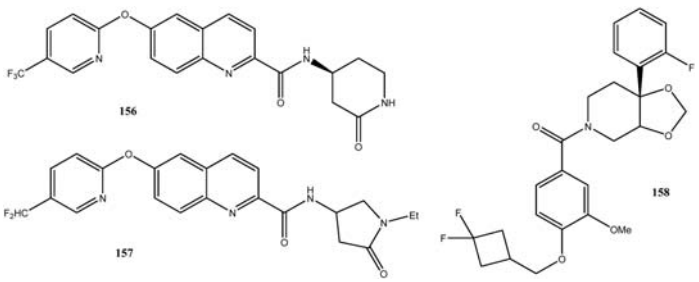

Fig. 34 Dual $Na_V1.7$–1.8 blockers.

$IC_{50} = 0.50\ \mu M$) was effective in rat pain models dosed orally at 30–100 mg/kg. It was clear however that there was no simple correlation between channel blocking efficiency *in vitro* and efficacy in monosodium iodoacetate model of osteoarthritis or spinal nerve ligation studies in the rat.

Vertex has also described classes of compounds with activity at both $Na_V1.7$ and $Na_V1.8$. Compounds from WO 2010002956 are discussed in relation to $Na_V1.7$ sulfonamides (*vide supra*) because of their similarity to compounds of that class. Compounds described in a more recent patent application[175] were suggested to be blockers of both $Na_V1.7$ and Na_V 1.8, and it was indicated that this dual action may make them more efficacious, supporting the hypothesis by noting that double knockouts of $Na_V1.7$ and $Na_V1.8$ in sensory DRG neurons diminish nociceptive behaviors to a greater degree than knockout of either channel alone. Detailed ion channel inhibition values were not disclosed; however, compound **158** is illustrative of the 314 compounds disclosed in this patent filing and was described as active.

7.04.3.3.3 $Na_V1.8$ blockers

$Na_V1.8$ was the first tetrodotoxin-resistant (TTX-r) voltage-gated sodium channel to be identified[176] and its predominant expression in DRG neurons and sensory fibers has led to its attracting interest as a potential target for pain.[177] $Na_V1.8$ knockout mice showed deficits in nociception following inflammation, supporting the involvement of $Na_V1.8$ in inflammatory pain. While some data from knockout mice suggested $Na_V1.8$ is not essential for development of neuropathic pain[178] this is contradicted by findings with selective small molecule blockers of $Na_V1.8$ (*vide infra*), and antisense[179] or siRNA knockdown of $Na_V1.8$ expression,[180] all of which show analgesic effects in neuropathic pain models. Furthermore, gain-of-function mutations of the $Na_V1.8$ channel that produce DRG neuronal excitability have been found in 3% of patients with painful neuropathy.[181] The functional and pharmacological properties of human and rat $Na_V1.8$ channels were explored with a variety of mostly nonselective sodium channel blockers.[182] Over the last decade, the search for potent and selective blockers of $Na_V1.8$ has resulted in the development of several compounds that have helped to define the effects of selective pharmacological block of $Na_V1.8$ and although some compounds emerged as potential treatments for pain, a successful controlled clinical trial of a $Na_V1.8$ blocker has yet to be reported. A recent review linking $Na_V1.8$ with several other disease states such as (MS) and cardiac disorders suggests a more complex role of $Na_V1.8$ in human physiology.[183]

An early report of small molecule blockade of $Na_V1.8$ activity involved the use of ambroxol (**Fig. 35**), a compound which has been used for the treatment of respiratory diseases for several years.[184] Ambroxol has modest selectivity for the $Na_V1.8$ channel over other sodium channels and showed efficacy in several preclinical models of neuropathic and inflammatory pain at doses of 1000 mg/kg.[185] More recently, ambroxol has been shown in uncontrolled studies to have some potential benefit for alleviation of neuropathic pain when applied topically to patients, the effects being attributed to its sodium channel-blocking properties.[186]

It has also recently been reported that the blockade of $Na_V1.8$ currents in nociceptive trigeminal neurons contributes to the anti-trigeminovascular nociceptive effect of several established drugs including the tricyclic antidepressant amitriptyline.[187] Furthermore, interaction with the slow inactivation state of $Na_V1.8$ has also been shown to be a property of carbamazepine,[188] and dexmedetomidine inhibits $Na_V1.8$ sodium channel activity in rat DRG neurons.[189]

The first efforts aimed at optimization of selective small molecule blockers of $Na_V1.8$ were described by Abbott/Icagen and led to the identification of A-803467,[190,191a] a molecule that has been widely studied both *in vitro* and *in vivo*. Proof of concept that a selective small molecule $Na_V1.8$ blocker could be analgesic was provided when A-803467 was shown to be active in preclinical models of inflammatory and neuropathic pain.[173]Further studies showed additive activity with a TRPV1 antagonist in rat neuropathic and inflammatory pain models[192], and more recent studies have shown A-803467 to be active in an animal model of osteoarthritis[193] but it may also have some activity at the cardiac $Na_V1.5$ channel.[194]

The poor solubility and resulting poor oral absorption and pharmacokinetic properties of A-803467 precluded its further development and Abbott/Icagen explored several closely related series in attempts to overcome these issues. Initial studies focused on replacement of the anilide with solubilizing groups leading to the piperazine analogues **159–161** (**Table 5**).[195]

The inclusion of basic nitrogen appeared to give enhanced $Na_V1.8$ blockage but the precise position of the N had only a moderate effect on activity. Introduction of lipophilicity enhanced potency and this was postulated to be important for interaction with hydrophobic regions of the binding site in the $Na_V1.8$ channel; however, these compounds showed only moderate selectivity for the $Na_V1.8$ channel over $Na_V1.2$ and $Na_V1.5$ channels. All three compounds gave sufficient plasma levels after oral administration to enable evaluation in a Chung SNL model of neuropathic pain with **161** having the lowest ED_{50} of 4.7 μmol/kg. Despite significant brain penetration (brain: plasma concentration ratio > 8) for all three analogues, no significant impairment of locomotor

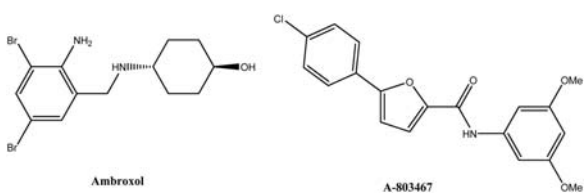

Fig. 35 Discovery of $Na_V1.8$ blockers.

[a]IC_{50}s (μM) by electrophysiology.

activity was observed but compound **161** did show some effects on mean arterial pressure and heart rate at doses that were low concentration multiples of the therapeutic concentration, possibly due to its $Na_V1.5$ activity.

Further studies by Abbot and Icagen focused on replacement of the furyl ring in A-803467 with alternative heterocycles, and several 5- and 6-membered replacements were found to retain activity at $Na_V1.8$.[196] The 3,5-pyridine was chosen for further profiling due to favorable $Na_V1.8$ blocking potency and solubility. Optimization of the anilide portion, aimed at further improvement of solubility by disrupting the planarity of the biaryl anilide system, led to benzyl and picolinyl amides with the picolinyl compounds being favored due to the presence of the basic nitrogen. From these studies, representative compound **162** (Table 6) and the related compound **163** were profiled in a range of *in vitro* pharmacokinetic and *in vivo* studies. Increased solubility and reduced metabolism led to higher plasma levels after oral dosing than the furanamide series and both showed dose-dependant attenuation of mechanical allodynia in the Chung SNL model of neuropathic pain, without discernible side effects.

The closely related analogue **164** (A-887826) has been profiled in a range of electrophysiology assays and was shown to be a state but not frequency-dependent blocker of $Na_V1.8$, a property common to this series of $Na_V1.8$ blockers.[197] It appears that **164** was chosen for further in-depth study due to the higher solubility imparted by the morpholino substituent; however, this substituent also reduces the selectivity against other channels such as $Na_V1.2$. Compound **164** was shown to be approximately 10-fold more potent than A-803467 and dose dependently reduced tactile allodynia in a rat model of neuropathic pain. The analgesic-free plasma concentrations were in the range of 3–10 nM, consistent with the IC_{50} for block of rat DRG TTX-r sodium current.

[a]IC_{50}s (μM) by electrophysiology.

A pyrazine central core was also chosen for further SAR investigation[198] leading to compound **165** emerging with favorable solubility and *in vitro* clearance. Further pharmacokinetic profiling indicated modest exposure (oral bioavailability = 18%) and the compound showed dose-dependent inhibition of tactile allodynia in the Chung SNL model of neuropathic pain with an ED_{50} of 78 mg/kg. To date, none of these compounds have been reported to have progressed into human clinical studies.

Pfizer has developed a selective series of $Na_V1.8$ blockers with structural similarities to lamotrigine which is a weak but non-selective a weak but non-selective $Na_V1.8$ blocker.[199] The initial screening lead **166** (**Fig. 36**) was modified to provide **167** with improved $Na_V1.8$ potency and selectivity. Reversal of the amide moiety in **167** gave compound **168** (PF-01247324), a material that has been profiled in some detail[200] and that has been prepared on a kilogram scale.[201] Manual patch electrophysiology indicated that **168** had an IC_{50} at human $Na_V1.8$ of 0.19 μM and >50-fold selectivity over other channels. Furthermore **168** blocked native TTX resistent currents in both human and rat DRG neurons in both frequency-dependent and state-dependent manner. Mutation of key residues in the local anesthetic binding site of the $Na_V1.8$ channel reduced the blocking potency of **168** suggesting some overlap in binding sites. Compound **168** (PF-0127324), has high oral bioavailability ($F = 91\%$ in rat) and showed attenuation of allodynia after oral dosing in rodent models of inflammatory and neuropathic pain, providing pharmacological evidence with this novel chemotype that $Na_V1.8$ channels have a role in these pain states. $Na_V1.8$ channels are upregulated in the cerebellum in multiple sclerosis and $Na_V1.8$ expression is linked to ataxia and MS-like symptoms in mice. Oral dosing of **168** in a mouse MS model led to a significant improvement in motor skills and cerebellar-like symptoms compared to vehicle-treated animals suggesting that $Na_V1.8$ blockers may merit further study for the treatment of MS.[202] Similar but less pronounced reversal of the rapid, asynchronous electrical activity in cerebellar Purkinje neurons had been seen previously with the Abbott compound A-803467 but this required delivery to the CSF by intracerebroventricular injection, due to poor oral bioavailability. Further optimization by Pfizer focused on the instability of the acetamide and on reducing lipophilicity.[201] Small heterocyclic replacements for the acetamide, including pyrazole and isoxazole, retained $Na_V1.8$ potency and selectivity. Further efforts to reduce lipophilicity by replacing the pyridine core with a pyrazine led to a more than 10-fold drop in $Na_V1.8$ inhibition. An analysis of SAR in the pyridine series with the emphasis on lipophilicity, potency, and solubility resulted in the identification of pyrazole **169** and isoxazole **170**. These two derivatives were active in a tibial nerve transection model of neuropathic pain in rat. In addition, **169** (**PF-04531083**) appeared to have little effect on other peripheral or CNS activities. Clinical studies on compound **169** are discussed later.

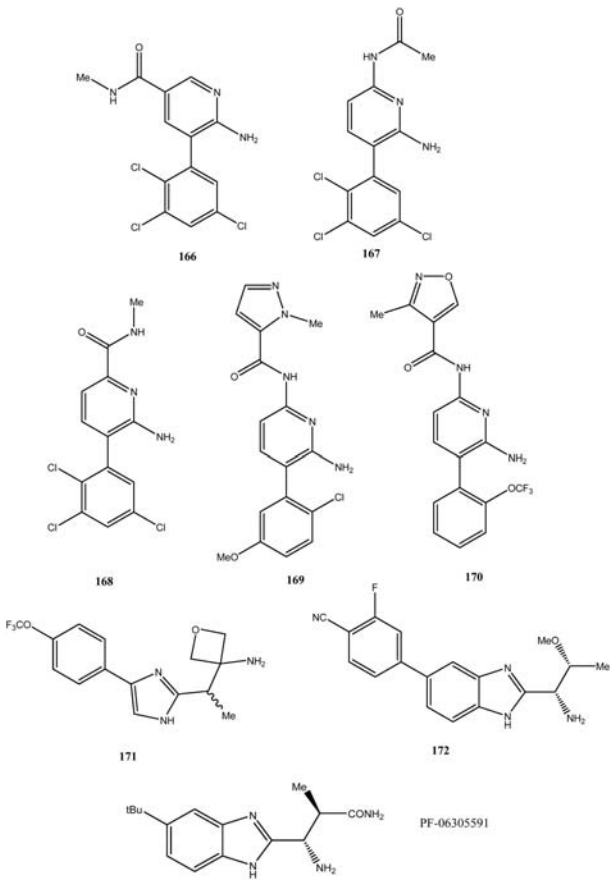

Fig. 36 Pfizer $Na_V1.8$ blockers.

Pfizer has also published patent applications on novel series of aryl imidazoles exemplified by **171**[203] and on related aryl benzimidazoles such as **172**.[204] These show potent block at the inactivated state of $Na_V1.8$ but no Na_V selectivity data was reported. Most recently, the analogue PF-06305591 was disclosed as a clinical candidate at two scientific meetings.[205] It was noted to have a 31 nM IC_{50} against $Na_V1.8$ and a pK_a of 5.9 and a log *D* of 2.1 and is discussed in the clinical section.

Another company with a major interest in $Na_V1.8$ blockers is Vertex; it has published a series of patent applications on structurally related compounds that show potent $Na_V1.8$ blocking activity.[206] Selected examples from these filings are shown in **Table 7**; however, no selectivity data was reported. One application (WO 201508961) describes a series of prodrugs suggesting that there may have been issues with bioavailability in at least some of the series.

[a]IC_{50}s assessed by electrophysiology.

Some unrelated compounds have also been shown to be $Na_V1.8$ blockers but with a range of activities at other targets, for example, menthol has been shown to block both $Na_V1.8$ and 1.9 at a high concentration in a use-dependent manner.[207]

7.04.3.3.4 $Na_V1.9$ blockers

$Na_V1.9$ is preferentially expressed in small diameter DRG neurons and in intrinsic myenteric neurons. The status of $Na_V1.9$ as a target for pain has been debated for several years. An early study using $Na_V1.9$ antisense oligodeoxynucleotide treatment did not report amelioration of neuropathic pain but recently clear links to pain conditions have been described.[208] Experimental evidence supports a role for $Na_V1.9$ in inflammatory and diabetic neuropathy pain, although a general role in neuropathic pain is less clear.[209] Expression of $Na_V1.9$ has been shown to increase in DRG neurons following inflammation in rat hind paw.[210] Although expression levels of $Na_V1.9$ do not appear to be altered in small DRG neurons from diabetic rats, increased $Na_V1.9$ levels in large-diameter neurons suggest a contribution to painful diabetic neuropathy.[211] However, $Na_V1.9$ mRNA and protein levels and current density are downregulated in several animal models of neuropathic pain.[212]

A number of painful peripheral neuropathies and familial episodic pain conditions have now been associated with $Na_V1.9$ mutations and shown to be related to increased DRG excitability.[11] Equally, $Na_V1.9$ mutations associated with familial conditions resulting in an inability to experience pain have been related to a decrease in DRG excitability. It has also been shown that the $Na_V1.9$ channel is a key determinant of cold pain sensation.[213] To date, no $Na_V1.9$-specific molecules have been reported; however, it is likely that a portion of the activity of pan-active state-dependent sodium channel blockers will be associated with $Na_V1.9$ inhibition.[214] More specifically, amitriptyline, a tricyclic antidepressant (**Fig. 37**) which is widely used to manage various chronic pain conditions, an activity attributed to its Na_V block, has been shown to have an effect on $Na_V1.9$ currents in nociceptive trigeminal neurons.[215]

A patent application on $Na_V1.9$ was published by the University of Aix-Marseilles claiming the use of cholesterol as a $Na_V1.9$ blocker and describing means of delivering this compound as a transdermal patch. The filing describes the efficacy of cholesterol in a number of pain models including carrageenan-induced pain in the rat treated using a 5.6-mM solution via transdermal delivery.[216] The treatment was shown to be at least as effective as ibuprofen under the test conditions; however, channel selectivity data was not reported. This group also described antibody approaches to channel blockade (*vide infra*).

7.04.4 Clinical Studies

A summary of the reported status of clinical Na_V blockers in early 2016 is shown in **Table 8**. A number of companies have disclosed that they are entering Phase I clinical studies with novel selective sodium channel blockers. DaiNippon Sumitomo[217] has reported

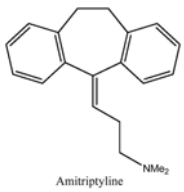

Fig. 37 Amitriptyline—a $Na_V1.9$ blocker.

Table 8 Status of clinical phase sodium channel blockers

Compound	*Mechanism*	*Company*	*Study*	*Comments*
DSP-2230	$Na_V1.7,8$	DaiNippon Sumitomo	Ph I	Target Neuropathic Pain
NKTR-171	Na_V	Necktar Therapeutics	Ph I	Peripheral
DS-1971a	$Na_V1.7$	Daiichi Sankyo	6 Ph I studies completed	PhII planned in Diabetic Neuropathy

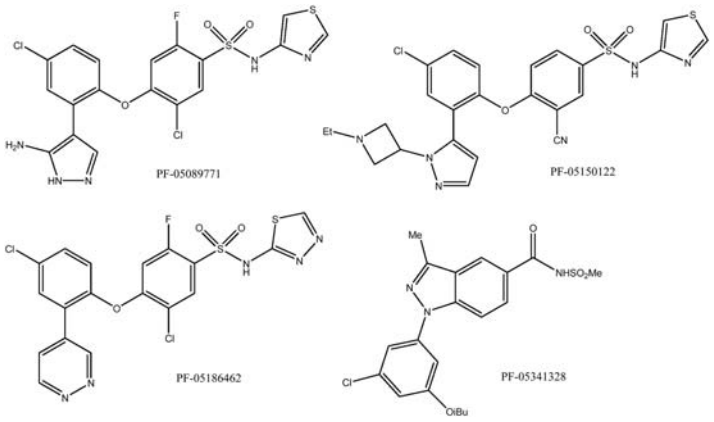

Fig. 38 Pfizer microdosing candidates.

that DSP-2230, an inhibitor of both $Na_V1.7$ and $Na_V1.8$, but of undisclosed structure, is being developed for the treatment of pain and is presently in Phase I; however, to date no outcomes have been reported. Necktar Therapeutics has similarly advanced its undisclosed lead NKTR-171 into Phase I, as a peripherally restricted Na_V blocker but with undisclosed selectivity.[218] Daiichi Sankyo's compound DS-1971a, another sodium channel blocker of undisclosed structure, has completed six Phase I studies and a Phase II study is planned.[219] Pfizer undertook a microdosing study which was used to select a lead $Na_V1.7$ blocker PF-05089771 for full clinical development from four potential candidates (**Fig. 38**), ahead of heterocyclic analogues PF-05186462, PF-05241328, and PF-05150122, which all showed poorer PK properties.[220] This material has now being evaluated in a number of Phase II studies. Likewise the newest Pfizer $Na_V1.8$ blocker PF-06305591 has been selected for clinical evaluation and in Phase I studies showed an exposure of 10 x the IC_{50} at a 40-mg bid dose, and an eight hour-half-life.[207]

Over the past 5 years there have been more than a dozen later phase clinical studies of sodium channel blocking agents against pain conditions. Many of these have looked into the efficacy of currently marketed drugs or compounds with an unselective sodium channel pharmacology[221] or have examined their activity in combination therapies.[222] Several studies are also being conducted into the use of toxins, including tetrodotoxin.[223] The state-dependent pan-Na_V blocking agent ralfinamide[224] was assessed by Newron as a treatment for pain. Ralfinamide is a brain-penetrant molecule, but the compound has a range of additional activities including N-type calcium channel inhibition and NDMA receptor antagonism. In 2010 it failed a Phase IIb/III trial in lower back pain[225] despite earlier success in a Phase II clinical study of neuropathic pain.[226]

A number of studies have now been undertaken with new, more selective agents. In 2014 a study into the efficacy of CNV1014802, a selective and state-dependent $Na_V1.7$ channel blocker, for treatment of the painful facial neuropathy trigeminal neuralgia, reported success.[227] Details of the trial protocol have also been disclosed.[19] Following an initial 21-day open-label treatment period with CNV1014802 at a dose of 150 mg three times a day (tid), patients who showed a successful response in the final week of the period, defined as a 30% or more reduction in numbers of paroxysms, or severity of paroxysms, relative to the run-in period, were then randomized to a 28-day double-blind treatment period with either CNV1014802 150 mg tid or placebo. All patients entering the study had to have a prespecified number of paroxysmal attacks of at least moderate severity. A total of 67 patients were recruited into the study and 69% of those patients completing the open label period were randomized as clear responders into the double-blind phase of the study. CNV1014802 was well tolerated and the study showed a consistent reduction of pain severity and number of paroxysms in all primary and secondary outcomes. In the primary endpoint of the study there was a treatment failure rate of just 33% for CNV1014802 vs. 65% for placebo and a favorable separation from placebo on the Kaplan Meier time to relapse. CNV1014802 showed a 2.3 unit decrease in the numerical rating scale for pain intensity, 60% reduction in paroxysms vs. 12% in placebo, and pain severity dropped by 55% vs. 18% placebo by the end of the study. There were no serious adverse events related to the drug and the adverse event profile of the drug was similar to placebo in the double-blind phase of the study.

CNV1014802 also proved effective in a Phase II study of lumbosacral radiculopathy (sciatic pain) (LSR).[228] The trial was a randomized, double-blind, placebo-controlled cross-over study designed to evaluate the efficacy and safety of orally administered CNV1014802 at a dose of 350 mg twice per day, in 81 patients with pain associated with LSR. There was a statistically significant difference in the primary endpoint between CNV1014802 and placebo (Pain Intensity-Numerical Rating Scale (PI-NRS) mean change at week 3, -0.43; $p=0.0265$). Additional exploratory analyses showed that for the subset treated by CNV1014802 alone, comprising 60% of patients randomized, there was an enhanced statistically significant reduction in pain (PI-NRS mean change at week 3, -0.72; $p=0.0039$). There were no serious adverse events related to the drug in this trial and as seen in all previous clinical studies, CNV1014802 was very well tolerated. The report notes that CNV1014802 was delivered at an effective therapeutic dose without any requirement for dose titration.

A recent report gave notice of plans for the start of a CNV1014802 Phase-III study. This indicated that it is in development for several pain indications. It is anticipated that a Phase III study will be initiated to confirm the efficacy of CNV1014802 in patients

with trigeminal neuralgia. Plans to initiate a Phase II trial in patients with LSR in 2016 were also disclosed and a study into the effect of this compound on erythromelelgia has recently been announced.[229]

Xenon has reported that their clinical candidate XEN402, Funapide, is presently being developed for conditions including osteoarthritis, neuropathic pain, post-herpetic neuralgia, and erythromelalgia. The spirocyclic class typically has low solubility and the compounds are being developed for human use in both topical and oral formulations. A study in 2014 reported success in treatment of inherited erythromelalgia (IEM).[230] An exploratory, randomized, double-blind, 2-period crossover study was conducted in four SCN9A mutation-proven IEM patients. In each treatment period of 2 days, separated by a 2-day washout period, patients were orally administered XEN402 (400 mg twice daily) or matching placebo. In three patients, pain was induced by heat or exercise during each treatment arm. A fourth patient, in constant severe pain, required no induction. Patient-reported outcomes of pain intensity and/or relief were recorded, and the time taken to induce pain was measured. The ability to induce pain in IEM patients was significantly attenuated by XEN402 compared with placebo. XEN402 increased the time to maximal pain induction and significantly reduced the amount of pain (42% less) after induction ($p = 0.014$). This indicated that XEN402 blocks $Na_V1.7$-mediated pain associated with IEM, thereby demonstrating target engagement in humans and underscoring the use of rare genetic disorders with mutant target channels as a novel approach to rapid proof of concept.

Challenges evidently still remain in bringing new classes of sodium channel blocker to market. A Phase IIb study on the XEN402 (now renamed TV-45070 following a transaction between Xenon and with Teva Pharmaceuticals) was conducted into osteoarthritis pain in the knee.[231] Unlike the IEM study, TV-45070 dosed topically at 4% and 8% concentrations did not demonstrate a statistically significant difference from placebo in efficacy endpoints. The companies noted that TV-45070 demonstrated a favorable safety and tolerability profile, with no drug-related serious adverse events. They rationalized that low drug plasma levels coupled with the favorable tolerability profile do support topical application and continued development in neuropathic pain. Results are awaited from the ongoing post-herpetic neuralgia Phase IIb study, expected in the second half of 2016.

Pfizer progressed the first $Na_V1.8$ lead **PF-04531083** (compound **169**) into human clinical studies,[232] the first reported selective $Na_V1.8$ blocker to reach the clinic. However a clinical trial for dental pain was terminated after interim analysis of results, presumably due to a lack of efficacy. No results have been reported for a clinical trial with the same compound aimed at heat pain for UV damaged skin.

7.04.5 Conclusions

This is an exciting time for sodium channel blocker research with success reported in several Phase II studies into pain using agents designed to have specific sodium channel blocking activity, and late-stage trials are expected to report in the next few years. The wealth of research suggests that there are now the tools to answer key questions about the link between specific channel blockers and human disease pharmacology. With the first clinical proof of concept studies reporting positive efficacy data or multiple new chemical entities, there must be a real prospect of novel effective therapies becoming commercially available for the benefit of patients suffering from conditions such as trigeminal neuralgia and other types of chronic neuropathic pain.

7.05.1 Introduction

7.05.1.1 Migraine Prevalence and Symptoms

Migraine is a debilitating neurological syndrome, usually presenting with severe headache pain, nausea, and heightened sensitivity to sound (phonophobia), light (photophobia), smell, and tactile sensations.[1,2] Beyond the individual suffering, it is also recognized as a significant source of lost productivity. In 2009, it was estimated that migraine attacks cost the US economy at least 17 billion dollars per year in direct costs, missed workdays, and reduced performance.[3] Severe migraine is considered by the World Health Organization to be comparable to quadriplegia in its impact on the daily life of individual sufferers. Despite many decades of research, the vast majority of migraineurs are underserved by existing therapies, because of both inadequate efficacy and treatment-limiting side effects.[4]

It is estimated that migraine affects 12–20% of the global population, with women sufferers more than twice as compared to men sufferers. Unlike most other neurological conditions, migraine mainly afflicts those in middle age or younger. In women, prevalence increases until about age 40, after which it begins to decrease and approach that of men.[5] Although the frequency of attacks varies widely, about 1% of Americans are considered to have chronic migraine, defined as more than 15 days with headache per month, with prevalence inversely related to income.[6]

Migraine is increasingly recognized to be a highly complex disorder with multiple, patient-specific factors determining the character of a given episode. This may partly explain the heterogeneity of treatment responses seen with various therapies. Duration of attacks vary widely, from a few hours to several days or more.[7] Since everyday tasks usually aggravate the symptoms, migraineurs often require immobility and isolation during attacks. A typical migraine episode usually consists of several phases.[8] In the prodromal phase, experienced by roughly 80% of patients, the individual is aware that an attack is imminent hours or even days before the onset of pain. Many migraineurs (20–30%) experience visual auras—moving rings or spots of light—before and/or during the initial phase of headache pain. The overall headache phase, where the pain is often unilateral, typically lasts from 4 to 72 h and is usually accompanied by one or more associated symptoms such as nausea, photophobia, phonophobia, and tactile sensitivities. Finally, the postdromal phase is marked by physical and mental fatigue, along with residual signs of neuronal hyperexcitability such as allodynia. There is a strong hereditary component in migraine with many reports of positive family histories. This is especially true of familial hemiplegic migraine where approximately 50% of sufferers possess a mutation in a voltage-gated Ca^{2+} channel gene, *CACNA1A*, strong evidence for the involvement of ion channels in the aura that is a hallmark of this condition.[9]

7.05.1.2 Migraine Pathophysiology

In many individuals, migraines are brought on by specific stimuli or triggers. These can vary greatly between migraineurs and include specific foods (chocolate, cheeses, and red wine, in particular), changes in weather, hormone levels, disrupted sleep patterns, and stress. However, many sufferers need no obvious trigger to bring on an attack. Migraineurs may have an increased tendency toward intermittent neuronal excitability, possibly due to inherited mutations in, for example, ion channels[10,11] that

lower their threshold for neuronal firing in reaction to modest physiological changes such as menstrual hormone fluctuations, emotional stress, and even awakening from sleep.

The basic causal mechanisms that lead to migraine pain and associated symptoms are still matters of investigation and debate. Through the last half of the 20th century, a "vascular-only" hypothesis prevailed.[12] According to this model, migraine headache pain could be explained by the physical dilation of dural and extracranial blood vessels. Briefly, a given migraine trigger results in vasoconstriction leading to localized ischemia. This is followed by an excessive compensatory response by the trigeminovascular system (TGVS) in which blood vessels are dilated by neuronal secretion of vasoactive peptides such as calcitonin gene-related peptide (CGRP), neuropeptide Y, and substance P, leading to activation of the perivascular sensory nerve projecting to the brain.[13] In this model, the TGVS, which innervates the face and the meningeal blood vessels surrounding the brain, is responsible for migraine pain. In addition, cortical spreading depression (CSD), a self-propagating wave of neuronal depolarization in the cortex of the brain, is thought to be directly responsible for the visual aura that precedes headache for approximately one-third of migraineurs.

Many researchers believe that a combination of environmental factors and a lowered threshold for cortical hyperexcitability leads to CSD, possibly in all migraineurs since aura may only manifest itself when CSD occurs in visual areas of the brain.[11] CSD, which may be promoted by low magnesium concentrations leading to enhanced *N*-methyl-D-aspartate receptor activation, results in extracellular release of a number of neuronally active substances that may activate or sensitize meningeal nociceptors.[14] It is thought that the activated TGVS secretes neuropeptides that cause vasodilation and increase blood vessel permeability, leading to plasma extravasation and mast cell degranulation, all resulting in dural inflammation.[15] Other vasoactive substances have been identified in afferents supplying intracranial vessels including serotonin (5-HT), nitric oxide, substance P, neurokinin A, and vasoactive intestinal peptide.[16] Most of these can also mediate neurotransmission in the central nervous system (CNS) and thus may have multiple functions in migraine pathophysiology, complicating the interpretation of mechanism-based therapies.[17]

Recent findings, especially from positron emission tomography (PET) imaging studies,[18] have stressed the potential importance of central dysfunction in migraine, in particular, the periaqueductal gray (PAG), a region of the brain well known to be involved in the pain desensitization pathway. A number of researchers now believe that altered brainstem activity may be critically important in both triggering and lowering the threshold for migraine attacks.[1] The lowered threshold for neuronal hyperexcitability that many or most migraineurs possess may be triggered by what would normally be considered minor day-to-day stresses or stimuli. Repeated migraine attacks could result in a chronic state of dysregulation of pain pathways that might explain the resistance to acute therapy that some migraineurs eventually experience.[19] A recent meta-analysis of 40 published clinical studies of acute and chronic migraine patients sought to identify common biomarkers in cerebrospinal fluid (CSF) and blood.[20] As expected, CGRP was commonly found to be increased in both compartments. Other potential biomarkers frequently identified were nerve growth factor (NGF, only increased in CSF), glutamate, and beta-endorphin (significantly decreased in migraineurs), suggesting pathways for further investigation.

7.05.1.3 Medications for Migraine

The majority of migraine sufferers remain undiagnosed or misdiagnosed, commonly with either sinus- or tension-type headache, despite efforts to motivate patients to seek physician care and treatment.[21] Among the undiagnosed population, there is a high degree of self-treatment with over-the-counter medications. Antimigraine drugs can be divided into two classes: abortive and preventative. The former has been dominated by over-the-counter analgesics, such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) and, since the early 1990s, by the triptans (5-$HT_{1B/1D}$ agonists) most of which are now available as generics. Overuse of several types of acute migraine medications has been shown to result in progression to increasingly chronic migraine conditions in some patients.[22]

Preventative treatments are primarily used by frequent and chronic migraineurs along with acute treatments and include a wide range of drug classes (**Table 1**). Most of these prophylactic agents are older drugs whose mechanisms of action are often incompletely understood and whose biological activities and/or side effect profile determines who can use them. Notably, there are no approved disease-specific treatments for migraine prevention. NSAIDs are also used for migraine prophylaxis, either intermittently or daily, especially if migraine triggers are predictable.[23] However, their adverse effects on the GI tract, a result of cyclooxygenase-1 (COX-1) inhibition, can make chronic use problematic.

7.05.1.4 Older Acute Migraine Drug Classes

7.05.1.4.1 Ergot alkaloids

Ergotamine (**1**, **Fig. 1**) has been used as an acute antimigraine agent since 1925. Prominent side effects such as severe nausea and chest tightness were common until it was largely replaced by dihydroergotamine (**2**, DHE) in 1945.[25] DHE, especially in its intravenous (IV) and subcutaneous (SC) formulations, remains a highly effective abortive treatment for severe migraine. Ergotamines display complex pharmacology through interactions with a variety of neurotransmitter targets, including not only the serotonin 5-HT_{1B} and 5-HT_{1D} receptors ($IC_{50} \leq 1$ nM), known to be involved in the antimigraine activity of the triptans, but also 5-HT_{2B} and 5-HT_{2C} receptors ($IC_{50} < 10$ nM) that may contribute to efficacy.[26] They also bind with high affinity ($IC_{50} < 10$ nM) to 5-HT_{1A} and 5-HT_{2A} receptors; noradrenaline α_{1A}, α_{2A}, and α_{2B} receptors; and dopamine D_{2L}, D_3, and D_4 receptors. Antimigraine activity was long thought to be solely due to constriction of meningeal arteries, but newer evidence suggests that ergotamines, like

Table 1 Currently used preventative migraine therapies[24]

Drug class	*Examples*
Anticonvulsants	Topiramate
	Valproate
	Gabapentin
Antidepressants	Tricyclics
	Duloxetine
ACE inhibitors	Lisinopril
Calcium channel blockers	Verapamil
	Flunarizine
Beta adrenergic blockers	Atenolol
	Propranolol
Melatonin agonists	Ramelteon
Miscellaneous	Vitamin B12
	Botulinum toxin
	Coenzyme Q10
	Magnesium
	Glucocorticoids

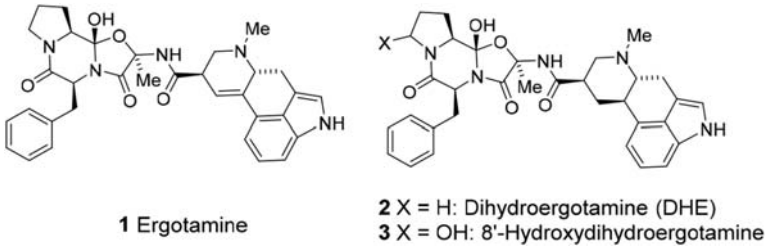

Fig. 1 Ergotamine, dihydroergotamine (DHE), and the metabolite of DHE, 8′-hydroxydihydroergotamine.

the triptans, exert additional effects on neurotransmission and neurogenic inflammation.[27] DHE has been used as both an abortive and an preventative migraine therapy, but recently, the European Union has limited ergot alkaloids to acute indications, in part due to an increased risk of fibrosis with chronic use.[28] DHE has low oral bioavailability due to extensive oxidative metabolism in the liver and poor gut penetration. However, upon repeated oral administration, a prominent active metabolite, 8′-hydroxydihydroergotamine (**3**, 8′-OH-DHE), is formed, which has a long half-life (10–13 h). This has been postulated to account for the low rate of headache recurrence seen with DHE.

7.05.1.4.2 5-HT$_{1B/1D}$ agonists (triptans)

The vascular theory of migraine, supported by the efficacy of the ergotamines, led to an effort in the last quarter of the 20th century to develop more selective abortive medications, focusing on the role of serotonin (**Fig. 2**). This work specifically targeted agonism of the 5-HT$_{1B/1D}$ receptor subtypes known to be involved in vasoconstriction,[29] in order to avoid the multiplicity of pharmacological effects serotonin can elicit.[30]

Sumatriptan (**5**) was introduced by Glaxo in 1991 and was a milestone in migraine treatment, being not only the first rationally designed compound for this indication but also the first that was free of severe side effects in most patient populations.[31,32] By bismethylation of the amino group and replacement of the hydroxyl of the serotonin indole core with a sulfonamide side chain, a great degree of selectivity had been obtained for 5-HT$_{1B/1D}$ over the 14 other known 5-HT$_1$ receptors. Sumatriptan has fairly low oral bioavailability (see **Table 2**[33,34]) and is also available in SC and intranasal (IN) formulations. Interestingly, there has been no simple pharmacodynamic/pharmacokinetic (PK/PD) relationship for migraine efficacy in humans, leading to speculation regarding the importance of rate of absorption on activity.[35] In general, SC injection provides not only the most rapid and profound migraine relief but also the most pronounced on-target side effects. Sumatriptan remains the most prescribed triptan, and numerous reviews on it have been written.[36,37]

The six subsequent "second-generation" triptans developed by Glaxo and other companies, mostly through the 1990s, with the intention of improving pharmacological and pharmaceutical properties, all retain the tryptamine core of serotonin. Rizatriptan, zolmitriptan, and almotriptan utilize the indole C3 dimethylaminoethyl group found in sumatriptan and differ in the indole C5 substituent. Frovatriptan and eletriptan contain conformationally restricted aminoethyl groups—frovatriptan with its *N*-methylaminocyclohexeno group fused at C2 and C3 of the indole scaffold and eletriptan with its indole C3 *N*-methylpyrrolidin-2-ylmethyl side chain. All "second-generation" triptans are potent 5-HT$_{1B/1D}$ receptor agonists, differing somewhat in their

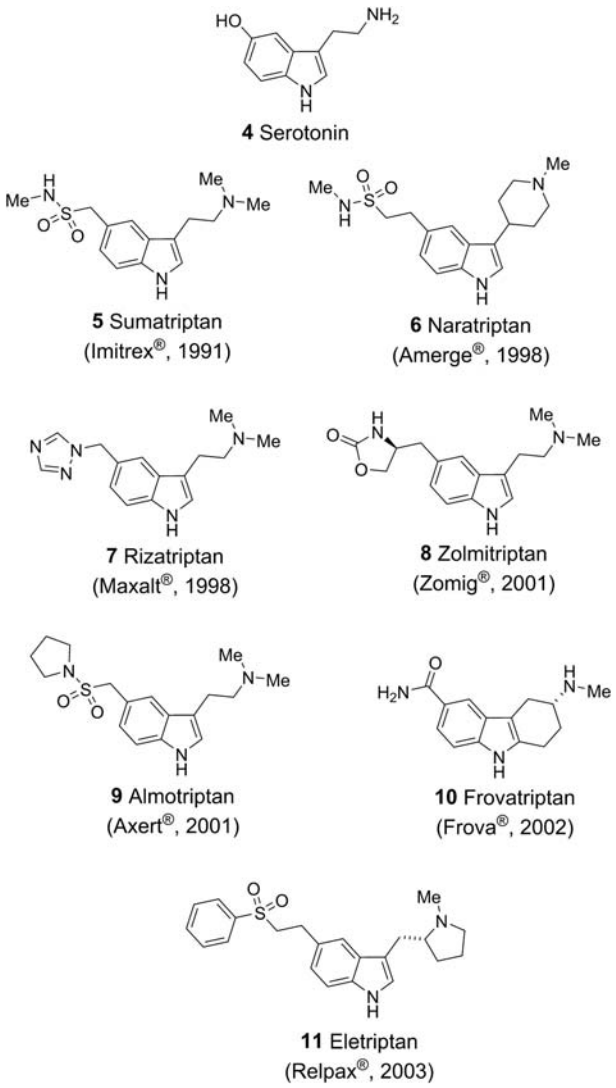

Fig. 2 Serotonin and the triptans, including the year of FDA approval for triptans.

off-target 5-HT_1 profiles.[38] They also differ, sometimes greatly, in their physiochemical and absorption, distribution, metabolism, and excretion (ADME) properties, as well as CNS penetrance (Table 2). At the time of their discovery and development, there was hope that these differences would lead to superiority in clinical efficacy and a reduction in adverse events compared to sumatriptan. However, there are still insufficient data to show clear distinctions between the individual triptans.[39] As shown in Table 2, the triptans provide relief in approximately 60% of migraine attacks with significant headache recurrence after 24 h for all members. Differences experienced in patients are likely due to individual variations in metabolism or genetics. As a result, migraineurs will

Table 2 Comparison of clinical pharmacokinetic and efficacy of marketed triptans

often switch to a new triptan until they find the most effective one for them or when the efficacy of a given triptan begins to diminish.

Sumatriptan has direct, dose-dependent vasoconstrictive effects on intracranial blood vessels that have been correlated with its antimigraine activity.[40] All triptans share this property, and accordingly, the majority of adverse events associated with triptan use are a result of vasoconstriction of tissues other than cranial arteries, including cardiac vessels and other vasoactive tissues. In rare cases, ischemic cardiac events have been reported with triptan use.[41] Off-target blood vessel and tissue vasoconstriction is the major adverse event with this class, limiting the number of doses allowed per migraine attack and during the course of a month. CGRP receptor antagonists represent a newer mechanism that does not involve active vasoconstriction and may provide safer antimigraine agents.

7.05.2 Calcitonin Gene-Related Peptide

7.05.2.1 CGRP and Migraine

Migraine is a complex and heterogeneous neurological disorder that defies simple explanations.[42,43] Nonetheless, significant progress in understanding the nature of migraine and its underlying causes has been made over the past few decades. Multiple lines of evidence have pointed to a key role for CGRP in migraine pathophysiology and led to interest in the peptide as a therapeutic target.[44] CGRP, a 37-amino acid neuropeptide that was first described in 1982,[45] is widely expressed in the peripheral and central nervous systems and has been implicated in a range of biological functions,[46] including vasodilation,[47,48] nociception,[42,49] inflammation,[50,51] and regulation of insulin release.[52,53]

Based on its apparent role in cerebrovascular regulation, Edvinsson postulated that the peptide could be involved in migraine pathophysiology over 30 years ago.[54] This hypothesis has subsequently been substantiated by a number of key studies, including some that resulted from an important collaboration between Edvinsson and Goadsby. Examining the craniovascular levels of several neuropeptides during migraine attacks, they observed a significant increase in the levels of CGRP in migraineurs during an attack, while the concentrations of other neuropeptides, such as neuropeptide Y or substance P, were unchanged.[55] In a follow-up experiment, it was found that these migraine-associated elevations of CGRP could be returned to baseline by successful treatment of the headache with sumatriptan.[56] Further compelling evidence for the importance of CGRP in migraine was provided by another study in migraineurs demonstrating that IV infusion of the peptide could induce a migraine-like headache.[57] These and other studies have pointed to a crucial role for CGRP in migraine and, by the late 1990s, led to significant interest in the development of novel therapeutics that could block the effects of the neuropeptide.

7.05.2.2 CGRP Receptor Structure and Function

CGRP, calcitonin (CT), amylin (AMY), and adrenomedullin (AM) comprise the calcitonin family of peptides.[58,59] In spite of significant differences at the level of amino acid sequence, these related peptides share key structural features, including an *N*-terminal cyclic structure formed with a Cys–Cys disulfide bond and a C-terminal amide group.[58] The cyclic moiety at the *N*-terminus of CT family peptides is important for receptor activation, and its removal can convert the endogenous agonist into an antagonist. For example, deletion of the first seven amino acids from CGRP affords a functional antagonist of the CGRP receptor ($CGRP_{8-37}$).[59] Like CGRP, the other CT family peptides are widely distributed and involved in a variety of biological processes.[58] Two forms of CGRP are known: α-CGRP, produced by alternate splicing of the CT gene, and β-CGRP, which is encoded by a separate gene.[59] Fig. 3 details the primary structures of human α-CGRP and β-CGRP, which differ by three amino acids. Although α-CGRP and β-CGRP possess very similar activities, they differ in terms of distribution, with α-CGRP being more prevalent in primary neurons while β-CGRP predominates in enteric neurons.[60]

The CGRP receptor (CGRP-R) is a multimeric protein and consists of the calcitonin receptor-like receptor (CLR) and receptor activity-modifying protein (RAMP) 1, with the RAMP1 protein being essential for production and function of the CGRP-R.[61,62] CLR is highly homologous to the calcitonin receptor (CTR), and both proteins are known to associate with RAMPs.[63] CLR and CTR are members of the secretin family (family B) of G-protein-coupled receptors (GPCRs), and they share a number of structural features with other family B GPCRs, including seven-transmembrane domains and large *N*-terminal extracellular domains (ECDs) that are essential for binding of their peptide agonists.[63] Like these GPCRs, the RAMPs are also transmembrane proteins, and each RAMP possesses a single-transmembrane domain attached to a significant *N*-terminal ECD.[61] The association of CLR and CTR with different RAMPs leads to pharmacologically distinct receptors.[63] As already mentioned, the CGRP-R results from coexpression of CLR and RAMP1. However, CLR is also known to form high-affinity AM receptors, known as the AM_1 and AM_2 receptors, by association with RAMP2 or RAMP3, respectively.[62] The coexpression of CTR with RAMP1, RAMP2, or RAMP3 is known to produce

α-CGRP NH_2-ACDTATCVTHRLAGLLSRSGGVVKNNFVPTNVGSKAF-NH_2

β-CGRP NH_2-ACNTATCVTHRLAGLLSRSGGMVKSNFVPTNVGSKAF-NH_2

Fig. 3 Primary structures of human α-CGRP and β-CGRP.

receptors for AMY, designated the AMY_1, AMY_2, and AMY_3 receptors, respectively.[62] Because CTR is similar to CLR in terms of primary structure, the AMY_1 receptor (CTR/RAMP1) is structurally similar to the CGRP-R (CLR/RAMP1) so it is not surprising that some small-molecule CGRP receptor antagonists also bind to the AMY1 receptor (*vide infra*).

In principle, the RAMPs could exert their effect on the binding of endogenous ligands, such as CGRP and AM, via an allosteric mechanism in which they alter the peptide binding site on CLR or by interacting directly with the ligand. The experimental evidence has favored the latter possibility since the earliest reports on CLR/RAMP1 (the CGRP-R). Cross-linking studies using [^{125}I]CGRP showed that the agonist appears to interact with both CLR and RAMP1.[61,64] Experiments with both chimeric receptors and deletion mutants demonstrated that the ECDs of both CLR and RAMP1 are important for agonist binding and selectivity.[65,66] Site-directed mutagenesis of human RAMP1 revealed that Trp84 in the ECD of this protein is particularly important for the potency of CGRP.[67] Antagonists of the CGRP-R also appear to interact with the ECDs of both CLR and RAMP1. A number of residues in both ECDs have been shown to contribute to binding of antagonists, with CLR Met42, RAMP1 Trp74, and RAMP1 Trp84 being especially important for receptor affinity.[62,67–70] It should be noted that some small-molecule CGRP receptor antagonists do not appear to interact with the ECD. For example, the hydroxypyridine class of antagonists block CGRP in a RAMP-independent manner[71] and are believed to interact with transmembrane domain 7 (TM7) in CLR and make no contact with the ECDs of either CLR or RAMP1 (*vide infra*).[69]

Therefore, before any detailed structural information on the CGRP-R was obtained, the available evidence indicated that both CGRP and CGRP receptor antagonists made a number of key interactions with the ECDs of both CLR and RAMP1. Indeed, the known data are consistent with the two-domain model for family B GPCRs described by Hoare more than a decade ago.[72] A schematic representation of this model for the CGRP receptor is illustrated in **Fig. 4**. Consistent with the mutagenesis and cross-linking studies, the two-domain model emphasizes a key role for the ECD in binding of both the peptide agonist and antagonists. According to the model, the C-terminal portion of CGRP initially binds to the ECD of the receptor, formed by the *N*-termini of CLR and RAMP1. Thus, anchored to the receptor by its C-terminal region, the CGRP *N*-terminus is brought into proximity with the juxtamembrane portion of CLR. This "affinity trap" greatly increases the local concentration of the CGRP *N*-terminal region, enabling it to interact with CLR and induce a conformational change that results in activation of the receptor. Based on the known mutagenesis data, most small-molecule antagonists are thought to block the effects of CGRP by preventing the peptide's initial interaction with the ECD of CLR/RAMP1.[62]

For many years, detailed structural data were available for only a few GPCRs, although significant progress has been made in past decade.[73] Even today, obtaining such information is complicated by the membrane-bound nature of GPCRs and the challenges of expressing, isolating, and purifying the proteins.[74] The CGRP receptor has the added complication of being a heterodimer. However, since most small-molecule antagonists of the CGRP-R apparently bind to the ECD, a team at Vertex Pharmaceuticals attempted to obtain structural data for this extracellular portion. They successfully expressed, purified, and refolded a soluble form of the CGRP-R ECD comprising a complex of the truncated *N*-terminal domains of CLR and RAMP1.[75] This soluble CGRP-R ECD bound the peptide CGRP with relatively low affinity ($IC_{50} = 12\ \mu M$) but had much higher affinity for known small-molecule antagonists ($K_D < 0.02\ \mu M$), consistent with the two-domain model (**Fig. 4**) in which the peptide also interacts with other portions of the CGRP-R.[75] Importantly, the CGRP-R ECD complex was crystallized, and the structure of the CLR–RAMP1 ectodomain was solved (**Fig. 5**).[76]

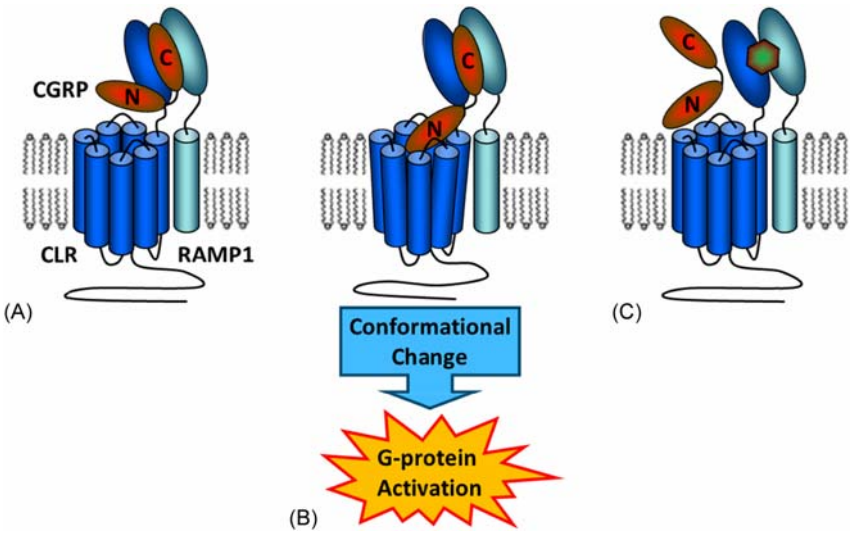

Fig. 4 Schematic two-domain model of CGRP receptor activation. (A) The C-terminal portion of CGRP *(red)* binds to the extracellular domains of CLR *(blue)* and RAMP1 *(teal)*, producing an increase in the local concentration of the CGRP *N*-terminus. (B) The *N*-terminal portion of CGRP interacts with the CLR juxtamembrane region, producing a conformational change in the GPCR that leads to G-protein activation and signaling. (C) A small-molecule antagonist *(green)* blocks binding of CGRP to the extracellular domains of both CLR and RAMP1, preventing receptor activation.

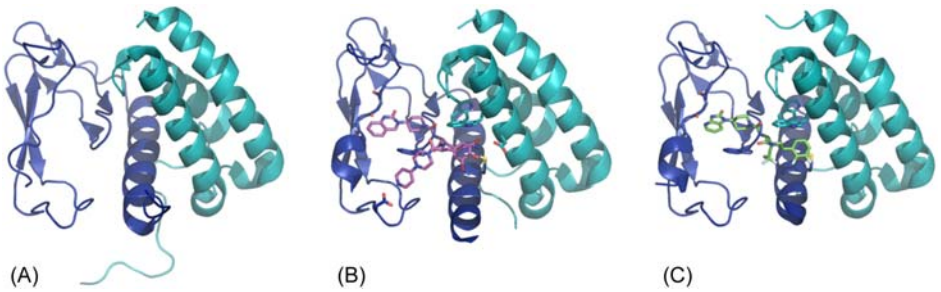

Fig. 5 Crystal structures of CLR–RAMP1 ectodomain complexes depicted as ribbon diagrams.[76] CLR *(blue)* and RAMP1 *(teal)* are shown as (A) unliganded (PDB ID 3N7P), (B) complexed with olcegepant *(magenta)* (PDB ID 3N7S), and (C) complexed with telcagepant *(green)* (PDB ID 3N7R).

The crystal structure of the unliganded CGRP-R ectodomain complex is shown in Fig. 5A. The ECD of CLR (shown in blue) exhibits some features that are similar to known structures of the ECDs of other family B GPCRs, such as those of the parathyroid hormone (PTH) receptor[77] or gastric inhibitory polypeptide (GIP) receptor.[78] Common features in these GPCR structures include a helix (residues 35–53 in CLR) and a finger-like structural motif (residues 65–81 in CLR) that is stabilized by a pair of disulfide bonds.[76] The RAMP1 ectodomain (shown in teal) contains a three-helix bundle, and two of these helices pack against the *N*-terminal helix in CLR in a perpendicular fashion, forming an interface at which multiple interactions that apparently stabilize the CLR–RAMP1 heterodimer occur. The overall structure of the RAMP1 ECD reported by ter Haar et al. is similar to a previously described crystal structure of the RAMP1 ECD alone.[79] The structures of other family B GPCR ectodomains, for example, the PTH1 receptor and the GIP receptor, have been reported as complexes with their respective endogenous ligands (PTH and GIP), in which the peptides bind in a helical conformation.[77,78] Based on the similar overall structure of the CLR ECD, the Vertex group suggested that the CGRP peptide might bind in the pocket formed at the interface between CLR and RAMP1.[76] This binding mode would place the peptide ligand close to residues that have been shown to be important for the interaction of CGRP with its receptor by mutagenesis studies.[59]

7.05.2.3 CGRP Receptor Antagonist Binding

Since the description of the first small-molecule CGRP receptor antagonists, there has been speculation about how they were able to block the binding of a 37-amino acid peptide, and a basic model for their action was developed (Fig. 4). It was recognized that many of the small-molecule antagonists possessed some common features, including a terminal cyclic amide or urea moiety that appeared to be a crucial element in the so-called "privileged structure"[80] found in these molecules (Fig. 6). In both olcegepant[81] (**12**) and telcagepant[82] (**13**), for example, a bicyclic *N*-aryl urea at one end of the structure was known to be critical for potency (Fig. 6).

The Vertex team revealed how these privileged structures and other key moieties contribute to binding to the CGRP-R when they solved the crystal structures of the CGRP ECD complex bound to both olcegepant (**12**) and telcagepant (**13**) (Figs. 5 and 7).[76] These structures demonstrated how a small molecule could bind to and antagonize a family B GPCR (Fig. 7). In the crystal structures of the complexes with **12** and **13**, the privileged structure amide moiety is involved in hydrogen-bonding interactions with the backbone elements of CLR Thr122.[76] Additionally, these structures revealed the important role of several residues that have been shown to function in antagonist binding by mutagenesis studies.[67–70] For example, CLR Met42, RAMP1 Trp74, and RAMP1 Trp84 contribute to the formation of a hydrophobic pocket at the interface of the two proteins. In the crystal structures of the complexes, this pocket

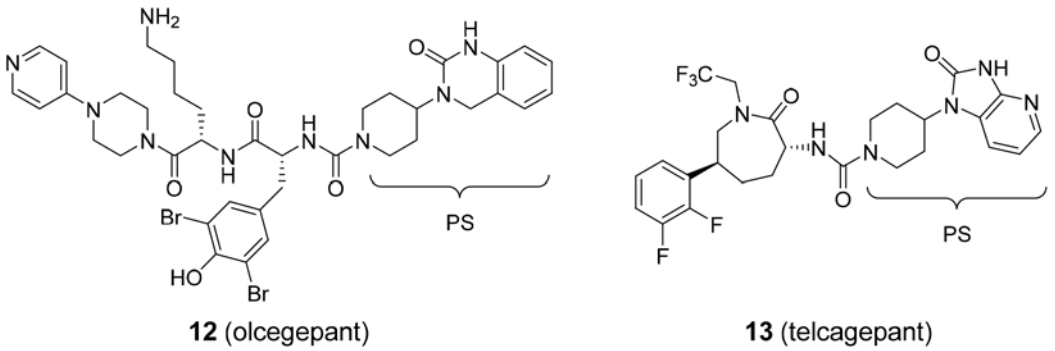

Fig. 6 Structures of olcegepant and telcagepant showing the privileged structure (PS) moiety in each.

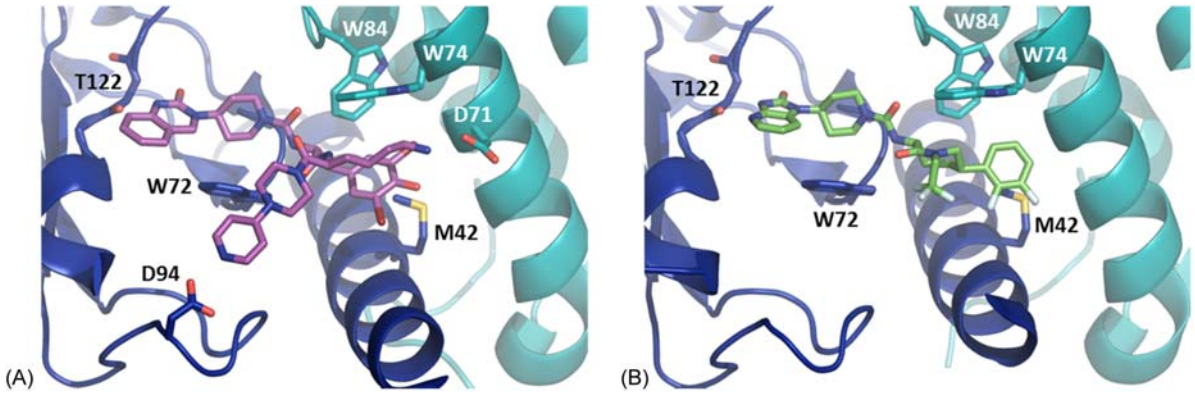

Fig. 7 Crystal structures of the CLR–RAMP1 ectodomain complexes with small-molecule antagonists bound.[76] View of small-molecule antagonist binding site formed by CLR *(blue)* and RAMP1 *(teal)* complexed with (A) olcegepant *(magenta)* (PDB ID 3N7S) and (B) telcagepant *(green)* (PDB ID 3N7R). Side chains of selected residues involved in antagonist binding are shown and labeled in *black* (CLR residues) or *white* (RAMP1 residues).

accommodates aromatic rings in the antagonists that contribute significantly to receptor affinity: the dibromophenol in **12** and the difluorophenyl ring in **13**. Other residues appear to interact with the antagonists in these complexes, notably CLR Trp72, which stacks against the piperidine rings of the privileged structures and also forms a hydrogen bond from the indole NH to carbonyl groups in both **12** and **13**.[76]

The X-ray crystallography work also revealed that both **12** and **13** exhibit a similar binding topology, with an extended conformation that allows them to bridge a distance of about 18 Å from the Thr122 hydrogen bonding interactions with the privileged structure to the hydrophobic pocket at the CLR/RAMP1 interface.[76] Overall, it appears that these small-molecule antagonists need to span this appreciable distance in order to effectively block binding of CGRP.[76] This observation is consistent with reported structure–activity data for analogs of olcegepant and telcagepant, which clearly reveal the importance of the hydrogen bond donor–acceptor pair in the privileged structure and the aromatic ring that binds in the hydrophobic pocket.[81,82] The requirement to bridge across this binding site, coupled with the apparent need for other hydrogen-bonding interactions, such as those with CLR Trp72, may explain why so many potent small-molecule CGRP-R antagonists are relatively large molecules with multiple amide groups. The nature of the antagonist-binding site therefore appears to favor these structures that, by their nature, do not conform to known guidelines for orally bioavailable drugs such as the Lipinski "rule of five."[83] This observation highlights the difficulty of designing orally acting compounds that target this family B GPCR.

Thus, the hydrophobic pocket at the interface of CLR and RAMP1 appears to be crucial for binding of antagonists, and the residues CLR Met42, RAMP1 Trp74, and RAMP1 Trp84 have been shown to affect antagonist-binding affinity and, in the case of RAMP1 Trp84, agonist potency.[67,84] One of these residues can also have a profound impact on the species selectivity observed for most small-molecule antagonists, which typically display much higher affinity for the CGRP receptors of primates compared with nonprimates.[62] This selectivity can make it difficult to achieve meaningful CGRP blockade in rodents, and consequently, nonhuman primate models have been developed to allow in vivo evaluation of CGRP-R antagonism. Examples include models based on facial flushing in marmosets[85] or capsaicin-induced dermal vasodilation in rhesus monkeys.[86] A team at Merck demonstrated that this species selectivity appeared to be controlled by a section of the RAMP1 protein, specifically by RAMP1 residue 74, which is Trp in most primates but Lys in rat and mouse. Interestingly, mutation of this residue in rat RAMP1 to Trp produced a mutant rat CGRP receptor with humanlike pharmacology.[68] The demonstration that a humanlike CGRP-R could be produced in rodents via a single-amino-acid substitution inspired studies that led to the production of transgenic mice with humanized CGRP receptors and such engineered animals could prove to be valuable tools for investigating the in vivo properties of CGRP and its receptor.[87]

7.05.3 Small-Molecule CGRP Receptor Antagonists

7.05.3.1 CGRP Receptor Antagonists From Boehringer Ingelheim

7.05.3.1.1 BIBN4096 BS

The first small-molecule CGRP receptor antagonist discovery effort was carried out by scientists at Boehringer Ingelheim (BI), and it was successful in demonstrating the first clinical proof of concept for CGRP receptor antagonism in the acute treatment of migraine with BIBN4096 BS (olcegepant, compound **12**).[81] A high-throughput screen against the human CGRP receptor expressed in SK-N-MC cells (a human neuroblastoma cell line) led to the identification of a dipeptide analog containing L-Lys and an unusual amino acid, D-3,5-dibromotyrosine (**14**, Fig. 8) as a weakly potent but verifiable hit ($IC_{50} = 17\ \mu M$). The related aniline (**15**) also showed some activity. The other three combinations of amino acid stereoisomers were inactive ($IC_{50} > 300\ \mu M$), fixing the stereochemical preference of the receptor for this chemotype. Related 3,5-dibromoanilines in the BI compound collection were

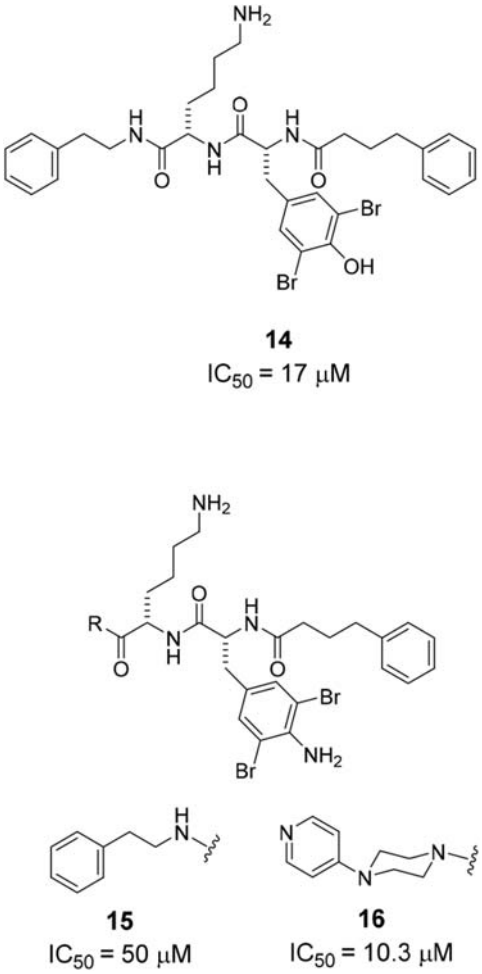

Fig. 8 Early lead structures in the development of olcegepant.

tested, and significantly better activity was seen for the constrained, heterocyclic *N*-4-pyridylpiperazine (**16**, $IC_{50} = 10.3$ μM). This Lys substituent was the mainstay of subsequent structure–activity relationship (SAR) and indeed remained in olcegepant.

Further SAR work was carried out using the somewhat more potent D-dibromotyrosine core. Table 3 shows the evolution of what became the first of a series of GPCR-privileged structures that confer specificity and potent antagonist activity against the CGRP receptor (*vide supra*). Some advantage had already been seen with ureas as *N*-terminal substituents, and methoxy-substituted phenethylamines **17** ($IC_{50} = 1000$ nM) and **18** ($IC_{50} = 200$ nM) brought activity down to the submicromolar level. Exploration of isosteric piperazine- and piperidine-constrained anisoles **19** ($IC_{50} = 226$ nM) and **20** ($IC_{50} = 250$ nM) maintained activity, while a presumably better hydrogen bond accepting cyclic urethane further enhanced CGRP receptor binding by fivefold (**21**, $IC_{50} = 44$ nM). Profound improvements in potency were realized by the further addition of a hydrogen bond-donating urea NH_2 (**22**, $IC_{50} = 4.7$ nM), incorporation of this into an imidazolone (**23**, $IC_{50} = 0.2$ nM), and ring expansion into a tetrahydroisoquinolone (**12**, BIBN4096 BS, olcegepant, $IC_{50} = 0.03$ nM). Olcegepant possesses higher affinity for the human CGRP-R than the endogenous ligand and is 150-fold more potent than the peptide antagonist $CGRP_{8-37}$. Compound **24** is comparably potent. However, the phenylimidazolone in **24** has been shown to be oxidatively unstable.[88] The BI scientists have not yet reported SAR for alternatives to the core amino acids, but it is surely notable that the L-Lys-D-dibromotyrosine portion of the screening lead remained in the compound that entered clinical trials.

BIBN4096 BS (Fig. 9) was shown to be a highly potent, full antagonist ($pA_2 = 11.1$) in a cyclic AMP (cAMP) assay in SK-N-MC cells. The compound is three log units less potent against rat and other nonprimate CGRP receptors ($IC_{50} = 6.4$ nM).[85] This is not seen with the peptide antagonist $CGRP_{8-37}$, but has been found to be a common feature among small-molecule CGRP antagonists. As described earlier, this divergence has been ascribed to the critical difference in hydrophobicity of residue 74 of the RAMP1 component protein of the CGRP-R, which for primates is Trp, while nonprimates have Lys or Arg.[68] Interestingly, BIBN4096 BS is reported to be a competitive antagonist at the human receptor, expressed in SC arteries, at low concentrations (c.0.01 nM), but noncompetitive at higher concentrations (0.1–1 nM).[89]

12		0.03
24		0.05

Aspects of the SAR leading to olcegepant can be better appreciated in the context of the Vertex CGRP receptor ectodomain X-ray structural studies, in which the compound was cocrystallized with the protein complex (Fig. 10).[76] As expected, since the compound spans a portion of the interface between CLR and the RAMP1 protein, it binds in a highly extended state, covering about 18 Å. The GPCR-privileged tetrahydroisoquinolone urea, which has been postulated to mimic the C-terminal Phe-NH_2 of the CGRP peptide,[90,91] forms highly optimized donor–acceptor-pair hydrogen-bonding interactions with the Thr122 carbonyl and NH. This structural picture makes it easier to understand the evolution of the pharmacophore comparing, for example, compound **21** (Table 3; no hydrogen bond donor, $IC_{50}=44$ nM) with compound **23** (Table 3; benzimidazolone NH, $IC_{50}=0.2$ nM). Further significant improvements in potency were then achieved as the aryl ring was further extended into a largely lipophilic pocket with olcegepant ($IC_{50}=0.03$ nM) and compound **25** ($IC_{50}=0.05$ nM).

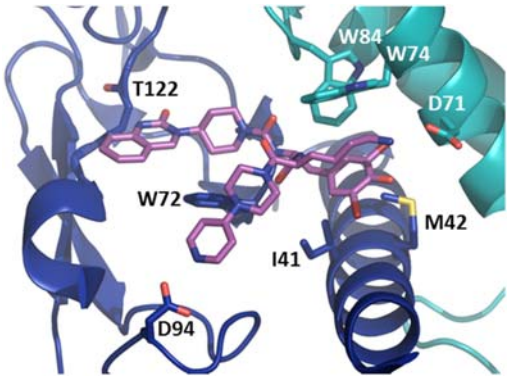

Fig. 9 Crystal structure of the CLR–RAMP1 ectodomain complex with olcegepant (compound **24**) *(magenta)* showing the binding site formed by CLR *(blue)* and RAMP1 *(teal)*.[76] Side chains of selected residues involved in antagonist binding are shown and labeled in *black* (CLR residues) or *white* (RAMP1 residues).

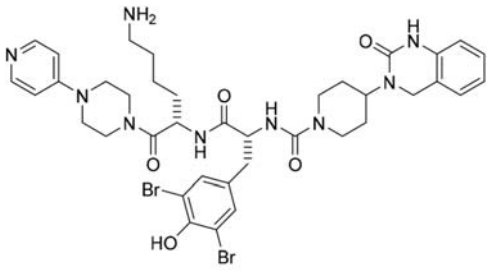
The importance of the Trp74 residue of RAMP1 for binding of compounds like olcegepant to the primate CGRP-R is illustrated in Fig. 10, where, as discussed earlier, it forms a hydrophobic pocket, along with RAMP1 Trp84, CLR Met42, and CLR Ile43, which interacts with the dibromotyrosine side chain and the alkyl portion of the lysine. Replacement of RAMP1 Trp74 with Lys or Arg would remove the lipophilic ceiling to this pocket and significantly alter the electrostatic environment.

Olcegepant has been used as a biochemical tool compound in numerous studies that have elucidated the mechanisms and consequences of CGRP receptor antagonism.[92] In order to differentiate it from the triptans as a "nonvasoconstricting" antimigraine agent, olcegepant was tested in ex vivo preparations of dog and human coronary arteries. In contrast to sumatriptan but in accordance with the expected mechanism of CGRP receptor antagonism, it was found to have no inherent vasoconstrictive properties.[93]

In a marmoset model of neurogenic vasodilation in which TGVS-mediated secretion of CGRP was induced by direct electrical stimulation of the trigeminal ganglion, IV-administered olcegepant was found to inhibit the resulting increases in facial blood flow (a surrogate marker for vasodilation) in a potent, dose-dependent manner with $ED_{50} = 3\ \mu g\ kg^{-1}$.[85] The compound was similarly tested in rats in both a facial blood flow and a intravital model. Electric stimulation resulted in dilation of the middle meningeal artery and cortical pial arterioles. However, olcegepant only caused a significant reduction in dilation of the former, which is not protected by the blood–brain barrier (BBB), suggesting a purely peripheral action of the compound.[94]

As might be expected for a fairly large (MW = 870) and highly polar molecule containing more than 10 hydrogen-bonding groups and several ionizable functionalities, olcegepant showed very low oral bioavailability in animals ($F_{PO} < 1\%$ in rat and dog) and was largely unbound by plasma proteins.[81] As a result, clinical proof of concept and safety studies were carried out using an IV formulation.

A phase I study in healthy volunteers specifically addressed the potential cardiovascular safety issues around CGRP-R antagonism. No significant changes in electrocardiogram, blood pressure, pulse rate, or forearm blood flow were seen with IV doses up to 10 mg.[95] Other phase I studies examined cerebrovascular effects of olcegepant (2.5 or 10 mg, IV) using brain imaging[96] and the ability of the compound (at a 2.5 mg dose) to prevent CGRP-induced headache in healthy volunteers.[97] Again, no undesired effects were observed. The compound effectively inhibited CGRP-induced headache in the 6 of 10 patients in which it manifested itself, and imaging appeared to confirm that pain relief, at least in this model, occurred without significant effects on major CNS blood vessels, including the middle cerebral artery.



12

Olcegepant (BIBN4096 BS)

Fig. 10 Olcegepant (BIBN4096 BS), the first CGRP antagonist to be tested in the clinic.

A multicenter, double-blind, randomized phase II clinical trial of olcegepant was carried out in 126 patients with migraine receiving placebo or total doses of 0.25, 0.5, 1.0, 2.5, 5.0, or 10.0 mg (IV, total dose) infused over a period of 10 min.[98] No serious adverse events were observed up to the highest dose. Mild paresthesia (8%) was the only significant adverse event reported. Mean maximal C_{max} levels were dose-proportional. Human V_d (20 L) generally reflects a highly polar molecule with limited bilayer membrane permeability. Total plasma clearance (C_L) was 12 L h^{-1} and terminal $T_{1/2} = 2.5$ h.

Two hours following a 2.5 mg dose, 66% of patients reported significant migraine pain relief. The therapeutic response was similar to that observed for oral triptans in previous clinical trials, though less than that reported for sumatriptan, dosed SC.[99] No further improvement in the primary or secondary end points was seen at higher doses, and no significant efficacy was seen at the next lower dose (1 mg). Patients treated with olcegepant also exhibited significant superiority over the placebo group with regard to most secondary end points, including pain-free response rate at 2 h; rate of sustained response over 24 h; rate of headache recurrence; improvement in nausea, photophobia, phonophobia, and functional capacity; and time to meaningful pain relief. It is worth noting that a total plasma $C_{max} > 200$ nM appeared necessary for olcegepant ($K_i = 0.014$ nM) to demonstrate robust clinical efficacy. If indeed peripheral CGRP-Rs are the target for olcegepant, this may represent at least a 1000-fold required coverage over binding K_i. On the other hand, if the target receptors are on the abluminal side of the dilated blood vessels, then this may partly reflect a permeability barrier for the highly polar molecule. A further possibility involves the hypothesis that the blood–brain barrier is somewhat compromised during migraine attack. Olcegepant on its own would not be expected to be significantly brain-penetrant. However, a leaky BBB might allow a fraction of the compound in plasma into the CNS to act on central CGRP receptors. This is a controversial issue, and it has been argued that it is not necessary to invoke a leaky BBB in this regard and that if even a small fraction of the 200 nM total plasma olcegepant entered the CNS, it might be sufficient to act on central CGRP-Rs.[100] In May 2006, BI announced that it had discontinued development of olcegepant.[101]

From a marketing point of view, an injectable CGRP antagonist may be unlikely to be more than a niche product. There is evidence in the patent literature that BI had explored noninjectable formulations of olcegepant, most prominently a powder inhalation form.[102]

7.05.3.1.2 BI 44370

Further work at BI resulted in a small-molecule CGRP receptor antagonist, BI 44370 (compound **41**, **Fig. 16**),[88] which could be dosed orally, and that was tested in clinical trials for acute migraine.[103] However, published reports describing the evolution of this compound from olcegepant have not yet appeared. In their medicinal chemistry paper on the work leading to olcegepant,[81] the authors state that progress had been made on "novel CGRP antagonists of reduced size and structural complexity," perhaps implying that oral or at least non-IV dosing was a further goal of the program. In the published applications cited in that paper, some idea of the approaches tried can be gleaned from looking at the many examples prepared, even though no discrete biological data are provided. Selected exemplified compounds that show some of the structural variety explored are shown in **Figs. 11–14**. They demonstrate a clear focus on reducing polar surface area and suggest that alternative D-amino acids were investigated early on.[104] Not surprisingly, the Lys residue in olcegepant is missing from all but a handful of exemplified compounds, and the central urethane NH is often replaced by a methylene[105] and later an oxygen.[106] Several series were investigated in which the entire C-terminal substituent and the carboxyl itself on the D-amino acid core were eliminated, with or without structural constraint.[107,108]

BI has disclosed two orally bioavailable CGRP receptor antagonists that were in late-stage phases of preclinical development.[88] The first, BIBP 5371 (compound **40**, **Fig. 15**), contains the succinimidyl diamide core seen in WO 2004037810 (**Fig. 14**) in place of the more polar ureidoamide in olcegepant and a chlorotrifluoromethylaniline replacing the dibromophenol. The tetrahydroisoquinolone portion of the olcegepant GPCR-privileged structure, which was found to be prone to benzylic oxidation under fairly mild conditions[88], was subjected to ring expansion to a more lipophilic and presumably more stable benzodiazepinone.

Despite lacking the L-Lys portion of olcegepant, BIBP 5371 suffered only a fourfold reduction in binding potency ($K_i = 0.14$ nM), while oral bioavailability was greatly improved compared with olcegepant (for BIBP 5371, rat $F_{PO} = 43\%$, dog $F_{PO} = 22\%$, and rhesus monkey $F_{PO} = 19\%$). Unfortunately, toxicological studies demonstrated species-dependent phospholipidosis that was significant enough to halt development based on fears of potential organ damage. In response, an in vitro assay was developed to measure intracellular phospholipid content in a U937 cell line challenged with 12.5–400 μM compound concentrations.

Further optimization led to BI 44370 (compound **41**, **Fig. 16**),[88] containing an amidourethane core and a dimethylphenol residue. The *N*-methylpiperazine of BIBP 5371 that presumably contributes to its phospholipidosis activity was replaced by a less basic morpholine ($pK_a = 6.5$). BI 44370 is 10-fold less potent against the human CGRP-R than olcegepant and showed somewhat poorer oral bioavailability than BIBP 5371 (rat $F_{PO} = 31\%$, dog $F_{PO} = 11\%$, and rhesus monkey $F_{PO} = 10\%$), but it did not cause phospholipidosis. In addition, the compound retained a fairly low degree of plasma protein binding ($f_u = 10\%$ and 13% for human and rat, respectively).

On the basis of its overall preclinical profile, BI 44370 was advanced to phase I clinical trials, where it was well tolerated.[103] Subsequent phase II efficacy studies were carried out with BI 44370 at three doses (50, 200, and 400 mg) in comparison with an active comparator, eletriptan (40 mg), and placebo, with the primary end point being pain freedom at 2 h. Only the 400 mg dose showed significant superiority in response rate compared with placebo (27.4% vs. 8.6%). The 200 mg dose showed a trend toward activity (21.5% response rate) that was statistically significant for some secondary end points, while the 50 mg dose was similar to placebo (7.8% response rate). The primary response rate for eletriptan in this study was 34.8%. The occurrence of adverse events at all doses of BI 44370 was similar to placebo, as was that of eletriptan at 40 mg. The current development status of BI 44370 is unknown.

7.05.3.2 CGRP Receptor Antagonists From Merck

7.05.3.2.1 Caprolactam-based CGRP receptor antagonists

The program to develop orally acting CGRP receptor antagonists at Merck started from the micromolar benzodiazepinone-based lead **42** (Fig. 17), which was identified in a high-throughput screen.[91] Compound **42** had modest binding affinity ($K_i = 4.8$ μM) and similar potency in a functional assay based on CGRP-stimulated production of cAMP in cells (cAMP $IC_{50} = 6$ μM).[91] It is worth noting that **42** was not an optimal lead for discovering an orally bioavailable drug: it had relatively poor ligand efficiency (LE = 0.18 kcal mol^{-1}) and a significant number of hydrogen bond donors and acceptors, which correlated with a calculated polar surface area that predicted poor passive permeability (PSA = 147 $Å^2$).[109] However, the structure was novel with respect to other

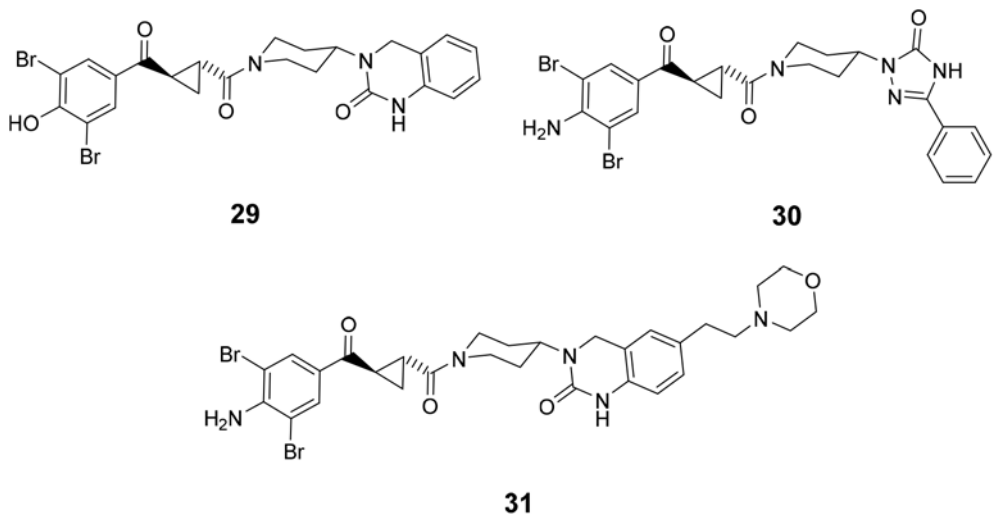

Fig. 12 Selected examples from WO 2001032648, published May 10, 2001.

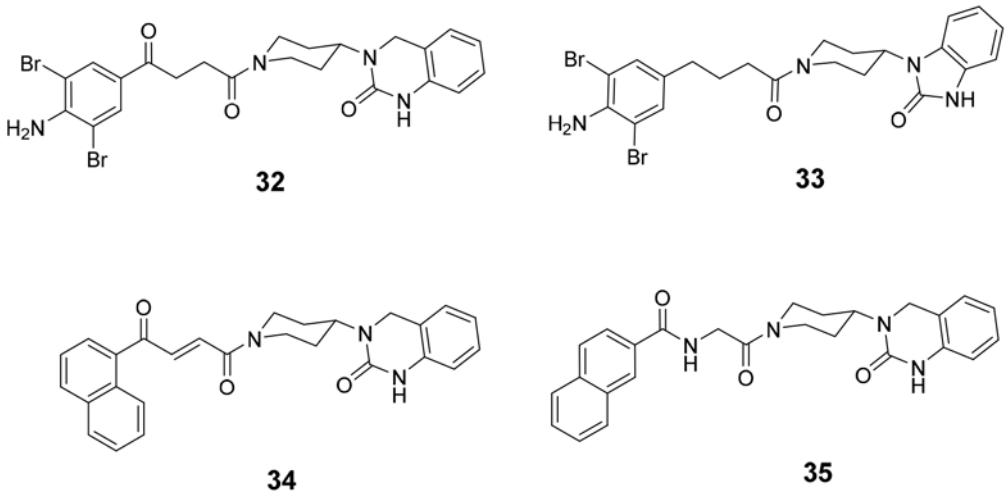

Fig. 13 Selected examples from WO 2001032649, published May 10, 2001.

CGRP receptor antagonists known at the time, many of which were based on a D-tyrosine backbone like the BI antagonist olcegepant (**12**), and the Merck team explored a number of approaches to optimize this benzodiazepinone lead.

One such approach was based on the hypothesis that the spirohydantoin moiety in compound **42** could be a "privileged structure" analogous to the piperidinyldihydroquinazolinone in olcegepant (**12**); both contained a secondary amide hydrogen bond donor–acceptor pair embedded in a heterocycle. To test this hypothesis, the 2-aminotetralin spirohydantoin in **42** was replaced with the piperidinyl-based privileged structure from **12** to provide compounds with similar receptor affinity to the high-throughput screen (HTS) lead.[91] The team built upon this encouraging result by discovering that replacement of the *N*-methyl substituent on the benzodiazepine with a trifluoroethyl group led to a nanomolar CGRP receptor antagonist (**43**, Fig. 17). This

hybrid antagonist **43** ($K_i = 44$ nM; cAMP $IC_{50} = 38$ nM) had modest oral bioavailability in rats ($F_{PO} = 10\%$) but represented a promising start to the quest for an orally acting agent.[91]

One drawback of the piperidinyldihydroquinazolinone privileged structure was that it was found to be chemically unstable. In analogy with the reported instability of **12** (*vide supra*), compound **43** was found to undergo oxidation of the quinazolinone benzylic site under mild conditions.[110] To address this liability, a survey of alternative piperidinyl-based privileged structures was undertaken, with an emphasis on quinazolinone replacements that eliminated the oxidation-prone benzylic position but maintained the hydrogen bond donor–acceptor pair. This study identified a number of alternative privileged structures, most notably the piperidinylazabenzimidazolone found in **44** ($K_i = 23$ nM; cAMP $IC_{50} = 49$ nM), which provided good potency and improved stability.[110] This privileged structure has been used widely in small-molecule CGRP receptor antagonist discovery.

In parallel with the effort to identify alternative privileged structures to the piperidinyldihydroquinazolinone in **43**, work to improve upon the benzodiazepinone portion of such compounds was underway. In general, the benzodiazepinone derivatives possessed poor pharmacokinetic properties with low oral bioavailability, and believing that poor solubility and high lipophilicity were in part to blame, the team sought to identify other scaffolds that could have improved physicochemical properties. One successful strategy was to replace the benzodiazepinone with a simple caprolactam and attempt to optimize the substitution and stereochemistry of this system.[111] This systematic investigation identified a (3*R*,6*S*)-3-amino-6-aryl substitution pattern as being optimal, to give antagonists like **45** (**Fig. 17**; $K_i = 25$ nM; cAMP $IC_{50} = 36$ nM), which had reduced MW compared with the earlier **43**.[111]

Combining the structural changes embodied in **44** and **45** led directly to compound **46** ($K_i = 11$ nM; cAMP $IC_{50} = 38$ nM), which exhibited significant oral bioavailability in rat and dog.[82] When the cell-based cAMP assay was conducted in the presence of 50% human serum, the potency of **46** shifted about ninefold (cAMP + HS $IC_{50} = 340$ nM), suggesting that plasma protein binding would lead to more modest in vivo potency. In order to improve CGRP receptor antagonist potency, an exploration of substitution around the caprolactam system was conducted.[82] Initial investigation of the C-6 position was conducted in the absence of a substituent on the caprolactam nitrogen atom, and this survey is summarized in **Table 4**. Replacement of phenyl with alkyl (e.g., isopropyl) or benzyl groups led to reduced CGRP-R affinity, as did incorporation of a pyridyl nitrogen to give **51** or **52**. A variety of substituents on the phenyl ring were explored, including hydroxy, methoxy, and methyl, but all such groups resulted in decreased in vitro potency with the exception of some halogen substituents.[82] Notably, 2-fluorophenyl (**56**, $K_i = 22$ nM) and 3-fluorophenyl (**57**, $K_i = 51$ nM) appeared to offer modest advantages over phenyl (**47**, $K_i = 83$ nM), and the combination of these two substituents

led to a 20-fold increase in affinity in the 2,3-difluorophenyl analog (**58**, $K_i = 3.4$ nM). This modification along with a trifluoroethyl substituent on the caprolactam nitrogen, which provided a good balance of potency and pharmacokinetics, led to telcagepant (MK-0974, **13**, Fig. 17), which had significantly improved binding affinity for the human CGRP-R ($K_i = 0.77$ nM) compared with compound **46**.[82]

Telcagepant (**13**) was also found to have high binding affinity for the rhesus monkey CGRP-R ($K_i = 1.2$ nM) but significantly lower affinity for nonprimate CGRP-Rs, such as those from dog ($K_i = 1200$ nM) or rat ($K_i = 1190$ nM).[112] Telcagepant was highly selective, demonstrating little to no affinity for human AM receptors AM_1-R and AM_2-R and >10,000-fold selectivity against a panel of over 160 receptors, enzymes, and transporters.[82,112] Studies with the radiotracer [^{3}H]telcagepant demonstrated saturable and reversible binding to native human CGRP-R in SK-N-MC cell membranes ($K_D = 1.9$ nM), and the radioligand could be displaced in competition binding studies by both agonist CGRP and antagonist $CGRP_{8-37}$.[113] In kinetic binding studies, the off rate of [^{3}H]telcagepant was found to be 0.51 min^{-1} with a half-life of 1.3 min.[113]

The published crystal structure of telcagepant bound to the ectodomain CGRP-R complex revealed the details of how this orally bioavailable small molecule is able to block binding of the 37-amino acid agonist CGRP to its receptor (Fig. 18).[76] Although telcagepant is significantly smaller than olcegepant, they exhibit similar binding topology, spanning approximately 18 Å from the CLR Thr122 hydrogen bond donor–acceptor site to the hydrophobic pocket that accommodates the difluorophenyl ring of telcagepant. The key azabenzimidazolone ring in the privileged structure of telcagepant is involved in hydrogen-bonding interactions with the backbone amide nitrogen and carbonyl of CLR Thr122, and the piperidinyl moiety forms an edge-to-face stack with CLR Trp72, while a weak hydrogen bond is apparent between the CLR Trp72 indole nitrogen atom and the carbonyl of the caprolactam ring.[76] The caprolactam trifluoroethyl substituent of telcagepant makes a significant hydrophobic interaction with the side chain of CLR Ile41, and the difluorophenyl ring binds in the previously described hydrophobic pocket, making productive interactions with both RAMP1 Trp74 and RAMP1 Trp84. Interestingly, the difluorophenyl ring of telcagepant binds deeper in this pocket than the dibromophenol ring of olcegepant and appears to be closer to CLR Met42, consistent with published data that revealed telcagepant to be more sensitive than olcegepant to mutation of this methionine residue.[70] It was hypothesized that enhanced binding to this hydrophobic pocket in combination with an additional hydrogen bond from the azabenzimidazolone group led to the increased ligand efficiency of telcagepant compared with olcegepant.[76]

In the functional cAMP assay, telcagepant was a potent antagonist of human CGRP-R (cAMP $IC_{50} = 2.2$ nM), and this functional potency shifted fivefold in the presence of 50% human serum (cAMP + HS $IC_{50} = 11$ nM).[112] This shift suggested a significant degree of plasma protein binding, and experimental results were consistent: human plasma $f_u = 4.1\%$. Because of the pronounced species selectivity of telcagepant and other small-molecule CGRP receptor antagonists, in vivo potency was assessed in nonhuman primates using the rhesus monkey capsaicin-induced dermal vasodilation (CIDV) model.[86] In this model, capsaicin is applied to the forearm of an anesthetized rhesus monkey, causing local CGRP release and vasodilation of dermal blood vessels. The resulting increase in blood flow is quantitated using laser Doppler imaging, and this effect may be blocked by a CGRP receptor antagonist, allowing the in vivo potency of the compound to be measured. Importantly, this noninvasive pharmacodynamic assay could be translated to the clinic, providing a direct link between the preclinical and clinical studies on a compound.[114] In the rhesus monkey CIDV assay, telcagepant blocked the effects of CGRP with EC_{50} and EC_{90} values of 127 and 994 nM, respectively.[112] The fact that the in vivo EC_{50} (127 nM) is about 10-fold higher than the in vitro serum-shifted IC_{50} (11 nM) suggests that a higher level of CGRP receptor occupancy is required to block the CIDV signal in vivo compared with the level of occupancy required to block cAMP production in cells.

[c]Compound dosed IV in DMSO vehicle.

The preclinical pharmacokinetic properties of telcagepant are summarized in Table 5. The compound had low to moderate plasma clearance and short plasma half-lives in rat, dog, and monkey.[115,116] Although this profile was indicative of a relatively short plasma half-life in humans, this was not considered a liability for acute treatment of migraine. While telcagepant had good oral bioavailability in rat (F_{PO} = 22%) and dog (F_{PO} = 35%), the oral bioavailability in rhesus monkey was low and not dose-proportional: after oral dosing of monkeys, the area under the curve (AUC) was found to be 0.48 μM · h after a 5 mg kg^{-1} dose but 42 μM · h after a 30 mg kg^{-1} dose.[116] Further studies indicated that saturable, intestinal first-pass metabolism contributed to the low oral bioavailability and nonlinear oral pharmacokinetics in rhesus monkeys.[116] Overall, the preclinical studies on telcagepant revealed it to be a potent and selective orally bioavailable CGRP receptor antagonist and it was selected as the first orally acting compound in this class to be advanced to clinical trials.

Initial studies on the pharmacokinetics and tolerability of telcagepant confirmed that it was orally bioavailable in humans, with a T_{max} of approximately 1–2 h and oral bioavailability of about 45–50% at clinically relevant doses.[117,118] Consistent with preclinical observations, oral administration of telcagepant produced greater than dose proportional increases in exposure.[118] After IV dosing, the terminal half-life of telcagepant was found to be 8–9 h.[118] Telcagepant was found to be generally well tolerated in these studies.[117,118]

One attractive feature of the rhesus monkey capsaicin-induced dermal vasodilation pharmacodynamic model was that, by virtue of its noninvasive nature, it could be readily translated into the clinical setting.[114] Assessment of telcagepant in this human CIDV assay after oral dosing determined that the human CIDV EC_{90} value was 909 nM, in excellent agreement with the preclinical value found in rhesus monkey (CIDV EC_{90} = 994 nM).[119] This PD assay, which translated predictably from the preclinical to the clinical setting, became a key tool for evaluation of subsequent compounds of interest.

In a phase II randomized controlled trial of telcagepant in acute treatment of migraine, seven doses of telcagepant (from 25 to 600 mg) were evaluated along with placebo and an active comparator—rizatriptan (10 mg).[120] For the primary end point of pain relief at 2 h, doses of 300 mg (68.1%) and 600 mg (67.5%) of telcagepant were superior to placebo (46.3%) and similar to rizatriptan (69.5%), indicating that these doses of telcagepant were effective for the acute treatment of migraine.[120] Telcagepant was generally well tolerated, with a similar incidence of adverse events (AEs) to placebo in this study,[120] and it was subsequently evaluated in a number of phase III trials.

A placebo-controlled study of two doses of telcagepant (150 or 300 mg, administered using a liquid-filled capsule formulation) demonstrated that the 300 mg dose was effective as an acute treatment for migraine with efficacy comparable with that of zolmitriptan at 5 mg but with fewer associated AEs.[121] Another placebo-controlled phase III trial evaluated three doses of telcagepant (50, 150, and 300 mg) and showed that the 150 and 300 mg doses were effective in terms of pain relief and reduction of other symptoms, including nausea, photophobia, and phonophobia.[122] The 300 mg dose was slightly more effective than the 150 mg dose, and both were generally well tolerated, consistent with earlier reports.[122] Telcagepant was also shown to be effective for intermittent treatment of up to four migraine attacks.[123] A long-term tolerability study showed that telcagepant 300 mg (dosed using the 300 mg liquid-filled capsule or a bioequivalent 280 mg tablet formulation) was generally well tolerated when used for intermittent treatment of migraine for up to 18 months, with a lower incidence of drug-related AEs than rizatriptan at 10 mg.[124]

As already noted, CGRP receptor antagonists, in contrast to triptans, do not appear to cause direct vasoconstriction. This issue has been studied experimentally using human isolated coronary arteries, in which telcagepant was found to antagonize CGRP-mediated relaxation with a pA_2 value of 8.43,[125] consistent with other measures of its in vitro potency.[112] While zolmitriptan induced concentration-dependent contraction of these arteries, telcagepant produced no changes in their contractile tone at concentrations of up to 30 μM.[126] These preclinical studies suggest that CGRP receptor antagonists could offer improved cardiovascular safety compared with triptans.[125] A number of clinical studies have examined the cardiovascular safety profile of telcagepant, for example, in patients with stable coronary artery disease,[127,128] or stable angina,[129] and they have concluded that telcagepant was generally well tolerated in these patients. Other studies have indicated that telcagepant does not affect nitroglycerin-induced vasodilation in healthy subjects[130] and does not appear to have a hemodynamic interaction with sumatriptan.[131]

More recently, the results of studies examining the use of telcagepant for migraine prevention have been reported. In a placebo-controlled trial, telcagepant was administered twice daily at two doses (140 and 280 mg).[132] Unfortunately, this trial was terminated prematurely because a small number of patients were found to have elevated levels of liver transaminases, indicating a risk of hepatotoxicity. Although this study was not completed, the data obtained showed that in migraine patients, telcagepant reduced the number of headache days by 1.4 days per month compared with placebo, suggesting that a CGRP receptor antagonist could be useful for migraine prophylaxis.[132] In another placebo-controlled study conducted with more than 4000 female migraine

patients, telcagepant 140 mg was dosed once daily perimenstrually for seven days to evaluate the safety and efficacy of this treatment for headache prophylaxis.[133] Although telcagepant did not reduce monthly headache frequency, the incidence of perimenstrual headaches was lower with telcagepant compared with placebo. In this study, telcagepant was found to be generally well tolerated, with a similar incidence of AEs for the drug-treated and placebo-treated patients. However, dosing of telcagepant was associated with a low incidence of liver transaminase elevations.[133] Based on an assessment of data across the clinical program, Merck announced that the development of telcagepant was discontinued.[134]

After telcagepant was selected as a clinical candidate, the Merck team sought to identify a compound that would have a lower projected clinical dose.[135] The team focused on improving both pharmacokinetic properties and potency in order to achieve this goal. One approach to improving pharmacokinetics that was explored was replacement of the caprolactam ring by a simpler and more rigid pyridinone, which was hypothesized to be less subject to oxidative metabolism.[136] A systematic exploration of substitution of the pyridinone core identified the optimal substituents for CGRP-R affinity as trifluoroethyl at the 1-position and 2,3-difluorophenyl at the 5-position, consistent with observations in the caprolactam series and leading to compound **59** (Fig. 19).[136] Although pyridinone **59** ($K_i = 17$ nM and cAMP $IC_{50} = 18$ nM) was not equipotent with telcagepant, it did exhibit improved pharmacokinetics in rat and dog, with low plasma clearances and longer half-lives (rat, $Cl_p = 0.8$ mL min^{-1} kg^{-1} and $T_{1/2} = 6.3$ h and dog, $Cl_p = 0.2$ mL min^{-1} kg^{-1} and $T_{1/2} = 3.3$ h).[136]

Another approach to reducing oxidative metabolism in compounds like telcagepant was modification of the piperidinyl-based privileged structure, which was known to undergo oxidative metabolism and *N*-dealkylation with loss of the azabenzimidazolone.[137] To address this potential liability, a number of novel privileged structures based on spiropiperidines were synthesized and evaluated. This study led to the identification of a number of interesting CGRP receptor antagonists with comparable potency to telcagepant, including **60** (Fig. 19, $K_i = 1.7$ nM and cAMP $IC_{50} = 3.3$ nM) and **61** (Fig. 19, $K_i = 1.1$ nM and cAMP $IC_{50} = 2.7$ nM), and as hypothesized, these compounds had reduced propensity for metabolism on the terminal ring of the spirocyclic system.[137] Combining the spirocyclic privileged structure from **61** with a fused imidazoazepane, designed to improve solubility, followed by optimization of the imidazole C5 substituent, led to preclinical candidate MK-2918 (**62**, Fig. 19).[135]

MK-2918 had high CGRP-R affinity ($K_i = 0.05$ nM) and was more potent than telcagepant in vitro (cAMP + HS $IC_{50} = 0.63$ nM) and in vivo (rhesus monkey, CIDV $EC_{90} = 300$ nM). MK-2918 had an excellent overall selectivity profile but modest oral bioavailability in rat, dog, and monkey ($F_{PO} = 5$–16%), in part because of significant formation of an active metabolite: the alcohol that results from *O*-dealkylation of the methyl ether. Further analysis suggested that this active metabolite should contribute significantly to clinical efficacy and the clinical dose was therefore anticipated to be lower than that of telcagepant.[135] On the basis of this lower projected dose and its overall profile, MK-2918 was selected as a preclinical candidate, but no clinical data for the compound have been reported.

7.05.3.2.2 Spiroindane-based CGRP receptor antagonists

As described, the initial approach to optimization of HTS lead **42** was to replace the aminotetralin part of the structure with a piperidinyl-based privileged structure, and this led to telcagepant and MK-2918. In a complementary approach, the spirohydantoin portion of **42** was retained and formed the basis of a screen for alternatives to the benzodiazepinone using a rapid analog strategy.[138] This approach quickly led to submicromolar lead structures that were modified to provide **63** (Fig. 20, $K_i = 21$ nM; cAMP $IC_{50} = 78$ nM), in which the benzodiazepinone was replaced with a simpler substituted benzimidazolone

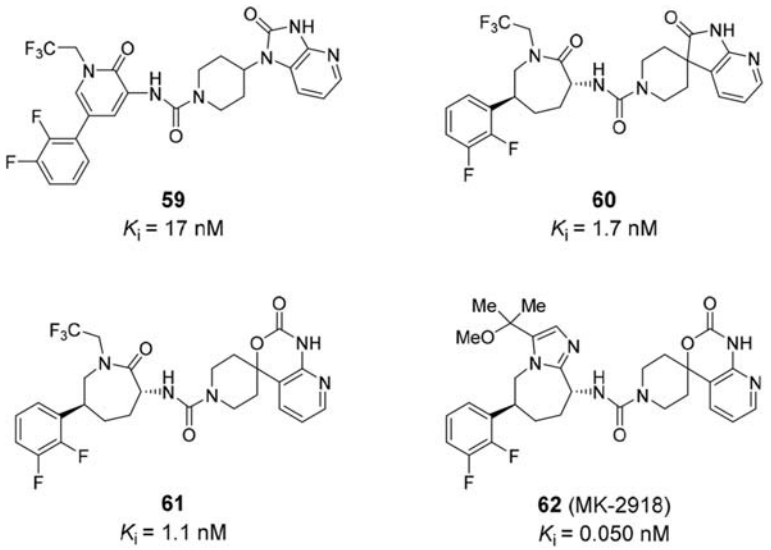

Fig. 19 Pyridinone and azepane CGRP receptor antagonists from Merck.

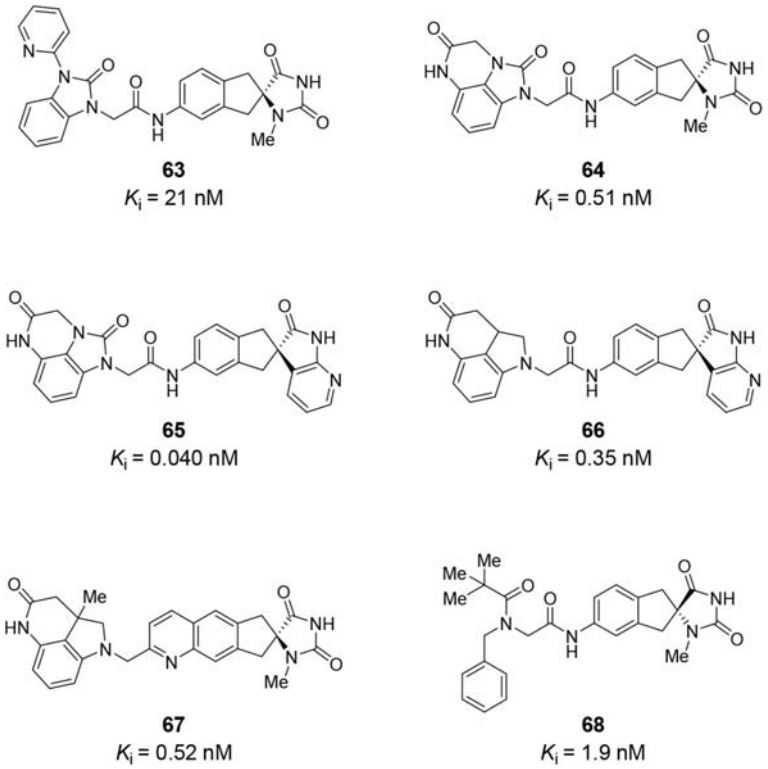

Fig. 20 Spiroindane-based CGRP receptor antagonists from Merck.

and the (*R*)-enantiomer of the spirohydantoin was preferred in terms of CGRP-R affinity.[138] Compound **63** had good oral bioavailability in rat, dog, and monkey (F_{PO} = 29–83%), and further optimization was directed at improving CGRP receptor antagonist potency.

