Quadruplex sequences are not randomly distributed in the human genome, outside of telomeres, where they comprise telomeric DNA (of which the 100–150 3′-terminal nucleotides, i.e., 15–25 d(TTAGGG) repeats, are single-stranded). Instead, there is an overabundance of quadruplex sequences in promoter regions, especially close to the transcription start site, and in nuclease hypersensitive regions (notably characterized in the c-*MYC* gene[47]) where they often overlap with SP1 transcription factor sites. A number of these occurrences have been characterized in vitro using biophysical and sometimes structural methods, and shown to be capable of forming stable quadruplexes. The occurrence of an extensive quadruplex sequence in the c-*MYC* promoter is the best-studied and validated.[48–51] Quadruplex characterized in promoter sequences includes *BCL-2*, *VEGF*, h*TERT*, *HSP90*, *HIF*, *k-RAS*, *h-RAS*, *B-RAF*, c-*KIT*, *RET*, and the androgen receptor (AR) as notable examples[52–67]; these are all well-validated genes involved in proliferation and oncogenesis and several are also established anticancer targets at the protein and enzyme levels. Several promoter quadruplexes have full structural assignments, mostly from 2-D NMR studies and in two instances from crystal structure analyses. The targeting of these quadruplexes by small molecules is the focus of much of this article. The approach offers a contrasting alternative to direct gene-product targeting, not least because some of these genes have long been considered to be "undruggable" at the protein level.

Quadruplex-forming sequences are also overrepresented in 5′- and 3′-untranslated regions (UTRs) of a number of genes,[68–73] with some genes having multiple occurrences in promoters as well. These UTR quadruplexes can form very stable RNA quadruplexes, few of which have been characterized to date, although there is evidence that they may play a role in translational regulation. A recent and surprising finding has been that telomeric RNA can be transcribed, to form telomeric RNA sequences (TERRA),[74–78] which in turn can form stable quadruplex multimers.[79] However, the biological function of TERRA is still not clear and thus its potential as a therapeutic target has yet to be determined.

The occurrence of quadruplex sequences and the demonstration that these can fold in vitro to form stable structures does not necessarily mean that they can form in a cell, let alone have biological significance and function. These key issues have been

addressed by the use of quadruplex-specific antibodies to demonstrate their existence, initially in macronuclei of the ciliate organism *Stylonychia lemnae*.[80] Quadruplexes have been shown to play a role in yeast telomere replication and maintenance, possibly with a transient existence once telomeric proteins are released since quadruplexes are effectively unwound by the RecQ helicase. More recently, two distinct quadruplex-specific antibodies have been used to unequivocally demonstrate the existence of DNA and RNA quadruplexes in human cancer cell lines.[81–84] Overall, the evidence strongly suggests that quadruplexes are significantly more prevalent in cancer cells than in normal nontransformed cells. This conclusion has been reinforced by the finding that they are present in primary tumor tissue and not in surrounding normal tissue.[85] A rationale for this selectivity has been provided by the seminal findings[83,86,87] that helicases such as the Werner's syndrome RECQ helicase, the Bloom's syndrome helicase, and FANCJ are all able to unwind quadruplexes during replication, at least in normal cells. Thus quadruplexes normally would have a transient existence, although this may still provide for specific roles in the regulation of transcription within particular genes. However in many cancer cells, the activity of these helicases can be compromised by mutations at their active sites, thus hindering quadruplex unwinding. Also there is evidence from a number of studies that quadruplex formation within the genome induces profound DNA damage responses leading to cancer cell apoptosis[88,89]; the observations that DNA repair pathways in many cancer cells are defective[90] provide a further rationale for promoter quadruplexes being selective and plausible anticancer targets.

The presence of quadruplex elements in the promoters of a number of major cancer-relevant genes has led to the hypothesis, first elaborated for c-*MYC*[48,49] that their stabilization by appropriate small molecules, would result in decreased transcription for that particular gene leading to an anticancer effect.[91] Importantly, such targets include a number long considered to be undruggable, at least at the protein level. A large number of studies have indeed shown such downregulation, accompanied by increased inhibition of cancer cell growth (see Section **Oncogene expression control by small molecules in cancer cells** in this article). It is important though to bear in mind that most studies have only demonstrated correlative relationships between promoter quadruplex affinity and direct effects on the expression of the gene involved. This has been highlighted by a careful cell-based study[92] using the c-*MYC* promoter binding compound 11-piperazinylquindoline which has shown that although c-*MYC* levels are reduced, this is not a consequence of direct c-*MYC* promoter targeting, but is presumed to be a consequence of targeting another gene. On the other hand, a distinct quadruplex-binding compound, this time the dimethylethanamine ellipticine derivative NSC-338258, does have a direct effect on c-*MYC* expression, using the same cell lines and careful approach,[93] emphasizing the importance of the exact nature of the quadruplex-stabilizing ligand.

Although it is not clear that a given small molecule can be specific for a particular quadruplex promoter target, this is of lesser importance if the gene and its gene product is a driver of cancer maintenance and progression in that cell type. Thus c-*KIT* is a major driver of gastrointestinal cancer and *k-RAS* of pancreatic and nonsmall-cell lung cancer. c-*MYC* is of major importance in many cancers, as is h*TERT*. Poly-quadruplex targeting may well offer advantages for the common human cancers, especially when confronted with problems of tumor heterogeneity and single-target resistance. These issues continue to affect more conventional single-protein/enzyme targeting in cancer, notably when using kinase inhibitors and again suggest therapeutic advantage for quadruplex targeting.

Cancer cell selectivity can also arise when targeting telomeric quadruplexes, although the basis for that selectivity is not as clear-cut as the targeting of promoter quadruplexes. The original telomere targeting concept, developed using the first quadruplex-targeting small molecules (disubstituted anthraquinones: see Section **Quadruplex-small molecule recognition**), was that they induce the single-stranded telomeric DNA overhang to fold into quadruplexes, which would resist elongation by the reverse transcriptase enzyme telomerase, whose expression is elevated in almost all tumor cell types and primary tumors. It was subsequently shown that this mode of telomerase inhibition results in cellular senescence and selective cancer cell apoptosis both in cells and in human tumor xenografts. However, telomerase inhibition alone is not the major contributor to the rapidity of observed effects since telomerase enzyme inhibition results in only a relatively small amount of telomeric DNA shortening per round of replication. A number of studies have shown that small molecules can effectively displace bound telomeric proteins and thus directly induce quadruplex formation.[94–96] These quadruplex complexes are not resolved by helicases during cancer cell replication, for the reasons outlined earlier, and the resulting quadruplex-folded telomeric DNA then appears as a DNA damage signal. DNA damage response markers such as γ-H2AX protein and ATM/ATR levels are upregulated both in cells and in xenograft experiments.[89,97–100]

5.09.2 Quadruplex Native Structure Overview

A quadruplex comprises a stable core of two or more G-quartets with four in-plane guanines Hoogsteen hydrogen-bonded together (**Fig. 1**), with intervening loops of general sequence linking the G-quartets. In addition, and uniquely to quadruplexes, the requirement for alkali metal ions is met by a central ion channel which also coordinates to O6 atoms of the guanine bases. The G-quartets are π–π stacked at a 3.4 Å separation. The four strands result in four external grooves, of varying dimensions, whose walls are lined with phosphodiester groups (imparting negative electrostatic potential). The floors of the grooves consist of the edges of the G-quartet core G bases.

The mutual orientations of the four polynucleotide strands in a quadruplex are important determinants of overall structure, and define the nature of the intervening loops.[10,16] A parallel orientation for any two strands requires the connecting loop to be folded back on itself, and is termed "strand-reversal" or "propeller" since it is oriented away from the G-quartets. Other loop types

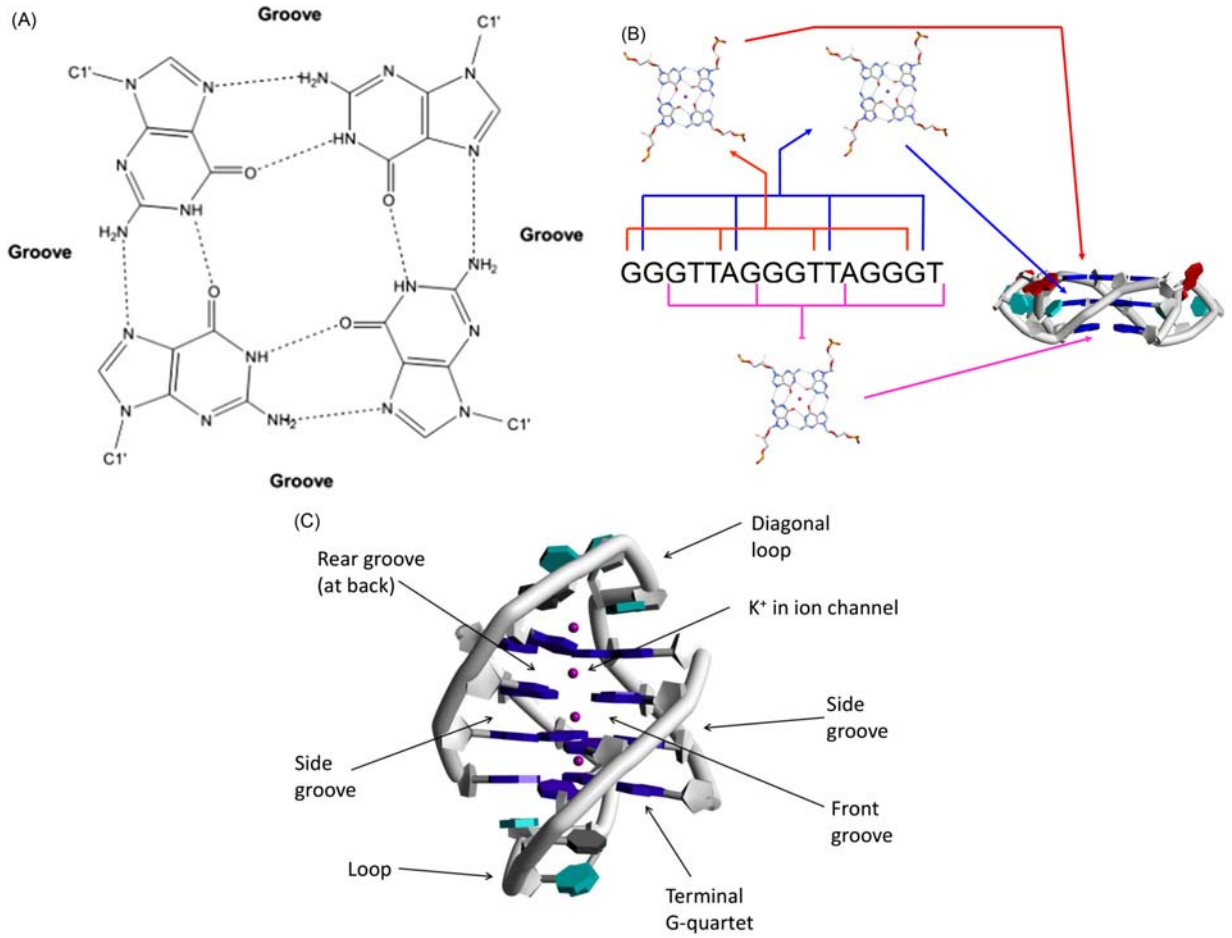

Fig. 1 (A) The G-quartet, showing the four in-plane guanine bases, each involved in four Hoogsteen hydrogen bonds. (B) G-quartet core assembly (in the human telomeric DNA quadruplex,[101]) showing the way in which each G-quartet is built up from a guanine in each G-tract. (C) The grooves and loops of a typical (bimolecular) quadruplex structure. (B, C) Taken with permission from Neidle, S. Quadruplex Nucleic Acids as Novel Therapeutic Targets, *J. Med. Chem.*, **2016**, *59*, 5987–6011.

are diagonal and lateral (edgewise), which connect antiparallel strands (Fig. 2). Diversity in quadruplex tertiary structures occurs with differing patterns of G-tract length, strand orientation, and loop sequence—appropriate longer loop sequences can themselves form stable secondary structural elements involving, for example, duplex and hairpin elements. Examples are where loops comprise repeating AT or AG sequences, which can form stable short duplex stems, as found in one of the c-*KIT* promoter quadruplexes (Fig. 3). In addition, if loop sequences contain G residues, then these can participate in G-quartet formation by inserting themselves into the G-quartet stem, in addition to the Gs in the G-tracts. This results in added complexity to the resulting structures. The human intramolecular telomeric 4-repeat sequence is highly polymorphic, at least in dilute solution, and a variety of quite diverse folds [parallel, antiparallel, and mixed (3 + 1)] have been observed, driven by slight differences in flanking sequence and changes in the coordinating central channel metal ion.[101–108] The exact nature of the biologically relevant quadruplex formed within a single-stranded telomeric DNA sequence continues to be controversial, although solution NMR and CD studies at higher concentrations and/or in crowding conditions tend to favor the parallel form[109,110] as observed in the crystalline state.[101] Considerations of the available surface area on the terminal G-quartets of telomeric quadruplexes have suggested that the preferred topology for a given small-molecule complex is dependent on the size of the bound chromophore moiety of the ligand.[111]

"Simple" quadruplexes based around the canonical quadruplex sequence have overall structural features in common, and all are organized with a single stem of at least two stacked G-quartets. A large number of distinct folds produced as a consequence of variations in loop type and strand direction have been observed experimentally for human telomeric quadruplex sequences.[101–108] In general, the loops connecting the quartets are the most variable feature defining distinct quadruplex folds—the variables of loop length and sequence can in turn result in variable groove dimensions. Table 1 lists some of the crystal and NMR structures of native promoter quadruplexes available from the Protein Data Bank (PDB). Compared to the very large numbers implied by the bioinformatics searches, these can only represent a minute fraction of quadruplex space in the human

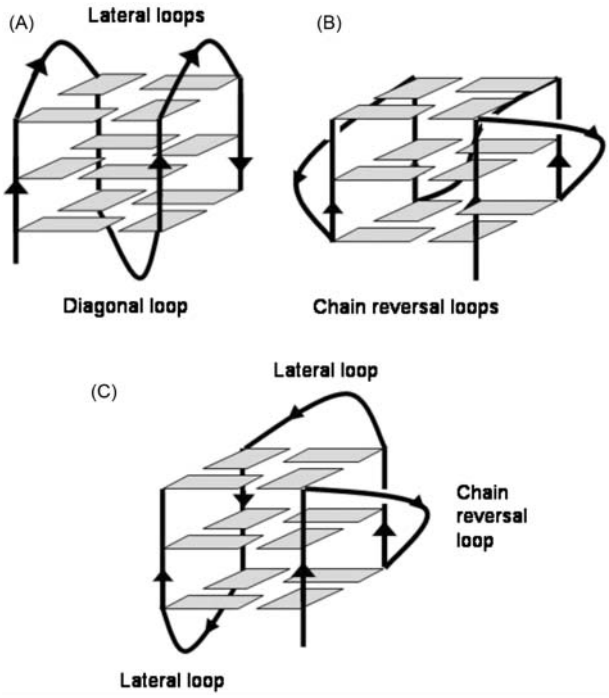

Fig. 2 Simple quadruplex loops in detail, in three distinct quadruplex folds. In each case the phosphodiester chain and its 5′–3′ direction is indicated by the *arrows* on the heavy lines. (a) an antiparallel fold, (b) an all-parallel fold, (c) a hybrid (mixed) fold. All three have used intramolecular human telomeric quadruplexes as exemplars.

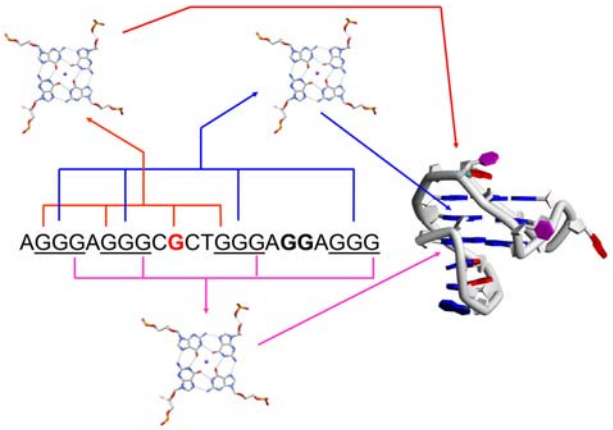

Fig. 3 The structure and assembly of the c-*KIT*1 promoter quadruplex, showing the added complex as a result of a loop guanine (shown in *bold red color*), inserted into the G-quartet stem.[63–65]

genome. A number of loop sizes and sequences are overrepresented in the human genome, with short single-nucleotide loops being common—these result in many quadruplexes having all-parallel strands as a consequence of the steric requirements of propeller loops. More complex quadruplexes are barely represented in the known database of structures; the c-*KIT*1 quadruplex is a notable example of a nonsimple quadruplex, with a guanine from G-tract linkers being inserted into a G-quartet formation so that a large and deep groove is formed.[63–65] The c-*KIT*2 quadruplex sequence can form a dimer as well as an all-parallel monomeric quadruplex,[112,113] in striking contrast to the stability of the unique c-*KIT*1 topology.[114] Polymorphism is not a universal feature of quadruplex structures, and depends on the nature of the sequence itself, with greatest variability shown by those sequences containing more than four G-tracts.

To date, there is little structural information on quadruplexes embedded in a duplex environment, apart from two crystal structures of small molecules bound to RNA quadruplex aptamers embedded within a duplex stem.[115,116] These quadruplexes have highly unusual folds.

5.09.3 Quadruplex-Small Molecule Recognition

A number of crystal structures of complexes between quadruplexes and small molecules are available in the PDB, as well as several NMR structures (Table 2). All concur in showing the bound molecules stacked on a terminal G-quartet of the stack, most commonly on the 5′ end, regardless of whether the quadruplex itself is tetramolecular, bimolecular, or unimolecular. This surface-binding mode is contrary to early predictions that small-molecule ligands would insert intercalatively in between adjacent G-quartets, analogous to intercalation into duplex DNA, and is in accord with a large number of biophysical studies. Some ligands comprise

entirely, or almost entirely, a planar chromophore. However, the overwhelming majority also have at least one pendant substituent, which typically terminates in a cationic charge group such as a substituted amine. These substituents reside in the quadruplex grooves, although the crystal structures demonstrate that the cationic groups do not directly interact with phosphate groups, but instead interact indirectly via bridging water molecules in the grooves.

The database of crystal structures involving the human telomeric sequence, either in bimolecular or unimolecular quadruplexes, has them complexed with a diversity of ligands, based for example on acridine,[118,121] porphyrin,[117,125] berberine,[124] square-planar metallo-containing,[122] or naphthalene diimide cores.[119,123,129] Crystal structures of a native RNA telomeric quadruplex[120] and in a complex with a disubstituted acridine compound[121] are also available—this latter structure highlights some significant differences between DNA and RNA telomeric quadruplex recognition in that the latter has a significantly larger end-quartet surface area, enabling two acridine molecules to be bound. The native RNA quadruplex fold as observed in the crystalline state retains its parallel architecture in solution.[130]

The availability of these crystal structures has enabled comparisons to be made of the dependence of quadruplex flexibility on the nature of the bound ligand.[131] In general, the G-quartet core is highly stable and retains its stacked structure in all complexes. Similarly the overall parallel fold seen in the native crystal structure is maintained. However, the 5′-TTA loops have highly variable conformations, which result in changes in groove dimensions and in accessibility to the terminal quadruplex-binding platform. Thus in silico screening of ligand or fragment libraries should take these flexibilities into account in order to obtain meaningful ranking orders of relative affinity. Even so, the marked close similarities in core stacked G-quartets and in overall topology, for example, between the human parallel telomeric quadruplex and the human *VEGF* quadruplex (**Table 1**), suggest that docking with subsequent molecular dynamics simulations could be useful in producing stereochemically and energetically plausible models for small-molecule complexes.

A small number of NMR structures of quadruplex-ligand complexes are currently available in the PDB, with a c-*MYC* quadruplex[126,128] and with an antiparallel human telomeric quadruplex.[127] All three structures show the respective ligand chromophores bound in the conventional end-stacking mode, with substituents neighboring quadruplex grooves. As with the crystal structures, these NMR models provide useful starting points for structure-based design, although there has been rather little such work reported in the literature to date.[123] The overwhelming majority of quadruplex-binding compounds have been obtained either by (i) simple conceptual arguments invoking the terminal planar quartet as the binding platform and the requirement for at least one cationic substituent and (ii) screening of compound libraries.

In silico screens have been undertaken, for example, using the ZINC or NCI (National Cancer Institute, USA) databases, mostly with human telomeric structures, but also with several of the reported c-*MYC* quadruplexes.[132–137] Hits have tended to display the structural characteristics of known quadruplex-binding ligands, although a few studies have resulted in the finding of groove-binding compounds. These tended to have lower quadruplex stabilization effectiveness, as judged by thermal stabilization experiments, and none have been progressed to date as serious drug candidates.

5.09.4 Telomeric Quadruplexes as Therapeutic Targets

The telomere length maintenance enzyme telomerase[138] is a specialized reverse transcriptase, which is expressed in the majority (c. 85%) of cancer cells and primary tumor material and serves to maintain telomere length from attrition and thus plays a major role in cancer cell immortalization.[139,140] There is a close relationship between the upregulated expression of telomerase and early stages of oncogenesis. This has led to a persistent interest in telomerase as a potentially major therapeutic target in cancer,[141] although as yet no antitelomerase drug has reached regulatory approval.

Several ways of inhibiting telomerase action have been reported, most of which involve intervention at the telomerase catalytic subunit (hTERT in humans) active site.[141] This directs the assembly of nascent telomeric DNA onto the 3′ end of telomeric DNA end, which occurs on a complementary RNA template (hTR) and uses a pool of nucleotide triphosphates, with its substrate, the 3′ end of telomeric DNA, hybridizing onto the template. This implies that telomeric DNA must be single-stranded at the point of hybridization, so folding of the 3′ single-stranded end of telomeric DNA (the extreme 100–200 nucleotides at this end) into a quadruplex arrangement has been shown to effectively inhibit hybridization and thus the enzymatic activity of telomerase.[142] Folding can be facilitated by a quadruplex-binding small molecule (first demonstrated with disubstituted anthraquinone derivatives[143]) whose quadruplex affinity is sufficient to compete off telomere-binding proteins, notably hPOT1.[144] Quadruplex-directed telomerase inhibition has been subsequently developed into an anticancer strategy by a large number of studies which have shown[32,36,145–150] that cellular inhibition of telomerase function results in senescence and apoptosis with upregulation of the retinoblastoma pathway via the cyclin-dependent kinase (CDK) inhibitor p21 and increased expression of the tumor suppressor protein $p16^{INK4a.}$

These effects have been frequently observed to occur with much greater rapidity in many cancer cell types than were expected, apparently contradicting the standard model of telomerase-driven telomere maintenance[151] since the onset of replicative senescence normally occurs only when telomeric DNA is shortened to a critical length, requiring an extended time-lag. Mean telomere length in the MCF7 cell line is c. 6 kilobases, and c. 100 nucleotides are lost per round of replication, that is, at least 30 days would be required for the onset of senescence, whereas growth-inhibitory effects are typically observed within a few hours or less. It is now generally concluded, in large part on the basis of data from quadruplex-binding agents (**Figs. 4** and **5**) including quinoline-based triazine compounds,[147] the cyclic oligo oxazole natural product telomestatin,[94] the acridine derivatives RHPS4[98–100] and

BRACO-19,[150] and the bis(quinolinyl)pyridine-dicarboxamide derivative pyridostatin[152] that rapid telomere uncapping, of associated proteins (including hTERT), is the initial consequence of ligand binding. This then leads to rapid DNA damage responses and a cascade of responses with altered regulation of, in particular, p21/$p16^{INK4a}$ kinases, p53, PARP, and ATM/ATR pathways.[97–100] The DNA damage responses result in senescence and the rapid appearance of phosphorylated histone γ-H2AX foci. Evidence for DNA damage has been obtained following in vivo tumor xenograft experiments with, in particular, RHPS4

and telomestatin.[97–100] Selectivity for cancer cells may be due to deficiencies of the DNA damage response in many cancer types, as discussed earlier in this article.

5.09.5 Oncogene Expression Control by Small Molecules in Cancer Cells

We discuss in this article examples of the large number of small molecules that have been evaluated against various promoter quadruplex targets and describe the biophysical studies on quadruplex binding in relation to their biological activity.

Many families of small molecules with antiproliferative activity in cancer cell lines have been shown to bind and stabilize strongly in vitro a number of DNA quadruplex structures found in the promoter regions of oncogenes, thus suggesting a potential application of these molecules as new anticancer drugs.[31,36,91] In this section, we review quadruplex-binding small molecules whose mechanism of action has been suggested to be, at least, in part through regulation of oncogene expression. It is hope that the reader will obtain a comprehensive view of the range of targets amenable to the approach. At the same time the current state of the art is that rather few of these small molecules appear to have selectivity for a single quadruplex, although this is hard to directly assess in view of the large number of quadruplexes potentially present in the genome. Even so, data to date does indicate that some selectivity can be achievable, at least for driver oncogenes in a particular cancer type. It is to be hoped that medicinal chemistry optimization of pharmacological properties will lead in the near future to compounds suited to clinical evaluation in several currently hard-to-treat cancers.

5.09.5.1 c-*MYC*

c-*MYC* is a proto-oncogene belonging to the basic helix–loop–helix-leucine zipper (bHLHZip) transcription factor family which includes two other genes (*MYCN* and *MYCL*) originally found in neuronal cells (N) and in lung cancer (L). The c-MYC protein can control the transcription of large numbers of genes involved in cell cycle progression, cell growth, differentiation, apoptosis, metabolism, DNA replication, and mRNA maturation.[153] One of those genes is h*TERT* (the catalytic domain of human telomerase) whose transcription is activated by c-MYC. Cancer genome sequencing analyses revealed that c-*MYC* is one of the most amplified genes across many solid cancers, including almost all serious ovarian and breast carcinomas, a large fraction of lung, and head and neck squamous cell carcinomas, and endometrioid tumors of a more serious subtype.[154] In addition, chromosomal translocation of

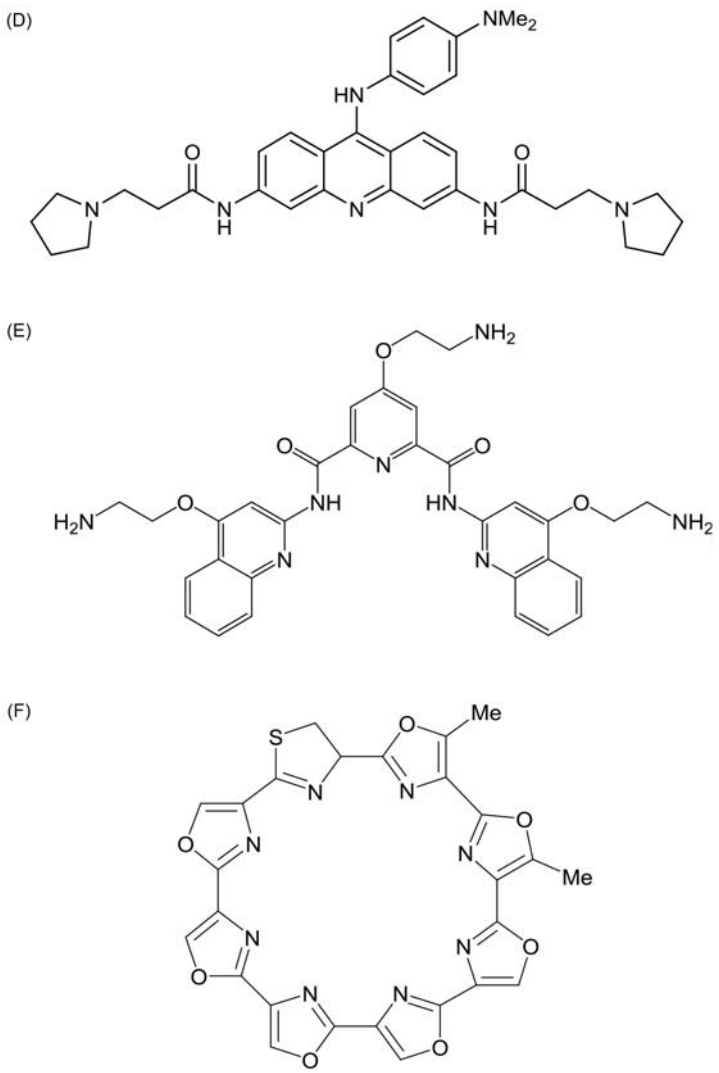

Fig. 5 (*continued*).

c-*MYC* can be particularly found in leukemias and lymphomas such as in Burkitt's lymphoma.[155] The activity of MYC can also be deregulated at the level of expression and stability of *MYC* mRNA and protein.[156]

For these reasons, c-*MYC* has been considered an attractive target for anticancer therapy. Pharmacological inhibition of the c-MYC protein has not been possible to date and it is commonly considered to be an "undruggable" target, although recent studies have provided important proof-of-concept that inhibiting MYC protein–protein interactions may be an effective therapeutic strategy.[157,158] Also, since the discovery of the quadruplex-forming sequence in NHE III1 element of the c-*MYC* promoter and its role in c-*MYC* transcription regulation, several small molecules with the capacity to bind and stabilize c-*MYC* quadruplex DNA structures and to repress c-*MYC* expression in cancer cell lines have been investigated.

The first proof-of-principle that stabilization of quadruplex in the c-*MYC* NHE III1 by small molecules could silence c-*MYC* expression arrived from studies with porphyrins TMPyP4 and TMPyP2 (Fig. 6).[49] In a Taq polymerase stop assay, TMPyP4 at concentrations ranging from 0.5 to 5 μM inhibited transcription of c-*MYC* by stabilization of quadruplex chair conformation, whereas the much weaker quadruplex-ligand isomer TMPyP2 had a lesser effect.[48] To further study the role on gene transcription of the reported quadruplex in the NHE III1 of c-*MYC*, a luciferase reporter assay and two Burkitt's lymphoma cell lines were used. In the Ramos cell line, the quadruplex-forming sequence of the c-*MYC* promoter is preserved after chromosomal translocation, whereas in the CA46 cell line c-*MYC* transcription is no longer regulated by the NHE III1 quadruplex-forming sequence. These studies showed that repression of c-*MYC* expression by TMPyP4 was dependent on the presence of a promoter wild-type sequence or the quadruplex element in the c-*MYC* promoter.[48] In agreement with these studies, it was shown that increasing concentrations of TMPyP4 (1–10 μM) correlated with a decrease in NM23-H2 driven unfolding of the quadruplex, thus justifying the c-*MYC* transcription decrease observed.[159]

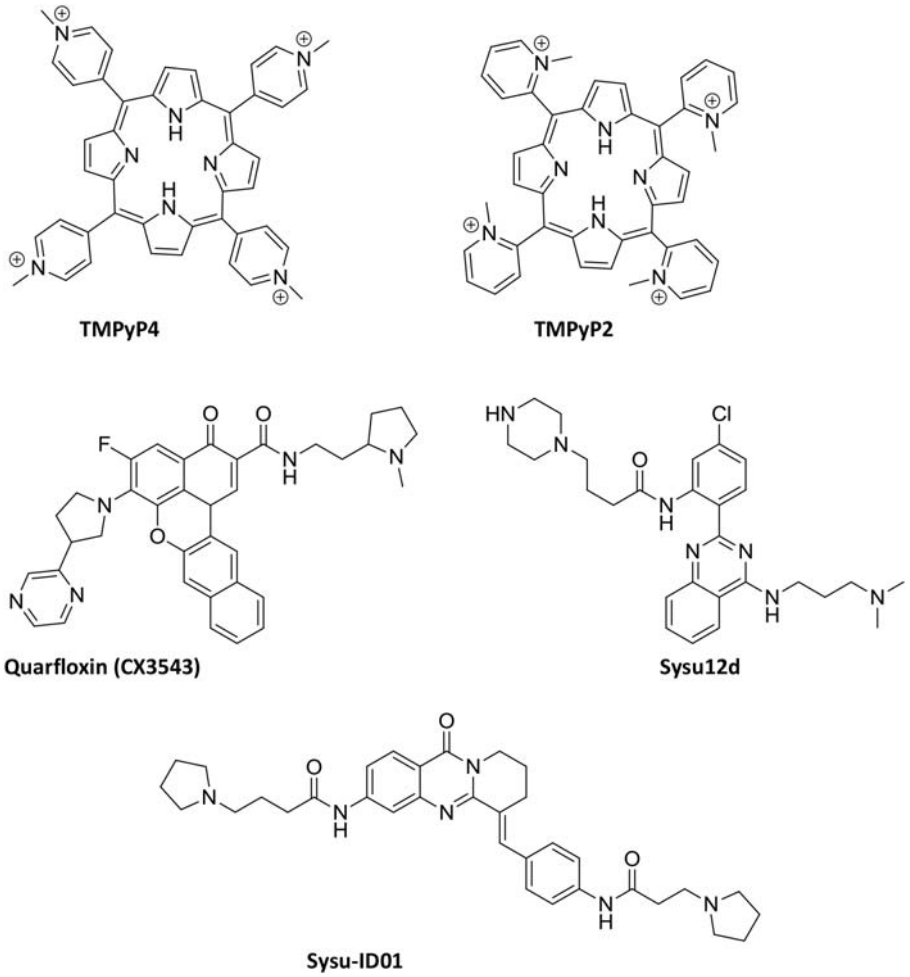

Fig. 6 Structures of porphyrins (TMPyP4 and TMPyP2), quarfloxin, and quinazoline (Sysu12d and Sysu-ID01) derivatives reported as c-*MYC* promoter quadruplex-interactive small molecules and oncogene expression downregulators.

Quarfloxin (also known as CX-3543, Fig. 6) is a first-in-class quadruplex-targeted drug which has reached Phase II clinical trials in human cancers. It is a fluoroquinolone derivative developed from the antibiotic norfloxin via a series of compounds with a larger aromatic surface area and a mechanism of action that involves both topoisomerase II poisoning and quadruplex DNA binding.[160] Further efforts to increase selectivity to quadruplex structures over duplex DNA led to quarfloxin, a compound with an optimized aromatic structure and quadruplex groove-binding side chains. It has greater selectivity than TMPyP4 for parallel quadruplex structures, including that in the c-*MYC* promoter.[91] It has anticancer activity in xenograft models and is devoid of gyrase or topoisomerase II poison activity. However, further studies on the mechanism of action of quarfloxin suggest that its anticancer activity is probably due to an indirect effect on c-*MYC* expression, among other mechanisms, rather than to direct binding to the c-*MYC* promoter quadruplex. Quarfloxin was shown to accumulate in the nucleoli of cancer cells where it can disrupt nucleolin ribosomal DNA quadruplex complexes leading to inhibition of RNA polymerase I and cellular redistribution of nucleolin into the nucleoplasm.[161] This redistribution is a common response to cellular stress, which results in apoptosis through various different pathways.[162–166] Nucleolin has high selectivity for the c-*MYC* promoter quadruplex and inhibits its transcription.[167] This indirect mechanism might explain the observed c-*MYC* transcription inhibition in HCT116 colorectal tumor tissues taken from mice treated with quarfloxin.[91]

The mechanism of action of quarfloxin inspired the studies on anticancer activity of a 2,4-disubstituted quinazoline derivative, Sysu12d (Fig. 6). CD spectroscopy and DNA melting assays have indicated that Syu12d can bind and stabilize the c-*MYC* quadruplex-forming sequence Pu27, and that it is selective for this quadruplex compared to a double-strand DNA sequence. This quinazoline derivative also inhibited c-*MYC* transcription in a PCR-stop assay and in HeLa cancer cells. Sysu12d at a 10 μM concentration was found to downregulate the expression of nucleolin, whose transcription is regulated by c-MYC. Moreover, Sysu12d at concentrations >1 μM disrupted the nucleolin–quadruplex rDNA complex, probably by competing with nucleolin for the quadruplex-binding site. This effect could contribute to the observed repression of RNA polymerase I transcription induced by Sysu12d, which was more evident in HeLa cancer cells than in the nonmalignant HEK293 cell line. Also as a consequence, p53

and caspase-3 were activated leading to apoptosis. Further contributing to the apoptotic effect is the observed BCL-2 downregulation and Bax upregulation induced by Sysu12d. In addition, it is notable that Sysu12d does not phosphorylate H2AX at Ser139, unlike other DNA-damaging agents. Thus, 2,4-disubstituted quinazolines may represent a new anticancer scaffold with a multifunctional mode of action.[168] Interestingly, the related quinazolone Sysu-ID01 (Fig. 6) showed weak quadruplex stabilization activity but high capacity to disrupt the binding of NM23-H2 transcription factor to Pu27, resulting in downregulation of c-*MYC* transcription and other NM23-H2-associated genes, and leading to apoptosis and cell death of HeLa cancer cells. Further studies, including molecular modeling, suggest that Sysu-ID01 inhibits NM23-H2 transcriptional activity by competing with Pu27 DNA for the same pocket of NM23-H2.[169]

The tetracyclic aromatic core indolo[3,2-*b*]quinoline structure (quindoline) with one or two basic side chains has been extensively investigated for binding to c-*MYC* quadruplex and inhibition of oncogene transcription in cancer cells. From all C11-substituted quindoline derivatives tested, IQi (Fig. 7) showed the greatest inhibition of the c-*MYC* quadruplex sequence (Pu27) amplification in a PCR-stop assay and was threefold more selective for the c-*MYC* quadruplex DNA structure than for calf thymus DNA in a competition dialysis experiment. IQi was able to repress c-*MYC* transcription by 25% in HepG2 and Ramos cell lines at 10–12.5 μM after 24 h but not in the CA46 cell line in which c-*MYC* transcription is not regulated by the NHE III1 quadruplex-forming sequence.[170] The solution structure of a 2:1 IQi—c-*MYC* quadruplex complex has been studied by NMR, showing one IQi molecule bound to the top G-quartet and another to the bottom G-quartet of this quadruplex (Fig. 4E). The crescent-shape quindoline structure provided optimal overlay with two guanines of the G-quartet, whereas the diethylamino group of the side chain interacted with the DNA phosphate backbone contributing to the orientation and stabilization of the ligand.[127] Further optimization of IQi led to the close analogue SYUIQ-05 (Fig. 7) which inhibited c-*MYC* transcription and protein expression in the Ramos cell line by approximately 25% after 48 h of drug (0.1 μM) exposure, but not in CA46 cells, probably due to the ability of this compound to disrupt the binding of the NM23H2 protein to the c-*MYC* quadruplex.[171]

The mechanism of action of 11-piperazinylquindoline derivatives has been reported (Fig. 7) to be targeting the c-*MYC* promoter quadruplex.[92] In a competition dialysis experiment, compound PPQ4 demonstrated four- to fivefold selectivity to all quadruplex structures compared to duplex DNA, whereas compound PPQ12 showed notable affinity to the parallel *HIF-1α* quadruplex structure and surprisingly only low affinity to a c-*MYC* quadruplex, or other more complex quadruplex structures. However, other in vitro experiments have suggested that PPQ12 has the capacity to bind to and stabilize the c-*MYC* promoter quadruplex sequence. The effect of compounds on expression of c-*MYC* and on other genes with quadruplex-forming sequences in their promoter sequences has been evaluated in the colorectal cancer HCT116 cell line. PPQ4, at IC_{50} concentrations (23 μM), downregulated the expression of c-*MYC*, h*TERT*, *PDGFRβ*, and *VEGF-A* after 24 h drug exposure, but not of *HIF1-α*. PPQ12 at 31 μM was able to downregulate c-*MYC*, h*TERT*, and *PDGFRβ* after 6 h, but the effects were completely reversed after 24 h. These observations together with results from competition dialysis indicate that these compounds are not selective for the c-*MYC* oncogene. In order to examine the involvement of the c-*MYC* quadruplex structure on mechanism of action, an exon-specific assay was used in CA46 cells. In this assay, amplification of exon 1 is used to monitor the effects on the nontranslocated, quadruplex-maintaining c-*MYC* gene, while amplification of exon 2 predominantly represents c-*MYC* expression from the translocated, quadruplex-lost chromosome. Results from this experiment also indicated that anticancer activity and cellular repression of c-*MYC* by PPQ4, PPQ12, or IQi are not dependent on direct targeting of the quadruplex in the c-*MYC* promoter.[92]

Several small-molecule hits against the c-*MYC* quadruplex have been recently identified using an in silico approach.[172] From these, the phenoxazone derivative B5, the pyrazolo[3,4-*d*]pyrimidine D2, and the triazine C2 (Fig. 7) showed greater inhibitory effect on cell proliferation and a larger decrease in the effects on c-*MYC* mRNA levels in the Ramos cell line than in the CA46 cell line, thus suggesting selectivity for the c-*MYC* quadruplex. The direct effect of compounds on c-*MYC* promoter activity was studied by the PCR-stop assay. Compounds C2 and D2 inhibited the activity of the c-*MYC* wild-type promoter but not of a mutant sequence unable to form quadruplex up to a concentration of 200 μM, whereas B5 showed lower selectivity for the quadruplex structure. In the same assay, none of the three compounds inhibited the activity of quadruplex-forming sequences from the *BCL-2*, *VEGF*, and *HIF-α* promoters. However, by CD, using a molar equivalent of ligand, none of the compounds was able to stabilize the oligonucleotide by increasing its melting temperature or altering the parallel conformation of c-*MYC* quadruplex.[172] Virtual high-throughput screening has identified the natural product-like carbamide (CB1, Fig. 7) as a potent stabilizer of the c-*MYC* quadruplex. Further NMR and molecular modeling experiments indicated a groove-binding mode for CB1. Activity of CB1 via c-*MYC* quadruplex binding was confirmed by its ability to inhibit Taq polymerase-mediated c-*MYC* quadruplex DNA amplification but only at high concentrations of CB1.[173]

The binding affinity and selectivity of three dihydroindolizidino indole derivatives for quadruplex DNAs compared to calf thymus DNA have been studied by a DNA melting assay, isothermal titration calorimetry, and ESI-MS. Compound DHII-4CPh (Fig. 7) was the best quadruplex DNA ligand of the series and the most selective, inducing an increase in 17°C of the human telomeric quadruplex melting temperature and showing a threefold selectivity for this quadruplex compared to duplex calf thymus DNA in the same assay. Selectivity for the c-*MYC* quadruplex was further confirmed by a luciferase reporter and a PCR-stop assay using the c-*MYC* promoter quadruplex-forming sequence and a mutated nonquadruplex forming sequence as control. DHII-4CPh selectively inhibited quadruplex-regulated DNA transcription. Moreover, DHII-4CPh inhibited the proliferation of melanoma cancer cells and reduced c-*MYC* expression by 50% in cells incubated with IC_{50} concentrations of compound (4 μM).[174] The bis-triazolylcarbazole derivative BTC-f (Fig. 7) was also identified as a good stabilizer of promoter quadruplex-forming sequences. This compound showed antiproliferative activity in several cancer cell lines (IC_{50} between 4 and 8 μM) but not in normal mouse myoblast C2C12 cells up to concentrations of 45 μM, and induced a dose-dependent reduction of c-*MYC* mRNA and protein levels

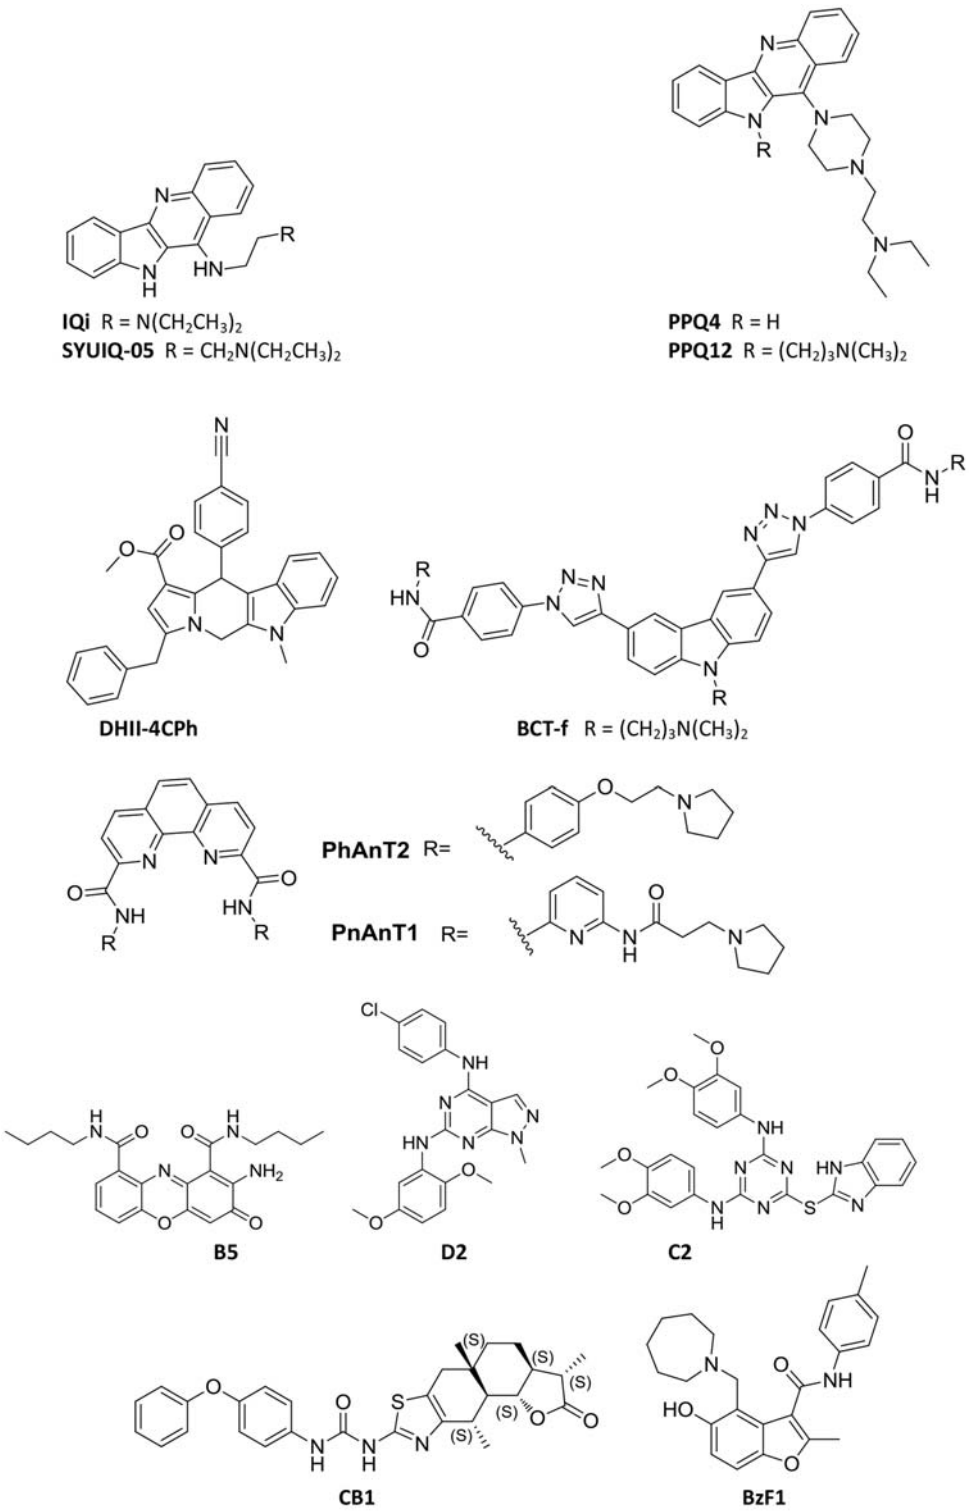

Fig. 7 Structures of quadruplex-interactive small molecules reported as c-MYC expression downregulators.

in liver carcinoma HepG2 cells, as well as triggering apoptosis and cell cycle arrest in the sub-G1 phase.[175] This cancer cell line, which overexpresses c-MYC, was also used to study the anticancer mechanism of two phenanthrolines (PhAnT1 and PnAnT2, Fig. 7) with moderate to weak ability to stabilize the c-*MYC* promoter quadruplex in a melting assay ($\Delta T_m \sim 10°C$ and 5°C, respectively, at 1 μM of ligand).[176,177] Contrary to data obtained by the DNA melting assay, PhAnT2 showed greater antiproliferative

activity than PhAnT1, c-*MYC* gene transcription downregulation, and inhibition of c-MYC, Sp1, and hTERT protein expression.[178] These compounds also increased p53 expression and induced a reduction in cyclin/CDK protein levels, leading to cell cycle arrest in different phases, and apoptosis of HepG2 cells.

In order to identify c-MYC-interactive small molecules with new chemotypes, another screening approach has been used. A small-molecule microarray screen of 20,000 compounds identified the benzofuran derivative BzF1 as a selective ligand of the c-*MYC* promoter quadruplex (Myc22-G14T/G23T) compared to duplex DNA or RNA.[179] Further studies, by surface plasmon resonance (SPR), confirmed that BzF1 (**Fig. 7**) in vitro binds reversibly to c-*MYC* quadruplex but has weaker or no affinity to other gene promoter quadruplexes. Furthermore, decreased c-*MYC* transcription induced by BzF1 correlated with decreased viability across a panel of multiple myeloma cell lines. In addition, the compound at 10 μM has minimal effect on cell viability in a Burkitt's lymphoma cell line harboring a c-*MYC* promoter translocation. Gene expression analysis and qPCR demonstrated that BzF1 is able to reduce the expression of c-*MYC* and c-*MYC* target genes but has no effect on the expression of several other quadruplex-regulated genes, in agreement with biophysical experiments, and demonstrating the selectivity of BzF1 to the c-*MYC* quadruplex.[179]

5.09.5.2 h*TERT*

The h*TERT* gene encodes for the catalytic domain of human telomerase, which is expressed in 85–90% of all cancers but not in somatic cells. Expression of h*TERT* is regulated by the core promoter, which contains a G-rich region of 12 consecutive G-tracts that can form a unique end-to-end stacked quadruplex structure, consisting of an all parallel quadruplex linked to an atypical quadruplex. The formation of this tandem quadruplex structure masks three of the five Sp1-binding sites found in the h*TERT* promoter, thus acting as a transcription repressor. Expression of h*TERT* is also regulated by c-*MYC* which binds to the h*TERT* promoter E-box region activating transcription.[180]

Quadruplex-binding ligands such as TMPyP4 (**Fig. 6**), BRACO-19 (**Fig. 5**), and the triazine 12459 (**Fig. 8**) have been shown to inhibit telomerase activity.[147,150,181] In the case of TMPyP4, this may occur through multiple mechanisms. TMPyP4 might inhibit telomerase activity by preventing telomerase access to telomeres due to induction of quadruplex structures in telomere 3′-overhang, or by stabilizing the quadruplex structure in the c-*MYC* promoter thus leading to decreased levels of c-MYC, a h*TERT* transcription activator. In addition, TMPyP4, but not its positional isomer TMPyP2, induced a dose-dependent decrease of h*TERT* promoter amplification product in a *Taq* polymerase arrest assay.[180] Thus, inhibition of polymerase activity by TMPyP4 may also be due to inhibition of h*TERT* expression[181] by direct targeting and stabilization of the h*TERT* promoter quadruplex. After in vitro and in vivo treatment with BRACO-19, hTERT protein levels in the nuclei of the human uterus carcinoma cell line UXF1138L were

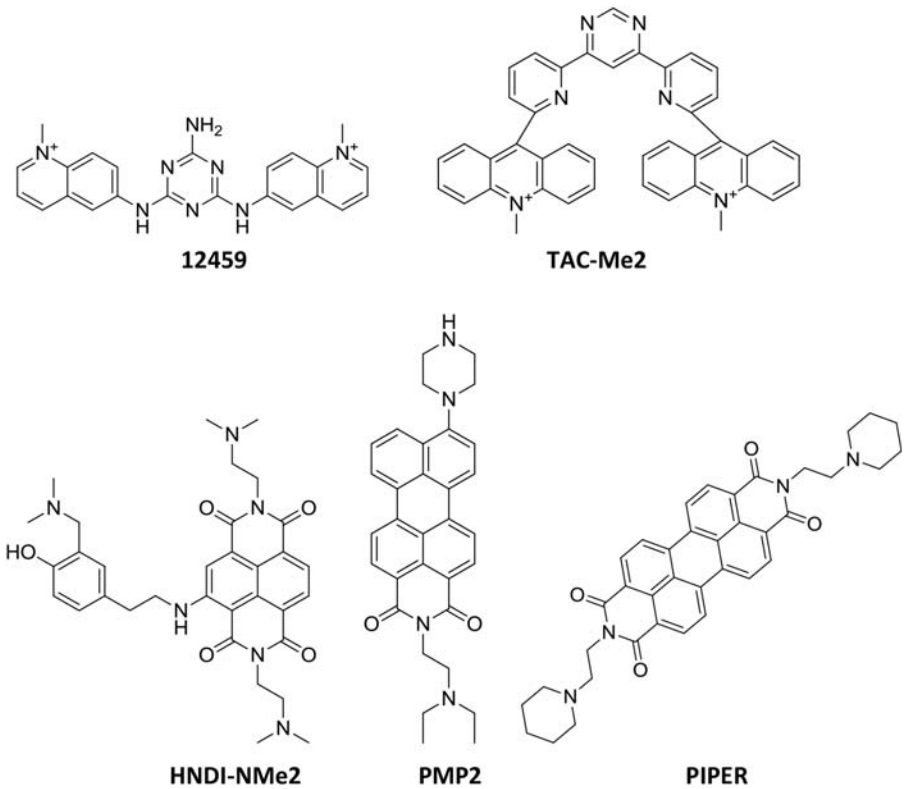

Fig. 8 Structures of G-quadruplex-interactive small molecules with reported h*TERT* expression regulatory activity.

drastically decreased, whereas in the cytoplasm hTERT colocalized with ubiquitin.[150] These observations are consistent with a decrease in h*TERT* expression via stabilization of the h*TERT* promoter quadruplex and hTERT degradation due to BRACO-19-induced displacement of telomerase from telomeres. For the triazine 12459 another mechanism leading to inhibition of telomerase activity has been proposed. Incubation of the human A549 lung carcinoma cell line with 10 μM of 12459 for 48 h induced overexpression of an inactive $-\beta$ h*TERT* transcript and a drastic decrease of the active $(+\alpha,+\beta)$ transcript, which was not observed after cells treated with other quadruplex ligands such as BRACO-19. Thus, triazine 12459 causes an alteration in the h*TERT* mRNA splicing pattern, probably by stabilization of quadruplex structures that can be formed in h*TERT* spliced intron 6.[182]

Not all telomeric quadruplex ligands reduce telomerase activity and/or telomerase expression. The bis-acridine compound TAC–Me2 (Fig. 8) increased the melting temperature of a telomeric quadruplex sequence and showed a twofold selectivity for this compared to duplex DNA in a competitive dialysis assay. At low concentrations (0.5–2.0 μM), TAC-Me2 inhibited the proliferation of glioblastoma multiforme cell lines in a concentration-dependent manner, had minimal effects on cell cycle, apoptosis, and telomere length but increased h*TERT* expression and induced a DNA damage response.[183]

Telomestatin (Fig. 5), in common with TMPyP4, decreased the full-length product of the G-rich sequence in the h*TERT* promoter, in a dose-dependent manner, but it also increased the amount of different premature primer extension products. It was suggested by analysis of these products that telomestatin preferentially recognizes the external G-quartets, while TMPyP4 binds between two tandem h*TERT* quadruplex.[180] Despite the potential of telomestatin to repress h*TERT* expression in vitro, this has not yet been demonstrated in cancer cells. However, telomestatin does potently inhibit telomerase activity and has antitumor activity in vitro and in vivo.[184]

Substituted naphthalene diimides are established quadruplex-binding ligands. The trisubstituted compound HNDI-NMe2 (Fig. 8) has high affinity for the human telomeric quadruplex sequence hTel22.[185] Fluorescence resonance energy transfer (FRET) competition experiments revealed that the best competing sequence to disrupt the complex between HNDI-NMe2 and this quadruplex was the h*TERT* full-length quadruplex sequence, followed by c-*MYC* and *BCL-2* quadruplex sequences. The c-*KIT2* sequence was a poor competitor, whereas both c-*KIT1* and duplex DNA were unable to disrupt the complex.[186] Compound HNDI-NMe2 was able to significantly impair melanoma cell growth by causing telomere dysfunction and inhibition of telomerase activity, likely as a consequence of its induced decrease of mRNA expression levels of c-*MYC* and h*TERT*.[185] However, in the small-cell lung cancer cell line H69, compound HNDI-NMe2 increased mRNA levels of c-*MYC* although it decreased h*TERT*, *BCL-2*, and c-*KIT* transcription. Also, in the same cell line, c-MYC and BCL-2 protein levels were not affected, whereas c-KIT was decreased after cell exposure to HNDI-NMe2. These observations suggest that the effect of HNDI-NMe2 on gene expression is markedly dependent on cell type. Subsequent gene analysis showed cell-dependent modulation of genes implicated in telomere function and cancer mechanisms by this particular naphthalene diimide compound.[186]

The perylene derivatives PMP2 and PIPER (Fig. 8) have been shown to induce in vitro h*TERT* promoter and telomeric quadruplex formation. However, PMP2 is a superior intramolecular quadruplex inducer compared to PIPER and has a preference for the h*TERT1* quadruplex (the parallel quadruplex from G-tracts 1–4 of 26 bp) than to telomeric DNA G-rich sequences. In addition, compounds PMP2 and PIPER, at concentrations higher than 16 μM, induced the formation of an h*TERT2* intermolecular quadruplex (G-tracts 5–12, 44 bp) in the same duplex–quadruplex competition assay. PMP2 is consistently a superior inhibitor of h*TERT* expression than PIPER. At 6 μM, PMP2 reduced h*TERT* mRNA to 37% of the control in A549 lung cancer cells. PMP2 also decreased in vitro telomerase activity in a dose-dependent manner using a crude protein extract of cells treated with the compound. In addition, long-term treatment of A549 lung cancer cells with subcytotoxic concentrations of PMP2 and PIPER induced telomere shortening, reduction of cell proliferation, tumorigenicity, and cellular senescence.[149]

5.09.5.3 The *RAS* Family

The RAS membrane-bound family of G-proteins (k-RAS, h-RAS, and N-RAS) act as switches between the endothelial growth factor receptor (EGFR) and the nucleus, controlling downstream processes associated with cell growth and apoptosis. k-*RAS* is one of the most frequently mutated oncogenes in human cancers, in particular in pancreatic, colorectal, and lung cancers.[154,187,188] k-RAS mutated proteins are locked in the GTP-active state and constitutively transmit signals for cell proliferation to the nucleus, via the MAP-kinase cascade. Importantly, deletion of the mutant k-*RAS* allele in colon cancer cell lines dramatically reduces cellular proliferation,[189] highlighting the fact that many tumors harboring mutant k-*RAS* are k-RAS-dependent. The importance of therapeutic modulation of k-RAS signaling has been widely recognized and several approaches have been reported in the past, but none has led to an approved new anticancer drug to date.[188]

The human k-*RAS* gene promoter contains a 32-mer and a 52-mer sequences upstream of the transcription start site that can form stable quadruplex structures (KRAS32R[58,190] and KRASmid,[191] respectively). KRAS32R can form a mixed parallel and antiparallel quadruplex involving the G-tracts 1-2-3-5, whereas the 21-mer region (21R) can form a three-layer parallel quadruplex, involving the G-tracts 1-2-3-4.[58,190,192,193] Similarly, the h-*RAS* promoter has also two neighboring quadruplex-forming sequences (HRAS-1 and HRAS-2) containing copies of GC-boxes recognized by the MAZ and Sp1 transcription factors.[194] These DNA quadruplex structures have been previously shown to play an important role in the repression of k-*RAS*[58,190] and h-*RAS*[194] transcription. Quadruplex-forming motifs have also been identified in the 5′ UTR of k-*RAS* and N-*RAS* mRNA and shown to be involved in translation inhibition.[195,196]

Three quadruplex-ligand chemical types have been identified as k-*RAS*/h-*RAS* expression downregulators: porphyrins, anthrathiophenediones, and indoloquinolines. The well-established quadruplex ligand TMPyP4 (Fig. 6) and its noninteractive

quadruplex isomer TMPyP2 have been used to probe the role of the promoter quadruplex-forming sequences in the regulation of k-*RAS* expression. FRET melting assays suggest that TMPyP4 is a poorly selective k-*RAS*21R-quadruplex ligand compared to duplex DNA,[197] although it has been reported that this compound is able to repress k-*RAS* transcription. In a dual luciferase assay, TMPyP4 (3–20 μM 24 h prior to transfection) reduced mouse k-*RAS* promoter activity by 80%[190] and also decreased k-*RAS* mRNA levels by 30% in Panc-1 cells incubated by 12 or 24 h with 50 μM of the compound, whereas TMPyP2 had no effect on k-*RAS* transcription in the same assay.[58] In another study, TMPyP4 (3 μM) incubated with cells for 72 h after transfection reduced human k-*RAS* promoter activity by 25% but did not inhibit k-*RAS* transcription in colon cancer HCT116 cells at a 12 μM concentration.[197] However, at the same concentration (12 μM), TMPyP4 reduced the levels of k-RAS protein in HCT116 cells by more than 50%. These results are in agreement with the reported ability of TMPyP4 to preferentially accumulate in cellular cytoplasm[195] and inhibit N-*RAS* translation,[196] due to its capacity to bind and stabilize UTR1 and UTR2 RNA quadruplex-forming sequences.[195,198] However, it has been proposed that this translation inhibitory activity of TMPyP4 is not related to its ability to stabilize the quadruplex motifs in 5′-UTR k-*RAS* mRNA but rather to its nonspecific binding affinity to nucleic acids.[196] Substitution of a methyl group of TMPyP4 by a C14-alkyl chain does not affect binding affinity to RNA quadruplex nor cellular distribution but increases by 25- to 50-fold compound uptake by human pancreatic cancer Panc-1 cells and murine melanoma B78-HI cells, as well as showing k-*RAS* translation inhibition upon photo-activation of cells incubated with nanomolar concentrations of compounds.[195,198] In addition, inhibition of metabolic activity, clonogenic growth, and cell migration of photo-activated melanoma cells by TMPyP4 and its C14 derivative also correlated with their cellular uptake. Peritoneal injection of 3 mg/kg of the C14 derivative or 30 mg/kg of TMPyP4, followed by irradiation 7 h after compound administration, inhibited the growth of the subcutaneous B78-H1 melanoma tumor in C57/BL6 mice. However, contrary to TMPyP4, the C14 derivative also affected in vivo tumor growth even in the absence of irradiation. Analysis of porphyrin biodistribution after peritoneal injection in mice showed that compounds accumulate preferentially in tumor tissues, liver, and kidneys. Moreover, TMPyP4 showed greater subcutaneous tumor accumulation after 9 h injection than the C14 derivative which may reflect the reduced diffusion capacity of the more lipophilic porphyrin C14 derivative.[198]

The guanidine phthalocyanine DIGP (**Fig. 9**) and its zinc-containing analogue (DIGP-Zn) have been studied in a search for quadruplex ligands with superior selectivity and improved cellular uptake and distribution properties compared to TMPyP4. Using a polymerase stop assay, it was shown that DIGP is a good quadruplex-stabilizing ligand for both parallel (k-*RAS*) and antiparallel (h-*RAS*) structures, whereas its zinc-containing analogue is more specific for the parallel structure. DIGP also showed selectivity for quadruplex structures compared with duplex DNA, exhibited good cellular uptake and higher localization in the nuclei and nucleoli, in contrast to DIGP-Zn, which preferentially localizes in the perinuclear region. DIGP (5 μM) has been shown to downregulate h-*RAS* promoter activity to 35 ± 10% of the control in a dual luciferase assay.[199]

A series of anthrathiophenediones with guanidine-alkyl side chains of different length (ATDs, **Fig. 9**) have been investigated for their binding to h-*RAS* DNA quadruplex and N-*RAS* RNA quadruplex structures, together with their cellular uptake, intracellular localization, and repression of h-*RAS* expression in bladder cancer cells.[200] In vitro binding affinities determined by FRET titration and melting assays showed that quadruplex-binding potency increases with the side chain length but surprisingly, cellular uptake experiments have shown that ATD1, with shorter alkyl-guanidino side chains, shows greater accumulation (10-fold) inside bladder cancer cells than analogue ATD13 having longer side chains. Moreover, it was also found that cellular uptake of ATD1 must occur primarily by endocytosis, whereas the more lipophilic analogues (ATD10/12/13) probably cross the cellular membranes by passive diffusion. It was also shown that ATD1 has superior antiproliferative activity ($IC_{50} = 4$ μM) against cancer cells than analogues ATD10/12/13 and is 10-fold more selective for bladder cancer cells than nonmalignant cell lines. Compound ATD1 was shown to localize in the cytoplasm and nucleus of bladder cancer and nonmalignant cells, decreased h-RAS protein levels in bladder cancer cells treated with 5 μM of compound, decreased to 25% of the control h-*RAS* promoter activity, and increased the cell population in the G0/G1 phase in T24 bladder cancer cells. It was also found, using a caspase 3/7 assay, that ATDs do not induce apoptosis in cancer cells, which suggests a cytostatic mechanism of action. The mechanism of h-*RAS* expression downregulation by ATDs has been further investigated. It has been suggested that ATD1 represses *h-RAS* transcription by stabilizing quadruplex structures thus compromising MAZ-GST unfolding activity.[194] More recently, the anticancer activity of a series of chloroacetamidine (CATD) analogues was also studied.[201] Compared to ATDs, these more lipophilic compounds showed superior cell permeation, probably by endocytosis, and induced a large apoptotic response in T24 bladder cancer cells treated with 2.5–5.0 μM of CATDs, as shown by PARP-1, caspases 3/7, and annexin V/propidium iodide assays, accompanied by downregulation of cyclin D1 and blockage of cells in G2 phase. CATD1 (**Fig. 9**), the most potent compound of the series, inhibited metabolic activity ($IC_{50} = 2.7$ μM), colony formation, and h-*RAS* expression, at both mRNA (to ~34% of control) and protein levels (to ~4% of control), in T24 bladder cancer cells exposed to 5 μM of compound for 24 h. To investigate if inhibition of h-*RAS* expression was due, at least in part, to binding of CATD1 to h-*RAS* promoter quadruplexes, a luciferase reporter assay was used. T24 cells were treated with 100 and 200 nM of compound 4 h before transfection with the h-*RAS* promoter and two mutant vectors unable to form quadruplex structures. After 48 h, CATD1 reduced by 40% luciferase expression driven by the h-*RAS* promoter, but had no effect on gene expression driven by mutant promoters. Finally, treatment by intratumoral injection of nude mice bearing a T24 xenograft with 1.7 mg/kg of CATD1, for 4 days (days 1, 8, 15, and 22), inhibited tumor growth and increased median survival time from 32 to 54 days.[201]

Indolo[3,2-*b*]quinolines with three alkylamine side chains (IQ3A1a and 2a, **Fig. 9**) have been shown by a FRET melting assay to efficiently and selectively (10-fold) stabilize the DNA quadruplex motifs present in the k-*RAS* promoter compared to duplex DNA, inhibit the proliferation of HCT116 colon cancer cells with 100-fold selectivity compared to primary rat hepatocytes. They decrease k-RAS protein levels in a dose-dependent manner.[202] A subsequent study showed that increasing the length of side chains in

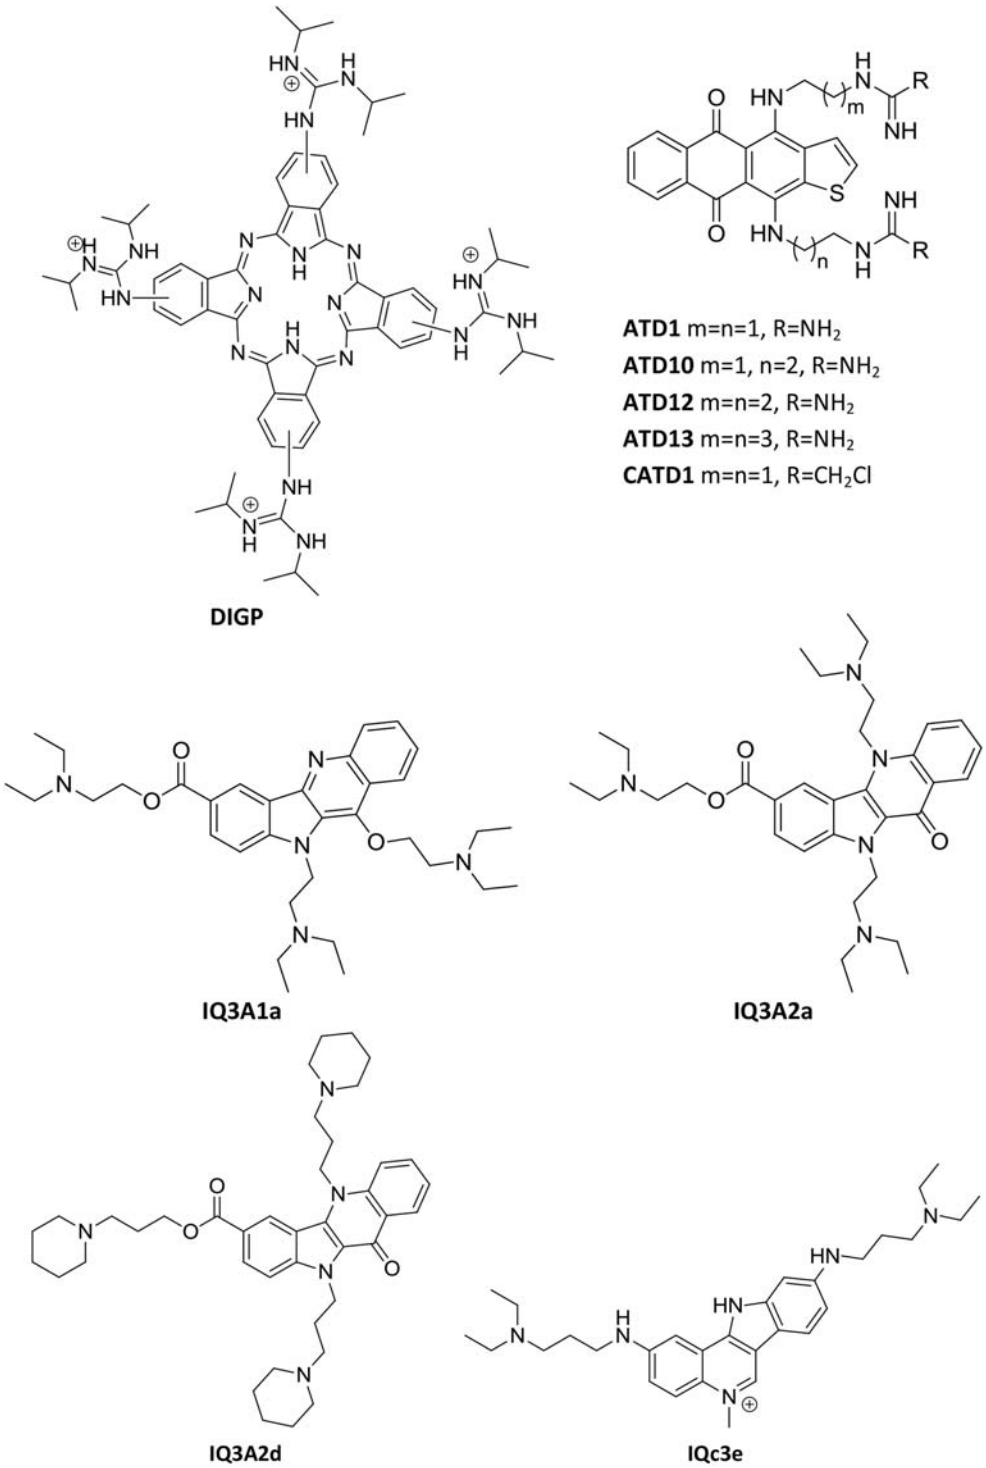

Fig. 9 Structures of guanidine phthalocyanine DIGP, anthrathiophenediones with guanidine-alkyl side chains (ATDs) or chloroacetamidine analogue CATD1 and indoloquinolines (IQ3As and IQc3e) reported as quadruplex-interactive molecules and *RAS* oncogene expression repressors.

compound IQ3A2d increased both the quadruplex thermal stabilization effect and the antiproliferative activity in HCT116 and metastatic SW620 colon cancer cells ($IC_{50} < 2.69$ μM), without producing cell death in nonmalignant HEK293T human embryonic kidney, and CCD18co human colon fibroblast cells. Moreover, IQ3A compounds significantly reduced k-*RAS* promoter activity in a luciferase reporter assay, reduced k-*RAS* mRNA and protein steady-state levels at IC_{50} concentrations, and increased p53 protein steady-state levels and cell death by apoptosis in HCT116 cells (mutant k-*RAS*, wild-type *p53*). Furthermore, induction of apoptosis

and increase in p53 levels were shown to be k-RAS-dependent, as k-*RAS* silencing in HCT116 p53 wild-type [p53(+/+)) and null (p53(−/−)] isogenic cell lines induced a higher level of cell death. A greater level of IQ3A-induced cell death in HCT116 p53(+/+) cells compared to HCT116 p53(−/−) was also observed.[203] The effects of the regioisomeric indolo[3,2-*c*]quinolines (IQcs) (with one and two alkylamine side chains) on selectivity to k-*RAS* DNA and RNA quadruplex motifs and regulation of k-*RAS* expression in colon cancer cell lines were also investigated.[197] FRET melting assays showed that disubstituted indolo[3,2-*c*]quinoline IQc3e (Fig. 9) is the most potent analogue ($\Delta T_m = 22°C$) and a selective DNA quadruplex k-*RAS*21R stabilizer (50-fold selectivity), compared with duplex DNA and telomere quadruplex. The results also suggested that IQc3e is an effective stabilizer of DNA quadruplex k-*RAS*32R, but only a moderate stabilizer of RNA quadruplexes UTR1 and UTR2. CD experiments showed that IQc3e binds to the parallel quadruplex k-*RAS*21R without inducing any change in quadruplex topology, whereas under the same conditions IQc3e induces a topology change from parallel/antiparallel hybrid to an antiparallel form on binding to telomeric quadruplex,[204] which may explain the observed selectivity of IQc3e for the k-*RAS* quadruplex and suggests a more general preference of IQc3e to bind to parallel quadruplexes. Moreover, compound IQc3e preferentially inhibited the proliferation of k-*RAS* mutant cancer cell lines ($1.45 < IC_{50} < 4.80\ \mu M$), downregulated k-*RAS* promoter activity in a luciferase reporter assay, and reduced both k-*RAS* mRNA and protein steady-state levels in mutant k-*RAS* colon cancer cell lines. Additionally, IQcs induced cell death by apoptosis in colon cancer cell lines but not in nonmalignant HEK293T cells.[197]

5.09.5.4 *VEGF* and *VEGFR*

Angiogenesis, the formation of new blood vessels, is essential for tumor growth and progression since it provides oxygen and nutrients to proliferating tumor cells. During tumor growth, these cells can adapt themselves to an angiogenic phenotype, producing and secreting proangiogenic molecules. Among these is the vascular endothelial growth factor (VEGF), particularly VEGF-A, a cytokine with a key role in angiogenesis regulation. VEGF-A binds to tyrosine kinase receptors such as VEGF receptors (VEGFR-1 and VEGFR-2) expressed on the surface of endothelial cells, activating signaling cascades leading to several cellular processes involved in angiogenesis.[205–207] The development of anti-VEGF/VEGFR agents for cancer therapy, including antibodies, engineered proteins, and small molecules targeting VEGFR-2, has been actively pursued but so far with more disappointing results in clinical trials than one would expect from preclinical evidence.[208]

VEGF overexpression in tumor cells can be induced by several factors including the activation of oncogenes, the inactivation of tumor suppressor genes, cis-acting elements, and transcription factors. Studies on *VEGF* transcription activation revealed that the *VEGF* promoter contains a 36-bp G/C-rich sequence (between −85 and −50 of transcription starting site), consisting of at least three SP1 binding sites essential for transcription.[209] The G-rich strand of the *VEGF* promoter is characterized by the presence of five runs of three or more contiguous guanines separated by one or more nucleotides, thus having the potential to form two alternative intramolecular quadruplex structures. The 20-mer sequence containing four 5′ runs of guanines (VEGF-Pu20) was shown by electrophoretic mobility shift assay, the dimethyl sulfate foot-printing technique, the DNA polymerase stop assay, CD spectroscopy, and computer-aided molecular modeling, to form an intramolecular propeller-type parallel-stranded quadruplex structure.[210] Further studies by NMR confirmed the parallel-stranded structure of the 22-mer analogue sequence with G-to-T mutations of two loop residues.[53] There is evidence for the formation of quadruplexes in the polypurine/polypyrimidine tract of the *VEGF* promoter in vitro and in vivo.[211,212] In addition, using a chromatin immunoprecipitation assay it has been shown that nucleolin and hnRPNK can bind to the G-rich and C-rich sequences, respectively, of the *VEGF* promoter in vivo, probably acting as transcription activators.[212,213]

Transcription of *VEGF* can also be controlled by quadruplex-ligand small molecules. Using a DNA polymerase assay, it has been shown that the core-modified expanded porphyrin analogue Se2SAP (Fig. 10) is able to interact in a concentration-dependent manner with the quadruplex (Pu20) in the *VEGF* promoter, being 10-fold more effective in binding than TMPyP4. In addition, Se2SAP (25–50 μM) decreased *VEGF* mRNA levels by 50–80% in kidney (A498 and 786-O), endometrial (HEC1A), and breast (MDA-MB231) cancer cells after 24–48 h treatment, whereas TMPyP4 showed a reduced effect and TMPyP2 was ineffective in the same assays.[210] The perylene derivatives PIPER, PMP1, and PMP2 (Figs. 8 and 10) induced a reduction of both *VEGF* mRNA and protein levels in A549 lung cancer cells incubated for 24 h with compounds at concentrations lower than the respective IC_{50} values (52, 3, and 4 μM, respectively, for PIPER, PMP1, and PMP2). The perylene monoimide derivative PMP2 showed the highest level of transcriptional inhibitory activity followed by PIPER, PMP1, and TMPyP4, being also the compound with the greatest capacity to bind to the *VEGF* promoter quadruplex and stop polymerase product extension. However, duplex/quadruplex competition assays have also shown that all three perylene derivatives have only a slight preference for quadruplex structures over duplex DNA. To demonstrate that these compounds induce transcriptional repression by induction of quadruplex formation in G-rich gene promoters, mRNA levels of other genes containing quadruplex motifs in their promoters (c-*MYC* and *BCL*-2) and of constitutively expressed genes (*Max* and *GADPH*) or inducible genes (*Cox*) were evaluated after treatment of A549 cells with PIPER, PMP1, and PMP2. This key experiment demonstrated that perylene derivatives only repress the transcription of genes with quadruplex-forming sequences in promoter regions (*VEGF*, c-*MYC*, and *BCL*-2), thus supporting the hypothesis of a mechanism of transcription repression by inducing the formation of a quadruplex in promoters and also showing that these perylene-based compounds are not *VEGF*-specific suppressors. Moreover, PMP2 was also shown not to be cell-specific, as it also represses *VEGF* expression in the MCF-7 breast cancer cell line, the HCT-15 colon cancer cell line, and the HeLa cervical cancer cell line.[214]

A series of N5-methyl indolo[3,2-*b*]quinoline derivatives has also been evaluated for its ability to stabilize the *VEGF* quadruplex, downregulate *VEGF* expression in cancer cells, and inhibit angiogenesis.[215] Among the compounds tested SYUIQ-FM05 (Fig. 10)

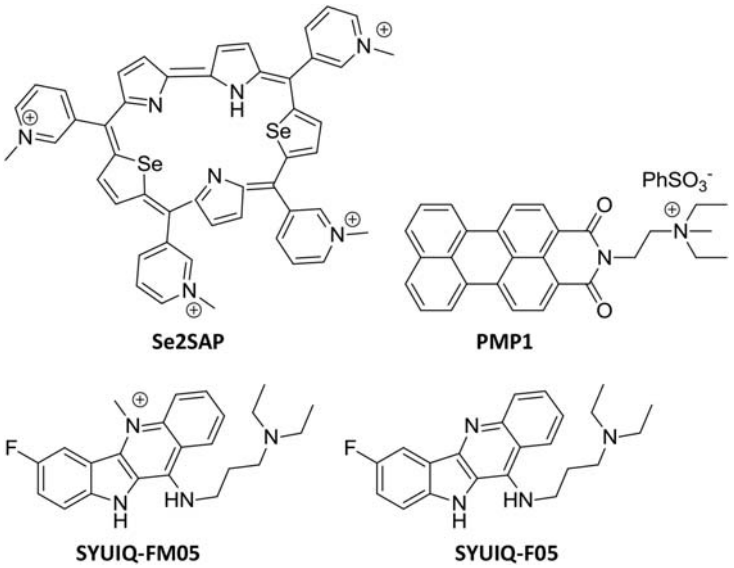

Fig. 10 Structures of G-quadruplex-interactive small molecules with reported *VEGF* expression modulatory activity.

showed the greatest interaction with the *VEGF* promoter quadruplex in a PCR-stop assay and also the highest activity in cancer cells. SYUIQ-FM05 inhibited the short-term proliferation of MCF-7 breast cancer cells ($IC_{50} = 0.96$ μM), downregulated transcription and translation of *VEGF* in MCF-7 cells after 48 h drug exposure, and at 0.5 μM concentration decreased *VEGF* promoter activity by up to 30% in a luciferase reporter assay. SYUIQ-FM05 also showed antiangiogenic potential in a chick embryo assay. The compound showed an inhibitory response to new blood vessels formation in a chorioallantoic membrane of 63% compared with the control, which is higher than that of the control drug thalidomide (53%) and of the analogue SYUIQ-F05 (55%) (**Fig. 10**).