An interesting approach to potency enhancement was realized when a glycine substituent on the benzimidazolone was constrained to give the tricyclic moiety found in **64** (Fig. 20; K_i = 0.51 nM and cAMP IC_{50} = 2.4 nM).[139] Compared to the pyridyl-substituted **63**, the tricyclic benzimidazolone conferred a 40-fold increase in CGRP-R affinity. Potency was enhanced further by rational modification of the spirohydantoin moiety based on analogy with the key role played by the azabenzimidazolone privileged structure in compounds like telcagepant. Specifically, the spirohydantoin was replaced with a spiroazaoxindole to give compounds like **65** (Fig. 20; K_i = 0.04 nM and cAMP IC_{50} = 0.28 nM), which was about 500-fold more potent than **63** in the radioligand binding assay.[140]

While **65** was a highly potent CGRP receptor antagonist, it was not orally bioavailable in rat or dog. In related compounds, it was observed that the probability of good oral exposure was significantly higher when the calculated PSA < 130 Å^2, suggesting that membrane permeability was a key limitation to absorption.[109,138] Compound **65** had a high PSA (149 Å^2) and low aqueous solubility (0.24 μg mL^{-1} at pH 7.4 for amorphous material), and attempts to improve both of these parameters led to indoline **66** (Fig. 20, K_i = 0.35 nM and cAMP IC_{50} = 2.4 nM).[141] Indoline **66** was about 10-fold less potent than benzimidazolone **65** in vitro, but it had reduced PSA (125 Å^2), and it was anticipated that the weakly basic indoline nitrogen would help to enhance solubility at acidic pH. Indeed, **65** was found to be orally bioavailable in rat, dog, and monkey (F_{PO} = 25–49%), consistent with the design hypothesis, and it had in vitro and in vivo potency that was similar to telcagepant.[141]

Another approach to reducing PSA in this series was to replace the central amide bond, and conformational analysis indicated that a quinoline-based central constraint may be a good mimic of the bioactive conformation of amides like **63**.[142] This hypothesis led to compounds like quinoline **67** (Fig. 20, K_i = 0.52 nM and cAMP IC_{50} = 2.2 nM), in which the spirohydantoin was reintroduced, in part to improve solubility.[142] Not only did this central constraint prove to be an effective mimic of the amide's bioactive conformation, but also it helped improve the pharmacokinetic profile, and **67** had good oral bioavailability in rat, dog, and monkey (F_{PO} = 38–59%).[142] Quinolines like **67** also served as inspiration for the design of compound **68** (Fig. 20, K_i = 1.9 nM), which resulted from a strategy of structural simplification to facilitate rapid exploration of SAR.[143] Intriguingly, the preferred stereochemistry of the spirohydantoin **68** had switched to (*S*) from (*R*) in earlier compounds like **63**, and this stereochemical change correlated, not surprisingly, with very different SAR for this new series.

Compound **68** had many positive attributes. It was a structurally simple CGRP receptor antagonist with nanomolar receptor affinity and good ligand efficiency (LE = 0.35 kcal mol^{-1}). For comparison, LE = 0.27 kcal mol^{-1} for olcegepant and 0.31 kcal mol^{-1} for telcagepant. However, it was not potent enough to have a low projected clinical dose, and it lacked optimal

selectivity for the CGRP-R over the AM_2 receptor (CLR/RAMP3): for **68**, AM_2/CGRP selectivity = 370-fold.[143] The early exploration of SAR in this new series established that fluoro substitution of the terminal phenyl ring increased CGRP-R affinity and selectivity against the AM_2 receptor. It was also discovered that the acyclic *N*-benzylpivalamide end group could be cyclized to give a substituted piperidinone ring. Combining these modifications with the potency-enhancing spiroazaoxindole replacement for spirohydantoin afforded the picomolar antagonist piperidinone **69** (Fig. 21, $K_i = 0.039$ nM and cAMP $IC_{50} = 0.16$ nM).[143]

The excellent receptor affinity of **69** was matched by good selectivity versus the AM_2 receptor (AM_2/CGRP selectivity = 4100-fold) and translated into very good cell-based functional potency in the presence of 50% human serum (cAMP + HS $IC_{50} = 0.35$ nM). Unfortunately, while it had moderate oral bioavailability in rat ($F_{PO} = 12\%$) and dog ($F_{PO} = 44\%$), it was not orally bioavailable in monkey ($F_{PO} = 0\%$), which precluded full evaluation of its in vivo pharmacology because such antagonists have significantly reduced potency at nonprimate CGRP receptors (*vide supra*).[144] It was thought that the low oral bioavailability in monkey was due in part to intestinal first-pass metabolism, in analogy with telcagepant. Since the piperidinone ring of **69** was known to be subject to significant metabolism in vitro, the team sought to incorporate polar functionality into this ring with the dual goals of reducing metabolism and increasing aqueous solubility. These design considerations led to morpholinones like **71** and piperazinones like **74** (Fig. 21 and Table 6).[144]

In analogy with the earlier caprolactam-based antagonists, a difluorophenyl substituent on the lactam ring led to increased CGRP receptor affinity (compare compounds **69** and **70** in Table 6), although in this context, a 3,5-difluorophenyl was preferred to 2,3-difluorophenyl.[143] This similarity suggested that the 3,5-difluorophenyl ring in compounds like **69** might be binding to the same hydrophobic pocket as the 2,3-difluorophenyl of telcagepant.

Incorporation of an oxygen atom to give a morpholinone ring produced compounds like **71**, which maintained the high receptor affinity of the corresponding lactam **70**. It was discovered that replacement of the geminal methyl substituents in **71** with the ethyl substituents in **72** led to improvements in the rat PK profile.[144] Addition of the potency-enhancing fluoro substituents afforded morpholinone **73**, which was highly potent ($K_i = 0.018$ nM and cAMP $IC_{50} = 0.32$ nM) and had superior oral bioavailability to lactam **69** in rat ($F_{PO} = 59\%$) and dog ($F_{PO} = 72\%$) but not in monkey ($F_{PO} = 0\%$).[144]

Piperazinone **74** was also potent ($K_i = 0.034$ nM and cAMP $IC_{50} = 0.17$ nM) and more soluble than the morpholinone, especially at acidic pH, and this correlated with at least measurable oral bioavailability in monkey ($F_{PO} = 7\%$).[144] The piperazinone series became a major focus for the team, and it was discovered that incorporation of geminal diethyl substituents on the piperazinone ring (compound **75**; Table 6) led to improved rat pharmacokinetics, in analogy with results for the morpholinone

antagonists. The importance of the difluorophenyl substituent to CGRP-R affinity of these piperazinones is illustrated by the spirocyclohexyl analogs **77** and **78**, in which inverting the C6 stereocenter from *R* to *S* leads to a potency loss of more than 30-fold (**Table 6**). The optimal balance of potency, selectivity, and pharmacokinetics in this series was obtained by replacing the gem dimethyl substituents on the piperazinone ring in **74** with a spirocyclopentyl ring, leading to MK-3207 (**76**) (**Fig. 21**, $K_i = 0.021$ nM), a picomolar CGRP receptor antagonist with oral bioavailability in rat, dog, and monkey.[144]

The high affinity and binding kinetics of MK-3207 were investigated using the [^{3}H]MK-3207 tracer, revealing that the K_D was 60 pM and that the higher affinity compared with telcagepant (**13**) ($K_D = 1.9$ nM) resulted from a reduced off rate (0.012 min^{-1}) and longer dissociation half-life (59 min).[145] MK-3207 had excellent cell-based potency (cAMP $IC_{50} = 0.12$ nM) that was slightly shifted in the presence of 50% human serum (cAMP + HS $IC_{50} = 0.17$ nM), consistent with a good unbound fraction in plasma. Interestingly, while the plasma unbound fraction of MK-3207 was similar in human ($f_u = 9.4\%$) and monkey ($f_u = 9.6\%$), it was significantly lower in rat ($f_u = 0.8\%$).[144] The high in vitro potency of MK-3207 translated to the in vivo CIDV monkey PD model, in which it was determined to have an EC_{90} value of 7 nM.[145] Based on these data, MK-3207 was about 50-fold more potent than telcagepant in vitro and approximately 100-fold more potent in vivo.

As expected, MK-3207 also had high affinity for rhesus monkey CGRP-R ($K_i = 0.024$ nM) but significantly reduced affinity for nonprimate CGRP receptors, such as those of rat ($K_i = 10$ nM) and dog ($K_i = 10$ nM).[145] The compound was found to have high selectivity for the human CGRP-R versus the related AM_1 (>600,000-fold), AM_2 (>6500-fold), and AMY_3 (>5000-fold) receptors but relatively low selectivity against the AMY_1 receptor (30-fold). When tested in a panel of 169 receptors, enzymes, and transporters, MK-3207 was found to >50,000-fold selective for human CGRP-R versus any of these other targets.[145]

The preclinical pharmacokinetic profile of MK-3207 is summarized in **Table 7**. In rat and dog, it had low plasma clearance and excellent oral bioavailability ($F_{PO} = 67$–74%). However, in rhesus monkey, the clearance was moderate, and the oral bioavailability was modest at low doses ($F_{PO} = 9\%$ at 2 mg kg^{-1}) but increased at higher doses ($F_{PO} = 41\%$ at 20 mg kg^{-1}), suggesting that saturable first-pass metabolism played a role, in analogy with telcagepant. The plasma half-life was short in all three preclinical species but compatible with acute treatment of migraine in the clinic. Overall, MK-3207 had an attractive profile in terms of potency, selectivity, and pharmacokinetics, and it was selected as a development candidate with the potential for a low clinical dose.[146]

Table 7 Preclinical pharmacokinetics of MK-3207

Species	Dose (mg kg^{-1})	F_{PO}[a] (%)	Cl_p[b] (mL min^{-1} kg^{-1})	IV $T_{1/2}$[b] (h)
Rat	10 (PO); 2 (IV)	74	11	0.6
Dog	2 (PO); 0.5 (IV)	67	8.0	1.0
Monkey	2 (PO); 0.5 (IV)	9	15	1.5

[a]Compound dosed PO in 1% Methocel vehicle.
[b]Compound dosed IV in DMSO vehicle.

MK-3207 was found to be orally bioavailable in humans with rapid absorption (T_{max} = 1–2 h) and a terminal plasma half-life after oral dosing of around 9–18 h.[147] The human CIDV PD assay was, once again, found to translate well from the preclinical setting, providing a human CIDV $EC_{90} \approx 14$ nM.[147] A detailed PK/PD analysis suggested that a 20 mg dose of MK-3207 would effectively block the CGRP receptor peripherally and that this dose should provide similar clinical efficacy to telcagepant.[147] In a placebo-controlled phase II study, seven doses of MK-3207 (from 2.5 to 200 mg) were evaluated with a primary end point of pain freedom at 2 h.[148] For this primary end point, doses of 10, 100, and 200 mg were found to be superior to placebo. It was not possible to conclude that the 200 mg dose was more effective than any dose from 10 to 100 mg, and 10 mg may have represented the plateau of efficacy,[148] a suggestion that is consistent with the PK/PD modeling.[147] Although MK-3207 was generally well tolerated in this study, in extended phase I clinical trials, delayed liver test abnormalities were observed, usually after cessation of dosing, and the development of MK-3207 was discontinued.[148] The observation of liver transaminase elevations with both telcagepant and MK-3207 raises the possibility that these effects could be mechanism-related. However, the patterns of clinical findings with telcagepant and MK-3207 were quite different from one another, suggesting that these effects may be specific to these compounds.[132]

The ability to evaluate CGRP receptor antagonists in a variety of rat and mouse models could provide key insights into the in vivo activity of CGRP and the consequences of inhibiting its actions. Unfortunately, the pronounced species selectivity observed with most small-molecule CGRP receptor antagonists presents significant challenges for evaluation of their in vivo pharmacology in rodents; most orally bioavailable antagonists are simply not potent at rodent CGRP receptors. MK-3207 offered some promise because, even though it was >400-fold less potent at the rat CGRP-R, it was still a nanomolar antagonist (K_i = 10 nM). Unfortunately, MK-3207 was significantly less potent as a CGRP receptor antagonist in vivo in the rat CIDV PD model (EC_{50} = 58 μM), and its low unbound fraction in rat plasma (f_u = 0.8%) was thought to contribute to this.[149] Based on these observations, the team tried to identify a potent rat CGRP receptor antagonist with reduced plasma protein binding.

It was known that the C-6 piperazinone stereocenter in MK-3207 could have a profound influence of plasma unbound fraction in rat and addition of a methyl substituent at this position led to a significant increase in rat unbound fraction.[144,149] This modification was combined with a spiroazaindane privileged structure to give MK-8825 (**79**, Fig. 21), which possessed improved unbound fraction (rat f_u = 23%) and nanomolar potency at the rat CGRP-R (K_i = 17 nM). MK-8825 was orally bioavailable in rat (F_{PO} = 28%) and had improved potency compared with MK-3207 in the rat CIDV model (EC_{50} = 7.4 μM).[149] Importantly, MK-8825 has been successfully used to study the effects of CGRP receptor antagonism in a number of rodent studies.[150–153]

Analogs of MK-3207 also proved to be useful starting points for development of a PET tracer to enable an assessment of central CGRP receptor occupancy (RO) with compounds like telcagepant. The high receptor affinity of MK-3207 was excellent, but its P-glycoprotein (P-gp) transport ratio (25) was far from optimal for a potential PET ligand. It was known that the C6 methyl substituent, in addition to increasing rat plasma unbound fraction, also led to reduced P-gp susceptibility, perhaps because of increased steric bulk that shielded the piperazinone amide moiety.[154] Substituting the piperazinone 4-position with another methyl group produced compound **80** (MK-4232, Fig. 21), which had attenuated P-gp efflux (transport ratio = 1.7) and appeared to achieve significantly higher CNS penetrance compared with MK-3207. This *N*-Me substituent also provided a convenient location for introduction of an ^{11}C-label to produce [^{11}C]MK-4232, the first PET tracer for the CGRP receptor.[154]

[^{11}C]MK-4232 has been used to address one of the key controversies in the field, whether CGRP receptor antagonists like telcagepant work in the periphery or the CNS, an issue that has been discussed in detail elsewhere.[42,155] The PET tracer allows a direct way to determine the extent of central CGRP receptor occupancy (RO) achieved by a clinically efficacious dose of a CGRP receptor antagonist. Administration of [^{11}C]MK-4232 to healthy volunteers revealed the highest level of tracer binding in the cerebellum, consistent with autoradiography experiments with [^{3}H]MK-3207.[145,156] The PET tracer was used to evaluate central CGRP RO achieved by two doses of telcagepant: the clinically efficacious dose of 140 mg and a supratherapeutic dose of 1120 mg.[156] Although the high dose produced moderate levels of occupancy (CGRP RO = 43–58%), the efficacious dose produced little or no central occupancy (CGRP RO ≤ 10%).[156] Even the level of occupancy achieved by the 1120 mg dose is unlikely to block the CGRP-R effectively, since orthosteric antagonists usually require high levels of occupancy to exert a therapeutic effect.[157] These results indicate that central CGRP-R occupancy is not necessary for antimigraine efficacy by a CGRP receptor antagonist and that the clinical results achieved are due to peripheral modes of action.[156] It is, of course, possible that greater antimigraine efficacy could be achieved by a compound that effectively antagonized the CGRP-R in both the periphery and the CNS. There have been reports of CGRP receptor antagonists with enhanced CNS penetrance, and the hypothesis could be tested directly if such a compound can be advanced into clinical trials.[158,159]

A number of other novel CGRP receptor antagonists have been reported by the Merck team. Attempts to incorporate a quinoline central constraint to replace the central amide in compounds like **69** (Fig. 21) led to a different substitution pattern compared with earlier quinoline CGRP receptor antagonists like **67** (Fig. 20). This initially unexpected result is exemplified by **81** (Fig. 22, K_i = 0.30 nM), and it was consistent with the change in stereochemical preference observed with this novel series of antagonists.[143,160] Related work in the same structural series described the replacement of the central amide with hydrocarbon linkers such as the (*E*)-alkene found in **82** (Fig. 22, K_i = 0.040 nM).[158] These compounds generally had reduced susceptibility for P-gp efflux, indicating the potential for making truly brain-penetrant CGRP receptor antagonists. For example, **82** was not a P-gp efflux substrate (transport ratio = 1.4) and was orally bioavailable in rat (F_{PO} = 51%).[158]

More recently, a series of oxazolidinone CGRP receptor antagonists, derived from MK-3207 via a scaffold-hopping approach, were described.[161] This work led to the identification of compound **83** (Fig. 22, K_i = 0.15 nM and cAMP IC_{50} = 0.15 nM), which

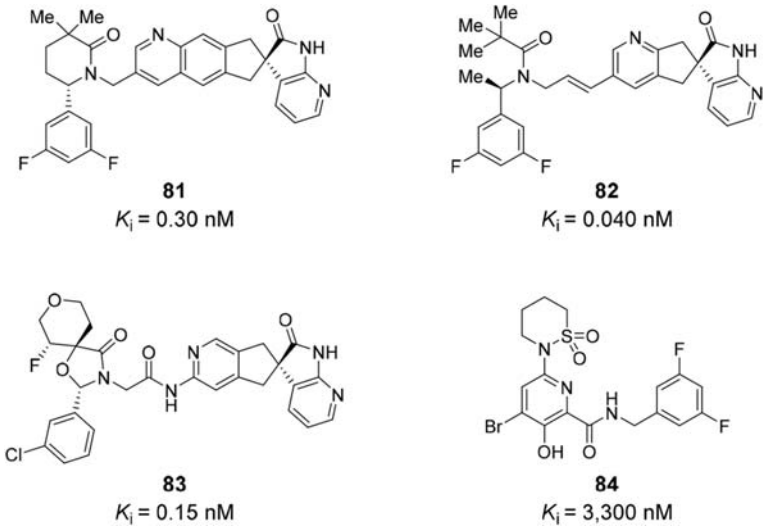

Fig. 22 Other CGRP receptor antagonists from Merck.

had excellent rat pharmacokinetics (F_{PO} = 100% and IV $T_{1/2}$ = 7 h) and in which the 3-fluoro substituent on the tetrahydropyran ring provided a substantial potency boost.[161]

All the Merck small-molecule CGRP receptor antagonists described herein were derived from the same HTS lead (**42**) and are believed to bind to the same site in the CGRP ECD as olcegepant and telcagepant. An interesting exception to this binding mode is compound **84** (Fig. 22; K_i = 3300 nM and cAMP IC_{50} = 2700 nM),[71] which was derived not from **42** but from the HIV integrase inhibitor L-870,810.[162] In contrast to other small-molecule CGRP receptor antagonists, the binding affinity of **84** was dependent upon the presence of a divalent cation such as Mg^{2+}, and **84** apparently interacts with transmembrane domain 7 in CLR and not with the ECDs of either CLR or RAMP1.[69,71]

7.05.3.3 CGRP Receptor Antagonists From Bristol–Myers Squibb

7.05.3.3.1 Intranasal BMS-694153

Researchers at Bristol–Myers Squibb began a small-molecule CGRP antagonist program attempting to improve the oral pharmacokinetics of published leads such as olcegepant and **85**[163] (Fig. 23) by balancing polarity and lipophilicity and reducing the number of rotatable bonds.

To this effect, a series of compounds based on D-benzothiophen-3-ylalanine were prepared to explore various spirocyclic GPCR-privileged components.[164] Selected examples are shown in Fig. 24 along with IC_{50} data from competition binding experiments with [^{125}I]CGRP against the human CGRP receptor expressed in SK-N-MC cells. In comparison with the compound containing the benzimidazolone (**86**) component used by BI and Merck, most of these compounds lose some degree of potency. Notably, there seems to be no preference for the location of the critical hydrogen bond-donating NH on either side of the carbonyl in dihydroquinolinone (**88**, IC_{50} = 23 nM) or dihydroisoquinolinone (**89**, IC_{50} = 29 nM). There is an enhanced effect of having two urea NH's (**91**, IC_{50} = 5 nM) that is not seen with the carbamate (**90**, IC_{50} = 20 nM). It appears that other spatial relationships, that is, between the aryl ring and the carbonyl (**92** and **93** vs. **88** and **89**), are more important for binding.

In general, the benzothiophenes showed good in vitro metabolic stability but poor Caco-2 cell permeability, possibly due to active efflux. Although compounds such as **91**, **86**, and **101** (Tables 8 and 9) demonstrated good CGRP binding affinity (for **101**, K_i = 0.55 nM), the chemotype presented an obvious liability with extremely potent CYP3A4 inhibition with the 7-benzyloxyresorufin (BZR) substrate (IC_{50} = 0.084 μM). SAR studies identified purely hydrophobic aromatic residues such as benzothiophene as being primarily responsible for this strong interaction. A number of benzimidazolone-containing analogs containing various D-amino acid side chains were prepared (Table 8).[165] It was found that CGRP-R binding potency and CYP inhibition did not track (**94** and **95**), and increasing polarity distal to the attachment point of the side chain residue resulted in reduced CYP3A4 inhibition (**96** vs. **94** and **98** vs. **97**, in particular).

With the more optimized quinazolinone GPCR-privileged component, the 5-substituted indazole (**102**, K_i = 0.23 nM) and benzoxazolone (**103**, K_i = 0.27 nM) were identified as attractive leads (Table 9).[166] Further SAR work showed that substitution at the 7-position with small, lipophilic groups such as methyl, ethyl, or chloro boosted CGRP-R binding potency into the picomolar range with compounds like **104** (K_i = 0.010 nM), **105** (K_i = 0.0050 nM), and **106** (K_i = 0.039 nM). It can be seen, however, that CYP3A4 inhibition is significantly increased with compound **105**, possibly due to shielding of the polar NH by the larger ethyl group. Interestingly, the nitrile group, not often considered highly polar, reduces the potency of **107** almost 300-fold in comparison with the 7-chloro compound, **106**.

Compound **104** represented an attractive lead, but this class of CGRP-R antagonists demonstrated poor oral bioavailability, most likely due to very limited absorption of these large (MW > 600), polar molecules. The BMS group therefore investigated IN delivery as an alternative and potentially more attractive mode of administering these compounds to treat migraine attacks.[167]

Traditionally formulated oral medications can require several hours before they reach effective concentrations in plasma or target tissues due to passage and absorption through the gut. For migraine, it would be greatly advantageous to have a convenient, faster-acting formulation. In principle, this not only would shorten the duration of headache pain but also, by aborting the attack in its early stages, might reduce its severity.[168] In addition, migraine-associated nausea can limit the effectiveness of oral delivery.[169] Injectable agents are generally fast-acting but are not yet convenient for individual patient use. IN delivery would seem well suited

for migraine treatment, given a compound with appropriate target potency and physical properties. Two triptans, sumatriptan (Imitrex®) and zolmitriptan (Zomig®), are available as IN formulations. The efficacy of sumatriptan nasal spray has been reported to be inconsistent, with patients showing the lack of tolerance for its unpleasant taste.[170] In contrast, zolmitriptan nasal spray has shown a rapid onset of action in comparison with oral triptans,[171] high response rates, and an improved tolerability profile, though "unusual taste," possibly a human sensory characteristic of the common tryptamine core, remains the most prominent adverse event.[172]

Compound properties necessary for IN delivery are somewhat different than for oral dosing, and the formulation options available for optimization are more limited.[173] The molecule must be very potent at the biological target because of the need to deliver a relatively small dose to the nasal cavity.[174] In addition, the compound must have very good aqueous solubility, as the

[c]Inhibition of recombinant human cytochrome P450 3A4 (CYP3A4) degradation of 7-benzyloxyresorufin (BZR) and 7-benzyloxy-4-trifluoromethylcoumarin (BFC).
[d]Aqueous solubilities from solid (for details, see aforementioned text).

maximum volume of liquid that can be delivered in each human nostril is only about 0.1 mL.[175] Despite the high degree of polar surface area that these properties imply, the compound must also show sufficient permeability at the nasal membrane.

The aqueous solubility of compound **104** (15 mg mL^{-1} at pH 5.0 from amorphous solid) was not sufficient to support intranasal dosing (Table 10). Interestingly, simple addition of a fluorine atom at C-8 of the quinazolinone (compound **108**, BMS-694153) had the dramatic effect of increasing aqueous solubility to >500 mg mL^{-1} from crystalline free base (pH 1.0–6.8) while preserving CGRP-R binding potency (K_i = 0.013 nM) and acceptable CYP3A4 inhibition (IC_{50} = 6.7 μM). The compound was shown to be a full antagonist at the human CGRP receptor in SK-N-MC cells (cAMP EC_{50} = 0.034 nM), highly selective (>10,000-fold) against related human AMY, AM, and CT receptors, but essentially inactive against the rat CGRP receptor.

In two ex vivo experiments using preparations of human intracranial arteries, BMS-694153 both reversed (EC_{50} = 0.06 nM) and prevented (K_b = 0.028 nM) CGRP-induced blood vessel dilation with potency comparable to its receptor activity. In contrast, BMS-694153 did not cause active vasoconstriction of ex vivo human coronary artery rings at concentrations up to 10 μM. In these experiments, sumatriptan produced concentration-dependent vessel contraction up to 59% of maximum (induced by addition of 10 μM serotonin) with EC_{50} = 311 nM. As a surrogate for the cardiovascular side effects seen with triptans, these results again suggest that BMS-694153 and other CGRP receptor antagonists may be free of the mechanism-based cardiovascular (CV) liabilities displayed by the triptans.

Along with the reduced risk of "triptan-like" cardiovascular liabilities predicted by the ex vivo blood vessel studies, BMS-694153 also showed a low likelihood for ion channel-mediated CV adverse events. At 30 μM, the compound produced 19% inhibition of human Ether-à-go-go-related gene (hERG) channel activity and showed minimal effect on sodium channel activity. In addition, BMS-694153 demonstrated no significant potential for other off-target liabilities in a broad panel of receptors, ion channels, and enzymes.

As a measure of in vivo efficacy, the BMS group employed a marmoset facial blood flow model similar to that used by BI. However, instead of electrical stimulation-induced CGRP release, α-CGRP was given IV (10 μg kg^{-1}) prior to and at three time points following SC dosing of BMS-694153. This allowed assessment of individual baseline response to CGRP and duration of in vivo inhibition by the antagonist. At a dose of 0.03 mg kg^{-1}, BMS-694153 demonstrated robust inhibition (>60%) of CGRP-induced increases in facial blood flow at 15, 60, and 105 min. At 0.01 mg kg^{-1}, 50% inhibition was observed at 60 and 105 min, while modest activity (c.30%) was seen at 15 min. No inhibition was seen at 0.003 mg kg^{-1}. Comparing exposure with efficacy, total plasma levels of approximately 10 nM were associated with robust activity in this model.

IN pharmacokinetics were assessed in the rabbit. When sprayed as an aqueous solution, BMS-694153 was efficiently absorbed from the nasal cavity. The IN bioavailabilities at 1.0 and 0.3 mg kg^{-1} were 59% (C_{max} = 1200 nM) and 55% (C_{max} = 360 nM), respectively with T_{max} occurring within 10 min for both doses, suggesting the potential for rapid onset of efficacy. When dosed IV (0.5 mg kg^{-1}), mean clearance was 13 mL min^{-1} kg^{-1}, volume of distribution (steady state) was 2.7 L kg^{-1}, and $T_{1/2}$ was 11 h. BMS-694153 also showed good bioavailability when dosed intratracheally (F_{IT} = 73%) and SC (F_{SC} = 43–100%, depending on the vehicle) in rats. Oral bioavailability in cynomolgus monkey and rat was very low (F_{PO} < 0.3%), probably due to active efflux and/or poor bilayer permeability (Caco-2 P_c < 15 nm s^{-1}). The compound at 10 μM demonstrated very low binding to plasma proteins from several species including human (f_u = 35–77%).

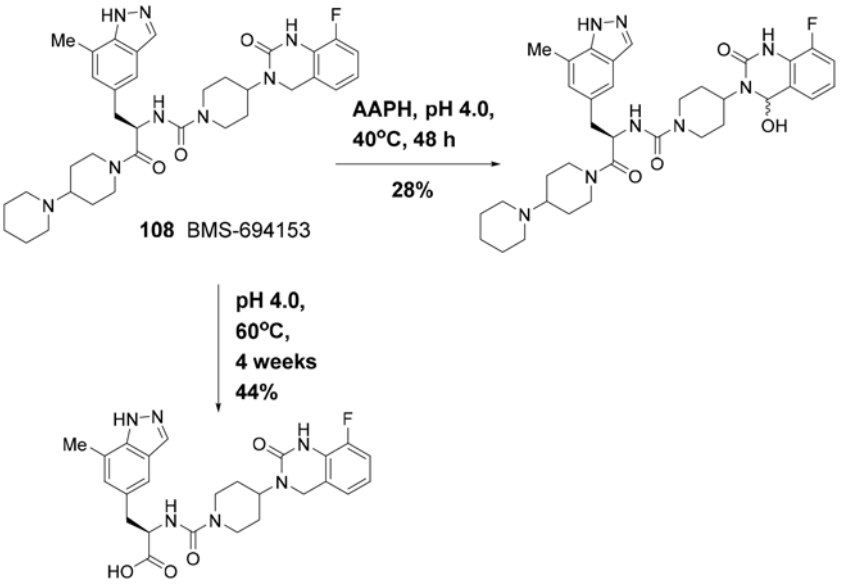

Fig. 25 Degradation pathways of BMS-694153.

7.05.3.3.2 Intranasal BMS-742413

Preclinical development of BMS-694153 was hampered by two issues: chemical stability and IN irritation.[176] Oxidative degradation of the fluorodihydroquinazolinone benzylic methylene group in aqueous solution occurred slowly, and this was accelerated by light. There was also some degree of hydrolytic instability of the carboxamide (illustrated in Fig. 25).[177] Nasal irritation and atrophy of the olfactory epithelium were observed in rat toxicological studies, and these issues were more difficult to design around since their cause was not well understood.

In order to address the chemical stability issue, the fluorodihydroquinazolinone in BMS-694153 was replaced by a 2-quinolone in **109** (BMS-742413, Fig. 26), effectively making a formerly sensitive, electron-rich position electron deficient and oxidatively stable. A second change was the inclusion of an additional protonatable nitrogen in the form of an *N*-methylpiperidinylpiperazine amide.

BMS-742413 ($K_i = 0.023$ nM) demonstrated binding potency that was comparable with BMS-694153 ($K_i = 0.013$ nM) and was a full antagonist at the human CGRP-R (cAMP $EC_{50} = 0.022$ nM). In the human ex vivo intracranial artery model mentioned earlier, the compound reversed and prevented CGRP-induced dilation with subnanomolar potency ($EC_{50} = 0.88$ nM and $K_b = 0.091$ nM, respectively).

BMS-742413 also showed robust activity in the marmoset facial blood flow model. At 0.03 mg kg^{-1} (SC), strong inhibition of CGRP-induced increases in facial blood flow was observed at 15 (48%), 60 (80%), and 105 min (70%). Total plasma levels from 15 to 105 min, associated with significant activity, ranged from 25 to 31 nM.

The inclusion of a second amino group may have mitigated any negative effect on solubility of exchange of the fluorodihydroquinazolinone with the quinolone. With a high-polar surface area (116 $Å^2$), BMS-742413 retained excellent aqueous solubility from crystalline material (105 mg mL^{-1} at pH 8.5 and >300 mg mL^{-1} at lower pH values) and low plasma protein binding (human $f_u = 37\%$). As a consequence, bilayer permeability (Caco-2 and parallel artificial membrane permeability assay (PAMPA))

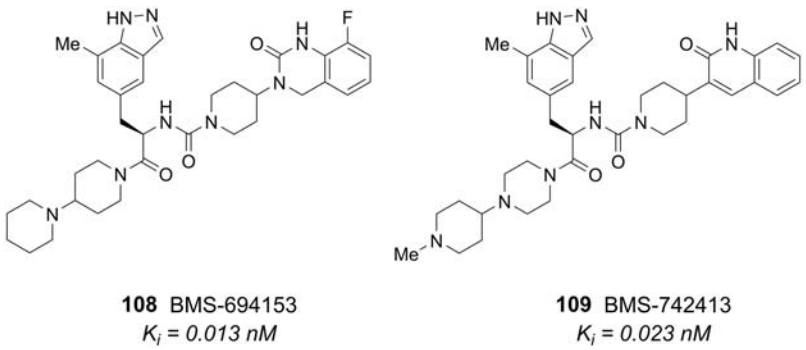

Fig. 26 Structures of BMS-694153 and BMS-742413.

was poor, and oral exposures in mouse and cynomolgus monkey were very low ($F_{PO}=1.4\%$ and 0.3%, respectively). In contrast, absorption of BMS-742413 in rabbit after IN dosing appeared to be rapid and quite efficient. Absolute bioavailabilities were found to be dependent on solution concentrations, with $F_{IN}=13\%$ at 10 mg mL^{-1} ($C_{max}=0.12$ μM) and $F_{IN}=30\%$ at 100 mg mL^{-1} ($C_{max}=2.0$ μM). T_{max} occurred within 20 min for each dose. The compound also showed excellent exposure in rat when dosed SC ($F_{SC}=82\%$). Despite the presence of two tertiary amines and two aromatic rings, but perhaps as a result of its high overall polarity, BMS-742413 caused a low degree of hERG inhibition in a patch clamp assay (9.5% and 22% inhibition at 10 and 30 μM, respectively).

Regarding the two issues that complicated development of BMS-694163, both the solution stability and toxicological profile of BMS-742413 were significantly improved. A 40 mg mL^{-1} solution in succinate buffer (pH 6, 40°C) showed only 0.3% degradation after 3 months. This may suggest that the protonated distal piperidine nitrogen in BMS-694153 intramolecularly activates the amide carbonyl toward hydrolysis and that neither of the two new protonatable nitrogens are properly placed to do this. The potential for off-target systemic toxicity was deemed low based on a 10-day rat study at doses up to 30 mg kg^{-1} day^{-1} (SC). The critical IN toxicity studies showed no significant findings at doses and volumes (75 and 175 mg mL^{-1} in 12.5 μL succinate buffer) matching those where BMS-694153 demonstrated irritation and olfactory epithelial atrophy. Importantly, the dosing volume used in rats was allometrically scaled from the human. At higher concentrations and volumes, dose-dependent irritation, including epithelial inflammation and atrophy, was seen, but these issues were markedly less severe than for BMS-694153. Overall, BMS-742413 represents a promising antimigraine agent that has the potential to provide rapid relief when delivered either IN or SC.

The BMS team also explored carbamates as core urea replacements in this chemotype, with the hope that they might be less susceptible to amide hydrolysis and that loss of the hydrogen bond donor would favorably modulate ADME properties.[177] As shown in Fig. 27, the carbamate backbone was highly tolerant to typical variations used by the BMS group in the GPCR-privileged structure component, with compounds **110**, **111**, and **112** showing CGRP-R potencies that were perhaps somewhat better than corresponding ureidoamides. In addition, even the simplified isoquinoline (**113**) demonstrated subnanomolar affinity ($IC_{50}=0.18$ nM).

A small set of amides that was also prepared showed nothing superior to the piperidyl-piperidine. However, the importance of the distal piperidine was emphasized by the simple piperidine amide, **114** (Fig. 28), which was 100-fold less potent ($IC_{50}=1.8$ nM).

The chemical stability of **112** was clearly superior to BMS-694153 under both the oxidative (97% remaining after 48 h) and hydrolytic (99% remaining after 4 weeks) conditions shown in Fig. 25. The latter result suggests anchimeric assistance of the backbone urea in the degradation of the ureidoamide. Compound **112** also possessed very good aqueous solubility (>50 mg mL^{-1} at pH 7.0 from amorphous solid).

7.05.3.3.3 Orally delivered rimegepant (BMS-927711)

The BMS group continued to try to optimize their lead structures for oral delivery. Further backbone modification of the carbamates to corresponding succinyl diamides again yielded compounds that showed potent, though somewhat diminished, hCGRP-R binding and antagonist activities.[178] As shown in Table 11, methylene substitution (compounds **115**, **116**, and **118**) resulted in a fairly consistent reduction in binding potency compared to either ureas or carbamates. Like the carbamates, potent compounds tested were full antagonists with potencies comparable to their binding affinities. However, the succinyl diamides had neither the aqueous solubility needed for intranasal delivery nor the inherent bilayer permeability (assessed in the PAMPA assay) that would justify testing for oral bioavailability.

Radical simplification of the GPCR-privileged component to minimize hydrogen bonding potential was explored using the BMS-694153 core (examples shown in Table 12).[180] In comparison with the simple phenylpiperidine (**119**), moderate binding potency was seen with compounds having a chloro substituent, perhaps a modestly polarizable mimic of the amide carbonyl oxygen, in the 2-position (**120**), or naphthylene (**121**), which is nearly isosteric with the quinolone and quinazolinone privileged structure components. Combining these two elements resulted in subnanomolar potency for chloronaphthylene, **122**, and for the corresponding cyanonaphthylene, **123**. Several of these compounds showed measurable but still modest PAMPA permeability, where the parent, BMS-694153, showed none at all. However, Caco-2 permeabilities remained poor, perhaps due to active efflux.

Another approach taken by the group was to constrain the D-amino acid side chain indazole with the C-terminal amide nitrogen into a cyclic structure that might approximate the CGRP-R binding conformation and reduce the number of rotatable bonds. This work remains unpublished except in the patent literature, and two examples reported to possess both hCGRP-R binding, and functional activities in the most potent category ($IC_{50} = 0.1–10$ nM) are shown in Fig. 29.

Since bilayer permeability of these compounds that contain multiple amide bonds was generally poor, the BMS group investigated replacement of the D-amino acid carboxy amide group with various heterocycles (**Fig. 30**). This approach typically involves using an sp^2 nitrogen that mimics the amide carbonyl oxygen and tends to rely on the heterocycle to provide additional lipophilicity and substitution vectors to further explore SAR. It is often used in neuroscience drug discovery as a means to improve CNS penetration of a given chemotype.[181]

A series of imidazoles were prepared that kept the 7-methylindazole side chain and the quinazolinone GPCR-privileged component constant and probed substitutions that would yield favorable target potency and significantly improve ADME properties.[182] Selected compounds are shown in **Table 13**. The diversity of substituents reported is limited but suggests that groups on the 2-nitrogen of the imidazole may be taking advantage of the mostly hydrophobic part of the receptor occupied by the pyridylpiperazine in olcegepant[76] and where the imidazole NH is certainly disfavored (**126**, $IC_{50}=97$ nM vs. **127**, $IC_{50}=4.8$ nM). Various fluoro-substituted benzyl analogs showed subnanomolar binding potency with favorable in vitro metabolic stability. However, unlike the IN compounds, these apparently had poor aqueous solubility. When the more polar pyridylmethyl derivatives were made, subnanomolar potency was again achieved, but metabolic stability was greatly diminished. The possibility that this was due to pyridyl *N*-oxidation was addressed by steric blocking with methyl (**134**, $IC_{50}=0.13$ nM) and both chloro and methyl (**135**,

$IC_{50} = 0.078$ nM). This failed to improve stability. Compound **135** demonstrated only modest PAMPA permeability (33 nm s^{-1} at pH 7.4) but was taken into a rat PK study where it showed high IV clearance and no detectable oral exposure at 1 mg kg^{-1}.

A further small set of imidazole carbamates was made to remove the core urea NH and more closely mimic the structure of the IN compounds (Table 14).[182] Hydrophobic groups such as cyclohexyl (**137**) and benzyl (**138**) again provided subnanomolar binding activity, with somewhat improved PAMPA permeability in the case of the former. However, in vitro metabolic stabilities were still too poor to justify progression.

More extensive work was done using pyridine as an amide bioisostere with its potential advantages such as somewhat higher lipophilicity and different substitution vectors (Fig. 31).[183] As with the intranasal compounds, ureas (**139**) and carbamates (**140**) were somewhat more potent than the corresponding amides (**141**). Unusually, for CGRP-R antagonists, reasonable Caco-2 permeability was observed for several modestly potent examples in the succinyl diamide series. However, these compounds did not show good oral exposure in rats, possibly due to poor metabolic stability (Table 15).

Attempting to incorporate protonatable nitrogens that might improve physical properties, the BMS group found that the 4-position on the pyridine was optimal. In Table 16, it is seen that moderate Caco-2 permeability can still be achieved with a highly potent piperidine analog such as **147**. Interestingly, the corresponding morpholine, **148**, suffers an eightfold loss of potency, suggesting that the ring is binding in a hydrophobic pocket. No oral exposure data are disclosed for these compounds, but they are reported to be rapidly metabolized in human and rat microsomes.

Further work led to a small set of 6-chloro, 4-*N*,*N*-dimethylamides in which the effect of the GPCR-privileged structure component was explored (Table 17). Only one of these highly potent compounds, the quinolone (**150**), showed significant Caco-2 permeability, and as with other compounds in this series, rat oral exposure was low (F_{PO} = 4.5%). It was noted that these compounds, in contrast to the intranasal agents discussed earlier, possessed poor aqueous solubility.[183] One compound, the azabenzimidazolone, **152** (IC_{50} = 0.071 nM), was tested in the marmoset facial blood flow model using oral dosing. Somewhat surprisingly, the compound showed moderate activity (31% inhibition of CGRP-induced increases in facial blood flow), albeit at a rather high dose (10 mg kg^{-1}).[184]

The failure to optimize physiochemical properties and achieve good oral exposure with CGRP-R antagonists containing the 7-methylindazole led the BMS group to combine several previous design approaches,[184] namely, cyclic constraint, a carbamate linkage to the GPCR-privileged component, the pyridine-amide bioisostere, and a 2,3-difluorophenyl ring, the hydrophobic residue used by the Merck group in telcagepant.[82] As mentioned earlier, a cocrystal structure of telcagepant with the CGRP-R ectodomain

[d]Rat oral bioavailability (dose and vehicle not reported).

showed the difluorophenyl ring to bind in the same pocket as the dibromophenol of olcegepant but, more deeply, displacing a bridging water molecule that formed a hydrogen bond to the latter.[76] Its lack of an obvious hydrogen bond donor was considered advantageous in the context of a chemotype that is still somewhat large (MW > 500) and rich in hydrogen-bonding groups. The resulting compound, **153** (BMS-846372, Fig. 32), showed very potent binding (K_i = 0.070 nM) and functional antagonist (cAMP IC_{50} = 0.22 nM) activities. As expected, the enantiomer of BMS-846372 was much less active (K_i = 920 nM).

In the marmoset facial blood flow model, the compound was dosed SC at 7 mg kg^{-1} and showed strong (52–60%) inhibition of CGRP-induced effects at 60 and 105 min post dose. Robust in vivo activity was associated with rather high total plasma levels of BMS-846372 (≥1000 nM), especially in comparison with the first intranasal compound, BMS-694153, where much lower levels (>10 nM) were similarly effective.[167] BMS-846372 binds to plasma proteins to a much greater extent (human f_u = 2.3%) than the intranasal compounds (human f_u > 30%), and this may be largely responsible for the difference. BMS-846372 showed good PAMPA permeability (800–1000 nm s^{-1}) and reasonable human microsomal stability ($T_{1/2}$ = 24 min). The compound

[d]Rat oral bioavailability (dose and vehicle not reported).

demonstrated good oral bioavailability in rat ($F_{PO}=29\%$), dog ($F_{PO}=34\%$), and cynomolgus monkey ($F_{PO}=38\%$), especially in comparison with previous program compounds.

Despite the significant improvement in oral exposure, development of BMS-846372 was hampered by poor physical properties. Crystalline solubility of the free base was very poor (<2 μg mL^{-1}), and salt formation with various acids led to hydrolysis of the carbamate linkage, presumably through activation by the protonated pyridine.[185] A search for positions on the core structure that were tolerant of helpful polarity led to synthesis of the *S*-hydroxyl derivative, **154** (**Fig. 33**), which showed activity comparable to the parent ($K_i=0.081$ nM) and was 50-fold more potent than the *R*-isomer (**155**, $K_i=4.3$ nM). As might be expected, **154** had a somewhat higher free fraction in human plasma ($f_u=4.1\%$), improved aqueous solubility (66 μg mL^{-1}, from amorphous solid), and better human microsomal stability ($T_{1/2}=70$ min).

Further optimization led to the corresponding amine, **156** (rimegepant, BMS-927711).[185] This provided even better binding potency ($K_i=0.027$ nM) and a higher human serum free fraction ($f_u=6.9\%$). As a result, the plasma protein-adjusted affinity of rimegepant was much improved over BMS-846372 (0.39 nM vs. 3.0 nM). Human microsomal stability was also superior ($T_{1/2}=83$ min vs. 24 min), but the most dramatic improvement was in aqueous solubility from crystalline material (50 μg mL^{-1} vs. <2 μg mL^{-1}).

Despite the addition of a primary amine, bilayer permeability of rimegepant was still reasonable, though with some expected pH dependency ($P_C=190$ nm s^{-1} at pH 5.5 and $P_C=320$ nm s^{-1} at 7.4). This suggests that steric crowding may mitigate the absolute polarity of the amino group. With this good balance of physical properties, oral exposures with solution dosing were quite good in

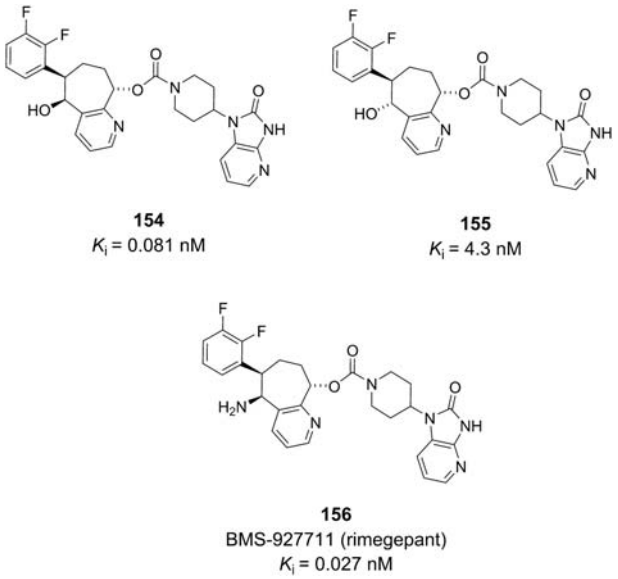

Fig. 33 Substituted analogs of BMS-846372 leading to rimegepant.

rat (F_{PO} = 45%) and cynomolgus monkey (F_{PO} = 67%). Indeed, even when dosed as a crystalline suspension, bioavailability in the monkey remained favorable (F_{PO} = 48%).

When dosed SC at 7 mg kg^{-1} in the marmoset facial blood flow model, rimegepant showed strong (>65%) inhibition of CGRP-induced effects at all time points 15, 60, and 105 min post dose. The magnitude of the effect at 15 min (c.65%), associated with total rimegepant plasma levels of 400 nM, was comparable with that seen with the more lipophilic BMS-846372 at 1900 nM and increased to c.80% at 105 min (total plasma levels c.800 nM). These observations were consistent with the higher intrinsic potency and f_u of rimegepant compared with BMS-846372.

A potential risk in incorporating an amino group into a lipophilic compound is blockade of various ion channels, leading to, among other things, cardiovascular liabilities. However, rimegepant caused <30% inhibition of the hERG potassium channel at 30 μM and had no significant effect on L-type sodium and calcium channels expressed in HEK293 cells. Against a panel of eight recombinant human CYP isoforms, the compound showed low levels of inhibition (IC_{50} > 20 μM, except for CYP3A4, where IC_{50} = 17 μM).

Limited further exploration was carried out on this chemotype (Fig. 34),[186] primarily by replacement of the core pyridine with pyrazine (**157**), thiazole (**159**), and 2-trifluoromethylthiazole (**160**). It is interesting that compound **158**, the urea analog of **157**, suffers a 10-fold loss in binding potency. Although the carbamates in this series demonstrated binding potency that was comparable to rimegepant, their microsomal stability was poor in comparison.

Based on its favorable overall profile and promising pre-IND toxicological study results, BMS decided to proceed with clinical development of rimegepant. Preclinical studies in the marmoset facial blood flow model in conjunction with multispecies pharmacokinetics suggested that a 75 mg oral dose in humans might be efficacious. In a phase I study in healthy subjects, a single 75 mg dose did indeed result in plasma levels ($T_{1/2}$ 10–12 h) commensurate with robust activity in the primate model (≥700 nM).[187] In addition, the compound was well tolerated up to 1500 mg as a single dose and at a daily dose of 600 mg for up to 14 days. Interestingly, food intake delayed T_{max} from 1 to 4 h, and famotidine (antacid) coadministration reduced C_{max} by 26% and AUC by 42%.

In a randomized, double-blind, placebo-controlled, dose-finding study, rimegepant was tested in 885 patients as an abortive migraine therapy at six single doses (10, 25, 75, 150, 300, and 600 mg).[188] High-dose (100 mg) sumatriptan was included as an active comparator. The primary end point was pain freedom at 2 h, with a number of secondary and exploratory outcomes, and safety evaluations. As predicted by the preclinical PK/PD studies, rimegepant was significantly superior to placebo (15.3%) at doses of 75 mg (31.4%), 150 mg (32.9%), and 300 mg (29.7%) and comparable to 100 mg sumatriptan (35%), in the 2-h pain freedom measure of efficacy (though the study was not powered to make direct comparisons with sumatriptan[189]). There were no serious adverse events in the trial, and the side effect profile was "placebo-like," with no marked pattern (unlike the triptans and ergot alkaloids).

7.05.3.4 Other Small-Molecule CGRP Receptor Antagonists

7.05.3.4.1 SmithKline Beecham and GlaxoSmithKline

The earliest reported small-molecule CGRP receptor antagonists were discovered by researchers at SmithKline Beecham.[190] A high-throughput screen identified quinine analog **161** (Fig. 35) as a micromolar antagonist of the CGRP-R: it displaced ^{125}I-CGRP from SK-N-MC cell membranes with an IC_{50} value of 5.9 μM and exhibited a functional IC_{50} value of 26 μM in a cell-based cAMP assay.

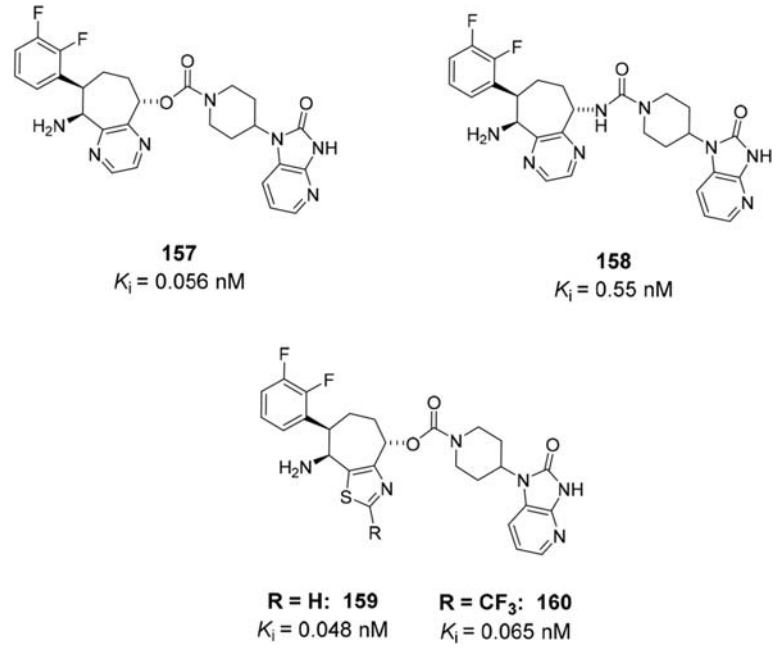

Fig. 34 Alternate heterocyclic analogs of rimegepant.

Limited SAR exploration demonstrated that the 4-chlorophenyl substituent was important for CGRP-R affinity. Compound **161** was also found to be selective for the human CGRP-R with respect to other receptors, including the AM receptor ($IC_{50} > 30$ μM).[190]

Another high-throughput screening lead identified at SmithKline Beecham was SB-211973 (**162**, Fig. 35), which exhibited activity in a binding assay with $IC_{50} = 1.9$ μM.[191] Optimization of this HTS lead led to a series of nitrobenzanilides exemplified by SB-(+)-273779 (**163**, Fig. 35), which had reduced molecular weight and improved in vitro potency: Binding $IC_{50} = 310$ nM; cAMP $IC_{50} = 390$ nM. Compound **163** was also shown to block CGRP-induced hypotension in rats at a dose of 10 mg kg^{-1} IV, although other data indicated that the compound may bind irreversibly to the CGRP-R.[191]

More recently, a group at GlaxoSmithKline focused on the development of novel, orally acting CGRP receptor antagonists.[192] They developed a pharmacophore model based on earlier reported small-molecule antagonists from Merck and BMS and used this to identify a novel series of oxadiazole-based antagonists represented by **164** (Fig. 35, cAMP $K_i \approx 13$ nM). Compound **164** reportedly had the most optimal balance of solubility and permeability in this series, and it exhibited oral bioavailability in rat ($F_{PO} \approx 14\%$) albeit with a delayed absorption profile that was considered suboptimal for acute treatment of migraine.[192]

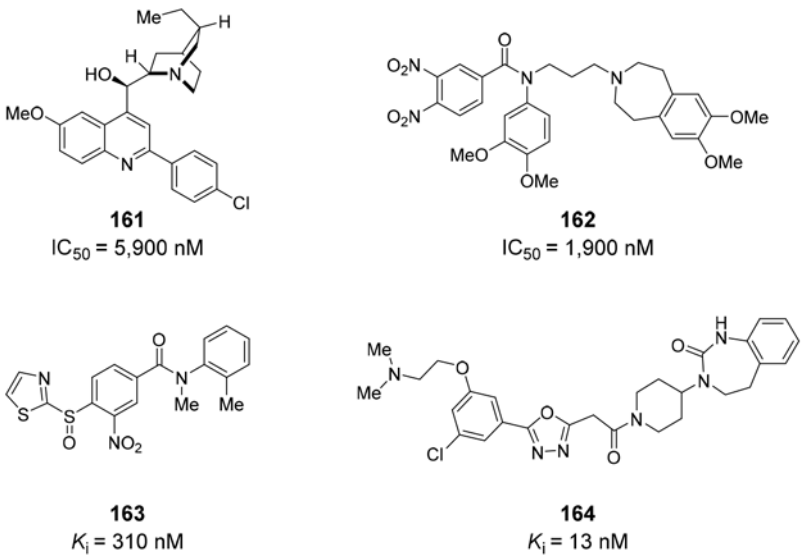

Fig. 35 CGRP receptor antagonists from SmithKline Beecham and GlaxoSmithKline.

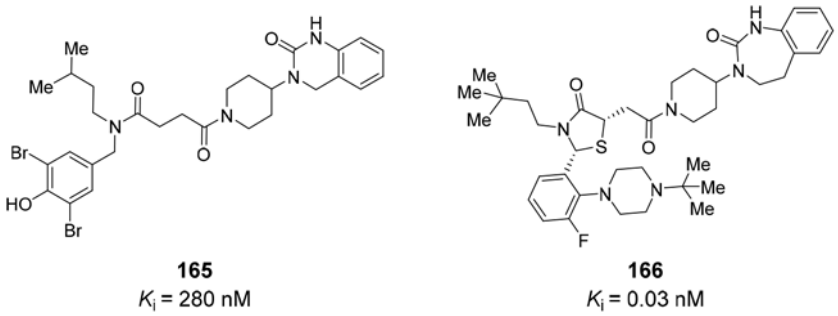

Fig. 36 CGRP receptor antagonists from Vertex.

7.05.3.4.2 Vertex

The Vertex CGRP program was focused on identifying potent, orally bioavailable CGRP receptor antagonists that, in contrast to olcegepant and telcagepant, would be CNS-penetrant.[159] Starting from truncated analogs of olcegepant, they identified **165** (Fig. 36, $K_i = 280$ nM) and optimized this flexible lead structure by incorporating conformational constraints. The most successful of these led to thiazolidinone **166** ($K_i = 0.03$ nM and cAMP $IC_{50} = 1$ nM), which was orally bioavailable in rat ($F_{PO} = 13\%$) and exhibited a moderate brain–plasma ratio (B:P = 0.51), suggesting that such compounds could be optimized to give potent, CNS-penetrant, orally acting receptor antagonists.[159]

7.05.3.4.3 Neurogen

Two patent applications from Neurogen claim small-molecule CGRP receptor antagonists: biaryl ketones such as **167**[193] and aryl amides such as **168**[194] (Fig. 37). A number of the aryl amide compounds were reported to have cell-based IC_{50} values of less than 2 μM. Interestingly, some of the claimed compounds appear to be similar to those claimed in patent applications from BI.[195,196]

7.05.3.4.4 Grünenthal

Grünenthal GmbH disclosed a series of cyclopentenone-based compounds with micromolar activity against the CGRP-R represented by **169** and **170** (Fig. 38).[197] The compounds are closely related to known inhibitors of cyclooxygenase-2[198] but have a dimethylaminomethyl substituent on the cyclopentenone ring. They were reported to functionally antagonize the CGRP receptor with IC_{50} values of 13 μM (compound **169**) and 32 μM (compound **170**).[197]

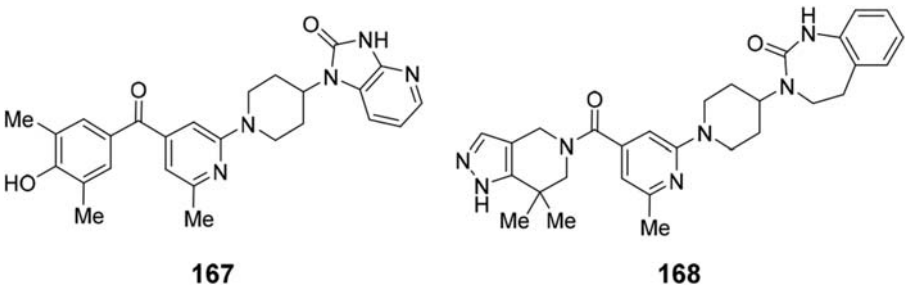

Fig. 37 CGRP receptor antagonists from Neurogen.

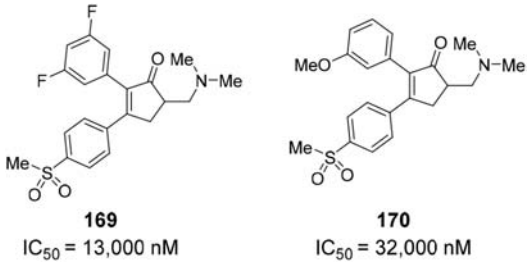

Fig. 38 CGRP receptor antagonists from Grünenthal.

7.05.4 Biologics

7.05.4.1 Monoclonal Antibodies

By virtue of their extended pharmacokinetics, monoclonal antibodies (IgG1 MW approx. 150 kDa) are potentially attractive agents for preventative therapy since they can be dosed with reduced frequency compared with most small molecules, potentially improving compliance and providing long-term coverage against disease-causing targets. It is not clear if the chronic blockade of CGRP or its receptor could lead to adverse events. Since CGRP is the most potent known vasodilator peptide, the possibility of cardiovascular effects has been raised, and long-term safety studies with CGRP-blocking monoclonal antibodies will be needed to address such potential concerns.[199] There are currently four humanized antibodies in development for migraine prevention. Three of these are targeted to CGRP itself, while the fourth binds to the CGRP receptor.

7.05.4.1.1 AMG-334 (Amgen)

AMG-334 is a fully human monoclonal antibody that binds with high affinity ($K_i = 0.020$ nM) to the human CGRP-R and competes with ^{125}I-CGRP.[200] Like the small-molecule agents already discussed, it behaves as a full antagonist at the human (cAMP $IC_{50} = 2.3$ nM) and cynomolgus monkey (cAMP $IC_{50} = 5.7$ nM) receptors. Also like the small-molecule antagonists, it shows >5000-fold reduced activity against nonprimate receptors. Preclinical in vivo assessment was thus carried out in a capsaicin-induced dermal blood flow model in cynomolgus monkeys, where it demonstrated dose-dependent activity measured at days 2 and 4 post dose.

In a 12-week phase II study, patients with frequent episodic migraine (4–14 migraine days/month) were given monthly SC doses of AMG-334 (7, 21, and 70 mg) or placebo, with reduction in monthly migraine days being the primary end point.[199] Only the 70 mg dose showed superiority over placebo (−3.4 days vs. −2.3 days), reducing the average number of monthly migraine days by 1.1 in comparison. Treatment was well tolerated, with adverse events being "placebo-like." Only 3% of patients developed neutralizing antibodies to AMG-334, and this was not associated with adverse events.

7.05.4.1.2 LY2951742 (Lilly)

LY2951742 is a neutralizing humanized monoclonal antibody against human ($K_D = 0.031$ nM) and rat ($K_D = 0.246$ nM) CGRP, respectively.[201] It effectively reduces cAMP production in human SK-N-MC cells with $IC_{50} = 0.35$ nM against human CGRP and $IC_{50} = 1.05$ nM against rat CGRP. In a rat capsaicin-induced dermal blood flow model, LY2951742 (4 mg kg^{-1}, SC) showed an approximately 65% reduction in increased blood flow when dosed 5 days before the capsaicin challenge. The antibody also showed significant activity in two arthritis pain models. [201]

LY2951742 was tested in a 12-week, placebo-controlled migraine prevention study at one dose level (150 mg, SC) given every 2 weeks.[202] Results for the primary end point were similar to those seen for AMG-334 in a similar patient population, with the net difference in monthly migraine days between placebo and antibody being −1.2. LY2951742 had a long elimination half-life (28 days) and was well tolerated.

7.05.4.1.3 ALD403 (Alder BioPharmaceuticals)

ALD403 is another anti-CGRP antibody that is reported to have very high affinity ($K_D < 0.020$ nM) for both the alpha and beta forms of human CGRP.[203] A proof-of-concept phase II study in frequent migraineurs was carried out to assess the safety and efficacy of a single 1000 mg IV dose of ALD403 or placebo. The primary end points were the change from baseline to trial weeks 5–8 in the frequency of migraine days and safety after 12 weeks. There were no obvious safety concerns in this short trial. The difference in migraine days between antibody treatment (−5.6 days) and placebo (−4.6 days) was 1 day.

7.05.4.1.4 TEV-48125 (formerly known as LBR-101, Teva Pharmaceuticals)

The anti-CGRP (IgG2) antibody, TEV-48125, reported to bind with high affinity to the alpha and beta forms of human CGRP, was originally discovered by scientists at Rinat, a small biotechnology company in South San Francisco that was acquired by Pfizer.[204] TEV-48125 (formerly known as PF-04427429) was characterized preclinically in several rat and cynomolgus monkey PD studies. Impressively, a single dose of TEV-48125 was able to inhibit CGRP-induced vasodilation upon weekly capsaicin challenges over 2 months. TEV-48125 was assessed for safety and tolerability in a series of phase I studies in healthy volunteers.[205] By the time the results were reported, the asset had been acquired by Labrys Biologics and renamed LBR-101. When given as a single IV infusion of up to 2000 mg or in two 300 mg doses 1 week apart, the antibody was well tolerated. Mean terminal half-lives for the 30–2000 mg doses ranged from 40 to 48 days, with dose-dependent C_{max} levels. In the meantime, Teva Pharmaceuticals acquired Labrys.

TEV-48125 was reformulated for SC dosing and tested in two large phase II migraine prevention studies in both frequent episodic and chronic (8–14 days of headache per month) migraineurs.[204] In the chronic migraine study, TEV-48125 was given in three SC injections every 28 days over 3 months in two dosing paradigms, (1) 675 mg/225 mg/225 mg and (2) 900 mg/900 mg/900 mg, and compared with placebo.[206] The primary end point was change from baseline in the number of hours with headache in the third month. The differences compared with placebo were −22.74 h for the 675/225 mg group and −30.41 h for the 900 mg group. In the frequent episodic migraine trial, TEV-48125 was given in three SC injections, 28 days apart, in two dosages, 275 and 675 mg, with the primary end point being change from baseline in the number of migraine days during the last 3 weeks. The results for the primary efficacy measure were comparable for the two dosing groups (difference from placebo

for 275 mg is −2.81 days and for 675 mg is −2.64 days). All dosing regimens in these two trials were well tolerated, and there were no serious adverse events.

In summary, the four antibodies so far in clinical trials have shown strikingly similar degrees of efficacy in these initial phase II preventative migraine studies. In theory, monoclonal antibodies should not readily cross the BBB, though there is controversy over its integrity during a migraine attack in some patients.[207] Therefore, considering that all of the small-molecule CGRP-R antagonists that have reached phase II have shown at least "triptan-like" efficacy, this supports the idea that inhibiting the activity of peripheral CGRP can both abort and prevent a significant proportion of migraine attacks. It is reassuring that there were no obvious safety issues, especially concerning cardiovascular function, during these trials. Larger phase III studies, already in progress, will be needed to further define the efficacy and safety of these monoclonal antibodies.

7.05.4.2 Spiegelmers

A German company, NOXXON, has developed a class of artificial oligonucleotides that are mirror-image aptamers,[208] called Spiegelmers, which can bind with high affinity to proteins and other targets.[209] Unlike aptamers, these agents use unnatural ribonucleic acids made from L-ribose. This imparts a great deal of in vivo stability toward degradation (though not renal clearance) since they are not recognized by endogenous nucleases. The unnatural stereochemistry of these oligonucleotides also means that typical selection techniques used against natural targets cannot be used to produce Spiegelmers. Instead, mirror-image protein targets must be generated, conventional aptamers selected against those, and L-ribose versions of the best binders synthesized. These Spiegelmers bind to the natural target with the same affinity as the aptamer leads but are resistant to degradative nucleases. Importantly, evidence so far suggests that Spiegelmers are nonimmunogenic.[210] In order to avoid rapid renal clearance, Spiegelmers are conjugated to a sizable (e.g., 40 kDa) polyethylene glycol (PEG) chain.

NOXXON had progressed an anti-CGRP Spiegelmer, NOX-C89, which was selected against rat D-CGRP and had modest affinity for the human peptide ($IC_{50}=16$ nM) and no selectivity against AMY ($IC_{50}=27$ nM).[211] Subsequently, it was replaced by a more potent and selective Spiegelmer, NOX-L41, which had been selected against human D-CGRP ($IC_{50}=0.5$ nM) and showed no detectable binding to human AMY and other members of the CT family.[212] Affinity had also been improved by direct modification of the ribonucleic acid (RNA) backbone, by replacement of cytidine-41 with deoxycytidine. Conjugation of a branched 40 kDa PEG chain to the 5′ end of the 50-mer, NOX-L41, modulated association/dissociation rates, but did not change the equilibrium binding constant for human CGRP ($K_D=0.4$ nM). NOX-L41 also bound with good affinity to rat CGRP ($IC_{50}=4.0$ nM).

Pharmacokinetics in rat at 10 mg kg^{-1} resulted in nearly identical IV and SC half-lives (8.1 h and 8.2 h, respectively), with a T_{max} approximately 24 h for the SC dose. Clinical pharmacokinetics has been shown with three other Spiegelmers against other targets to be improved on going from rat ($T_{1/2}=6$–8 h) to human ($T_{1/2}=23$–50 h).[209] NOX-L41 at 10 mg kg^{-1} (SC and IV) was tested in a rat neurogenic inflammation model, where it effectively inhibited plasma protein extravasation (PPE) in dura mater upon electrical stimulation of the trigeminal ganglia. Intravital two-photon microscopy was used to show a somewhat delayed accumulation of the Spiegelmer in the dura (equilibrium reached after 2 h), even with IV dosing, potentially explaining the lower activity seen at earlier time points.

7.05.5 Conclusion

The last few decades have seen significant advances in the understanding of migraine attacks and their causes. Importantly, the first migraine-specific class of drugs, the triptans, was introduced, and triptans have had a significant positive impact for many patients, although some concerns remain about their tolerability and vasoconstrictive properties. While there are still many unanswered questions about migraine pathology, the fact that CGRP plays an important role has become widely accepted.

The data implicating CGRP led to interest in agents that could block its effects as potential migraine therapeutics. Gratifyingly, there have been multiple clinical studies on both small molecules and monoclonal antibodies that achieve the goal of CGRP blockade and have shown efficacy for the treatment of migraine. However, none of these have achieved regulatory approval as of the time of this writing.

The dosing frequency and properties of monoclonal antibodies have led to interest in using them for migraine prevention. The available clinical data suggest that antibodies that target either the CGRP peptide or the CGRP receptor may have utility for this purpose. The studies published to date also indicate that these biologics are generally well tolerated. Larger, phase III clinical trials will be needed to assess the safety and efficacy of these agents, but the initial results are certainly encouraging.

In the small-molecule field, the first demonstration of clinical efficacy with a CGRP receptor antagonist was reported more than a decade ago with the IV-administered olcegepant. Since that time, four orally acting CGRP receptor antagonists have been evaluated for the acute treatment of migraine. Overall, the data from these clinical trials are consistent and demonstrate that CGRP receptor antagonists can provide similar efficacy to the triptans but with a much lower incidence of adverse events. Moreover, a variety of preclinical and clinical studies have demonstrated that CGRP receptor antagonists do not cause vasoconstriction, in contrast to triptans, and these studies suggest that CGRP receptor antagonists may have a superior cardiovascular safety profile compared with triptans.

Concerns have been raised about the possible association of CGRP blockade with liver injury, following the observation of elevated levels of liver transaminases after dosing with both MK-3207 and telcagepant. The possibility that these observations could

be due, in part, to CGRP receptor antagonism cannot be ruled out at this time. However, the pattern of findings with these two compounds was reportedly quite different, suggesting that these effects may be specific to these molecules rather than mechanism-based.[132] Additional studies with other CGRP receptor antagonists should lead to a better understanding of these issues.

Perhaps, one of the lessons to be taken from the work reviewed here is that developing an orally bioavailable small-molecule antagonist for a family B GPCR is not trivial. In the present case, such a small molecule must effectively block binding of the 37-amino acid CGRP peptide to an extensive binding site on its receptor. The structural studies reported for the CGRP-R ectodomain complex with olcegepant and telcagepant highlight these challenges and help to explain why potent CGRP receptor antagonists tend to be large, somewhat rigid molecules with multiple hydrogen bond donors and acceptors. Understandably, it has often been challenging to reconcile these properties with good oral pharmacokinetics. A potential solution is intranasal delivery of a molecule such as BMS-742413, although compound design for that route of delivery is, in many ways, just as difficult. While four orally acting CGRP receptor antagonists have demonstrated clinical efficacy, two have been discontinued, and the status of the others (BI 44370 and rimegepant) is unclear. Nonetheless, CGRP blockade is a clinically validated mechanism, and we remain hopeful that one of these compounds or another CGRP receptor antagonist may become an approved treatment for migraine. Such an achievement would represent the first new migraine-specific therapeutic agent in some time and would surely provide great benefit to the many patients who frequently suffer from this complex disorder.

7.06.1 Introduction

The orexin ligands are a pair of excitatory neuropeptides that are most often termed orexin-A and orexin-B, or hypocretin-1 and hypocretin-2, respectively. Sakurai identified these neuropeptides in 1998 and demonstrated their ability to invoke an increase in intracellular Ca^{2+} concentrations by activation of what was at that time an orphan G-protein coupled receptor (GPCR).[1] The receptors were characterized by Sakurai and given the names orexin-1 (OX1R) and orexin-2 (OX2R). In an independent manuscript, De Lecea showed that mRNA originating in the hypothalamus coded for the prepro-orexin peptide, which is the precursor to orexin-A and orexin-B.[2] This precursor peptide is expressed in the hypothalamus in neurons that project into areas of the central nervous system that have been associated with sleep regulation, addiction and reward, panic, and food intake among other behaviors. De Lecea used the hypocretin nomenclature (Hcrt-1 and Hcrt-2) to describe these new peptides. For the remainder of this article we will use the term orexin. These independent publications by Sakurai and De Lecea describing the orexin system were the motivation behind nearly two decades of research in academic and industrial laboratories that continue to develop and prosper. This research has been the subject of various reviews.[3]

In regard to the roles of the orexin receptors in the CNS, one interesting aspect in terms of drug discovery is the localization of the receptors.[4] While some areas of the CNS contain both receptors, differentiated roles of the receptors are suggested by selective receptor expression in areas of the brain thought to play a role in sleep–wake, reward, addiction, stress, anxiety, and other neuropsychiatric disorders. For example, localization of the OX2R primarily in histaminergic neurons in the tuberomammillary nucleus is consistent with what is now understood for the OX2Rs with respect to their role in wake promotion and as an important modulator of arousal. Piper et al. demonstrated that intracerebroventricular (i.c.v.) administration of orexin caused rats to spend more time awake.[5] A phenotype similar to narcolepsy was observed in rodents whose prepro-orexin gene had been knocked out, or whose orexigenic neurons have been ablated.[6] Further support for the role of orexin in the modulation of sleep–wake cycles came from Stanford University[7] when it was shown by Mignot that a colony of narcoleptic canines had mutated or nonfunctional OX2 receptors. In addition, human narcoleptic patients were shown to have attenuated orexin levels and reduced orexinergic neurons, providing clinical evidence for the modulation of orexin signaling as a potential treatment for sleep disorders.[8] Over the years, there has been a debate in the literature on whether to target both orexin receptors or only the OX2 receptor. This began with a publication from Janssen, which demonstrated that selective antagonism of the OX2R is sufficient to induce and prolong sleep in rodents.[9] Furthermore, a selective OX1R antagonist had no effect on these parameters. These findings have since been replicated by others.[10] In the Janssen study, it was demonstrated that a dual orexin receptor antagonist failed to induce sleep in mice lacking the OX2 receptor but succeeded in the OX1 knockout mice. Subsequent manuscripts suggested that antagonism of the OX1R concurrent with the OX2R reduced REM sleep latency and duration to a greater extent than nonrapid eye movement (NREM), which disrupts the physiological balance of REM and NREM sleep.[11] In contrast to the OX2R, the OX1Rs are selectively located in the bed nucleus of the striata, amygdala, cingulate cortex, and noradrenergic neurons of the locus coeruleus. These areas of the brain are commonly thought to play a role in anxiety, stress, or reward. Studies corroborating the role of the orexins, specifically the OX1R in complex psychiatric disorders, are emerging that is consistent with brain localization in these areas.[12] For example, in an animal model of panic disorders, selective activation of orexinergic neurons via lactate infusion also correlates with anxiety measures in the social interaction test or open field test.[12a,13] These responses are blocked or attenuated with either siRNA or selective OX1R antagonists. Another method to induce panic is CO_2.[14] It has been shown that activation of the OX1R is a critical component of CO_2-mediated anxiety and hypertension attenuated hypercapnic gas-induced pressor and anxiety

responses. Interestingly, the anxiety measures and autonomic responses are attenuated with a selective OX1R antagonist or an OX1R/OX2R antagonist, but not a selective OX2R antagonist. Both dual and selective OX1R antagonists have demonstrated efficacy in other models of conditioned fear or stress such as the fear-conditioned startle paradigm.[15] Colocalization of both receptors in the ventral tegmental area is consistent with a variety of studies that have appeared, suggesting the possibility that OX1R antagonists would be useful for the treatment of addictive disorders and withdrawal. As examples, selective OX1R antagonists have attenuated conditioned place preference and reinstatement induced by morphine, stress-induced cocaine reinstatement, cocaine-induced behavioral and synaptic plasticity, precipitated morphine withdrawal, and nicotine self-administration. A reduction in the self-administration of ethanol was recently reported using a selective OX2R antagonist. However, most studies have demonstrated an attenuation using selective OX1R antagonists in the intake, cue- and stress-induced reinstatement of ethanol. As will be covered in the section regarding clinical candidates, the work that was summarized earlier has led to dual OX1R/OX2R or selective OX2 antagonists entering the clinic for the treatment of insomnia or related disorders.[3a] All of these data prompted numerous pharmaceutical companies and academic researchers to further investigate the pharmacological effects of modulation of the orexin system, and as such, many dual OX1R/OX2R receptor antagonists and selective OX1R or OX2R antagonists have been studied,[3b] primarily with the goal of treating sleep disorders by antagonizing the OX2 receptors.[16] Considering that most OXR antagonists are primarily undergoing clinical trials for the treatment of insomnia and related sleep disorders, many of the medicinal chemistry efforts described in this article have focused on an appropriate duration of action in human and as such, compounds with a relatively short predicted half-life have been advanced into the clinic, given the likelihood that longer acting compounds would be expected to have detrimental effects, including next-day drowsiness. Although a significant amount of literature exist studying OX1R antagonists, to date, no known selective OX1R antagonist has entered human clinical trials. A synopsis of the medicinal chemistry related to various dual and selective orexin receptor ligands is reviewed herein.

7.06.2 Actelion

7.06.2.1 Tetrahydroisoquinolines

Actelion was the first to demonstrate efficacy in human patients for the treatment of sleep disorders with an orexin antagonist.[17] In 2007, Actelion published a Nature Medicine paper describing **ACT-078573**, a compound that is now known as almorexant (**1**), which is shown in **Fig. 1**. This publication represented a turning point in the orexin field as it was the first disclosure of an OXR antagonist in human patients with insomnia. At doses of 200 mg or greater patients receiving almorexant showed signs of decreased wakefulness consistent with preclinical studies in rat and dog without signs of cataplexy. Subsequent to this initial report, phase III clinical trials of almorexant were discontinued due to safety concerns in Jan. 2011.

Actelion has published a variety of medicinal chemistry papers describing the tetrahydroisoquinoline template before and after the disclosure of almorexant.[15b,18] The primary goal of these initial investigations was to replace the 6,7-dimethoxy-tetrahydroisoquinoline with 1-ethyl-3-methyl-tetrahydro-1*H*-pyrazolo[4,3-c]pyridine as shown in **Table 1**. The initial studies focused on the SAR of the pendant phenethyl moiety represented as R_1.[18a] Generally speaking, mono-*para*-substituted phenyls tended to have the most effect on OX1R potency, for example, **2**–**5**. For example, although compound **2** demonstrated that this replacement was tolerated for the OX2R, potency for the OX1R receptor was diminished giving a selective OX2R antagonist. Certain di- and trisubstituted analogs, such as **6**–**8**, were shown to provide dual OX1R/OX2R antagonists with excellent potency. Compounds **7** and **8** were progressed into an EEG study and showed to increase time spent in non-REM sleep to a lesser extent than that observed for almorexant after a 100 mg/kg PO dose. Noteworthy here was that replacement of the $-CH_2CH_2-$ linker in **5** with a $-CH_2O-$ in **9** completely depleted OX1R potency.

Further studies focused on 5,6,7,8-tetrahydroimidazo[1,5-*a*]pyrazines as illustrated in Table 2.[18c] Interestingly, replacement of the pyrazole in **2**, with the imidazole in **10**, resulted in slightly diminished OX2R potency, but a complete loss in OX1R potency. Further replacements, such as a cyano (**11**) or CF_3 (**12**), began to restore potency for the OX1R. Eventually, the researchers at Actelion found that a chlorine in this position improved potency at both receptors providing the dual OX1R/OX2R antagonist **13**.

With the chlorine held constant, in order to investigate the effect of substitutions in this area of the molecule, further SAR was generated as shown in Table 3. Going from the ethyl in **13** to the methyl in **14** had minimal impact on potency at both receptors as shown. However, the *n*-propyl substituted analog **15** began to reduce OX1R potency. The *i*-propyl or cyclopropyl analogs **16** and **17** were found to be similar to the ethyl-substituted analog **13**. Compounds **13** and **17** were evaluated in vivo in rats for their ability to penetrate into the brain. After a 100 mg/kg PO dose brain/plasma (B/P) ratios were determined to be 0.06 and 0.07, respectively. This can be compared to the B/P ratios for **1**, which were shown to be 0.32.

Next, the focus was placed on the pendant phenethyl substituent with aims of increasing brain penetration and potency.[18b] Shown in Table 4 is the representative SAR in regard to potency and selectivity for the OX1 and OX2 receptors. Generally

speaking most substitutions on the phenethyl portion had minimal impact on OX2R potency. As observed in the pyrazolo-tetrahydropyridines series, replacement of the $-CH_2CH_2-$ linker with $-CH_2O-$ was detrimental to OX1R potency, for example, **13** versus **18**. Although replacement of the $-CF_3$ in **13** with an $-OCF_3$ (**19**) resulted in a loss of potency at both receptors, a $-OCHF_2$ (**20**) resulted in a potent and selective OX2R antagonist. The disubstituted analogs **21–23** further demonstrate that subtle changes in structure seem to affect the OX1R potency more so than the OX2R potency. Cyclopropyl-substituted compounds were studied next. As shown for compounds **24–26**, similar trends were observed as with the ethyl-substituted compounds. In general, only minor improvements in brain penetration were observed for these compounds, and none of these compounds appeared to be superior to almorexant in this regard. However, compound **21** did show similar efficacy in promoting sleep as demonstrated by a significant decrease in the amount of time spent in active wake after a 100 mg/kg PO dose.

Additional studies related to the almorexant core that were conducted by Actelion resulted in the selective OX1R antagonist **ACT-335827**, Table 5.[15b] Beginning with tetrahydroisoquinoline **27**, Actelion began an investigation in library format using an Ugi four-component coupling. The initial campaign yielded **28**, which was shown to be a potent and selective OX1R antagonist

with limited penetration into the CNS. Subsequent to the identification of **28**, compound **29** was also identified. Although OX1R potency and selectivity for OX1R was reduced for **29**, improved brain penetration and plasma levels after an oral dose provided a rationale for further refinement. Additional modifications to the amide portion of the molecule while keeping the phenyl substituent R_2 constant resulted in the *n*-butyl amide **30**. In this case, both potency and selectivity were improved relative to **29** while maintaining good penetration into the CNS after a 100 mg/kg PO dose. Further modifications led to the identification of **ACT-335827** (**31**). This molecule maintained potency, selectivity, and brain penetration with increased plasma levels after an oral dose relative to **31**. Analogous to almorexant, at a high dose (300 mg/kg PO), the selective OX1R antagonist **ACT-335827**

Table 5 Human OX2R and OX1R FLIPR-based data and B/P for compounds **27–32**

(**31**) was effective decreasing reactions in the fear-potentiated startle paradigm, suggesting that OX1 antagonism is responsible for efficacy. This compound was tested in a variety of stress-related paradigms and shown to be efficacious without decreasing wakefulness, as would be expected from a selective OX1R antagonist.

7.06.2.2 Substituted Lactams

In an effort to identify new templates, Actelion disclosed their work which began with the lead compound **33** shown in Fig. 2.[19] The primary goals were the improvement of potency at both OX1R and OX2R concurrent with improvements in metabolic stability. In vitro studies indicated that the primary site of metabolism in **33** was oxidation of the sulfur to the sulfone or sulfoxide. Based on this, carbon-linked replacements were studied. As such, the corresponding pyrrolidin-2-one (**34**), piperidin-2-one (**35**), and azepin-2-one (**36**) were evaluated. The piperidin-2-one **35** was chosen for further follow-up based on improved potency at the OX2R relative to **34** and **36**. Additional SAR allowed the team to identify compound **37**, which was shown to have improved potency at the OX1R and a good brain to plasma ratio. However, high predicted metabolism of **37** necessitated further studies. Metabolism on the substituted dimethoxy aryl ring was predicted to be the main driver of the observed metabolic instability. While replacements for this moiety did result in potent molecules at both receptors, it was reported that these changes did not result in improved microsomal stability.

Further modifications to the core included morpholine (**38**), piperazines (**39–40**), and the [3.1.0] bicycle (**41**), all of which were detrimental to potency as is shown in Fig. 3. A key finding in regard to improvements in intrinsic clearance for the series was methylation alpha to the amide carbonyl of the pyrrolidinone template. This resulted in the racemic diastereomers **42** and **43**. Although the *trans*-diastereomer **42** was shown to be only moderately potent at both receptors, an improvement in microsomal stability warranted further investigation.

Further studies focused primarily on manipulation of the methyl group to substituents such as ethyl, fluoro, chloro, amino, and hydroxyl led to compound **44**, Fig. 4, which exhibited low predicted clearance in human microsomes. In order to improve OXR potency, changes to the benzyl moiety were performed.[19] This resulted in **45**, a compound that maintained favorable clearance along with good potency at both the OX1R and OX2R. Changes to the 2,5-dimethoxyphenyl group led to the identification of **46**, which in this case is a selective OX2R antagonist with good brain penetration and low predicted clearance. The authors proposed

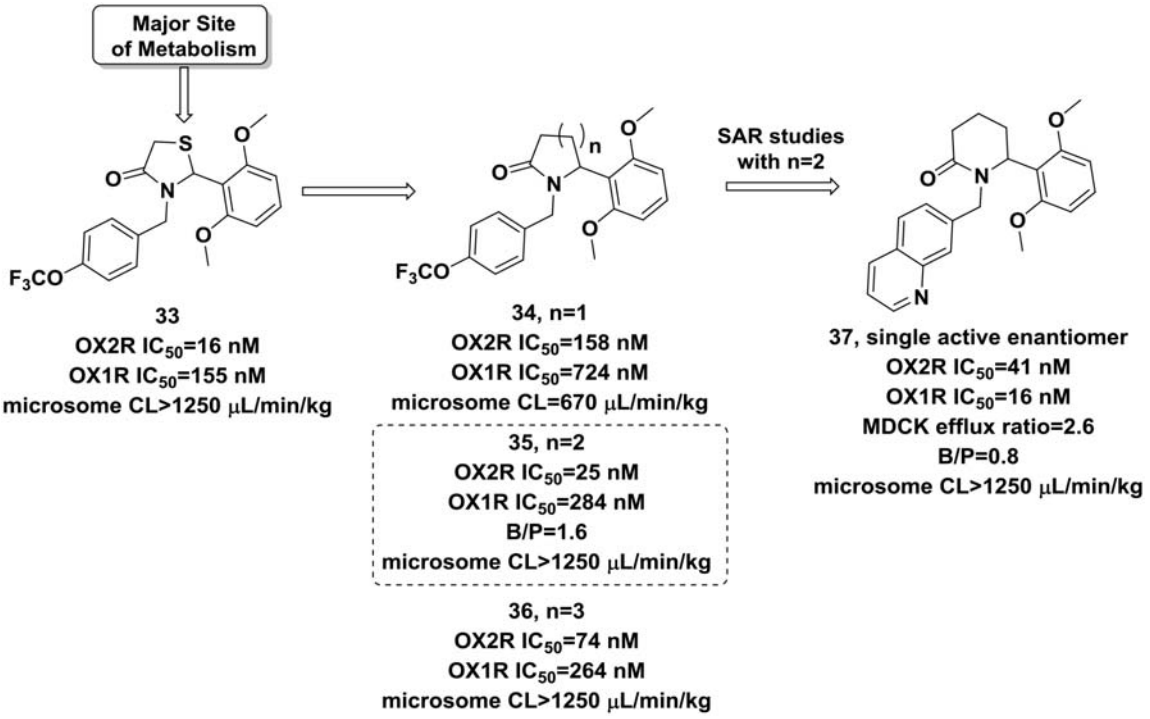

Fig. 2 Evolution of compound **37**.

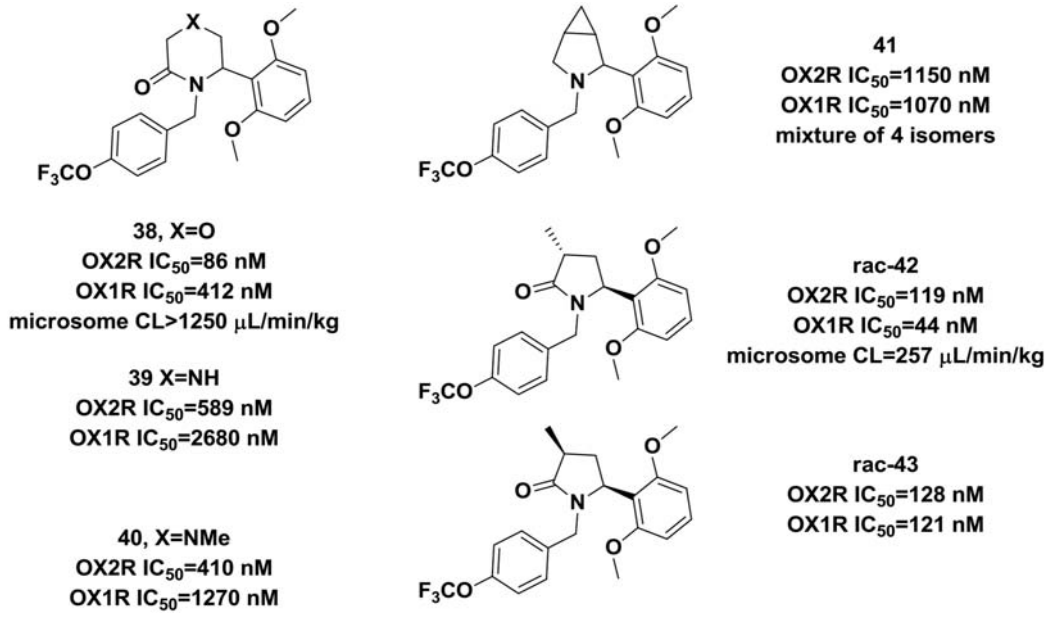

Fig. 3 Modifications to the piperidine core.

an intramolecular hydrogen bond which may mask the influence of the hydroxyl group in regard to brain permeability. Subsequent evaluation of **46** in male rats to determine its effects on sleep–wake cycles demonstrated that compound **46** had activity similar to almorexant after a 100 mg/kg PO dose.

7.06.2.3 Proline Sulfonamide ACT-462206

Actelion has also studied proline-based sulfonamides based on the high-throughput screening (HTS) hit **47**, which is shown in Fig. 5.[15c,20] While this molecule possesses recognized structural alerts, potency, brain penetration, and moderate clearance were

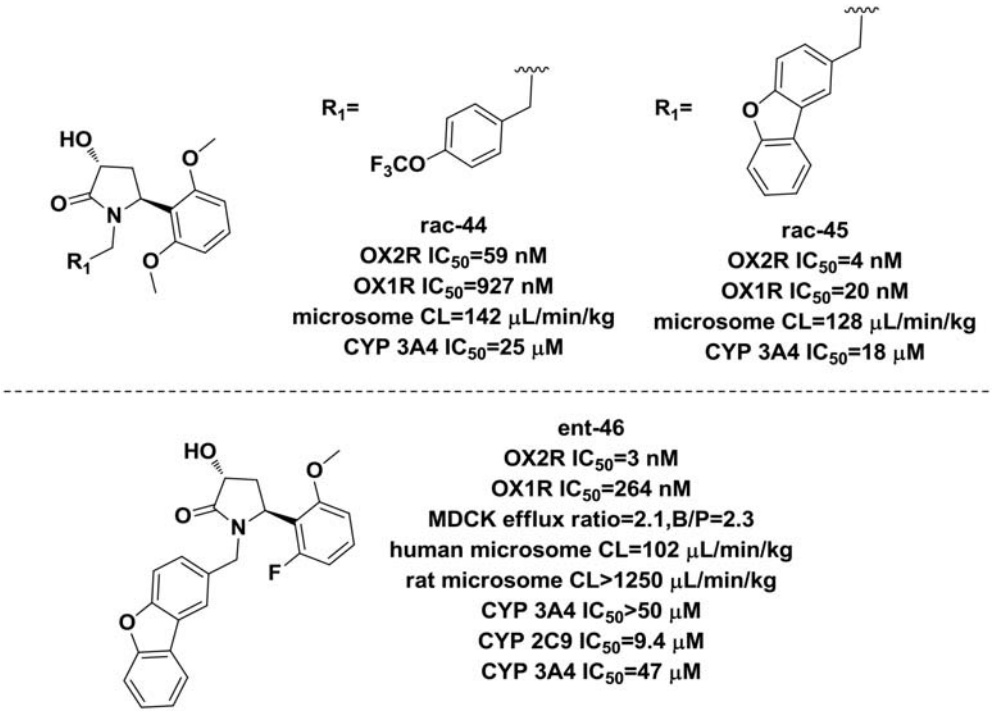

Fig. 4 Compound **46**, a selective OX2R antagonist with good drug-like properties.

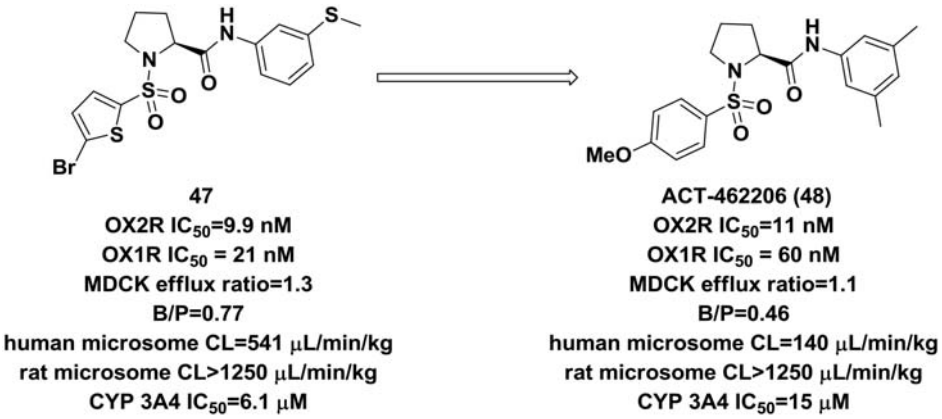

Fig. 5 Characterization of ACT-462206 (**48**).

all in acceptable ranges for an insomnia indication. Specifically, the authors were interested in exploring variations to the bromothiophene, the anilide, and the thioether moiety. Alternatives to the proline core were also investigated, and it was determined that the proline-based core was optimal. These variations led to the identification of compound **48** (ACT-462206), which is a compound that showed a dose-dependent reduction in sleepiness in human volunteers at doses of 200 mg and above. Preclinically compound **48** was also assessed in models of stress and anxiety and shown to be efficacious. A summary of these studies is shown in Table 6.

7.06.2.4 1-Acyl-2-benzylpyrrolidines

A series of 1-acyl-2-benzylpyrrolidines were also disclosed by Actelion.[21] This work began with the acylthienopiperidine **49** as shown in Fig. 6. Recognizing that the thiophene was not relevant for activity, the team quickly transformed the lead structure into piperidine **50** and subsequently pyrrolidine **51**. Both of these compounds had the advantage of improved metabolic stability, and in addition to that the calculated lipophilic ligand efficiency (LLE) of these molecules was increased from 3.5 to 4.8 and 4.7,

Table 6 In vivo data and results for the OX1R/OX2R antagonist **ACT-462206**

Test	*Result*
Fear-potentiated startle	Decreased startle reflexes at doses of 100 and 300 mg/kg
Resident intruder rat model	Decreased the social stress-induced increases of locomotion, body temperature, and heart rate at 100 mg/kg
Conditioned place preference induced	Decreased locomotor without affecting conditioned place preference induced by Morphine conditioning at 100 mg/kg
Morris water maze	No effect
Passive avoidance learning paradigm	No effect up to 300 mg/kg
Rotarod	No effect
Sleep promoting effects in rats and dogs	Dose-dependent decrease in total wake with conserved sleep architecture

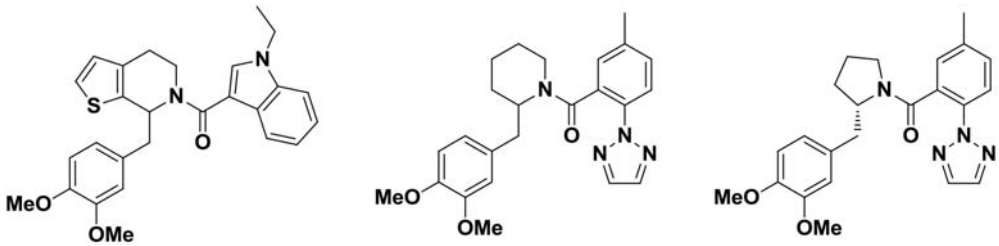

Fig. 6 Discovery of 1-acyl-2-benzylpyrrolidine **51**.

respectively. Based on these attributes, the enantiomerically pure pyrrolidine template **51** was chosen for the development of additional SAR as will be outlined here.

In attempts to further improve upon the human microsomal stability, SAR was carried out on the acylbenzamide portion of the molecule.[21] Representative examples are shown in Table 7. With the presumption that the toluyl methyl was a metabolic hot spot, compound **52** was prepared and characterized. As shown in the table, this compound maintains potency at OX2R, has slightly reduced potency at OX1R, and improved microsomal stability. The compound was brain penetrant with a brain to plasma ratio of 0.4. Further studies were focused on further reducing the Log P. Replacement of the triazole with the pyrimidine **53** gave a molecule with similar properties and a slightly lower brain to plasma ratio. The picolinic amide **54** possessed good stability in microsomes; however a loss in OXR potency was observed. Replacing the central core with a thiazole led to the identification of compound **55**, a potent OXR antagonist with moderate stability in microsomes and a good brain to plasma ratio of 0.97. Although **55** had the lowest LLE, it was chosen as the lead molecule for further follow-up due to improved penetration into the CNS.

Replacement of the pendant aryl ring with alternative substituted aryls eventually led to the identification of **56** shown in Fig. 7. Although the brain to plasma ratio of this compound is 0.3, the authors point out the increased plasma levels that were obtained after an oral dose. This led to free brain concentrations of 60 nM which are well above the measured IC_{50} at either receptor. Compound **56** was demonstrated to be an insurmountable antagonist with similar effects on sleep–wake cycles in male rats as has been reported for other dual orexin receptor antagonists.

7.06.2.5 *N*-Glycine-Sulfonamides

In 2008, Actelion reported a series of *N*-glycine-sulfonamides as dual OX1R/OX2R antagonists.[22] Workers at Actelion began with the HTS hit **57** (Fig. 8). Although this molecule possessed excellent selectivity for the OX2R over the OX1R, the goal of the research was to improve potency at the OX1R. Highlighting a common issue in the orexin field, especially at the time, this molecule had an oral bioavailability of 1%.

Initial efforts of the Actelion team focused on the SAR of the *tert*-butyl phenyl sulfonamide, specifically on the aryl portion. A summary of these data is outlined in Table 8. Replacement of the *tert*-butyl substituent with the dimethoxy (**58**) resulted in a slight loss in affinity while maintaining excellent selectivity. Alternative monosubstituted aryls were not tolerated as shown in the table for compounds **59**–**63**. Interestingly, although the *para*-methylphenyl compound **61** was shown to result in a loss in OX2R potency,

moving the methyls around (**62** and **63**) the ring to the *meta*- and *ortho*- increased OX2R potency relative to **61**. The team at Actelion reported that they were most interested in dual OX2R/OX1R antagonists.

The Actelion team then focused on the anilide portion of the molecule, shown as R_1 in Table 9. SAR studies quickly determined that placing substituents in a 2,5-disubstituted arrangement maintained OX2R potency and increased OX1R potency as shown in compounds **64** and **65**. Expanding the SAR of the diethyl amide resulted in the identification of heterocycles that yielded a further increase in OX1R potency as shown for the pyridine, pyrazine, and pyrazole substituents in **66–69**. These compounds have the added benefit of improved oral bioavailability in rat. Specifically, compound **66** was shown to have an oral bioavailability of 35%. Although brain penetration of this compound was quite low, it was shown to be effective in increasing the time spent in non-REM and REM sleep. Following this publication, Roche reported on the in vitro activity of a tool compound now known as EMPA which is a selective OX2R antagonist from the same structural class. This compound has been found to have tremendous utility in the orexin field as a radioligand tracer for ex vivo autoradiography and in vitro binding assays.[23]

7.06.3 Banyu

7.06.3.1 Tetrahydroisoquinolines

In 2003 a team at Banyu Tsukuba Research Institute disclosed the first nonpeptide selective OX2R receptor antagonists based on a tetrahydroisoquinoline scaffold. First, an HTS screen uncovered **70** (Table 10), which is a nonselective and weak OXR antagonist. Simply removing the bromine (**71**) gave a 30-fold increase in OX2R potency, without any significant change in OX1R potency. Attempts were made to improve the physicochemical properties of these compounds (mainly poor solubility), and this work lead to compounds such as **72**. Subsequent modifications of the benzyl moiety provided more soluble, selective OX2R antagonists, including **74**.[24]

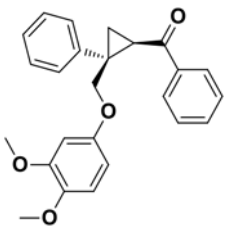
7.06.4 Eisai

7.06.4.1 N-Aryl-2-Phenylcyclopropanecarboxamides

Eisai has published several reports on cyclopropanecarboxamides as potent orexin receptor antagonists. The Eisai team reported the serendipitous discovery of cyclopropane **75** (Fig. 9) as a weak OX2R antagonist while pursuing this chemotype in another discovery program.[25] Notably, this chemotype contains the dimethoxyphenyl moiety found in many other orexin antagonists and also adopts the "U-shaped" conformation found in other orexin chemotypes. The authors added a hydrogen bond acceptor donor to this lead compound and very quickly were able to generate high-affinity OXR antagonists. The 2-pyridyl analog **77** resulted in a significant loss of OX1R affinity, and removal of the 3,4-dimethoxy moiety results in a very weak OXR antagonist. The authors focused on pyridyl and heteroaromatic substituents in order to remove the potential liabilities associated with the aniline. Thiazoles (**80**



75
OX2R K_i=8.7 μM
OX1R K_i=>10 μM

Fig. 9 Compound **75**.

and **81**) and isoxazoles were tolerated; however compounds with these substituents showed P-gp efflux. In the end the cyanopyridine **82** had the best balance of affinity and physicochemical properties; therefore this compound was profiled in more detail (and as the single enantiomer). It should be noted that compounds **75–81** shown in Table 11 were tested as racemic mixtures. Compound **82** reduced locomotor activity in a mouse and, at high doses (30 and 100 mg/kg PO), decreased wakefulness and increased non-REM sleep.

7.06.4.1.1 E2006

The medicinal chemistry group at Eisai later reported that compound **82** was not suitable for clinical development because of time-dependent CYP3A inhibition, poor solubility, and some reversible CYP inhibition. For these reasons, further optimization of this series was explored in order to find a clinical candidate. Given that the time-dependent CYP inhibition was most likely related to the 3,4-dimethoxy moiety, the researchers made modifications to this portion of the molecule to try to reduce the CYP liability while at the same time improving solubility. As such, numerous heteroaromatic substituents were installed, including those shown in Table 12.[26] The pyridine compounds **83** and **84** were much less potent than **82** and in some cases retained the time-dependent cytochrome P450 inhibition (TDI) liability. However, other heterocycles including a pyrazole (**85**), pyrimidine (**86** and **87**), or a pyrazine (**88**) provided high-affinity compounds with improved TDI and solubility. Compounds **86–88** were tested as single enantiomers. Compound **86** was chosen for further optimization, primarily due to improved solubility and TDI potential.

The optimization of **86** led to the compounds shown in Table 13. In this work, a variety of substituted pyridines were profiled as single enantiomers, with variable results in affinity, solubility, and TDI liability. For the most part TDI was reduced (**94** is the exception). Compounds **91** and **93** were found to have high affinity, and both compounds reduced wake time when dosed at 30 mg/kg. Moving to the phenyl ring attached to the cyclopropane ring, the researchers were able to generate very high-affinity OXR ligands (**95–98**). Based on an analysis of all the in vitro data, compound **96** appeared most promising and was selected for further profiling. Compound **96** has good physicochemical properties, is metabolically stable, and has low efflux and reduced CYP interactions. The compound effectively distributes into the CNS and induces sleep following oral administration. In contrast to earlier compounds from the series, compound **96** increased both non-REM and REM sleep. Finally, **96** (E2006) was chosen as a candidate for clinical development. E2006 advanced into efficacy trials in 2015 (NCT02350309).[27] The doses tested were 5 and 10 mg in subjects with insomnia disorder. No results have been posted.

An analog of **96** was also evaluated as a positron emission tomography (PET) radioligand in rat and monkey. In this study, the researchers evaluated several potential ligands including compounds **99** and **100** shown in Fig. 10. However, they were unable to identify a PET ligand that was suitable for use in rat or nonhuman primate.[28] This is most likely due to a requirement for more potent compounds, given the low B_{max} value for OX2R (the measured B_{max} value for [^{3}H]-EMPA was 6.5 nM). The authors assert that the B_{max}/K_i should be greater than 5 in order to generate a successful OXR PET ligand.

7.06.5 GlaxoSmithKline

7.06.5.1 SB-649868 and Substituted Piperidines

While a review of the patent literature is not the subject of this article, a patent literature search revealed numerous patent applications from GSK related to the piperidine template contained in the compounds shown in Fig. 11. Although GSK has not published extensively on the SAR related to this series, one manuscript appeared in 2011 describing the SAR leading to **SB-649868** (**105**) which was reported to promote sleep in healthy volunteers.[29] The program began with a lead molecule related to compound **101**. Potency could be improved through the installation of the 2-arylbenzamide shown in **102** and **103**. Rapid in vitro clearance values (>50 mL/min/kg in rat) of **103** were attributed to the ether functionality in these compounds. Replacement of the ether linkage with the amide **104** was tolerated and resulted in lower predicted clearance of 19 mL/min/kg in rat and 23 mL/min/kg in human. Subsequent to these findings, additional SAR studies on both amide molecules resulted in the discovery of **SB-649868 (105)**, which has rat and human in vitro clearance values of 8.7 and 15.1 mL/min/kg, respectively, suggestive of a low to moderate clearance. Preclinical in vivo studies in rat revealed a clearance of 24 mL/min/kg, an oral bioavailability of 85% and demonstrated that the compound was brain penetrant. Following this manuscript and the discontinuation of **SB-649868**, a report appeared discussing the metabolic fate in humans.[29d] Although the half-life of **SB-649868** was 4–6 h, the radioactive half-life was measured at approximately 40 h. The circulating metabolites were found to be compounds **106** and **107**. A mechanism for the formation of these metabolites was proposed by the authors and summarized in a recent review from Merck.[3a] The proposed mechanism was supported by trapping of an epoxide intermediate with glutathione.

In addition to the molecules mentioned earlier, two other tool compounds originally discovered by GSK that have found utility as selective OX1R antagonists are **GSK1059865** (**108**) and the cyclopropyl compound **109**, Fig. 12.[13a,30] Although both of these molecules are only disclosed in the patent literature, but appear to offer advantages to existing tool compounds. The neuroanatomy or neuronal substrate responsible for behavior outcomes of **GSK1059865** and the selective OX2R antagonist from Janssen, **JNJ-10307049** (**134**), were mapped using fMRI. Consistent with previous reports, the OX2R antagonist was shown to promote sleep, whereas the OX1R antagonist had no effect in an EEG study. However, **GSK1059865** was able to inhibit a cocaine-induced conditioned place preference in rat and 10 and 30 mg/kg s.c. consistent with previous findings using other selective OX1R antagonists. In this initial report, theoretical brain receptor occupancy was calculated based on plasma pharmacokinetics and brain to blood ratios to estimate the dose required to occupy the OX1R. This has since been confirmed using ex vivo

autoradiography by Janssen.[13a] Additional investigations by Janssen and researchers at Indiana University demonstrated that compound **109** was able to attenuate the anxiety-like behaviors induced by sodium lactate or CO_2.[13b] Interestingly in the CO_2-induced panic model, a dual orexin receptor antagonist and a selective OX1R antagonist were both efficacious. However, the selective OX2R antagonist **JNJ-10397049** did not attenuate the effects of CO_2.

7.06.5.2 GSK Early Selective OX1R Tool Compounds

The first medicinal chemistry paper describing nonpeptidic orexin antagonists was published by GSK in 2001.[31] This paper detailed the progression of the HTS hit **110** to SB-334867 (**111**), Table 14. Although the starting point **110** was selective over the OX2R receptor, selectivity over the serotonin 5-HT_{2B} and 5-HT_{2C} receptors was an issue that needed to be addressed in order for this series of molecules to provide useful tool compounds. In order to improve the selectivity profile of **110**, efforts were focused on changes to both sides of the diaryl urea. This culminated in the discovery of **SB-334867**. Hydrolytic instability of **SB-334867** has also been reported by researchers at Research Triangle Institute. Although **SB-334867** is not ideal with regard to off-target affinities, solubility and stability at low pH, it has been the most widely utilized tool compound used to elucidate the role of the OX1R in vivo. This compound was essential in the early understanding of the orexin system; however given the issues associated with **SB-334867**, many of the in vivo behavioral data should be analyzed and interpreted carefully.

Table 14 Cell-based FLIPR data for the human OX2 and OX1 receptor and off-target activities for compounds **110** and **SB-334867 (111)**

Compound	*R_1*	*OX1R pK_B*	*OX1R pK_B*	*5HT2B pK_i*	*5HT2C pK_i*
110		7.5	5.6	8.6	7.6
111 **SB-334867**		7.4	5.7	5.4	<5.3

Following the initial report of **SB-334867**, additional selective nonpeptidic selective OX1R antagonists were described that have also served as tool compounds. These are shown in **Table 15**. While the relative benefits of **SB-408124 (112)** and **SB-410220 (113)** are unclear, these analogs do not contain the methylbenzoxazole, the reactive moiety in **SB-334867**. Also shown in the table is **SB-67042 (114)**. Although, this compound, when R=H is not an acceptable in vivo tool due to poor solubility, the tritiated compound, that is, when R=^{3}H, has been crucial to the orexin field as a radioligand for both binding assays and ex vivo receptor occupancy studies.

Table 15 Binding data for the human OX2 and OX1 receptor for compounds **111–114**

Compound	*R_1*	*OX1R K_i*	*OX2R K_i*

112 **SB-408124**		21.7	1405
113 **SB-410220**		8.7	503
114 **SB-674042**		1.1	129

7.06.5.3 Triazolo-Thioamides

Unrelated to the compounds mentioned earlier, GSK has also reported on compound **115**.[32] This compound is a high-affinity selective OX2 receptor antagonist obtained from a HTS (Fig. 13). Attempts to make improvements in potency first focused on screening commercially available libraries which did not result in meaningful improvements in potency. While the in vivo properties of **115** were not described, the reported high intrinsic clearance would be expected to limit its utility. The compound does have excellent selectivity versus the OX1 receptor and a panel of 300 other receptors.

7.06.6 Heptares

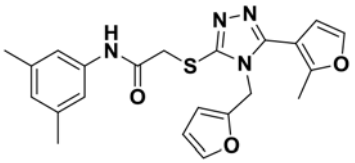
7.06.6.1 2*H*-pyrido[2,3-*e*][1,2,4]thiadiazin-3(4*H*)-one 1,1-dioxides

Hetpares recently disclosed a series of 2*H*-pyrido[2,3-*e*][1,2,4]thiadiazin-3(4*H*)-one 1,1-dioxides that are dual OX2R/OX1R receptor antagonists. The team at Heptares had a number of screening strategies which lead to the identification of **116** as a viable lead compound with a structure unlike most of the known chemotypes at the time (Fig. 14).[33]

Initial exploration of this chemotype resulted in significant improvements in OX2R affinity. First, the undesirable methylenedioxy substituent was removed. This change also improved OX2R affinity slightly. Further improvements in OX2R and OX1R affinity were realized with the addition of substituents on the benzyl ring in the 2,4- and 2,6-positions as exemplified by compounds **118** and **119** in Table 16. Substitution in the 4-position was desirable for metabolic stability, and multiple substitutions proved most advantageous for affinity as shown for compounds **120** and **121**.

In order to reduce lipophilicity and optimize physicochemical properties, the authors' next goals were to remove the potentially risky dimethoxyphenyl substituent, modify the masked aniline moiety, and add heteroatoms to the core in order to reduce the lipophilicity of the resulting compounds.

Some key compounds in this exploration are shown in Table 17. A nitrogen is tolerated at several positions of the dimethoxyphenyl moiety, and a nitrogen was tolerated in the 5-position of the core. Balancing the overall compound profile including an analysis of microsomal stability, in vivo pharmacokinetics, and OX2R receptor kinetics, compound **125** was chosen for further profiling. Compound **125** has fast OXR kinetics with a dissociation half-life of 4.2 min at OX2R and 0.8 min at OX1R. The authors compared this to the much slower dissociation $t_{1/2}$'s for suvorexant of 210 and 24 min (OX2R and OX1R, respectively), and they assert that this property (fast dissociation) may provide a better profile for a sleep drug, in particular with respect to next-day somnolence effects. The authors demonstrated that compound **125** is permeable, Ames negative; has no hERG affinity (>10 μM), or measurable CYP inhibition; and has no reactive metabolites in their assays. The compound efficiently binds to the OX2R in rat frontal cortex as measured by ex vivo autoradiography and promoted sleep in rat, primarily through an increase in REM sleep,



115
OX2R pK_i=8.8

as expected. Overall, compound **125 (HTL6641)** was considered the best compound in the series, given the requirements for the treatment of insomnia (rapid onset, relatively short human half-life, and rapid dissociation kinetics).

7.06.7 International Institute for Integrative Sleep Medicine

7.06.7.1 OX2R Agonists

Research groups at the International Institute for Integrative Sleep Medicine in collaboration with Kitasato and Showa Universities and the University of Texas Southwestern Medical Center became interested in OX2R agonists in order to investigate their effects on

Table 17 Human OX2 and OX1 receptor pK_i's for compounds **122–125**

Compound	*Structure*	*OX2R* pK_i	*OX1R* pK_i
122		8.3	7.9
123		9.6	9.0
124		9.2	8.9

excessive sleepiness and narcolepsy. First, a HTS campaign identified a weak hit compound (**126**).[34] The authors then made numerous modifications to the core structure and to the substitution patterns on all the aromatic rings in order to improve stability and affinity. These efforts led to compounds with both improved potency and efficacy as shown in Table 18. Modifications to **126** quickly demonstrated that a diamine linker could provide similar efficacy, and after some additional SAR investigations the authors identified the *m*-phenylenediamine core as shown in **127** as a viable starting point. Small changes quickly lead to the more potent and efficacious compounds **128–131**. The authors note that these compounds show moderate to good selectivity over OX1R agonism (60- to 280-fold, for those reported). Compound **131** was docked into a model of OX2R based on the crystal structure reported for suvorexant,[35] and the authors assert that slight movements in TM5 and TM6 may account for the difference between agonism and antagonism.[34,36] Finally, the dimethylamino compound **132** was prepared in order to improve solubility since compounds **130** and **131** were insoluble in water, precluding in vivo work. Compound **132** also has good selectivity over OX1R ($EC_{50} = 2.75\ \mu M$) and promoted wake in mice after i.c.v. injection (Fig. 15).

7.06.8 Johnson & Johnson/Janssen Pharmaceuticals

7.06.8.1 4-Phenyl-[1,3]dioxanes

Johnson & Johnson/Janssen has had a long-standing interest in the discovery and development of selective OX2R antagonists. In 2004, the team at Johnson & Johnson reported on a series of 4-phenyl-[1,3]dioxanes that are highly selective OX2R antagonists.[37] A HTS campaign yielded the dioxane **133**, and some limited medicinal chemistry led to the identification of **JNJ-10397049** (**134**), which is a potent and selective (600-fold over OX1R) OX2R antagonist. **JNJ-10397049** also has good selectivity over a panel of 50 receptors, ion channels, and transporters. In a subsequent report, the same group reported that **JNJ-10397049** achieved high levels of OX2R receptor occupancy in a rat brain following subcutaneous administration as measured by ex vivo autoradiography.[9] **JNJ-10397049** was also shown to decrease the latency to persistent sleep, demonstrating that OX2R antagonism is sufficient to promote sleep. The authors also showed that coadministration of an OX1R antagonist with an OX2R antagonist attenuated the effects of a selective OX2R antagonist. This leads them to conclude that a selective OX2R antagonist may provide an advantageous sleep profile as compared to dual OX1R/OX2R antagonists.[9,11] Later, **JNJ-10379049** was also shown to attenuate ethanol self-administration in rat (Fig. 16).[38]

7.06.8.2 Octahydropyrrolo[3,4-*c*]pyrroles

The researchers at Janssen have also reported on a series of octahydropyrrolo[3,4-*c*]pyrroles that are selective OX2R antagonists.[39] In this case, they stated that the dioxane moiety in **JNJ-10379049** proved essential for activity and was also the cause of poor oral bioavailability due to its inherent acid instability. For this reason, another HTS was conducted which provided numerous lead compounds, including the diazepane **135**, a compound which was also used as a lead for the team at Merck.[40] After exploring a variety of diamine core structures, the team settled on the octahydropyrrolo[3,4-*c*]pyrrole core, as exemplified by structure **136**, which proved to be a modest OX2R antagonist with >10-fold selectivity over OX1R. This compound was optimized for potency and selectivity by making changes to both the benzamide and the heteroaromatic substituents (examples include compounds **137–140**); however all the compounds in this set suffer from poor metabolic stability, likely due to the physicochemical properties of the compounds. In this series the dimethylpyrimidine generally provided good selectivity over OX1R, and the substituent on the benzamide was then used to optimize the physicochemical properties in order to improve the pharmacokinetic profile (Fig. 17).

A variety of benzamides were evaluated and are shown in Table 19. The 2-triazolophenyl substituent shown in compounds **141–144** provided relatively potent compounds with good physicochemical properties and good selectivity over OX1R. Overall, compound **144** (**JNJ-42847922**) had the best in vitro and in vivo profile, and this compound was chosen as a clinical candidate and is currently in development.

7.06.8.2.1 JNJ-42847922

JNJ-42847922 (**144**, Fig. 18) is a high-affinity OX2R antagonist with 80-fold selectivity over OX1R and has no other measurable effects in a panel of ion channels transporters or receptors. The compound has no affinity (>10 μM) for the hERG channel and was found to have modest microsomal stability in rat and human (ER 0.85 and 0.84). In rat, **JNJ-42847922** has relatively high clearance (CL = 40.0 mL/min/kg) and modest bioavailability (%F = 24%). **JNJ-42847922** dose-dependently occupies the OX2R in rat with an EC_{50} of 171 ng/mL and induced sleep in rat following oral administration. The compound has relatively high clearance in all preclinical species and based on these data was predicted to have a short human $t_{1/2}$ of between 1.2 and 1.8 h.[39] The dose estimation in human was calculated to be 250 mg, which was based on a calculated human EC_{50} of 330 ng/mL.

The synthesis of **JNJ-42847922** that was used to support 5-day rat and dog toleration studies is shown in Fig. 19. First, the carboxylic acid **145** is converted to 2-fluoro-6-[1,2,3]triazol-2-yl-benzoic acid and activated as the acid chloride to give **146**, which is then coupled with (3a*R*,6a*S*)-2-(4,6-dimethylpyrimidin-2-yl)octahydropyrrolo[3,4-*c*]pyrrole(**148**) (which was prepared in a two-step procedure from 2-benzyl-5-(4,6-dimethylpyrimidin-2-yl)-octahydropyrrolo[3,4-*c*]pyrrole(**147**)). Finally, recrystallization provided in excess of 100 g of **JNJ-42847922**.

JNJ-42847922 dose-dependently induces and prolongs sleep in rats, these effects persist upon 7-day repeated dosing, and the compound shows no effect in the OX2R knockout mouse, indicating that the sleep effects observed in the wild-type mouse are OX2R dependent. The compound does not induce a place preference in rat and has no effect on motor coordination. **JNJ-42847922** has entered human clinical trials, and pharmacokinetic data for a single dose of 10, 20, 40, and 80 mg were recently reported.[41] In human, **JNJ-42847922** has a half-life of approximately 2 h and a t_{max} of 0.33–0.5 h. Somnolence was reported at all doses, and the incidence of somnolence appeared to be dose dependent. In early 2016 Janssen's development partner Minerva Neurosciences issued a press release indicating that **JNJ-42847922** (MIN-202) had positive efficacy signals on key sleep parameters in patients with insomnia disorder.[42]

7.06.9 Merck

7.06.9.1 Proline bis-Amides

The research group at Merck has published extensively on their efforts to progress orexin antagonists into the clinic. The efforts at Merck have been reviewed several times recently[3a] and are summarized here as well. One of the first reports from Merck noted that HTS efforts identified the proline bis-amide **149** of unknown stereochemistry as a potent OX2R and OX1R antagonist.[43] Medicinal chemistry efforts designed to optimize potency and brain penetration led to compound **150**, a compound that effectively entered the CNS and showed efficacy in a model of induced locomotion inhibition (Fig. 20).

7.06.9.2 Diamines/MK-4305 (Suvorexant)

Merck also discovered a diazepane lead via HTS (**135**), and after significant optimization compound **152** was identified and found to dose-dependently reduce locomotor activity and induce sleep in rat.[40] Unfortunately, **152** has low bioavailability in rat due to high clearance, a characteristic of many potent OXR antagonists. The team also noted that this compound existed in solution as two major rotamers and an NMR analysis revealed that the low energy conformations had a U-shaped structure (nuclear overhauser effects between the amide phenyl ring and the quinazoline).[44] Preference for this U-shaped conformation was confirmed in the solid state by an X-ray crystal structure of **152**. A macrocyclic analog of **152** was subsequently prepared (**153**), and this compound also proved to be a potent OX2R and OX1R antagonist, as shown in Fig. 21. These data also suggest that the bioactive conformation

of all of these OXR antagonists is the U-shaped structure. Many other groups subsequently utilized a variety of core structures to induce such a U-shaped conformation and produce potent OXR antagonists. One example from the Merck team is shown as compound **154**.[45] This compound is a potent OXR antagonist; however the 2,3-diazabicyclo[3.2.1] octane core did not improve the pharmacokinetics of this analog over the diazepane structure (e.g., **152**). Related work produced the 2-carbon bridged version **155** which also offered no improvements in pharmacokinetic parameters.[46] In efforts to overcome the metabolic liabilities associated with **152** and **154**, a series of substituted diazepanes were prepared and profiled.[35] Several of these are shown in **Table 20**. Compound **158** had reasonable bioavailability in dog and decreased active wake in rat; however it was subject to bioactivation and the formation of reactive metabolites. The fluoroquinazoline was thought to be responsible for the bioactivation, and consequently a series of heterocyclic replacements were investigated, including the benzoxazoles **159** and **160**. The benzoxazole **160** had low dog clearance, good bioavailability, and a low propensity to produce reactive metabolites. The compound readily penetrates the CNS, is permeable, not a substrate for efflux, and was shown to be very selective over a large panel of other target enzymes, receptors, and ion channels. Compound **160** significantly increased delta and REM sleep in rats at 30 mg/kg. Based on the overall preclinical profile of **160**, the compound was predicted to have low to moderate clearance in human with a rapid onset of action. Ultimately, this compound (**160**, suvorexant) was chosen for clinical development and is the first OXR antagonist to be approved for use in humans.

7.06.9.3 MK-4305 (Suvorexant/Belsomra)

A summary of the work that lead to the discovery of MK-4305 (**160**) was described in the last section and in 2010 Merck reported that **MK-4305** entered Phase III clinical trials for the treatment of primary insomnia.[35] In 2011, Merck reported on the synthesis of over 25 kg of **MK-4305** via preparation of racemic **161**, classical resolution of **161** following crystallization as the dibenzoyltartrate salt, and coupling with 5-methyl-2-(2*H*-1,2,3-triazol-2-yl)benzoic acid to form **MK-4305** in an overall yield of 19% in five steps.[47] The sequence is summarized in Fig. 22.

In 2011, Merck reported that **MK-4305** dose-dependently promoted sleep in rats, dogs, and monkeys[48] and in 2014 the results of a 12-month clinical trial assessing safety, toleration, and efficacy in human.[49] The authors note that they concluded that 30 or 40 mg of suvorexant appeared to be safe and well tolerated in that trial; the authors also noted that the FDA thought the data supported 10–20 mg doses of suvorexant. In 2014, the FDA approved the use of suvorexant (Belsomra) for use in the treatment of insomnia. Belsomra remains the only orexin antagonist approved for use in humans.

7.06.9.4 Piperidines/MK-6096 (Filorexant)

Additional OXR antagonists include the 2,5 disubstituted piperidines **162–168**.[50] The 2,5 trans substitution on the piperidine was designed to enforce a diaxial structure, thereby inducing a U-shaped conformation which should be optimal for OXR binding. Several examples are shown in Table 21. The goal was to improve the pharmacokinetic properties of **(±)-162**. A number of heterocycles were profiled, and some were not tolerated (e.g., **163**); however the 2-pyridyl substituent produced high-affinity OXR antagonists (**164–168**). Modifications of the amide also lead to high-affinity compounds, and the authors note that the 5-methyl substituent on the benzamide was needed for optimal OX1R activity. From this work, compound **167** (**MK-6096**, Filorexant) emerged as the most interesting compound in the series. **MK-6096** is a potent OXR antagonist with good preclinical

pharmacokinetics in dog and high clearance in rat. Efficacy in sleep was demonstrated for **MK-6096** in dog. Based on microsomal clearance, the human pharmacokinetics was expected to be similar to dog. **MK-6096** is not a CYP inhibitor, showed no TDI, is selective in a broad screening panel, and shows no cardiovascular liabilities. Based on these and other data,[51] **MK-6096** was chosen as a candidate for clinical development. In 2012, the team at Merck reported using a biocatalytic transamination as a key step to prepare the substituted piperidine core of this molecule and subsequently to synthesize **MK-6096** in multikilogram quantities.[52] **MK-6096** has been in several clinical trials. In one trial, **MK-6096** (Filorexant) was dosed at 10 mg for 3 months and efficacy in migraine was assessed. The compound had no statistically significant effect in this study.[53] **MK-6096** was also clinically evaluated in patients with insomnia. In this Phase II study, **MK-6096** showed a significant decrease to sleep onset and improvements in sleep maintenance.[54]

Related piperidines have also been evaluated as OXR antagonists.[55] In this case, the ether linker on the molecule was replaced with a carbon linker and the resulting compound (**169**) had reasonably good OX2R affinity. The authors also prepared the olefin **170** and some acetylenes, as represented by **171** shown in **Fig. 23**. These changes lead to high-affinity OXR antagonists, and **171** had good pharmacokinetics and showed efficacy in increasing sleep however; compound **171** and all other acetylene analogs produced time-dependent CYP 3A4 inhibition and, as such, work on this series was terminated.

7.06.9.5 2,5-Diarylnicotinamides

The team at Merck has also reported on selective OX2R receptor antagonists. Starting with lead structure **172** (**Fig. 24**), the team prepared a series of diarylnicotinimides.[56] Several modifications of the benzyl moiety revealed the dimethoxy compound **173** as a potent and selective OX2R antagonist; however this compound had high clearance in rat, prompting further investigations on this series. Focusing on the dimethylphenyl substituent, several 2,5-disubstituted nicotinamides were profiled. From this group **174** emerged as a viable candidate for further profiling. Compound **174** is an extremely high-affinity OX2R antagonist; however the exposure of this compound in the brain is limited, likely due to the fact that the compound is a P-gp substrate. Despite this, **174** did show efficacy in a rat sleep EEG model.

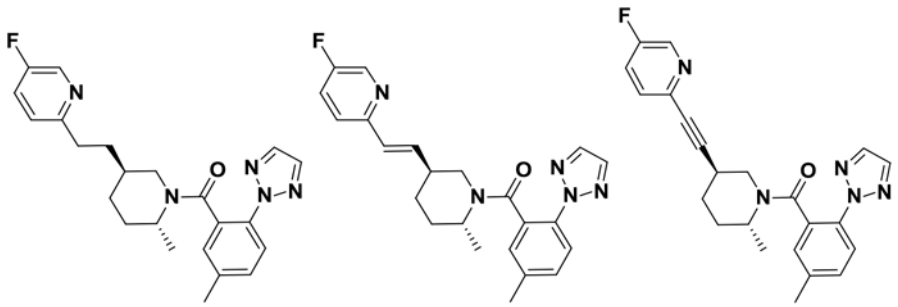

Fig. 23 Compounds **169–171**.

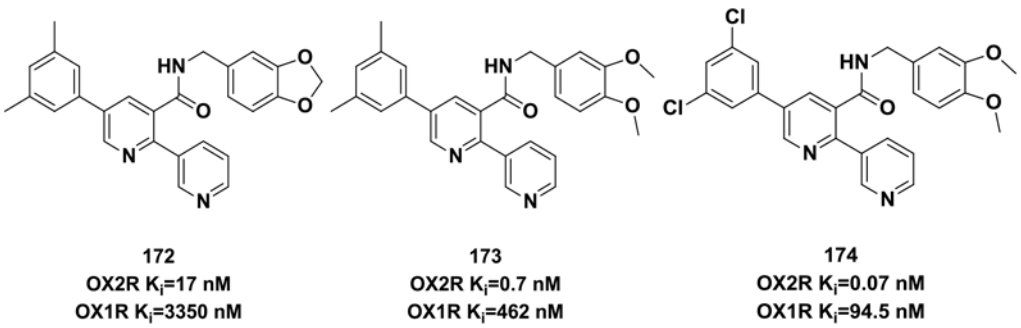

Fig. 24 Compounds **172–174**.

7.06.9.6 MK-1064

Compound **174** was subsequently reported to be a CYP 3A4 inhibitor, and follow-up efforts to optimize this series included work that resulted in the selection of an OX2R antagonist suitable for clinical development.[57] This work focused primarily on optimization of the benzamide while closely monitoring CYP inhibition, reactive metabolite formation, P-gp activity, and metabolic stability. Compounds **175** and **176** (Fig. 25) are examples of compounds with improved physical properties, unfortunately **175** suffered from a P-gp liability and **176** produced reactive metabolites. Since the reactive metabolites were thought to arise from the reactivity of the dimethoxyphenyl ring, several variations of this substituent were prepared and profiled. Compound **177** (**MK-1064**) was ultimately selected for additional profiling because it had high OX2R affinity, an acceptable P-gp profile, and low bioactivation potential. **MK-1064** has reasonable pharmacokinetics in rat, dog, and rhesus monkey; effectively occupies the OX2R in rat brain; and promoted sleep in mouse, rat, dog, and rhesus monkey. **MK-1064** was predicted to have low clearance in human, and the human half-life was estimated to be 2–16 h. In toleration studies in rat, no drug-related changes were noted, and in CV studies in dog, no signals were observed. **MK-1064** was chosen as a candidate for clinical trials, and it appears that a Phase I trial was conducted at doses of 50, 120, and 250 mg. In the clinic, MK-1064 was found to decrease latency to persistent sleep (LPS) and wake after sleep onset (WASO).[58] No further data has been reported for this compound.

7.06.9.7 MK-3697

After it was determined that the 2-pyridyl moiety on the nicotinamide was responsible for hydrolysis of the amide observed during salt screening exercises (compare **177** and **178**, Fig. 26),[59] efforts also focused on optimizing the nicotinamides for chemical stability. For this portion of the research, the SAR of the nicotinamide was explored with the goals of maintaining OX2R selectivity and optimizing clearance in dog.

The OX2R and OX1R affinities are very sensitive to the position of the nitrogen on the nicotinamide ring (compare **179–180** and **181** in Table 22). Overall, **181** had the best profile, and this compound was also found to have the lower clearance in dog; therefore it was used as a lead for further optimization. Compound **181** was found to be stable at low pH; however it also had CYP 3A4 TDI potential, similar to that seen for **MK-1064**. This work produced a number of substituted 2-aryl analogs, including **183–188**. Substitution is tolerated with variable selectivity, and some 5-membered heterocycles are tolerated. Compounds **183**, **184**, **186**, and **188** also had relatively low clearance in dog. Compound **187** was also stable at pH 2 and showed reduced risk for TDI, and as such, it was chosen for further profiling. This compound had good bioavailability in rat and dog and showed significant reductions in active wake in mouse, rat, and dog. Ultimately **187** (**MK-3697**) was chosen as a preclinical candidate. To our knowledge no clinical data has been reported for **MK-3697** although one report indicated that the compound was in Phase II clinical trials.[60]

7.06.9.8 Piperidine Ethers

Modifications of the MK-6096 core structure also lead to selective OX2R antagonists, as exemplified by **189** and **190** shown in Fig. 27. In this work, **(±)-189**, a compound with a shorter linker to the aryl ether attached to the piperidine, provided a lead compound which was further elaborated with the correct substitution and stereochemistry on the piperidine to give **191**, a potent OX2R antagonist with modest OX1R selectivity.[61] Additional exploration of the aryl ether produced **191**, a potent and selective OX2R antagonist. Compound **191** also promotes sleep in rat although this compound has a shorter duration of action than **MK-6096**.

7.06.9.9 Diazepanes

Recently Merck also disclosed a series of diazepanes that were prepared as a follow-up to the quinazoline-based compounds such as **158**. Select compounds from this set are shown in Table 23. As mentioned earlier, some of the quinazolines suffered from bioactivation and it was thought that monocyclic replacements for the quinazoline, with the proper substitution, may reduce the bioactivation potential for these compounds. Indeed, high-affinity OXR antagonists were prepared (**189–192**).[62] Compound **192** had the best preclinical profile, reduced GSH adducts, and showed efficacy, reducing wake in rats. Further exploration, which included removal of the methyl group on the benzamide (known to reduce OX1R affinity in other analogs) and modification of the pyrimidine, provided the selective OX2R antagonists **193–196**. Compound **196** induced sleep in mouse; however due to its pharmacokinetic profile high doses were required, and this compound would be expected to have a relatively short duration of action.

7.06.9.10 MK-8133

In a separate report, Merck disclosed further optimization of the piperidine core, with the goals of preparing selective OX2R antagonists, and this work lead to the identification of another clinical candidate, **MK-8133**.[63] The team first explored the SAR of methyl substituted pyridines (**197–200**, Table 24) and found that the 4-methylpyridine **199** provided the best OX2R affinity

and OX1R selectivity. Further optimization of the substituent in the 4-position of the pyridine produced numerous compounds, represented by **201–205** here. These changes produced compounds with variable OX2R affinity and selectivity, as one might expect. Ultimately, larger substituents in the 4-position gave the best profile and cyano (**204**) proved to have the best balance of OX2R affinity, selectivity over OX1R, and functional activity (FLIPR assay). As such, this is the substituent that was installed for subsequent optimization of the benzamide substituent. This work led to the identification of compounds **206** and **207** as interesting leads. Compounds **204**, **206**, and **207** were characterized further in rat and dog, and it was compound **207** that had the best overall profile in rat and dog (high %F and moderate clearance). In addition, this compound was not a significant substrate for P-gp, had no off-target activities, had improved solubility over compound **204**, and distributed into the CNS. After oral administration to mice, rats, or dogs, compound **207** decreased active wake, as expected. Compound **207** (**MK-8133**) was subsequently identified as a potential clinical candidate.

7.06.10 Novartis

7.06.10.1 Spirocyclic Amino-Amides

Novartis's interest in orally active selective OX2R antagonist began with the spirocycle **208**.[64] As summarized in Fig. 28, the initial iterations were aimed at attempting to understand the role of the amide carbonyl or putative hydrogen bond acceptor highlighted in blue. For example, was this carbonyl in fact acting as a hydrogen bond acceptor or was it necessary to force a particular

conformation? In order to mimic the *E* and *Z* isomers of the amide bond, reverse amides **209** and **210** were synthesized to probe this question. Interestingly, both were found to have near equal potency for both orexin receptors as the lead **208**. This led to the conclusion that the amide carbonyl was only present to either fix a particular conformation or that these three molecules had alternative binding modes which were forming hydrogen bonds with different residues in the active site.

Based on ligand efficiency (LE), the Novartis team began their SAR studies with compounds related to **209**, Table 25. A good increase in potency for both receptors was realized by substitution on the pendant phenyl ring, as exemplified by compound **211**. Although the LE was maintained in this case due to the increased potency, the overall cLogP had increased. Therefore efforts

were focused on decreasing cLogP while maintaining potency by incorporating heterocyclic replacements, such as substituted indoles, for the benzyl group. The resulting 4-substituted indole **212** provided a further improvement in OX2R potency. Additional selectivity over the OX1R was evident as well. Next, modifications were focused on the quinoxaline portion. The OX2R selectivity inherent in this series was further improved by utilizing the 4,6-dimethylpyrimidine as shown in **213**. In rat PK experiments all of these compounds were found to have high clearance resulting in poor exposure after an oral dose. This was exemplified by compound **212** which has a clearance greater than hepatic blood flow, a C_{max} of 18 nM, an oral bioavailability (F) of 5%, and a low brain to blood ratio of 0.2. Next, the team investigated further analogs related to compound **210**. Using this isomer and applying the same substituents as found in **212** gave compound **214**, which was found to be less potent at both orexin receptors. Moving the attachment point to the 3-position (**215**) gave a molecule with similar potency and a slight improvement in LE (not shown). Additional examples here included compounds **216–218**. Although the unsubstituted pyrimidine **216** has a relatively dramatic loss in OX2R potency, this could be restored by monosubstitution in the 4-position (**217**) or disubstitution in the 4,6-position (**218**). Selectivity over the OX1R was also maintained with these heterocycles. Compound **217**, which is now known as IPSU, was chosen for further characterization. In vivo, this molecule gave improved pharmacokinetics and brain penetration relative to compound **212** as shown in Table 26. Interestingly, OX1/OX2 selectivity was decreased in **217** slightly in mouse and reported to have only a 10-fold selectivity window due to a lower potency for the OX2R. This is an important characteristic that should be considered when evaluating **217** in mouse in vivo experiments.

7.06.10.2 Pyrazolopyridines

From a structural point of view, a distinct series of molecules was published by Novartis in 2015.[65] The initial hit from a HTS campaign designed to identify dual OX1R/OX2R antagonists was the racemic version of **219**. After establishing that potency resided with a single enantiomer (**219**), potency was improved at both receptors by replacing the R_1 benzamide with a 4-methoxyphenyl (**220**) or the substituted pyrazole **221** as shown in Table 27.

After identifying that the 3-position aryl ring could be modified with only a moderate loss in potency, for example a cyclopropyl as in compound **222**, this area of the molecule was targeted to reduce lipophilicity. Select examples are shown in Table 28. In addition, after identifying the major metabolic pathways in vitro, compounds **223–225** were designed to reduce metabolism on the 3-position phenyl ring. Although potency was good for compound **224** and moderate for **225**, metabolism was not improved

with this strategy. According to the authors, the cyclopropyl compound **222** (16%F and a [br]/[bl] ratio of 0.13) provided an optimal balance of good plasma exposure after an oral dose along with sufficient brain penetration. Clearly, improvements in oral bioavailability and brain penetration are still desired.

7.06.11 Research Triangle Institute

7.06.11.1 Tetrahydroisoquinolines

Following up on the HTS hit **226** (**27**) reported by Actelion, researchers at Research Triangle Institute (RTI) have published SAR around the tetrahydroisoquinoline template shown in Table 29.[66] These studies initially focused on SAR at the 7-position (R_1) and the benzamide (R_2). All of the compounds shown in this table have a reported K_e of >10,000 nM at the OX2 receptor. Focusing first on R_1, increasing the size of the substituent from Me (**226**) to Et (**227**) to CH_2CF_3 (**228**) resulted in a progressive increase in potency. On the benzamide, a variety of changes were evaluated. Highlighted here are the 2-, 3-, and 4-pyridyl analogs (**229–231**). The 2- and 3-pyridyl were comparable to the benzyl group. As previously noted, the potency could be improved by incorporating the $-CH_2CF_3$ group in the 7-position as shown for compound **232**. While in vivo data related to pharmacokinetics or brain penetration were not provided, after a 20 mg/kg i.p. dose compound **232** did attenuate development of place preference induced by cocaine, consistent with other OX1R antagonists. In a subsequent paper, further exploration of the SAR resulted in the identification of the selective OX1R antagonists **233** and **234** (Fig. 29).[67] Similar to results obtained using **SB-334867**, compound **233** was able to attenuate the development of cocaine-induced behavioral sensitization at 10 mg/kg i.p. after repeated dosing.

7.06.11.2 Diarylureas related to SB-334867

Researchers from Research Triangle Institute have also reported on additional SAR related to **SB-334867 (111)**, Table 30.[68] The goal of these initial studies was to identify parts of the molecule, wherein linkers could be installed. These linkers were then envisioned as an attachment point for CB1 ligands resulting in bivalent ligands for the OX1 and CB1 receptors. After replacement of the naphthyridine in **SB-334867 (111)** with the 8-fluoroquinoline, studies were shifted to replacement of the benzoxazole. These efforts resulted in the identification of anilines **235–237**. The conclusions by the authors that this could be an area of the molecule that would tolerate further substitutions.

An additional paper from RTI has appeared detailing the hydrolytic instability of SB-334867.[69] The general observations from the paper were that when the HCl salt of SB-334867 is utilized, caution needs to be taken because of the fact that hydrolysis occurs to generate the ring-opened compound **238** as shown in Fig. 30 Although the free base of SB-334867 was found to be stable for at least 1 year, when the HCl salt was stored as a solid at 15°C for 15 months under argon in a sealed container, new resonances that appeared in the ^{1}H NMR spectrum were observed due to the formation of **238**. A refrigerated solution of

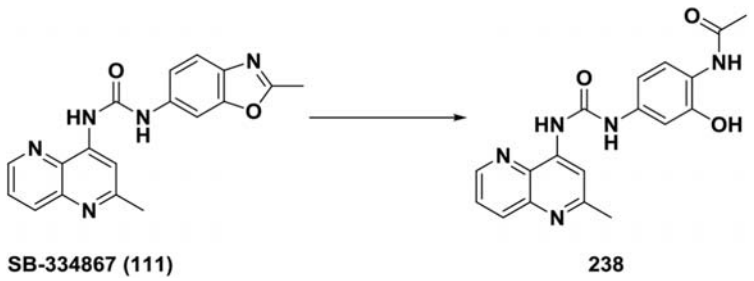

Fig. 30 Decomposition of **SB-334867** to **238.**

SB-334867 as the free base was stable for 3 months in 100% DMSO in a tightly capped vial. This is in contrast to a solution that was not protected from moisture and stored at room temperature. In this case, the hydrolysis product was observed in 33% after 3 months. These studies lead to the concern that many studies that have utilized either the free base of **SB-334867** or the HCl salt should be analyzed closely. The free base is notoriously insoluble in aqueous media, and the HCl salt could decompose if not handled properly.

7.06.12 Rottapharm

7.06.12.1 Bicyclic [5.2.0] and [4.2.0] Diamines

Rottapharm has also investigated bicyclic [5.2.0] and [4.2.0] analogs as shown in Table 31.[70] Initially, the [5.2.0] piperidine analog **239** was first compared with the [4.2.0] pyrrolidine analog **240**. Although **240** did show improved potency for OX1, selectivity over the OX2R was similar in both cases. In addition moderate oral bioavailability (40% F, 1 mg/kg PO) and low brain

penetration (B/P = 0.03) were reported for compound **240**. Further efforts were focused on modifications to the amide portion of these templates. Changing the phenyl pyrimidine to a thiazolo-phenyl benzamide, which is present in **SB-649686**, gave diverging results for these templates. Both molecules, **241** and **242**, retained their potency for the OX1R, while the pyrrolidine **242** gained a significant amount of potency for the OX2R. Since the goals of the Rottapharm team were to discover dual OX1/OX2 receptor antagonists, further efforts were focused on the pyrrolidine template as this template had already been shown to provide dual antagonists. This was apparent in the trifluoromethyl substituted compound **243** as well. Utilization of the 4,6-dimethylpyrimidine reversed this trend to give the moderately selective antagonist **244**. Efforts to reduce cLogP resulted in compounds **245** and **246** which maintained activity for the OX1 receptors. Unfortunately these molecules were CYP 3A4 time-dependent inhibitors. This issue was alleviated by replacing the pyrimidine ring with a phenyl ring. A key compound of note is the trifluoromethyl pyridine **247**. Simply moving the trifluoromethyl group from the 5-position to the 4-position gave a potent and selective OX2R antagonist that was a result of decreased OX1R potency. This theme has been discussed by others and reiterated here. Often times in the orexin field the pharmacology associated with a particular core can be modified with the pendant substituents to give dual or selective OX1R/OX2R antagonists.

7.06.13 The Scripps Research Institute

7.06.13.1 Piperidin-2-ylmethanamines

Based on patent disclosures and the work that has been disclosed in the primary literature surrounding **SB-649868**, workers at Scripps investigated the effect of methyl substitution on the piperidine ring of structures related to **SB-649868**.[71] Similarities between this work and **GSK1059865 (108)** are also apparent. This work began with compound **248** (Table 32) which was used as a benchmark for comparisons. The effect of methylation in the 3-position in a *cis*-orientation gave an OX1R antagonist with good potency and 100-fold selectivity over the OX2R. This is evident by comparing compounds **248** and **249**. Subsequent SAR led to compounds **250** and **251**. Both compounds maintained selectivity over the OX2R. Both of these molecules were also shown to have increased brain levels after 50 mg/kg ip dose when compared to **248**. Alternatively substituted piperidines in the three- and other positions on the piperidine ring did not appear to offer any advantages in regard to potency.

7.06.14 Taisho

7.06.14.1 TASP0428980

The research group at Taisho recently reported on a series of benzamides that were designed using ligand-based drug design. Using the U-shaped conformation disclosed by Merck and others, these researchers pursued the development of novel, short acting OXR antagonists in order to prevent any residual next-day effects in the clinic.[72] This work led to the preparation of **252**, a potent OXR antagonist. In efforts designed to reduce the lipophilicity of this lead other heterocyclic linkers (e.g., **253**, Table 33) were also prepared; however OXR affinity was reduced in most cases. The researchers also modified the alkyl substituent on the amide nitrogen and made changes to the substituents on the benzamide. In the end, the typical substituents that have been utilized in a variety of core series proved to have the best balance of affinity and lipophilicity and as such, compounds **255** and **256** were characterized further. Both were relatively short acting compounds, and **255** was chosen for additional studies due to the better brain distribution measured for this compound in rat. Compound **255 (TASP0428980)** was found to be very selective over >90 other targets, the brain to plasma ratio was measured at 0.17 in rat, and the predicted human half-life was assessed at between 1.2 and 1.4 h based on single species scaling in rat and dog.

7.06.15 Takeda

7.06.15.1 Spiropiperidine-Based Selective Orexin-2 Antagonists

Based on a template disclosed by Merck, workers at Takeda utilized the spirodiamine **257** (Fig. 31) as a lead for further optimization.[73] The template was chosen based on its desirable molecular properties. The initial work focused on modification of the pyrolidine ring to generate a fused aminal, as exemplified by compound **258**. This modification gave a moderately potent OX2R antagonist with poor selectivity over the OX1R and poor human microsomal stability. Replacement of the amino-quinoxaline with the phenyl urea as shown for compound **259** gave decreased potency, similar selectivity but slightly improved microsomal stability. In addition to that observation, the authors commented on the poor solubility and acid instability of the cyclic aminal of **259**. The strategy used to address these two issues was to reduce the electron density at the aminal carbon atom, which was expected to help stabilize the aminal. This was also thought to help with solubility by decreasing the symmetry in the molecule. An example of this is the fluorinated compound **260**, which was shown to decrease predicted

Table 32 Methylated piperidines **248–251**

Compound	R_1	*OX2R IC_{50} (nM)*	*OX1R IC_{50} (nM)*

249		858	8
250		>10,000	145
251		447	6

clearance to 2 mL/min/kg. In order to improve potency, substitution on the phenyl sulfonamide was explored. From this, the 3,4-dimethoxy phenyl compound **261** was identified as a potent OX2R antagonist with excellent selectivity over the OX1R receptor. Predicted human metabolic stability was measured as < 1 mL/min/kg. No information was disclosed on this molecule in relation to in vivo PK studies or brain penetration.

7.06.15.2 Benzoxazepine-Based Selective Orexin-2 Antagonists

Takeda also disclosed work beginning with the benzoxazepine **262**,[74] which was identified from a HTS campaign. The predicted rapid clearance for this compound initiated an investigation focusing on the likely metabolic hot spot, the 7-position methyl as indicated by R_1 in Table 34. The SAR was guided by analysis of Hammet (σ_p) and Hansch (π) parameters in this position. Replacement of the OMe in **262** with a less electron donating and lipophilic methyl group led to both a decrease in OX2R potency and microsomal stability. A small polar electron withdrawing group such as cyano (**265**) or lipophilic electron withdrawing

256		2.52	4.01

fluoro (**266**) resulted in reduced OX2R potency. However, increasing lipophilicity by replacement with a trifluoromethyl (**267**) or trifluromethoxy (**268**) restored OX2R potency and provided an improvement in microsomal stability. Ultimately the difluoromethoxy (**269**) substituted compound gave a potent OX2R receptor antagonist with excellent microsomal stability. Further profiling of **269** demonstrated selectivity over the OX1R receptor (OX1R $IC_{50} = 3000$ nM), good oral bioavailability in rat (52%), and low clearance 90 mL/h/kg. This compound was also able to reverse the orexin-A induced locomotion in rat suggesting central penetration. Brain exposure was predicted by the low efflux ratio of 0.4.

7.06.16 Summary of Compounds That Progressed to Clinical Trials

This section gives a summary of the OXR compounds that have progressed into human clinical trials and details the human doses that were given, the PK parameters of the compounds and select clinical efficacy/toleration data.

As shown in Table 35, many years of work by multiple research groups have resulted in the identification of numerous nonselective OXR and selective OX2R receptor antagonists that were deemed suitable to progress into human clinical trials. Several of these compounds have dropped out of the clinic for safety and/or efficacy reasons; however several compounds are still progressing, with promising efficacy results on sleep parameters. To date, one nonselective OXR antagonist, Belsomra, has been approved for use in humans. Given the sustained activity in the orexin field, it seems likely that other compounds will also eventually be approved for a variety of CNS indications.

Table 35 OXR antagonists that have progressed into clinical trials

Compound	Compound identifier/company name	Structure	OX2R IC_{50} (nM)	OX1R IC_{50} (nM)	Clinical doses tested	Human PK parameters	Comments	Status	Refs.
1	**ACT-078573 almorexant Actelion**		13	8	100, 200, 400, 600 mg	$t_{1/2}=1.6$ h $T_{max}=1.5$ h	Dose-dependent reduction in latency to sleep at doses >200 mg	Phase III, discontinued due to safety concerns	17,75
48	**ACT-462206 Actelion**		11 (K_i)	60 (K_i)	5, 25, 100, 200, 400, 1000, 1500 mg	$t_{1/2}=\sim$10 h @≥100 mg $T_{max}=1.5$–4.0 h	Well-tolerated without dose-limiting toxicity with a profile consistent with a sleep-inducing agent	Completed Phase I	15c,20
96	**E2006 Eisai**		3	6	5, 10 mg	Not reported	Tested in subjects with somnolence, no data reported	Phase I	27
105	**SB-649868 GlaxoSmithKline**		0.3 nM (K_i)	0.4 nM (K_i)	5, 15, 30 mg in RD, 10–80 mg in SD	RD $t_{1/2}=3$–6 h	Well-tolerated after single and repeated dose. Clinically relevant dose-dependent sleep promoting effects were observed	Completed Phase I, discontinued	29b–d
144	**JNJ-42847922 MIN-202 Janssen/Minerva**		10	800	10, 20, 40, 80 mg	$t_{1/2}=\sim$2 h $T_{max}=0.33$–0.5 h	Somnolence reported at all doses in healthy volunteers Efficacy reported in patients with insomnia disorder	Phase IIa	39,41

7.07.1 Introduction

7.07.1.1 Structural Determination of Gamma Secretase

γ-Secretase (GS) is a membrane-bound, multiprotein complex, which belongs to the aspartyl protease family of enzymes. In addition to amyloid precursor protein (APP), it processes several other type I integral membrane proteins, including Notch,[1] Jagged,[2] and CD44.[3] GS contains at least four components: anterior pharynx-defective 1 (Aph-1), presenilin enhancer protein-2 (Pen2), presenilin (PS1), and nicastrin (NCT),[4] comprising a total of 20 transmembrane domains (TMs). In human cells, two presenilin isoforms, PS1 and PS2, have been identified and two Aph1 homologues, Aph1a and Aph1b.[5] Together with NCT and Pen2, this can lead to six distinct GS complexes. All four components of the GS complex are required for protease activity. Presenilin-1, which comprises nine TMs, is endoproteolyzed during the assembly process of the GS complex to produce N- and C-terminal fragments, NTF and CTF, respectively, which remain associated as heterodimeric integral membrane proteins. The NTF protein contains TM domains TM1–6, whereas the CTF fragment contains the remaining three, TM7–9. The active site of GS consists of two aspartic residues (Asp257 and Asp385), which are found at the interface of the PS heterodimer, in TM6 and TM7. Aph1 contains seven TMs and plays an important role in the assembly, stabilization, and trafficking of GS complex. NCT contains a large, highly glycosylated ectodomain (ECD), which might be involved in the recognition of N-terminus of substrate protein, and one TM domain. Pen2 binds PS-1 directly and is important in the endoproteolysis of presenilin, as well as for GS activity.[6,7]

A considerable amount of work has been done to elucidate the structure of GS. Due to the complexity of GS, and therefore the difficulties in its isolation and purification, structural elucidation has been performed by electron microscopy (EM) experiments.[8,9] A first cryo-EM study was done at a resolution of 12 Å. The low resolution allowed the identification of only 19 of the 20 TM domains. Also, the identified TMs could not be assigned to the four components of GS complex and therefore could not provide any functional insight. More recently, Lu et al. reported a cryo-EM study at 4.5 Å, which revealed the three-dimensional structure of an intact human GS complex, in which the 19 TMs and a large, bi-lobed extracellular domain of NCT form a horseshoe-shaped TM domain. The low-resolution structure also allowed for the construction of a partial atomic model for NCT, which was found to be homologous in sequence and structure to glutamate carboxyl peptidase PSMA.[10] However, in this experiment, the 4.5 Å resolution could be applied only to ECDs, whereas the resolution for TM domains was of 5–7 Å. Further improvements in cryo-EM resolution have allowed structural refinement. At a resolution of 4.32 Å, a third TM domain was identified in Pen2, resulting in a total of 20 TMS for the GS complex.[11] This time, the 20 TMs could be assigned to the four components of the protease complex. Most recently, the same research group has reported elucidation of the first atomic structure of GS via single particle cryo-EM at a resolution of 3.4 Å Å, **Fig. 1**.[12] This model contains 598 residues in the TMs and 632 residues in the ECD and it confirms the previous TMs assignment to the GS subunits.

The model also confirms the horseshoe shape of TM domain of GS, which has a thin end, composed of the three TMs of Pen2, and a thick end, comprising the NCT TM domain. PS1 and Aph1 are located in the center of the horseshoe, whilst the TM domain of NCT interacts with TM1/5/7 of Aph1 via hydrophobic interactions. The remaining Aph1 TMs interact with TM8/9 of PS1. All three Pen2 TM domains bind to TM4 of PS1 and as a result the catalytic residues Asp257 and Asp385 are placed on the convex side of the horseshoe, and ~10.6 Å apart. The authors suggest that substrate binding, for instance, an inhibitor or a modulator, might trigger a conformational change that would bring the two aspartate residues in closer proximity, which is needed for proteolysis.

Most of the GS ECD is occupied by NCT ECD, which contains 11 glycans and interacts with the two ends of the TM horseshoe. The NCT ECD contains a small lobe and a large lobe. In the large lobe, a hydrophilic pocket containing residues Glu333 and Tyr337, previously reported as important in substrate recognition, is covered by an extended surface loop known as the lid and which comes from the small lobe, **Fig. 2**. The authors suggest that rotation of the large lobe relative to the small lobe around a central pivot (Phe 287) would cause the lid to open and allow substrate access to the putative binding site. This movement would also align the putative binding pocket in NCT with the cleavage site in PS1, positioning thus the substrate for cleavage.

Furthermore, the high resolution allowed for mapping and analysis of the mutations in presenilin known to be linked to familial Alzheimer's disease (FAD). Thus, more than two-thirds of the mutations present in the patients with FAD are derived from the PS-1 component of presenilin, the rest being attributed to PS-2 and APP.

In order to help elucidate the binding site of compounds to GS, in the absence of high-resolution protein structures, when drug discovery efforts were initiated, many groups have employed photoaffinity labeling (PALs) chemical probes. This work is discussed later, Section "**Photo-Activity Ligands**", once the different structural classes have been reviewed.

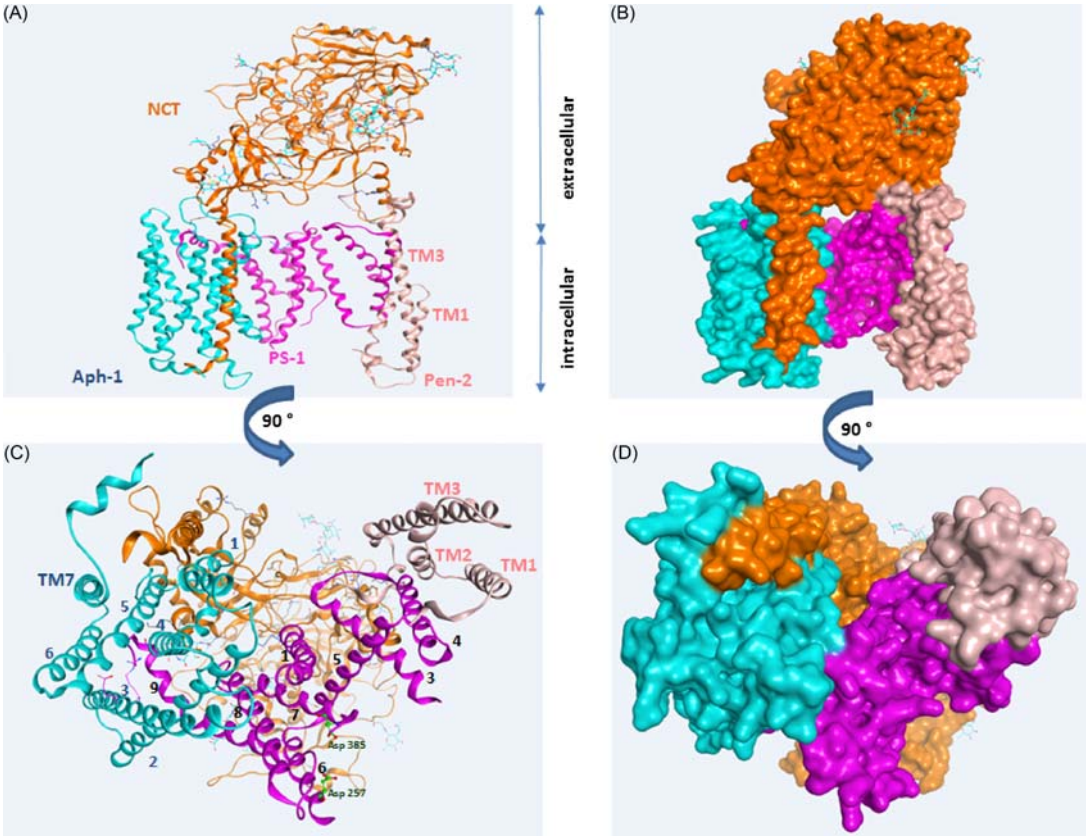

Fig. 1 Atomic model of GS, prepared using MOE software, from the deposited pdb 5A63 file.[12] (A) Ribbon representation; (B) surface view; (C) ribbon view from intracellular side, showing the TM domains. From the pdb deposited structure, TM2 of PS-1 could not be identified; (D) surface view from intracellular side.

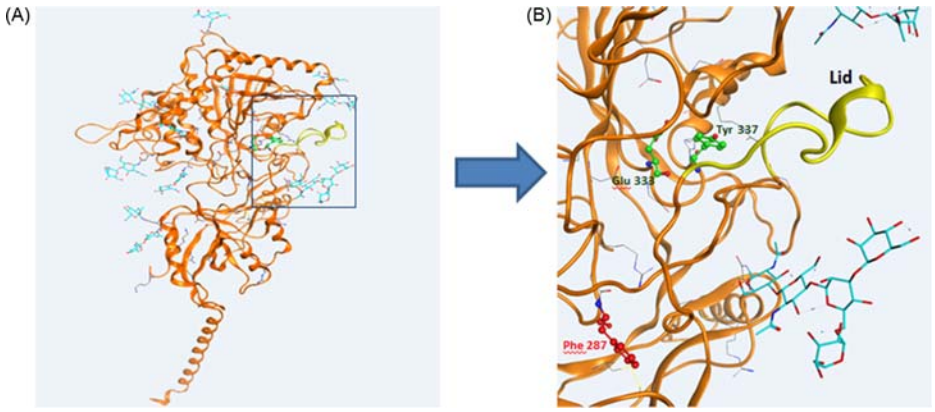

Fig. 2 Atomic structure of nicastrin, prepared using MOE software, from the deposited pdb 5A63 file.[12] (A) Ribbon representation, (B) enlarged view of the lid covering the hydrophilic pocket of Glu333 and Tyr337.

7.07.1.2 GS as Pharmaceutical Target for AD

The initial proteolytic cleavage of the TM APP by β secretase (β-site aPP cleaving enzyme (BACE)) forms two products, soluble APP (containing the extracellular domain of APP) and C99, a membrane-bound carboxy-terminal fragment (CTF). Subsequent cleavage of C99 in the TM domain of GS generates the Aβ peptides, with lengths of 37–43 aminoacids. Initial proteolysis at the membrane cytoplasm boundary, known as the ε site, releases APP intracellular domain into the cytoplasm, while leaving either $A\beta_{48}$ or $A\beta_{49}$ peptides embedded in the membrane. Each of these peptides is then successively cleaved by GS every three aminoacids, generating two product lines: $\varepsilon A\beta_{48}$-ζ $A\beta_4$-γ $A\beta_{42}$ or $\varepsilon A\beta_{49}$-ζ $A\beta_{46}$-γ $A\beta_{43}$-γ$A\beta_{40}$. The generated $A\beta_{40}$ and $A\beta_{42}$ can either be released in the

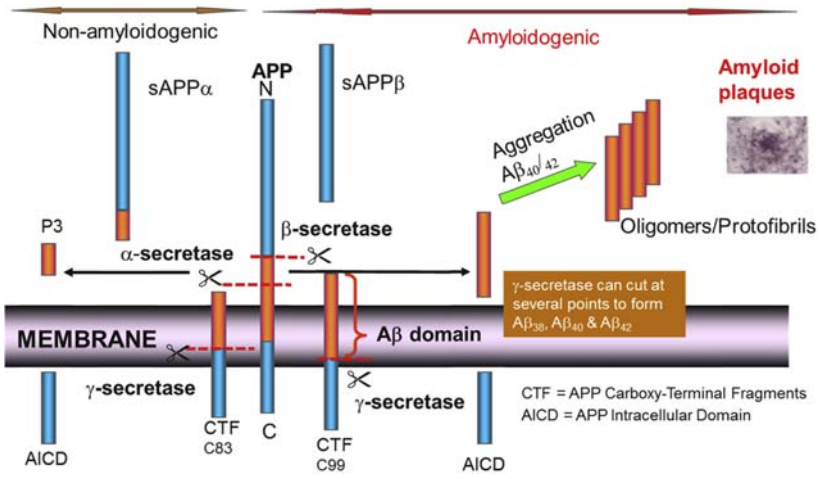

Fig. 3 Schematic of the amyloid pathway depicting the sequential cleavage of APP by β-secretase and γ-secratase. Also depicted, the alternative, nonamyloidogenic, sequential processing of APP by α-secretase and γ-secretase.

extracellular domain, or further cleaved to shorter isoforms, namely $A\beta_{39}$ and $A\beta_{38}$ from $A\beta_{42}$ product line and, respectively, $A\beta_{37}$ from $A\beta_{40}$ product line, Fig. 3.

The predominant forms of Aβ resulting from this process, $A\beta_{40}$ and $A\beta_{42}$, are known to have high propensity to aggregate and therefore comprise the main components of the senile plaques. Moreover, the amount of the longer isomer, $A\beta_{42}$, is selectively increased by mutations in the APP and presenilin genes, which are observed in familial AD. Therefore, many research groups consider $A\beta_{42}$ to be the main culprit in the pathogenesis of AD.[13]

Even in the absence of a molecular mechanism for the second cleavage step of APP, the GS complex has become one of the prime targets in the search for a disease modifying anti-AD drug.[14] A first major strategy to reduce the levels of $A\beta_{42}$ was via inhibition of GS. Various classes of γ-secretase inhibitors (GSIs) have been synthesized, including peptidomimetic compounds such as DAPT, aryl sulfonamides, cycloalkylcarboxamides, pyrazole-derived GSIs, to name just a few.[156] A number of GSIs have advanced into phase II and phase III clinical trials such as Semagacestat/LY-450149, ELND006, Avagacestat/BMS-708163, and Begacestat/GSI-953. However, the progression of all these compounds has been halted however due to the numerous side effects observed: liver toxicity, gastrointestinal effects, dermatological effects, and the absence of an effect on cognition. It became evident that GS has proteolytic activity on other substrates, such as Notch, which is essential for normal biological functions and whose inhibition leads to several undesirable side effects in the thymus, spleen, and intestine. While one approach to circumvent the problem has been the search for selective inhibitors with an acceptable degree of separation between APP and Notch activity, another has been the design of γ-secretase modulators (GSMs),[16] a class of compounds which are able to reduce the level of longer, neurotoxic Aβ peptides while maintaining the total Aβ level constant.

The first modulators of GS were nonsteroidal anti-inflammatory drugs (NSAIDs), discovered when epidemiological studies reported a reduced prevalence of AD among users of NSAIDs. Thus, drugs such as ibuprofen, indomethacin, and sulindac sulfide were able to decrease the production of $A\beta_{42}$ levels and stimulate those of $A\beta_{38}$ both in vitro and in vivo. Tarenflurbil (**1**), Fig. 4, was the first GSM to enter clinical trials. It was discontinued in PhIII, however, due to lack of efficacy resulting from insufficient potency and poor brain penetration, *vide infra*.

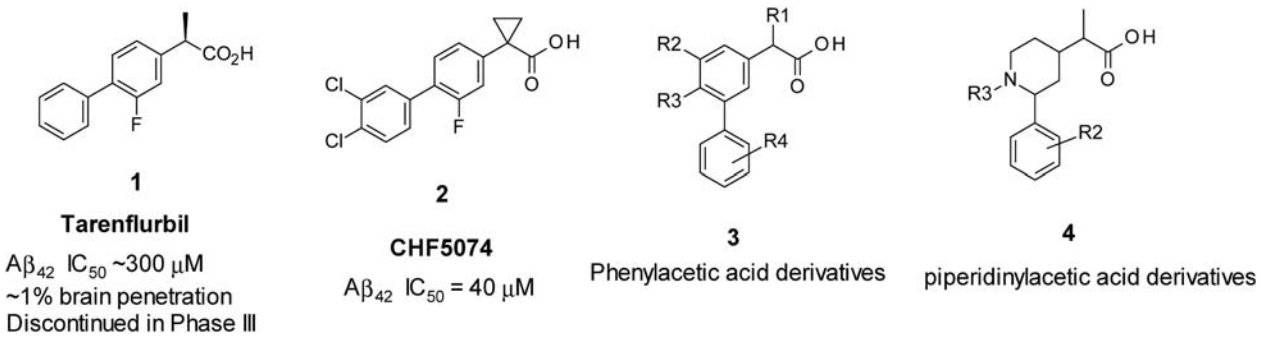

Fig. 4 Examples of NSAID and NSAID-derived GSMs.

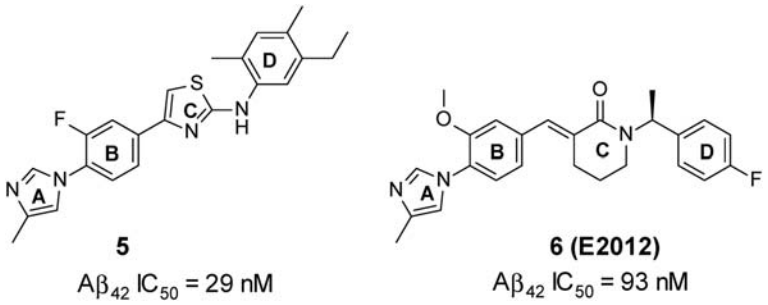

Fig. 5 Non-NSAID aryl-imidazole-derived GSMs.

This initial clinical trial was followed by a considerable amount of work aimed at discovery of more potent and more brain penetrant GSMs.[17] Initial design centered around the tarenflurbil structure, resulting either in direct analogs, such as CHF5074 (**2**), Fig. 4, *vide infra*, or in compounds in which the phenylacetic acid core of tarenflurbil was preserved, while the substituents at 3-, 4-, or/and 5-position were extensively explored, for example, **3**, Fig. 4, *vide infra*. Another class of NSAID-derived GSMs is represented by the piperidinyl-acetic acid derivatives targeting GSMs **4**, Fig. 4, with reduced lipophilicity (*vide infra*). In general, the NSAID-derived GSMs selectively reduce $A\beta_{42}$ levels and do not affect $A\beta_{40}$ levels, whilst compensating by increasing the levels of $A\beta_{37}$ and $A\beta_{38}$.

A second class of GSMs is represented by the non-NSAID, or aryl-imidazoles. The first compounds in this class were anilinothiazole **5**, followed by related cinnamide **E2012 (6)**, Fig. 5, *vide infra*.

As will become evident during this review, these two compounds represented the starting point in the design of novel series of non-NSAID GSMs for many research groups. The aryl-imidazole on left hand side has proven essential in most cases for the in vitro potency of GSMs and therefore difficult to replace. Thus, there are many similarities between the various (sub)-classes of GSMs, sometimes even overlaps. Since most of the exemplified compounds contain the four consecutive (heteroaromatic) rings, these were designated as **A**-**B** for the imidazo-aryl left hand side, **C**- for the central core, and **D**- for the (aromatic) appendage and referred to as such during the text. The pharmacophore consists of what is believed to be a hydrogen bond acceptor (HBA) moiety, fulfilled by the A-ring imidazole, and central HBA moiety, denoted by the C-ring/amide, and a lipophilic/aromatic moiety, as shown by the D-ring. In general, compounds from this series reduce $A\beta_{42}$ selectively over $A\beta_{40}$, but the levels of both proteins are generally reduced. To compensate, the shorter chain amino acids such as $A\beta_{37}$, $A\beta_{38}$, and $A\beta_{39}$ are generally increased.

This review steps through the work of each research group, by alphabetical order, and highlights key compounds from each series from both the primary peer-reviewed literature and the patent literature.

7.07.2 Modulators From Acturum Life Science

Formed in 2013 and based in the Biovation Park on the former AstraZeneca Sodertalje site, and with some of the former AstraZeneca chemists who worked on the GSM project, Acturum Life Science chemists have recently disclosed some of their work in the field. Although the compounds still include the aryl-imidazole moiety, linked via an amide to a triazole or pyrimidine, they do offer some structural diversity. Published examples have data in both HEK cells overexpressing APPSwe and mouse primary cortical neurons (PCN). Examples include the diaminotriazole derivatives with an azetidine on the right hand side, **7** and **8**,[18] the related benzyl analog, **9**,[19] and the diaminopyrimidine derivatives **10** and **11**,[20] Fig. 6.

7.07.3 Modulators From Amgen

Amgen have had a long standing interest in the amyloid field, directed mainly at the identification of BACE inhibitors, however they have also had a brief foray to the GS field. Published patent applications describe compounds from the aryl-imidazole template, where the methylimidazole has been replaced by a methylpyridine and the typical heterocycle has been replaced by an amide such as **12**[21] or a urea such as **13**,[22] Fig. 7. Analysis of the data on each series suggest that achieving sufficient potency appears to have been challenging, and the physicochemical properties also appear suboptimal.

7.07.4 Modulators From Ares Trading/Merck KGAA

Whilst still active in the neuroscience field, Merck KGAA (Merck Serono at the time) had an interest in GSMs and has a published patent application in collaboration with the chemistry group at BioFocus in the UK. The exemplified compounds come from the aryl-imidazole chemotype and resemble compounds disclosed by other companies. A typical example is shown by **14**,[23] Fig. 8.

7.07.5 Modulators From Astellas

The Astellas group has worked on carboxylic acid-derived GSM, which contains the familiar acetic acid moiety, which is linked to a central cyclohexane ring. Saturation of the central ring allows incorporation of a basic center, similar to derivatives disclosed by Pfizer (e.g., **118**, Fig. 35). The other key pharmacophoric elements project from the cyclohexane ring either from the 3,4-positions,

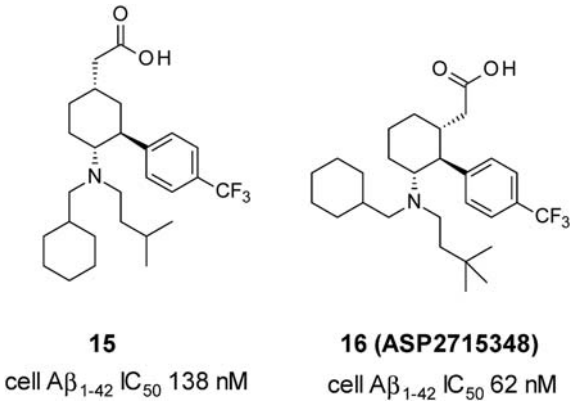

Fig. 9 Selected compounds from Astellas patent application, with ASP2715348 highlighted.

15, or in the 2,3-position, **16**, Fig. 9.[24] **15** was reported to reduce hippocampal $A\beta_{42}$ in vivo in a dose-dependent manner at doses of 3, 10, and 30 mg kg^{-1} with 25%, 45%, and 61% reductions, respectively, whilst **16** was reported to reduce hippocampal $A\beta_{42}$ in vivo by 29% following a 30 mg kg^{-1} dose.

Astellas have recently described the pharmacology of AS2715348 (**16**), Fig. 9,[25] in more detail. AS2715348 was found to inhibit $A\beta_{42}$ production in a cell-free system, IC_{50} 450 nM, and in H4 cells overexpressing APP, IC_{50} 128 nM, whilst exhibiting no inhibition of Notch up to 10 μM in the same cell line. The compound displayed little difference in activity across species; human $A\beta_{42}$ IC_{50} 62 nM (SK-N-BE(2) cells), mouse $A\beta_{42}$ IC_{50} 156 nM (neuro2A cells), rat $A\beta_{42}$ IC_{50} 121 nM (primary cortical neurons). In a time course study in rats, AS2715348 was found to reduce $A\beta_{42}$ in brain, CSF, and plasma following a 5 mg kg^{-1} oral dose, with maximal reductions of 33%, 32%, and 56%, respectively. The Br:Pl AUC was 0.22 showing reasonable penetration into the CNS, whilst the CSF C_{max} was 13 ng mL^{-1} and brain C_{max} was 379 ng g^{-1}. In a rat dose–response study, 1–10 mg kg^{-1} doses of AS2715348 caused a dose-dependent decrease in brain $A\beta_{42}$ (15–49%) 4.5 h after administration. In cynomolgus monkeys, a 10 mg kg^{-1} dose of AS2715348 caused a 34% reduction in plasma and brain $A\beta_{42}$, 34% in plasma, 21% in hippocampus, and 16% reduction in cortex, respectively, 4 h postdose, with a Br:Pl of ~0.4. The ability of the compound to reverse the cognitive deficits in 5.5-month-old Tg2576 mice was also assessed. In this model, the effect on cognition was assessed using the Y-maze 3 h after a single dose and again after a further 7 days, that is, a total of 8 days dosing. On day 1, a dose–response reversal of cognitive impairment was seen in three dose groups, 0.3, 1, and 3 mg kg^{-1}, with the 3 mg kg^{-1} group giving full reversal and a 0.1 mg kg^{-1} having no effect. After 8 days of dosing, the 0.3 and 1 mg kg^{-1} groups both had full efficacy whilst the 3 mg kg^{-1} group was efficacious also, but with lower significance. Interestingly, analysis of brain $A\beta_{42}$ levels at the end of the study showed the 0.3 mg kg^{-1} dose group had no effect on $A\beta_{42}$ levels, whilst the 1 mg kg^{-1} group had a slight effect and the 3 mg kg^{-1} group had $A\beta_{42}$ levels 31% lower than vehicle controls. Thus, although these data show a GSM is able to reverse the cognitive deficit in Tg2576 mice, the relationship between brain $A\beta_{42}$ and cognition is not clear.

Analysis of the Astellas pipeline reveals there are currently no GSMs undergoing clinical development and review of previous pipeline updates shows it is unlikely that they progressed a GSM to clinical trials.

7.07.6 Modulators From AstraZeneca

AstraZeneca disclosed in 2010 two series of potent GSMs having the classical imidazolo-anisole system linked to bicyclic aminopyrimidines (**17**) or pyridines (**18**), Fig. 10.[26,27] A subsequent patent application disclosed a series of potent analogs of **18**,[28] highly

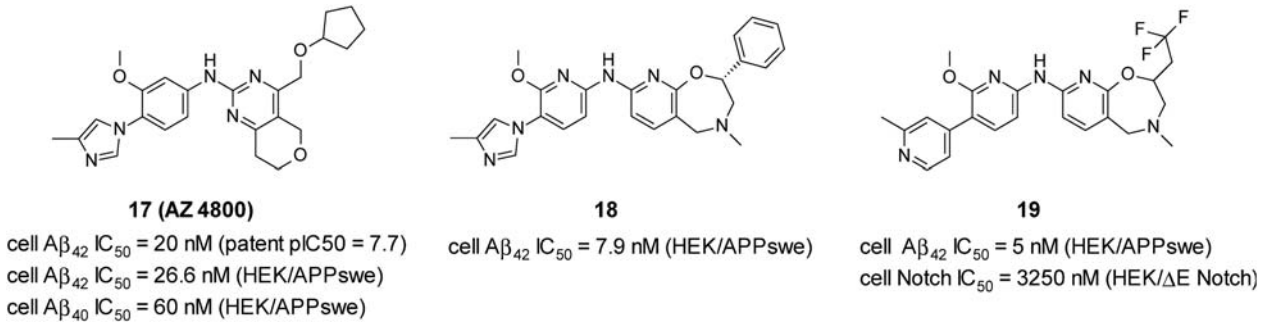

Fig. 10 AstraZeneca's bicyclic amino heterocycles.

selective over Notch, in which the aromatic appendage was replaced by aliphatic side chains (**19**, Fig. 10). This resulted in compounds with reduced aromaticity and lipophilicity.

The modulatory properties of **17**, also known as **AZ-4800**, were described in a report published at a later date. Thus, when tested in HEK cell lines expressing APP with Swedish mutation (APPswe), **AZ-4800** decreased the levels of both $A\beta_{42}$ ($IC_{50} = 26.6$ nM) and $A\beta_{40}$ ($IC_{50} = 60$ nM), while increasing the levels of $A\beta_{37}$ by 750% and $A\beta_{38}$ by 300%. **AZ4800** did not inhibit NICD translocation, showing about ~1000-fold selectivity for Aβ modulation over NICD formation. Furthermore, in vivo efficacy studies indicated that **AZ-4800** was able to penetrate the CNS and could decrease $A\beta_{42}$ levels in the brain of wild-type (C5BL7/6) mice.[29] Thus, acute p.o. dosing of **AZ-4800** at 75, 150, and 300 μmol kg^{-1} decreased $A\beta_{42}$ levels in brain homogenates by 26%, 40%, and 46%, respectively, 1.5 h postadministration. At these doses, the corresponding free concentrations of **AZ-4800** in the mouse brain were ~130, 340, and 880 nM, respectively, with a Br:Pl ratio of 2.4 (average of doses).

An analog belonging to the bicyclic aminopyridine series, **AZ-4126**, was also extensively used for in vivo studies.[30] This analog, presumably **18** based on the reported molecular weight ($MW = 442.52$ g mol^{-1})[31] and reference to the patent describing its preparation, was a potent GSM, causing a reduction in the levels of $A\beta_{42}$ ($IC_{50} = 6$ nM) and $A\beta_{40}$ ($IC_{50} = 22.5$ nM) in HEK/APPswe cells, while leaving the total level of Aβ unaffected. **AZ-4126** was tested at three doses in wild-type mice (C57BL/6), at doses of 10, 25, 50, and 75 μmol kg^{-1}, where it showed a dose-dependent reduction of both $A\beta_{42}$ (9, 17, 33, and 40%) and $A\beta_{40}$ (9, 19, 29, and 36%), 2 h postadministration. A more recent study evaluated the central effects of **AZ-4126** in guinea pig, which is also used as a preclinical model.[6] Thus, when **AZ-4126** was administered to the guinea pig at 30, 75, and 150 μmol kg^{-1}, it was able to significantly reduce the brain $A\beta_{42}$ levels in a dose-dependent manner by 16%, 34%, and 49%, respectively, 2.5 h after administration. In the same time, the brain $A\beta_{40}$ levels were reduced by 36%, 47%, and 68%, respectively. These reductions corresponded to unbound brain concentrations ($C_{u,b}$) of 6, 12, and 53 nM, respectively. In CSF, it significantly reduced $A\beta_{42}$ only at the highest dose (150 μmol kg^{-1}), by 53%. On the other hand, in a time course study, **AZ-4126** was administered at 150 μmol kg^{-1} and the effect on CSF Aβ peptides was assessed at 1, 6, 16, and 24 h after administration. The maximum effect was observed 1 h postdosing, when $A\beta_{37}$ levels increased to 170%, with return to vehicle levels after 24 h, while $A\beta_{40}$ decreased to ~70% and then returned to vehicle levels after 24 h, with no rebound effect. At 1 h postdose, the $C_{u,b}$ had the maximum value of 62 nM. Because $A\beta_{42}$ levels were below the limit of detection for some samples, they were excluded from further analysis.

In a report from 2013,[32] Astra Zeneca disclosed a series of analogs in which the amino-linked C-ring/core was replaced with a bicyclic triazole. The starting point for this series were GSMs possessing a triazolopiperidine core, already described in the literature by research groups at Eisai (**E2212**, compound **6**, Figs. 5 and 18), Roche (**131**, Fig. 38), and Janssen[33] depicted by structure **20** in Fig. 11. AstraZeneca's initial optimization efforts focused on replacing the classical A–B imidazole-anisole system. It was observed that two main factors were important to preserve GSM potency: (a) conservation of the aromatic character of A and B rings and (b) the strength and position of the HBA in the A-ring. The most potent analog resulting from this exploration was **21**, in which the imidazole A-ring was replaced by a pyridazine. Another noteworthy analog was **22**, which still showed modest potency despite having the aromatic ring replaced by an acetonitrile side chain.

AstraZeneca's next efforts were directed at identification of novel core structures, distinct from the ones reported by Janssen and Roche, and with improved overall physicochemical and drug-like properties. In order to decrease lipophilicty of compounds such as **20**, the fused piperidine ring was replaced with a fused tetrahydropyrimidone moiety. This resulted in identification of **23**, Fig. 12, a potent GSM which suffered from poor solubility (6 μM) and showed micromolar inhibition of the hERG channel (hERG $IC_{50} = 3.7$ μM). Pharmacokinetic (PK) profiling in mouse showed that **23** had good brain penetration, with Br:Pl of 0.72, moderate clearance (Cl = 21 mL min^{-1} kg^{-1}), short half-life ($t_{½} = 0.6$ h) and low oral bioavailability ($F = 32\%$). When administered orally to wild-type mice (C57BL/6) at 150 μmol kg^{-1}, it reduced $A\beta_{42}$ peptides by 24%, 1.5 h postadministration, while at lower dose of 50 μmol kg^{-1} it was inactive.

Attempts to increase the solubility of the tetrahydropyrimidone-derived GSMs were successful only when the amide bond on the core was reduced to an amine, yielding tetrahydropyrimidine derivatives. One of the most interesting examples from this new subseries was **24**, Fig. 12, which combined good in vitro potency with an improved overall profile. Not only was the kinetic solubility improved (63 μM), but this compound did not significantly inhibit the hERG channel (hERG $IC_{50} = 33$ μM). The PK profile was

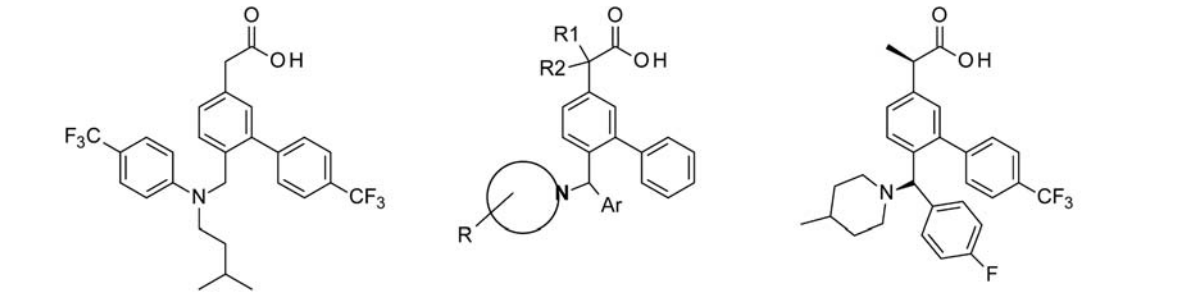
also improved, **24** having an excellent oral bioavailability of $F = 91\%$. Interestingly, an analysis of the GSM profiles of **23** and **24**, incubated for 5 h in HEK/APPswe cells, showed different behavior for the two compounds. Thus, **23** behaved as a typical GSM, lowering the levels of $A\beta_{42}$ and $A\beta_{40}$ and increasing the level of shorter $A\beta_{38}$ and $A\beta_{37}$. At concentrations of 10 nM, it inhibited the production of $A\beta_{42}$ without affecting the $A\beta_{total}$ levels and Notch cleavage. On the other hand, **24** switched its GSM characteristic to that of inhibitor of APP processing. In this case, 10 nM concentrations of **24** reduced the $A\beta_{total}$ levels, without affecting however the Notch processing.

7.07.7 Modulators From Biogen

GSM research at Biogen focused on the carboxylic acid series, aiming to improve potency and CNS penetration of the NSAID-like GSMs.[34] An early Biogen lead, **25** (**Fig. 13**), which reduced the $A\beta_{42}$ levels in APP-CHO cellular assay by 50% at 1 μM, was poorly brain penetrant, reaching 0.6 μM 4 h after being dosed at 50 mg kg^{-1}. To address this issue, more rigid analogs, which also incorporated basic amines (**26**, **Fig. 13**), were designed, by conformationally restricting the *i*-butyl side chain in **25** into a cyclic amine, while swapping the *N*-(trifluoromethylphenyl) substituent from the benzylic nitrogen to the benzylic position. Optimization of **26** structures led to the identification of preclinical candidate **BIIB042**, (**27** in **Fig. 13**). When tested in Chinese hamster ovary (CHO) cells overexpressing APP V717F mutation, this compound showed good lowering of $A\beta_{42}$ levels ($IC_{50} = 170$ nM) and increase of $A\beta_{38}$ ($EC_{50} = 150$ nM), while the $A\beta_{40}$ levels remained unchanged. The in vitro potency translated into 40% lowering of $A\beta_{42}$ in the brain of wild-type mice at 10 mg kg^{-1}, 4 h after administration. This effect corresponded to a total brain exposure of 4.6 μM and a Br:Pl ratio of 0.46.

More recently, **BIIB042** was assessed in efficacy studies in vivo.[35] First, the in vitro potency was confirmed in human H4 cells expressing human APP, where **BIIB042** reduced the levels of $A\beta_{42}$ ($IC_{50} = 64$ nM), increased $A\beta_{38}$ ($EC_{50} = 146$ nM), and had limited effect on $A\beta_{40}$. **BIIB042** demonstrated similar pharmacodynamic (PD) effects when tested in vivo across species. For instance, acute p.o. dosing of **BIIIB042** to CF1-mice at 3, 10, 30, and 100 mg kg^{-1} produced a significant modulation of Aβ peptides in a dose-dependent manner, both in brain and in plasma, when measured 4 h after dosing. For instance, at 100 mg kg^{-1} dose, $A\beta_{42}$ levels were reduced by ~60% in brain and 45% in plasma, whereas $A\beta_{38}$ levels increased by ~98% in brain and 82% in plasma. On the other hand, $A\beta_{40}$ peptides showed a more modest, non dose-dependent decrease, at 100 mg kg^{-1} being reduced by ~16% in brain



25

Fig. 13 Carboxylic acid derivatives from Biogen.

and ~25% in plasma. Br:Pl ratio was ~0.8 across all doses. Furthermore, it was determined that a compound brain concentration of 2.8 μM was required to reduce the brain $A\beta_{42}$ by 29%. Similar PK/PD effects were observed in brain, plasma, and CSF of the F344 rat. In a time course study, **BIIB042** was administered at a single dose of 10, 30, or 100 mg kg^{-1} to CF1 mice, and the PD effects were evaluated up to 48 h after dosing. At 10 mg kg^{-1}, a maximum 40% inhibition of brain $A\beta_{42}$ production was observed 4 h postdosing, whereas a maximum ~50% stimulation of $A\beta_{38}$ occurred 16 h postdoing. No effect was observed on $A\beta_{40}$ levels. At 10 mg kg^{-1}, the maximum brain exposure of **BIIB042** was achieved 4 h postdosing and reached a concentration of 7.5 μM. After 48 h, Aβ peptide levels returned to normal. Cynomolgus monkeys were also treated with a single 10 mg kg^{-1} dose of **BIIB042** in a 72 h time course experiment. A PK/PD relationship similar to that in rodents was observed. Subchronic administration of **BIIB042** to 5-month-old Tg2576 mice, at doses of 3, 10, 30, and 60 mg kg^{-1} day^{-1} for a total of 65 days produced a similar modulation of Aβ peptides to those observed in WT mice, for both soluble and insoluble peptides. Soluble brain $A\beta_{42}$ levels were reduced in a dose-dependent fashion, with a maximum ~50% reduction at 60 mg kg^{-1} day^{-1}. Soluble brain $A\beta_{38}$ levels showed a maximum 60% increase at 30 mg k^{-1} day^{-1}, while soluble brain $A\beta_{40}$ were unaffected. Insoluble brain $A\beta_{42}$ were also significantly and dose dependently reduced, at 60 mg kg^{-1} day^{-1} being reduced by 80%. Insoluble $A\beta_{40}$ were also reduced, a significant effect being observed only at a 60 mg kg^{-1} day^{-1} dose. **BIIIB042** was dosed chronically in 10 months old Tg2576 mice, at doses of 0.3, 1, 10, or 30 mg kg^{-1} day^{-1} and the PD effects analyzed 6 months after treatment. Both soluble and insoluble brain $A\beta_{42}$ levels were significantly decreased at 10 and 30 mg kg^{-1} day^{-1}. Soluble and insoluble brain $A\beta_{40}$ levels showed an increase at 0.3 and 1 mg kg^{-1} day^{-1}, no effect at 10 mg kg^{-1} day^{-1} and a significant decrease at 30 mg kg^{-1} day^{-1}. Soluble and insoluble brain $A\beta_{38}$ were increased at 0.3, 1, and 10 mg kg^{-1} day^{-1}, the effect being more pronounced for insoluble fractions at 0.3 and 1 mg kg^{-1}. At 30 mg kg^{-1} day^{-1} soluble $A\beta_{38}$ showed a slight decrease, while insoluble fractions were unaffected. Animals treated with 30 mg kg^{-1} day^{-1} of **BIIB042** had a significantly lower parenchymal plaque staining in the cortex and in the hippocampus.

Based on its PD effects and reduction of plaque pathology, BIIB042 was reported to have entered into advanced safety and tolerability studies, before its planned progression to clinical trials.[35] However, it appears that the compound did not reach the clinic and there has been no recent patent activity from Biogen in the GSM arena, suggesting that they are no longer working in the field.

7.07.8 Modulators From Bristol-Myers Squibb

The group at Bristol-Myers Squibb (BMS) has had a long standing interest in GS, having taken the GSI avagacestat (BMS-708163) to the clinic.[36] Since then they have switched focus to GSMs and publications are now emerging, which delineate their research. An HTS in human H4 cells expressing APP751 Swe mutant identified triazine hit **28**, which was homologated to give the benzyl analog **29**, which displayed a sixfold improvement in potency, Fig. 14.[37]

The introduction of a conformational constraint with simultaneous replacement of the triazine by a thiazole resulted in **30**, Table 1. Replacement of the imidazole HBA moiety was explored on this template as exemplified by **31–34**, all of which resulted in a substantial decrease in potency, Table 1.

Although found to be a potent inhibitor of CYP3A4, IC_{50} 700 nM, and having very high plasma protein binding (ppb, >99.8% in mouse and human), **30** was profiled in vivo in a 3×Tg mouse model at doses of 1, 3, 10, 30, and 100 mg kg^{-1} p.o., which resulted in 30%, 50%, and 50% reductions in brain $A\beta_{1-42}$ at the three highest doses, respectively. The brain concentration was measured at 8900 nM, with corresponding plasma concentration of 800 nM at the 30 mg kg^{-1} dose, 3 h postdose, which resulted in a Br:Pl of 1.1. Thus, the compound elicited moderate reductions in brain amyloid at relatively high doses and exposure, especially when considered in the context of CYP3A4 inhibition.

Another manuscript describes alternative cyclization strategies to optimize **29**, which resulted in compounds such as **35**, Fig. 15.[38] Despite promising in vitro activity, **35** failed to show efficacy in vivo at 30 mg kg^{-1} p.o., which was attributed to low CNS exposure.

Despite this, alternative cyclization strategies appeared more fruitful as shown by the patent literature and recent pharmacological data. Thus, scaffold hopping to give fused amino-triazole derivatives, such as **36**, and **37** (**BMS-869780**),[39] Fig. 15, resulted in potent cellular activity. Interestingly, both compounds incorporate the chloroimidazole, which would be expected to decrease the HBA ability of the imidazole N-atom, as shown by the activity of **32**. This moiety may also provide other favorable properties

including intellectual property as its use is not widespread. BMS-869780 (**37**) has been characterized in detail.[40] In mouse embryonic fibroblasts (MEF,M146V), to align data for experiments in 3×Tg mice, BMS-869780 reduced $A\beta_{1-42}$ and $A\beta_{1-40}$ with IC_{50} values of 22 nM and 34 nM, respectively. In the rat, ip administration of doses from 0.3 to 100 mg kg^{-1}, with efficacy assessed 5 h postdose resulted in significant reductions in brain $A\beta_{1-42}$ with the 3 mg kg^{-1} dose achieving nearly 50% reduction and the 30 and 100 mg kg^{-1} doses reaching essentially full reduction, c.75%. Brain $A\beta_{1-40}$ paralleled $A\beta_{1-42}$ but was reduced by ~90% at doses of 30 and 100 mg kg^{-1}. In a separate experiment, doses of 1.9, 22, 100, and 235 mg kg^{-1} BMS-869780 were given to rats, and brain amyloid peptides were measured 24 h later. Doses of 200 and 235 mg kg^{-1} resulted in strong reductions in $A\beta_{1-42}$ and $A\beta_{1-40}$, with the reductions compensated by increases in $A\beta_{1-37}$ (largest increase) and $A\beta_{1-38}$, resulting in no overall change in total Aβ levels. Time course studies on rats (10 mg kg^{-1} p.o.) and 3×Tg mice (30 and 100 mg kg^{-1} p.o.) resulted in calculated plasma concentrations of 1.9 μM and 4.0 μM to reduce brain $A\beta_{1-42}$ by 50%, respectively. Employing ppb data (99.5% in rat and 99.6% in mouse), resulted in calculated free plasma concentrations of 5.1 nM and 22 nM, respectively, which are in line with the in vitro the in vitro cellular data. Utilizing the in vivo activity data in conjunction with allometric scaling resulted in predicted human doses of 700 mg BMS-869780 to achieve 25% reductions in brain $A\beta_{1-42}$. In addition, BMS-869780 was found to activate PXR and to increase CYP3A4 expression in human hepatocytes at concentrations of 300 nM and above, with EC_{50} values in the 1 μM range. Furthermore, in a rat 4 day safety study (10, 30, 100 mg kg^{-1}), BMS-869780 showed signs of lipidosis in the liver at doses of 10 mg kg^{-1} (C_{max} 1.9 μM) and above, thus showing no separation between efficacy and hepatotoxicity. As a consequence, the further investigation of BMS-869780 was halted in search for compounds with increased in vivo potency and better separation over off-target effects.

A subsequent patent application describes examples, where the fused aminotriazole core has been replaced by a fused diaminopyrimidine core, such as **38**, **39**, and **40 (BMS932481)**,[41] Fig. 15, which are closer to the original HTS, **28** and early lead **29**. Ultimately, BMS-932481 (**40**) was progressed to PhI single ascending dose (SAD) and multiple ascending dose (MAD) clinical studies, and the detailed pharmacological profile[42] and clinical data[43] have recently been disclosed. As with other GSMs, BMS-932481 was found not to affect total Aβ levels in cellular assays, as the reduction in $A\beta_{1-42}$ and $A\beta_{1-40}$ were compensated by increase in $A\beta_{1-37}$ and $A\beta_{1-38}$. Profiling in vivo was conducted across several preclinical species, including rat, dog, and monkey. In the rat, doses of 1, 5, and 10 mg kg^{-1} i.v. of BMS-932481 resulted in up to 75% reductions in brain and CSF $A\beta_{1-42}$ with similar decreases in $A\beta_{1-40}$ levels, which was compensated by increases in $A\beta_{1-37}$ and $A\beta_{1-38}$ levels. The Br_{AUC}:Pl_{AUC} was ~0.6. In the dog, oral doses of 2, 5, and 30 mg kg^{-1} reduced CSF $A\beta_{1-42}$ and $A\beta_{1-40}$ levels to a similar extent, with the maximal effect being a 65% reduction in $A\beta_{1-42}$ 24 h postdose. There was a weak increase in $A\beta_{1-38}$, but $A\beta_{1-37}$ increased up to fivefold. In the monkey, i.v. administration of doses of 5 and 15 mg kg^{-1} resulted in pronounced parallel reductions of CSF $A\beta_{1-42}$ and $A\beta_{1-40}$ levels, with a maximal effect of 75% 12–24 h after the higher dose. $A\beta_{1-38}$ and $A\beta_{1-37}$ levels showed maximal increases of threefold and eightfold, respectively. In a human SAD study (10, 30, 100, 300, 600, 900, 1200 mg), CSF Aβ levels were monitored serially for 24 h after a 900 mg dose.

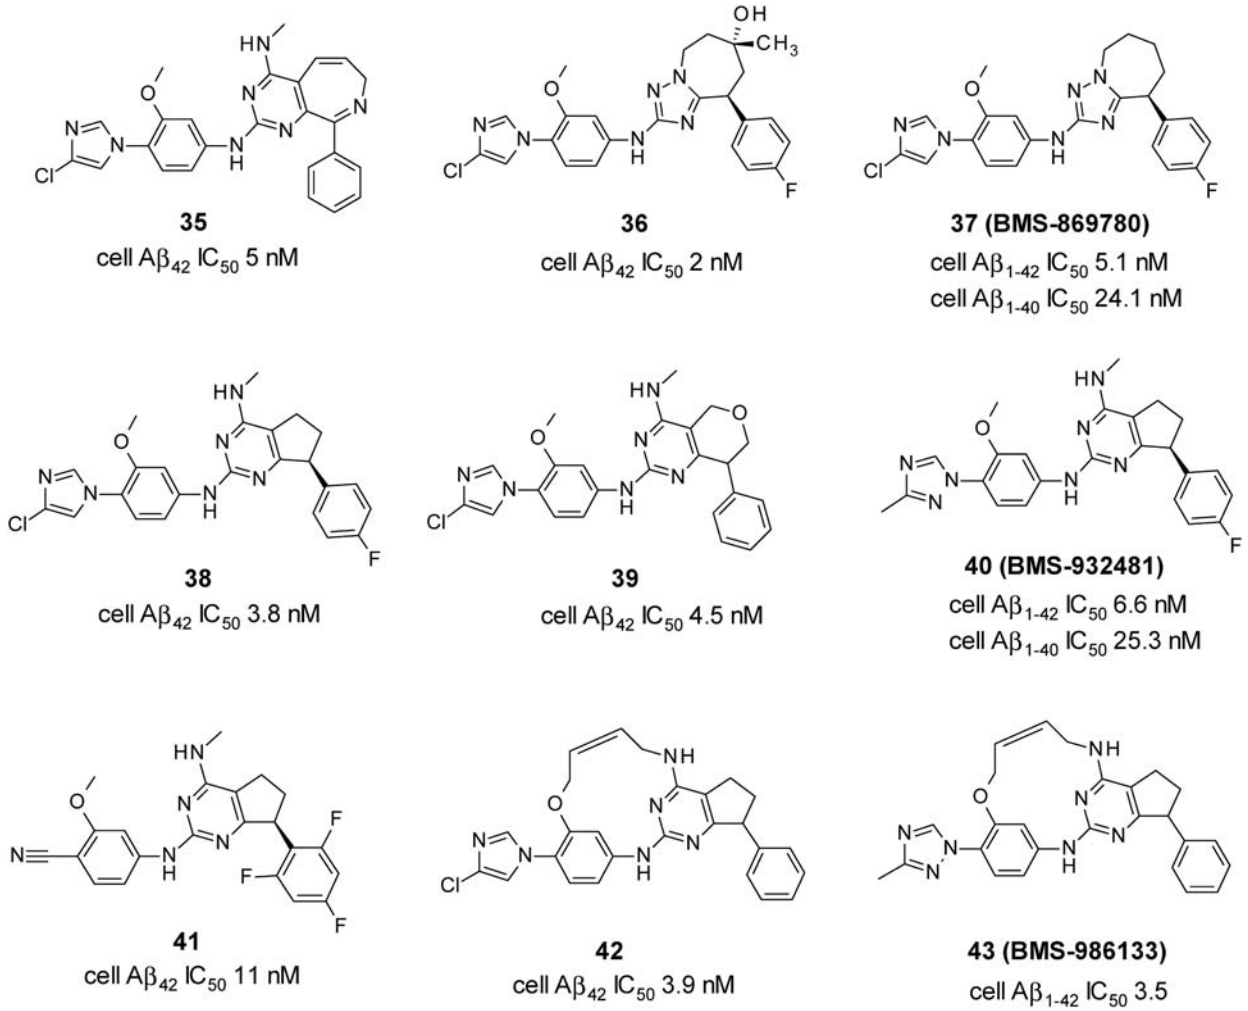

Fig. 15 Further compounds from BMS, including key compounds BMS-869780 (**37**), BMS-932481 (**40**), and BMS-986133 (**43**).

After initial increases (60% vs. predose), CSF $A\beta_{1-42}$ levels decreased slowly with maximal reductions of around 50% of predose levels 24 h postdose. The placebo treated volunteers also showed increased $A\beta_{1-42}$ (and $A\beta_{1-40}$) versus predose followed by a gradual return to near predose levels. The reductions in $A\beta_{1-40}$ levels were similar to those of $A\beta_{1-42}$, whilst $A\beta_{1-38}$ levels increased approximately twofold, there were stronger increases in $A\beta_{1-37}$, which increased by 12-fold. The CSF drug exposure was less than 1% ($\sim$10 nM at the 900 mg dose) that of the plasma exposure, with T_{max} 6 h postdose, in line with the plasma T_{max}. Repeat dose studies (MAD) were conducted with doses of 50, 100, and 200 mg for 28 days (50 and 100 mg) and 14 days (200 mg), with all doses resulting in increased C_{max} and AUC values after repeat dosing. CSF Aβ levels were measured 72 h postdose and showed concentration-dependent reductions; 38%, 46%, and $\sim$70% ($A\beta_{1-42}$), 36%, 44%, and $\sim$70% ($A\beta_{1-40}$), or increases; 292%, 518%, and 545% ($A\beta_{1-37}$) and 20%, 69%, and 68% ($A\beta_{1-38}$). As has been seen in other studies, placebo treated volunteers showed increased amyloid levels, thus drug effects were normalized to predose levels, rather than placebo. CSF amyloid levels were also measured 48 and 96 h after the 200 mg dose, and showed a similar magnitude of effect. The corresponding CSF concentrations were $\sim$3 nM (50 mg), 7 nM (100 mg), and 16 nM (200 mg). In the MAD study, several adverse events were detected, such as elevated bilirubin (all doses) and at the 200 mg dose there was a decrease in creatinine clearance and increases in ALT/AST levels. As a result, a sufficient therapeutic index could not be established and the progression of BMS-932481 was thus terminated.

A further patent application demonstrates that the imidazole can be replaced by a nitrile moiety in the fused diaminopyrimidine series, for example, **41**,[44] Fig. 15. In this instance, the nitrile presumably accepts a hydrogen bond in the same way as the imidazole, but does not result in marked decrease in potency, unlike previous compounds, that is, **30** versus **34**.

The BMS group has also described macrocylic aminopyridine analogs such as **42**[45] and **43** (**BMS-986133**), Fig. 15. Further data on BMS-986133 has recently been disclosed.[42] In the rat doses of 2.5, 5, and 15 mg kg^{-1} i.v. produced similar effects on brain Aβ peptides to that of BMS-932481.

Thus, despite considerable commitment to the amyloid field with particular focus on GS, having progressed both a GSI and a GSM to the clinic, it is disappointing that all of the compounds were terminated. Subsequently BMS have announced their

discontinuation in the neuroscience field. It can be seen from the clinical data with BMS-932481 that achieving sufficient efficacy with a suitable therapeutic index has proved a considerable challenge for GSMs. Although BMS-932481 showed a reduction in CSF amyloid in humans, the efficacy was limited compared to that seen for BACE inhibitors. Despite the fact that the efficacious CSF concentrations were low, total plasma concentrations and doses were relatively high. Thus, perhaps the lipophilic nature of the compounds, coupled with off-target activity and relatively high total exposures results in a narrow TI.