A G-rich sequence within the promoter region of *VEGFR-2* can form an antiparallel quadruplex structure which has been shown to be implicated in the expression of this receptor, thus representing another potential target for anticancer therapy.[216] The well-established quadruplex ligand RHPS4 (**Fig. 5**) has been shown to inhibit tumor angiogenesis by targeting the *VEGFR-2* quadruplex and inhibits the expression of this gene. RHPS4 (0.5 μM) strongly inhibited *VEGFR-2* mRNA and protein levels in human umbilical vein endothelial cells (HUVEC) after 72 h incubation. The transcriptional activity of RHPS4 on other angiogenesis-related genes containing quadruplex sequences in their promoters has also been evaluated. RHPS4 downregulates the expression of *VEGF-A*, *VEGFR-1*, *IL1R*, *CXCR-1*, and *AChRβ1* but not that of *FGFR* and *EGFR*, which may be a consequence of the structural diversity of their quadruplexes. The expression of nonquadruplex-containing genes (*IL10R* and *AChRα1*) was unaffected by RHPS4. Moreover, RHPS4 inhibited HUVEC proliferation and almost completely abrogated VEGF-A stimulated endothelial cell migration. However, RHPS4 did not affect cell viability, apoptosis, or senescence, nor activate the DNA damage response. Finally, RHPS4 impaired angiogenesis in a xenograft model. Immunohistochemical analysis of the tumor tissue after treatment with RHPS4 revealed a massive decrease in the number of blood vessels and *VEGFR-2* expression. In vivo *VEGFR-2* expression inhibition was further confirmed by mRNA quantification.[216]

The 5′-UTR of human *VEGF* contains two internal ribosomal entry sites (IRES A and B) which are involved in cap-independent translation initiation. A 17-nucleotide sequence within the 294-nucleotide fragment of IRES A was shown to fold into a RNA quadruplex with an upregulation effect on translation by direct recruitment and interaction with the 40S ribosomal subunit.[217,218] However, another study indicated that in stress conditions the quadruplex within the VEGF IRES is dispensable for cap-independent function and activation. Moreover, it was also found that stabilization of that RNA quadruplex, including by small molecules, inhibited in vitro the cap-independent translation of *VEGF* mRNA.[219]

5.09.5.5 c-*KIT*

The c-*KIT* proto-oncogene encodes for a tyrosine kinase receptor that upon activation by its ligand (the cytokine stem cell factor) promotes cell proliferation and differentiation.[220,221] Mutations or overexpression of c-*KIT* result in aberrant function that contributes to oncogenicity in melanocytes, mast cells, myeloid cells, and gastrointestinal stromal tumors (GIST). More than 80% of GIST cells express mutated c-KIT proteins that are constitutively activated, thus escaping normal activation control by its natural cytokine ligand.[222] Consequently, inhibition of the c-KIT enzyme domain with kinase inhibitors such as imatinib and sunitinib has become the clinical practice for GIST therapy.[223] However, the emergence of drug resistance due to mutations in the ATP binding site of the enzyme has been a major factor in the search for alternative approaches.

The promoter region of c-*KIT* contains G-rich sequences that can fold into two quadruplexes (c-*KIT1* and c-*KIT2*). Crystal and NMR structures are available for both (see earlier sections in this article). Evidence for the inhibition of c-*KIT* expression in cancer

cells has been provided by selective c-*KIT* promoter quadruplex ligands.[224] A series of 3,8,10-trisubstituted isoalloxazines was designed and synthesized as quadruplex ligands based on a previous observation that oxidized riboflavin (7,8-dimethyl-10-ribityl-isoalloxazine) is a quadruplex ligand. All isoalloxazines examined showed a preference for binding to the c-*KIT2* quadruplex structure over c-*KIT1* (threefold selectivity for compound IAXZ-a, Fig. 11) and also over the human telomere quadruplex sequence (14-fold selectivity for IAXZ-d), but none of the compounds showed significant binding affinity to duplex DNA, as determined by SPR or by a FRET melting assay. At 5 μM concentrations, both IAXZ-a and IAXZ-d were not cytotoxic to the breast cancer cell line MCF-7 or to the GIST cell line HGC-27, but induced a significant reduction or even complete suppression of c-*KIT* expression in both cell lines, as measured by mRNA levels. IAXZ-d showed the greatest inhibitory activity. In the MCF-7 cell line, which shows low basal levels of c-*KIT* expression, IAXZ-d almost completely suppressed the expression of this oncogene after 6 h drug exposure and in the HGC-27 cell line expressing higher levels of c-*KIT*, it reduced the c-*KIT* transcript to a 50% level.[224]

The effects on stabilization of c-*KIT1* and c-*KIT2* quadruplex structures and repression of c-*KIT* expression in cancer cells have also been reported with the known quadruplex ligands TMPyP4, BRACO-19, and the tetra-substituted naphthalene diimide 4-NDII-1[225] (Fig. 11).[226] In a FRET melting assay, all three compounds showed a lower capacity to stabilize c-*KIT1* compared to c-*KIT2* and a telomeric quadruplex, with compound 4-NDII-1 showing the greatest overall ability to stabilize c-*KIT2* and telomeric quadruplexes. A FRET competition assay with increasing concentrations of calf thymus DNA indicated that 4-NDII-1 has modest selectivity (<30-fold) to quadruplexes compared to duplex DNA, similar to TMPyP4 (Fig. 6) and BRACO-19 (Fig. 5). 4-NDII-1 also showed greater short-term growth-inhibitory activity against a range of cancer cell lines ($IC_{50} = 0.02–1.6$ μM), including the primary c-KIT-dependent gastrointestinal tumor cell line GIST882. Moreover, in this cell line the IC_{50} of 4-NDII-1 was comparable to that of the anticancer drug imatinib. Expanding the panel of cancer cell lines, the high level of potency of 4-NDII-1 against c-KIT-dependent GIST cell lines was further confirmed, in contrast with low activity against c-KIT-negative lines. In addition, 4-NDII-1 induced 90% downregulation of c-*KIT* transcription and a complete inhibition of protein expression in the patient-derived GIST882 cell line treated with a concentration of compound (1 μM) close to the IC_{50} value, whereas no significant changes in c-*KIT* transcription were induced by imatinib, BRACO-19, or TMPyP4. Finally, other data supporting the hypothesis of 4-NDII-1 acting at the c-*KIT* gene level comes from the observations of the significantly lower effect of this compound on repressing other cancer-associated genes with quadruplex in promoters, such as c-*MYC*, h*TERT*, and N-*RAS*. However, due to its potent telomeric

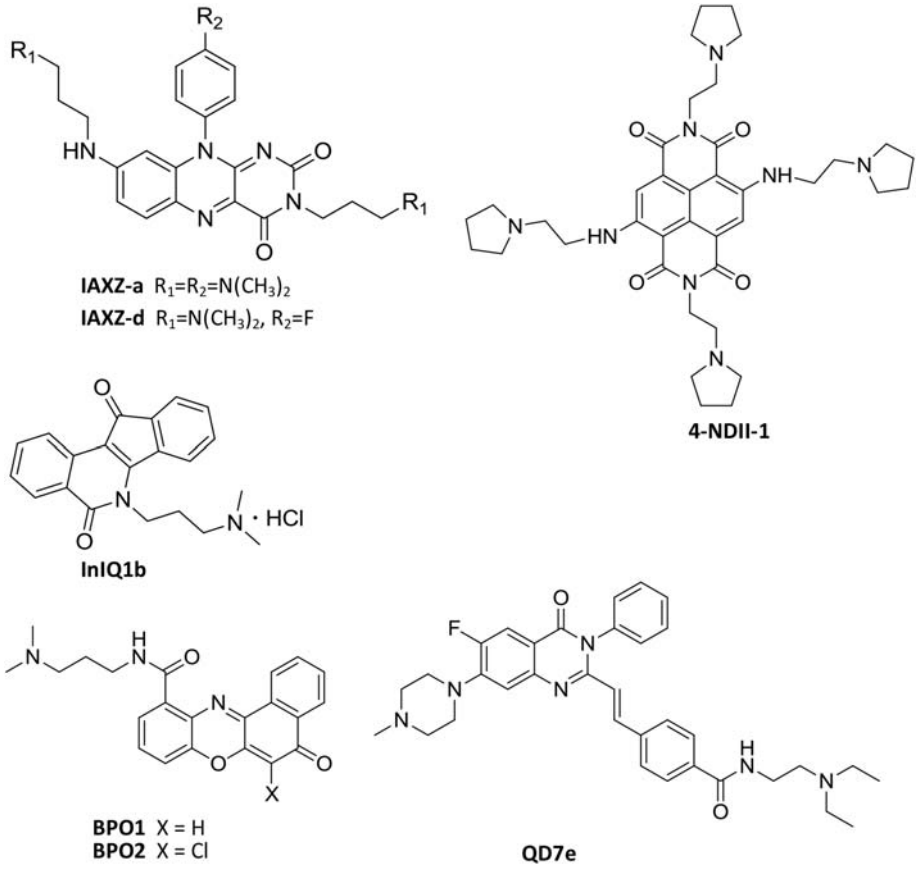

Fig. 11 Structures of G-quadruplex-interactive small molecules with reported c-*KIT* expression modulatory activity.

quadruplex stabilization capacity, level of telomerase inhibitory activity[225] and long-term growth-inhibitory activity, it was suggested that 4-NDII-1 has a dual mechanism of action in GIST882 cells, which also strongly express telomerase.[226]

The benzo[*a*]phenoxazines BPO1 and BPO2 (Fig. 11) were identified as quadruplex selective c-*KIT* promoter targeting molecules, from a library of 173 small molecules interrogated with a luciferase reporter assay driven by the c-*KIT* promoter. The effects of BPO1 and BPO2 on c-*KIT* expression downregulation were further confirmed by incubating human gastric carcinoma HGC-27 cells with 5 μM of each compound. Both compounds reduced by 2.6–2.9-fold the mRNA levels of c-*KIT2*. A greater affinity of both ligands to the c-*KIT2* quadruplex compared to c-*KIT1*, c-*MYC*, and telomere quadruplex sequences was also found by SPR, with selective affinity for the c-*KIT2* quadruplex over duplex DNA.[227]

The established quadruplex ligand and telomerase inhibitor indolo[3,2-*b*]quinoline derivative SYUIQ-FM05 (Fig. 10) with antiproliferative and senescence-induction activities[170,228] has also been examined for c-*KIT* transcription inhibitory activity in c-KIT-positive K562 leukemia cells.[229] SYUIQ-FM05 inhibited cellular growth in this cell line with an IC_{50} of approximately 10 nM and at equitoxic concentrations suppressed c-*KIT* transcription by 7.7-fold, which produced a proportional loss of total c-KIT protein and an apoptotic response. In addition, SYUIQ-FM05, as well as the clinical c-KIT inhibitor imatinib, downregulated downstream MEK and ERK activation. A decrease in *BCL-2* transcription and an increase in *Bax* expression were also found in these treated cells, although these effects were less pronounced than on c-*KIT* expression. These findings support the anticancer potential of SYUIQ-FM05, or related c-*KIT* quadruplex ligands, in the treatment of c-KIT-positive cancers. Other aromatic tetracyclic compounds, the 6-substituted indenoisoquinolines (e.g., InIQ1b, Fig. 11) were also found by a FRET melting assay to be potent and selective quadruplex ligands, particularly of c-*KIT1* compared to c-*KIT2* and telomeric quadruplex sequences.[230] InIQ1b showed antiproliferative activity against two c-KIT-positive cancer cell lines, the primary GIST cells GIST882 and the colorectal cancer cell line HT-29, with IC_{50} values, respectively, of 4.1 and 0.3 μM, which compare with that of imatinib in GIST882 cells ($IC_{50} = 1.7$ μM). Moreover, at IC_{50} concentration, InIQ1b greatly decreased the levels of both c-*KIT* mRNA and c-KIT protein in GIST882 cells.[230]

A series of quinazolone derivatives (QD), constituting a novel unfused aromatic system, has been designed, synthesized, and evaluated for inhibition of c-*KIT* expression in cancer cells, based on previous in vitro evidence of selective binding of compounds with a quinazolone core to quadruplex structures.[231,232] These QDs were designed to include an expansion of the aromatic system via the introduction of a benzene ring and a benzylidene group into the quinazolone moiety, and two protonatable amino side chains (e.g., QD7e, Fig. 11). FRET melting, SPR, and CD experiments demonstrated that QDs, with this adaptive scaffold, could effectively bind and stabilize c-*KIT1* and c-*KIT2* quadruplexes with high selectivity against duplex DNA. From all derivatives tested, compound QD7e has prominent activity in cancer cells, inhibiting the growth of the human gastric carcinoma cell line HGC-27 (having overexpressed c-*KIT*) ($IC_{50} = 8.8$ μM). At a 5 μM concentration, it inhibited by 45% luciferase activity driven by the wild-type c-*KIT* promoter, an inhibitory effect twofold greater than that observed with a mutant construct. It decreased by 52.5% the c-*KIT* mRNA levels in HGC-27 cells incubated with 5 μM of the compound.[232] However, these cellular effects could not be fully explained by c-*KIT* quadruplex interactions (other genomic quadruplex targets could also be involved) and these QDs are apparently less potent quadruplex stabilizers and c-*KIT* transcription inhibitors than other reported fused-aromatic compounds.

5.09.5.6 BCL-2

The *BCL-2* (B-cell lymphoma 2) gene encodes for a mitochondrial membrane protein that functions as an inhibitor of apoptosis. *BCL-2* has been found to be overexpressed, due to gene amplification or translocation,[233] in a wide range of human tumors including B-cell and T-cell lymphomas and breast, prostate, cervical, colorectal, and non-small-cell lung carcinomas.[234–240] Increased BCL-2 levels have also been associated with poor prognosis and resistance to chemotherapy or radiotherapy.[241,242] It has been shown that inhibition of BCL-2 activity or expression by small molecules[243,244] or antisense oligonucleotides[245,246] can decrease cellular proliferation and enhance chemotherapy efficacy. Thus, effective modulation of *BCL-2* expression offers promise for cancer therapeutics. Although targeting the protein directly is challenging, drugs with this mechanism have been developed (e.g., ABT-737, ABT-263, ABT-199), and one (venetoclax, ABT-199) has obtained regulatory approval. These high molecular-weight compounds have significant pharmacological problems and alternatives are still sought.

A 39-bp GC-rich element located 57–19 base pairs upstream of the P1 promoter of *BCL-2* has been reported to be the binding site of multiple transcription factors.[247–249] The 39-mer G-rich strand (Pu39) of this GC-rich element contains six runs of 3–5 consecutive guanines with the potential to form 15 intramolecular quadruplex structures. It has been shown that the quadruplex formed on the central four G-runs (midquadruplex) folds in K^+ solution into a stable three quartet mixed parallel/antiparallel quadruplex with three loops of 1, 7, and 3 nt,[250,251] whereas guanine runs 1, 2, 4, and 5 can fold into another thermodynamically stable quadruplex (1245quadruplex) with a parallel structure and with one 13-nt and two 1-nt chain-reversal loops.[52] The possibility of two interchangeable quadruplex existing within the same region of the *BCL-2* promoter suggests that these two structures may be recognized by different proteins and small molecules which in turn could differentially modulate *BCL-2* gene transcription. Moreover, a second 32-bp GC-rich sequence has been identified −451 bp upstream of the P1 promoter and shown to be implicated in *BCL-2* transcription activation.[252] The G-rich strand of this sequence (labeled p32) can fold into an intramolecular hybrid-type quadruplex and inhibition of its formation through base mutations downregulates *BCL-2* expression.[253]

The indoloquinolines SYUIQ-F05 and SYUIQ-FM05 (Fig. 10) have been shown to decrease *BCL-2* promoter activity in a luciferase assay using the Pu39 construct rather than in the assay with a mutant Pu39 construct. They decrease *BCL-2* transcription and protein levels in HL-60 cells and leukemia K562 cell lines incubated with 0.4 μM concentration of compounds and inhibit cell

proliferation and induce apoptosis in HL-60 tumor cells. SYUIQ-FM05 showed greater activity than SYUIQ-F05 in all assays, in agreement with the observed higher in vitro binding and stabilization of the quadruplex-forming sequence Pu39.[229,254] The 2,4-disubstituted quinazoline SYSU12d (Fig. 6) has also been shown to be a potent quadruplex ligand, able to downregulate c-*MYC* expression which in turn induced a series of cellular events leading to activation of p53 and apoptosis. Contributing to the apoptotic effect is probably the ability of this quinazoline (>2.5 μM) to decrease BCL-2 protein levels in HeLa cells.[168]

As previously mentioned, the quadruplex-mediated regulation of gene expression by the naphthalene diimide derivative HNDI-NMe2 (Fig. 8) depends both on gene and cell type.[186] FRET and CD experiments have shown that HNDI-NMe2 is able to bind to and stabilize the 37mer G-rich strand of the *BCL-2* promoter, maintaining a parallel quadruplex structure, and to decrease mRNA levels in both the melanoma SKMel-5 cell line and the small-cell lung cancer H69 cell line, by 1.6- and 5-fold, respectively, when cells were treated for 48 h with subcytotoxic concentrations of compound (0.6–0.4 μM). However, HNDI-NMe2 did not affect BCL-2 protein levels in the H69 cell line, which, it has been suggested, may be due to compensatory responses activated by cells to cope with the drug.[186] Consistent with the observation that the induced effects of quadruplex-binding ligands on gene expression are cell-type dependent is another study with a related tetra-substituted naphthalene diimide. 4-NDII-MM41 (Fig. 12) has been shown to be a potent stabilizer of several quadruplex structures in vitro and to inhibit cell growth, in particular in pancreatic cancer cells.[123] 4-NDII-MM41 showed an IC_{50} of 10 nM in the MIA PaCa-2 pancreatic adenocarcinoma cell line. Further studies into the mechanism of anticancer activity of this compound revealed that it is not a telomerase inhibitor (in common with other related tetra-substituted naphthalene diimides), does not appear to induce a major DNA damage response in cells, but significantly

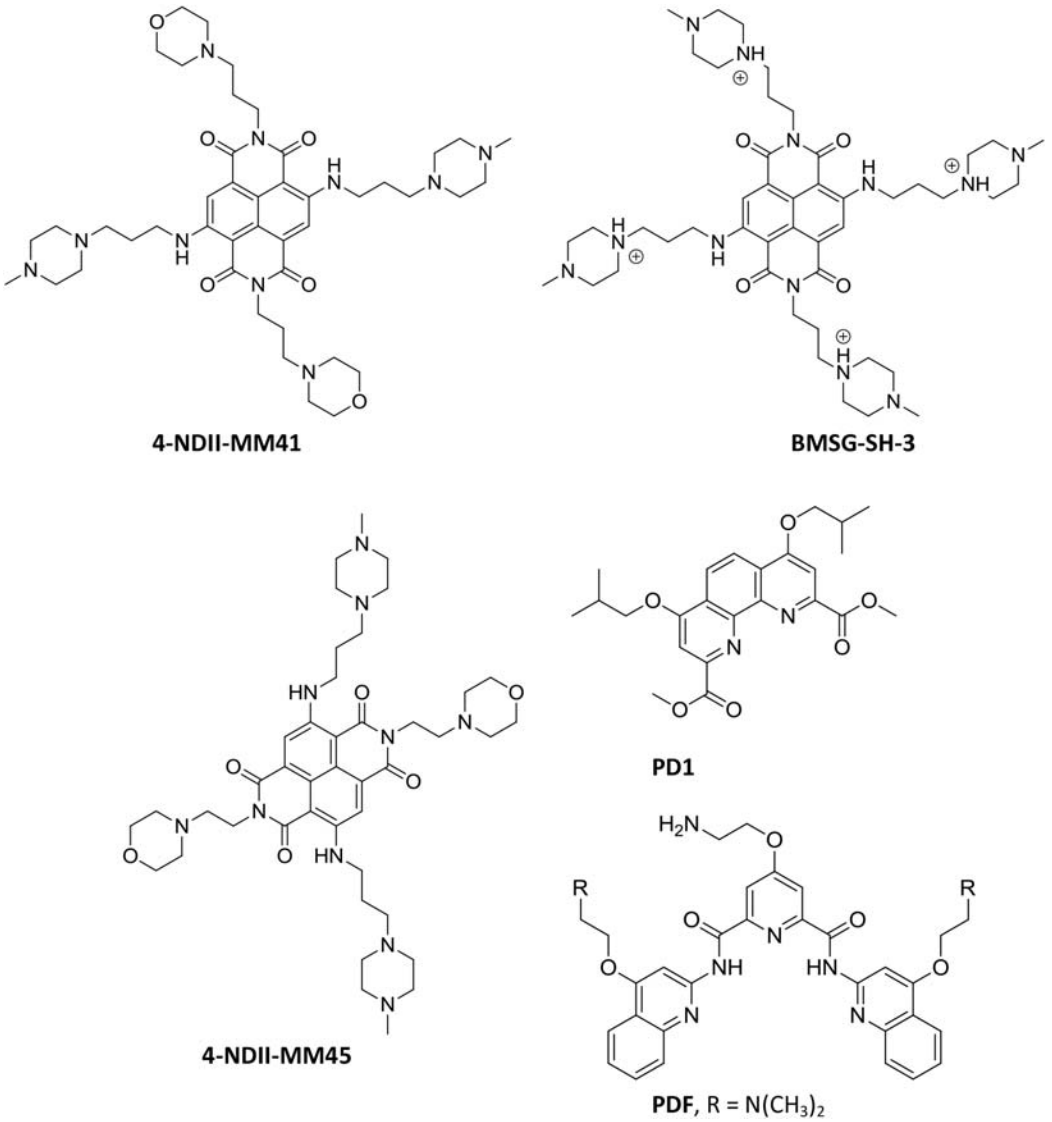

Fig. 12 Structures of tetra-substituted naphthalene diimides (4-NDII-MM41, 4-NDII-MM45, BMSG-SH-3), pyridostatin analogue PDF, and a phenanthroline derivative (PD1) with reported oncogene expression modulatory activity.

downregulates the expression of the antiapoptotic *BCL*-2 gene.[123] Moreover, 4-NDII-MM41 showed in vivo antitumor activity against the MIA PaCa-2 pancreatic cancer xenograft model. Tumor growth decreased by 80% after treatment with 15 mg/kg twice-weekly of 4-NDII-MM41 administered intravenously and levels of BCL-2 and k-RAS proteins were reduced by c. 40% and 30%, respectively, in tumors from treated animals. In addition, whole-animal imaging showed that 4-NDII-MM41 is preferentially localized in the tumor mass 4 h postadministration; it is able to penetrate into the center of the tumor mass and in tumor tissues it is exclusively localized in nuclei.[255]

The p32 G-rich DNA sequence located upstream of the *BCL*-2 P1 promoter has been shown in vitro to form an intramolecular quadruplex hybrid-type structure, which seems to be an essential factor in the binding of transcription factors, thus acting as an activator of gene expression. The phenanthroline dicarboxylate compound PD1 (**Fig. 12**) downregulated *BCL-2* expression in A549 cells, determined by measuring mRNA levels, and in a luciferase assay driven by a constructed vector that included the p32 sequence. Similarly, luciferase activity was also decreased when cells where cotransfected with a pGL vector in which the central guanines in each G-tract of the p32 sequence were mutated to thymine. To further understand the role of p32 on *BCL*-2 expression regulation and how PD1 can affect this, the interaction between PD1 and the p32 quadruplex was studied by fluorescence spectroscopy and CD. It was shown that PD1 can induce a conformational transition in the p32 quadruplex, increasing its antiparallel character, but cannot actually induce quadruplex formation or enhance quadruplex stability. Thus, the design of small molecules targeting the p32 quadruplex in the *BCL*-2 promoter must consider the disruption of the quadruplex structure and not only the increasing of quadruplex stability.[253] The pyridostatin analogue PDF (**Fig. 12**) showed high binding affinity and selectivity (6.5-fold) to the *BCL*-2 quadruplex (MidG4-G15T/G16T) compared to double-strand DNA sequences, as well as antiproliferative activity ($IC_{50} = 1–2$ μM) in human laryngeal squamous carcinoma Hep-2 cells. Moreover, PDF decreased both *BCL*-2 transcription in Hep-2 cells treated with PDF (1–10 μM) and *BCL*-2 promoter activity in a luciferase reporter assay.[256]

5.09.5.7 HSP-90

Heat-shock proteins (HSP) are a family of proteins that act as molecular chaperones, preventing the formation of nonspecific protein aggregates and assisting proteins in their correct folding. HSP90 is the most studied member of this family and it has been found to be overexpressed in several cancers. HSP90 activity has been associated with a larger number of cellular signaling pathways where it has an antiapoptotic role.[257] Moreover, HSP90 also plays a role in telomere maintenance and telomerase regulation.[258,259] HSP90 has been widely recognized as an important target for cancer therapy and several inhibitors are currently under investigation.[260–262] However, emergence of resistance to these inhibitors via mutations in the ATP binding site may occur.[263] Targeting the HSP90 gene rather than the gene product may reduce susceptibility to resistance.

The presence in the promoter region of *HSP90* of a sequence with five short guanine tracts able to form quadruplex structures of mixed topology in high K^+ concentrations has been reported, as well as the possibility of these quadruplex being selectively targeted and stabilized by small molecules.[55] The indoloquinolines IQ3A1a and IQ3A2a (**Fig. 9**) have shown moderate induced thermal stabilization of the 21mer *HSP90*A quadruplex and decreased HSP90 protein expression in HCT116 and SW620 colon cancer cells, although the major effect of these compounds in these cancer cell lines was observed to be on k-*RAS* expression.[202,203]

The naphthalene diimide derivative BMSG-SH-3 (**Fig. 12**), a potent in vitro stabilizer of promoter *HSP90* quadruplex structures, showed significant in vivo antitumor activity against a model for pancreatic cancer. At a dose of 3 mg/kg three times per week, BMSG-SH-3 decreased tumor volume by 50% over the 26 days of the experiment. In addition, the compound localized in tumors and reduced the levels of HSP90 in treated MIA PaCa-2 tumor cells. BMSG-SH-3 has also the capacity to stabilize quadruplex structures in telomeres and inhibit telomerase,[264] which itself is regulated by HSP90. Thus, it has been proposed that the simultaneous targeting of these quadruplex may be an effective antitumor strategy.[265] Moreover, BMSG-SH-3 did not induce a major cellular DNA damage response, nor showed significant hERG activity, and was not localized in the hearts of treated animals, consistent with a lack of cardiotoxicity.[265]

5.09.5.8 *HIFα*

Hypoxia-inducible factor-1 (HIF-1) is a transcription factor that mediates cellular responses to hypoxia, such as increased glycolysis, resistance to apoptosis, and increased angiogenesis. HIF-1 is a heterodimer constituted by a HIF-1β subunit, that is constitutively expressed, and an oxygen-dependent HIF-α subunit. Of the three α isoforms, HIF-1α is the one playing a major role in hypoxia signaling.[266,267] HIF-1α protein has been found to be overexpressed in many human tumors including renal cancers,[268] osteosarcomas, and chondrosarcomas.[269,270] Moreover, levels of serum VEGF, whose gene is a HIF target, were found to be significantly higher in Ewing's sarcoma patients than in healthy controls. HIF-1α is thus an attractive molecular target for the development of novel drugs for these cancers in particular.

Quadruplex-forming sequences have been located in the promoter region of both the *HIF*-1α and the *HIF*-2α genes and shown to be implicated in the regulation of expression of these genes.[56,271–273] A family of naphthalene derivatives with disubstituted triazole side chains has been investigated for their quadruplex binding and stabilizing ability, repression of *HIF*-1α and *HIF*-2α expression and antiproliferative activity in a panel of cancer cell lines. From all the derivatives tested, compound CL67 (**Fig. 13**) showed the optimal binding affinity constants to *HIF*-1α and *HIF*-2α quadruplexes, as determined by SPR, and no significant binding to a control duplex DNA sequence. Further studies by CD showed that CL67 does not induce any conformational change on binding to the parallel *HIF*-1α quadruplex. More importantly, CL67 showed high levels of antiproliferative activity and selectivity for renal,

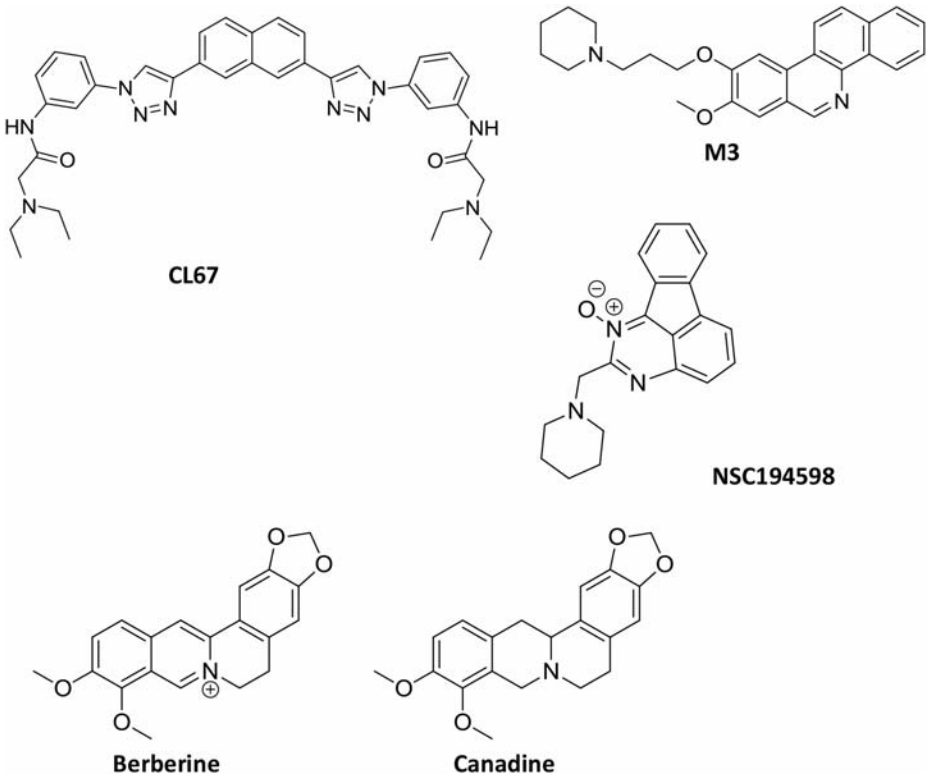

Fig. 13 Structures of G-quadruplex-interactive small molecules with reported effects on expression of *HIF-1α* and *RET*.

osteo-, and Ewing's sarcomas, all of which express HIF-1α protein. It inhibited in a dose-dependent manner both mRNA and HIF-1α and HIF-2α proteins in osteosarcoma and renal carcinoma cell lines, leading to inhibition of HIF transactivation and subsequent reduction in expression of downstream target genes, both in cancer cell lines and in a mouse xenograft model of renal cancer.[271,272] Moreover, this inhibition by CL67 was shown to be independent of pathways controlling oxygen-dependent HIF degradation and expression of HIF-α subunits.[272]

Four other quadruplexes have been identified in the *HIF*-1α promoter and 5′-UTR (S1-S4) by multiple spectroscopic and biochemical methods. The S1-quadruplex has been shown to be the most significant for *HIF*-1α transcription repression by blocking the AP2-binding site. The benzo[*c*]phenanthridine derivative M3 (Fig. 13) was shown to bind preferentially to the S1-quadruplex, inducing conformational change and repressing *HIF*-1α expression in the MCF-7 cell line (which only has low-level expression of *HIF*). M3 also repressed the transcription of several downstream genes such as *VEGF* and *GluT1* but not of upstream regulators such as *AP2*.[273]

5.09.5.9 The Androgen Receptor

An increase in AR protein has been associated with the majority of castrate-resistant prostate cancers in the clinic.[274] Knockdown of AR has been shown to cause cancer cell growth inhibition both in vitro and in a xenograft model of castrate-resistant prostate cancer.[275] Several approaches to downregulate AR transcription have been recently pursued.[276,277] A G-rich sequence able to form a stable quadruplex has been identified 116 bp upstream of the *AR* transcription start site by NMR spectroscopy, CD, UV spectroscopy, and UV thermal melting experiments.[67] The naphthalene diimide derivative 4-NDII-MM45 (Fig. 12) showed potent ability to stabilize the *AR* quadruplex at submicromolar concentrations using a FRET melting assay. It also inhibits prostate cancer cell growth and represses *AR* transcription at the mRNA and protein levels in a dose-dependent manner in these cells, and in a luciferase reporter assay driven by AR promoter. mRNA levels for AR target genes were shown to be downregulated, as well some AR upstream transcription factors that may contribute to repress *AR* transcription, such as c-MYC and SP1, together with upregulation of Jun.[67,274] Thus, a poly-targeting mechanism of action has been suggested for 4-NDII-MM45.

5.09.5.10 RET

The *RET* (rearranged during transfection) proto-oncogene encodes a receptor tyrosine kinase that has been implicated in the development of several human cancers, in particular thyroid cancer.[278,279] In these cancers, RET aberrant function can be due to

mutations or protein overexpression.[280–283] The possibility of targeting RET in these rarer cancers using small molecules, monoclonal antibodies, or gene therapy has been investigated in several studies.[284]

A G-rich sequence containing two GC-boxes essential for SP1-mediated transactivation of the *RET* promoter has been identified[285] and shown to be able to form intramolecular quadruplex structures in vitro,[66,286] which can be stabilized by quadruplex ligands such as TMPyP4, telomestatin, and NSC194598. The indeno[1,2,3]quinazoline derivative NSC194598 (**Fig. 13**) has been shown to more strongly inhibit transcriptional activity in the presence of a wild-type *RET* promoter than in the presence of a quadruplex-mutated one, to inhibit *RET* mRNA expression in a human medullary thyroid carcinoma cell line (TT) harboring a MEN2A-type mutation, but to induce little effect on other genes with known quadruplexes in their promoters (*VEGF*, *HIF*-1α, h-*RAS*). It was also shown that NSC194598 prevents *RET* promoter binding by RNA polymerase II, SP1, and nucleolin, and induces both apoptotic and necrotic cell death in TT cells at concentrations below 2.5 μg/mL.[287]

In another study, berberine, a N^+-containing isoquinoline derivative, was shown by DNA melting and DMS footprint assays to interact more strongly to RET wt quadruplex-forming sequences than the tetrahydro isoquinoline analogue canadine (**Fig. 13**). In agreement with these observations, berberine (2.5 μg/mL) downregulated RET transcription and reduced RET protein levels in a medullary carcinoma TT cell line, without significantly affecting the expression of c-*MYC* and *VEGF*, whereas canadine showed no effect on *RET* expression in the same cell line. Moreover, berberine had minimal effect on *RET* transcription in the papillary thyroid carcinoma TPC1 cell line, which lacks the quadruplex-forming sequence in its *RET* promoter due to chromosomal rearrangement, thus suggesting that oncogene expression is downregulated by quadruplex targeting. However, this was not supported by luciferase reporter assay data since berberine (10 μg/mL) decreased the luciferase expression driven by both the *RET* promoter itself and a *RET* mutated promoter unable to form a quadruplex. Further studies revealed that berberine prevents the binding of SP1 and RNA PolII to the *RET* promoter in TT cells and inhibits the phosphorylation of Akt in a dose-dependent manner, leading to induction of apoptosis. Interestingly, berberine showed no effect on the RET downstream signal transduction pathway MEK/ERK, which could be explained by the fact that this pathway is also governed by other growth factor receptors such as VEGFR and EGFR.[288]

5.09.5.11 MET

Human MET (c-MET or hepatocyte growth factor receptor) is a membrane tyrosine kinase that can be activated by the hepatocyte growth factor, then activating several downstream signaling cascades such as RAS/MAPK, PI3K/Akt, c-SRC, and STAT3/5.[289] MET abnormal activation has been identified in kidney, breast, stomach, liver, and brain cancers, and consequently several approaches to targeting MET have been developed, including the use of receptor antagonists,[290–292] antibodies,[293] and small-molecule inhibitors.[294]

Bioinformatic studies have identified a quadruplex-forming sequence within the proximal promoter region of *MET* (−48 to −26 bp upstream of the TSS) which contains a SP1-binding site. This G-rich sequence (Pu23WT) was confirmed to fold into an intramolecular parallel quadruplex by CD. TMPyP4 (**Fig. 6**) stabilizes this quadruplex structure in vitro and represses luciferase expression driven by Pu23WT but not that driven by MET promoter mutants unable to form stable quadruplexes.[295] Moreover, treatment of liver and gastric cancer cells with 50 μM of TMPyP4 decreased MET expression at both mRNA and protein levels, probably due to TMPyP4 blockage of SP1 recruitment to its binding site in the Pu23WT sequence, as shown by ChIP assays. Treatment of cancer cells with TMPyP4 also results in cell proliferation inhibition, cell cycle arrest in G1 phase, and cell migration retardation, probably due to downregulation of *MET* expression, although other gene promoters containing quadruplex sequences, such as *SRC* and k-*RAS*, may be also targeted by TMPyP4.[295]

5.09.5.12 c-*SRC*

c-SRC (cellular Rous sarcoma) is a nonreceptor tyrosine kinase that has been associated with the initiation and proliferation of several tumors, including melanoma,[296] colon,[297–299] breast,[300,301] and prostate[302] cancers, and is a validated therapeutic target of several tyrosine kinase inhibitors.[302,303]

Pyridostatin (**Fig. 5**) is a pyridine-2,6-bisquinolinedicarboxamide derivative with high affinity and selectivity for DNA quadruplexes (both in telomere and promoters). It is able to induce alteration of shelterin at telomeres,[88] induce a DNA damage response, and produces long-term growth inhibition of cancer cells incubated with IC_{50} concentrations of compound.[152] A chromatin immunoprecipitation sequencing analysis of DNA damage indicated by the damage marker γH2AX showed that pyridostatin targets genes containing clusters of quadruplex-forming sequences.[89] Pyridostatin (2 μM in MRC-5-SV40 cells) downregulated, after 8 h of drug treatment, all the γH2AX-positive target genes, including the oncogenes c-*MYC* and *SRC*, but did not affect the negative controls, such as h-*RAS*. The *SRC* oncogene was the most affected, with its mRNA levels being reduced by over 95%.[89] Importantly, this study allowed the identification of 25 quadruplex-forming sequences in the *SRC* coding region, from which 23 were shown by CD and NMR to form stable quadruplexes of different topologies. Finally, pyridostatin reduced SRC protein levels and SRC-dependent cellular motility in human breast cancer cells, strongly suggesting *SRC* as a target of this compound.[89] More recently, a photo-activated prodrug of pyridostatin was developed by linking a nitroveratryl group to one of the side chain amines. This prodrug upon 10–30 min of UV-light irradiation shows, in common with pyridostatin, high stabilization of a *SRC* quadruplex, cell growth inhibition, and oncogene (c-*MYC*, *SRC*, and *RET*) transcription downregulation activity.[304]

5.10.1 Introduction

The processing of pre-mRNA to mature mRNA in metazoans is one of the numerous critical processes for development and normal functioning of cells that is mediated by ribonucleoproteins (RNPs) (see Fig. 1).[1] The importance of the pre-mRNA splicing process as a source of evolutionary adaptability of metazoans appears to justify the significant burden that is born by each cell that must orchestrate the synthesis and regulation of some 200 proteins and numerous functional RNPs, which are critical for the pre-mRNA splicing process. This process involves the highly regulated combinatorial removal of intervening sequences from pre-mRNA followed by the ligation of exons to form mature mRNA, which is then exported into the cytosol from the nucleus. This splicing process is catalyzed and regulated by a highly complex macromolecular complex called the spliceosome (see Fig. 2).[1–3] The spliceosome is a unique macromolecular machine in its complexity, given that it has thousands of pre-mRNA substrates and potentially millions of

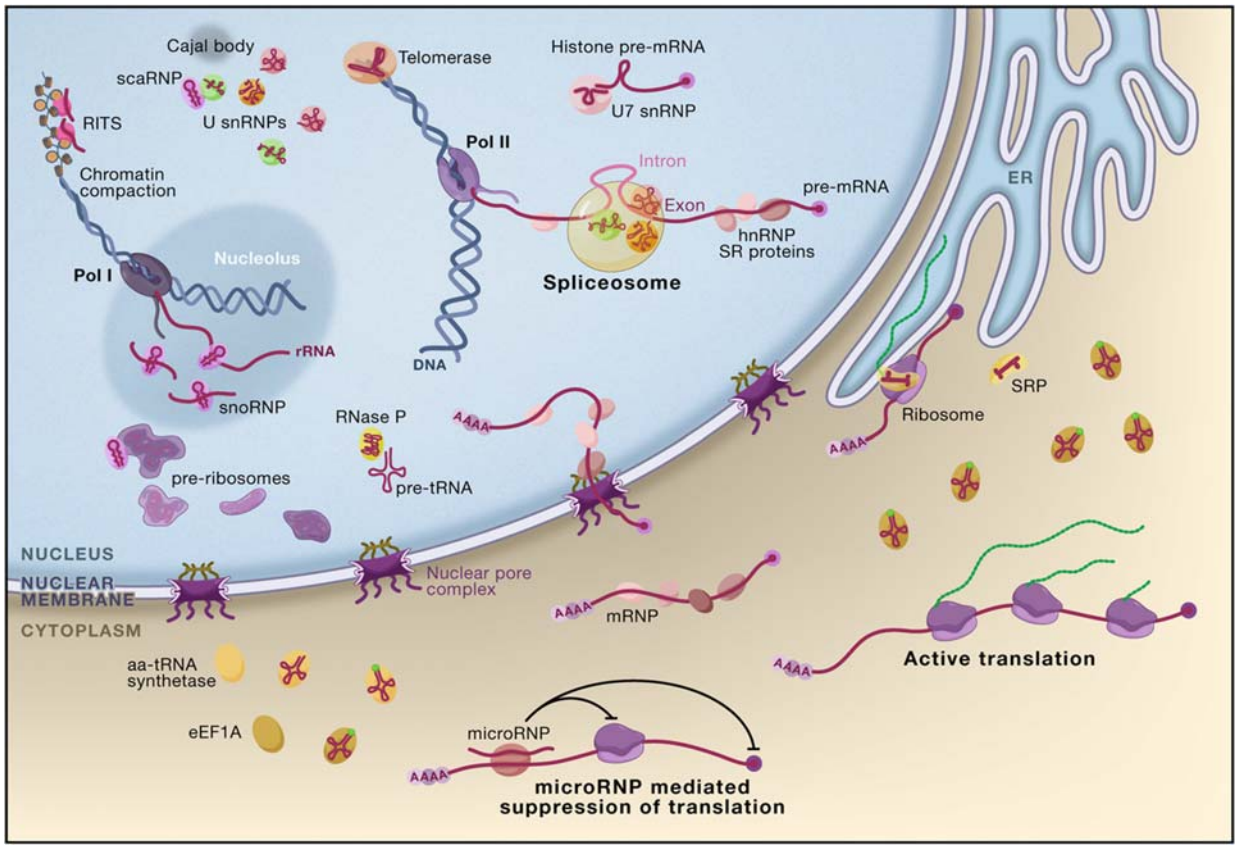

Fig. 1 RNPs in gene expression and its regulation[3]: RNPs play extensive roles in gene expression and its regulation. Here, the major activities of RNPs during gene expression in a eukaryotic cell are depicted. Following transcription by RNA polymerases II (RNA Pol II), pre-mRNAs are bound by diverse proteins, such as hnRNP and SR (serine-arginine-rich) proteins. Pre-mRNAs, containing exons *(red)* and introns *(pink)*, are subjected to processing by a range of RNPs that include uridine-rich (U-rich) small nuclear RNPs (U snRNPs) that make up the spliceosome. Certain RNAs such as pretransfer RNAs and mRNA transcripts encoding histones also undergo processing by specific RNPs (RNase P and U7 snRNP, respectively). Small nucleolar RNPs (snoRNPs) and small Cajal body RNPs (scaRNPs) mediate maturation of RNA components of RNPs such as ribosomal RNAs (transcribed by RNA polymerase I, RNA Pol I) and snRNAs, respectively. Small RNAs can form microRNPs that function to regulate translation. In certain organisms, RNA-induced transcriptional silencing (RITS) complexes, which contain small-interfering RNAs, mediate heterochromatin formation and maintenance. Telomerase, a box H/ACA snoRNP, replenishes the terminal telomeric repeats of chromosomes to maintain genomic stability. In the cytoplasm, the ribosome is the key RNP that directs the translation of mRNA into protein. It also functions with the signal recognition particle (SRP) RNP to direct protein translocation into the endoplasmic reticulum (ER). tRNAs also form complexes in the cytoplasm with aminoacyl-tRNA (aa-tRNA) synthetases, which charge tRNAs with the corresponding amino acid, and with translation elongation factor eEF1A.[3] Reprinted from Wahl, M. C.; Will, C. L.; Luhrmann, R. The Spliceosome: Design Principles of a Dynamic RNP Machine. *Cell* **2009**, *136*, 701–718, with permission from Elsevier.

spliced, and alternately spliced, mature mRNA products that are produced in the transcriptome of each cell; additionally each of these splicing reactions requires regulation that is controlled by the specifics of the environment of the particular cellular phenotype that is undergoing the process of transcription and splicing.[1]

The spliceosome is a complex of five small nuclear RNPs (snRNPs) (U1, U2, U4, U5, and U6) and approximately 200 associated proteins.[2,3] This pre-mRNA maturation process also includes alternative splicing (AS), which is the mechanism that allows for different forms of mature mRNAs to be generated from the same pre-mRNA. Commonly, AS patterns determine the inclusion or exclusion of portions of the coding sequence in the mRNA, giving rise to protein isoforms that differ in their peptide sequence. Alternate splicing is regulated by numerous spliceosomal trans-acting proteins, which are in turn regulated by cis-acting regulatory sites on the pre-mRNA that are the substrates for the spliceosome.[2] Since pre-mRNAs for a given gene may contain many different exon and intron combinations, there are often a very large number of possible mRNAs that can result in a correspondingly large set of resulting proteins that may have very different, even opposing, biological functions within the cell. Numerous genes are subject to splicing events that can be either oncogenic or serve to limit potential tumorigenesis, examples include BCL-2-like protein 1, VEGF-A, Fas Cell Surface Death Receptor (FAS), pyruvate kinase isozymes M1/M2 (PKM), or MDM2 (as described in a recent review).[4]

Recently, there has been a strong acceleration in spliceosome-related research and in the rate of appearance of high-profile publications on this topic, many of which have a significant impact on oncology drug discovery. A search of Pubmed with the query "spliceosome" shows 92 publications in 2000 but 229 publications for 2015. Some of the major recent accomplishments in this

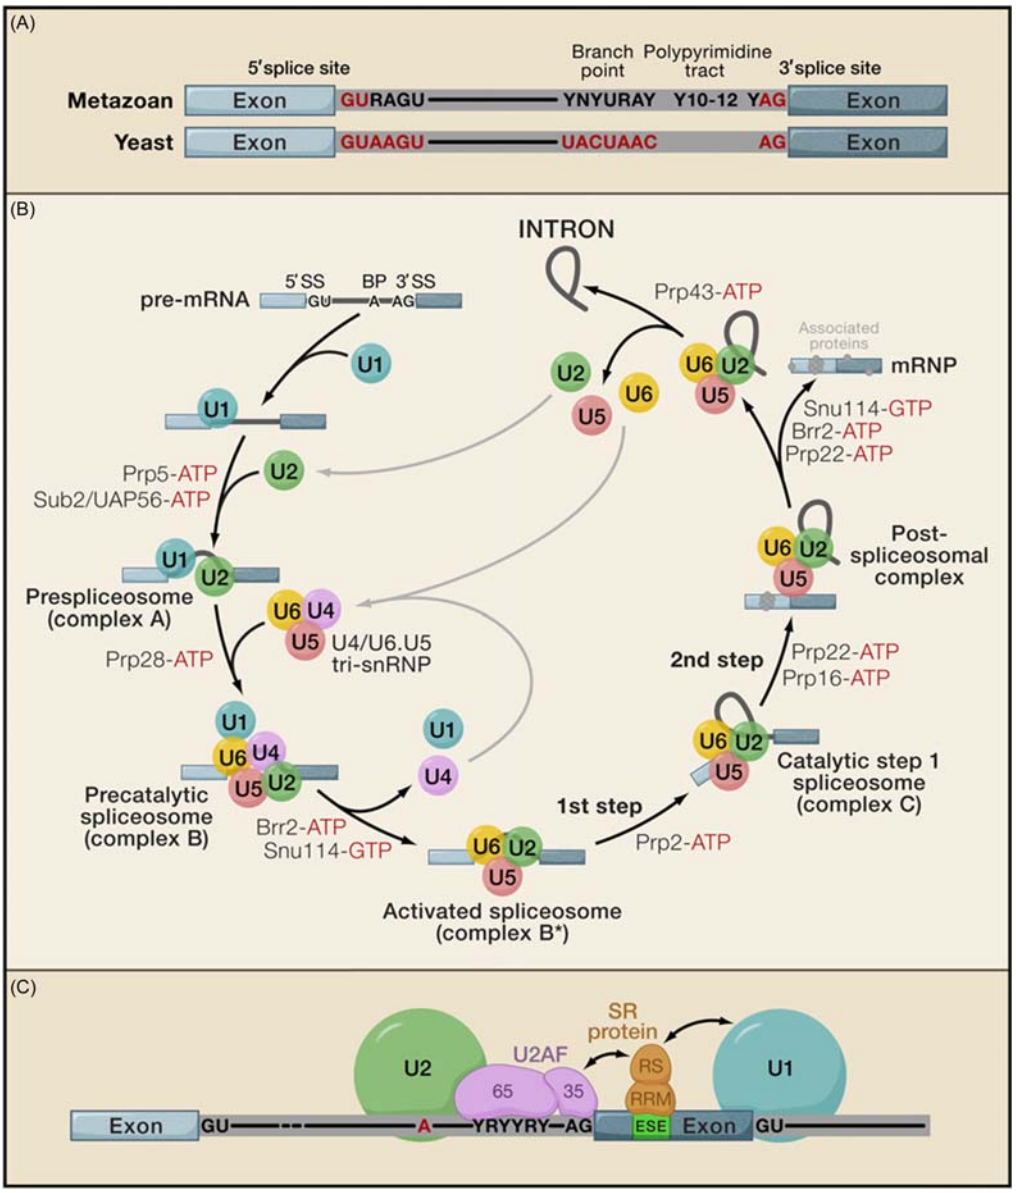

Fig. 2 Pre-mRNA splicing by the major spliceosome[3]: (A) conserved sequence elements of metazoan and yeast pre-mRNAs. Here, two exons *(blue)* are separated by an intron *(gray)*. The consensus sequences in metazoans and yeast at the 5′ splice site (SS), branch point sequence (BPS), and 3′ splice site (SS) are as indicated, where N is any nucleotide, R is a purine, and Y is a pyrimidine. The polypyrimidine tract is a pyrimidine-rich stretch located between the BPS and 3′ SS. (B) Cross-intron assembly and disassembly cycle of the major spliceosome. The stepwise interaction of the spliceosomal snRNPs *(colored circles)*, but not non-snRNP proteins, in the removal of an intron from a pre-mRNA containing two exons *(blue)* is depicted. Only the spliceosomal complexes that can be resolved biochemically in mammalian splicing extracts are shown. Eight evolutionarily conserved DExD/H-type RNA-dependent ATPases/helicases act at specific steps of the splicing cycle to catalyze RNA–RNA rearrangements and RNP remodeling events. These enzymes include Sub2 (UAP56 in humans), Prp5, Prp28, Brr2, Prp2, Prp16, Prp22, and Prp43 (with Brr2 and Prp22 acting at more than one step in the cycle). The GTPase Snu114 also functions at several steps during the cycle. In yeast, Prp28 acts at a later stage during spliceosome activation (the B complex to B* complex transition). Several of these proteins, such as Prp5, Prp16, and Prp22, also carry out proofreading functions at the stages where they are shown. (C) Cross-exon splicing complexes form on long introns during the earliest stage of spliceosome assembly. An SR protein containing a serine-arginine-rich (SR) domain and RRM (RNA recognition motif) is depicted as interacting with an exonic splicing enhancer (ESE). The U1 *(blue)* and U2 *(green)* spliceosomal snRNPs and the two subunits of the U2 auxiliary factor (U2AF), U2AF65 and U2AF35, are also shown interacting with the splice sites flanking the exon.[3] Reprinted from Wahl, M. C.; Will, C. L.; Luhrmann, R. The Spliceosome: Design Principles of a Dynamic RNP Machine. *Cell* **2009**, *136*, 701–718, with permission from Elsevier.

field include the very recent reports of the cryo-EM structures of spliceosome components that have clarified numerous aspects of the splicing process at near (but not at) atomic resolution.[5,6] The complexity of the spliceosome and the current lack of high-resolution structures complicate progress in understanding many of the critically important molecular and functional mechanisms associated with pre-mRNA splicing. Since the splicing process is critical to the normal functioning of the cells of higher organisms,

this area will remain an active area of research for the foreseeable future. However the remaining mysteries surrounding the splicing process do not diminish the importance of this fascinating molecular machine, which is now recognized as a major frontier for molecular biology and, more recently, for oncology target discovery. The discovery of new small molecules that modulate splicing will likely be key in the facilitation of a more detailed understanding of this emerging field. The prominence of pre-mRNA splicing in the regulation of gene expression also makes it an attractive and innovative potential target for therapeutic intervention in numerous diseases, including cancer.[4,7–9] This article will be focus specifically on the numerous developments that have led to the emergence of a new field: *spliceosome medicinal chemistry*.

5.10.1.1 Pre-mRNA Splicing and the Spliceosome

Nearly all human RNA polymerase II (RNA Pol II) transcripts undergo pre-mRNA splicing, a nuclear process where sequences called exons (exported sequences) are joined together and the intervening sequences (introns) are removed.[10] Exons are surrounded by three characteristic sequence elements: the 5′ and 3′ splice sites located at the exon-intron border and the branch point located 18–50 nucleotides (nt) upstream of the 3′ splice site. Two splicing systems operate in humans, a major one where the introns are marked by GU-AG bases and a minor one (accounting for less than 0.5% of introns) marked by AU-AC dinucleotides.[11] The splice sites are recognized through interaction with five small nuclear RNAs (snRNAs), the U1, U2, U4, U5, and U6 snRNAs. Through base complementarity, the U1 snRNA recognizes the 5′ splice site and the U2 snRNA binds to the branch point sequence. The U4/U5 and U6 snRNAs form a complex (the U4/U5/U6 tri-snRNP) involved in splicing catalysis. Human splice sites characteristically adhere weakly to consensus sequences, and only the GU-AG dinucleotides are consistently conserved in the major spliceosome. The removal of introns occurs in two steps: in the first step, the first nucleotide of the intron is ligated to an adenosine branch point by a nucleophilic attack of the branchpoint 2′-OH on phosphorus to form a 5′-2′ phosphodiester bond, and in the second step the two exons are ligated through another nucleophilic attack on phosphorus by the exon 3′-OH to form the phosphodiester bond between the 5′ and 3′ exons.

The vast majority (>95%) and possibly all multiexon genes undergo AS, where an exon is either included or skipped in the final pre-mRNA.[12,13] On average, a human gene contains a median of 26 exons per gene and generates 3.4 isoforms, indicating that AS increases the coding capacity of the human genome more than threefold. AS is more abundant in humans than in other species, for example, mice generate only 2.4 isoforms per gene and *C. elegans* 1.2 isoforms.[10] The overall purpose of AS is to increase the diversity of the mRNA expressed from the genome.[14] A genome-wide analysis showed a large influence of alternative splice variants on protein interaction networks. Within an interaction network, most AS variants behave more like distinct proteins than like minor variants,[15] suggesting that AS generates functionally distinct proteins from a single gene. The deregulation of alternative pre-mRNA splicing is a hallmark of cancer[16] (**Fig. 3**).

5.10.1.2 Recognition of Exons

Exons on average constitute less than 10% of a human pre-mRNA. They have to be recognized with high fidelity, as omission of a single nucleotide will generate a frameshift that usually generates aberrant proteins. Because of the poor conservation of the splice sites, additional RNA sequences (cis elements) are needed for their recognition. These cis-elements bind to proteins that can be subdivided into two classes: serine-arginine-rich (SR)-proteins and heterogenous nuclear RNPs (hnRNPs). SR-proteins are RNA-binding proteins characterized by an RNA-binding domain and an RS domain that interacts with other proteins.[17] hnRNPs are a diverse group of nuclear proteins that bind to pre-mRNA.[18] As a general rule, SR-proteins promote exon inclusion as they bind to components of the spliceosome, whereas hnRNPs antagonize an interaction of the spliceosome with the pre-mRNA, resulting in exon skipping.[19] An increasing number of recent examples showed that in addition to proteins, noncoding RNAs can bind to regulatory cis-elements and change splice site selection.[20] The presence of splicing enhancers can explain the action of synonymous mutations in many cases, if a mutation does not change the predicted open reading frame but causes a disease. In many cases, these mutations act through a change in affinity of a splicing regulatory protein, which causes a modification of alternative exon usage.[21] Similar to the splice sites, splicing enhancers and silencers follow only degenerate consensus sequences. In the case of exonic splicing regulatory elements, this allows for the coexistence of splicing signals and code requirements.[22]

5.10.1.3 Circular RNAs

In nearly all protein-coding mRNAs described so far, the alignment of the exons in mRNAs corresponds to the corresponding sequence in the DNA. However, more than 25 years ago, mRNAs with "scrambled exons" were reported, that is, rather than having exon 1-2-3, mRNAs with exons 1-3-2 were described.[23] This result was not investigated further, since the genesis of these exons had not been elucidated at the time. Subsequent advances in RNAseq technology showed that these "scrambled exons" were part of circular RNAs (circRNAs). Circular RNAs are generated from splicing in large lariats or are generated by intramolecular splicing of RNAs that are constrained through base pairing; for example some are due to strong secondary structures that are present in inverted repeat sequences. The formation of circular RNAs due to strong secondary structures might be important for humans, since 11% of the human genome consists of Alu elements.[24] Because Alu elements originate in structural 7SL RNA, Alu elements can dimerize through the Alu domains that show self-complementarity. Since Alu elements are primate specific, they may generate primate-specific circular RNAs.

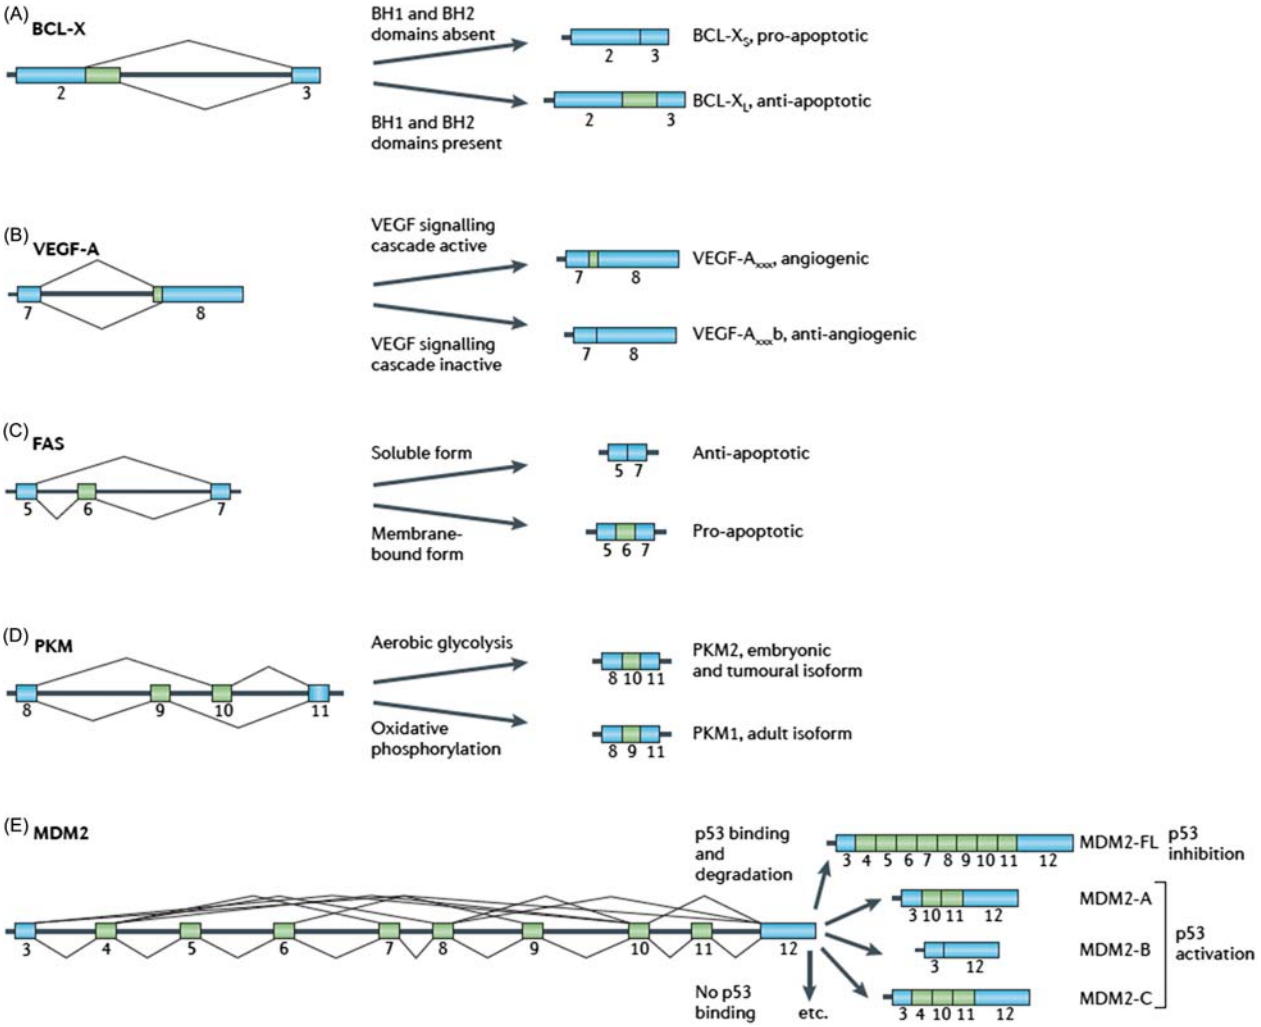

Fig. 3 Examples of regulated alternative splicing (AS) events relevant for cancer progression.[4] Alternative patterns of intron removal are represented, corresponding to alternative 5′- or 3′-splice site usage (A,B) or exon inclusion or skipping, either as cassette single exons (C), mutually exclusive alternative exons (D), or complex patterns of exon skipping (E). Alternative regions of the precursor mRNA are represented as *green boxes*, and constitutive exons are shown in *blue*. The numbers correspond to the exons involved in the AS event for each of the indicated genes. The examples also illustrate the diverse functional outcomes of the encoded alternative protein products, which regulate programmed cell death (A,C), formation of blood vessels (B), the metabolic advantage of tumor cells (D), or inactivation of the tumor suppressor p53 (E). See text for additional explanations. BCL-X, BCL-2-like protein 1; PKM, pyruvate kinase isozymes M1/M2; VEGF, vascular endothelial growth factor.[4] Reprinted by Bonnal, S.; Vigevani, L.; Valcarcel, J. The Spliceosome as a Target of Novel Antitumour Drugs. *Nat. Rev. Drug Discov.* **2012**, *11*, 847–859, with permission from Macmillan Publishers Ltd.

Most circRNAs are less than 1% of the linear mRNAs made from the same locus, but in some cases the circRNA is 10-fold more abundant than the linear mRNA from the locus.[25–27] Studies in cancer showed that circRNAs change their expression more strongly than mRNAs upon cell transformation.[28] circRNAs are mainly cytosolic and can be translated into protein.[25,29] In general, circular RNAs are much more stable than linear mRNAs, as they will not be degraded by the exosome, which acts like an exonuclease. In addition, most circRNAs do not contain 3′ untranslated regions (UTR) that promote deadenylation and exosomal degradation. Due to their circular structure that recapitulates the binding of the poly(A) tail to the mRNA cap in linear RNAs, circRNAs are potentially excellent ribosomal substrates, allowing for efficient translation in vitro and in vivo.[29] Thus, in addition to AS, the generation of circular RNAs, performed by the spliceosome, greatly increases the coding capacity of the human genome.

5.10.1.4 The Spliceosome

As discussed above the splicing reaction of the major spliceosome is performed by the spliceosome, an RNA–protein machine of about 4.8 MDa. The spliceosome contains at least 170 proteins that associate with five RNAs (U1, U2, U4, U5, and U6), generating the U1, U2, U4, U5, and U6 snRNPs.[3,30] Similar to the ribosome, these snRNPs assemble in a step-wise fashion on the pre-mRNA,

and rearrangements of the snRNPs bring together the splice sites allowing for the catalysis to be performed. The substrate of the spliceosome is pre-mRNA that is bound to many regulatory factors, such as SR-proteins and hnRNPs, which expose specific splice sites to the spliceosome. In most human internal exons, the 3′ and 5′ splice sites are paired across the exon through an interaction of U1 and U2 snRNPs, which is referred to as exon definition.[31] In yeast and in a subset of large human exons, the splice site pairing occurs across introns, which is referred to as intron definition. Most of our understanding of the splicing reaction comes from in vitro splicing assays that employ an in vitro RNA with two exons having one splice site each flanking a short intron. These in vitro substrates are recognized according to the intron definition model.

In spliceosome assembly,[3] first U1 snRNP binds to the 5′ splice site, aided by the base complementarity between the U1 snRNA and the 5′ splice site (**Fig. 2**). The branch-point-binding protein (BBP or SF1) binds to the branch point, aided by a protein interaction of RNA recognition motif 3 (RRM3) of the U2 auxiliary factor (U2AF65) binding to the polypyrimidine tract of the 3′ splice site. This protein complex is called the E (early) complex. In the next step the U2 snRNP associates with the complex and replaces BBP, forming the prespliceosome "complex A." The RNA component of U2 snRNP binds to the branch-site, which causes the branch-adenosine to bulge out of a short helix. A protein interaction between the U2 component SF3B1 (SAP155) and the RRM3 of U2AF helps to displace the BBP from its bound form with U2AF65. The entry of the U6/U4/U5 tri-snRNP, catalyzed by prp28, forms the precatalytic spliceosome "complex B." Several RNA helicases (brr2, snu114, and prp2) cause a rearrangement in this complex, which releases U4 and U1, and the U6 snRNA binding to the 5′ splice site. In this activated spliceosome (B* complex), the branch point is brought into close proximity to the 5′ splice site, allowing for the formation of the lariat in the first step of splicing, leading to the catalytic "C complex." The C complex contains the free first exon, and the lariat bound to the second exon. Using the prp8, prp16, prp18, and slu7 components, the second step of splicing, which involves the ligation of the two exons, is carried out. Another RNA helicase, prp22 releases the remaining U6/U2/U5 snRNPs and the lariat from the spliced RNA in the postspliceosome complex. After catalysis, the U6, U2, and U5 snRNPs are removed from the lariat using snu114, Brr2, and prp43, are then recycled for another round of catalysis, and the intron is degraded. In vitro studies using small synthetic U2 and U6 snRNA fractions can generate a phosphodieseter bond using a lariat-analog as a substrate, indicating that the spliceosome is a ribozyme.[32,33]

5.10.1.5 The Spliceosome is Linked to Other Nuclear Processes

The mechanism of the spliceosome has been determined biochemically using a nuclear extract made under high salt conditions.[34] When spliceosomes are prepared using physiological salt conditions larger spliceosome complexes, termed supraspliceosomes are observed.[35–37] These preparations contain other mRNA processing factors, showing that pre-mRNA splicing in vivo is linked to other RNA processing steps. Pre-mRNA splicing occurs during RNA pol II transcription, and there is evidence for cotranscriptional splicing. For example, a fast-moving RNA polymerase promotes alternative exon skipping[38,39] and snRNPs and processing factors are loaded on the carboxy terminal domain of RNA pol II prior to transcription. However, since RNA pol II has an elongation rate of 3–4 kb/min, large introns are likely spliced out after transcription. There is accumulating evidence that chromatin structure is linked to exon selection. The average length of a human cassette exon of 145 nt corresponds well with the length of DNA in a nucleosome and in fact, splice sites preferably correspond to DNA located at the end of a nucleosome.[40,41] Histone modifications, such as H3K4me3, assist in the recruitment of U2 snRNP components to sites of active transcription, which could promote exon recognition.[42] The U2 snRNP component SF3B1 physically interacts with histone H3, suggesting a physiological link.[43] It is possible that pre-mRNA splicing affects chromatin changes, in return, as DNA encoding exons are characterized by the H3K36me3 modification. This modification is lower in DNA corresponding to alternative exons, when compared to constitutive exon. Since on average alternative exons of the same pre-mRNA assemble less spliceosomes than the constitutive exons,[41] this suggests that the activity of the spliceosome is reflected in the H3K36me3 modification. Components of the spliceosome also participate in transcriptome surveillance. The U1 snRNA is more abundant than the other spliceosomal U2, U4, U5, and U6 snRNAs. U1 snRNA binds to specific sites on pre-mRNA that are not recognized as splice sites and which prevents premature cleavage and polyadenylation.[44]

5.10.1.6 Mutations in Spliceosomal Proteins

Similar to the ribosome, the spliceosome is evolutionary, highly conserved from yeast to humans. Underlining its central role in metazoans germ line mutations in core spliceosomal proteins are rare and include PRP3, PRP6, PRP8, Brr2, and PRP31, causing dominant nonsyndromic retinitis Pigmentosa.[45–48] Mutations in the minor spliceosome small nuclear RNA U4atac cause microcephalic osteodysplastic primordial dwarfism type I[49] (**Table 1**). In contrast to germ line mutations, numerous somatic mutations of core spliceosomal and pre-mRNA-associated proteins have been detected in cancer cells using RNAseq (**Table 2**). Interestingly, they cluster in components that recognize the 3′ splice site, namely, U2AF35 (U2AF1), ZRSR2, a binding partner for U2AF[51] and the U2 snRNP component SF3B1 (**Fig. 4**).[54,55] Similarly, mutations in several, but not all proteins binding to splicing regulatory elements on the pre-mRNA have been detected. They include SRSF1 (SF2/ASF); SRSF2 (SC35).[56] These proteins generally promote exon recognition. In addition, SRSF1 plays a role in genome stability.[57]

5.10.1.7 Mutations in Pre-mRNA

In addition to mutations in the spliceosome, mutations on the pre-mRNA that affect splicing are associated with cancer[58–60] (reviewed in Refs. 61 and 62). Lists of alternative exons deregulated in different cancer cells have been compiled in the literature

Table 1 Germ-line mutations of the spliceosome leading to human disease

Gene	*Function*	*Disease*	
PRP3 U4/U6 SnRNP 90 KDa Protein	Part of the U4/U5/U6 tri-snRNP	Retinitis pigmentosa	47
PRP6 U5 SnRNP-Associated 102 KDa Protein	Part of the U4/U5/U6 tri-snRNP	Retinitis pigmentosa	50
PRP8 U5 SnRNP-Specific Protein (220 KD)	Scaffold for snRNPs during the splicing reaction	Retinitis pigmentosa	46
Brr2 U5 SnRNP-Specific 200 KDa Protein	RNA helicase	Retinitis pigmentosa	48
PRP31	U4/U6 SnRNP 61 KDa protein	Retinitis pigmentosa	45
U4atac	snRNA in the minor spliceosome	MOPD type I	49

MOPD, microcephalic osteodysplastic primordial dwarfism

Table 2 Somatic mutations of the spliceosome in cancer cells

SF3B1	U2 component, recognition of 3′ splice site	Chronic lymphocytic leukemia, myelodysplasia	55,76
SF3A1	U2 component, recognition of 3′ splice site	Myelodysplasia	76
PRPF40B	U1 and U2 component	Myelodysplasia	76
SF1	Recognizes branchpoint, 3′ splice site	Myelodysplasia	76
U2AF35	recognition of 3′ splice site	Myelodysplasia	76
U2AF65	recognition of 3′ splice site	Myelodysplasia	76
ZRSR2 zinc finger (CCCH Type), RNA-binding motif and serine/arginine rich 2	Second step of splicing in major splicesome; recognition of 3′ splice site in minor spliceosome	Myelodysplasia	76
SRSF2 (SC35)	Promotes exon inclusion	Myelodysplastic syndromes	129

(see, e.g., Refs. 58, 60, and 63). About 20% of point mutations in cancer are synonymous mutations, that is, mutations located in protein coding exons that do not affect the reading frame.[64] Up to 8% of these somatic mutations are selected in cancer cells, suggesting that they are functional. They frequently affect splicing regulatory sequences (exonic enhancers or silencers) and thus contribute to the deregulation of splicing. Examples include BRCA2 in breast cancer,[65] APC in familial adenomatous polyposis,[66,67] and TP53 in multiple tumors.[64] A much larger number of point mutations are found in intronic regions, but they are mechanistically poorly understood.[68] The best understood effects are the alterations of splice sites. Mutations affecting the conserved AG-GT splice site dinucleotides always abolish usage of the affected splice site, which usually results in the skipping of the exon unless a cryptic splice site is activated. Mutations outside the conserved AG-GT dinucleotides mostly modulate exon usage. However, the mechanistically less well understood mutations are associated with deep intronic alterations that can also affect splice site usage in cancer, usually due to activation of cryptic exons, for example in BRCA2.[69]

5.10.2 The Spliceosome as a Cancer Target

Aberrations in pre-mRNA splicing, in the case of MDM2, for example, were recognized as a feature of tumors as early as 1996,[70] and reviewed in 2002.[71] Subsequently, it was recognized that aberrant pre-mRNA splicing was a global property of the tumor transcriptome; these observations were reviewed as early as 2004 with the prediction that this understanding might lead to new opportunities for the diagnosis[53] and treatment of cancer.[72,73] However, despite much suggestive data, it was difficult to prove that splicing aberrations are actually oncogenic.[61] In the past few years, much more information has been obtained through genomic and transcriptomic studies of tumors.[74,75] Such splicing aberrations are now recognized as another predominant feature of cancer and the spliceosome is now seen as a validated antitumor target.[4,9] In the following, we will explore the history and the evolution of thought regarding the spliceosome as it is relevant to cancer medicinal chemistry by the exploration of applied and basic research studies, which hold the potential to initiate some transformative changes in the treatment of certain cancers.

In parallel to the work described above, strong evidence has continued to mount that aberrant splicing of pre-mRNA is a driver of tumorigenesis[61] and that modulation of this process may be a valid target for cancer therapy.[4,9] It has been known for some time that the deregulation of exon usage is a hallmark of cancer and recent groundbreaking discoveries have identified recurrent mutations in SF3B1 (and/or other splicing factors) in multiple forms of cancer including: myelodysplastic syndromes (MDS),[76,77] chronic lymphocytic leukemia (CLL),[78] acute myeloid leukemia (AML),[79,80] breast cancer,[81,82] lung adenosarcoma,[83] and uveal melanoma.[84] These genetic studies have also fueled complementary research in the therapeutic significance of spliceosome recurrent mutations. Very recently, the selective sensitivity of tumors to agents that target SF3B has also been linked to overexpression of MYC and published as part of a collaborative multidisciplinary effort.[85]

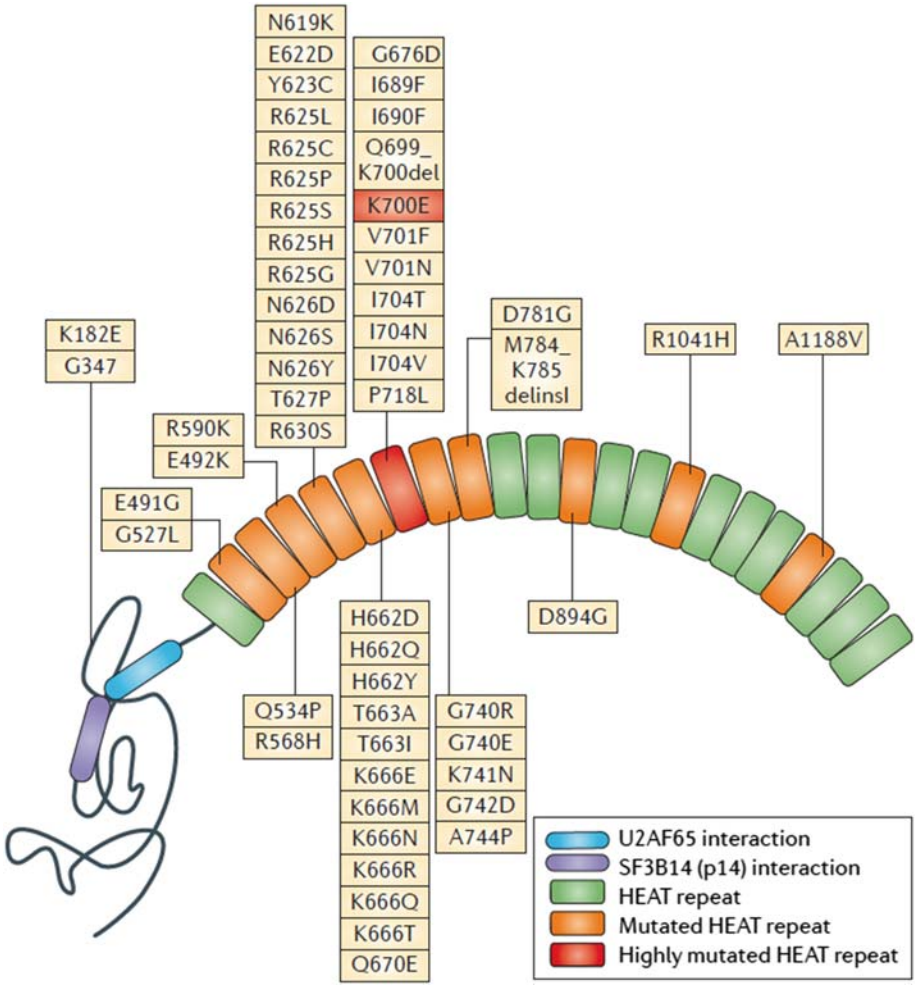

Fig. 4 Recurrent mutations in the drug protein target SF3B1. The scheme depicts the domain organization of splicing factor 3B subunit 1 (SF3B1) according to Ref. 52. The amino-terminal region is involved in interactions with other splicing factors, whereas the carboxy-terminal domain encompasses 22 HEAT (huntingtin, elongation factor 3, protein phosphatase 2A, target of rapamycin 1) repeats. Repeats harboring mutations found in chronic lymphocytic leukemia and/or myelodysplastic syndrome tumor samples are represented in orange, and the most frequent mutation and its corresponding repeat are represented in *red*.[46,53] U2AF65, U2 snRNP auxiliary factor of 65 kDa.[4] Reprinted by Bonnal, S.; Vigevani, L.; Valcarcel, J. The Spliceosome as a Target of Novel Antitumour Drugs. *Nat. Rev. Drug Discov.* **2012**, *11*, 847–859, with permission from Macmillan Publishers Ltd.

5.10.2.1 Mechanism of the Selective Antitumor Activity of Spliceosome Targeted Agents

5.10.2.1.1 Synthetic lethal spliceosome pairs

Since the discovery of the first small molecule antitumor agents that target the spliceosome, there has been substantial confusion in regard to the mechanism of selective activity of the spliceosome-targeted agents. This confusion has been in part due to numerous early reports describing these agents as "splicing inhibitors," which led in turn to the development of an incorrect conceptual framework for understanding the true mechanism of action of these agents. Though it is now well established that these agents act by the modulation of alternate splicing due to a reduction in the fidelity of 3′-splice site selection this confusion remains prevalent even in some recent literature reports. While many mechanisms may play a role in the selective killing of tumor cells by the agents discussed below, it is becoming clear that nononcogene addiction is an important mechanism that can explain the selectivity in many cases.[86] The nononcogene addiction concept provides a platform for the exploration of a large number of potential targets for anticancer therapies, whose change of function could selectively reverse oncogenic phenotypes. Several groups have carried out synthetic lethal RNA interference screens designed to identify genes whose silencing is specifically cytotoxic for cells carrying particular oncogenic mutations, in order to take advantage of this concept in the development of new anticancer approaches and in the elucidation of the mechanism of action of antitumor agents, including those agents that modulate splicing. These latter studies have relied on the use of "synthetic lethal" genetic studies using various screening strategies (e.g., siRNA and shRNA libraries that specifically "knock down" genes) to elucidate the aberrant splicing dependence of tumors bearing certain mutations. This topic has very recently been authoritatively reviewed.[87]

One of the first reports of the synthetic lethal dependence of a specific mutation on splicing function is that of Hubert et al.[85] These investigators searched for glioblastoma multiforme (GBM)-lethal genes using genome-wide RNAi screens in multiple GMB stem cells (GSCs), patient isolates, and neural stem cells (NSCs) in order to classify the genes that are differentially required for GSC expansion. These studies revealed that the plant homeodomain-finger domain protein (PHF5A) was differentially required for expansion and viability of several GSC isolates. Further, molecular studies demonstrated that GSCs have a novel requirement for PHF5A activity. Knockdown of PHF5A resulted in splicing changes in thousands of essential genes, some of which are expected to alter cell division and growth. Also, these authors showed that sensitivity to U2snRNP perturbation could be established in NSCs and fibroblasts overexpressing MYC. Although MYC is not frequency amplified in GBM, MYC is coordinately activated by mutations in p53 and PTEN. In summary, this study established that patient-derived GSCs are vulnerable to perturbation in splicing, which results in a reduction in GSC viability and loss of GBM tumor maintenance. The authors also showed that splicing modulators such as sudemycin C1 showed selective toxicity to GBMs and fibroblasts overexpressing MYC. Since standard of care therapies is ineffective against GBM, the authors concluded that targeting PHF5A and/or U2 snRNP activity offers a new therapeutic inroad for this GBM.

Another more recent study also identified sudemycin sensitivity and a synthetic lethal partner in MYC-driven triple negative breast cancers.[88] In this work, it was found that the spliceosome is a target in MYC-driven cancers. These researchers identified the BUD31 protein as an MYC-synthetic lethal gene in human mammary epithelial cells, and showed that BUD31 was required for spliceosome assembly and catalytic activity. Activity of SF3B1 and other splicing factors associate with BUD31 are also required by oncogenic MYC. MYC activation induces an increase in total pre-mRNA synthesis, suggesting an increased burden on the core spliceosome to process pre-mRNA. In contrast to normal cells, reduction of functional SF3B1 in MYC-hyperactivated cells leads to splicing aberrations, widespread effects on pre-mRNA maturation, and deregulation of many critical cell processes. Genetic or pharmacological modulation of the spliceosome in vivo impairs survival, tumorigenicity, and metastatic inclination of MYC-dependent breast cancers. Importantly, this work showed that a reduction in SF3B1 activity is effective in human MYC-dependent breast cancer patient-derived xenografts (PDX) in vivo using the SF3B1 targeted agent sudemycin D6 (SD6) that was developed in the Webb laboratory.[88]

5.10.2.1.2 Tumors bearing spliceosome mutations are vulnerable to splicing modulation

Following the identification of many common spliceosome recurrent mutations in the MDS, CLL, and AML, there was initially confusion regarding the functional effects of these mutations, since little was known regarding the precise functional consequences of these splicing mutations. The observed recurrent mutations are consistently heterozygous and only very rarely occur together, indicating that one wild-type copy of the normally functional gene product is essential. Given that the spliceosome has important regulatory functions, the standard expectations of "gain of function" or "loss of function" are likely undefined with respect to the splice-site regulatory subunits, given the current understanding that the spliceosome components that are mutated are involved in the *fidelity* of 3′-splice site recognition. Thus, for these proteins a different concept: *change of function*, must be considered. Many researchers hypothesized that such cancers might be particularly sensitive to agents that target SF3B1 since these mutations seemed to produce an oncogenic splicing program. Thus, agents such as SD6 or E7107 were used to test this hypothesis (see **Figs. 5** and **6**).

One of the first such studies that was reported found that the spliceosome modulators sudemycin D1 and D6 showed selective cytotoxicity in primary CLL cells when compared with normal lymphocytes and tumor cells from other B-lymphoid cancers, with a slight bias for CLL cases bearing spliceosome mutations.[107] This work reported that sudemycin exhibited antitumor activity in

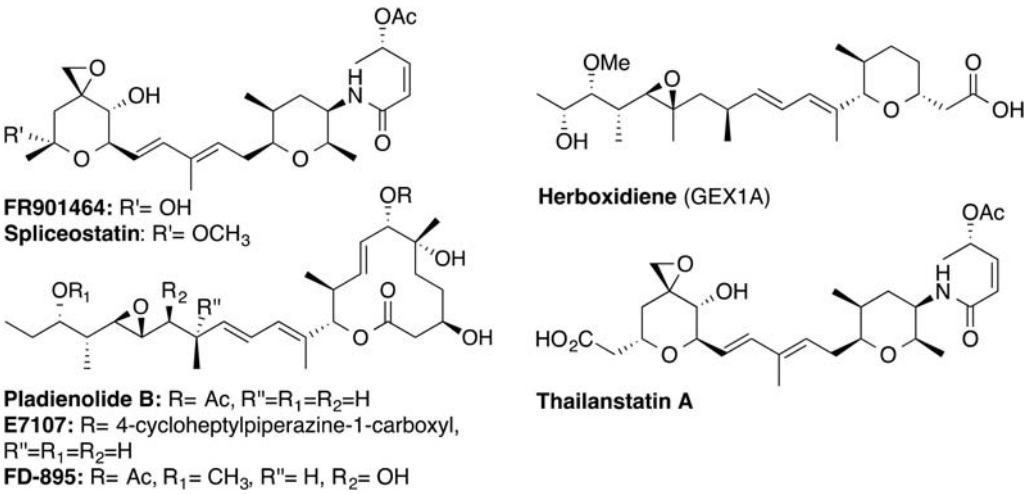

Fig. 5 Natural product spliceosome modulators and active derivatives (FR901464,[89,90] meayamycins,[52] pladienolides,[91,92] FD-895,[93–95] herboxidiene,[96,97] and thailanstatin A).[98]

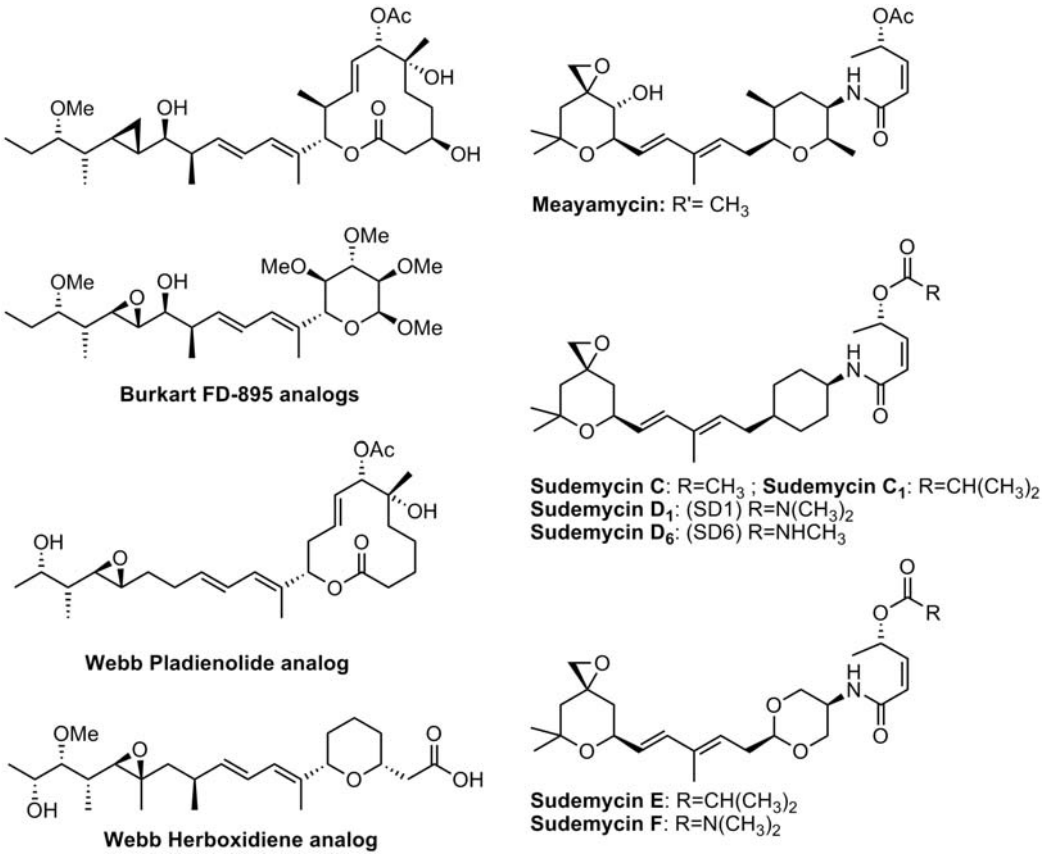

Fig. 6 Active totally synthetic analogs of splicing modulatory natural products discussed in the text. The *left panel* shows the Burkart analogs,[99,100] the weakly active Webb pladienolide analog,[101] and 6-norherboxidiene,[102,103] meayamycin,[52] and the sudemycins.[104–106]

NOD/SCID/IL2Rγ −/− (NSG) mice engrafted with primary cells from CLL patients.[107] This study showed a remarkable selectivity of the SF3B1 targeted agent SD6 for most of the CLL genotypes, which may indicate a common mechanism is driving CLL in addition to the spliceosome mutations and that this common mechanism results in selective susceptibility to any additional reduction in 3′-splice site fidelity. In another conceptually related publication, the authors tested this hypothesis using mice genetically engineered to express a mutated allele of SR splicing factor 2 (Srsf2P95H), which is recurrent in individuals with MDS and AML, in an inducible manner in hematopoietic cells.[108] These mice rapidly succumbed to fatal bone marrow failure, demonstrating that Srsf2-mutated cells depend on the wild-type Srsf2 allele for survival. These authors also showed that treatment with the spliceosome modulator E7107[109,110] specifically showed anticancer activity in both isogenic mouse leukemias and PDX AMLs carrying spliceosomal mutations. Thus, the authors of this publication concluded that:

> Collectively, these data provide genetic and pharmacol evidence that leukemias with spliceosomal gene mutations are preferentially susceptible to addnl. splicing perturbations in vivo as compared to leukemias without such mutations. Modulation of spliceosome function may thus provide a new therapeutic avenue in genetically defined subsets of individuals with MDS or AML.[108]

5.10.2.2 Natural Products and Derivatives Targeting *SF3B1*

In 2007, two research groups (from Astellas Pharma, Inc. and Eisai Co, Ltd., respectively) independently reported two structurally dissimilar bacterial natural products, FR901464 (FR) and pladienolide (Fig. 5), both targeting a similar site on the SF3B subunit of the spliceosome.[109,111] This work proved to be foundational for the field of small molecules that target SF3B1. Subsequent work inspired by these 2007 publications reported additional natural products that were shown to target the SF3B subunit. These subsequent reports include herboxidiene (GEX1A)[97] (isolated from Streptomyces sp. A7847) and the thailanstatins (isolated from *Burkholderia thailandensis*).[98] A similar interaction with the SF3B subunit (which is part of the spliceosomal U2 snRNP that recognizes the branch point and the 3′-splice site) is also likely for the macrolide natural product FD-895, given its potent biological activity

and its high structural and pharmacophore similarity to pladienolide.[95] Many of these bacterial fermentation products show cytotoxic IC_{50}s in the low nanomolar range in several tumor cell lines and have been reported to have a similar distinctive effect on the cell cycle in mammalian cell lines, including cell cycle arrest in the G1 and G2/M phases.[90] Several of these natural products have also been reported to show potent antitumor activity in vitro and in vivo.[89,91]

Work in this area led to the development of the semisynthetic pladienolide analog E7107 (Fig. 5) that entered Phase I clinical studies,[76,109,110] without the benefit of many subsequent recent discoveries relevant to mechanism of action, tumor selectivity, and patient stratification.[4,9] The clinical trials of E7107 were suspended and never reinitiated due to the ocular toxicity of this compound.[110] These results strongly supports the use of pharmacodynamic assays that have recently been reported, as an integral part of the splicing modulatory drug development process, as was used for SD6, since the pharmacodynamics for this class of drugs has unique features. The most notable feature of this class of drugs is the long-lasting cytotoxic effects following drug "washout" in vitro.[104] Though this washout effect is most notable for tumors, we inferred that this is likely to also be the case for sensitive, rapidly dividing normal tissue. We concluded that pulsatile treatment (via slow intravenous infusion) with a fast-acting drug, which possesses a relatively short half-life, is a critical criterion to use in the development of drugs in this class.[105] In contrast to this requirement, observed in our studies, E7107 was optimized on the basis of developing a longer half-life when compared to the parent natural product (pladienolide) series.

Though researchers initially characterized these compounds as "splicing inhibitors," the mechanism was subsequently elucidated and these compounds are now understood to effect alternate splicing,[105] through altering the 3′-splice site selection fidelity of the spliceosome[112] and are correctly understood to be splicing modulators and not general inhibitors of splicing.[4,9] One of our important contributions to this field has been our publication of cell-based splicing assays that use a PCR readout,[104] or a luciferase reporter,[113] and the observation that the *cytotoxicity potency of a range of natural or synthetic splicing modulators correlates to the potency for splicing modulation in this assay*.[102,105] It has also been shown that the potencies of pladienolide, herboxidiene, and sudemycin in cell-based cytotoxicity assays correlate with the potencies in a cell-based luciferase splicing reporter assay.[113] Evidence has been presented that this latter cell-based splicing reporter assay specifically reports on-target spliceosome modulatory pharmacodynamic activity in real time. The structures for the compounds discussed above are presented in Fig. 5.

5.10.2.3 Synthetic natural product analogs targeting *SF3B1*

The initial analogs of the natural product FR901464 were prepared as part of work that examined novel total synthetic routes to this compound first by the Jacobsen group,[114,115] and then by the Koide group[116,117] who also developed more chemically stable analogs (meayamycins),[52] and explored the structure-activity for a set of synthetic analogs of this compound class.[118,119] FD-895 is another natural product that is structurally related to pladienolide, which shows similar splicing modulatory and antitumor activity, and was the target of the successful total synthesis and analoging effort by the Burkart group.[95,100] Most remarkably, the Burkart group recently developed a completely novel, active structural analog, which replaces the macrolide component of FD-895 with a sugar scaffold.[100] This latter work is a tour de force and truly an extraordinary example of natural product molecular design.

As part of an effort to develop a class of drug-like synthetic spliceosome modulators the Webb group reported the design and synthesis of FR analogs that contain only 3 chiral centers (the sudemycins),[104–106,120] pladienolide analogs,[101] and several herboxidiene analogs (including a pladienolide–herboxidiene hybrid),[102] which included many new active compounds that effectively modulate alternate splicing.[104] Additionally, we recently reported our results from a genome-wide array analysis of sudemycin treated tumor cells; we found that sudemycins cause a rapid wide-ranging change in alternate pre-mRNA splicing. This same paper also showed that a biotin-labeled sudemycin probe directly interacts with the SF3B1 protein.[43] Our lead optimization work has primarily focused on the sudemycins, which are chemically stable synthetic molecules that were designed based on the known FR structure–activity relationships and the application of a hypothetical consensus pharmacophore model that is derived from molecular overlays of FR and PD.[106] This work ultimately led to SD6,[105] which is currently in preclinical Investigational New Drug (IND) development, with clinical studies for the treatment of myelodysplastic syndromes expected to start in 2018. The structures for the compounds discussed above are presented in Fig. 6.

5.10.2.4 Inhibitors of the CDC-Like Kinases

Compounds that inhibit members of the cdc-like kinase (CLK) family of kinases are known to modulate pre-mRNA splicing through the inhibition of SR protein phosphorylation.[121] The medicinal chemistry of this emerging area has been extensively reviewed.[121,122] Several diverse marine natural products[122] and synthetic compounds[123,124] have been found to be inhibitors of the CLK family (Figs. 7–9).[122] Several groups have shown that selective CLK inhibitors modulate splicing through their action on spliceosome components.[123,124] This area is nascent and may be fertile ground for the discovery of new compounds for cancer and other diseases that are associated with splicing aberrations. With the recent insights on the biology of the spliceosome medicinal chemistry in this area, as discussed above, drug discovery targeting the various CLKs (especially CLK1 and CLK2) is likely to expand in near future.[121]

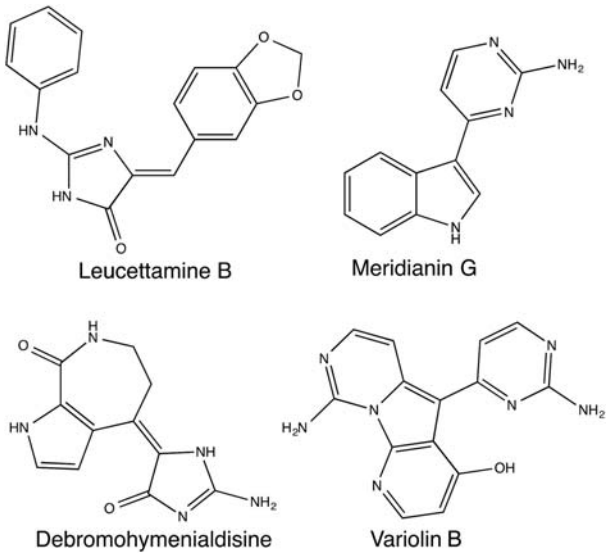

Fig. 7 Examples of marine natural products targeting CLKs.[122]

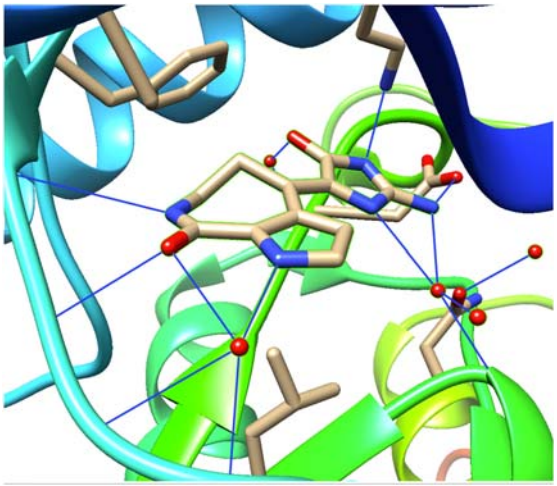

Fig. 8 A representation of the structure of debromohymenialdisine (K0010) bound to CLK1 using the published coordinates,[125] highlighting the hydrogen bonds to the ligand *(as blue lines)*. This figure was prepared using UCSF Chimera.[126]

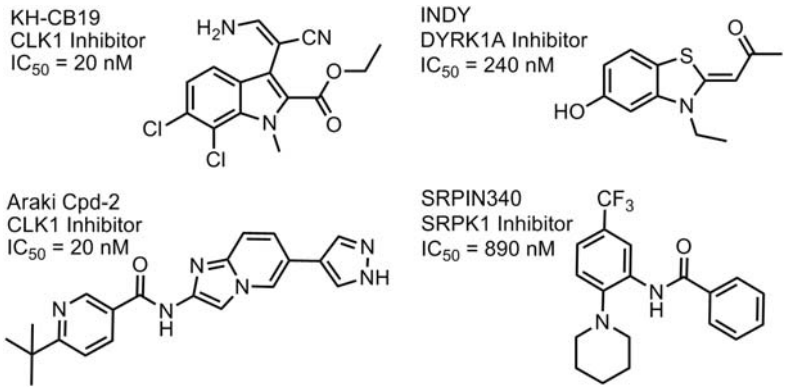

Fig. 9 Synthetic CLK, DYRK1A, and SRPK1 inhibitors showing cell-based activity[121]: KH-CB19,[124] Araki Cpd-2,[123] INDY,[127] and SRPIN340[128]

5.10.3 Conclusions

As discussed earlier, combined progress in natural product screening, target identification, spliceosome-related medicinal chemistry, and high-throughput transcriptome sequencing has led to a remarkable convergence of independent research areas, which have simultaneously identified new oncology drug targets and new small-molecule therapeutic agents. There is good reason to believe that these insights will lead to an expansion of spliceosome medicinal chemistry and the development of many new selective and highly effective chemotherapeutics for a range of cancers.

Abbreviations

ADCC Antibody-dependent cell-mediated cytotoxicity, in which antibody binding to foreign cells recruits cytotoxic effector cells

ADO Adenosine

APCs Antigen-presenting cells, which process and present antigens to T cells

ARG Arginase

CD4 Cell surface marker for activated T helper cells

CD8 Cell surface marker for activated cytotoxic T cells

COX Cyclooxygenase

CTLA4 T-cell checkpoint receptor, modulating immune suppression

DC Dendritic cell, one major subtype of antigen-presenting cells

CGN2 General controlled nonrepressed kinase, an immunosuppressive enzyme which detects cellular amino acid levels

eATP Extracellular ATP

GPI Glycosylphosphatidylinositol, membrane glycolipid which can be covalently attached to protein C-termini to link them to the membrane

IDO Indolamine 2,3-dioxygenase
IFN Interferon
iNOS Inducible nitrogen oxide synthetase
MDSC Myeloid-derived suppressor cell, immunosuppressive immune cells derived from bone marrow
MHC Major histocompatibility complex, surface proteins which present antigens to the TCR
NK cell Natural killer cell, key component of the innate immune system
PD1 T-cell checkpoint receptor, modulating immune suppression
PD-L1 Ligand that activates PD1, often overexpressed in cancer cells
PI3K Phosphatidylinositol-3-kinase
ROS Reactive oxygen species
STING Stimulator of interferon genes, immunostimulatory protein of the innate immune system which responds to cytosolic DNA
TAM Tumor-associated macrophage
TCR T-cell receptor, responsible for antigen recognition
TDO Tryptophan 2,3-dioxygenase
TLR Toll-like receptors, proinflammatory pattern recognition receptors of the innate immune system which recognize conserved elements of pathogens
TME Tumor microenvironment
Treg Regulatory T cell that mediates immunosuppression

5.11.1 Introduction

In 2011 the FDA approved Ipilimumab (anti-CTLA4, trade name Yervoy, Bristol-Myers Squibb) for the treatment of metastatic melanoma. In 2014 anti-PD1 antibodies Keytruda (Merck) and Opdivo (Bristol-Myers Squibb) were approved by the FDA for the same indication. These immune checkpoint inhibitors, as well as their combinations, have demonstrated remarkable clinical activity in multiple cancer types ranging from hematologic tumors to solid malignancies. Furthermore, a significant portion of the patients developed durable responses and remain cancer free years after the treatment. The success of these three agents has firmly established that the immune system plays an important role in the control of tumorigenesis and that the tumor must develop immune escape mechanisms in order to grow. Already cancer immunotherapy is established as one of the important pillars of cancer treatment adding a powerful new intervention in addition to surgery, hormone therapy, radiation therapy, chemotherapy, and cancer targeted therapy. Basic immunology research and pharmaceutical development in the field of immuno-oncology is now intensely focused on understanding the immune escape mechanisms developed by tumors and identifying methods to reestablish an effective immune response to the tumor. A number of approaches are being actively explored including the development of vaccines, recombinant cytokines, antibodies, autologous T cells, and small molecule drugs. Herein we describe the rationale for small molecule drug immunotherapies in cancer, and detail some of the specific targets that should be considered for developing new cancer immunotherapies.

5.11.2 Concept and History of Immuno-Oncology

In the mid-19th century, Rudolf Virchow observed the presence of leukocytes in tumors, providing the first clue of a functional role for the immune system in cancer biology.[1] Several decades later, William Coley made the observation that some cancer patients inadvertently infected by bacteria experienced profound tumor regressions. Based on this observation, he developed and conducted the first immunotherapy treatment of cancer.[2] His treatment, termed Coley's Toxins, contains two bacterial strains of *Streptococcus pyogenes* and *Serratia marcescens*. He and others used this therapy to treat different types of tumors. Although the outcome varied among the patients, the drug induced partial or even complete regression of tumors in a small percentage of patients. The mechanism of action of Coley's Toxins, however, remained a mystery for many decades after its first use which in part impeded its acceptance among immunologists and oncologists. From the late 19th century to the first half of the 20th century, the field of immunology was almost entirely devoted to the development of antitoxins (antibodies) against various diseases through vaccination. This field, which was pioneered by Edward Jenner's groundbreaking work on the development of the first vaccine against smallpox, has greatly advanced medical research and improved public health.[3] Consequently, the humoral immune system (immunity mediated by macromolecules such as antibodies in extracellular fluids) remained the focus of immunology research until the early 1960s when researchers unveiled the cellular arm of the human immune system.[4] It is now clear that cellular immunity, mediated by leukocytes, constitutes the major defense mechanism against cancer. Various types of immune cells such as neutrophils, NK (natural killer) cells, macrophages, dendritic cells (DCs), T cells ($CD4^+$ T helper cells and $CD8^+$ cytotoxic T cells), and B cells form the two lines of the human defense system: the innate immune system (nonspecific immunity) and the adaptive immune system (antigen-specific immunity). These cells work in a highly coordinated fashion both spatially and temporally, through the secretion of signaling molecules such as cytokines and chemokines or through direct cell–cell interactions, to control the body's intricate and highly effective defense system against both foreign and endogenous insults including cancer.

The concept of cancer immune-surveillance was first conceived by Paul Ehrlich in 1909[5] and formally proposed by Sir Macfarlane Burnett and Lewis Thomas in 1957.[6] The key tenet of this hypothesis is that cellular immunity is critical in protecting the body

from neoplastic disease. This concept was initially erroneously challenged owing to a lack of good understanding of the cellular immune system as well as the unavailability of suitable experimental model systems,[7] but has been well validated with various studies carried out since the 1990s. For example, it was shown that endogenously produced IFNγ (interferon γ), a critical cytokine involved in cellular immunity, could protect the host against transplanted tumors and inhibit tumorigenesis of chemically induced or spontaneous tumors in a number of studies carried out on mice.[8] Furthermore, RAG2$^{-/-}$ mice (mice that lack NKT, T and B cells) developed MCA (methylcholanthrene, a potent carcinogen)-induced sarcoma more frequently and rapidly than the wild-type controls.[9] In humans, individuals with severe immune deficiency have a higher probability of developing cancers[10,11] and there is a positive correlation between tumor immune infiltrate and increased survival in patients.[12]

Based on the concept of tumor immune surveillance, the tumor must develop mechanisms to escape immune control in order to grow; hence the concept of cancer immunoediting. There are three phases in this process: elimination, equilibrium, and escape (the three E's of cancer immunoediting).[13] In the elimination phase immune-surveillance results in the detection and destruction of tumors. Tumors that survive the elimination phase enter the equilibrium phase where the immune response is able to contain, but is not sufficient to eradicate the tumor cells. Through genetic mutations and Darwinian selection, newly mutated cancer cells may possess increased resistance to immune attack and these cells will eventually escape the immune surveillance and grow into clinically observable tumors. Cancer cells that successfully escape immune surveillance are conferred a selective growth advantage in the face of an increasingly ineffective adaptive immune response. The goal of cancer immunotherapy is to reestablish immune surveillance by interfering with various cancer immunoediting mechanisms.

5.11.3 Immunity in the Tumor Microenvironment (TME)

Both the innate and the adaptive immune systems participate in tumor immune surveillance. The innate immune system responds to generic signals to elicit rapid immune responses without the need of presensitization. This system is comprised of several different types of immune cells: NK cells, granulocytes (neutrophils, basophils, and eosinophils), mast cells, γδT cells, macrophages, and DCs. Macrophages and DCs are professional antigen-presenting cells (APCs) that serve as an important link between the innate and adaptive immune responses and will be described in more detail in the subsequent section. Among the remaining innate cell types, NK cells have a predominant role in innate immunity against tumor. NK cells express a range of inhibitory and activating receptors that allow them to recognize healthy versus "stressed" cells including tumor cells. The inhibitory KIR and CD94-NKG2A receptors bind to the major histocompatibility complex (MHC) class I molecules on normal cells and prevent the cytolytic activity of NK cells. It is known that certain tumor cells downregulate MHC class I to evade the antigen-specific adaptive immune response. These tumor cells therefore can be recognized as "missing-self" cells and can induce the cytolytic function of NK cells.[14] In addition to inhibitory receptors, NK cells possess a number of activating receptors such as NKG2D, NCRs, and DNAM1. These receptors recognize a range of ligands that typically are not expressed on normal cells but their expression can be upregulated on infected cells and rapidly proliferating cells such as tumor cells (induced-self recognition). For example, NKG2D recognizes MICA, MICB, and ULBP1-ULBP6 that are predominantly expressed on "stressed" cells. NK cells also carry receptor CD16 that recognizes the Fc region of the IgG antibodies, activating antibody-dependent cell-mediated cytotoxicity (ADCC) against antibody-tagged cells. In addition to the direct cytolytic activity, NK cells and other innate cells can also secret cytokines and chemokines to shape the immune response. One of the important cytokines secreted by NK cells is IFNγ which has a critical role in cellular immunity against cancer. Tumor cells may evade NK cell killing by shedding of the activating ligands, or through induction of chronic activation of NK cells leading to NK cell anergy.[15]

The adaptive immune response is a higher level defense system that is initiated by the recognition of specific antigens by B cells and T cells. T cell-mediated adaptive responses play the more critical role in immune surveillance against cancer and will be described in more detail here. Tumor cells, although derived from normal cells, have been shown to express tumor-specific antigens that can be detected by the immune system. These antigens include neoantigens created by mutations in tumor cells, antigens that are overexpressed in tumor cells, and germline antigens that are silent in normal tissue but expressed in cancers.[16] Tumor antigens can be presented directly on the surface of the tumor cells by the MHC class I molecule, or captured by professional APCs such as DCs and macrophages, and presented on the surface by MHC class I and II molecules. APCs possess membrane-associated and intracellular pattern recognition receptors (PRRs) that sense pathogen-associated molecular patterns (PAMPs) such as bacterial lipopolysaccharide (LPS), bacterial or viral nucleic acid, bacterial lipopeptides, fungal glucans, etc., as well as damage-associated molecular patterns (DAMPs) such as cell components released during cell damage and death. APCs actively sample the surrounding tissue antigens and have the ability to engulf cell debris and pathogens through processes such as phagocytosis. Detection of PAMPs initiates the immune response against pathogens whereas detection of DAMPs initiates the immune response against necrotic tissues including necrosis induced by tumor cell growth. In addition, one specific type of apoptosis termed immunogenic cell death (ICD) has gained importance in the field of immuno-oncology. ICD can be induced by certain cytotoxic agents or radiation and can initiate effective immune responses.[17] Recognition of PAMPs and DAMPs by PRRs leads to the activation of APCs with the upregulation of a number of costimulatory molecules such as CD40, CD80, CD86, and MHCs on DCs that interact with specific surface molecules on the T cells and enhance T cell activation. At the same time, activated APCs secret various cytokines/chemokines to boost the immune response, and enhance the antigen processing and presentation activities to T cells. The effector T cells are composed of CD8^{+} cytotoxic T cells and CD4^{+} T helper cells that recognize antigens presented by MHCI and MHCII complexes, respectively. These cells are the main players in the development of effective adaptive immune responses against specific insults.

When APCs carrying the antigens move to the nearby draining lymph nodes, they present antigens to effector T cells with matching T-cell receptor complexes (TCRs). T cells, once activated through antigen recognition, go through clonal expansion. T cells expressing antigen-specific TCRs traffic and infiltrate the tumor bed. Activated $CD4^+$ T cells coordinate actions of various immune cells through secretion of soluble factors and through direct ligand–receptor interactions to ensure an appropriate immune response. $CD8^+$ T cells carry out the mission of direct recognition and killing of tumor cells harboring the same antigens. For effective immune-surveillance, this cycle must operate optimally. Tumors, on the other hand, have developed multiple mechanisms to interfere with various steps in this cycle in a way to promote immune escape and boost tumor growth.[18] Some of the major immune-suppressive mechanisms in the TME are briefly described below.

5.11.3.1 Modulation of T Cell Activation and Differentiation

T cell activation requires the binding of TCR to the matching peptide antigen presented by MHC complexes on APCs or tumor cells. In addition, the level and outcome of T cell activation is further controlled by a number of surface coreceptors that, upon binding to their respective ligands, produce costimulatory (interactions that further boost T cell activation) or coinhibitory/immune checkpoint signals (interactions that dampen the T cell response). Common T cell costimulatory receptors include CD28, ICOS, OX40, and CD137. Notable checkpoint coinhibitory signals are represented by PD1, CTLA-4, TIM3, LAG3, and A2aR.[19] These costimulatory and checkpoint interactions are crucial to ensure the proper level of the immune response toward a specific insult. It is known that tumors directly interfere with the T cell activation process by either downregulating the MHC complexes to make tumor cells less visible to the T cells[14] or inducing the inhibitory immune checkpoint pathway, particularly in the TME, to inhibit the T cell function.[19] PD-L1, the ligand for PD1, one of the major checkpoints during T cell activation, is upregulated in a number of tumors to induce T cell anergy, an induced tolerance state of T cells.[20]

$CD4^+$ T cells, upon activation, can differentiate into various functional classes that lead to different immune outcomes. Two of the major CD4 subtypes are termed Th1 and Th2 $CD4^+$ T cells.[21] The generation of these subtypes of T cells is controlled by the specific cytokine milieu to which the $CD4^+$ T cells are exposed during activation. Specifically, IL-12 and IL-4 are the main cytokines that induce Th1 and Th2 response, respectively.[22] The Th1 response leads to the production of IFNγ and upregulation of T cell surface costimulatory molecules such as CD40 ligand that promote the activation of macrophages and $CD8^+$ T cells and is one of the major cellular immune responses against tumor. The Th2 response leads to the secretion of cytokines such as IL-4, IL-5, IL-10, and IL-13 that have multiple functions including the defense against extracellular parasites, induction of the IgE production of B cells and the allergic reaction, and more relevant to the tumor setting, downregulation of the immune activity and promotion of tissue repair and regeneration. The Th2 response helps with the proper resolution of the immune response and the reestablishment of normal homeostasis. Tumors have developed mechanisms to bias the immune response toward the Th2 polarization by inducing the secretion of Th2 differentiating cytokines, hence suppressing immune attack and boosting tumor cell growth and invasion.

5.11.3.2 T Regulatory Cells (Tregs)

A specific subset of $CD4^+$ T cells called T regulatory cells or Treg cells play a major role in immune regulation to maintain systemic immune homeostasis. The forkhead box P3 (FOXP3) protein is expressed in this subset of cells and is the master transcription factor that controls the expression of genes to mediate the immune suppression function of Tregs.[23] Tregs exert their inhibitory activity through multiple mechanisms: secretion of the inhibitory cytokines such as IL-10 and TGFβ[24]; inhibition of target cells through direct cell–cell interactions[25]; constitutive expression of the T cell activation marker CD25 that results in the depletion of IL-2 (the ligand for CD25 and an essential growth factor for effector T cells) and starvation of effector T cells[26]; expression of additional inhibitory molecules such as CD39 and CD73 that produce extracellular adenosine, an important immune inhibitory molecule that leads to adenosine pathway activation in effector T cells and the inhibition of their functional activity.[27]

5.11.3.3 Myeloid-Derived Suppressor Cells (MDSCs)

Under healthy conditions, immature myeloid cells (IMCs) generated in bone marrow differentiate into granulocytes, macrophages, or DCs. Under certain pathological conditions including cancer, the differentiation of IMCs is partially blocked leading to the accumulation of a heterogeneous population of immature myeloid cells called MDSCs. These MDSCs possess strong immunosuppressive activity. The accumulation of MDSCs in tumors has been shown to inhibit T cell proliferation and activation.[28] There are two types of MDSCs based on their cellular origin, monocytic MDSCs and granulocytic MDSCs, that mediate their suppressive activities through overlapping but differential mechanisms.[29] Both subsets of MDSCs degrade arginine by upregulating the expression of arginase I and inducible nitric oxide synthase (iNOS or NOS2). Arginine is an essential nutrient for T cells and arginine deprivation constitutes one of the major mechanisms of MDSC-mediated immune suppression.[30] MDSCs also have increased expression of reactive oxygen species (ROS).[31] Superoxide anions, together with NO (nitric oxide, another product of iNOS), produce peroxynitrite that can suppress T cell function by nitration and nitrosylation of different amino acids on TCR and CD8 molecules on the surface of T cells, which causes the T cells to become unresponsive to antigen-specific stimulation.[32] In general, monocytic MDSCs generate high levels of NO and low levels of ROS whereas granulocytic MDSCs generate high levels of ROS and low levels of NO.[29] It is important to note that ROS and NO can have a direct cytotoxic effect on tumor cells as well.[33] This needs to be taken into

consideration when evaluating strategies of targeting MDSCs for cancer therapy. One additional mechanism of MDSC-mediated suppression activity is the ability of MDSCs to promote Treg development through secretion of specific cytokines as well as through direct cell–cell interactions.[34]

5.11.3.4 Tumor-Associated Macrophages (TAMs)

Analogous to the Th1 and Th2 $CD4^+$ T cells, macrophages can be stimulated and polarized into M1 and M2 subtypes to represent the two extremes of a continuous spectrum of macrophage phenotypes. M1 macrophages are activated by IFNγ and bacterial products. These macrophages secret IL-12, a major cytokine in the induction of the Th1 polarization of $CD4^+$ T cells. Therefore, M1 macrophages play an important role in mediating the immune attack on tumor. On the other hand, M2 macrophages are activated by Th2 cytokines such as IL-4 and IL-10. They express high levels of IL-10 and low levels of IL-12 and induce Th2 T cell differentiation.[35] TAMs are conditioned by the immune-suppressive tumor environment and have acquired the phenotype of the M2 macrophages. TAMs inhibit T cell activation and function and promote tumor growth and metastasis.[36]

5.11.3.5 Modulation of DC Function in Tumor

Human DCs are mainly derived from monocytes. There are two major DC subsets that are phenotypically and functionally distinct, conventional DCs (cDCs), and plasmacytoid DCs (pDCs). Tissue resident cDCs are immature DCs with high phagocytosis activity, allowing them to actively take up tissue antigens. However, immature DCs have low antigen presentation activity and do not induce T cell activation. Upon engaging PAMPs and DAMPs, DCs are activated with upregulated antigen presentation activity. Multiple factors in the TME inhibit the proper differentiation of DCs in tumor, including immunosuppressive cytokines, hypoxia, and upregulated extracellular adenosine production. These factors collectively induce the differentiation of immunosuppressive DCs with reduced IL-12 and enhanced production of IL-10, IL-6, IL-8, VEGF, COX2, TGFβ and IDO to bias the T cells toward Th2 polarization and T cell anergy.[37] In addition, DCs express a number of costimulatory and coinhibitory molecules on the surface that interact with various T cell coreceptors to fine tune the T cell activation and differentiation process. Immunosuppressive TME tips the balance of these interactions in favor of immune regulation. One notable example is the upregulation of PD-L1 expression on DCs leading to inhibition of T cell function.[38] Plasmacytoid DCs are one of the major producers of IFNα (interferon α), a type I interferon that plays critical role in initiating innate immunity and promoting Th1 adaptive response. Evidence exists that plasmacytoid DCs have impaired ability to produce IFNα in TME through, for example, the downregulation of toll-like receptor 9 (TLR9), a PRR that is selectively expressed on plasmacytoid DCs within DC lineage and induces downstream IFNα production.[39]

5.11.3.6 Current Status of Immuno-Oncology Therapy

Current strategies in the field of immuno-oncology are designed to reverse tumor immune tolerance by boosting the antigen presentation process or by directly activating T cells. Given the importance of the T cell surface receptor–ligand interactions in immune modulation, many antibody drugs are being developed to target these interactions with the goal of stimulating immune responses against tumor. The current marketed antibody drugs include cytotoxic T lymphocyte-associated antigen 4 (CTLA4) blocking antibody ipilimumab (Yervoy; Bristol-Myers Squibb) and programmed cell death protein 1 (PD1) blocking antibodies pembrolizumab (Keytruda; Merck) and nivolumab (Opdivo; Bristol-Myers Squibb). These antibodies work via distinct mechanisms to boost T cell activity. Ipilimumab, a fully human IgG1 mAb, relieves CTLA-4 mediated inhibition at the priming phase of T cell activation. Pembrolizumab and nivolumab are humanized mAbs that help reactivate anergic T cells by blocking the PD1/PD-L1 interaction. The critical importance of tumor control by T cells is further illustrated by autologous cell and gene therapy approaches. For these approaches, TCRs are genetically engineered to either render them high affinity toward a tumor cell-specific surface protein through the chimeric antigen receptor (CAR) technology, or build high affinity and specificity toward the tumor antigen/MHC complexes preferentially expressed on tumor cells. A patient's own T cells are transduced with the engineered TCR and reinfused into the same patient through a process called adoptive cell transfer (ACT).[40] These T cells then selectively bind to and kill the tumor cells possessing the targeted antigen(s).

5.11.4 Small Molecule Targets

While the targeting of cell surface protein–protein interactions is currently best achieved with therapeutic mAbs, there are many alternative processes and pathways that are open to intervention by traditional small-molecule drugs. As detailed by Adams et al.[32b] traditional small molecule medicines offer a number of potential advantages over recombinant protein approaches. These include (1) well developed processes to discover, develop, and advance compounds into the clinic; (2) the potential for orally active drugs that can be fine tuned to deliver a variety of exposure and duration of action profiles; (3) access to the CNS and the potential greater exposure in the TME; (4) access to intracellular targets; and (5) the potential of a pill versus an infusion to provide greater access of these medicines to the patient. Below we detail some of the most promising small-molecule drug targets for immunotherapies in cancer and the current status of discovery efforts.

5.11.4.1 Amino Acid Catabolism

Amino acid levels are a key indicator of cellular fitness to engage in metabolically demanding activities. Amino acids are not only required building blocks for protein synthesis, but their metabolites also provide input into the Krebs cycle as well as nitrogen to support nucleotide and phospholipid synthesis. A number of amino acid sensing systems have evolved which directly regulate key cellular functions.[41] Immune response is sensitive to amino acid levels,[42] and catabolism of cysteine, glutamine, phenylalanine, tryptophan, and arginine have been implicated in regulation of immune responses in tumors, especially through modulation of T-cell proliferation and activation.[17,43]

5.11.4.1.1 Tryptophan

5.11.4.1.1.1 Background

The first and rate-limiting step in tryptophan catabolism is oxidative cleavage of the pyrrole ring to generate *N*-formyl kynurenine. In humans, this is accomplished by one of three heme-containing enzymes. Tryptophan 2,3-dioxygenase (TDO, EC 1.13.11.11) is a tetrameric enzyme constitutively expressed in liver and brain. It has relatively stringent substrate specificity and is thought to be involved in the metabolism of dietary tryptophan to produce nicotinamide adenine dinucleotide (NAD^+) and to limit production of serotonin.[44] Indolamine 2,3-dioxygenase (IDO1, EC 1.13.1.52) is an inducible, monomeric enzyme. While it is widely found throughout the body, high levels are expressed mainly in the antigen-presenting dendritic cells and macrophages, where it is induced by a number of inflammatory stimuli.[45] More recently, IDO2, a paralog of IDO1, has been described. It shares about 40% homology with IDO1 and is constitutively expressed in liver and circulating and plasmacytoid dendritic cells.[44,46] IDO2 is a considerably less active enzyme than IDO1 both in vitro and in cell-based assays,[44,47] and its significance in immune regulation is unclear. Although the three enzymes share the same substrate, there are significant differences in substrate and inhibitor specificity among them,[47,48] suggesting that potent, selective inhibitors will likely be easier to obtain than potent pan-active ones.

IDO1, IDO2, and TDO have been reported to be highly expressed in various tumor types,[49] but most of the target validation has been performed with IDO1. IDO1 is thought to act mostly through induction, activation, or suppression of various T cell and dendritic cell functions, which lead to an immunosuppressive tumor environment.[50] Two mechanisms of action are known to be engaged as the result of oxidative metabolism of tryptophan. The decrease in tryptophan levels activates the stress response GCN2 kinase, which senses uncharged tRNA, and inactivates mTOR, complementary pathways which lead to T cell cycle arrest and apoptosis.[48,51] Additionally, kynurenine, a catabolic product dependent on tryptophan oxidation (**Fig. 1**), is both a regulatory molecule and an endogenous ligand for the aryl hydrocarbon receptor, and is thought to regulate both immune response and IDO activity.[48,52]

5.11.4.1.1.2 IDO1 inhibitors

Among the first IDO1 inhibitors described were tryptophan analogs (**Fig. 2**) like DL-1-methyl tryptophan (DL-1MT, **1**), a substrate-competitive inhibitor which exhibits a modest K_i of 6.6 μM.[53] When the isolated enantiomers of **1** were examined, the L-enantiomer was more potent in the biochemical assay as expected, but it was the D-enantiomer **2** which was significantly more potent in in vivo tumor proliferation assays.[54] This finding suggested that there was an additional target for **2**, and IDO2 was quickly identified as a new protein inhibited by **2**.[55] The consensus now, however, is that **2** is a poor inhibitor of both IDO1 and IDO2,[56] and the mechanism of its in vivo activity is still poorly understood. Despite the ambiguity of the in vivo mechanism of **2**, NewLink Genetics has taken it forward under the name Indoximod into a variety of clinical trials. The most recent data available show a combination of **2** with gemcitabine and nab-paclitaxel giving a 45% objective response rate (ORR) in a Phase 2 trial in metastatic pancreatic

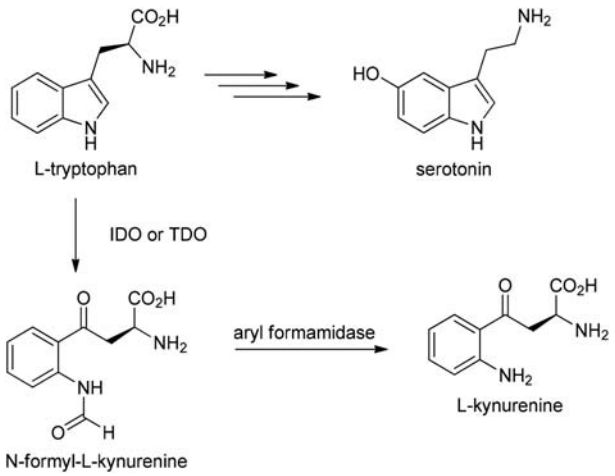

Fig. 1 Relevant pathways of tryptophan metabolism.

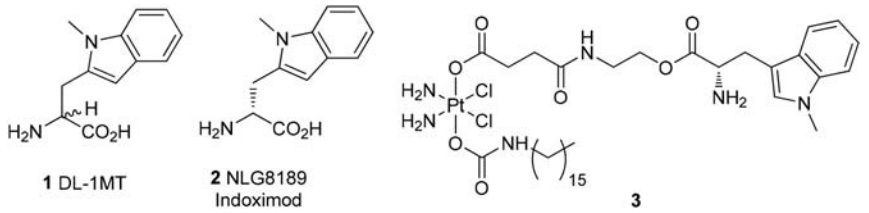

Fig. 2 IDO inhibitors.

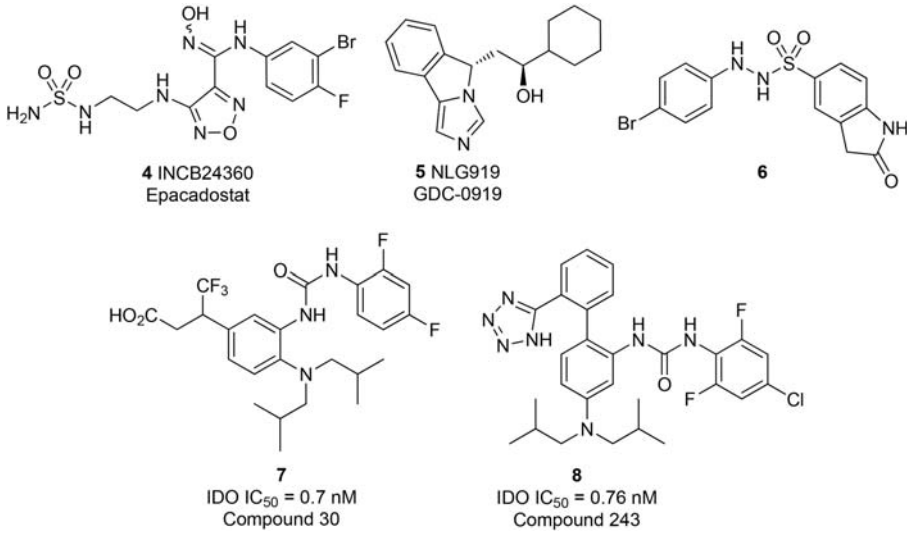

Fig. 3 IDO1 inhibitors.

cancer,[40a] and combinations with checkpoint inhibitors ipilimumab (CTLA-4), pembrolizumab (PD1), and nivolumab (PD1) giving objective response rates of 36–53% in a Phase Ib/II trial of unresectable stage 3 or 4 melanoma.[57] These combinations with **2** were significantly more efficacious than either agent singly. Taking advantage of the observation that **2** selectively accumulates in tumors,[54] the platinum-containing pro-drug **3** was shown to inhibit kynurenine production more potently than **2** and to induce apoptosis in a cis-platin-resistant SKOV3 ovarian cancer cell line.[58]

Investigators at Incyte disclosed the first potent, selective inhibitors of IDO and demonstrated *in vivo activity* in a mouse melanoma model.[59] This led to the development of INCB24360 (Epacadostat, **4**, Fig. 3), which has been advanced into a number of clinical trials.[60] Compound **4** is a potent inhibitor of IDO1 with an IC_{50} of 72 nM, and activity in cell-based kynurenine production assays in the 10–20 nM range. It is active in an in vivo tumor growth model with PAN02 pancreatic cancer cells but only in immunocompetent mice and not immunodeficient mice.[60] It has been in clinical trials in combination with the checkpoint inhibitor pembrolizumab (PD1) and in preliminary results showed a 57% ORR and an 86% disease control rate (DCR) in stage 3/4 melanoma and a 40% ORR and 80% DCR in stage 3/4 renal cell carcinoma.[61] INCB24360 has advanced to Phase III trials in combination with pembrolizumab and also in trials with nivolumab (PD1) and atezolizumab (PD-L1). Investigators at NewLink Genetics have recently disclosed a potent, selective IDO1 inhibitor, NLG919, which displays an IC_{50} of 28 nM against IDO1 and potent activity in cell-based and in vivo tumor models with B16F10 melanoma tumors.[62] While the structure has not been disclosed, it is thought to be **5** or a closely related structure. Investigators are currently recruiting for a clinical trial of **5** in combination with atezolizumab.

The phenylsulfonylhydrazide **6** has recently been described as a potent and selective inhibitor of IDO1, with an IC_{50} of 36 nM.[63] It demonstrates good single agent activity in a mouse CT-26 colorectal cancer model, showing decrease in kynurenine levels, increase in Trp/kynurenine ratio, decrease in tumor volume, and inhibition of tumor growth after oral dosing. Investigators at Bristol-Myers Squibb have recently disclosed potent IDO1 inhibitors **7**[64] and **8**,[65] which appear to be structurally related to **4**.

There is a single crystal structure of a high-affinity ligand, the racemate of **5**, bound to IDO1, shown in Fig. 4.[66] The bound ligand clearly shows the *S* configuration at the pyrrole moiety but the electron density can accommodate either configuration of the alcohol moiety. The imidazole nitrogen interacts with the heme iron as expected, and the phenyl and cyclohexyl moieties occupy distinct hydrophobic binding pockets. The alcohol makes a key hydrogen bond to one of the propionic acid side chains of the heme, but otherwise all the interactions between the ligand and enzyme are hydrophobic.

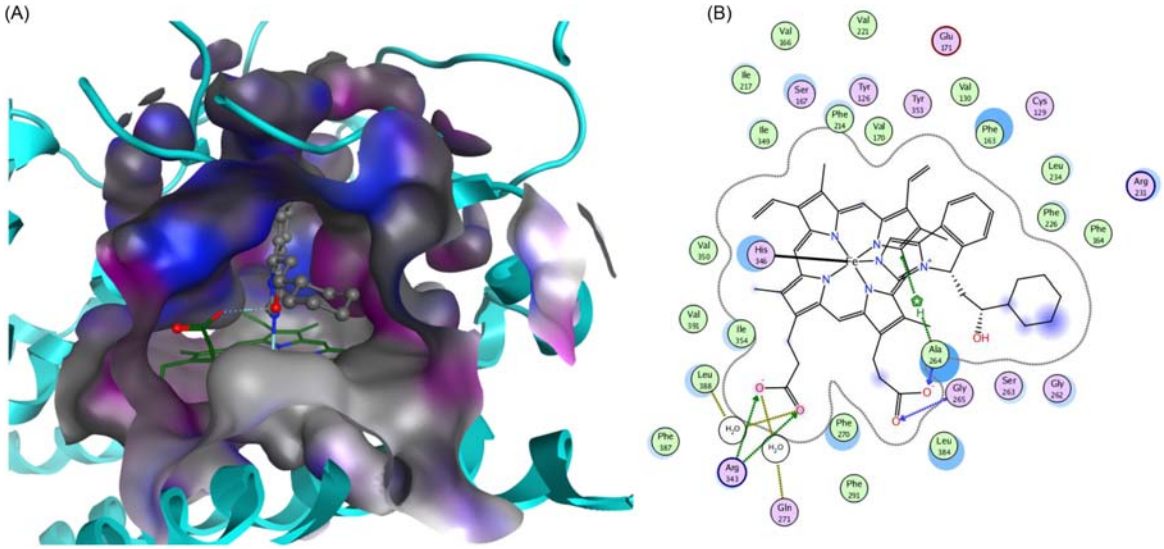

Fig. 4 (A) Racemate of **5** bound to IDO1 (5EK3). The heme is colored *dark green*, and the surface is colored *gray* (hydrophobic), *blue* (polar), and *red* (exposed). (B) Interaction map for rac-**5** bound to IDO. Figures drawn using MOE 2015.1001 (Chemical Computing Group).

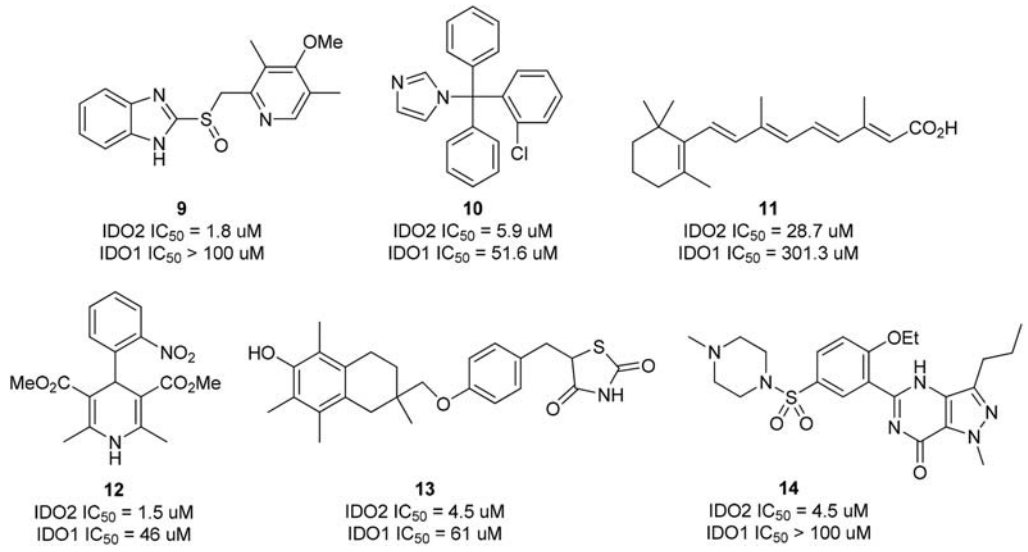

Fig. 5 IDO2-selective inhibitors.

5.11.4.1.1.3 IDO2 inhibitors

It may be due to the low intrinsic activity of IDO2 and its greater sensitivity to its redox partner[44] that few potent IDO2-specific inhibitors have been described. However, this does suggest that IDO2 is unlikely to be an important target for regulation of tryptophan metabolism. Screening of a set of 640 FDA-approved drugs has identified several compounds (Fig. 5) with micromolar potency against IDO2 and about 10-fold or better selectivity against IDO1, including the proton pump inhibitor tenatoprazole (**9**), the antifungal chlortrimazole (**10**), the prototypical retinoic acid nuclear receptor ligand retinoic acid (**11**), the antihypertensive nifedipine (**12**), the PPAR ligand troglitazone (**13**), and the PDE5 inhibitor sildenafil (**14**).[67]

5.11.4.1.1.4 TDO inhibitors

Despite the interest in TDO in brain neurochemistry as a source of serotonin and kynurenine-derived neuroactive compounds,[68] there has been surprisingly little progress in discovering TDO inhibitors. The first potent inhibitor was the pyridyl vinyl indole **15** (Fig. 6),[69] and despite extensive SAR studies around that template, only substitutions of the pyridine with a carboxylate or tetrazole (**16**) have given compounds with significant activity.[70] Structure-based design around the isatin scaffold yielded **17**, which exhibits submicromolar activity against TDO and 10-fold selectivity over IDO1.[71] There is only one crystal structure of a eukaryotic

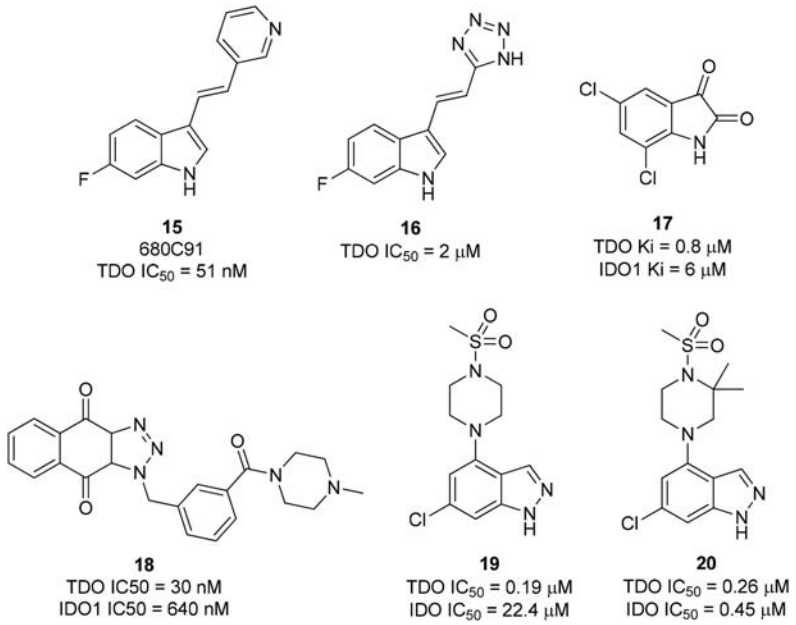

Fig. 6 TDO inhibitors.

TDO, that of the fruit fly *Drosophila melanogaster*,[72] which only shares 59% homology to the human sequence, but it was sufficient to create a homology model which was used for virtual screening by Wu et al.[73] Optimization of screening hits led to the naphthoquinone **18**, which demonstrates a 30 nM IC_{50} against TDO and 20-fold selectivity against IDO1. Investigators at IOmet Pharma (recently acquired by Merck) have disclosed 4-amino substituted indazoles represented by **19** and **20**.[74] They exhibit submicromolar TDO activity, but more interestingly, small changes in structure impart large changes in IDO1 activity, which range from 100-fold selectivity to equipotency, and represent the first potent dual TDO/IDO1 inhibitors reported.

5.11.4.1.2 Arginine

5.11.4.1.2.1 Arginase

Arginine levels are controlled by the activities of two catabolic enzymes, arginase (EC 3.5.3.1) and nitric oxide synthase (EC 1.14.13.39), shown in Fig. 7. ARG1 is a cytosolic enzyme expressed in the liver, and the closely related isoform ARG2 is a mitochondrial enzyme found in diverse number of cells. In the tumor environment ARG1 is highly expressed in, and secreted by, the immunosuppressive MDSCs and TAMs. The depletion of arginine is monitored by the stress response kinase GCN2, which is activated by uncharged transfer RNA, and is a pathway common to both arginine and tryptophan depletion. In addition to regulating transcriptional and translational programs responsible for cell growth and proliferation,[75] GCN2's activation specifically depletes the CD3ζ chain of the TCR receptor, compromising the ability of T cells to mount a response to antigen. Arginase levels are elevated in MSDCs in both renal cell carcinoma and breast cancer,[76] and inhibition of arginase blocks the growth of lung carcinoma in mice.[77]

MDSCs also express inducible nitric oxide synthase (iNOS), which converts arginine to nitric oxide. Nitric oxide is thought to suppress T cell function either by *S*-nitrosylation of critical cysteine residues of proteins or through its regulation of guanylyl cyclase and cyclic GMP-dependent kinases.[75] While the expression of arginase and iNOS is usually mutually exclusive in normal cells, this is not true for MDSCs and TAMs, and the two enzymes compete for available arginine. When arginine levels

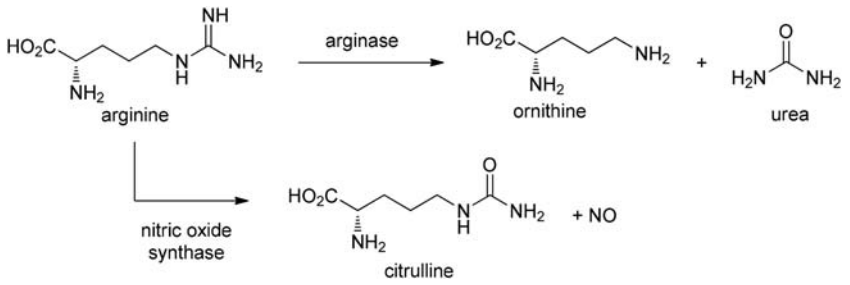

Fig. 7 Arginine catabolism by arginase and nitric oxide synthase.

are depleted by arginase, iNOS switches to superoxide production, ultimately generating reactive oxygen and nitrogen species, which are immunosuppressive in themselves. Given the fact that iNOS activity is immunosuppressive either in the presence or absence of arginine, it was anticipated that dual inhibitors of arginase and iNOS would be optimal for restoring immune function.

5.11.4.1.2.2 Arginase inhibitors

The development of arginase inhibitors quickly followed publication of a crystal structure and elucidation of a mechanism of action.[77] The arginine α-amino and carboxyl groups are anchored to surface residues through networks of water molecules, and the side chain projects down a long tunnel toward a pair of Mn^{2+} ions, which polarize a water molecule positioned to attack the guanidine. This led to the of transition state analogs **21** (2-(*S*)amino-6-boronohexanoic acid, ABH Fig. 8)[76] and its thio analog **22** (S-(2-boronylethyl)-L-cysteine, BEC),[78] in which a trigonal boronic acid mimics the guanidine moiety and accepts the water molecule to form a tetrahedral mimic of the enzymatic transition state, shown clearly in the cocrystal structure of ARG1 with **21** (Fig. 9).[79] Substitution at the α-carbon has been shown to improve potency, with the tropane-containing **23** the most potent inhibitor identified to date. Although ARG1 and ARG2 have only 54% sequence homology, they share very similar active sites,[80] and most inhibitors show very little selectivity between the two isoforms.[81]

N-Hydroxy-L-arginine (**24**) and *N*-hydroxy-L-nor-arginine (**25**) appear more structurally related to nitric oxide synthase intermediates, but they are inhibitors of arginases 1 and 2. X-ray crystallography shows the N-hydroxy group displaces the nucleophilic water that bridges the two manganase atoms, with the shorter nor-arginine analog providing higher potency and the only significant selectivity between ARG1 and ARG2.[82]

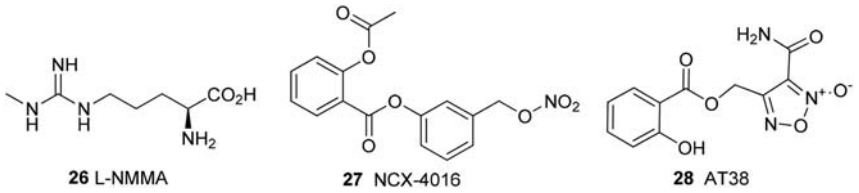

Fig. 10 iNOS inhibitor and dual inhibitors of ARG1 and iNOS function.

5.11.4.1.2.3 Dual inhibitors of arginase/iNOS function

The hypothesis that inhibition of both arginase and iNOS simultaneously would restore T-cell function was demonstrated in collagen gel matrix-supported organ cultures taken from prostate carcinomas treated with a combination of **24** and **26**, an iNOS inhibitor (Fig. 10).[83] Despite the fact that arginase and iNOS utilize the same substrate, generating a dual enzymatic inhibitor has proved elusive.

Compound **27**, NCX-4016, a nitroaspirin that inhibits cyclooxygenase and releases nitric oxide, was the first reported small-molecule drug to inhibit both arginase and iNOS activities in murine in vivo tumor model.[84] The mechanism of action is inhibition of target expression rather than inhibition of enzymatic activity. The more potent nitroaspirin analog **28**, AT38, was identified in a screening protocol using a co-culture of T cells with MDSCs.[85] In vivo, AT38 produced a large influx of T lymphocytes into mouse tumors, and combining AT38 with an adoptive cell transfer of cells recognizing an engineered antigen (EG7-OVA) produced a high number of durable responses.[85]

5.11.4.2 Purinergic Signaling in Immune Cells

The conditioning of the TME toward an antiinflammatory milieu is a major method of immune tolerance.[86] Cellular stress in the form of tissue injury, infection, or ischemia acutely elevates local levels of extracellular ATP (eATP) initiating multiple proinflammatory events, including the recruitment and activation of macrophage and DCs.[87] To reestablish tissue homeostasis, the immune system invokes a number of antiinflammatory pathways. One strategy that invading tumor cells can employ to avoid detection is to upregulate immunosuppressive and downregulate immunostimulatory pathways mediated by purinergic signaling.[88] For example, the sequential hydrolysis of eATP by the ectonucleotidases CD39 and CD73 lowers the levels of proinflammatory eATP and elevates the levels of immunosuppressive extracellular adenosine (eADO). In the TME eADO concentration can increase 10–20-fold above normal levels (Fig. 11)[89] to levels sufficient to activate both A_{2A} and A_{2B} receptor signaling on the infiltrating lymphocytes, thereby initiating a compensatory response that shields the tissue/tumor from excessive inflammation.

The high eADO level has been proposed to maintain the TME in a state of chronic immune suppression, allowing the tumor to grow unconstrained by the immune system.[90] Both CD73 and CD39 are expressed on Tregs and other cells in the TME

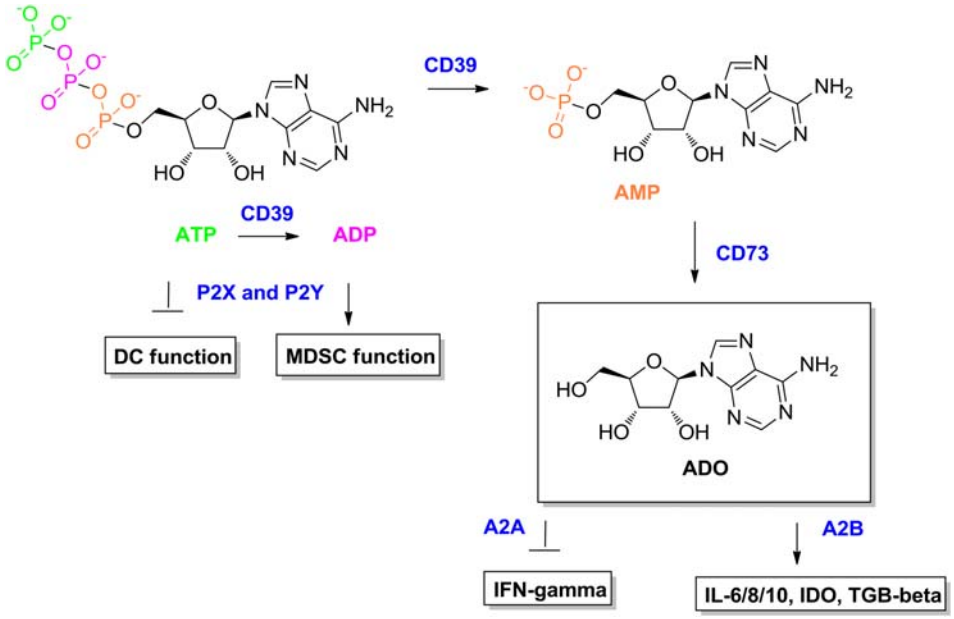

Fig. 11 Adenosinergic signaling pathway.

(B cells and tumor exosomes) providing additional enzymatic capacity to convert eATP to eADO, which can then bind to A_{2A} receptors on Teff cells to silence the antitumor immune response.[27b,91] Tregs also express A_{2A} receptors, which creates an autocrine loop to enhance other immunosuppressive mechanisms of Tregs.[92]

5.11.4.2.1 P2X and P2Y receptor modulators

There are seven subtypes of P2X ion channel receptors (P2X1–7) and eight subtypes of G protein-coupled P2Y receptors, many of which are expressed on immune cells in the TME. Elevated eATP can activate the P2 receptors on DCs to enhance specific $CD8^+$ T cell cytotoxicity.[87] Activation of P2X7R is believed to be an important proinflammatory pathway to stimulate the immune response. If so, a P2X7R agonist or an inhibitor of ATP degradation would boost the antitumor immunity. However, in human tumors overexpression of P2X7R is better correlated with promoting tumor growth and progression.[93] Conversely, P2X7R-deficient mice demonstrate accelerated tumor growth and metastatic spreading.[94] Thus the potential impact of a P2X7R agonist on tumor growth remains unclear. The effect of ATP on P2Y11 receptors present on DCs is to change the cytokine profile toward Th2 immunity and in doing so favor immunosuppressive rather than immunostimulatory pathways.[95]

Potent antagonists of P2X7 have been described, exemplified (Fig. 12) by the bio-isosteric compounds dihydro-[1,2,4]triazolo[4,3-a]pyrazin-8(5H)-one **29** (hP2X7 $IC_{50}=0.7$ nM)[96] and 6,7-dihydro-1H-[1,2,3]triazolo[4,5-c]pyridine **30** (hP2X7 $IC_{50}=4.2$ nM)[97] which demonstrate low-nanomolar antagonism in Ca^{2+} efflux FLIPR assays. Since the majority of researchers have been pursuing mood disorders, the focus has been on improving the CNS-penetration of these antagonists. A detailed exploration of the structural determinants for P2X receptor binding has been published by Dal Ben et al.[98] providing insight into the variations between the P2X 1–7 receptors, the differences between human and rat P2X receptors (important for the interpretation of rat models of CNS disorders) and progress toward the synthesis of subtype selective receptor compounds.

Similarly, detailed reviews of P2Y receptor agonists and antagonists by Jacobson et al.[99] highlight the breadth of research into nucleoside and non nucleoside modulators of this large class of GPCRs. For example, structural modifications within an adenosine template can result in conversion of a potent and selective pyrophosphate-based P2Y1 agonist MRS2365 (**31**; P2Y1 $pEC_{50}=9.4$) into a potent and selective diphosphate-based antagonist MRS2500 (**32**; P2Y1 $pIC_{50}=9.0$) (Fig. 13).[100]

The successful synthesis of both selective agonists and antagonists for those P2 receptor subtypes provides hope that this may prove true for the entire receptor family. As such, we may soon have the tools to discern which P2 receptors may have therapeutic utility to boost the immune response to cancer.

5.11.4.2.2 Adenosine receptors (A_1, A_{2A}, A_{2B}, and A_3)

While the overall impact of eATP on the innate immune response in the TME is unclear, the role of its phospho ester hydrolysis product, ADO, is not: ADO is uniformly immunosuppressive.[101] There are four ADO binding G protein-coupled receptors (A_1, A_{2A}, A_{2B}, and A_3) with different affinities for ADO, enabling cellular responses over a range of physiological levels of ADO. Lymphocytes primarily express the A_{2A} or A_{2B} receptors, whereas tumors may express any one or a combination of these four ADO receptors.[102] Due to the low affinity for ADO, the A_{2B} receptor can only initiate signaling when ADO is outside of the normal physiologic range. Both the A_{2A} and A_{2B} receptors are positively coupled to Gs-dependent adenylyl cyclase, leading to increased production of cAMP as the second messenger for intracellular signal transduction.

5.11.4.2.2.1 A_{2A} receptor antagonists

The A_{2A} receptor is widely expressed on leukocytes, including lymphocytes, DCs, NK cells, and T cells, and binding of ADO suppresses the immune functions of these cells.[103] Of particular interest to immune suppression are the regulatory effects of

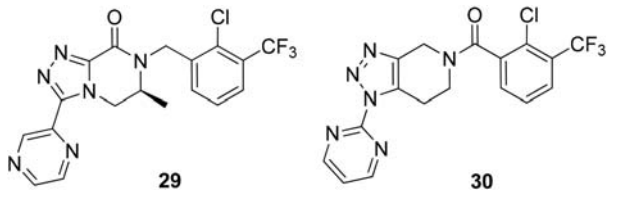

Fig. 12 P2X7 antagonists.

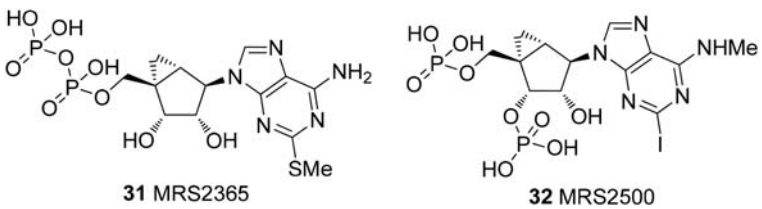

Fig. 13 Conversion of potent P2Y1 agonist into potent and selective P2Y1 antagonist.

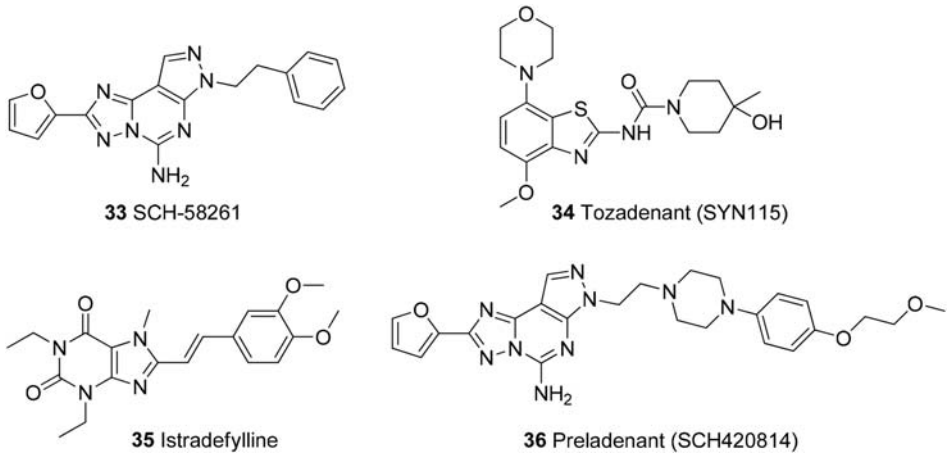

Fig. 14 Selective A_{2A} receptor antagonists.

A_{2A} receptor activation on T cells, in which ADO significantly blunts TCR-mediated cytotoxicity and cytokine production, inhibits T cell proliferation,[27b] and induces the expansion of Tregs that have stronger immunosuppressive activity due to increased expression of CD39, CD73, and CTLA-4.[92]

SCH58261 (**33**) (Fig. 14) is a potent and selective A_{2A} antagonist (bovine A_{2A} $K_i = 2.0$ nM; bovine A_1 $K_i = 201$ nM)[104] which was shown to decrease metastatic spread in murine syngeneic models of metastatic disease (B16F10 melanoma and 4T1.2 breast carcinoma).[105] Furthermore, the combination of an A_{2A} antagonist, either **33** or SYN115 (**34**) (A_{2A} $K_i = 4.9$ nM[106]), with a T cell checkpoint blocker (anti-PD1) was more effective than the individual agents in several murine tumor models.[107] The additional efficacy of an adenosine antagonist with T-cell checkpoint blockade is supportive of a nonredundant role for ADO in the immune response in cancer. Two A_{2A} receptor antagonists, istradefylline (**35**) (A_{2A} $K_i = 12$ nM[106]) and preladenant (**36**) (SCH420814; A_{2A} $K_i = 1.1$ nM[106]), have been studied in phase II and III clinical trials of Parkinson's disease,[106] demonstrating modest efficacy which was sufficient to gain registration approval in Japan for **35**. The preclinical data for A_{2A} antagonists in combination with anti-PD1[108] checkpoint antagonists provide a compelling rationale for testing this combination in the clinic.