7.07.9 Modulators From Boehringer-Ingelheim

Boehringer Ingelheim entered the GSM field in 2013,[46–48] when they reported a series of aryl-imidazole GSMs in which the conserved left hand side was attached to bicyclic aminopyrimidines, fused to five- or six-membered aliphatic heterocycles. GSMs with a similar pattern were reported by BMS (*vide supra*, Section "Modulators From Bristol-Myers Squibb"). A dihydrothienodiaminopyrimidine series provided moderate modulators of GS, the most potent analog in this series being **44**, Fig. 16, with an $IC_{50} = 90$ nM for lowering $A\beta_{42}$ in H4 neuroglioma cells stably expressing human APP695 isoform. An interesting analog was **45**, in which the ubiquitous imidazole moiety of the aryl-imidazole left hand side was replaced by a 5-methyl-oxazole. This analog was somewhat less potent than **44**, but had higher selectivity for reduction of $A\beta_{42}$ over $A\beta_{total}$. Improved potency was obtained when the central pyrimidine ring was fused to six-membered saturated heterocycles, such as in dihydropteridinones **46**–**48**, Fig. 16. Interestingly, in all these series, an RHS aromatic appendix on the central core did not seem to be required for potency.

7.07.10 Modulators From Dainippon Sumitomo

Researchers at Dainippon Sumitomo appear to have entered the GSM latterly with patent applications appearing in 2011. They have focused their efforts on the aryl-imidazole chemotype, and have recently detailed their lead generation strategy.[49] Starting from what is believed to be E2012 (**6**), Figs. 5 and 18, the group prepared an aryl-imidazole acid (**49**) and combined it with amines (**50**) to generate a library of compounds which were screened at 2.5 μM. Optimization of the amine substituent resulted in the identification of **51**, Fig. 17, which exhibited similar potency to **E2012**, **5**, (IC_{50} 250 nM) in a rat-fetus primary neuronal cellular assay. A 100 mg kg^{-1} oral dose of **51** reduced $A\beta_{42}$ by 55% and 66% in the hippocampus and plasma of the mouse. The group has disclosed several other series, all based on the aryl-imidazole template, such as amino-oxadiazole **52**,[50] amide derivative **53**,[51] Fig. 17, which shows some similarity to derivatives from Pfizer (**120** and **121**, Fig. 36), and trans-olefin **54**,[52] an analog of **59** (proposed to be E2212, Fig. 18), where the methylimidazole has been replaced by a methylpyridine (Fig. 17).

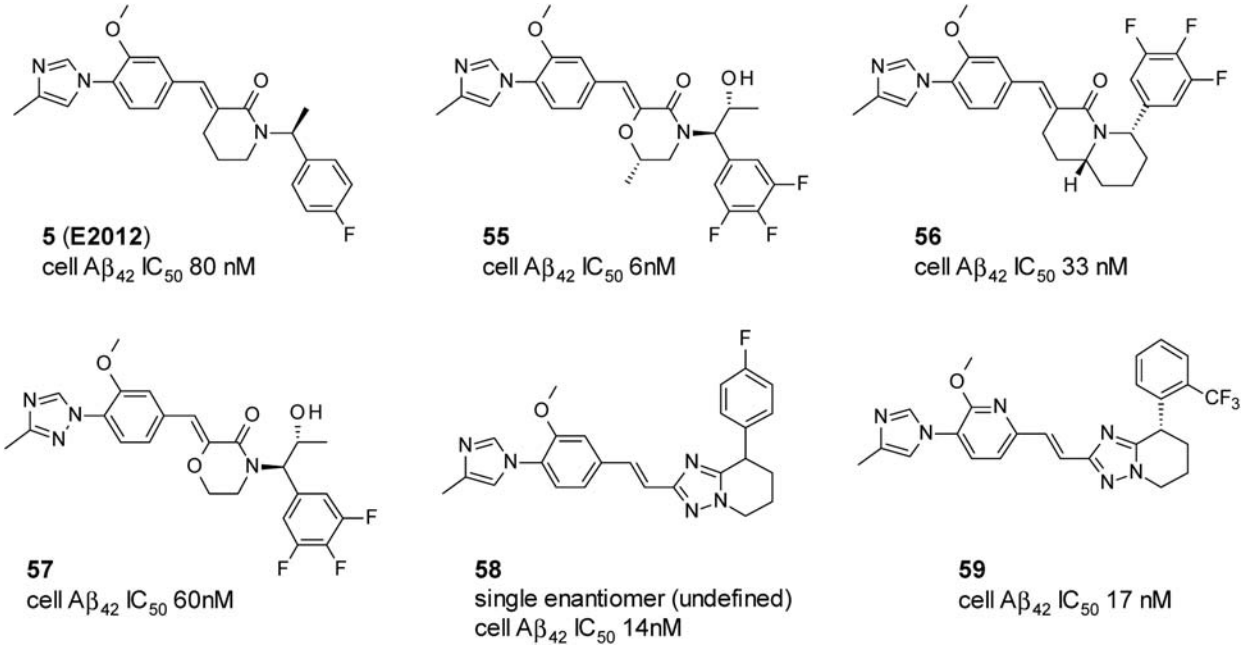

Fig. 18 Key compounds from Eisai patent applications, including the proposed structures of E2102 (**6**) and E2212 (**59**).

7.07.11 Modulators From Eisai

Eisai was one of the pioneers in the GSM arena, where they have focused on the aryl-imidazole structural class. The first patent application appeared in 2005,[53] detailing more than 100 examples, of particular note was **6**, Fig. 18, widely accepted to be E2012, which inhibits $A\beta_{42}$ production in cells with an IC_{50} of 80 nM. Analysis of the structure, in conjunction with the significant body of the literature on its analogs, allows one to propose that the key pharmacophoric elements are an HBA on the left hand side, represented by the imidazole, an HBA in the central region, fulfilled by the amide, and a lipophilic/aromatic moiety on the right hand side.

Following this publication, many groups have prepared and profiled **6** and initiated drug discovery projects delivering related analogs. E2012 entered phase 1 clinical trials in 2006, but was terminated due to effects on cholesterol metabolism, however data are only now beginning to appear. A recently published manuscript demonstrates that E2012 was found to induce cataracts in rats, and that this was not mediated by GS inhibition or modulation.[54] The formation of cataracts was found to be due to 3β-hydroxysterol Δ24-reductase (DHCR24) inhibition, which mediates the last step of cholesterol synthesis, and inhibition results in increased levels of desmosterol, with concomitant reductions in cholesterol levels. It was found that prolonged dosing was required

to see the effect as this was first observed in 13-week-rat toxicology studies, but could be detected after 2 weeks dosing. In the rat, doses of 3 and 10 mg kg^{-1} for 91 days did not affect desmosterol or cholesterol levels, however doses of 30 and 60 mg kg^{-1} had a clear effect. Thus, there was insufficient separation between amyloid lowering doses and those which affected desmosterol conversion to cholesterol.

Subsequent patent applications highlight several derivatives, such as the morpholinone derivative **55**,[55] including follow-up applications,[56] the constrained piperidone derivative **56**.[57] Other patent disclosures include analogs of **55**, where the imidazole has been replaced by a triazole to give compounds such as **57**.[58] The series also evolved to include olefin derivatives with a substituted heterocycle, most notably triazolopiperidine derivatives such as **58**,[59] which were ultimately optimized to **59**, which is widely speculated in the literature to be **E2212**,[60] Fig. 18. Details of the PhI study with E2212 have recently been published.[61] In the SAD study, volunteers received doses of 10, 20, 25, 50, 75, 100, 125, 150, 200, or 150 mg. The compound was well tolerated and it was concluded that the maximum tolerated dose had not been reached. The C_{max} and AUC were found to increase linearly with dose and the half-life ranged from 12.5–19.0 h with renal excretion being the major route of elimination. The effect of E2212 on plasma $A\beta_{x-42}$ was assessed, with ~50% reduction observed following 200 and 250 mg doses, with weaker effects seen at lower doses, that is, ~40% reduction following 100, 125, or 150 mg doses. The authors note that the PKPD relationship and modeling indicate that further increases in dose might not result in further reduction of $A\beta_{x-42}$, although they conclude that E2212 is suitable for further progression.

The group at Pfizer has published data on the characterization of E2012 (**6**) and **59** in preclinical species.[62] **6** was dosed to the guinea pig at doses of 32 and 100 mg kg^{-1} p.o. with effects on brain and CSF amyloid assessed a several time points postdose. Maximal reductions in brain $A\beta_{42}$ of 60% were recorded 9 h after the 100 mg kg^{-1} dose, whilst CSF $A\beta_{42}$ was reduced by 84% and 68% 4 and 9 h after the 100 mg kg^{-1} dose, respectively. PK–PD modeling of the time course study resulted in free brain concentration of 98 nM to reduce brain $A\beta_{42}$ by 50%.

59 was dosed to the rat (15 and 100 mg kg^{-1} p.o.) and the guinea pig (1, 3, 10, 30, and 100 mg kg^{-1} p.o.). In the rat, the lower dose produced 48% and 64% reductions in brain and CSF $A\beta_{42}$ levels, respectively, whilst the higher dose resulted in sustained reductions with the maximal effect at 20 h postdose (70% reduction of brain $A\beta_{42}$ and 97% reduction of CSF $A\beta_{42}$). PK–PD modeling resulted in a calculated free brain concentration of 1.3 nM to reduce brain $A\beta_{42}$ by 50%. In the guinea pig, Eisai-6 showed significantly enhanced potency over E2012, with a 1 mg kg^{-1} dose reducing $A\beta_{42}$ by 55% and 43% in the brain and CSF after 4 h, whilst the 10 mg kg^{-1} dose caused 68% and 82% reductions, respectively. A time course study showed maximal effects at 6 and 9 h postdose with prolonged effects. PK–PD modeling resulted in a calculated free brain concentration of 2.1 nM to reduce brain $A\beta_{42}$ by 50%, thus showing an almost 50-fold improvement over E2012.

The Eisai group has also investigated cinnamide isosteres, including ureas,[63] but it would appear that no compounds of significant interest have emerged from this chemotype.

Thus, after many years of research and pioneering the field with the aryl-imidazole class of GSMs, it seems that the Eisai group is no longer active in the field. Despite having progressed two compounds to the clinic, analysis of the company pipeline would suggest that the development of E2012 and E2212 is not being actively pursued, and at least E2012 has been terminated. Since this period, Eisai has been extremely active in the BACE inhibitor field and is currently progressing the BACE inhibitor E2609 in the clinic in partnership with Biogen.

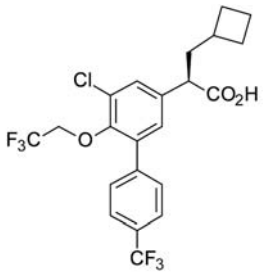
7.07.12 Modulators From Forum/EnVivo

The group at Forum, originally called EnVivo, has shown long-term commitment to the identification of GSMs, having first prepared carboxylic acid derivatives, then latterly aryl-imidazole and related derivatives.

7.07.12.1 Carboxylic Acid Derivatives

Early work from the Forum (then EnVivo) group identified several carboxylic acid derivatives, which are closely related to the NSAID template.[64–67] The preclinical profile of EVP-0015962 (**60**), Fig. 19, which is believed to be EVP-0962, a GSM that reached PhII clinical trials, has recently been disclosed.[68] In a cellular assay (human neuroglioma H4 cells stably transfected with wild-type human APP751) the EVP-0015962 (**60**) showed high potency for a carboxylic acid derivative, reducing $A\beta_{42}$ with an IC_{50} of 67 nM and increasing $A\beta_{38}$ with an EC_{50} of 33 nM. Further analysis revealed that $A\beta_{42}$ and $A\beta_{39}$ were decreased whilst $A\beta_{38}$ and $A\beta_{33}$ levels were increased, and $A\beta_{40}$ and $A\beta_{37}$ did not change. Surprisingly, the potency was found to be almost 10-fold lower in rat primary neocortical cultures, $A\beta_{42}$ IC_{50} of 427 nM and an $A\beta_{38}$ EC_{50} of 384 nM. In a Tg2576 mouse study, a 30 mg kg^{-1} p.o. dose reduced brain $A\beta_{42}$ levels by 39% with corresponding brain concentrations of 4.3 μM 4 h postdose, but a 10 mg kg^{-1} was inefficacious, despite brain levels of 1.3 μM. A 50 week study in Tg2576 mice, at doses of 20 and 60 mg kg^{-1} p.o. showed 53% and 89% reductions of brain $A\beta_{42}$, respectively. Both doses also reduced plaque area and number relative to vehicle treated animals. In this study, the brain concentrations were measured at 2.5 and 8.3 μM for the 20 and 60 mg kg^{-1} doses, respectively. EVP-0015962 (**60**) also showed a reversal in the contextual fear conditioning model following 11 weeks treatment at 20 and 60 mg kg^{-1} in Tg2576 mice.

EVP-0962 has progressed to clinical studies, where it was assessed in a small PhII trial, *vide infra*. However, the status of the compound is currently unknown, but it seems that it is no longer being progressed. Furthermore, due to recent issues with its nAChR



EVP-0015962 (**60**)
cell $A\beta_{42}$ IC_{50} 67 nM (H4-APP_{751})
cell $A\beta_{42}$ IC_{50} 427 nM (rat PCN)
measured logD 3.88

Fig. 19 Structure of EVP-0015962 (**60**), thought to be EVP-0962.

α7 agonist/PAM, encenicline (EVP-6124), it appears that Forum Pharmaceuticals no longer exists, thus the progression of all assets would also cease.

7.07.12.2 Aryl-Imidazole Derivatives

Recently, the focus of the Forum group has shifted to the aryl-imidazole-derived templates, with the publication of several recent patent applications. The compounds all contain a morpholine moiety fused to a heterocycle, such as an aminopyrimidine. Prominent derivatives include **61**, Fig. 20.[69] Related examples, typified by **62**,[70] display a piperidine moiety in place of the typical methoxyphenyl ring, in conjunction with a methoxy-pyridine as the HBA motif, Fig. 20.

Subsequent patent applications demonstrate the aryl motif on the morpholine N-atom can be moved to the adjacent C-atom, that is, **63**, and even be replaced by alkyl groups such as **64**.[71] These chemotypes have then been combined to yield compounds such as **65**, and the related THP derivative, **66**,[72] Fig. 20.

Thus, although there is no published information on why the Forum group has changed focus to the aryl-imidazole template, the fact is suggestive that the carboxylic acid derivatives may have encountered some issues and that the aryl-imidazole template is seen as more attractive.

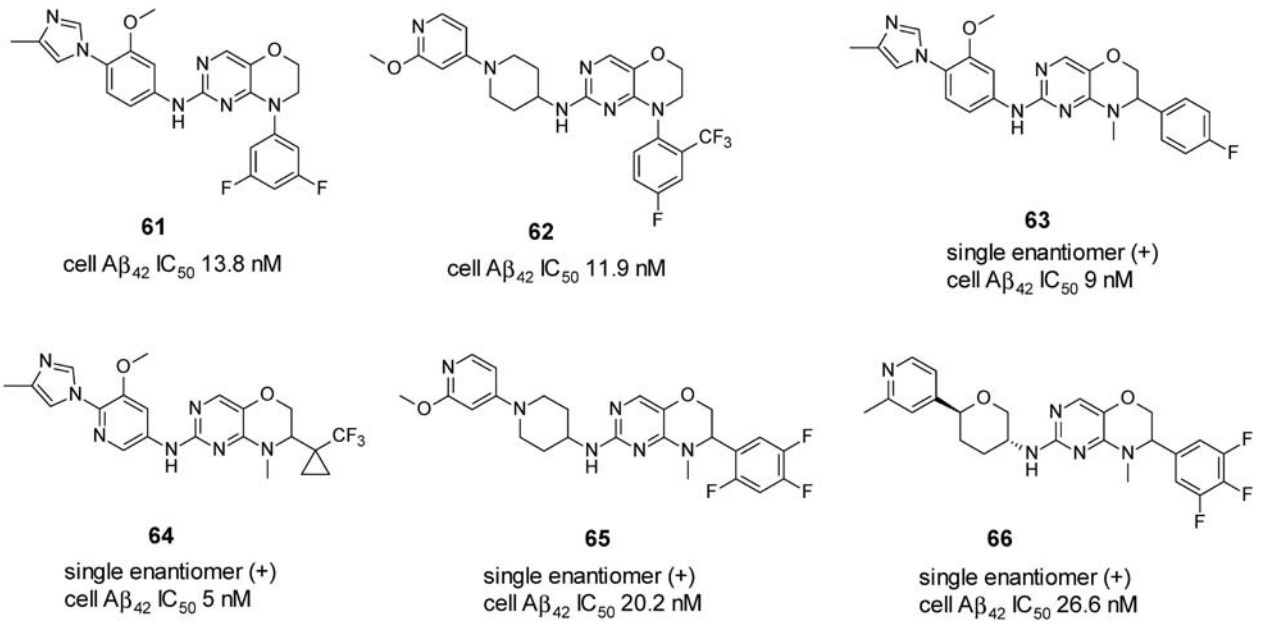


Fig. 20 New derivatives from Forum Pharmaceuticals.

7.07.13 Modulators From GlaxoSmithKline

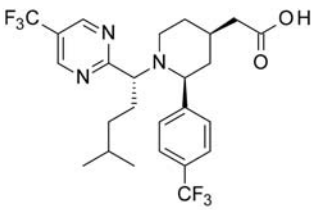
7.07.13.1 Carboxylic Acid Derivatives

In 2010, scientists at GSK disclosed their research aimed at identifying novel carboxylic acid GSMs.[73] Their interest focused on the piperidine analogs similar to the ones reported by Merck (**103** Fig. 30, *vide infra*) which, although still suffering from suboptimal drug-like properties, had reduced lipophilicity versus earlier carboxyllic acid GSMs reported in the literature (such as **76**, Fig. 24 and **101**, Fig. 30). To further lower the lipophilicity of **103**, various heterocyclic aromatic groups were introduced on the 1-position of the piperidine ring. Optimization efforts resulted in identification of compounds **67** and **68**, Fig. 21. These compounds showed moderate inhibition of $A\beta_{42}$ production in SHSY5Y cells, after 48 h incubation, no significant effect on $A\beta_{40}$ production and showed selectivity over Notch (Notch $IC_{50} > 20$ μM in both cases). Compound **68**, also known as **GSM-10 h**, was further profiled. After 24 h incubation in SHSY5Y cells, **GSM-10 h** showed a typical GSM profile, inhibiting $A\beta_{42}$ production ($IC_{50} = 1$ μM), stimulating $A\beta_{38}$ ($EC_{50} = 500$ nM) showing no significant effect on $A\beta_{40}$ and $A\beta_{total}$. **GSM-10 h** displayed consistent PK across species, with low blood clearance ($Cl_b = 4$ mL $min^{-1} kg^{-1}$ in mouse and rat and 3 mL $min^{-1} kg^{-1}$ in dog), moderate volumes of distribution ($V_{dss} = 1.4$, 2.3 and 1.1 L kg^{-1} in mouse, rat and dog, respectively), a moderate half-life ($t_{1/2} = 4.3$, 6.6, and 5.2 h in mouse, rat, and dog), and high oral bioavailability ($F_{po} > 100\%$ in mouse and rat and 75% in dog). When dosed orally at 5 mg kg^{-1} in a mouse CNS penetration study, **GSM-10 h** demonstrated good CNS exposures with concentrations of 5.6 μM, 2 h postdose, and a Br:Bl ratio of 0.74.

GSM-10 h was further assessed in a rat model of endogenous Aβ production.[74] The in vitro potency was confirmed in primary rat cortical neurons, where, after a 48-h incubation, **GSM-10 h** reduced $A\beta_{42}$ with an IC_{50} of 350 nM and had no significant effect on $A\beta_{40}$ levels. Acute p.o. dosing of **GSM-10 h** to the rat at 3, 10, 30, and 100 mg kg^{-1} significantly reduced $A\beta_{42}$ levels in a dose-dependent manner in plasma and in CSF, 6 h postadministration. At the highest (100 mg kg^{-1}) dose, $A\beta_{42}$ levels were reduced by 75% in plasma and 66% in CSF, corresponding to brain and plasma concentrations of 34 and 28 μM, respectively. In the brain, **GSM 10 h** had weaker efficacy, showing only 21% and 30% reductions in $A\beta_{42}$ at doses of 30 and 100 mg kg^{-1}, respectively. The authors remarked that brain amyloid was extracted with guanidine hydrochloride, which extracts both soluble and deposited amyloid, the latter representing a larger proportion of the extracted amyloid. Since the compound could only reduce soluble amyloid, this would explain the difference in **GSM-10 h** effect on $A\beta_{42}$ in brain versus CSF (which contains only soluble amyloid). Upon subchronic, 5-day oral administration, **GSM-10 h** showed an increased effect on lowering brain $A\beta_{42}$, by 38% and 48% at 30 and 100 mg kg^{-1}, respectively, 6 h postadministration. The profile of decreasing CSF and plasma $A\beta_{42}$ was similar to that of the acute dosing. The corresponding brain and plasma concentrations at 100 mg kg^{-1} dose were 52 μM and 79 μM, respectively, higher than in the acute study, which could account for the marginal increase in efficacy. In a time course study, rats were orally dosed with 30 mg kg^{-1} of **GSM-10 h**, the PD effects in the three compartments being assessed up to 72 h postdose. Maximum compound exposure was observed 3 h postdose (17.8 μM in brain and 18.3 μM in plasma), whereas the maximum $A\beta_{42}$ lowering occurred 6 h postdose in all three compartments. The amyloid levels returned to baseline 24 h after administration, and showed no rebound, unlike the effects observed with GSIs.

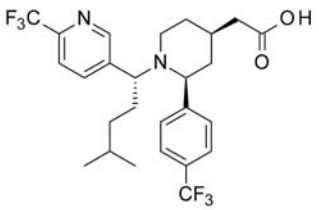
7.07.13.2 Arylimidazole Derivatives

An HTS campaign at GSK identified **69**, Fig. 22, a compound which in cellular assays inhibited both the production of $A\beta_{42}$ peptides as well as Notch processing. In **69**, the classical GSM A-B left hand side was linked via a C—C bond to a pyridazine central core containing a benzamide appendage.[75] An optimization program focused on improving the potency of **69**, as well as the selectivity over Notch. Replacing the amide in **69** with a benzyl amine led to significant increase in $A\beta_{42}$ and $A\beta_{40}$ potency, as in **70** and **71**. Interestingly, it was found that minor modifications could switch the profile from GSMs to Notch agonists, at high concentrations.



67

cellular $A\beta_{42}$ IC_{50} = 794 nM (SHSY5Y/APPswe)
cellular $A\beta_{40}$ IC_{50} > 20 μM (SHSY5Y/APPswe)
cellular Notch IC_{50} = 25 μM



68
GSM-10h

cellular $A\beta_{42}$ IC_{50} = 316 nM (SHSY5Y/APPswe)
cellular $A\beta_{40}$ IC_{50} = 6.3 μM (SHSY5Y/APPswe)
cellular Notch IC_{50} > 20 μM

Fig. 21 GSK carboxylic acid GSMs.

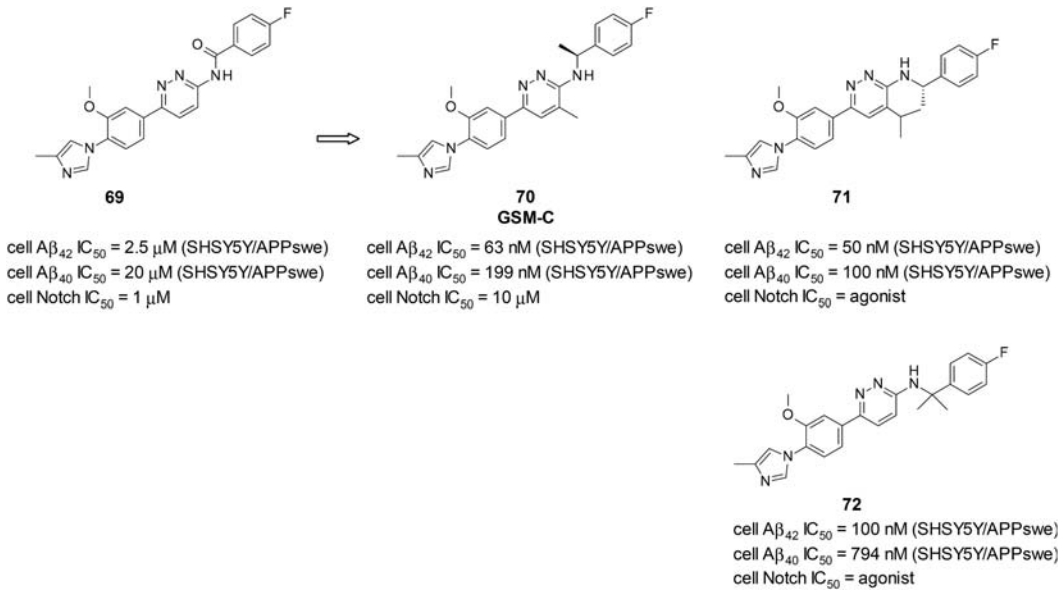


Fig. 22 Aryl imidazole derivatives with substituted aminopyridazine cores from GSK.

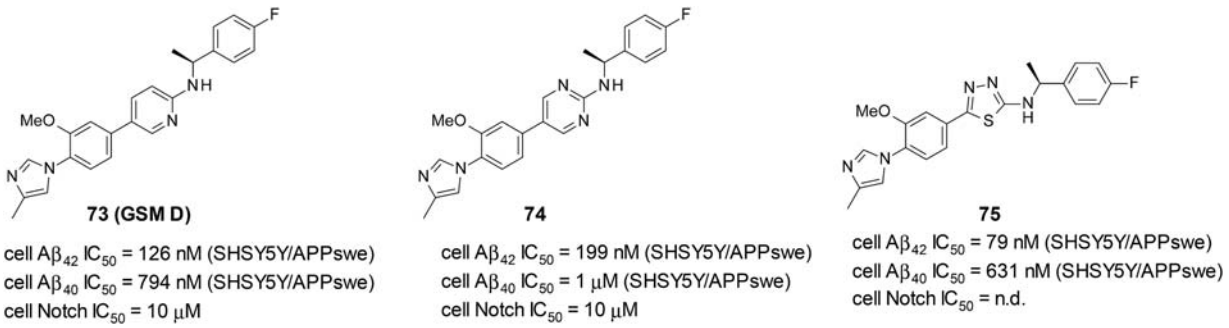

Fig. 23 Aryl imidazole derivatives with different amino heterocycle cores from GSK.

For instance, while **70** showed a 60-fold improvement for $A\beta_{42}$ inhibition, replacement of the Me substituent on the pyridazine ring with an iPr group as in **71** enhanced Notch processing, showing a greater than 30% increase of luciferase activity at 10 μM concentrations. The same was observed for analogs in which the benzylic position was disubstituted (**72**), Fig. 22.

Explorations around the central pyridazine core in **69** showed that it could be replaced by other heterocycles, such as pyridine in **73** and thiadiazole in **75** (Fig. 23).[76] Explorations around the arylimidazole left-hand side in **73** failed to provide an alternative to the ubiquitous imidazole ring.

Based on their favorable ADME profiles, **70** and **73** were further profiled in vivo in the rat, where both compounds displayed a good overall PK profile, with low clearance (5.2 and 12.2 mL $min^{-1} kg^{-1}$), acceptable half-life ($t_{1/2}$ = 3.1 and 3.3 h), and excellent bioavailability (F_{po} = 98% and 100%). Upon oral administration to rat, at 30 mg kg^{-1}, **70** and **73** displayed high (total) brain concentrations of 9.1 μM and 8.7 μM, respectively. Both compounds were then assessed in vivo efficacy studies, in Sprague Dawley rats.[77] Thus, in a dose–response study, oral administration of **70** at 3, 10, 30, and 100 mg kg^{-1} produced a significant reduction of $A\beta_{40}$ and $A\beta_{42}$ levels in plasma, CSF, and brain, in a dose-dependent manner, as determined 6 h postdosing. Under these conditions, **73** showed weaker reduction of $A\beta_{40}$ and $A\beta_{42}$ levels in brain and CSF. For **70**, the necessary doses to reduce the $A\beta_{42}$ by 50% in the three compartments were 77 mg kg^{-1} in brain; 66 mg kg^{-1} in CSF and 2.8 mg kg^{-1} in plasma. In a time course experiment, rats were orally dosed with 30 mg kg^{-1} of **70** and **73**, the PD effects in the three compartments being assessed up to 51 h postdosing. Compound **70** was again more efficacious than **73**. For **70**, the maximum compound exposure was observed 6 h postdosing (13 μM in brain and 26 μM in plasma), whereas the maximum reduction in $A\beta_{42}$ occurred at ~12 h postadministration in brain (~40% reduction) and 16 h in plasma (~91% reduction). After 51 h the amyloid levels returned to baseline and showed no rebound. Upon subchronic, 5-day oral administration of a 30 mg kg^{-1} dose of **70** and **73**, significant reduction of both $A\beta_{40}$ and $A\beta_{42}$ was observed, both in brain (63% and 58% for **70** and 17% and 23% for **73**) and in plasma (82% and 93% for **70** and 36% and 63% for **74**) at the end of the treatment.

7.07.14 Modulators From Janssen

7.07.14.1 Carboxylic Acid Derivativess

Janssen has been long active in the field of GSMs. Starting in 2007, researchers at OrthoMcNeil/Janssen in collaboration with Cellzome published a series of patents around NSAID-derived GSMs. These applications claimed a series of 3,5-disubstituted aryl acetic acid analogs, resulting from the explorations around the methyleneoxy linker in arylacetic acid GSM **76**, Fig. 24, developed by Cellzome.[78] Analogs from these patent applications are shown in Fig. 24, and they include ether (**77**), amine (**78**), amide (**79**), or carbon (**80** and **81**) linkers.[79–82] Compounds **77** and **78** were tested in vivo in mice and it was found that at a 30 mg kg^{-1} oral dose, **77** displayed a more pronounced, 43% reduction, of $A\beta_{42}$ levels versus the 18% $A\beta_{42}$ reduction shown by **78**, 4 h after administration.[79] On the other hand, when tested in rat, **78** showed a slightly improved 30% reduction in the $A\beta_{42}$ levels 4 h after treatment.

Analogs of **76** in which the linker was completely removed, leading to terphenyl derivatives, were also claimed in the 2009 patent application (**82** and **83**, Fig. 25).[83]

Apart from cellular potencies, the patent also discloses results from the in vivo testing of these compounds in mice and rats (species not specified). Compound **85**, the (S) form of **83**, Fig. 25, showed a 40% reduction of $A\beta_{42}$ levels in both species, 4 h after an oral administration of a 30 mg kg^{-1} dose. Compounds with reduced aromaticity and lipophilicity, which incorporated cyclic amines such as the piperidinyl derivative **86**, Fig. 25, were also disclosed in a different patent application.[84] Compound **86**, one of the most potent in this series, still incorporates a highly lipophilic trifluoromethyl group. A Janssen report from 2013 described

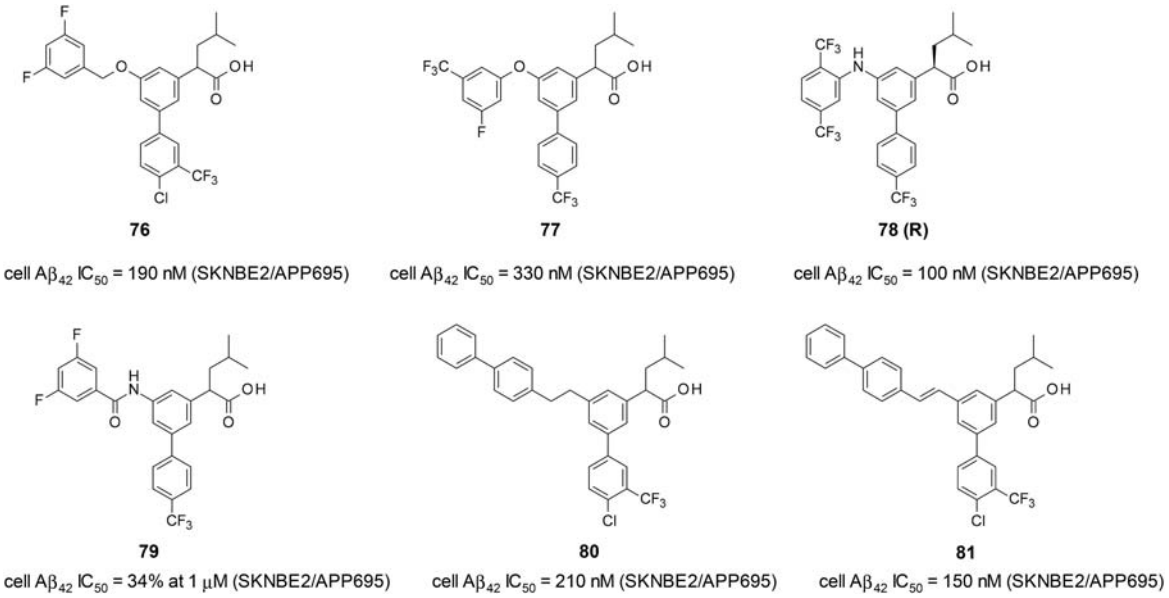

Fig. 24 Cellzome and OrthoMcNeil/Janssen carboxylic acid GSMs.

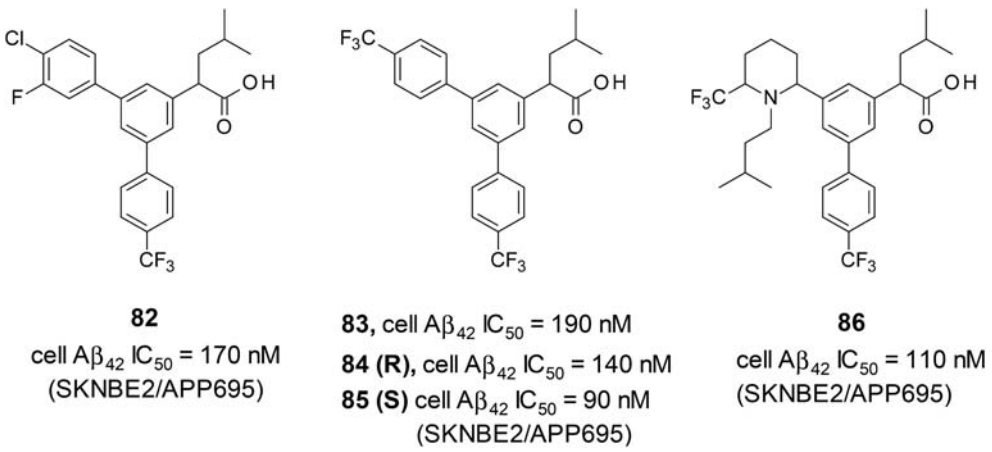

Fig. 25 Cellzome and OrthoMcNeil/Janssen terphenyls and piperidines GSMs.

the behavior of **85**, also known as JNJ-40418677, in efficacy studies in vivo in mice.[85] First, the in vitro potency was confirmed in SKNBE-2/(WT)APP cells, when **85** inhibited $A\beta_{42}$ production with an IC_{50} of 200 nM after a 16 h incubation, and in rat primary cortical neurons, where IC_{50} was 185 nM after a 48 h incubation. The levels of $A\beta_{total}$ remained unchanged in both cellular tests. When dosed at 10, 30, 100, and 300 mg kg^{-1} in nontransgenic mice, **85** showed a dose-dependent reduction in brain $A\beta_{42}$ of 18%, 36%, 61%, and 69%, respectively, 4 h after administration. In a time course experiment, nontransgenic mice were orally dosed with 30 mg kg^{-1} of **85**, the PD effects in the brain being assessed up to 24 h postdosing. The maximum compound exposure in brain was observed 6 h postdosing (~13 μM) whereas the maximum reduction (55%) of $A\beta_{42}$ and the maximum increase (78%) in $A\beta_{38}$ occurred at 6 h postadministration. After 24 h, $A\beta_{42}$ levels remained ~16% below baseline. The levels of $A\beta_{total}$ in brain remained unchanged at all time points after treatment with **85**. Following 7 months of chronic administration of **85** to 6-month-old transgenic Tg2576 mice, the compound produced a significant reduction in brain $A\beta_{42}$ and $A\beta_{40}$ levels, both soluble and deposited, at doses of 60 and 120 mg kg^{-1} day^{-1}. Unlike the effect observed in nontransgenic mice, there was no increase in the $A\beta_{38}$ levels at 20 and 60 mg kg^{-1} day^{-1}, whereas at 120 mg kg^{-1} day^{-1} a decrease in $A\beta_{38}$ deposition was observed. The chronic administration of **85** produced also a significant inhibition in the formation of plaques in the brain of Tg2576 mice, as well as a dose-dependent reduction in the number of plaques formed.

Further development of compound **85** was halted[86] due to liver toxicity and related side effects, such as increases in bilirubin and liver enzymes (ALT/AST), which were observed in an advanced canine model.

7.07.14.2 Aryl Imidazole Derivatives

As with many other research groups, Janssen's research into aryl imidazole GSMs was inspired by **E2012** (**5**, Figs. 6 and 18).[87] Computational studies suggested that replacement of the E-double bond in **E2012** with an NH-linker would provide an amino-pyridone in which the preferred, low energy conformation would be as drawn in **87**, Fig. 26. This compound would preserve a similar geometry to that of **E2012**, due to favorable electrostatic interactions. Schering/Merck also described a series of GSMs with similar amino-pyridone C-ring (**150**, Fig. 41, *vide infra*). Compound **87** was sevenfold less potent than **E2012** and did not show a significant effect on amyloid peptides when tested in vivo in mice. Conformational restriction of **87** via cyclization of the benzylic side-chain into the pyridone central ring provided imidazopyridine **88**, Fig. 26, in which the aromatic appendage needed to be attached to the 2-position of the imidazopyridine ring for potency.

Although **88** was still approximately twofold less potent than **E2012**, it produced a 35% lowering of $A\beta_{42}$ levels in mouse brain, 4 h after an oral administration of a 30 mg kg^{-1} dose. Isosteric replacement of the imidazopyridine core resulted several subseries of potent in vitro and in vivo analogs, which suffered however from suboptimal drug-like properties, such as high lipophilicity, poor solubility, and binding to the hERG channel. Further optimization led to the identification of **89**, Fig. 26, in which the

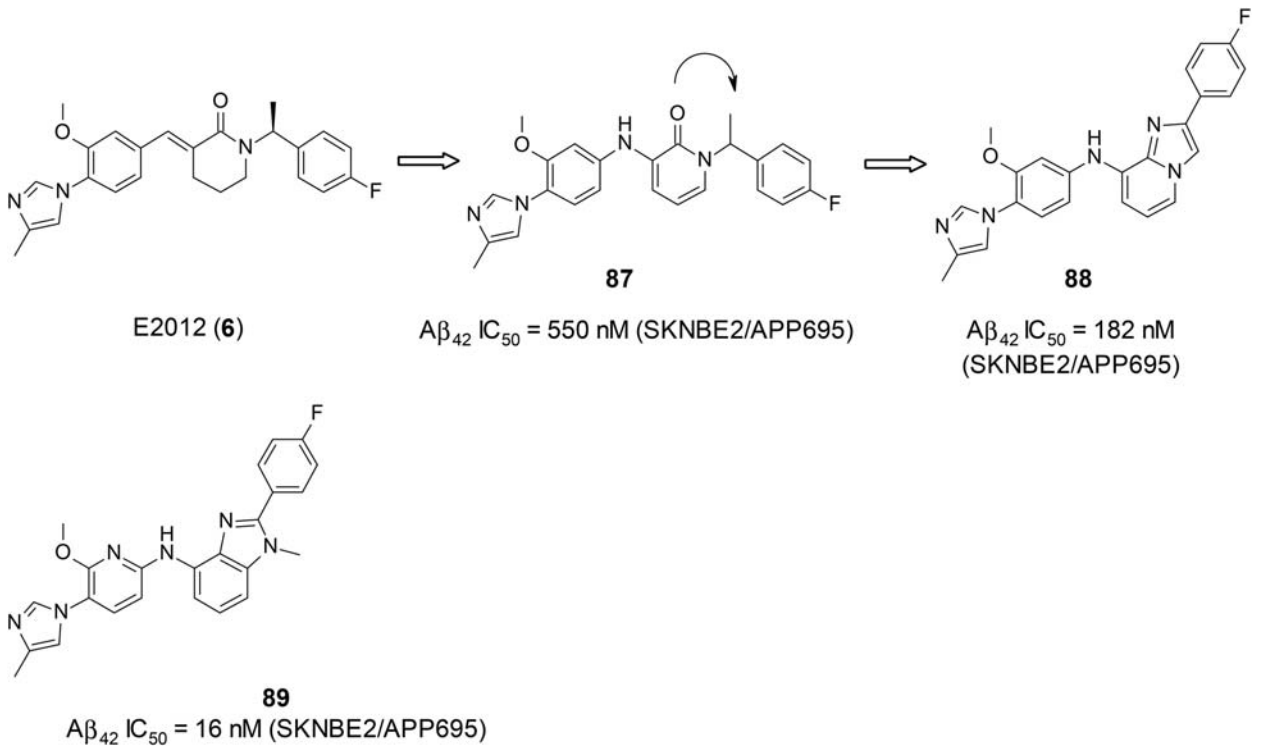

Fig. 26 Bicyclic GSMs from Janssen.

imidazopyridine was replaced by a benzimidazole isostere and, in order to decrease lipophilicity, the left hand side anisole ring was replaced by a methoxypyridine. This compound showed weak affinity for binding to the hERG channel ($IC_{50} = 8.5$ μM), which translated into a weak inhibition of the potassium membrane current recorded with an automatic patch clamp system (30% inhibition at 3 μM vs. 17% for the vehicle). Upon evaluation of the PK profile across species, **89** displayed good, and rapid, absorption in mouse ($C_{max} = 2293$ ng mL^{-1}, $T_{max} = 0.5$ h at 10 mg kg^{-1} p.o.) and dog ($C_{max} = 648$ ng mL^{-1}, $T_{max} = 0.8$ h at 5 mg kg^{-1} p.o.), and a good, but slow, absorption in rat ($C_{max} = 1973$ ng mL^{-1}, $T_{max} = 4$ h at 10 mg kg^{-1} p.o.). High bioavailability was observed in all species, 64% in dog, 95% in rat, and 100% in mouse. In a 24 h time course experiment, **89** was administered orally to mice, at 10 and 30 mg kg^{-1}, where it displayed a dose-dependent reduction of $Aβ_{42}$ and an increase in $Aβ_{38}$ levels in plasma and brain. The maximal effect for modulation of Aβ peptides was observed 4 h postdosing at 10 mg kg^{-1}, when the production $Aβ_{42}$ was inhibited by 51%, while that of $Aβ_{38}$ stimulated by 41%. Maximum brain exposure of **89** was 2.8 μM, also achieved 4 h postdosing. At 30 mg kg^{-1}, a maximum 65% increase in $Aβ_{38}$ levels was observed 4 h postdoing, whereas a maximal decrease in $Aβ_{42}$ levels, of 71%, occurred 8 h postdosing. The maximum brain exposure of 15.6 μM was achieved after 4 h. No significant effect was observed on the total level of Aβ peptides, although there was a trend for reduction at the 8 h time point. After 24 h, Aβ levels returned to normal, with the exception of $Aβ_{42}$, for which, at the 30 mg kg^{-1} dose, the levels were still reduced versus vehicle. An additional analysis performed in this experiment showed that at 48 h, the $Aβ_{42}$ levels had returned to normal. In a 24 h time course experiment performed in the beagle dog, **89** was administered orally at 20 mg kg^{-1}. The maximum PD effect in dog CSF was observed 8 h postdosing, when $Aβ_{38}$ levels were increased by 84%, whereas $Aβ_{42}$ and $Aβ_{40}$ decreased by 48% and 36%, respectively. The maximum compound exposure in dog CSF (4.1 μM) was observed 4 h postdosing. Finally, **89** showed good modulation of Aβ peptides in the brain and CSF of rat, where it was dosed at 10 mg kg^{-1} in a 25 h time course experiment. A decrease in $Aβ_{40}$ and $Aβ_{42}$ was observed in both compartments, as well as an increase in $Aβ_{38}$. A particularly strong increase was observed in $Aβ_{37}$ levels in both compartments, namely fourfold in brain and eightfold in CSF. Compound **89** still suffered from suboptimal physicochemical properties, that is, high logP, high aromaticity, and low solubility, which manifested in signs of liver toxicity after dosing in the dog at 20 mg kg^{-1}.[88] A parallel Hit Hopping search starting with **87** resulted in the identification of amide **90**, Fig. 27, which displayed a approximately fivefold loss in potency.[89] Pfizer also reported their work around a similar series of benzamides (*vide infra*, Fig. 36). Cyclization of the benzylic moiety in **90** onto the amide carbonyl moiety provided the conformationally restricted **91**, Fig. 27, having a triazole core directly linked to the A-B system. Further optimization included removal of the hydrogen bond donor (HBD) by introduction of a methyl substituent on the triazole N-atom, and introduction of a linker between the triazole core and the aromatic appendage. A methylene linker provided **92**, Fig. 27. Further restriction of the free rotation in **92** led to the identification of a series of bicyclic triazolo-amines, which allowed for the discovery of **93**, Fig. 27, a compound with reduced lipophilicity compared to **89**.[90] Compound **93** combined high in vitro potency with favorable ADME parameters. When tested in vivo in mice, it demonstrated a 62% reduction of brain $Aβ_{42}$ levels, together with a 66% increase in $Aβ_{38}$ levels, 4 h postdosing, which corresponded to a brain concentration of 2.8 μM and a Br:Pl ratio of 0.23. The free fraction of **93** in brain was $f_{u,b} = 2.2\%$, relatively high when compared to other reported GSMs. When screened in the dog, at an oral dose of 20 mg kg^{-1}, **93** demonstrated a strong, 50%,

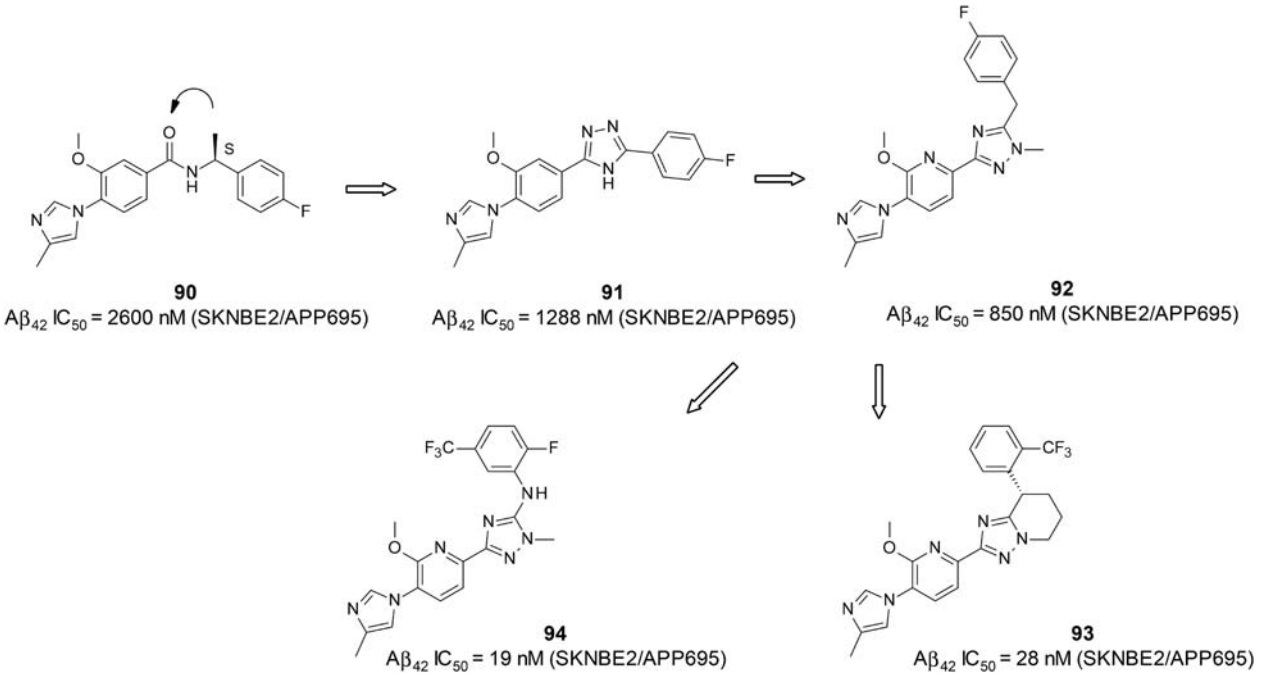

Fig. 27 Assorted triazole-derived GSMs from Janssen.

reduction in $A\beta_{42}$ levels in CSF, and a 28% increase in $A\beta_{38}$ levels, 8 h postadministration. This corresponded to a 19 μM concentration of compound in dog plasma. No increases in liver enzymes were observed despite the high plasma levels, suggesting that the liver toxicity observed with **89** was due to the high lipophilicity of the compound, and not target related.

In a parallel effort, replacement of the methylene linker in **92** with an amino-linker led to an anilinotriazole series of potent GSMs.[91] Upon subsequent optimization of this series, it was observed that for some analogs there was a disconnect between the in vitro potency and in vivo activity. The authors remarked that the presence of an ortho-substituent on the aromatic appendage was of crucial importance to obtain in vivo active compounds. In this series, **94**, Fig. 27, was identified as a GSM which combined good in vitro potency with improved physicochemical and ADME properties. For instance, when it was compared to **89**, **94** demonstrated reduced aromaticity and lipophilicity (c log *P* 4.6 vs. 5.9), better lipophilic efficiency (3.1 vs. 1.8), better kinetic solubility (39 μM vs. 3 μM), and displayed a weaker potential to inhibit CYP450 enzymes (all $IC_{50} > 10$ μM). The potential cardiovascular risk raised by the moderate inhibition of the potassium membrane current (52% at 3 μM, i.e., higher than that of **89**) did not translate in vivo in anesthetized guinea pigs. When it was orally administered to mice at 30 mg kg^{-1}, **94** showed a strong 55% reduction of $A\beta_{42}$ levels, accompanied by a strong 53% stimulation of $A\beta_{38}$, 4 h after dosing. At this time, the brain concentration of **94** was 14 μM and the Br:Pl was 0.8. As a typical GSM, **94** was highly bound to plasma and brain proteins; for instance, the brain-free fraction was $f_{u,b} = 0.5$ %, which was however improved versus that of **89** ($f_{u,b} < 0.05$ %). This resulted in a free brain concentration (69 nM), which was higher than the in vitro IC_{50} by a factor 3.6. The authors also noted that due to the low $f_{u,b}$ observed in this series, high exposure of compounds in mouse brain were required to achieve in vivo activity. In a 24 h time course experiment, **94** was administered orally to mice at 30 mg kg^{-1}, where it displayed a maximum reduction of $A\beta_{42}$ levels (61%) 6 h after treatment, while the maximum stimulation (67%) of $A\beta_{38}$ levels was observed 2 h postdosing, after which time it plateaued until 8 h postdosing. No effect was observed on the total level of Aβ peptides. After 24 h, $A\beta_{42}$ levels returned to normal, while a slight decrease from vehicle (19%) was observed for $A\beta_{38}$. Upon oral administration of 20 mg kg^{-1} of **94** to the dog, a maximal 56% reduction of CSF $A\beta_{42}$ was observed 8 h postdosing, combined with a 54% reduction of $A\beta_{40}$ and 31% increase in $A\beta_{38}$ levels. The corresponding concentration of **94** in dog plasma was 6.7 μM. The authors also mentioned that in a one week repeated dose study in dog, at 10 and 20 mg kg^{-1}, no increase in liver enzymes (ALT and AST) was observed.

A subsequent patent application from Janssen described GSMs with imidazolo-indoles for the left hand A-B system, as well as compounds in which the imidazole was replaced by a nitrile moiety.[92] GSMs having the ubiquitous imidazole replaced by a nitrile moiety were also reported by BMS, *vide supra*, for example, **34**, Table 1 and **41**, Fig. 15. Notably, this modification preserved the modulation of Aβ peptides both in vitro and in vivo, as shown for compounds **95** and **96** in Fig. 28. As can be inferred from the reported in vivo effects of the claimed compounds, compound **96** was a particular example of a potent GSM which, upon oral administration of a 30 mg kg^{-1} oral dose to nontransgenic mice, strongly inhibited the production of $A\beta_{42}$ peptides, but it did not show a significant increase in the $A\beta_{38}$ levels from the baseline, 4 h postadministration.

More recent applications from Janssen disclosed yet another chemical class of GSMs, in which a central piperazino-pyridone core is substituted with the conserved imidazole or triazole on the left hand side, while various substituents are claimed on the piperazinone right hand side (**97–99**, Fig. 29).[93,94] As will be described later in this review, Pfizer has also claimed GSMs containing a piperazino-pyridone core,[95] *vide infra* (Fig. 36), which appeared a few months before a similar publication of Janssen, WO 2013171712. The most interesting compounds from the Janssen applications are illustrated in Fig. 29 and Table 2. To be noted is **99**, which upon oral administration to nontransgenic mice at a 30 mg kg^{-1} dose, produced a strong modulatory effect on the amyloid peptides 4 h after administration. Finally, restriction of the piperazinone substituents into the piperazinone ring led to novel tricyclic GSMs, such as **100**, Fig. 29, in which a fused 6,6,5-tricycle has a flexible aromatic appendage at position 3.[96]

Further progression of compound **89**, also known as JNJ-42601572, was halted, due to the aforementioned liver toxicity. Moreover, in a tissue distribution study in rats, **89** showed a liver:plasma ratio of 8.5.[86] Compound **94** was described as the next generation of GSM and may have been selected for further development, although no active work with this compound has yet been reported.

7.07.15 Modulators From Merck

7.07.15.1 Carboxylic Acid Derivatives

Research in the GSM area started at Merck more than a decade ago, when they reported carprofen-derived modulators.[97] Their initial work on the phenyl-acetic acid class of GSMs focused on the exploration of 3,4-positions of the phenyl ring.[98] This led to analogs such as trifluoromethylaryl **101** (Fig. 30). Subsequent work focused on reducing the lipohilicity in this series by replacing the central aromatic core with a piperidine ring. This exercise led to compounds such as **102** and **103**,[99] Fig. 30, in which however the c log *P* remained suboptimal. Compound **103**, also known as **GSM-1**,[100] is a potent carboxylic acid GSM, which was further evaluated in in vivo studies. Thus, when it was administered to transgenic mice expressing APP_{Swe} at 3, 10, and 30 mg kg^{-1} dose, **103** demonstrated a dose-dependent reduction in $A\beta_{42}$ levels, with a maximum 69% reduction at 30 mg kg^{-1}, 4 h after treatment.[101] Simultaneously, the levels of $A\beta_{38}$ increased in a dose-dependent manner, while $A\beta_{40}$ and $A\beta_{total}$ levels were not significantly changed.

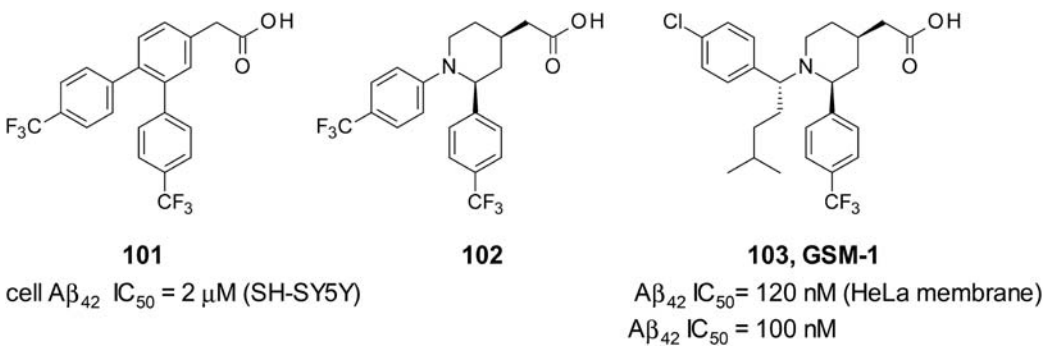

Fig. 30 Merck aryl and piperidine acetic acid GSMs.

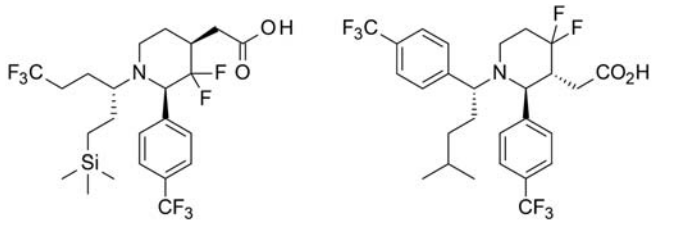

Fig. 31 Merck difluorpiperidine GSMs.

During optimization efforts around the piperidine acetic acid derivatives **103**, Merck researchers incorporated a di-F substitution on the piperidine ring, both at the 3- and at the 4-positions.[102] Two representative examples from this series, **104** and **105**, are shown in Fig. 31. Not only was the di-fluoro substitution tolerated at both 3- and 4-positions of the piperidine, but replacement of the aromatic substituents on the piperidine nitrogen with alkyl moieties was also allowed.

Despite the moderate in vitro potency of **104** and **105**, both compounds showed a robust reduction of $A\beta_{42}$ levels of 64% and 84%, respectively, when dosed at 10 mg kg^{-1} in APP-YAC transgenic mice, after 7 h p.o. administration. For compound **105**, this effect was achieved at a brain concentration of 0.58 μM and a Br:Pl of 0.51. Moreover, **105** demonstrated a dose-dependent lowering of $A\beta_{42}$ in rats, when dosed orally, at 1, 3, 10, and 30 mg kg^{-1}, and with an $ED_{50} = 5$ mg kg^{-1}, brain $EC_{50} = 1$ μM, and plasma $EC_{50} = 3.7$ μM. No adverse Notch effects were observed when **105** was tested in a 7-day oral rat safety study, at 250 mg kg^{-1} day^{-1}.

7.07.15.2 Aryl-Piperazine Derivatrives

A piperazinyl-pyrimidine derivative identified at Merck after an HTS campaign showed weak modulation of Aβ peptides and inhibited the production of $A\beta_{42}$ versus $A\beta_{40}$ by a factor ~2 (**106**, Fig. 32).[103] Initial SAR studies provided **107**, which incorporated a di-methyl substituent on the piperazine ring. When compared to **106**, **107**, Fig. 32, showed improved potency for $A\beta_{42}$ inhibition, which resulted in a 17-fold selectivity over the inhibition of $A\beta_{40}$. A round of optimization focused on improving potency and selectivity for $A\beta_{42}$ over $A\beta_{40}$, and led to the identification of a *tert*-butyl-aniline as an optimal substituent on the pyrimidine ring. Upon optimization of the physicochemical parameters of the series, it was found that polar groups were tolerated on the central pyrimidine ring. This resulted in the identification of **108**, Fig. 32, as a potent inhibitor of $A\beta_{42}$ production, with high selectivity (24-fold) over inhibition of $A\beta_{40}$ and 180-fold selectivity over Notch. Importantly, this is an example of non-NSAID GSMs structurally different from the aryl-imidazole class. The modulation pattern of Aβ peptides is also different, resembling more the NSAID-like GSMs.

Speculating that the high potency in **108** was due to hydrogen-bond interactions of the hydroxymethyl moiety on the pyrimidine ring, subsequent optimization focused on finding isosteres that would enhance this interaction. This led to the identification of purine analog **109**, Fig. 33, a potent GSM with high selectivity over $A\beta_{40}$ and Notch. Exploration around the 4-methoxyphenyl-piperazine left hand side revealed that this region was now more tolerant to substitution than in the pyrimidine series. For instance, it allowed the identification of **110**, Fig. 33, in which the piperazine ring was replaced with a piperidine and the anisole ring with a pyrimidine connected to the piperidine ring via an O-linker. The pyrimidine ring in **110** preserved the HBA properties of the methoxy moiety in **109**.

Compounds **109** and **110** were administered to APP-YAC transgenic mice at an oral dose 100 mg kg^{-1} and the effect on Aβ peptides was evaluated 6 h postdosing. Both compounds demonstrated a strong reduction of $A\beta_{42}$ peptides, corresponding to 73% for **109** and 69% for **110**. Only **110** showed a slight 26% reduction of $A\beta_{40}$ levels. The corresponding brain concentrations were 7.8 μM for both compounds.

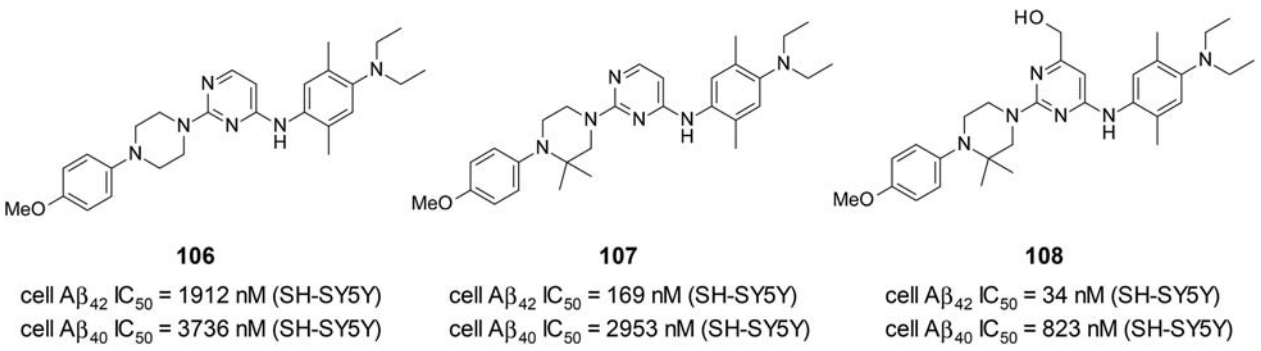

Fig. 32 Merck piperazinyl-pyrimidine GSMs.

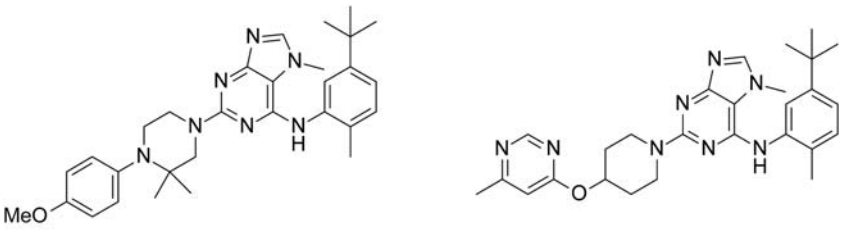

Fig. 33 Merck purine GSMs.

7.07.15.3 Aryl Imidazole Derivatives

In order to identify novel non-carboxyllic acid GSMs, scientists at Merck considered modifications of Eisai cinnamide series.[104] Starting from **E2012** (**6**, Figs. 5 and 18), their initial efforts focused on investigating amide replacements. This exploration allowed identification of **111**, an olefinic quinazolinone with modest in vitro potency. While this compound displayed an acceptable rat PK profile (Cl_p 6.8 mL $min^{-1}kg^{-1}$, $V_{dss}=1.8$ L kg^{-1}, $t_{1/2}=5.8$ h, $F_{po}=59\%$), the quinazolinone series in general suffered from suboptimal properties, that is, poor solubility, which resulted in low oral bioavailability, and hERG liabilities. To address these issues, in a subsequent exploration the double bond linker was replaced by various five-membered ring heterocycles.[105] Compounds in which the double bond was substituted by a 1,2,3-triazole central core (ring C) were selected for further optimization. Analogs with benzyl substituents on the triazole core had low potencies, **112**, being the most potent of the series. Replacement of the hydrophobic benzyl substituent in **112** with amides provided analogs with a slight increase in potency (**113**),[106] Fig. 34. Conformational restriction of the amides to give lactams, as shown by **114**, allowed the identification of triazolo-azepinones with improved in vitro potency. Such an example is **115**, Fig. 34, which combined good in vitro potency ($IC_{50}=9$ nM) with low hERG binding ($IC_{50}=5$ μM). Unfortunately, these compounds had no effect on Aβ peptides when tested p.o. in SD rats or APP YAC mice, at 50 mg kg^{-1}, due to low brain exposures and suboptimal brain:plasma ratios, in general <0.1.

More recently, Merck disclosed their optimization studies towards improving central lowering of $Aβ_{42}$ of triazolo-azepinones. In a first optimization round, a series of triazolo-benzazepinones was identified,[107] with analogs which lowered $Aβ_{42}$ levels in Sprague Dawley rats and transgenic APP-YAC mice brains in a dose-dependent manner after single oral dose. A lead in this series, **116**, Fig. 34, displayed an ED_{50} of 15 mg kg^{-1} when dosed orally in both species. When tested at highest dose (100 mg kg^{-1}) in a dose-dependent study in SD rat, **116** showed a total brain concentration $C_b=35$ μM, 6 h after dosing, and a 92% reduction of $Aβ_{42}$ levels in rat brain. This compound displayed an acceptable rat PK profile with good bioavailability (Cl_p 38 mL $min^{-1}kg^{-1}$, $V_{dss}=4.8$ L kg^{-1}, $t_{1/2}=0.8$ h, $F_{po}=190\%$). In dog, **116** had high clearance ($Cl_p=82$ mL $min^{-1}kg^{-1}$) and no oral bioavailability. Rhesus PK for **116** showed moderate plasma clearance ($Cl_p=17$ mL $min^{-1}kg^{-1}$) but no oral bioavailability. Compound **116** was then evaluated in an acute PK/PD study in a cisterna-magna-ported rhesus model, when it was administered via i.v. infusion at a dose of 50 mg kg^{-1}. Compound **116** significantly lowered the $Aβ_{42}$ levels in rhesus CSF, with sustained $Aβ_{42}$ reduction over 20 h. Further profiling of **116** revealed that it was a potent inhibitor of serotonin re-uptake transporter, with an $IC_{50}=32$ nM.

Optimization of the benzoazepinone series focused on improving the PK parameters, via modification of the conserved methylimidazole-anisole moiety (A-B ring), which was identified as a potential metabolic liability.[108] Fluoroaryl derivative **117**, Fig. 34, one of the leads identified after this exploration, showed good in vitro potency (58 nM), low hERG binding (hERG $IC_{50}=8.3$ μM), and an improved Br:pl ratio of 1. When dosed at 100 mg kg^{-1} in APP YAC Tg-mice, **117** demonstrated significant lowering of $Aβ_{42}$ brain levels (74%) 6 h postdosing. It also showed an ED_{50} of 5.8 mg kg^{-1} in SD rats. Compound **117** had an improved PK profile in both SD rat and dog, with low clearance (Cl = 17 and 22 mL $min^{-1}kg^{-1}$, respectively) and good oral bioavailability ($F_{po}=55$ and 74%, respectively).

From the latest report, which occurred in 2015, it would appear that Merck might have advanced compounds from the benzazepinone series (exemplified by **116**) to preclinical development. As of yet, there is no subsequent publication around **116** and analogs.

7.07.16 Modulators From Pfizer

7.07.16.1 Carboxylic Acid Derivatives

Researchers at Pfizer disclosed in 2011 a series of carboxylic acid GSMs, which contained aminocyclohexanes or aminotetrahydropyrans as central core,[109] similar to those reported by Merck (vide supra). GSMs **118** and **119**, Fig. 35, were among the most potent and most tested analogs. Similar potencies were observed for both compounds, however, **119** is less lipophilic. These derivatives are

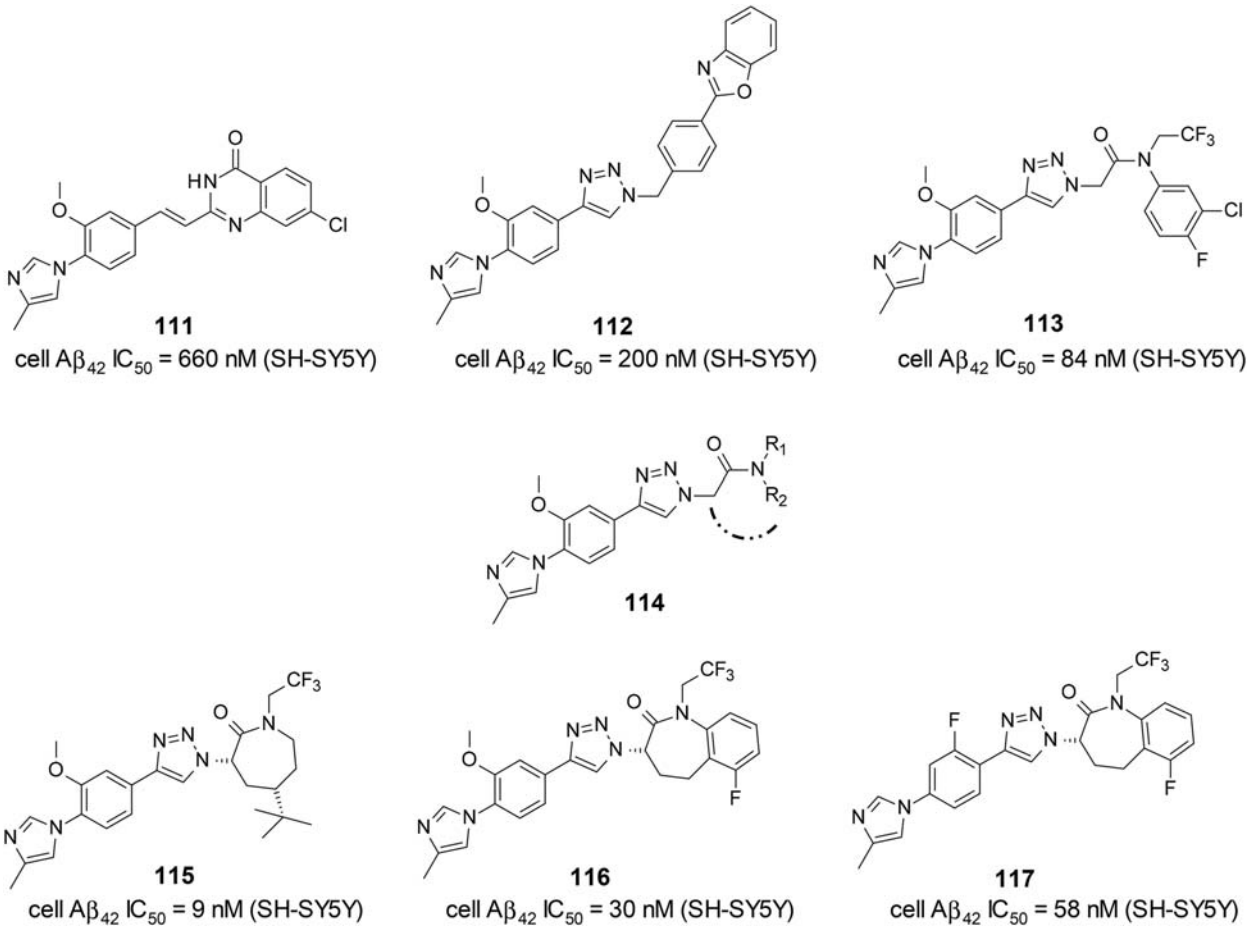

Fig. 34 Merck 1,2,3-triazole GSMs.

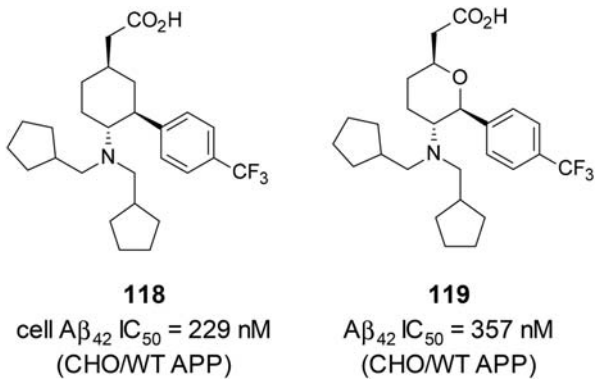

Fig. 35 Carboxylic acid containing modulators from Pfizer.

similar to those reported by Astellas, *vide supra*, for example, compound **15**, Fig. 9. It appears that interest in this series was short-lived as the focus of the Pfizer group's research has changed to the aryl-imidazole template.

7.07.16.2 Aryl-Imidazole Derivatives

Researchers at Pfizer started their search for novel non-NSAID GSMs from **E2012**, (**6**, Figs. 5 and 18) aiming to reduce lipophilicity in order to improve the overall drug-like profile. Replacement of the undesirable cinnamide olefin moiety in **E2012** with an amide bond,[110] as in **90**, Fig. 36, led to a significant decrease in potency. Amide-containing GSMs were also reported by Janssen (*vide supra*, Fig. 27). Optimization, which focused on the right hand side phenyl appendage delivered analogs with restored

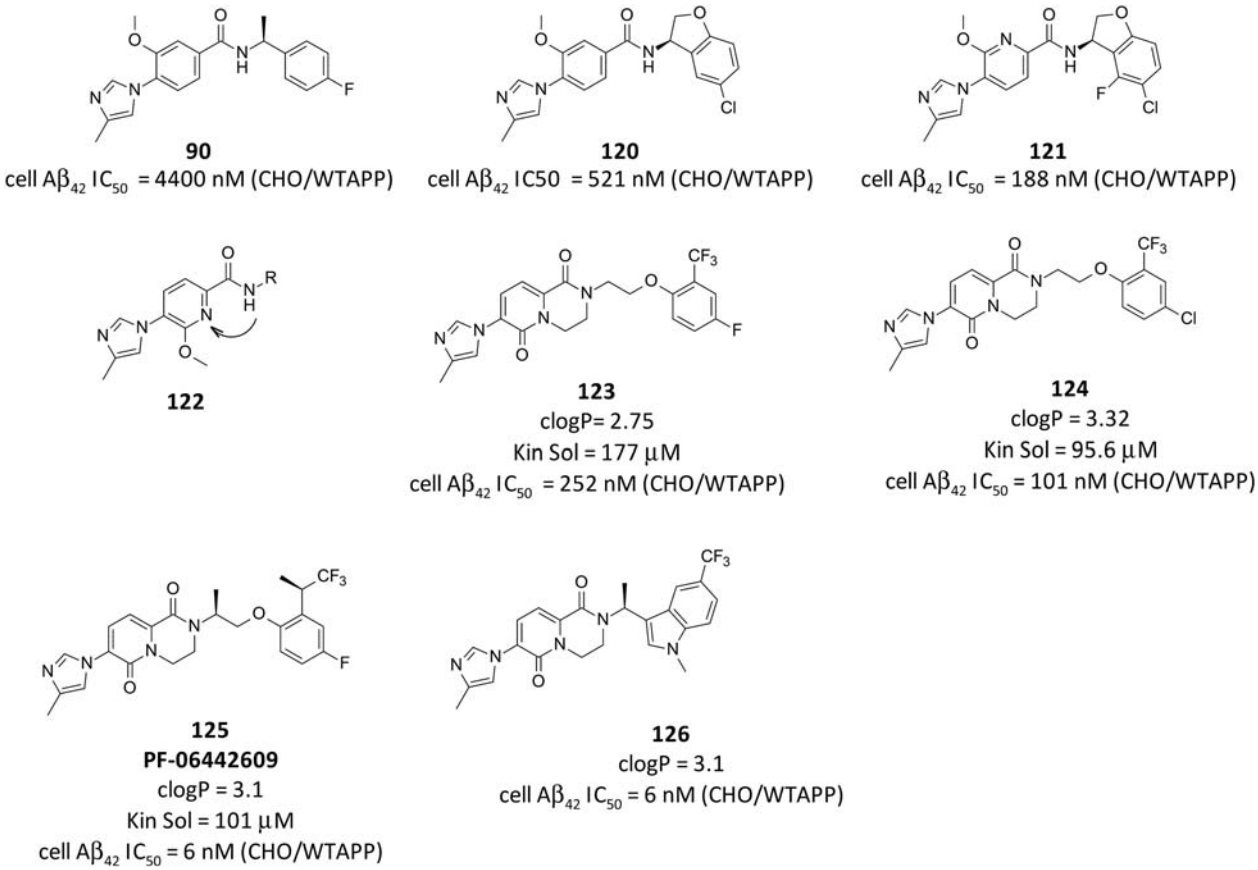

Fig. 36 Pfizer amide derivatives (**90**, **120**, and **121**) and piperazino–pyridone (**123–126**) GSMs.

potency, such as **120**, and **121**, Fig. 36. The PK profile of these compounds was evaluated in rat. **120** had a better overall profile than **121**, with lower clearance (Cl = 9.63 vs. 31.4 mL $min^{-1} kg^{-1}$), longer half-life ($t_{½}$ = 2.43 vs. 0.64 h), and better bioavailability (F = 100% vs. 51%). When tested in vivo in guinea pigs, at 100 mg kg^{-1}, **120** showed a better, 57% reduction of brain $Aβ_{42}$ levels 4 h postdosing versus 36% displayed by **121**. Bioanalysis revealed that the free brain concentration for **120** was 1038 nM, twofold higher than the IC_{50}; while for **121** the free brain concentration was $C_{u,b}$ = 89 nM, lower than the IC_{50} ($C_{u,b}/IC_{50}$ = 0.31). This might explain the difference in the in vivo potency of **120** and **121** and it is consistent with the trend observed for GSMs, that is, their characteristic high lipophilicity leads to compounds that are highly bound to brain tissue. As a result, a high total brain concentration is required for in vivo efficacy.

Cyclization of the amide N-atom in **122** onto the methoxypyridyl ring, Fig. 36, led to a novel type of GSMs, in which the conserved aryl-imidazole ring was replaced with a less lipophilic piperazino-pyridone scaffold.[111] GSMs containing a similar template have been disclosed also by Janssen, for example, compounds **97–99**, Fig. 29. GSM potency was maintained in this new series, as can be seen by examples **123** and **124**, Fig. 36. These compounds have an improved overall profile versus the majority of reported GSMs, being less lipophilic and having excellent kinetic solubilities, for instance. Compound **124** had a good PK profile in rat, with low clearance (Cl = 1.4 mL $min^{-1} kg^{-1}$), rather long half-life ($t_{½}$ = 6.88 h) and high oral bioavailability (F = 88%). The in vivo activity was assessed in a guinea pig efficacy model, at 10, 30, and 90 mg kg^{-1} oral doses. In this case, a dose-dependent reduction of Aβ peptides in brain was observed, which was more pronounced for $Aβ_{42}$ than for $Aβ_{40}$. For instance, when it was dosed at 30 mg kg^{-1} and 4 h postoral dosing, **124** showed a significant decrease of brain $Aβ_{42}$ (44%) levels, combined with a moderate decrease of $Aβ_{40}$ (31%). At this dose, no significant effect was observed on $Aβ_{38}$ peptides (8% increase). Bioanalysis revealed that the free brain concentration of **124** at 30 mg kg^{-1} was 72 nM ($F_{u,Br}$ = 0.8%). Optimization efforts aimed to improve the cellular potency of **124**, and identified highly potent compounds such as **125** and **126**,[112,113] Fig. 36. Indole-substituted piperazinone derivatives have also been disclosed in a patent application from Janssen, which published sooner, for example, compounds **97–99**, Fig. 29, covering compounds with an indole appendage as in **126**.[114] Compound **125**, also known as PF-06442609, has an F-atom strategically introduced on the phenyl ring to block oxidative metabolism. This compound combined excellent single-digit in vitro potency with good physicochemical and ADME properties. Rat PK parameters were acceptable, **125** showing moderate clearance (Cl = 34.1 mL min^{-1}), acceptable half-life, and oral bioavailability ($t_{½}$ = 1.15 h, F = 51%). Compound **125** was evaluated in a guinea pig time-course experiment, when it was dosed orally at 60 mg kg^{-1}. The lowering of Aβ peptides and the corresponding brain exposures were measured at 1, 3, 6, 9, and 24 h postdose. The maximal effect seemed to be obtained 3 h

postdose, when $A\beta_{42}$ and $A\beta_{40}$ were significantly reduced by 41% and 50%, respectively, while $A\beta_{38}$ levels increased by 46%. This corresponded to an unbound brain concentration of 225 nM.

Compound **126** was also examined in an in vivo efficacy study in rat. Despite its high in vitro potency and acceptable intrinsic apparent clearance in human liver microsomes (28.3 mL $min^{-1}kg^{-1}$), when dosed orally at 30 mg kg^{-1}, **126** showed a low reduction of brain $A\beta_{42}$ and $A\beta_{40}$ 4 h after exposure (21% and 20%, respectively). This corresponded to low compound exposures in brain ($C_{u,b}=5$ nM, and Br:Pl of 0.7), which were attributed to PgP-mediated efflux after comparison with brain exposures in Pgp knockout mice.

According to the Pfizer pipeline, it appears that Pfizer has identified a GSM, PF-06648671 with suitable properties to progress to clinical studies, *vide infra*. Thus, it appears that long-term commitment to the field has paid off. Whether this compound will differentiate over the previously terminated GSMs from this structural class, *vide infra*, remains to be seen.

7.07.17 Modulators From Roche

7.07.17.1 Aryl Imidazole Derivatives

The group at Roche has published details of their early work on aryl-imidazole-related temples. An HTS delivered **127**,[115] which selectively lowered $A\beta_{42,}$ in human neuroglioma H4 cells overexpressing human APP. Optimization resulted in the discovery of RO5220778 (**128**),[116] Fig. 37. As **128** displayed adequate PKs in the mouse, Cl_p 18.3 mL $min^{-1}kg^{-1}$, V_{dss} 4.6 L kg^{-1}, $t_{½}$ 2.5 h, F_{po} 25%, Br:Pl 0.4–2.1, it was profiled in an efficacy study in the APPSwe Tg mouse. Doses of 10, 30, and 100 mg kg^{-1} p.o. reduced brain $A\beta_{42}$ by 18%, 35%, and 65%, respectively, 4 h postdose, resulting in a calculated ED_{50} of 40 mg kg^{-1}.

Subsequent iterations of this series have been disclosed in a series of patent applications. Analogs have been divulged with either an aminotriazole, such as **129**, or amino-pyrazole, such as **130**,[117] with a substituted *N*-benzyl group on the right hand side, Fig. 38. It is noteworthy that these compounds also have a nitrile group in place of the methoxy group, however this might be reflected by suboptimal potency. Related fused triazolopyridine derivatives have also been described, such as **131** and **132**,[118] Fig. 38, which offer enhanced potency.

Alternatively, replacement of the aminotriazole in compounds such as **129** by an aminopyrimidine results in compounds such as RO5434400 (**133**),[116,119] Fig. 38. Whilst displaying modest potency in H4 cells, enhanced potency was observed in rat primary neurons, $A\beta_{42}$ IC_{50} 31 nM. Doses of 3–100 mg kg^{-1} p.o. to APP-Swe resulted in dose-dependent reductions in brain $A\beta_{42}$, with around 60% at 100 mg kg^{-1}. Furthermore, a 30 mg kg^{-1} dose of RO54434400 reduced CSF $A\beta_{42}$ in the rat by around 50% 6 h postdose. However, RO54434400 was found to inhibit multiple CYP enzymes, 3A4 IC_{50} 1.4 μM, 2D6 IC_{50} 1.1 μM, 2C9 IC_{50} 1.5 μM, and display time-dependent CYP inhibition and produce reactive metabolites. It was also found to block the hERG channel, IC_{50} 1.5 μM, thus making it unattractive for further progression.

This series was modified further to deliver amino-triazines such as **134**,[120] which displayed weak activity, Fig. 38. The replacement of the methoxyphenyl moiety has been described for a range of derivatives. For example, replacement of the methoxyphenyl moiety in **131** and **133** resulted in piperidine derivatives with a C-linked heterocyclic replacement for the methylimidazole, to give **135** (RO5506284) and **136**, respectively,[121] Fig. 38. Further derivatives have also been disclosed whereby a bicyclic piperidine has been incorporated, such as **137**,[122] Fig. 38. RO5506284 (**135**) has been the subject of a recent publication detailing a longitudinal study in APP-Swe mice whereby amyloid levels were tracked with the use of positron emission tomography (PET).[123] Interestingly, the potency quoted in the literature implies the compound is 10-fold more potent than originally denoted in the patent application. In an acute dose–response study in the APP-Swe mouse, RO5506284 (**135**) reduced brain $A\beta_{42}$ in a dose-dependent manner, with reductions of 20%, 48%, and 73% 4 h after oral doses of 10, 30, and 100 mg kg^{-1}, respectively. Subsequently, a 30 mg kg^{-1} oral dose of RO5506284 (**135**) was administered to APP-Swe mice for 6 months, starting at 12 months of age, and amyloid reductions monitored temporally by PET as well as upon termination by PET, ELISA, and histochemistry. The results showed a 56% reduction in fibrillary Aβ plaques compared to vehicle controls, primarily due to the lower number and density of smaller plaques, showing that RO5506284 prevents new plaque formation. It has been reported that RO5506284 inhibits CYP2D6, IC_{50} 1 μM, and shows GSH adducts when incubated with human liver microsomes, which was attributed the thiadiazole moiety.[116] Thus, it seems that RO5506284 did not progress beyond preclinical investigation.

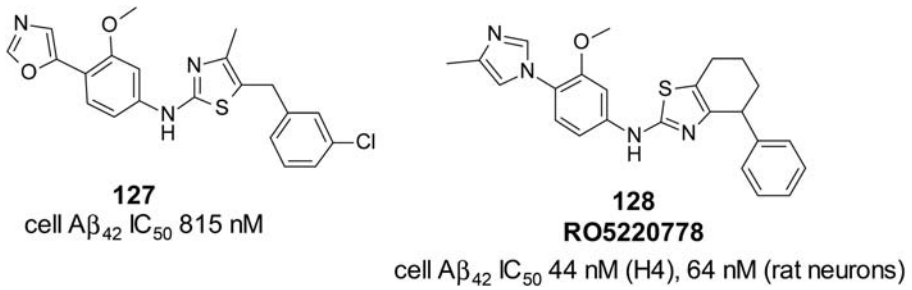

Fig. 37 Early compounds from Roche, including HTS hit **127** and optimized lead, **128**.

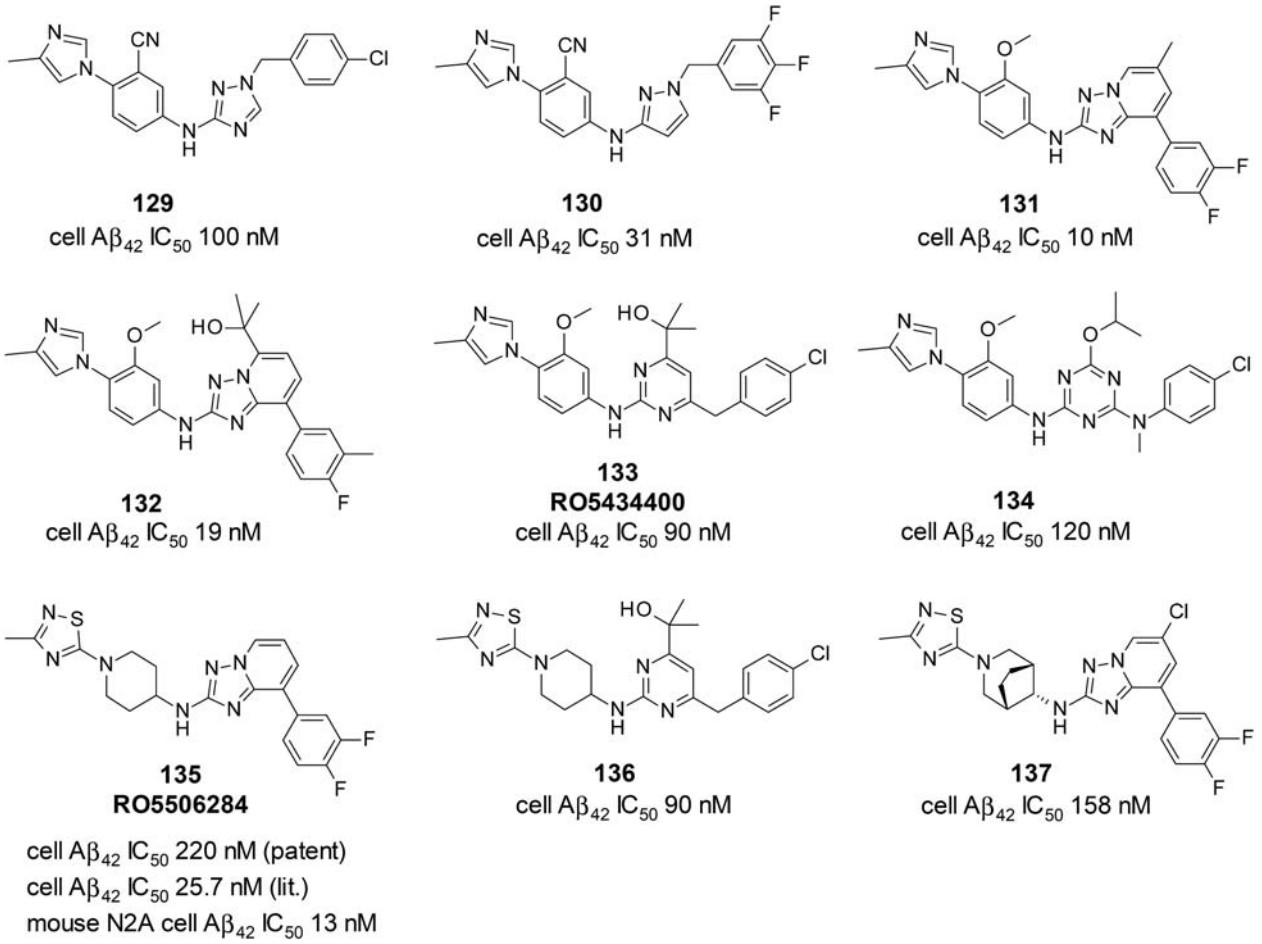

Fig. 38 Selected derivatives from Roche patent applications, including RO5506284 (**135**).

7.07.17.2 Other Derivatives

A more recent patent application details a novel chemotype that had not previously been described. The compounds consist of an indole core with an anilide in the 2-position, usually containing a fluorinated aniline, often 3-fluoro aniline. The 5-position of the indole contains some polar or basic functionality, such as substituted piperidines. Although the potency described is moderate, the discovery of a new template offers the possibility of a completely different profile and therefore different properties and off-target activities. Pertinent examples include **138** and **139**,[124] Fig. 39.

In summary, Roche have invested significant effort to the GSM field, but despite this prolonged research on multiple templates it does not seem that Roche have progressed any GSMs to clinical studies. Overall, it appears that CYP450 issues (inhibition, TDI, and reactive metabolites) in addition to the high efficacious concentrations of compounds and suboptimal physicochemical properties have precluded further advancement.

7.07.18 Modulators From Satori

The Satori group tackled the identification of GSIs by taking a different approach to all other groups and screening natural products, using a cellular assay (H4 cells expressing human wild-type APP).[125] This resulted in the identification of **140**, $A\beta_{42}$ IC_{50} 100 nM, $A\beta_{40}$ IC_{50} 6300 nM, the extract of the black cohosh plant, Fig. 40. Compound **140** displayed an unusual modulatory profile compared to other modulator chemotypes. In CHO cells (either expressing APP_{wt} or mutant APP_{V717F}), 1 μM **140** decreased $A\beta_{42}$ and $A\beta_{38}$, whilst it increased $A\beta_{37}$ and $A\beta_{39}$ and marginally lowered $A\beta_{40}$.

Initial optimization investigated reduction of the enol ether with concomitant replacement of the xylopyranose by esters.[126] However, more fruitful changes resulted when the xylopyranose was replaced by a morpholine, with the rationale of incorporating a basic center to increase CNS penetration. This resulted in the identification of compounds such as **141** and **142**, Table 3.[127] A mouse PK study revealed an encouraging profile for **141**, having a longer half-life than **142** by virtue of its greater volume of

distribution, which was thought to be due to the higher pKa of **141**. Neither **141** nor **142** was efficacious in a mouse efficacy study, even though **141** demonstrated good levels of exposure in the brain, 2117 nM and 3586 nM at 4 and 8 h after a 30 mg kg^{-1} dose, respectively. The lack of efficacy for **142** could be due to its low brain exposure, 269 nM and 658 nM, 4 and 6 h after a 100 mg kg^{-1} dose.

Further optimization resulted in replacement of the labile acetate group by an ethyl ether, to give derivatives such as **143** and **144**, Table 3.[128] The ability of **143** and **144** to penetrate the CNS was assessed in the mouse via i.v. administration, with samples collected 6 h postdose. Compound **143** showed moderate CNS penetration, Br:Pl 0.26 when using total levels but low Br_u:Pl_u (0.025). Compound **144** showed better CNS penetration, with Br:Pl 0.49 and Br_u:Pl_u 0.11, however the Br_u:Pl_u implies both are subject to active efflux. Profiling **143** in vivo (mouse) a 100 mg kg^{-1} i.p., resulted in a 46% decrease in brain $A\beta_{42}$ levels 6 h after dosing. Consistent with the in vitro profile, $A\beta_{38}$ levels were also reduced (31%), however the $A\beta_{40}$ levels were also reduced by a similar magnitude (30%), which would not be expected by the in vitro profile. In this study, **143** showed high exposure in the brain (23 μM total, 23 nM free) and plasma (12 μM, 132 nM free), which resulted in a Br:Pl 2, remarkably different from the i.v. study, however the Br_u:Pl_u 0.17 is still low. A similar study with **144** at 100 mg kg^{-1} p.o. elicited a 26% reduction in brain $A\beta_{42}$ levels 6 h postdose. A similar reduction in brain $A\beta_{38}$ (31%) was observed, whilst the reduction in $A\beta_{40}$ was not statistically significant. In this study, the brain concentration was 20 μM (40 nM free), with corresponding plasma concentration 15 μM (120 nM free), Br_u:Pl_u 0.3. Finally, in a 5-day efficacy study, **144** administered at 50 mg kg^{-1} p.o. produced a 42% reduction in brain $A\beta_{42}$ 8 h after final dose. The brain concentration was 31 μM (unbound brain 62 nM) with corresponding plasma concentration 16 μM (free 128 nM). A lower dose (10 mg kg^{-1} p.o.) failed to deliver statistically significant reductions in brain $A\beta_{42}$ or $A\beta_{38}$.

It appears that despite the structural diversity over other series, CYP inhibition was also an issue for this series as it was reported that **143** potently inhibits CYP3A4, IC_{50} 1.1 μM, whilst **144** has weaker activity, IC_{50} 12 μM.[129] It was also reported that time-dependent CYP inhibition was a general problem for the series. Ultimately, overcoming these issues led to the identification of SPI-1865 (**145**), Table 3, cell $A\beta_{42}$ IC_{50} 110 nM, CYP450 3A4 IC_{50} 37 μM. A rat PK study (1 mg kg^{-1} i.v. and 100 mg kg^{-1} p.o.) showed low clearance (0.5 mL min^{-1} kg^{-1}), moderate V_d (5.8 L kg^{-1}), and long $t_{½}$ (129 h), with moderate bioavailability (50%). PKs in the mouse have been described in less detail but appear similar, Table 3.[130] It was also noted that the T_{max} was extremely long, 40 h, which was hypothesized to be due to lymphatic absorption, which may be related to the lipophilicity of SPI-1865, clogP 5.7. This slow T_{max} appears general to the series. In vivo efficacy in the rat was assessed 24 h after a 100 mg kg^{-1} oral dose. SPI-1865 had measured plasma and brain concentrations of 14 and 33 μM, respectively, resulting in a Br:Pl of 2.4. A reduction in brain $A\beta_{42}$ of 50% was observed, representing moderate efficacy, but at a very high dose.[129] In a 14 day exploratory safety study, SPI-1865 was found to be tolerated at 90 mg kg^{-1} day^{-1}, with a corresponding average plasma concentration of 40 μM. Thus, there would appear to be no therapeutic window between efficacious dose and a tolerated dose, although there may be a narrow window in terms of concentrations.[129]

Table 3 Summary of key derivatives (**141**–**145**) from Satori, including development compound SPI-1865 (**145**)

Compound	*141*	*142*	***143*** *(SPI-1802)*	***144*** *(SPI-1810)*	***145*** *(SPI-1865)*

Btb			99.9%	99.8%	99.9%

In a rat dose–response study, oral doses of 10, 30, and 100 mg kg^{-1}, SPI-1865 reduced brain $A\beta_{42}$ levels by 21%, 37%, and 50%. The corresponding brain concentrations were 2.8, 11, and 33 μM and plasma concentrations were 3.3, 8.5, and 14 μM, respectively, resulting in Br:Pl 0.9–2.4. A follow up repeat dose (6 days) study in the rat was conducted at oral doses of 10, 30, and 60 mg kg^{-1}, which resulted in 24%, 44%, and 66% reductions of brain $A\beta_{42}$ 24 h after the final dose. Brain and plasma concentrations were similar for both studies.

A 6-day dosing study was also conducted in Tg2576 mice, with doses of 10, 30, 60, and 90 mg kg^{-1} being administered once daily and efficacy assessed 24 h after the final dose. None of the doses produced a statistically significant reduction in brain or CSF $A\beta_{42}$ levels, although plasma $A\beta_{42}$ was reduced at the top two doses. Total brain concentrations of 0.5, 1.3, 3.9, and 6.9 μM were achieved (Br:Pl 0.5–1.1), thus based on the rat efficacy and exposure, one would have expected to see reductions in brain $A\beta_{42}$ in the highest dose groups. In a follow up study, the efficacy of SPI-1865 was assessed in CD1 mice at dose of 15, 30, and 50 mg kg^{-1} b.i.d. for 6 days, with efficacy measured 6 h after the final dose. Brain $A\beta_{42}$ levels were reduced at all doses, 22%, 39%, and 47%, respectively. The brain concentrations from this study were measured at 3.6, 8.7, and 22 μM (Br:Pl 1.1–2.9) at doses of 15, 30, and 50 mg kg^{-1}, respectively. Thus similar levels of brain $A\beta_{42}$ reduction were observed in the CD1 mouse and the rat at similar brain concentrations but no effects were seen in the Tg2576 mouse. Calculated Br_u:Pl_u ratios for the three ascending dose groups in the CD1 mouse are 0.05, 0.08, and 0.12, which implies active efflux. Direct PK–PD modeling predicted a brain concentration of 3.8 μM (total, 27 nM unbound) to reduce brain AB42 levels by 50%, with 25.2 μM (176 nM unbound) to reduce the levels by 50%, thus showing good agreement with the cellular data.

Based on these data, SPI-1865 was selected as a development candidate, however, it has recently been disclosed that the development of SPI-1865 has been halted due to the finding that it disrupted adrenal function in monkeys, an observation that is believed to be unrelated to GS modulation.

Whilst the Satori work has established that complex natural product derivatives with multiple HBA/HBD motifs can penetrate the CNS to some extent, the preclinical efficacy appears somewhat limited compared to other series. It is also concerning that SPI-1865 was not efficacious in the Tg2576 model despite achieving similar free and total brain concentrations to those in the wild-type mouse and rat where efficacy was demonstrated.

7.07.19 Modulators From Schering-Plough

Prior to the merger with Merck in 2009, Schering-Plough were also active in the field of aryl-imidazole GSMs. Some of their disclosed structures are shown in the Fig. 41. The design of these compounds originated from E2012 (**6**, Figs. 5 and 18), in which the cinnamide double bond and carbonyl moiety were incorporated into five-membered ring heterocycles.[131] This modification generated a novel class of fused 5,6-bicyclic heterocycles GSMs, such as the tetrahydrotriazolopyrimidine **146** and pyrazolopiperidine **147** (Fig. 41). When tested in vivo in rat, **146** showed no efficacy at 30 mg kg^{-1} 3 h postadministration, which might be attributed to insufficient brain concentration (0.49 μM). Compound **147** on the other hand showed modest reduction of $A\beta_{42}$ levels in the rat CSF (16%) 3 h after a 30 mg kg^{-1} dose. Further optimization, via aromatization of the piperidine ring in **147**, led to a novel pyrazolopyridine series of GSMs.[132] The PgP efflux observed in analogs of this series was mitigated by introduction of a Cl atom on the pyridine ring. The best chloropyridine analog was **148**, Fig. 41, which, in a single dose rat efficacy study, reduced CSF $A\beta_{42}$ by 45% 3 h postdose (30 mg kg^{-1}), with corresponding brain and plasma concentrations of 1.22 and 5.02 μM, respectively.

Other modifications of **E2012** involved replacement of the double bond linker.[133] For instance, compound **149**, Fig. 41, mimicked the *E*-configuration of the double bond in **E2012** via a H-bond between the hydroxyl group and the carbonyl moiety of the pyridazinone ring. This modification led however to a drastic loss in potency. Optimization of **149** led to aminopyridinone **150**, a potent GSM in which the amine linker locks the molecule in an active conformation via intramolecular hydrogen bonding to the carbonyl moiety of the pyridine ring. Pyridone-type GSMs were also described by Janssen, for example, compound **87**, Fig. 26. Compound **150** however demonstrated weak efficacy in rat, when dosed orally at 100 mg kg^{-1}, reducing the $A\beta_{42}$ by 26% in brain and 40% in CSF.

In 2010–2013, Schering-Plough disclosed yet another class of aryl imidazole GSMs derived from **E2012** template. Recognizing that in **151** (Fig. 42), a potent analog of **E2012**, a bulky tetrahydropyranyl moiety allows hydrogen bonding interactions only for the LHS lone pair of electrons of the lactam carbonyl moiety,[134] a formal cyclization from the carbonyl moiety into the benzylic position provided oxadiazolines (**152**, Fig. 42) and oxadiazines (**153**, Fig. 42) as bioisosteres, which maintain the LHS HBA capabilities of **151**.

Further exploration of **152** allowed the identification of more potent GSM **154**, Fig. 42. When dosed orally in rat at 10 mg kg^{-1}, **154** reduced $A\beta_{42}$ by 66% in CSF and 37% in the cortex, 3 h postdosing and with a brain exposure of 0.54 μM. In the same study, oxadiazine **153** reduced $A\beta_{42}$ by 65% in CSF and 63% in the cortex, 3 h after oral administration of a 3 mg kg^{-1} dose to rat. The corresponding brain exposure was found to be 1.47 μM. The PK profile of **SP-7** in rat showed that this compound had a low clearance of 1.4 mL min^{-1} kg^{-1}, a low V_{dss} of 0.4 L kg^{-1} and a moderate half-life of 3.5 h together with 100% oral bioavailability. Furthermore, **153** showed no QTc prolongation in the dog, despite exhibiting 76% inhibition of hERG at 10 μM. Further optimization of **153** aimed to improve its overall profile and focused on modification of the central core. This resulted in the identification of **155** and **156**,[135,136] Fig. 42. A highly potent GSM, morpholino oxadiazine **155** reduced $A\beta_{42}$ levels in rat CSF by 60% of 3 h after a 20 mg kg^{-1} oral dose. Compound **156**, having similar activities in vitro ($A\beta_{42}$ IC_{50} = 39 nM) and in vivo (61% reduction of $A\beta_{42}$ in CSF) with **153**, proved to be a weaker hERG inhibitor (33% inhibition at 10 μM). Compound **155** employs a similar cyclization strategy to that used by Eisai, for example, compound **55**, Fig. 18.