5.11.4.2.2.2 A_{2B} receptor antagonists

A_{2B} receptors are expressed at low levels across multiple cell types, but expression is significantly upregulated under hypoxic conditions. The A_{2B} receptor is the least sensitive of the four adenosine receptors, requiring micromolar ADO concentrations that are only achieved under conditions of physiological stress. On classically activated macrophages which release proinflammatory cytokines and are central elements of the cellular immune response, activation of the A_{2B} receptor plays a prominent role in M1 to M2 switching, thereby suppressing the antitumor T cell response and stimulating tumor angiogenesis.[109] Elevated ADO derived from the activity of CD73 also activates A_{2B} receptors on myeloid precursor cells to drive expansion of MDSCs and thereby suppress Teff activity.[110]

The first in vivo demonstration of antitumor activity of a selective A_{2B} receptor antagonist was achieved using intratumoral injections of ATL801 (**37**; A_{2B} $K_i = 19$ nM),[111] to reduce the growth of bladder and breast cancers in mice (Fig. 15).[112] Intratumoral

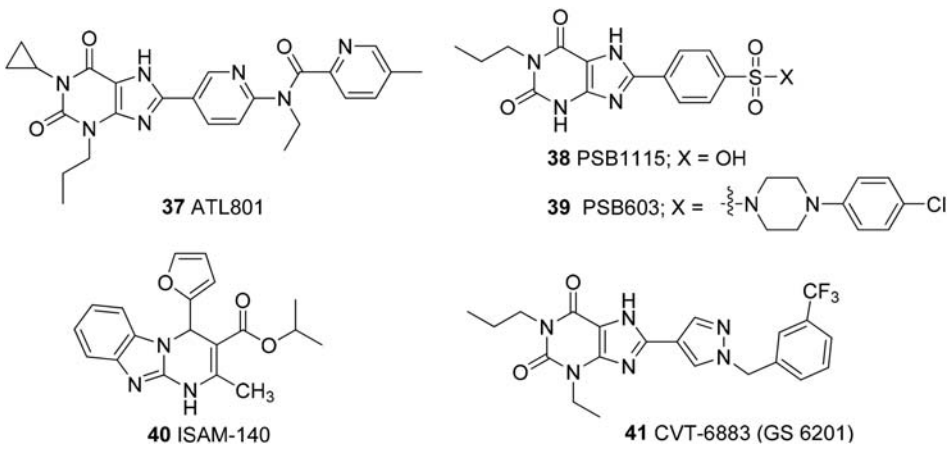

Fig. 15 Selective A_{2B} receptor antagonists.

injection of a different A_{2B} selective antagonist PBS1115 (**38**; A_{2B} $K_i = 53$ nM; A_{2A} $K_i = 24{,}000$ nM)[113] provided in vivo support for an A_{2B} receptor-dependent role in the accumulation of tumor-infiltrating MDSCs.[114] Lastly, both in vitro and in vivo data using the selective A_{2B} antagonist PSB603 (**39**; A_{2B} $K_i = 0.55$ nM; A_{2A} $K_i > 10{,}000$ nM)[115] showed enhanced antitumor immunity due to the inhibition of differentiation of naive $CD4^+$ T cells to Tregs.[116] These results support the prediction that high ADO levels within the TME are sufficient to trigger engagement of low affinity A_{2B} receptors to drive MDSC suppression of tumor immunity and differentiate naive T cells into a Treg suppressive lineage. Researchers from Spain and Sweden synthesized and screened libraries of 3,4-dihydropyrimidin-2(1H)-ones derived through the Biginelli condensation resulting in potent and selective A_{2B} antagonists exemplified by compound ISAM-140 (**40**; A_{2B} $K_i = 3.5$ nM; $A_1/A_{2A}/A_3$ $K_i > 10{,}000$ nM).[117] Several groups are pursuing the clinical development of A_{2B} antagonists for antiinflammatory indications (inflammatory bowel disease [IBD] and chronic obstructive pulmonary disease [COPD]) with one selective antagonist CVT-6883 (**41**; A_{2B} $K_i = 22$ nM; A_{2A} $K_i = 3280$ nM),[118] deemed well tolerated in phase I safety trials.[118]

5.11.4.2.3 ATP metabolism: CD73 and CD39 nucleotidases

The homeostatic extracellular concentration of ADO is low (20–200 nM), but can quickly rise (1000–10,000 nM) under stress.[88,101,119] Such rapid changes require robust mechanisms to synthesize and degrade ADO. The primary pathway for the generation of ADO in the TME is through the sequential phosphate ester hydrolysis of ATP by two ectonucleotidases, CD39 and CD73. Both CD39 and CD73 are plasma membrane anchored phosphatases with active sites that face outward into the extracellular environment.[120]

5.11.4.2.3.1 ENTPD1/CD39 (NTPDase1)

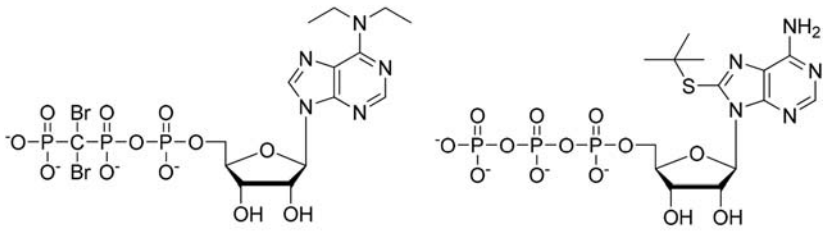
CD39 is expressed on the surface of endothelial cells and subsets of leukocytes, particularly on B cells. CD39 converts eATP first to ADP and then, without release, ADP is converted in a second step to AMP. There are multiple lines of evidence linking elevated CD39 expression to immune suppression and increased tumor susceptibility.[21,27a,b,121] Small molecule inhibitors of CD39 have been used to provide evidence for the CD39 involvement in the production of ADO. ATP-analog ARL 67176 (**42**) is a competitive inhibitor of human CD39 with a $K_i = 11$ μM[122] but also has similar activity versus NTPDase3 ($K_i = 18$ μM) and NPP1 ($K_i = 12$ μM). The 8-butylthio analog of ATP (**43**) was also shown to be a modest inhibitor of CD39 ($K_i = 5.6$ μM) (**Fig. 16**).

These tool inhibitors have many shortcomings[123] with marginal selectivity and potency and while they have been used for in vivo experiments, the pharmacokinetic behavior of these compounds has not been characterized. Polyoxotungstate POM-1 (**44**), a high molecular weight metal complex with a reported CD39 $K_i = 2.6$ μM,[124] raises similar concerns. The lack of potent and selective drug-like CD39 inhibitors may be indicative of the challenge posed by this target.

5.11.4.2.3.2 CD73 (ecto-5′-nucleotidase, e5′NT)

CD73 is a GPI-anchored di-Zn^{2+} metallophosphatase specific for the dephosphorylation of purine and pyrimidine ribo- and deoxyribonucleoside monophosphates with adenosine monophosphate (AMP) being the preferred substrate. Consistent with the proposed nonredundant role of CD73 for the conversion of ATP to ADO, CD73 expression is directly regulated by HIF-1α.[125] CD73 is overexpressed in multiple solid tumor types (colorectal, prostate, and breast) and leukemias, and in a number of aggressive and difficult to treat tumors (glioblastoma and ovarian tumors) (**Fig. 11**).[91]

Adenosine 5′-(α,β-methylene)diphosphate (AMPCP, **46**), a nonhydrolysable ADP-mimetic (**45**), is one of the first potent and selective CD73 inhibitors described and has been widely used as a tool to elucidate the role of CD73 catalytic activity in suppressing immune responses to cancer (**Fig. 17**). In vitro, 40–100 μM concentrations of **46** block ADO production by Tregs,[126] adenosine-dependent chemotaxis of human breast tumor 4T1.2 cells,[127] and glioma derived adenosine-mediated suppression of Teff cell proliferation.[128] Several research groups have published in vivo results showing that **46** (20 mg kg^{-1}, either intraperitoneal or intratumoral injection) reduces tumor growth rates, cytokine production, and metastasis in B16 melanoma.[127,129] A search for more potent AMPCP-derived antagonists resulted in a number of modifications such as the *N*-benzyl analog compound **48**,[130] which is



$Na_6[H_2W_{12}O_{40}].21H_2O$

44 POM-1

Fig. 16 CD39 inhibitors.

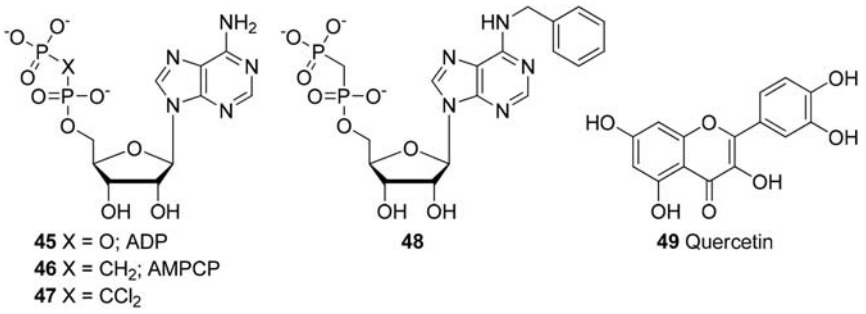


Fig. 17 CD73 inhibitors.

reported to have a K_i for human CD73 of 2.2 nM relative to 88 nM for **46**. The same authors also investigated modifications at the methylene bridge of the nonhydrolysable diphosphate linker, with the best being the α,α-dichloro group, compound **47** having a $K_i = 292$ nM versus rat CD73, showing no improvement over **46** (rat CD73 $K_i = 197$ nM). The availability of active recombinant soluble CD73 has encouraged several groups to develop moderate to high throughput assays suitable for diversity screening to discover new inhibitor classes.[131] The X-ray structure of both free and inhibitor-bound (**46**) forms of human CD73 have recently been published.[132] In the presence of **46**, CD73 adopts a closed conformation bringing the purine binding pocket adjacent to the catalytic zinc centers (**Fig. 18**). This form should mimic relatively closely the state of CD73 when phospho-hydrolysis occurs. Pivoting around the linkage of the two CD73 domains results in an open form of the enzyme.[132] This opening and closing of CD73 allowing reactant to enter; closure to allow catalysis to occur; then reopening to release product must occur rapidly given the high Kcat for this enzyme.[133]

The poly-phenolic compound quercetin (**49**) has been shown to inhibit the conversion of AMP to adenosine by the U138MG glioma cell line ($IC_{50} = 45$ μM)[36] and in the T24 human bladder cancer cell line (48% inhibition at 100 μM after 72 h).[134] This may be due to direct inhibition of CD73 catalysis, disruption of CD73 association with membranes, negative modulation of CD73 mRNA levels, or a combination of the above.[36] That said, a PubMed search for **49** performed in 2016 returned over 13,000 hits referring to a plethora of diverse biological effects, therefore forming conclusions from activities displayed by such molecules should be cautioned against. With the required discovery tools available, further progress in this area may soon be forthcoming.[135]

5.11.4.2.4 COX-2 and EP2/EP4 receptor antagonists

Contrary to the historic observation by Coley that *acute* activation of the immune system stimulates an immune response to cancer,[2] there is an abundant literature linking *chronic* inflammation to tumor promotion and progression.[136] Treatment of IBD and ulcerative colitis patients with NSAIDS (either nonselective COX-1/2 or selective COX-2 inhibitors) slows disease progression. Long-term prophylactic treatment with either nonselective COX-1/2 inhibitors such as indomethacin (**50**) or COX-2 selective

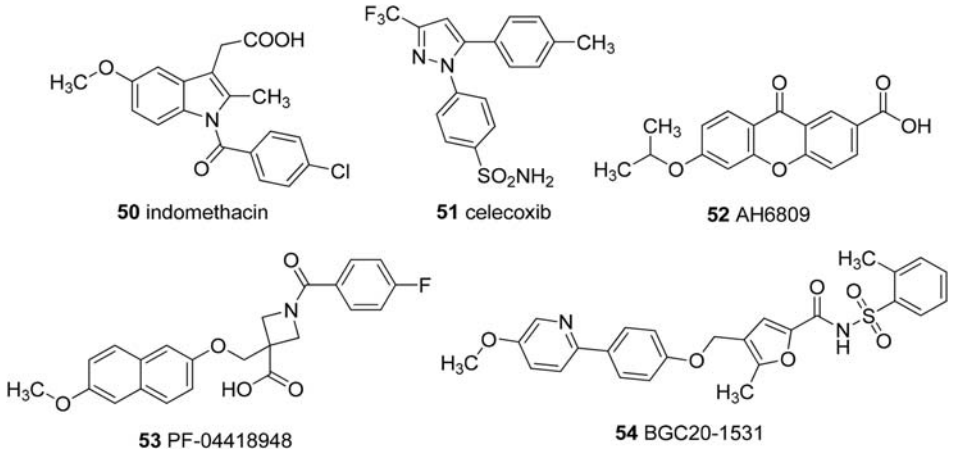

Fig. 19 COX1/2 and EP2/4 antagonists.

inhibitors such as celecoxib (**51**) (COX-2 $IC_{50} = 0.04\ \mu M$; COX-1 $IC_{50} = 15\ \mu M$)[137] led to the regression of adenomas.[138] Prostaglandin E2 (PGE2), a metabolite of COX-2, has direct effects on the immune system favoring a proinflammatory (Th1) immune response acutely,[139] whereas sustained levels enhance the activity of multiple immunosuppressor cells (Fig. 19).[140]

PGE2 signals through a set of four G protein-coupled receptors (EP1–4) which are coupled to different signal transduction pathways. In lymphocytes, PGE2 activation of the EP2 and EP4 receptors is positively coupled to adenylyl cyclase leading to elevated cAMP and subsequent activation of PKA.[141] Treatment of human Tregs with either a nonselective COX inhibitor **50** or an EP2 receptor antagonist AH6809 (**52**; EP2 $K_i = 1150$ nM)[142] decreased Treg-mediated suppression, whereas a selective EP4 receptor antagonist had no effect.[143] As demonstrated by the use of selective EP receptor antagonists, the production of immunosuppressive TGFβ by MDSCs requires the EP2 receptor or a combination of EP2 and EP4 receptors.[144] In murine splenic NK cells, which express all four PGE2 receptors, a selective EP4 agonist inhibited IFN-γ production, whereas selective EP1–3 agonists did not.[144a] These results implicate elevated cAMP as the primary signal leading to immunosuppression, irrespective of which EP receptor is predominant (EP2 or EP4).

Selective PGE2 receptor antagonists have recently been studied clinically for a variety of nononcology indications. Among these agents are selective EP2 antagonists such as compound PF-04418948 (**53**; EP2 $K_i = 16$ nM; cAMP functional assay; EP2 = 1.8 nM; EP1, -2 and -3 > 10,000 nM)[142,145] and EP4 antagonists such as BGC20-1531 (**54**; EP4 $K_i = 12$ nM; EP1–3 > 10,000 nM).[146] Thus far the direct effects of EP antagonists on tumor proliferation and angiogenesis have been the focus of preclinically investigations, but with the recent successes in immuno-oncology and a growing literature highlighting the role of EP signaling in immune tolerance, this emphasis may shift to immune regulation and extend into clinical investigations.[144a]

Upon activation of ADO (A_{2A} and A_{2B}) and PGE2 (EP2 and EP4) receptors, adenylyl cyclase is activated to produce cyclic AMP (cAMP), as a common second messenger. Of the nine transmembrane bound forms of adenylyl cyclase, AC VII is the isoform known to be most highly expressed in lymphocytes and macrophages.[147] The convergence of the ADO and PGE2 pathways on a single isoform of adenylyl cyclase that is preferentially associated with the hematopoietic linage provides an opportunity to block both immunosuppressive pathways with a single agent.[148] Isoform-selective inhibition of AC VII is therefore highly appealing in principle; however, there are currently no known potent, isotype-selective inhibitors for any of the AC isoforms.[149] The availability of structural data for soluble adenylyl cyclases[150] and comparison with the transmembrane ACs holds promise for the future realization of potent and selective AC inhibitors.

5.11.4.3 Pattern Recognition Receptors (PRRs)

The innate immune response to microbial infection relies on a network of pattern recognition receptors that recognize pathogen-associated molecular patterns (PAMPs) as "danger signals" to mobilize both the innate and adaptive immune response to eliminate the invading organism and restore homeostasis. The most well-studied surveillance receptors for bacteria and fungi are the Toll-like receptors (TLRs), which reside on plasma or endosomal membranes.[151] TLRs are expressed on antigen-presenting immune cells, such as monocytes/macrophages, B cells, neutrophils, dendritic cells, and on epithelial cells. TLRs are integral transmembrane glycoproteins possessing either an extracellular (TLR1, -2, -4, -5, -6, and -10) or luminal (TLR3, -7, -8, and -9) ligand-binding domain and a cytoplasmic signaling Toll/interleukin-1 (IL-1) receptor homology domain. They mainly recognize evolutionarily conserved structures on pathogens, such cell surface components of bacteria [lipopolysaccharide (TLR4) and flagellin (TLR5)] or fungi [zymosan (TLR2) and mannan (TLR4)]. Viruses require intracellular access for replication; hence the immune system relies on intracellular receptors to sense these foreign components and mount a defensive response. Multiple sensing mechanisms have evolved to fulfill this role. In the TLR family viral RNAs are recognized by TLR3 (membrane) or TLR7/8 (endosomal) and unmethylated CpG DNA from multiple classes of pathogens can be detected by endosomal TLR9. Recently, the cyclic GMP–AMP synthase (cGAS)/STING

pathway has emerged as an additional intracellular sensing mechanism.[152] When engaged, these PRRs trigger both a proinflammatory (IL-1, TNFα) cytokine response and an innate adaptive type I interferon response. The balance of these pathways determines the nature of the immune surveillance. TLRs and STING are also expressed on tumor cells. The outcome of either TLR or STING stimulation depends which receptors are expressed and the tumor type and can either inhibit or promote tumor growth.[153]

TLR homo- or hetero-dimerization or the formation of higher oligomers upon binding of an agonist is required to initiate the signaling cascade leading to the expression of immunostimulatory cytokines and a subsequent activation of the immune response. The crystal structures of TLR family members have revealed that these receptors share many structural elements, such as the "question mark" or horseshoe-shaped motif containing several leucine-rich repeat units (LRRs) around which two TLRs dimerize.[154] These structures have also revealed the interactions required for ligand binding and signaling and offer promising starting points for the rationale design of new ligands. Until recently small molecule agonists had only been described for TLRs 7/8, thereby limiting the development and type of agonists that have entered into clinical trials. Our discussion of TLR agonist is restricted to the receptors that bind traditional small molecules (TLR7/8 and TLR4) or for which synthetic or semisynthetic ligands are available and have allowed the development of SAR (TLR4 and TLR9).

5.11.4.3.1 TLR7/8

In 2002 Hemmi and coworkers determined TLR7 to be the target of the imidazoquinoline immune response modifiers imiquimod (**55**) and resiquimod (**56**) (Fig. 20).[155] Subsequently both TLR7 and TLR8, which are endosomal TLRs binding the single-stranded RNAs of RNA viruses, were found to be activated by this class of immune modulators molecules. An NF-κB-luciferase reporter assay in HEK 293 cells cotransfected with either TLR7 or TLR8 was first used to identify that 3M-001 (**57**) selectivity activates TLR7 where as 3M-002 (**58**) selectively activates TLR8.[156] Functional differences for the selective stimulation of these receptors were determined in human PBMCs and purified cellular subtypes derived from PBMCs. IFNα is predominately associated with TRL7 activation which is most predominate in plasmoid dendritic cells (pDCs) while TNFα and other proinflammatory cytokines are associated with TLR8 activation in myeloid dendritic cells, monocytes, and monocyte-derived dendritic cells.[156] The luciferase reporter assays are well suited for routine screening and HTS configuration, but they should not be used in place of functional assays which can detect subtle changes in receptor signaling that can be missed in reporter assays. Instead cytokine profiles in human PBMCs[157] are believed to provide a more physiologically relevant readout for activation of the two pathways.

By phylogenetic analysis TLR7, TLR8, and TLR9 form a subfamily within the TLRs. All three bind to single-stranded nucleic acids and as noted above require dimerization to signal. Both TLR7 and TLR8 exist as preformed dimers and are believed to recognize viral uridine- and guanosine-rich ssRNAs. In addition to the imidazoquinolines, guanosine nucleotide analogs, such as loxoribine (**59**) (Fig. 21), are weak agonists which suggest that these small heterocycles are being recognized as mimetics of the natural ligand.

68		n.d.	9

Fig. 22 Analysis of ligand cocrystal structures (**64–67**) bound to the ectodomain of human TLR8 used to design potent TLR8 selective agonist **68**.

The crystal structures of TLR8 with and without the imidazoquinoline ligand have revealed that the binding of two imidazoquinoline ligands (2:2 complex) induces a conformational change which brings the TIR domains together to activate signaling.[158] X-ray structures imply that activation by the natural ssRNA ligand does not involve binding of the intact oligomer but instead two ssRNA degradation products: uridine which was found to occupy the same site as the imidazoquinoline ligands and a short oligonucleotide which binds at a second site on the receptor thus forming a 2:2:2 complex.[159] Given the dual TLR7/8 agonists properties of the early ligands, one presumes that TLR7 activation follows a similar mechanism, but without an X-ray structure this remains speculative.

Until the 2013 publication of the first ligand-TLR8 structures optimization of potency and selectivity relied upon traditional SAR studies. Functional cellular assays examining the relative potency for induction of IFNα (TLR7) versus TNFα (TLR8) continues to be the preferred method to judge selectivity. New scaffolds discovered include the TLR7 selective 8-oxopurines SM360320 (**60**)[160] which are structural variants of the imidazoquinolines retaining a hydrogen bond donor–acceptor pair and the TLR8 selective benzazepine VTX-2337 (**61**).[161]

One of the first applications of the TLR8 X-ray structural data was the development of a homology model of TLR7 and a docking pose for GS-9620 (**62**) consistent with its high TLR7 selectivity.[162] The new 6,6-scaffold of **62** was derived by ring expansion of the 6,5-ring system of the 8-oxopurine scaffold present in **60** while retaining the two donor acceptor pairs. Further expansion to a 6,7-scaffold resulted in loss of all activity. Several research groups have noted the importance of an N-9 basic group to afford high potency and selectivity for IFNα versus TNF. This cytokine profile is in part a reflection of TLR7 versus TLR8 selectivity of these agonists. An addition consideration is the highly acidic nature of the endosomal compartment which drives endosomal enrichment of these basic amines resulting in enhanced potency/selectivity.[157] For example, **62** has a minimal effective concentration (MEC) for stimulation of IFNα in hPBMCs of 1 nM and is a 100-fold selective versus TNFα compared with a 1000 nM MEC for stimulation of IFNα and 0.3-fold selectivity for TNFα for the analog of **62** lacking the pyrrolidinyl methyl.

The research group of Prof David at the University of Kansas published their initial exploration of TLR7 SAR in 2009. More recently, the emphasis has shifted to TLR8 selective agonist developed using traditional SAR and the application of X-ray structure guided rationale design (Fig. 22). The cocrystal structure of furoquinoline (**64**), a selective TLR8 agonist derived from the imidazoquinoline scaffold, revealed a key salt bridge between the exocyclic 4-amino and Asp543 and suggested disconnections at the furan would be tolerated. The resulting simple bicyclic 3-pentylquinolin-2-amine (**65**) was eightfold more potent ($EC_{50}=200$ nM) and retained the high TLR8 selectivity of **64**.[163] Further structure-guided optimization of this reduced-complexity scaffold was based upon an analysis of the TLR8 cocrystal structures for the *meta*- and *para*-N1-aminomethylbenzyl-substituted imidazoquinolines (**66** and **67**). The differing selectivity and potency of these compounds suggested that the introduction of a basic amine replacement for benzylic amine on the quinolin-2-amine scaffold of **65** could lead to enhanced potency. The resulting optimized n-pentylamine (**68**) is the most potent and selective TLR8 agonist described thus far.[164]

5.11.4.3.2 TLR4

TLR4 was discovered as the primary target mediating the potent inflammatory response to the lipopolysaccharide (LPS) component of the endotoxin produced by gram-negative bacteria. It is the most studied TLR family member. TLR4 is activated by a broad variety of components from infectious organisms, such as fungal mannan and viral glyocoproteins. HMGB1 is an endogenous TLR4-activating DAMP and a key component of immunogenic cell death. HMGB1 release and subsequent activation of TLR4 promotes tumor antigen recognition.[17] The activation by LPS involves the transfer of the TLR4/LPS complex from CD14 to MD-2 resulting in an LPS/MD-2/TLR4 dimeric complex. This dimeric complex, which has been studied both by crystallography and NMR, has 5 of the 6 acyl lipid chains of LPS binding into a hydrophobic pocket on MD-2.[165] The electrostatic interaction of the 4-phosphate of monophosphoryl lipid A (MPLA, **70**) (Fig. 23) with arginine and lysine residues of TLR4 appears critical for activity and explains this requirement for agonist activity in other LPS derivatives.[166] The formation of this intracellular complex

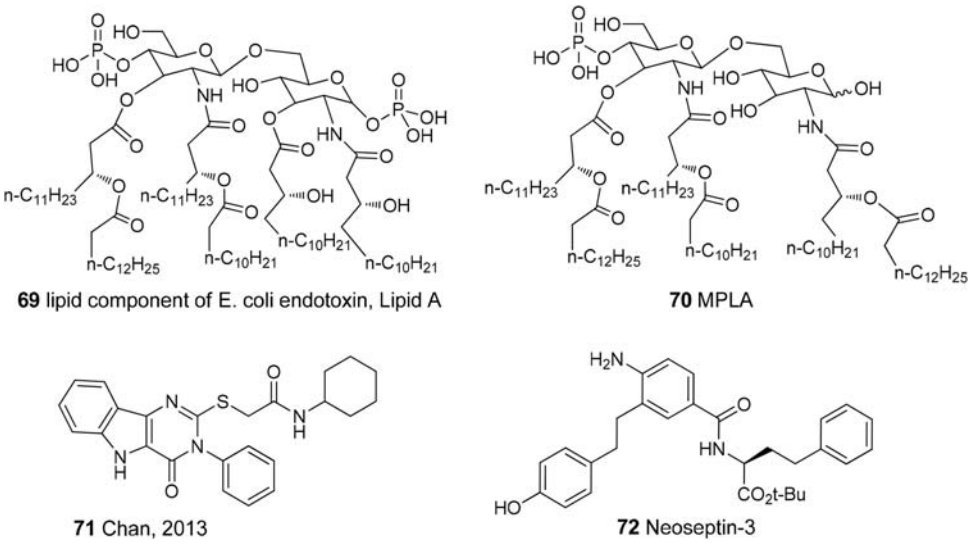

Fig. 23 TLR4 agonist ligands.

activates proinflammatory responses mediated by MyD88 signaling and a TRIF-dependent pathway leading to type I IFN production. Semisynthetic analogs of lipid A (**69**), such **70** have been pursued in order to favor the TRIF over the MyD88 pathway and thereby reduce toxicity and also to improve the pharmaceutical properties.[165]

Until recently all the reported small molecule agonists of TLR4 were modified Lipid A analogs. However, using cellular screens directed to find novel immune stimulants several new classes of TLR4 ligands have been discovered. In 2013 Chan et al. found substituted pyrimido[5,4-b]indoles as potent NFκB activators employing a cell-based high-throughput screen (HTS). The most potent hit compound (**71**) selectively stimulated TLR4 and no other TLR.[167] This same research group of Cottam at the Moores Cancer Center has reported on a second 4-aminoquinazoline hit from HTS. Interestingly, for this second series, the compounds were human but not mouse active. There was no activity with other TLRs and the TLR4 activation was MD-2 dependent and CD14 independent. Computational studies for both hit series indicated that the compounds bind primarily to human MD-2 in the TLR4/MD-2 dimeric complex.[168] Yet a third series has been reported by the Boger group at Scripps Research Institute from screening of compounds libraries for TNFα stimulatory activity in primary mouse peritoneal macrophage cultures. The crystal structure the murine TLR4/MD-2/Neoseptin-3 (**72**) asymmetrical dimer revealed binding within the hydrophobic pocket of MD-2, inducing an active receptor complex similar to that induced by lipid A. Compounds **72** and **69** utilize different residues to achieve receptor activation; demonstrating that TLR4/MD-2 agonists need not mimic the binding of LPS. The Neoseptins, which were discovered by screening against mouse TLR4/MD-2, were in not active the human TLR4. Hence agonist activity for these nonnative ligands, which may utilize nonconserved binding motifs, is not necessarily maintained across species.[169]

5.11.4.3.3 TLR9

TLR9 recognizes bacterial and viral DNA containing the cytosine–phosphate–guanine (CpG) dideoxynucleotide motif. Viral DNA is not methylated and methylated CpG oligos demonstrate reduced binding affinity and ability to activate signaling. X-ray crystal structures of TLR9 with a set of agonist and antagonist DNA-12mers provide a structural basis for understanding receptor activation.[170] Agonistic CpG-DNA binds to form a symmetrical TLR9–CpG-single-stranded DNA complex with 2:2 stoichiometry in which the agonistic DNA binds to two equivalent positions in the dimer, forming a bridge to link both of the TLR9 monomers. Antagonist DNA binds as a monomeric 1:1 complex with TLR9 partially overlapped the agonist binding site. Hence as has been noted for all other TLRs, agonism requires formation of a conformationally active dimer. The unique requirement for agonist bridging to "glue" the TLR9 monomers together to form an active complex may explain why non-DNA agonists have yet to be discovered. Conversely, this new structural information should facilitate the design of non-DNA agonist of TLR9.

5.11.4.3.4 TLR agonist in development for IO

Because of the crucial role played by the TLRs in the innate immune response to infectious pathogens, selective agonists have found utility in multiple indications. For example, as vaccine adjutants to promote maturation of APCs, such as dendritic cells, which in turn directs the induction of adaptive immune responses. TLR agonists have also been used as antiviral and anticancer agents. The imidazoquinoline imiquimod (**55**) was first approved in 1997 as a 5% topical cream for the treatment warts caused by human papillomavirus (HPV) infection and in 2004 FDA approval was obtained for the treatment of superficial basal cell carcinoma. At the time of its initial approval the target (TLR7/8 agonism) responsible for its mechanism of action was unknown and no previous antiviral therapy had been approved that induced the production of antiviral cytokines that enhanced cellular immunity. Our present understanding of TLR7/TLR8 agonists is that the antitumor effects are primarily mediated by activation of DC and NK cells

to directly kill tumor cells, and by the suppression of Tregs.[153a] Compound **57** is a more potent and more selective activator of TLR7 than **55**. In vitro studies have shown that **57** directly activates APCs, such as dendritic cells. The improved solubility of **57** at physiologic pH facilitated i.v. formulations which were used in a phase I trial.[171] Motolimod (**61**) is a small-molecule TLR agonist with 30-fold selectivity for TLR8 over TLR7. The high TLR8 selectivity coupled with the preferential expression of TLR8 in monocytes and myeloid dendritic cells produces a unique pattern of cytokines which activate NK cells and augment ADCC, a property not shared by TLR7 or TLR9 agonist.[161] A phase I trial is complete and phase II trials are ongoing.[172]

In the syngeneic CT-26 tumor model the antitumor response to chemotherapy was dependent on expression of TLR4 in dendritic cells which provided the "danger signal" to break tumor antigen tolerance.[173] This dependence was correlated to the release of high levels of HMGB1 and HSP70, known activators of TLR4. Compound OM-174 (structure not shown), a TLR4 agonist in which three of the six lipid tails of Lipid A have been removed, induced the complete regression of tumors and hemorrhagic ascites in 90% of the tumor bearing rats in a colon cancer metastasis model.[174] Phase I i.v. infusion repeat dose (given twice weekly for a total of 15 doses) studies have determined the maximally tolerated dose.[175] MPLA (**70**) and aminoalkyl glucosamine phosphates have been used as vaccine adjuvants, including a therapeutic cancer vaccine based on the tumor-specific protein melanoma-associated antigen 3 (MAGE-A3).[176] TLR9 agonists induce type 1 IFN secretion in DCs, promoting a Th1 response of cytotoxic DC, NK, and T cells as well as promoting M2 to M1 switching,[177] all of which contribute to tumor-specific immune responses and the reversal of immune suppression. A number of CpG-containing TLR9 agonists (IMO-2055, CPG 7909, and MGN1703; structures not shown) have been evaluated in Phase I/II trials in solid tumors, often in combination with chemotherapy.[153a] To date there has been no clear clinical demonstration of a standalone benefit using any of these systemically administered TLR agonists.

5.11.4.3.5 STING

In 1991 Professors Baguley and Denny of the Cancer Society Research Center, University of Auckland published on a series of xanthenone acetic acids that they were pursing to develop anticancer agents targeting the immature vasculature of solid tumors.[178] In a series of subsequent publications they found that one of these compounds, 5,6-dimethylxanthenone 4-acetic acid (DMXAA, **75**) (Fig. 24), following a single i.p. dose totally eradicated murine MC38 tumors. In addition to the acute effects on tumor vasculature, **75** activated NK cells and induced the release of cytokines, such as TNFα and IFNβ from TAMs. In 2013, Conlon et al. demonstrated the induction of IFNβ to be dependent on the direct binding of **75** to STING.[179]

The recently elucidated STING (stimulator of interferon genes) pathway of cytosolic DNA sensing is an innate immune mechanism driving type I IFN production with particular relevance to the recognition of tumor antigens. STING is an adaptor protein located on the endoplasmic reticulum. Upon binding of a cyclic dinucleotide (CDN) agonist STING dimerizes and binds to TANK-binding kinase 1 (TBK1). This complex then traffics to the perinuclear regions of the cells facilitating TBK1 phosphorylation of transcription factors, IRF3 and NF-κB, leading, respectively, to type I interferon production and proinflammatory cytokine synthesis.[180] The natural mammalian agonist, 2′3′-cGAMP (**73**), is produced by the enzyme cyclic GMP–AMP synthase (cGAS),

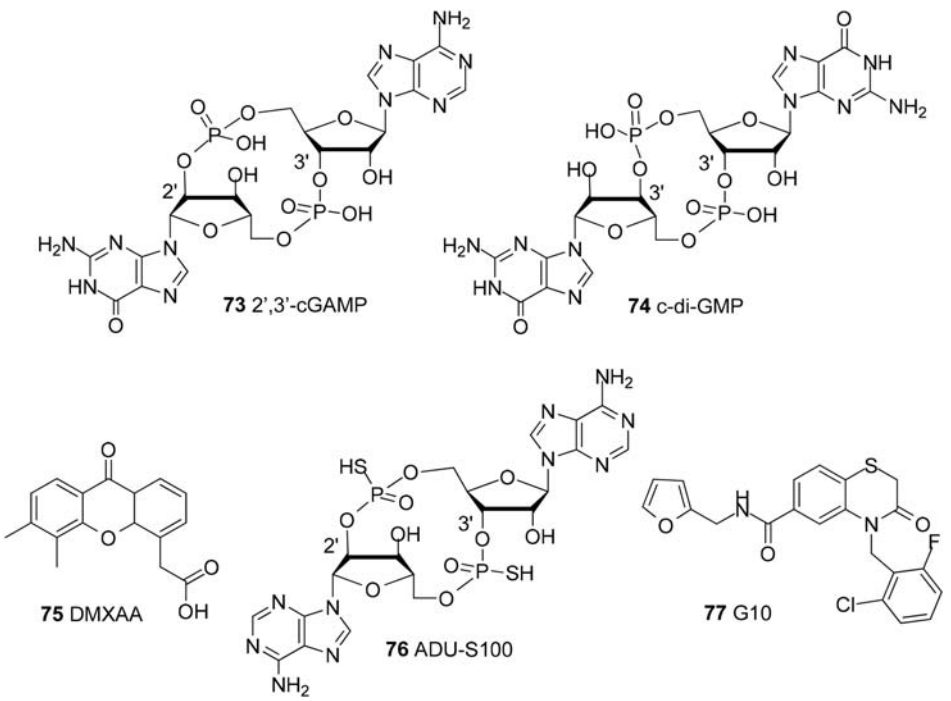

Fig. 24 STING ligands.

which uses ATP and GTP as substrates to produce a CDN with one 2′,5′-phosphodiester linkage and one canonical 3′,5′ linkage. In cells at homeostasis there exist regulatory mechanisms to maintain low levels of cytosolic dsDNA. When the concentration of cytosolic DNA rises sufficiently to form dsDNA-cGAS complex, catalytic active enzyme is formed and the synthesis of **73** is initiated. The recognition of cytosolic DNA appears to be sequence-independent; hence signaling can be initiated by either microbial or mammalian dsDNAs. This mechanism is fundamentally distinct from TLR9, which recognizes unmethylated CpG dsDNAs that are produced only by microbial organisms. Acting in its role as a sentinel to fight off microbial invasion, STING can detect both DNA and RNA viruses, as well as, bacterial DNA. Additionally, bacterially produced second messenger 3′3′-CDNs also bind and activate mammalian STING.[181] It was the X-ray crystallographic elucidation of the binding mode for bacterial CDN (c-di-GMP, **74**),[182] which subsequently led to discovery of cGAS and the unique mammalian ligand **73**.[183] Depending on the organism, the activation of the STING pathway by bacterial CDNs can either enlist the immune system to fight the infection or in some cases to facilitate survival of the bacteria.[184] Several features of the STING pathway suggest that, relative to other PRRs, STING may be uniquely endowed with the ability to detect and defend against tumor antigen. This premise rests upon: (1) the finding that $CD8a^+$ dendritic cells are the key cells essential for tumor antigen-specific $CD8^+$ T cell priming,[185] (2) this priming is dependent on type I IFN production,[185] and (3) the production of type I interferon in response to tumor antigen is uniquely dependent on detection of tumor-derived DNA by STING and not other PRRs.[186] Thus the DNA-cGAS-STING-IFNβ pathway forms the bridge between tumor sensing and a spontaneous adaptive T cell responses. If the STING pathway is an important defense blocking tumorigenesis then one might anticipate that the deregulation of STING signaling could be a trait acquired by tumor cells to avoid detection. Such deregulation has been recently been demonstrated in a majority of the 11 colorectal carcinoma cell lines that were studied which displayed a loss of IFR3 function. The major defect in these cell lines was a loss of cGAS expression. While this study was restricted to colorectal carcinoma cell lines, it may be that the loss of STING pathway during cancer development is a common theme.[187]

Multiple structures of the C-terminal domain of STING show the protein crystallizes as a symmetrical dimer in both free and ligand bound states. The CDN ligands bind into a V-shaped pocket at the dimer interface and are anchored to STING by a network of hydrogen bonds. Depending on the ligand and STING ortholog, ligand binding can induce a subtle conformational shift of the α2-helices which appears coupled to formation of a cap that completely encompasses the ligand. This observation has led to the suggestion that this "closed" form is the active agonist conformation.[188] While all cyclic-GAMP isomers (3′-3′, 2′-3′, or 3′-3′) have the potential to bind and activate both murine and human STING, for human STING this is dependent on which human allelic variant is tested. Xanthenone **75** binds to murine STING in the same V-shaped pocket as the CDNs with 2 molecules of **75** per STING dimer and shares in common with **73** several key contacts. Specifically the ketone groups of **75** hydrogen bond to the hydroxyl of T266 and the carboxylates are anchored with a salt bridge to the guanidine side chain of R237. For **73**, the free oxygens of the phosphodiesters make both these contacts. Human STING is not activated by and does not bind to **75** and related analogs. This surprising discovery, which was first described by Conlon et al.[179], was traced to a single residue, G230, which is an isoleucine in murine STING.[189]

In 2000 before these discoveries were made, **75** began Phase I clinical trials began in New Zealand. The development of **75** was later continued by Novartis into Phase II/III, but to date the results have been disappointing with the failure of two Phase III trials.[190] While it is clear that **75** has some clinical activity, it is also equally clear that the exciting curative results seen in mouse models did not translate into clinical efficacy, a result which is no doubt attributable to the loss of STING agonism in going from mice to human STING. Several researchers have reported preclinical activity for the endogenous CDN ligand (**73**) in murine tumor models. In the CT-26 syngeneic model, Li et al. reported dose-dependent inhibition of tumor growth following continuous subcutaneous dosing (5, 10, and 20 mg kg^{-1}) for 20 days.[191] In the same MC38 murine model which was used to discover **75**, compound **73** was effective when dosed intratumorally on days 2 and 6 following radiation, but had no activity by itself.[192] The initial radiation results in rapid tumor cell death releasing tumor antigen. The addition of a STING agonist provides the type I IFN signal required to prime DCs to the released antigen and initiate an adoptive T cell-mediated immune response. Other than the CDNs, there are no known human active direct STING agonists. However, there has been a report of a STING pathway agonist G10 (**77**) discovered using an HTS to find IRF3 activators.[193] The differing sensitivity of the human polymorphisms to the natural CDNs ligands and the dramatic species sensitivity to **75** are important considerations for researchers considering the development of STING agonists.

5.11.4.3.6 Targeted delivery of PRR agonists

Preclinically multiple drug delivery strategies are being explored for PRR agonists. The goal of these strategies is to maximize delivery and retention in draining lymph nodes where antigen processing and presentation occurs, as well as, T cell priming and activation. An additional consideration for cancer is to maximize the concentration of the PRR agonist in the tumor, the site where tumor antigen is highest. The reliance on endogenous antigen to provide an immune response when boosted by an external adjuvant has been termed "in situ" vaccination.[194] Hence the use of PRR agonists to stimulate the immune response to cancer can be viewed as a therapeutic vaccination which relies primarily on cytotoxic $CD8^+$ T and NK cells and not B cell antibody-mediated immunity normally associated with a vaccine. One additional consideration for targeted delivery is that systemic activation of PRRs is problematic as the ensuing cytokine response can lead to serious toxicity. For example, bacterial toxic shock is largely the result of the cytokine storm (notably TNFα) resulting from the recognition of bacterial endotoxin by the TLR4 receptor. Clinically the maximum tolerated dose of the TLR agonists is typically associated with fever, injection site pain, transient hypotension, and nausea. The lack

of targeted delivery of these agents likely explains the poor clinical results seen as single agent treatments and the same consideration may also contribute to their limited efficacy when used in combination with other therapies.[195]

The simplest form of targeted delivery is direct injection into the tumor. While intratumoral (i.t.) injection limits the types of human cancers that can be treated, researchers have reported multiple preclinical examples of dramatic improvements in efficacy. Examples of TLR agonists being clinically investigated using i.t. administration are IMO-2125 (TLR9, structure not shown)[196] and 3M-052 (**63**, TLR7/8).[197] The synthetic oligonucleotide IMO-2125 is essentially inactive in murine syngeneic models when dosed s.c., but effects a high number of durable responses when dosed i.t. Furthermore, i.t administered IMO-2125 induced tumors to express PD1, which suggests that efficacy would be improved if PD1 were blocked. The combination of IMO-2125 and anti-PD1 demonstrated additive efficacy in mouse models.[196] Compound **63**, a TLR 7/8 agonist, was designed as a slow release drug depot by attachment of an octadecanoic (stearic) amide to the imidazoquinoline scaffold. Similar to IMO-2125, **63** demonstrated additive activity when combined with immune checkpoint inhibitors.[198] The CDNs have relatively short plasma half-lives and as noted earlier provide modest activity when dosed systemically. The short plasma $T_{1/2}$ appears to be primarily the result of phosphodiesterase cleavage of the 2′-5-phosphate linkage. Li et al. demonstrated that the instability of **73** could be significantly improved by replacement of the nonbridging oxygens of the phosphates with sulfur.[199] The resulting bisphosphothioate analog of 2′,3′-cGAMP had similar affinity for hSTING and was 10-fold more potent at inducing IFNβ secretion from human monocytic THP1 cell line. Corrales et al., at Aduro BioTech, extended this observation by preparing and examining the activity of both cyclic-GAMP and cyclic-diAMP bisphosphothioate analogs. Based upon improved stability, good agonist activity across all the major human STING haplotypes, and potent i.t. antitumor activity, dithio-(Rp,Rp)-[cyclic[A(2′,5′)pA(3′,5′)p] (**76**, ADU-S100) was selected as a clinical development candidate.[200]

The development of targeted delivery approaches applicable to all tumor types is a major challenge. While historically these drug delivery technologies have been explored primarily for the delivery of PRR agonists as traditional vaccine adjuvants, many are equally applicable for the development of "in situ" cancer "vaccines." Discussed below are several examples of such approaches that have some promising preclinical results. Covalent incorporation of Imidazoquinoline TLR7/8 agonist into HPMA polymers improved retention at the injection site and draining lymph nodes. However, in order to achieve enhanced vaccine immunogenicity the efficient uptake of the polymer by APCs was required.[201] In addition to its role in immune regulation, the lymphatic system provides a pathway for the transport of dietary lipids. Serum albumin (SA), which is the primary transporter of fatty acids, is preferentially taken up by lymphatic capillaries leading to an accumulation of SA in draining lymph nodes. The Irvine lab at MIT has proposed the concept of albumin "hitchhiking" to achieve selective lymphatic delivery and demonstrated the selective accumulation of an amphiphilic CpG oligonucleotide TLR9 agonist linked to a lipophilic carrier with high SA binding affinity.[202] The same principle that leads to selective transport of SA into the lymphatic system applies to simple liposomal formulations which have long been known to accumulate in the lymphatic system and tumors. Liposomal formulations of Pacitaxel and Doxorubicin have been developed and approved as cancer chemotherapies which offer reduced toxicity and enhanced efficacy. Liposomal formulations of the STING agonist (c-di-GMP **74**) have recently been reported by two research groups. Encapsulation of **74** within PEGylated lipid nanoparticles redirected **74** to dLNs resulting in enhanced adjuvant effectiveness and reduced systemic cytokine induction.[203] Similarly intravenous administration to mice of **74** encapsulated within YSK05-liposomes efficiently induced the production of IFNβ and activation of NK cells, resulting in a significant antitumor effect in the B16-F10 lung metastasis mouse model.[204]

Going forward, important considerations which relate to pro- and antitumor roles attributed to TLR and STING signaling are the strength of the immune stimulation and the duration of the signal.[195] Chronic infection and inflammation resulting in continuous low-level stimulation promotes cytokine signals that lead to Treg stimulation and impaired Teff cells. Conversely, as outlined above, there is compelling preclinical data to suggest that robust acute activation of the PRRs can enhance APC function leading to amplification and activation of tumor-specific Teff cells. The translational of the impressive findings achieved with targeted delivery into the clinic will require drug discovery researchers to match the right agonist with the right delivery system.

5.11.4.4 Kinase Inhibitors

The introduction of the BCR-ABL kinase inhibitor imatinib for the treatment of CML (2001) marked the beginning of targeted personalized treatment of cancer.[205] Mechanistically, imatinib and most other oncology directed kinase inhibitors target oncogenic drivers of tumor growth and survival. However, as discussed by Adams et al., direct immune regulatory effects have also been observed for some of these inhibitors (KIT and BRAF).[32b] Discussed below are several examples of kinases that regulate innate immunity independent of their action on tumor cells and as such could be important targets for the development of new immuno-oncology therapies.

5.11.4.4.1 TGF-β RI/ALK5 inhibitors

Transforming growth factor-β (TGF-β) belongs to a family of cytokines which acts through serine/threonine receptor kinases. Its activity profile is a complex one. It can act directly on tumor cells to promote an antiproliferative effect, but tumors quickly lose their sensitivity to it even as they overexpress TGF-β. It induces a profound immunosuppressive activity via recruitment and activation of regulatory T cells and pro-metastatic MDSCs, and is thought to be a major contributor to the immunosuppressive TME.[206] It is this aspect of TGF-β activity which has made it an attractive immuno-oncology target.

TGF-β's mechanism of action is every bit as complex as its biology. It is synthesized as a precursor molecule but is cleaved in the Golgi before being secreted. It remains noncovalently associated with the propeptide (latency-associated protein, LAP) and forms

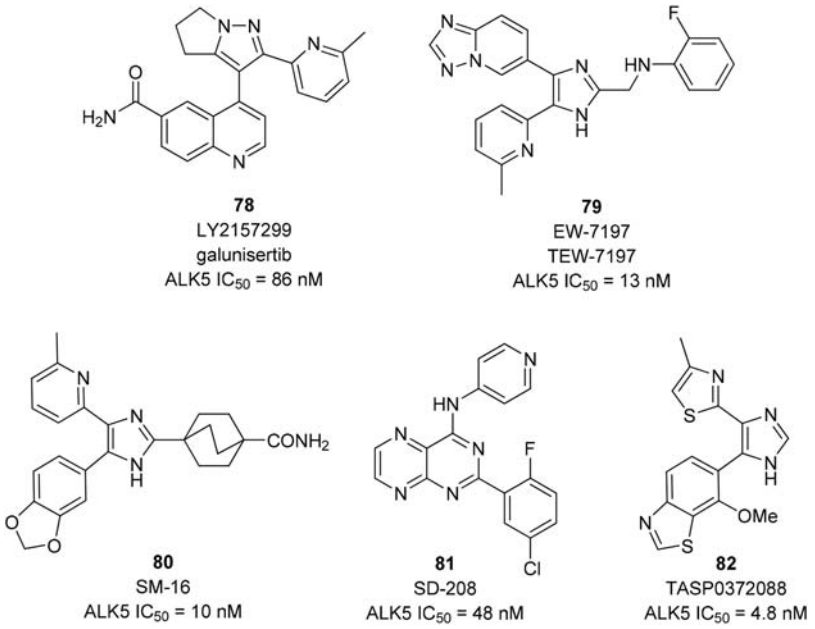

Fig. 25 ALK5 (TGF-β R1) antagonists.

additional interactions with other extracellular proteins (latent transforming growth factor-β binding proteins, LTBPs) to form a complex (large latent complex, LLC), which sequesters the TGF-β. The free cytokine is released from the LLC under a variety of conditions, which include proteolysis as well as interaction with integrins.[207]

There are three TGF-β receptors, two of which are involved in the signal transduction. The catalytically inactive TGF-β RII binds TGF-β, forming a dimeric complex. This is turn recruits the catalytically active TGF-β RI (also known as activin-like receptor kinase 5, ALK5), which then dimerizes and is activated. The active receptor complex is thus a tetramer of two TGF-β RI and two TGF-β RII receptors. The activated complex phosphorylates the downstream targets, the transcription regulators SMAD2 and SMAD3, which then bind to SMAD4 and translocate to the nucleus.[207c] The role of TGF-β RIII is less clear. Like TGF-β RII, it is enzymatically inactive. It is expressed in very high levels and may serve as local reservoir for TGF-β, and it can interact with TGF-β RII to promote formation of the TGF-β RI/TGF-β RII signaling complex.[208]

Because of the strong associations of TGF-β with pathophysiological states, there has been a great deal of activity in the design, synthesis, and evaluation of ALK5 inhibitors, as documented in the cited reviews.[209] While potent and selective ALK5 inhibitors were developed, various toxicities including a worrying hyperplastic valvular heart toxicity was observed in multiple, diverse ALK5 inhibitor chemotypes, suggesting that this was an on-target effect.[210] These results considerably dampened the enthusiasm for further development of ALK5 inhibitors. Researchers at Lilly, noting the reduced cardiac toxicity of LY2157299 (**78**) (Fig. 25), performed an extensive pharmacological study and determined that intermittent dosing or continuous low dosing abrogated the cardiac toxicity in preclinical species,[211] and they were able to advance **78** into clinical trials.[212] Compound **78** is now in Phase III trials both as a single agent and in combination with gemcitabine, and to date has not displayed any Grade 3 or 4 toxicities or cardiotoxicity, while demonstrating a PD response based on measuring reduction in phospho-SMAD2 levels. It is possible that the cardiotoxicity may not be as significant an issue in humans compared with rat or dog.

Researchers at the Ewha Women's University in Seoul developed EW-7197 (**79**), a potent and selective ALK5 inhibitor.[213] They paid particular attention to cardiotoxicity during preclinical development and did not observe any toxicity in rat or dog in 28 day studies at doses 20-fold above pharmacologically active doses. They have just entered Phase I clinical trials in collaboration with MedPacto and OncoVenture.

Compound SM-16 (**80**), developed by Biogen Idec,[214] and SD-208 (**81**), developed by Scios,[215] have been used for preclinical validation of the TGF-β pathway in immune regulation. In a syngeneic AB12 mesothelioma model, **80** has been shown to inhibit tumor growth through $CD8^+$ cytotoxic T cells, with no effect when the model is run in immunodeficient SCID mice.[214] In the same model, **80** also increases the number of tumor infiltrating macrophages, NK cells, and $CD8^+$ CTLs.[216] In an LN-308 glioma model, **81** also increases the number of tumor infiltration NK cells, macrophages, and $CD8^+$ CTLs, and isolated peripheral blood lymphocytes (PBLs) or purified T cells from treated mice show enhanced lytic activity against LN-308 cells in culture compared to PBLs or T cells from naïve mice.[217]

Researchers at Taisho Pharmaceutical Co. have taken a slightly different approach with their ALK5 inhibitor TASP0372088 (**82**). In preclinical work, they have demonstrated a long-lasting PD effect for topically applied **82**.[218] Although their interest is in alopecia rather than an oncology application, topical administration in suitable skin cancers may represent an alternative approach to discharge potential cardiotoxicity risks.

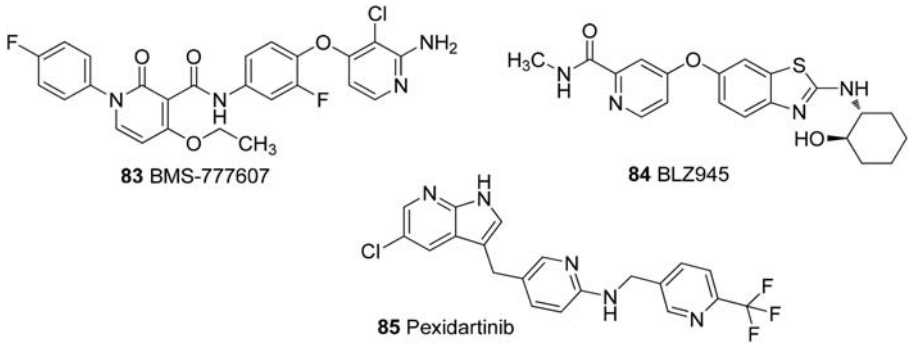

Fig. 26 RON and CSF-R1 inhibitors.

5.11.4.4.2 RON inhibitors

Initially identified on macrophages, RON is a receptor tyrosine kinase belonging to the hepatocyte growth factor receptor family.[219] Activation by macrophage-stimulating protein (MSP) promotes cell proliferation, survival, and chemotaxis.[220] The overexpression of RON protein or activating oncogenic mutants contributes to tumor growth, angiogenesis and chemoresistance.[220] A Met-family-selective inhibitor BMS-777607 (**83**; IC_{50}s for RON/Met/Axl/Tyro3 = 1.8/3.9/1.1/4.3 nM, respectively)[221] has been advanced into clinical trials as tumor-targeted agent (Fig. 26). Loss of RON function has been shown to promote an effective antitumor $CD8^+$ T-cell response which is believed to be the result of repolarization from an M2/TAM phenotype to a proinflammatory M1 macrophage.[222] In the murine PyMT tumor model using cells overexpressing MSP cells **83** significantly reduced outgrowth of lung metastasis, which suggests that clinically Ron inhibitors could prevent the growth of undetectable micrometastases into the overt tumors that are the ultimate cause of cancer mortality.

5.11.4.4.3 CSF-R1 inhibitors

Unlike previous kinase inhibitors which have been advanced primarily based upon their ability to directly inhibit tumor growth, the targeting of innate immunity has been proposed for inhibitors of colony-stimulating factor 1 receptor (CSF-1R) signaling which is exclusively expressed on cells of the myeloid lineage. Within the TME stimulation of CSF-1R promotes M1 to M2 polarization and TAM accumulation which was shown to be blocked by a small molecule CSF-1 kinase inhibitor BLZ945 (**84**; CSF-1R IC_{50} = 1 nM; >3000-fold selective vs 60 tested kinases) in a glioblastoma multiforme[223] and Pexidatrinib (**85**, PLX3397; CSF-1R IC_{50} = 11 nM)[224] in the MMTV-PyMT breast cancer model.[225] The combination of **85** with pacitaxel in the breast cancer model or with checkpoint inhibition (anti-CLT4 or anti-PD1 mAbs) in a mouse pancreatic model[226] afforded a significant increase in response over the monotherapies.

5.11.4.4.4 TAM receptor signaling inhibitors

The TAM (Tyro3/Axl/MerTK) signaling network is a powerful and broadly acting pathway for the inhibition of inflammation and induction of this pathway delimits a cycle of inflammation that governs innate immune system homeostasis.[227] Neutralization of MerTK in allogenic mixed leukocyte reactions, as well as autologous dendritic cell–T cell cultures has been shown to increase T cell proliferation and induce IFN-γ production.[228] Pan-TAM family inhibitors with varying degrees of selectivity, such as the previously mentioned **83** (MerTK IC_{50} = 14 nM),[221] are well known as reviewed by Baladi et al.[229] Recently researchers at UNC have used structure-guided design to discover of a highly potent and selective MerTK inhibitor UNC2881 (**86**; MerTK/Axl/Tyro3 IC_{50} = 4.3/360/250 nM, respectively).[230] Similarly, optimization of an alternative pyrazolopyrimidine scaffold furnished selective MerTK inhibitors such as UNC569 (**87**; MerTK/Axl/Tyro3 IC_{50} = 2.9/37/48 nM, respectively) (Fig. 27).[231] The utility of such selective inhibitors in the clinical setting has yet to be demonstrated.

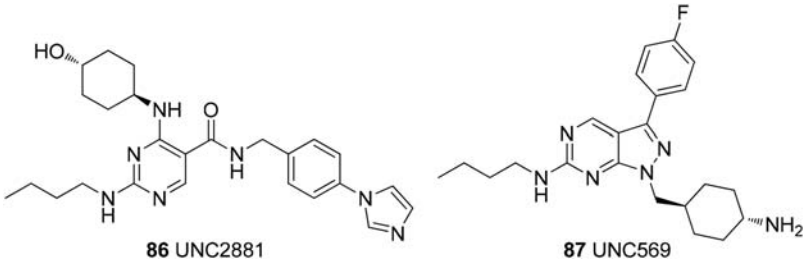

Fig. 27 Selective MerTK inhibitors.

5.11.4.4.5 PI3K inhibitors

The development of inhibitors for oncogenic PI3Kα was an early focus of interventions directed at the lipid kinase family. These initial PI3K inhibitors blocked a number of lipid kinases and were often pan-active across all four human PI3K isoforms. As chemist's knowledge has increased in this area, so has our ability to discover and design more selective lipid kinase inhibitors. While PI3Kα and PI3Kβ are broadly expressed, the expression of PI3Kδ and PI3Kγ is restricted to leukocytes making these isoforms particularly attractive targets to regulate innate and adoptive immunity while minimizing the effects on other tissues. In addition to a potential utility for the treatment of cancer, selective inhibitors are being pursued for the treatment of a variety of immune and inflammatory disorders.[232] Idelalisib (**90**), aPI3Kδ-selective inhibitor, has achieved dramatic responses in certain B cell malignancies, leading to its approval as a second line treatment of chronic lymphocytic leukemia (CLL). In these malignant B cells PI3Kδ activation is a critical component of the B-cell receptor signaling pathway promoting survival and proliferation.[233] Ali et al. have recently uncovered an additional role for PI3Kδ in maintaining the regulatory checkpoint in T cells.[234] The authors propose that immune regulation is due to the effect on cells of the innate immune system differentially impairing Treg and MDSC function, such that the balance shifts from immune tolerance to an enhanced immune response to the tumor. They further speculate that immunoregulatory effects of PI3Kδ inhibition may contribute to the efficacy of idelalisib in CLL and could have potential application across a broad range of solid tumors. PI3Kγ plays an important role in the innate immune response of myeloid cells by mediating integrin (α4β1)-dependent macrophage chemotaxis into tumors. Genetic blockade (p110γ kinase-dead cells/mice) of PI3Kγ in myeloid cells suppressed inflammation, growth, and metastasis of implanted (Lewis lung carcinoma) and spontaneous tumors (PyMT spontaneous breast carcinomas).[235] These results were confirmed with moderately selective PI3Kγ inhibitors that had no direct effect on tumor cells in culture, demonstrating that the PI3Kγ-dependent tumor growth was dependent on myeloid cell which do express PI3Kγ and not a direct effect on the tumor which does not express PI3Kγ.

Similar to protein kinases, ATP-competitive lipid kinase inhibitors make a critical hydrogen bond to a backbone amide NH in the hinge region connecting the upper and lower lobes. The hydrogen bond acceptor on the inhibitor is often a sp^2 heteroaromatic nitrogen, but can also be an oxygen lone pair of a more spatially demanding morpholine hinge binder, as present in the prototypical pan-PI3K inhibitor LY294002 (structure not shown).[236] The spacial placement of the gatekeeper is also slightly different from that of a protein kinase. Both these features contribute to the general observation of nonoverlapping inhibition profiles between these lipid and protein kinase families. Hence while the initial PI3K inhibitors were often pan-active lipid kinase inhibitors, they were in general inactive toward protein kinases. Sadhu et al. reported on the first highly selective PI3Kδ inhibitor (IC87114, **88**) in 2003 (Fig. 28).[237] The structural basis for the selectivity of **88** and PIK-39 (**89**) is the formation of an induced-fit pocket in the phosphate binding P-loop.[238] In the apo enzyme, Met-752 and Trp-760 are packed against each other, but in the presence of idelalisib (**90**) these two residues move 6–7 angstroms apart, opening a hydrophobic specificity pocket.[239] Williams and Shokat present calculations that are in agreement with the X-ray structures which indicate that formation of this specific pocket in the P-loop is energetically more favorable for the delta over the gamma isoform (all PI3K isoforms have these same residues).[240] The orthogonal disposition of the quinazolinone to the plane of the hinge binder motif has been described as a propeller-shaped conformation and is a characteristic of the majority of PI3Kδ selective inhibitors. Examples of propeller-shaped PI3Kδ selectivity inhibitors which utilize the same 4-substituted purine hinge binder are duvelisib (**91**) and AMG-319 (**92**).[241] Related inhibitors employing alternative hinge binders and further modification of the quinazolinone are AM-8508 (**93**)[242] and TGR-1202 (**94**).[243] While the induced-fit pocket favors delta over gamma, researchers at Infinity Pharmaceuticals have recently reported the structure of IPI549 (entire structure not discernible in the view presented in poster) bound to PI3Kγ having this same propeller-binding mode.[244] Hence it does appear that the P-loop of PI3Kγ is sufficiently flexible to make this pocket energetically accessible for the gamma isoform.

While less prevalent, "flat" molecules that do not engage the induced-fit pocket can also achieve high delta selectivity. Examples are **95**,[234] a close analog of GDC-0941 (structure not shown) whose structure in PI3Kδ is known,[240] and the 4,6-diaryl quinazoline (**96**), which was derived using a structure-based design hypothesis from a pan-active PI3K inhibitor (Fig. 29).[245] Interestingly, when cocrystallized in PI3Kδ the structure of **96** revealed a different binding mode from the proposed rationale. Finally, Vertex has reported the design of a highly gamma selective inhibitor (**97**) that does not rely of the induced-fit pocket, but instead on a favorable interaction with glutamate 814, which is unique to the gamma enzyme. This binding mode has not yet been demonstrated in a cocrystal structure.[236]

Clinically trials are currently on going for selective orally active PI3Kδ inhibitors in a number of B-cell-related malignancies and autoimmune disorders.[232] COPD and asthma are also being pursued, but current trials are restricted to inhaled delivery. As might be anticipated dual gamma/delta PI3K inhibition provides potent antiinflammatory activity,[246] but there is concern for increased toxicity as this would effectively block all PI3K activity in lymphocytes. To date no clinical trials have been initiated exploring the potential utility of selective PI3Kδ inhibitors as immunoregulatory agents for solid tumors. Phase I trials in subjects with advanced solid tumors for the first PI3Kγ inhibitor (IPI-549) have recently begun.[244] In mouse syngeneic tumor models IPI-549 demonstrated additive efficacy with both anti-CTLA4 and anti-PD1, providing a strong rationale to pursue this approach in the clinic.

5.11.4.5 Checkpoint Inhibitors

The targeting of T-cell checkpoint receptors and their ligands with inhibitory antibodies has been the first successful therapeutic application of immuno-oncology.[19] Despite the success of antibody-based approaches, there still remains a keen interest in small

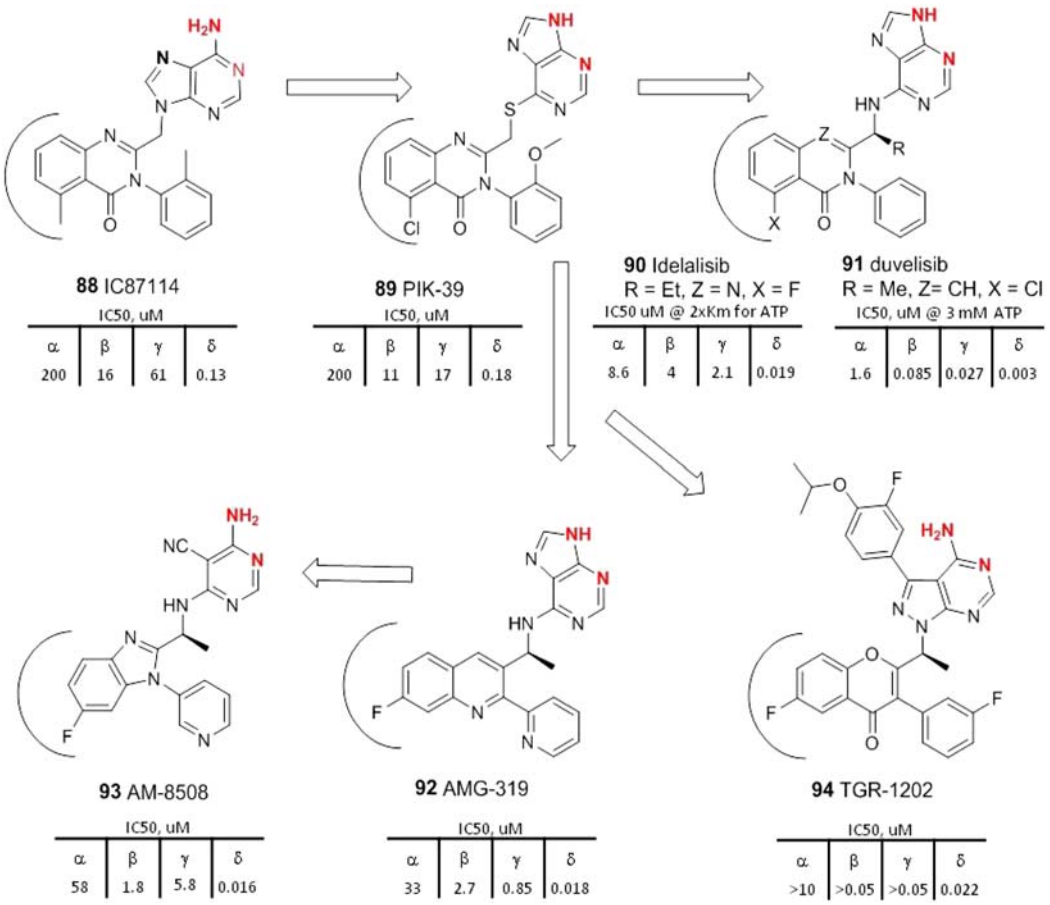

Fig. 28 Progression for discovery of highly selective PI3Kγ inhibitors utilizing the P-loop induced-fit pocket (illustrated with *half circle*). Hinge binder donor–acceptor shown in *bold red*.

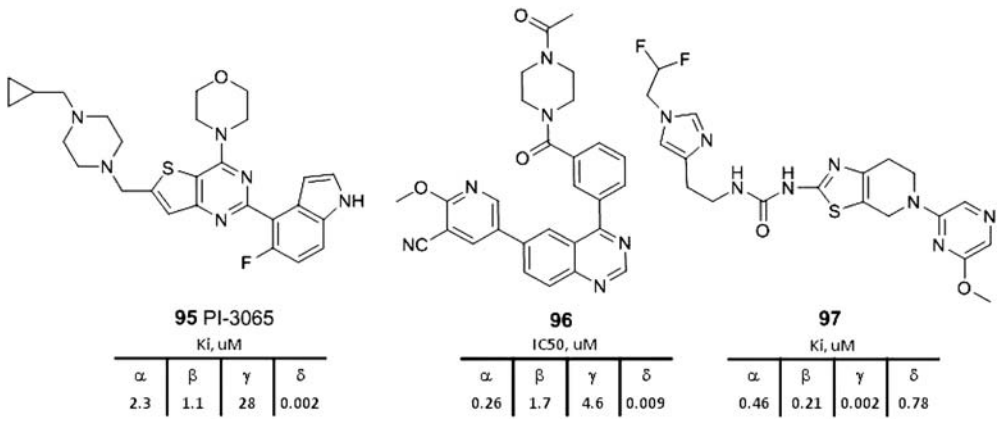

Fig. 29 Isoform-selective PI3K inhibitors.

molecule inhibitors of checkpoint ligand–receptor interactions, which might provide significant advantages in cost of goods, convenience in dosing, and more finely tuned modulation of the immunostimulatory response.

5.11.4.5.1 Small molecule inhibitors

Researchers at Bristol-Myers Squibb recently reported biarylmethoxyphenyl (**99**–**101**) and biarylmethoxpyridiyl (**98**) scaffolds as potent inhibitors of the interaction of PD1 and PD-L1, as measured by a Homogeneous Time-Resolved Fluorescence (HTRF)

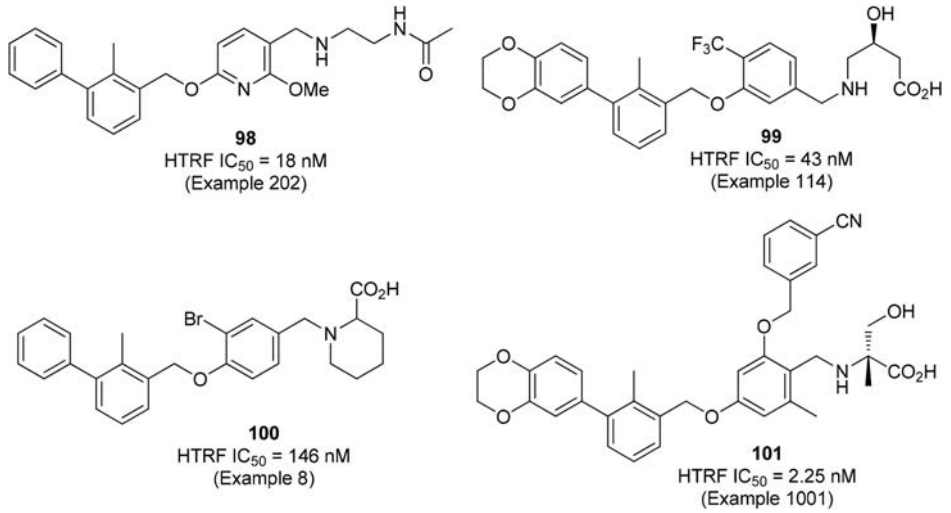

Fig. 30 Small molecule inhibitors of PD1/DP-L1 interaction disclosed by Bristol-Myers Squibb.

binding assay using soluble, extracellular domain constructs of PD1 and PD-L1. Cellular or in vivo data for these compounds has not been reported (Fig. 30).

The mechanism of action of these compounds has been determined by solution studies and X-ray crystallography using soluble, extracellular domain constructs of the two target proteins.[247] The compounds bind selectively to PD-L1 and cause its dimerization, and they are capable of dissociating preformed PD1/PD-L1 complexes. Crystal structures of the PD-L1 dimer complexed with **98** and **100** have been obtained. PD-L1 adopts the same Ig V-type topology that the apo-protein displays. The two PD-L1 monomers are oriented in a C_2 symmetric fashion with the ligand sandwiched between them, as shown in Fig. 31. Interestingly, the binding site of the small molecule is the same as the interaction site with PD1[248] and would completely occlude the interaction of PD1 and PD-L1, as shown in the overlay in Fig. 31B. It is unclear what effect, if any, dimerizing PD-L1 on the presenting tumor cell might have.

Compound **98** binds in a long, cylindrical, hydrophobic cleft at the PD-L1 dimer interface, and most of its interactions with PD-L1 are hydrophobic, as shown in Fig. 32. The biaryl moiety binds in a pocket lined by Ile^{54}, Tyr^{56}, Met^{113}, Ala^{121}, and Tyr^{123} of one monomer and Ile^{54}, Met^{115}, and Ala^{121} of the other monomer. The hydrophobic cylinder is closed across the top by several intermolecular hydrogen bonds between the two monomers. The acetyl ethylene diamine chain projects out of the cylinder toward solvent space, and makes the only hydrophilic interaction, a hydrogen bond with Asp^{122} of one of the monomers. Compound **100** binds in a very analogous manner (5JO8).[247]

Residues from the *blue* monomer are indicated as A and the cyan monomer as B. Figures drawn using MOE 2015.1001 (Chemical Computing Group).

Researchers at Aurigene Discovery Technologies screened peptides derived from the interaction interface of PD1 and PD-L1 used the results to create pharmacophore models which were in turn used to design small molecule peptidomimetics, which are potent inhibitors of the interactions of PD-L1, PD-L2, and VISTA[249] with PD1.[250] Aurigene has disclosed diacylhydrazine ureas (exemplified by **102**),[251] cyclized diacylhydrazine ureas (**103**),[252] 1,2,4-oxadiazole ureas (**105**),[253] 1,3,4-oxadiazoles (**106**), and thiadiazoles,[254] which exhibit potent inhibition of PD1 in a mouse splenocyte proliferation assay. Mouse splenocytes expressing PD1 are isolated, cultured, and stimulated with murine anti-CD3 and anti-CD28 antibodies. The cells are then treated with a soluble PD-L1 construct in the presence or absence of compound. The amount of proliferation compared to untreated controls is a measure PD1/PD-L1 inhibition. The precise mechanism of action of these compounds has not been disclosed (Fig. 33).

Aurigene has identified a candidate molecule, CA-170 (AUPM-170), which has been licensed to Curis for development and has just entered Phase I clinical trials. CA-170 demonstrates sub-200 nM potency in a number of cell-based assays, is approximately equipotent against PD-L1, PD-L2, and VISTA, and exhibits good in vivo pharmacokinetics, with low clearance, high exposure, and good oral bioavailability.[250] While the structure of CA-170 has not yet been disclosed, it is likely to come from one of the four chemotypes shown above. Aurigene has more recently identified AUPM-327, a dual antagonist of PD-L1 and TIM-3 activation of PD1, which is current undergoing preclinical evaluation.[255] Its structure has also not been disclosed.

Fig. 34 Cyclic peptide inhibitors of PD1/PD-L1 interaction.

5.11.4.5.2 Peptide inhibitors

Researchers at Bristol-Myers Squibb have reported cyclic 12–14 residue peptides exemplified by **107**[256] and **108**[257] as potent inhibitors of the PD1/PD-L1 and CD80/PD-L1 interactions as measured by the same HTRF assay discussed previously. The macrocyclic rings are generally closed by alkylation of a cysteine side-chain thiol with an amino-terminal chloroacetyl group, but other ring closures such as ring-closing metathesis to generate an olefin are also exemplified. Compound **107** was also evaluated in a cell-based binding assay using a murine B-cell line (LK35.2) that stably overexpresses PD-L1 with a soluble, fluorescently labeled PD1 construct, and in an IFNγ production assay using donor-derived CMV^+ T cells, in both cases generating subnanomolar IC_{50} values. The precise mechanism of action of these macrocyclic peptides has not been disclosed, but since it is known that both PD1 and PD-L1 adopt the primarily β-sheet IG-V fold,[248] it is likely that these peptides are meant provide a complementary docking surface to one of the protein components, most likely PD-L1 (**Fig. 34**).

Chang et al.[258] reported a novel approach to developing a PD-L1 inhibitory ligand using a mirror-image approach.[259] They chemically synthesized an all-D version of the PD-L1 IG-V domain, which provides the PD1 binding element, and used that to screen and optimize a yeast-display library of dodecapeptides for binding. They then synthesized the all-D versions of the peptides they had selected and measured their binding affinity to PD-L1 and their ability to block the PD1/PD-L1 interaction. The compound corresponding to the D-amino acid sequence NYSKPTDRQYHF (^{D}PPA-1), bound to PD-L1 with a affinity of 510 nM in a Surface Plasmon Resonance (SPA) assay and blocked interaction of cellular PD1 with a soluble PD-L1 construct at 1 mg mL^{-1} concentrations. As the D-peptide was completely stable in 10% human serum for 24 h, it was tested in vivo in a mouse CT-26 tumor model. The peptide was injected at 2 mg kg^{-1} either subcutaneously at the site of the tumor or intraperitoneally, and demonstrated a significant antiproliferative effect compared to untreated mice as well as mice treated with 5-FU. While the authors did not demonstrate that their response was due to immune stimulation or compare it to standard PD1 or PD-L1 antibody therapy, it is nevertheless an interesting result.

5.11.5 Conclusion

We began with a summary of the function of the innate and adaptive immune system with respect to tumor recognition and elimination, followed by a discussion of the factors leading to tolerance and the failure of the immune system to eradicate these malignant cells. We then turned to a discussion of selected pathways and targets that have the potential to stimulate an effective immune response to cancer, highlighting those targets most readily amenable to disruption by "traditional" small molecule drugs (nonbiologics). The discussion was not exhaustive, but instead illustrative, of the tremendous potential of medicinal chemistry to impact cancer immunotherapy. For example, not covered was the potential importance of chemokine antagonists[260] and epigenetic regulators.[261]

Our growing understanding of the direct effects of small-molecule drugs on the immune system and the TME provides a basis for exploring small molecule drugs either alone or in combination with a wide range of established oncology drugs. Additionally multiple modalities of non-small molecule drugs are being developed (e.g., mAbs, cellular therapy, oncolytic viruses) with the

goal of boosting the immune system's attack of the tumor.[32b] It is clear that there are multiple intervention points and that drug combination studies offer the advantage of disrupting the cancer immunoediting process simultaneously at different points to maximize the therapeutic effect.[262] Importantly, numerous preclinical studies have demonstrated significant, even synergistic, value in combining immuno-stimulating small molecule drugs with other therapies. Some of these combinations are now being tested in the clinic. Until recently the war on cancer that began in the 60s was devoted almost exclusively to the discovery of cytotoxic agents. Viewing cancer as a failure of immune surveillance promises to greatly enlarge the list of available druggable target. Many of these new targets will be intracellular and as such out of the reach of the therapeutic mAbs that began the new era of cancer immunotherapy. Between the known and those yet to be discovered new targets, medicinal chemists will have multiple opportunities to make a contribution to immuno-oncology therapy, the latest front in the war on cancer.

5.12.1 Introduction

In the roughly 10 years that have passed since the previous edition of this work, the medicinal landscape for treating immunology/inflammation disorders has undergone substantial changes. This period witnessed the peak of the selective cyclooxygenase-2 (COX2) antiinflammatory agents and their subsequent decline amid cardiovascular safety concerns, the approval of multiple oral treatments for multiple sclerosis (MS) where previously only injectable therapeutic options existed, and the first new approval for lupus therapy in decades in Benlysta. Perhaps the greatest shift has been the continued emphasis of biopharmaceuticals. Heralded by the introduction of the anti-tumor necrosis factor (TNF) agents in the late 1990s (etanercept, infliximab), the commercialization of biologics for controlling a variety of proinflammatory cytokines (TNFα, IL-6, IL12/IL-23, IL-17) either through direct interaction with the cytokine, or through interaction with the cytokine receptor (eg, IL-6R for tocilizumab), has continued to grow over the past decade. In the following sections, we highlight significant advances and setbacks in the area of immunology research in the past decade with a focus on small molecules.

5.12.2 Clinical Success

While the emphasis of this article is on small-molecule approaches in immunology/inflammation, given the impact that biotherapeutics have had on the field, it is useful to reflect on the large molecules (biologics) approved over the last decade-and-a-half. **Table 1** lists the biologics that have gained marketing approval for immunology/inflammation related indications in this time frame.

Biologic therapies have also set a new standard for small molecules, which now often strive to achieve a "biologic-like efficacy" with the convenience of oral dosing. While this is a challenging goal, it is one that has been met by some of the new small-molecule drugs, as evidenced by comparison of independent clinical trial results and even in head-to-head clinical trials involving biologic comparator arms.[1] Shown in **Table 2** are small molecules that have gained marketing approval since 2003 in the area of immunology/inflammation/allergy. Further details of these new drugs (see **Fig. 1** for structures) are provided in the remainder of this section.

5.12.2.1 Everolimus: (Certican/Zortress)-First approval: 2003

Evirolimus is a close analog of sirolimus (rapamycin), modified by the addition of a hydroxyethyl group on the C40 hydroxyl, an alteration made to enhance solubility as well as improve pharmacokinetic properties.[2] This modification reduced the elimination half-life in comparison to sirolimus, which obviated the need for a loading dose, although the dosing frequency is twice daily, compared to once daily for sirolimus. Everolimus, like sirolimus, exerts its efficacy primarily through initial complexation with the receptor protein FKBP12 and subsequent inhibition of mTORC1 (mechanistic target of rapamycin complex 1). Initially

Table 1 Biologic/large molecule drug approvals: immunology/inflammation

First approval	*Generic name (USAN/INN)*	*Trade name*	*Indication(s)*	*Class/MOA*
2001	Kineret	Anakinra	Rheumatoid arthritis (RA)	IL1-receptor antagonist
2003	Alefacept	Amevive	Chronic plaque psoriasis	Inhibition of LFA-3/CD2 interaction
2004	Natalizumab	Tysabri	Relapsing remitting multiple sclerosis (RRMS)	Anti-a4-integrin mAB
2006	Abatacept	Orencia	(RA)	T cell co-stimulation blocker
2008	Certolizumab pegol	Cimzia	RA, Crohn's disease (CD), psoriatic arthritis (PsA)	Anti-TNF
2008	Rilonacept	Arcalyst	Cryopyrin-associated periodic syndromes (CAPS)	IL-1 trap
2009	Canakinumab	Ilaris	Gout, active systemic juvenile idiopathic arthritis (SJIA), CAPS, familial cold autoinflammatory syndrome (FCAS) and Muckle-Wells syndrome (MWS)	IL1-beta blocker
2009	Ustekinumab	Stelara	Psoriasis (Ps), PsA	Anti-IL-12 IL23
2009	Golimumab	Simponi	RA, PsA, ankylosing spondylitis (AS), ulcerative colitis (UC)	Anti-TNF
2010	Tocilizumab	Actemra	RA, SJIA, PJIA	IL-6 receptor inhibitor
2011	Belatacept	Nulojix	Organ rejection: Kidney transplant	T cell co-stimulation blocker
2011	Belimumab	Benlysta	Lupus	Anti-BAFF antibody
2013	Alemtuzumab	Lemtrada	Multiple sclerosis (MS)	CD52—targeting monoclonal antibody
2013	Anakinra	Kineret	RA	Anti-IL-1
2014	Vedolizumab	Entyvio	UC	Anti-$\alpha_4\beta_7$ integrin
2015	Secukinumab	Cosentyx	Ps, PsA, AS	Anti IL17-A antibody

Table 2 Small-molecule drug approvals: immunology/inflammation/allergy

First approval	*Generic name (USAN/INN)*	*Trade name*	*Indication(s)*	*Class/MOA*
2003	Everolimus	Certican	Transplant rejection	FKB12 FK506 binding inhibitor: derivative of rapamycin
2003	Lumiracoxib	Prexige	Antiinflammatory	Selective Cox-2 inhibitor
2004	Ciclesonide	Alvesco	Asthma, chronic obstructive pulmonary disorder (COPD)	Inhaled corticosteroid
2005	Nepafenac	Nevanac	Antiinflammatory eye drops	Cox-1/Cox-2 inhibitor (prodrug of amfenac)
2009	Iguratimod	Iremod	RA, osteoarthritis (OA)	Antirheumatic agent
2010	Dalfampridine	Ampyra	MS (walking function)	K+ channel blocker
2010	Fingolimod	Gilenya	RRMS	S1P1 agonist
2010	Roflumilast	Daxas; Daliresp	COPD	Phosphodiesterase IV (PDE4) inhibitor
2011	Bilastine	Bilaxten	Allergy	Antihistamine
2012	Teriflunomide	Aubagio	RRMS	Dihydroorotate dehydrogenase inhibitor
2012	Tofacitinib	Xeljanz	RA	JAK3 inhibitor
2013	Dimethyl fumarate	Tecfidera	RRMS	MOA unknown; activates NRF2 pathway
2014	Apremilast	Otezla	Ps, PsA	Phosphodiesterase IV (PDE4) inhibitor

approved for kidney transplant (2003 by European Medicines Agency; 2004 by the Food and Drug Administration), everolimus has continued to gain expanded indications over the years in immunology applications (heart transplant (2010) and liver transplant (2012/2013)), in addition to approval for multiple oncology applications and for use in drug eluting coronary stents.[2–4]

5.12.2.2 Lumiracoxib: (Prexige)-First approval: 2003

Lumiracoxib is an inhibitor of the COX-2 enzyme, with excellent selectivity over COX-1 and therefore was purported to offer improved efficacy without undesired gastrointestinal issues associated with compounds that inhibit COX-1.[5] It is a very close structural analog of the nonsteroidal antiinflammatory drug (NSAID) diclofenac, in which the 2,6-dichloroaniline has been replaced by a 2-chloro-6-fluoroaniline. Under late-stage development at the time the cardiovascular safety profile of selective COX-2 inhibitors (eg, Vioxx) was being called into question, lumiracoxib was the last compound of this class to have received marketing approval to date. The European medicines agency granted marketing authorization in 2003 but the drug was not made available in the United Kingdom because of cardiovascular safety concerns of the class. The approval was granted only in limited regions, and in recent years the approval has been withdrawn by multiple agencies because of concerns about liver toxicity.[6]

5.12.2.3 Ciclesonide: (Omnaris/Alvesco)-First approval: 2004

Ciclesonide is an inhaled corticosteroid (ICS) administered in the form of a nasal spray, intended for the treatment of nasal symptoms associated with allergic rhinitis, or an aerosol inhaler for the control and prevention of asthma. The first worldwide approval for ciclesonide came in Feb. 2004 from the Australian Health Agency (TGA) for the treatment of asthma in adults and adolescents 12 years of age and older.[7] With six other members of the ICS class of drugs, ciclesonide was proposed to differentiate in part based on its prodrug nature, a property shared with just one other member of the class.[8] Exposure to the active moiety (des-ciclesonide), which is formed through hydrolysis of a carboxylic acid ester, would be more restricted as compared to other ICSs, therefore avoiding side effects such as local irritation.

5.12.2.4 Nepafenac: (Nevanac)-First approval: 2005

Nepafenac, a prodrug of the NSAID amefenac in which the carboxylic acid has been replaced by a primary carboxamide, was approved in 2005 for the treatment of inflammation and pain associated with cataract surgery.[9] Intended for ocular administration, nepafenac is able to distribute more deeply into the eye tissue than other ocularly delivered NSAIDs, where the amide then undergoes bioconversion to the carboxylic acid, revealing the cyclooxygenase-1 (COX1)/COX2 inhibitor amefenac.[10]

5.12.2.5 Iguratimod: (Iremod)-First approval: 2009

Iguratimod is a disease-modifying antirheumatic drug (DMARD) that was approved for use in rheumatoid arthritis (RA) patients in China and Japan in 2009. While the mechanism of iguratimod's efficacy is not fully understood, it has been shown to downregulate NFkB and suppress the production of a variety of proinflammatory cytokines.[11] More recently, it has been shown to disrupt IL-17 signaling in fibroblast-like synoviocytes, which is of particular relevance to the demonstrated clinical utility in RA.[12] Iguratimod also has been investigated in the MRL/lpr preclinical mouse model of lupus, where it was found to be protective with respect to kidney injury as well as reducing proteinuria and the appearance of anti-double stranded DNA autoantibodies.[13]

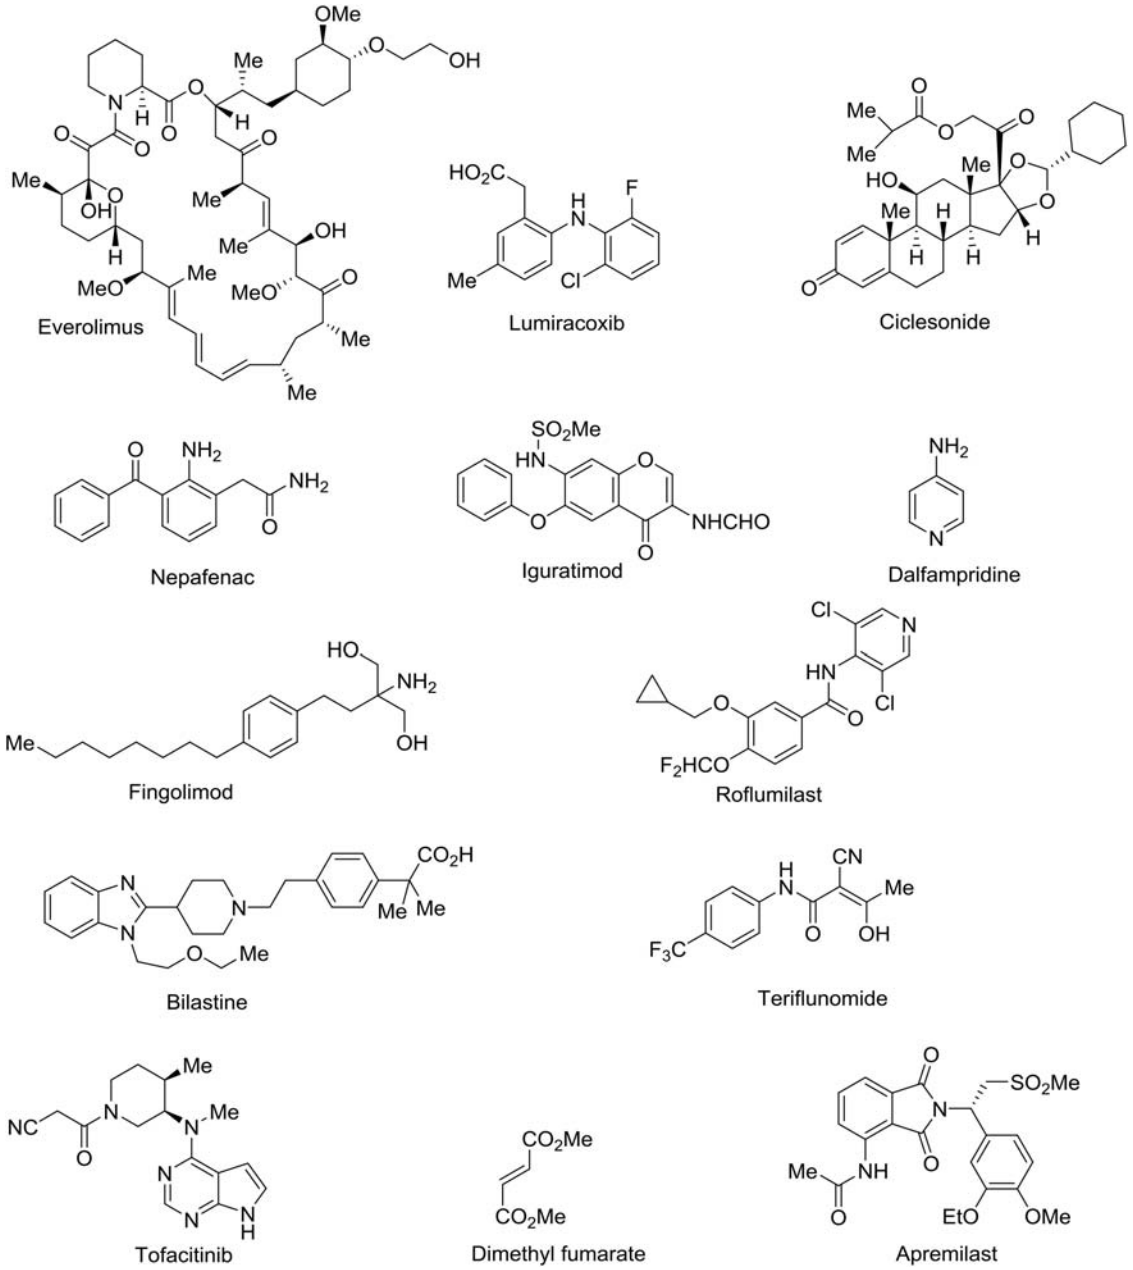

Fig. 1 Structures of small-molecule drugs approved between 2003 and 2014 for autoimmune and inflammatory disorders.

5.12.2.6 Dalfampridine: (Ampyra/Fampyra)-First approval: 2010

Dalfampridine, with the simple structure of 4-aminopyridine, is a broad-spectrum potassium channel blocker that was approved for use in a subset of MS patients. While not disease-modifying, dalfampridine is used to treat a specific symptom (decrease in walking ability) associated with MS.[14] It is believed to achieve the beneficial effects by increasing nerve conduction speed, although the precise mechanism has not been characterized. In Phase 3 trials, administration of an extended release formulation of dalfampridine produced a clinically meaningful improvement in walking ability in a subset of MS patients.[15]

5.12.2.7 Fingolimod: (Gilenya)-First approval: 2010

Fingolimod, the first oral drug approved for the treatment of relapsing remitting multiple sclerosis (RRMS), was shown to be superior to either placebo (FREEDOMS trial) or intramuscular interferon beta-1a (TRANSFORMS trial) at reducing the annualized relapse rate.[16] Acting as a prodrug, fingolimod is converted in vivo to a phosphorylated metabolite that binds to and activates

four of the five S1P (sphingosine-1-phospahte) receptors, S1P-1,3,4,5.[17] Agonism of S1P-1 by fingolimod leads to prolonged internalization and downregulation of this receptor, which disrupts the ability of certain lymphocyte subsets to egress from the lymphatic system, where they remain sequestered. This reduction in circulating lymphocyte levels, preventing autoreactive T cells from reaching the central nervous system (CNS), is believed to be key to fingolimod's efficacy in RRMS, although additional mechanisms involving effects directly on CNS-resident cells also have been investigated.[18,19]

5.12.2.8 Roflumilast: (Daxas/Daliresp)-First approval: 2010

Roflumilast has been approved to reduce the risk of exacerbations in patients with severe chronic obstructive pulmonary disease (COPD).[20] Its activity arises through inhibition of phosphodiesterase-4 (PDE4) enzymes, leading to subsequent accumulation of intracellular cAMP (cyclic adenosine monophosphate) and suppression of inflammatory cell activation. Roflumilast is significantly metabolized through N-oxidation and both the parent and metabolite share similar PDE4 inhibition and pharmacokinetic profiles.[21] Earlier examples of PDE4 inhibitors (eg, rolipram) faltered in development because of a narrow therapeutic window between efficacy and gastrointestinal (GI) effects, with the latter believed to be caused by action on a particular subtype of the enzyme (PDE4D). Although both the parent molecule and the N-oxide metabolite act on multiple PDE4 subtypes, including PDE4D, roflumilast was able to demonstrate an acceptable GI safety profile.

5.12.2.9 Bilastine: (Bilaxten)-First approval: 2011

Bilastine is an antihistamine that was approved for the treatment of allergic rhinitis and urticaria.[22] As a second-generation H1-antihistamine, bilastine has limited CNS penetration and therefore avoids the sedative effects of first-generation antihistamines. Bilastine was shown to bind selectively to the histamine H1 receptors, with a lack of significant activity at a variety of other targets, including H2-, H3-, serotonin, bradykinin, muscarinic, and calcium receptors.[23] In clinical trials, treatment with bilastine was improved versus placebo in reducing nasal symptoms scores of patients with seasonal allergic rhinitis and was associated with an improvement of symptom scores in patients with chronic urticaria.[24]

5.12.2.10 Teriflunomide: (Aubagio)-First approval: 2012

Teriflunomide, approved for the treatment of relapsing MS, is the primary active metabolite of leflunomide (Arava), which had been approved previously for treatment of RA and psoriatic arthritis. An inhibitor of dihydroorotate dehydrogenase, teriflunomide disrupts the de novo synthesis of pyrimidines in rapidly proliferating cells, which reduces the activity of select T and B lymphocytes.[25] Cells that are resting or dividing slowly are spared by teriflunomide. In clinical trials, teriflunomide was noninferior to interferon beta-1a in the prevention of relapses and superior to placebo in both the prevention of relapses and the prevention of disability progression.[26]

5.12.2.11 Tofacitinib: (Xeljanz)-First approval: 2012

Tofacitinib, used in the treatment of RA, was the first approved drug from the Janus kinase (JAK) inhibitor class.[27] The JAK family of nonreceptor tyrosine kinases (JAK1, 2, 3 and TYK2) mediate inflammatory gene transcription via signaling through STAT (signal transducers and activators of transcription) proteins, and their inhibition can control the production of proinflammatory cytokines. In biochemical assays, tofacitinib shows potent activity on JAK1, 2, and 3, with modest selectivity ($\sim$10-fold) against TYK2. In cellular and human whole blood assays, a preference of about 30-fold was noted for JAK1/3 signaling versus JAK2 signaling.[28] Clinical trials of tofacitinib in RA patients demonstrated efficacy similar to that obtained with TNF inhibitors, with ACR20, ACR50, and ACR70 response rates of 66%, 37%, and 20%.[29] Beyond RA, tofacitinib has shown promise in a variety of preclinical models of other diseases and is undergoing trials for lupus, psoriasis, psoriatic arthritis, organ transplant, Crohn's disease, ulcerative colitis (UC), and alopecia.[30]

5.12.2.12 Dimethyl Fumarate: (Tecfidera)-First approval: 2013

Fumaric acid esters (FAEs), mixtures of dimethyl fumarate (DMF) and other FAE salts, have been used as oral treatments of psoriasis for decades.[31] Administration of FAEs to psoriasis patients with concomitant MS showed relief of the MS symptoms.[32] More recently, DMF, with an enteric coated formulation intended to reduce gastrointestinal side effects, was evaluated as a single compound for the treatment of MS, for which it received marketing approval.[33] In vivo, one of the esters of DMF is hydrolyzed rapidly to give monomethyl fumarate (MMF), which serves as the likely bioactive species. Although not completely understood, the mechanism by which DMF (or MMF as the active moiety) exerts its beneficial effects is thought to involve upregulation of the nuclear factor (erythroid-derived 2)-like 2 (Nrf2) pathway.[34]

5.12.2.13 Apremilast: (Otezla)-First approval: 2014

Apremilast was the second drug approved in the PDE4 class, although the approved indications of severe plaque psoriasis or psoriatic arthritis differ from that of roflumilast (approved for COPD). The discovery of apremilast arose from the continued medicinal chemistry efforts on the thalidomide substructure. The observed biologic activity of this modified series (blockade of TNFα release) was discovered to arise through direct inhibition of PDE4 enzymes, with optimization for this activity in cellular and whole blood assay formats, leading to the identification of apremilast.[35] In fact, the modifications led to ablation of activity against the original molecular target of thalidomide (cereblon).[36] Apremilast was found to be selective for the PDE4 family of enzymes relative to other phosphodiesterases (PDE1–3, 5–11) but was found to have relatively little selectivity across the PDE4 subtypes (4A–4D). Despite inhibiting PDE4D, which previously was associated with negative gastrointestinal effects, apremilast was able to demonstrate an acceptable therapeutic window in the clinic. Evaluated in multiple Phase 3 trials for psoriasis, patients receiving 30 mg apremilast twice a day achieved significant improvement over placebo in PASI-50 (55–58% vs. 17–20%) and PASI-75 (29–33% vs. 5–6%) scores.[37] In a separate Phase 3 trial, apremilast was compared against etanercept and was able to approach the activity of the biologic after 16 weeks with PASI-75 response rate of 39.8% versus 48.2% for etanercept (both significantly higher than that of placebo at 11.9%). Ongoing and planned trials with apremilast include investigations for Behcet's disease, UC, atopic dermatitis, and ankylosing spondylitis.[38]

As can be seen by comparing the two tables in this section, the impact of biologic treatments has been quite notable in this therapeutic area. Still, in the preceding decade, patients have gained access to novel small-molecule drugs that are useful for the treatment of a variety of serious autoimmune/inflammatory diseases. In the following sections, we highlight compounds and new pathways that show potential comparable to the marketed drugs, as well as discuss some compounds and targets that have failed to bear out such potential.

5.12.3 Clinical Promise

This section of the article highlights small molecules that are in late-stage clinical trials (completed Phase 2 or in Phase 3) for the treatment of autoimmune disorders with a focus on RA, inflammatory bowel disease (IBD) (UC and Crohn's), psoriasis, lupus, and MS.

5.12.3.1 CF-101

Adenosine is an extracellular signaling molecule that acts via the adenosine receptors and suppresses synaptic transmission. Adenosine receptors belong to the GPCR (G-protein-coupled receptor) family and there are four subtypes: A_1, A_{2A}, A_{2B}, and A_3. The A_3 adenosine receptor (A_3 AR) is overexpressed in inflammatory cells, and A_3AR agonists induce downregulation of the NFkB signaling pathway, resulting in decreased TNF-α levels by monocytes and synoviocytes and leading to antiinflammatory effects.[39] CF-101, an adenosine analog, is a potent agonist of A_3 AR with a K_i of 0.47 nM and with >1000-fold selectivity over A_1. It is also selective versus A_{2A} AR (K_i 560 nM), and A_{2b}AR receptors (K_i of 42,300 nM).[40] Based on its efficacy in preclinical models of RA and IBD,[41] CF-101 was taken into clinical trials for RA and psoriasis. In a 12-week multicenter, randomized, double-blind, placebo-controlled, parallel-group Phase 2b study involving 79 patients with active RA, CF-101 dosed at 1.0 mg achieved ACR20 responses of 48.6% at Week 12 ($p=0.0352$), which was significantly higher statistically than that of the placebo group (25.0%).[42] Phase 3 trials in RA patients are planned. CF-101 was also tested in a Phase 2/3 double-blind, placebo-controlled study in 326 patients with moderate-to-severe plaque psoriasis. However, this study did not achieve its primary efficacy endpoint.[43]

5.12.3.2 Masitinib

Masitinib is a tyrosine kinase inhibitor that inhibits the stem-cell factor (SCF) receptor, KIT (kinase inhibitor targeting) in both biochemical ($IC_{50}=200\pm40$ nM) and cellular assays ($IC_{50}=150\pm80$ nM).[44] Since SCF is upregulated in inflammatory conditions, it represents a potential therapeutic target for the treatment of inflammatory diseases. For example, masitinib treatment at 12.5 and 25 mg kg^{-1} (i.p. twice a day) led to a significant reduction in disease in an experimental autoimmune encephalomyelitis (EAE) mouse model, a preclinical model of human MS.[45] In a multicenter, randomized, placebo-controlled, Phase 2a trial with 35 patients, masitinib treatment orally at 3-6 mg/day had a positive effect in MS-related impairment in primary progressive MS and relapse-free secondary progressive MS patients as evidenced by an improvement in multiple sclerosis functional composite scores (MSFC) relative to baseline, compared with a worsening MSFC score in patients receiving placebo $+103\pm189$% versus -60 ± 190% at month-12, respectively.[45] Based on this data, a Phase 2b/3 study to compare efficacy and safety of masitinib to placebo in the treatment of patients with primary progressive or relapse-free secondary progressive MS is ongoing.[46] In a multicenter, open-label, dose-ranging, Phase 2a study, masitinib treatment administered orally to 43 patients (who had inadequate response to DMARDs) at an initial dose of 3 mg kg^{-1} per day or 6 mg kg^{-1} per day achieved ACR20, ACR50, and ACR70 responses of 54%, 26%, and 8%, respectively.[47] However, it is important to note that the efficacy analysis of this Phase 2 study is hampered by the lack of a placebo group. A Phase 2b/3 study to assess the efficacy and safety of masitinib in comparison to methotrexate in patients with active RA with inadequate response to methotrexate or to any disease-modifying antirheumatic is in progress.[48]

5.12.3.3 CCX354

CC-Chemokine Receptor-1 (CCR1), which belongs to the G-protein coupled receptor family, is expressed on circulating cells such as monocytes, macrophages, T-lymphocytes, and neutrophils that are mobilized during inflammation. CCR1 binds eight chemokine ligands that regulate the processes of cell migration.[49] Synovial joints from patients with chronic RA express high levels of CCR1-expressing monocytes/macrophages and CCR1 associated chemokines like CCL3 and CCL5, suggesting CCR1 antagonists would provide beneficial effects for patients with RA. CCX354 is a potent CCR1 antagonist, which completed a randomized, placebo-controlled ($n=54$) Phase 2 proof-of-concept clinical trial in 160 patients with moderate-to-severe RA who were partially responsive to methotrexate therapy.[50] In this clinical trial, patients were given 100 mg of CCX354 twice daily ($n=53$), or 200 mg once daily ($n=53$) for 12 weeks. All patients continued to receive their regular methotrexate dose. In the patient group satisfying the prespecified criteria of C-reactive protein (CRP) (>5 mg L^{-1}) and tender/swollen joint count (>8), ACR20 response at Week 12 was 30% in the placebo group, 44% in the 100 mg twice daily group ($p=0.17$), and 56% in the 200 mg (once per day) group ($p=0.01$). In the patient group naïve to biological treatment, the 200 mg (once daily) group showed statistical significance for the ACR20 response (62% vs. 26% for placebo, $p=0.002$), while only a trend toward efficacy was observed in the 100 mg (twice daily) group (41% vs. 26%, $p=0.18$). At the time of this writing, no further updates were available regarding Phase 3 clinical trials with CCX354 for the treatment of RA.

5.12.3.4 TRK-170

TRK-170 is an orally active, small-molecule alpha4beta1/alpha4beta7 integrin antagonist. In preclinical studies, TRK-170 dosed at 50 mg kg^{-1} once a day, in a HLA-B27 rat model of chronic colitis (resembling UC), significantly reduced the number of animals with diarrhea and rectal bleeding, and showed a greater reduction in colonic symptoms when compared to prednisolone, which was accompanied with a decrease in the messenger RNA (mRNA) expression of proinflammatory mediators.[51] A two-part, multicenter, randomized, placebo-controlled, double-blind study of TRK-170 for the treatment of Crohn's disease has been completed,[52] but as of this writing, results from this study have not been disclosed.

5.12.3.5 GLPG0974

GPR43 (also referred to as FFA2) is a G-protein coupled receptor that is involved in the mediation of inflammatory responses. GPR43 is activated by short-chain fatty acids (SCFA) resulting in neutrophil activation and migration. In patients suffering from IBD, GPR43 expression is upregulated in the colon. GLPG0974 is a potent small-molecule antagonist of GPR43 and inhibits SCFA-induced neutrophil activation and migration in plasma with an IC_{50} of 27 nM.[53] In addition, GLPG09074 is a potent inhibitor of the FFA2-induced CD11b activated epitope expression ($IC_{50}=483\pm72$ nM). This assay was used to monitor target engagement in healthy volunteers and patients. GLPG09074 was tested in an exploratory, Phase 2, randomized, double-blind, placebo-controlled, proof-of-concept study in 45 patients with mild-to-moderate UC.[54] Patients were treated for 4 weeks with 200 mg twice a day of GLPG09074 or placebo (2:1 randomization). GLPG09074 was safe and well-tolerated and biomarker data indicated that neutrophil activation and influx were reduced, suggesting a role for GPR43 in UC. However, the reduction in neutrophil influx was not accompanied by a measured clinical difference between the GLPG09074 and placebo groups in the four-week treatment period.[55] Galapagos is performing subgroup analyses and considering additional indications for GLPG09074.[56]

5.12.3.6 PF-4171327

PF-4171327 (fosdagrocorat), a phosphate ester prodrug of PF-251802 which is a selective glucocorticoid (GC) receptor agonist, is being developed for the treatment of RA. In preclinical studies, PF-4171327 showed reduced transactivating (TA) potential in comparison to classic GCs while maintaining the ability to transrepress the expression of inflammatory genes, raising the possibility of retaining the beneficial antiinflammatory effects of GCs while minimizing the side effect profile from TA. For example, PF-4171327 did not suppress osteocalcin expression and showed a reduced induction of phosphoenolpyruvate carboxykinase and tyrosine aminotransferase gene expression in primary human hepatocytes, compared to prednisolone. A randomized, double-blind Phase 2 study was conducted to determine the efficacy and safety of PF-04171327 after 8 weeks of treatment. Patients ($n=323$) were randomized to receive oral tablets of PF-04171327 at doses of 1, 5, 10, or 15 mg, prednisone at doses of 5 or 10 mg, or placebo once daily for 8 weeks, in addition to methotrexate.[57] ACR20 scores were superior to placebo at the 10 and 15 mg once daily doses and the 15 mg dose met the criteria for noninferiority to once a day prednisone 10 mg. ACR50 and ACR70 response rates at week 8 showed a similar pattern, with the at 10 mg dose having highest response rate. At the 10 mg dose, PF-04171327 met noninferiority criteria versus once a day prednisone at 5 mg for bone formation biomarker P1NP; the 15 mg dose was comparable to prednisone. There was no dose response for the bone resorption biomarker uNTX/uCr. Glycated hemoglobin (HbA1c) changes for all doses of PF-04171327 were comparable with prednisone 5 mg. At the time of this writing, no further updates were available regarding Phase 3 clinical trials with PF-4171327 for the treatment of RA.

5.12.3.7 GED-0301

One of the characteristics of Crohn's disease is gut inflammation that is accompanied by a decrease in the activity of the immunosuppressive cytokine transforming growth factor (TGF)-β1 and increased levels of the protein SMAD7. SMAD7 binds to the TGF-β receptor and prevents antiinflammatory TGF-β signaling. GED-0301 (morgensen) is a 21-base single-strand phosphorothioate oligonucleotide that hybridizes to the human SMAD7 mRNA and reduces the levels of SMAD7 protein via degradation of its mRNA and restores TGF-β signaling. In preclincal studies, morgensen was shown to alleviate Crohn's disease-like colitis in mice and restore TGF-β signaling in mucosal cells from humans with Crohn's disease.[58] The efficacy of morgensen was tested in a double-blind, placebo-controlled Phase 2 trial. Patients were randomly assigned to receive 10 ($n=41$), 40 ($n=40$), or 160 mg ($n=43$) of GED-0301 or placebo ($n=42$) per day for 2 weeks and then were evaluated at days 15, 28, and 84.[59] Clinical remission (primary endpoint) at both days 15 and 28 were 55% at the 40 mg dose and 65% at the 160 mg dose, compared to 12% for the 10 mg dose and 10% ($p<0.001$) for the placebo groups. Additionally, 67% of patients (6 of 9 patients) reached glucocorticoid-free remission at Day 84 with 160 mg GED-0301 once daily, versus 11% (1 of 9 patients) with placebo ($p=0.04$). Based on this encouraging data, a Phase 3 trial is planned with GED-0301.

5.12.3.8 LY3009104 (INCB028050, Baricitinib)

JAKs, which consist of four family members (JAK1, JAK2, JAK3, and TYK2), play pivotal roles in cytokine receptor signaling and are associated with both adaptive and innate immune responses. Since JAK family kinases regulate the IL-6 and IL-10 pathways, inhibition of JAK kinases provides a novel approach for the treatment of RA. Tofacitinib is the first JAK inhibitor approved for the treatment of RA. Unlike tofacitinib, which is a nonselective JAK family kinase inhibitor (enzyme $IC_{50's}$ for JAK1, JAK2, JAK3, and TYK2 are 3.2, 4.1, 1.6, and 34 nM respectively), LY3009104 (formerly INCB0280050) is a selective inhibitor of JAK1 and JAK2 (enzyme $IC_{50's}$ for JAK1, JAK2, JAK3, and TYK2 are 5.9, 5.7, >400, and 53 nM respectively).[60] Preclincal efficacy with LY3009104 was demonstrated in multiple models of arthritis.[60] A multicenter, randomized, double-blind, placebo-controlled Phase 3 study to evaluate the efficacy and safety of LY3009104 in patients ($n=684$) with inadequate response to conventional DMARDS was conducted. At Week 24, ACR20, ACR50, and ACR70 response rates were 61%, 42%, and 25%, respectively, in the LY3009104 2 mg group (orally, once a day) compared with LY3009104 4 mg group (orally, once a day) (65%, 44%, and 24%, respectively) and placebo (42%, 22%, and 8%, respectively).[61] Additional Phase 3 trials with LY3009104 in RA are ongoing.

LY3009104 also completed Phase 2 trials in psoriasis.[62] In a double-blind, Phase 2b trial, patients ($n=238$) were randomized to receive LY3009104 (2, 4, 8, and 10 mg orally, once a day) or placebo for 12 weeks. At week 12, a significantly greater proportion of patients achieved PASI75 in the 8- and 10-mg LY3009104 groups compared with placebo (43% and 54%, respectively, vs. 15%). Additional information regarding further clinical progression of this compound in psoriasis was unavailable at the time of this writing.

5.12.3.9 VX-509

VX-509 (decernotinib) is a potent JAK3 inhibitor (enzyme $IC_{50}=2.5$ nM) that is being evaluated in clinical trials for RA. Although its biochemical potency for other JAK family members is <10-fold, the cellular selectivity is between 25- and 150-fold.[63] VX-509 was evaluated in a Phase 2b trial for RA at once-daily (100, 150, 200 mg) and twice-daily (100 mg) doses in combination with methotrexate in 350 patients.[64] At 24 weeks, ACR20 scores for the 100 and 150 mg once-daily groups were 60.6% and 61.1%, respectively, compared to 16.9% in the placebo group ($p<0.001$ for both groups). The ACR20 scores for the 200 mg once-daily and the 100 mg twice-daily groups were 61.1% and 62.5%, respectively ($p<0.001$ for both). The ACR50 responses for the four dose groups at six months were 38%, 38.9%, 40.3%, and 47.2%, respectively, compared with 7% of placebo recipients ($p<0.001$). ACR70 responses were seen in 16.9%, 18.1%, 15.3%, and 25%, respectively, compared with 2.8% for placebo ($p<0.01$). Plans for further progression of VX-509 were unavailable at the time of this writing.

5.12.3.10 ACT-128800

ACT-128800 (ponesimod) is an $S1P_1$ receptor modulator that is in clinical trials for the treatment of MS and other autoimmune conditions. Like fingolimod, which was approved for the treatment of MS in 2010, ACT-128800 induces reversible lymphopenia by inhibiting T-cell egress from the thymus and lymph nodes, thereby preventing T-cell infiltration to sites of inflammation. The safety and efficacy of ACT-128800 was evaluated in a double-blind, placebo-controlled, dose-finding Phase 2b study in 464 patients with RRMS.[65] Patients were randomized to receive once-daily oral ACT-128800 10, 20, or 40 mg, or placebo for 24 weeks. ACT-128800 reduced the number of new T1-weighted gadolinium-enhancing lesions by 43%, 83%, and 77% at 10, 20, and 40 mg, respectively, and the number of new or enlarging nonenhancing T2 lesions by 31%, 56%, and 34% at the 10, 20, and 40 mg doses. In addition to being selective for the $S1P_1$ receptor, ACT-128800 differs from fingolimod in other aspects. For example, fingolimod requires a phosphorylation–dephosphorylation cycle in vivo for its activation/deactivation, but this step is not required for ACT-128800 and may contribute to its low pharmacokinetic/pharmacodynamic variability. In addition, ACT-128800 has a terminal half-life of about 32 hours, compared to about 8 days for fingolimod.[65] A multicenter, randomized, double-blind, active-controlled, superiority study to compare the efficacy and safety of ACT-128800 to teriflunomide in subjects with relapsing MS

has been initiated.[66] In addition, an open-label, single-arm, multicenter Phase 2 trial was planned for an expected 30 patients with chronic graft versus host disease (GvHD) to assess the biological activity of ACT-128800.[67]

5.12.3.11 MT-1303

MT-1303 is a selective $S1P_1$ receptor agonist in various clinical trials for the treatment of autoimmune disorders. A multicenter, randomized, double-blind, parallel assignment Phase 2 extension trial is in progress in subjects with RRMS.[68] A multicenter, randomized, double-blind, parallel-group, placebo-controlled, Phase 2a trial was initiated in patients with moderate-to-severe chronic plaque psoriasis to evaluate the safety, tolerability, and efficacy of MT-1303.[69] The compound is also in two Phase 2 trials for the treatment of severe active Crohn's disease.[70,71]

5.12.3.12 RPC1063

RPC1063 (ozanimod) is a selective $S1P_1$ receptor modulator that demonstrates 269-fold selectivity for $S1P_1R$ ($EC_{50} = 0.16$ nM) over $S1P_5R$, and greater than 20,000-fold selectivity over $S1P_2R$, $S1P_3R$, and $S1P_4R$.[72] In a randomized, double-blind, placebo-controlled trial of oral RPC1063 in RRMS, the number of gadolinium-enhanced lesions at Week 24 were reduced by 91% and 94% in doses of 0.5 and 1 mg, respectively, compared with placebo. The cumulative number of new or enlarging T2 lesions from Weeks 12 to 24 also was reduced significantly in the 0.5 mg group (84%) and in the 1 mg group (91%) compared to placebo.[73] A Phase 3, multicenter, randomized, double-blind, double-dummy, active-controlled (beta interferon), parallel-group study to evaluate the efficacy and safety of RPC1063 (0.5 and 1.0 mg doses) in RRMS patients has been initiated.[74] RPC1063 also was tested in a multinational, multicenter, double-blind, randomized, placebo-controlled Phase 2 trial in patients ($n = 199$) with moderate-to-severe UC.[75] Clinical remission (primary endpoint) was met by 16.4% of patients on the 1 mg dose as compared to 6.2% of patients on placebo ($p < 0.05$). Statistical significance was not achieved in the low dose (0.5 mg) group.[76] However, in the maintenance portion of the study, clinical remission at Week 32 was statistically significant at both the 1 mg group and 0.5 mg dose group ($p < 0.05$) compared to placebo. Based on this data, a Phase 3, multicenter, randomized, double-blind, placebo-controlled trial of RPC1063 (1.0 mg) as induction and maintenance therapy for moderate-to-severe UC has been initiated.[77]

It is clear from the discussion above that small-molecule modulators of different targets/pathways that are in advanced clinical trials hold promise for the treatment of various autoimmune disorders. These compounds have the potential to have meaningful impact on the quality of life of patients by providing physicians with a range of therapies that provide the best possible treatment for these disorders. During the past decade, there has been an evolution in disease focus in the autoimmune/inflammation clinical space. While applications toward RA continue to grow in significance, an earlier emphasis on inflammatory pain, allergy, and transplant has diminished, despite the fact that these are not considered to be solved problems. On the rise are therapies directed toward MS and IBDs (Crohn's, UC).

5.12.4 Clinical and Preclinical Struggles

Given the exceptionally difficult path to the discovery and development of new drugs, it is natural that there would be a long list of compounds and targets that did not lead to success. Some of these disappointments are notable because of the stage of development that was reached (late-stage clinical trials, or even reaching market), while others are noted for the perceived potential based on preclinical data and the level of industry engagement that was put forth. This section will outline some of the setbacks that have occurred over the last 10–15 years.

5.12.4.1 COX2 Inhibitors

At the end of the 1990s, a decade or more of research into the identification of safer analgesics, culminated with the first approvals of a new class of compounds, the selective cyclooxygenase-2 (COX2) inhibitors. Targeting the same family of enzymes as aspirin and NSAIDs such as ibuprofen, naproxen, and many others, but sparing activity on COX1, the new inhibitors offered the potential to achieve similar pain management with substantially reduced gastrointestinal side effects. The improved GI tolerability of this class was borne out in multiple trials, and the approved inhibitors (celecoxib, rofecoxib, valdecoxib) quickly achieved blockbuster status, with combined worldwide sales of more than $6 billion in 2004.[78] However, with larger clinical trials, particularly those exploring higher doses, results pointed to increased cardiovascular safety concerns. The specific details of the multiple clinical trials and the resulting FDA and EMEA actions have been reviewed previously,[79] but the result was the removal of market authorization of rofecoxib and valdecoxib and a black box warning for celecoxib.

It is ironic that although cast as a disappointment, the sales of celecoxib, which was allowed to remain on market, were almost $3 billion worldwide in 2014 and the drug was among Pfizer's key products.[78] Maintaining clear blockbuster status a decade after the cardiovascular safety profile of the class was questioned, that drug can hardly be considered a failure. However, the 2004 sales for Pfizer's COX-2 franchise (celecoxib and valdecoxib combined) were $4.6 billion and had been anticipated to rise, so there was clear impact on market potential.[80] In addition to the effect on the marketed drugs of this class, the development of other COX2 inhibitors, exemplified by lumiracoxib and parecoxib, also stalled. Poised for marketing approval in 2004/2005 on the basis of the largest

trial with a COX2 inhibitor, lumiracoxib was unable to garner FDA approval despite showing no difference in myocardial infarction between it and either naproxen or ibuprofen.[5] Lumiracoxib was approved in non-US regions, although issues with liver toxicity subsequently led to marketing withdrawal in some areas.[81] Similarly, the FDA issued a nonapprovable letter for parecoxib (an injectable prodrug of valdecoxib) although it was made available in the European Union and other regions.[82] Development of numerous other COX2 inhibitors in earlier stages was subsequently discontinued in light of the uncertain future of the class.

5.12.4.2 p38 MAP Kinase Inhibitors

In the first decade of the millennium, perhaps no other discreet target in immunology/inflammation received as much attention from the industry as p38 MAP kinase. Significant drug discovery efforts were in place for this kinase at nearly every major pharma company as well as numerous smaller biotech companies. The excitement was driven initially by preclinical data demonstrating a clear role for p38α in the production of a variety of proinflammatory signaling molecules (eg, TNFα).[83] With the success of the anti-TNFα biologics, a small-molecule approach with the potential to match their efficacy seemed to be an opportunity that no one wanted to miss out on. As quality inhibitors of p38α were identified, favorable in vivo data in preclinical models across a range of diseases (autoimmunity and beyond) continued to emerge, bolstering confidence in this target.[84] Early compounds to reach the clinic (SCIO469; BIRB796), aimed at treating RA and Crohn's disease, showed no clear efficacy, and only transient decreases in CRP were observed, suggesting potential escape mechanisms for p38 inhibition.[85,86] Elevation of liver enzymes, an adverse event reported for multiple p38 inhibitors, was found to be dose-limiting for both SCIO469 and BIRB796.[87] Toxicity concerns also plagued VTX-745, which was dropped from clinical development because of CNS toxicity observed in animal studies.[88] The limited and sometimes transient signs of efficacy (tachyphylaxis) demonstrated by the early clinical compounds led to a souring of the field, with articles about the "unfulfilled promise" of p38 and a commentary headlined "Inhibition of p38: has the fat lady sung?" highlighting the prevailing sentiment.[87,89] Nevertheless, trials in RA with some compounds ultimately were able to show sustained efficacy. A dual mechanism of inhibition (blocking both the activation of p38 as well as its activity) was highlighted for BMS-582949, which showed sustained improvement in ACR 20 response in patients with active RA relative to placebo over 12 weeks.[90,91]

With sustained challenges in applying p38 inhibition in RA, companies have turned their attention to a number of alternative indications, with COPD being commonly targeted. Eight p38 inhibitors, four orally administered as well as four inhaled inhibitors, have been evaluated clinically for treating COPD with the available data having been reviewed recently.[92] Of the four oral agents, only acumapimod (BCT-197) remains in development, having recently completed a Phase 2 evaluation as monotherapy or in combination with prednisone although results have not been disclosed.[93] Of the inhaled approaches, three (PF-03715455; AZD-7624; RV-568) appear to be under continued development.[92] Additional indications evaluated with p38 inhibitors include surgical pain (talmapimod), neuropathic pain (dilmapimod), ovarian cancer (LY2228820), and Alzheimer's disease (VX-745). Furthermore, a variety of cardiovascular disorders have been targeted with p38 inhibitors. In one of the most advanced trials with a p38 inhibitor, losmapimod was examined in a Phase 3 study for treatment of acute coronary syndrome.[94] The planned interim review of data from the first part of the stepwise study design did not indicate efficacy against the primary endpoint, casting doubt on the further evaluation in this indication.[95] The development road for p38 kinase inhibitors has been extremely rough, and the tenacity of the industry with regard to this class is noteworthy, although only time will tell if the investment was worthwhile.

5.12.4.3 Chemokine Receptor Modulation

Chemotactic cytokines, or chemokines, are a family of signaling molecules that exert their cellular trafficking abilities through interaction with varied G-protein coupled receptors (GPCRs).[96] Although two small-molecule drugs have been approved in this space (CCR5 antagonist maraviroc and CXCR4 antagonist plerixafor), their indications (HIV infection and mobilization of stem cells, respectively) lie outside of the immunology/inflammation area for which the most effort in CCR development has been directed.

The selection of drug targets within this family could be viewed as daunting, with at least 40 chemokines and 19 functional CCRs identified so far. A few members of this family have emerged as preferred targets and have been the subject of recent reviews.[97,98] As highlighted in those reviews, compounds have reached clinical stage evaluation for CCR1, CCR2, CCR3, CCR4, CCR5, CCR9, CCR1/2 dual, CCR2/5 dual, CXCR1, CXCR1/R2 dual, CXCR3, and CXCR4. The areas of clinical focus include immunology/inflammation indications (MS, RA, psoriasis, COPD, lupus, asthma, allergic rhinitis, Crohn's) as well as conditions outside of that area (HIV, multiple myeloma, atherosclerosis, diabetic retinopathy, pain, stem-cell mobilization, and Type 2 diabetes). While many of the studies are ongoing, or have completed but results are not disclosed, the lack of clear success in RA, for example, is counter to the expectations.[98] Possible reasons for the lack of progression have been debated, with an early hypothesis of redundancy within the chemokine system being challenged by analysis of clinical trial data, suggesting that inadequate target coverage is to blame.[99,100]

5.12.4.4 TACE Inhibitors

As previously discussed, the clinical benefit of controlling TNFα levels has been clearly established for a variety of autoimmune disorders with biologic therapeutics, bringing focus on molecular targets that could achieve the same effect with small-molecule intervention. TACE, or TNF-alpha converting enzyme, plays a key role in the production of active soluble TNFα and is therefore one such promising target. TNFα is a cytokine produced as a membrane-bound form that is cleaved by the zinc-metalloprotease

TACE to liberate the soluble form, which then is able to act on TNFα Receptor I to elicit a variety of proinflammatory responses.[101] Belying the specificity suggested by the name, TACE is involved with the processing of a host of substrates beyond TNFα to reveal their active forms.[101] While this extended role may in some cases lead to enhanced benefit in other diseases, it also may play a role in undesired side effects of TACE inhibition.

Further side effect concerns were potentially related to inhibition of structurally related targets. Early work in the area focused on compounds derived from broad-spectrum inhibitors of matrix metalloproteinases (MMPs) with poor specificity for TACE and whose development was challenged by toxicity.[102] In particular, musculoskeletal toxicity (tendonitis) was attributed to inhibition of MMP1 or MMP14, leading subsequent efforts to be directed at the identification of TACE inhibitors with a more selective MMP inhibition profile.[103,104] Various campaigns were successful in identifying clinical development compounds, the two most advanced of which were progressed to Phase 2 evaluation. Investigations with BMS-561392 (DPC-333) were halted because of hepatotoxicity concerns noted in preclinical studies that were postulated to be mechanism-based.[101,105] While apratastat (TMI-005) completed a Phase 2 evaluation for RA without signs of hepatotoxicity, further development was not undertaken as a lack of efficacy was noted.[106] One recent hypothesis for the lack of clinical efficacy of TACE inhibitors despite good preclinical validation was suggested to be upregulation of caspase-1, which was observed in human cells but not in mice.[107]

Advances in the treatment of autoimmune and inflammation disorders during the last 15 years have accompanied significant struggles in areas that held, or still hold, great potential for human therapeutic application. A number of other targets could be added to the list provided here, including inhibitors of kinases such as spleen tyrosine kinase (SYK), zeta-chain associated protein kinase 70 kDa (ZAP70), or IKK (IkB Kinase) that have proven reluctant to identification of clinically successful molecules or have been challenged by toxicity concerns. Disrupting cell surface interactions such as lymphocyte function-associated antigen 1 (LFA-1) with small-molecule inhibitors was likewise met with clinical disappointment. Dissociated glucocorticoid receptor modulators, able to derive the benefit of steroids while minimizing their varied and often serious side effects represent one version of a holy grail in small-molecule immunotherapy. Despite widespread attention, the desired profile has not yet been fully validated clinically.

5.12.5 Emerging Specific Targets

Despite major success in developing targeted immune therapies in the last decade, there is significant unmet clinical need in therapies directed to a number of autoimmune disorders such as lupus, UC, Crohn's disease, RA, etc. Both small-molecule and biological therapies targeting a number of mechanisms are being investigated to bring successful therapies to the market. We summarize the approaches being taken to target the innate and adaptive immune system by employing small-molecule therapeutics.

5.12.5.1 Interleukin-1 Receptor-Associated Kinase 4 (IRAK4)

IRAK4 belongs to the serine–threonine kinase family and is involved in the signal transduction pathways used by interleukin-1 receptor (IL-1R), interleukin-18 receptor (IL-18R), and toll-like receptors (TLRs) of the innate immune response.[108] Of the four mammalian IRAKs, IRAK-4 is the most important from a drug target perspective since it is indispensable for IL-1R/TLR signaling. When ligands derived from different microorganisms or endogenous stimuli bind to either IL-1R or TLR, the adaptor protein MyD88 binds to the receptor via the intracellular toll and interleukin-1 receptor (TIR) domain present on IL-1R, IL-18R, and TLRs. MyD88 acts as a scaffolding protein and recruits IRAK-4, which subsequently recruits either IRAK-1 or IRAK-2 via death domain interactions. Phosphorylation of IRAK-1 by IRAK-4 results in autophosphorylation and activation of IRAK-1 and the release of IRAK-1 from MyD88. IRAK-1 then binds to TNF receptor-associated factor 6 (TRAF6) leading to the activation of NFkB and the production and secretion of proinflammatory cytokines.[109] In addition, it has been observed that cells derived from IRAK-4 deficient patients exhibit impaired responses to IL-1, IL-18, or exogenous MyD88-dependent TLR ligands.[110] These data suggest that targeting IRAK-4 offers the potential for the development of new therapeutics for the treatment of inflammatory diseases.

The involvement of IRAK-4 in TLR7 and TLR9 induced IFNα production, coupled with the observation that dual inhibition of TLR7 and TLR9 in lupus-prone mice results in amelioration of disease symptoms, suggests that IRAK-4 may be a suitable therapeutic target for lupus.[111] In addition, since IRAK-4 is involved in signal transduction pathways used by IL-1R, IL-18R, IRAK-4 inhibitors have the potential for the treatment of RA, osteoarthritis (OA) (IL-1R),[112] IBD (IL-18R), and inflammasome associated diseases including gout, adult onset Still's disease, systemic juvenile idiopathic arthritis (SJIA), and cryopyrin-associated periodic syndromes (CAPS).[113]

Full-length IRAK-4 has a molecular weight of 52 kDa and is composed of 460 amino acid residues. The kinase domain of IRAK-4 is composed of 269 amino acids. Six crystal structures of the kinase domain of IRAK-4 have been reported, three of which are for the apoenzyme with the other three with small-molecule inhibitors bound. One of the novel structural features related to the kinase domain of IRAK-4 is the presence of a tyrosine gatekeeper residue (Y262). Because of the large tyrosine residue, the entrance to the internal hydrophobic pocket is blocked, resulting in lack of accessibility of inhibitor into the pocket. However, this creates a unique extended front pocket (adenosine triphosphate binding pocket), which allows for the design of highly selective inhibitors.[114]

A potential issue with IRAK-4 inhibition is the susceptibility of children with IRAK-4 deficiency to bacterial infections (*P. aeruginosa*, *S. aureus*). Interestingly, adult patients with this deficiency have decreased susceptibility to infections.[115] Although as of this writing no IRAK-4 inhibitors have entered clinical trials, a number of pharmaceutical companies and academic

laboratories are involved in the identification of potent and selective inhibitors, as judged by the activity in the patent and open literature.[116] Proof-of-principle studies in the clinic with IRAK-4 inhibitors will provide insights into future design and development of therapeutics for the treatment of variety of autoimmune disorders based on IRAK-4 .

5.12.5.2 Receptor-Interacting Protein (RIP)

RIP kinases belong to the serine–threonine kinase family, which has seven members: RIP1, RIP2 (RICK/CARDIAK), RIP3, RIP4 (DIK/PKK), RIP5 (SgK288), RIP6 (LRRK1), and RIP7 (LRRK2).[117] From an immunology/inflammation perspective, there has been significant interest in targeting RIP1, 2, and 3.[118a–c] Less research has focused on RIP4-7, as their physiological functions remain incompletely understood. The RIP kinases share a homologous kinase domain but have different functional (nonkinase) domains.

RIP1 and RIP3 are both critical components of the necroptotic cell-death signal transduction pathway.[119] As both kinases are highly expressed in intestinal epithelial cells, inhibition of either target could protect the intestinal epithelial barrier if necroptosis is active during IBD.[120a,b] RIP1 KO mice die within 1–3 days of birth[121]; however, kinase dead knockin mice have been reported to be healthy and viable,[122a–c] implying that an RIP1 scaffolding function is responsible for the pro-survival role in the nuclear factor kB (NFkB) pathway. RIP3 KO mice are viable and demonstrate protection from disease state.[123]

Although highly specific RIP3 inhibitors are unknown, *in vitro* tool molecules have been reported.[124a,b] Crystal structures of mouse RIP3 kinase domain (mRIP3) and the mRIP3-mixed lineage kinase domain-like complex have been reported.[125] Significant synthetic efforts around both Type II and Type III RIP1 inhibitors have been delineated in a number of patents and publications.[126a–g] Crystal structures for Type II[126a] and Type III[127] inhibitors have been acquired with the kinase domain of human RIP1. Small-molecule inhibitors reported to date have demonstrated *in vivo* activity in a PD model.[126a,b] To date, there is no direct evidence that inhibition of RIP1 or RIP3 will have an impact on IBD disease course or remission in humans.

RIP2 signals through the nucleotide-binding oligomerization domain (NOD)1/2 cytosolic sensors,[117] which are activated by components of the bacterial wall. The NOD/RIP2 signaling pathway has been implicated in a variety of autoimmune diseases, including IBD, MS, and Blau syndrome.[128] RIP2 KO mice are viable and demonstrate a critical role in both adaptive and innate immunity.[129a,b] Loss of function NOD2 mutations are highly associated with Crohn's disease.[130]

A number of RIP2 inhibitors have been reported in the literature.[131] Some of these small-molecule inhibitors have demonstrated efficacy in rodent models of autoimmune diseases.[128] To date, only one crystal structure has been reported for RIP2 with the known Type II inhibitor, ponatinib.[132] Although promising for a number of autoimmune diseases, it remains unknown if inhibition of RIP2 could affect the gut microbiota and/or render patients susceptible to intestinal inflammation.

Within the RIP family of kinases, work around RIP1, 2, and 3 to develop small-molecule tool compounds has led to exciting data in *in vivo* PD (pharmacodynamic) and efficacy studies. Significant work remains to translate this early work into drugs, but the promising results observed to date provide a compelling argument to continue on these targets as an avenue to modulate a number of autoimmune diseases.[133]

5.12.5.3 Toll-Like Receptors (TLRs)

TLRs are Type I transmembrane proteins that are expressed by cells of the innate immune system, such as macrophages, B cells, and dendritic cells and beyond the immune system, including epithelial cells, endothelial cells, and tissue resident cells. TLRs play a critical role in the early innate immune response by recognizing pathogen-associated microbial patterns (PAMPs), which are exclusively expressed by microbial pathogens, or danger-associated molecular patterns (DAMPs) that are endogenous molecules released from necrotic or dying cells. Although 10 TLRs have been characterized in humans, from an autoimmune disorder treatment perspective, there has been most significant interest recently in targeting TLR7, 8, and 9.[134] In addition, it has been shown that in TLR7 and TLR9 double-knockout mice, in TLR7 knockout mice, and in TLR7 and TLR8 double-knockout mice, lupus disease, and disease-associated parameters were abrogated.[135–137] Moreover, activation of TLR7, 8, and 9 by immune complexes leads to the production of proinflammatory cytokines like TNF-α and IL-1β along with Type I interferons.[138] Knockout studies and activation pathways described above for TLR7, 8, and 9 clearly suggest that antagonists of these proteins have the potential to treat autoimmune diseases such as lupus, psoriasis, and RA.

TLR7, 8, and 9 are located in the endosome. TLR7 and 8 bind ssRNA, whereas TLR9 binds (ds)DNA containing unmethylated CG dinucleotides.[139] All TLRs have an extracellular ectodomain and an intracellular Toll/IL-1 receptor homology (TIR) domain. A single stretch of about 20 transmembrane amino acids joins both the domains. The ectodomain of TLRs consists of 19–27 consecutive leucine-rich repeat (LRR) motifs and is responsible for recognizing structural patterns in various microbial molecules, in addition to endogenous nucleic acids (vide supra).[140] Recent advances in obtaining crystal structures of the extracellular domains of TLR8 and TLR9 in the absence and presence of ligands open up new opportunities for drug design.[141,142] This is evidenced in the application of crystallographic information in the discovery of novel small-molecule TLR8 agonists.[143]

Oligonucleotides targeting TLRs are in clinical trials. For example, Idera has a TLR7/9 oligo (IMO3100) and TLR7/8/9 oligo (IMO-8400 IMO-9200) which are in Phase 2 trials for psoriasis.[144] However, Dynavax's TLR7/9 oligo (DV1179) did not meet the pharmacodynamic endpoints related to reduction in interferon alpha-regulated genes in a Phase 1a/2b trial for lupus.[145] A number of pharmaceutical companies (Kowa, Janus, Eisai) and academic labs are involved in the identification of potent and selective inhibitors, as judged by the activity in the patent[146] literature. While the ongoing clinical trials will shed more light on the role of TLRs in innate and adaptive immune signaling, it is clear that targeting TLR7, 8, and 9 offers the promise to address unmet clinical need for diseases such as lupus.

5.12.5.4 Retinoic Acid-Related Orphan Receptor γt (RORγt)

The retinoic acid-related orphan receptor (ROR) nuclear hormone receptor family consists of three members: RORα, RORβ, and RORγ. RORγt is a splice variant of RORγ and plays a central role in the differentiation and proliferation of Th17 T cells.[147] This subset of T cells has been linked to the pathology of a number of autoimmune and inflammatory diseases including psoriasis, IBD, RA, and MS.[148] In addition, genetic data with RORγ/RORγt deficient mice clearly suggests the critical role played by this nuclear hormone receptor in the pathogenesis of multiple autoimmune diseases.[149a–c] Therefore, targeting RORγt has emerged as an important strategy for therapeutic intervention in the treatment of autoimmune disorders.[150]

Full-length RORγt consists of 497 amino acids and like most nuclear hormone receptors has a variable N-terminal A/B domain, a highly conserved DNA-binding domain, a hinge domain that connects the DNA-binding domain to the carboxy-terminal ligand binding domain (LBD). The LBD facilitates coactivator and/or corepressor binding to the receptor and consists of 12 α-helices and two additional helices H2′ and H11″.[151] The structural information of small-molecule modulators bound to the LBD of RORγt along with high throughput screens for hit identification has allowed for the discovery of several novel series of RORγt inverse agonists both in academia and industry.[152]

As of this writing, JPT-151 (Japan Tobacco) and VTP-43742 (Vitae Pharmaceuticals), both small-molecule inverse agonists of RORγt, have entered clinical trials.[153,154] These compounds, along with others at various stages of preclinical development, may provide pharmacological validation of the target both from efficacy an and safety perspective. Given the importance of the IL-17/Th-17 axis in autoimmunity, RORγt inverse agonists have the potential to become standard of care for the treatment of a variety of autoimmune disorders.

5.12.5.5 Tyrosine-Kinase 2 (Tyk2)

Tyk2 belongs to the JAK family of nonreceptor tyrosine kinases, which also includes JAK1, JAK2, and JAK3. Members within this family are known to be critical regulators of signal transduction pathways used by the classical Type I and Type II immune cytokine receptors and, as a result, have emerged as promising targets in the treatment of various cytokine-dependent inflammatory and immune disorders.[155] More specifically, Tyk2 has been linked to the downstream receptor signaling of the p40 containing cytokines IL-23 and IL-12 as well as the Type I interferons (IFNα and IFNβ), IL-6, and IL-10 families.[156] Upon receptor activation, Tyk2, in combination with either JAK1 or JAK2, phosphorylates the intracellular receptor domains, which in turn recruit specific STAT proteins. The STATs subsequently are phosphorylated, causing disassociation from the receptor and the formation of STAT dimers that translocate into the nucleus and trigger gene transcription processes leading to an inflammatory response. Studies in Tyk2-deficient mice have suggested that Tyk2 is required for IL-23, IL-12, and Type I interferon signaling, but not IL-6 and IL-10 responses.[157] In humans, only two patients lacking the Tyk2 protein have been reported, and only one of these patients was thoroughly studied for defective cytokine responses.[158] These studies indicated a potentially broader role of Tyk2 signaling in humans versus mouse since IL-6 and IL-10 pathways also were found to be Tyk2-dependent.

Inhibition of Tyk2 has attracted significant attention within the pharmaceutical industry primarily because of the potential to block the signaling pathways of the p40 cytokines IL-23 and IL-12. IL-23 is known to be critical for the expansion and survival of T_H17 cells, which have been associated with the pathogenesis of serious autoimmune diseases including psoriasis and IBD.[159] In addition, IL-12 is essential for T_H1 cell development and the production of IFNγ, which stimulates the innate and T cell-mediated immune response.[160] Overstimulation of T_H1 cells can lead to tissue damage and chronic inflammation in autoimmune diseases, such as systemic lupus erythematosus (SLE). Clinical validation using monoclonal p40 antibodies, which block the IL-23 and IL-12 pathways, has proven to be beneficial therapeutically in both animal models as well as in patients having various autoimmune diseases.[161] For example, ustekinumab, a p40 antibody, has been approved for the treatment of plaque psoriasis and psoriatic arthritic and also is being investigated in the treatment of Crohn's disease.[162] Tyk2 inhibition is also promising because of the potential to target the type 1 interferon pathways. Elevated levels of interferons have been correlated with disease activity in lupus (SLE) patients and validation of this pathway has been demonstrated with sifalimumab, an IFNα antibody and anifrolumab, an antibody targeting the IFN receptor. Both drugs showed significant inhibition of disease progression compared to placebo in a Phase 2 trial.[163]

Most recent efforts within the industry have focused on the development of small-molecule inhibitors of Tyk2. While a recent report[164] describing studies of ATP-competitive small-molecule inhibitors concluded that inhibition of Tyk2 in humans is restricted to only the IL-12 and IL-23 pathways, more recent studies[165] using ligands that selectively bind to the unique pseudokinase JH2 domain of Tyk2 (rather than the active JH1 kinase domain) have demonstrated that potent inhibition of Type 1 IFN signaling, in addition to inhibition of IL-23 and IL-12 signaling, is possible. Despite these efforts, small-molecule Tyk2 inhibitors have not yet been reported in clinical trials to date. Future efforts likely will clarify the role of Tyk2 inhibition in cytokine signaling and better define the true potential of small-molecule Tyk2 inhibitors in the treatment of autoimmune diseases.

5.12.5.6 Protein Kinase C Theta (PKCθ)

PKCθ is a serine–threonine kinase belonging to the diacylglycerol dependent protein kinase C (PKC) subfamily (PKC δ, ε, η, θ).[166] PKCθ has a limited expression profile being found in muscle, nerves, and T cells. On engagement of the T cell receptor, PKCθ migrates to the immunological synapse, where it interacts with LCK (lymphocyte-specific protein tyrosine kinase) and the

cytoplasmic domain of CD28. Its activation results in downstream activation of the mitogen-activated protein kinase pathway, which in turn activates nuclear factor of activated T cells, activator protein 1, and NFkB.[167,168] This results in activation of effector T cells (T_{eff}). PKCθ also has been shown to mediate the negative feedback in regulatory T cells (T_{reg}) and inhibition of PKCθ promotes T_{reg} proliferation, which may be an alternate or contributory mechanism by which PKCθ inhibition can suppress T_{eff} cell function.[169]

Much of the evidence for the potential therapeutic benefit of PKCθ inhibition comes from PKC$\theta^{(-/-)}$ mouse studies. For example, PKC$\theta^{(-/-)}$ mice showed decreased disease severity in the collagen induced arthritis (CIA)[170] model, and transfer of $CD4^{+}CD45RBhi$ T cells from PKC$\theta^{(-/-)}$ mice failed to induce colitis.[171] It also has been reported that PKC$\theta^{(-/-)}$ mice exhibit decreased severity in myelin oligodendrocyte glycoprotein (MOG) induced EAE;[172] however, in a conflicting report, the disease was exacerbated.[173] Thus there appears to be evidence that PKCθ may be a target for several autoimmune mediated diseases. However, in the absence of PKCθ kinase dead mouse studies, it is difficult to establish whether kinase activity or altered immune synapse composition or both contribute to the observed efficacy in PKC$\theta^{(-/-)}$ animal models.

Full-length PKCθ has a molecular weight of ~110 kDa and is composed of 706 amino acid residues. The kinase domain PKCθ is composed of 254 amino acids. Four crystal structures of the kinase domain of PKCθ have been reported to date, and all the structures have small-molecule inhibitors bound. Novel structural features of the PKC family include a C-terminal tail, which can be either ordered or disordered in crystal structures. It has been hypothesized that if an inhibitor makes optimal contacts with the C-terminal tail of PKCθ that this interaction can contribute to increased selectivity against PKCα.[174]

Sotrastaurin, a nonselective PKC family inhibitor, showed similar efficacy to mycophenolic acid when either agent was combined with tacrolimus, basiliximab, and corticosteroids in clinical kidney transplantation studies. However, as sotrastaurin showed limited benefit over standard of care, its clinical development has been halted.[175] Recently disclosed preclinical selective PKCθ inhibitors were able to inhibit staphylococcal enterotoxin B induced IL-2 production in mice and have demonstrated efficacy in a MOG-induced EAE mouse disease model and a T cell transfer colitis mouse disease model.[176] These results are consistent with the efficacy observed in the PKC$\theta^{(-/-)}$ mouse studies and suggest that selective inhibition of the kinase activity of PKCθ plays a role in blocking signal transduction from the immune synapse. The identification of selective PKCθ inhibitors with good pharmacokinetic profiles will allow for proof-of-principle studies in the clinic and accelerate the development of this class of compounds for the treatment of several T cell mediated diseases.

5.12.5.7 Bruton's Tyrosine Kinase (BTK)

BTK is a member of the TEC family of nonreceptor tyrosine kinases and is expressed in all hematopoietic cells, except T cells and plasma cells. Of the five mammalian TECs, BTK is the most important from a target perspective since it is indispensable for signaling through the B cell receptor (BCR) in B cells.[177] In addition to B cells, BTK is critical for signaling in low affinity activating Fcγ receptors (eg, FcγRIII and FcγRIIa) in monocytic cells as well as for FcεRI signaling in mast cells and basophils, where BTK regulates the expression of proinflammatory cytokines, chemokines, and cell adhesion molecules in response to receptor activation.[178] RANK signaling, which regulates osteoclastogenesis from monocytic precursors, is also BTK-dependent.[179]

B cells are central to the pathogenesis of autoimmune diseases such as RA as evidenced by the clinical data for rituximab (Rituxan), a B cell-depleting anti-CD20 antibody.[180] Besides being a source of autoantibodies, B cells can impact autoimmunity through their role as antigen-presenting cells and as sources of proinflammatory cytokines and chemokines such as IL-6 and TNFα.[181] Since the kinase activity of BTK plays a critical role in BCR-dependent proliferation of B cells, as well as expression of costimulatory molecules (eg, CD86) and proinflammatory cytokines, pharmacological inhibition of BTK is expected to affect many mechanisms by which B cells may mediate autoimmunity. There is a significant body of evidence from genetic and pharmacological studies in animal models supporting the utility of BTK inhibitors against autoimmune indications, such as RA or SLE. BTK-deficient mice are resistant to both CIA as well as the (NZB X NZW)F1 model of lupus.[182] Pharmacological inhibition with BTK inhibitors has demonstrated benefit against the CIA and collagen antibody-induced arthritis models as well as in murine lupus models.[183] The critical role of BTK in B cells also is seen in X-linked agammaglobulinemia (XLA) immunodeficiency in humans. Inactivating mutations in the BTK gene in XLA patients cause loss of mature B cells and circulating antibodies.[184]

Full-length BTK has a molecular weight of 76 kDa and is composed of 659 amino acid residues. The kinase domain of BTK is composed of 258 amino acids. Twenty-four crystal structures of the kinase domain of BTK have been reported to date, of which 4 are for the apoenzyme and 20 are with small-molecule inhibitors bound. The key structural feature related to the kinase domain of BTK is the noncatalytic cysteine (C481) residue in the extended hinge region.[185] There are only 10 other kinases that possess a similar cysteine in the kinase active site, creating an opportunity to design selective covalent inhibitors.[185] Numerous companies have targeted this residue to prepare irreversible BTK inhibitors, with the most successful being Imbruvica (Ibrutinib; Pharmacyclics/J&J), which is approved for various non-Hodgkin's lymphomas.[186,187]

A potential issue with BTK inhibition could be increased infections, also observed in XLA patients.[188] To date, the clinical side effects for Imbruvica do include infections, along with increased bleeding and cytopenias.[189] As of the writing in this article, several BTK inhibitors have entered clinical trials for the treatment of an autoimmune indication, including covalent inhibitors from Celgene (CC-292), Hanmi (HM71224), and Principia (PRN1008),[190a,b] with the most advanced appearing to be CC-292, currently in Phase 2 trials in RA.[191] The efficacy data for these and other compounds entering clinical trials is eagerly awaited, since small-molecule inhibitors of this mechanism have the potential to compete with biologics for the treatment of autoimmune diseases such as RA.

5.12.5.8 NFkB-Inducing Kinase (NIK)

NIK (MAP3K14) is a serine–threonine kinase belonging to the STE group of kinases. NIK plays an important role in the activation of the noncanonical NFkB pathway. This pathway is activated by signals from several receptors including CD40, Lymphotoxin βR and BAFF-R, which are responsible for the development and activation of B cells. In resting cells, NIK is degraded rapidly by a complex of TNF receptor-associated factors (TRAFs) and cellular inhibitors of apoptosis. Upon receptor activation, NIK dissociates from this complex and accumulates in the cytoplasm where it phosphorylates IKKα at Ser_{176}, which activates IKKα to phosphorylate p100 at Ser_{866} and Ser_{870}. This phosphorylation event triggers the processing of p100 to p52, which together with RelB, translocates to the nucleus to effect transcription events associated with the noncanonical NFkB signaling pathway.[192] The importance of NIK in B cell development and secondary lymphoid organ development has been confirmed in mice in which NIK has been deleted conditionally.[193] Studies with $NIK^{(-/-)}$ mice have demonstrated that these mice are resistant to MOG-induced EAE and show defects in Th17 differentiation.[194] While NIK clearly plays an important role in adaptive immunity, it also has been reported to play a role in Type I interferon production as part of the innate immune response to viral pathogens.[195] Immune-compromised patients have been identified[196] who have a single-point mutation in the activation loop of NIK, which renders the kinase incapable of phosphorylation of IKKα. These immune-compromised patients exhibit B cell lymphopenia, impaired memory B cell differentiation, abnormal NK cell development, and decreased development of follicular helper T cells. The NIK transgenic mouse data and the phenotype observed in immune-compromised patients with an inactivating mutation in NIK suggest that NIK inhibitors may provide a therapeutic benefit in the treatment of human autoimmune diseases.

Full-length NIK is composed of 947 amino acid residues containing a TRAF binding domain, a kinase domain, and an IKKα binding domain. The kinase domain of NIK is composed of 280 amino acids. Eight crystal structures of either the human or mouse kinase domain of NIK have been reported, with five of the structures having small-molecule inhibitors bound.[197] Novel structural features for this kinase include a mobile glycine rich loop that exists in multiple conformations in the reported crystal structures and a back pocket beyond the methionine gatekeeper that some inhibitors are able to access.[198]

There are several patents[199] and publications[200] which disclose small-molecule inhibitors of NIK, although little to no pharmacologic proof-of-concept has been reported for these inhibitors. Significant advancements in preclinical and clinical development will be required to determine if selective NIK inhibitors will be useful as therapeutic agents for the treatment of autoimmune diseases.

A number of other targets involved in cellular and signaling pathways that lead to inflammation and autoimmunity are being pursued in academic labs and the pharmaceutical industry. For example, selective PAD4 (protein arginine deiminase 4) inhibitors have been identified,[201] and show the potential for therapeutic intervention in autoimmune disorders like RA. A Phase 1 clinical study with the vascular adhesion protein-1 inhibitor, RTU-1096 having anti-inflammatory and immunomodulatory effects has been completed.[202] There is significant effort targeting macrophage migration inhibitory factor (MIF) inhibitors with either anti-MIF antibody or specific MIF antagonists for the treatment of inflammatory and autoimmune diseases.[203] Other targets that are being pursued include inhibitor of 5-Lipoxygenase Activating Protein, CB2 (Cannabinoid Receptor 2) agonists, adenosine receptor modulators, NOD Inhibitors, EP4 antagonists, P2X7 antagonists for the treatment of inflammatory diseases.

5.12.6 Emerging Paradigms

Genetic, immunological, environmental, and hormonal factors, among others, act in concert and contribute to autoimmunity. This section discusses new mechanisms targeting these factors for the treatment of inflammation and autoimmune disorders. These novel and alternative intervention strategies have the potential to satisfy the unmet medical needs that exist in these diseases. Although these targets are challenging from a small-molecule therapeutic perspective, significant progress has been made in identifying compounds that have advanced to the clinic or are being used as tools for proof-of-principle studies.

5.12.6.1 Targeting Epigenetic Mechanisms to Treat Autoimmune Disorders

Epigenetics is defined as the heritable change or alteration of gene expression without underlying modifications in their nucleotide sequence. Epigenetic processes involve DNA methylation, modifications to histones, and regulation by noncoding RNA. Alterations to these processes can result in autoimmune disorders such as SLE, RA, MS, and systemic sclerosis (SSc).

DNA methylation and demethylation are important processes occurring in cells that contribute to cellular proliferation and differentiation. DNA methyltransferases (DNMT) are a group of enzymes that establish methylation of CpG (cytosine-guanine) dinucleotides and inhibit gene transcription by blocking accessibility to transcriptional activators. Demethylation on the other hand can be induced by inhibiting DNMT. Analysis of $CD4^+$ T cells from patients with SLE, RA, MS, and Sjögren's syndrome (SS) has indicated decreased expression of methylation related genes like DNMT1 and hypomethylation of interferon-regulated genes, such as IRF5, IFIT2, STAT1, and USP18.[204] Therefore, DNMT has been proposed as an epigenetic target to improve the outcome of patients suffering from MS and SSc. In preclinical studies, 5-aza-2′-deoxycytidine, a DNMT inhibitor, was shown to prevent autoimmune encephalomyelitis, suppress CNS inflammation, and increase Treg (regulatory T cell) population in the EAE model in mice.[205] In addition, 5-aza-2′-deoxycytidine reversed the hypermethylation of DKK1, SFRP1, and FLI1 in fibroblasts from patients with SSc.[206] However, nucleoside inhibitors such as 5-aza-2′-deoxycytidine are nonspecific DNMT inhibitors and

therefore have the potential for significant off-target liabilities (eg, myelosuppression). Therefore, the emphasis has shifted to identifying isoform-specific DNMT inhibitors to eliminate nonspecific toxicity while improving clinical outcomes.

Analogous to DNA methylation, histones (H1, H2A, H2B, H3, H4, and H5) are another source of epigenetic alteration. Histones are the major protein components of chromatin and they act as spools around which DNA binds. Posttranslational modifications of histones such as acetylation and methylation are maintained by enzymes like methyltransferases and demethylases, and histone acetyltransferases and deacetylases (HDAC). The $CD4^+$ T cells of SLE patients display hypoacetylation (H3 and H4),[207] whereas H4 is hyperacetylated in B cells of patients with SSc (because of decreased HDAC2 and HDAC7).[208] In clinical trials involving 17 patients, the nonselective HDAC inhibitor, givinostat, showed therapeutic benefit in systemic juvenile idiopathic arthritis, particularly in terms of the arthritic components of the disease.[209] However, nonselective HDAC inhibitors have been associated with serious side effects such as thrombocytopenia and cardiovascular issues, which is why the field is moving toward identifying selective HDAC inhibitors for the treatment of autoimmune disorders.[210a,b] Since each HDAC controls the expression of a large number of genes, it will be interesting to see if isoform-specific HDACs will provide the desired therapeutic benefit without affecting normal physiological functions.

Lysine acetylation is a histone modification that allows bromodomain-containing proteins to bind to and regulate gene expression. Bromodomains are 110-amino acid long and specifically bind to lysine residues in histone tails. The human genome encodes a total of 61 bromodomain proteins. It was shown recently that targeting BET (bromodomain and extra-terminal domain), a member of the bromodomain family, with a small-molecule inhibitor leads to antiinflammatory effects.[211] More recently, it was shown that BET plays an important role in human and murine TH17 differentiation, as well as in the activation of previously differentiated TH17 cells.[212] In vitro, a selective small-molecule inhibitor of BET (JQ1) blocked the expression of signature Th17 cytokines, including IL-17, IL-21, and GM-CSF (granulocyte macrophage colony-stimulating factor) without affecting Th1, Th2, and Tregs. *In vivo*, JQ1 decreased IL-17 production and decreased severity in mouse models of arthritis (CIA model) and MS (EAE) when dosed at 30 mg kg^{-1} twice daily.[212] The *in vitro* results obtained with JQ1 are in contrast with the results obtained with GSK525762, another BET inhibitor, which suppressed the proinflammatory functions of Th1 cells but did not affect Th17 cells.[213] In addition to BET, several bromodomain proteins have been described as potential targets for the treatment or prevention of autoimmune and inflammatory diseases (ATAD2, BAZ1B, SP110, SP140).[214] Since the current inhibitors are relatively unselective and affect multiple immune cells, the tolerability and safety profiles of these compounds are a cause for concern. JQ1 is in clinical trials for oncology indications and the safety data from these trials along with the identification of isoform selective BET and other bromodomain family of inhibitors will be crucial for advancing these compounds into the clinic for treating autoimmune disorders.

MicroRNAs (miRNAs) are small noncoding regulatory RNAs of about 22 nucleotides and are involved in regulating gene expression via translational repression, mRNA destabilization, and degradation. Aberrantly expressed miRNAs modulate multiple genes related to autoimmunity and therefore play a significant role in the pathogenesis of disorders such as SLE, MS, RA, and SSc. Common miRNAs that are dysregulated in autoimmune diseases are miR-21, miR-29a and b, miR-30a and b, miR-146a, miR-155, and let-7a. miRNA sponges and antisense oligonucleotides against miRNAs have been used to demonstrate in vitro and in vivo efficacy by suppressing miRNA function and blocking their effect on the expression of endogenous target genes.[204] Except for one report of a small-molecule inhibitor affecting miR-21 expression,[215] small-molecule approaches have yet to make an impact in this area, although they have the potential to target multiple steps of miRNA assembly and function and provide an alternate approach for the treatment of autoimmune disorders.

5.12.6.2 Inflammasome

The inflammasomes are high molecular weight intracellular protein complexes that activate inflammatory caspases leading to the processing of the proinflammatory cytokines IL-1β and IL-18. Both IL-1β and IL-18 are key players in the initiation and maintenance of a number of pathological processes associated with autoimmune disorders and inflammation. Inflammasome activation has also been associated with several neurologic disorders such as Alzheimer's disease, MS, and Parkinson's disease; metabolic disorders such as atherosclerosis, type 2 diabetes, and obesity; and autoinflammatory diseases such as gout and CAPS.

Unlike other transcriptionally regulated cytokines, which are released in the active form upon induction, IL-1β and IL-18 are synthesized as proforms in response to stimulation of toll-like receptors by pathogen-associated molecular patterns (PAMPs) as well as by damage associated molecular patterns (DAMPs). The proforms require processing for secretion and biologic activity.[216] Four different mammalian inflammasomes have been characterized to date, and they are defined by the LRR–containing Nod-like receptor (NLR) proteins that they contain: the NLRP1/NALP1b inflammasome; the NLRC4/IPAF inflammasome; the NLRP3/NALP3 inflammasome; and the AIM2 containing inflammasome.[217]

Structurally, three domains characterize the NLRs: a C-terminal LRR domain, an intermediate nucleotide-binding and oligomerization domain (NOD, also called NACHT domain), and an N-terminal pyrin (PYD) domain. NLRP1 has an additional C-terminal caspase activation and recruitment domain (CARD). Although the mechanisms have not been described in detail, activation is thought to be triggered by recognition of a stimulus via the LRR domain. This results in recruitment and oligomerization of the adaptor protein ASC via interactions with the PYD domain. ASC also contains a C-terminal CARD domain that subsequently recruits pro-caspase 1, resulting in its autoproteolytic activation.

Small-molecule approaches targeting the inflammasomes have been challenging from a screening perspective because of the tendency of these proteins to form aggregates. Despite this challenge, significant inroads are being made to identify inhibitors of

these targets to fully understand their role in autoimmune diseases. For example, using a recombinant GST-His-Thrombin-NLRP1 protein a diverse set of ATP-competitive inhibitors with micromolar potencies have been identified for NLRP1.[218] In a major breakthrough, two groups recently reported the identification of MCC950 and β-hydroxybutyrate as novel inhibitors of the NLRP3 inflammasome.[219,220] These inhibitors should help clarify the role of NLRP1 and NLRP3 in autoimmunity and inflammation and lead to therapeutics that halt progression of inflammatory diseases.[221]

5.12.6.3 Autophagy

Autophagy is a cellular process that involves sequestration and degradation of intracellular pathogens and damaged organelles in order to maintain cytoplasmic homeostasis.[222] Autophagy plays a multifaceted role in both innate and adaptive immunity leading to protection against disease.[223] In innate immunity, autophagy is involved in regulation of cytokine production, inflammatory transcriptional regulation, oxidative stress and inflammasome activation, in addition to its role in pathogen degradation. In adaptive immunity, autophagy plays an important role in T cell maturation and polarization, T and B lymphocyte homeostasis, and antigen processing and presentation. Given the central role of autophagy in these important immune processes, any dysregulation will lead to the development of autoimmune disorders and inflammation. In addition, genetic association studies have confirmed the link between defects in autophagy and autoimmune diseases, particularly Crohn's[224] and SLE.[225] MTOR inhibitors such as rapamycin have been shown to be protective against intestinal inflammation[226] and SLE[227] both in mouse models and patients.[228] However, the precise role of small-molecule inhibitors in the clinical modulation of autophagy in various diseases is still unclear. For example, compounds such as rapamycin do not directly regulate the autophagy process but rather are involved in activating or inhibiting a number of other cellular processes, raising the question of specificity. Identification of key targets that regulate autophagy will help in the development of selective modulators with an appropriate signaling bias and improved therapeutic index. In addition, because of polymorphism associated with some autoimmune disorders such as Crohn's and SLE (vide supra), identification of predictive biomarkers may be necessary for future autophagy therapy.