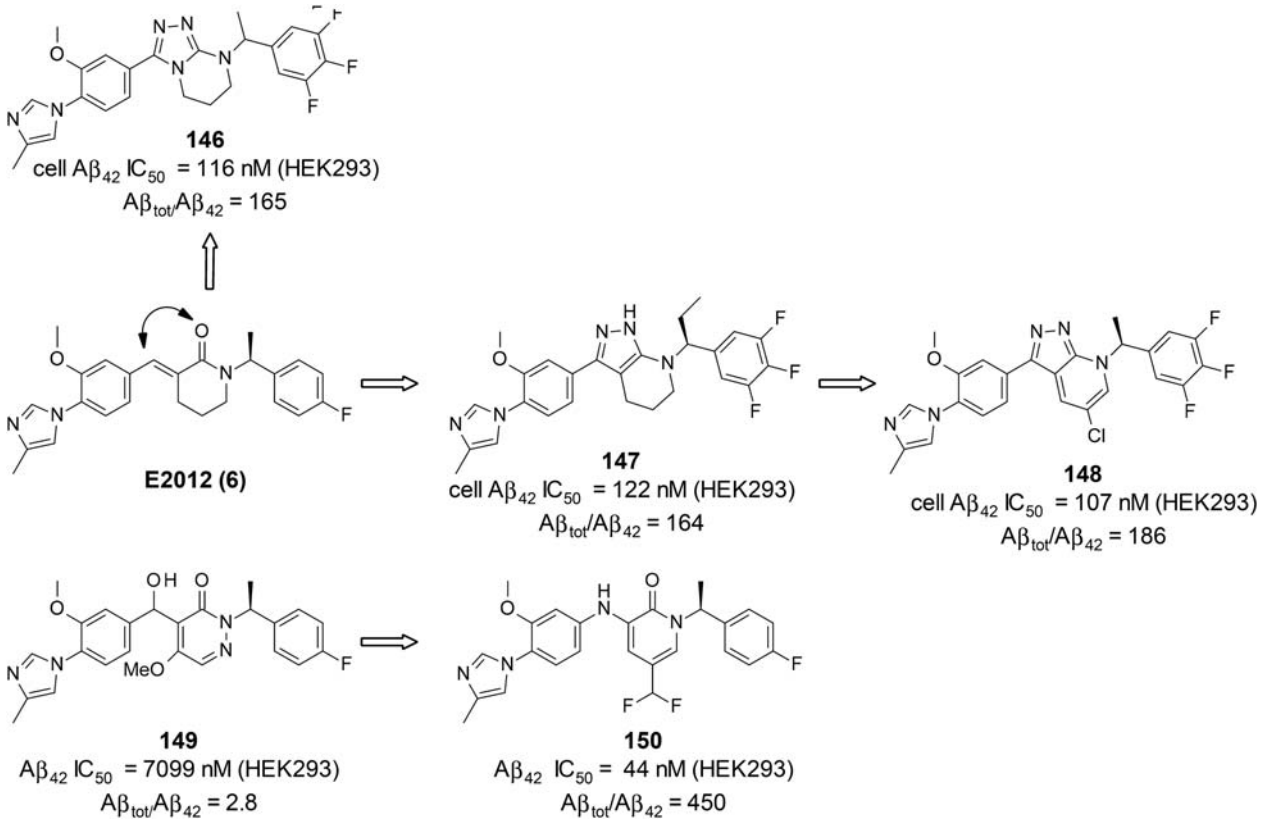

Fig. 41 Schering-Plough aryl imidazole GSMs.

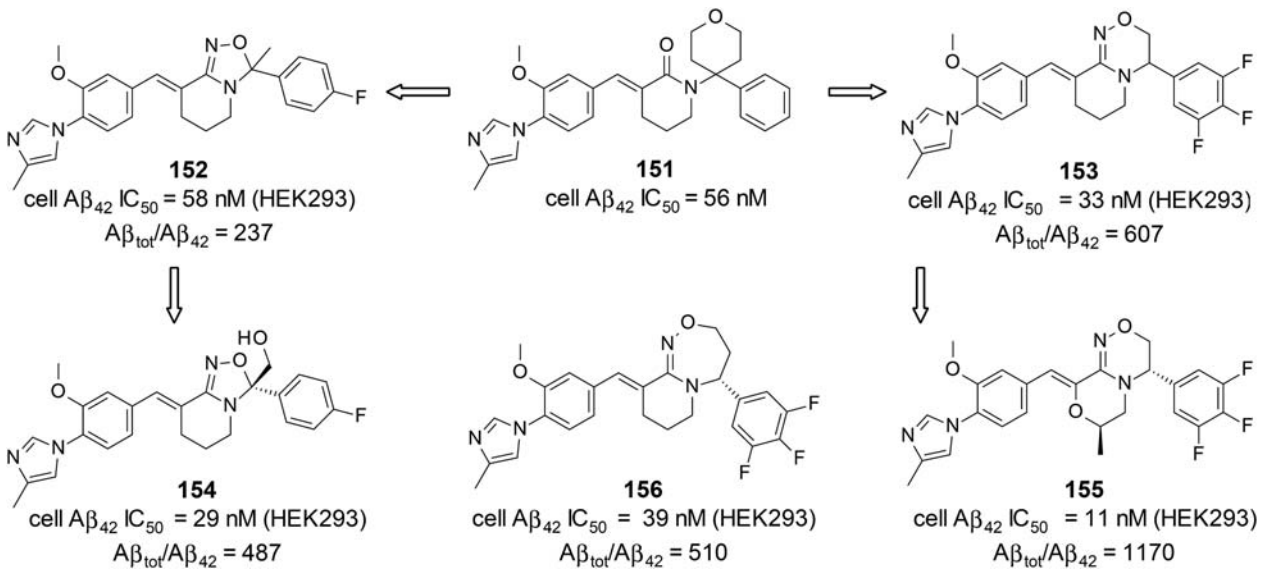

Fig. 42 Schering-Plough. Fused oxadiazolines and oxadiazines as GSMs.

7.07.20 Modulators From Shionogi

In a patent application from 2010,[137] researchers at Shionogi claimed GSMs in which the aryl-imidazolo GSM A-B system was linked to give a central sulfonamide core linked to a substituted thiophene. These compounds were weakly potent in lowering $A\beta_{42}$, with IC_{50}'s being in micromolar range. The best compounds claimed in the patent are **156** and **157**, Fig. 43.

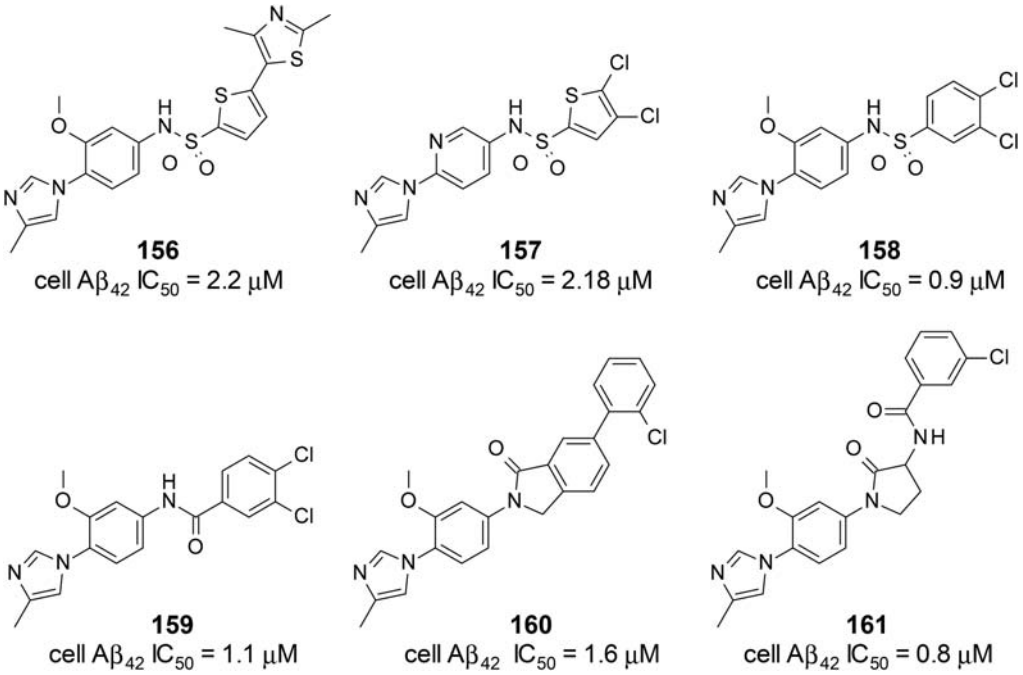

Fig. 43 Sulfonamide derivatives (**156–158**) and amide/lactam (**159–161**) GSMs from Shionogi.

In a subsequent application,[138] the thiophene was replaced with a phenyl ring, as in **158**, which showed a slight, twofold, increase in potency when compared to the thiophene analog. Replacement of the sulfonamide with a reversed amide, as in **159**, kept the potency within the same (1 μM) range. Cyclization of the reversed amide into a lactam ring generated analogs such as fused lactam **160** and more flexible **161**, Fig. 43.

7.07.21 Modulators From Takeda

An HTS screening campaign of Takeda's in-house compound collection identified a piperazine derivative with GSM properties.[139] Initial modifications led to **162**, Fig. 44, which lowered $A\beta_{42}$ in primary neuronal cells and had no effect on $A\beta_{40}$ levels. In vivo in mice, however, **162** did not show significant lowering of $A\beta_{42}$ 3 h after being dosed orally at 100 mg kg^{-1}. This result could be partially explained by a suboptimal bioavailabity of **162**, as suggested by its high clearance in mouse hepatic microsomes (Cl = 150 mL min^{-1} mg^{-1}). Further optimization around **162** focused on replacing the ubiquitous imidazole moiety and identified a methyloxazole analog with improved primary potency over **162**, but which still had high metabolic clearance. Subsequent optimization around the central piperazine core (C-ring) and the naphtylethylurea (D-ring) allowed identification of **163**, Fig. 44. This compound was a potent GSM with high selectivity over Notch and low metabolic clearance (Cl = 67 mL min^{-1} kg^{-1}) in mouse hepatic microsomes, and it was further profiled. When tested in IMR-32 neuroblastoma cells in a concentration-dependent manner (0.001–1 μM), **163** significantly inhibited $A\beta_{42}$ production (up to ~50% at ~0.55 μM), while $A\beta_{40}$ levels showed a slight increase

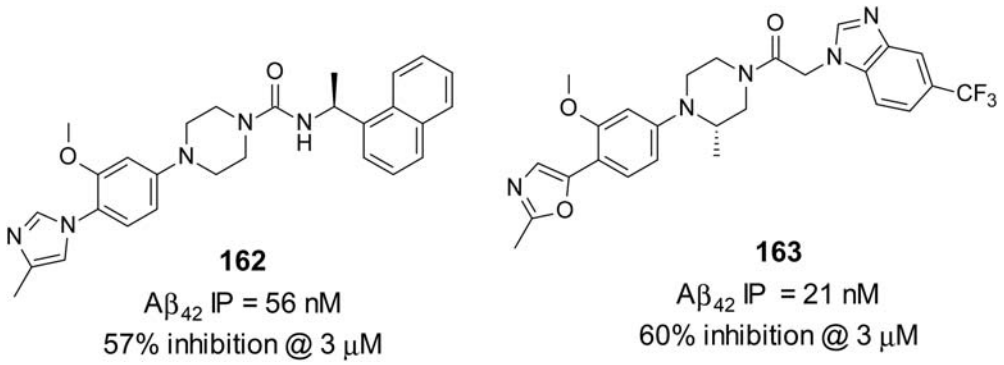

Fig. 44 Takeda aryl-imidazole GSMs. *Note*: *IP*, inflection point.

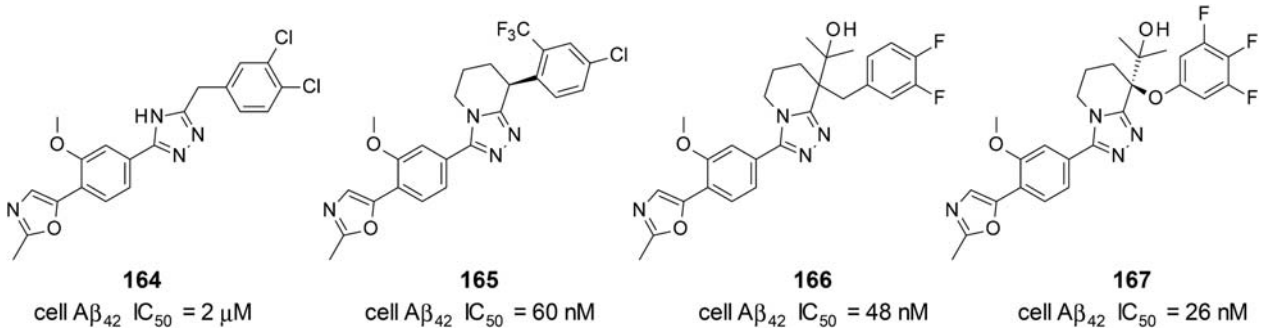

Fig. 45 Takeda bicyclic triazole GSMs.

(up to ~25% at 0.55 μM) and $A\beta_{total}$ remained unchanged. Compound **163** showed an acceptable PK profile in mice, having a low total clearance (Cl_{tot} = 117 mL h^{-1} kg^{-1}) and a good bioavailability (F = 46%).

When tested in vivo in C57BL/6 mice, **163** reduced brain $A\beta_{42}$ by 41% 3 h after being dosed orally at 100 mg kg^{-1} and had no significant effect on $A\beta_{40}$ levels. No corresponding brain exposure was reported.

In a new round of optimization, researchers at Takeda considered attaching the previously identified oxazolylphenyl moiety to various right-hand C–D systems existing in reported GSMs, such as the 3-benzyl-1,2,4 triazole derivatives reported by Janssen (such as **92**, Fig. 27).[140] These modifications led to **164**, Fig. 45, a weakly active GSM. Addition of a conformational constraint to fix the active conformation of **164** and further optimization led to the identification of **165**, Fig. 45, in which the central triazole core was fused into a triazolopiperidine. This was a potent GSM with improved physicochemical properties and drug-like parameters (LLE = 3.6). Compound **165** produced a strong reduction of $A\beta_{42}$ (50%) and $A\beta_{40}$ (75%) in brain of C57BL/6 mice, 3 h after oral administration, which corresponded to a brain exposure of 4.76 μM and Br:Pl ratio of 0.36. Given the high brain and plasma concentrations at the pharmacological dose of **165**, researchers at Takeda applied an LLE-based optimization approach to find safer analogs that could show pharmacological effect at lower drug exposures.[141] This led in a first step to **166**, Fig. 45, in which a polar hydroxypropyl moiety was introduced at the 8-position of the triazolopiperidine core. Equipotent to **165**, with increased LLE (4.3), **166** however suffered from high clearance in mouse liver microsomes (Cl = 93 mL min^{-1} mg^{-1}). The suboptimal metabolic stability of **166** was then addressed, by modification of the metabolically labile benzyl and hydroxypropyl moieties. This led to the identification of **167**, Fig. 45, a potent GSM which preserved the high LLE and had good microsomal stability (Cl = 7 mL min^{-1} kg^{-1}). When it was orally administered to C57BL/6 J mice at 6 mg kg^{-1}, this compound showed a strong, 60%, decrease in brain $A\beta_{42}$ which corresponded to exposures of 1.3 μM in brain and 6.4 μM in plasma, significantly improved with respect to **164**.

In a recently reported in vivo efficacy study,[142] the GSM behavior of **167** was first confirmed in Neuro2A mouse cells expressing human Swedish mutant APP(N2a-APPsw), when dose-dependent decreases in $A\beta_{42}$ and $A\beta_{40}$ and increase in $A\beta_{37}$ levels were observed. The total Aβ levels were not affected and there was no activity against Notch (IC_{50} > 10 μM). A chronic 58-day oral administration study with **167** to Tg2576 mice, at 10 and 30 mg kg^{-1} day^{-1}, led to significant and dose-dependent reductions of both soluble and insoluble brain $A\beta_{42}$ levels. At the highest 30 mg kg^{-1} day^{-1} dose, this corresponded to a ~60% reduction of soluble $A\beta_{42}$ in brain and ~50% reduction of insoluble $A\beta_{42}$. The reported brain concentrations after treatment with **167** at 10 and 30 mg kg^{-1} day^{-1} were 0.301 and 1.325 μg g^{-1} (0.58 and 2.57 μM), respectively. At both doses, **167** was reported to display a tendency to inhibit plaque deposition. In addition, in the novel object recognition test, treatment with **167** significantly recovered preference ratios to 65% and 67% at 10 mg kg^{-1} and 30 mg kg^{-1}, respectively. Moreover, continuous cognitive improvement was observed up to 7 days after cease of **167** administration. Compound **167** was described as a potential candidate therapy for disease modification in AD. As expected for a GSM **167** did not display any of the adverse effects observed with GSIs and Notch-sparing GSIs. The current status of **167** is unclear but perhaps more reports around **167** will follow in the literature.

7.07.22 Modulators From UCSD/Neurogenetics Inc/Torrey Pines Therapeutics

The University of California, San Diego, in collaboration with the Tanzi group and spin out companies of different guises were early entrants to the GSM field. Neurogenetics Inc. changed name to Torrey Pines Therapeutics in Mar. 2005 and under the latter name, the group disclosed the aryl-imidazole template, which was exemplified by compounds such as **168** and **5**,[143] Fig. 46. These compounds were extremely important and essentially seeded the field. A recent publication describes the identification of their series. Compound **168** was discovered from a screen of 80 k compounds and was found to reduce $A\beta_{42}$ production in CHO cells overexpressing wild-type APP695, with an IC_{50} of 1512 nM.[144] Optimization of the series utilized an SH-SY5Y cellular assay, overexpressing APP751, and resulted in the identification of **5**, which displayed significantly improved activity, Fig. 46. Further characterization of **5** in mixed brain cell cultures from Tg2576 mice confirmed the activity; $A\beta_{42}$ IC_{50} 29 nM, $A\beta_{40}$ IC_{50} 90 nM, $A\beta_{38}$ EC_{50} 170 nM. In vivo profiling in the mouse at 50 mg kg^{-1} for 3 days showed that **5** penetrated the CNS with a Br:Pl of 0.93. Efficacy was initially assessed by dosing **5** to Tg2576 mice for 3 days at 12.5, 25, 50, and 100 mg kg^{-1} p.o., with read out 6 h after final dose. Analysis revealed strong affects on

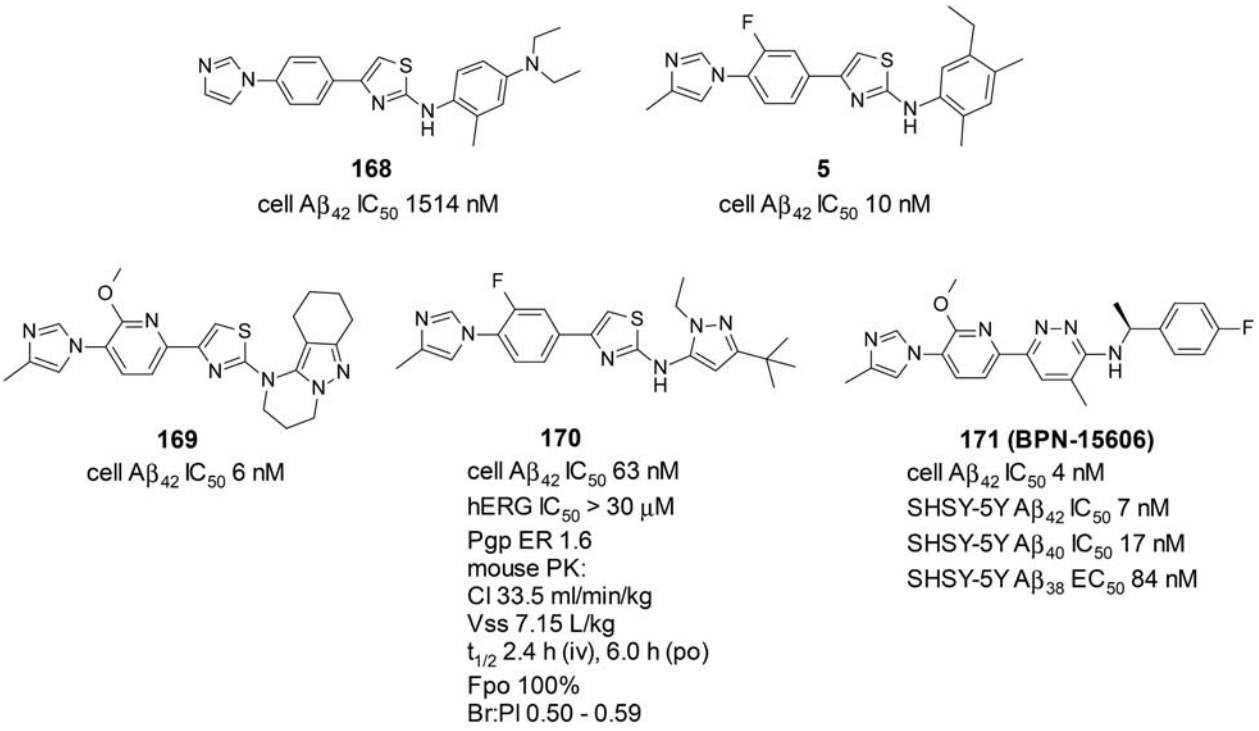

Fig. 46 HTS hit **168** and optimized compound **5**, with more recent examples from the patent literature from UCSD/Neurogenetics/Torrey Pines Therapeutics.

plasma $A\beta_{42}$ levels but weak, ~30% and 40% reductions on brain $A\beta_{42}$ following 30 and 100 mg kg^{-1} doses, respectively, despite high total brain concentrations (29.5 and 66.4 μM, respectively). A follow on study assessed the effect of a 50 mg kg^{-1} p.o. dose of **5** for 7 months to preplaque bearing Tg2576 mice. Quantification of the effect was assessed by two different Aβ extraction methods—DEA and formic acid, the former showing the larger effect. Analysis of DEA-extracted brain Aβ showed a 76% reduction of brain $A\beta_{42}$, and a similar reduction of brain $A\beta_{40}$ (73%). Surprisingly, $A\beta_{38}$ in the brain was also reduced by 76%, in contrast to the in vitro profile where $A\beta_{38}$ levels are increased. The reduction in soluble amyloid levels were accompanied by a reduction in plaque area in the cortex and hippocampus relative to vehicle treated control mice.

The group at UCSD has maintained an active interest in the area as shown by patent activity. Thus, more recent publications from the group have reported aminothiazoles such as **169**,[145] Fig. 46. A related manuscript also describes close analogs of **169**, or which **170**, Fig. 46, represented the most interesting example.[146] The prime drive in the optimization was to improve the solubility over examples such as **170**, as this series generally had very low solubility, <0.1 μM at neutral pH. Compound **169** showed moderate activity in a SH-SY5Y cell assay, but showed no major CYP450 interactions and minimal hERG activity as well as a suitable PK profile in the mouse. Solubility was also marginally improved at 4.7 μM at pH 7.4.

Finally, a very recent patent application hints that the group may have moved away from the aminothiazole series as, working with Albany Molecular Inc., they have disclosed a series of aminopyridazines, such as **171**,[147] Fig. 46. Compound **171** is an extremely close analog of the well-characterized compound **70** from gsk, Fig. 22, Section "Modulators From GlaxoSmithKline", first disclosed some 7 years ago,[148] where the methoxyphenyl ring has been replaced by a methoxypyridyl ring. In addition to the in vitro characterization, in vivo profiling was also conducted with **171**. PKs in the rat showed low clearance (1.5 mL min^{-1} kg^{-1}) and good half-life (5.9 h) and oral bioavailability (60%). Efficacy was assessed in both the mouse and the rat. In the mouse doses of 10, 25, and 50 mg kg^{-1} for 7 days resulted in 36%, 69%, and 85% reductions in brain $A\beta_{42}$ levels, with similar effects on $A\beta_{40}$. Similar efficacy was observed in the rat with doses of 5, 25, and 50 mg kg^{-1} producing reductions of 43%, 73%, and 85% in $A\beta_{42}$ levels. Again, the effect on $A\beta_{40}$ levels was very similar to those on $A\beta_{42}$. In addition to brain amyloid levels, $A\beta_{42}$ was also measured in CSF where reductions of 43%, 73%, and 86% were measured, again showing high concordance with the reductions in the brain. Thus, it would appear that **171** is of significant interest to the group and may be further advanced.

7.07.23 Photo-Activity Ligands

As mentioned in the introduction, the lack of high resolution protein crystallography has presented researchers with challenges to understand the binding mode and binding site of GSMs. In the absence of a crystal structure of a GSM-protein complex, one

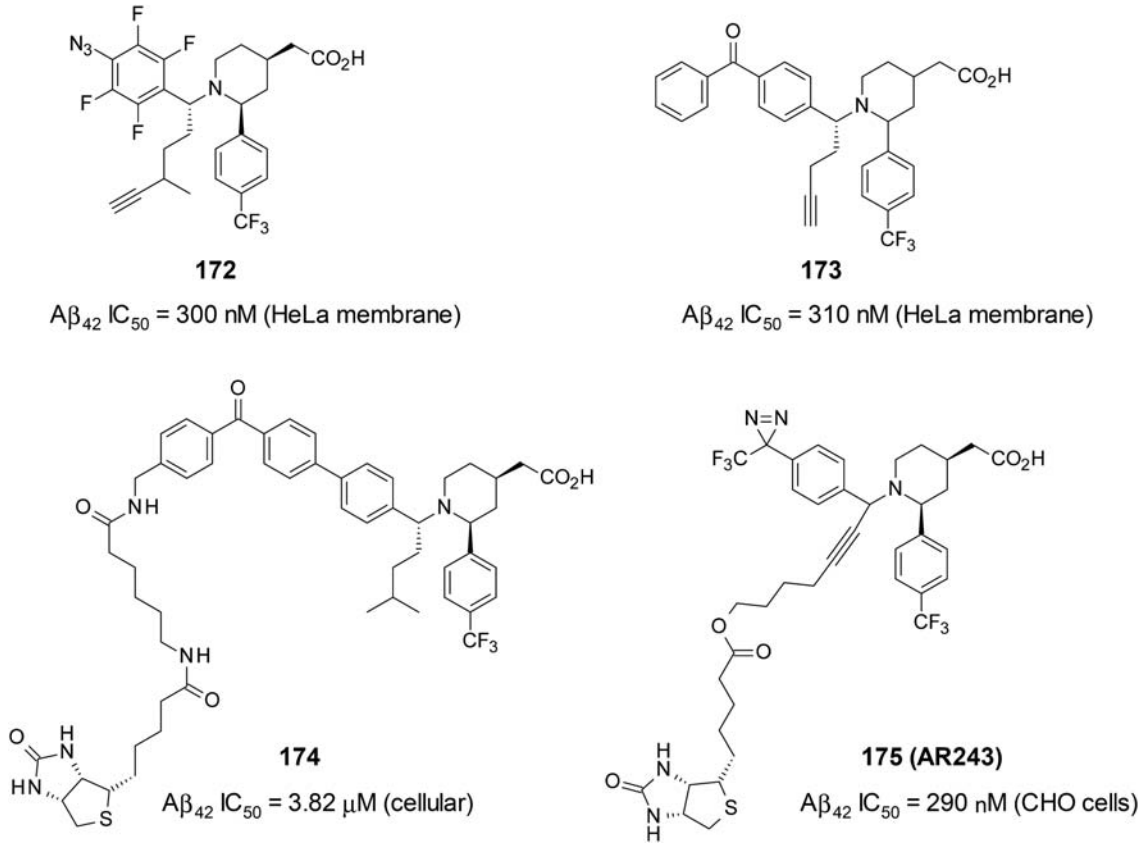

Fig. 47 PALs derived from GSM-1 (**103**).

technique that has been applied to improve the understanding of the mode of action of GSMs is photoaffinity labeling.[149] This method involves introducing a photolabile group into a biologically active molecule, which under UV irradiation can form a covalent bond with the target protein, at its binding site. Most commonly used photolabile moieties include azides, trifluormethyl diazirines, and benzophenone.

In the NSAID class of GSMs, compound GSM-1 (**103**, Fig. 30) has been extensively utilized in photoaffinity labeling studies. For instance, researchers at Pfizer and academic collaborators developed a GSM-derived photoprobe in which the parent molecule incorporated both a photolabile group,[150] such as an azide (**172**) or benzophenone (**173**), Fig. 47, and an alkyne moiety. After crosslinking, the alkyne was subjected to click chemistry conjugation with an azide-linked biotin tag which allowed isolation and purification of the target protein–ligand complex via immobilization on an avidin column, using the strong binding interaction between avidin and biotin.[151] The pure, biotynilated protein–ligand complex can then be obtained by washing it off the column, with the aid of a buffer. Western blot analysis showed that **172** and **173** labeled PS1-NTF and that labeling was diminished in the presence of two GSMs from the same class—meaning it was specific binding. Moreover, the authors report that GSM-1 (**103**) enhanced the photolabeling of GSI-derived photoprobes. This result implies that the binding of GSM-1 (**103**) to an allosteric site of PS-1 causes a conformational change in the active site thus increasing GS binding of an orthosteric ligand (a gain of function).

These findings were confirmed in a study by Ohki et al.,[152] in which they utilized photoprobe **174**, Fig. 47, having the biotin tag already attached to the PAL. In addition, using fluorescence lifetime imaging and surface cysteine availability (SCAM) methods, the study suggested that GSM-1-type of modulators bind to a hydrophobic extracellular/luminal side of the TMD1 in PS1, which provokes the conformational changes in GS active site. Moreover, the authors demonstrated that GSM-1 (**103**) affects the γ-cleavage site of GS, and not the ε or ζ-sites.

In a third independent report, Jumpertz et al. confirmed the PS1-NTF binding site of GSM-1 (**103**) in living cells.[153] Their PAL incorporated a biotin label on the aliphatic side chain of GSM-1, whereas the photosensitive group used was an (trifluoromethyl) diazirine. This resulted in a PAL with nanomolar potency, **175**, much improved over **174**. In addition to previous studies, competition experiments suggested that GSMs from the same class, such as **85** (Fig. 25), bind to the same site as GSM-1 (fully displace **175** PS-NTF binding), whereas some of the aryl-imidazole GSMs tested (an analog of **107**, Fig. 32 and E2012) only partially overlapped, showing reduced displacement of **175**. Intriguingly, the GSK aryl-imidazole derivative, **70** (Fig. 22), fully displaced **175**, suggesting an identical binding site.

The binding site of different types of aryl-imidazole GSMs (Fig. 48) has also been investigated. Early work done by Ebke et al. on a photoprobe derived from compounds such as Ro-57-BpB (**134**, Fig. 38),[154] identified binding to PS2-NTF as well to PS1 NTF.

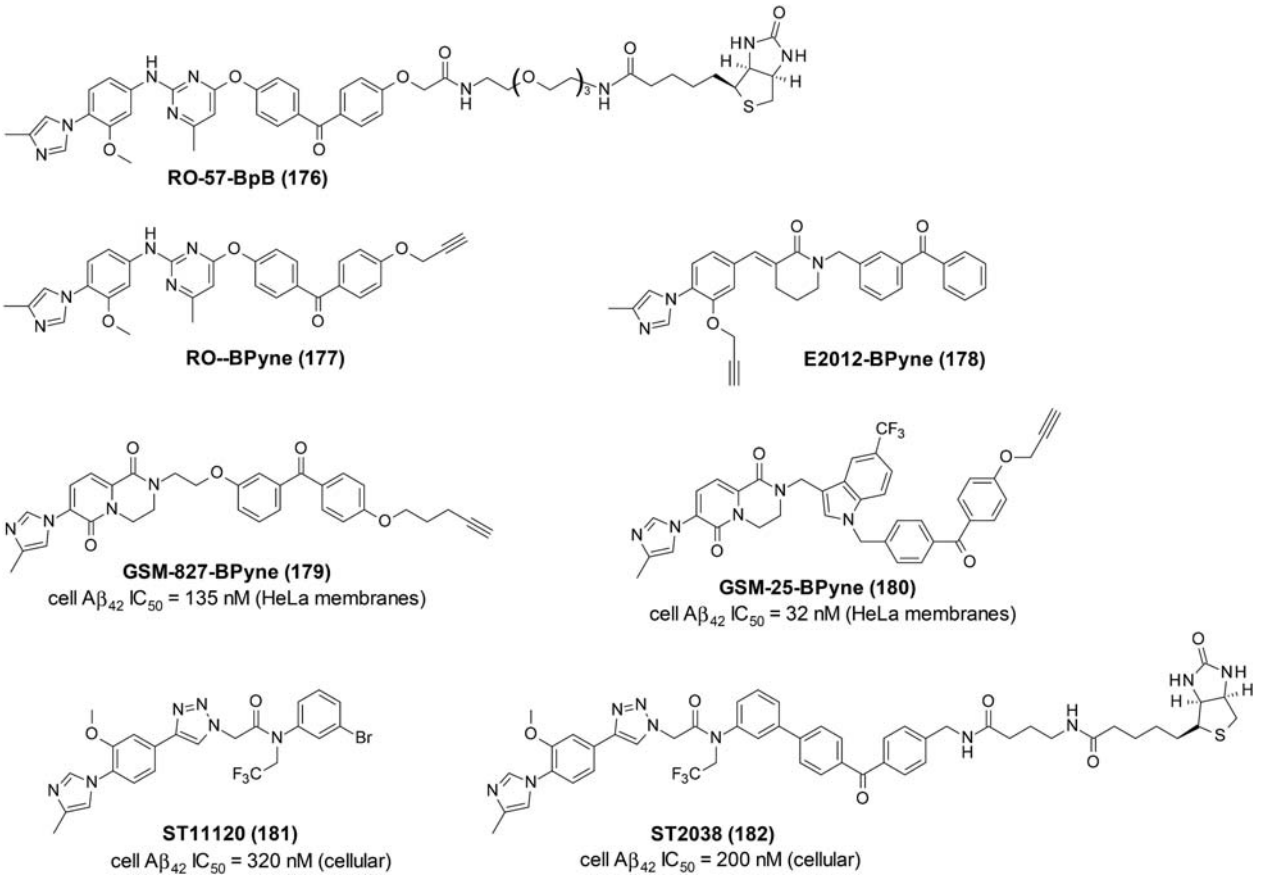

Fig. 48 Aryl-imidazole-derived GSM photoprobes.

Competition experiments revealed that the binding to PS-NTF was completely displaced by E2012 analogs, but only partially by Torrey-Pines analogs. On the other hand, carboxylic acid GSM-1 (**103**) only partially competed for PS1-NTF (confirming previous findings), however, GSM-1 completely displaced Ro-BpB from PS2-NTF binding site. Finally, transition state analog L-685,458 displayed moderate competition, whereas GSIs such as begacestat competed very weakly or not at all. These findings were partially confirmed in a later study by Pozdnyakov et al. by cross-linking experiments of a clickable photoprobe, RO-Bpyne (**177**, Fig. 48)[155] with PS1-NTF, however no mention was made of PS2-NTF crosslinking.

The research group in Pozdnyakov et al. also investigated the binding of an E2012-derived clickable photoprobe, E2012 B-Pyne, **178**, Fig. 48.[155] This probe specifically labeled PS1-NTF in cell membranes, live HeLa cells and primary neuronal cultures. The photolabeling of E2012-B-Pyne (**178**) was enhanced when the crosslinking was performed in the presence of active-site directed GSI, L-685,458 (L458). The authors suggest that the binding of L-685,458 to the active site of PS-1 produces a conformational change that leads to a better fit of E2012 to the binding site. This observation opposes the Ro-57BpB experiment (*vide supra*), suggesting a different binding site for GSMs belonging to the same aryl-imidazole class. Neither GSM-1 (**103**) nor BMS-708,163 inhibited the binding of **178** to PS1-NTF in competition experiments, suggesting different binding sites for E2012 and both GSM-1 and GSIs.

Recently, Pfizer prepared clickable photoprobes of a new type of GSM scaffolds, in order to verify whether their binding site is similar to that reported for other aryl-imidazole-type GSMs.[111,113] (X REF J Med Chem 2014, 57, 1046 and BMCL 2015, 25, 908) Thus, cross-linking experiments performed with 1 μM of a clickable photoprobe derived from **126** (Fig. 36), GSM25-Pyne (**180**, Fig. 48), revealed that GSM25-BPyne (**180**) also labeled PS1-NTF. The labeling was diminished in the presence of GSMs belonging to the same series as **126**, showing specific binding. Similarly, GSM-827 B-Pyne (**179**, Fig. 48), derived from the **124** series (Fig. 36) showed specific binding to PS1-NTF. Moreover, unlike E2012-BPyne, crosslinking of **179** in the presence of GSI L-685,458 did not produce a significant increase in the binding to PS1-NTF.

In a recent report,[156] Takeo et al. investigated GSM mode of action utilizing cross-linking experiments performed with two photoprobes derived from **113** (Fig. 34), namely ST2038 (**181**, Fig. 48) and ST1120 (**182**, Fig. 48), in addition to systematic mutagenesis. A first PAL experiment was aimed at understanding the effect of GSMs on the conformation of GS. To this end, ST-1120 (**181**) was incubated with two GSI PALs prior to crosslinking: 31C-Bpa, a PAL derived from a transition-state-type GSI, which binds to PS1-NTF and CTF, and Pep.11-Bt, a PAL derived from helical-peptide-type GSI pep.11, which binds to the initial substrate binding site within PS1-NTF. The authors observed that **181** enhanced the binding of 31C-Bpa, and decreased the binding of

Pept11-Bt. This result would suggest that **181** might affect the conformation of the GS active site by facilitating the formation of the transition state of GS. This finding is also in agreement with the previous observations of Crump et al. (*vide infra*) from cross-linking experiments done in the presence of GSM-1. Furthermore, the authors also tested ST1120 (**181**) in PS2-containing GS cultured cells, which confirmed the results of Ebke et al. (with RO-57, *vide infra*), indicating a preference of ST1120 to bind to PS2 over PS1 (IC_{50} $A\beta_{40}/A\beta_{42}$ for PS2 = 271/51 nM vs. IC_{50} $A\beta_{40}/A\beta_{42}$ = 5538/320 nM for PS1).

Photoaffinity labeling experiments with ST2038 (**182**) incubated in membrane fractions isolated from mouse brain, indicated that **182** binds to both PS-NTF and Aph-1. Again, competition experiments with GSM-1 (**103**) suggested that **103** and **182** binding sites partially overlap, whereas **182** does not share the same binding site with GSIs 31C and peptide Pep.11. An alanine scanning analysis, in which each of the amino acid residues from PS2 that is conserved in PS1 was replaced by alanine, was performed in order to identify the specific PS2 residues to which **181**-type GSMs bind. The potency and labeling of **182** to the resultant mutants was verified, which showed that labeling efficiencies of **182** to PS2 Y112A, N141A, and Y246 mutants were decreased. This therefore suggests that these aminoacid residues could be directly involved in the binding of **182**. As the authors mention, there is of course the possibility that the alanine substitution affects the architecture of the binding site (i.e., and as a result the GSM does not bind in it anymore). Utilization of a homology model of human PS1 derived from the reported crystal structure of the archaea PSH[157] allowed the identification of the ST-1120 binding pocket. This was found to be an extracellular pocket formed by HL1/TM2/TM5 of PS. Further analysis using the SCAM method provided evidence that the binding of ST1120-type GSMs to the extracellular pocket provokes conformational changes in the catalytic site of PS which, in turn leads to an increase in the cleavage activity of GS.

In conclusion, more light has been shed on the mode of action of GSMs via the use of PALs. Thus, it seems that, regardless of chemical class, GSMs consistently bind to PS1-NTF, some of them showing even better binding to PS2-NTF. For both types of GSMs, the binding site seems to be placed in different extracellular pockets of PS1. Most of the time, GSMs from the same class seem to bind to the same site, but there are also exceptions. The consensus is that the allosteric binding of GSMs induces a conformational change in the catalytic site of GS, which generates a GS gain of function, ultimately resulting in increased production of shorter Aβ peptides at the expense of the longer isoforms. Another recent advance is represented by the determination of the first atomic structure of GS, with the aid of high-resolution cryo-EM. Perhaps further refinement/understanding of GSM binding sites in PS/GS will allow for the design of more drug-like GSMs is after all not so distant.

7.07.24 Clinical Compounds

Several GSMs are now known to have entered clinical trials, and key compounds from the carboxylic acid and aryl-imidazole derivatives are listed in **Tables 4** and **5**. Unfortunately, the picture painted by the clinical development is not one of optimism, but highlights the challenges/difficulties which have been encountered.

In the carboxylic acid series, the most progressed derivative, (*R*)-flurbiprofen (**1**), **Table 4** and **Fig. 4**, failed in PhIII. However, this may not be unexpected as the compound has extremely weak GSM activity, $A\beta_{42}$ IC_{50} 307 μM,[158] and failed to impact CSF $A\beta_{42}$ levels in the clinic and minimally impacted plasma $A\beta_{42}$ levels.[159] As a result, although there was initial encouragement from a 24-month trial in mild to moderate AD patients,[160] this was not confirmed in a large 18 month trial, where there were no improvements in the rate of cognitive decline or loss of activities of daily living in patients with mild AD.[161] Retrospective analysis of published preclinical data in Tg2576 mice may help shine light on possible reasons for failure.[162] Oral administration at doses of 10, 25, and 50 mg kg^{-1} for 3 days, with three mice per dose reduced brain $A\beta_{42}$ were observed at all doses, but there was no dose–response; the reductions were 26%, 60%, and 34% at the 10, 25, and 50 mg kg^{-1} doses, respectively. The plasma concentrations were also not linear with dose; 83, 117, and 78 μM at 10, 25, and 50 mg kg^{-1}, respectively, whilst the corresponding brain concentrations were 1.5, 2.6, and 2.5 μM, respectively. Thus, the total brain exposures are far inferior to the estimated in vitro IC_{50}, and an in vivo concentration response relationship was also lacking. In addition to the low animal numbers in the in vivo study, these may be confounding factors in the failure of this compound.

CHF5074 shares a similar structure to flurbiprofen, **Table 4**, and has also been investigated in the clinic. Preclinical data indicates CHF5074 has weak GSM activity, IC_{50} = 3.6 μM,[163] although it is still some 85-fold more potent than flurbiprofen. Again, CHF5074 has failed to show modulation of $A\beta_{42}$ in the clinic despite having progressed to PhII trials. Despite this, the compound has been licensed by Cerespir and renamed CSP-1103.[164] The mechanism of action has been rebranded and it is claimed to have several modes of action[165] in addition to its primary GSM pharmacology, namely to reduce tau pathology[166] and restore normal microglial function by increasing phagocytosis and decreasing the production of pro-inflammatory cytokines.[167] According to the Cerespir website they are working with regulators to finalize PhIII protocols.

A third compound from the carboxylic acid series, EVP-0962 (**60**), **Table 4** and **Fig. 19**, from Forum/EnVivo Pharmaceuticals has also progressed to PhII,[168] showing considerably improved in vitro potency over the two aforementioned compounds. In the PhII study, EVP-0962 was dosed (10, 50, 100, and 200 mg) for 14 days to patients with MCI or early AD and CSF amyloid levels were assessed,[169] however no data have been published on the outcome.

Recently, it has been shown that ibuprofen does not impact Aβ levels in plasma or CSF in human or monkey. Thus, this support the fact that the low CSF penetration (~1% that of plasma, with a human CSF conc ~12 μM), coupled with weak modulatory activity (IC_{50} ~250 μM) is insufficient to deliver efficacy.[170]

In the aryl-imidazole series, the picture is not much better than the carboxylic acid series. Despite the promise of a different template with increased potency and CNS penetration, this series has also struggled to deliver compounds to the clinic. Despite the huge effort expended by numerous research groups, a limited number of compounds have progressed to clinical studies, **Table 5**.

Table 4 Summary of compounds from the carboxylic acid series that have entered clinical trials

Compound	*Company*	*Stucture*	*IC_{50} (nM)*	*Status*
MPC-7869 (*R*)-flurbiprofen/tarenflurbil (Flurizan)	Myriad/Lundbeck		307,000	Terminated
CHF5074	Chiesi/Cerespir		3600	Unknown
EVP-0962	Forum/EnVivo		67 (H4-APP_{751}) 427 (rat PCN)	Unknown

Table 5 Summary of key aryl-imidazole derivatives to progress to human clinical trials, including purported structure of E2212

Compound	*Company*	*(Proposed) structure*	*IC_{50} (nM)*	*Status*
E2012 (6)	Eisai		80	Terminated (PhI), lenticular opacity
E2212 (59)	Eisai		17	Terminated (PhI)
BMS-932481 (40)	BMS		6.6	Terminated (PhI), liver toxicity
PF-06648671	Pfizer	Not disclosed	Not known	PhI

The aryl-imidazole class was led by E2012, which was the first compound from this class to enter clinical. There is still little published information on this compound, but some data has been presented at conferences. In rat primary cortical neurons E2012 reduced both $A\beta_{42}$ and $A\beta_{40}$ with an IC_{50} of 100 nM,[171] and the modulatory mechanism of action was confirmed by demonstrating lack of accumulation of APP-CTF and lack inhibition of notch processing.[172] Preclinical efficacy in the rat was observed at doses of 10 and 30 mg kg^{-1} p.o., which effected reductions in CSF $A\beta_{40}$ and $A\beta_{42}$ levels.[53] The PhI study commenced in 2006, with doses ranging from 1–800 mg.[173] Lowering of plasma $A\beta_{42}$ was reported, with a 53% reduction observed following the 400 mg dose. As discussed under the Eisai section (**Modulators From Eisai**) it has now been publicly disclosed that the progression of E2012 has been terminated, due to lenticular opacity/cataracts in preclinical toxicology studies.

A second compound from Eisai, E2212 has one SAD trial listed, which was scheduled for completion in Nov. 2012.[174] As there are no further trials ongoing and the compound has not been listed on the company pipeline since the FY2012 Financial Results Presentation on May 13, 2013, it is assumed that its progression has been halted.[175] The widely purported structure of E2212 is depicted in **Table 5**, however, there has not been an official link between this structure and compound number from Eisai.

More recent efforts have seen the progression of BMS-932481 to PhI studies. However, the development of this compound was terminated following the MAD arm of the PhI trial due to liver toxicity, which occurred at doses required to effect changes on $A\beta_{42}$ levels. The effects on CSF $A\beta_{42}$ in the clinic appear modest, considering the potency of the compound. This may be a result of suboptimal CNS pentration and high nonspecific binding. These issues appear to have dogged the series in general, in addition to CYP inhibition, hERG inhibition, and high lipophilicity. However, there are also some positives to be taken from this data as it is the first time that a GSM has demonstrated efficacy by modulating CSF $A\beta_{42}$ levels.

Most recently, Pfizer have advanced PF-06648671 to PhI studies. Until lately the mechanism of action had not been confirmed for this compound, however, the PhI trial detailed the biomarkers, which were measured and included $A\beta_{42}$, $A\beta_{40}$, $A\beta_{37}$, $A\beta_{38}$, and $A\beta_{tot}$, thus implying that this compound is indeed a GSM.[176] Currently, the compound has completed SAD study (Dec. 2014–Mar. 2015)[177] and a 14-day MAD (Dec. 2015–Oct. 2016)[178] is ongoing. The doses detailed for the MAD study, which includes a CYP3A4 interaction arm, are 4, 12, 40, 100, 200, and 360 mg.

A recent presentation has confirmed the mechanism of action of this compound and provides further details.[179] In the phase 1, SAD study two cohorts were examined, with each subject receiving up to three doses of PF-06648671 and a placebo. Single doses of 2, 4, 12, and 40 mg were tested in Cohort 1, and 120, 240, and 360 mg were tested in Cohort 2. PF-06648671 was found to be generally safe and well tolerated in healthy subjects after single oral doses up to 360 mg (no clinical abnormalities were identified and no significant changes on safety ECG, telemetry, vital signs, or labs were observed). The maximum tolerated dose was not been established.

Following single doses under fasted condition, PF-06648671 was absorbed rapidly with a median T_{max} of 1–1.5 h. The mean terminal $t_{½}$ ranged from 13.9 to 23.1 h. The C_{max} and AUC_{inf} increased by ~88- and 140-fold over the dose range of 2–360 mg. The food effect was also assessed at 120 mg with a high-fat breakfast. In this case, a delayed median T_{max} of 4 h was observed. The AUC_{inf} slightly increased by 23%, whilst the C_{max} decreased by 24% compared to the fasted state.

Significant, dose-dependent reductions in plasma $A\beta_{42}$, $A\beta_{40}$, and $A\beta_{total}$ were observed. The placebo-adjusted maximal change from baseline was −56.9% and −68.8% for plasma $A\beta_{42}$ and $A\beta_{40}$, respectively, after a single dose of 360 mg. The authors reported that a multiple ascending dose study in healthy adult and elderly is ongoing with the effect on CSF Aβ being evaluated at steady state.

Thus, although the full picture is not yet available for PF-06648671, the effects on plasma $A\beta_{42}$ can be compared to those published for E2012 and BMS-932481, as the data is available from the SAD studies with each compound. Thus, at a dose of 400 mg, E2012 reduced plasma $A\beta_{42}$ by 53%, whilst 300 mg of BMS-932481 reduced plasma $A\beta_{42}$ by ~40%. The effects of BMS-932481 on plasma $A\beta_{42}$ appeared to plateau at 600 mg, as doses of 600 and 900 mg both produced ~60% reductions of plasma $A\beta_{42}$. As noted, recently released data on PF-06648671 reveals that a 360 mg dose produced a 57% reduction in plasma $A\beta_{42}$. Thus, taken together, the effects of PF-06648671 on plasma Aβ do not appear stringer than either of the two forerunner compounds, which have both been terminated. Therefore, unless the CNS penetration and efficacy of PF-06648671 is significantly improved realtive to E2012 and BMS-932481, it would appear unlikely that greater central efficacy will be observed. However, if PF-06648671 shows sufficient efficacy and progresses beyond this stage, it would represent a major breakthrough for the field and perhaps encourage other groups to return to the field. Conversely, Pfizer also have a BACE inhibitor (PF-06751979) which is progressing in parallel in clinical trials. Based on other publicly available data from a range of companies, BACE inhibitors appear to offer improved efficacy over GSMs and are further advanced with Verubecestat/MK-8931 from Merck currently undergoing PhIII trials. Thus, Pfizer will be in the unique position of being able to compare contemporaneous clinical trial data on a GSM and BACE inhibitor and decide on their progression.

Thus, a decade after the first GSM from this class entered PhI studies, no compound has yet progressed beyond this stage. PF-06648671, from Pfizer, is the latest GSM to enter clinical trials but has only progressed to PhI so far, which highlights the challenging nature of this field.

7.07.25 Conclusion

From this review, it is evident that a considerable amount of research has been conducted in the GS field. Early work centered on the carboxylic acid series, following on from the identification of the GSM profile of some NSAIDs. As can be seen, this series has

encountered issues in trying to optimize potency to the single-digit nanomolar range. In addition, the high lipophilicity has also proved challenging to modulate. Furthermore, optimizing CNS penetration and nonspecific (plasma protein and brain tissue) binding (ppb and btb) represents further challenges. Few groups have published detailed PK–PD relationships on compounds from this series, however, the relationship between free drug concentrations and efficacy is not always apparent. Currently, it seems that no research groups are actively working on carboxylic acid derivatives and most have switched to the aryl-imidazole-derived template, typified by the UCSD/Torrey Pines and Eisai compounds. Despite appearing more CNS drug-like and offering the promise of better CNS penetration and better potency, this class of compounds has not been without challenges. Compounds generally show good PK profiles in preclinical species as demonstrated by multiple compounds. However, many groups have struggled to manage CYP inhibition, hERG inhibition, as well as high ppb and btb, which is in part due to the high lipophilicity of these derivatives. The latter appear to manifest in high total concentrations to drive efficacy, which may ultimately be linked to off-target and toxicological issues. Despite several derivatives showing good levels of in vitro potency, in vivo efficacy has generally been weak, and is certainly weaker than that observed with BACE inhibitors. As data emerges on compounds which have entered the clinic, it can be seen that three out of four have been stopped, thus not boding well for further derivatives. Despite this, it appears that some research groups are active in the area, although many also appear to have stopped work, as inferred from patent activity.

Thus, ultimately it appears that weak clinical effects on central amyloid levels, coupled with suboptimal safety profiles, mean that it currently looks unlikely that GSMs will make it to launch. Comparative efficacy data would suggest BACE inhibitors offer the highest likelihood of delivering a drug and they are currently making excellent progress, with a number of compounds in late stage clinical trials. Despite this,there are many lessons that can be learned from the GSM field.

Acknowledgments

The authors would like to thank Dr E. Jacoby for his contribution to the Figs. 1 and 2.

92. Minne, G.; Bischoff, F. P.; Gijsen, H. J. M.; Velter, A. I.; Pieters, S. M. A.; Berthelot, D. J-C. Preparation of Substituted Indole Derivatives as Gamma Secretase Modulators. PCT Patent Application WO 2013010904, Published January 24, 2013.
93. Rombouts, F. J. R.; Trabanco, A. A.; Gijsen, H. J. M.; Macdonald, G. J.; Bischoff, F. P.; Alonso de Diego, S.; A.; Velter, A. I.; Van Roosbroeck, Y. E. M. Substituted 3,4-Dihydro-2*H*-pyrido[1,2-A]pyrazine-1,6-dione Derivatives Useful for the Treatment of (Inter Alia) Alzheimer's Disease. PCT Patent Application WO 2013171712A1, Published November 21, 2013.
94. Bischoff, F. P.; Velter, A. I.; Rombouts, F. J. R.; De Cleyn, M.; Van Brandt, S.; Gijsen, H. J. M.; Zavattaro, C.; Van Den Keybus, F. A. M. Novel Substituted Pyrido-Piperazinone Derivatives as Gamma Secretase Modulators. PCT Patent Application WO 2014111457, Published July 24, 2014.
95. Am Ende, C. W.; Fish, B. A.; Green, M. E.; Johnson, D. S.; Mullins, P. B.; O'Donnell, C. J.; Pettersson, M. Y.; Stiff, C. M.; Subramanyam, Ch.; Tran, T. P.; Navaratnam, T. Preparation of Pyrido[1,2-a]pyrazine-1,6-dione Derivatives as γ-Secretase Modulators. PCT Patent Application WO 2012131539, Published October 4, 2012.
96. Bischoff, F. P.; Gijsen, H. J. M.; Van Den Keybus, F. A. M.; Rombouts, F. J. R. Novel Tricyclic 3,4-dihydro-2*H*-pyrido[1,2-a]pyrazine-1,6-dione Derivatives as Gamma Secretase Modulators PCT Patent Application WO 2014096212, Published June 26, 2014.
97. Beher, D.; Bettati, M.; Checksfield, G. D.; Churcher, I.; Doughty, V. A.; Oakley, P. J.; Quddus, A.; Teall, M. R.; Wrigley, J. D. Treatment for Alzheimer's Disease and Related Conditions. PCT Patent Application WO 2005013985, Published February 17, 2005.
98. Blurton, P.; Burkamp, F.; Churcher, I.; Harrison, T.; Neduvelil, J. Arylacetic Acids and Related Compounds and Their Preparation, Pharmaceutical Composition and Their Use for the Treatment of Diseases Associated With Depositions of β-Amyloid Peptides in the Brain Such as Alzheimer's Disease. PCT Patent Application WO 2006008558, Published January 26, 2006.
99. Hannam, J. C.; Kulagowski, J. J.; Madin, A.; Ridgill, M. P.; Seward, E. M. Preparation of Piperidines and Related Compounds for Treatment of Alzheimer's Disease. PCT Patent Application WO 2006043064, Published April 27, 2006.
100. Bulic, B.; Ness, J.; Hahn, S.; Rennhack, A.; Jumpertz, T.; Weggen, S. *Curr. Neuropharmacol.* **2011,** *9,* 598–622.
101. Page, R. M.; Baumann, K.; Tomioka, M.; Perez-Revuelta, B. I.; Fukumori, A.; Jacobsen, H.; Flohr, A.; Luebbers, T.; Ozmen, L.; Steiner, H.; Haas, C. J. *Biol. Chem.* **2008,** *283,* 677–683.
102. Stanton, M. G.; Hubbs, J.; Sloman, D.; Hamblett, C.; Andrade, P.; Angagaw, M.; et al. *Bioorg. Med. Chem. Lett.* **2010,** *20,* 755–758.
103. Rivkin, A.; Ahearn, S. P.; Chichetti, S. M.; Kim, Y. R.; Li, C.; Rosneau, A.; Kattar, S. D.; Jung, J.; Shah, S.; Hughes, B. *Bioorg. Med. Chem. Lett.* **2010,** *20,* 1269–1271.
104. Fischer, C.; Shah, S.; Hughes, B. L.; Nikov, G. N.; Crispino, J. L.; Middleton, R. E.; et al. *Bioorg. Med. Chem. Lett.* **2011,** *21,* 773–776.
105. Fischer, C.; Zultanski, S. L.; Zhou, H.; Methot, J. L.; Brown, W. C.; Mampreian, D. M.; et al. *Bioorg. Med. Chem. Lett.* **2011,** *21,* 4083–4087.
106. Fischer, C.; Zultanski, S. L.; Zhou, H.; Methot, J. L.; Shah, S.; Nuthall, H.; et al. *Bioorg. Med. Chem. Lett.* **2012,** *22,* 3140–3146.
107. Fischer, C.; Zultanski, S. L.; Zhou, H.; Methot, J. L.; Shah, S.; Hayashi, I. *Bioorg. Med. Chem. Lett.* **2015,** *25,* 3488–3494.
108. Methot, J. L.; Fischer, C.; Li, C.; Rivkin, A.; Ahearn, S. P.; Brown, W. C.; et al. *Bioorg. Med. Chem. Lett.* **2015,** *25,* 3495–3500.
109. Am Ende, C. W.; Fish, B.A.; Johnson, D. S.; Lira, R.; O'Donnell, C. J.; Pettersson, M. Y.; Stiff, C. M. Aminocyclohexanes and Aminotetrahydropyrans and Related Compounds as γ-Secretase Modulators. WO 2011092611A1, August 4, 2011.

110. Petterson, M.; Johnson, D. S.; Subramanyam, C.; Bales, K. R.; Am Ende, C. W.; Fish, B. A.; Green, M. A.; Kaufmann, G. W.; Lira, R.; Mullins, P. B.; et al. *Bioorg. Med. Chem. Lett.* **2012,** *22,* 2906–2911.
111. Petterson, M.; Johnson, D. S.; Subramanyam, C.; Bales, K. R.; Am Ende, C. W.; Fish, B. A.; Green, M. A.; Kaufmann, G. W.; Mullins, P.; Navaratnam, T.; et al. *J. Med. Chem.* **2014,** *57,* 1046–1062.
112. Petterson, M.; Johnson, D. S.; Humphrey, J. M.; Butler, T. W.; Am Ende, C.; Fish, B. A.; Green, M. E.; Kaufmann, G. W.; Mullins, P. B.; O'Donnel, C. J.; et al. *ACS Med. Chem. Lett.* **2015,** *6,* 596–601.
113. Petterson, M.; Johnson, D. S.; Humphrey, J. M.; am Ende, C.; Evrard, E.; Efremov, I.; Kaufmann, G. W.; Stepan, A. F.; Stiff, C. M.; Xie, L.; et al. *Bioorg. Med. Chem. Lett.* **2015,** *25,* 908–913.
114. The Pfizer patent application describing indole-substituted piperazino pyridones was published in 2015: Pettersson, M. Y.; Johnson, D. S.; Subramanyam, C.; O'Donnell, C. J.; Am Ende, C. W.; Green, M. E.; Patel, N. C.; Stiff, C. M.; Tran, T. P.; Kauffman, G. W.; Stepan, A. F.; Verhoest, P. R. Preparation of Novel Bicyclic Pyridinones as Gamma-Secretase Modulators. PCT Patent Application WO 2015049616, Published April 9, 2015.
115. Lübbers, T.; Flohr, A.; Jolidon, S.; David-Pierson, P.; Jacobsen, H.; Ozmen, L.; Baumann, K. *Bioorg. Med. Chem. Lett.* **2011,** *21,* 6554–6558.

7.08.1 Introduction

7.08.1.1 Alzheimer's Disease and the Amyloid Hypothesis

Alzheimer's disease (AD) continues to represent a huge unmet, global need. According to the Alzheimer's Association, more than 5 million Americans are currently living with AD, who require support from 15 million caregivers. The net estimate is that AD and other dementias will cost $236 million in the United States alone in 2016.[1] Worldwide, in 2015, it was estimated that 46.8 million people were suffering from Alzheimer's and related dementia, with an associated cost of $818 billion.[2] AD was first described in 1906 in a lecture by Alois Alzheimer.[3] In this seminal report, the key pathological hallmarks were characterized as amyloid plaques and neurofibrillary tangles, consisting of aggregated tau protein.[4] Despite this, it took considerable time before our understanding of the disease pathology progressed to a level to enable informed drug discovery. Key events were the genetic associations found between amyloid precursor protein (APP) and the disease via the amyloid cascade,[5–8] which uncovered links to the disease at multiple points.[9] APP exists in three different isoforms, which vary in length, having either 695, 751, or 770 amino acids, with the 695 variant being predominantly expressed in the CNS.[10] APP is processed sequentially by β-secretase (BACE1) and γ-secretase, to generate amyloid proteins of varying length, most commonly $A\beta_{1-40}$ and $A\beta_{1-42}$, the latter of which is considered the main pathogen (Fig. 1A). Several mutations in APP have been uncovered and linked to the progression of AD. Of particular note are the Swedish mutations (K670N and M671L) which are proximal to the BACE cleavage site—which cleaves between M671 and D672, and render the protein more susceptible to cleavage by BACE (Fig. 1B). Further mutations in APP, proximal to the BACE cleavage site, namely A673T and A673V, have been found to be protective (causing approximately 50% reduction in BACE cleavage) and pathogenic, respectively.[11] Although these mutations confer strong support, recent literature suggests that the neuropathology associated with the recessive A673V mutation may be somewhat distinct from other forms of AD (sporadic AD or familial AD (FAD) linked with a dominant trait),[12] thus highlighting the potential need for careful patient selection in clinical studies.

Further support of the amyloid cascade hypothesis comes from individuals with Down's syndrome. APP is expressed on chromosome 21, thus individuals with Down's syndrome, who have a triplication of chromosome 21, express higher levels of APP. As a result, these individuals produce higher levels of Aβ and suffer from cognitive impairment, although the correlation is the subject of debate.[13] Furthermore, there is a report of a 78-year-old female with Down's syndrome that did not suffer from dementia. Autopsy revealed incomplete triplication of chromosome 21, with no triplication of the APP gene, thus conferring additional support to the link between APP/Aβ and dementia.[14]

However, the amyloid cascade hypothesis has received scrutiny as some posit that amyloid deposit accumulation may be a consequence of the disease, rather than the cause.[15]

Taken together, the pathology and the genetic evidence make a strong case for the involvement of the amyloid cascade in disease pathology, thus highlighting β- and γ-secretase as attractive points of intervention. Both targets have received intensive effort in terms of drug discovery, while some companies have worked on both simultaneously. At times progress has been made on one more than the other, only for the pendulum to swing back to the other. Neither target has been without challenge; however, currently BACE seems to be the more tractable of the two and inhibitors continue to progress clinically. This article will deal exclusively with BACE inhibitors, while a companion chapter will deal with γ-secretase.

7.08.1.2 Challenges With Early BACE Inhibitor Discovery

Since its discovery in 1999,[16–19] BACE has proven an appealing target to the scientific community. Chemists flocked to start drug discovery projects to identify BACE inhibitors as it was assumed to be a druggable target, based on previous experience in the protease inhibitor field, for example, HIV protease and related targets. However, High Throughput Screening (HTS) campaigns in multiple companies drew blanks, and hence chemists turned to substrate-based drug design. Progress was made quickly with the availability of a crystal structure with a high affinity peptide, transition state inhibitor OM-99-2[20] which aided design and facilitated the identification of potent in vitro inhibitors. The structure, residue labeling, and binding mode to BACE are depicted in Fig. 2, which shows the hydroxyl moiety acting as the transition state mimic for the cleaved amide bond, and interacts with the catalytic aspartic acid diad (Asp32 and Asp228), while the inhibitor makes a further 10 hydrogen bonds with BACE. The availability of BACE crystal structures has provided another advantage over γ-secretase, which is a complex of several proteins and lacks structural information. However, this has not been the deciding factor in the success of BACE inhibition.

Unfortunately, the rapid progress was soon hampered by a series of problems, which ultimately proved insurmountable. Firstly, it was found that CNS penetration was extremely limited, predominantly due to P-gp mediated efflux. Further problems were to come when chemists discovered that many inhibitors had very poor exposure after oral dosing, found to be mainly due to extremely rapid metabolism by CYP3A. Peptidomimetic derivatives have been reviewed extensively and there are many excellent reviews on this subject.[21–25] Some groups tried to pursue the peptidomimetic derivatives and increase potency to subnanomolar levels in order to try to compensate for the extremely low CNS penetration, however to no avail. The challenges outlaid earlier are exemplified by seminal work from GSK, Bristol Myers Squibb (BMS), and Merck. Researchers at GSK devoted significant effort to the discovery of peptidomimetic BACE inhibitors, from which GSK188909 (**2**) (Fig. 3) was identified as an advanced lead. However, administration of this compound at a dose of 250 mg/kg i.p. to TASTPM mice[26] resulted in a brain concentration of only 0.62 μM and no significant effect of brain $A\beta_{40}$ levels. When the P-gp inhibitor GF120918 was administered 5 h prior to GSK188909 (**2**), the brain concentration of GSK188909 (**2**) was measured at 5.43 μM, that is, approximately ninefold higher. The increased brain concentrations resulted in a 68% reduction in brain $A\beta_{40}$ levels compared to vehicle controls.[27] One further complicating factor of this work is

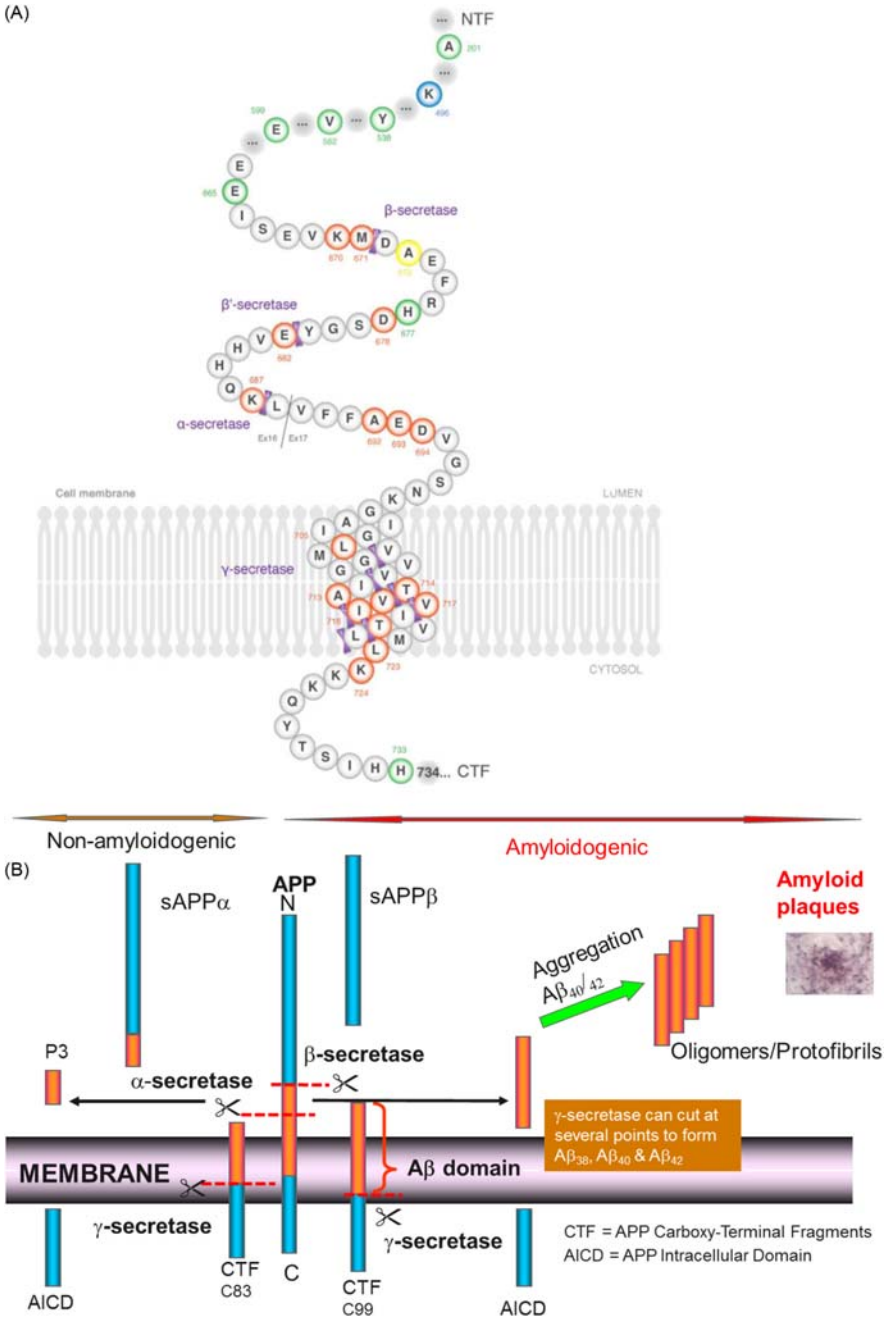

Fig. 1 (A) Sequence of APP with known mutations highlighted, Courtesy of Alzforum. *Red*=pathogenic mutation, *green*=nonpathogenic mutation, *yellow*=protective mutation, *blue*=unclear. (B) Depiction of sequential cleavage of APP by β- and γ-secretase to yield $A\beta_{40}$ and $A\beta_{42}$, and subsequent oligomerization.

that TASTPM mice express APP with the Swedish double mutation, K595N/M596L (in addition to a PS-1 mutation, M146V). This makes APP a better substrate for BACE cleavage, thus resulting in higher IC_{50} values, exemplified by GSK188909 (**1**), which shows sixfold lower activity in APP_{Swe} expressing cells than in cells expressing APP_{wt}. Similarly, BMS found that it was possible to reduce plasma $A\beta_{40}$ levels, but not brain $A\beta_{40}$ levels in the mouse with BACE peptidomimetic derivatives, such as compound **3** (Fig. 3).[28] This compound showed potent activity in biochemical and cellular assays. Subcutaneous dosing resulted in effective reductions in plasma $A\beta_{1-40}$ levels in the wild-type mouse, ED_{50} 0.6 mg/kg s.c., with an identical ED_{50} in P-gp KO mice. However, compound **3** had no effect on brain $A\beta_{1-40}$ levels in the wild-type mouse up to the highest dose of 100 mg/kg, whereas in P-gp KO mice the ED_{50} was estimated at 30 mg/kg s.c. for an effect on brain $A\beta_{1-40}$. This again highlights the challenge of overcoming P-gp mediated efflux with peptidomimetic BACE inhibitors. Researchers from Merck succeeded in overcoming the challenge of identifying peptidomimetic BACE inhibitors which were not P-gp substrates, for example, TC-1 (**4**) (Fig. 3), P-gp ER 2.3 (mouse), 2.5 (monkey), and

human (1.9). Despite this, TC-1 (4) was still found to be heavily metabolized by CYP3A4 and required coadministration with a CYP3A4 inhibitor, ritonavir, in order to demonstrate efficacy.[29] When TC-1 (4) was administered to rhesus monkeys, in the presence of ritonavir, the plasma clearance decreased from 24 to 7 mL/min/kg, while the $t½$ increased from 1 to 3 h and the oral bioavailability increased dramatically from $<1\%$ to 83%. In the rhesus monkey, ritonavir administration 2 h before an oral dose of TC-1 (4) at 15 mg/kg twice daily for 3.5 days resulted in average free plasma and CSF concentrations of 13.5 and 25 nM, respectively, thus showing free permeation of the compound into the CNS. Furthermore, this resulted in an average reduction of $A\beta_{40}$ by 61% in plasma and 42% in CSF, respectively.

Thus, these publications exemplify the challenges to identify peptidomimetic BACE inhibitors devoid of P-gp efflux with low metabolic clearance suitable for clinical progression. Only one peptidomimetic BACE inhibitor appears to have progressed to the clinic, CTS-21166/ASP1702 (structure not disclosed), which entered PhI studies in Jun. 2007.[30] Intravenous (iv) administration at doses from 7.5 to 225 mg led to reductions of up to 60% in plasma amyloid, however no effect was reported on CSF amyloid

levels.[31] Thus, the clinical data appear to recapitulate the challenges observed preclinically. While the initial results offered a breakthrough and resulted in a partnership with Astellas, the development of CTS-21166/ASP1702 was ultimately terminated, presumably due to the issues discussed earlier, and Astellas and CoMentis officially ended their agreement in Oct. 2014.[32] Ultimately these challenges appear to have been insurmountable and all research groups eventually switched to focus their research efforts on guanidine-derived BACE inhibitors, which proved extremely fruitful, despite significant challenges.

The breakthrough came when research groups utilized fragment or high concentration screening. Multiple groups identified compounds containing a guanidine derivative that bound to the active site and made highly complementary interactions with the catalytic aspartic acid diad. Although initial inhibitors were weak in terms of potency, the use of SBDD enabled rapid gains in potency. Despite this, several challenges still existed, namely CYP2D6 metabolism/inhibition, hERG inhibition (both mainly due to the basic center), and CNS penetration.

This article illustrates how multiple research groups have addressed these issues and, that the result of long-term commitment to the field has resulted in a fruitful return, with a range of inhibitors from multiple groups now in late-stage clinical trials. It thus seems that after nearly 17 years of research, the dedication will pay off, and the field is now poised at a stage which could provide the biggest breakthrough in neuroscience, with compounds having the potential to slow or even halt the progression of AD. Research from each group is reviewed in turn, based on the alphabetical order of lead company or research group.

7.08.2 Inhibitors Reported by Amgen

Amgen's interest in BACE dates back to the early 2000s with considerable activity in optimizing hydroxethylamine (HEA) type inhibitors. A focus on reduction of molecular weight, hydrogen bond donors (HBDs) and acceptors, and TPSA resulted in a potent and orally efficacious compound **5** (Fig. 4).[33] However, lowering of brain amyloid levels remained suboptimal, with a 100 mg/kg

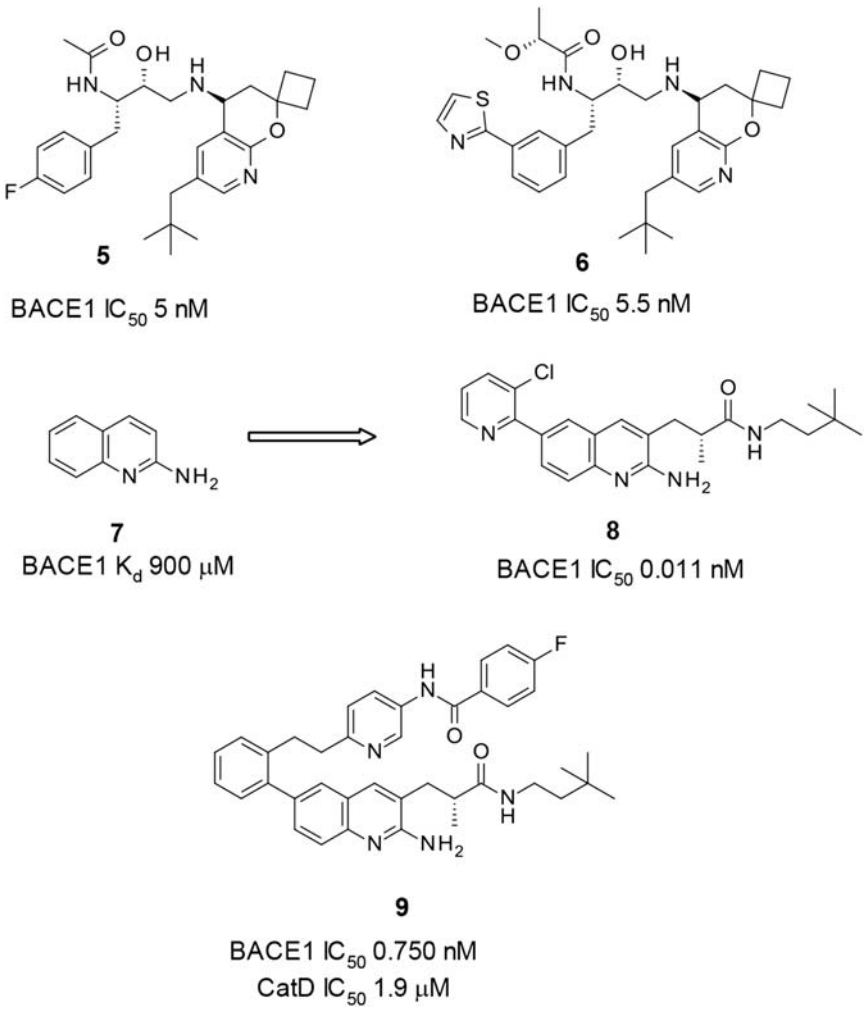

Fig. 4 Structures of peptidomimetic derivatives **5** and **6**, and FBDD ligands **7–9** from Amgen.

p.o. dose only achieving 35% $A\beta_{40}$ reduction in rat brain after 4 h. Analogous compounds with a strongly reduced P-gp efflux, such as **6** (Fig. 4), did demonstrate more robust Aβ lowering in brain and CSF after a PO dose of 30 mg/kg, but their increased size may have attributed to a suboptimal pharmacokinetic (PK) profile.[34]

Amgen has also described a series of 2-aminoquinolones originating from a fragment-based Surface Plasmon Resonance (SPR). Optimization of the initial 2-aminoquinolone hit **7** was guided by ligand efficiency (LE) and SBDD and led to compounds with subnanomolar potency. Physical property optimization led to compound **8** (Fig. 4). When tested in rats, a 60 mg/kg oral dose showed 42% reduction in CSF after 2 h. Lipophilicity of **8** remains high with a clogP of 4.4, and metabolic stability was again suboptimal. In a recent addition to this work, a second-site fragment screen using ^{19}F NMR spectroscopy delivered a fragment targeting the S3 binding site of BACE1.[35] Linking this fragment to a suitable analog of **8** delivered highly potent inhibitors as demonstrated by **9** (Fig. 4). The crystal structure of **9** bound to BACE is depicted in Fig. 5 and shows the multiple pockets being filled by this type of inhibitor. The fluorophenyl group of **9** extends deep into the S3 pocket providing potency. In addition, a significantly enhanced selectivity over Cathepsin D (>2000-fold) is achieved due to the structural differences in the S3 pocket between BACE1 and Cathepsin D. With a molecular weight over 600 and a cLogP above 7, the physicochemical properties remain far from optimal for a CNS drug.

Most of the Amgen efforts focused on the reported 5,5-diaryl substituted aminohydantoin inhibitors, which display an optimal hydrogen-bonding interaction with the catalytic aspartyl diad in the BACE enzyme. Replacement of the hydantoin core in **10** by an oxazoline heterocycle and linking of the two aryl substituent to form a tricyclic xanthane system led to **11** (Fig. 6).[36,37] These compounds suffered from hERG[36] inhibition, which could be mitigated by the introduction of a nitrogen atom in the 3- or 4-position.[36,38] Additionally, the nitrogen at these positions resulted in the formation of direct or water-bridged hydrogen bond with Trp76 near the flap of the enzyme, resulting in an increase in BACE1 potency. Optimization of the P3 and P2′ side chains for both aza-analog series led to **12** and **13**, respectively, which showed robust and sustained Aβ lowering in vivo. Both compounds have been progressed into toxicological studies. **12** displayed numerous toxicities, including retinal toxicity. Although no direct link to Cathepsin D inhibition could be made, **12** did show submicromolar inhibition of this enzyme in vitro ($IC_{50}=0.66$ μM).[36] In a 1-month rat toxicity study, also **13** (AMG-8718) displayed retinal thinning.[39]

The investigations of Amgen have since then focused on 6-ring warheads with vectors allowing deeper interaction into the S3 pocket. The data indicate they are significantly more selective over Cathepsin D, as shown by earlier, similar competitor series. Fig. 7 shows six examples of six patent applications in chronological order. The first application still exemplifies compounds containing the typical tricyclic core explored previously, but with an amide-linked P3 substituent, exemplified by **14**.[40] While highly potent, the molecular weight of these compounds greatly exceeds 400, making them unlikely candidates for a CNS drug. A number of patent applications describe compounds containing monocyclic, spirocyclic, tricyclic, and bridged 5-amino-1,4-thiazine 1, 1-dioxide warheads. These have similarity to earlier compounds from Schering/Merck, and several observations can be derived from them. A typical exemplification in the first patent in this series is **15**[41] which bears some resemblance to compounds from Roche, for example, **167** (Fig. 48), and Schering-Plough/Merck, for example, **189** (Fig. 52). The fluoromethyl substituent will lower the pK_a of the amidine group, and in **15** this may contribute to the loss of cellular potency versus enzymatic inhibition. The replacement of the often used heretoacryl amide P3 substituent with a bioisosteric 2-aminonaphthtyridine system still results in potent molecules. Cyclization between the 1,4-thiazine 1,1-dioxide warhead and the P1-phenyl core led to tricyclic structures as in **16**.[42] Interestingly, both 4aR and 4aS diastereomers are reported to have almost equal potency for BACE1 inhibition. In rat, an

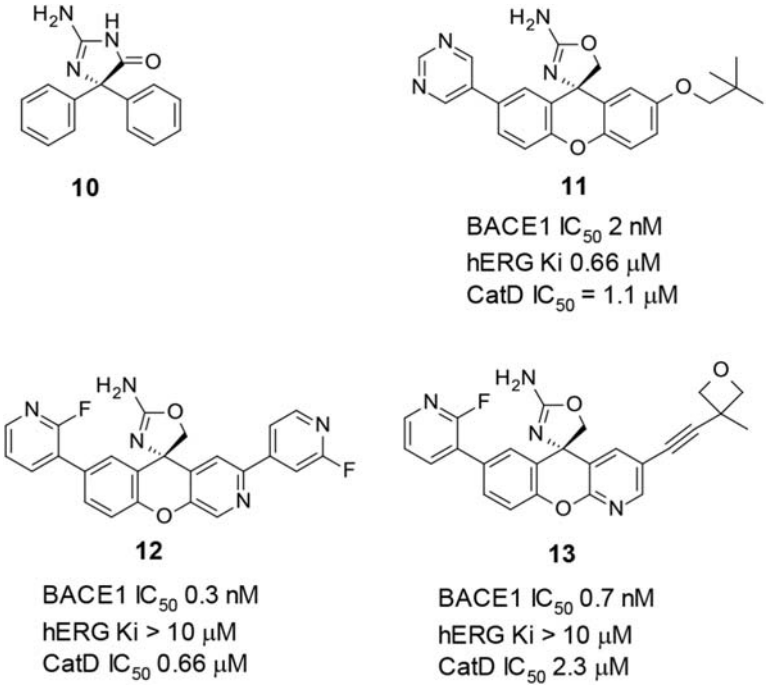

Fig. 6 Acylguanidine **10** and isourea derivatives **11**–**13** from Amgen.

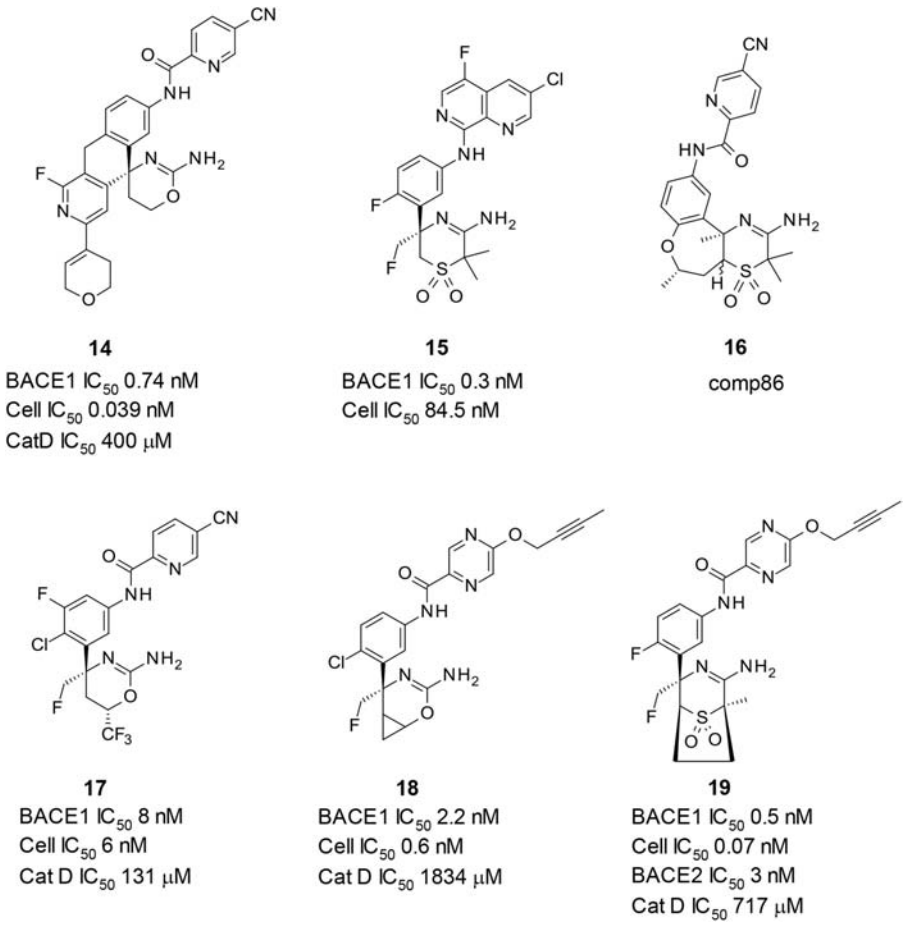

Fig. 7 Isourea and sulfonyl amidine derivatives from Amgen.

oral dose of 10 mg/kg resulted in a 79% Aβ reduction in CSF and brain, 4 h after dosing. Utilizing the isourea/1,3-dihydro-oxazine warhead, researchers from Amgen have described compounds such as 17,[43] which bears similarity to compounds from Roche, for example, **155** (Fig. 43), and **18**,[44] with a cyclopropyl ring fused to the 1,3-dihydro-oxazine ring. The last application around this series describes bridged amino thiazine dioxide compounds as exemplified by **19**.[45] These examples highlight the significantly improved selectivity over Cathepsin D inhibition compared to the earlier tricyclic compounds in Fig. 6. Exemplified compounds in the later patent applications replacing the amide P3 linker with fused and monocyclic heterocycles generally resulted in poorly active compounds.[43–45] Most compounds bear fluoro-containing electron-withdrawing groups on the warhead, expected to modulate the pK_a of the amidine. The most potent compounds have additional acetylene substituents as in **18**, penetrating deep into the S3 pocket, as demonstrated before by other companies (e.g., **162**, Fig. 47 from Roche and **215**, Fig. 54 from Shionogi).

Thus, after sustained commitment to the field from the outset, despite significant effort expended on a range of chemotypes, ultimately ending up with amidine and isourea derivatives with S3 pocket targeting anilides, it appears that Amgen were not successful in achieving the balance of properties required in a single molecule for progression to the clinic. However, they have since entered into a collaboration with Novartis to codevelop and cocommercialize the Novartis BACE inhibitor CNP520 (see what follows), which is currently progressing this compound through clinical trials.

7.08.3 Inhibitors Reported by Astellas

Astellas entered the BACE inhibitor field through a collaboration with Comentis on their peptidomimetic series. Although the lead compound from Comentis, CTS-21166, was one of the first compounds to progress to the clinic it was rapidly terminated, presumably due to low oral exposure and low levels of CNS penetration and efficacy.[32] Data reported at a conference demonstrated that CTS-21166/ASP1702 was a potent BACE inhibitor, enzyme IC_{50} 2.5 nM, cell IC_{50} 3.9 nM. Single or multiple doses of 100 mg/kg p.o. to the rat resulted in modest reductions of soluble $A\beta_{40}$, c. 23% or 30% versus vehicle. In a rat microdialysis time course study, a single iv dose of 15 mg/kg resulted in ~50% reduction of CSF $A\beta_{40}$ levels. In a baboon microdialysis study, an iv dose of 1 mg/kg resulted in a 28% reduction of brain $A\beta_{40}$ levels. Brain penetration (Br:Pl) was assessed in the mouse (0.5), rat (0.18–0.39), dog (1.3), and baboon (0.37), which implied some degree of CNS penetration; however, CSF:Pl levels were much lower in rat (0.02–0.09) and baboon (0.02).[46] Since this early entry, Astellas and Comentis have shifted their focus to spirocyclic isoureas. This series has been disclosed in a relatively large patent application, which highlights three key compounds, including their hERG data and in vivo efficacy. Thus, **20**, **21**, and **22** (Table 1) all show potent cellular activity and weak hERG activity[47]. All three compounds reduced brain amyloid levels in the rat at reasonable doses, even though they are not single enantiomers.

7.08.4 Inhibitors Reported by AstraZeneca

AstraZeneca obtained their initial amidine-type hit **23** from a fragment-based approach using Nuclear Magnetic Resonance (NMR) screening. In collaboration with Astex, structure-based drug design led to **24** with the ethyl linker required for optimal filling of the P1/P3 pocket (Fig. 8).[48] The relatively modest potency of this compound may be related to the flexibility of the ethyl linker, and subsequent efforts by AZ show a focus on series with high conformational constraint, often resulting in more potent BACE inhibition.

Starting from the dihydroisocytosine warhead present in **24** and **25**, scaffold hopping via the ring contracted aminohydantoin **26** led to bicyclic aminoimidazole **27**.[48] Interestingly, the evolution from 6-ring warheads to 5-ring warheads is the opposite from the

Table 1 Summary of data for three key isourea derivatives from Astellas

Compound	**20**	**21**	**22**
Structure			BACE FRET IC_{50} (nM)	44.7	99.1	91.4
BACE FRET Ki (nM)	10.3	61.2	52.7
Cell IC_{50} (nM)	0.78	3.1	0.63

Rat brain ↓$A\beta_{40}$ @ 1 mg/kg (time)	Not tested	19% (3 h)	21% (3 h)
Rat brain ↓$A\beta_{40}$ @ 3 mg/kg (time)	24% (2.5 h)	34% (3 h)	35% (3 h)
Rat brain ↓$A\beta_{40}$ @ 10 mg/kg (time)	31% (2.5 h)	Not tested	Not tested

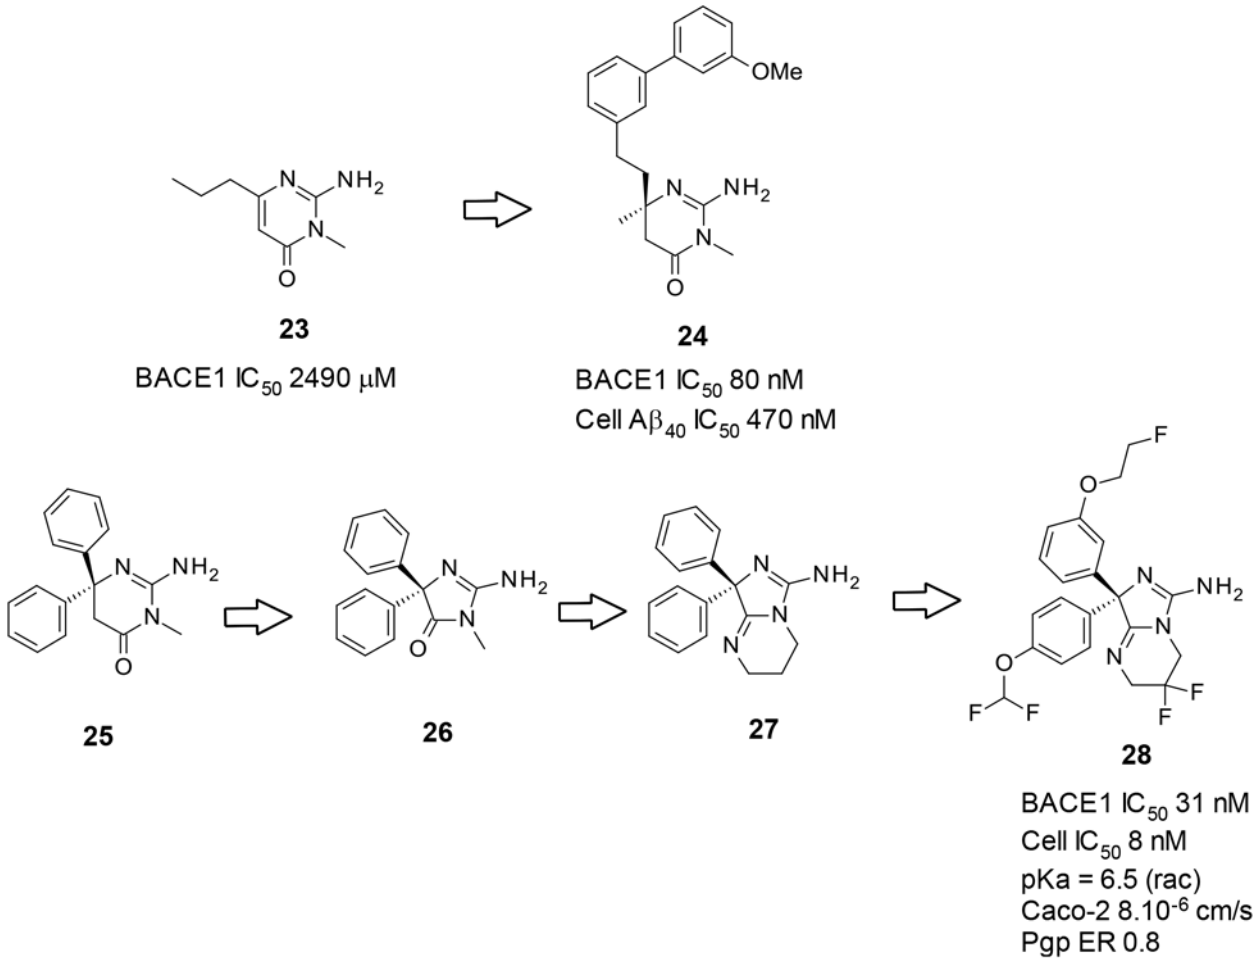

Fig. 8 Early compounds and lead generation summary of work from AstraZeneca.

evolution in the Schering–Merck BACE program (see later). Optimization of the aminoimidazole **27** led to **28** (Fig. 8) with the difluoro substitution lowering the pK_a of by about 1 log unit, leading to improved permeability. The alkoxy substituents in **28** resulted in a further improved permeability and efflux profile compared to the more often used biaryl substitution pattern. Nevertheless, **28** still suffered from significant efflux in vivo, only resulting in significant lowering of amyloid in mouse brain when coadministered with the pan-efflux inhibitor GF120918.[48]

In a further elaboration of the fused 5-ring warheads, a series of amino-isoindoles was optimized.[50] The introduction of a fluorine atom adjacent to the amidine reduced the pK_a, presumably by forming a weak internal hydrogen bond with the exocyclic amidine nitrogen, and was key in achieving central amyloid lowering activity. The series displayed significant affinity for the hERG channel, attributed to the combination of relatively high basicity and lipophilicity. However, reduced lipophilicity was linked to increased efflux. Optimization and balancing of lipophilicity led to compounds **29** and **30** (Fig. 9). The 5-propynyl-3-pyridinyl group in **30** has a deep interaction within the S3 subpocket which leads to subnanomolar cellular potency, translating into a larger in vitro margin to hERG inhibition of **30** versus **29**. However, in vivo, **29** had a superior profile to **30**, attributed to the high unbound brain/plasma ratio for **29**, which could be explained by the reduced lipophilicity of **29** versus **30** and other analogs. Based on the overall best properties, **29** was selected for clinical evaluation (AZD3839).[51] In a Phase 1 clinical study, AZD3839 reduced plasma $A\beta_{40}$ and $A\beta_{42}$ in healthy volunteers, with estimated potencies (EC_{50}) of 46 and 59 nM, respectively.[52] The maximum effect obtained after a dose of 300 mg was ~55%, which is rather moderate considering the high dose. In addition, the compound also caused a dose-dependent prolongation in QTc, which can be linked to hERG inhibition. The combination of moderate efficacy and QTc prolongation has likely contributed to the termination of further development of AZD3839.

Recognizing that the core, amidine containing structures play a crucial role in the druglike profile of the final compounds, AstraZeneca has published on their workflow to identify novel promising amidine containing cores.[53] Profiling of de novo designed ideas was carried out as an iterative creation and prioritization process of core structures using in silico models for permeability, hERG activity, and BACE1 inhibition, followed by a manual evaluation of metabolic liabilities and synthetic feasibility. A number of new cores with promising activity and reduced hERG activity have been identified using this approach.[54] The fact that several of

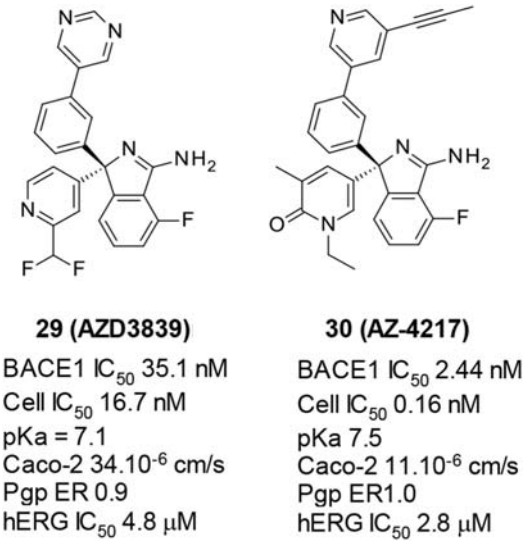

Fig. 9 Structures of AZD3839 (**29**) and AZ-4217 (**30**) from AstraZeneca.

these cores were subsequently and independently reported by other companies illustrates the success of this approach. While not necessarily originating from this work, a monocyclic series of aminoimidazoles were also reported as a promising series of BACE inhibitors and exemplified by **31**, showing good target potency, low hERG inhibition, and decent CNS exposure in vivo (Fig. 10). This particular core has since appeared in multiple AstraZeneca patent applications describing double spiro aminoimidazoles. The replacement of one of the aryl substituents in **31** by a cyclohexyl ring, spiro-cyclized to the warhead and aryl substituent resulted in series of compounds exemplified in Fig. 10. In the first patent in this series, **32** was one of the exemplified compounds, for which a subsequent process patent was published describing the large-scale synthesis of a camsylate salt.[55,56] This compound is also known as AZD3293 or LY3314814, and is currently in Phase2/3 clinical trials in collaboration with Eli Lilly.[57] The in vitro and in vivo pharmacological profile has been reported, indicating subnanomolar enzymatic and cellular potency with a markedly slow target off-rate ($t½ \sim 9$ h).[58] AZD3293 shows high potency in vitro in a range of assays, but is approximately 100-fold less potent in Tg2576 mouse neurons. Despite showing low efflux in a CaCo-2 assay, it appears to be a strong P-gp substrate. It was also found that AZD3293 produces a major active metabolite in vivo which is also a P-gp substrate (ER > 30). Although the structure of the metabolite has not been disclosed, one may hypothesize that it is the O-desmethyl analog, the presence of a hydroxyl group could explain the P-gp efflux and decreased plasma protein binding (ppb). In the mouse and dog, this slow off-rate may have contributed to a prolongation of the amyloid lowering effect beyond its plasma and CSF exposure. Despite the long duration of action, the compound shows a moderate maximal reduction of brain $A\beta_{42}$ in the mouse, ~40%, after a 100 μmol/kg p.o. dose. Maximal reductions in $A\beta_{42}$ were significantly greater in the guinea pig; Ab42 reduced by ~80% (brain after 4 h) and ~90% (CSF after 8 h) following a 30 mmol/kg p.o. dose. While selective for Cathepsin D, the compound did not show selectivity over BACE2.

In a Phase 1 multiple ascending dose (MAD) trial, AZD3293 was dosed for 14 days in mild to moderate AD patients at 15, 50, or 150 mg.[59] At steady state, the mean effective half-life was 16–21 h. Significant amyloid reduction was seen in plasma and CSF at all doses tested. At day 14, $A\beta_{42}$ levels in CSF were reduced by 52%, 76%, and 90% for the 15, 50, and 150 mg doses, respectively. Additional patent applications describe further variations on this class of double spiro BACE inhibitors, exemplified by the most potent analogs in Fig. 10: **33**,[60] **34**,[61] **35**,[62] **36**,[63] and **37**.[64] In **37**, the aminoimidazole is replaced with an aminopyrrole with the additional fluoro-substituent likely having a similar effect on basicity as described for **29** and **30** (Fig. 9).

In conclusion, sustained commitment from the AZ group has resulted in the identification of at least two development compounds which have progressed to clinical studies. Furthermore, both AZD3839 and AZD3293 represent a different structural class from most of the compounds in clinical development. Whether this will offer any benefit remains to be seen, but they do avoid the presence of an aniline structural alert present in many of the competitor BACE inhibitors in clinical development. Since announcing their withdrawal from neuroscience, AZD3293 is being advanced under an alliance with Lilly (see later), whereby Lilly lead the clinical development. The compound is currently undergoing PhII/III clinical trials.