5.12.6.4 Microbiome

The microbiome has been defined as the microorganisms that populate the human gut, skin, and other organs of the body. These microorganisms share a commensal, symbiotic, or pathogenic relationship with the human body. Because of the proximity of the microbiome to epithelial and mucosal cells, they affect and regulate the immune, cardiovascular and nervous systems. For example, factors that change the balance and composition of gut bacteria can lead to dysbiosis and changes in immune function. For autoimmune disorders, microbiome research has focused particularly on the treatment of RA, MS, and IBD (UC and Crohn's).[229] Although fecal microbial transplant and microbiota based therapies have garnered significant attention for the treatment of these disorders, research is shifting slowly to the identification of small-molecule drugs as a treatment therapy for autoimmune diseases.[230] One reason for this is the increased understanding of the processes that lead to these diseases by comparing healthy and diseased microbiota from mucosal biopsies and using bioinformatics technology to identify targets that are modulated by the microbiome. For example, SGM-1019 an orally delivered small molecule from Second Genome, Inc. recently completed double-blind, placebo-controlled, single ascending oral dose trial in healthy subjects.[231] Although the target of SGM-1019 has not been disclosed, Second Genome plans to evaluate the compound in Crohn's disease. Enterome is developing EP-8018 for the treatment of Crohn's disease.[232] This compound is supposed to limit binding of a type of bacteria called adherent-invasive *E. coli* to the CEACAM6 receptor leading to the suppression of TNF production. Another area of research gaining momentum is to identify natural product drug leads from small molecules produced by the human microbiome. A success story in this area is FDA approval in 2012 of linaclotide (a homolog of the enterotoxin peptides produced by *E. coli* that cause diarrhea) for the treatment of irritable bowel syndrome. Human microbiome research is expected to take off in the coming years to answer fundamental questions related to the understanding of mechanisms causing disease and identifying targets leading to transformative therapeutics.[233]

5.12.6.5 Targeting the Complement System for Inflammatory Disorders

The complement system was classically defined as being a component of the innate immune system that complements or helps antibodies and phagocytic cells to clear pathogens. However, it has been established that the complement system plays an important role in bridging the innate and adaptive immune responses. Since three different pathways activate the complement cascade (the classical complement pathway, the alternative complement pathway, and the lectin pathway), a number of targets are available for therapeutic intervention. Activation of the complement system results in the release of proinflammatory anaphylatoxins such as C3a and C5a resulting in tissue damage and contributing to the pathogenesis of several autoimmune diseases such as SLE, SS, SSc, dermatomyositis (DM), MS, and RA.[234] Biologic as well as small-molecule strategies have been employed for interfering with the complement system cascade in experimental models of autoimmune disease. For example, PMX53, a small-molecule C5a mimetic that binds to the C5a receptor, showed preclinical efficacy in a rat antigen-induced arthritis model.[235] However, the compound did not reduce synovial inflammation when administered to RA patients in clinical trials.[236] It has been reported that pharmacological inhibition of C5a with PMX205, a small-molecule C5a receptor antagonist, prevented dextran sulfate sodium induced colitis in mice[237] suggesting antagonists of C5a have the potential for the treatment of IBD. Compared to

C5a, therapeutic modulation of C3a with small-molecule antagonists has been challenging, although tool molecules continue to be identified to dissect the role of C3a and its receptor in autoimmune disorders.[238a,b] To the best of our knowledge, no small-molecule complement antagonists are in clinical trials for the treatment of SLE, SS, SSc, DM, MS, or RA. CCX168 (ChemoCentryx), a small-molecule C5a antagonist is being evaluated in Phase 2 clinical trials for antineutrophil cytoplasmic Ab-associated renal vasculitis (NCT01363388).[239] The increasing interest in academia and industry to identify highly specific complement inhibitors will help analyze complement modulation pathways and identify therapies for treating autoimmune disorders in the coming years.[240a,b]

5.12.6.6 Regulatory T Cell Therapy

T regulatory cells (Tregs) are $CD4^+CD25^+$ T cells that express the transcription factor Foxp3 and play a critical role in regulating immune suppression and preventing autoimmune diseases by suppressing self-reactive T cells. In addition to $CD4^+$ T cells, Tregs suppress the proliferation, activation, and cytokine production of $CD8^+$T cells, B cells, antigen-presenting cells, and natural killer cells.[241] Foxp3 knockout mice develop thyroiditis, diabetes, dermatitis, and IBD[242] and a similar phenotype is seen in humans with mutations of the Foxp3 gene.[243] Therefore, there is significant interest in augmenting Treg population to treat human autoimmune disorders. The concept is to isolate Tregs and then adoptively transfer them to patients with autoimmune disorders to potentially suppress the ongoing autoimmune response. Although conceptually simple, the challenge has been to isolate highly pure Tregs using the best cell surface marker, since a small percentage of contaminated T cells potentially can exacerbate the autoimmune disease.[244] However, there is a certain level of plasticity associated with Tregs since cells that are originally $Foxp3^+$ can convert to nonregulatory $Foxp3^-$ pathogenic effector cells.[245,246] This would suggest that the stability of Tregs still would be questioned even if a pure population can be generated and adoptively transferred. Despite these challenges, a strategy to rapidly generate Tregs and adoptively transfer them to suppress immune responses in a mouse model of arthritis has been demonstrated.[247] More importantly, significant success using Treg therapy was achieved in acute graft versus host disease (aGVHD) in a clinical setting.[248,249] The pioneering work using Tregs for treating patients with aGVHD disease has laid the foundation to study Treg therapy in other autoimmune diseases.[250] Although targets for Treg modulation have yet to be validated with small-molecule intervention, one can anticipate significant activity in this area during the next decade.

5.12.7 Conclusion

In addition to the emerging paradigms described above, other innovative approaches are being employed to modulate immunological functions for the treatment of inflammatory and autoimmune disorders. For example, as described above, irreversible BTK inhibitors have opened up a potential new paradigm for the modulation of immunologic pathways relevant to diseases such as RA. Additionally, the application of DNA-encoded chemical library technologies has resulted in the identification of macrocyclic[251] and small-molecule inhibitors[252] of IL-17A with potential utility for the treatment of psoriasis and other autoimmune disorders. Modulation of antibody recognition using antibody-recruiting small molecules is an avenue of research that is being pursued for manipulating immune function.[253]

From an immune tolerance perspective, modulation strategies targeting Tregs (*vide supra*) will continue to remain the focus of attention for therapy in many autoimmune disorders.[254,255] In addition, combination therapies targeting two or more pathways are being considered in order to potentiate efficacy in autoimmune disease.[256] This will be particularly true for diseases that have proven refractory to treatment with single agents, such as lupus nephritis.

Moving forward, precision medicine paradigms will be used increasingly for the treatment of autoimmune disorders. Because of the heterogeneity of inflammatory disorders, identifying patient populations that respond to targeted therapies based on their underlying disease pathogenesis is important (stratified medicine), since patients are likely to receive greater clinical benefit.[257] Bioinformatics, "omics" technologies, and biomarkers are being used as stratification tools for predicting patient subsets that will respond to a particular treatment. For example, transcriptomics (mRNA), metabolomics (metabolites), proteomics (proteins), and genomic technologies, in combination with bioinformatics, are being employed to derive a clear relationship between abnormalities in the immune system and disease pathology. Biomarkers on the other hand are helpful in identifying patients who likely would benefit from treatment (predictive biomarkers) or where patients have an increased risk of disease progression (prognostic biomarker). This will lead to greater clinical benefit for patients with the underlying disease pathophysiology and spare patients from exposure to drugs that carry some risk for whom they would have little benefit.[258] In addition to benefiting the patient, economic benefits over the long term will be quite significant if stratified medicine approaches are considered for the treatment of inflammatory and autoimmune diseases.

It is clear from the discussion throughout this article that the past decade has witnessed our ability to bring forward breakthrough oral therapies for the treatment of autoimmune disorders. Because of the increased understanding of the immune system and the introduction of revolutionary new technologies during the past decade, small-molecule therapeutics have the potential to treat diseases of high unmet medical need and significantly change the clinical landscape of autoimmune disorders during the next decade.

Acknowledgments

The authors would like to sincerely thank Leacy Prior and Tisha Zawisky for literature searches, Dr. Julie Carman for critical review of the article, and Dr. William J. Pitts, Dr. Amy Hart, Dr. Stephen T. Wrobleski, and Dr. Joseph A. Tino for their contributions.

5.13.1 Small Molecule Immunosuppressants in Inflammatory Disease

5.13.1.1 Cytokine Signaling

In chronic inflammatory diseases such as rheumatoid arthritis (RA), there is pathologic activation of cytokine signaling in affected tissues. Several key signaling pathways are involved in the pathogenesis of RA and other inflammatory diseases, many of which use intracellular protein kinases for signal transduction.[1] Inhibiting these kinases modulates the inflammatory reaction and reduces disease activity. Specifically inhibiting intracellular signal transduction pathways that modulate immune cell functions such as surface receptors, signaling proteins, and transcription of nuclear proteins was postulated as a reasonable approach to treating chronic inflammation conditions such as RA and psoriatic arthritis (PsA).[2] There are a number of intracellular signaling pathways implicated in RA and other inflammatory diseases: JaK-STAT, MAPK, SyK, Btk, and PDE4 inhibitors and drugs targeting these pathways are in various stages of development; a JaK inhibitor for use in RA and a PDE4 inhibitor for use in PsA and psoriasis (PsO) are approved in many countries. This section will provide a summary of what is currently known about their clinical efficacy and safety.

5.13.1.2 MAP Kinases

5.13.1.2.1 MAP kinase pathway

The MAPK pathway is a critical regulator of processes such as cell proliferation, differentiation, growth, and survival.[3,4] Cytokines that signal through the MAPK pathway include tumor necrosis factor (TNF)-α, interleukin (IL)-1, IL-2, IL-6, IL-7, and IL-10.[5–7] MAPKs make up a family of more than 20 serine/threonine kinases.[8] The three groups of MAPKs that have been well characterized include the extracellular signal-regulated kinases (ERKs), the c-Jun N-terminal kinases (JNKs), and the p38 MAPKs.[9] Upon receptor activation, MAPKs are activated by sequential phosphorylation of upstream MAPKs and MAPKs. The MAPK pathway is activated in RA and psoriasis.[10,11] Activated ERK, JNK, and p38 MAPKs have been detected in synovial tissue isolated from patients with RA but not in synovial tissue isolated from patients with osteoarthritis. Significantly higher levels of activated MAPK-4 and MAPK-7 were observed in synovial samples from patients with RA compared to patients with osteoarthritis. In psoriasis, epidermal sections from psoriatic lesions show elevated levels of activated MAPK and ERK compared with healthy skin.[12]

5.13.1.2.2 MAP kinase inhibitors in RA

Several MAPK inhibitors have been developed and studied in RA. As a group, they have had disappointing efficacy, possibly because of the redundancy in the systems, and/or significant toxicity. Compounds that did not demonstrate efficacy include pamapimod (1), an oral inhibitor of the p38 MAPK α-isoform, SCIO-469 (2), and VX-702 (3).[13–18] Two of these p38 inhibitors were efficacious in RA, BMS-582949 (4) and VX-745 (5). The development of both compounds was halted because of neurologic adverse events noted in animal studies. At this time, no MAPK inhibitors are under development for the treatment of RA.

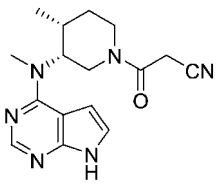
5.13.2 Jakinibs in RA

5.13.2.1 Tofacitinib

Tofacitinib (**6**) is a small-molecule chemical pan JaK inhibitor.[19] By binding to Jak3/1/2, tofacitinib inhibits activation of STAT molecules and downstream signaling, resulting in modulation of inflammatory responses.[20,21]



tofacitinib, **6**

5.13.2.1.1 Clinical development of tofacitinib

The approved dose of tofacitinib in most countries is 5 mg orally twice daily and may be used as monotherapy or in combination with conventional synthetic disease-modifying antirheumatic drugs (csDMARD) including methotrexate (MTX); its approvals have been based on the results of 6 pivotal, randomized, double-blind, placebo-controlled phase III trials.[22–27] An 11 mg once-daily tablet has recently been introduced. Tofacitinib has not been tested, and is not approved for use, in combination with biologic disease-modifying antirheumatic drugs (bDMARDs). Clinical studies evaluating the use of tofacitinib in patients with ankylosing

spondylitis, juvenile idiopathic arthritis, ulcerative colitis, and PsA are currently under way; the full results of these trials have not been presented prior to submission of this article for publication. An additional study comparing tofacitinib as monotherapy or in combination with MTX to adalimumab plus MTX should be available in 2017.

5.13.2.1.2 Pivotal clinical trial results with use of tofacitinib as monotherapy

ORAL Solo Phase 3 study investigated tofacitinib 5 and 10 mg BID compared to placebo as monotherapy over 6 months in patients with active RA who had had an inadequate response to at least 1 csDMARD or bDMARDs.[22] At 3 months, significantly more patients treated with either dose of tofacitinib achieved an American College of Rheumatology 20%, 50%, and 70% (ACR20/50/70) improvement response and improvement in physical function, as measured by the health assessment questionnaire-disability index (HAQ-DI), compared with placebo.

ORAL Start study investigated the efficacy of 5 and 10 mg tofacitinib monotherapy versus MTX monotherapy in patients with active RA who were naïve (93%) or received no more than 3 doses of MTX (7%) over 24 months. In this study, clinical, functional, and radiographic responses were assessed.[23] Both doses of tofacitinib monotherapy demonstrated significant improvements in ACR20/50/70 responses, disease activity score (DAS)28-erythrocyte sedimentation rate (DAS28-ESR) < 2.6, and HAQ-DI responses compared to MTX monotherapy. In addition, both doses achieved significance in preventing structural damage compared with MTX, as assessed by change in van der Heijde-modified total sharp score (vdHmTSS) as early as 6 months, which was maintained at 24 months.

5.13.2.1.3 Use of tofacitinib in combination with csDMARDs

ORAL Sync clinical trial investigated the efficacy and safety of tofacitinib 5 and 10 mg on background csDMARDs compared to patients on background csDMARDs taking placebo in a 12-month trial; all patients had active RA in spite of background csDMARDs.[24] Patients treated with either dose of tofacitinib plus csDMARDs achieved significantly greater ACR20 responses and DAS28(ESR) < 2.6 at 6 months compared with placebo plus csDMARDs. At 3 months, significantly more patients improved their HAQ-DI with either dose of tofacitinib compared with placebo.

ORAL Standard study compared patients with active RA in spite of MTX therapy, which was continued, treated with tofacitinib 5 or 10 mg orally BID to patients treated with placebo. In this trial, an additional comparator arm included adalimumab (ADA) plus MTX which was also compared to placebo plus MTX but not to tofacitinib.[25] Patients treated with either dose of tofacitinib plus MTX or ADA plus MTX achieved significantly greater ACR20/50/70 responses and percentages of patients achieving DAS28-ESR < 2.6 at 6 months than placebo plus MTX. At month 3, HAQ-DI improvement was significantly greater in patients treated with combination of tofacitinib and MTX as well as ADA plus MTX compared to placebo plus MTX. The clinical and functional responses achieved with tofacitinib were similar to those achieved with ADA compared with placebo, although the responses were numerically higher with tofacitinib.

ORAL Scan clinical study investigated the efficacy and safety of tofacitinib 5 and 10 mg orally BID with background MTX compared to patients on background MTX taking placebo in a 12-month study which assessed the clinical, functional, and radiographic efficacy of tofacitinib 5 and 10 mg BID in patients with active RA in spite of MTX, to placebo. Structural damage was assessed by the vdHmTSS.[26] At 6 months, patients treated with either dose of tofacitinib achieved statistically significant improvements in ACR20/50/70, DAS28-ESR < 2.6 at month 6 and HAQ-DI scores at month 3.The 10 mg dose of tofacitinib plus MTX statistically significantly inhibited structural damage compared with placebo plus MTX; the 5 mg tofacitinib dose did not. Tofacitinib also achieved significant improvements in patient-reported outcomes, including Patient Global Assessment of disease activity, patient-reported pain, HAQ-DI, and health-related quality of life at months 3 and 24 vs baseline.[27]

ORAL Step clinical study evaluated tofacitinib 5 and 10 mg orally BID in patients with active RA who were on background MTX who had failed ≥ 1 TNF antagonist.[28] At 3 months, statistically significantly more patients treated with tofacitinib—MTX combination therapy achieved ACR20/50/70 responses, DAS28-ESR < 2.6, and HAQ-DI improvement compared with patients treated with placebo plus MTX. Tofacitinib was also associated with significant improvements in Patient Global Assessment of Disease Activity and Short Form 36 Health Survey version 2 physical and mental component summary scores vs placebo.[29]

5.13.2.1.4 Long-term efficacy (LTE) of tofacitinib

Long-term efficacy of tofacitinib, both 5 and 10 mg BID, either as monotherapy or in combination with csDMARDs, from pooled data of 2 open-label extension trials (LTE) including 4858 patients with RA showed sustained ACR20/50/70 responses, maintenance of DAS28 < 2.6, and improvement in HAQ-DI up to month 72. Approximately 36% of the patients in the LTE discontinued treatment over this time frame, 2.7% for lack of efficacy.[30,31]

5.13.2.1.5 Safety (Table 1)

The safety of tofacitinib has been assessed in 12 phase 2 and 3 trials and two LTE of 5671 patients with median tofacitinib exposure of 2.35 years[22–26,28,32–34]

5.13.2.1.5.1 Infections

The most common adverse event (AE) reported during the first 3 months of treatment was infection, occurring in 20% of patients in the 5-mg BID groups and 22% in the 10-mg BID groups compared with 18% in the placebo groups.[34] Serious infection events (SIE) were reported in 11 patients who received tofacitinib compared with 1 patient who received placebo in the phase 3 studies. In the

LTE, SIE occurred in 4.5–7.2% of patients with an incidence rate of 2.9–3.1/100 patient-years.[30,31,33] The most frequent investigator-reported infection and infestation AE were nasopharyngitis (12.7–16.3%), upper respiratory tract infection (10.5–14.5%), and urinary tract infection (6.6–10.3%). Tuberculosis (TB) has been reported in the LTE of tofacitinib, primarily in countries with high endemic rates of TB. For this reason, patients should be screened for latent TB prior to initiating therapy.[34] Other opportunistic infections, similar to those observed with bDMARD therapy, have been reported as well. Herpes zoster (HZ) was reported in ~4% of patients receiving tofacitinib.[30,31,34] with an incidence of closer to 8% in Japan. The incidence of serious HZ (multidermatomes or systemic involvement) has been reported as occurring in ~1% of patients.[34] Although HZ is also reported in patients receiving bDMARDs, the incidence is lower than with tofacitinib.

5.13.2.1.5.2 Malignancies

Of 5671 tofacitinib-treated patients, 107 developed malignancies; the most common were lung cancer in 24 patients, breast cancer in 19, and lymphoma in 10. Twenty of the lung cancer patients were current or former smokers. This incidence is not different than what has been reported in patients with active RA. The types of malignancies and the overall incidence rates have remained stable over time with continued tofacitinib exposure. The standardized incidence ratio as compared with the US National Cancer Institute Surveillance, Epidemiology, and End Results database is ~1[35] The rate of occurrence is similar to what has been reported with the use of bDMARDs.

5.13.2.1.5.3 Hematology

In the LTE, a decrease in hemoglobin and neutrophils in 4.6% and 1% of patients, respectively, were reported.[30] The neutropenia has not been associated with infections or SIE. Importantly, lymphopenia of <500 cells/mm^3 was seen in $<1.0\%$ of patients; ~50% of patients with lymphopenia developed an SIE.[30,36]

5.13.2.1.5.4 Liver tests

Elevated liver aminotransferases >3 times the upper limit of normal were reported in 2.0% (alanine aminotransferase) and 0.9% (aspartate aminotransferase) of patients treated with tofacitinib in combination with a csDMARD, primarily MTX.[30] In contrast, elevated liver tests did not occur more frequently than with placebo in patients treated with tofacitinib monotherapy.

5.13.2.1.5.5 Lipids and cardiovascular events

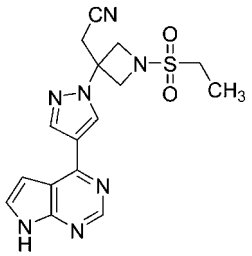
Elevated lipids occurred in ~20% of patients treated with either 5 or 10 mg tofacitinib BID.[34] The elevations occurred rapidly but can be treated effectively with the use of lipid-lowering agents.[37] It is not clear, however, if the increase is pathogenic.[38] A 3-year follow-up of patients with RA suggests that tofacitinib does not appear to increase the risk of cardiovascular events or lead to changes in blood pressure; the question is still not resolved, however, as longer follow-up with many more patients is needed to answer this question definitively.[39]

5.13.2.1.5.6 Tofacitinib in other autoimmune diseases

Additional clinical studies of tofacitinib in patients with juvenile idiopathic arthritis, ulcerative colitis, and PsA are currently under way; results have not yet been reported.

5.13.3 Baricitinib

Baricitinib (7) is an investigational oral, once-daily Jak1/2 inhibitor currently in development for the treatment of RA.



baricitinib, **7**

5.13.3.1 Phase 2b Clinical Trial of Baricitinib I

A dose-ranging, placebo-controlled, phase 2b study investigated baricitinib in combination with MTX; placebo 1, 2, 4, and 8 mg doses were evaluated. The 4 and 8 mg doses plus MTX demonstrated significant clinical improvement with ACR20 responses at 12 weeks of 76% with either 4 or 8 mg compared to 41% with placebo ($p < .001$) with a safety profile that favored the 4 mg dose.[40]

5.13.3.2 Four Pivotal Phase 3 Clinical Trials Have Been Reported

5.13.3.2.1 Use of baricitinib as monotherapy compared to combination therapy in MTX naïve patients

RA-BEGIN was a phase 3 study of baricitinib in 584 patients administered as monotherapy or in combination with MTX in patients with early active RA who had limited or no prior treatment with csDMARDs.[41] Patients were randomized to MTX, baricitinib 4 mg QD as monotherapy, or baricitinib 4 mg QD + MTX for up to 52 weeks. The primary endpoint was the noninferiority of baricitinib 4 mg monotherapy to MTX on ACR20 response at week 24. ACR20 response at week 24 favored baricitinib 4 mg monotherapy vs MTX (77% vs 62%, $p \leq .01$). Compared to MTX, baricitinib 4 mg monotherapy produced significantly greater improvements in multiple secondary measures of disease activity including ACR50/70 response, DAS28(ESR), CDAI and SDAI remission, and low disease activity (LDA). MTX in combination with baricitinib 4 mg had similar efficacy as baricitinib monotherapy, suggesting that baricitinib does not require MTX for clinical or functional efficacy. Radiographic progression was assessed in this trial. Baricitinib in combination with MTX was statistically superior to MTX monotherapy; Baricitinib monotherapy was numerically, but not statistically, superior to MTX. Clinically, the change in all three groups (MTX, baricitinib plus MTX, and baricitinib monotherapy) was all very similar. Patient-reported outcomes were statistically superior with baricitinib as monotherapy or in combination with MTX, compared to MTX, many as early as week 1.[42] Rates of treatment-emergent adverse events (TEAEs) and serious adverse events (SAEs) were similar across groups although there were more laboratory abnormalities in patients treated with MTX either as monotherapy or in combination.

5.13.3.2.2 Baricitinib in combination with csDMARDs

5.13.3.2.2.1 Baricitinib in patients who failed a TNFi

RA-BEACON enrolled 527 patients with active RA on csDMARDs with an inadequate response to at least one TNF inhibitor.[43] Patients were treated with either 2 or 4 mg of baricitinib or placebo. Both doses of baricitinib were superior to placebo with ACR20 responses achieved in 49% and 55% of patients on 2- and 4-mg doses, respectively, compared with 27% of patients receiving placebo at week 12 (either dose vs placebo $p \leq .001$). DAS28(ESR) < 2.6 was improved in both baricitinib arms vs placebo.

5.13.3.2.2.2 Baricitinib in csDMARD-IR with evaluation of radiographic progression

RA-BUILD study enrolled 684 patients with active RA and an inadequate response to csDMARDs therapy.[44] Patients were treated with either 2 or 4 mg of baricitinib or placebo. Both doses of baricitinib were superior to placebo with ACR20 responses in 66% and 62% of patients on 2- and 4-mg doses of baricitinib vs 40% of patients receiving placebo (either dose vs placebo $p \leq .001$). Radiographic progression, measured by the vdHmTSS, was significantly less with both doses of baricitinib vs the placebo arm.

5.13.3.2.2.3 Baricitinib in csDMARD-IR compared to adalimumab (ADA)

RA-BEAM enrolled 1305 patients with active RA despite stable background MTX who were randomized to placebo, baricitinib 4 mg QD, or adalimumab 40 mg biweekly.[45] The primary endpoint was ACR20 response at week 12. ACR20 response at week 12 for baricitinib vs PBO was 70% vs 40%, $p \leq .001$. At weeks 12 and 24, statistically significant improvements in ACR 20/50/70 & HAQ-DI response rates, and DAS28, CDAI, and SDAI LDA and remission rates were seen for baricitinib vs PBO. Compared to adalimumab, baricitinib was superior with respect to ACR20/50/70 response, improvement in DAS28-CRP, and HAQ-DI

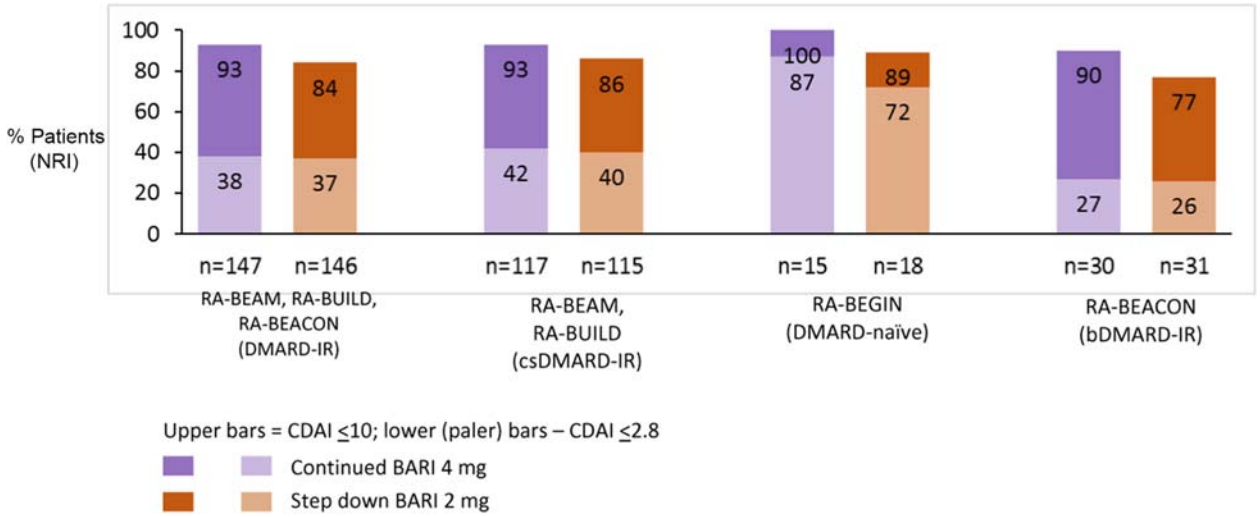


Fig. 1 Baricitinib dose step-down following disease control in patients with rheumatoid arthritis.[46] Upper bars, CDAI <10; lower (paler) bars, CDAI <2.8.

improvement. Compared to placebo, daily diary measures of morning joint stiffness duration and severity, worst tiredness, and worst joint pain were significantly improved in patients receiving baricitinib.

The phase 3 studies of baricitinib demonstrated clinical efficacy of both 2 and 4 mg QD dose in patients with active and an inadequate response to csDMARDs or bDMARDs. In general, greater, more rapid, and more consistent treatment effects were observed for the 4 mg dose across multiple measures.

5.13.3.3 Baricitinib Long-Term Extension Study

In the LTE, RA-BEYOND, the effects of baricitinib dose step-down in patients who had achieved sustained CDAI <10 in csDMARD-IR or CDAI <2.8 in RA-BEGIN, was investigated.[46] Patients who completed a baricitinib phase 3 trial (RA-BEGIN, RA-BEAM, RA-BUILD, or RA-BEACON) could enter the LTE and those patients who had received baricitinib 4 mg for at least 15 months and who had achieved sustained LDA or remission (defined by CDAI score at 2 consecutive visits at least 3 months apart) were rerandomized in a double-blind manner to continue receiving baricitinib 4 mg or to step down to 2 mg QD (RA-EXTEND).[46] At the time of this report, disease activity was assessed at the 12-week time point following rerandomization. Among the patients who achieved satisfactory and sustained disease control with the 4 mg QD dose, randomized, double-blind dose reduction to 2 mg QD there was a modest, statistically significant increase in disease activity across measures at the subsequent 12-week time point. However, many patients in both the continued 4 mg and reduced to 2 mg groups retained a state of LDA or remission that had initially led to their re-randomization (Fig. 1). These data suggest that 4 mg QD is the most efficacious dose for patients with RA and most patients who achieve sustained disease control with baricitinib 4 mg maintained sustained LDA or remission 12 weeks after being rerandomized, in a blinded manner, to 2 mg QD.

5.13.3.4 Safety of Baricitinib

The integrated safety analysis of baricitinib has been reported in abstract form on six studies of baricitinib 4 mg QD compared to placebo and dose-response assessments on four studies with baricitinib 2 and 4 mg QD and PBO arms.[47] Three thousand four hundred and sixty-four patients were exposed to baricitinib (4214 pt-yrs (PY); 2166 patients >1 year and 467 >2 years. In the controlled periods of these studies, there were no increases seen in deaths, AEs leading to study drug discontinuation, malignancies, major cardiac events, or serious infection for baricitinib vs placebo. HZ was reported more frequently for baricitinib vs placebo. In randomized, controlled periods of the studies, TB was reported in two patients, one treated with baricitinib and one with adalimumab. In the LTE, 6 TB events were reported (baricitinib 4 mg: two with incomplete TB screening, three without organism confirmed). All TB occurred in endemic areas. Two GI perforations were reported (0.05/100 PY). No confirmed opportunistic infections were reported. Baricitinib treatment was associated with neutropenia, liver test abnormalities, and lipid elevation, similar to tofacitinib; few patients (<1%) discontinued due to abnormal lab results (Table 2).

Table 2 Integrated safety analysis arms[47]

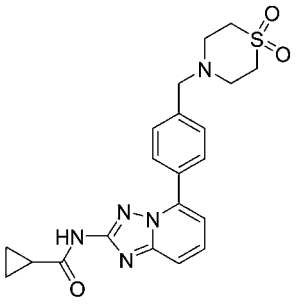
5.13.4 Filgotinib

Filgotinib (GLPG0634; **8**) is an oral, once-daily Jak1-selective inhibitor that was found to improve response to MTX in a 4-week proof-of-concept study.[48] After 4 weeks of treatment with GLPG0634 200 mg once daily or 100 mg twice daily, significantly higher ACR20 scores and improvement in DAS28(CRP) and CRP were seen compared with placebo.



filgotinib, **8**

5.13.4.1 Filgotinib as Monotherapy[49]

The efficacy and safety of filgotinib as monotherapy versus placebo were evaluated in 283 patients with active RA with inadequate response to MTX in a phase 2B study. Patients were randomized to placebo, 50, 100, or 200 mg of filgotinib once daily for 24 weeks. At week 12, a statistically significant higher ACR20 response versus placebo was observed with all three doses of filgotinib. For other key efficacy endpoints (ACR50, ACR-N, DAS28 (CRP), CDAI, SDAI) all doses showed significant difference versus placebo. By week 12, 24–45% of patients on filgotinib achieved DAS28(CRP) $\leq$ 3.2 in a dose-dependent manner, compared to 14% in placebo-treated patients. Safety was similar to tofacitinib and baricitinib (Table 2).

5.13.4.2 Filgotinib in Combination With MTX[50]

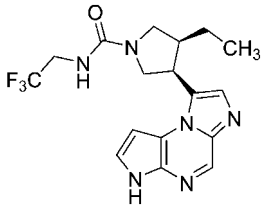
The efficacy and safety of filgotinib in combination with MTX versus placebo were evaluated in 594 patients with active RA with inadequate response to MTX in a phase 2b study. Patients were randomized to placebo or one of three doses of filgotinib (50, 100, or 200 mg) QD or BID for 24 weeks. At week 12, a statistically significant higher ACR20 response versus placebo was observed with 200 mg daily dose of filgotinib. For other key efficacy endpoints (ACR50, ACR-N, DAS28(CRP), CDAI, SDAI) all doses showed significant differences versus placebo. No statistically significant difference between QD and BID regimens was seen. By week 12, 24–50% of patients on filgotinib achieved DAS28(CRP) ≤ 3.2 in a dose-dependent manner, compared to 14% on PBO. The 100 mg BID and 200 mg QD doses appeared to have the best efficacy. Safety was similar to the monotherapy study. Patient-reported outcomes were reported from these 2 phase 2b studies.[51] Filgotinib therapy led to a rapid improvement in all assessed PROs including patient's visual analog scale (VAS) disease activity, patient's VAS pain, HAQ-DI, FACIT-F, SF-36 PCS, and SF-36 MCS. After 24 weeks of treatment, filgotinib in combination with MTX as QD or bid or as monotherapy demonstrated comparable benefit.

5.13.4.3 Safety of Filgotinib[52]

At week 24 of the phase 2b program, SAE and TEAE were seen in all dose groups; 39% of PBO and 41% of filgotinib (TEAE) and 1% of PBO and 4% of filgotinib (SAE). Infections occurred in 10% PBO and 19% filgotinib groups. No opportunistic infections, cancers, or deaths occurred. In the filgotinib groups, for the first 4 weeks, a dose-dependent decrease in mean neutrophil and a small reduction in platelet counts were seen; mild increase in mean creatinine was apparent which remained stable up to week 24. A dose-dependent increase in hemoglobin was seen during the first 12 weeks which was stable up to week 24. No meaningful increase in transaminase was seen. Neutropenia, lymphopenia, decreased NK cells, and decreased creatinine were seen as with other Jakinibs. With the higher dose, JAK2 effects were seen on hemoglobin. There has been no mention of HZ in the filgotinib program as yet (Table 3).

5.13.5 ABT 494

ABT-494 (**9**) is an oral Jak1-selective inhibitor that was investigated in two-phase 2b studies.



ABT-494, **9**

5.13.5.1 Efficacy of ABT-494 (Upadacitinib)

5.13.5.1.1 ABT-494 in MTX-IR[53]

In a 12-week double-blind placebo-controlled study phase 2b study, the safety, efficacy, and dose response of ABT-494 on background MTX were characterized vs placebo in 299 patients with active RA and an inadequate response to MTX. Patients were randomized to ABT-494 3, 6, 12, or 18 mg BID, 24 mg QD, or matching placebo. ACR20 response rates at week 12 were significantly higher with ABT-494 at 6 mg BID (68%), 12 mg BID (80%), and 24 mg QD (76%) vs placebo (46%); ACR50 and ACR70 response rates and change from baseline in DAS28(CRP) were also statistically significantly improved for all ABT-494 doses (except ACR70 in 12 mg BID) vs placebo. ACR responses were seen within 2 weeks. DAS28(CRP) <2.6 was achieved by significantly more patients on ABT-494 (except 24 mg QD) vs placebo. DAS28(CRP) ≤ 3.2 and CDAI ≤ 10 were achieved by significantly more patients on ABT-494 (except 24 mg QD for CDAI) vs placebo.

5.13.5.1.2 ABT-494 in TNF IR[54]

In a 12-week double-blind placebo-controlled study phase 2B study, the safety, efficacy, and dose response of ABT-494 were characterized vs placebo in 276 patients with active RA and an inadequate response to ≥ 1 anti-TNF bDMARD on background MTX. All patients had failed ≥ 1 anti-TNF therapy prior to enrolment; 28% ≥ 2 anti-TNFi and 20% had also received non-anti-TNF bDMARD. Patients were randomized to ABT-494 3, 6, 12, or 18 mg BID or matching placebo. The proportion achieving ACR20 at week 12 was significantly higher for all ABT-494 groups vs placebo ($p<.01$). ACR50 and ACR70 responses were statistically significantly higher at doses of ≥ 6 mg BID. Changes in DAS28(CRP) from baseline were significantly greater for all doses of ABT-494 vs placebo. There were significant differences in ACR20 response and change in DAS28(CRP) from baseline at week 2 ($p\leq .007$) for 6, 12, and 18 mg BID vs placebo. DAS28(CRP) <2.6 and ≤ 3.2 were achieved statistically significantly more often in the 12-mg BID dose group vs PBO.

5.13.5.2 Safety of ABT-494

5.13.5.2.1 MTX-IR[53]

AE incidence was numerically higher with ABT-494, with a trend of dose dependence (Table 4). The incidence of infections was similar across groups. One serious infection (community-acquired pneumonia) occurred with ABT-494 12 mg BID. One patient receiving ABT-494 3 mg BID and 2 receiving 24 mg QD had nonserious zoster infections (single dermatomes). No deaths occurred during the study. ABT-494 treatment resulted in dose-dependent increases in both low and high density lipoprotein cholesterol. Liver function test elevations were sporadic, with no clear dose dependence. Mean hemoglobin values remained stable or increased at lower doses, most notably in patients with an elevated CRP at baseline. Dose-dependent decreases in hemoglobin were seen at higher doses.

In TNF-IR, the incidences of AEs were numerically higher in ABT-494 dose groups, with some trend toward dose dependency (Table 5)[54] The majority of infections were mild. There was one SIE (bronchiectasis) in the placebo group and none in the

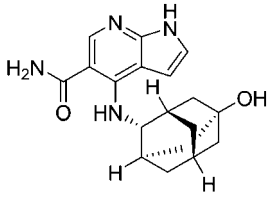
ABT-494 treatment groups. Five patients had nonserious events of HZ: one patient each in the ABT-494 3, 12, and 18 mg BID treatment groups, and two patients in the placebo group. One patient in the 6-mg BID dose group reported two events of nonmelanoma skin cancer (basal cell and squamous cell carcinomas). There was one report of anemia in the 18-mg BID dose group. No deaths were reported during the study.

5.13.6 Peficitinib (ASP015K)

Peficitinib (**10**) has selectivity for Jak1/3 with more selectivity over JAK2; it is dosed once daily (QD).



peficitinib, **10**

5.13.6.1 Peficitinib as Monotherapy

The efficacy, safety, and dose response of peficitinib monotherapy in 281 Japanese patients with active RA were evaluated in a 12-week, double-blind study.[55] Patients, 25.3% of whom had previously used an anti-TNF therapy, were randomized equally to once-daily peficitinib 25, 50, 100, 150 mg or placebo. Peficitinib 50, 100, and 150 mg QD each achieved a statistically significantly higher ACR20-CRP response at week 12 compared to placebo, with a dose response. ACR50/70 response and DAS28-CRP < 2.6 were significantly higher in the 100 and 150 mg dose groups. Dose-dependent improvement in DAS28-CRP was also seen. AE incidence was similar between placebo and combined peficitinib groups (64.3% vs 64.0%). The most frequently reported AEs in the combined treatment groups as compared to placebo were nasopharyngitis (13.3% vs 5.4%), RA (12.4% vs 32.1%), blood creatine phosphokinase (CPK) increase (4.9% vs 0%), and diarrhea (3.6% vs 1.8%). The incidence of infections and SIE were similar between placebo and peficitinib (21.4% vs 24.9% and 1.8% vs 2.7%, respectively). The safety profile was generally comparable among the peficitinib groups.

5.13.6.2 Peficitinib in MTX-IR

The efficacy, safety, and dose response of once-daily peficitinib in 289 patients with active RA with an inadequate response/intolerance to csDMARDs and not currently on concomitant MTX (although concomitant hydroxychloroquine and sulfasalazine were allowed) was evaluated in a 12-week, double-blind, placebo-controlled trial.[56] Patients were treated with 25, 50, 100, 150 mg or placebo. Allowed concomitant csDMARD therapies were antimalarials and/or sulfasalazine. A statistically significant dose response at week 12 was seen for ACR20 with the highest response seen in the peficitinib 100 and 150 mg groups. ACR50/70 response and DAS28-CRP < 2.6 were also higher in the 100 and 150 mg dose groups as compared to placebo. Dose-dependent improvement in DAS28-CRP was seen, with statistically significant differences shown in the 100 and 150 mg dose groups by week 4. The incidence of AEs was similar between combined peficitinib groups and placebo (41.6% vs 43.1%). The most frequently reported AEs with peficitinib as compared to placebo were upper respiratory tract infection (5.5% vs 3.9%), nausea (5.0% vs 0%), and diarrhea (3.8% vs 2.0%). The incidence of infections and SAE was similar between peficitinib and placebo (13.4% vs 13.7% and 4.2% vs 3.9%, respectively). No meaningful differences in absolute neutrophil and lymphocyte counts or hemoglobin were seen between peficitinib and placebo. The safety profile was comparable among the peficitinib dose groups, except for a higher incidence of dyspepsia, headache, and CPK increased in the 100 and 150 mg groups.

5.13.6.3 Peficitinib in MTX-IR

The efficacy, safety, and dose response of once-daily peficitinib in 378 patients with active RA with an inadequate response to MTX study were evaluated in a 12-week, double-blind, placebo-controlled study.[57] In this study, a dose response on ACR20 was not shown. Numerically greater ACR20 responses than placebo were seen in the peficitinib 50 and 150 mg groups, with statistical significance shown in the 50 mg group only. A statistically significant dose response was demonstrated in change in DAS28-CRP and DAS28-ESR, with effects seen as early as week 1. AE was similar between combined peficitinib groups and placebo (47.7% vs 47.2%). The most frequently reported AE in the combined peficitinib groups' vs placebo were headache (2.9% vs 1.4%) and hypercholesterolemia (2.0% vs 1.4%). The overall incidence of infections and SAE were similar between peficitinib and placebo (18.3% vs 26.4% and 1.0% vs 0%, respectively). No meaningful differences in absolute neutrophil and lymphocyte counts and hemoglobin

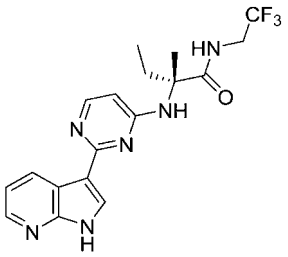
were seen between peficitinib and placebo. More AEs leading to study drug discontinuation and all three SAEs occurred in the 100 and 150 mg groups.

5.13.6.4 Peficitinib Summary

Because of the disparate results between the monotherapy and MTX-IR study, the development of peficitinib was halted on a global basis although there are continuing phase 3 studies being conducted in Japan.

5.13.7 VX-509 (Decernotinib) Oral-Selective JAK3 Inhibitor

VX-509 (**11**) has been developed as a more specific inhibitor of JaK 3 compared to tofacitinib.



VX-509, **11**

5.13.7.1 VX-509 as Monotherapy

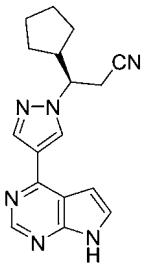
As monotherapy, VX-509 achieved improvement in the signs and symptoms of RA in a 12-week dose-ranging phase 2 study in 204 patients who were csDMARD-IR; patients were treated with VX-509 25, 50, 100, or 150 mg BID or placebo.[58] Primary endpoints at week 12 included the ACR20 response and degree of DAS28(CRP) improvement. DAS28-CRP scores were significantly decreased in patients treated with VX-509 at doses of 50, 100, and 150 mg BID daily compared with placebo ($p \leq .001$). ACR20 responses were 61%, 65%, and 66% in patients treated with VX-509 50, 100, and 150 mg twice daily, respectively, compared with 29% in patients given placebo ($p < .007$). Patients receiving VX-509 achieved clinically meaningful improvements in patient-reported outcomes including HAQ-DI, VAS assessment of general health, and the Short Form-36 Health Survey (all $p < .001$).[59] The safety of VX-509 appeared to be similar to tofacitinib.

5.13.7.2 VX-509 in MTX-IR

In a 24-week, randomized, placebo-controlled, double-blind, phase 2 study, four dosing regimens of VX-509 in combination with MTX were administered to 358 patients with active RA who were MTX-IR.[60] Patients were treated with placebo or VX-509 100 mg QD, 150 mg QD, 200 mg QD, or 100 mg BID. After 24 weeks of treatment the proportion of patients achieving ACR20/50/70, DAS28(CRP) < 2.6, and DAS28(ESR) < 2.6 and the decrease from baseline in DAS28(CRP) were statistically significantly greater in each of the VX-509 dose groups compared to the placebo group. Over 24 weeks, the percentage of patients with any AE was higher in all VX-509 dose groups combined (59.9%) relative to placebo (42.3%) and led to study discontinuation in 9.1% and 8.5% of patients in the VX-509 and placebo groups, respectively. The most common AEs in the VX-509 group were headache (8.7%), hypercholesterolemia (5.2%), and diarrhea (4.5%). SAEs occurred in similar proportions of patients receiving VX-509 (7.3%) or placebo (5.6%), but there were more SIE in the VX-509 group (3.5%) compared with placebo (1.4%). Through 24 weeks there were two SAEs that resulted in death; one was cardiac failure in the VX-509 100 mg BID group and one was pancytopenia in a patient with pneumonia in the VX-509 200 mg QD group. Elevations in transaminase levels and decreases in median neutrophil and lymphocyte counts were observed in the VX-509 groups and were generally mild. Safety profiles were comparable across groups receiving VX-509.

5.13.8 Ruxolitinib

Ruxolitinib (INCB018424; **12**) is an oral Jak1/2 inhibitor that is currently approved by the US Food and Drug Administration for the treatment of myelofibrosis. This agent has shown suggested efficacy in several preclinical models of arthritis. In a small phase 2a study of 16 patients, ruxolitinib demonstrated increased rates of ACR20 response and a decrease in DAS28 at a dose of 15 mg twice daily.[61]

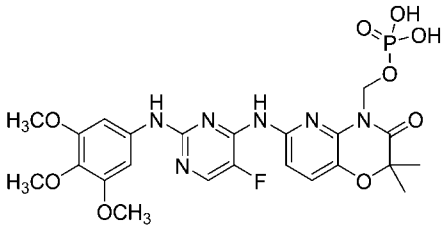


ruxolitinib, **12**

5.13.9 Syk Inhibitors

Syk is expressed in many different cell types and is essential in the development and activation of T-cell, B-cell, and Fc receptor signaling; mast cell degranulation; neutrophil and macrophage phagocytosis; and platelet activation.[62–65]

The oral Syk inhibitor fostamatinib (R788; **13**) was assessed in combination with MTX in 2 randomized, placebo-controlled, double-blind phase II trials of patients with RA.[66,67] In both trials, fostamatinib-treated patients achieved significantly improved clinical responses compared with placebo. Significant diarrhea and hypertension were seen in a number of patients. A randomized, placebo-controlled phase II trial of fostamatinib in patients with RA, who experienced treatment failure during previous biologic disease-modifying antirheumatic drug therapy, failed to show a difference between fostamatinib and placebo.[68] A randomized, placebo-controlled phase IIb trial of the safety and efficacy of fostamatinib as monotherapy did show that fostamatinib was superior to placebo at week 6 in decreasing DAS28(CRP) but was inferior to adalimumab monotherapy at week 24.[69] The results of two published randomized, double-blind, placebo-controlled phase III trials evaluating fostamatinib in patients with RA and inadequate response to TNFi or MTX demonstrated limited efficacy and relatively high rates of diarrhea and hypertension.[70,71] Because of the failure of these studies, and its adverse event profile, development of fostamatinib was suspended as of Jun. 2013.

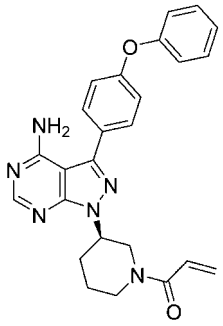


fostamatinib, **13**

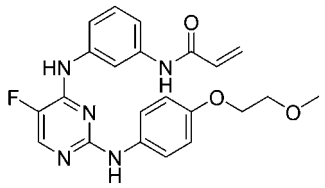
5.13.10 Btk Inhibitors

Btk, a member of the Tec family of cytoplasmic protein tyrosine kinases, is predominantly expressed in hematopoietic cells including B-cells and those of myeloid lineage (e.g., macrophages). These cell lineages are thought to be important contributors to the development of inflammatory arthritis and other autoimmune diseases.[72,73] Animal models suggest that Btk inhibition can lead to inhibition of B-cell receptor-dependent cell proliferation and a reduction of inflammatory cytokine production from myeloid cells. This is due to prevention of signaling through the FCyRIII receptor.[73,74] Because these target cells play important roles in autoimmunity, there is interest in testing Btk inhibition in patients with RA.

The Btk inhibitor ibrutinib (PCI-32765; **14**) has demonstrated efficacy in animal models of arthritis and is currently in phase II trials for treatment of B-cell lymphomas.[2,75,76] A second Btk inhibitor, CC-292 (**15**), has also exhibited efficacy in a collagen-induced arthritis animal model and is in early clinical trials for treatment of B-cell lymphomas.[2]



ibrutinib, **14**

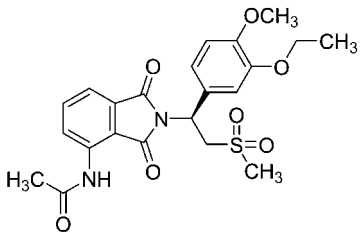


CC-292, **15**

5.13.11 PDE4 Inhibitors

In addition to targeting intracellular protein kinases, small-molecule inhibitors of phosphodiesterase signaling pathways are under development to treat autoimmune and inflammatory diseases.[73] Phosphodiesterases are enzymes that hydrolyze the 3′ phosphate bond of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) and, through degradation of these intracellular secondary messengers, regulate many downstream biologic processes. They are classified into 11 different subfamilies (PDE1-PDE11), each exhibiting different degrees of specificity for cAMP and cGMP.[77,78] PDE4 demonstrates specificity for cAMP and is expressed in many tissues including the brain, heart, lungs, and inflammatory cells such as B- and T-cells, neutrophils, eosinophils, macrophages, and mast cells.[79–81]

Apremilast (**16**) has been approved by the US Food and Drug Administration for the treatment of adults with active PsA.



apremilast, **16**

5.13.11.1 Psoriatic Arthritis

The efficacy and safety of apremilast to treat PsA have been evaluated in four randomized, double-blind, placebo-controlled phase III trials (PALACE-1-4).[82–85] In these studies, patients were randomized to receive either apremilast 20 or 30 mg BID or placebo for 24 weeks. The primary endpoint for the trials was achievement of an ACR20 response at week 16. Patients with poor response at week 16 were randomized to 20 or 30 mg apremilast; all patients receiving placebo were randomized to active treatment by week 24–52. Patients receiving csDMARDs were allowed to continue stable doses of MTX, sulfasalazine, leflunomide, or a combination of these.

PALACE-1 was a 52-week double-blind, placebo-controlled phase 3 study which enrolled 504 patients with active PsA who were csDMARD or bDMARD-IR.[82] Significantly more patients in the apremilast 20- and 30-mg BID groups achieved the primary endpoint of ACR20 response at week 16 compared with placebo (30.4%, 38.1%, and 19.0%, respectively). AE occurring in $\geq$5% of patients included diarrhea, nausea, headache, and urinary tract infection. Diarrhea was generally, but not always, self-limited. A dose escalation strategy at the initiation of therapy appeared to ameliorate this toxicity. After week 52, patients could continue open-label apremilast treatment for up to 4 years. An analysis at week 104 demonstrated sustained improvements with continued therapy and no additional safety concerns.[86]

PALACE-2 was a 52-week double-blind, placebo-controlled phase 3 study, which enrolled 484 patients with active PsA.[83] Significantly more patients treated with apremilast 20 and 30 BID achieved the primary endpoint of ACR20 at 16 weeks compared with placebo (38.4% and 34.4% vs 19.5%, respectively). At 52 weeks, patients receiving apremilast 20 and 30 from randomization achieved multiple endpoints including observed ACR20 responses (52.9% and 52.6%, respectively), mean change in health assessment questionnaire-disability index (HAQ-DI) from baseline (-0.192 and -0.330, respectively), and mean change from baseline in Short Form-36 Physical Functioning domain score (5.05 and 6.35, respectively). In addition, patients with baseline psoriasis body surface area of $\geq$3% achieved significant psoriasis area and severity index (PASI)-75/PASI-50 results (27.1%/49.2% and 39.3%/58.9%, respectively). Through week 52, adverse events occurring in $\geq$5% of apremilast-exposed patients were diarrhea, nausea, upper respiratory tract infection, headache, and nasopharyngitis.

PALACE-3 was a 52-week double-blind, placebo-controlled phase 3 study, which enrolled 506 with PsA and $\geq$1psoriatic lesion $\geq$2 cm at baseline.[84] Significantly more patients receiving apremilast 20 and 30 achieved an ACR20 at 16 weeks compared with placebo (29.4% and 42.8% vs 18.9%, respectively). At 52 weeks, patients originally randomized to receive apremilast 20 and

Table 6 Safety over 2 years[92]

AEs (%)	*Apremilast 30 mg, 0–52 weeks (n = 721)*	*Apremilast 30 mg, 52–104 weeks (n = 520)*
≥1 SAE	6.5	6.3
Diarrhea	16	4
Nausea	15	2
Headache	10	3

30 achieved multiple endpoints including ACR20 responses (56% and 63%, respectively), mean change in HAQ-DI from baseline (−0.332 and −0.350, respectively), and mean change from baseline in Short Form-36 Physical Functioning domain score (5.05 and 6.35, respectively). In addition, patients with baseline psoriasis body surface area of ≥3% achieved significant PASI-75/PASI-50 results (28.6%/49.2% for apremilast 20 and 39.1%/54.7% for apremilast 30). Overall, patients receiving apremilast 30 achieved higher responses than those receiving apremilast 20, and placebo patients randomized to apremilast at weeks 16 or 24 achieved similar results with those originally randomized to apremilast. Apremilast was generally well tolerated, and AE occurring through 52 weeks in ≥5% of apremilast-exposed patients were diarrhea, nausea, upper respiratory tract infection, headache, nasopharyngitis, and vomiting. Data through week 104 showed sustained disease activity decreases and symptom relief and improved physical function.[87]

PALACE-4 evaluated apremilast in 527 patients with PsA who had not received previous csDMARDs.[85] Significantly more patients treated with apremilast 20 and 30 BID achieved an ACR20 at 16 weeks compared with placebo (28.0% and 30.7% vs 15.9%, respectively). At 52 weeks, using an as observed analysis, 55% of patients randomized to receive apremilast 20 and 58% of patients randomized to receive apremilast 30 achieved ACR20 responses. Responders, through week 104, showed sustained outcomes including ACR response, HAQ-DI improvement, changes in dactylitis severity scores, and PASI responses.

In a pooled 52- and 104-week efficacy post hoc analyses of PALACE 1-3, apremilast improved enthesitis, dactylitis, swollen joint and tender join counts, HAQ-DI, Short Form-36 Physical Functioning domain, and work productivity (Work Limitations Questionnaire).[88–90]

The safety of apremilast has been assessed in a pooled analysis of 1493 patients from PALACE 1–3.[91] No additional safety findings were identified. The most common adverse events reported were diarrhea (weeks 0–52: 13.9%; weeks 53–104: 2.9%), nausea (weeks 0–52: 12.2%; weeks 53–104: 1.8%), headache (weeks 0–52: 9.4%; weeks 53–104: 3%), upper respiratory tract infections (weeks 0–52: 9.1%; weeks 53–104: 6.5%), and nasopharyngitis (weeks 0–52: 6.2%; weeks 53–104: 5.8%). The incidence of diarrhea, nausea, and headache were greater at the apremilast 30 dose. Serious adverse events occurred in 5.6% of patients receiving apremilast 20 and 6.5% in patients receiving apremilast 30 through week 52 (**Table 6**)[92]

Apremilast did not appear to have any significant effects on laboratory measurements.[93] Abnormal hematology and chemistry laboratory values were reported infrequently, and median values did not change significantly from baseline. Changes were transient and did not require specific treatment or lead to study discontinuation. Laboratory changes included alanine aminotransferase and aspartate aminotransferase values ≥1 times the upper limit of normal, and alanine aminotransferase and aspartate aminotransferase values ≥3 times the upper limit of normal, which returned to normal or baseline in most patients even with continued apremilast treatment. No cases of liver function test elevations meeting Hy's law were reported.

5.13.11.2 Psoriasis

Apremilast has been evaluated for the treatment of psoriasis in several phase III trials. In the double-blinded, placebo-controlled phase 3 ESTEEM 1 and 2 trials, patients with moderate to severe plaque psoriasis were randomized to apremilast 30 mg BID or placebo.[94,95] At week 16, patients randomized to receive placebo were switched to apremilast through study week 32. Patients randomized to apremilast who experienced a ≥75% PASI reduction in ESTEEM 1 and ≥50% PASI reduction in ESTEEM 2 at week 32 were rerandomized to continue receiving apremilast or to switch to placebo with switch back to apremilast if PASI response was lost. Patients randomized to placebo at baseline and switched to apremilast at week 16 who experienced the predefined response at week 32 continued apremilast for up to 5 years. All patients without predefined response at week 32 continued apremilast with the option to add topical agents and/or ultraviolet B phototherapy, based on investigator discretion. The results from both trials demonstrated significantly higher rates of PASI response at week 16 with apremilast vs placebo ($p < .0001$). Among patients rerandomized at week 32 to apremilast or placebo, most of those who continued apremilast (61% in ESTEEM 1 and 80.3% in ESTEEM 2) maintained their PASI response through week 52, whereas 48.4% (ESTEEM 2) to 83.1% (ESTEEM 1) of those rerandomized to placebo lost PASI response and switched to apremilast before week 52. Additionally, in ESTEEM 1 and 2, nail disease improvement was investigated. At week 16 the response was NAPSI50, 33% and 45% APREMILAST vs 15% and 19% PBO (week 16).

5.13.12 Behçet's Disease

Apremilast showed improvement in the signs and symptoms of Behçet's disease in a 12-week randomized, placebo-controlled phase 2 trial in 111 patients with active oral ulcers.[96] Patients without major organ involvement and with ≥2 oral ulcers were

randomized to either apremilast 30 mg BID or placebo. The primary endpoint was the number of oral ulcers at week 12. At 12 weeks, the mean number of oral ulcers for patients receiving apremilast was 0.5 ± 1.0 compared with 2.1 ± 2.6 for patients receiving placebo ($p < .001$). A higher rate of patients receiving apremilast reported improvements in oral ulcer pain, complete response (oral ulcer free), and reduction in genital ulcers compared with patients receiving placebo.

5.13.13 Conclusion

Small molecule oral agents affecting the kinase and PDE4 pathways have been shown to be of value in the treatment of patients with rheumatic disease including RA and PsA. One Jakinib (pan JAK inhibitor), tofacitinib, is FDA approved for the treatment of RA, either as monotherapy or in combination with csDMARDs. Tofacitinib has been shown to be more effective than MTX clinically, functionally, and radiographically as monotherapy in MTX naïve patients, effective in patients who are csDMARD-IR as monotherapy or combined with a csDMARD, and effective in combination with MTX after incomplete response to a TNFi. In a trial which compared tofacitinib plus MTX to MTX in a MTX-IR population, an adalimumab plus MTX arm was included. Adalimumab plus MTX was superior to MTX plus placebo in this same population. Although not powered to be a head-to-head comparison of tofacitinib to adalimumab, tofacitinib appeared to be numerically superior to adalimumab clinically and functionally. A phase 3B study is currently underway to compare tofacitinib monotherapy to tofacitinib plus MTX to adalimumab plus MTX in a powered head-to-head comparison in MTX naïve patients. The results should be available in 2017.

Other Jakinibs in development, including baricitinib, ABT-494, and filgotinib, have shown similar efficacy so far. Baricitinib has completed its phase 3 program and will be evaluated by the FDA and EMA for approval in early 2017. Baricitinib is distinctive in that in a head-to-head trial against adalimumab, both with background MTX, baricitinib was more effective than adalimumab clinically and functionally with similar radiographic effects. Also, in a trial comparing baricitinib monotherapy to combination with MTX, there did not appear to be a difference between the two clinically or functionally; the combination was statistically superior radiographically but the difference was not significant clinically. ABT-494 and filgotinib are currently in phase 3 studies. Peficitinib has shown mixed results. In phase 2 studies, monotherapy appears to be effective as well as in combination with sulfasalazine and/or hydroxychloroquine. A study in MTX-IR failed. Phase 3 studies are in progress.

An oral small molecule inhibitor of PDE4, apremilast, has been approved for use in PsA. Although its efficacy is not as dramatic as the TNFi or inhibitors of IL17 on the joints and skin, its favorable safety profile has led to widespread acceptance of its use prior to bDMARDs.

Other small molecules working intracellularly, with different mechanisms of action, are being investigated in a number of rheumatic diseases. If they are successful in their clinical trials, they have the potential to be additional valuable agents for our therapeutic armamentarium.

Unfortunately, not all small molecules affecting intracellular mechanisms have been successful. A number of inhibitors on the MAPK pathways and of the SyK pathway have failed, either for lack of efficacy or tolerability.

Much still needs to be done to find the optimal inhibition of these pathways both with respect to efficacy and safety. Second- and third-generation molecules may have better results and be effective in other rheumatic diseases. The future should be interesting.

5.14.2.2	Teriflunomide	447
5.14.2.3	Dimethyl Fumarate	447
5.14.2.4	Laquinimod	447
5.14.2.5	Interferon β-1b	448
5.14.2.6	Interferon β-1a (IFN-β-1a; Avonex, and Rebif)	448
5.14.2.7	Peginterferon β-1a	449
5.14.2.8	Natalizumab	449
5.14.2.9	Alemtuzumab	450
5.14.2.10	Glatiramer Acetate	450
5.14.2.11	Mitoxantrone	450
5.14.2.12	Rituximab	451
5.14.2.13	Cyclophosphamide	451
5.14.2.14	Adrenocorticotropin Hormone (ACTH)	451
5.14.2.15	Methotrexate	452
5.14.2.16	Cladribine	452
5.14.3	**Other Neurodegenerative Disorders**	453
5.14.3.1	Alzheimer's Disease	453
5.14.3.2	Therapeutic Approaches in AD	454
5.14.3.2.1	Donepezil	455
5.14.3.2.2	Rivastigmine	456
5.14.3.2.3	Galanthamine	456
5.14.3.2.4	Memantine	456
5.14.3.2.5	Select drugs in development for AD treatment	457
5.14.3.3	Parkinson's Disease	458
5.14.3.4	Therapeutic Approaches in PD	458
5.14.3.4.1	Carbidopa/levodopa	458
5.14.3.4.2	Pramipexole	459
5.14.3.4.3	Ropinirole	459
5.14.3.4.4	Bromocriptine	459
5.14.3.4.5	Cabergoline	459
5.14.3.4.6	Pergolide	459
5.14.3.4.7	Rotigotine	462
5.14.3.4.8	Anticholinergics (trihexyphenidyl and benzotropine)	462
5.14.3.4.9	Apomorphine	462
5.14.3.4.10	Amantadine	462
5.14.3.4.11	COMT inhibitors (entacapone and tolcapone)	462
5.14.3.4.12	MAO-B inhibitors (selegiline and rasagiline)	463
5.14.3.4.13	Istradefylline	463
5.14.3.4.14	Levodopa formulations	463
5.14.4	**Conclusion**	464

5.14.1 Introduction

Multiple sclerosis (MS) is the most common chronic inflammatory disease of the central nervous system (CNS), with distinct demyelination of axons and brain atrophy with an early onset that affects young to middle-aged adults.[1] Recent studies suggest that the disease progression in MS integrally involves neurodegeneration along with autoinflammatory component.[2] MS is diagnosed usually late after the disease onset based on gadolinium (Gd)-enhanced magnetic resonance imaging (MRI), and until recently, definitive diagnosis was difficult due to the lack of diagnostic tools.[3] The exact causes of MS are still unknown, but MS is considered to be a disease of multifactorial origin with a strong inflammatory component based on the detection of autoreactive T cells, B cells, and macrophages in active MS lesions.[4] In the past 20 years, significant progress was accomplished in understanding and moderating the acute inflammatory components of MS, but the pathophysiological mechanisms of the underlying neurodegeneration, which causes irreversible damage to the CNS and physical disability, are still not completely understood. MS is gaining acceptance as a neurodegenerative disease, and in general, many neurodegenerative diseases are challenging to diagnose early and to identify a unique target for the development of therapeutics.

The complex patterns involved in the onset and progression of the disease and diagnostic challenges in MS historically are related to a number of controversies and differences in opinions in various aspects of MS.[5] These challenges are also due to the poor understanding of the molecular mechanisms and relationship between relapses and disability progression due to neurodegeneration. MS has classically been considered as an autoimmune, white matter disease. Overall, physical disability progression and brain and spinal cord atrophy were regarded as consequences of global inflammation of normal-appearing white matter (NAWM), and gray matter involvement was considered secondary. Recent histopathology studies and MRI techniques indicated that the pathology in MS is a prominent gray and white matter disease.[6] Inflammatory demyelination of gray matter occurs early in MS, and following this observation, immunomodulatory drugs were introduced and became the main therapeutic option for the treatment of MS. Although early therapy of MS with immunomodulatory drugs protects the CNS from the consequential damage due to inflammatory attacks, disability progression and neurodegeneration continue to deteriorate the clinical status of the patient. This indicates that antiinflammatory treatment is not adequate to treat and/or manage MS successfully. Due to the lack of a single target responsible for the disease onset and/or progression and complex factors involved during the clinical course of MS, it is now well recognized that therapeutic approaches must manage the disease and prevent worsening of the disability, achieved through so-called disease-modifying therapies (DMTs). There is now considerable understanding and acceptance that chronic inflammatory processes continuously disturb neuroaxonal homeostasis and promote neurodegeneration. Clinical outcomes in these situations depend on the balance of damage due to inflammation and any remaining capacity for neuronal self-protection. Hence, suitable drugs that promote the remyelination are also considered to be potentially efficacious.

There are four clinical types of MS, all of which are characterized on the basis of inflammatory and neurodegenerative disease states using MRI-based diagnostic tools. This measurement system is recently introduced and updated from the previously established measurement system.[7,8] These four types are the following: (1) *Clinically isolated syndrome (CIS)*: CIS is the first episode of neurological symptoms caused by inflammation and demyelination in the CNS. Although this does not meet the criteria for definitive MS diagnosis, when CIS is accompanied by brain lesions on MRI, the patient has a high likelihood of a second attack leading to the diagnosis of MS. It is also reported that optic neuritis many times is one of these CISs that often leads to clinically diagnosed MS.[9] (2) *Relapsing–remitting MS (RRMS)*: In the RRMS stages of the disease, clearly defined attacks, in the form of relapses or inflammatory exacerbations, are experienced by the patients. These attacks are episodes of acute worsening of clinical symptoms, followed by partial or complete recovery for a period of time with no disease progression. RRMS is further characterized as active stage with CNS lesions and/or relapses, not active and worsening stage with increased disability resulting from symptoms that do not completely disappear following a relapse, or not worsening stage. RRMS is the most common form of MS when patients are diagnosed, and almost 85% of patients are diagnosed at this stage.[10] (3) *Primary progressive MS (PPMS)*: A slow and continuous worsening of the disease from the onset of symptoms is observed in the patients with the PPMS, almost with no relapses or remissions. The rates of progression over time may vary among different patients with occasional plateaus and minor, albeit temporary, improvements in the clinical symptoms. Similar to RRMS, PPMS is further characterized as active with MRI activity and/or relapses, not active and progressing—exhibiting a confirmed increase in disability over a given period of time, or not progressing. PPMS is the second most commonly diagnosed form of MS, amounting to up to 15% of MS diagnoses. (4) *Secondary progressive MS (SPMS):* This type of MS is characterized by a combination of RRMS-like and PPMS-like disease courses; patients experience an initial period of RRMS, followed by a steadily worsening disease course with or without occasional flare-ups, minor recoveries (remissions), or plateaus. It must be noted that majority of patients with RRMS will eventually transition to SPMS. However, early diagnosis and early and ongoing treatment with a DMT have been shown to delay SPMS, and age plays an important role for the onset of progressive phase of the disease.[11]

The role of immune system in MS has been explored in-depth over the past several decades, and a number of immunomodulatory approaches are used to develop novel therapeutics. This article is particularly interested in looking into neurodegeneration and nonimmunologic mechanisms that are emerging and gaining traction with a focus on protein citrullination. These nonimmunologic mechanisms are also known to play a role in other neurodegenerative diseases such as Parkinsons' disease (PD) and Alzheimer's disease (AD). Thus, in the latter sections of this article, therapeutic approaches in these two diseases are described in the context of neurodegeneration.

5.14.1.1 Citrullination and Neurodegeneration

Protein arginine deiminases (PADs) are a family of five isozymes, PAD1–4 and PAD6, and these are comparatively less-studied enzymes for their role in various disease conditions.[12] They are involved in the posttranslational modification of peptidyl Arg residues, specifically those on the surface of the proteins and accessible for a biochemical transformation. They hydrolyze the terminal guanidinium moiety of peptidyl Arg into peptidyl citrulline residue, altering the surface charges on the protein surface. PADs have a wide range of tissue distribution and play a role in many physiological processes. PAD2 and PAD4 are in general associated with neuronal cells and neurodegeneration. PAD2 is expressed broadly in the skeletal muscle, brain, spleen, and secretory glands.[13–16] In particular and of relevance, PAD2 is found in various compartments of the brain such as in the cerebral cortex, hippocampus, and cerebellum.[17] PAD2 is present in myelin basic protein (MBP)-producing oligodendrocytes and is implied to play a role in myelin formation and plasticity within the CNS.[18] Elevated PAD2 and PAD4 activities are associated with hypercitrullinated MBP (and other cellular proteins in the neurons) and neurodegeneration.[19] PAD4, the only isozyme with a nuclear localization signal, is also expressed in white blood cells[20] and has been implicated in the immune response by initiating neutrophil extracellular traps (NETs) via chromatin remodeling.[21] The ability of PAD4 to enter the nucleus indicates a role for genetic regulation via epigenetic modification of histones, especially histone H3.[20] Overall, elevated levels of active PAD2/PAD4 enzymes and hypercitrullination play a definitive role in driving neuronal cell death and neurodegeneration in MS.

PADs cause the deimination of peptidyl arginine residues in a stepwise mechanism utilizing the two catalytic residues, Asp350 and Asp473 (PAD4 amino acid numbering) in the active site of these enzymes. Interaction of the positively charged guanidinium group with the negatively charged Asp side chains yields to the nucleophilic attack of Cys645 onto the guanidine group, followed by the displacement of ammonia with a water molecule. His471, which is in proximity to Cys645, participates as a proton donor and a proton acceptor in various steps of this hydrolysis process.[22] The formation of a tetrahedral intermediate with ammonia is the rate-limiting catalytic event, and this ammonia molecule is the leaving group during hydrolysis.[23] PADs are entirely Ca^{2+}-dependent enzymes. In fact, up to six Ca^{2+} ions are required for the optimal function of these enzymes. Mechanistic and mutagenesis studies of PAD4 confirmed that Ca^{2+} ions play a role in the organization and integrity of the active site at the C-terminal domain and in catalysis.[22–26]

5.14.1.2 Calcium Imbalance

Abnormal calcium influx is being considered at the root of a number of disease conditions in the recent times. Under various stress conditions, such as hypoxia and chemically induced ischemia,[27,28] the reversal of Ca^{2+}/Na^{+} exchange is seen in partially demyelinated axons due to overaccumulation of intracellular Na^{+} ions.[29,30] This phenomena is also seen upon interactions of immune cells with axons.[31] Due to its importance in activating PADs in vivo and the necessity of sufficient Ca^{2+} concentrations that are approximately 100 times greater than homeostatic cytosolic levels,[14] there is a high likelihood that PADs are dysregulated leading to their hyperactivity.[32–34] There is also emerging evidence of voltage-gated calcium channels (VGCCs) involvement in neurodegeneration via Ca^{2+} regulatory mechanisms. These channels may not carry high amounts of Ca^{2+} in neurons due to toxicity.[35] Some of these channels, such as L-type channels, are essential for Ca^{2+}-dependent regulation of prosurvival gene programs in the cells. However, there is a strong evidence that VGCC-dependent neurotoxicities are involved in a number of neurodegenerative diseases, adversely affecting the neurons, microglia, and neurovasculature. Data show a beneficial effect of drugs acting on VGCCs in several neurodegenerative and neurovascular diseases.[35] In particular, within the scope of this article, enhanced expression and activities of L-type Ca^{2+} channels were observed with Ca^{2+} overload in AD and chronic hypoxia conditions. On the other hand, in PD, VGCC-dependent neurotoxicity is observed without Ca^{2+} overload in the neurons. In MS, enhanced chemokine release and associated pathogenic mechanisms in the microglial compartments are shown to play a role in the VGCC-dependent neurotoxicity. Thus, VGCCs, which are usually required for neuronal survival, may take part in neurodegeneration under certain abnormal conditions. For example, high concentrations of Ca^{2+} could in turn activate normally quiescent or moderately active systems such as PADs, which leads to an apoptotic state of the neuronal cell (vide infra). VGCCs may also promote neuronal cell death without carrying excess Ca^{2+} in instances when they carry metal ions into neuronal cytoplasm or when a pathological decrease in their activity weakens Ca^{2+}-dependent prosurvival gene programs.[35]

Citrullination of proteins (or deimination of Arg residues on protein surfaces) increases with age even under normal conditions, and its potential significance to neurodegeneration may be relevant although must be proved further.[17,36] Shimada et al. showed that PAD2 protein and its corresponding mRNA levels steadily increased in the mouse brains up to 30 months of age.[17] In another study, a western blot analysis of citrullinated proteins in brain extracts from 8-week-old and 10- to 12-month-old mice and from humans in the ages of 29–40 years and 67–71 years showed an increase in deimination in the tissue from older subjects compared with that from younger subjects.[37] Such observations make one to consider the relationship between neurodegeneration and aging and any synergistic relationship for most of the neurodegenerative diseases to occur in aged population. Overall, evidence supports that hypercitrullination and elevated PAD activity are associated with neurodegeneration. Such a molecular insult to neuronal cells could be acute in nature, such as in hypoxic ischemia (HI), or chronic, such as in MS, PD, and AD.

5.14.1.3 Acute Neuronal Injury

Although this book article does not deal with neuronal injury, following discussion is somewhat relevant to events that may lead to neurodegeneration and subsequent manifestation of neurodegenerative conditions. HI occurs when the blood flow to cells and

organs becomes reduced; this lower concentration of oxygen due to decreased blood flow is insufficient for healthy function. The pathophysiology of HI involves membrane depolarization, brain edema, increased neurotransmitter release with inhibition of uptake, increased intracellular Ca^{2+}, and other events that eventually may lead to neuronal death.[38] Survivors of HI insult may show permanent neurological consequences including mental retardation, cerebral palsy, epilepsy, or learning disability.[39]

Increased intracellular calcium and its relevance in HI insult indicate a potential association of PADs and citrullination with HI. Indeed, protein citrullination has been observed in neonatal murine models of HI. Following HI induction, Lange et al. found an increase in deiminated (or citrullinated) proteins due to PAD enzymes, accompanied by cell death, activated microglia, and neuronal loss.[40] A direct relationship between HI insult and the induction of PAD activity was established using a covalent PAD inhibitor, Cl-amidine, where cell death and the levels of deiminated histones decreased in the presence of this PAD inhibitor.[40] *N*-methyl-D-aspartate (NMDA) glutamate receptors mediate the accumulation of calcium within the myelin sheath when chemical ischemia is induced, and this clearly affects the calcium levels and thus PAD activity in the neurons.[27] This process is similar to the aforementioned discussion leading to Ca^{2+} balance in the cells and potentially leading one to consider NMDA receptors as drug targets for the treatment of demyelinating diseases such as MS. This mechanism could be an independent mechanism for drug targeting.[27]

5.14.1.4 Chronic Neurodegeneration

MS is one of the common chronic demyelinating diseases with an early onset that affects young to middle-aged adults.[1] MS is often diagnosed late after the disease onset due to the lack of appropriate and accurate diagnostic tools, but MRI is helping to change that.[3] The exact causes of MS are quite debated and could be multifactorial, but MS is considered to be a disease of multifactorial origin with a strong inflammatory component based on the detection of autoreactive T cells, B cells, and macrophages in active MS lesions.[4] There is significant evidence that MS is composed of neurodegenerative and inflammatory components.[2] Majority of the current therapeutics are immunomodulatory, and the leading theory is an autoimmune theory for the root causes of MS. However, in the past decade, causes other than autoimmune in nature are put forward to account for the progressive neurodegenerative nature of this disease. One such molecular mechanism involves PAD enzymes, and hypercitrullination has been found to be associated with MS and its progression in studies of patient brain samples. It is observed that citrullination was more prominent in lesions compared to NAWM in both animal models and in human.[41,42] Other most prominently hypercitrullinated proteins found in tissues isolated from patients with MS include glial fibrillary acidic protein (GFAP),[43] MBP,[44,45] and histones.[46] Citrullinated MBP is also found in large spinal cord and small white matter extracellular brain lesions in addition to the brain lesions surrounded by astrocytes with peptidyl citrulline that colocalized with GFAP in murine models of MS.[43]

Of the five PAD isoforms, PAD2 and PAD4 may be the most relevant to MS, as both were found to be significantly upregulated in MS NAWM.[47] In rodent species, specifically in rats, PAD2 localizes to oligodendrocytes and is responsible for the citrullination of MBP when external Ca^{2+} is added in vitro to brain homogenates.[19] Studies on PAD2 knockout mice demonstrated that the enzyme was necessary for the citrullination of MBP and GFAP.[48] On the other hand, transgenic mice with overexpressed PAD2 cDNA showed thinning of myelin sheath and its degradation.[49] These data suggested that in rodents, upregulated PAD2 preceded MS-like disease progression. Enzyme activity levels of PAD2 and PAD4 were found to be elevated in peripheral blood mononuclear cells (PBMCs) isolated from MS patients, although this does not directly connect to the changes in the CNS.[50,51] With these data, one is led to the broad conclusion that the development and progression of MS may be associated with PAD dysregulation and hypercitrullination, which in turn may be related to the intracellular Ca^{2+} aberrations.

The MHC class II HLA-DRB1*1501 loci is highly associated with an increased risk of developing MS, and environmental factors such as vitamin D may also play a role in this context.[52,53] However, there seems to be no link between PAD genes and HLA-DRB1*15.[54] Nevertheless, epigenetic regulation appears to exist, and the two CpG islands in the promoter region of PAD2 have been found to be significantly hypomethylated in NAWM[55] and the PBMCs[50] of MS patients. These were positively correlated with increased transcription of PAD2 and associated enhanced citrullination, leading to hypercitrullination of proteins in the cell.

A link between PAD enzymes, the citrullination process they are responsible for, and hypercitrullination that contributes to MS pathogenesis via the generation of immunogenic antigens could be conceived where these modified or citrullinated proteins cause an inflammatory response and a break in autoimmunity. Although current evidence in animals does not fully support this idea and more evidence is needed, intent here is to provide a plausible explanation that MS may not be an autoimmune disease entirely and could have CNS origins. MBP is one of the most prominently citrullinated proteins associated with MS, and it plays a key role in maintaining the structural integrity of the myelin sheath via synergistic interactions with phospholipids.[56] The hypercitrullinated form of MBP, due to changes in the surface charges, was found to loosen the myelin sheath from its native C-shaped curvature. Such structural elements trigger digestion enzymes such as cathepsin D,[57] an aspartic protease that is known to be upregulated in the brains of patients with MS in regions around plaques.[58,59] Such digested myelin proteins and others generate potentially immunodominant epitopes with tertiary structures such as α-helical structure.[60,61] These modified protein epitopes may be protected from further digestion, allowing these epitopes to leave the CNS to interact and activate the peripheral immune system. Interestingly, citrullinated MBP was found to be more reactive to T cells than its noncitrullinated counterpart.[60] Furthermore, citrullinated epitopes of MBP were found to cause a Th1 polarized response in T cells isolated from patients with MS.[62] As described earlier, elevated PAD2 in the periphery has been associated with its epigenetic regulation in PBMCs.[50] Thus, to bring this all together, one can conceive that PAD2 primes the peripheral immune system for attack against citrullinated MBP in the CNS by generating citrullinated epitopes from the MBP, which is elevated in lymphoid tissues during experimental autoimmune

encephalomyelitis (EAE), typically induced in mice.[63] Typically, peptide of myelin oligodendrocyte glycoprotein (pMOG) is used as an antigen to induce EAE in mice. Evidence supports that citrullinated brain proteins in EAE mice generate neoantigens in due time, ultimately leading to nonspecific anticitrulline autoantibodies.[64] Citrullinated pMOG, however, cannot induce EAE in mice but can prime T cells to cause a relapse of EAE that was previously in remission in the EAE mice.[65] This leads one to suggest that hypercitrullination can exacerbate the inflammatory response in the mouse models of MS, and autoantibodies may also play a role in this event. While further studies are needed to identify the proteins involved in immune reactivities, which is no trivial task, IgG sensitivity to citrullinated MBP does not appear to be one of the significant components in the immunoreactive role played by citrullinated MBP in MS.[66]

Interestingly, PAD2, which is present in the nucleus, and PAD4, due to its nuclear localization signal, can citrullinate nuclear peptidyl Arg residues. Histone citrullination has been associated with MS, as the accumulation of citrullinated histones in NAWM of MS is suggested to lead to cellular apoptosis.[46] In these studies, translocation of PAD4 from cytosol into the nucleus was shown to be regulated by TNF-α in human oligodendroglial cells prior to demyelination. The apoptosis of oligodendrocytes may also initiate an autoimmune response if cellular debris is not cleared.[67–69] PAD4 upregulates the transcription of several human endogenous retroviruses (HERVs) and immune-related genes including TNF-α and IL-8, as a part of its epigenetic control. Citrullination of histone H3R8 reduces the binding affinity of the repressor protein HP1-α to the promoter regions of the aforementioned genes in PBMCs isolated from the MS patients.[51] Mastronardi et al. also noted a functional deficiency of HP1-α repressor protein in studies involving PAD4 and histones,[46] and interestingly, covalent inhibition of PAD4 reversed the derepression of HERVs and the cytokines. Increased transcription of cytokines may provide feedback for the priming of neutrophils.[72] Its worth noting that under normal conditions, histone H3 citrullination by PAD4 triggers a number of nuclear events leading to the formation of NETs in response to inflammatory stimuli for the trapping and killing of bacteria.[21,70,71] Furthermore, patients with MS were found to possess greater quantities of overactive neutrophils possibly because of the chronic inflammatory environment in MS.[72] These studies connect the PAD enzymes and immune reactivity to neurodegeneration or the loss of neurons overall via apoptosis and epigenetic control, primarily with evidence from in vitro studies and in vivo mouse models in MS. While it is not yet clear if these events occur in the human form of MS, inhibitors of PAD in the animal models of MS provide indirect evidence for the validity of these pathways in MS.[73] In fact, an in silico screening of PAD4 active site using chemical libraries led to a hydantoin-based derivative that inhibited these enzymes noncovalently.[74] This PAD inhibitor also exhibited good in vivo efficacy reducing the physical disability in the autoimmune encephalomyelitis mouse model and immune cells infiltration into the brains of the treated mice.[74] Preclinical and clinical development of compounds targeting nonimmunologic targets such as in the preceding text remains to be seen in the coming years.

Astrocytes play an important role in neuronal metabolism through the activation of the astrocyte–neuron lactate shuttle (ANLS). Their role is also significant in controlling the levels of extracellular glutamate, production of antioxidant molecules, disposal of neuronal waste products, storage of energy in the form of glycogen, and expression of neurotrophic factors. These mechanisms are essential for brain activity and cognition, and they also contribute to neuronal degeneration.

New DMTs can potentially be designed to regulate mechanisms and targets such as NMDA receptors, VGCCs, neuronal nitric oxide synthase (nNOS), oxidative stress from reactive oxygen species, and protein aggregation. Neurodegenerative diseases such as AD and PD are characterized by progressive neuroaxonal injury, indicating that they share a common pathophysiological pathway.[75] Due to the advanced neuroaxonal compromise at the time of initial onset of clinical symptoms, identification and development of neuroprotective therapies have proved to be challenging. Therefore, in order to ensure immediate neuroprotective therapies, methods for early identification of neurodegeneration are essential. The role of neuroaxonal injury in MS is more sufficiently understood, and the earlier manifestation in life and the earlier diagnosis in the course of the disease can be achieved in comparison with AD and PD. Therefore, MS can potentially be used as a model disease to study the degeneration and regeneration of the CNS. It is generally believed that inflammation leads to neurodegeneration in MS, but the reverse mechanism of neuroaxonal injury may also be true; the neuroaxonal degeneration leads to inflammation. Animal models of AD and PD displayed the initial inflammation that is followed by a degenerative process in most cases, indicating the similarity between MS and the classic neurodegenerative diseases. Other similarities between MS and the neurodegenerative diseases include iron and mitochondrial dysregulation, abnormalities in α-synuclein and tau protein, and a number of immune mediators. Using MS as a clinical model to study the course of neuroaxonal injury in the brain may signify a progress in treatment strategy development for AD and PD.

MRI techniques, such as nuclear magnetic resonance spectroscopy (NMR), magnetization transfer ratio (MTR), and myelin water imaging, aid in providing more pathology-specific data in MS studies. Moreover, optical coherence tomography (OCT) is used to quantify optic nerve integrity and retinal ganglion cell loss as markers of neuroaxonal injury. This is a non-MRI technique that still needs to be assessed on the reliability of the information obtained from the technique. Potentially, these techniques can be used to follow degeneration and regeneration longitudinally in MS patients and differentiate the effects of various drugs under investigation.

5.14.2 Therapeutic Approaches in MS

Therapeutic approaches in MS have evolved over the past several decades, from small molecules with immunomodulatory properties to monoclonal antibodies reducing the autoimmune insults, and the current treatment objective to delay or halt the progression of irreversible disability.[76] Disease-modifying drugs or disease-modifying therapeutics (DMDs or DMTs) including β-interferon and glatiramer acetate (Copaxone) have been shown to reduce relapse rates in RRMS as detected by MRI (Table 1). However, the

Table 1 Chemical structures of drugs for the treatment of multiple sclerosis

Drug name	*Chemical structure*
Fingolimod	Teriflunomide	Dimethyl fumarate	Laquinimod	Interferon β-1b	Biologic drug
Interferon β-1a	Biologic drug
Peginterferon β-1a	Biologic drug
Natalizumab	Biologic drug
Alemtuzumab	Biologic drug
Glatiramer acetate	Mitoxantrone	Rituximab	Biologic drug
Cyclophosphamide	Adrenocorticotropin hormone (ACTH)	Peptide drug
Methotrexate	Cladribine	
long-term effects of DMTs on MS progression are not very clear, and majority of the immunomodulators do not help with the progressive MS disease and delaying the disability progression.[76] Most of the current research efforts are directed at the discovery and development of agents that will help progressive phases of MS and those that delay or prevent disability in the MS patients. Later, a number of drugs currently marketed for MS are described providing an overview of the current therapeutic approaches (Table 1).

5.14.2.1 Fingolimod

Fingolimod is a sphingosine-1-phosphate (S1P) receptor modulator that prevents T and B lymphocyte egress from lymph nodes,[77,78] reducing peripheral blood lymphocyte counts by 70% of baseline within 3 months of treatment initiation.[79,80] Fingolimod is the first oral therapy approved as a first-line treatment in various countries during 2010–11.[81,82] In the European Union, fingolimod is approved as a second-line treatment, except for patients with highly active RRMS, for whom it can be prescribed as a first-line therapy.

In an analysis of six randomized clinical trials including a total of 5152 participants, three doses of fingolimod were investigated. In this study, 1621 were control patients, and 3531 patients were treated with oral fingolimod at three doses: 2061 patients with 0.5 mg/day, 1376 patients with 1.25 mg/day, and 94 patients with 5.0 mg/day.[79] In the control group, 923 participants were treated with placebo and 698 with others DMTs. The treatment duration was 6 months in three trials, 12 months in one trial, and 24 months in two trials. When fingolimod 0.5 mg/day treatment was compared to that with placebo, the drug at 24 months increased the probability of being relapse-free, but it did not prevent disability progression. Clinical benefit was observed for other measures of inflammatory disease activity including much reduced ARR, MRI activity, and Gd-enhancing lesions. The mean change of MRI/T2-weighted lesion load was reduced when treated with fingolimod at 12 and 24 months. No significant increased risk of discontinuation due to adverse events was observed for fingolimod 0.5 mg/day compared to placebo at 6 and 24 months. Serious adverse events were not observed for fingolimod at 0.5 mg dose compared to placebo at 6 and 24 months, but at 1.25 mg/day dose for 12 months, there is a higher risk of discontinuation of fingolimod treatment due to adverse effects. Even at 0.5 mg/day dose of fingolimod, a significant increased risk of discontinuation due to serious adverse events was observed compared to placebo at 6 months.

When fingolimod 0.5 mg/day was compared with intramuscular interferon β-1a, the drug treatment with fingolimod for 12 months slightly increased the number of participants free from relapse or from Gd-enhancing lesions and decreased the relapse rate, but in these cases, disability progression was not affected. Higher number of patients chose to continue fingolimod as compared with other DMTs due to favorable adverse events profile in the 6-month term, but there was no significant difference in the 12-month term when compared with treatment with interferon β-1a. Overall, the treatment with fingolimod in RRMS patients is effective in reducing inflammatory disease activity compared to placebo, but it may lead to little or no difference in preventing disability worsening, due to neurodegenerative component of MS. Over a 24-month period, brain volume loss was reduced in fingolimod-treated patients compared with both placebo-treated patients[79] and interferon β-1a-treated patients.[83] Three major clinical trials and their extensions investigated the safety profile of fingolimod, including 3916 patients altogether with up to 7 years of treatment.[79,80,84,85] Adverse effects related to the immunosuppressive properties of fingolimod included a moderately increased risk of lower respiratory tract infections compared to placebo.[80] No increase in risk of malignancy was observed in patients treated with fingolimod compared to placebo in these studies.

Serious cardiac side effects due to fingolimod therapy have been reported in the literature, including cases of asystole or cardiac arrest.[86,87] S1P receptors, the targets for fingolimod, are expressed in many tissues including the cardiovascular system and have roles in heart rate and blood pressure regulation. These effects are responsible for the cardiovascular adverse events when treated with fingolimod.[88] Upon treatment initiation, fingolimod leads to a dose-dependent bradycardia. This effect is transient, with heart rate reaching its nadir 4–5 h after the first dose. In most cases, bradycardia is asymptomatic, and heart rate is back to baseline after a month of continuous treatment.[79,80] Other cardiac side effects include first- and second-degree atrioventricular (AV) conduction blocks, with a pooled incidence in both phase III trials of 4.7% (1.7% in the placebo group) and 0.2% (0% in the placebo group), respectively.[84] Absolute contraindications for fingolimod therapy within the 6-month period prior to initiating treatment include incidences of myocardial infarction, unstable angina, stroke or transient ischemic attack, class III/IV heart failure or heart decompensation, Mobitz II second-degree or third-degree AV block, sick-sinus syndrome, and prolonged QTc or treatment with class Ia or III antiarrythmic drugs.

A recent study suggests subtle subclinical macular oedema may occur more frequently in fingolimod-treated patients compared to placebo.[79,80,89,90] Elevation of liver enzymes three times above the upper limit was reported in 8% of fingolimod-treated patients compared with 1.9% in the placebo group, and any higher titers of the liver enzymes require treatment cessation.[84] More recently, several cases of atypical, tumefactive demyelinating lesions have been reported in fingolimod-treated MS patients, suggesting fingolimod may have a paradoxical effect in some MS patients.[91,92] MS patients on fingolimod have similar cellular and humoral immune responses to influenza vaccination compared with healthy controls.[93] For safety reasons, live attenuated vaccines are contraindicated while on fingolimod treatment, and immunization status (including VZV) should be checked prior to treatment initiation.

Preclinical studies with fingolimod have demonstrated embryotoxicity and teratogenicity. Female patients are therefore advised not to become pregnant while treated with fingolimod, and a 3-month washout period with normalization of blood tests before conception is recommended.[94]

5.14.2.2 Teriflunomide

Teriflunomide is the active metabolite of leflunomide, an antirheumatic small-molecule drug. Teriflunomide inhibits a key enzyme, dihydroorotate dehydrogenase (DHODH), in the de novo pyrimidine synthesis pathway.[95] De novo pathway is favored over the salvage pathway in rapidly proliferating cells such as activated lymphocytes. Immunomodulatory properties of teriflunomide are manifested by the inhibition of lymphocyte proliferation.[96] Teriflunomide is approved as a first-line treatment of RRMS by the FDA, EMA, and Swissmedic.

In the TEMSO phase III study, teriflunomide 14 mg/day reduced ARR by 31.5%, which was confirmed subsequently by a second phase III study, TOWER.[97,98] In both studies, the risk of sustained accumulation of disability was significantly reduced in patients taking 14 mg/day teriflunomide.[97,98] In TEMSO trial, MRI evidence of disease activity was significantly reduced in patients taking 14 mg teriflunomide. However, brain volume loss did not differ significantly between teriflunomide and placebo-treated groups.[97] The efficacy of teriflunomide, in terms of ARR reduction, is comparable with that of the first-line injectable treatments interferon β-1a, but "treatment satisfaction questionnaire for medication (TSQM)" scores were higher for teriflunomide, underscoring the benefit of an oral formulation on patient's quality of life.[99] A phase II study showed no benefit of teriflunomide as an add-on therapy in patients receiving interferon β-1a.[100]

In phase II trials, long-term follow-up of patients from phase II trials up to 8.5 years, and phase III trials, no serious adverse events were observed. Side effects included nausea, diarrhea, and reversible hair thinning.[97,101,102] Tuberculosis (TB) reactivation was reported in patients treated with leflunomide, and if the TB test was positive, treatment was mandatory prior to teriflunomide initiation. A slight increase in blood pressure and elevated transaminase levels were reported.[97,101,102] Teriflunomide activates cytochrome P450, and drug–drug interactions with other drugs could occur, including with warfarin, antibiotics, and antiepileptics. Patients treated with teriflunomide were shown to have a normal response to influenza vaccine, but live attenuated vaccines are contraindicated.[103] Preclinical studies with teriflunomide in rats, rabbits, and mice have demonstrated embryotoxicity and teratogenicity,[94] and female patients are advised not to become pregnant while treated with teriflunomide.

5.14.2.3 Dimethyl Fumarate

Dimethyl fumarate (DMF), a fumaric acid ester (**Table 1**), exhibits both immunomodulatory and neuroprotective effects, but the exact mechanisms of action remains to be elucidated.[104] In vitro studies on PBMCs showed that DMF and its metabolite, monomethylfumarate, stimulate cyclic adenosine monophosphate (cAMP) production.[107] cAMP is a small-molecule second messenger that has been shown to modulate immune response. These findings suggest that DMF may provide protection against MS by inhibiting immune cell function via the cAMP signaling pathway.[107] More research is needed to understand the complete molecular mechanisms responsible for the clinical efficacy of DMF. Fumaric acid esters in fact have been in clinical use in Germany for psoriasis treatment under the brand name Fumaderm.[105] An oral formulation of DMF, delayed-release DMF, also known as gastroresistant DMF, is a recently approved oral DMT for RRMS.[106–108] Two randomized clinical trials, viz. *Determination of the efficacy and safety of oral fumarate in relapsing–remitting MS* (DEFINE) and *Comparator and an oral fumarate in relapsing–remitting multiple sclerosis* (CONFIRM), demonstrated significant efficacy in reducing relapse rate and disease activity based on MRI scans, due to DMF treatment. The DEFINE study also indicated a significant effect of DMF on disability worsening, although low incidences of disability worsening in the CONFIRM trial render the reduction in disability worsening among the DMF-treated groups statistically insignificant when compared to that with placebo treatment. In DEFINE study, oral DMF 240 mg *b.i.d.* reduced ARR by 53% compared to placebo.[109] Risk of disability progression was reduced by 38% compared to placebo in the DEFINE study but did not reach significance in the second phase III trial, CONFIRM.[109,110] Brain volume loss was not assessed in either phase III trials.

Overall, DMF demonstrated a good safety profile and acceptable tolerability, and no serious side effects were reported in phase II and III trials.[109–111] Most common side effects such as gastrointestinal events and flushing reactions are transient with moderate severity.[108] Most frequent side effects included flushing (31%), diarrhea (13%), nausea (11%), and abdominal pain (10%).[110] Patients enrolled in phase III trials were allowed to be vaccinated. However, available data are insufficient to assess safety or efficacy of vaccines in combination with DMF. Animal studies showed embryolethality and teratogenicity in various animals, and female patients taking DMF are advised not to become pregnant.[94] Patients switching from interferons or glatiramer acetate to DMF exhibited greater benefit, whereas patients pretreated with more potent immunotherapies did not benefit. This opened up the possibility for using DMF as switching treatment or as an add-on strategy in patients with breakthrough disease. In a retrospective analysis of medical records at two German MS centers, 644 MS patients treated with DMF were studied for safety and efficacy; the ARR decreased from 0.52 at baseline to 0.35 and the annualized disability progression from 0.15 to 0.10. This postmarketing, retrospective study concluded that DMF is an overall safe and effective drug that reduces relapse rate and disability progression in MS patients.[106]

5.14.2.4 Laquinimod

Laquinimod is a quinolone-3-carboxamide derivative approved for RRMS treatment (**Table 1**). In Jan. 2014, it received a negative evaluation from the EMA, due to potential risks observed in animal studies.[81] Laquinimod is a CNS and peripheral immunomodulator with both antiinflammatory and neuroprotective properties.[112–114] Laquinimod seems to modulate CNS immunity

independent of effects on the peripheral immune system, which is a potentially different mechanism than the current immunomodulators.[112,115] The exact mechanisms of action of laquinimod remain to be fully understood as well.

In ALLEGRO phase III study, laquinimod 0.6 mg *q.d.* reduced ARR by 23% compared to placebo.[116] MRI markers of disease activity reduction and reduction in confirmed disability progression by 36% and 48% at 3 and 6 months, respectively, compared to placebo were observed in the ALLEGRO study.[116] Brain volume loss over a 24-month period was reduced in laquinimod-treated patients compared with patients receiving placebo.[116] In BRAVO phase III trial, laquinimod 0.6 mg *q.d.* treatment was compared to that with placebo and interferon β-1a (Avonex) *q.d.*[117] Compared to placebo, there was no significant reduction in ARR in patients receiving laquinimod, thereby failing to reproduce the results of ALLEGRO.[117] However, similarly to what was observed in ALLEGRO,[117] brain volume loss over a 24-month period was reduced in laquinimod-treated patients. No serious adverse events were reported in phase II and III trials.[80,116–118] Side effects included a moderate increase in the risk of urinary tract infection, abdominal pain, back pain, and elevated liver transaminase.[80,116,118]

5.14.2.5 Interferon β-1b

Interferon β-1b (Betaseron) was first introduced in 1993 for the treatment of RRMS and is a recombinant IFN-β produced in *Escherichia coli*.[119] The amino acid structure of Betaseron is slightly modified from that of the native human IFN-β molecule. The Met1 is absent, and a Ser residue is substituted for Cys17. IFNβ-1b is also not glycosylated, unlike natural interferon-β. The mechanism of action of IFN-β in MS is not known. Interferons are cytokines and accordingly are immunomodulatory agents. Numerous immune system abnormalities are identified in MS patients, and IFN-β treatment helps modulate the immune-mediated inflammatory responses.[125] HLA-DR expression on circulating blood cells increases abnormally during MS disease activity, and when treated with IFN-β, this is gradually reduced. CD8 regulatory cell function is deficient when MS is active, and IFN-β treatment partially reverses this deficiency. Interestingly, treatment with IFN-β lowers the production of interferon-γ (IFN-γ), which exaggerates the MS attack. Despite a clear understanding of IFN-β effects on the immune system at the molecular level, it is still unclear how this drug achieves therapeutic effect in MS patients.

In a phase III double-blind placebo-controlled trial in patients with RRMS, the Betaseron reduced MS attack frequency by 34% and 30% during 2 and 5 years, respectively, of the course of the treatment.[120,121] Mean attack duration and steroid use were reduced significantly in the drug-treated group. Progression of permanent disability was reduced in Betaseron-treated group when compared with the placebo group, although statistically insignificant. Based on the annual MRI scans on all patients, disease burden increased ~5% annually over the five-year course of the trial, but the disease burden did not change in the treated patients.[122] Subsequent studies using Gd-enhanced MRI scans showed an 85% reduction in disease activity in patients receiving Betaseron.[123] Betaseron treatment also helped improve few select measures of cognition in MS patients.[124] Based on the clinical outcomes using two dose regimens (1.6 and 8 MU *s.c.* every other day) for Betaseron, higher doses of the drug were more effective than the lower doses.[120,121] All the early studies were primarily confined to RRMS patients only.

A recent placebo-controlled study in SPMS over a 2-year period showed MRI findings similar to the earlier ones. Patients with continued attacks superimposed on progressive disease had 33% reduction in attack frequency, which is comparable with those observed in the earlier trial. Median time to progression to disability has reduced by 38% ($p=0.0007$), a significant beneficial effect on progression of disability, and this was consistent regardless of disability status at entry into the trial, when treated with Betaseron. As is with other cytokine and interferon treatments, systemic side effects in the form of flu-like symptoms including fever, chills, sweating, and muscle aches are common with interferon β-1b treatment. Lower doses of interferon β-1b (3–4 MU *s.c.*) and subsequently increasing to the recommended dose could be considered, as well as evening administration of the drug to alleviate some of the suffering due to side effects. Acetaminophen can be used as an adjuvant therapy to lessen systemic side effects.[120,121,125]

5.14.2.6 Interferon β-1a (IFN-β-1a; Avonex, and Rebif)

Two interferon β-1a products are approved, one marketed by Biogen and the other by Merck Serono. Avonex, a Biogen product, is a recombinant IFN-β preparation and is a close structural mimic of betaseron and the sequence of native IFN-β. A portion of the preparation may lack the first amino acid, Met1 in the full native IFN-β sequence, and the protein is glycosylated. It is produced in Chinese hamster ovary (CHO) cells. The drug was approved in 1996 at the dose of 6 MU and is given intramuscularly once weekly. Avonex reduced MS attack frequency by 9% in the first year and by 18% over the 2-year span of a clinical trial conducted on RRMS patients with very mild early MS disease.[126] In a subgroup analysis with 87 patients who were treated with Avonex for 2 years, MS attack frequency was reduced by 32% ($p=0.03$), and treated patients had significantly less projected accumulating disability than placebo-treated patients. MRI scans showed 35% fewer Gd-enhancing lesions and, in turn, 35% less disease activity in treated patients than that in the placebo group after first year of treatment ($p=0.02$) and 52% less disease activity after second year of treatment ($p=0.05$). Only minimal changes in blood parameters were noted. Side effects such as flu-like symptoms were comparable but less frequent to those seen with Betaseron treatment.

Rebif (EMD Merck Serono) is also an IFN-β-1a preparation, very similar to Avonex. It is also produced in CHO cells. Rebif is not currently marketed in the United States but is available in other countries. Preliminary studies had shown that subcutaneous and intramuscular administration gave comparable responses for a range of biologic markers that are induced by IFN-β, and subcutaneous administration is convenient for the patients. Rebif was evaluated in clinical trials at two doses, 6 and 12 MU *s.c.* three times

a week over 2 years in RRMS patients. Both doses of Rebif reduced attack frequency, by 29% for the 6-MU dose and by 32% for the 12-MU dose, when compared with the patients receiving placebo.[127] At the higher dose, there was a 37.5% reduction in major MS attack. Time to progression of disability based on expanded disability status scale (EDSS) was 18.2 months for the Rebif 6-MU dose group versus 11.8 months for the placebo group. In the 12-MU dose arm, time to progression of disability was 21 months, slightly higher than that for the 6-MU Rebif dose. The accumulation of disease burden was significantly lessened in Rebif treatment groups: 1.2% improvement in the 6-MU treatment arm and 3.8% improvement in the 12-MU treatment arm in comparison with 10.9% worsening in the placebo arm after 24-month treatment with Rebif. CNS lesions and disease activity were 81% and 87.5% lower for the 6- and 12-MU Rebif treatment arms, respectively.[128] Overall, the effect of the higher dose was only slightly better than that of the lower dose for the majority of parameters evaluated.

5.14.2.7 Peginterferon β-1a

US Food and Drug Administration (FDA) approved peginterferon β-1a in 2014 for RRMS and marketed as Plegridy by Biogen Idec. Peginterferon β-1a is the pegylated follow-on biologic of Avonex (interferon β-1a).[129,130] Pegylation extends the half-life of interferon β-1a permitting a less frequent administration of the drug than that of the unpegylated product.[131] The recommended dosage of peginterferon β-1a is 125 μg *s.c.* every 14 days with a prefilled pen-type syringe.[132] The FDA's approval of this drug was based on results of the 2-year, randomized phase III double-blind clinical trial, ADVANCE study, in which efficacy and safety were evaluated. One-year ADVANCE study results indicated that after 48 weeks of treatment with peginterferon β-1a, patients had a significantly reduced relapse rate and might be an effective treatment of RRMS with less frequent administration.[133]

In a placebo-controlled multicenter study, patients with RRMS were randomly assigned to receive subcutaneous injection of placebo or 125 μg of peginterferon β-1a once every 2 weeks or every 4 weeks. Out of the 1512 patients, 1332 patients completed 48 weeks of treatment.[133] In the first year of the study, ARR for peginterferon β-1a once every 2 weeks treatment was lower (0.256) than that of placebo recipients (0.397) ($p=0.0007$). For those who took peginterferon β-1a every 4 weeks, the annualized relapse rate was 0.288. This 2-year study confirmed the clinical benefits of peginterferon β-1a.[134] The most common adverse events associated with peginterferon β-1a are minor in general such as injection-site reactions, flu-like symptoms, pyrexia, and headache.[133] There is no significant difference between the placebo and drug-treated groups in serious adverse events such as relapse, pneumonia, and urinary tract infection.[133]

5.14.2.8 Natalizumab

Natalizumab is a humanized monoclonal antibody that targets the lymphocyte adhesion molecule, α4β1 integrin. Binding of this monoclonal antibody disrupts the interaction of α4β1 integrin with vascular adhesion molecule VCAM-1 and interferes with the migration of the peripheral lymphocytes from blood vessels into the CNS.[135] Natalizumab (Tysabri) is approved for treatment of active RRMS in Europe, North America, and other countries globally.[81,136]

Natalizumab was approved by the FDA in 2004 before the completion of phase III trials SENTINEL[137] and AFFIRM due to its remarkable efficacy.[138] However, it was withdrawn from the US market after two patients were diagnosed with progressive multifocal leukoencephalopathy (PML) in natalizumab treatment groups.[139,140] Both phase III trials confirmed high efficacy of natalizumab 300 mg infusion every month, and the treatment reduced ARR by 68% compared to placebo.[138] Natalizumab also reduced the accumulation of new and enlarging T2 lesions, Gd-enhancing lesions,[141] and the risk of sustained disability progression.[110,138] Besides the risk of PML, other serious adverse events included hypersensitivity reactions. Additional research and analyses of risks and benefits of natalizumab treatment eventually led to the recommercialization of natalizumab in more than 65 countries globally.

In a recent Danish study involving RRMS patients who started their first second-line treatment with natalizumab or fingolimod between 2011 and 2015, no differences were found in clinical disease activity between natalizumab- and fingolimod-treated RRMS patients, and EDSS was similar between the two groups.[136] It must be noted that, despite recommercialization of natalizumab after the risk–benefit analysis, more than 370 cases of PML have been diagnosed worldwide among the 700,000 natalizumab recipients.[142] In phase III trials, the presence of antinatalizumab antibodies was noted potentially affecting its clinical efficacy, and majority of these cases appear to be neutralizing antibodies.[138] The incidence of antinatalizumab antibodies was measured in 9% of natalizumab-treated patients; one third of these patients were transiently positive with no clinical significance, and the remaining were persistently positive with loss of clinical efficacy of natalizumab.[143] Natalizumab treatment is not effective in antiaquaporin 4-positive neuromyelitis optica (NMO) patients and must be excluded before the initiation of natalizumab treatment.[144–146] Live-attenuated vaccines are permitted in natalizumab-treated patients, unlike other immunomodulating drugs for MS treatment, and vaccination against influenza in patients treated with natalizumab yields effective humoral immune response.[147] Animal studies show teratogenicity when treated with natalizumab; thus, female patients on natalizumab are advised not to become pregnant.[148] In general, increased susceptibility for infections and the development of anti-antibody antibodies with or without clinical implications when treated with monoclonal antibody therapeutics are some of the common concerns. Thus, these factors would have to be monitored on a continuing basis when antibody treatments are used.

5.14.2.9 Alemtuzumab

Alemtuzumab (Lemtrada) is a humanized monoclonal antibody targeting CD52 antigen on mature lymphocytes specifically depleting T and B lymphocytes, and it is a fast-acting drug.[81,149] After the treatment initiation, B cells are replenished to baseline within 3–6 months with a distinct pattern, and T-cell counts slowly rise toward normal within 12 months, without returning to baseline.[150] These changes lead to long-lasting changes in adaptive immunity. In 2013, alemtuzumab was approved by the EMA for RRMS.

Two phase III studies, CARE-MS I and CARE-MS II, evaluated the efficacy of alemtuzumab and compared with interferon-β-1a (Rebif). In CARE-MS I and its extension CAMMS223, alemtuzumab reduced ARR by 54.9% and 66% at 2 and 5 years, respectively, compared with that with Rebif treatment.[151] In CARE-MS II, which included MS patients who relapsed on prior interferon or glatiramer acetate (Copaxone) therapy, alemtuzumab reduced ARR by 49.4% compared with that with Rebif.[152] A significant reduction in sustained disability progression was observed in alemtuzumab-treated patients compared with interferon-treated patients in CARE-MS II.[150,152] A significant reduction in new or enlarging T2 lesions and Gd-enhancing lesions in alemtuzumab-treated patients compared with those treated with Rebif was also observed.[150,152] Brain volume loss was reduced in alemtuzumab-treated patients compared to placebo- and interferon β-1a-treated patients.[150,152]

Studies involving six clinical trials and their extensions investigated safety profile of alemtuzumab; 90% of patients reported infusion-associated reactions including headache, skin rash, and pyrexia; an increased risk of autoimmune conditions including autoimmune thyroid disease, immune thrombocytic purpura, hematologic, renal, and dermatologic autoimmune diseases was also observed.[150–154] Cumulative risk of autoimmune disease in MS patients following alemtuzumab treatment was about 22.2% at 12–18 months after the initiation of the treatment and is due to the change in the balance of the immune system from a Th1-mediated response toward a Th2-mediated response. Upper respiratory tract, urinary tract, herpes (predominantly cutaneous), and localized fungal infections were more frequent in alemtuzumab-treated patients.[150,152] The benefit–risk ratio of alemtuzumab should be assessed for each patient due to its relatively high rate of side effects and complex administration requiring herpes simplex prophylaxis, methylprednisolone premedication, and antipyretic and antihistaminic coadministration.

In a meta-analysis of three randomized clinical trials in patients with RRMS, treatment with alemtuzumab 12 mg was better than subcutaneous interferon β-1a at 24 months; outcomes for relapse-free survival, sustained disease progression-free survival, number of participants with at least one adverse event, and number of participants with new or enlarging T2-hyperintense lesions on MRI were all better in patients receiving alemtuzumab.[155]

5.14.2.10 Glatiramer Acetate

Glatiramer acetate (GA; Copaxone, Teva Pharma) is an acetate salt of a random polymer of four amino acids, L-alanine, L-lysine, L-glutamic acid, and L-tyrosine at a molar ratio of 4.2:3.4:1.4:1.0, respectively (**Table 1**).[156,157] This drug may capture the antibodies or may reduce inflammatory response targeted toward antigenic epitopes from MBP; thus, GA carries similar charge to that of MBP and shares some cross-reactivity with MBP. GA is approved as a DMT for the treatment of relapsing forms of MS.[156,158,159] Pretreatment with GA is known to decrease the incidence and severity of EAE in mouse models of MS.[156] The postulated mechanisms of action include desensitization, enhanced production of antigen-specific suppressor T cells, inhibition of MBP-specific effector T cells, and competition for the peptide-binding site of the MHC class II antigen.[156,160,161] Its mechanism of action is only being elucidated in recent times, and GA modulates both the innate and adaptive immune systems.[162] These mechanisms include alteration of regulatory T-cell function[163–165] with induction of a T-helper 1 (Th1) to Th2 cell shift. This T-cell subtype shift results in an enhanced antiinflammatory cytokine profile,[166–170] alterations in the function of antigen-presenting cells (APC),[163] and modulation of B-cell function.[162] GA exhibits neuroprotective effects that are mediated by neurotrophic factors, and GA treatment exhibits reduction in demyelination and promotes remyelination.[162] GA is administered for extended periods of time.[171,172] Glatiramer acetate and similar therapies are indicated to reduce the frequency of exacerbations in patients with relapsing MS and are commonly initiated when patients show signs of relapsing MS.[158,172–176]

Initial trials demonstrated the safety but did not convincingly prove the efficacy of GA in the treatment of MS.[161,177] A 2-year multicenter placebo-controlled phase III trial of GA in 251 patients with RRMS demonstrated a beneficial treatment effect.[156] There was observable reduction in ARR (0.59 relapses in the treatment group vs. 0.84 relapses in the placebo group), percentage of patients remaining relapse-free at 2 years (78.4% in the treatment group vs. 75.4% in the placebo group), and median time to first relapse (287 days in the treatment group vs. 198 days in the placebo group). As with other immunomodulators, progression of the disease and worsening of the lesions were not altered in the treatment group when compared with that receiving placebo.[178] On the other hand, side effects in the GA-treated patients are mild and infrequent and are generally well tolerated. GA produced a systemic reaction in about 15% of patients receiving GA, characterized by flushing, chest tightness, and palpitations, and these reactions are resolved spontaneously in less than 30 min. GA is one of the first-line therapies for RRMS.

5.14.2.11 Mitoxantrone

Mitoxantrone (MTX) is a synthetic anthracycline with antineoplastic, immunomodulatory, and antiinflammatory effects.[179,180] Due to its mode of action and the chemical class of compound, it has direct applications as an anticancer agent and is used in treatment of breast, prostate, ovarian, stomach, and liver cancer. MTX is used as a second line of treatment for SPMS and RRMS in patients such

as those who do not respond to treatment with IFN-β-1a and GA.[181] This drug inhibits the activity of T lymphocytes, B lymphocytes, and macrophages and also affects the synthesis of antibodies. MTX is currently approved for aggressive, adult RRMS or SPMS and pediatric MS and has shown efficacy in several clinical trials.[182–184] However, it is not widely used due to safety concerns including high incidence of cardiotoxicity, liver toxicity, amenorrhea, and treatment-related leukemia due to its primary effects on cell topoisomerase II and triggering apoptosis.[185–188] Interestingly, cardiomyopathy and leukemia may occur many years after treatment cessation.[189] The most dangerous side effects of MTX treatment are cardiotoxicity, induction of leukemia, and colorectal cancer.[190] There is the lack of studies describing MTX effectiveness and safety in treatment of PPMS.

5.14.2.12 Rituximab

Rituximab is a genetically engineered, chimeric monoclonal antibody that targets the CD20 cell-surface antigen on B lymphocytes, and it induces antibody-directed cell cytolysis (ADCC) and complement-directed cytolysis (CDC) of the target cells.[191] Proof-of-concept data for the B-cell depletion upon treatment with the drug in RRMS patients were obtained in the HERMES trial, essentially one of the first clinical studies to evaluate rituximab in adults with RRMS (NCT00097188). In a randomized study with 104 patients in a 2:1 ratio to rituximab 1000 mg or placebo infusions on study days 1 and 15, rituximab-treated patients had a 91% reduction in the brain lesions at weeks 12, 16, 20, and 24 (primary end point) compared with those treated with placebo ($p < 0.001$). The ARR at 24 weeks with rituximab treatment was 56% lower than that on placebo (0.37 vs. 0.84, $p = 0.04$).[192] Safety concerns with rituximab in phase II trial included primarily infusion-related reactions (78.3% vs. 40% on placebo), but there was no increase in serious infection-related adverse events. Other adverse events were minor as well.[192]

Rituximab was not superior to placebo in preventing 12-week confirmed disability progression in a 96-week OLYMPUS trial of 439 PPMS patients (NCT00087529).[193] However, in a preplanned subgroup analysis, patients under age 51 with Gd-enhancing brain lesions at baseline were less likely to progress in disability on rituximab than placebo.

5.14.2.13 Cyclophosphamide

Cyclophosphamide was first used in an MS patient in 1966.[194] Cyclophosphamide is an immunosuppressive agent that was commonly used in the treatment of MS.[195] Cyclophosphamide is an alkylating agent (**Table 1**) and belongs to the class of nitrogen mustard agents that bind to DNA and disrupts cell replication. Cyclophosphamide is converted to active metabolites in the liver, one of the major active metabolites being 4-hydroxycyclophosphamide, and targets rapidly proliferating malignant cells. It has been used in the treatment of cancer, immune-mediated disorders such as Wegener's granulomatosis, nephrotic syndrome, multiple myeloma, and disorders of the peripheral nervous system.[196] The mechanism of action of cyclophosphamide lends itself to serve as a general immune suppressant inhibiting both cell-mediated and humoral immunity. Cyclophosphamide suppresses interleukin-12 (IL-12) and Th1-type responses[197] and enhances Th2 and Th3 activity, potentiating inflammatory mediators such as IL-4, IL-10, transforming growth factor-β, and eosinophils that further help suppress immune response.[196,198] Cyclophosphamide upregulates antiinflammatory CCR4+ IL-4-producing T cells while normalizing CCR5+ and CXCR3+ T cells in SPMS patients,[199] favoring a Th2-type response. Overall, its mode of action and in vivo efficacy indicate that cyclophosphamide has a more selective immune therapeutic effect rather than serving solely as a general immune suppressant.[195]

Hommes et al. conducted an open-label clinical study on 32 patients diagnosed with chronic progressive MS, investigating the efficacy of cyclophosphamide 400 mg *i.v.* combined with prednisone 100 mg *q.d.*[200] More than 50% of the treated patients showed clinical improvements in neurological signs and disability measures, and sustained improvements were observed following treatment up to 3 years. In a larger cohort of 110 patients treated with cyclophosphamide *i.v.* with up to 2 g exposure over a 1- to 2-week period, improvements in clinical measures were observed in most cases, and 62% of patients have shown stabilization of disease over 2–4 years. These data suggest that immunosuppression may interfere with the MS disease pathology and perhaps prevent disease progression.[201]

Cyclophosphamide was evaluated for its efficacy in pediatric MS as well. Pediatric MS has a different temporal profile of the disease with potentially more clinical relapses than one observes in adult MS.[202] There are also significant differences in structural neuroimaging of the brain and the disease-associated cerebrospinal fluid (CSF) inflammatory profiles.[203–205] A smaller multicenter clinical study involved the retrospective evaluation of 17 children with RRMS. Patients were treated with various regimens of cyclophosphamide, with doses in the range of 600–1000 mg/m^2.[206] In the majority of patients 1 year post treatment, relapse rate and EDSS have reduced, and the treatment was well tolerated. The general side effects include nausea, vomiting, alopecia, transient immunosuppression, amenorrhea, hemorrhagic cystitis, gonadal toxicity (in both men and women), bladder cancer, and future risk for malignancies. Overall, one can conclude that cyclophosphamide may be an appropriate therapeutic for pediatric MS disease that may be refractory to routine immunomodulatory treatments. The risk of bladder carcinoma appears to be associated with cumulative exposures of over 100 g of the drug and the long duration of exposure to cyclophosphamide.[207,208]

5.14.2.14 Adrenocorticotropin Hormone (ACTH)

ACTH first received new drug application approval from US FDA in 1952, and later in 1972, its use for the treatment of MS was added. Recently, in 2010, FDA approved ACTH gel under an orphan drug designation for infantile spasms and permitted the new label to include MS in addition to 17 other indications.[209] ACTH influences both the corticotropic and melanocortin

pathways.[210] ACTH induces cortisol production and exerts antiinflammatory actions by targeting melanocortin receptors present on immune cells. The endogenous agonists for these receptors, viz. ACTH, α-, β-, and γ-melanocyte stimulating hormones, are also produced locally by immune cells. These agonists act on the endogenous antiinflammatory tissue-protective pathway involving the melanocortin system. Thus, drugs such as ACTH and ACTH-like melanocortin drugs are devoid of steroidogenic actions and associated side effects.

ACTH, in a gel formulation, is a gelatin suspension administered intramuscularly or subcutaneously.[211] In a double-blind randomized controlled study in 1989, relative efficacy of intravenous methylprednisolone (IVMP) was compared with ACTH for the treatment of MS relapses.[212] The study included 61 patients randomized to receive treatment with either IVMP (1 g daily) for 3 days or ACTH *i.m.* (80 units for 7 days, 40 units for 4 days, and 20 units for 3 days). Both groups improved over the course of the study without a significant difference in the rate of recovery or final outcome at 3 months. A 2000 Cochrane Collaboration review concluded that both IVMP and ACTH result in acceleration of recovery and improvement in relapse-related disability.[213]

5.14.2.15 Methotrexate

Methotrexate is an antimetabolite and has been used in the treatment of neoplastic diseases, psoriasis, and rheumatoid arthritis for several decades. It is a potent oral immunosuppressant as well and has been commonly used as an "off-label" treatment for MS. Methotrexate inhibits dihydrofolate reductase (DHFR), an enzyme responsible for the conversion of dihydrofolate into tetrahydrofolate, thus inhibits cell proliferation and growth. Other beneficial antiinflammatory effects within the immune system are theorized, and the exact mechanism by which this is accomplished is currently unknown. Overall, the mechanism of action provides a rationale for its use in cancer and autoimmune disease.

In a randomized trial with 45 patients with RRMS, chronic progressive MS, and progressive MS, methotrexate treatment was evaluated over 18 months.[214] The aim was to study the efficacy of methotrexate in MS by assessing differences in relapse rate and EDSS. Patients were randomized to receive either methotrexate 2.5 mg every 12 h for three consecutive doses once a week (7.5 mg/week) or placebo. There was no difference between the treatment group and placebo group in suppressing exacerbations; however, when evaluating the subgroup of RRMS patients, there was a suggested benefit with fewer relapses observed in the treated versus untreated group (36% vs. 41%, $p=0.05$). Overall, methotrexate treatment was well tolerated, with minor side effects including nausea, elevation in liver function tests, and hair thinning.

Further studies on the impact of methotrexate treatment on chronic progressive MS also confirmed the efficacy of methotrexate for its immunosuppressive activity. In a study of 60 patients with clinically definite chronic progressive MS, participants were stratified by EDSS score (3.0–5.5 and 6.0–6.5) and were randomized to receive either methotrexate (7.5 mg/week) or placebo for 2 years, followed by an observation period of 1 year.[215] The principal finding of this investigation was that there was less progression of impairment in patients with EDSS greater than 6.0. Adverse effects were found to be similar between methotrexate- and placebo-treated groups. Although the number of patients evaluated was modest, this study provided data that methotrexate may have promise in MS patients with chronic progressive MS who have more disability. The mechanisms as to why this may occur are unclear but may be related to an immunosuppressive, antiinflammatory, or immunoregulatory effect. Contrast-enhanced MRI was performed every 6 weeks for 6 months on 31 chronic progressive MS patients, among which 16 patients received methotrexate (7.5 mg/week) and 15 patients received placebo.[216] Overall, there was no significant difference in the lesions between the two groups.

The effects of intrathecal methotrexate in patients with refractory MS disease were evaluated in a retrospective study.[217] The hypothesis for this study is grounded in the idea that orally administered therapy may be suboptimal for the treatment of spinal cord disease, the area of the CNS believed to be principally responsible for clinical impairment in progressive MS patients. SPMS subgroup ($n=87$) exhibited improvement in EDSS scores when compared with baseline data ($p=0.014$). This significant benefit was not observed in the PPMS subgroup ($n=34$) despite recording stable EDSS scores in 82% of subjects. Intrathecal methotrexate was well tolerated and may have benefits in progressive patients with treatment-unresponsive MS. It is possible that intrathecal delivery might provide this additional benefit over oral administration of methotrexate.[218,219]

A review of the data on oral methotrexate and its effects on relapse prevention and benefits due to sustained EDSS progression scores strongly suggest that methotrexate alters the course of the disease in progressive MS patients.[205,220] Methotrexate treatment is primarily used due to the convenience that it is orally administered weekly, but newer oral immunomodulatory therapeutics such as fingolimod and others with better outcomes have gained the market in recent times.

5.14.2.16 Cladribine

Although this drug failed to show efficacy, it is included in this section to highlight the strategy behind the development of cladribine, a nucleoside drug, and its efficacy as an immunomodulator. Cladribine (2-chloro-2′-deoxyadenosine) is an adenosine deaminase-resistant purine nucleoside drug licensed for the treatment of hairy cell leukemia (**Table 1**).[221] This drug was evaluated for efficacy via parenteral route for the treatment of progressive MS and an oral dosage form for the treatment of RRMS.[222] This molecule is a prodrug and enters the cell via the purine nucleoside transporters. Cladribine is then phosphorylated by deoxycytidine kinase.[223,224] In cells in which the ratio of deoxycytidine kinase to deoxynucleotidase is high, such as lymphocytes and monocytes, cladribine is phosphorylated to its corresponding triphosphate derivative, 2-chloro-2′-deoxy-ATP, which is the active form. Accumulation of this triphosphate form disrupts cellular metabolism and damages DNA, causing cell death.[225] These processes lead

to lymphocyte depletion and long-lasting lymphopenia, essentially leading to immunomodulation. Two phase II clinical trials involving progressive MS patients published in 1994 and 1996 showed that treatment with four monthly courses of 0.7 mg/kg cladribine was associated with significant disease stabilization measured with the EDSS and scripps neurological rating scale (SNRS).[226,227] In a multicenter study, however, cladribine did not have any significant clinical improvements for the treatment of progressive MS.[228]

The outcomes in RRMS patients, when treated with cladribine, were more encouraging than those in progressive MS patients. In the first double-blind, placebo-controlled, randomized trial with 52 RRMS patients, both the frequency and severity of relapses were reduced, and MRI enhanced lesions were completely suppressed by 6 months of treatment with cladribine.[229] In the CLARITY phase III trial (cladribine tablets treating multiple sclerosis orally), the long-term efficacy and safety of cladribine tablets (either 3.5 or 5.25 mg/kg) versus placebo were analyzed.[230] The annualized rate of relapse (ARR) values (the primary end points) were 0.14 and 0.15, respectively, in the two cladribine groups, compared with 0.33 in the placebo group, translating to relative ARR reductions of 57.6% and 54.5%, respectively. The risk of 3-month sustained progression of disability was also lower in the cladribine group (hazard ratio, 0.67 for the 3.5 mg/kg group and 0.69 for the 5.25 mg/kg group). Brain MRI revealed significant reductions in the extent of T2-weighted lesions (by 73.4% and 76.9%, respectively) and Gd-enhanced lesions (by 85.7% and 87.9%, respectively) in the aforementioned two groups. Overall, treatment with cladribine tablets for 96 weeks significantly reduced relapse rates in the RRMS patients, the risk of disability progression, and MRI measures of disease activity.[230]

Preliminary findings of the phase III ORACLE MS (oral cladribine for early MS) trial on the efficacy of cladribine in delaying conversion to clinically definite MS (CDMS) were released in 2014.[231] The treated groups exhibited significant delays in such conversion, accompanied by risk reductions of 67.3% and 61.9% in the two dose groups, 3.5 and 5.25 mg/kg, respectively, relative to placebo. Moreover, such treatment also significantly delayed the time to conversion to McDonald MS, compared with the placebo, echoing the efficacy seen in the CLARITY trial. Although cladribine may be more effective than the traditional drugs used for MS treatment, several adverse effects have limited its use. Dose-dependent myelosuppression, opportunistic infections (herpes zoster and TB), and malignancies have been linked to cladribine use and potentially limiting its use for the treatment of RRMS.[230] Benign uterine leiomyomas (smooth muscle tumors) and three cases of cancer were noted in patients in the CLARITY study.[232] Furthermore, secondary exacerbation of latent TB and latent herpes zoster led to implementation of screening measures in all ongoing trials using cladribine. Due to the negative feedback from the FDA and the European Medicines Agency, cladribine tablets were not further pursued for global approvals for marketing.[233]

Aforementioned therapeutics more or less capture the most popular therapeutic strategies deployed for the treatment of MS. While RRMS condition can be treated successfully with DMTs with various drugs available today, it is still a challenge to address the progressive forms of MS. Intense research and efforts are dedicated to develop novel DMTs that can prevent or reverse neurodegeneration in the progressive MS. There are no drugs yet that are directly addressing the neurodegeneration and progressive decline or loss of function in MS.

5.14.3 Other Neurodegenerative Disorders

In line with the concept of neurodegeneration due to progressive deterioration of the structure and/or function of neurons, other neurodegenerative diseases could include AD, PD, amyotrophic lateral sclerosis (ALS), Huntington's disease (HD), Down's syndrome (DS), glaucoma, age-related macular degeneration (AMD), and diabetic encephalopathy (DE). Clinical symptoms, disease progression and prognosis, and therapeutic approaches are quite diverse addressing these diseases. They do share similar biochemical reactions that lead to neurodegeneration. AD, ALS, and PD all share common features that include elevated oxidative stress levels and impaired energy metabolism in the nervous system.[234] Here, we will focus on PD and AD primarily and cover therapeutic options briefly in the context of neurodegeneration. Much of the treatments currently in market are only effective in alleviating some of the pathological symptoms, but most are unsuccessful at preventing neurodegeneration. Therefore, more innovative treatments are required for neurodegenerative disorders.

5.14.3.1 Alzheimer's Disease

The clinical manifestations in AD include irreversible loss of memory and thinking ability. Neuritic plaques, neurofibrillary tangles, and degeneration of several neural systems and neurotransmitters have all been connected to AD pathology. The difficulty in determining a singular neural pathway, affected by the disease leading to the deterioration of cholinergic system, suggests that there is an underlying mechanism for the degeneration and dysfunction of more than one of these neural pathways.[235] Moreover, the neuritic plaques found in the brains of AD patients have been associated with neuroinflammation through the colocalization of inflammatory peptides.[236,237] In AD, much of senile plaques were found to be composed of amyloid-β (Aβ), and Aβ is also believed to assist the onset of neurodegeneration.[235] The apparent relationship between PAD expression and AD progression signifies the potential use of citrullinated proteins as markers for neurodegeneration.[238–243]

It also appears that PAD enzymes are involved in neurodegenerative pathways associated with AD also, although more investigations are needed. Aβ peptides can increase the concentration of cytosolic Ca^{2+}, and PADs are calcium-dependent, hence, the suggestion of a link between PADs and AD progression.[239] Therefore, an increase in PAD activity, mediated by Aβ peptides, may be associated with the neuroinflammation mechanism of the disease. In the study conducted by Arif and Kato, increased activity

and higher levels of PAD2 within the hippocampus were observed in the rat model of AD after amyloid peptides were infused into the brain; however, PAD2 enzyme activation was inhibited by the administration of memantine (an NMDA antagonist used in the treatment of AD).[239] One can deduce that Aβ inhibits glutamate uptake in neurons, resulting in its accumulation and subsequent activation of NMDA receptor-induced Ca^{2+} influx into the cell, which activates the PAD2 enzyme. Arif and Kato also proposed the activation of glial cells by Aβ as an alternative mechanism leading to the activation of PAD2 due to their colocalization in astrocytes and microglia.[239] The study conducted by Nicholas showed immunohistological evidence of deimination within extracellular amyloid plaques in humans with AD.[240] Deiminated proteins were detected in the nuclei of neurons whose cytoplasm was immunoreactive for phosphorylated tau, implicating that histones may be a target for this process in these cells.

Along with amyloid proteins catalyzing increased PAD levels and their activation, the citrullinated forms of other proteins, such as vimentin and GFAP, were found in hippocampal tissues from patients with AD. In healthy humans, the citrullinated proteins were not observed.[238] PAD2 also citrullinates GFAP in AD which was shown using monoclonal antibodies against citrullinated GFAP. In addition to elevated PAD2 levels in AD patients, the role of PADs in AD pathogenesis and neurodegeneration then becomes apparent.[238,239] PTCD2, an antigen target of an AD diagnostic antibody, was found as the citrullinated form in the AD brains.[329] Therefore, potentially citrullinated proteins and their degraded fragments may enter the blood and lymphatic circulation and cause an immune response that produces the autoantibodies observed in AD.[329] More studies must be executed in order to determine the exact molecular mechanism of PAD enzymes in AD.

5.14.3.2 Therapeutic Approaches in AD

Current treatments in market for AD are designed to alleviate the symptoms and improve the quality of life of the patients temporarily (Table 2). In older patients suffering with AD, dementia and disability are commonly caused by AD.[244] Targeting cell-signaling pathways associated with neurodegeneration could be a potential strategy in decreasing neuroinflammation and excitotoxicity and improving cognitive functions. Molecular mechanism of each drug is briefly described later along with clinical evidence, to draw attention to therapeutic approaches employed for the treatment of AD and associated clinical conditions.

Table 2 Chemical structures of drugs for the treatment of Alzheimer's disease

Drug name	*Chemical structure*
Donepezil	Rivastigmine	Galanthamine	Memantine	Solanezumab	Biologic drug
Gantenerumab	Biologic drug
Resveratrol	
5.14.3.2.1 Donepezil

Neuroprotective agents with multiple mechanisms of action are used for the treatment of AD, and donepezil mechanism of action is related to the neuroprotective effects of this compound.[245] Donepezil is a potent, noncompetitive, and reversible acetylcholine esterase (AChE) inhibitor (**Table 2**).[246] In an in vitro study using neuroblastoma SH-SY5Y cells against okadaic acid or $A\beta_{25-35}$, donepezil exhibited neuroprotective effects along with galanthamine and rivastigmine.[247] The blocker of phosphoinositide 3-kinase (PI3K)-Akt reversed the protective effects of galanthamine and donepezil but not the effect of rivastigmine.[247] It is suggested that the mechanism of action of donepezil is likely not related to AChE inhibition, but possibly to the inhibition of the activation of glycogen synthase kinase 3 (GSK-3) and Akt enzymes.[247,248] Incubation of cortical neurons in the presence of donepezil prevented glutamate-induced apoptosis and consequently apoptotic neuronal death.[249,250] It was observed that donepezil causes loss of $\Delta\psi_m$, increases the release of cytochrome *c* to the cytosol, and modulates the expressions of Bcl-2 family proteins and the activation of caspase-9.[251] The loss of $\Delta\psi_m$ is usually associated with the formation of mPTPs followed by the diffusion of cyt *c* into the cytosol, which is normally associated with the inner membrane in mitochondria. Cytosolic cyt *c* activates procaspase-9 by binding to Apaf-1, which leads to caspase-9 activation and the subsequent activations of downstream executioner caspases (caspases-3, caspases-6, and caspases-7)—a well-established cascade of events.[251] Levels of cytosolic cyt *c* were elevated by donepezil in HL-60 cells, which suggested the involvement of the mitochondrial pathway in donepezil-induced apoptosis. These findings suggest that donepezil modulates the protein levels of Bid, Bax, Bcl-2, and Bcl-xl and that this results in loss of $\Delta\psi_m$ and release of cyt *c* from mitochondria.[251] This supports the mechanism that donepezil induces apoptosis in HL-60 cells via a mitochondria-mediated, caspase-dependent pathway. In vivo, it was found to increase the extracellular acetylcholine levels in the cerebral cortex and hippocampus of the rat.[250]

In three clinical studies investigating the efficacy and safety of donepezil,[252,253] patients were considered to have AD if they met the standard criteria: (1) diagnostic and statistical manual of mental disorders (third edition, revised) and National Institute of Neurological and Communicative Disorders and Stroke criteria for probable AD, (2) a minimental state examination (MMSE) score between 10 and 26 inclusive, and (3) a clinical dementia rating score of 1 or 2.[254] In a phase II multicenter, double-blind, placebo-controlled trial, dose-ranging study, among 161 patients of 96% white, aged 55–85 years randomized into four treatment arms, donepezil 5 mg once daily for 12 weeks exhibited significant clinical improvements in cognitive function in patients with mild to moderately severe AD.[252] Treatment arms consisted of placebo or 1, 3, or 5 mg/day of donepezil, respectively, for 12 weeks and then 2 weeks of single-blind, placebo washout period.[252] The efficacy of donepezil was acquired using ADAS-cog and CGIC as a primary measure and uniform activities of daily living (ADL), MMSE, Clinical Dementia Rating-Sum of the Boxes, and quality-of-life scores assessed by the patient (QOL-P) or the caregiver as a secondary measure. Patients receiving 5 mg/day had a significant improvement in their ADAS-cog scores ($p < 0.01$) at 3, 9, and 12 weeks as well as after the 2-week washout period compared to the placebo.[252] Some of the common adverse events included gastrointestinal events such as nausea, vomiting, diarrhea, gastric upset, constipation, and dizziness.

In the aforementioned study, an intent-to-treat analysis was conducted.[252] The adjusted mean changes in the ADAS-cog from baseline for placebo and treatment with the 5-mg/day groups were 0.7 (clinical decline) and −2.5 (clinical improvement), respectively ($p < 0.02$). A dose–response relationship was observed.[252] Based on the clinician evaluation (CGIC), most of the study patients did not have a change in their condition over the course of the 12-week study, and likely explanation is that AD patients do not show significant cognitive decline in 12 weeks.[252] In therapeutics development for AD, it necessary to have a longer evaluation period to detect a change based on clinician assessment (CGIC) scores. Fewer treatment failures also occurred in the donepezil-treated group (11%) compared with the placebo group (20%). Treatment with donepezil did not result in a significant improvement in the secondary measures of efficacy. Although there was an improvement in QOL-P, donepezil treatment was not any better than the placebo due to extensive patient variability.[252] The promising results from the phase II trials prompted the completion of two phase III randomized, double-blind, placebo-controlled trials, 15 and 30 weeks' duration.[253] Patients were randomized to receive placebo or donepezil at two doses: 5 or 10 mg/day. Efficacy was measured by using the ADAS-cog and the CIBIC-Plus. Baseline scores on the ADAS-cog ranged from 4 to 61 units (mean 26 units). Patients ranged in age from 50 to 94 years (mean 73 years); 62% were women, and most (95%) were white. In the 30-week study, 473 patients were randomized to the three treatment arms, placebo or donepezil, 5 or 10 mg. The trial was divided into a 24-week treatment phase followed by a 6-week single-blind, placebo washout phase. After 24 weeks of treatment, the mean differences in the ADAS-cog change scores for the 5-mg/day group and the 10-mg/day group compared with placebo were 2.8 and 3.1 units ($p < 0.001$), respectively. Thus, the difference between the two treatment groups was not significantly different, and the effects of the treatment were similar to that of placebo after the washout period. This suggests that the disease continues to progress during drug therapy and that donepezil did not alter the underlying disease process. Majority of patients (62–68%) taking donepezil showed no change or improvement in the CIBIC-Plus rating compared with those taking placebo (47%). Because of the progressive nature of AD, one can consider the "no-change status" in clinical condition over a 6-month period as a positive treatment effect. Donepezil treatment did not show any correlation to the outcomes based on the age, gender, and ethnicity of patients. In a subpopulation of the patients who completed the 30-week phase III trial and those that were on treatment for a long-term, an open-label study with 5–10 mg/day was investigated to understand the long-term efficacy of donepezil.[255] Patients maintained performance levels above the baseline scores for up to 40 weeks on an average, and collected ADAS-cog scores of 2 years suggested this benefit could extend as long as 2 years supporting the long-term use of donepezil in AD.[255]

5.14.3.2.2 Rivastigmine

Rivastigmine is another AChE inhibitor and is a potent compound that has been used for the treatment of a variety of neurological disorders. This compound has found its use for the treatment of AD, due to its AChE inhibitory activity. This is a noncompetitive pseudoirreversible inhibitor (Table 2). The pharmacokinetic properties of rivastigmine are quite different from donepezil due to this reason.[256–258] Rivastigmine inhibits AChE activity in the CSF of AD patients.[259–261] It allows greater selectivity of AChE inhibition in the CNS than in the periphery.[257,262] Thus, AD patients who are deteriorating on selective AChE inhibitor or those who cannot tolerate donepezil could potentially benefit from switching to rivastigmine.[263,264] Rivastigmine inhibits AChE with a long binding to its active site, up to 10 h, and it inhibits butyrylcholinesterase (BuChE) as well. As rivastigmine is a dual inhibitor, it can provide longer sustained efficacy than selective inhibitors and also can delay the formation of amyloidogenic proteins.[265] During the degeneration of primary rat neurons, rivastigmine reduced the secretion of Aβ while increasing α-secretase cleaved, secreted APP.[266] The increase in α-secretase cleaved secreted APP levels may potentially take part in cellular metabolic activity and enhanced neuronal survival.[266]

Rivastigmine exhibits effects on lymphocyte mitochondria. Biochemical analyses suggest that rivastigmine has a role in attenuating 3-nitropropionic acid-induced (complex II inhibitor) behavioral, biochemical, and cellular alterations.[267] Additionally, rivastigmine significantly reduced the oxidative damage while improving mitochondrial complex enzyme activities in different regions of the rat brain such as striatum, cortex, and hippocampus. This means that rivastigmine can potentially be an effective therapeutic agent for managing several neurodegenerative diseases beyond AD. When rivastigmine-treated AD patients were compared to control or untreated patients, higher oxidative and enzymatic activities were observed, including oxidation of pyruvate–malate (substrate of complex I) and glycerol-3-phosphate (substrate of complex III) and enzymatic activities of complexes II, III, and IV. The difference between treated and untreated AD patients and between treated patients of AD and controls was apparent.

5.14.3.2.3 Galanthamine

Galanthamine is a competitive inhibitor of AChE and allosteric activator of nicotinic acetylcholine receptors.[268,269] Its later activity, the allosteric modulation of nicotinic ACh receptors that is responsible for its therapeutic benefit in AD (Table 2).[270] Increased density of α7 nicotinic receptors and upregulation of antiapoptotic protein Bcl-2 after the incubation with galanthamine were observed in human neuroblastoma SH-SY5Y cells.[271] Furthermore, it was shown that galanthamine protected PC12 cells against the Aβ-induced apoptosis. It prevented Aβ aggregation, morphological changes of endoplasmic reticulum and mitochondria, and loss of $\Delta\psi_m$, as well as accumulation of ROS.[272] Galanthamine-induced cytotoxicity was not observed in human HepG cells, and also the oxidative stress markers were not affected at concentrations lower than 100 μM.[273] In an in vivo study in mice, galanthamine restored complex I and complex II activity and protected the mice brains from neurodegeneration, where the neurodegeneration was induced by intrahippocampal administration of kainic acid.[274] Thus, in vitro and in vivo studies indicate the prospects for galanthamine in the treatment of AD.

In vivo data in humans on galanthamine appear to have some variations, especially in the pharmacokinetics parameters. Surgical patients were given *i.v.* injection of galanthamine to reverse neuromuscular blockade after a surgery.[275] In these patients, maximum plasma concentration (C_{max}) of galanthamine was achieved at 2 min, and the serum concentration decreased rapidly between 2 and 30 min and then decreased slowly. The half-life ($t_{½}$) was found to be 4.4 h, and the mean cumulative urinary excretion was observed to be 28% of the administered dose, while biliary excretion was found to be 0.2%. Moreover, it is noted that only negligible amounts of the metabolites, epigalanthamine, and galanthaminone were detected.[276] In a study by Mihailova et al.,[276] young male volunteers were subjected to single oral and subcutaneous injection doses of galanthamine. Unlike previous studies, this study showed a quite dissimilar result where the C_{max} range was about 20 times greater than previous records. Although the reason for the diverse result is unclear, it may be due to different assay methods used in the study. T_{max} was observed to be 2 h for both types of doses, and the absorption kinetics exhibited a slow phase followed by a fast phase. Moreover, both doses achieved bioequivalence in rate and extent of absorption, and $t_{½}$ was not significantly different from the previously reported values.[275] In a study comparing an elderly AD patient and a healthy volunteer, it was observed that multiple oral doses of 15–55 mg galanthamine in the AD patient resulted in a steady-state near-peak plasma concentration of 32–182 ng/L.[277] Furthermore, in the healthy volunteer, 10 mg of *i.v.* injection resulted in a peak plasma concentration of about 180 ng/mL which correlated with the values obtained in the AD patient. It was concluded that galanthamine concentrations were dose-dependent, and the overall $t_{½}$ for galanthamine observed in this study was 8–10 h which is significantly longer than the $t_{½}$ values obtained in the other studies.

5.14.3.2.4 Memantine

Memantine is a noncholinergic alternative to AChE inhibitors such as rivastigmine and a low-affinity uncompetitive antagonist of NMDA receptors (Table 2). Memantine is used for treatment of moderate-to-severe stage of AD.[278] Memantine blocks the extensive activity of NMDA receptors but does not accumulate to interfere with normal synaptic transmission, and hence no disruption of normal physiological activity.[279,280] Via inhibition of NMDA receptors, memantine prevents the mitochondrial swelling, increases oxidative stress, and decreases $\Delta\psi_m$ induced by berberine in vitro in primary neurons from mice and rats.[281] In vitro, it prevents irreversible electrophysiological changes induced by the inhibitor of complex II (3-nitropropionic acid). However, it was shown to be ineffective in protecting complex I as the rotenone toxicity (complex I inhibitor) was not influenced in spiny striatal neurons.[282] Memantine is similar to AChE inhibitors in that it reduces Aβ levels in neuronal cultures in APP/PS1 transgenic mice.[283] Moreover, memantine is also neuroprotective as it inhibits Aβ-induced neurodegeneration and enhanced cerebral glucose utilization[268] and decreases brain glucose metabolism.[284] Memantine reduces the mitochondrial dysfunctions and mitochondrial

calcium, reverses $\Delta\psi_m$, and reduces ROS production induced by okadaic acid in the rat brain mitochondria. In a study that investigated the effect of memantine in ibotenic acid (IBO)-treated AD model in rats, it was found that glial cell activation can potentially play a significant role in the AD pathology and correlate with the changes of neuropeptide levels in the AD brain that is recovered by memantine treatment.[285] In a different study that examined the protective effects of memantine on $A\beta_{25-35}$-induced changes in peptidergic and glial systems,[286] it was found that treatment with memantine significantly increased $A\beta_{25-35}$-induced changes of neuropeptides, their metabolizing enzymes, and glial marker proteins. It was suggested that memantine exerts its protective effects by modulating the neuropeptide system as a consequence of suppressing the glial cells and oxidative stress in the AD model rat brain. Moreover, it was revealed that memantine protects against Aβ-induced neurotoxicity and learning impairment in rats.[287] Therefore, it was concluded that memantine protects against neurodegeneration induced by Aβ at therapeutic concentrations. Memantine also showed protection of cultured neurons against Aβ-induced toxicity by reducing the tau phosphorylation and its related signaling mechanisms.[288] However, memantine did not change either the conformation or the internalization of $A\beta_{1-42}$, and it was unable to reduce Aβ-induced potentiation of extracellular glutamate levels.

In a study that examined memantine as a NMDA receptor antagonist for the treatment of AD, patients with moderate-to-severe AD were randomly assigned to receive either placebo or 20 mg/day of memantine for 28 weeks. This multicenter study included 252 patients where 67% were women and the mean age was 76 years. According to CIBIC-Plus scores, patients under treatment showed better outcome than placebo. Memantine did not exhibit any significant adverse events in this study, and therefore, it was concluded that memantine reduced clinical deterioration, a phase associated with distress for patients and burden on caregivers, in moderate-to-severe AD.

5.14.3.2.5 Select drugs in development for AD treatment

Immunotherapy is a promising strategy for a variety of diseases, and AD treatment is seeing several strategies as well. Antibodies directed against Aβ are among the popular because they clear plaques and reverse cognitive deficits in mouse models. However, their clinical success has been limited due to side effects. Here, two antibodies, solanezumab and gantenerumab, are described and the ongoing efforts to develop this new class of AD therapeutics. In addition, a small-molecule drug, resveratrol, is gaining much popularity and is explored for the treatment of AD. Resveratrol is discussed in the context of its potential for the treatment of AD.

5.14.3.2.5.1 Solanezumab

Solanezumab, an IgG1 antiamyloid monoclonal antibody, binds to the mid-domain of the Aβ peptide.[289] It is shown to increase the clearance of soluble Aβ, and in preclinical studies, it was observed that murine anti-Aβ monoclonal antibody, from which solanezumab was derived, reduced brain amyloid plaque deposition in the transgenic APP^{V717F} mice.[290,291] Another correlation between plasma Aβ accumulation and plaque deposition was also apparent. Phase I and phase II studies done on patients with mild-to-moderate AD revealed that target engagement was present due to dose-dependent increases in plasma and CSF total Aβ.[292,293] This may be because during solanezumab movement from plasma to the CNS, it binds to Aβ in the compartment with accumulation of measureable total Aβ in CSF.[292] More complex effects of solanezumab on unbound Aβ in CSF were observed. In a phase II study with AD patients, 12-week treatment with solanezumab showed a dose-dependent increase in CSF free $A\beta_{1-42}$ while showing dose-dependent decrease in CSF free $A\beta_{1-40}$ although the cause of the difference is not yet apparent. $A\beta_{1-42}$ is the predominant form of Aβ, while $A\beta_{1-40}$ is a much less abundant form in amyloid plaque.[293] One possible hypothesis is that solanezumab may be altering equilibria so that concentrations of free $A\beta_{1-42}$ in CSF might be different from those of free $A\beta_{1-40}$. Solanezumab is known to have similar affinity for the two Aβ isoforms, and the relative abundance of each isoform is different in amyloid plaque consisting primarily of $A\beta_{1-42}$.[293,294] Mouse model of AD benefited from both active and passive immunizations by Aβ peptide, showing clearance of aggregated Aβ deposits and improving memory and learning. When a similar study was done on humans using solanezumab, it was observed that the drug only showed significant beneficial effect in mild AD cases in the secondary outcome, but not in the primary end point.[295] Two phase III studies, EXPEDITION and EXPEDITION2, are identical placebo-controlled studies to assess the effects of solanezumab on cognitive and functional decline over 80 weeks in patients with mild-to-moderate AD. These studies used secondary analyses of efficacy, biomarker, and safety end points. The results showed that cognitive and functional decline was less when under treatment for patients with AD compared to placebo using various clinical measurement scales, ADASC subscale, MMSE, and ADCSA of Daily Living functional scale Instrumental ADLs. Baseline-to-end point changes did not exhibit any difference between treatment groups. Plasma/CSF biomarker findings indicated target engagement by solanezumab, and the drug also showed adequate safety. This drug is a biologic molecule, and it remains to be seen if any neuroprotective effects or prevention and reversal of neurodegeneration would be seen as a result of the treatment with solanezumab.

5.14.3.2.5.2 Gantenerumab

Gantenerumab, a monoclonal antibody drug, binds an epitope in the N-terminus of oligomeric and fibrillar Aβ, which leads to microglia-mediated phagocytic clearance of plaques.[296] It showed a failure in one of the phase III trials in patients with mild-to-moderate AD, and it is currently in phase III trials (Scarlet RoAD and Marguerite RoAD) in patients with earlier stages.[297] It was shown that gantenerumab decreases the tau levels in the CSF significantly. However, it did not have much effect in reducing Aβ levels. It is believed that higher concentration of gantenerumab can potentially achieve clinical significance.

5.14.3.2.5.3 Resveratrol

Resveratrol (trans-3,4′,5-trihydroxystilbene) is a naturally occurring polyphenol that is being explored for its potential to treat AD by mimicking the caloric restriction through extending the lifespan of several small organisms (Table 2).[298–302] Resveratrol can also delay various age-related phenotypes such as abnormal glucose metabolism,[303] and patients with AD can benefit from its effect on cognitive deterioration under this treatment.[304,305] It is currently under investigation to determine its benefits in treating dementia in patients with mild cognitive impairment (MCI), which could progress to AD. The direct molecular targets of resveratrol have yet to be identified in vitro and in vivo. However, it has been hypothesized that resveratrol modulates cellular processes by activating key metabolic sensor or effector proteins, such as AMP-activated protein kinase (AMPK), sirtuin 1 (SIRT1), and peroxisome proliferator-activated receptor γ coactivator-1α (PGC-1α).[306–308] Binding of resveratrol to SIRT1 in vitro leads to the activation of deacetylase activity of the enzyme.[309] However, recent studies have indicated that the relationship between resveratrol and SIRT1 in vitro may be an artificial observation and that in vivo, resveratrol may target other proteins,[310,311] although it appears that SIRT1 is still required in resveratrol metabolic functions in vivo by taking parts in energy sensing network involving AMPK and PGC-1α.[306,312]

Although many studies support the beneficial effects of resveratrol in AD in vitro and in vivo, large-scale clinical trials have yet to be completed to prove its benefits. However, it appears that resveratrol is well tolerated and no marked toxicity was reported. On the other hand, resveratrol exhibits poor bioavailability, low water solubility, and chemically unstable.[313,314] With oral administration or *i.v.* injection in humans, resveratrol was quickly metabolized within 2 h.[315] Various studies in animals and in humans have shown that resveratrol has poor intestinal uptake, and unmetabolized form of resveratrol was difficult to detect in plasma.[313] The pharmacokinetics of *trans*-resveratrol (200 mg *t.i.d.* oral administration) was shown to be independent of age but with relatively low plasma concentrations.[316] In animal models, resveratrol appears to be bioavailable and bioactive.[317] Although recent studies have attempted in finding the most effective route of administration for resveratrol,[318–321] none of them appeared to be efficacious.

Various clinical trials are underway to determine the benefits of resveratrol on neurodegenerative diseases such as AD even though there are many difficulties.[322] One study (a double-blind, placebo-controlled, and crossover trial) on healthy young volunteers consuming 500 mg resveratrol showed that the levels of total hemoglobin were remarkably higher in the frontal cortex during task performance,[323] but it failed to show its effect on cognitive performance.[322,324] In a randomized controlled trial (RCT) versus placebo, 60 AD patients were given liquid resveratrol with glucose and malate as a dietary supplement delivered in grape juice. The ADAS-cog scores were assessed at regular intervals up to 1 year after study commencement.[324,325] In another multi-interventional clinical trial in MCI, resveratrol supplementation or caloric restriction or omega-3 supplementation or placebo was provided for 6 months, and then, the ADAS-cog scores would be assessed.[325] In a separate, but similar randomized, double-blind, placebo-controlled study with 119 patients, patients received 500 mg daily with dose escalation by 500 mg every 13 weeks.[326] In this 52-week phase II trial, resveratrol and its major metabolites were measurable in plasma and CSF, contrary to the earlier studies. Aβ40 levels in the CSF and plasma declined more in the placebo group than the resveratrol-treated group with a significant difference by the end of study. Interestingly, brain volume loss was increased in the resveratrol-treated group compared to placebo. Overall, this study provided plausible evidence that resveratrol is reasonably safe and is well tolerated in AD patients. It also alters biomarker levels. Additional studies are needed to confirm any beneficial effects of resveratrol.

5.14.3.3 Parkinson's Disease

PD is a neurological disease that exhibits several motor and nonmotor neuron-related symptoms. Unlike the studies in MS, the link between PAD enzymes and PD is only recently being discovered. Neurodegenerative aspects of this disease are caused by the death of dopaminergic neurons in the substantia nigra region of the brain and the presence of Lewy bodies (intraneuronal protein aggregates).[327] In another independent study, using the brain tissue from the PAD patients, immunoreactivity for the deiminated (hypercitrullinated) proteins was shown to be localized to GFAP and in the cytoplasm of dopamine neurons within the substantia nigra region.[328] These studies indicated the involvement of substantia nigra and hypercitrullination of proteins within this region as one of the biochemical consequences. One of the most useful target antigens for the antibody diagnosis of AD and PD, known as pentatricopeptide repeat domain 2 (PTCD2), was discovered in the citrullinated form in the brain.[329] However, the root cause of such neurodegeneration associated with hypercitrullination and PAD activity still needs to be explored.[330] In addition to many factors associated with neurodegeneration in PD, neuroinflammation also contributes to the degeneration of dopaminergic neurons; one of the factors is shown to be a mutated kinase, leucine-rich repeat kinase 2 (LRRK2) potentially exacerbating inflammation and leading to the neurodegeneration seen in PD.[331]

5.14.3.4 Therapeutic Approaches in PD

5.14.3.4.1 Carbidopa/levodopa

Levodopa is now widely used as a PD treatment.[332] Some of the drawbacks of the treatment includes large daily dosage, delayed onset of 1–2 months prior to showing therapeutic benefits, and numerous side effects. In PD, substantia nigra degenerates, which leads to the disruption of nigrostriatal pathway and reduction of striatal dopamine.[333] This reduction or loss of dopamine and denegeration of the brain lead to the clinical symptoms seen in PD. Dopamine is a polar molecule and cannot cross the blood–brain barrier. Thus, a precursor of dopamine, levodopa, has been developed, which delivers dopamine into the brain, and levodopa

is commonly discussed as a prodrug due to this character (Table 3). Levodopa becomes absorbed in the small bowel and quickly becomes catabolized by aromatic L-amino-acid decarboxylase (AADC) and catechol-*O*-methyltransferase (COMT). It was observed that gastric AADC and COMT can degrade levodopa. Therefore, levodopa is usually given with AADC inhibitor, carbidopa. Thus, when levodopa/carbidopa is administered, levodopa enters the brain and is decarboxylated to generate dopamine. The exact site of decarboxylation of exogenous levodopa to dopamine in the brain has yet to be determined. However, most of striatal AADC is found in nigrostriatal dopaminergic nerve terminals where dopamine is synthesized and stored in the terminals and becomes released to stimulate the postsynaptic dopamine receptors and mediates the antiparkinsonian action of levodopa. Metabolic conversion, storage, and release are omitted since dopamine agonists act directly on postsynaptic dopamine receptors.

5.14.3.4.2 Pramipexole

Along the lines of addressing dopamine deficiency, a variety of dopamine receptor agonists are deployed for the treatment of PD. Pramipexole is a dopamine D2/D3 receptor agonist that is used for treating PD symptoms (Table 3).[334] In vitro and in vivo models have shown that pramipexole can potentially have disease-modifying properties in PD.[335–337] The ability of pramipexole to protect against cell death in dopaminergic and nondopaminergic cells was investigated in vitro.[335,338] Preincubation of dopaminergic SHSY-5Y cells and nondopaminergic JK cells with either the active (−)- or inactive (+)-enantiomer forms of pramipexole at 10 μM concentration decreased cell death in response to 1-methyl-4-phenylpyridinium (MPP+) and rotenone, and the cells were protected. Interestingly, the protective effect was not prevented by dopamine receptor blockade using sulpiride or clozapine. Concentration of pramipexole for its protective effect was less than that required for its antioxidant activity. Supporting its antiapoptotic action in these cell lines, pramipexole reduced caspase-3 activation, decreased the release of cytochrome *c*, and prevented the fall in the mitochondrial membrane potential. From this study, it is suggested that pramipexole may be exhibiting neuroprotective effects independent of dopamine receptor occupation or antioxidant activity. Further studies must be established to conclude whether this neuroprotective action represents disease-modifying effect in PD. An RCT with a group of patients with early PD, receiving an early start of treatment, another group receiving a delayed start, and another group receiving just placebo, also known as Pramipexole On Underlying Disease (PROUD), was established to determine the disease-modifying effects of pramipexole.[339] From this investigation, it was suggested that pramipexole lacks disease-modifying effects, although it is still an effective option for symptomatic treatment for PD.[340]

5.14.3.4.3 Ropinirole

Ropinirole (Requip, GlaxoSmithKline) is indicated for the treatment of early and advanced Parkinson's disease.[341] Ropinirole, a nonergoline dopamine agonist, binds to dopamine D2-like receptors (Table 3).[342] Similar to dopamine, its selectivity toward dopamine receptors is in the order of D3 > D2 > D4. A randomized, placebo-controlled, double-blind, parallel-group, 6-month study was established to determine the efficacy and safety of ropinirole in early PD patients with limited or no prior dopaminergic therapy.[343] Patients ($n = 241$; Hoehn and Yahr stages I–III, mean age 62.8 years), stratified by concomitant use of selegiline, were randomized to ropinirole ($n = 116$) or placebo ($n = 125$). The starting dose of ropinirole was 0.25 mg *t.i.d.* with titration to at least 1.5 mg *t.i.d.* Primary efficacy end point was the percentage improvement in unified Parkinson's disease rating scale (UPDRS) motor score. Ropinirole-treated patients had a significantly greater percentage improvement in UPDRS motor score than patients who received placebo (+24% vs. −3%; $p < 0.001$). Ropinirole showed high-tolerability and infrequent withdrawals, with most of adverse events being related to peripheral dopaminergic activity. This drug is metabolized by the liver, and its elimination half-life is 5.8 h.[341] As a monotherapy, ropinirole improves signs and symptoms in early PD. In advanced PD with motor fluctuations, employed as an adjunct to levodopa, ropinirole reduces off time and allows for a reduction of levodopa dose in these patients.