7.08.5 Inhibitors Reported by Boehringer Ingelheim/Vitae

After initial efforts on ethylenediamine peptidometic BACE inhibitors, Boehringer Ingelheim started exploring guanidine containing warheads incorporated in 2-aminobenzimidazoles **38**[65] and 2-aminoquinazolones **39** (Fig. 11).[66]

As appreciated by other companies, both types of BACE inhibitor series apparently did not yield the desired combination of in vitro potency and in vivo efficacy, because in 2009 an alliance was established between Boehringer and Vitae Pharmaceuticals

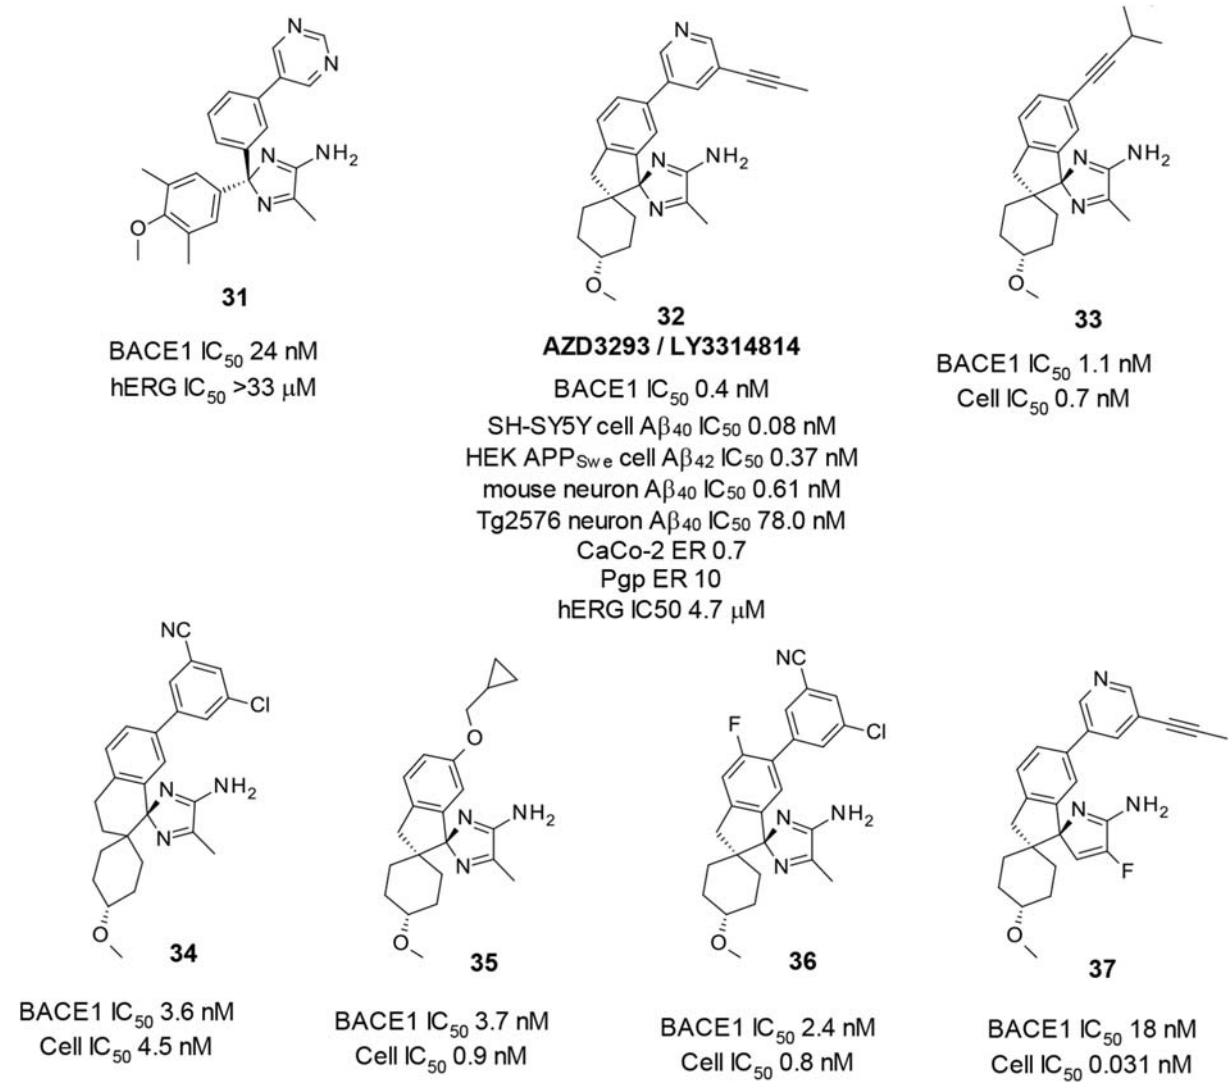

Fig. 10 Spiro-imidazolines from AstraZeneca.

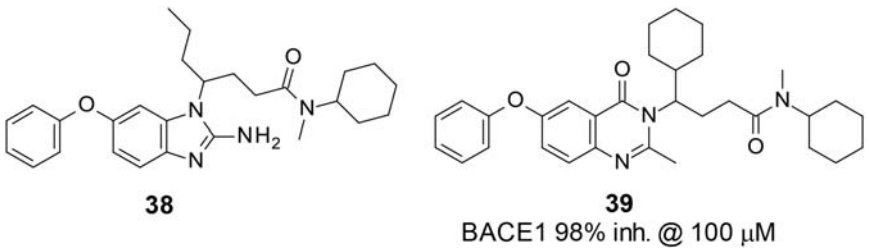

Fig. 11 Early derivatives from Boehringer Ingelheim.

focusing on aminohydantoin inhibitors. The first patent in this series describes conformationally restricted, double spiro aminohydantoins of relatively large molecular weight, for example, **40** (Fig. 12).[67] Another application describes fused bicyclic warhead variations as exemplified by **41** (Fig. 12) having considerable similarity to series described by AstraZeneca.[68] Overlap with AstraZeneca series is also clear for another application, describing variations containing an aminoimidazole warhead, as exemplified by **46**.[69] Additional patent applications claim aminohydantoin subseries with reduced molecular weight and reduced aromatic ring count with variations of hydantoin N-alkyl groups directed toward P1′, and small substituents on both the cyclohexyl moiety directed to P2′ and on the aryl moiety directed into P3, for example, **42** and **43** (Fig. 12).[70] The more recent patent applications

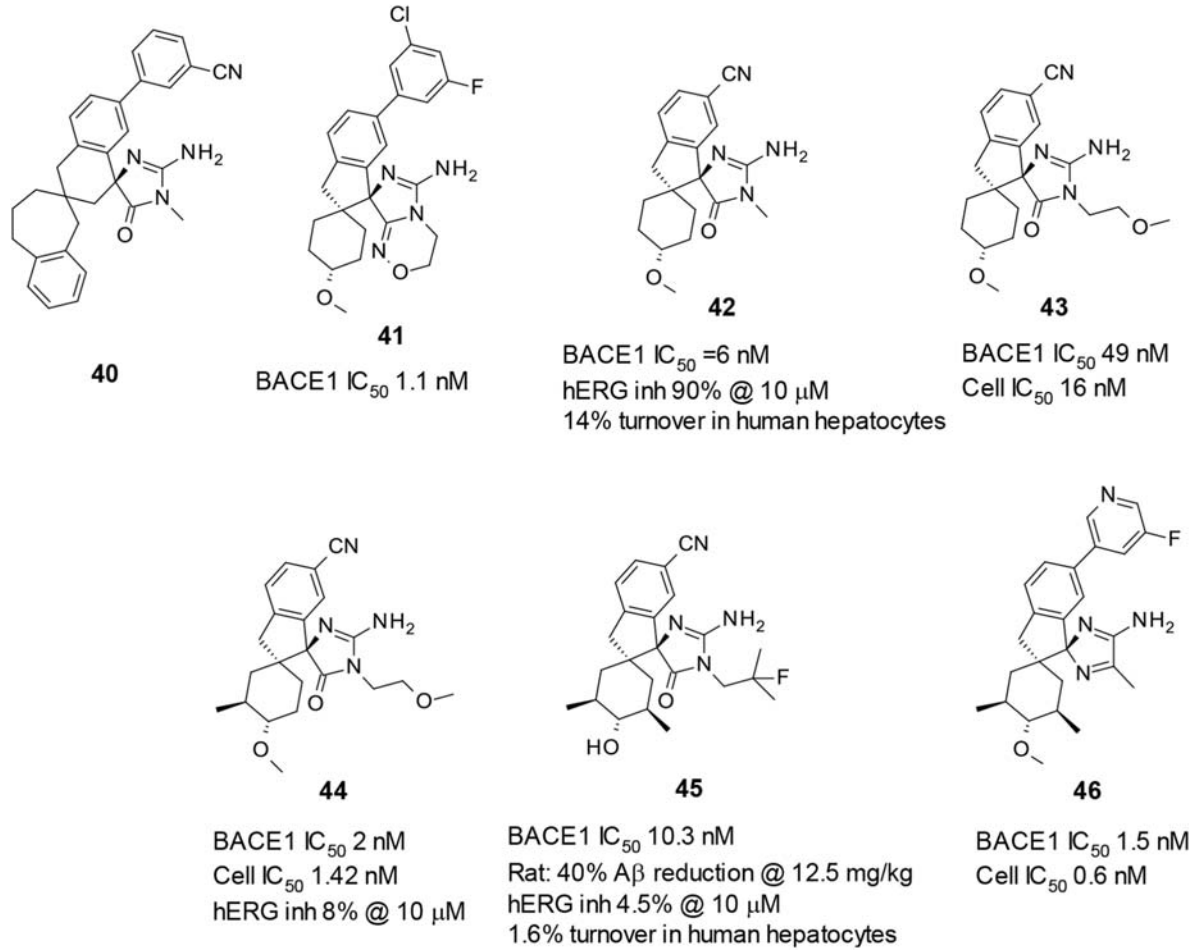

Fig. 12 Recent examples from Boehringer Ingelheim/Vitae.

around this series contain close analogs with additional methyl substituents directed into P2′, for example, **44** and **45** (Fig. 12).[71,72] Comparative data over the earlier applications indicate improvements in potency, reduced hERG inhibition, lower propensity to cause phospholipidosis, and increased metabolic stability in human hepatocytes, as illustrated by the data in Fig. 12.

From this series, BI1181181 has been progressed into Phase I clinical trials, and single doses of this compound induced a sustained reduction in CSF Aβ peptide concentrations in healthy volunteers: a single dose of 50 or 100 mg resulted in a 63.6% or 82.7% reduction 24 h after dosing, respectively.[73] During the MAD trial, skin reactions were observed in some participants. Further progression of BI1181181 has been put on hold, and the alliance between Boehringer and Vitae has been dissolved.[74]

7.08.6 Inhibitors Reported by BMS

Despite being late entrants to the BACE field, BMS have managed to find novel chemical matter. To date, three patent applications have been published, all employing the isothiourea warhead. The first patent application described THF-fused isothioureas, such as **47** (Fig. 13).[75] Compounds from this series are isomeric to the compounds detailed by Eisai who have detailed the other two isomeric series (see later) and would be expected to bind in a similar manner. Compounds such as **47** display moderate cellular activity, IC_{50} 24 nM, however, as they are aminals it is unclear how stable they are to hydrolytic conditions. The second patent application detailed tricylic derivatives such as **48**, cell IC_{50} 8.8 nM (Fig. 13).[76] These derivatives would also be expected to bind in a similar mode, with the amide donating an H-bond to the carbonyl group of Gly 230.

A third patent application detailed compounds which appear to be of more interest, highlighted by **49** and **50** (Fig. 14).[77] Both compounds possess the 2,5-dimethylisoxazol-3yl group. Interestingly, the amide **49**, IC_{50} 5 nM, and biaryl derivative **50**, IC_{50} 8 nM, display similar levels of activity, whereas in other series the amides generally show much higher activity than the corresponding biaryl analogs (Lilly and Eisai, described later). In the biaryl series, the methyl group in the 4-position on the dihydrothiazine ring enhances potency 7.5-fold, as the corresponding desmethyl derivative displays an IC_{50} of 60 nM.

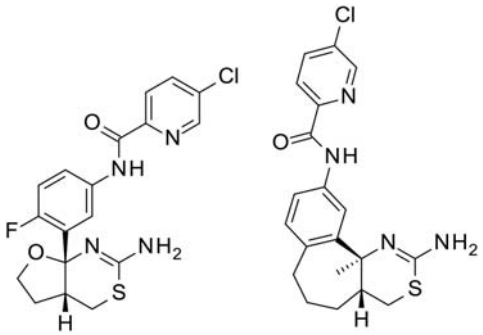

Fig. 13 Initial isothiourea derivatives from BMS.

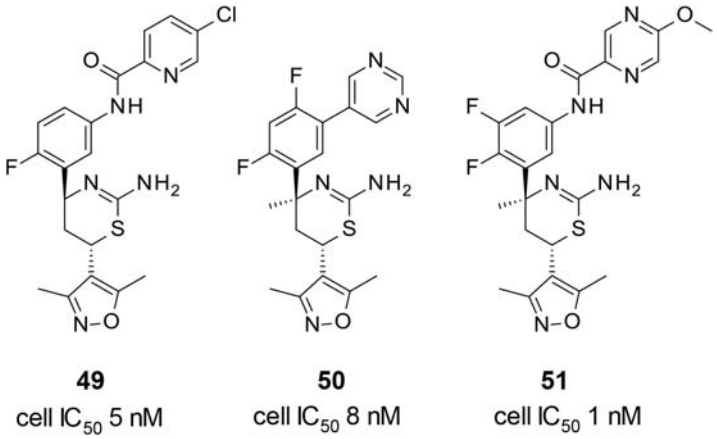

Fig. 14 Later isothiourea derivatives from BMS.

A subsequent publication from BMS has provided further detail in **49** and **50** (Fig. 14)[78] including crystallographic information on the binding modes, as depicted in Fig. 15 for **50**. Whereas in the acylguanidine/dihydroiminopyrimidine series from Merck (see later) the 4-methyl group was essential to place the phenyl ring in a pseudoaxial position, with **50** calculations revealed that the methyl group to have little effect on the orientation of the phenyl ring. Thus, the major role of the 4-methyl group appears to be hydrophobic interaction with isoleucine 118. The pseudoaxial orientation of the phenyl ring may be favored due to the pseudoequitorial orientation of the dimethylisoxazole. Furthermore, the dimethylisoxazole is perpendicular to the dihydroisothiazine and accepts two hydrogen bonds from Gln73 and Thr72. Despite promising in vitro results, **50** displayed weak in vivo activity at 30 mg/kg p.o., due to a combination of poor metabolic stability and low CNS penetration. As the metabolic issues were attributed to oxidation of the pyrimidine, emphasis shifted to the amide series, exemplified by **49**. A crystal structure with **49** revealed similar binding interactions to **50**, with the amide forming the expected H-bond interaction with the C═O of Gly230. Further optimization resulted in the identification of **51** (Fig. 14), which demonstrated potent cellular activity, IC_{50} 1 nM. In vivo efficacy was demonstrated in the mouse where a 10 mg/kg oral dose resulted in an 85% reduction in brain amyloid. In the rat, a dose response study (5 h time point) resulted in an ED_{50} of ~3 mg/kg p.o. Estimated EC_{50} concentrations in plasma and brain were 260 nM (13 nM free) and 160 nM respectively. CNS exposure was moderate with Br:Pl 0.30–0.46. **51** demonstrated minimal CYP interactions, but quite potent hERG inhibition, IC_{50} 0.64 μM, although this was argued to deliver a 49-fold separation over the free plasma EC_{50} (13 nM). The parent compound was found to be nonmutagenic in an Ames assay, and although the aniline was confirmed as an in vivo metabolite its mutagenicity was not assessed. Despite the progress made, it is unlikely that compounds have progressed beyond the preclinical stage as BMS recently announced that they have stopped research in the neuroscience area.

7.08.7 Inhibitors Reported by Eisai

Eisai have been active in the amyloid field for a considerable time, tackling both γ-secretase and β-secretase. The efforts on BACE involved a global collaboration spanning the United Kingdom and Japan and have resulted in at least one development compound,

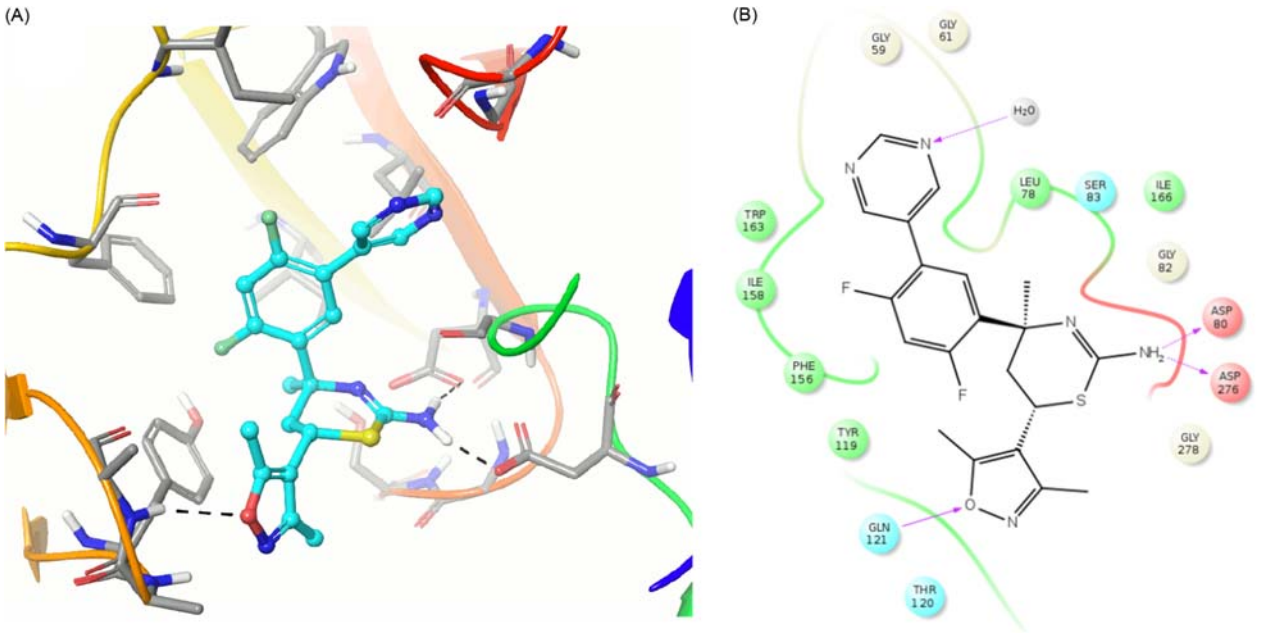

Fig. 15 (A) Crystal structure of **50** bound to BACE (PDB 5ENK). (B) Depiction of the interactions of compound **50** with BACE.

E2609, which is currently undergoing PhII/III trials in collaboration with Biogen. The compounds disclosed by Eisai center primarily on the isothiourea/aminodihydrothiazine template exemplified by spiro cycles, THF-fused and pyrrolidine-fused derivatives. In addition to these derivatives, Eisai have also described THF-fused acylguanidines and were the first to disclose the isourea/aminodihydrooxazine warhead, fused to a THF ring. Examples illustrating each of the series are highlighted.

A patent application published in 2009, detailing aminodihydrothiazine derivatives with a fused ring, including cyclopentyl, cyclohexyl, THP, THF, and pyrrolidine.[79] Pertinent examples from this application are **52** and **53**, both of which inhibit $A\beta_{42}$ production in cellular assays with IC_{50} 7 nM (Fig. 16). A subsequent patent application has recently published detailing pharmaceutical compositions and salts of **52**.[80] THP-fused aminodihydroisothiazine derivatives have also been the subject of a patent application, with selected examples including **54** (Pfizer, described later), **55**, and **56** (Fig. 16).[81] The addition of the methyl group next to the S-atom on the 1,3-thiazine ring, as in **56**, was also detailed.

Further in vivo data on **53** has been disclosed in subsequent patent applications.[82] While **53** displays good Br:Pl of 0.8, when total levels are used, further analysis of free levels, Br_u:Pl_u 0.15 and CSF:Pl_u 0.21, shows potential efflux, P-gp ER 20.7. Despite this, **53** shows potent reduction of CSF and brain $A\beta_{40}$ levels, 76% and 59% reductions in CSF and brain, respectively, 4 h after a 10 mg/kg oral dose.

Further patent applications on the THF-fused aminodihydrothiazine series have described biaryl derivatives[83] and two filings have covered fluoromethyl and difluoromethyl-substituted THF derivatives, with a methoxy pyrazine amide (four examples), exemplified by **57**, and trifluoromethyl-substituted THF derivatives, exemplified by **58** and **59**.[84] In the case of **57**, compounds from this

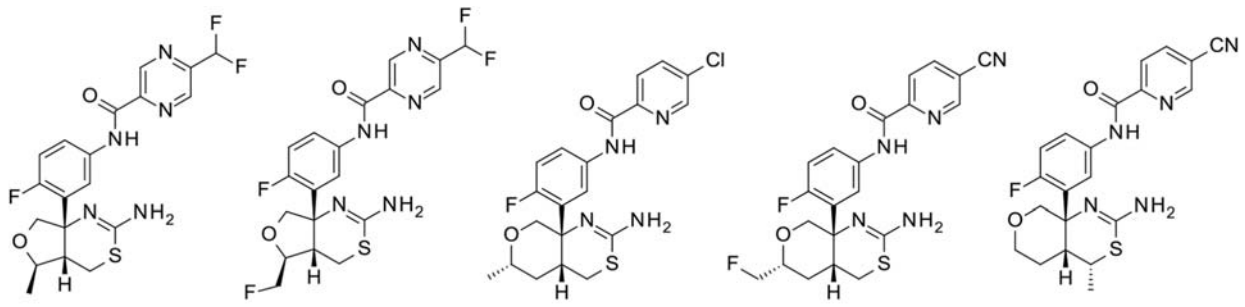

Fig. 16 Early examples from Eisai patent applications.

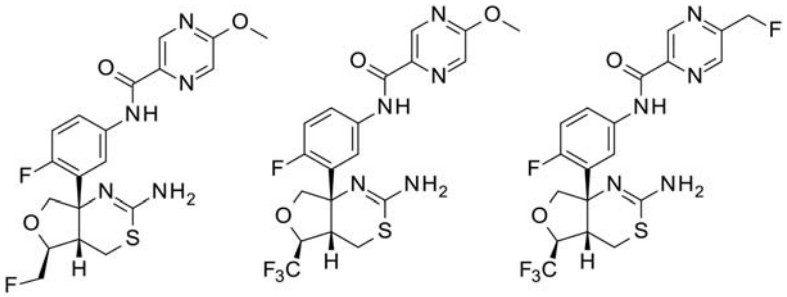

Fig. 17 Further prominent THF-fused isothiourea derivatives from Eisai.

series appear to have improved metabolic stability over close analogs in human liver microsomes.[82] **57** demonstrated potent in vitro, cell IC_{50} 4 nM, and in vivo activity in the rat, where an oral dose of 10 mg/kg resulted in 85% and 63% reductions of $A\beta_{40}$ in CSF and brain, respectively, 4 h postdose. Derivatives in this application also appeared to show improved CNS penetration over **53**, for example, **57** showed Br_u:Pl_u 0.5–0.6 and CSF:Pl_u 0.6–1.2.

Both **58** and **59** were well characterized in rat in vivo efficacy studies (Fig. 17). **58** showed marked reductions in brain (70%) and CSF (85%) $A\beta_{40}$ levels, 6 h after an oral dose of 10 mg/kg. As predicted by low in vitro P-gp efflux, ER 0.7, **58** readily penetrated the CNS in the same study, with Br_u:Pl_u 1.3 and CSF:Pl_u 1.0, 2 h postdose, with resultant free brain concentration of 30 nM.

59 also effectively penetrated the CNS, displaying Br_u:Pl_u 0.8 and CSF:Pl_u 0.5, in line with minimal P-gp efflux, ER 1.7. In the rat, **59** caused a 68% and 82% reduction of brain and CSF $A\beta_{40}$, respectively, 4 h after an oral dose of 10 mg/kg. The highest free brain concentration (87 nM) was measured 2 h postdose.

A UK patent application has published detailing the structures of three metabolites (**60–62**, Fig. 18) of **59** with their cellular activity.[85]

The isomeric THF-fused aminodihydrothiazine derivatives were exemplified in a GB patent application.[86] Overall, these derivatives, as exemplified by **63** with a cell IC_{50} of 8 nM (Fig. 19), appear to have a similar profile to compounds from the isomeric THF series, although there are only three examples. Rat in vivo data for **63** revealed marked lowering of brain and CSF $A\beta_{40}$, 56% and 84%, respectively, 6 h postdose at 30 mg/kg. At this time point, the free brain and CSF concentrations were 108 and 101 nM, respectively, giving good coverage of the cell IC_{50}. While the total Br:Pl was 1.0, the Br_u:Pl_u and CSF:Pl_u were 0.2.

An ensuing patent has also described pyrrolidine-fused aminodihydrothiazines, of which **64** is of particular note (Fig. 19).[87] **64** displays good activity in cellular assays, IC_{50} 14 nM, and a P-gp ER 7.4. Despite this, in vivo assessment in the rat at 60 mg/kg p.o. revealed good CNS penetration with a Br_u:Pl_u 0.9 and CSF:Pl_u 0.8, 3 h postdose. The Br_u and CSF concentrations were 8 and 6 nM, respectively, which resulted in a 47% decrease in CSF $A\beta_{40}$ levels but no effect on brain $A\beta_{40}$. It was noted that the lack of efficacy in brain could be due to low plasma levels in rat, which could be due to low metabolic stability, and that metabolic stability is better in human than rat, implying that the compound may be efficacious in human. In rat, **64** has moderate CLb, 53.3 mL/min/kg, and Vd, 2.62 L/kg, resulting in a $t½$ of 1.4 h.

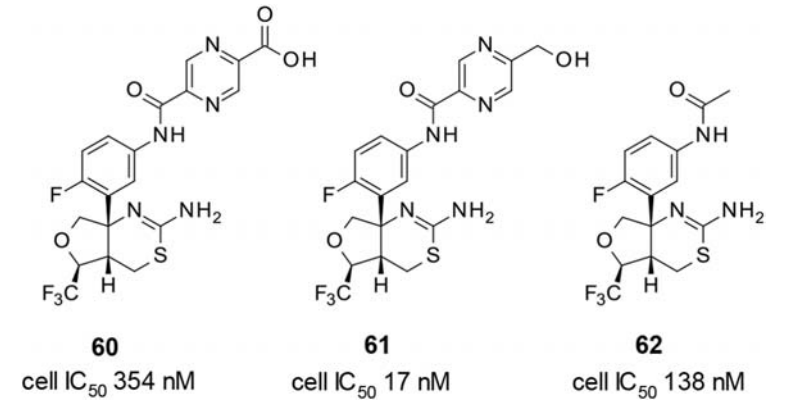

Fig. 18 Metabolites of compound **59**.

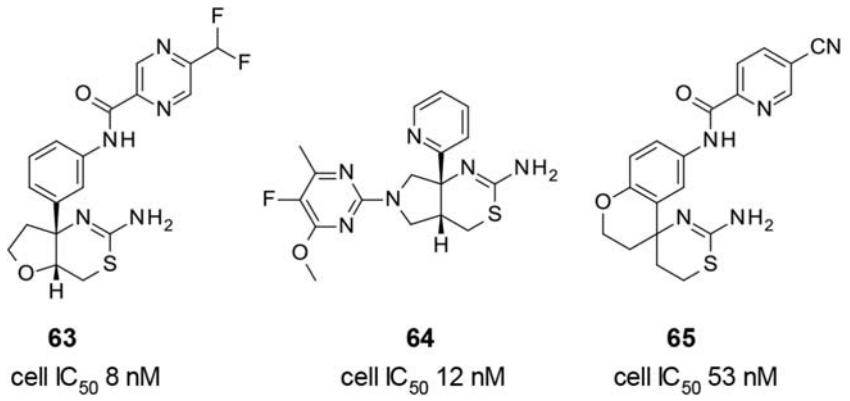

Fig. 19 Further selected chemotypes from Eisai.

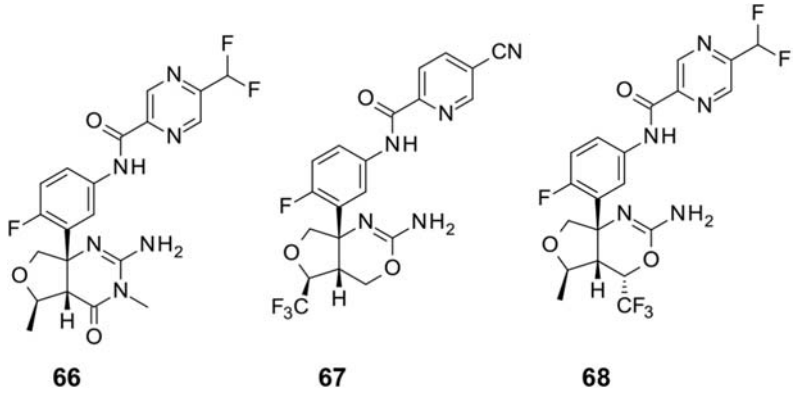

Fig. 20 THF-fused derivatives with alternative warheads from Eisai.

A patent application detailing spirocyclic analogs of the aminodihydrothiazines, such as **65,**[88] shows these derivatives appear to have weaker activity in general (Fig. 19). However, similar structural modifications have been tried on other templates by multiple groups, for example, Merck Serono and Roche on several templates (see later).

In addition to the isothiourea warhead, the Eisai group have also patented other THF-fused warheads, such as the acylguanidines, for example, **66**,[89] and isoureas, for example, **67** and **68** (Fig. 20).[90]

From conference activity, it is clear that Eisai have progressed at least one compound into clinical development, that is, E2609, although the structure of this compound has not been disclosed. In a single ascending dose (SAD) study, E2609 was administered at doses of 5, 10, 25, 50, 100, 200, 400, and 800 mg. The plasma Cmax increased proportionally with dose and the half-life ranged from 7.3 to 16.1 h. Plasma $A\beta_{1-x}$ levels were reduced by ~80% at doses from 25 to 100 mg, while higher doses resulted in prolonged reductions of >90%.[91] Repeat dosing for 14 days demonstrated that E2609 penetrated the CNS, with a CSF:Plasma (total) of ~0.2. Dose-dependent reductions in CSF $A\beta_{1-x}$ levels were demonstrated at a single time point, 12 h postfinal dose, whereby 56% (25 mg), 71% (50 mg), 83% (100 mg), and almost 90% (200 mg) absolute changes were shown.[92] This resulted in placebo-corrected reductions of 46% (25 mg), 62% (50 mg), 74% (100 mg), and 80% (200 mg).[93] Based on these results, E2609 was progressed to a Ph2 study in partnership with Biogen, whereby the compound will be dosed for 18 months to subjects with mild cognitive impairment (MCI) due to AD, and to subjects with mild to moderate AD.[94]

7.08.8 Inhibitors Reported by Elan

Elan have had a long standing interest in the amyloid field, focusing mainly on γ-secretase; however, they have also explored BACE inhibition and have a published patent application describing isothioureas/1,3-thiazines and isoureas/1,3oxazines. These compounds contain the common fluorophenyl anilides but offer diversity by means of a spiro ring on the 6-position of the oxazine/thiazine. Key compounds are depicted by **69**, **70**, and **71** which highlight the improved potency of the isothioureas over the isoureas (Fig. 21). In vivo efficacy proved moderate as at doses of **69** at 10, 30, 60, and 100 mg/kg an reduced brain $A\beta_{x-40}$ levels (guanidine extracted) by 23%, 31%, 31%, and 40%, respectively, 3 h postdose. A rat time course study at 30 mg/kg p.o. with **70** is

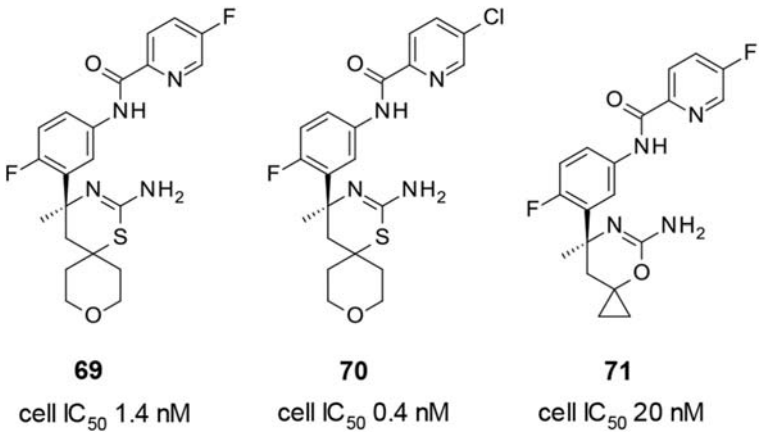

Fig. 21 Key compounds from Elan.

claimed to reduce $A\beta_{x-40}$ in brain and CSF for more than 12 h. As well as showing weaker in vitro activity, the isourea **71** showed weaker in vivo activity, whereby a 100 mg/kg oral dose to the rat resulted in only a 25% reduction of brain $A\beta_{x-40}$ 3 h postdose.

7.08.9 Inhibitors Reported by Genentech/Array BioPharma

Investigators from Genentech and Array BioPharma have collaborated around the optimization of spirocyclic BACE inhibitors. Structure-based design and a focus on conformational restriction led to low molecular weight BACE inhibitor **72** with only one rotatable bond (Fig. 22).[95] Despite being a significant substrate for P-gp-mediated efflux, **72** reduced CSF Aβ in rodents and monkey, with monkey showing a 65% reduction in $A\beta_{40}$ 8 h after a 100 mg/kg dose. Compounds from this series suffered from μ- and κ-opioid agonistic activity[96] as well as Cathepsin D inhibition. Both undesired activities could be diminished during further elaboration of this series into tricyclic tetrahydropyranyl chromanes, leading to **73** (Fig. 22).[97] The profile of this series was further tuned by shifting the position of the oxygen in the tetrahydropyranyl ring, and introduction of a bridgehead β-methyl group giving **74** (Fig. 22).[98] The β-methyl group was postulated to form a favorable hydrophopic interaction with Tyr132 in the BACE1 active site, but to clash with the flexible loop in CatD. As in the other series, compounds with the acyl guanidine Asp-binding moiety provided the most potent analogs, but the aminooxazolines had a more favorable efflux ratio. In rats, **74** reduced CSF $A\beta_{40}$ by 69%, 5 h after a 60 mg/kg dose, despite a relatively low coverage ratio of 2.1. In yet another attempt to improve BACE1 potency in this series, the oxygen of the tetrahydropyranyl was moved to the 6-position, supported by the possibility of forming a hydrogen bond with the NH of Trp76.[99] From this series, **75** (Fig. 22) was tested in rat at 60 mg/kg and although achieving a coverage ratio of free brain concentration over cellular IC_{50} of >10, the maximal Aβ reduction reached was only 40%.

In a parallel approach to target the BACE1 enzyme, Genentech has been developing bispecific antibodies with arms targeting both BACE1 and the transferrin receptor (TfR). A low affinity for TfR has been shown to take advantage of the receptor-mediated transcytosis properties of TfR resulting in a significantly increased trafficking of the antibodies across the BBB. This concept has now been proven to reduce amyloid levels in CSF in both mice and monkeys.[100]

Thus, despite a considerable investment, it does not appear that Genentech have progressed a BACE inhibitor to clinical trials. However, their parent company Roche has also had a significant interest in the BACE field and progressed at least one compound to the clinic.

7.08.10 Inhibitors Reported by Janssen

The initial work of Janssen on BACE inhibitors describes a series of 2-aminoquinazolines exemplified by **76** (Fig. 23).[101] Similarly substituted 2-aminoquinazolones were later on reported by Boehringer (**39**, Fig. 11). Cocrystallization of **76** with the BACE1 enzyme showed the typical amidine hydrogen bond network of two of the nitrogens of the aminoquinazoline with the catalytic aspartate dyad. The large side chain from the third nitrogen formed a hairpin loop with itself to position the N-cyclohexyl group into the S1 pocket. The α-cyclohexyl group was added to occupy the S1′ pocket, resulting in a compound with low nanomolar potency. An oral dose of 30 mg/kg of **76** in rats lowered $A\beta_{40}$ levels by 40–70% in plasma, but significant efflux prevented central activity. Compared to other series, the requirement of a bend conformation to optimally reach the S1 binding pocket prevents an energetically favored binding pose and the required linkers do not allow for achieving high LE. In addition the high basicity with pK_a values around 11 and high lipophilicity of this series was thought to be detrimental for a CNS lead. Subsequent efforts reported by Janssen focused on alternative series with cyclic amidines of moderate basicity and providing more optimal vectors into the

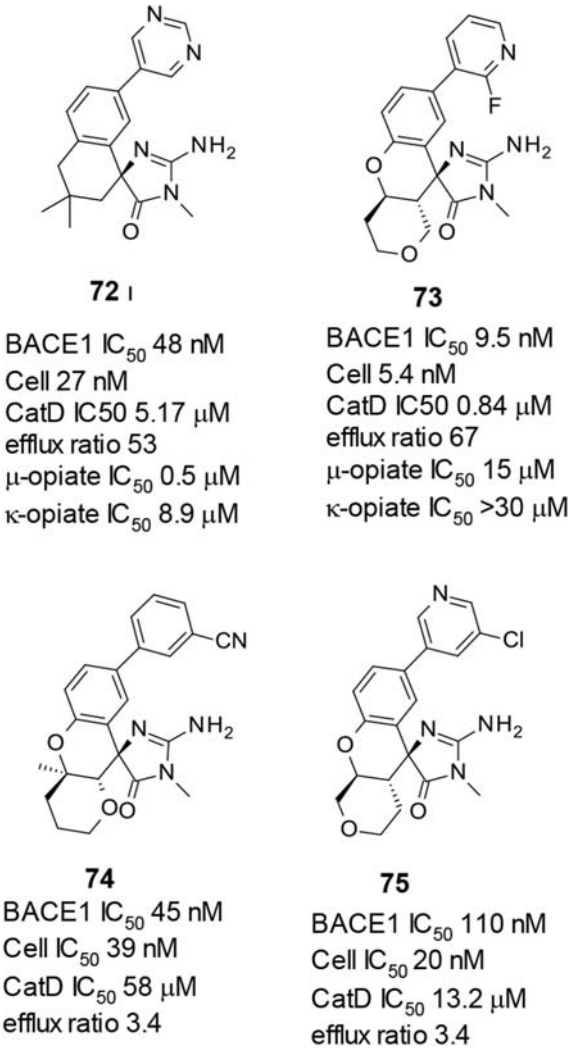

Fig. 22 Selected derivatives from Genentech/Array BioPharma.

various binding pockets. This resulted in two series of isomeric aminopiperazinones, exemplified by **77** and **78** (Fig. 23) of which **78** can be considered as a reverse amide isomer of aminodihydropyrimidones such as **24** (Fig. 8).[102] Both **77** and **78** were evaluated in a mouse in vivo model for brain penetration and **78** was also assessed for central lowering of Aβ levels. Both compounds showed low (**77**) to moderate (**78**) brain penetration, and a rapid decrease in plasma concentration attributed to low metabolic stability. Nevertheless, a relatively high dose of 60 mg/kg of **78** given subcutaneously led to a 73% reduction in brain Aβ levels, 4 h after dosing. Further work has been reported around a similar series of 3-amino-1,4-oxazine compounds, and fine-tuning of the basicity of the amidine group via the introduction of electron-withdrawing substituents.[103] Compounds with an unsubstituted 3-amino-1,4-oxazine had a pK_a of 9–9.6 and showed poor brain penetration due to P-gp-mediated efflux. Introduction of a 6-fluoro-susbtituent reduced the pK_a to values below 8 and led to compounds with a significant and long-lasting central amyloid reduction in mice and dogs. For example, a single oral dose of 2.5 mg/kg **79** (Fig. 23) in dog led to 90% reduction of CSF $A\beta_{42}$ up to 50 h postdosing.

Two subsequent patent applications describe further variations of the substituted 3-amino-1,4-oxazine series. One application describes compounds with a difluoromethyl substituent as the electron-withdrawing group, exemplified by **80** (Fig. 23),[104] and the other one replacing the common amide linker with amino linked heterocycles (**81**) (Fig. 23).[105] The iminomorpholine template is closely related to that described by Roche and Novartis, the latter of whom appear to have secured the patent space with the first published patent application (see later).

In what can be considered a continuation of the aminopiperazinone series, a number of patents have appeared incorporating 5-ring heteroaryl isosteric replacements of the piperazinone amide. This resulted in fused heteroaryl aminopiperazine compounds, exemplified by **82–88** (Fig. 24).[106–108] The synthesis of the tricyclic version **89** (Fig. 24) of the pyrrolopiperazines series has also been described, with the aim to reduce the high pK_a (~10) of the unsubstituted aminopyrrolopiperazines.[109] As with the 1,4-oxazines such as **79**, electron-withdrawing groups have also been incorporated in the bicyclic piperazines as shown in **84** and **88**,[110] with **84** showing 84% reduction in brain $A\beta_{42}$, 4 h after an oral dose of 30 mg/kg in mouse.[111] Central activity is not obvious

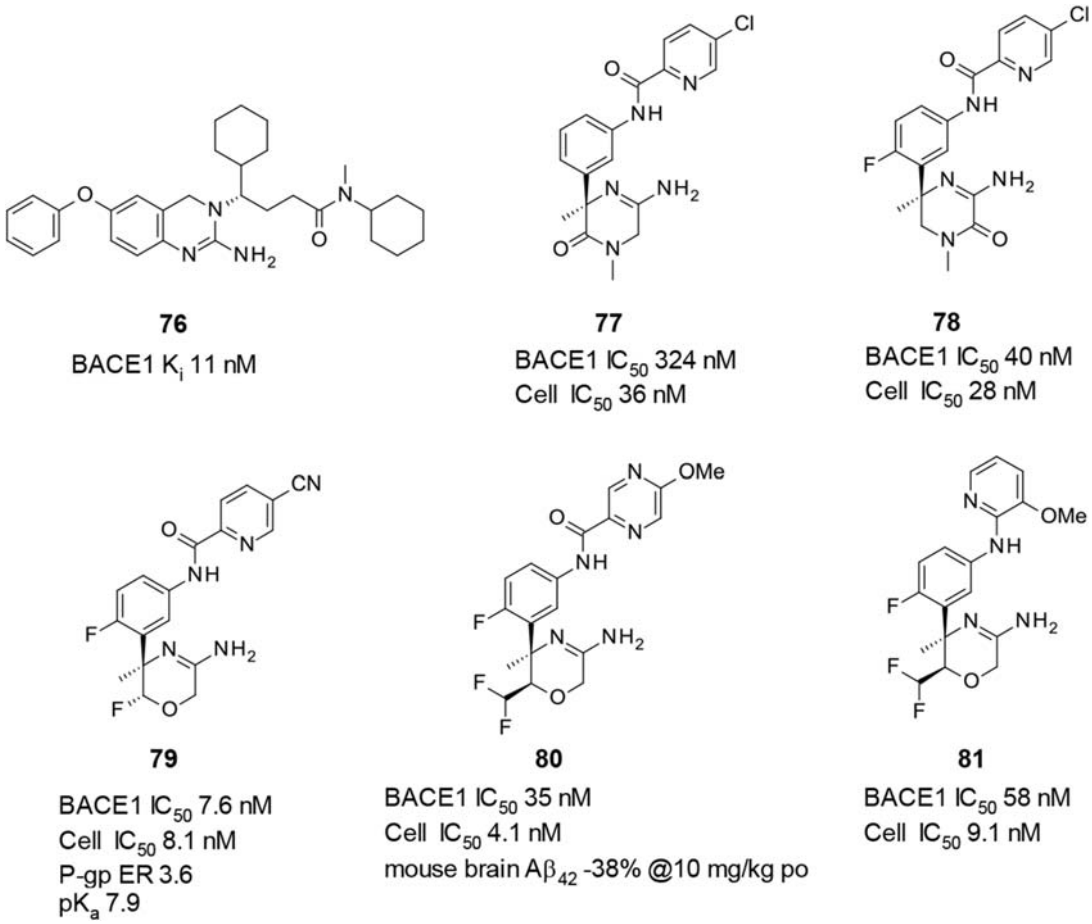

Fig. 23 Initial examples from Janssen.

for all of the fused piperazine subseries, as **86** and **87** and their analogs were not able to significantly lower amyloid levels in mouse at the tested dose of 10 mg/kg s.c.[112,113]

In another example of pK_a modulation of the basic amidine via decoration of the amidine containing heterocycle with electron-withdrawing groups, the synthesis and activity was described for a pair of 2-amino-pyrrolidine containing compounds, **90** and **91**.[114] The basicity of the CF_3-substituted analog **91** was reduced by over 2 log units versus **90**, in addition to a fivefold increase in potency (Fig. 25).

In summary, the Janssen group have been extremely active in the field and have published compounds covering a range of chemotypes, although most contain an amidine-derived warhead with an S3 pocket targeting anilide. Despite this, there has been no public disclosure of a compound progressing to the clinic. Ultimately, however, the group have progressed a compound to clinical trials in partnership with Shionogi (see later).

7.08.11 Inhibitors Reported by Lilly

The research group at Lilly has been a stalwart in the amyloid field, having tackled both γ-secretase and latterly BACE. In addition to having progressed semagacestat (γ-secretase inhibitor) to PhIII, they have progressed several BACE inhibitors to clinical development, pioneering the path and being the first group to publicly demonstrate clinical effects on central amyloid levels with a BACE inhibitor.

The chemical matter from the group at Lilly has been focused almost exclusively on isothioureas/aminodihydrothiazines. The initial compounds were simple derivatives, but these were succeeded by THF-fused and the pyrrolidine-fused derivatives. Two compounds have been terminated in clinical development, for nontarget related reasons, and at the time of writing Lilly are progressing LY3314814/AZD3293 (**32**, Fig. 10) licensed from AstraZeneca, currently PhII/III and LY3202626 (structure undisclosed), currently PhI.

For their first foray into clinical development, researchers at Lilly identified LY2811376 (**92**, Table 2). This compound was shown to lower Aβ species in a FRET assay, IC_{50} 239 nM, and cellular assays, HEK SwAPP IC_{50} 300 nM ($A\beta_{1-40}$) and 299 nM

HEK SwAPP $A\beta_{1-42}$ IC_{50} (nM)	299	19.7	n.d.	n.d.
PDAPP neuron $A\beta_{1-40}$ IC_{50} (nM)	102	10.7	20.2	49.9
PDAPP neuron $A\beta_{1-42}$ IC_{50} (nM)	94.7	9.23	16.3	36.5

($A\beta_{1-42}$), PDAPP mouse neuron IC_{50} 102 nM ($A\beta_{1-40}$) and 94.7 nM ($A\beta_{1-42}$).[115] Initial data demonstrated that LY2811376 (**92**) reduced amyloid levels in the PDAPP mouse, 3 h postdose CSF $A\beta_{1-x}$ was reduced by 60% following a 10 mg/kg s.c. dose, whereas brain $A\beta_{1-x}$ was reduced by 50% at 30 mg/kg s.c. Further characterization in the PDAPP mouse showed 47%, 64%, and 68% reductions in cortical $A\beta_{1-x}$ 3 h after 10, 30, and 100 mg/kg oral doses, respectively, with a corresponding Br:Pl 1.7–2.2.[116] In vivo efficacy was confirmed in the dog, where a 5 mg/kg oral dose resulted in ~70% reduction in CSF $A\beta_{1-x}$ 9 h postdose.

LY2811376 (**92**) entered PhI clinical trials in Dec. 2008[117] and completed SAD and MAD studies demonstrating 58% reduction of CSF $A\beta_{1-40}$ and $A\beta_{1-42}$ approximately 18 h after an oral dose of 90 mg, in healthy volunteers. The effect in CSF was slightly less pronounced than that in plasma, 80% reduction ~7 h postdose. The T_{max} in CSF was reached ~5 h postdose, somewhat delayed compared to the plasma T_{max} 2 h, and the CSF:Pl_{tot} AUC was ~0.3, showing good distribution into the human CNS. Disappointingly, further development of this compound was halted due to a finding in a preclinical 3-month rat toxicological study, where autofluorescent material was found in the retinal epithelium at doses ≥30 mg/kg. This finding was adjudged to be compound specific and not related to BACE inhibition as the same effects were not seen in BACE KO mice.[116]

Ultimately, these issues resulted in Lilly progressing a second compound, LY2886721 (**93**, Table 2) into clinical studies. Initial data reported in a patent application showed improved in vitro activity over its predecessor, BACE FRET IC_{50} 20.3 nM, and cellular assays, HEK SwAPP IC_{50} 18.5 nM ($A\beta_{1-40}$) and 19.7 nM ($A\beta_{1-42}$), and PDAPP mouse neuron IC_{50} 10.7 nM ($A\beta_{1-40}$) and 9.23 nM ($A\beta_{1-42}$).[118] In vivo, PDAPP mouse, LY2886721 (**93**) reduced $A\beta_{1-x}$ by 54% in brain cortex 3 h postdose following 10 mg/kg oral administration. Further characterization of this compound has recently been detailed.[119] In the dog, a 1.5 mg/kg oral dose of LY2886721 (**93**) resulted in strong reductions of $A\beta_{1-x}$ in CSF, 80% reduction 9 h postdose, with slightly stronger effects seen in plasma. In this study, the CSF_{AUC}:free $plasma_{AUC}$ was ~0.9, demonstrating excellent CNS penetration. In healthy volunteers, doses of 5–70 mg LY2886721 (**93**) were assessed in a SAD, showing ~80% reduction in plasma amyloid levels at the highest dose, which did not significantly differentiate from the 35 mg dose. Following a single 35 mg dose to healthy volunteers, the maximal CSF $A\beta_{1-40}$ reduction, 40%, was observed ~17 h postdose. Following 14 days administration of the 35 mg dose, CSF $A\beta_{1-40}$ levels were reduced by 58%, whereas a 70 mg dose resulted in a maximal 74% reduction of CSF $A\beta_{1-40}$ levels. Unfortunately PhII studies were terminated due to effects on liver enzymes, again not related to BACE inhibition.

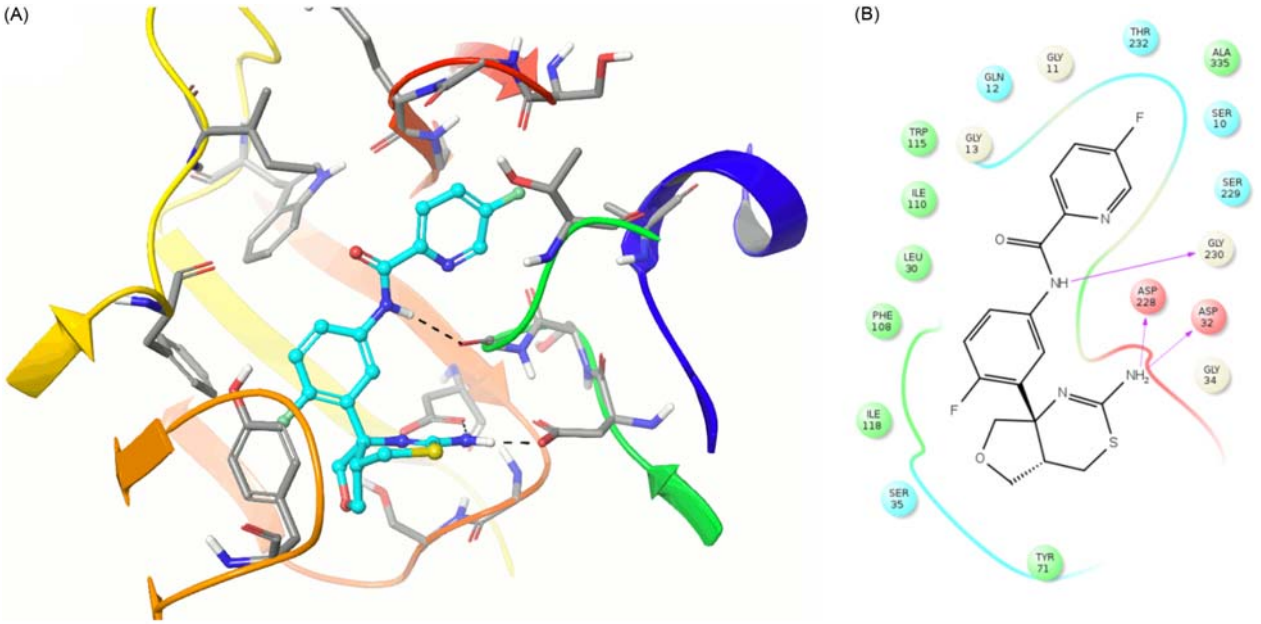

Fig. 26 (A) X-ray crystal structure of LY2886721 (**93**) bound to BACE (PDB code 4X7I). (B) Depiction of LY2886721 (**93**) interactions.

The crystal structure of LY2886721 (**93**) bound to BACE has been published, and is depicted in Fig. 26. The isothiourea interacts with the catalytic aspartic acid diad, while the anilide forms a hydrogen bond with Gly230 and the pyridyl moiety extends into the S3 pocket.

The final patent application from this series has appeared more recently, the key difference being the addition of a fluorine atom at the ring junction,[120] presumably to modulate the basicity of the warhead. The application covers isothioureas, for example, **94**, as well as isoureas, for example, **95**, Table 2, which are generally more basic, and may therefore benefit more from the presence of the fluorine atom (Table 2). Head to head data for a matched pair shows that the isoureas have weaker in vitro activity, **95** BACE FRET IC_{50} 45 nM, PDAPP neuron IC_{50} 49.9 ($A\beta_{1-40}$) and 36.5 nM ($A\beta_{1-42}$) than the isothioureas, **94** BACE FRET IC_{50} 6.66 nM, PDAPP neuron IC_{50} 20.2 ($A\beta_{1-40}$) and 16.3 nM ($A\beta_{1-42}$), respectively (Table 2). The potency difference in vivo was less pronounced, with a 10 mg/kg oral dose of **94** resulting in a 34% and 46% reduction of $A\beta_{1-x}$ in hippocampus and cortex, whereas **95** at the same dose resulted in a 26% and 26% or 24% reduction, respectively. In addition to the two highlighted compounds, the methoxypyrazine amide analog of **94** also appears to be a favored compound, showing 40% and 45% reduction of $A\beta_{1-x}$ in hippocampus and brain amyloid level after a 10 mg/kg oral dose. Both **94** and **95** are specifically claimed, and given the strength of the in vitro and in vivo results for these compounds, versus previous development compounds, either one of these compounds could have been nominated as a development candidate.

Following on from the THF-fused derivatives, the focus of the Lilly group appears to have shifted to pyrrolidine-fused aminodihydrothiazines, which are related to the aminodihydropyrimidone series from Merck and Eisai. Moving to this series meant an initial step back in terms of in vitro potency, to similar or weaker levels than displayed by LY2811376 (**92**, Table 2). A first patent application disclosed **96**, BACE FRET IC_{50} 172 nM, PDAPP neuron IC_{50} 2240 ($A\beta_{1-40}$) and 2870 nM ($A\beta_{1-42}$) respectively (Table 3).[121] Despite the much weaker activity in the PDAPP neuron assay, **96** still demonstrated efficacy in vivo in the PDAPP mouse, at an oral dose of 30 mg/kg it reduced $A\beta_{1-x}$ by 45% and 52% in hippocampus and cortex, respectively. This compound

Table 3 Initial pyrrolidine-fused isothiourea derivatives from Lilly

Compound	**96**	**97**
Structure		FRET IC_{50} (nM)	172	105
PDAPP neuron $A\beta_{1-40}$ IC_{50} (nM)	2240	455
PDAPP neuron $A\beta_{1-42}$ IC_{50} (nM)	2870	412

in addition to the 5-cyano-thiophene-2-yl analog were both specifically claimed, thus representing key compounds. A subsequent patent application detailed three key compounds, the most prominent being **97** with improved in vitro activity, particularly in cellular assays, FRET IC_{50} 105 nM, PDAPP neuron IC_{50} 455 ($A\beta_{1-40}$) and 412 nM ($A\beta_{1-42}$), respectively (**Table 3**).[122] Thus the in vitro activity levels were in line with the initial clinical candidate, LY2811376 (**92**), providing confidence that human efficacy could be observed. In vivo efficacy was demonstrated in the PDAPP mouse at 10 and 30 mg/kg p.o., with amyloid measured 3 h postdose. The lower dose provided marginal efficacy, reducing $A\beta_{1-x}$ by 19% and 23% in hippocampus and cortex, respectively, whereas the higher dose resulted in $A\beta_{1-x}$ reductions of 46% and 53% in hippocampus and cortex, respectively.

In order to increase potency in the pyrrolidine-fused series, the group at Lilly have added the amide substituent present in the most potent BACE inhibitors to pick up additional interactions, principally the HBD interaction with Gly230. Thus, recent patent applications have described **98** and **99** (**Table 4**).[123] Both compounds demonstrated subnanomolar activity in vitro **98** BACE FRET 0.6 nM, PDAPP neuron IC_{50} 0.5 nM ($A\beta_{1-40}$) and 0.5 nM ($A\beta_{1-42}$), Lilly-6 BACE FRET 0.6 nM, PDAPP neuron IC_{50} 0.13 nM ($A\beta_{1-40}$) and 0.135 nM ($A\beta_{1-42}$). **98** displayed potent in vivo efficacy in the PDAPP mouse, with 43%, 59%, and 66% reductions in cortical $A\beta_{1-x}$ after 1, 3, and 10 mg/kg oral doses, respectively. Similar effects on amyloid were seen in the hippocampus. **99** has been the subject of a subsequent patent application, detailing the synthesis, crystalline forms, and its use in the treatment of AD.[124] Additional in vivo efficacy data was provided in this application, demonstrating potent amyloid lowering activity in the PDAPP mouse; 31%, 39%, and 61% reduction in hippocampal $A\beta_{1-x}$ at oral doses of 0.3, 1, and 3 mg/kg 3 h postdose, respectively.

A recent patent application has published, describing a single compound, **100**, this compound having the central phenyl ring replaced by a pyridine (**Table 4**).[125] Only in vitro activity data were presented. As with analogs, **100** showed potent in vitro activity, BACE FRET 0.9 nM, PDAPP neuron IC_{50} 0.65 nM ($A\beta_{1-40}$) and 0.91 nM ($A\beta_{1-42}$) respectively. An even more recent patent application has published, again containing a single compound, **101**, which differs from **100** by the replacement of the central pyridine ring by a fluorophenyl ring (**Table 4**).[126] The patent application describes a similar level of characterization to other patent applications, whereby **101** shows extremely potent in vitro activity, PDAPP neuron IC_{50} 0.275 nM ($A\beta_{1-40}$), 0.228 nM ($A\beta_{1-42}$), and strong in vivo efficacy in a dose–response study in the PDAPP mouse—doses of 0.3, 1, and 3 mg/kg p.o. resulted in reductions of 28%, 42%, and 64% in brain cortex, respectively, 3 h postdose. A subsequent patent application discloses the combination of a BACE inhibitor, such as **101** and very close analogs, with an Aβ antibody.[127]

The analysis here further commentary on Lilly's patenting strategy relative to their clinical studies. Thus, clinical studies with LY2811376 (**92**) commenced in Dec. 2008, while the patent application only published on 5th Nov. 2008. For LY2886721 (**93**), the fist clinical studies commenced in Jun. 2010, while the patent application covering the compound did not publish until 13th Jan. 2011. Thus, one can see that Lilly are happy to aggressively push compounds forward while carrying significant patent risks due to the extremely competitive nature of the field.

Based on the analysis presented here, one may posit that Lilly have identified several further development candidates, however it would appear that only one further compound discovered by the Lilly group has progressed to the clinic, namely LY3202626. The analysis reveals that LY3202626 is most likely represented by **99**, **100**, or **101**. The publication of a recent patent application describing the tosylate salt of **101**[128] would suggest that this compound is LY3202626.

Lilly's commitment to the AD field, and in particular the BACE inhibitor field should be commended. The company has expended significant research efforts over the years to identify BACE inhibitors. This work has resulted in exciting and challenging times as early compounds demonstrated efficacy on pharmacodynamics (PDs) and disease biomarkers, but disappointment as compounds were discontinued due to toxicological issues. A third proprietary compound is currently undergoing clinical development, in addition to AZD3293/LY3314814 (**32**, **Fig. 10**), licensed from AZ which is undergoing PhII/III studies

7.08.12 Inhibitors Reported by Lundbeck

Lundbeck have also been late entrants to the field, with five published patent applications, three of which published in May 2016. The first publication describes thiazole isothiourea derivatives, where a second aromatic group is attached via a methylene linker. Overall these compounds display weak activity, as shown by **102**, with a BACE1 binding Ki of 1.9 μM (Fig. 27).[129] A second application describes fluorinated amidine derivatives, exemplified by **103** (Fig. 27).[130] Several derivatives show potent binding to BACE1, and five analogs are reported to lower $A\beta_{40}$ in rat brain 3 h after oral administration at 30 mg/kg. Three compounds including **103** also have activity reported at 10 mg/kg. Of these, **103** appears to be the most active, displaying good CNS penetration, Br:Pl 0.5, and reducing brain amyloid by 66% and 61% at doses of 10 and 30 mg/kg, respectively. The total brain concentrations achieved were 412 and 1606 ng/g following doses of 10 and 30 mg/kg, respectively.

Recently, three further patent applications have appeared, which described related analogs. One of the patent applications describes analogs of **103**, such as **104** (Fig. 27)[131] which have only one fluorine atom at the 5-postion of the iminopiperidine ring. **104** was found not to be a P-gp substrate in vitro and displayed the strongest in vivo activity to date among the compounds they have described, whereby a 3 mg/kg oral dose to the rat resulted in a 52% decrease in brain $A\beta_{40}$ 3 h postdose. A Br:Pl of 2.2 was also recorded in this study, with a total brain concentration of 610 ng/g. No data on free brain or plasma concentrations was provided. **105** (Fig. 27) with additional fluorination on the central phenyl ring as well as the 6-fluoromethyl group displayed a similar in vitro profile.[132] Rat in vivo data for **105** was provided only at doses of 10 and 30 mg/kg p.o., whereby the compound lowered brain $A\beta_{40}$ by 43% and 50% 3 h postdose, respectively. The Br:Pl ranged from 1.3 to 1.8, with total brain exposure of 1758 and 4210 ng/g at 10 and 30 mg/kg, respectively. The third patent is best exemplified by **106** (Fig. 23).[133] It can be seen that the increased fluorination results in a more potent series, however in vivo activity appears weaker than other series. Doses of 10 and 30 mg/kg of **106** resulted in 24% and 38% decreases in brain $A\beta_{40}$ levels in the rat. The weaker efficacy could be due to the lower Br:Pl (0.3) than other series, for example, **104** and **105**, which resulted in lower total brain concentrations of 511 and 2284 ng/g at doses of 10 and 30 mg/kg, respectively. It could also be that there are differences in brain tissue binding between the subseries which may also impact the in vivo efficacy, as the total brain concentration for **106** were similar to **103** which displays much better in vivo efficacy.

In the three most recent patent applications, it can be seen that the amidines were generally not P-gp substrates, however there were certain amide motifs which clearly resulted in P-gp efflux, reflecting a specific recognition pattern. Overall, the amidines appear to demonstrate acceptable levels of in vitro potency while not being subjected to P-gp efflux. The in vivo activity appears moderate, with some subseries, that is, **104** and **105** appearing more potent than others. However, it is not known whether α-fluoro-amidine, present in **103** and **104**, is stable to hydrolysis and whether this template suffers from hERG and CYP2D6 inhibition.

Currently, there are no BACE inhibitors listed on the Lundbeck pipeline, so it is unclear if any compounds have progressed beyond the preclinical stage.

7.08.13 Inhibitors Reported by Merck Serono/Merck KGAA

Another late entrant to the BACE field, Merck Serono, who under the name Ares Trading SA, have published a single patent application on their work.[134] The compounds are related to the spirocyclic series from Eisai, for example, **65** (Fig. 19), whereby the phenyl ring has been replaced by a thiophene, to give compounds such as **107**, which is claimed to display submicromolar activity in enzymatic and cellular assays (Fig. 28). Other warheads such as acylguanidine **108** are also described, with similar activity (Fig. 28). It would appear that Merck Serono are no longer active in the field.

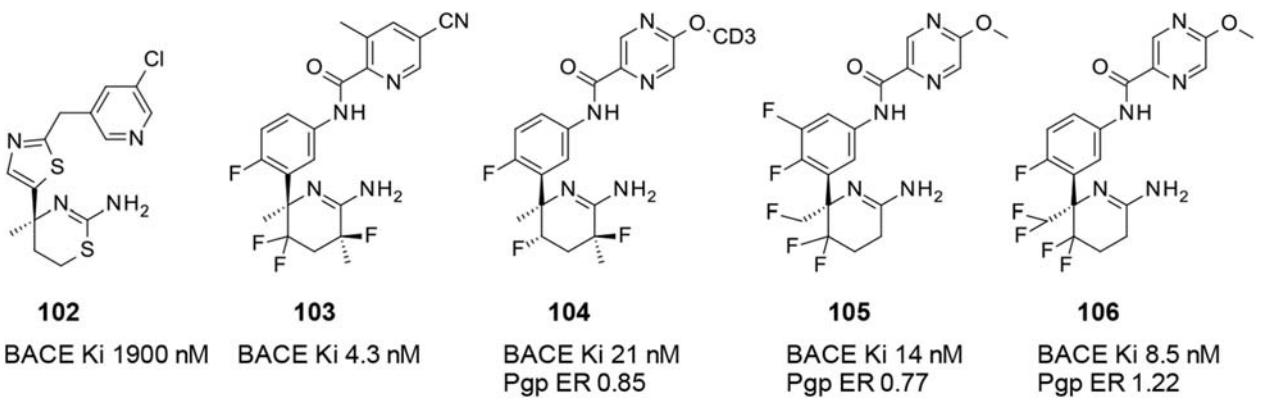

Fig. 27 Isothiourea derivative **102**, and fluorinated amidine derivatives (**103–106**) from Lundbeck.

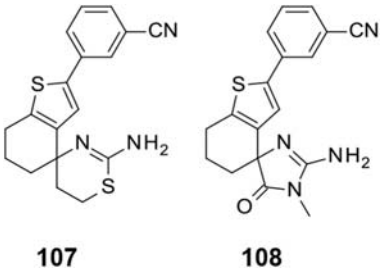

Fig. 28 Examples from Merck-Serono.

7.08.14 Inhibitors Reported by Noscira

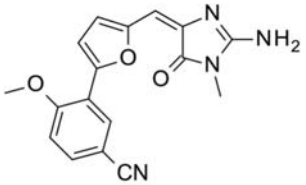
Noscira, based in Spain, have published one patent application, describing conjugated acylguanidine derivatives, such as **109**, with weak in vitro activity, IC_{50} 220 nM in a recombinant enzyme assay, cell IC_{50} 1.15 μM (Fig. 29).[135] No further publications have appeared and it does not look like these derivatives have progressed beyond early preclinical characterization.

7.08.15 Inhibitors Reported by Novartis

Novartis have expended a significant effort in the field and analysis of the published patents reveal several key compounds, all based on the iminomorpholine/1,4-oxazine template, with the exception of the latest published patent application. It appears that several companies, including Janssen, had been interested in this template, but Novartis managed to secure the primary published patent application. The first patent application from Novartis, covering **110** and **111** (Fig. 30) published on 27th Jan. 2011, just 4 weeks ahead of that from Roche, covering **144** and **145** (Fig. 41), which published on 24th Feb. 2011. Similarly, patents from Janssen covering **79**, **80**, and **81** (Fig. 23), published on 13th Jun. 2013. Again, this serves to highlight the competitive nature of the field.

Initial compounds, centered on the iminomorpholine template as depicted by **110**,[136] Fig. 30, the difluoromethyl group presumably serves to orient the fluoro-anilide in the axial location while reducing the pK_a of the guanidine moiety, as it may be expected that the β-oxygen atom does not sufficiently modulate the basicity of the guanidine. This series was quickly followed up by more key examples, such as **111** and **112** (Fig. 30), which have been described in several patent applications.[137–139] The close analog of **112**, namely **113** (Fig. 30), appeared in the second patent application,[137] the addition of a methyl group *ortho* to the amide may have been intended to reduce amide cleavage. The addition of fluorine atoms either on the 5-methyl, as shown by **112** and **113**, or at the 2-position are presumably to reduce the pK_a on the guanidine moiety, which is probably still too basic despite the β-oxygen on the morpholine.

Further pharmacological data on **111**, also known as **NBI-360**, have recently been published.[140] In vitro characterization of **NBI-360** revealed BACE1 enzyme inhibition IC_{50} of 5 nM (human and mouse, slightly more potent than the original report). Significantly weaker activity was observed in a HEK cell line overexpressing SwAPP IC_{50} 33 nM, than that against wild-type APP, IC_{50} 3 nM, presumably due to the fact that SwAPP is a better BACE substrate than wild-type APP. **NBI-360** is not a P-gp substrate (ER 1.9) and shows good CNS penetrations, rat Br:Bl 0.86 (AUC), which equates to a Br_u:Bl_u of 0.32, assuming brain tissue and ppb are equal. In the dog, the compound also penetrated the CNS, CSF:Pl 0.023, which when corrected for free plasma concentrations equates to CSF:Pl_u of $\geq$2.3, although this value could be significantly overestimated due to the high ppb in the dog. The PK profile was characterized in the mouse, rat, and dog which were all used to investigate efficacy. Low clearance and volume of distribution was observed in the dog, perhaps due to high ppb, but the $t^1/_2$ was 36.2 h. In the mouse and rat the $t^1/_2$ was 3.6 and 2.7 h,



109

BACE IC_{50} 220 nM

cell IC_{50} 1150 nM

Fig. 29 Selected example from Noscira patent application.

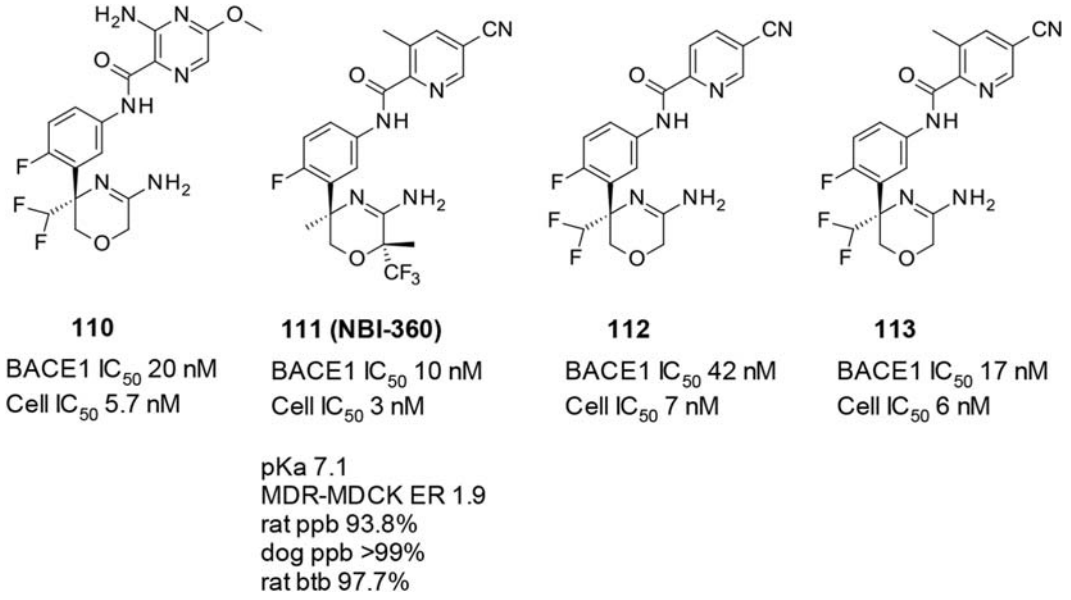


Fig. 30 Initial iminomorpholine derivatives from Novartis, including NBI-360 (**111**).

respectively, and both showed moderate to high oral bioavailability. A dose–response time course study in the rat showed a strong reduction of $A\beta_{40}$ levels in CSF and forebrain with a maximal effect in brain of 91% 4 h postdose (30 μmol/kg). This resulted in a calculated ED_{50} of 1.6 μmol/kg for $A\beta_{40}$ lowering in the forebrain at the 4 h time point (direct modeling). In the dog, an oral dose of 0.5 mg/kg (1.1 μmol/kg) p.o. resulted in ~80% reduction of CSF $A\beta_{40}$ 12–24 h postdose, resulting in a calculated plasma concentration of 59 nM to reduce CSF $A\beta_{40}$ by 50%, which corresponds to a CSF concentration of 1.4 nM, which is similar to the cell IC_{50}. In preplaque APP51/16 transgenic mice (3–5 months of age), a single dose of 30 μmol/kg resulted in ~80% decrease of brain $A\beta_{40}$ 4 h postdose. A follow-up study in older mice (8 months of age) with dosing for 4 days resulted in 15% and 52% reduction of brain $A\beta_{40}$ 24 h postdose at 30 and 100 μmol/kg, respectively. Finally, a chronic (6 weeks) study in older mice (starting at 14.5 months of age) at a dose of 100 μmol/kg p.o. showed >90% reduction of CSF $A\beta_{40}$ at 4 h and approximately 60% at 24 h postfinal dose. Analysis of plaque growth compared to baseline showed that **NBI-360** treatment prevented plaque growth over the 6-week treatment period, thus demonstrating the potential of a BACE inhibitor to halt disease progression.

Although the characterization of **NBI-360** demonstrates an encouraging profile, it would appear that this compound may not have progressed to the clinic. No mention is made of the hERG or cardiovascular safety profile, which have represented significant challenges in the BACE inhibitor field. In addition, during the chronic (6 weeks) mouse study patches of gray hair appeared on **NBI-360**-treated mice. This has been attributed to BACE2 inhibition.[141]

A related patent application disclosed further analogs with a variety of substituents on the pyridyl amide as well as additional fluorination on the central phenyl ring.[142] Of more interest, a subsequent patent application described further examples of **111** and **113**, where the central phenyl group has been replaced by a pyridine ring.[143] Pertinent examples are highlighted by **114**, **115**, and **116** (Fig. 31). This change appears not to affect BACE potency, although the in vivo profile may be improved (see later). It is unclear if they offer any other benefit apart from avoidance of an aniline structural alert.

Additional analogs in this series have been disclosed where the amide has been replaced by isosteres, for example, **117** and **118**,[144] where the amide has been replaced by a fused pyridine or by a fused pyrimidine respectively (Fig. 32). Many research groups have tried this type of strategy on other templates, but other issues would be anticipated, and as such it is unlikely that compounds have progressed from this subseries.

Finally, the group at Novartis applied the pyridine replacement in the isourea/dihydroaminooxazine series. The patent discloses head to head in vivo data with the corresponding phenyl analogs patented by Roche. The pyridine not only maintains potency in vitro but drastically improves the in vivo efficacy, demonstrated by in vivo efficacy studies in the SD rat at a dose of 10 μmol/kg, with sampling 4 h postdose. With the data provided, it is unclear whether this improvement is due to increased metabolic stability, increased CNS penetration, or a combination of both. However, it is clear that there are several key compounds in this patent application, such as **119**, **120**, **121**, and **122** (Fig. 33). In particular **119** and **120** demonstrated potent in vivo efficacy. The Novartis patent application takes advantage of the fact that Roche patents covering the 1,3-oxazine derivatives only claim substituted phenyl ring. The Novartis patent published on 28th Feb. 2013, ahead of near neighbors Roche, who were just over 18 months behind with their pyridyl analogs, for example, **152** and **153** (Fig. 43) (see later), which published on 16th Oct. 2014.

From this analysis it seems there have been several key compounds identified by the group at Novartis. It is not known how many of these compounds have completed toxicology studies, however it appears that only one compound has progressed to clinical trials. Due to a strategic decision to exit neuroscience, it was announced in Sep. 2015 that the Novartis BACE inhibitor

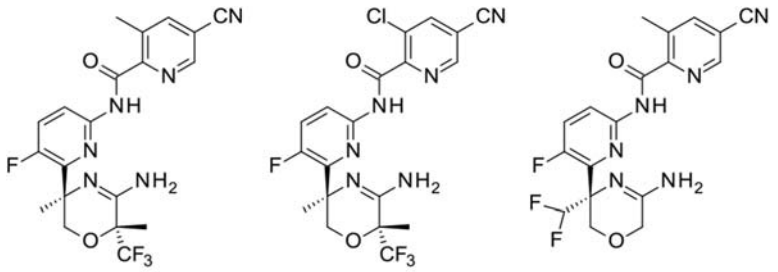

Fig. 31 Follow-on iminomorpholine derivatives with a central pyridine ring from Novartis.

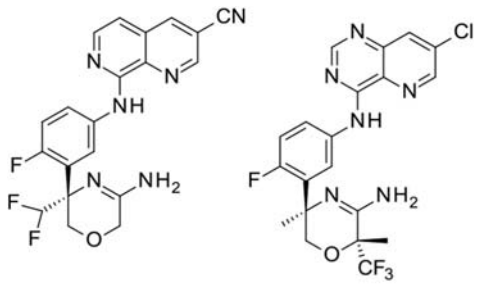

Fig. 32 Amide isosteres from Novartis.

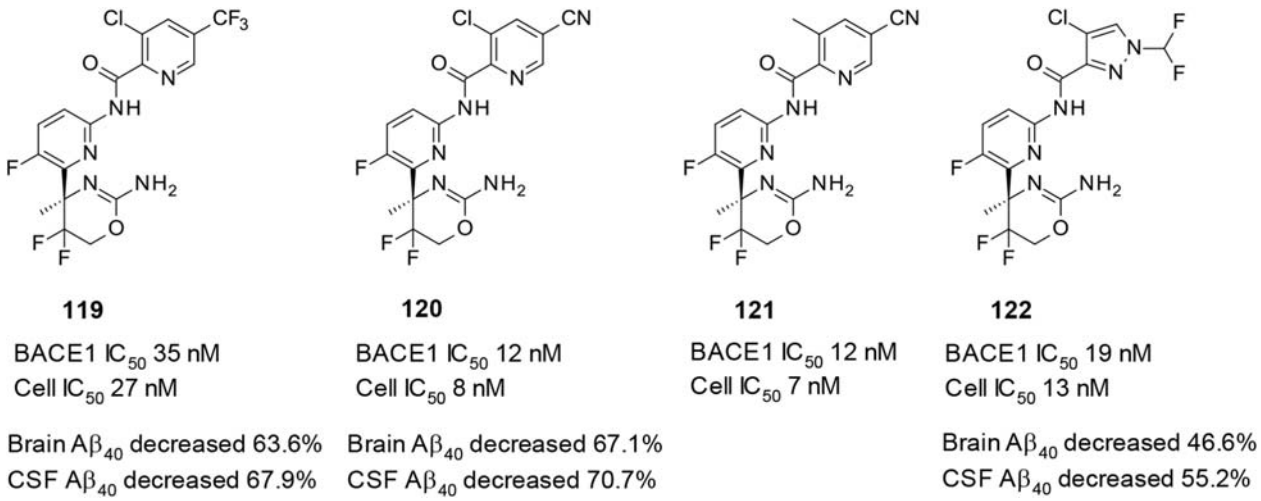

Fig. 33 Key isourea derivatives from Novartis containing a central pyridine ring.

undergoing clinical development (PhI/IIa), **CNP-520** has been partnered with Amgen.[145] This compound is currently in PhII, and in addition to a standard safety and tolerability trial over 13 weeks, **CNP-520** is also being tested in a 5-year prevention trial in APOE4 carriers. This study is being conducted in partnership with the Banner Alzheimer's Institute as part the Alzheimer's Prevention Initiative (API) and will also include an arm with the Aβ vaccine CAD-106.[146] The trial seeks to treat cognitively normal, healthy older (60–75 years of age) individuals who have a higher risk of developing AD due to them possessing two copies of the APOE4 gene. All

participants are required to undergo at least two amyloid Positron Emission Tomography (PET) scans (18F-florbetapir), although CSF collection is voluntary. It is anticipated that 430 individuals will be treated with **CNP-520** and the trial is expected to complete in 2023. It may be hypothesized that **CNP-520** is represented by one of the key compounds highlighted here, for example, **114**, **115**, **116**, **119**, or **120**.

7.08.16 Inhibitors Reported by Pfizer

Pfizer have had a long standing interest in the amyloid field, tackling both β- and γ-secretase. Their work has covered several areas, with the initial focus being on fragment hits and spiropiperidine derivatives, as well as alternative lead generation strategies including fragment screens, before shifting to amidine derivatives. The following section highlights pertinent examples from each area.

7.08.16.1 Spiropiperidine Derivatives

Before Pfizer turned their attention to the amidine derivatives, which ultimately proved successful, they had directed research on several other series. One prominent series, which produced a clinical development candidate, was the spirocyclic piperidine series, which is closely related to that from Schering-Plough/Merck ("Inhibitors Reported by Schering-Plough/Merck" section). The main difference between the Pfizer and Merck compounds is that the Pfizer compounds contain a spiro sulfamide, whereas those from Merck contain a spiro aminohydantoin, which displays additional substitution (cyclohexyl) on the exocyclic N-atom.

The Pfizer compounds are exemplified by **123–125** in Table 5.[147] The starting point, **123**, displayed weak in vitro activity and was found to be a weak P-gp substrate. The P-gp efflux was confirmed in vivo in the mouse. The sulfamide NH was capped with a methyl group to reduce the HBDs, resulting in **124** which displayed reduced P-gp efflux and increased CNS penetration in the mouse. A crystal structure of **124** with BACE revealed that the protonated piperidine N-atom interacts directly with the catalytic water, which site directly between the two carboxylates of the aspartic acid diad. Furthermore, the compound was found to display a folded conformation whereby the two phenyl rings π-stack with one another. One oxygen of the sulfamide was found to accept hydrogen bonds from the backbone NH of Thr272 and Gln73. This information also allowed the group to hypothesize that adding a hydroxyl group ortho to the isopropoxy moiety could make a HBD interaction with the carbonyl of Phe108 (not shown), which was confirmed by crystallography, **125**, depicted in Fig. 34. This change resulted in a dramatic increase in potency, however P-gp efflux also increased somewhat, reflected also by the in vivo CNS penetration.

Mouse in vivo studies with **125**, subcutaneous dosing, revealed reductions of brain $A\beta_{40}$ of 40% and 60% at 100 and 300 mg/kg, respectively. Lower doses, 10 and 30 mg/kg, did not achieve statistically significant effects. CSF $A\beta_{40}$ levels were also reduced by 44% and 54% at 100 and 300 mg/kg, respectively. The authors note that **125** still lacks sufficient potency for progression. Potency was enhanced by changing from the sulfamine to a cyclic urea and then eventually to the dehydrolactam **126** (**PF-05297909**) (Table 5).[148] Although enzymatic activity was not altered, the cellular inhibition was improved threefold compared to **125**.[149] In the rat, doses of 30 and 100 mg/kg resulted in 35% and 50% reductions in brain $A\beta_{40}$, and 69% and 80% reductions in CSF $A\beta_{40}$. Efficacy was confirmed in the monkey, where a 30 mg/kg subcutaneous dose resulted in a 60% reduction of CSF amyloid ~6 h postdose. Efficacy was also confirmed in the dog, where **PF-05297909** showed ~10-fold increased potency compared with other preclinical species (mouse, rat, monkey). Modeling predicted the effective human dose to be 525 mg. As there were concerns about whether clinical efficacy could be achieved at a tolerated dose, **PF-05297909** (**126**) was advanced to the clinic under an exploratory Investigational New Drug (IND) application. This allowed the compound to progress to a clinical setting with a reduced toxicology package, and only 150 g drug substance,[150] to assess whether the desired reductions of $A\beta_{40}$ could be seen in human CSF.

Table 5 Summary of key compounds from the Pfizer spiropiperidine series

Compound	**123**	**124** (**PF-04976081**)	**125**	**126** (**PF-05297909**)
Structure				BACE 1 IC_{50} (nM)	1300	2400	100	80
Cell IC_{50} (nM)	2900	1800	100	32
Pgp ER	3.8	1.7	3.4	3.3
Mouse Br:Pl	0.67	0.97	0.35	n.d.
Mouse Br_u:Pl_u	0.22	0.65	0.27	n.d.

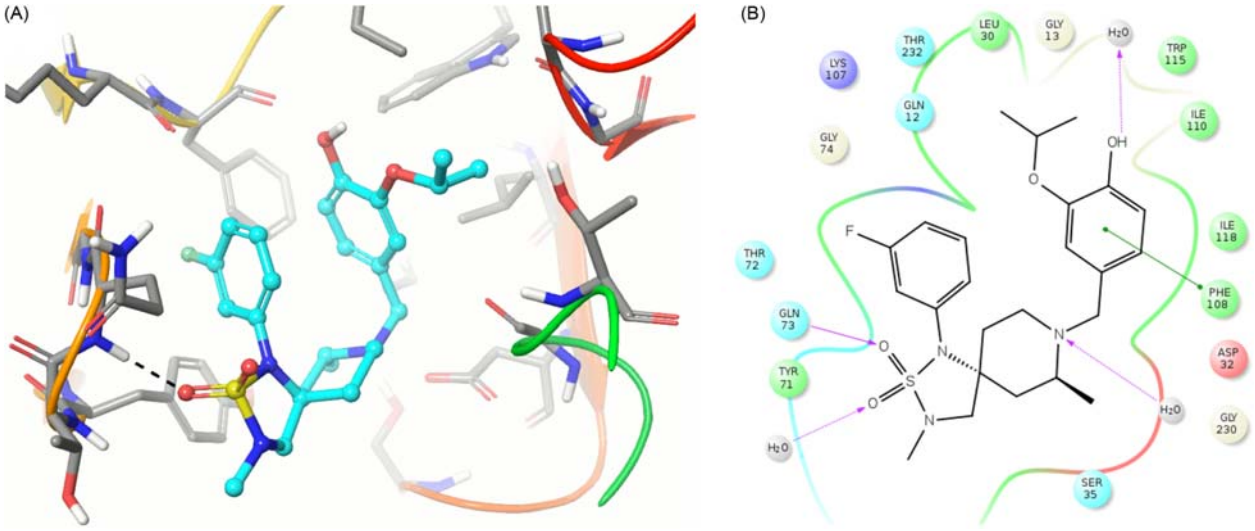

Fig. 34 (A) **125** bound to BACE showing key interactions and the folded conformation with intramolecular π-stacking (PDB code 4FM7). (B) Residues around **125** with interactions.

A two-part PhI study was initiated in Sep. 2011, commencing with a SAD study at doses of 25, 100, 250, and 525 mg[151] which demonstrated lowering of plasma amyloid at 250 and 325 mg[152] (note discrepancy between higher doses quoted in two references). This was followed by a human PK/PD study measuring CSF amyloid levels after the Maximum Tolerated Dose (MTD) of 325 mg.[151] Unfortunately, it was found that the maximum tolerated dose of 325 mg did not result in sufficient reductions in CSF amyloid levels, despite showing robust effects on plasma amyloid.[151] Based on this data, the progression of **PF-05297909** was terminated and the search for a compound with increased potency and CNS penetration was initiated, which resulted in a change of chemotype (see later).

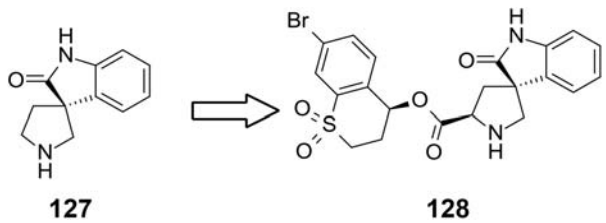
7.08.16.2 Spiropyrrolidine Derivatives

The group from Pfizer also described a somewhat related spiropyrrolidine series, where the amine moiety was found to directly interact with both of the catalytic aspartic acids. This series was discovered through an X-ray fragment screen which produced a single hit, **127** (Fig. 35), with an estimated K_D of 1.4 mM, LE 0.31 kcal/mol/atom.[153] Elaboration via SBDD culminated in the identification of **128** (Fig. 35), with a K_D of 1 μM, determined by NMR, and a cellular IC_{50} of 4 μM.

This work highlights the challenges in the identification of highly potent BACE inhibitors and demonstrates the criticality of optimal binding interactions with the catalytic aspartic acid diad in order to be able to deliver compounds of sufficient potency.

7.08.16.3 Isothioureas and Related Derivatives

Having initially preferred alternative chemotypes, it was only latterly that Pfizer turned to the amidine derivatives in order to improve potency, focusing on the isothiourea/aminodihydroisothiazine class. A recent publication details their initial work, whereby they chose to avoid the S1/S3 subpocket of BACE, occupied by the aryl amide of most compounds, in order to try to increase CNS penetration. To this end, it was found that a THP-fused aminodihydrothiazine allowed the appendage of groups to interact with the flap region (see later), and resulted in the identification of **129** (Fig. 36).[154] **129** shows low P-gp efflux and good CNS penetration in the mouse, Br_u:Pl_u 1.42. In vivo efficacy was demonstrated in the rat (brain and CSF) at doses of 10 and 150 mg/kg s.c., whereby both doses achieved a seemingly maximal reduction of brain amyloid, ~70% but the higher dose



127 **128**

Fig. 35 Summary of fragment hit, **127**, from X-ray fragment screen and optimization to **128**.

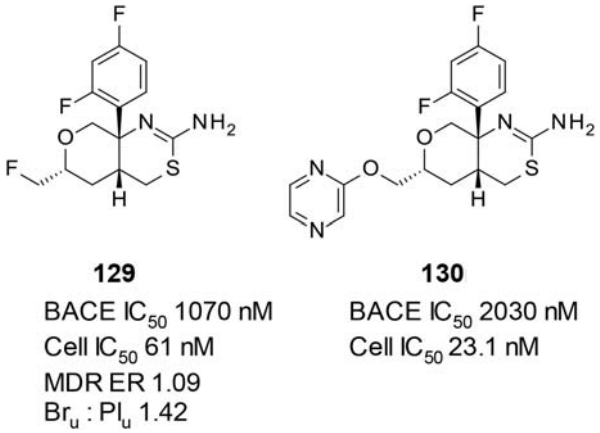


Fig. 36 Initial THP-fused isothiourea derivatives from Pfizer.

resulted in a more sustained reduction. The effect on CSF amyloid levels was somewhat stronger than the brain. This resulted in an efficacious free brain concentration of 371 nM. A single dose of 18 mg/kg p.o. to the dog resulted in up to 74% reduction in CSF amyloid levels compared to vehicle. In transgenic PS1/APP mice (8–9 months of age), a dose of 30 mg/kg s.c. lowered CSF $A\beta_{40}$ by 79%. A further study in transgenic PS1/APP mice at 100 mg/kg p.o. for 2 months (starting from 6.5 months of age) using two photon imaging demonstrated that **129** was able to prevent plaque growth. Finally, a 14-day rat toxicology study with **129**, at doses of 25 and 75 mg/kg, indicated no overt toxicity and no retinal toxicology. These data indicate the potential of this series to yield a safe and efficacious compounds suitable to progress to clinical evaluation, however the group noted that an enhancement in potency was required compared to **129**. Many groups have speculated that this phenomenon is due to compounds displaying higher concentrations in the lysosome, where BACE is located, due to the acidic nature of this compartment.

The structure of **129** bound to BACE has been published and is shown in Fig. 37. The binding mode is similar to other structures with the isothiourea binding to the catalytic aspartates, and **129** has also been the subject of a patent application,[155] along with several related analogs that represented initial attempts to interact with the flap region, including ether-linked heterocycles such as **130** (Fig. 36).[156] Interestingly, both compounds display weak activity in a BACE enzyme assay, but significantly improved activity in a cellular assay, **129** showing 17-fold improved activity and **130** displaying nearly 100-fold more potent activity in a cellular assay.

Subsequent patent applications have detailed addition of aromatic groups in place of the fluoromethyl group in **129** which resulted in a significant increase in potency. Examples include **131** (Fig. 38),[157] which maintains the 2,4-difluorophenyl ring and adds the 4-pfluorphenyl ring on the THP ring. Interestingly, in addition to showing potent cellular activity, these derivatives

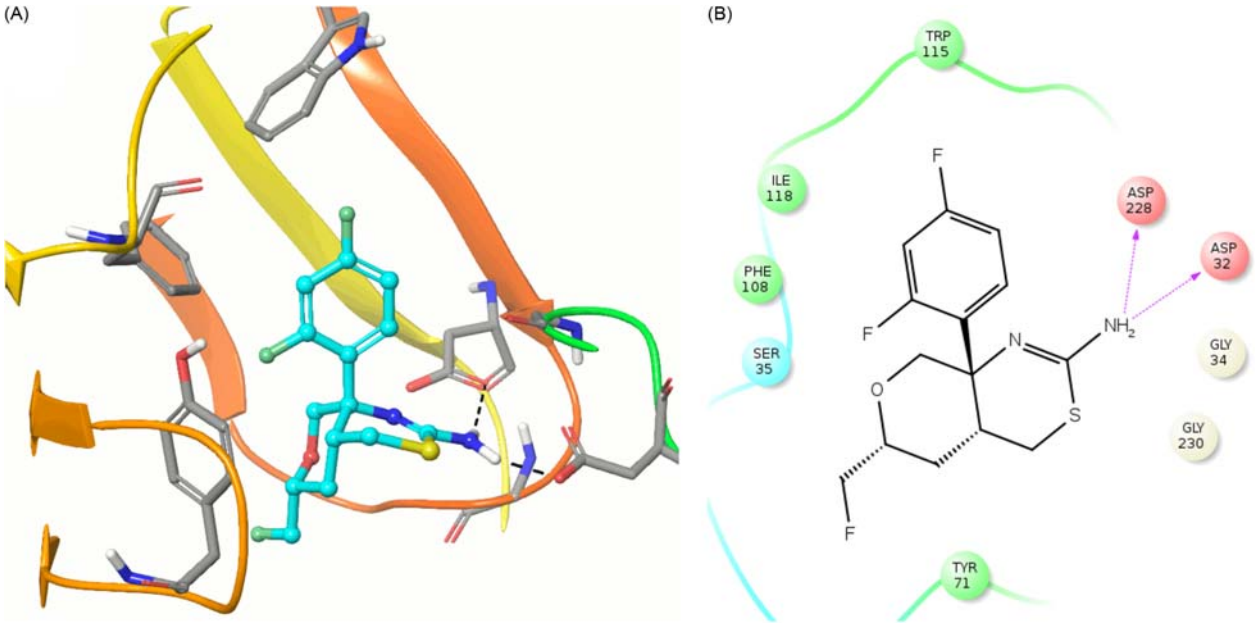

Fig. 37 (A) Crystal structure of **129** bound to BACE (PDB code 4WY6). (B) Depiction of residues interacting with **129**.

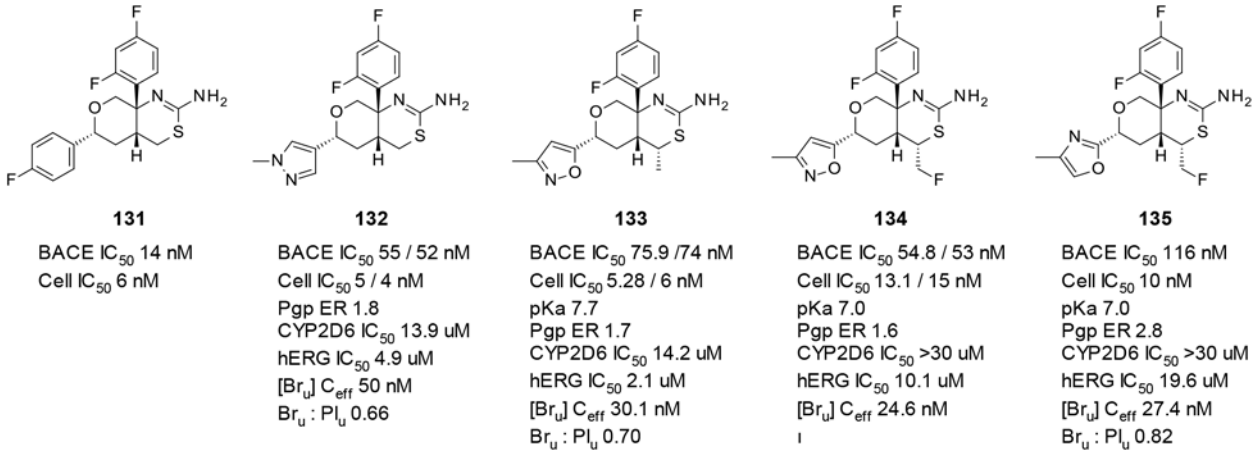

Fig. 38 Follow-on THP-fused isothioureas from Pfizer. Note, there is a slight discrepancy between biological data reported in the patent literature and journal literature for some compounds, for example, **132**, **133**, **134**. Where this is the case the patent literature data is reported first, followed by the peer-reviewed literature data.

also show potent inhibition in a BACE enzyme assay, which is in stark contrast to initial derivatives such as **129** and **130**. It appears that 5-membered heteroaryl groups are particularly preferred. In particular, the methyl pyrazole derivative, **132** (Fig. 38)[158] has been the subject of a recent publication[159] where it has shown a very good overall profile with low P-gp efflux (ER 1.8) and good CNS penetration in the mouse, Br_u:Pl_u 0.66. In vivo efficacy was demonstrated in the mouse (brain and CSF) at doses of 10 and 50 mg/kg s.c. Maximal effects on $A\beta_{x-42}$ were observed 6 h postdose where the 50 mg/kg dose caused a 60% reduction and the 10 mg/kg dose demonstrated ~40% reduction in brain $A\beta_{x-42}$. Using indirect modeling, the free brain concentration to effect a 25% reduction in brain $A\beta_{x-42}$ at steady state ($[Br_u]$ C_{eff}) was calculated to be 50 nM, which would require a free plasma concentration of 76 nM. It should be noted that this is the concentration to reduce brain amyloid levels by 25%, which many believe would be the minimal amount necessary, and it may optimally be able to reduce amyloid levels by at least 50% or 90%. However, it was found that **132** undergoes oxidative demethylation by CYP2D6. The desmethyl metabolite is a weak BACE inhibitor (BACE IC_{50} 599 nM), but a potent CYP 2D6 inhibitor (IC_{50} 370 nM). The deuteromethyl analog is described in a subsequent patent application,[160] presumably in an attempt to slow demethylation. **132** was crystallized with CYP2D6 and this information was used to identify additional analogs, which resulted in the addition of a methyl group on the aminodihydrothiazine ring which reduces CYP2D6 binding by virtue of a steric clash and thus results in decreased metabolism. Switching the N-methyl pyrazole to the 3-methyl isoxazole to give **133** (Fig. 38) is well tolerated and as the methyl group is no longer attached to a heteroatom, demethylation cannot occur. However, it is not known if the methyl on the isoxazole is still oxidized and whether this leads to the formation of an active metabolite. Replacement of the methyl group on the dihydrothiazine ring by a fluoromethyl group resulted in the optimized derivatives **134** and **135** (Fig. 38). Both compounds retain the desired BACE activity and low P-gp efflux, while having lower hERG and CYP2D6 inhibition. Furthermore, both compounds maintain good levels of CNS penetration in the mouse and also satisfactory $[Br_u]$ C_{eff} levels. As a result of these data, both **134** and **135** were progressed to long-term safety studies.

The structure of **132** bound to BACE has been published and is shown in Fig. 39. Overall the binding mode is very similar to **129** (Figs. 36 and 37).

A related patent application has detailed nonaromatic groups, such as the THF-derivative **136** (Fig. 40),[161] although this results in a significant drop in potency, both in enzymatic and cellular assays. It is not known whether these derivatives show improved metabolic stability or whether the newly installed THF ring is subjected to oxidation.

The latest set of derivatives from this series was also disclosed in a 2014 patent application.[162] Key compounds, such as **137** and **138** (Fig. 40), maintain the methyl pyrazole and methyl isoxazole respectively but include the benzonitrile rather than the difluorophenyl of previous examples. One further prominent example, **139** (Fig. 40), has a substituted benzylamine moiety, presumably to try to pick up the HBD interaction with Gly120.

In Oct. 2015, a patent application disclosed a series of thiazole amides with comparative data showing advantages over close analogs,[163] including examples disclosed by Eisai, "Inhibitors Reported by Genentech/Array BioPharma" section. The most prominent examples, **140** and **141**, are detailed in Table 6. Both compounds show potent activity while balancing CYP2D6 and hERG activity with low P-gp efflux. In addition, both show low clearance in human hepatocytes. The ability to balance the profile is attributed to the thiazole which reduces the basicity, as denoted by pK_a, of the isothiourea. Although the regioisomeric thiazole, **142**, has a similar pK_a, it is almost inactive at BACE. Interestingly, while maintaining the same pK_a as **141**, **142** appears to be a stronger P-gp substrate. Comparative examples from Pfizer, (**143**) and Eisai (**54**), Table 6, show that these analogs with a central fluorophenyl ring in place of the thiazole have a worse overall profile, most notably in terms CYP2D6 and hERG inhibition, which may be due to the stronger basicity of the isothiourea in these analogs. Furthermore, **143** shows stronger P-gp-mediated efflux and both

Table 6 Summary of the latest key compounds from Pfizer

Compound	**140**	**141**	**142**	**143**	**54**
Structure					BACE1 IC_{50} (nM)	41	33	>100,000	3	1
Cell IC_{50} (nM)	5	4	13600	<1	<1
CYP 2D6 IC_{50} (μM)	>30	>30	15% I @ 3 μM	<0.030	<0.030
hERG IC_{50} (μM)	9.9	9.0	11.97	0.4	0.2
Pgp ER	2.2	2.4	7.1	5.1	3.0
pK_a	6.8	6.9	7.0	8.3	8.7
GSH trapping	Negative	Negative	Not determined	Not determined	Not determined

143 and **54** display higher clearance in human liver microsomes. Finally, it is also pointed out that compounds such as **143** and **54** contain an aniline structural alert, whereas **140** and **141** do not. Whilst this is correct, both **140** and **141** contain an aminothiazole, which may also present the same (mutagenic) risk as the aniline fragment. Hence, despite a lot of effort spent on nonamide derivatives, it seems the Pfizer group may have come full circle and ended up with an amide derivative as their best compound.

Currently, inspection of the Pfizer development pipeline indicates three compounds undergoing phase 1 trials for AD. Of these, PF-02521729 has completed a single Phase 1 study, but does not appear to affect the amyloid pathway as no measurement of amyloid species was undertaken. PF-06648671 appears to be a γ-secretase modulator as the one trial aims to measure CSF levels of $A\beta_{37}$ and $A\beta_{38}$, in addition to $A\beta_{40}$ and $A\beta_{42}$, following a 300 mg dose. This trial is expected to complete in Mar. 2016. A third compound, PF-06751979, is undergoing a 14-day MAD study, which will assess CSF Aβ fragments including $A\beta_{1-40}$, $A\beta_{1-42}$, Aβ total, $A\beta_{x-40}$, $A\beta_{x-42}$, sAPPα, and sAPPβ, indicating it to be a BACE inhibitor. Thus PF-06751979 could be represented by one of the above structures, quite possibly **140**.

In summary, it is evident that Pfizer have progressed at least two compounds to candidate selection and beyond. The piperidine series highlights some of the challenges and confirms the translatability of preclinical efficacy. Continued research from the group resulted in similar chemotypes to those described by other groups, however it appears that the sustained effort has been rewarded by the identification of a compound which is currently undergoing clinical trials.

7.08.17 Inhibitors Reported by Roche

The group at Roche have devoted considerable effort to BACE for a sustained period of time, which has resulted in the publication of over 30 patents which cover a range of templates, including acylguanidines[164,165] (as BACE2 inhibitors), dihydroisothiazine/isothioureas (also initially as BACE 2 inhibitors),[166] 1,3-thiazepines/isothioureas[167] iminomorpholines, homo-iminomorpholines, as well as others. However, the majority of their effort has been directed toward dihydrooxazines/isoureas. The disclosed research also includes a collaboration with Siena Biotech.

The competition in the field is also evident, as Roche appear to have lost the battle to gain intellectual property on several templates, as will be discussed here.

The iminomorpholine/1,4-oxazines offer an interesting insight to the competiveness of the BACE field. The first patent from Roche on this template published on 24th Feb. 2011, just 4 weeks after a similar patent claiming the same core from Novartis, which published on 27th Jan. 2011, Novartis section. Pertinent examples in the Roche application include **144** and **145** (Fig. 41), which show potent in vitro activity.[168] It might be anticipated, from the key examples disclosed by Novartis and from the homomorpholine derivatives disclosed by Roche, that further control of the basicity of the guanidine moiety is necessary on this template. Follow-up application on the same template covered analogs with amide replacements[169] and biaryl derivatives with an additional aryl ring in place of the methyl group.[170]

A subsequent series of patent applications described examples with a homologated ring template, namely the homomorpholines or 1,4-oxazepines. Pertinent examples from the key patent application are exemplified by **146**, **147**, and **148** (Fig. 41), which contain additional fluorine atoms to reduce the basicity of the guanidine moiety.[171] Related examples with amide surrogates were the subject of subsequent disclosures,[172,173] as well as biaryl derivatives.[174]

The mainstay of work from Roche has been directed to the isourea/1,3-oxazine series, from which at least 16 patent applications have been disclosed. An early patent application described biaryl derivatives with a 5-membered ring isourea, but these derivatives had weak in vitro activity.[175] The next patent application in this series described the simple 6-membered ring isourea/1,3-oxazine derivatives, as denoted by **149** (Fig. 42).[176,177] In addition, one example detailing a fused THF-derivative, **150** (Fig. 42), was also disclosed. Hence, it appears that Roche may have been in the process of investigating the THF-fused analogs when a patent

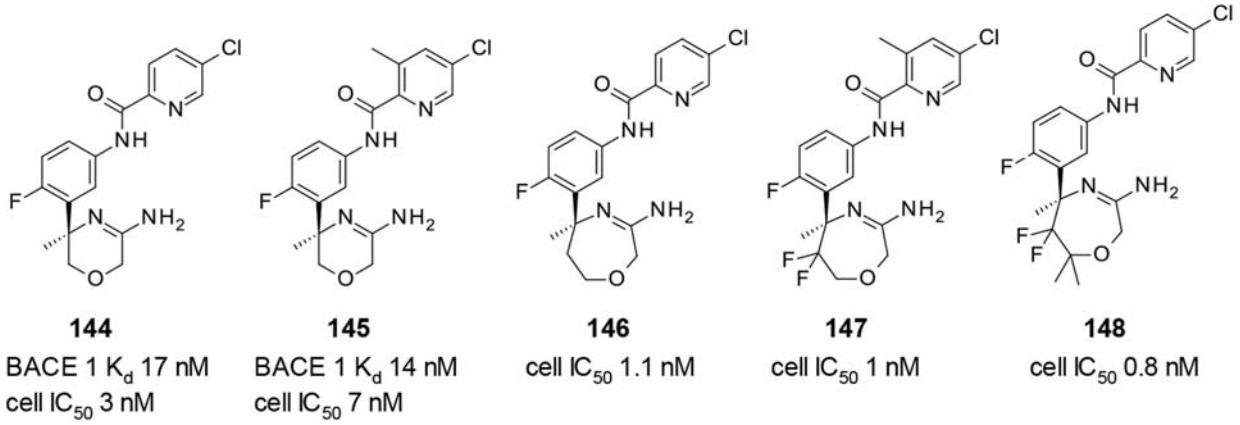

Fig. 41 Early chemotypes from Roche, including iminomorpholines **144** and **145**, and the homologous derivatives **146–148**.

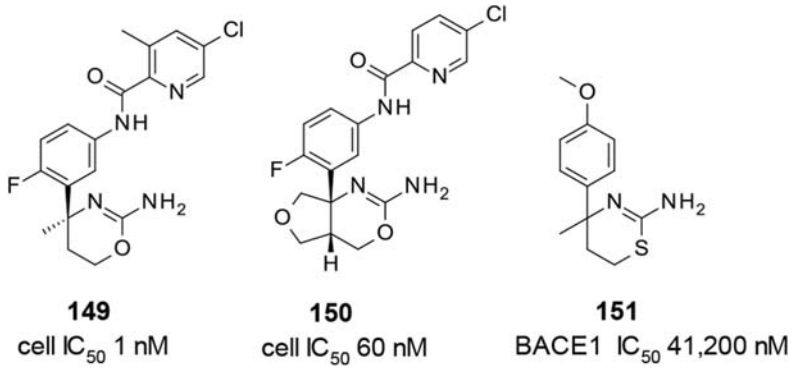

Fig. 42 Early isoureas from Roche, **149** and **150**, with HTS hit, isothiourea derivative **151**.

published from Eisai, claiming the same compounds—Eisai patent application published on 11th Jan. 2011, whereas the Roche case published on 16th Jun. 2011, Eisai section. Again, this highlights the extreme competiveness of the field.

A recent manuscript describes an overview of the Roche BACE research project, including the identification of the hit matter, that is, isothiourea derivative **151** (Fig. 42), which originated from an HTS campaign. It is noted that **151** had been synthesized more than 30 years ago as part of an analgesic project. This is one of the few HTS campaigns to identify any hits. It may have been easy to overlook **151** due to its weak potency, however, in the context of fragment hits, this compound displays good LE, 0.41 kcal/mol/nonhydrogen atom.[178,179] The manuscript details many of the subseries and the effect of degrees of fluorination on the basicity of the isourea as well as in vitro and in vivo potency.[180] The unfluorinated 1,3-oxazine was found to be strongly basic, pK_a 9.8, which resulted in weak in vivo activity. Addition of 2-fluorine atoms was found to reduce the pK_a of the isourea moiety by 2.5 log units. The reduction in pK_a was found not only to improve in vivo activity, via reduction of P-gp-mediated efflux, but also to reduce hERG and CYP2D6 activity. The basicity could be decreased substantially without negatively impacting potency, compounds with pK_a 5.8 still showed potent enzyme and cell inhibition, whereas when the pK_a reached 5.1 this appeared to have a negative impact on cellular activity with an approximate drop of 20-fold. Prominent examples from this article are shown in Fig. 43 and include **152** (**RO5508887**),[181] **153**, **154** (pK_a 7.0, P-gp ER 1.9, hERG: 75% inhibition at 10 μM),[182] **155** (pK_a 6.3, P-gp ER 1.6, hERG: 39% inhibition at 10 μM),[183,184] (two separate patent applications), and **156** (pK_a 5.9, P-gp ER 1.5, hERG: 48% inhibition at 10 μM)[181] which have been described in patent applications. All compounds displayed potent in vivo activity, by reduction of brain Aβ_{40} in the mouse 4 h postoral dose of 10 mg/kg; **152** (**RO5508887**) 78%, **153** 66%, and **155** 88%. Furthermore, two compounds produced efficacy at lower doses: **154** 78%, 88%, and 95%; **156** 41%, 71%, and 93% reductions at 1, 3, and 10 mg/kg, respectively. Despite the strongest efficacy, **154** did not appear to be profiled further, perhaps because of its hERG inhibition. Instead, **152** (**RO5508887**) was studied in further detail. A single time point (4 h) dose–response study in the mouse revealed strong efficacy with approximately 32%, 78%, 95%, 97%, and 99% reductions in brain Aβ_{40} at doses of 0.3, 1, 3, 10, and 30 mg/kg and good CNS penetration, with Br:Pl 1–1.5 (0.3–3 mg/kg) and 2.3–3.4 (10–30 mg/kg). In a rat time course study, an oral dose of 1 mg/kg produced robust reductions in CSF Aβ_{40} and Aβ_{42} levels, with maximal reductions of around 70% 4–8 h postdose. PK/PD modeling resulted in a free plasma/brain EC_{50} of 20 nM which corresponds well with the cellular activity, IC_{50} 12 nM. In addition,

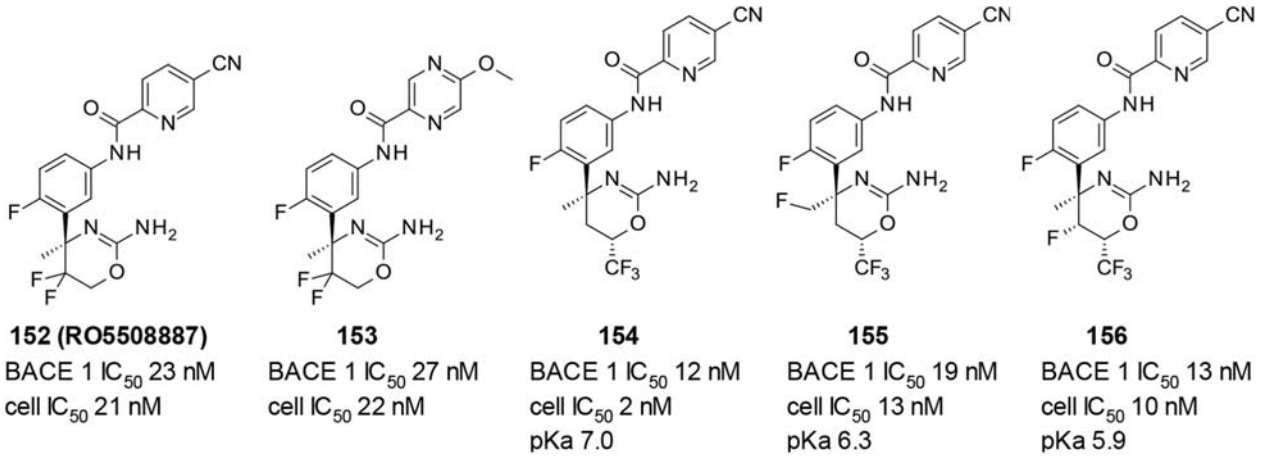

Fig. 43 Further isourea derivatives from Roche with varying degrees of fluorination.

152 (**RO5508887**) was found to have an acceptable PK profile in the rat, CL 16.8 mL/min/kg, Vdss 11.5 L/kg, $t½$ 8.9 h, and Fpo 68%. The compound appeared free of CYP450 liabilities with $IC_{50} > 25$ μM at 2C9, 2D6, and 3A4. Further pharmacological characterization of the compound has been described recently.[185] Cellular activity was confirmed in rat cortical neurons, IC_{50} 55 nM, showing considerably weaker activity than Eisai compounds in a similar same assay ("Inhibitors Reported by Genentech/Array BioPharma" section). Characterization in APP transgenic mouse models revealed similar efficacy in APP_{Lon} mice to wild-type mice, but much weaker efficacy in APP_{Swe} mice, presumably due to the increased propensity for APP_{Swe} cleavage by BACE. When dosed chronically (4 months) to APP_{Lon} mice, 13–14 months of age, **152** (**RO5508887**) reduced brain $Aβ_{42}$ by 28% and 69% and $Aβ_{40}$ by 45% and 69% at doses of 30 and 90 mg/kg, respectively. CSF amyloid was measured at several time points and revealed near complete reduction (almost equivalent to untreated wild-type mice) of $Aβ_{40}$ and $Aβ_{42}$ 5 h postdose. CSF amyloid levels had almost returned to baseline 8 h postdose, whereas the higher dose resulted in sustained (70–80%) reductions 8 h postdose. A dose proportional reduction in plaque area and number was seen in the cortex and hippocampus, however both measurements exceed the baseline values at the start of the study, indicating the BACE inhibitor treatment did not fully prevent new plaque formation. Based on these data, **152** (**RO5508887**) was selected as a development candidate and advanced to clinical trials (see later).

Several of the Roche compounds have been crystallized with BACE, including **152** and **154**. The structure of **154** is shown to illustrate the binding mode, with is similar to other BACE inhibitors which contain an anilide, with the anilide NH donating a hydrogen bond to the Gly230 carbonyl and the picolinamide moiety extending into the S3 pocket (Fig. 44).

In addition to these compounds, further analogs have been described with varying degrees of fluorination, for example monofluorination (rather than difluorination at the 5-position)[186] have been disclosed. A further patent application discloses derivatives where the fluorophenyl ring has been replaced by a fluoropyridine, for example, **157** (Fig. 45).[187] As mentioned under the Novartis

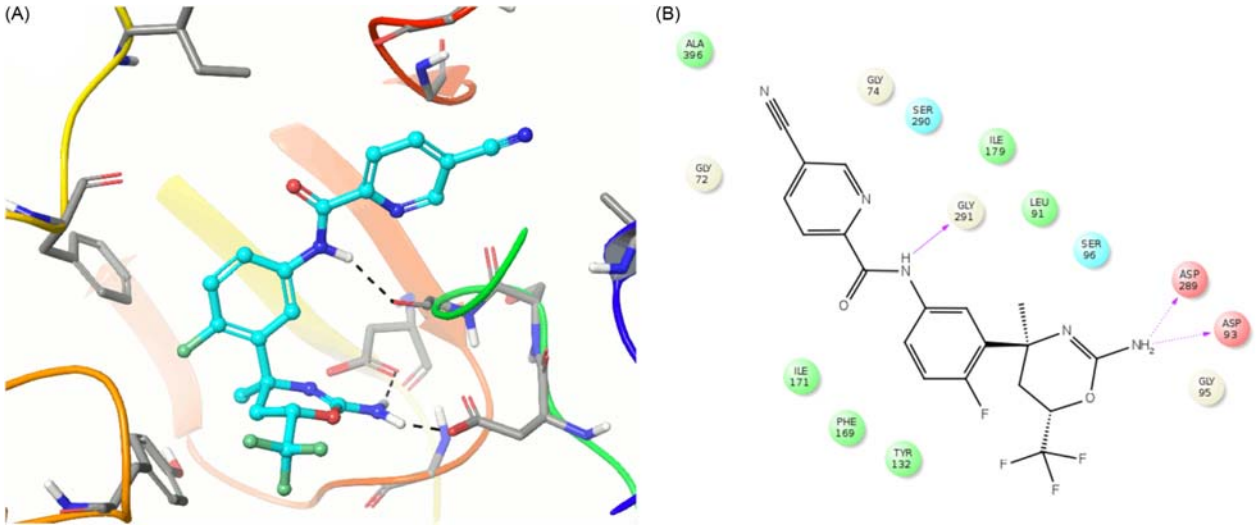

Fig. 44 (A) **154** bound to BACE (PDB code 4J1F). (B) Depiction of key residues interacting with **154**.

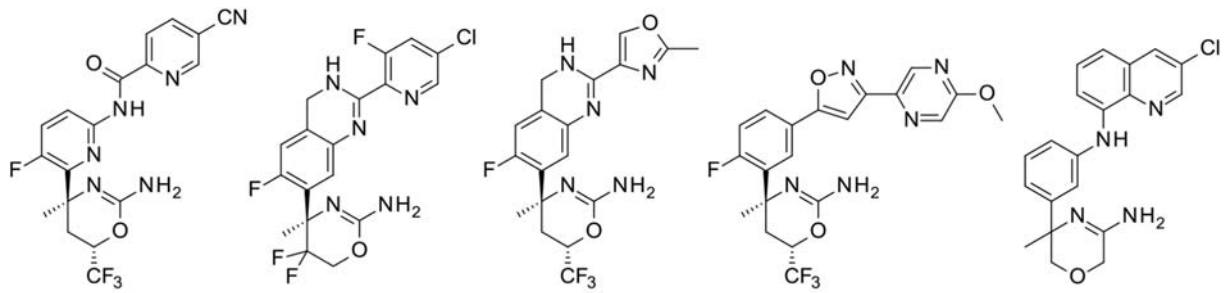

Fig. 45 Isourea derivative, **157**, with a central pyridine ring, isourea derivatives with amide isosteres, **158** and **159**, isourea **160** which lacks the amide and iminomorpholine derivative **161** with amide isothere.

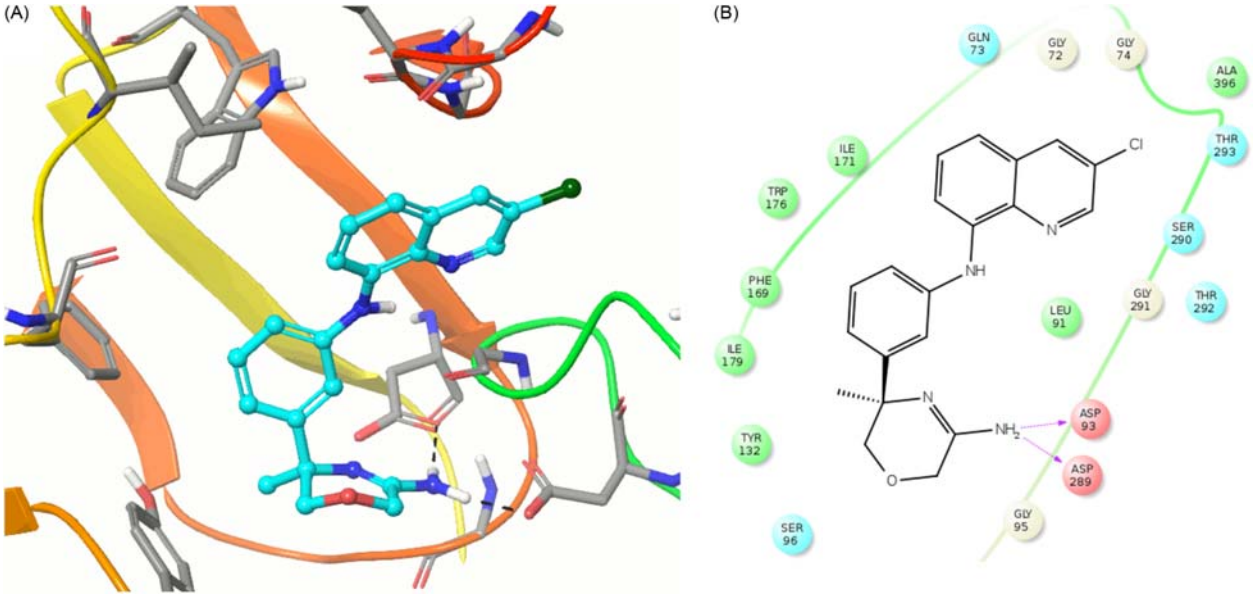

Fig. 46 (A) Binding mode of **161** with BACE (PDB code 5F00). (B) Depiction of vicinal residues to **161**.

section, the Roche patent published just over 18 months (10th Oct. 2014) after a similar patent from Novartis (28th Feb. 2013). Several patent applications also describe examples where the amide has been replaced by various groups,[188] the most pertinent include the dihydroquinazolines **158**[189] and **159**[190] as well as the isoxazole **160**,[191] Fig. 45. It is claimed that derivatives such as **158** are sufficiently basic, pK_B 7.15, that they are protonated when bound to BACE and therefore mimic the amide by being able to act as HBDs. Taken together, these examples highlight the prominence of the 5,5-difluoro[1,3]oxazine and the 6-trifluoromethyl[1,3]oxazine templates.

A recent manuscript shows that compounds with amide isosteres, such as iminomorpholine **161** (Fig. 45) can bind to BACE in the same manner, and make the same interactions, as their amide counterparts.[192] The binding mode of **161** is depicted in Fig. 46. Closely related analogs to 161 have been described by Novartis, "Inhibitors Reported by Novartis" section, compounds **117** and **118** (Fig. 32).

Other compounds of note include the PET ligand **162** (Fig. 47).[193] This compound was tritium labeled for in vitro autoradiography studies in the Sprague–Dawley rat which showed widespread binding in the brain, but highest density in the dentate gyrus and CA3 regions of the hippocampus, cerebellum, pallidum, and substantia nigra. Similar binding was seen in both monkey and human brain slices. Furthermore, the in vitro data was confirmed ex vivo in the rat. The methyl group on the acetylene was labeled

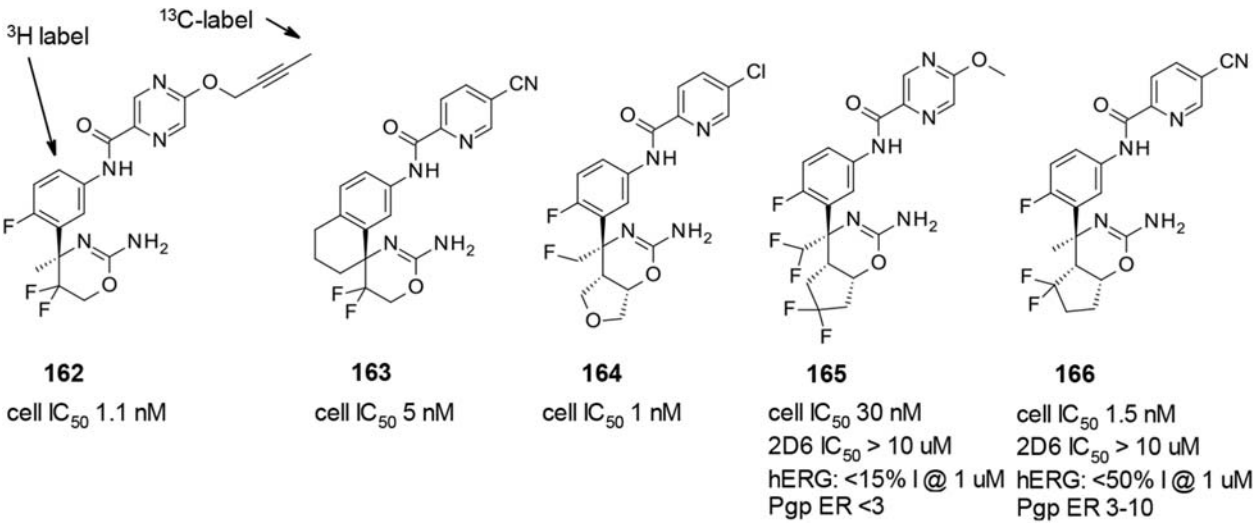

Fig. 47 Radiolabelled isourea derivative **162**, spirocyclic isourea derivative **163**, and fused-isourea derivatives **164–166** from Roche.

with ^{11}C to enable in vivo PET studies in the baboon, which showed very similar results to the rat studies. While this data appears encouraging, it is unclear if this ligand offers sufficient signal to noise and whether any further studies were conducting in humans. In addition, several companies have shown that it is possible to reduce CSF Aβ in humans, thus providing target engagement and disease biomarker modulation, thereby limiting the need for PET enzyme occupancy studies.

Spirocyclic derivatives have also been the subject of a patent application, for example, **163** (Fig. 47). A range of ring sizes were investigated in this series, thus both 5- and 6-membered rings, that is, indane and tetralin substructures, were assessed with the indanes yielding weaker activity. Similarly, 6-membered isoureas proved better than the homologous 7-membered counterparts. Thus, although **163** shows potent in vitro activity, the series appears to be generally weaker that other series.[194]

Although the intellectual property for the initial THF-fused [1,3]oxazines/isoureas may have been secured by Eisai, Roche found additional ways to fuse a 5-membered ring to the [1,3]oxazine template, yielding the bicyclic THF series exemplified by **164**,[195] Fig. 47, and the analogous series where the THF has been replaced by a difluorocyclopentyl ring, such as **165** (Fig. 47).[196] In addition to potent in vitro activity, examples such as **165** were found to have weak CYP2D6 activity and P-gp efflux as well as moderately weak hERG inhibition and >50% lowering of Aβ in vivo after a 30 mg/kg dose (no further details described). Finally, the isomeric-fluorinated cyclopentyl derivatives have also been described, as exemplified by **166** (Fig. 47).[197] This series displayed almost identical in vitro activity to the regioisomeric series, in vivo activity also appears good (>70% reduction of Aβ) however, P-gp ER and hERG may not have been as good.

Latterly the group at Roche have returned to amidine and guanidine moieties as the key warhead motif and control the basicity coming from a moiety in the beta-position, for example, β-sulfonyl amidines such as **167** (Fig. 48),[198] which is closely related to compounds from Schering-Plough/Merck ("**Inhibitors Reported by Schering-Plough/Merck**" section), such as **189** (Fig. 52). The patent application covering these derivatives from Roche published on 18th Nov. 2013, with an initial application date of 24th May 2012, some 5 months before the publication of the Schering-Plough/Merck application, which published on 18th Oct. 2012. Interestingly, several identical compounds are exemplified by both applications. The corresponding 7-membered homologs appear somewhat weaker in terms of in vitro activity.[199] It is not known whether the basicity of the amidine is sufficiently tempered in this series, however no further fluorination to this end has been disclosed. Replacement of the sulfone moiety by a sulfoxime with concomitant cyclization has yielded some potent compounds with in vivo activity, for example, **168** and **169** (Fig. 48).[200] Interestingly, all four stereoisomers of **168** were prepared and tested in vitro and in vivo. While all four compounds (S- and C-atom α- to the

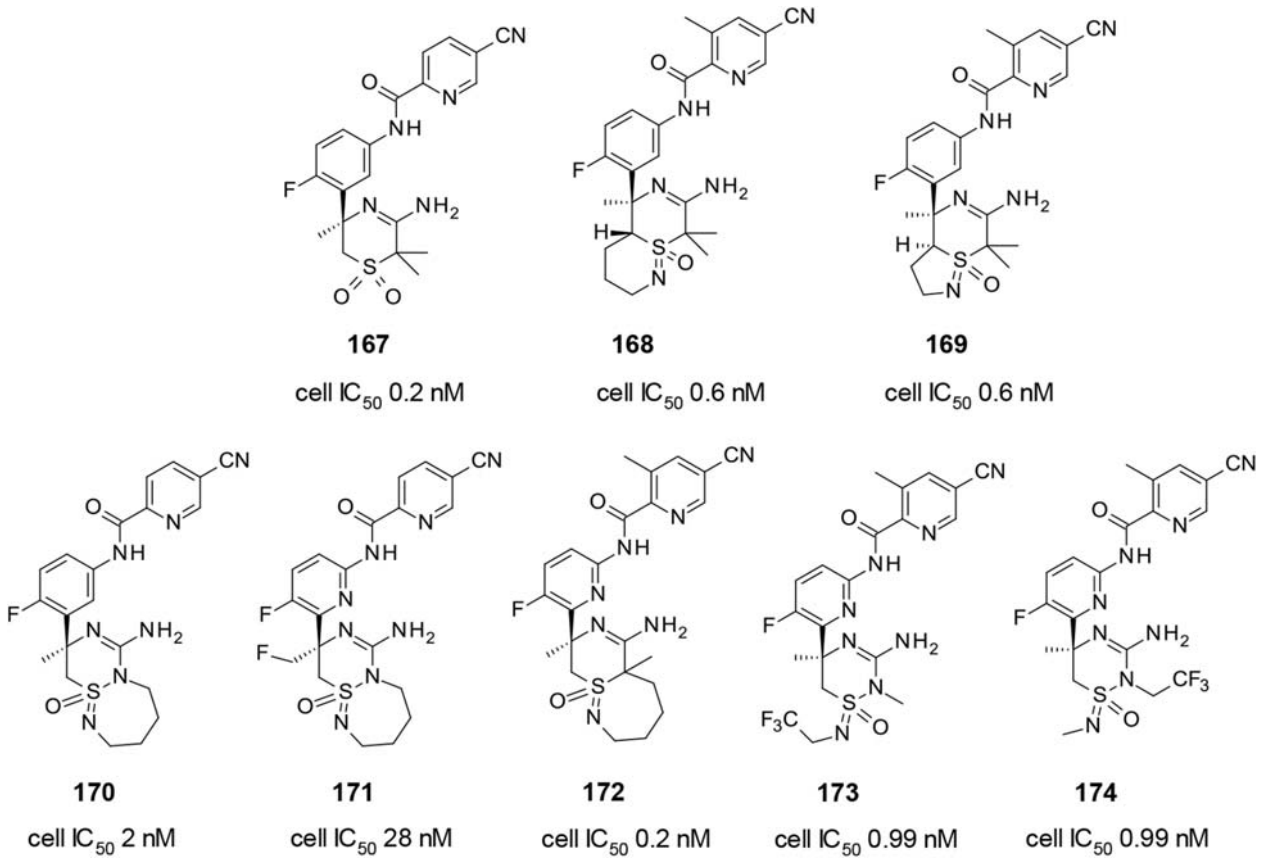

Fig. 48 Amidine derivatives containing sulfone (**167**) and sulfoximine groups (**168** and **169**) and bicyclic analog (**172**). Sulfoximinylguanidine derivatives (**173** and **174**) including bicycles (**170** and **171**).

sulfur) displayed similar in vitro activity, only **168** showed good levels of in vivo activity in the mouse, reducing Aβ in the brain by 62% 4 h after a 30 mg/kg oral dose. Furthermore, when in the fused 5-membered ring analogs, such as **169** (Fig. 48), the stereochemistry at the C-atom α- to the S-atom is inverted. Again, **168** showed potent in vivo activity, causing a 60% reduction in brain Aβ 4 h after a 30 mg/kg dose in the mouse.

The next iteration of analogs has described sulfoximinylguanidines containing a fused alkyl ring linking the guanidinyl N-atom to the sulfonimidamide N-atom. Examples have been described with both a central fluorophenyl ring, for example, **170**,[201] and with a central fluoropyridyl ring, for example, **171** (Fig. 48),[202] although the latter appear to have significantly weaker in vitro activity in general. A follow-on patent application has described analogs of **171** where the bridgehead N-atom has been replaced by a C-atom, resulting again in an amidine warhead, for example, **172** (mixture of diastereomers) (Fig. 48).[203] Despite showing potent cellular activity, these derivatives show comparatively weak in vivo activity; a 30 mg/kg oral dose of **172** resulted in a 52% reduction of brain $A\beta_{40}$ in the mouse. Monocyclic sulfoximinylguanidines, such as **173** and **174** (Fig. 48), have also been described.[204] It is noteworthy that control of basicity can be achieved by substitution on the N-atom of the sulfonimidamide (**173**) or on the guanidine N-atom (**174**), even though the latter may no longer be basic.

Thus, this analysis demonstrates the significant commitment the Roche group have invested in the BACE field. The work has delivered several compounds which appear to have good overall profiles, balancing primary activity with off-target activities, such as hERG, CYP2D6 inhibition while simultaneously minimizing P-gp efflux. Although it is not possible to assess how many compounds have entered preclinical development, or even progressed into toxicological studies, to date it appears only one compound has entered clinical development, namely **RO0550887** (**152**, presumed to be RG7129). This compound entered clinical trials in Oct. 2011, completing SAD studies which measured plasma PK and $A\beta_{1-40}$ and $A\beta_{1-42}$.[205] A PhI MAD study commenced in Jul. 2012, which measured similar parameters following daily administration for up to 30 days.[206] A PK/PD study commenced in May 2012, measuring plasma and CSF amyloid following a single oral dose in healthy volunteers has also been conducted.[207] The development of **RO5508887** was terminated in 2013. The reasons have not been disclosed, although there were rumors it was due to liver toxicity. Roche have remained highly committed to the BACE field but so far, despite several compounds displaying at least similar profiles to **RO5508887** no compounds have entered clinical development. In the meantime, the field has advanced significantly which now leaves Roche perhaps too far behind.

7.08.18 Inhibitors Reported by Schering-Plough/Merck

7.08.18.1 Early Peptidomimetic Inhibitors

Before the merger of Merck and Schering Plough, both companies had independent programs aimed at BACE inhibitors, with early efforts mainly directed toward HEA peptidomimetic BACE inhibitors, as exemplified by TC-1 (4, Fig. 3), as discussed in the "Introduction" section. Merck explored isophthalamide derived subseries, which generally suffered from strong efflux and lacking central activity in vivo models. In addition to compounds such as TC-1 (**4**), Schering has also explored isophthalamide HEA inhibitors, with the amine conformationally restrained into various saturated heterocycles, such as pyrrolidine **175**[208,209] and piperazinone **176** (Fig. 49).[210] Although potent BACE1 inhibitors were obtained, cellular activity was suboptimal, and in vivo central Aβ lowering could not be achieved.

7.08.18.2 Spiropiperidine Derivatives

Moving away from the HEA-type inhibitors, Merck has reported on a series of aminohydantoin spiropiperidine inhibitors, originating from a high-throughput screening.[211] In this series, exemplified by **177** (Fig. 49), the key interaction with the catalytic aspartic acid residues takes place via hydrogen bonding of the protonated piperidine nitrogen through intermediary water molecules. Modeling indicated that the actual ligand-bound conformation is a relatively high energy conformation. Substitution of the piperidine with a 2-methyl group induced a favorable conformational restraint stabilizing the bioactive conformation and optimized the occupation of the binding pocket, resulting in a 200-fold potency increase compared to the desmethyl analog.[212] The binding mode of **177** to BACE is similar to that of compounds **124** and **125**, Table 5 and Fig. 34, from Pfizer.

7.08.18.3 Amidine and Guanidine Derivatives

The efforts of the Schering group have subsequently also evolved around nonpeptidic BACE1 inhibitors. Fragment-based NMR screening led to the identification of the isothiourea fragment hit **178** (Fig. 50), which displayed an optimal hydrogen bond donor–acceptor interaction with the catalytic aspartate dyad in BACE1.[213,214] Guided by structure-based design, fragment **178** was evolved into diphenyl iminohydantoin **179** (Fig. 50), a fragment with high LE also identified and used by other companies (Amgen, AstraZeneca, Wyeth).[215] In fact, the amidine containing heterocycle motif has since then become the main focus in BACE inhibitor design offering optimal vectors toward P1, P3, and P2′, and seems to have completely taken over the more classical transition state inhibitor approaches. Expansion of **179** into the S3 pocket led to the high-affinity iminohydantoin **180** (Fig. 50).[216] In rat, this compound was shown to have reasonable brain penetration with a Br:Pl of 0.3 and was able to reduce CSF $A\beta_{40}$ by 54% after a single oral dose of 30 mg/kg. The reduced cellular activity of **180** compared to the enzymatic activity was addressed by increasing the pK_a of the basic amidine via ring-expansion of the aminohydantoin core into a slightly more basic 6-membered amino-dihydropyrimidinone. An increased pK_a should lead to accumulation of the compound into the acidic endosomes where BACE1 is acting. In addition, to the change in pK_a, by adding an additional sp^3 carbon the orientation of the substituents into P1 and P2′ is also affected. Larger groups such as the cyclopropyl in **180** or aryl in **179** now tend to clash with Ile 118 so smaller substituents like methyl are therefore optimal. Optimization of the aminodihydropyrimidone series led to the highly ligand efficient inhibitor **181** (Fig. 50), with in rat a further enhanced Br:Pl ratio and in vivo efficacy, showing 81% reduction in CSF $A\beta_{40}$ after a 10 mg/kg oral dose.[217]

Fusion of the aminodihydropyrimidone heterocycle with N-substituted pyrrolidine allowed targeting of the S2′ pocket.[218] A first round of exploration led to **182** (Fig. 50), which occupies both S1–S3 and S2′ pockets. Although **182** did show central amyloid lowering in rats, efficacy was reduced compared to **181**. Overall the size and PSA of this molecule rendered the properties unsuitable for a CNS drug, having modest brain penetration, significant hERG inhibition, and time-dependent CYP3A4 inhibition attributed to bioactivation of the fluoropyrimidine moiety leading to a reactive metabolite. Further efforts were directed toward reducing molecular weight and lipophilicity via removal of the S3 targeting cyanophenyl group, and to regain activity via optimization of the S2′ group.[219] X-ray cocrystallization of **182** and analogs indicated a key hydrogen-bonding network with Trp76 via a water molecule in a subpocket termed S2″. Substitution of the pyrimidine with a 4-methoxy group led to a shift of the pyrimidine group in the S2′ pocket, allowing displacement of two conserved water molecules, and burying the methoxy substituent deeply in the S2″ pocket (**183**) (Fig. 50). The addition of a methyl substituent directed into S2′ enhanced the potency significantly and resulted in a reduction of the time-dependent CYP3A4 inhibition. The improvement on time-dependent CYP3A4 inhibition was attributed to increased steric demand around the pyrimidine or redirecting metabolism to the methyl substituent. These variations culminated with the identification of **183**, which was extensively profiled. Clearance in rat, dog, and monkey was relatively high, exceeding liver blood flow in rat and, which was attributed to low plasma stability in these species. Despite being a P-gp substrate (ER >30), **183** showed good CNS penetration in the rat, Br:Pl 0.8, and monkey, Br:Pl 3.2. However, when considering CSF exposure, the CNS penetration appears lower; rat CSF:Pl 0.008, monkey CSF:Pl 0.01, although it should be noted that the extent of ppb cannot be taken into account due to plasma stability issues. A rat dose–response study revealed $A\beta_{40}$ ED_{50} of 5.2 mg/kg (for effect in CSF) and 12.7 mg/kg (for effect in cortex), with complete reduction in both compartments seen at doses ≥ 30 mg/kg. In the monkey a 100 mg/kg oral dose resulted in a 77% reduction of CSF $A\beta_{40}$ after 24 h. In the same study, a 10 mg/kg dose resulted in a 22% reduction of CSF $A\beta_{40}$ after 12 h. In a separate, acute dose terminal study, a 10 mg/kg oral dose resulted in a 58% reduction in $A\beta_{40}$ in the cortex and a 35% reduction in CSF.

The binding mode of **183** to BACE is depicted in Fig. 51 and shows the acylguanidine interacting with the aspartic acid diad and the pyrimidine extending into the S2′pocket.

In a further extension of the amino-dihydropyrimide series, the planar carbonyl group in this heterocycle was replaced with a tetrahydral sulfonyl group, which was predicted to lead to an overall similar shape and orientation of substituents.[220] Indeed, this yielded equipotent iminothiadiazine dioxide compounds (**181** vs. **184**) (Fig. 50). The lower basicity of **184** compared to **181** resulted in a reduced cellular potency, but in vivo potency was enhanced, explained by an improved permeability and CNS penetration. **184** was not progressed further due to only modest Cathepsin D selectivity and formation of glutathione adducts, attributed to the propynylpyridine moiety. Replacement of this moiety with a substituted picolinamide group, as also seen in other BACE programs, strongly reduced Cathepsin D affinity, due to the CatD S3 subpocket being smaller than that in BACE1. BACE1 affinity was further increased fivefold via the introduction of a 6-fluoro-substituent, in analogy with the chloro-substituent in **184**. The pyridyl nitrogen is thought to play an important beneficial role by forming an internal hydrogen bond to the amide hydrogen. This allows an optimal coplanar conformation, positioning the picolinamide into S3, and the masking of the amide H-bond donor helped to enhance permeability and reduce efflux. As a consequence compounds such as **185** (Fig. 50) display robust CNS activity

in both rat and monkey, despite a rather high PSA (calculated at 115 $Å^2$), for a CNS drug. The Br:Pl ratio in rat for **185** was 0.57, again an improvement over the direct amino-dihydropyrimidine analog. In vitro, **185** inhibited the hERG channel with an IC_{50} of 2.2 μM, which was estimated to be sufficiently higher (~27-fold) than the projected human Cmax exposure levels. Combining all desired properties, **185** was selected for further development and is currently progressing in Phase 3 clinical trials (MK8931 or verubecestat). Initial data indicate a good translation of amyloid reduction in preclinical species in CSF Aβ reductions in healthy volunteers and patients. The terminal half-life of MK8931 was 14–24 h, and dose-dependent reductions in CSF Aβ peptides levels were observed, with over 90% reduction of $Aβ_{40}$ levels at the highest dose tested (550 mg). This was confirmed in a Phase 1b study, where patients with mild-to-moderate AD received a daily dose of 12, 40, and 60 mg doses for 7 days, achieving a sustained reduction in CSF $Aβ_{40}$ levels of 57%, 79%, and 84%, respectively. Phase 3 trials are ongoing targeting prodromal and mild-to-moderate AD. The selected doses of 12 and 40 mg are predicted to achieve >50% and >75% reductions in CSF Aβ peptides, respectively.

Further work of the Merck team seems to have focused around further exploration and securing the chemical space around the iminothiadiazine dioxide type of BACE inhibitors. Analogs without S3 targeting substituent, but having substituents directed toward S2′ are exemplified by **186**[221] and **187** (Fig. 52).[222] Comparative data indicate an enhanced solution stability of the iminothiadiazine dioxide analogs over their corresponding aminidihydropyrimidone analogs, as well as reduced efflux, with **187** having a reported P-gp efflux ratio of 1.6 versus 7.7 for the corresponding pyrimidone **183**. The THF-fused **188** (Fig. 52) can be considered a direct analog of LY2886721 (**93**, Table 2).[223] A one atom modification (sp^2 N to sp^3 C) led to multiple patent applications on iminothiazine dioxide analogs, such as **189**,[224] **190**,[225] and **191** (Fig. 52),[226] having similar or enhanced enzymatic potency compared to their iminothiadiazine dioxide analogs. For example, spiro-cyclized iminothiazine dioxide **195**[227] showed a BACEi Ki of 8 versus 70 nM for the corresponding imino thiadiazine analog **194** (Fig. 52).[228] Reinsertion of a nitrogen in the

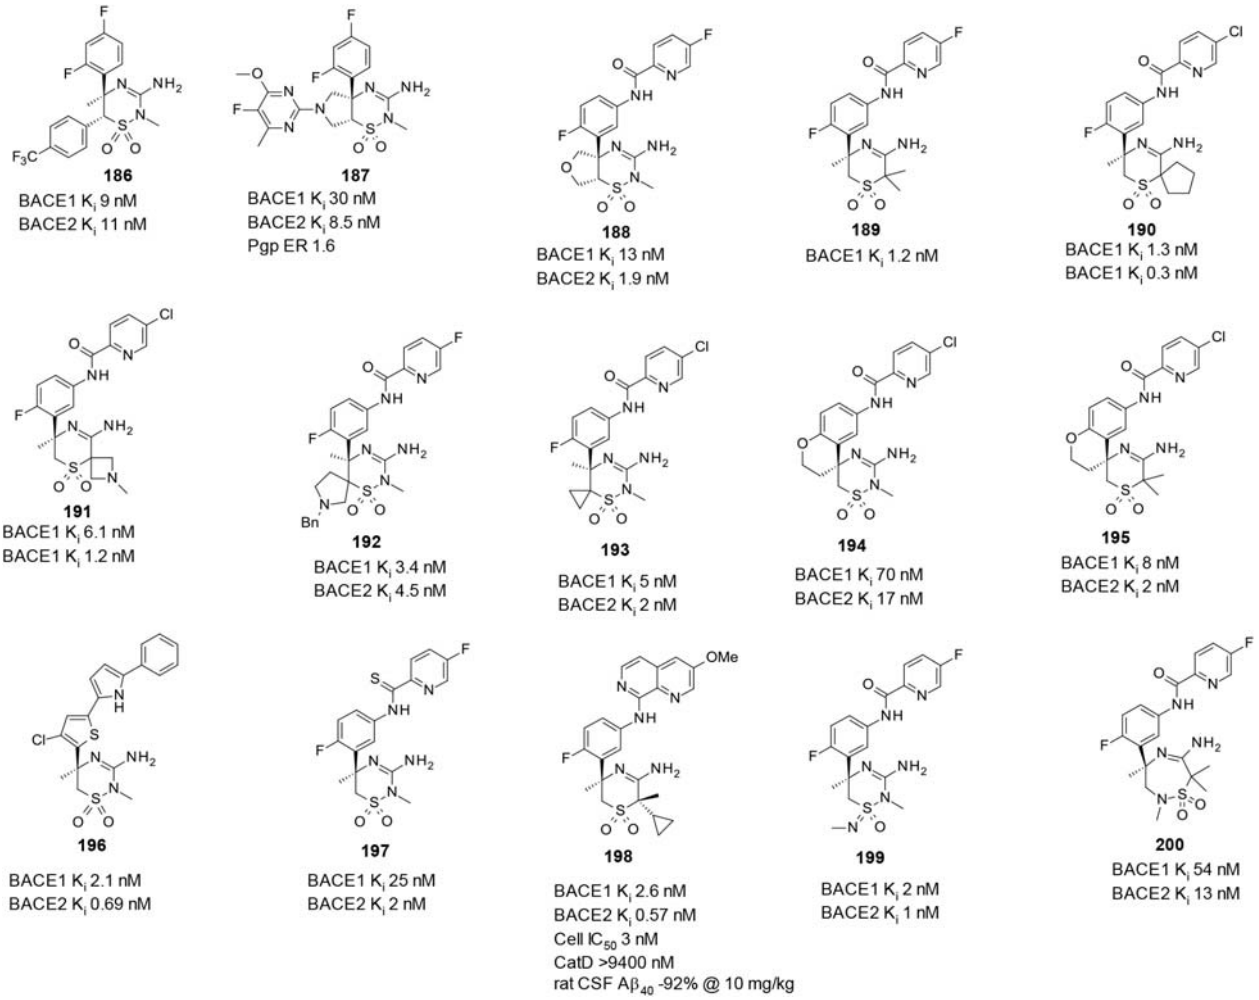

Fig. 52 Selected recent examples from patent applications from Schering-Plough/Merck.

ring led to reversed sulfonamides exemplified by **200** (Fig. 52) in general having reduced potency.[229] Additional variations include C2- and C-6 spiro-substituted analogs such as **190**, **192**,[230] and **193** as well as S-imino-S-oxo iminothiazine derivatives (**199**) (Fig. 52).[231] Most applications contain a multitude of variations on the S1–S3 targeting substituents, for example, **198** which showed excellent in vivo central activity in rat (Fig. 52).[232] A few applications specifically claim bioisosteric amide modifications such a heteroaromatic rings (**196**)[233] or thioamides (**197**) (Fig. 52).[234] In most patent applications, BACE1 and BACE2 enzymatic data have been reported. In general, no to minimal selectivity is observed for the various subseries, in agreement with the lack of selectivity reported for MK-8931 (**185**).

The intensive and persistent efforts toward BACE inhibitors by the Schering/Merck teams have clearly paid off with MK8931 (**185**) now furthest ahead in clinical development. Initiated by FBDD and guided by SBDD, their program has established the optimal vectors toward the various pockets culminating in the highly ligand efficient **185**. Although the high intrinsic TPSA of the iminothiadiazine dioxide warhead would perhaps be counterintuitive for a CNS drug, the acceptable brain penetration and demonstrated efficacy in clinical trials have proven its worth and illustrate the value of exploring beyond the traditional boundaries of CNS druglike properties.

7.08.19 Inhibitors Reported by Shionogi

Initial patent applications of Shionogi describe 2-amino-1,3-thiazine containing BACE inhibitors.[235,236] These are among the first examples of BACE inhibitors with data indicating very efficient lowering of amyloid peptide levels in the brain. For example, **201** (Fig. 53) reduced $A\beta_{40}$ levels in mice by 79%, 3 h after a 10 mg/kg oral dose. Very similar 2-amino-1,3-thiazine examples have been described by Roche as BACE2 inhibitors,[165] and the isothiourea warhead has since been used by multiple companies as evidenced in several of the previous paragraphs. Subsequent applications by Shionogi describe analogs with various substitution patterns on

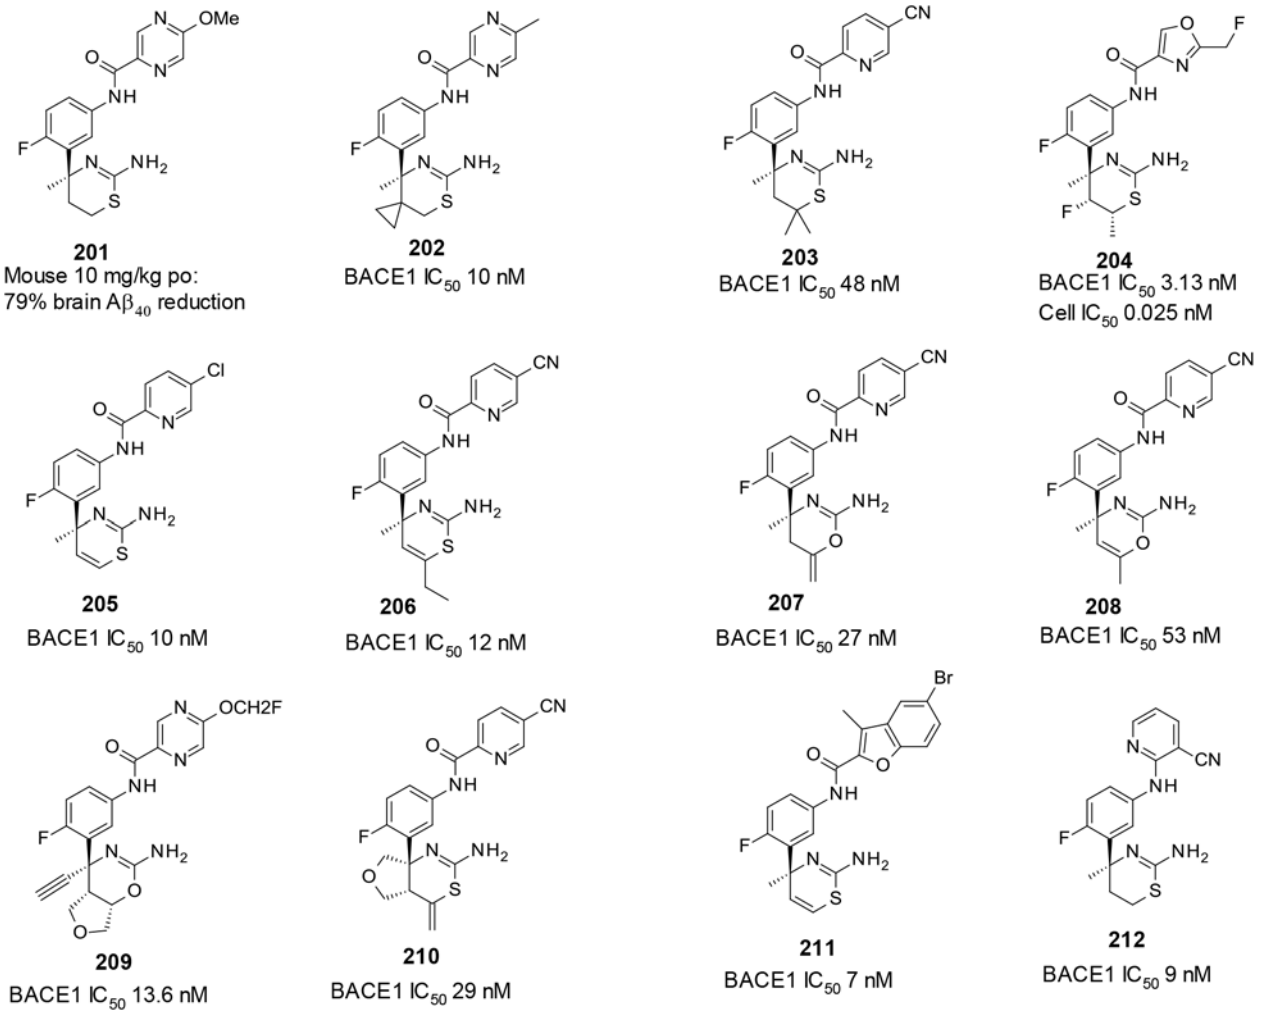

Fig. 53 Selected examples covering multiple patent applications from Shionogi.

the thiazine ring including spirocyclic **202**,[237] dialkyl substituted **203**,[238] and electron-withdrawing groups such as fluoro- and fluoroalkyl substituted thiazines such as **204** (Fig. 53).[239] Also compounds incorporating endo- or exocyclic double bonds have been described in various patent applications (**205**, **206**, Fig. 53).[240,241] Similarly substituted 2-amino-1,3-oxazine congeners also appear in several of these or separate patent applications, as exemplified by **207**[242] and **208** (Fig. 53).[243] Fused bicyclic oxazines, such as **209**,[244] and thiazines are also claimed, with **210** (Fig. 53), having similarity to LY2886721 (**93**, Table 2).[245] While most analogs contain the usual picolinamide moiety targeting the S3 pocket, interesting alternatives are also exemplified showing good potency such as **211**[239] and **212** (Fig. 53).[246] The 2-aminopyridyl substituted **212** shows resemblance to Amgen's **15** (Fig. 7) with the aminopyridyl being a successful bioisosteric replacement of the more common amide linker. Similar S3-binding groups have also been described by Roche.[168]

In addition to 2-amino-1,3-thiazines and oxazines, Shionogi has also explored a diversity of other warhead variations. Staying within the theme of sulfur-containing warheads, isomeric 4-amino-1,3-thiazines such as **213**[247] and noncyclic isothioureas such as **214**[248] have been described (Fig. 54). In another application, a series of aminopyrimidone BACE inhibitors such as **215** are described, but also a series of 2,3-diaminopyridine containing compounds (**216**), although the latter series seems to suffer from reduced potency (Fig. 54).[249] Several types of fused bicyclic warheads have been described, such as napthyridine derivatives (**217**)[250] and fused aminodihydropyrimidines exemplified by **218** (Fig. 54), which can be considered a bioisosteric version of the aminopyrimidone inhibitors described by Shionogi and other companies.[251]

A few papers describe a conformational restriction approach on the ethyl-linked aminopyrimidone series of BACE inhibitors, previously described by AstraZeneca (**23**, Fig. 8).[252,253] Replacement of the flexible ethyl linker in **219** with a rigid cyclopropyl linker having the optimal cis-(1*S*,2*R*) configuration triggered an induced fit of BACE1, leading to a novel binding mode, with the *para*-bisaryl containing **220** showed significantly higher potency than the corresponding ethyl analog (Fig. 55). X-ray analysis revealed a CH–π interaction of the cyclopropane ring with Tyr71 in BACE1. For metasubstituted bisaryl analogs, no potency improvement was observed for the cyclopropyl-linked compounds. However, introduction of an additional ethyl spacer between the two aryl

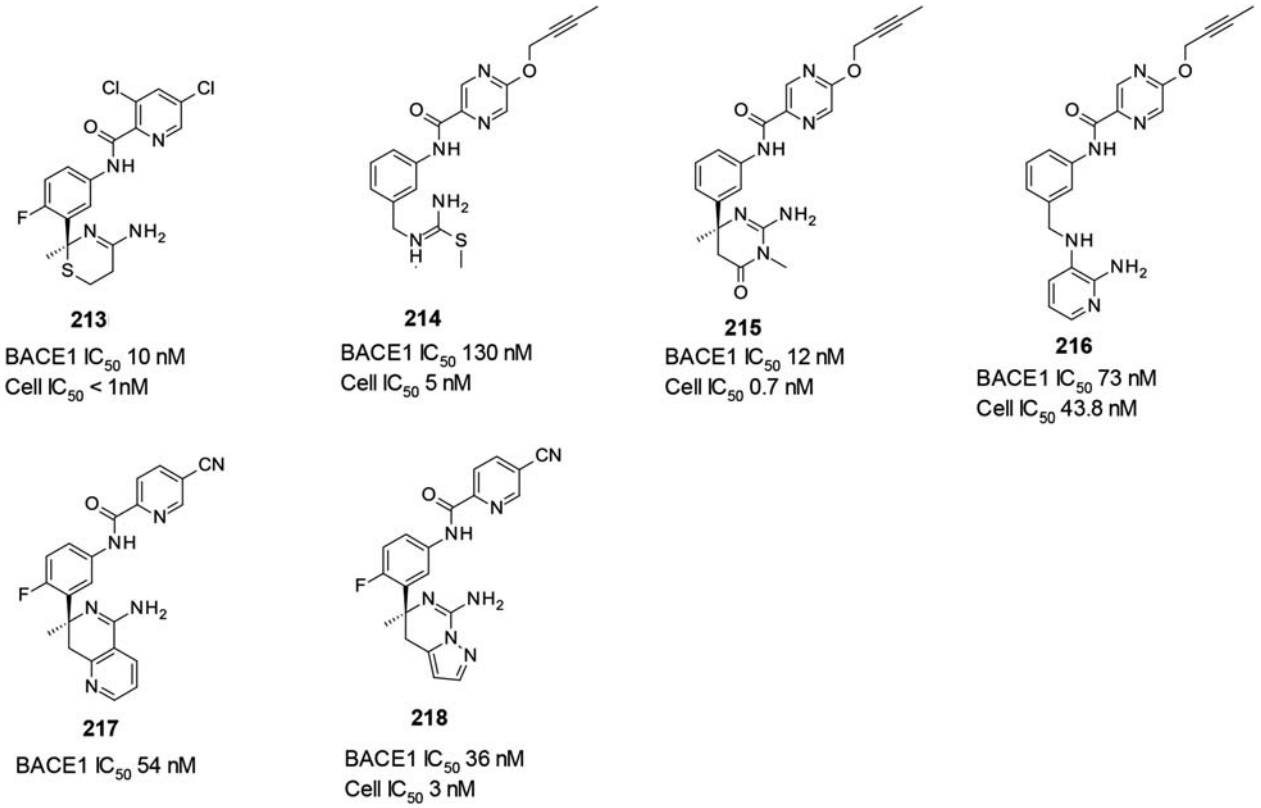

Fig. 54 Selected derivatives with alternative warheads and templates from Shionogi.

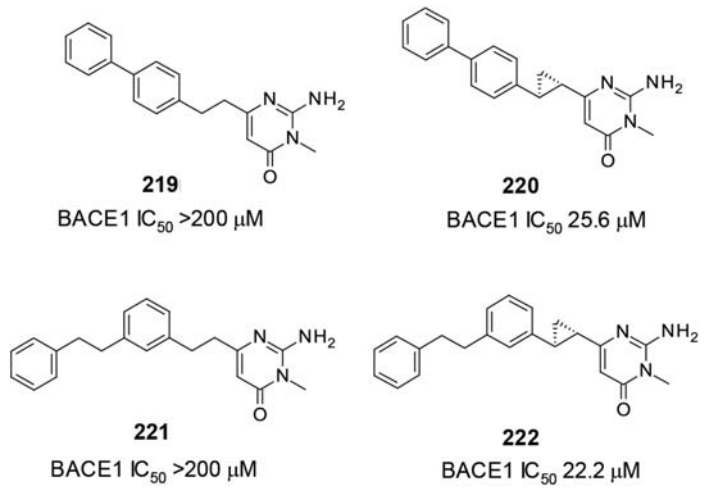

Fig. 55 Conformationally constrained aminopyrimidone derivatives from Shionogi.

rings again resulted in inhibitory activity for the rigidified **222** compared with undetectable activity for the flexible ethyl analog **221** (Fig. 55). Overall, potency of these rigid analogs remained in a very moderate micromolar range, illustrating the importance of having a quaternary center next to the amidine to optimally direct substitution into S1–S3.

Shionogi were one of the earliest entrants to the amidine-derived template, with particular focus on isothioureas. The group have published multiple patent applications and have ultimately identified at least one development candidate, JNJ-54861911, which has progressed to clinical studies in collaboration with Janssen. Results from a Phase 1 MAD study indicated that this compound reduced CSF $A\beta_{40}$ levels by 50% after 2 weeks of treatment, while the 30, 50, and 90 mg doses reduced levels by more than 80%, indicating a comparative efficacy versus competitor clinical candidates.[254]

7.08.20 Inhibitors Reported by Wyeth

Wyeth was among the first companies to identify guanidine containing scaffolds as having an optimal interaction with the catalytic Asp-dyad. Two series of BACE inhibitor have been developed, originating from hits **223** and **224** (Fig. 56) both identified via high-throughput screening using a FRET assay screen. Note that **224** has also been reported by AstraZeneca. Initial publications describe the optimization of the more potent acylguanidine hit **223**, already displaying single-digit micromolar BACE inhibition. A cocrystal structure of BACE1 with **223** indicated four key hydrogen-bonding interactions between the acylguanidine group in **223** and the two catalytic aspartic acid residues Asp32 and Asp228.[255] In addition, the two phenyl groups extended into the S1 and S2′ pockets. It also provided guidance for further optimization of the hit: substitution of the *para* position of the P1 phenyl group should provide a vector into the S3 pocket, and substitution of the non-Asp interacting third nitrogen of the guanidine should allow access to the S1′ pocket. Exploration of the SAR around these regions led to **225** (Fig. 56) having a significantly improved potency for BACE1. Difficulties in the synthesis of these trisubstituted pyrroles prompted the replacement of the pyrrole by a thiophene as in **226** (Fig. 56), allowing a more facile exploration of this series.[256] The *n*-propoxyphenyl group covered the S1–S3 pocket with minimal strain, contributing to the potency of **225**. While *para*-substituents of more significant size did fit into the S1–S3 pocket, the potency increase was suboptimal, attributed to a significant strain in these molecules.[257] Polar substituents targeting the S1′ pocket as in **225** showed relatively high levels of BACE1/Cathepsin D selectivity (85-fold for **225**), while analogs containing aromatic groups had poor selectivity.[258] To overcome the poor brain penetration of these acylguanidine-containing compounds, bioisosteric replacement of this polar group was investigated resulting in a series of 2-aminopyridine containing derivatives.[259] A crystal structure comparison of **223** with prototype **227** (Fig. 56) showed an almost perfect overlap of the acylguanidine and aminopyridine groups, and the reduced TPSA of **227** resulted in a significantly enhanced brain to plasma ratio of 1.7 compared to 0.04 for

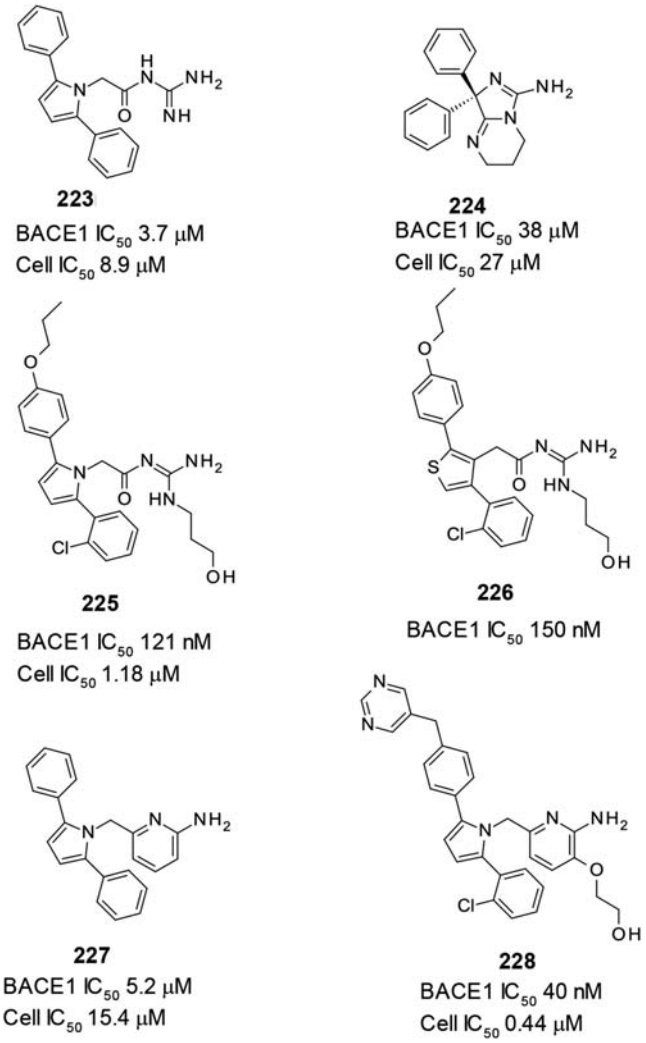

Fig. 56 Acylguanidine and related derivatives from Wyeth.

223. Potency could also be maintained, with optimized compound **228** (Fig. 56), having low nanomolar potency, albeit reduced brain penetration due to the introduction of the additional alkyl alcohol group.

Hit **224** was also explored using a traditional SAR approach supported by molecular modeling studies based on the cocrystal structure of BACE1 with **224**.[260] Similarly to **223**, the two phenyl groups extend into the S1 and S2′ pockets, but in **224** the meta-position of the P1 phenyl group offered the optimal vector into the S3 pocket. SAR exploration led to the identification of the 3-pyridyl substituent with the pyridyl nitrogen having an interaction through a water bridge with Ser229 in the S3 pocket. Interaction within the S2′ pocket was enhanced by the introduction of a *para*-trifluorometoxy group, resulting in a further 15-fold potency boost. Optimized compound **229** (Fig. 57) had a more than 1000-fold improvement in potency over **224**. The introduction of the additional fluoro-substituent in **229** was not driven by potency but based on metabolic properties. **229** was also evaluated in vivo using Tg2576 mice. A dose of 30 mpk led to a 71% reduction in $A\beta_{40}$ plasma levels 6 h after dosing, but no significant reduction in brain $A\beta_{40}$ was observed, presumably due to poor brain exposure of **229**.

The tetrahydropyrimidine ring in **224** and **229** extends toward solvent, therefore further improvements in potency via changes in this region were difficult to attain. Removal of this ring led to compounds containing an aminohydantoin core such as in **230** (Fig. 57) which was also explored by other groups. Compared to **224**, the less lipophilic and lower molecular weight **230** showed a 10-fold improvement of both enzymatic and cellular potency.[261] Saturation of the P2′ phenyl group, and optimization into S3 led to compounds such as **231** (Fig. 57) having low nanomolar potency. In a further exploration of this series, it was recognized that a 4-pyridyl P2′ group created a hydrogen-bonding interaction with Trp76, contributing to an increased potency, as exemplified by **232** (Fig. 57).[262] Taking advantage of the differences in amino acid sequence in the S2′ pocket of BACE1 and BACE2, further substitution of the pyridyl group led to highly selective BACE1 ligands such as **233** (Fig. 57) with over 500-fold selectivity against BACE2.[263] The large steric ethyl-substituents apparently clash with the BACE2 enzyme backbone, but were shown to interact with Tyr71, Val69, and Ser35 in the S2′ pocket of BACE1, with one of the ethyl groups also displacing two conserved waters. Selectivity over Cathepsin D was >5000-fold. Replacement of the pyridyl P2′ group with substituted pyrazole or thiophene heterocycles also provided potent and selective compounds.[264] With all of these compounds still suffering from poor brain penetration, a stepwise exploration of the S3 and S2′ regions was carried out to reduce the efflux liability in this series, attributed to the electron richness of the heterocycle substituents used before (pyridyl as in **229**, **232** pyrimidyl as in **233**).[265] Replacement of the heteroaryl

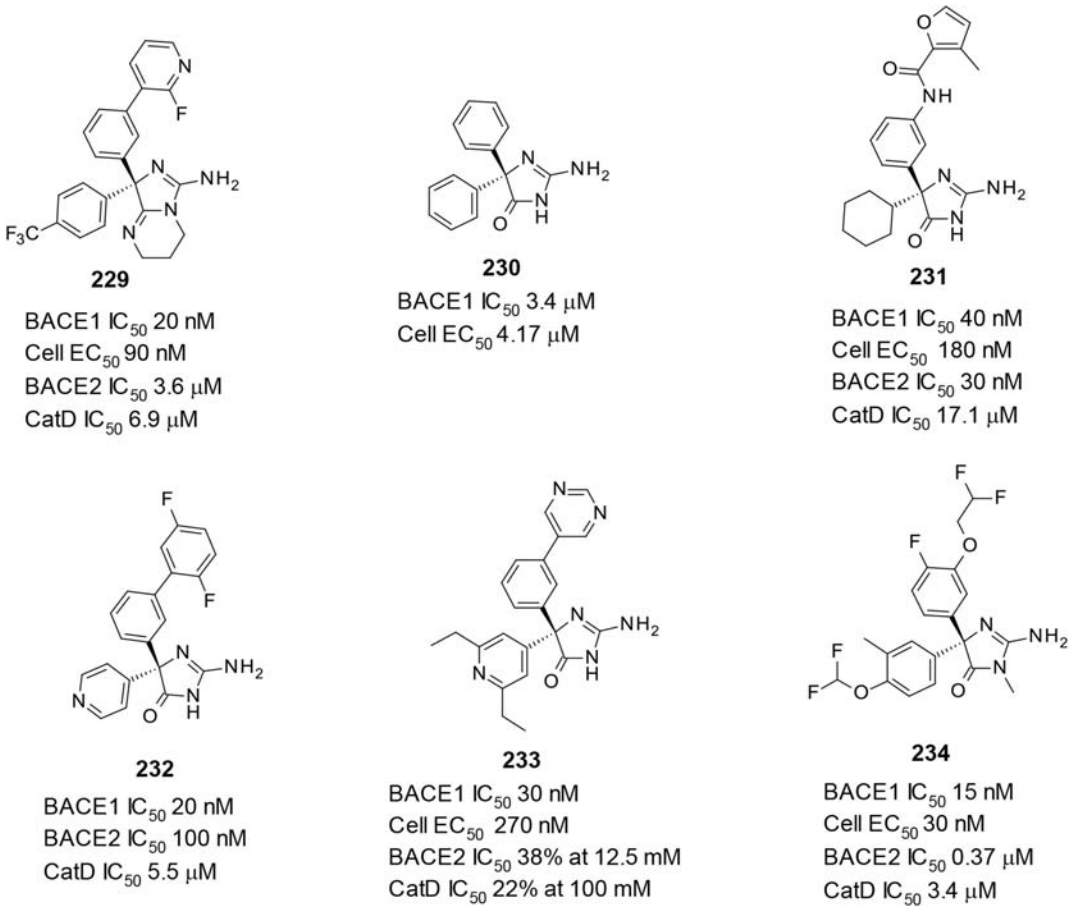

Fig. 57 Further examples from Wyeth.

substituents at the *meta*-P1 phenyl with alkyl and alkoxy groups led to **234** (Fig. 57). The additional *para*-fluoro-substituent decreased CYP450-mediated metabolism, and the overall improved physicochemical properties resulted in an enhanced brain permeability of 40–70% compared to 5–10% for previously described analogs. Despite this increase in brain penetration, **234** was not able to reduce $A\beta_{40}$ levels in the brain of Tg2576 mice after a 30 mg/kg p.o. dose. This was attributed to a significant increase in brain tissue binding, resulting in low central free drug exposure.

After the merger of Wyeth with Pfizer, further development of this series seems to have been halted in favor of the efforts described in the section of Pfizer (see earlier text).

7.08.21 Inhibitors Reported by vTv/TransTech/HighPoint

TransTech, subsequently rebranded to HighPoint Pharmaceuticals, now vTv Therapeutics, has disclosed a series of imidazole-based BACE inhibitors. The series have been covered by a series of patent applications, with the culmination of one compound, HPP854, entering PhI clinical trials. The first application[266] covered compounds with weak affinity, but subsequent applications detailed compounds such as **235**,[267] **236**,[268] and **237** (Fig. 58),[269] all of which apparently display reasonable activity in enzyme and cellular assays.

Inspection of the structures shows no similarity with other published BACE inhibitors and no peer-reviewed publications or crystal structures have appeared to shed light on the mode of action. However, the compounds contain a very high proportion of aromatic rings in addition to probably intramolecular hydrogen bonds, hence it would be anticipated that they would display low solubility. Furthermore, it seems that no other groups have shown interest in these series, hence the profile of these compounds appears not to have proven of interest to the BACE community. Despite this, ultimately one compound, HPP854, progressed to a PhI study and was investigated in subjects with MCI or mild AD. The trial started in Oct. 2011 and assessed doses of 5–800 mg HPP854.[270] The study was terminated and no further development has been reported.

7.08.22 Summary of Clinical Development Compounds and Clinical Outlook

As highlighted, multiple groups have identified and progressed development compounds into clinical development, although several have been terminated. Table 7 summarizes the development compounds, the companies developing them, and their current status.

Merck are the furthest progressed with MK-8931/verubecestat. Two large PhII/III trials, APECS and EPOCH, are currently underway. APECS, a PhIII trial, is assessing MK-8931/verubecestat in patients with prodromal AD in a total of 1500 participants. The primary efficacy outcome of the study is change from baseline in the Clinical Dementia Rating Scale-Sum of Boxes (CDR-SB) score following 104 weeks of treatment. EPOCH, a Phase II/III of MK-8931/verubecestat in patients with mild-to-moderate AD, commenced in Nov. 2012, and is currently estimated to complete in mid-2017. Efficacy will be assessed by change from baseline in the Alzheimer's Disease Assessment Scale Cognitive Subscale (ADAS-Cog) score, as well as the change from baseline in the Alzheimer's Disease Cooperative Study–Activities of Daily Living (ADCS–ADL) score, following 78 weeks of treatment.

Other companies, such as Eisai/Biogen, Lilly/AstraZeneca, and Janssen, appear to be following closely behind, pushing compounds rapidly through PhII and into PhIII trials. Eisai have recently announced the successful completion of the PhII trial of E2609, which will subsequently progress to two PhIII studies at 50 mg/day, each of 24 months duration.[271] Lilly recently announced that AZD3293 has been granted a fast track designation by the FDA. In addition to the ongoing PhII/III trial (AMARANTH), a second PhIII trial (DAYBREAK-ALZ) in people with mild AD has begun enrolling participants in the 3rd quarter of 2016.[272]

Analysis of the compounds in development and the compounds covered by each of the companies reveals that a lot of the compounds have similar features, such as an anilide. In addition, it is likely that a lot of companies are developing compounds which contain the isothiourea warhead, for example, Eisai, Janssen, Lilly, and Pfizer, although MK-8931 (Merck) has the sulfonyl-guanidine warhead and AZD3293 (Lilly/AZ) utilizes an amidine and lacks the typical anilide, RG7129 (Roche) utilized an isourea and CNP-520 (Novartis/Amgen) likely employs an isourea or iminomorpholine/β-alkoxyamidine. LY2811376 and LY2811376,

Table 7 Summary of key compounds which have progressed to clinical studies with their current status

Compound	Lead company/discoverer	Structure	Current status	Doses	Comment	Patient population
CNP520	Amgen/Novartis	Not disclosed	PhII/III	1, 10, 25, and 75 mg	NCT02791191 NCT02565511	Prevention in APOE4 carriers
CTS-21166	Astellas/Comentis	Not disclosed	Terminated (PhI)		NCT00621010 HEA peptidomimetic showed plasma amyloid reduction after iv administration	N/A
AZD3839	AstraZeneca		Terminated (PhI) due to QTc prolongation		NCT01348737	
BI 1181181/VTP 37948	Boehinger Ingelheim/Vitae	Not disclosed	Terminated (PhI)		NCT02254161	
E2609	Eisai/Biogen	Not disclosed	PhII started Nov. 2014	5, 15, and 50 mg	NCT02322021 18-Month trial with 700 participants. Primary endpoint slowing of cognitive decline (ADCOMS)	MCI due to AD or prodromal AD plus positive amyloid PET scan
JNJ-54861911	Janssen/Shionogi	Not disclosed	PhII/III started Oct. 2015	5 and 25 mg	NCT02569398 54-Month trial in 1650 participants with read out in 2023. Primary endpoint slowing of cognitive decline (ADAS-PACC)	Patient population: asymptomatic people at risk
LY2811376	Lilly		Terminated (PhI)		NCT00838084 Terminated due to retinal toxicity	
LY2886721	Lilly		Terminated (PhII)		NCT01561430 Terminated due to liver toxicity	
LY3202626	Lilly	Not disclosed	PhII		NCT02791191	52-week mild AD

(Continued)

Table 7 Summary of key compounds which have progressed to clinical studies with their current status—cont'd

AZD3293/ LY3314814	Lilly/AstraZeneca		PhII/III (AMARANTH)	20 and 50 mg	NCT02245737	24-Month study in early AD, e.g., MCI
MK-8931 Verubecestat	Merck		PhII/III	12 and 40 mg	EPOCH: NCT01739348 APECS: NCT01953601	Prodromal and mild-to-moderate
PF-05297909	Pfizer		Discontinued PhI	25, 100, 250, and 525 mg	NCT01462851 Compound did not achieve sufficient lowering of CSF Aβ at 325 mg dose despite lowering plasma Aβ	Sep. 2011–Feb. 2012
PF-06751979	Pfizer	Not disclosed	PhI	SAD: 3, 12, 40, and 125 mg MAD: 5, 15, 50, and 70 mg	NCT02509117 SAD plus human CSF PK/PD at 525 mg dose	Combined SAD and MAD (14d)
RO5508887/ RG7129	Roche		Discontinued PhI	N/A	NCT01461967	N/A
HPP854	TransTech/High Point Pharmaceuticlas	Not disclosed	Discontinued (PhI)		NCT01482013	May not be a BACE inhibitor

containing the isothiourea warhead, were both terminated due to nontarget related toxicity, albeit from a different origin. However, a structurally differentiated warhead does not guarantee success, as shown by the termination of the isourea RG7129 from Roche. Several compounds have now passed the hurdle of initial Phase I and II safety trials and are progressing in late-stage clinical trials. This indicates that intrinsic toxicity can be avoided with BACE inhibitors. However, the safety profile of chronic exposure to BACE inhibitors, as likely required for a successful treatment, still needs to be firmly established.

7.08.23 Conclusion

After many years of arduous research by multiple competing groups around the world, the BACE inhibitor field is currently poised at a very exciting moment in time. Not only has the extremely competitive field become collaborative, turning foes into allies, in order to share the risks and costs of the clinical development projects, but also multiple compounds have now progressed into PhII clinical trials and beyond. It would appear that sustained research in the field has resulted in success in terms of the delivery of compounds which are suitable to assess the mechanism in a clinical setting. There are many things that can be learned from this research, for example, alternative screening approaches such as fragment screening may make undruggable targets druggable and chemists should not be fixated with the identification of highly potent hits from HTS campaigns. As clinical data and preclinical data become available, it is possible to correlate human CNS penetration ($CSF:Pl_u$) with preclinical data and this will help to guide future discovery. Furthermore, the field has shown the persistency and ingenuity of medicinal chemists and their ability to overcome multiple issues, including hERG inhibition, P-gp efflux, CYP inhibition, and metabolism. Modulation of the pK_a of the amidine-containing warheads has been instrumental, especially in dealing with hERG inhibition and P-gp efflux. As illustrated by many examples throughout this article, this has been achieved by incorporation of the amidine function into various heterocyclic ring systems, and by decoration of these heterocycles with electron-withdrawing groups.

Over the many years of BACE research, most companies have had considerably sized teams of chemists dedicated to this target. This is understandable when considering the difficulty of the target, the high competitiveness, as illustrated by the many overlapping patent scopes, and last but not least, the complexity of the synthesis. Most of the compounds shown in this overview contain multiple chiral centers, fused or bridged nonaromatic ring systems, and require 10–20 synthesis steps to prepare. BACE therefore highlights the importance of synthetic organic chemistry, as illustrated nicely by the work of Lilly on conformationally restricted BACE inhibitor prototypes.[273] Most of the compounds that have progressed do not show selectivity over BACE2. The consequences of this are currently unknown, but the more recent patents tend to show inhibition constants for both BACE1 and BACE2, indicating a raised interest in selectivity ratios. Furthermore, new substrates are being identified for BACE1 and the impact of potentially chronic inhibition of the processing of other proteins is currently unknown.[274]

Several important questions remain, such as: How much amyloid reduction should be targeted? How does the amyloid reduction in human CSF relate to the reduction in human brain? Which patient population should be treated, at which stage of the disease and for how long? Which other proteins does BACE cleave and what will the relevance of these be? The ongoing suite of clinical trials with multiple compounds is set to provide answers to these questions. Improved biomarkers to select patients and follow disease progression, targeting of various stages of the disease including prevention, and the multiyear exposure to BACE inhibition in humans should ensure a thorough testing of the amyloid hypothesis and targeting it via BACE inhibition. The combined treatment with a BACE inhibitor and drugs targeting other mechanisms may also prove beneficial. For example, Roche has reported that the combined treatment of APP_{London} transgenic mice with the BACE inhibitor RO5508887 (**152**) and the anti-Aβ antibody gantenerumab significantly enhanced the antiamyloid effect, including an enhanced clearance of preexisting amyloid plaques.[275] A similar effect of targeting both synthesis and clearance in the amyloid cascade has been presented by Lilly via the combination of LY2811376 (**92**) and the plaque targeting antibody N3pG.[276]

The field is now poised to deliver what could be the biggest results ever seen in neuroscience. Should one of these compounds manage to deliver a slowing, or even, a halting, of disease progression, the results would have a huge impact on the lives of millions of AD sufferers and their carers and families. Although several challenges remain to be addressed, if successful, the field of AD will have changed dramatically and it will no longer be viewed as a life sentence.

7.09.1 Introduction

When the British physician Henry Hyde Salter in 1860 discovered that his asthmatic breathing eased when he drank two strong cups of coffee on an empty stomach,[1] he was little aware, that the bronchodilator properties was caused by the alkaloid constituents caffeine (**3**), theophylline (**4**), and theobromine (**5**) (Fig. 1). Two morning cups of strong coffee contain a mixture of xanthines (**1**) corresponding to a dose of ~300 mg theophylline. At the same time, the three xanthines had been isolated from beans of coffee and cacao and from tea leaves in 1820, 1842, and 1888, respectively. Their chemical structures were proven via chemical synthesis in 1895.[2] The stimulatory effects on the central nervous system (CNS) were later shown to be caused by these same heterocyclic purines[3] although most of the available data suggest that caffeine, in the doses that are commonly consumed, acts primarily by blocking adenosine A1 and A2A receptors.[4] Subsequently, theophylline was successfully introduced as treatment, first as a diuretic and for cardiovascular disease and later for airway disease. In spite of being unselective phosphodiesterase (PDE) inhibitors, the xanthine-scaffold has played an important role in PDE drug discovery, and many chemical series and drug candidates have been derived from this bicyclic purine.

The mechanism of action (MoA) of xanthines at the time was unknown; however, in 1958 Sutherland and Rall found that caffeine and theophylline were acting as nonselective, albeit weak, inhibitors of the newly discovered PDE enzyme.[5] The PDE was found to be a metallohydrolase present in tissue extracts from the heart, brain, and liver and was activated by magnesium ions. The PDE was found to be responsible for the degradation of the heat-stable cyclic nucleotide (cN) 3′–5′ cyclic adenosine monophosphate (cAMP) first isolated from liver extracts.[6] PDE was later also shown to degrade 3′–5′ cyclic guanosine monophosphate (cGMP) first isolated from rat urine.[7] The cyclic nucleotides were shown to be intracellular second messengers, which mediated many of the cellular effects of neurotransmitters and hormones. It became apparent that steady-state levels of cAMP and cGMP in cells and tissues are determined by the balance of syntheses by adenylyl cyclase (AC) and guanylyl cyclase (GC), degradation by PDEs, and extrusion out of the cell by ABC transporter multidrug resistance-associated protein 4 and 5, MRP4 and MRP5[8] (Fig. 2).

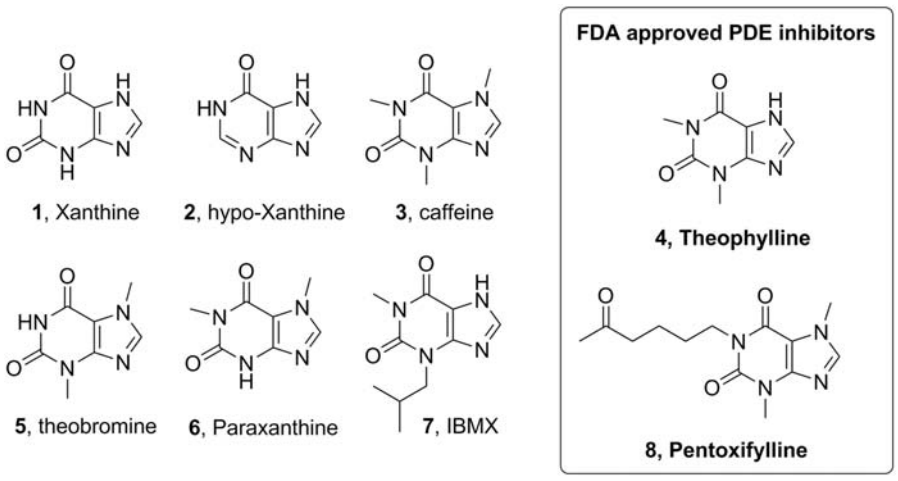

Fig. 1 Xanthine and xanthine analogues pioneered the PDE drug discovery and were among the first PDE inhibitors to be approved drugs.

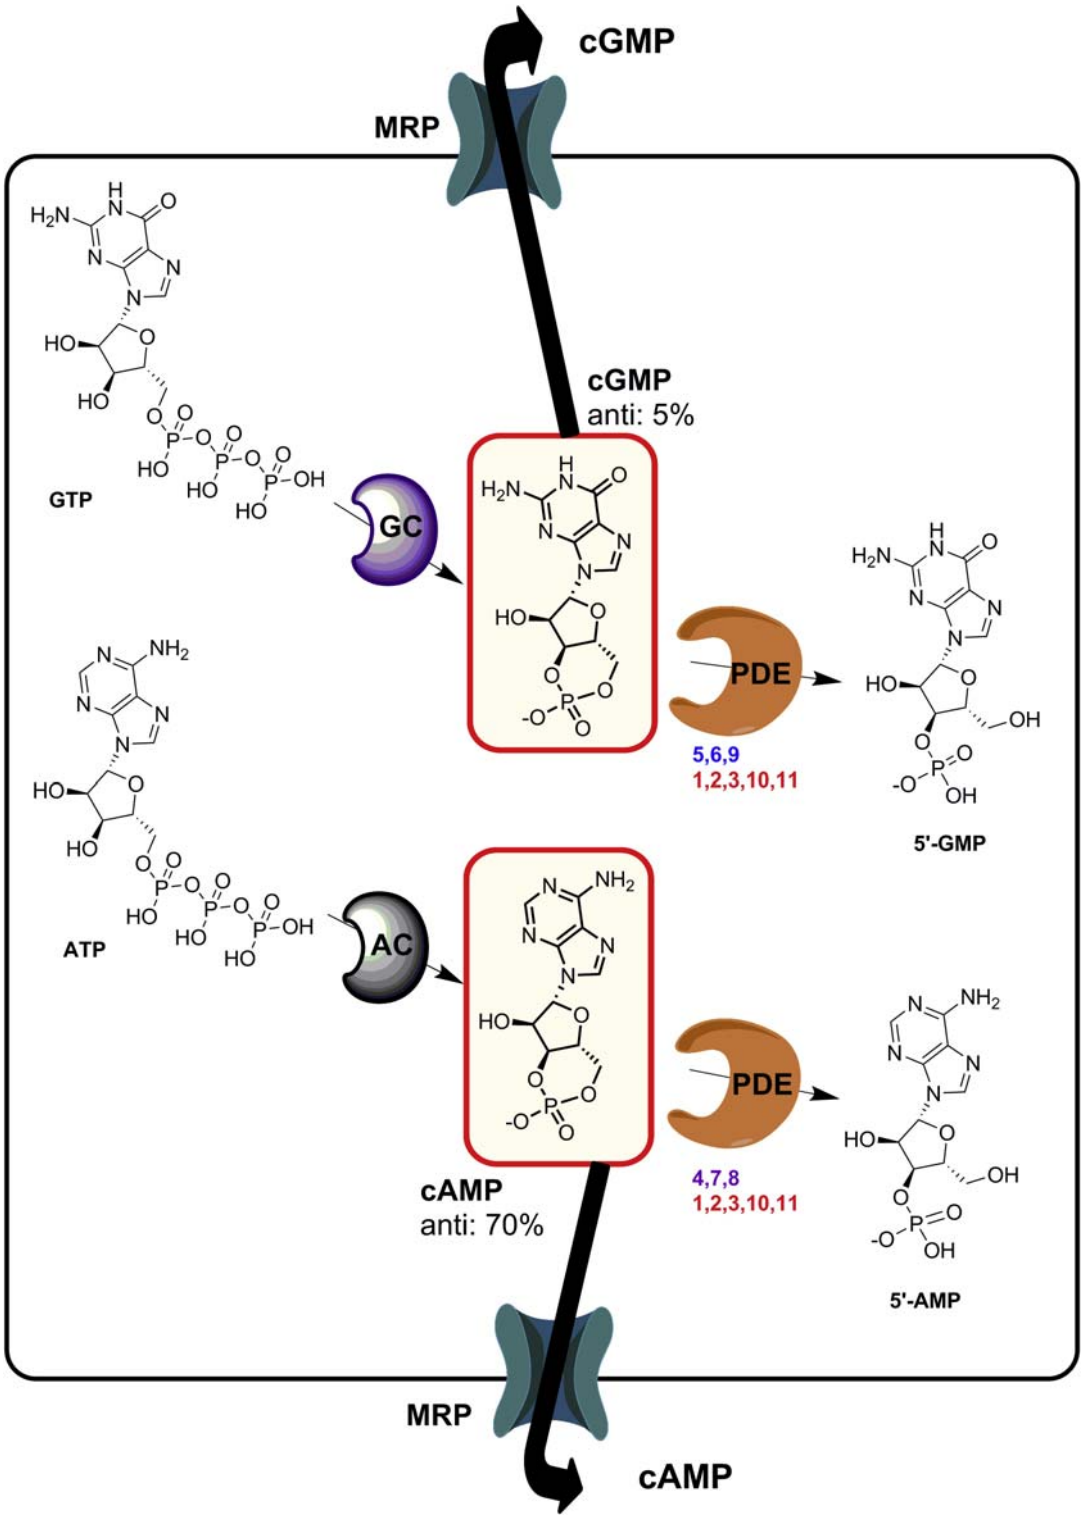

Fig. 2 Overview of the cellular systems responsible for regulating cyclic nucleotide (cN) levels in the cell. An enzyme system responsible for the formation of cAMP in the presence of ATP, named adenylate cyclase, AC (EC 4.6.1.1) and the corresponding system responsible for the formation of cGMP in the presence of GTP, named guanylate cyclase, GC (EC 4.6.1.2) are shown. Another enzyme system, 3′,5′-cyclic-AMP phosphodiesterase (PDE, EC 3.1.4.17) and 3′,5′-cyclic-GMP phosphodiesterase (PDE, EC 3.1.4.35), is responsible for hydrolyzing cNs. Furthermore, cNs are known to be effluxed from cultured cells or isolated tissues by members of the multidrug resistance protein family, MRP4 and MRP5. For Enzyme nomenclature, see http://enzyme.expasy.org/.

Table 1 Cyclic nucleotide phosphodiesterase gene families

PDE	*PDE isozyme families*	*Substrate selectivity*	*Localization in the brain*
PDE1	CaM-dependent PDEs	cGMP and cAMP (dual)	Hippocampus, cortex, olfactory bulb, striatum (highest expression levels), thalamus, amygdala, cerebellum; expression levels are in general highest for 1A and lowest for 1C
PDE2	cGMP- stimulated PDEs	cGMP and cAMP (dual)	Hippocampus, cortex, striatum, hypothalamus, amygdala, midbrain
PDE3	cGMP-inhibited PDEs	cGMP and cAMP (dual)	Throughout the brain low expression levels
PDE4	cAMP-specific PDES	cAMP	Hippocampus, cortex, olfactory bulb, striatum, thalamus, hypothalamus, amygdala, midbrain, cerebellum; expression levels are in general highest for 4A–4D (differs per brain structure) and lowest for 4C
PDE5	cGMP-specific PDEs	cGMP	Hippocampus, cortex, cerebellum
PDE6	Photoreceptor PDEs	cGMP	Pineal gland
PDE7	HCP1–PDE	cAMP	Hippocampus, cortex, olfactory bulb, striatum, thalamus, hypothalamus, midbrain; expression levels are in general highest for 7B
PDE8		cAMP	Hippocampus, cortex, olfactory bulb, striatum, thalamus, hypothalamus, midbrain; expression levels are in general highest for 8B
PDE9		cGMP	Hippocampus, cortex, olfactory bulb, striatum, thalamus, hypothalamus, amygdala, midbrain, cerebellum
PDE10	Striatal-enriched PDE	cGMP and cAMP (dual)	Hippocampus, cortex, striatum (highest expression levels), midbrain, cerebellum
PDE11		cGMP and cAMP (dual)	Throughout the brain low expression levels

The cell membrane-bound anion transporters MRP4 and MRP5 are low-affinity cN transporters that function as overflow pumps, decreasing steep increases in cGMP and cAMP levels under conditions where cN synthesis is strongly induced and PDE activity is limiting. In some cells, this export might be of similar importance for intracellular cGMP and cAMP signals as degradation by PDEs.[9]

Early nomenclature categorized the different PDEs according to their chromatographic eluent properties, their order of discovery, their substrate specificity, and kinetic and regulatory properties. The completion of the Human Genome Project in 2001 established that there are 21 PDE genes in humans, which are subdivided into 11 PDE families (**Table 1**). It has been shown that each PDE isoform exhibits a unique expression pattern across the brain (**Table 1**), and this expression pattern is highly conserved between rats, mice, and humans. Furthermore, it has been shown that PDE1B, PDE1C, PDE2A, PDE4A, PDE4D, PDE5A, PDE7A, PDE8A, PDE8B, PDE10A, and PDE11A showed an age-related increase or decrease in mRNA expression in at least one of the four brain regions examined (hippocampus, cortex, striatum, and cerebellum). In contrast, mRNA expression of PDE1A, PDE3A, PDE3B, PDE4B, PDE7A, PDE7B, and PDE9A did not change with age.[10]

When AC is activated, it continuously catalyzes the conversion of ATP into cAMP, and when GC is activated, it continuously catalyzes the conversion of GTP into cGMP. This results in high concentrations of cAMP or cGMP and a strong amplification of the signal. Once cAMP and cGMP are synthesized, these cNs transduce signal-encoded information by acting through a number of cellular effectors. These include cAMP- or cGMP-activated protein kinases [protein kinase A (PKA) or PKG, respectively], cyclic nucleotide-gated ion channels, a family of two cAMP-activated guanine nucleotide exchange proteins [exchange factors directly activated by cAMP 1 (EPAC1) and EPAC2], and a limited group of enzymes from the PDE family, which contain allosteric cN-binding sites in addition to their catalytic sites.[11] Divergent N- and C-termini allow differential regulation of PDEs by other intracellular signaling pathways. A simplified view of the signaling pathways is summarized in **Fig. 3**.

7.09.2 PDE Structure and PDE Binding Site Topology

Since the first publication in 2000 of a PDE crystal structure of the APO-structure of the PDE catalytic domain of PDE4B,[12] there are now structures of the catalytic domains of 9 of the 11 human PDE families, the structures of PDE6 and PDE11 being the only ones still lacking. The number of PDE crystal structures continues to grow with a rate of about 20 per year, and more than 230 PDE crystal structures were deposited in the Protein Data Bank in the beginning of 2016. PDE structures of 5 of the 13 PDE inhibitors that have been approved for use as pharmaceuticals have been published crystallized in complex with their respective PDE targets. Five comprehensive reviews of PDE crystal structures have been published.[13]

The PDE families have relatively rigid pockets at the active sites. The catalytic domains of PDEs are composed of approximately 350 amino acids and have been shown to share a similar topography, folded into 16 helices (H1–H16). An overlay of all published PDE crystal structures showed that PDEs share a highly conserved fold, with an overall RMSD of C-α atoms of 1.2 Å,[13,14] underscoring the high degree of topological homology and similarity within their catalytic domains. However, slight structural differences in these domains determine whether the PDE has dual substrate specificity (PDE1, PDE2, PDE3, PDE10, and PDE11) or is cGMP-specific (PDE5, PDE6, and PDE9) or cAMP-specific (PDE4, PDE7, and PDE8). Importantly, the subtle structural differences also form the basis for subtype-selectivity among PDE ligands. All PDE inhibitors crystallized to date have been found to bind to the

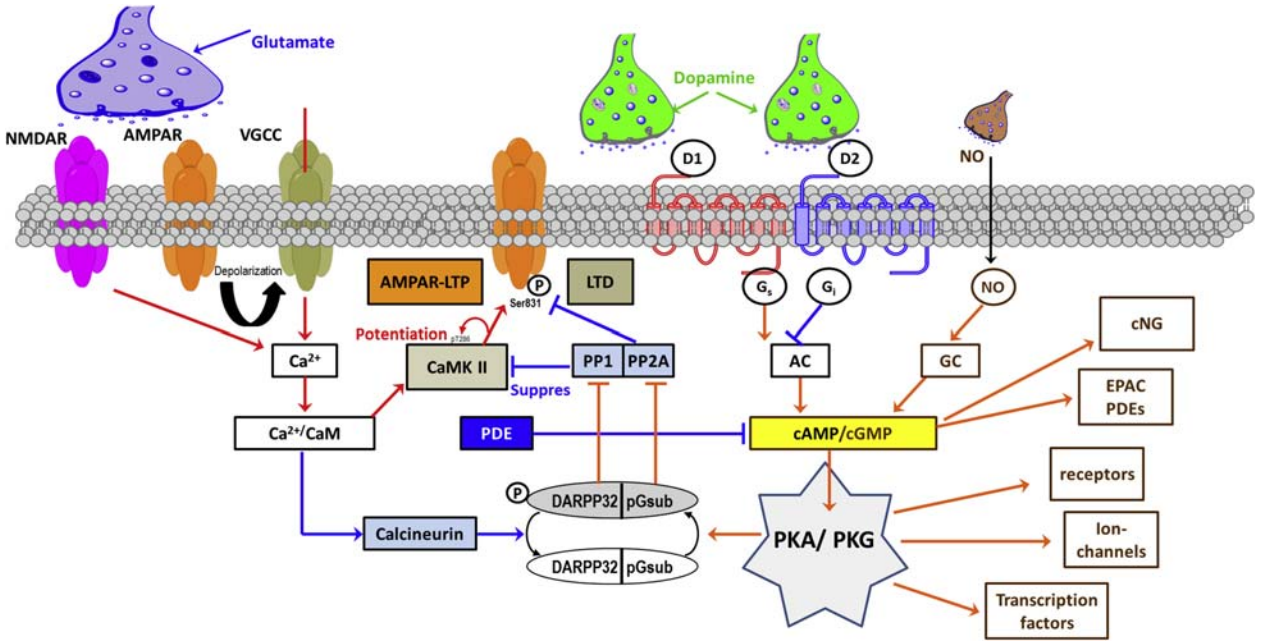

Fig. 3 A simplified view of the signaling pathways, where PDEs are involved.

substrate binding pocket of the PDE catalytic domain. The catalytic active site forms a deep hydrophobic pocket with a total of 57 residues identified as pocket residues[14] and includes a substrate binding region formed between H13 and H16. The pocket has a metal binding (MB) region at the apex of H6–H13, that contains a PDE-specific, histidine-containing signature motif, HD(X2)H(X4)N, that forms the binding sites for the two divalent metal ions that are essential for the catalytic function of PDEs. One of the histidines (His160 in PDE4D2) has been proposed to serve as a general acid for catalysis. Thirteen of the 57 pocket residues are conserved across all PDEs, and 11 of these are in MB regions. The two other conserved amino acids play important roles in substrate and inhibitor binding and are an invariant glutamine residue (Gln-369 in PDE4D2, Gln-453 in PDE9A2, and Gln-726 in PDE10A2), and a phenylalanine residue (Phe372 in PDE4D2 and Trp621 in PDE11A2). To describe the interactions between the ligands and the substrate binding pocket in a consistent manner, a systematic nomenclature for the residues of the binding pocket has been proposed (Fig. 4).[14] The pocket is divided into 10 regions consisting of: The invariant glutamine (Q) and neighboring regions Q1 and Q2; the hydrophobic clamp (HC) regions HC, HC1, and HC2; the MB regions MB, MB1, and MB2; and the solvent filled (S) region S. Based on the alignment of the pocket residues, a nomenclature was introduced numbering the 57 pocket residues according to its position from number 1 to number 57. In addition, a prefix is given indicating in which pocket region the amino acid is placed. In this nomenclature, the invariant glutamine is named QQ.50 since the residue is a glutamine (Q), placed in the Q-pocket (Q) in position 50. Correspondingly, in this nomenclature the conserved phenylalanine in the "roof" of the HC is named FHC.52. This nomenclature allows an easy and consistent way of comparing different structures and interactions cross PDE families.

7.09.3 CNS Drug-Like Properties

The concept of drug-likeness was introduced in the late 1990s as a guide for molecule design in hit- and lead optimization. Drug-like was defined as those compounds that have sufficiently acceptable ADME properties and sufficiently acceptable toxicity properties to survive through the completion of human phase 1 clinical trials. Analysis of the distribution of physicochemical properties of marketed drugs shows that they fall within a relatively narrow range of possible values. Therefore, the term "drug-like" is used to describe physicochemical properties of compounds that fall within this range. It appears that CNS drugs fall within an even more narrow range. Physicochemical properties determine important drug parameters like solubility, permeability, metabolic stability, transporter effects, and plasma- and tissue-free fractions, thereby impacting oral bioavailability and exposure to drug targets in vivo (pharmacokinetics), which is a prerequisite to pharmacodynamics (PDs) and toxicity. Drug-likeness, therefore, can be understood as a way to relate physicochemical properties to ADME-T and other in vivo parameters. The meaning of "drug-like" is dependent on mode of administration. The route of drug administration associated with the greatest patient compliance is the oral route, which is also the most cost effective and most convenient. This is why most of the drugs that are available in the marketplace are administered via the oral route. Oral-drug space is a generic term that describes the area of chemical space in which oral drugs have a high probability of being found. It can in principle be defined using any number of physicochemical or

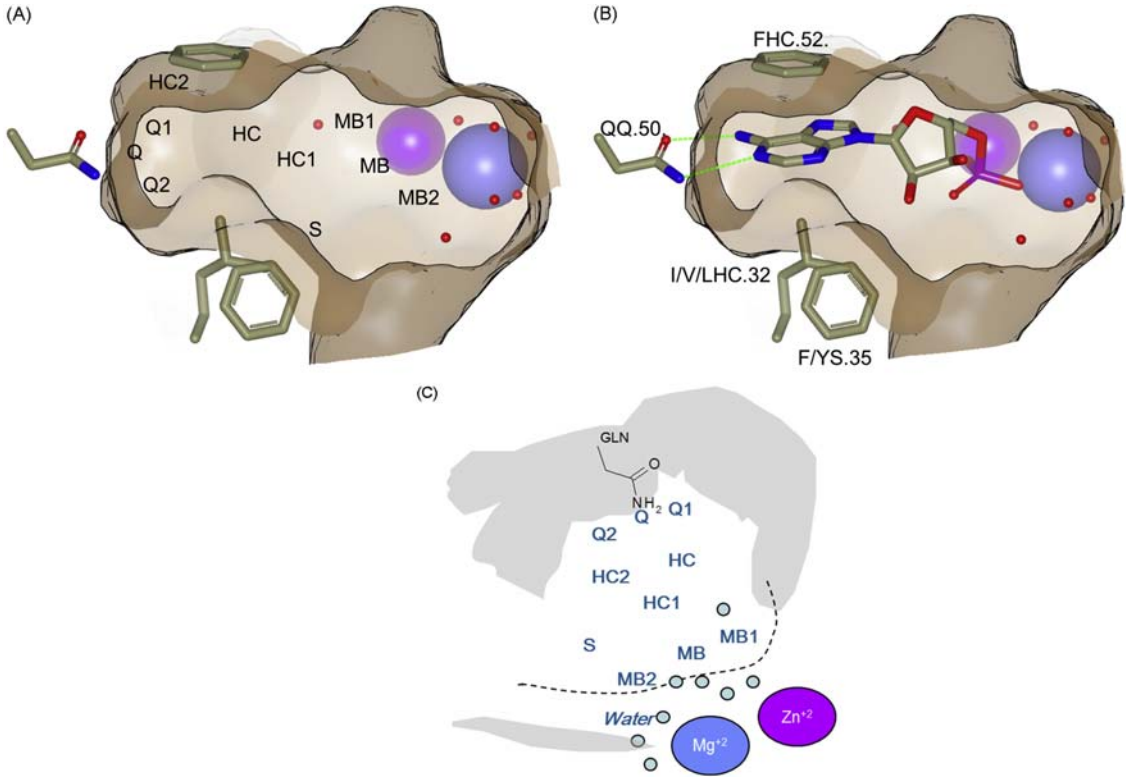

Fig. 4 (A) The PDE pocket is divided into 10 defined regions of the substrate binding site. The substrate binding site includes the Q, Q1, and Q2 regions that surround the important invariant glutamine residue QQ.50, the HC, HC1, and HC2 regions that surround the hydrophobic clamp (I/V/LHC.32 and FHC.52) and the S region solvent filled subpockets. The metal binding (MB) site is divided into the MB, MB1, and MB2 regions. (B) The PDE pocket shown with AMP in the binding site and some key-residues involved in substrate and inhibitor binding are highlighted. (C) The PDE pocket shown schematic, seen from the top.

theoretical descriptors. A descriptor is a structural or physicochemical property of a molecule or part of a molecule. Examples include log *P*, molecular mass (MW), and polar surface area (PSA). Most commonly the assessment of drug-likeness is performed by the use of rules, the original and most well-known of which is Lipinski's rule of five (Ro5, see **Table 2**).[15]

In 1997 Lipinski et al. analyzed the physicochemical properties of drugs in a database of about 2500 orally active drugs that had entered at least phase 2, based on United States Adopted Name (USAN) or International Nonproprietary Name (INN) names. From this analysis, the Ro5 was developed (see **Table 2**, rules of drug-likeness). The Ro5 is so named because all the essential physical properties are parameters of five, and it defines four simple physicochemical parameter ranges (MW $\leq$ 500, log $P \leq 5$, H-bond donors, HBD $\leq$ 5, H-bond acceptors, HBA $\leq$ 10) associated with 90% of orally active drugs that have achieved phase 2 clinical status. These physicochemical parameters are associated with acceptable aqueous solubility and intestinal permeability and comprise the first steps in oral bioavailability. When the Lipinski type analysis was applied to CNS-active compounds, a stricter CNS rule-of-4 (Ro4) was found (see **Table 2**). Of especially high importance for a CNS-active PDE ligand is that it is able to cross the blood–brain barrier (BBB) and have a good permeability across cell membrane in order to reach the intracellularly PDE-target. A small molecule

Table 2 Rules of drug-likeness and pgp substrates

Lipinski's Ro5	*Pgp substrates: Petrauskas*
– Molecular mass $<$500	Pgp substrates:
– Calculated log $P<5$	– N+O >8
– $<$5 Hydrogen-bond donors	– MW $>$400
– $<$10 hydrogen-bond acceptors	– Acid with p$K_a>4$
Lipinski's CNS Ro4	
– Molecular mass $<$400	● Pgp nonsubstrates:
– Calculated log $P<4$	– N+O <4
– $<$4 Hydrogen-bond donors	– MW $<$400
– $<$8 Hydrogen-bond acceptors	– Base with p$K_a>8$

with a low molecular weight (~<400 Da), a relatively high lipophilicity (cLogP in the range of 2–4) and low PSA (<80–90 Å^2), appears to be optimal for diffusion across the lipophilic BBB. It has become increasingly apparent that the endothelial cells in the CNS vasculature express many efflux proteins such as P-glycoprotein (P-gp), which protects the brain by actively pumping out molecules that enters the brain. In order to facilitate the design of compounds with higher likelihood of penetrating the brain, Petrauskas et al. made a classification analysis of P-gp substrate specificity and found that in order to avoid molecular features of P-gp, it is often advisable to keep the Ro4 (see **Table 2**).[16] However, since P-gp is a protein, its recognition of substrates is not governed only by physicochemical properties but by specific molecular recognition elements. Some attempts have been made to define this pharmacophore. Based on a comparison of a hundred compounds previously tested as P-gp substrates, Seelig proposed[17] that a set of well-defined structural elements is required for an interaction with P-gp. The recognition elements are formed by two (type I unit) or three electron donor groups (type II unit) with a fixed spatial separation. Type I units consist of two HBAs with a spatial separation of 2.5 ± 0.3 Å. Type II units contain either two HBAs with a spatial separation of 4.6 ± 0.6 Å or three HBAs with a spatial separation of the outer two groups of 4.6 ± 0.6 Å. In a similar attempt, Pajeva and Wiese proposed[18] a general pharmacophore model of P-gp drugs consisting of two hydrophobic points, three HBA points, and one HBD point. Since Lipinski's seminal report, a large number of additional analyses have been performed on huge datasets and generally have confirmed the central role of physicochemistry. During such an analysis, it was observed that the polarity and molecular weight of in vitro permeable and low clearance compounds are concentrated within an area with a base-line from log $D = -2.0$ to log $D = 5.0$ at MW = 200 and an apex at log $D = 1.0$–2.0 and MW = 450. These trends lead to a triangular-shaped area known as the golden triangle centered at log D 1.5, MW 350, and molecules within this area that are low clearance and permeable are said to obey the golden triangle rule.

7.09.4 PDE Inhibitors

There are 13 FDA approved PDE inhibitors, namely, the unselective PDE-inhibitors theophylline, pentoxifylline, and papaverine; the PDE3-inhibitors cilostazol, milrinone, amrinone, and enoximone; the PDE4-inhibitors roflumilast and apremilast; the PDE5-inhibitors sildenafil, vardenafil, tadalafil, and avanafil. Currently many PDE inhibitors are under development by the pharmaceutical industry across multiple indications. Within therapies to treat CNS diseases the interest for PDEs as targets continues to grow particularly for cognitive decline associated with aging and/or neuropsychiatric diseases such as Alzheimer's disease. The most active areas of research are within the PDE subtypes PDE1, PDE2, PDE4, PDE9, and PDE10, which are reviewed in the following sections.

7.09.4.1 PDE1

PDE1 was one of the first PDE families to be identified in 1970 when it was isolated from bovine and rat brain and was previously called calcium- and calmodulin-dependent PDE, due to its unique Ca^{2+}-dependent activation via calmodulin, thus representing an interesting regulatory link between cyclic nucleotides and intracellular Ca^{2+}.[19] PDE1 isoenzymes are encoded by three genes, PDE1A, PDE1B, and PDE1C. The N-terminal regions contain the regulatory calcium/calmodulin binding sites that activate the enzyme to increase V_{max}. Despite high structural homology within the C-terminal catalytic regions, the three PDE1 isoforms differ in substrate affinity. The affinity for cGMP is similar ($K_m \sim 1$ μM) across the three PDE1-subtypes; however, their affinities for cAMP differ up to 100-fold with the PDE1C having K_m around 1 μM, PDE1B has a K_m of 10–24 μM, and PDE1A has a K_m of 72–124 μM.[20]

The three isoforms have a differential distribution throughout the brain and the body; PDE1B is highly expressed in the striatum, whereas PDE1A is mainly found in the cortical areas, hippocampus, and vascular smooth muscle cells; and PDE1C is particularly highly expressed in the olfactory epithelium, heart, and bladder. In spite of the early discovery of PDE1, a lack of suitable potent and selective, permeable PDE1-inhibitors has hampered extensive understanding of its biological functions. However, during recent years, a growing interest has provided new discoveries and progress in the PDE1 field with a particular focus on the use of PDE1 inhibitors within neurodegenerative and neurologic diseases.[21,22]

Although currently there are no marketed drugs which sole MoA is via PDE1, the indole alkaloid vinpocetine (**9**) and the dihydropyridine nimodipine (**10**) (**Fig. 5**) both have been shown to be PDE1 inhibitors, albeit with relatively low to moderate potency (low micromolar IC_{50}). Both drugs are clinically used vasodilators. Vinpocetine is an alkaloid extracted from the periwinkle plant, and reported to have cerebral blood-flow enhancing and neuroprotective effects, and is used as a drug in Eastern Europe for the treatment of cerebrovascular disorders and age-related memory impairment.[23] Vinpocetine is not approved in the United States for pharmaceutical use, but it can be sold as a dietary supplement. With a dose of 10 mg vinpocetine, the C_{max} plasma concentration of vinpocetine has been measured to lie between 62 and 67 ng mL^{-1} (total conc.),[24] which is significantly lower than its potency on PDE1 (IC_{50}–10 μM), hence the reported effects of vinpocetine are unlikely to be caused by PDE1 inhibition, since this inhibition occurs at a fairly large dose and may not apply to standard supplemental dosages of vinpocetine. It appears that the main MoA of vinpocetine is that it blocks several ion channels (sodium, potassium, and calcium) and is an IKK kinase inhibitor.[25]

Nimodipine is an L-type voltage-gated calcium channel blocker but has additionally been found to act as an antagonist of the mineralocorticoid receptor. Nimodipine was originally developed for the treatment of high blood pressure due to the potent vasodilating effects of calcium antagonists, but the main use is in the prevention of cerebral vasospasm and resultant ischemia, a complication of subarachnoid hemorrhage. The regular dosage is 60 mg tablets every 4 hours, and the average, maximum nimodipine plasma concentrations (C_{max}) at a dose of 30 mg were 16.6 ng mL^{-1} (total concentration),[26] which is significantly lower than its potency on PDE1 (IC_{50}–1 μM), hence the reported effects of Nimodipine is unlikely to be mainly caused by PDE1 inhibition.

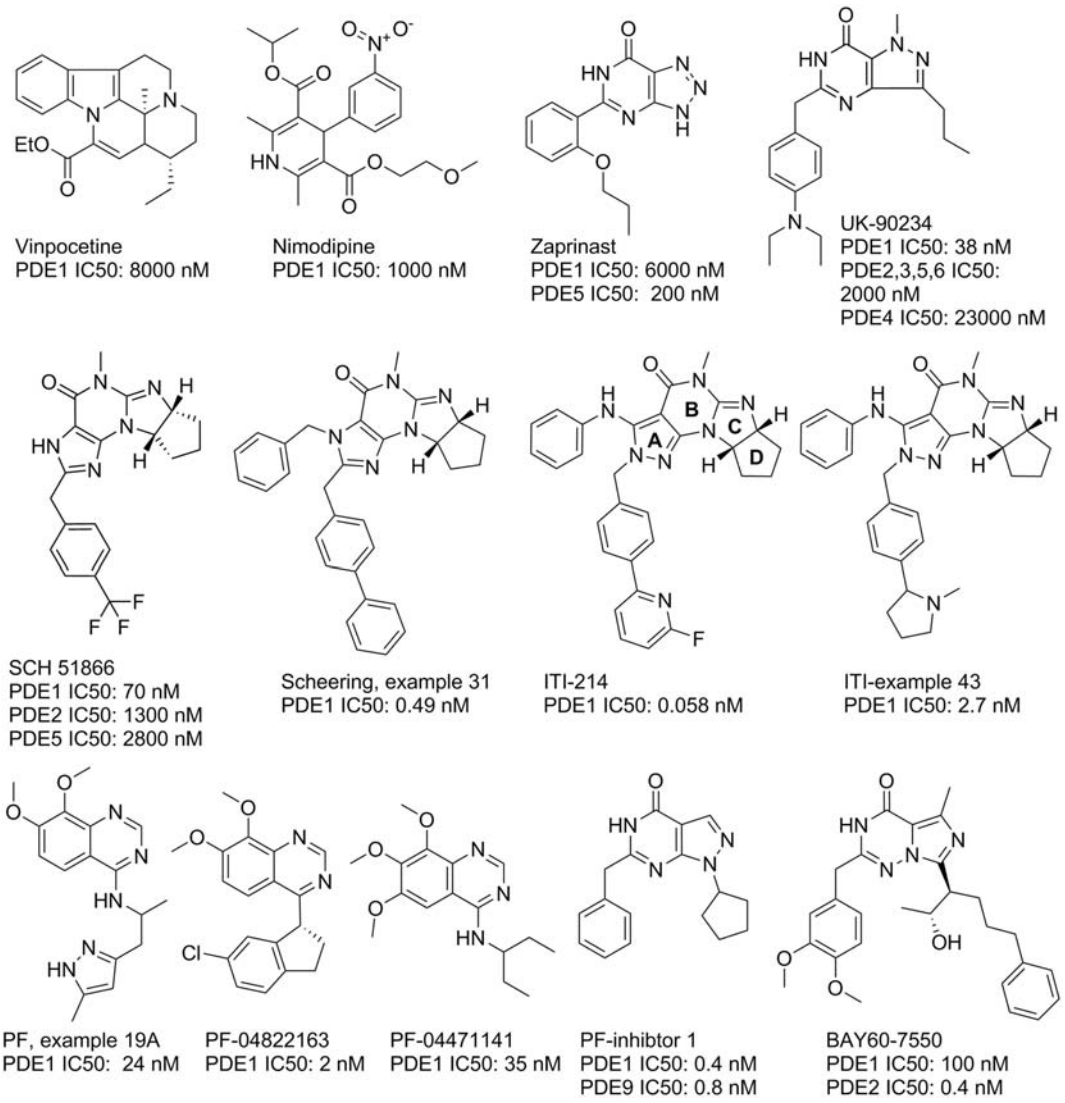

Fig. 5 Structures and IC_{50} values of some inhibitors of PDE1.

Another well-known nonpotent, nonselective inhibitor is zaprinast (**11**), which still lacks selectivity versus other PDE families and is a more potent PDE5 inhibitor. Although Zaprinast was an unsuccessful clinical drug candidate, it has found widespread use as a pharmacological tool.[27]

The recent era of selective PDE1 inhibitors begins with efforts from Schering in the 1990s to "hybridize" the nonselective xanthines like, for example, IBMX (**7**) (Fig. 1) to make them more guanine like resulting in a series of tetracyclic guanines, an example of which is SCH 51866 (**12**) (Fig. 5), which has undergone extensive pharmacological characterization. For unknown reasons, there are conflicting reports on the relative potency and selectivity of SCH 51866 in the literature. The original report from Schering reported SCH 51866 to be a dual inhibitor of PDE1 and PDE5 with equal potency and IC_{50} values of 70 and 60 nM, respectively.[28] However, more recently, SCH 51866 was reported to be PDE1-prefering (for recent IC_{50} values, see Fig. 5).[29] Initial research with SCH 51866 focused on use as a peripheral acting antihypertensive agent, but recent data showed that SCH 51866 also demonstrates CNS effect as it dose-dependently elevated brain striatal levels of cGMP, suggesting the compound to be CNS permeable and CNS-active. Further work in this series led to the highly potent and selective PDE1 inhibitor compound 31 (**13**) (Fig. 5) with subnanomolar potency on PDE1, which however lacked oral activity in contrast to SCH 51866, likely reflecting that compound 31 does not fulfill CNS drug-like properties.[30,31]

In the late 1990s Pfizer described a series of pyrazolopyrimidinones exemplified with UK-90,234 (**14**) (Fig. 5). The UK-90,234 series of compounds are relatively small in size compared with the tetracyclic guanine 31 (**13**) but still might be considered to be distant analogs of guanosine due to the 6,5-fused pyrimidinone ring system, and the PDE1 IC_{50} of 38 nM shows some selectivity versus PDEs 2–6 of 52–640-fold.[32] Although the potency toward PDE9 has not been revealed, subtle structural changes leading to

a structurally isomeric pyrazole pyrimidinone, PF-inhibitor 1 (**15**) and the structurally more distant BAY60-7550 (**16**) (Fig. 5), show that these types of 6,5-fused pyrimidinone lactam-ring systems can fulfill the structural and pharmacophoric requirements for affinity at the PDE9- or PDE2-binding site, since PF-inhibitor 1 has been reported to be an unselective dual PDE1 and PDE9 inhibitor with subnanomolar affinity for both PDE subtypes.[33]

Recently, the Pfizer group published a series of quinazoline derivatives, exemplified with the 3-pentyl amine derivative PF-04471141 (**17**) and the chloroindane derivative PF-04822163 (**18**) (Fig. 5).[34] For the first time within the PDE1 field, now the medicinal chemistry program gets support from X-ray structure showing the binding mode of the ligand PF-04471141 (**17**) (accession code 4NPV). The X-ray structure reveals that the quinazoline 7- and 8-methoxy groups accept a bifurcated H-bond from the side chain nitrogen of the PDE1 Gln-421 residue (Fig. 6A). Furthermore, the quinazoline N1-atom accepts a H-bond from the imidazole side chain of His-373, a signature amino acid specific for PDE1. The requirement for a quinazoline core in this series is further explained by the hydrogen bonding pattern at quinazoline-N3, which is 2.8 Å from a conserved water molecule, which is coordinated by H-bonds to the side chain phenol of Tyr-222, to the carbonyl of Asp-370, and to the catalytic Zn atom via a second well-ordered crystallographic water molecule. This network of water-mediated H-bonds is likely important for quinazoline potency, since both the cinnoline and quinoline templates, which retain N1 but lack the HBA at position 3, show no activity against PDE1.[34]

From the same series, another X-ray was deposited in PDB, namely, 8-dimethoxy-*N*-(1-(5-methyl-1*H*-pyrazol-3-yl)propan-2-yl) quinazolin-4-amine (**19**, PF example 19A, accession code 4NPW). This ligand showed the same binding mode with the same orientation of the quinazoline in the HC (HC, Fig. 6B), thereby demonstrating the ability of the quinazoline to be a purine mimetic.

Recently, Intracellular therapies (ITI) announced completion of a series of phase 1 studies for ITI-214, (6a*R*,9a*S*)-2-(4-(6-fluoropyridin-2-yl)benzyl)-5-methyl-3-(phenylamino)-5,6a,7,8,9,9ahexahydrocyclopenta[4,5]imidazo[1,2-*a*]pyrazolo[4,3-*e*]pyrimidin-4-(2*H*)-one (**20**, Fig. 5), a tetracyclic structure which has some similarity to Schering's earlier tetracyclic guanines.[35] The X-ray crystal structure of the catalytic domain of the human recombinant PDE1B complexed with ITI-214 was reported (accession code 5B25) and gave some insight into the interesting binding mode of this class of compounds. The pyrazolo[3,4-*d*]pyrimidinone

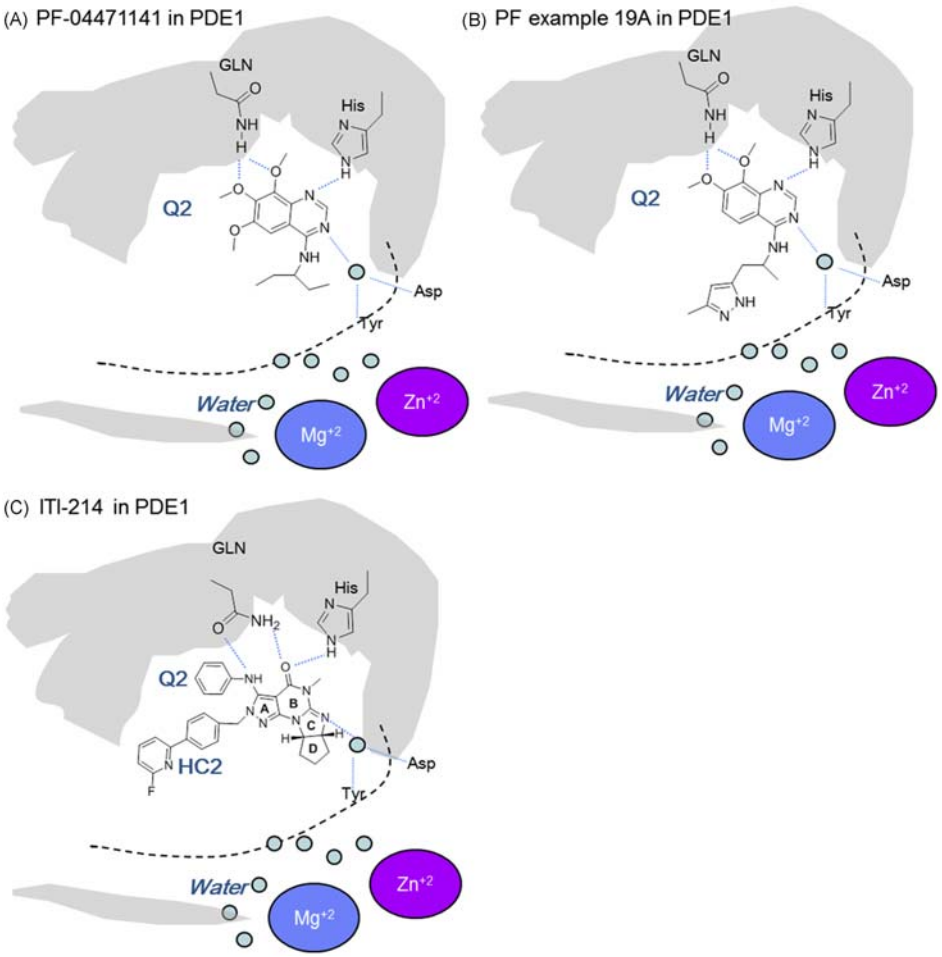

Fig. 6 (A) Cartoon of binding mode of PF-04471141 (**17**) in PDE1 based on X-ray PDB code 4NPV. (B) Cartoon of binding mode of PF example 19A (**19**) in PDE1 based on X-ray PDB code 4NPW. (C) Cartoon of binding mode of ITI-214 (**20**) in PDE1B, based on X-ray pdb code 5B25.

(ring **A**+B in **20**, Fig. 6C) core is held tightly by the HC formed by F424, L388, and F392 located above and below the aromatic core of ITI-214. The π–π stacking and hydrophobic interactions between these contact residues and the planar guanine-mimetic core contribute significantly to the picomolar affinity of ITI-214, which also seems to adopt a binding pose where the conserved Q421 is tilted out of the plane forming bidentate hydrogen bonds with the exocyclic carbonyl group of the pyrimidone and the anilino group. The HBD of the aniline N−H group at position 3 of the A-ring seem to play an important role in contributing to the affinity, supported by an observation, that removal of the hydrogen by N,N-substitution resulted in compounds that were significantly weaker inhibitors than monosubstituted analogues. In addition, replacing this N−H at position 3 with O, S, or CH_2 caused 35–90-fold decrease in PDE1 binding affinity.[35]

The ITI-214 compound is an important contribution to the PDE1 research since it is the first example of a PDE1 inhibitor that reached the clinic. Importantly, it was reported that multiple human clinical phase 1 studies have been completed. In these studies, ITI-214 demonstrated a favorable safety profile and was generally well tolerated across a broad range of doses both in healthy volunteers and in patients with schizophrenia with a pharmacokinetic profile that supports once daily dosing. According to the Company homepage, ITI is currently evaluating ITI-214 for several indications including cognition in patients with Parkinson's disease, dementia, schizophrenia, and other CNS and non-CNS disorders. Based on preclinical studies, ITI-214 may also have the potential to treat cardiac and vascular hypertrophy associated with diseases such as congestive heart failure and may also possess antiinflammatory activity for use in treating neuroinflammation and other major inflammatory diseases. The preclinical characterization of ITI-214 in rats was also reported, and ITI-214 showed procognitive properties in rodents.[36]

The elucidation of the biological function and role of PDE1 was previously hampered by lack of subtype selective compounds; however, recently the field has been moved significantly by the publication of novel PDE1 inhibitors and the pharmacological properties are emerging indicating a potential within cognitive dysfunction. However, PDE1 does also play a significant role in the regulation of the vascular tone, and PDE1 inhibitors might have a potential for treatment of non-CNS disorders in the cardiovascular system and might also be limiting the clinical use within the CNS indication space. In spite of the cardiovascular PDE1-effects reported in preclinical species, the most progressed PDE1 inhibitor from intracellular therapies (ITI-214) has currently completed phase 1 clinical studies and was reported to be safe and well tolerated.

7.09.4.2 PDE2

Native human PDE2A is a protein of 941 amino acids that is organized in four domains: (1) [N-terminus (1–214), (2) GAF-A (215–372), (3) GAF-B (393–541), and (4) catalytic (579–941)] and that functions as a homodimer. The near full length enzyme was crystallized and gave valuable insight to the structure and function of PDEs.[37] PDE2 is a dual substrate PDE, which is activated by cGMP. It is expressed in forebrain regions of the brain, including the cerebral cortex and hippocampus, regions known to be involved in learning and memory, and therefore has been pursued as a target to address CNS disorders, and especially AD.[22,38] It is also expressed in peripheral organs, particularly in the heart, where it plays a role in the regulation of the cardiac cyclic nucleotide cross-talk signaling network.[39]

One of the early reported PDE2 inhibitors was the adenine derivative EHNA, **22** (Fig. 7); however, this compound was subsequently found to lack the requisite selectivity and potency for conclusive pharmacological evaluation.[38] Nevertheless, an X-ray structure of EHNA in complex with the PDE2 catalytic site[40] showed (Fig. 8A) that EHNA binds in the binding pocket of PDE2 via bidentate H-bonds to the invariant Gln-859 which adopts the AMP-mode. The Q2 pocket in PDE2 is relatively small. However, a main finding was the observation of a "binding-induced hydrophobic pocket" (H-pocket, Fig. 8A). The deep H-pocket is generated by induced fit when EHNA binds to the PDE2A enzyme, where the aliphatic side chain of EHNA pushes Leu-770 out to the solvent-exposed surface of the protein and thereby opens up the deep H-pocket. This pocket is closed/blocked by Leu-770 in the absence of ligand (APO-structure—PDB 1Z1) and the pocket is also closed in structures where ligands bind in the binding site, but where a substituent is not protruding into the pocket. An improved tool compound for evaluating PDE2 inhibition was the imidazotriazinone compound BAY-60-7550, **23** (Fig. 7), which is selective with respect to other PDE isoforms (50-fold over PDE1C, >100-fold selectivity vs. other PDE isoforms). While the poor pharmacokinetic properties of BAY-60-7550 probably preclude its use in clinical studies, the compound has been a critical tool to validate the potential therapeutic utility of PDE2 inhibition and has demonstrated enhanced learning and memory and procognitive effects in a range of animal models.[38,41] However, BAY-60-7550 demonstrated poor brain uptake in rats 30 min after administration of a 10 mg kg^{-1} oral dose (B/P = 0.05, [P] = 72.9 ng mL^{-1}, and [B] = 3.6 ng g^{-1}), meaning that in vivo data with this compound should be treated with caution.[42]

The crystal structure of a PDE2a catalytic domain in complex with BAY-60-7550 has been published at a resolution of 1.9 Å.[43] BAY-60-7550 was shown to bind to the active site of PDE2 and interact with the conserved glutamine residue Gln-859 in a GMP-mode (Fig. 8B). The observation that the adenine derivative EHNA interacts with the GLN in AMP-mode and that the "guanine" core of the imidazotriazinone BAY-60-7550 interacts with the GLN in GMP-mode, support that the so-called glutamine-switch is responsible for the dual cAMP/cGMP specificity of PDE2a. Importantly, the authors, who were the first to report the discovery of the hydrophobic subpocket in PDE2 and named it the "H-pocket," describe in detail how the propylphenyl group of BAY-60-7550 was found to bind to the H-pocket between helices H11 and H14, which is formed mainly by hydrophobic residues: Leu770, Leu809, Ile866, Ile870, His773, and Leu774.[43] The authors argued that the origin of the high PDE2a selectivity of BAY-60-7550 is a combination of binding to the glutamine-switch, and to this new induced hydrophobic pocket as a specific selectivity pocket for PDE2, since it is not yet described in any other published PDE-inhibitor complexes.

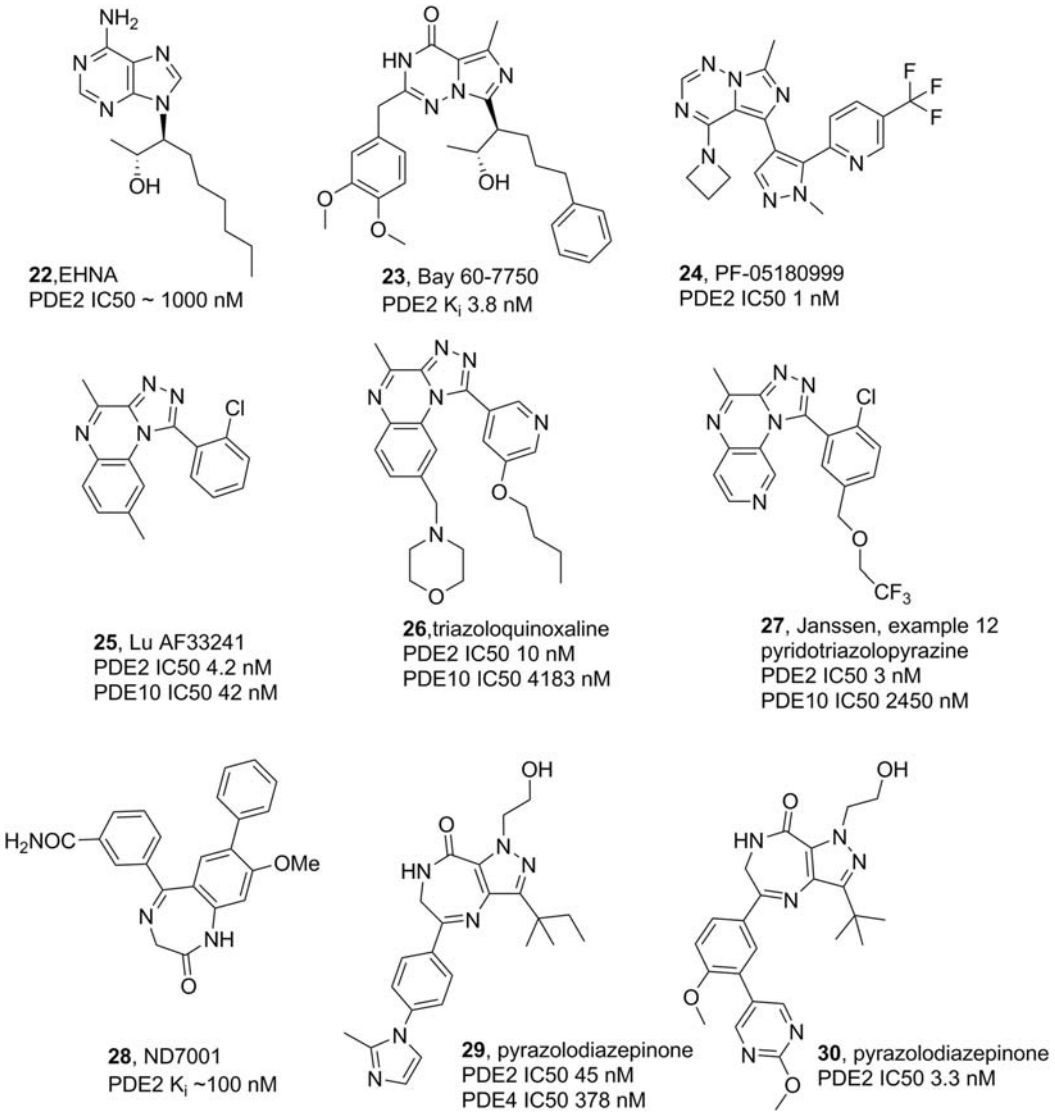

Fig. 7 Structures and IC_{50} values of some inhibitors of PDE2.

Other research groups have also found and used this H-pocket as a mean to develop PDE2 selective compounds. The clinically most progressed efforts have been reported by Pfizer, which presented the clinical candidate, PF-05180999, **24** (Fig. 7).[44] Docking experiments of PF-05180999 suggest that the high PDE2-potency and selectivity is obtained by the 2-(2-methyl-2*H*-pyrazol-3-yl)-5-trifluoromethyl-pyridine group occupying the H-pocket (Fig. 8B).[45] A PDE2 PET-ligand candidate was also reported from this series.[46]

Another compound developed by Takeda, TAK-915, has also been progressed to clinical trials (ClinicalTrials.gov Identifier: NCT02584569). This phase 1 study was conducted to examine the degree and duration of brain PDE2A enzyme occupancy/target engagement as a function of TAK-915 plasma concentration in order to guide dosing and schedule for future clinical studies in schizophrenia with TAK-915.

Several other groups also reported the observation and effective use of the H-pocket to obtain potent and selective PDE2 inhibitors. A series of [1,2,4]triazolo[4,3-*a*]quinoxalines was identified as dual PDE2/PDE10 inhibitors, originally invented by Biotie Therapies GMBH (later Biocrea) and later codeveloped with Wyeth/Pfizer and later again with Boehringer Ingelheim International Gmbh.[38] Simultaneously this series was actively explored by the Janssen group and the Lundbeck group. The Lundbeck group reported on the compound Lu AF33241, **25** (Fig. 7) as a novel, brain-penetrant, dual inhibitor of PDE2A and PDE10A.[47] The Janssen Group has published several reports on the optimization work in this series, for example, **26** (Fig. 7). Following the design hypothesis of utilizing the H-pocket as a selectivity pocket, structure-guided design led to the identification of the novel, potent, and selective PDE2 inhibitor *triazolo-quinoxaline example* **12**, **27** (Fig. 7).[42] An X-ray structure of *triazolo-quinoxaline* **26** in complex with the catalytic domain of PDE2 (PDB 4D08) confirmed that the lipophilic butyloxy-chain was positioned in the induced H-pocket. A

(C) Cartoon of binding mode of PF-05180999, **24** in PDE2, based on docking. (D) Cartoon of binding mode of Janssen, paper example 12 pyridotriazolopyrazine **27**, in PDE2, based on X-ray.

tritiated version of the triazolo[4,3-*a*]quinoxaline was used to demonstrate central occupancy of PDE2 inhibitors in a consistent dose–response manner and in vivo evaluation provided evidence that this series of compounds is able to engage the target and to increase cGMP levels in relevant brain regions. While solubility was increased compared with original HTS-hit, poor metabolic stability led to further lead optimization and introduction of pyridyl-like nitrogen in the benzene ring of the quinoxaline moiety resulting in series and a pyrido[4,3-*e*][1,2,4]triazolo[4,3-*a*]pyrazine series, for example, **27** (Fig. 7) maintaining high ligand efficiency and good overall physicochemical and ADME properties.[48] Also here, the H-pocket was being used to obtain potency and PDE2 selectivity (Fig. 8D). Due to the roof-like position of the H-pocket, very strict geometric requirements must be fulfilled in order to be able to reach this pocket. Since all compounds occupy the clamp-region with a purine isostere, the H-pocket can only be reached by a perpendicular 90-degree orientation of the substituent. In the dual inhibitors triazolo[4,3-*a*]quinoxalines like for example, Lu AF33241, this is achieved by introduction of an ortho-chlorine in the phenyl group, forcing the phenyl out of plane. Alternatively, a pyridyl nitrogen is introduced in the meta-position, which pick up a H-bond in the "floor" and thereby orients the butyloxy group towards the roof pocket. Notably, from this tricyclic series, both the Janssen group and the Biocrea group have identified PDE2 PET-ligand candidates.[49]

Another, older, well-characterized PDE2 inhibitor is the benzodiazepinone compound ND-7001 (IC_{50}–50-100 nM) from Neuro3d (now Evotec). Although structural information is not available with this compound, a molecular modeling study reported by Hamza and Zhan,[50] proposed that the phenyl-amide of ND-7001 serves as the primary anchor point with the amide hooking up in H-bonds with Gln-859 and the phenyl group in the clamp. Although the H-pocket was not known at that time, the ligand pose has the 7-phenyl group pointing toward the H-pocket. Biochemically, ND-7001 increases cGMP levels in primary neuronal cultures of rat cerebral cortical neurons, and in spite of being a pgp-substrate,[40] it was reported to have anxiolytic effects in a number of tests.[40] A clinical phase 1 trial was conducted with ND-7001, and the compound was reported to be safe and well tolerated to high doses and produced no sedation, memory disturbance, or withdrawal effects, but no further development has been reported since 2008.

Pfizer recently published articles discussing the discovery of a series of potent PDE2 inhibitors identified from a PDE4 diazepinone scaffold, for example, **29** in Fig. 7, mainly aimed at for non-CNS indications. In silico modeling studies suggested that this series of inhibitors would adopt a cGMP-like binding mode due to the orientation of the ligand with Gln-859. It was thought that this orthogonal binding mode, compared to cAMP-like binding mode found for PDE4, would allow for greater PDE2/PDE4 selectivity. After extensive SAR studies, the researchers identified the diazepinone compound **30** in Fig. 7 with good PDE2a potency ($IC_{50} = 0.003$ μM) and improved PDE4B selectivity (PDE4B $IC_{50} = 0.562$ μM). Based on the cLogP and TPSA values, the researchers did not expect this PDE2 tool compound to show good brain penetration.

In summary, several groups have invented potent and selective brain-penetrant PDE2 inhibitors and demonstrated procognitive properties of PDE2 inhibitors in rodent models. PET-ligands assisting target engagement studies in the clinic have been published, and several groups have advanced PDE2 clinical candidates into phase 1 studies, reporting them to be safe and well tolerated with Pfizer currently having the compound PF-05180999 (**24**) on clinical hold, whereas Takeda is progressing the compound TAK-915 for cognitive dysfunction associated with schizophrenia.

7.09.4.3 PDE4

PDE4 is a cAMP-specific hydrolase, which is the major enzyme responsible for the degradation of cAMP in the body and is represented by four genes (PDE4A, B, C, and D). PDE4A, B, and D are expressed in the brain. PDE4 isoforms differ in N-terminal sequences that determine cellular sublocalization and regulatory properties. All four proteins contain signature regulatory domains, called upstream conserved region 1 (UCR1; ~55 amino acids) and upstream conserved region 2 (UCR2; ~78 amino acids). UCR2 negatively regulates cAMP hydrolysis and is also needed for high-affinity binding of the PDE4 inhibitor rolipram, **37** (Fig. 9). Based on the variation of UCR1/2 of the N-terminus, the PDE4 isoforms can be divided into three classes: long, short, and super short. The long class of enzymes has both UCR1 and UCR2; the short has UCR2 only; and the supershort has only a truncated UCR2. UCR1 and UCR2 form a regulatory module that is disrupted by protein kinase A (PKA) by phosphorylation of UCR1, which increases enzymatic activity and sensitivity to rolipram. Another characteristic of the PDE4 enzymes is an extreme C-terminal sequence that is unique to each PDE4, and which is important in the design of PDE4 subtype selective inhibitors.

PDE4-selective inhibitors have potential therapeutic use in many disease areas but have had particularly high interest for CNS, inflammatory and respiratory diseases. More than 30 different PDE4 inhibitors have been developed and advanced to human clinical trials, mostly for the treatment of inflammatory diseases. Two PDE4 drugs are now on the market, roflumilast **31** (Fig. 9), showing clinical effectiveness in chronic obstructive pulmonary disease (COPD), and apremilast, **32** (Fig. 9) approved for the treatment of certain types of psoriasis and psoriatic arthritis. The development of PDE4 inhibitors as therapeutic drugs has been hampered by the dose-limiting emetic side effects (nausea and even vomiting) in humans. Currently, PDE4 inhibitors are being developed that show a strong reduction in emetic side effects, particularly the effect of roflumilast on nausea is mostly mild or moderate in intensity and occurs in only 5% of the subjects. The improved tolerability in comparison to other PDE4 inhibitors has been attributed to a pharmacokinetic profile with a lower peak-to-trough ratio, allowing a stable plasma concentration so that the drug remains in a narrow free concentration range.[51] Recently, CNS effects of roflumilast were demonstrated, and it was shown to improve memory in rodents at nonemetic doses.[52] Based on the results in rodents, a clinical trial involving healthy 18- to 35-year-old adults was performed using a single oral administration of a capsulated formulation containing 100, 300, or 1000 μg roflumilast.[53] In this clinical trial the group of healthy adults receiving a single oral dose of 100 mg of roflumilast showed a considerable improvement with respect to the number of correct words recalled (an average 2.5 words improvement after the third trial) in the verbal learning task (VL-T). EEG measurements performed simultaneously with VL-T testing revealed that event-related potential (ERP), P600 demonstrated the strongest increase of amplitude, also in the group of healthy adults receiving a single oral dose of 100 μg of roflumilast. In order (a) to confirm the results seen in the clinical trial with the healthy 18- to 35-year-old adults and (b) to detect whether perhaps even more substantial improvement might be observed in aged adults with a certain degree of cognitive impairment, a small clinical study was conducted with forty 60- to 80-year-old subjects with one group having a more pronounced cognitive decline (assessed with VL-T) as well as with an aged matched control group.[53] The two patients groups were tested for cognitive battery (Verbal Learning Task, Spatial Memory Task, and Stroop Task) and EEG battery (ERP's, sensory gating and novelty oddball task) tests. The data obtained from an interim analysis of that clinical trial based on nine subjects of the impaired group and four subjects of the control group appears to confirm the effects seen in the VL-T in the earlier trial with healthy adults after administration of 100 mg of roflumilast. All these data indicate that roflumilast administered in doses considerably lower than the approved once a day dose for the treatment of severe COPD (500 μg) is effective in improving cognitive impairment. Roflumilast has undergone two clinical studies, one proof of mechanism study in schizophrenia with roflumilast plus antipsychotics (ClinicalTrials.gov Identifier: NCT02079844) evaluating cognitive improvement. Another clinical trial investigated roflumilast and Donepezil ability to reverse scopolamine-induced cognitive deficits in healthy adults (clinicaltrials.gov identifier: NCT02051335). Results of the studies have not yet been published.

The other PDE4 inhibitor on the market, apremilast, has not yet been investigated for its potential CNS effects, but apremilast has been reported to be a pgp-substrate and the concentrations measured in the CNS were consistently low, indicating that penetration of the blood/brain barrier was poor.[54]

The prototypic PDE4 inhibitor, rolipram, **37**, showed efficacy in a small, open-label depression study in the early 1980s,[55] and since then an extensive body of preclinical and clinical efficacy data has been accumulated, however its development was

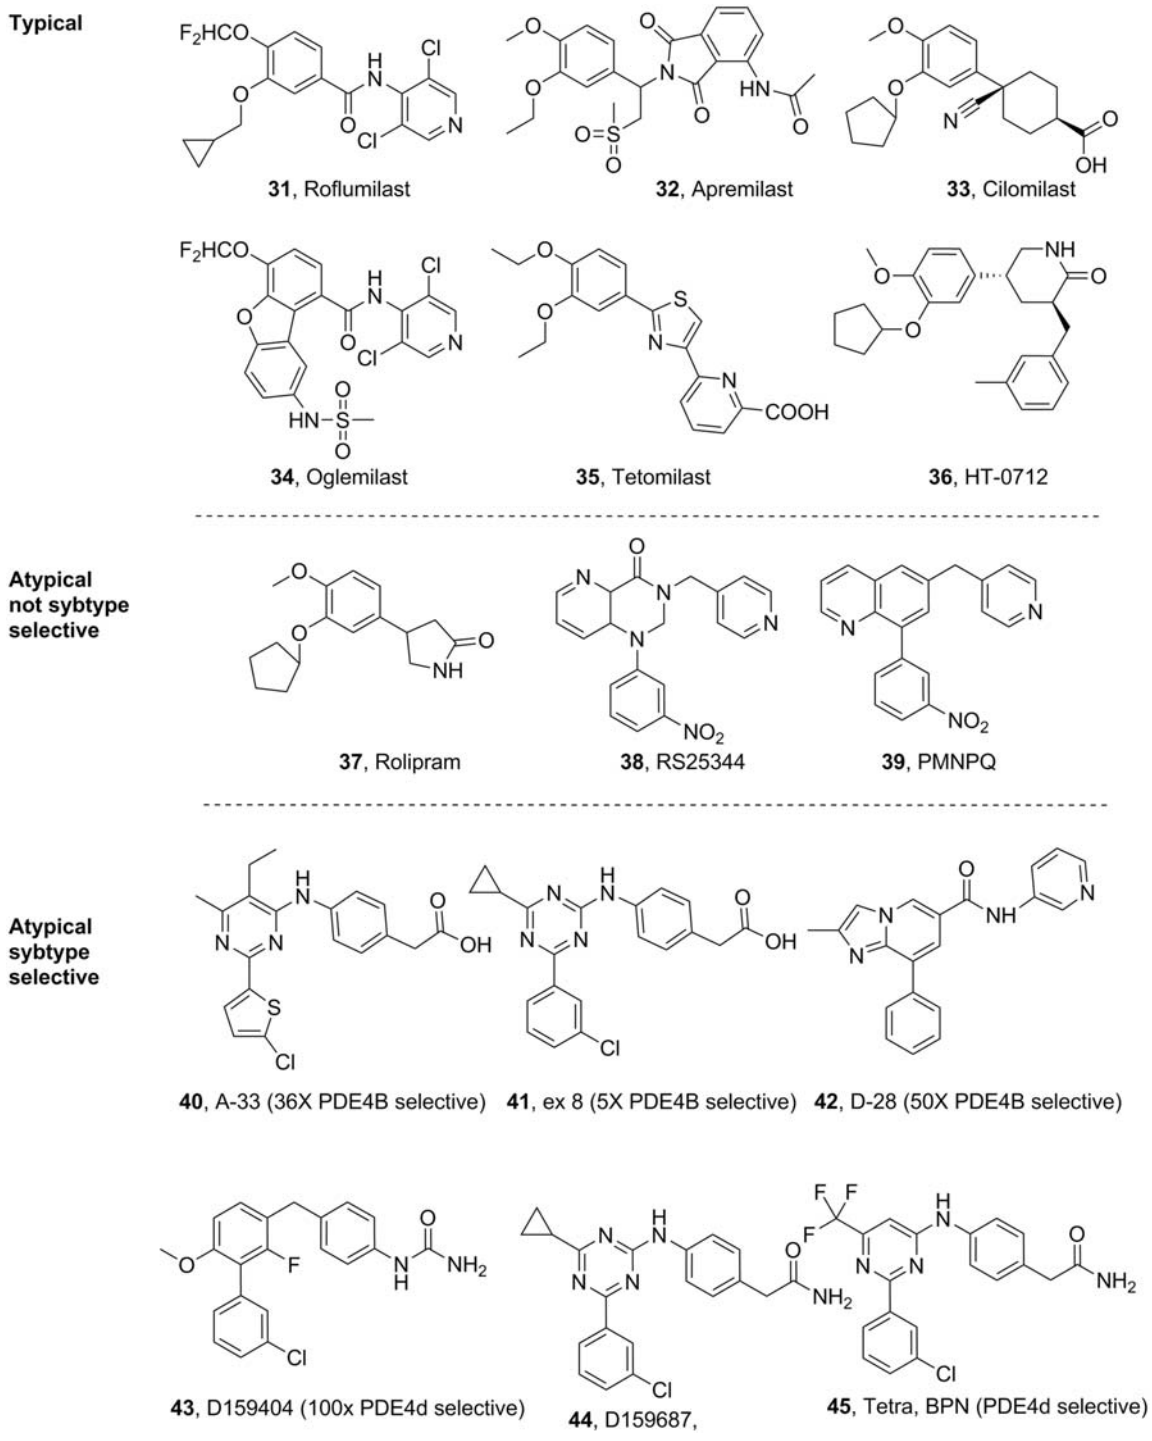

Fig. 9 Structures of some inhibitors of PDE4.

discontinued owing to its side effects. Nevertheless, Rolipram is a widely used PDE4 inhibitor that has been evaluated in multiple models of learning and memory and has been shown to reverse memory deficits in mouse models of AD and provide cognitive benefit in a range of rodent models.[22,56]

Detailed overviews of the binding mode of PDE4 inhibitors have been published, in which PDE4 inhibitors have been divided into three groups, based on their PDE4 subtype-selectivity and binding mode: (1) typical PDE4 inhibitors including roflumilast, **31**, and apremilast, **32**; (2) atypical inhibitors which are not PDE4-subtype selective including rolipram; and (3) atypical inhibitors which are PDE4-subtype selective including the PDE4D-preferring tool compound D159404, **43** (see Fig. 9).[57]

Inhibitors of PDE4 may be classified as "typical" or "atypical" (Fig. 9) based on whether they interact with the catalytic domain alone (like roflumilast) or with the catalytic domain plus one of the regulatory domains, that is either the UCR2 domain (like rolipram) or the C-terminal domain (like A-33, **40** see Fig. 9).[57] Atypical inhibitors are much more potent against long forms of PDE4 that contain both UCR1 and UCR2 compared to those containing only the catalytic domain. For example, PMNPQ, **39** (Fig. 9) is >10,000 more potent against the long-form variant PDE4D7 than against PDE4D catalytic domain.[57] By contrast, typical inhibitors, such as roflumilast, bind with nearly equal affinity to long isoforms and catalytic domain constructs. Both roflumilast and rolipram belong to the class of dialkoxyphenyl PDE4 inhibitors. This class also includes HT-0712, **36** (Fig. 9), which has been reported to have completed a clinical trial versus placebo in subjects with age-associated memory impairment, although no study results have been posted yet (ClinicalTrials.gov Identifier: NCT02013310). Several compounds from the dialkoxyphenyl family of compounds have been crystallized in the PDE4 catalytic domain, and they all share a common binding mode (Fig. 10).[58] The catechol ethers make a H-bond with the conserved GLN, and the phenyl group is sandwiched by the P-clamp. Substituents on the phenyl ring are exploring the ribose binding site and to some extent the phosphate binding site. The dialkoxyphenyl family of compounds almost all contains one carbon ether, for example, methoxy or difluoromethoxy, and a cyclic multicarbon ether, for example, cyclopentyloxy or cyclopropylmethyl. The smaller methoxy or difluoromethoxy group on the phenyl ring is tucked into a small pocket at the deep side of the Q1 pocket formed by Y233(PDE4B), N395(PDE4B), T407(PDE4B), and Y403(PDE4B).[58] The other alkoxy-group tends to be a larger hydrophobic group such as cyclopentyl, which occupy the larger hydrophobic Q2 pocket formed by F414(PDE4B), M411(PDE4B), M431(PDE44B), and F446(PDE4B).

The various substituents on the nonalkoxy positions of the phenyl scaffold explore the deep pocket close to the MB site, and how well they form interactions with residues lining this pocket determines their relative binding affinity. The relatively smaller pyrrolidinone substituent in rolipram has resulted in somewhat lower binding affinity of 570 nM. The pyrrolidinone group is stabilized mainly through hydrophobic interactions with M347(PDE4B), I410(PDE4B), and F414(PDE4B). Roflumilast binds similar to rolipram. The difluromethoxy group binds at the Q1 pocket, while the cyclopropyl methoxy group binds at the Q2 pocket. The difluromethoxy group fits the Q1 pocket better and makes more hydrophobic interactions with residues than the methoxy group. However, due to the relatively lower lipophilic surface area of the cyclopropylmethylether group, it makes fewer hydrophobic interactions than the larger cyclopentylether group. The dichloropyridyl group extends to the dimetal ion site and forms one H-bond to a water molecule that is coordinated to Mg^{2+}. The dichloro-atoms also form additional hydrophobic interactions with residues in the M-pocket. The dichloropyridyl substitution has compensated for the negative effect of the cyclopropylmethyl ether group and as a result has increased the potency significantly ($IC_{50}=0.84$ nM).

When it comes to binding mode of roflumilast and rolipram to long-form PDE4, however, there is a marked difference in observed interactions between ligand and binding site compared to binding to the catalytic domain only. Rolipram has been shown to bind to PDE4 possessing two binding sites, high-affinity (1–50 nM) and low-affinity (500–1000 nM) rolipram binding sites, and recently, it has been shown that these represent two different conformational states of the enzyme.[59] It has been shown that there is a difference between the interactions of rolipram binding in the catalytic site alone (the low-affinity binding site) compared to the interactions of rolipram binding in the long-form PDE4, where UCR2 of one subunit interacts with the catalytic domain of the other subunit and thereby introduces further interactions that identifies the basis of the high-affinity rolipram binding site (Fig. 10).[59] In the high-affinity binding mode, Tyr274 from the regulatory UCR2 helix forms one wall of the hydrophobic pocket occupied by the cyclopentyl group, and its phenolic hydroxyl oxygen from the tyrosine forms a hydrogen bond with the amide carbonyl oxygen in rolipram. Both these interactions are absent in the low-affinity binding mode. So, the difference is that rolipram makes two significant additional interactions with the regulatory helix. The hydrophobic cyclopentyl group is now completely buried in

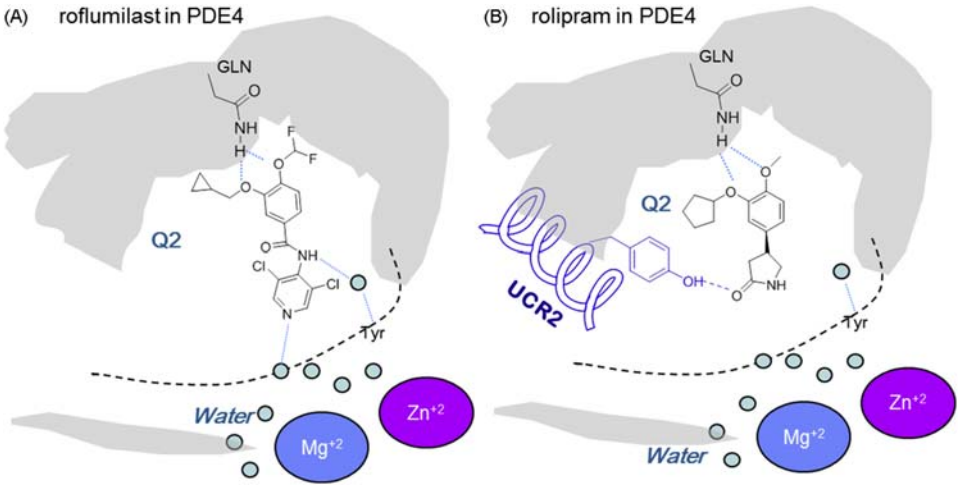

Fig. 10 Cartoon of binding mode of PDE4 inhibitors roflumilast and rolipram in PDE4 based on X-ray.

a hydrophobic pocket, whereas it was partially exposed to solvent in the catalytic domain structure. These additional interactions, which contribute to high-affinity rolipram binding, are only possible in dimeric PDE4 where the autoinhibitory domain of one subunit can interact with the catalytic domain of the other subunit.[59]

Recent progress in understanding the structural basis of PDE4 regulation has made it possible to design selective PDE4D and PDE4B inhibitors, which have been called negative allosteric modulators (NAMs) due to the interaction with either the UCR2 or the C-terminal domains. These act by modulating the closure of N- and C-terminal PDE4 regulatory domains across the active site, thereby inhibiting the enzyme.

PDE4B and PDE4D are therapeutic targets of high interest for CNS; however, it has been difficult to discover selective PDE4B and PDE4D inhibitors as there are no amino acid sequence differences in the active site that distinguish PDE4B from the other PDE4 subtypes.

It is possible to design small-molecule negative allosteric modulators of PDE4D that act through closing UCR2 over the active site. Indeed, rolipram inhibits PDE4 through that mechanism. Examples of such compounds are D159404, **43** (100× PDE4d selective); D159687, **44**; and Tetra, BPN-compounds, for example, **45** (**Figs. 9** and **11**). Notably, the UCR2-directed, partial inhibitor D159687 was 300-fold less emetic than rolipram, despite equal potency in cognition assays, and D159687 was 3000-fold less emetic than rolipram in the beagle dog, and 500-fold less emetic in monkey.[60] Thus, there is a striking difference between full and partial PDE4D selective-inhibitors directed against UCR2 with respect to PD tolerability. This could indicate that allosteric modulators that only partially inhibit PDE4D activity may achieve improved tolerability by maintaining temporal and spatial aspects of cAMP signaling.[60] Compounds able to bind UCR2, when located in the active site, share a common pharmacophore and binding pose. The pharmacophore consists of three elements: (1) a planar scaffold providing a hydrogen bond to Gln-535, (2) a linker, and (3) two aromatic substituents which create a clamp that holds UCR2 in the closed conformation. Key to the design of partial inhibitors was the deliberate weakening of the P-clamp interaction with the hydrophobic walls of the active site.[60]

Besides the role of UCR2 to function as a regulatory part when closing over the active site, a second, downstream C-terminal helix, termed CR3 (conserved region 3) is present in all PDE4 isoforms and was also shown to close over the active site by weakly engaging inhibitors (e.g., PMNPQ, **39** **Fig. 9**; PDB ID: 3G58). Recently, selective PDE4B inhibitors have been reported, which act by engaging the C-terminal CR3 regulatory domain, thereby locking the enzyme in a closed conformation and therefore closing the active site to access by cAMP.[61] Examples of PDE4B selective compounds are A-33,[62] ex-8,[63] and D-28 (**Figs. 9** and **11**). Notably, allosteric modulators that only partially inhibit PDE4D activity may achieve improved tolerability by maintaining temporal and spatial aspects of cAMP signaling.

In summary, whereas the use of PDE4 inhibitors for several peripheral diseases is now well established, the application within the CNS area has been lacking behind due to target-mediated side effects. Strategies to avoid particularly the emetic side effects by either utilizing pharmacokinetic strategies like with roflumilast or pursuing PDE4-subtpe selective compounds have resulted in several companies now having PDE4 compounds in clinical trials for cognitive dysfunction.

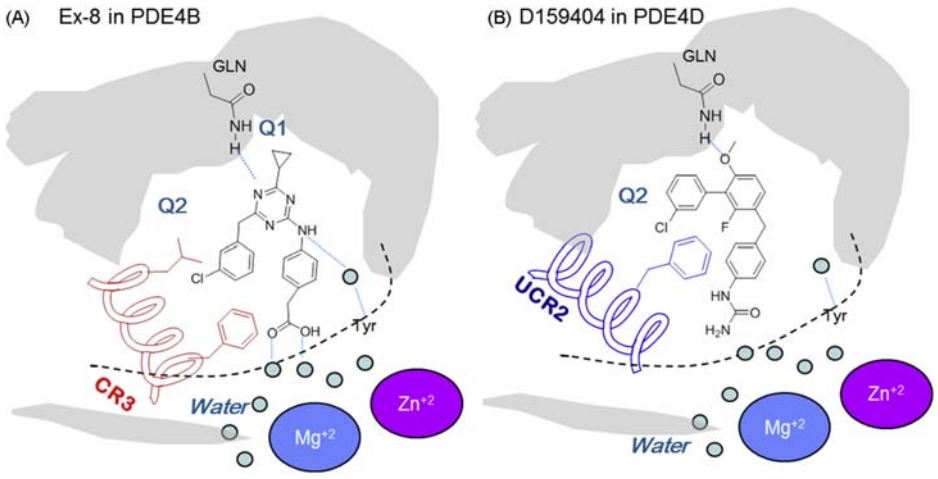

Fig. 11 Binding mode of PDE4 negative allosteric modulators (NAMs). (A) Binding of compound **41** in PDE4B showing key interactions. PDE4B NAMs are directed against CR3. The CR3 regulatory domain (*red*) is closed in cis across the active site of the same monomer. The cyclopropyl group has good shape complimentarily and fills the Q1 hydrophobic pocket in the active site. The amine in the Ar1 linker region is in position to make a H-bond to a conserved water molecule. Both Ar1 and Ar2 groups modulate PDE4B vs. PDE4D selectivity in the triazine series and reach out of the active site and engage the CR3 regulatory helix. The chlorophenyl Ar2 group on the triazine is in position to make hydrophobic interactions with CR3 Phe678 and Leu674, and the carboxylic acid group of Ar1 hydrogen bonds to multiple water molecules which engage CR3 (PDB: 4NW7). (B) Binding of D159404, compound **43** in PDE4D. PDE4D NAMs close the UCR2 regulatory domain (*blue*) in trans over the active site of the opposite catalytic domain in the PDE4 dimer, thereby preventing access by cyclic adenosine monophosphate and inhibiting the enzyme. D159404 forms a H-bond to the invariant GLN (Q610 in PDE4D7), while two arms project outward toward UCR2. Binding of the inhibitor completes a hydrophobic interaction surface for the closure of UCR2 by displacing water from the active site (PDB: 3IAD).

7.09.4.4 PDE9

PDE9 is a family of cGMP-specific enzymes first described in 1998 and has the lowest K_m among cGMP-specific PDE families (cGMP $K_m = 170$ nM, cAMP $K_m = 230$ μM), which might suggest that it could play a role in modulating basal levels of cGMP. Neuronal PDE9 expression has been detected in the cerebellum, cerebral cortex, caudate-putamen, and hippocampus.[64] Selective PDE9 inhibitors have been studied as potential therapeutics for the treatment of diabetes and CNS diseases such as Alzheimer's disease,[65] and several reports have been published demonstrating that PDE9 inhibitors showed memory improving effects in many animal pharmacological deficit models.[65]

PF-4447943, **46** (Fig. 12), a potent, selective, and brain-penetrant PDE9A inhibitor, has been reported to have been dosed in humans where it was well tolerated, and increased CSF cGMP levels, supporting central target engagement and demonstrating the translation of cGMP-measurement between humans and rodents.[66] However, despite strong preclinical efficacy in a range of rodent cognition models,[67] PF-4447943 did not improve cognition or behavior compared with placebo in a 12-week phase 2 clinical trial evaluating the efficacy in mild to moderate Alzheimer's disease.[68] This result is one of many, which highlights the general challenge of translation from preclinical animal models to human clinical efficacy trials, and particularly, finding the right clinical dose is challenging. Nevertheless, Starting in 2011, Boehringer Ingelheim thus far has conducted 10 phase 1 studies, testing both tablets and liquid formulations in a total of about 500 people in Germany, Belgium, South Korea, and the United States on their clinical candidate BI-409306 (chemical structure not disclosed, but examples from patent applications are compounds **48** and **49**, Fig. 12).[69] Eight studies were in healthy volunteers, while three in people with Alzheimer's disease and schizophrenia. The studies assessed safety, tolerability, pharmacokinetics and -dynamics, single or ascending doses given once or twice daily, as well as the effect of food on the drug's metabolism. In Dec. 2014 and Jan. 2015, respectively, two 3-month, multinational phase 2 trials of BI-409306 began in patients with prodromal AD. One study will compare four doses of BI-409306 to placebo in 288 people with mild to moderate AD who have not taken an acetylcholine esterase inhibitor or memantine in the past 3 months; the other will compare the same doses as add-on therapy in 336 patients who also take donepezil. For both studies, the primary outcome measure is the neuropsychological test battery, and secondary outcomes include the clinical scales: ADCS-MCI-ADL, CDR-SB, ADAS-Cog11, and ADCS-ADL. In Mar. 2015, data were presented at the 15th International Congress on Schizophrenia Research, Colorado, USA[70] from a randomized, parallel-group, double-blind, double-dummy, single dose, placebo-controlled trial on healthy male volunteers ($n = 20$), assessing the effect of different doses (25, 50, 100, and 200 mg qd po) of BI-409306 on cGMP CSF levels. Plasma levels of BI-409306 increased rapidly with a delay in reaching maximum CSF concentration. There was

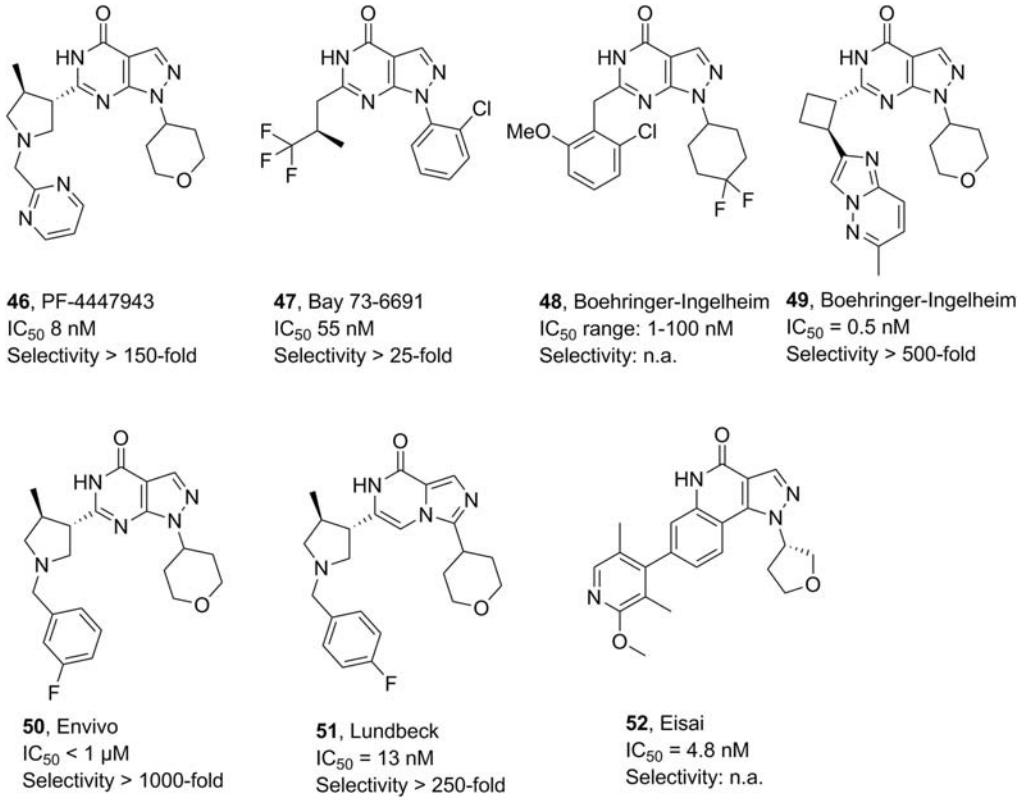

Fig. 12 Structures and IC_{50} values of some inhibitors of PDE9.

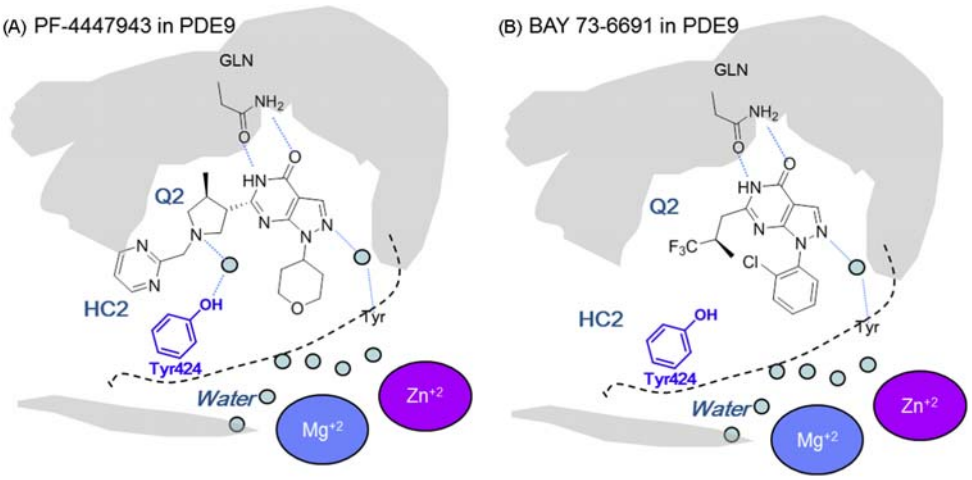

Fig. 13 Cartoon of binding mode of PDE9-inibitors PF-4447943, **46**, and BAY 73-6691, **47**, in PDE9 based on X-ray.

a dose-dependent increase in the cGMP level in CSF, thus validating the use of this biomarker. The drug was found to be safe and well tolerated at all doses.

Another PDE9 inhibitor from Eisai has also been progressed into clinical trials targeting Alzheimer's disease (E-2027, the chemical structure was not yet reported, but a patent application has been published on the Eisai-compound **52** shown in Fig. 12). This first-in-human study (ClinicalTrials.gov Identifier: NCT02415790), designed to assess the safety, tolerability, and pharmacokinetics (PK) of single oral ascending doses of E2027, will be administered to healthy adult participants to determine the maximum tolerated dose. Thereafter, the PD effects of single doses of E2027 on elevation of cGMP in the CSF in healthy adult participants will be evaluated across a broad dose range, to establish the PK/PD relationship.

The crystal structures of the PDE9A catalytic domain in complex with the substrate and with inhibitors reveal that the purine recognizing conserved GLN is locked in a conformation that facilitates a preference for cGMP. The mechanism of the catalytic process of PDE9 and the substrate specificity of PDE9 in the actual hydrolytic reaction was revealed by an unusual series of elegant experiments by X-ray studies by freeze-trapping of isolated structures of reaction intermediates accumulated at the reaction steady state in PDE9-crystal.[71] The X-ray structure of the clinical compound PF-4447943 (PDB code: 4E90)[72] is one of several examples[73] illustrating that a guanine-like motif is needed. The pyrimidinone core interacts with the donor–acceptor pair of the invariant Gln-453 in the GMP-mode (Fig. 13), and the GMP-mode of action promotes selectivity against the AMP preferring PDEs. Further selectivity enhancement is obtained by addressing the small Q2 pocket and particularly selectivity against the structurally similar PDE1 is obtained by forming a H-bond from the amino-group in the pyrrolidine to the PDE9 unique Tyr-424. Another clinical PDE9 compound is BAY 73-6691, **47**, which was the first reported potent and selective PDE9A inhibitor,[74] has also shown significant procognitive effects in animal models[75] and particularly in a transgenic animal model of AD.[76] An X-ray crystallographic study[65] of BAY 73-6691 and its enantiomer (PDB ID 3K3E and 3K3H) bound to PDE9A show a similar binding of the pyrimidinone lactam to Gln-435, the HC being occupied by the 1*H*-pyrazolo[3,4-*d*]pyrimidin-4(5*H*)-one core, the *N*-1 2-chlorophenyl in the ribose region, and 3,3,3-trifluoro-2-methylpropyl in Q2.[77]

Several other research groups have investigated PDE9 inhibitors for the treatment of cognitive impairment, specifically targeting Alzheimer's disease (Fig. 12),[40,65] for example, Boehringer Ingelheim, Envivo Pharmaceuticals, **50**, H. Lundbeck A/S, **51**, and notably there is a very strong similarity of the core structures for many of these and a strong preference among the known PDE9 inhibitors for a guanine like-motif like for example, 1*H*-pyrazolo[3,4-*d*]pyrimidin-4(5*H*)-ones, and it seems as if the PDE9 binding pocket is very strict in recognizing only a small narrow of chemotypes.

In brief, several PDE9 inhibitor compounds have been evaluated to be safe and well tolerated in the clinic, and clinical evaluation of the potential for testing cognitive impairment in patients is underway, with Boehringer Ingelheim being most progressed with their clinical candidate BI-409306.

7.09.4.5 PDE10

PDE10A has a narrow distribution pattern, with expression primarily limited to the brain and testes, and within the brain, PDE10A protein is expressed at high levels in the basal ganglia.[78] Inhibition of PDE10A as a mechanism to address the core symptom domains of schizophrenia has received considerable attention.[79] Inhibitors of PDE10 have been shown to be efficacious in multiple preclinical models thought to be predictive of antipsychotic action, and PDE10A inhibitors increase the functionality of striatal medium spiny neurons and produce antipsychotic-like effects in rodents by blocking PDE10A-mediated hydrolysis of cAMP and cGMP. By using a radiolabeled PDE10A inhibitor and an ex vivo PDE10 binding autoradiographic assay to explore the relationship between the PDE10 binding site occupancy and the observed biochemical and behavioral effects of PDE10 inhibitors in mice, it was

shown that PDE10A occupancy was positively correlated with striatal pCREB expression levels. PDE10A occupancy was also correlated with antipsychotic-like effects measured using the conditioned avoidance response model; a minimum of ~40% occupancy was typically required to achieve efficacy. In contrast, a clear relationship between PDE10A occupancy and catalepsy scores (a potential extrapyramidal symptom readout in rodent) was not evident.[80] Unfortunately, the sparse published clinical studies to date with selected PDE inhibitors have not revealed a procognitive or antipsychotic benefit in humans.[81] A recent trial with the PDE-10 inhibitor MP-10 (**53**, PF-02545920,[82] **Fig. 14**) for the adjunctive treatment of suboptimally controlled symptoms of schizophrenia was stopped based on interim analysis that indicated efficacy would not be achieved (ClinicalTrials.gov). However, phase 2 clinical trials within Huntington's Disease is still ongoing, including a 12-month open-label extension study of PF-02545920 20 mg dosed BID

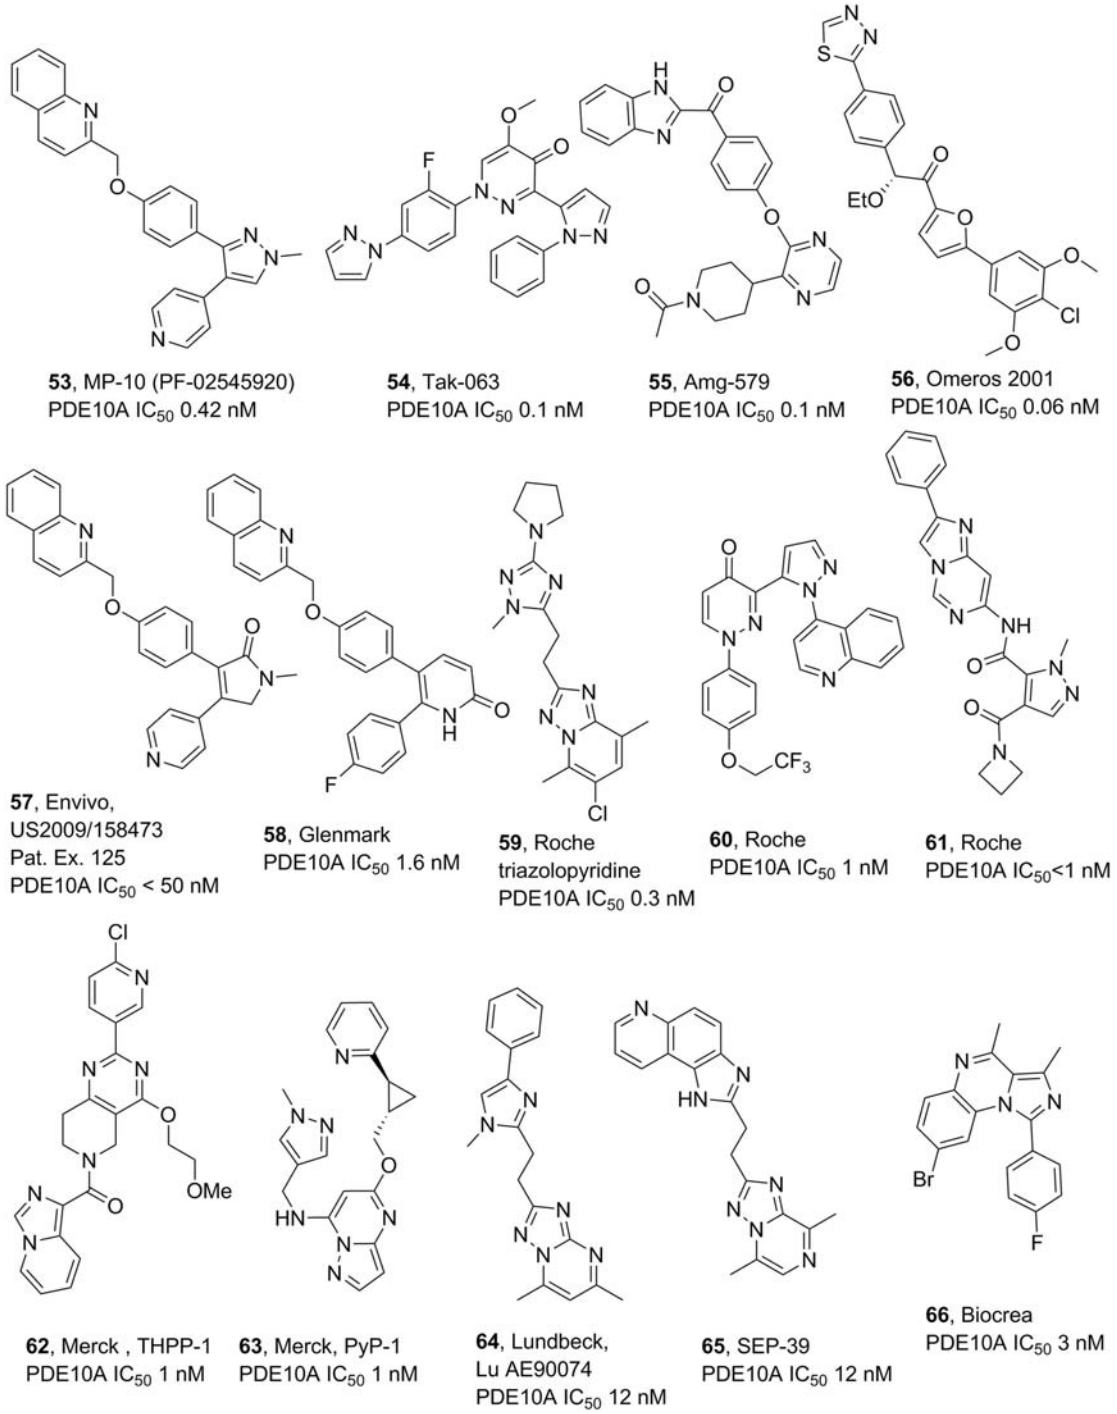

Fig. 14 Structures and IC_{50} values of some inhibitors of PDE10.

following a study in subjects with HD (ClinicalTrials.gov Identifier: NCT02342548). Several companies are currently pursing PDE10 inhibitors in the clinic (see Table 2).

Many X-ray structures of ligands in complex with the catalytic domain of PDE10 have been published, and many drug discovery programs have heavily used structure-based drug design approaches. One hit-finding strategy has been to conduct a fragment screen in the search for chemical matter to serve as starting points for lead optimization. The fragment approach, in which low-molecular-weight, weakly binding fragment hits are evolved toward drug-like compounds, has been more frequently practiced in recent years, with several reported examples applied to PDE10A.[83] Many research groups also report on SBDD used in the lead identification and lead optimization, and structural information on advanced preclinical and clinical compounds is publically available. A few key compounds are illustrated in Fig. 14, chosen in order to illustrate both the structure of some clinical candidates and also to show the high diversity among PDE10 chemotypes and binding modes.

The chemical structure of the clinical candidate TAK-063, **54** (Fig. 14) and the binding mode in PDE10 (Fig. 15) have been reported[84] along with extensive pharmacological profiling and target validation.[85] This compound has been progressed to clinical phase 2 in a PoC study targeting schizophrenia. Radiolabeled versions in the form of tritiated and [^{14}C]-labeled versions of TAK-063 have been developed and used in autoradiography studies to demonstrate that TAK-063 selectively accumulated in PDE10A expressing brain regions.[86] A close structural analogue from the same chemical series has also been developed as a [^{11}C]-PET ligand.[87]

Another clinical compound AMG 579, **55** (Fig. 14) was reported along with its binding mode in the X-ray of the catalytic domain of PDE10, and the pharmacological profile showed antipsychotic properties; however, the phase 1 trial has been terminated (ClinicalTrials.gov Identifier: NCT01568203).[88]

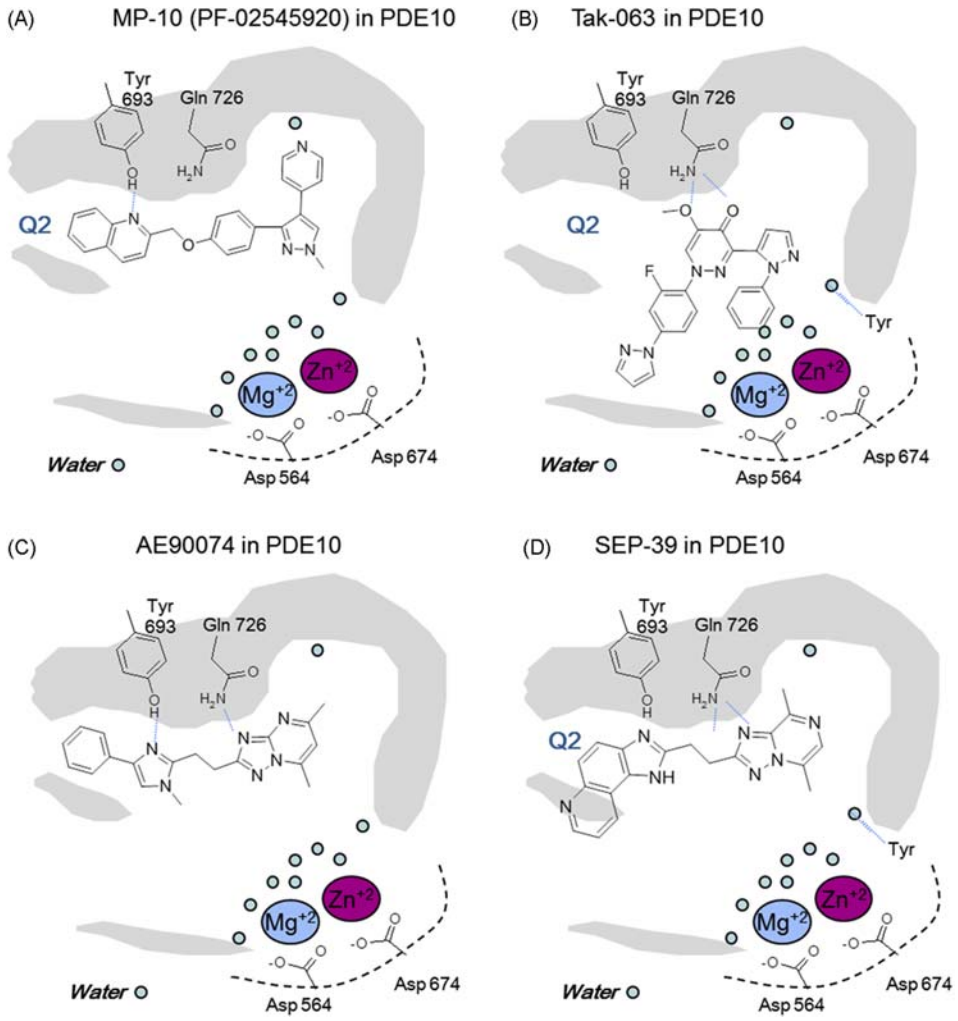

Fig. 15 (A) Cartoon of binding mode of MP-10, **53** in PDE10 based on X-ray. (B) Cartoon of binding mode of TAK-063, **54** in PDE10 based on X-ray. (C) Cartoon of binding mode of LU AE90074, **64** in PDE10, based on X-ray. (D) Cartoon of binding mode of SEP-39, **65** in PDE10, based on X-ray.

The chemical structure of other clinical compounds, OMS-824, RG-7203, FRM-6308, and LU AF11167, have not yet been disclosed, but a few selected PDE10 inhibitors from the companies behind those clinical programs are shown in Fig. 14 in order to illustrate the chemical space covered by these companies.[89] The Omeros group reported on the discovery, SAR studies and optimization studies of some of their PDE10 inhibitors,[90] but did not disclose the structure of their clinical candidate. The Roche group also has not yet disclosed the structure of their clinical candidate, but recently reported on a triazolopyridine, **59** and 3-pyrazolylpyridazin-4-one, **60** (Fig. 14) in a publication describing series of small-molecule drug discovery case studies where computational methods were prospectively employed to impact Roche research projects.[91] The binding mode of the triazolopyridine in the PDE10 binding pocket of the catalytic domain was revealed by an X-ray structure and it showed a similar binding mode to the Lundbeck compound Lu AE90074 **64**,[40] and the recently reported Sunovion compound SEP-39 **65**,[92] which all occupy the central clamp with a purine isostere hooking up with H-bonds to the conserved GLN and furthermore obtain potency and selectivity by occupying the Q2-pocket (Fig. 15). Extensive pharmacological profiling of SEP-39 showed it to be a potent (1.0 nM) inhibitor of PDE10A, with good selectivity (16,000-fold) against other PDEs.[93] In an in vivo occupancy study, the RO50 value was determined to be 0.7 mg kg^{-1} (p.o.), corresponding to plasma and brain exposures of 28 ng mL^{-1} and 43 ng g^{-1}, respectively, and 3 mg kg^{-1} (p.o.) SEP-39 significantly increased rat striatal cGMP concentrations. Furthermore, SEP-39 inhibits PCP-induced hyperlocomotion at doses of 1 and 3 mg kg^{-1} (p.o.) corresponding to 59–86% occupancy. In an EEG study, 3 and 10 mg kg^{-1} (p.o.) SEP-39 suppressed REM intensity and increased the latency to REM sleep, as also shown for other PDE10 inhibitors. SEP-39 had precognitive effects in the rat novel object recognition assay, and the precognitive effects appear to require less PDE10A inhibition than the reversal of PCP-induced hyperlocomotion or EEG effects.

The Merck group has published on two structurally different PDE10 inhibitor chemotypes. The results of an optimization from a novel HTS tetrahydropyridopyrimidine hit led to the compound, THPP-1, **62** (Fig. 14), which exhibits nanomolar potency, excellent pharmacokinetic properties, and a clean off-target profile.[94] It displays in vivo target engagement as measured by increased rat striatal cGMP levels upon oral dosing. It shows dose-dependent efficacy in a key PD assay predictive of antipsychotic activity. It was also reported to improve cognition in the rat and rhesus monkey.[95] More recently, the same group reported the discovery of PyP-1, **63** (Fig. 14), a potent, highly selective, and orally bioavailable pyrazolopyrimidine inhibitor of PDE10A.[96] PyP-1 exhibits subnanomolar potency (PDE10A $K_i = 0.23$ nM), excellent pharmacokinetic and physicochemical properties, and a clean off-target profile. PyP-1 displays dose-dependent efficacy in numerous PD assays that measure potential for antipsychotic activity and cognitive improvement. PyP-1 also has a clean preclinical profile with respect to cataleptic potential in rats, prolactin secretion, and weight gain, common adverse events associated with currently marketed therapeutics. Further, PyP-1 displays in vivo preclinical target engagement as measured by PET enzyme occupancy in concert with [^{11}C]MK-8193, a novel PDE10A PET tracer.[97] Interestingly, the tetrahydropyridopyrimidine has a binding mode in PDE10 (Fig. 16), where THPP-1 has a lack of interaction with Y693 in the PDE10A "selectivity pocket," which likely explains its suboptimal PDE5A, PDE6A, and PDE11A selectivities. In contrast, Pyp-1 was deliberately designed to make the requisite critical interactions in the selectivity pocket. The Envivo group (now Forum)[79] and the Glenmark group have both worked on chemotypes related to the quinoline based MP-10-like structures (Fig. 14), and presumably, they therefore may have the same binding modes (Fig. 15). The Envivo group replaced the central pyrazole of MP-10 with a 1-methyl-1,5-dihydro-2*H*-pyrrol-2-one (**57**), whereas the Glenmark group pursued a pyridin-2(1*H*)-one (**58**) replacement.[98] However, the Glenmark group also reported on a series of polycyclic heteroarene ethers, which exhibited high peripheral and adequate brain levels upon oral dosing in rodents and showed efficacy in multiple preclinical animal models related to psychiatric disorders, particularly schizophrenia.[99]

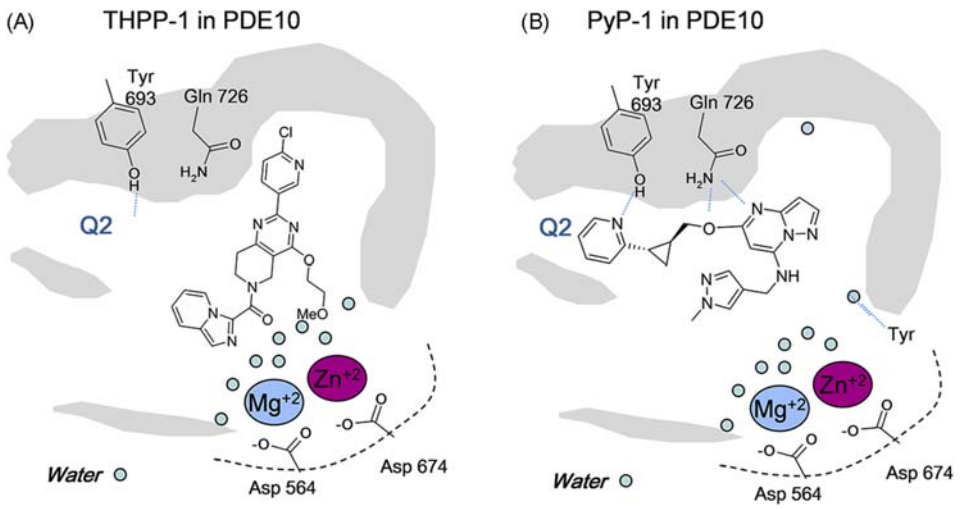

Fig. 16 (A) Cartoon of binding mode of THPP-1, **62** in PDE10 based on X-ray. (B) Cartoon of binding mode of PyP-1, **63** in PDE10 based on X-ray.

To further illustrate the diversity of possible chemotypes within the PDE10 inhibitor field, the tricyclic scaffold from Biocrea (**66** in Fig. 14)[100] is just one out of numerous tricyclic scaffolds which inhibits PDE10 but also other PDEs.[101]

In summary, numerous PDE10 inhibitors have been developed to date, and several compounds have been progressed to the clinic with Takeda and Pfizer currently having the most advanced PDE10 inhibitors which are being pursued for basal ganglia disorders like Huntington's disease and schizophrenia.

7.09.5 Conclusion

PDE inhibitors have been considered as possible therapeutic agents to treat impaired cognitive function linked to several brain disorders, including depression, schizophrenia, Huntington's disease, and Alzheimer's disease. The design of novel, selective inhibitors is being increasingly driven by improved understanding of the biology of PDEs and PDE inhibitors, as well as by structural insights from X-ray crystallography of PDE catalytic cores and PDE inhibitor cocrystal complexes. In addition to providing the basis for structure-based drug design, these studies have yielded information about the unique allosteric interactions between the regulatory and catalytic domains of PDEs. Whereas PDE inhibitors have been successfully marketed for a number of peripheral diseases, we have yet to see the first PDE inhibitor on the market for CNS diseases. With the current intense focus of CNS PDE drug discovery and with the many ongoing clinical trials with PDE inhibitors within CNS areas, the first CNS PDE inhibitor might be approved already in the near future.

7.10.1 Introduction

Protein kinases are essential in many biological processes. Protein phosphorylation by their corresponding kinases maintains signaling transductions, which are essential for cellular functions, such as growth, survival, and proliferation.[1] Of the about 518 known kinases, a small portion have been investigated and their dysfunction has been linked to various human diseases. Targeting the activity of those aberrant kinases as a therapeutic intervention for a variety of disorders has attracted a great amount of effort in pharmaceutical research over the last few decades. Of the 29 kinase inhibitors approved by the FDA since 2001, majority of them are in oncology and only two are for noncancer indications.[2–4] Nintedanib, a multikinases inhibitor inhibiting Vascular Endothelial Growth Factor Receptor (VEGFR), Fibroblast Growth Factor Receptor (FGFR), and Platelet Derived Growth Factor Receptor (PDGFR), was approved for idiopathic pulmonary fibrosis. The JAK1,3 inhibitor, tofacitinib, was approved for rheumatoid arthritis (RA). Although there are no approved kinase inhibitors indicated for central nervous system (CNS) diseases so far, kinase inhibitors have demonstrated activity against tumors that have metastasized to the brain.[5] However, at standard doses, they are not as efficacious in controlling metastasized brain tumors compared to their ability to control peripheral tumors, mainly due to their poor brain penetration, which leads to insufficient drug concentrations for target coverage in CNS. In addition, recent advances in the understandings of some neurodegenerative diseases have been linked to the aberrant signaling pathways that are controlled by different kinases. Inhibiting those malfunctioning kinase-mediated signaling pathways may be useful in providing therapeutic

benefits to patients. To this end, designing kinase inhibitors specifically indicated for CNS diseases requires special attention. A different set of physicochemical properties is needed to design candidates that can efficiently cross the blood–brain barrier (BBB). In this article, recent efforts in developing kinase inhibitors for both noncancer- and cancer-related diseases targeting CNS are reviewed. Two excellent reviews in this area have been published a few years back and this work will try to provide readers with some updates on the progress that researchers have made in the intervening years.[6,7]

7.10.2 Kinases Implicated in CNS Pathology

7.10.2.1 Neurodegeneration[8–11]

As the aging population continues to increase, the incidence of disability caused by neurodegenerative disorders will affect many people. The medical burden on the individual as well as the health care system will be significant. Common neurodegenerative diseases include Parkinson's disease (PD), Alzheimer's disease (AD), Huntington's disease (HD), amyotrophic lateral sclerosis, and atypical parkinsonian disorder among others. Unfortunately, there are no disease-modifying treatment options for these neurodegenerative diseases. Neurodegenerative disorders are mostly believed to be caused by several related processes such as hyperphosphorylation of the tau protein (tauopathies), $A\beta_{42}$ accumulation, neuronal apoptosis, and brain inflammation. Aberrant phosphorylation of tau by several key kinases has been identified in the process of tauopathies. Selective kinase inhibitors targeting their cognate kinases with some brain penetration information, either in vitro or in vivo, are summarized in the section "Small Molecule Kinase Inhibitors for CNS Disorders" (Fig. 1). The most active areas of research to develop kinase inhibitors targeting tau protein or α-synuclein hyperphosphorylation include targeting leucine-rich repeat kinase 2 (LRRK2), p38 mitogen-activated protein kinase (MAPK), and GSK3β. Kinases with newly identified roles, which may contribute to the pathology of neurodegenerative diseases, continue to emerge. For example, a connection was recently identified between 3-phosphoinositide-dependent protein kinase 1 and AD.[11]

7.10.2.2 Oncology[1,12]

Targeting aberrant kinase signaling with small molecule inhibitors has been one of the main frames in cancer therapy. Although most of the targeted malignancies are of peripheral origin, certain cancer types inevitably and preferentially undergo metastasis into the CNS, including the brain tissues and cerebrospinal fluid (CSF). Besides the highly metastasizing nature of the tumors, other reasons attributed to increasing cases of brain metastasis identified may be due to the prolonged systemic control with new drugs and the wider availability of CNS diagnostic tools. Lung[13] and breast[4] cancers are two examples where CNS metastases represent one of the major reasons for treatment failure and disease progression. Glioblastoma multiforme (GBM)[14] is a form of primary brain malignancy for which therapeutic intervention is desperately needed. Oncogenic kinase targets included in this article concerning recent developments in brain-penetrant small molecule kinase inhibitors specifically targeting CNS metastases are anaplastic lymphoma kinase (ALK), epidermal growth factor receptor (EGFR), phosphoinositide 3-kinase (PI3Kα), human epidermal growth factor receptor 2 (HER2), and ataxia-telangiectasia mutated kinase (ATM).

7.10.3 Challenges in Development of Kinase Inhibitors for CNS

Recently, Wu et al. nicely summarized all of the 28 kinase inhibitors approved by the FDA up to late 2015.[2,3] Their analysis showed that most compounds are in good compliance with the Lipinski's rule of five, except for the molecule weight (MW). About 30% of them have MW > 500. A new kid on the block came in late 2015 with the FDA approval of Tagrisso (AstraZeneca), which is an irreversible EGFR inhibitor for nonsmall cell lung cancer (NSCLC) with L858R, Exon19Del activating mutations, and T790M resistance mutation.[15] Similar to the analysis reported by Wu, we performed a study on the physicochemical properties of all 29 FDA-approved kinase inhibitors. Comparing these parameters against the literature reported median values for CNS drugs;[16] it is apparent that most of these marketed kinase inhibitors may have limited CNS penetration simply through passive diffusion (Table 1 and Fig. 2).

Most noticeable are the lower values for all of these physicochemical properties for CNS drugs compared with the kinase inhibitors. It may be challenging to maintain the activity for the primary pharmacology and selectivity with lower molecular weight compounds, especially designing type II kinase inhibitors to gain selectivity. However, this analysis may give a direction for future modification of currently approved kinase inhibitors or a new compound design to favor CNS penetration.

7.10.4 Designing Kinase Inhibitors for CNS Indications

7.10.4.1 Chemistry Approaches for Physicochemical Property Optimization

Over the years, several analytical tools and models have been developed to help medicinal chemists design compounds with good CNS penetration.[17–22] A number of excellent reviews have been published recently to summarize the chemistry strategies to facilitate efficient design of efficacious CNS drugs. The physicochemical properties that favor a drug's CNS permeability are reasonably clear, but to achieve a balance across all of these properties together with optimal target potency is challenging. The modification of a compound to satisfy one parameter to favor brain penetration will often affect other attributes that render the drug impenetrable to the brain or even to lose its target potency. A successful CNS drug development program depends on the medicinal chemist's ability to perform a highly balanced maneuver of different properties of a molecule at once to deliver a CNS drug candidate. Please find literature references for the successful design of CNS drugs summarized later.

The main mechanisms that allow small molecule drugs to penetrate into CNS are passive diffusion and/or active transport. Key compound properties that help increase the chance of having good brain penetration include: (1) minimized intrinsic clearance. Adequate drug exposure in systemic circulation can allow it to equilibrate into the CNS; (2) non-BBB efflux transporter substrates. There are several key efflux transporters that can be found on the BBB, with P-glycoprotein (P-gp, MDR1) and breast cancer resistance protein (BCRP) being the two most important transporters. In addition to them not being transporter substrates, compounds with a $P_{app} > 150–200$ nm s^{-1} are more favorable to counteract the transporters' efflux process.

In order to meet the above criteria to facilitate brain entry, the physicochemical properties of a compound need to be within certain boundaries.[23] The median values of the reported physicochemical properties of marketed drugs are: molecular weight = 305; hydrogen bond donor (HBD) = 1; TPSA = 45; c log P = 2.8; c log D = 1.7; pK_a = 8.4; rotatable bond = 4.5.[16]

Based on these values and other similar analysis, a good CNS drug designer should focus on optimizing compounds with properties: (1) molecular weight (< 450); (2) lipophilicity (c log P < 5; log $D \sim 2–3$); (3) polar surface area (PSA ~ 60–70 Å^2); (4) pK_a (7.5–10.5); (5) rotational bonds (< 8); (6) hydrogen bonding (H-bond donor < 3; H-bond acceptor < 7).

It has also been shown that the most important molecular properties affecting CNS penetration relate to the H-bonding propensity of the molecule. The higher hydrogen-bonding capability of a molecule will increase the risk of it being a transporter substrate and decrease its intrinsic permeability through the BBB. Another interesting observation is the lack of correlation between lipophilicity and free drug brain exposure. For a molecule with a higher molecular weight, a corresponding higher lipophilicity is required for optimal permeability in the absence of an active transport mechanism.

Besides considering these physicochemical property parameters individually, different models have been developed to consider them as a whole in a composite index. Recently, Raevsky and colleagues reported a comparative study of five different models including "rule of five", multiparameter optimization (MPO), logistic regression, random forest (RF), and support vector machine (SVM), for predicting brain permeability.[24] The authors suggested that focusing on a single parameter is unlikely to correctly predict

CNS+ or CNS− for a compound. Out of the five models compared, the RF and SVM models are superior in terms of accuracy compared with the other three models in classifying brain-penetrable compounds in their test set of compounds. Based on the modeling results for a set of selected compounds, the importance of physicochemical parameters affecting brain penetration was ranked in the order as follows: (1) TPSA, (2) H-bond acceptor and donor groups, and (3) electrostatic potential (H-bond ability of the strongest acceptor). The characteristic chemical functional groups in the tested compounds are represented in Fig. 3. A higher percentage of compounds with a tertiary amine moiety are predicted as CNS+ while the presence of a hydroxyl group in a molecule has a higher chance of brain penetration failure.

Recently, a new model using probabilistic MPO (pMPO) scoring function was proposed by Gunaydin from Merck.[25] In this approach, the author tried to combine two scoring functions (MPO & QED) into a more predictive model with one scoring function. The pMPO model minimizes the number of parameters needed to define an MPO score for a molecule by imposing boundaries with a probability distribution in a desired molecular space. This approach claimed to be less prone to the "double-counting error" presented in other scoring approaches. The scoring functions have been used to correlate two different end points in drug discovery. As an example, Gunaydin used the pMPO model to illustrate that the prediction of the "CNS drug-likeness" of a molecule

V.; Bachurin, S. O.; Dearden, J. C. Physicochemical Property Profile for Brain Permeability: Comparative Study by Different Approaches. *J. Drug Target.* **2016**, Published online, http://dx.doi.org/10.3109/1061186X.2015.1132224.

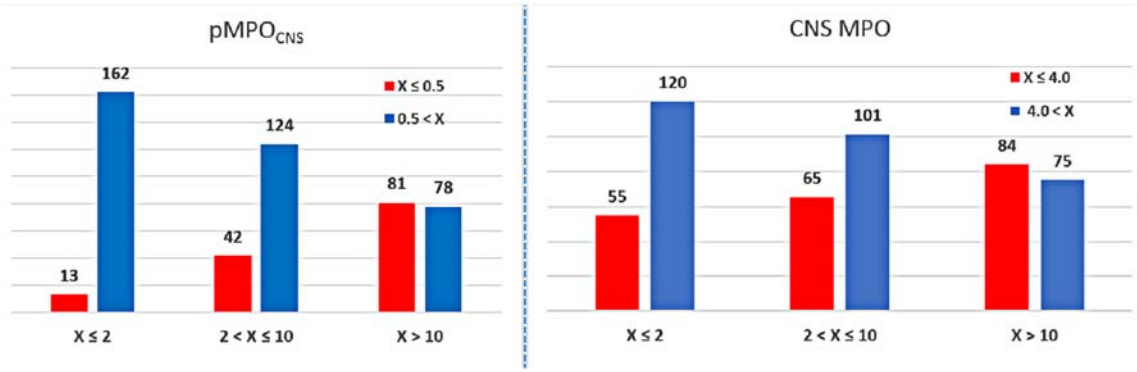

Fig. 4 Enrichment of benefit achieved with $pMPO_{CNS}$ and CNS MPO scores for predicting efflux liability of molecules (*x*-axis = effective efflux ratio; *y*-axis = number of compounds; CNS penetration: *blue* = favorable; *red* = unfavorable). Reproduced from Gunaydin, H. Probabilistic Approach to Generating MPOs and Its Application as a Scoring Function for CNS Drugs. *ACS Med. Chem. Lett.* **2016**, *7*, 89–93.

could correlate with the liability of its being a P-gp substrate. Analysis of a set of ~500 Merck internal compounds suggested that the $pMPO_{CNS}$ scoring function is better than the more commonly used CNS MPO scoring function[26] in predicting efflux liability (Fig. 4).

Other avenues to bring drugs into the CNS have also been explored when CNS penetration of a compound is not sufficient simply by using a passive diffusion mechanism to achieve the required drug concentration. Strategies include the use of transporter-mediated brain uptake (e.g., PEPT1) or liposomes/nanoparticles approach.[27–31] However, such methodologies are still in their infancy. With more experimentation, their practical application in the clinical setting may be realized in the near future.

7.10.5 Small Molecule Kinase Inhibitors for CNS Disorders

7.10.5.1 Leucine-Rich Repeat Kinase 2

The LRRK2 is a large protein (monomer ~240 kDa). It is widely distributed throughout the body and is found in elevated concentrations in brain, kidney, and heart tissues, as well as various immune cells.[32,33] LRRK2 protein sequence contains multiple domains, including ATP-binding kinase domain, GTPase domain, and several protein–protein interaction domains, such as ankyrin-like (ANK) domain, leucine-rich repeat domain, C-terminal of ROC-COR domain, and C-terminal WD40 domain.[34] However, most of the pathogenic LRRK2 variants are located in either the enzymatically active serine–threonine kinase domain or the GTPase domain of the protein. There is no published structure of LRRK2 or any of the individual protein domains due to its complexity. More recent studies suggested that several residue variants may affect LRRK2 kinase activity by modulating LRRK2 dimerization kinetics or by altering interactions between the ROC and COR domains. Activating mutants such as G2019S enhance LRRK2 kinase activity. Modulation of kinase function with small molecules might be achieved by interfering with ATP binding in the kinase domain, GTP binding and hydrolysis in the GTPase domain, or the LRRK2 dimerization equilibrium.

LRRK2 gene mutations are considered as a key driver of PD and several generic variants such as G2019S, R1441C/G, Y1699C, and I2020T have been confirmed as pathogenic contributors to the disease.[35–37] These variants are located in the activation loop of the kinase domain, the ROC domain, and on the dimerization interface of the COR domain. In particular, the most common and extensively characterized variant, LRRK2 G2019S, counts for 6% of all hereditary, and 1–2% of all idiopathic cases of PD.