5.14.3.4.4 Bromocriptine

Bromocriptine is a potent dopamine agonist that directly stimulates dopamine receptors and alleviates numerous symptoms of PD (Table 3).[344] Its pharmacological effects are similar to those of levodopa with respect to benefits and adverse effects. Bromocriptine can mitigate the drawbacks of chronic use of levodopa such as decline in efficacy, fluctuations in therapeutic response, and development of disabling abnormal involuntary movements. Bromocriptine achieved safety in dosages of up to 100 mg/day for 2 years, although some of the adverse effects are common to those due to levodopa.

5.14.3.4.5 Cabergoline

Cabergoline is a synthetic ergoline dopamine agonist and has a high affinity for D2 receptors.[345] It also has longer elimination half-life, thus continuously providing dopaminergic stimulation with once-daily administration. Furthermore, cabergoline has high tolerability and effectiveness in controlling PD symptoms. It is comparable with levodopa in that levodopa exhibits fluctuations in response during long-term use, but cabergoline appears to be less fluctuating. Cabergoline can also reduce the risk of developing drug-induced motor complications.

5.14.3.4.6 Pergolide

Pergolide is an agonist of D1 and D2 dopaminergic receptors.[346] In comparison with levodopa, which gradually loses its effectiveness during chronic use, pergolide at a dose of 2 mg/day improved PD symptoms and allowed patients to reduce the intake of levodopa dosage by as much as 50%. The adverse events of pergolide, although are manifested frequently, are mild and reversible.

Table 3 Chemical structures of drugs for the treatment of Parkinson's disease

Drug name	*Chemical structure*
Levodopa	Carbidopa	Pramipexole	Ropinirole	Bromocriptine	Cabergoline	Pergolide	Rotigotine	
Table 3 Chemical structures of drugs for the treatment of Parkinson's disease—cont'd

Drug name	*Chemical structure*
Trihexyphenidyl hydrochloride	Benzotropine	Apomorphine	Amantadine	Entacapone	Tolcapone	Selegiline	Rasagiline	Istradefylline	
5.14.3.4.7 Rotigotine

Rotigotine, a lipid-soluble, nonergot, D3, D2, or D1, dopaminergic receptor agonist, is effective in early and advanced PD treatments.[347] Rotigotine is unique due to its transdermal patch formulation that allows for continuous, once-daily administration leading to higher patient compliance. Rotigotine was shown to achieve high tolerability, and it can also be used as a combination with levodopa for patients with advanced PD.

5.14.3.4.8 Anticholinergics (trihexyphenidyl and benzotropine)

Anticholinergic drugs currently in market include benzotropine (Cogentin) and trihexyphenidyl hydrochloride (Artane) (Table 3). Deployment of this class of drugs goes back to 1940s and 1950s, where the use of benzotropine sulfonate was described for the treatment of PD symptoms.[348] Anticholinergic drugs are used as PD treatment to reduce the acetylcholine activity and to balance the production of dopamine and acetylcholine. Anticholinergic drugs antagonize the hyperactive cholinergic transmission via blockade of postsynaptic muscarinic receptors and restore the balance between DA and acetylcholine (Ach) systems in the striatum. ACh controls movement, and anticholinergic drugs are used in combination with levodopa, described earlier, to treat mild symptoms of tremors and rigidity without alterations in bradykinesia.[349,350] Anticholinergics were commonly employed in a number of conditions related to dystonia in the recent years.

Some of the adverse events that can be caused by anticholinergics include blurred vision, dry mouth, and urinary retention. Moreover, reactions in CNS such as confusion, dementia, and psychiatric symptoms can be seen in elderly patients. Anticholinergic drugs are not to be used with other drugs, and they are rarely used as primary drug therapy. There is also no evidence that these drugs provide neuroprotective effects, in the context of preventing or reversing neurodegeneration associated with PD.

5.14.3.4.9 Apomorphine

Apomorphine is a potent D1 and D2 dopaminergic agonist and is administered through subcutaneous injection at doses from 15 to 180 μg/kg.[351] Intranasal, sublingual, and rectal routes of administration have shown to cause local allergic effects and thus limited the use of other dosage forms. Apomorphine is able to achieve rapid onset of action and short-duration effect, and the maximal plasma concentration is established in 8–16 min. Its plasma half-life was observed to be 34–70 min, and the bioavailability was approximately 100%. Diminished sensitivity (tolerance) can also be observed in patients with repeated use of the drug. Due to this reason, it is discretely employed for routine therapeutic use. Apomorphine is also used in differential diagnosis between idiopathic PD, other Parkinson plus syndromes, and as a predictive test for dopaminergic responsiveness. Apomorphine was shown to alleviate akinesia, rigidity, and tremor. Either a continuous apomorphine subcutaneous infusion or multiple subcutaneous injections of apomorphine may be beneficial when levodopa treatment was temporarily interrupted. The side effects of apomorphine include nausea and hypotension. However, these adverse effects can be prevented with the use of domperidone, a peripheral dopaminergic antagonist. It was also shown that cutaneous fibrous nodules and psychiatric symptoms may occur at high dosages and with continuous infusion of this drug.

5.14.3.4.10 Amantadine

Amantadine, an NMDA receptor antagonist, is used alone to treat early PD or as an adjunct to treat advanced PD.[352] Amantadine, similar to memantine, belongs to the class of adamantine derivatives (Table 3). The mechanism of action for this drug in PD has yet to be discovered. Unlike other dopaminergic treatments, amantadine was shown to effectively control tremor and muscle rigidity (classified together under "impulse control"), although these symptomatic benefits could only be a short-term effect. The dose could range from 100 mg once daily to 100 mg three times daily. Some of the adverse effects include nausea, dizziness, insomnia, confusion, hallucinations, peripheral edema, and livedo reticularis. It was also shown that high serum concentrations could potentially cause severe psychosis in elderly, and it can also lead to additive adverse effects on mental function. Sudden withdrawal from the treatment could potentially cause exacerbation of PD symptoms or neuroleptic malignant syndrome and acute delirium. Patients with liver or renal dysfunction and older adults may require dosage adjustment and close monitoring.[353] A very recent study in 2016 concluded that amantadine and selective serotonin reuptake inhibitors (SSRIs), antipsychotics, anticonvulsants, opioid antagonists, etc. have insufficient proof on the efficacy of this drug based on the current literature evidence.[354] Additional research is necessary to confirm the utility of this drug for the treatment of PD symptoms.

5.14.3.4.11 COMT inhibitors (entacapone and tolcapone)

COMT inhibitors are shown to improve motor fluctuations and block the breakdown of levodopa, which allows increased levodopa level to reach the brain.[349,355,356] This class of drugs is primarily employed as an adjunct therapy with levodopa. It has been observed that using COMT inhibitors along with levodopa therapy reduces the end-of-dose failure patients experience as the effect of levodopa decreases and also decreases the motor fluctuations.[355,357] COMT inhibitors currently in market include entacapone (Comtan) and tolcapone (Tasmar), both of which are structurally related analogs (Table 3). Adverse effects of entacapone include increase in dyskinesias, gastrointestinal upset, dizziness, and drowsiness. Stalevo is still under investigation by the US Food and Drug Administration due to possible increased risk of prostate cancer.[358] Adverse effects of tolcapone include dizziness, drowsiness, excessive dreaming, nausea, vomiting, diarrhea, and increased sweating. Tolcapone may also cause life-threatening liver damage, and hence, patients under this treatment must be monitored with care.[359]

5.14.3.4.12 MAO-B inhibitors (selegiline and rasagiline)

Monoamine oxidase type B (MAO-B) inhibitors are intended to prevent the catabolism of dopamine in the brain and enhance dopamine levels (Table 3). Selegiline and rasagiline are two irreversible MAO-B inhibitors used alone to treat early PD or with levodopa for treatment of advanced PD.[360,361] Both compounds share similar structural features, with a prop-2-ynyl amino group as the active entity is responsible for their inhibitory activity. Selegiline is available in various dosage forms such as classical tablet, capsule, and in a lower-dose, orally disintegrating tablet formulation. Using orally disintegrating tablet formulation allows the drug to be absorbed through the oral mucosa, and it minimizes first-pass metabolism, increasing bioavailability and reducing serum concentrations of amphetamine metabolites. Rasagiline was shown to delay its progression of PD. In a double-blind, delayed-start trial of rasagiline, patients receiving 1 mg daily of the drug had significantly less disability after 72 weeks than those who received placebo, but those receiving 2-mg doses did not.[362] While the mode of action of this class of compounds appear to show prospects for neuroprotection in in vitro and in animal models of neurodegeneration, recent evidence suggests that MAO-A also must be playing a role in the neuroprotection.[363]

5.14.3.4.13 Istradefylline

Adenosine 2a (A2a) receptors antagonists are nondopaminergic drugs that have been under investigation to assess their effects on treating symptoms of PD for several years.[364] A2a receptors in the striatum can colocalize with dopamine D2 receptors on GABAergic striatopallidal output neurons of the indirect pathway and to GABAergic recurrent collaterals.[365] Adenosine A2a antagonists reduce the overactivity of the striatopallidal pathway and play a role in motor control.[366] In nonhuman *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-lesioned primates, A2a antagonists have improved motor neuron control with little development of dyskinesia. In levodopa-primed animals, treatment with A2a antagonists was also observed to improve motor function without worsening dyskinesia.[367–370] Furthermore, in rodent models, nonmotor functions such as memory, olfaction, and mood were also showing improvements.[371] Lastly, neuroprotective effects have been demonstrated in numerous models.[372,373] Istradefylline is the first one to complete phase III development, and it is now marketed for the treatment of PD.[374] In an early proof-of-concept, placebo-controlled study, istradefylline was used as an adjunctive therapy with levodopa in 15 PD patients with motor complications.[375] Istradefylline alone did not exhibit antiparkinsonian response to a low-dose, suboptimal levodopa infusion. At a dose of 80 mg/day, istradefylline with a low-dose levodopa infusion showed 36% increase in motor function UPDRS and with 45% less dyskinesia compared with an optimal-dose levodopa infusion alone. Clinical benefits of istradefylline were shown to last 76% longer after stopping levodopa infusion, when coadministered with levodopa infusion.[375]

In a separate study consisting of 83 PD patients with motor fluctuations and dyskinesia, 20 or 40 mg *q.d.* of istradefylline showed 1.7 h reduction in the off time compared to placebo ($p=0.004$).[376] Similarly, in one phase II study, patients with motor fluctuations that were given 40 mg/day istradefylline experienced 1.2 h reduction of off time compared with placebo ($p=0.005$).[377] In another phase II study, istradefylline 20 mg/day was observed to reduce off time by 0.64 h (4.35%, $p=0.026$), and istradefylline 60 mg/day reduced off time by 0.77 h (4.49%, $p=0.024$).[378] In this study, an increase in on time with dyskinesia was noted but was considered to be insignificant as it was an increase in nontroublesome dyskinesia. In a phase III trial, istradefylline 20 mg/day reduced off time compared with placebo by 0.7 h ($p=0.03$).[379] On the other hand, another phase III trial of istradefylline (10, 20, and 40 mg/day) has shown insignificant reductions in off time compared with placebo.[380] The reason for the failure of this study is unknown; istradefylline received a not approval letter from FDA in 2008 due to its efficacy results being insufficient enough to support its clinical utility, although phase III trials were carried out in Japan and other countries.[381–383] As a monotherapy in treating early PD, istradefylline was not able to show any significant improvement in UPDRS motor scores compared with placebo (-1.11, $p=0.228$).[384] Nonetheless, istradefylline showed high tolerability and mild efficacy in reducing off time in PD patients with motor fluctuations. In general, evidence for the use of A2a antagonists in early PD is very limited and is not supportive. However, patients already treated with dopaminergic drugs and exhibiting compromised efficacy in late-stage disease have benefitted from this class of drugs.[374]

5.14.3.4.14 Levodopa formulations

Due to the high efficacy of levodopa and its direct mechanism of action, significant effort was dedicated to new formulations for levodopa and adjunct therapies primarily to improve the pharmacokinetic properties of these drugs and ultimately lead to better patient compliance and/or comfort.

5.14.3.4.14.1 Levodopa/carbidopa intestinal gel (LCIG; duodopa)

Duodopa or LCIG is an aqueous intestinal gel which contains 20 mg/mL of levodopa and 5 mg/mL of carbidopa, and this gel is administered via a portable pump.[385] A 100 mL cassette contains 2000 mg of levodopa, which is enough for a full day of treatment. The cassette is used to attach to a portable infusion pump, and the gel is pumped through a transabdominal tube connected to a percutaneous endoscopic gastrostomy (PEG) tube with the tip positioned in the proximal jejunum or duodenum. The gel can be infused during waking hours or around-the-clock. It was shown to be effective in reducing motor fluctuations and dyskinesia in advanced PD.[385–387] In a randomized, crossover trial, nasoduodenal infusion of LCIG was compared with carbidopa/levodopa controlled release tablets 50/200 mg/and immediate release 12.5/50 mg.[388] The pharmacokinetics of LCIG revealed that the intra-individual variation for plasma levodopa concentration was 34% with oral medication compared with 14% with LCIG infusion ($p<0.01$). Also, motor assessments have shown increased near-normal state observations (80% vs. 61%, $p<0.01$) with LCIG compared with oral medication. Bradykinesia and dyskinesia have also shown reduction with LCIG.

A study named DIREQT (Duodopa infusion: randomized efficacy and quality of life trial) was conducted to compare the naso-duodenal infusion of LCIG to individually optimized combinations of pharmacotherapy in a randomized crossover trial using two 3-week treatment periods for 25 patients.[389] This study revealed that the median percentage of ratings in the functional on state increased significantly with LCIG compared to standard pharmacotherapy (100% vs. 81%, $p < 0.01$). Dyskinesia appeared to be uncommon and not different for the two treatment periods. Quality-of-life scores achieved significantly higher scores with LCIG. Multiple longer-duration open-label studies have also demonstrated benefit with LCIG delivered via PEG. In the HORIZON study, a 12-week, randomized, double-blind, double-dummy, double-titration phase III trial, LCIG showed a promising option for control of advanced Parkinson's disease with motor complications.[390] In this multicenter study, the primary end point was the change in motor off time from baseline to final visit. Patients receiving LCIG showed superior outcomes in the off times, and 14% of the patients showed significant adverse events mainly associated with the percutaneous gastrojejunostomy tube and related issues. In the United States, this drug was approved by US FDA in 2015. The main drawbacks of LCIG use is the invasiveness of the procedure, the inconvenience of carrying the pump, and the problems associated with managing device malfunctions, including tube dislocations and obstructions.

5.14.3.4.14.2 IPX066

IPX066 is an extended-release oral formulation of carbidopa/levodopa. In an open-label crossover study, IPC066 was compared with carbidopa/levodopa immediate-release (carbidopa/levodopa IR) formulation.[391] At a single dose, time to on was similar for both medications, but UPDRS motor scores were significantly better with IPX066 from hours 3 to 6 ($p < 0.05$), which indicated longer duration of action. The mean daily dosing frequency for IPX066 was 3.5 compared with 5.4 for carbidopa/levodopa IR. It was also observed that patients experienced 2 h less off time per day with IPX066 ($p < 0.0001$) despite the reduced frequency of drug administration. In a randomized double-blind phase III trial, 393 patients with fluctuations on carbidopa/levodopa IR were enrolled.[392] Patients were given a 3-week dose adjustment period of carbidopa/levodopa IR. They were then switched to IPX066 and underwent a 6-week adjustment phase using IPX066. And in the last 13 weeks, they were randomized to their adjusted IPX066 or carbidopa/levodopa IR regimen using a double-dummy design. The mean daily dosing frequency was 3.6 for IPX066 compared with 5.1 for carbidopa/levodopa IR. Results demonstrated that IPX066 provided a 1.1-h improvement in on time without troublesome dyskinesia compared with carbidopa/levodopa IR ($p < 0.001$). Thirty-nine percent of patients rated themselves as much or very much improved with IPX066 compared with 17% with carbidopa/levodopa IR ($p < 0.0001$). IPX066 maintains therapeutic levodopa concentrations for an extended period of time compared with carbidopa/levodopa IR. Although IPX066 has shown to be effective in early PD, the ultimate value of IPX066 in early disease may depend on whether more continuous dopamine stimulation can reduce the development of dyskinesia.[393]

5.14.4 Conclusion

While the well-established therapeutics for these diseases are still grounded in the theories and observations from the past century primarily focusing on the clinical symptoms, prevention and, if possible, reversal of neurodegeneration and disease progression are a priority for the new generation of therapeutics. MS and various neurodegenerative disorders such as AD and PD have benefitted tremendously due to the introduction of new diagnostic tools driving new avenues of research in the new millennium. Definitions of the disease states, a closer alignment with the progressive stages of the diseases and neurodegeneration, are introduced in the recent years, and they facilitate focused research efforts for novel drug targets and development of novel therapeutics. DMTs are considered to be the best course, once the disease is diagnosed appropriately, because disease onset takes several years and the root causes of the disease onset are complex. New DMTs addressing these diseases and neurodegeneration is the new frontier in research and therapeutics.

5.15.1 Introduction

One can broadly categorize the diseases that affect the immune system into states of immune deficiency and those of unnecessary activation. The latter category of diseases can be further divided into allergic, autoimmune, and the more recently described category of autoinflammatory diseases. Autoimmunity is characterized by an aberrant immune attack to organs and tissues without a clear initiating or sustaining external factor, such as an allergen or a microbe.[1] Moreover, although genetics contribute to the pathogenesis of autoimmune diseases, most diseases are not caused by single-gene mutations as is the case for autoinflammatory conditions.[2]

It is precisely this characteristic of autoimmunity that makes treatment challenging; there is no underlying mutation that can be either directly or indirectly targeted; there is no allergen that can be avoided or desensitized against; there is no missing immunoglobulin that can be substituted. The events that eventually lead to the development of autoimmune diseases are rather slow without a specific causative factor readily identifiable in the vast majority of cases. Although epidemiologic and genetic studies have shed little light into the etiology of these diseases, the use of both animal models and in vitro studies using blood cells and biopsy materials from patients has identified several key pathways that are important for the pathogenesis of these diseases.

This lack of a definite cause has made the treatment of these diseases to rely on nonspecific suppression of the activated immune system, in hopes that after a period of time the immune-suppression can be stopped with the immune system having reset itself in a more normal condition. This strategy causes significant problems, not the least of which are overwhelming infections in the immunosuppressed host. Recent advances in our understanding of the pathogenesis of certain autoimmune diseases though have allowed the design of rationale therapies that target key aspects of the autoimmune response allowing for control of the disease without global immune-suppression. This approach has already yielded significant improvements in the treatment of certain conditions such as rheumatoid arthritis (RA)[3] and vasculitis.[4] It has to be emphasized that these treatment regimens remain disease modifying and not curative as the autoimmune response is suppressed but not necessarily abolished.

In the case of systemic lupus erythematosus (SLE), target-specific disease-modifying therapies are still elusive. Several new molecules have been studied in animal models and early human studies with promising results leading for the first time after several decades to the approval of a new medication for SLE, with albeit modest efficacy. To understand the role of new therapeutics in SLE, we will discuss herein SLE pathogenesis, the current treatment paradigm, and the approach to move new medications from the bench to the bedside.

5.15.2 Loss of Tolerance and Development of Systemic Autoimmunity

Systemic autoimmunity is a disease that primarily arises from a dysfunctional adaptive immune system. The adaptive immune system is comprised by T and B lymphocytes that recognize foreign material in a specific manner and are able to mount well-coordinated responses to eliminate threats.

The central axiom of the nascent field of immunology in the early 21st century was that the main characteristic of adaptive immune system is the recognition of one's self from foreign material. Autoimmunity, or as it was called then "horror autotoxicus," happened when the immune system started recognizing self-proteins as foreign resulting in inflammatory damage of the tissues and organs where those proteins were found. This theory had its own merits but failed to recognize that the healthy immune system does not only contain specialized cells and molecules that recognize foreign proteins–antigens but also self-antigens. Rather than completely eliminating these self-reactive cell clones and antibodies, the immune system limits their reactivity by employing a variety of checks and balances. This mechanism is called immunologic tolerance and does not only refer to self-antigens but also any antigen that the immune system has learned to accept as nonharmful (reviewed in Ref. 5). Tolerance is achieved primarily in the central lymphoid organs, that is, the bone marrow for B cells and the thymus for T cells. In Figs. 1 and 2 the two-step process of T-cell education is shown. T cells that are not useful by not being able to recognize any antigen or T cells that react very strongly against self-antigens are eliminated from the lymphocyte pool and never populate the secondary immune organs, that is the spleen

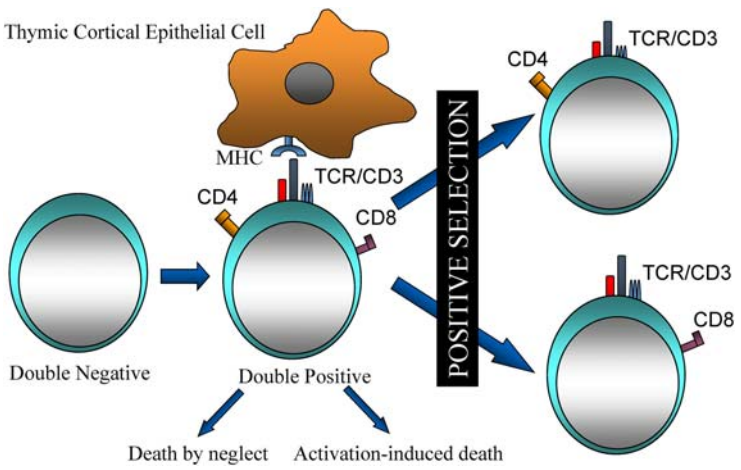

Fig. 1 Positive selection of T cells in the thymus. Immature T cells that have yet to express surface markers (double negative) evolve into TCR/CD3+CD4+CD8+ double positive T cells. At this stage the T cell has to prove that is functioning properly by interacting with the MHC complex on epithelial cells in the thymus. Incompetent T cells that do not recognize the MHC or cells that overreact to it die by neglect or activation-induced cell death. The double positive T cells that are selected become functional CD3+CD4+ or CD3+CD8+ T cells.

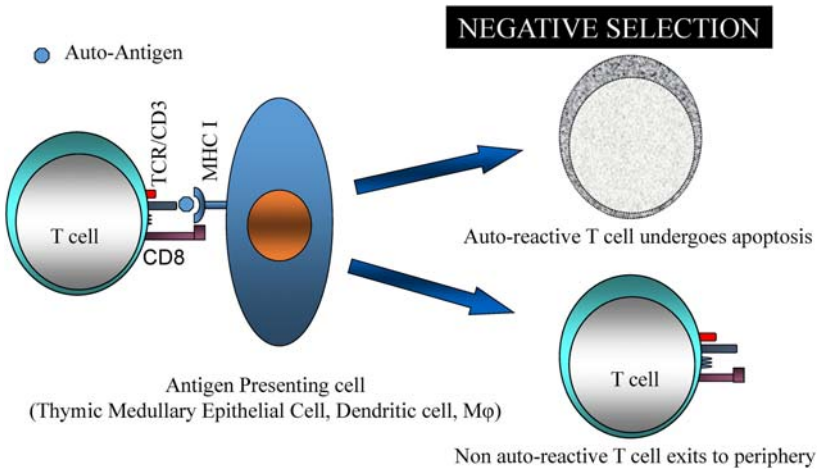

Fig. 2 Negative selection. Following the positive selection process the selected CD3+CD4+ or CD3+CD8+ T cells (here the CD8+ are shown) interact in the thymus with self-antigens that are presented to them by local cells. The cells that do not recognize self-antigens migrate to the secondary lymphoid organs (spleen, lymph nodes), while the autoreactive cells undergo cell death (apoptosis).

and lymph nodes. B cells undergo similar but not identical education in the bone marrow. Some T (and B) cells that are self-reactive do escape though from the primary (central) lymphoid organs, and hence a separate set of peripheral tolerance mechanisms is needed. One of the most important mechanisms is the regulatory T cells (Treg) that suppress aberrant activation of T cells and keep the immune system balanced.[6]

These regulatory check and balances can fail at various levels leading from benign autoimmunity to the appearance of detectable autoimmune reactions, inflammation, and end-organ damage. The first step in that process is the escape of autoreactive cells or clones (T or B cells) of the adaptive immune system from the regulatory constraints of the immune system: a process called loss of tolerance. This can be detected by the presence of autoantibodies and cytokines in the blood of otherwise healthy individuals as they are on their way to develop systemic autoimmune disease. Indeed, autoantibodies such as antinuclear or Sjogren syndrome-associated antibodies exist in the serum of patients with SLE several years before the clinical presentation of the disease.[7] In the second phase of this process, the autoimmune reaction evolves with recruitment of effector cells and molecules in various tissues resulting in inflammation. This second phase, called disease flare, besides causing symptoms and signs of the disease, if left untreated, may result in permanent tissue damage. The regulatory mechanisms of the immune system can limit the disease flare even without pharmacologic intervention bringing about the third phase of the disease, a period of clinical quiescence until the next flare. Some autoimmune diseases such as multiple sclerosis (MS) behave in this relapsing-remitting way, while others such as systemic vasculitis do not spontaneously remit without therapy. SLE has relapsing-remitting characteristics, but severe flares, such as nephritis, do not remit without therapeutic interventions (Fig. 3). The factors that contribute to the generation of autoimmunity (phase I), disease flare (phase II), and spontaneous resolution (phase III) are unclear for most autoimmune diseases in general and SLE in particular. In the case of SLE, the interplay between genetics, hormonal factors,[8] and viruses such as Ebstein Barr (EBV)[9] have been implicated in the development of autoimmunity, while ultraviolet light has been shown to cause disease flares.[10] It has to be noted that in the vast majority of cases of SLE neither the initiating nor the sustaining factors are identifiable.

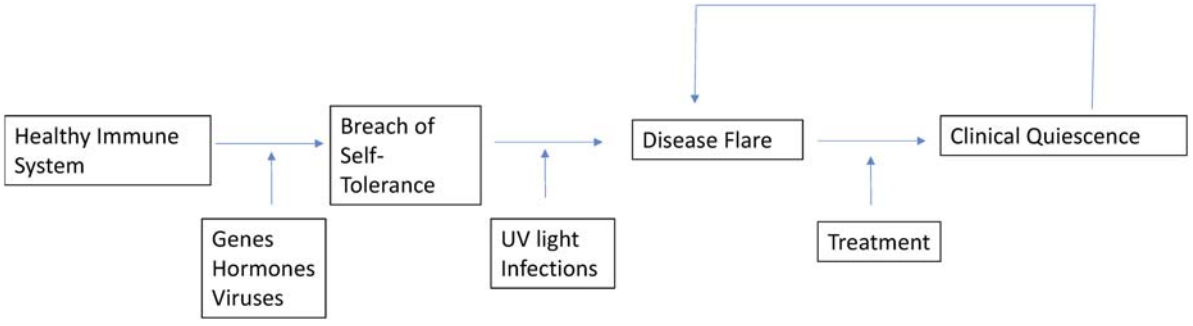

Fig. 3 Schematic representation of the etiology and pathophysiology of SLE.

5.15.3 Etiology and Pathophysiology of SLE

SLE is a relatively rare disease with a prevalence of 0.04–0.05% in the United States[11] and affects primarily women of childbearing years. Epidemiologic studies suggest that SLE is more common in women of Hispanic or African ancestry than Northern Europeans.[12] Genome-wide searches recognized several genes that increase the risk for SLE. Besides a strong association with the major histocompatibility complex (MHC) class II molecules DR2 and DR3, several genes that code for immune-regulatory molecules are associated with the disease (reviewed in Ref. 13). Genes are only one part of the puzzle of SLE pathogenesis though; as discussed above hormonal, environmental, and infectious factors have been implicated in disease pathogenesis, but their relative importance and contribution is heatedly debated. The rarity of the condition, the heterogeneity of presentation, and the long preclinical phase make the determination of disease etiology difficult.

Although lupus etiology is still unclear, the use of both murine models that approximate lupus and ex vivo studies using peripheral blood cells from patients with SLE and biopsy material from inflamed skin and kidneys has led to significant breakthroughs in our understanding of how damage occurs.

The sine-qua-non of SLE is the production of autoantibodies against cellular components and in particular DNA and RNA containing protein complexes. The immune complexes that are generated through the binding of these high-affinity antibodies to their cognate antigens are deposited in the target tissues and especially in the glomerular basement membrane of the kidney and the dermal–epidermal junction of the skin. The antibodies that are thought to be particularly important in this process are anti-double-stranded DNA antibodies. The levels of these antibodies in the serum rise and fall in parallel to disease activity and in particular kidney inflammation[14]; this makes their measurement particularly important for prediction of flares and response to therapy. The immune complexes either after depositing or while circulating lead to complement system activation, which in turn causes accumulation of inflammatory cells, initially polymorphonuclear leucocytes and later lymphocytes, in the tissues. Moreover, mononuclear cells either circulating or resident in the tissues get activated by the immune complexes or complement and produce an array of cytokines and chemokines that perpetuate the inflammatory response. The accumulation and deposition of all these cells and soluble mediators in the tissues leads to their eventual damage; characteristically this takes the form of destruction of the glomerular tuft in the kidney, and untreated or after repeated flares may lead to kidney failure.[15]

The production of autoantibodies by specialized B cells that become antibody-forming cells (AFC) is key for the initiation of the autoimmune response in lupus. The B-cell population as it matures in the bone marrow and gradually exits to the periphery contains autoreactive clones that are eliminated by a variety of mechanisms such as lack of help by other cells (such as T cells), or editing of their receptors. Extensive work in both animals and humans has clearly shown that autoreactive B cells can escape these checkpoints[16] during their ontogeny and eventually become autoreactive AFC that produce high-affinity pathogenic antibodies such as anti-dsDNA antibodies. The cytokine B lymphocyte stimulator (BLyS) plays an important role in the survival and maturation of early autoreactive B cells. Indeed, BLyS transgenic mice develop a lupus-like illness.[17] After extensive preclinical and clinical studies, the anti-BLyS antibody belimumab was found effective in reducing disease activity in patients with active lupus, becoming in 2011 the first drug to be approved for SLE after several decades. Complete elimination of mature B cells in SLE patients though using the depleting anti-CD20 antibody rituximab did not improve the outcomes when added to standard of care[18] suggesting a more complex picture.

The failure to contain autoreactive B cells is not only due to intrinsic B-cell factors but also to aberrant T cell:B cell interaction. T cells are critical for the production of pathogenic high-affinity autoantibodies by B cells through help they provide via a set of complementary molecules termed costimulatory molecules (Fig. 4). One such molecule is CD154 (also known as CD40 ligand, CD40L) that is expressed on activated T cells and is essential for the maturation, differentiation, and eventual antibody production by activated B cells. CD154 was therefore an early target for biologic therapy in SLE; BG9588, a humanized anti-CD154 antibody, was injected in patients with lupus nephritis[19] showing effectiveness in improving immunologic and kidney injury parameters. A few patients unfortunately developed thromboembolic events, possibly due to off target effects, halting further development of this therapy. Despite this setback, several anti-CD154 are currently in early stages of development.

Circulating immune complexes and/or nucleic acids can directly activate immune cells that bear Fc receptors and toll-like receptors (TLR), respectively. The monocyte system as well as B cells can therefore be activated via this mechanism as they express both types of receptors on their surface. The activated cells in turn produce an array of proinflammatory cytokines. One such cytokine that has been recognized to be ubiquitously expressed in SLE is interferon α (IFNα). Indeed, circulating white cells in the blood of patients with SLE have upregulated a certain set of genes that are influenced by IFNα; This transcriptional signature, called the interferon signature, may be important for the pathophysiology of the disease as attempts to block IFNα showed promising results in early trials.[20]

The complex autoimmune response that underlies SLE pathophysiology is schematically summarized in Fig. 4. It is the interaction of this abnormally activated system with the tissue targets that leads to the signs and symptoms of lupus that can be highly variable, difficult to treat, and even more challenging to predict.

5.15.4 Clinical Presentation of SLE: Challenges for Clinical Trial Design

Broadly autoimmune diseases are divided into organ specific, such as Hashimoto's thyroiditis or MS, and systemic, such as SLE. In the first category the autoimmune response targets a small number of localized self-antigens, while in the latter the

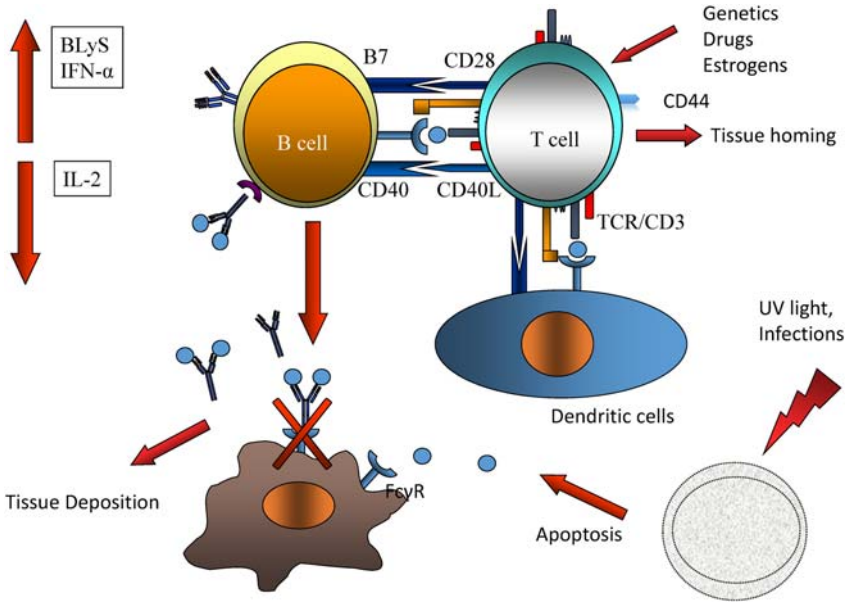

Fig. 4 The pathophysiology of systemic lupus erythematosus.

inflammatory response is widespread with numerous antigenic targets. SLE is the prototypic systemic autoimmune disease and is characterized by the presence of numerous autoantibodies against self-antigens that are primarily found in the nuclei of cells.[21] This complexity inevitably leads to a heterogeneous clinical presentation. Various organs and tissues are affected with the skin, joints, serosal surfaces (pericardium, pleura), kidneys, nervous system, and hematologic systems (neutrophils, red cells, platelets) being the most common.[22] Moreover, the type of tissue inflammation varies among individuals; for example, there are six different classes of lupus nephritis that differ widely in their presentation, prognosis, and treatment[23]; or the discoid variant of lupus dermatitis that leads to skin scarring differs substantially from the generally nonscarring malar rash.

A consensus has been reached in what constitutes SLE by using a set of criteria that are useful in clinical settings and indispensable in clinical trial design.[24] It is important to stress that a significant number of patients have a clinical picture consistent with SLE but do not fulfill the strict SLE criteria. Moreover, patients may exhibit clinical and laboratory findings that are consistent with more than one systemic autoimmune disease, such as lupus arthritis and myositis or skin lupus and erosive (rheumatoid) arthritis. These overlap syndromes can vary in severity and manifestations and are generally treated similar to the prototypic syndrome, that is, RA or SLE. A well-described overlap syndrome is mixed connective tissue disease, which is defined by the presence of an autoantibody against ribonuclear protein[25] and shares clinical characteristics with SLE, RA, myositis, and scleroderma.

Given these disease characteristics, rarity, heterogeneity, and unpredictability, clinical trial design has been challenging. The most successful trials have been the ones targeting the subgroup of patients with lupus nephritis. Class III and IV nephritis patients have similar enough presentations and courses of their disease to make the design of clinical trials easier. Starting in the 1970s, patients with nephritis were treated using unifying outcomes such as levels of creatinine concentrations in the serum, a measurement of kidney filtrating capability, and protein concentration in the urine, a measurement of glomerular membrane damage. The real challenge has been though to design an outcome measure for nonrenal lupus. At the end of the last century, the SLE disease activity index (SLEDAI) was validated as a good albeit imperfect composite index to capture disease activity in almost all the systems affected by SLE.[26] Another more complicated index, the British Isles Lupus Assessment Group (BILAG),[27] has also been extensively validated. These two indexes were used in the design of two new outcome measures that aim at capturing broadly disease activity changes in various tissues and organs in SLE patients. The SLEDAI-based SRI (SLEDAI response index) and the BILAG-based BICLA (BILAG-based Combined Lupus Assessment) are nowadays the standard outcome measure in clinical trials of generalized lupus. An improvement of the SLEDAI after treatment by 4, 5, or 6 points is regarded as significant (SRI-4, 5, or 6, respectively) allowing to report the outcome of a placebo controlled clinical trial in a meaningful manner. For example, in the study of the BLyS inhibitor belimumab in SLE, 52 weeks into treatment, 58% of patients on belimumab had an improvement in their baseline SLEDAI by 4 points or more (SRI-4) as opposed to 44% of the placebo group; this outcome led to the approval of belimumab for the treatment on nonrenal lupus.[28]

Besides the composite indexes SRI and BICLA, outcome measures pertaining specifically to tissue targets such as the kidneys (discussed earlier), skin (area and extent of skin damage), and joints are also significant. In addition, therapeutic trials are also evaluating future flare prevention and corticosteroid sparring. These new unifying outcome measures have allowed the exponential increase of clinical trials in SLE testing several biologics and small molecules.

5.15.5 Current Therapeutic Paradigm in SLE

As described earlier, the current therapeutic approaches in SLE consist primarily of nonspecific immune-suppressive medications. Treatment aims at (a) inducing remission of acute flares, (b) reducing frequency of flares, and (c) ultimately preventing organ and tissue damage.

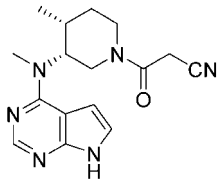
Since their discovery, corticosteroids have been the mainstay of treatment of SLE. As a general principle, corticosteroids are used for induction of remission of all but the very mild lupus flares, in which case nonsteroidal antiinflammatory medications and antimalarial medications are used. In moderate and severe lupus flares, besides using higher doses of corticosteroids, remission is achieved with the concomitant use of immune-modulator drugs such as mycophenolate, azathioprine, and methotrexate. In very severe flares, primarily affecting the kidneys and central nervous system, the alkylating agent cyclophosphamide is used as well. The use of immune-modulator drugs together with steroids has not been conclusively shown to improve short-term outcomes but helps (a) reduce the amount of corticosteroids used and (b) bridge the patient's treatment to the consolidation phase of therapy that may last for years following the induction phase.

These therapeutic phases have been best studied in patients who present with lupus nephritis. The current standard of care in these patients consists of a 6-month induction, followed by (at least) 18 months of consolidation. The goal of the induction period is to normalize kidney function and to prevent damage in the kidneys as measured by the amount of protein that is abnormally found in the urine. The standard of care for the induction period consists of corticosteroids and cyclophosphamide or corticosteroids and mycophenolate mofetil. In the consolidation period that lasts for at least one and a half years, patients are treated with mycophenolate mofetil or azathioprine. The goal of the treatment is complete renal remission characterized by normal kidney function and minimal proteinuria.

5.15.6 Novel Lupus Therapeutics: The Role of Small Molecules

In the era of targeted therapies, soluble mediators, such as cytokines and chemokines, and surface molecules are targeted primarily using an antibody or a modified decoy ligand against them. These biologic drugs have revolutionized the treatment of several autoimmune diseases, such as RA or Crohn's disease, but have been only marginally successful in SLE as discussed earlier.

The success of tofacitinib (**1**) in treating RA by blocking the Janus kinases (Jak)[29] clearly shows that blocking signaling molecules that are distal to a receptor:ligand interaction can be a viable alternative to biologics. Below we will discuss, important signaling pathways that affect the (auto)-immune response, and the effectiveness of small molecular inhibitors targeting them.



tofacitinib, **1**

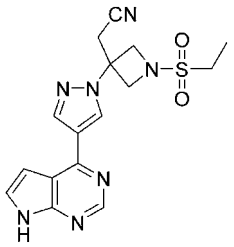
5.15.6.1 Kinases and Phosphatases

5.15.6.1.1 Janus kinases/signal transducer and activator of transcription

The cytokine milieu influences the way immune cells respond to antigenic stimuli. In the so-called three-signal model, lymphocytes bind to a presented antigen in a specific manner through their receptor; for this first signal to translate into a productive immune response, a second costimulatory response has to be delivered by a molecule on the antigen-presenting cell to its ligand on the lymphocyte. This response is further refined by circulating cytokines that bind to their receptor. This third signal makes the lymphocyte respond in different ways depending on the circumstances: for example, in the presence of interleukin-6 (IL-6), T cells may differentiate into proinflammatory T-helper cells-17 (Th17 cells), while in the presence of TGF-β, the same specificity T cells may differentiate into counter-inflammatory Treg cells.

There are several types of cytokine receptors that employ different intracytoplasmic molecules to transduce the signals inwards. Type I/II cytokine receptors use the Jak/signal transducer and activator of transcription (STAT) molecules (reviewed in Ref. 30). Numerous cytokine receptors belong to this category and regulate both proinflammatory (e.g., IL-6, IL-21, IL-23, IL-22) and regulatory processes (e.g., IL-2, IL-10). Importantly for SLE, Jak/STAT mediate IFNα signaling. This system is also used by hormone and hormone-like molecules that direct important functions, such as hematopoiesis,[31] which may result in significant side effects such as neutropenia or anemia when this system is blocked. There are four different Jak (Jak1, Jak2, Jak3, and Tyk2) and six STAT molecules. Proinflammatory molecules employ primarily Jak1 and Jak3, while erythropoietin and other hematopoietic hormones signal through Jak2.

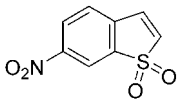
Following the realization that several of the proinflammatory cytokines such as IL-6 and IL-23 that play a role in autoimmune diseases, signal through the Jak/STAT pathway, the Jak inhibitor tofacitinib (**1**) was successfully introduced as a potent treatment in RA.[29] Tofacitinib (3-((3R,4R)-4-methyl-3-(methyl(7H-pyrrolo[2,3-d]pyrimidin-4-yl)amino)piperidin-1-yl)-3-oxopropanenitrile, **1**) is a potent inhibitor of Jak3 but also blocks less potently Jak1 and Jak2, theoretically blocking more IL-2, IL-4, and IL-21 than IL-6 signaling. Baricitinib (2-(3-(4-(7H-pyrrolo[2,3-d]pyrimidin-4-yl)-1H-pyrazol-1-yl)-1-(ethylsulfonyl)azetidin-3-yl)acetonitrile, **2**), a preferential Jak1/2 inhibitor, is also efficacious in RA, even in severe refractory cases.[32] The side effects of these compounds besides infections included elevation of cholesterol and cytopenias. Generally, these are potent antiinflammatory compounds that contain RA activity within few weeks from the initiation of therapy.



baricitinib, **2**

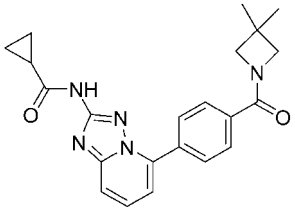
In the case of SLE, several pathogenic cytokines, such as the IFNs, Th17 related cytokines (IL-6, IL-23), and antibody production inducing cytokines (IL-21) signal through this Jak/STAT system. Tofacitinib (**1**) that blocks Jak1 and Jak3 is therefore an attractive option for SLE. In the murine lupus model MRL/*lpr*, tofacitinib (**1**), given before disease onset, resulted in a significant improvement of nephritis, by affecting antibody and proinflammatory cytokine production.[33] It did result in a decrease in red blood cell concentration in the blood, suggesting that it does block to some extent Jak2 as well. Tofacitinib (**1**) was effective even after the disease onset, suggesting that it may be beneficial in patients with SLE as well.

Jak/STAT inhibition can also be achieved by blocking the STAT molecules, potentially bypassing the nonspecific effects of Jak inhibitors. The importance of this pathway in SLE was shown in an early study of lupus-prone B6.Sle1ab mice, which had increased STAT3 expression in their B cells.[34] STAT3 was found to be essential for antinuclear antibody production, a hallmark of the disease in these mice. Later it was found that SLE T-cell migration to target tissues depends on STAT3 that is abnormally upregulated.[35] STAT3 plays a broader role in T-cell function, being critically important for the development of the proinflammatory Th17 subset,[36] T follicular helper cells,[37] and Treg cells[38]; these T-cell subsets are central in the pathophysiology of SLE in both humans and murine models of the disease. The importance of STAT3 in SLE was further underlined by a study comparing the genetic signatures of kidney tissues from three different murine models of lupus[39]; this study identified STAT3 as the top gene-regulating candidate in these mice. Stattic (6-nitro-1-benzothiophene 1,1-dioxide; 6-nitrobenzo[b]thiophene 1,1-dioxide, **3**), a STAT3 blocker, delayed the onset of disease in MRL/*lpr* mice.[40] Moreover, Stattic blocked the migration of T cells from SLE patients in response to chemokines, recapitulating earlier findings using gene silencing of STAT3. These preclinical results supported the inhibition of this pathway in SLE.



stattic, **3**

The first trial of Jak inhibition in SLE was done using specific Jak1 inhibitor solcitinib (**4**); the patients enrolled in the study had high baseline interferon signature,[41] as high IFNα is thought to play a role in SLE pathogenesis and it signals through Jak. This trial was stopped prematurely as there was no change in the IFN-related gene expression in an interim analysis. Two patients developed a reversible syndrome of fever, eosinophilia, and liver test abnormalities (DRESS syndrome).[42] The negative result of the study does not reflect on Jak inhibition in general as this compound failed to show biologic activity at least as this pertains to the IFN system. Further studies are needed given the positive preclinical data to assess the clinical usefulness of Jak inhibitors in SLE.



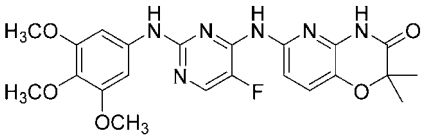
solcitinib, **4**

5.15.6.1.2 Spleen tyrosine kinase

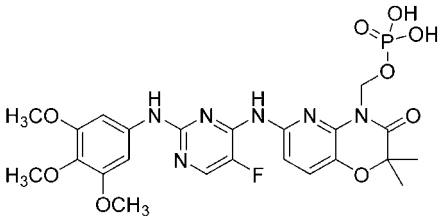
The tyrosine kinase Syk (spleen tyrosine kinase) is a member of Src kinases and is expressed in various types of hematopoietic cells, such as T cells, B cells, osteoclasts, monocytes, and neutrophils (reviewed in Ref. 43). A wide range of membrane-bound receptors on these cells closely associate with signaling molecules that bear the immuno-receptor tyrosine activating motifs (ITAM) structures containing the amino acid tyrosine. Once the receptor engages its ligand, tyrosines are phosphorylated and recruit Syk by binding to its Src homology 2 (SH2) domain. The engaged Syk activates downstream molecules such as Vav, phospholipase C-γ2 (PLCγ2), and PI3 kinase among others, starting a transcriptional program that differs depending on the cell type and surface receptor.

Receptors that are known to engage Syk via their ITAM include the Fc receptors that are expressed on B cells, monocytes, and neutrophils among other cells. These receptors engage IgG and are pivotal in phagocytosis of opsonized material, an essential step in elimination of infectious agents. Moreover, Syk associates with the main receptor of B cells, the B-cell receptor (BCR),[44] and transduces an activating signal inwards upon engagement of the BCR with its cognate antigen. In addition to the process of recognizing exogenous material, Syk kinase may also play a role in neutrophil effector functions that are necessary for host defense.[45]

Given the widespread expression of Syk in inflammatory cells, it became one of the first treatment targets in autoimmune diseases. The small molecule *N*4-(2,2-dimethyl-3-oxo-4H-pyrid[1,4]-oxazin-6-yl)-5-fluoro-N2-(3,4,5-trimethoxyphenyl)-2,4-pyrimidinediamine (R406, **5**)[46] blocks Syk kinase activity and was shown to be effective in vitro and in animals in inhibiting Syk-mediated signaling in a variety of cells. Given the importance of Syk in B-cell signaling through the BCR and antibody responsiveness through the Fc receptors, R406 (**5**) was developed into fostamatinib (**6**), a small-molecule kinase inhibitor with the intention to treat several autoimmune diseases. Late-phase clinical trials in patients with RA with fostamatinib (**6**) although encouraging initially showed a rather modest effect.[47] The main side effects included neutropenia and increase in the blood pressure. Currently the RA program has been abandoned, but trials are conducted in patients with immune thrombocytopenia (ITP) and hemolytic anemia.



R406, **5**



fostamatinib, **6**

In SLE, Syk was found to be abnormally expressed in peripheral blood T cells[48] from patients with both active and inactive SLE as part of a broader "rewiring" of the surface T-cell receptor (TCR) that employed FcRγ in lieu of CD3ζ chain as the main ITAM-containing signaling molecule. This change in SLE T cells is not merely substitution of one molecule for another but has significant implications in the way the SLE T cells handle cognate signals that are transmitted through their TCR. SLE T cells mobilize calcium in a very robust way once activated,[49] thus exhibiting an overexcitable phenotype as compared to healthy T cells; this phenotype is in turn associated with a different transcriptional program that enhances T cell help to B cells and production of proinflammatory cytokines.[50]

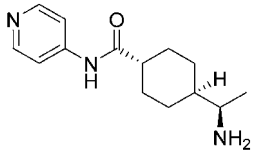
SLE therefore stands out from other autoimmune diseases in that Syk is not only playing a role in the production and handling of antibodies and immune complexes but is ectopically expressed in T cells and is a pivotal molecule in their aberrant function. A series of in vitro experiments showed that R406 (**5**) can indeed block TCR-mediated signaling in SLE but not healthy T cells.[51] Deng et al then used R788 (R406 orally available prodrug, **6**) to treat lupus-prone mice before the onset of the disease but also after disease initiation.[52] The investigators showed that there was complete abrogation of the inflammatory damage to the kidneys and the skin even when the drug was given after the disease was established in the target organs. Importantly, this effect of Syk inhibition persisted for several weeks after the discontinuation of the treatment.

Syk overexpression in SLE T cells and its prominent role in antibody production and handling by the B cell and monocyte compartments make it a very interesting therapeutic target in SLE. The preclinical studies support this line of thought and provided the necessary rationale for human trials that although initially planned have yet to be conducted.

5.15.6.1.3 Rho kinase (ROCK)

Rho kinase (ROCK) is an important cytosolic node that integrates activating signals from surface receptors leading to both cell proliferation and migration. ROCK is a 160 KDa serine/threonine kinase,[53] that is the target of the small GTPase Rho. There are two isoforms, ROCK1 and ROCK2, that are widely distributed in tissues, such as the eye, the central nervous system, and the spleen. Once Rho binds to ROCK, ROCK is activated and leads to downstream phosphorylation of target proteins that control the cytoskeleton arrangement and gene transcription.

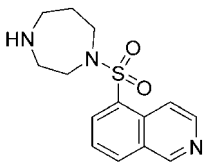
The first indication that ROCK may be important in SLE came after the observation that SLE T cells freshly isolated from patients showed an enhanced potential to adhere to hyaluronic acid migrate in response to chemokines.[54] This was proven to be secondary to the overexpression of the surface molecule CD44 that binds hyaluronic acid and spontaneous cytoskeletal rearrangements that enabled the formation of polar caps. The ezrin/radixin/moiesin (ERM) protein is the key molecule that precipitates those two processes. Indeed, phosphorylated ERM-containing T cells were present not only in the peripheral blood of patients but also in the kidneys of patients with nephritis. ROCK is directly responsible for the phosphorylation of ERM, and in vitro ROCK inhibition using the inhibitor Y27632 (**7**) resulted in a reversal of this process and "normalization" of the SLE T-cell phenotype. The proposed model postulated that TCR-mediated signals activated ROCK which through ERM phosphorylation enhanced the ability of SLE T cells to adhere and migrate to tissues.



Y27632, **7**

Parallel work in murine lupus models showed that ROCK2 phosphorylates the transcription factor interferon regulatory factor 4 (IRF4), an important factor for the polarization of T cells into the proinflammatory subset Th17.[55] ROCK2 through regulation of the IRF4 enables the spontaneous production of IL-17 and IL-21 by murine lupus T cells. IRF4 also influences B-cell responsiveness to IL-21,[56] an important step for the production of autoantibodies. ROCK therefore is playing a broad role in the aberrant T:B cell interaction in lupus and the production of high-affinity pathogenic autoantibodies.

The ROCK inhibitor fasudil (5-(1,4-diazepan-1-ylsulfonyl) isoquinoline, **8**) is the first inhibitor extensively studied in murine lupus. Fasudil (**8**) was shown to be efficacious when given to female MRL/*lpr* mice[55] and F1 mouse from crossing New Zealand Black and New Zealand White mice (NZBW F1 mice),[57] both murine models of lupus. The effect was more pronounced when given early in the disease course in NZBW F1 mice, suggesting a protective role against the disease; the effect on established nephritis though, where the cells have already migrated in the kidney may not be as pronounced. Fasudil (**8**) causes also vasodilation, and it is for this property that it has been evaluated in clinical trials of patients with angina pectoris[58] and pulmonary hypertension.[59] Fasudil (**8**) was generally well tolerated in these studies with only mild-to-moderate side effects attributable to the drug. A small but statistically significant elevation of the creatinine was observed in the angina pectoris study. Fasudil (**8**) was also tried in patients with vasospasm (Raynaud's) due to systemic sclerosis.[60] Fasudil (**8**) did improve blood flow to the digital arteries that are narrowed in this condition but did not have a significant clinical effect in this short trial.



fasudil, **8**

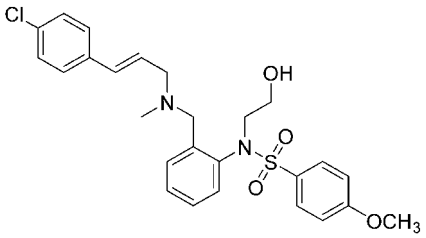
Overall, ROCK inhibition has clear antiinflammatory effects blocking the autoimmune response at several checkpoints (T-cell differentiation, T:B cell interaction, lymphocyte migration) in preclinical studies. Its added vasodilatory effect is of particular interest as it can improve compromised blood flow in patients with systemic autoimmune diseases. Fasudil (**8**), a clinically tried drug with acceptable safety profile, represents therefore an attractive agent for trials in SLE.

5.15.6.1.4 Calcium/calmodulin-dependent kinase IV

Signaling through the abnormally wired TCR that employs the Syk kinase as discussed earlier is associated with increased calcium influx into the T-cell cytosol. Early on it was observed that one of the kinases that depends on calcium, the serine/threonine kinase calcium/calmodulin-dependent kinase IV (CaMKIV) but not CaMKII, is abnormally activated in SLE T cells; it is not only found as expected in the cytosol of SLE T cells but also in the nucleus.[61] There it associates with the transcription factor c-AMP regulatory element modulator (CREM).[62] CREM in turn limits the production of the regulatory IL-2 cytokine and boosts the production of the proinflammatory cytokine IL-17.[63] The activation of CaMKIV in SLE T cells could be replicated in normal T cells by incubating

them with SLE patient-derived serum supporting the notion that the inflammatory milieu in SLE can prime the T cells, rendering them proinflammatory.

Following these early experiments, CaMKIV was targeted genetically[64] in lupus-prone mice, showing that its deletion can prevent the development of lupus. The small molecule 2-[*N*-(2-hydroxyethyl)-*N*-(4-methoxybenzenesulfonyl)]amino-*N*-(4-chlorocinnamyl)-*N*-methylbenzylamine (KN-93, **9**)[65] is a potent inhibitor of the kinase activity of CaMK. KN-93 (**9**) was therefore used in experiments in lupus-prone mice showing significant effect in alleviating disease.[66] The effect of the genetic deletion of CaMKIV was thought to be mediated by a boost in the Treg population.[64] KN-93's effect was somewhat different as it inhibited costimulatory molecule expression and proinflammatory cytokine production[66] and mesangial cell proliferation in the kidneys.[67] KN-93 (**9**) has therefore an effect on both circulating immune cells and local cells in the target organs, making it an interesting therapeutic option albeit with the potential for off target effects.



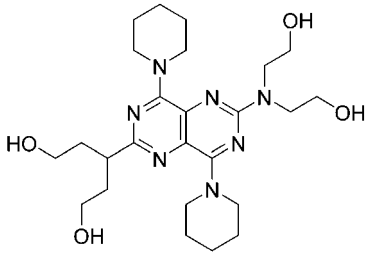
KN-93, **9**

5.15.6.1.5 Calcineurin/nuclear factor of activated T cells

Besides cytosolic kinases, calcium also activates the phosphatase calcineurin. Calcineurin, one of the first phosphatases to be targeted for therapy, then activates by dephosphorization the transcription factor nuclear factor of activated T cells (NFAT).[68] NFAT in cooperation with other transcriptional activators, such as the activator protein-1 (AP-1), initiates the transcription of several key genes, including IL-2 and CD154 among others. SLE T cells, when evaluated in vitro, express high levels of CD154, but because of skewed partnership between NFAT and AP-1, IL-2 production lags.[50] This transcriptional aberration is characteristic of T cells; it renders them good helpers for B cells (through CD154) to produce antibodies, whereas the support for counter-inflammatory Treg through IL-2 is limited. The calcineurin-NFAT duet therefore represents a good molecular target for therapy in SLE that can help normalize the SLE T cells phenotype.

Calcineurin inhibitors cyclosporine and tacrolimus[69] have been extensively used for transplant rejection prevention for several decades. They are well tolerated in general but have been associated with nephrotoxicity among other toxic effects.[70] In SLE and in particular lupus nephritis, they have been used off label for many years but are considered third or fourth line agents behind mycophenolate mofetil, cyclophosphamide, and azathioprine.[71] A recent study comparing tacrolimus to mycophenolate proved noninferiority of tacrolimus to mycophenolate as an induction agent.[72] In a limited number of patients with lupus nephritis, a strategy using low-dose mycophenolate mofetil and tacrolimus was found superior to cyclophosphamide.[73] Besides being an antiinflammatory agent, tacrolimus can be helpful in nephritis by stabilizing the podocytes,[74] thus limiting protein leak in the urine space, which in by itself can be nephrotoxic. These studies and especially the combination studies open the window for the use of these agents in lupus nephritis and in particular in patients who cannot tolerate the chemotherapeutic agent cyclophosphamide or high doses of mycophenolate.

To avoid some of the side effects of calcineurin inhibition, one could try to interfere specifically with the interaction of calcineurin and the NFAT molecule without globally inhibiting calcineurin phosphatase activity. In a chemical screen of such molecules the already approved drug dipyridamole (2-[[2-[bis(2-hydroxyethyl)amino]-4,8-di(piperidin-1-yl)pyrimido[5,4-d]pyrimidin-6-yl]-(2-hydroxyethyl)amino]ethanol, **10**), which is used for its vasodilator properties, was shown to be a calcineurin–NFAT interaction blocker.[75] SLE T cells treated with dipyridamole (**10**) in vitro were unable to help B cells produce excess immunoglobulins. Moreover MRL/*lpr* mice injected with dipyridamole (**10**) showed delayed onset of nephritis compared to placebo-treated mice.[76] Dipyridamole (**10**) is in general well tolerated, making this drug a good alternative to traditional calcineurin inhibitors as an add-on therapy in lupus nephritis.



dipyridamole, **10**

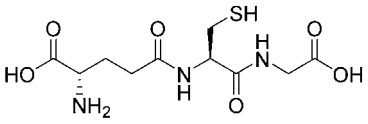
5.15.6.1.6 Mammalian target of rapamycin

The serine/threonine kinase mammalian target of rapamycin (mTOR) took its name when it was recognized as the target of the antibiotic/immune-modulatory molecule rapamycin or sirolimus.[77] mTOR is central in a variety of cellular functions including cell metabolism, proliferation, and differentiation. As a drug, rapamycin has been used with great success in allograft rejection prevention, acting synergistically with cyclosporine to improve kidney allograft survival.[78] It has also been used in drug-eluting stents to delay reocclusion of atherosclerotic vessels.[79]

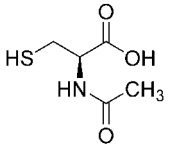
mTOR serves as a censor of the metabolic conditions and coordinates cell growth and proliferation.[80] When activated, mTOR phosphorylates several substrates including STAT3, S6 kinase (S6K), eukaryotic translation initiation factor 4E binding protein 1 (4EBP-1), and activating molecule in BECN1-regulated autophagy protein 1 (AMBRA-1) (reviewed in Ref. 81). mTOR has two interacting isoforms mTORc1 and mTORc2 that play a proinflammatory role by supporting CD4+ T cells[82] differentiation (Th1 and Th17 for mTORc1 and Th2 for mTORc2). SLE T cells are characterized by an enhanced mitochondrial hyperpolarization that upregulates mTOR activity in these cells.[83] This high mTOR activity may therefore contribute to the observed enhanced Th1, Th17 activity, and loss of Treg activity in SLE.

As mTOR links metabolism and cell activation/differentiation, it was targeted in a variety of autoimmune diseases, such as RA[84] with limited success. In SLE after positive animal trials, rapamycin was given in nine SLE patients who failed other therapies and had active disease.[85] In this proof of concept study, rapamycin was well tolerated and proved efficacious in reducing disease activity and the need for steroids. Importantly the overexcitable T-cell phenotype that is characteristic of SLE was reversed with the use of rapamycin.

Besides inhibition with rapamycin, mTOR activation can be targeted indirectly by glutathione (**11**), an antioxidant that regulates mitochondrial hyperpolarization and shown to be decreased in SLE.[86] Glutathione (**11**) can be boosted by its precursor *N*-acetyl cysteine (NAC, **12**), a compound used primarily for its antioxidant properties, such as in preventing contrast-induced nephropathy[87] and the treatment of acetaminophen overdose. In a double-blind placebo control trial, 36 patients were randomized to take NAC (**12**) at three different doses (1.2, 2.4, and 4.8 g/day) or placebo.[88] The highest dose of NAC (**12**) caused significant nausea. NAC (**12**) had the expected biologic effect of reducing mTOR activity by reversing mitochondrial hyperpolarization in T cells. There was a moderate effect on disease activity especially with the two higher doses of NAC (**12**); patients on the highest doses had the most benefit with five of six patients in that group achieving an improvement of three or more on the SLEDAI scale. That group also had the only dropouts (three) because of headache, nausea, and heartburn. Overall, NAC (**12**) has modest effects on disease activity with good tolerance in the medium but not the highest doses.



glutathione, **11**



N-acetyl cysteine (NAC), **12**

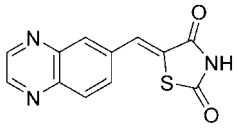
In conclusion, the mTOR pathway is activated in SLE, and its targeting with traditional or novel agents can be beneficial. Given the modest effectiveness of these drugs, their primary role would be in combination regimens with other immunosuppressives such as the calcineurin inhibitors as is commonly done for transplant rejection prevention.

5.15.6.1.7 Phosphaditylinositol-3 kinase

Class I phosphaditylinositol-3 kinase (PI3K) are heterodimeric kinases that are formed by a regulatory and a p110 catalytic subunit. They catalyze the formation of phosphatidyl-inositol-3,4-diphosphate and phosphatidyl-inositol-3,4,5-triphosphate.[89] They are subcategorized based on the catalytic subunit into: (a) class IA lipid kinases PI3K (p110α, β, δ) that are activated in response to 1st (TCR), 2nd (costimulatory), and 3rd (cytokine) activation signals; and (b) class IB (p110γ) that associates with G-coupled receptors.[90] The lipid second messengers that are generated by these kinases are prosurvival molecules. The main isoforms that are found in hematopoietic cells are p110δ (class IA) and p110γ (class IB). A rare disease called PASLI (p110δ-activating mutation causing senescent T cells, lymphadenopathy, and immunodeficiency) is due, as implied by its name, to an activating mutation of p110δ.

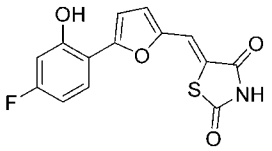
The importance of these kinases in autoimmunity is shown by a transgenic mouse that overexpresses the regulatory subunit and developed a lupus-like illness.[91] PI3K overactivity decreased cell death, accumulation of memory CD4+ T cells, and nephritis. The same research group used the MRL/*lpr* mouse model of lupus to test whether direct inhibition of the class IB PI3K p110γ with the compound AS605240 ((5Z)-5-(quinoxalin-6-ylmethylidene)-1,3-thiazolidine-2,4-dione, **13**) can improve disease outcomes.[92]

Both male and female mice (female mice have more severe disease) responded to the compound with decreased T-cell activation and resulting glomerulonephritis. AS605240 (**13**) also improved survival and overall had a result analogous to dexamethasone.



AS605240, **13**

Since p110δ is the other isoform found in hematopoietic cells and is known to regulate B- and T-cell activation, Suarez-Fueyo et al. asked whether it contributes to SLE pathology.[93] p110δ was upregulated in both total peripheral mononuclear cells and T cells of lupus patients, with a tendency to be higher in patients who had higher disease activity. This increase was correlated with increased survival of T cells upon activation and increased proportion of memory T cells. Inhibition of p110δ with AS252424 ((5Z)-5-[[5-(4-fluoro-2-hydroxyphenyl)furan-2-yl]methylidene]-1,3-thiazolidine-2,4-dione, **14**), but not p110γ, resulted in normalization of apoptosis by SLE T cells. The discrepancy between the relative importance of the two isoforms in human T cells (p110δ) and mouse models (p110γ) may be due to the different experimental condition (in vitro vs. in vivo) or in true differences in the role of these isoforms in mice and humans.



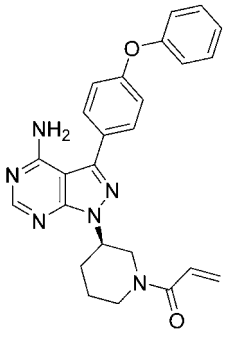
AS252424, **14**

Overall, the PI3K system plays an important role in the survival of T cells after activation and the generation of memory cells, two processes that are clearly abnormal in SLE and represents a promising therapeutic target in this disease. Since PI3K is important in cell survival numerous compounds targeting these enzymes are in trials for cancer but not for autoimmune diseases. A drug that inhibits p110δ, CDZ173 (structure not disclosed), which is currently in trials for PASLI, is also being tested in an early phase trial for the autoimmune disease Sjogren syndrome (clinicaltrials.gov; NCT02775916).

5.15.6.1.8 Bruton's tyrosine kinase

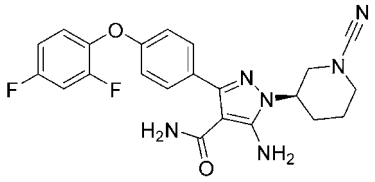
As B cells are the source of autoantibody production, limiting their activity is key in the treatment of the disease. Elimination of B cells with rituximab though did not result in significant outcome improvements suggesting that a more refined approach to B-cell modulation is needed. Targeting B-cell signaling is an important alternative to B-cell depletion therapies.

Bruton's tyrosine kinase (Btk) is a Tec family kinase that is activated following engagement of the BCR complex. *Btk* gene mutations are responsible for the X-linked agamma-globulinemia.[94] Following BCR engagement, Lyn is recruited and, by phosphorylating the BCR ITAM, recruits Syk. Syk in turn recruits and phosphorylates Btk. The activated Btk leads to the translocation of NfkB to the nucleus of B cells.[95] Btk may also bridge the BCR signal with a second signal from the nucleic acid sensing receptor TLR9.[96] Moreover, Btk is involved in Fc receptor signaling in monocytes, suggesting a crucial role for this kinase in the production and handling of antibodies.[97] As the importance of Btk became apparent, it was targeted with small-molecule inhibitors in cancer and autoimmunity. After a series of successful preclinical studies, the Btk inhibitor ibrutinib (**15**) became the first in class drug to show significant efficacy in the treatment of chronic lymphocytic leukemia among other B-cell malignancies.[98] Serious side effects were rare and included hypertension and cytopenias. Atrial fibrillation and hemorrhage were also observed in a minority of patients.



ibrutinib, **15**

Another Btk inhibitor, PF-06250112 ((R)-5-amino-1-(1-cyanopiperidin-3-yl)-3-(4-[2,4-difluorophenoxy]phenyl)-1H-pyrazole-4-carboxamide, **16**), was used in various doses in NZBW F1 mice starting at the age where autoimmunity was apparent, but clinical disease was still not evident. The compound significantly improved renal pathology, preventing complement and antibody deposition in the kidneys. Moreover, it inhibited cell accumulation in the kidneys and kidney damage, in an induced nephritis model, where animals were injected with nephrotoxic serum. In the murine lupus study, low-dose PF-06250112 (**16**) prevented kidney damage without affecting dsDNA antibody production to a significant extent. This speaks to the fact that as important the effect of this drug in the development of germinal centers and anti-dsDNA antibodies may be, limiting Fc receptor-mediated response to immune complexes may be equally or more critical.[99] Ibrutinib (PCI-32765, **15**) was also evaluated in B6.Sle1 and B6.Sle1.Sle3 murine models of lupus. It did limit humoral autoimmunity in both models. In the B6.Sle1.Sle3 that develops severe glomerulonephritis, ibrutinib (**15**) had a moderate effect in limiting kidney damage.[100]



PF-06250112, **16**

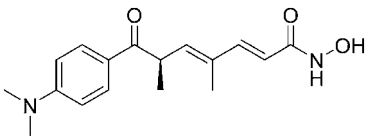
The fact that Btk inhibition is successful in murine models of the disease and Btk inhibitors have a good safety profile led to a phase Ib double-blind clinical trial (NCT02537028) of another inhibitor, MSC2364447C (structure not disclosed), in patients with lupus. This is a 4-week trial of two doses of the drug (25 or 75 mg) or placebo to determine safety conducted in patients with mild to moderately active disease with positive autoantibodies excluding patients with active central nervous disease. Overall, Btk inhibition may prove to be very important in the therapeutic armamentarium in SLE as it not only targets B cells and production of antibodies but also the interaction of Fc receptor bearing cells with these antibodies.

5.15.6.2 Modifiers of Chromatin

Ever since the realization that the lupus-inducing drugs procainamide and hydralazine can cause the disease by altering the methylation status of DNA,[101] there has been significant interest in epigenetic changes in the DNA and chromatin structure in SLE patients. Although genetics contribute to disease susceptibility, it is clear that cues from the environment are necessary for both disease initiation and flares. These environmental factors can cause epigenetic changes including methylation of cytosine on the DNA that is catalyzed by the DNA methyl-transferases (DNMT) and histone acetylation/deacetylation mediated by the histone acetylases and histone deacetylases (HDAC).

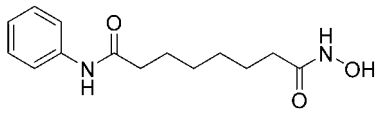
In SLE, and not only drug-induced lupus which is a somewhat different syndrome, T cells are characterized by an altered DNA methylation status. This change allows for more robust gene expression in the case of demethylated IL-17[63] or protein phosphatase 2A[102] and limited production of the overmethylated IL-2.[103] This change in the methylation status is directed by the aberrant expression of transcription factors such as CREM-α that silences IL-2 while increasing IL-17 production via methylation changes in the respective genes.[103,63]

CREM-α besides altering the methylation status of genes by recruiting DNMT enzymes, alters the histone acetylation status (as in the case of *IL-2*) by promoting histone deacetylation in the gene promoter area, limiting the ability of transcription factors to access the chromatin.[104] HDAC inhibition can therefore correct the underlying inability of SLE T cells to produce sufficient amounts of IL-2, a cytokine critical for the survival of Treg cells. Given these data, trichostatin A (TSA, **16**), a nonspecific HDAC inhibitor, was given in lupus-prone female NZBW F1 mice starting at 14–16 weeks of age.[105] TSA (**16**) improved renal pathology in mice as compared to controls, limiting autoantibody production. Importantly and in line with the in vitro human experiments, the main effect of TSA (**16**) was induction of Treg. The same group also showed that TSA (**16**) improved disease pathology in MRL/*lpr* mice by limiting proinflammatory cytokine production.[106]

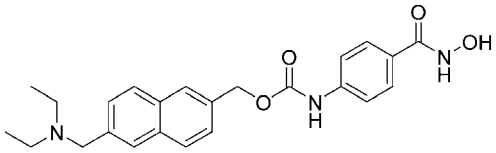


trichostatin A, **16**

Currently, HDAC inhibitors such as Vorinostat (suberoylanilide hydroxamic acid (SAHA, **17**)) are in clinical use for hematologic malignancies, such as cutaneous T-cell lymphoma.[107] Givinostat, another oral HDAC inhibitor, was successful in treating systemic onset juvenile RA in a short 12-week trial with good safety profile.[108] This trial paved the way for the evaluation of HDAC inhibitors in other inflammatory diseases, such as SLE.



SAHA, **17**

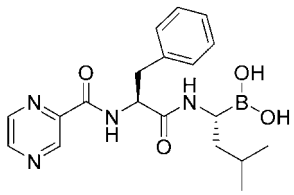


givinostat, **18**

5.15.6.3 Proteasome Inhibitors

Immune cells and especially antigen-presenting cells play an important role in disposing of degradation products from proteins that are either intrinsically produced in the cell or phagocytosed. The immune cell has to critically distinguish between microbial and self-products in this process as it has to dispose them differently. Proteins are degraded by the proteasome, a complex of large proteins in the cell that is crucial in cell homeostasis. In the immune cells, a specialized immunoproteasome is responsible for generating protein fragments to be presented in association with the MHC molecules. The interferons can also induce the immunoproteasome assembly in nonimmune cells.

Plasma cells, the terminally differentiated antibody-forming cells, depend on the proper assembly of the proteasome for their function and survival: The production of significant amounts of immunoglobulin by these cells leads inevitably to a large number of mis- or unfolded proteins that need to be degraded by the proteasome. In the absence or misassembly of the proteasome, these proteins may cause endoplasmic reticulum stress and subsequent programmed cell death (apoptosis).[109] This apparent reliance on the proteasome for their proper function led the successful clinical application of proteasome inhibitors, such as bortezomib (**19**), in the treatment of plasma cell dyscrasias, such as multiple myeloma.[110]

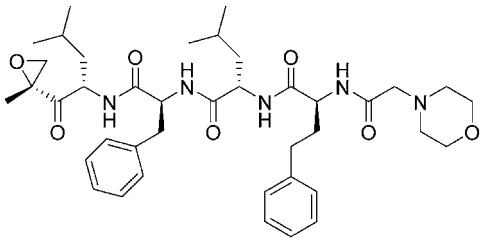


bortezomib, **19**

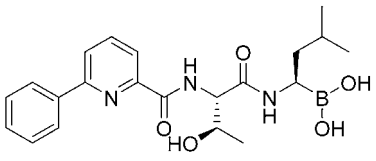
As I mentioned earlier, elimination of B cells (with anti-CD20 antibodies) or manipulation of B-cell signaling (with anti-BLyS, anti-CD22 antibodies, or Btk inhibitors) is not sufficiently efficacious in controlling SLE pathology. One explanation could be that all these medications do not directly affect the plasma cells, and especially the long-lived plasma cells.[111] Proteasome inhibitors represent exactly such medications.

Bortezomib (**19**) was evaluated in NZBW F1 and MRL/*lpr* lupus-prone mice where it was directly compared to cyclophosphamide and the corticosteroid dexamethasone.[112] The treatment was successful in limiting production of pathogenic autoantibodies, deposition of immunoglobulin to the glomeruli of the kidneys, preventing kidney damage and prolonging survival. The treatment was successful not only to prevent disease but to treat already established disease in these mice. Bortezomib (**19**) was also shown not only to affect plasma cells but also to prevent podocyte damage by preserving its ultrastructure. Whether that is a direct or indirect effect is still unclear though.[113]

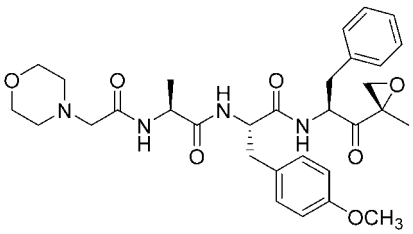
Bortezomib's effectiveness in treating multiple myeloma has spurred the creation and marketing of several proteasome inhibitors. Carfilzomib (**20**)[114] and delanzomib (**21**),[115] two newer inhibitors, were shown to be efficacious in the preclinical models of lupus NZBW F1 and MRL/*lpr* just as Bortezomib (**19**). Importantly, these studies showed the specific immunoproteasome inhibitor ONX 0914 (**22**) to be as effective as dual-specificity classic proteasome inhibitors.[114] In these studies, it became also apparent that besides inhibiting autoantibody production, Bortezomib (**19**) also blocked the production of IFNα, an important cytokine for lupus pathogenesis.



carfilzomib, **20**



delanzomib, **21**

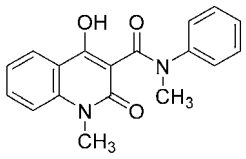


ONX-0914, **22**

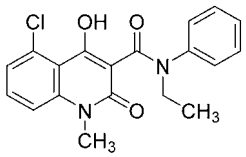
Given the wealth of preclinical results, 12 patients with refractory SLE were treated with 1–4 (median 2) cycles of intravenous Bortezomib (**19**). The treatment of these highly refractory patients resulted in impressive[116] improvement in most manifestations including pericarditis, rashes, proteinuria, and arthritis. The drug resulted in a decrease in both short- and long-lived plasma cell-derived autoantibodies but also in significant decreases in protective antibody titers. Bortezomib (**19**) caused significant side effects including neuropathy (two cases). A phase II clinical study on SLE, RA, and myasthenia gravis is under way (NCT02102594). The overall evidence with proteasome inhibitors in SLE is positive, but their usefulness may be limited by their significant neurotoxicity and nonspecific immunosuppression.

5.15.6.4 Quinoline Derivatives

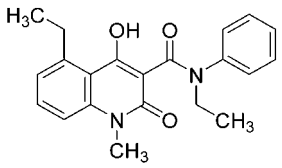
Linomide (**23**), a quinolone derivative, was the prototypic drug of this category of immunomodulators that although efficacious for MS[117] was withdrawn because of toxicity. Two more safe compounds related to linomide (**23**), Laquinimod (**24**) and Paquinimod (**25**), have since been developed.



linomide, **23**



laquinimod, **24**



paquinimod, **25**

The exact mechanism of quinolone derivatives remains unclear. Recently it was proposed that they may be targeting the interaction of the proinflammatory molecule S100A9 with the TLR4 and the RAGE (receptor for advanced glycation end products).[118] The danger sensing proinflammatory proteins S100 are upregulated in SLE[119] and may induce the production of the proinflammatory cytokine IL-17 by CD8+ T cells.[120]

Late-phase trials have shown that laquinimod (5-chloro-*N*-ethyl-4-hydroxy-1-methyl-2-oxo-*N*-phenyl-1,2-dihydroquinoline-3-carboxamide, **24**) has modest effects in MS.[121] Murine studies showed that laquinimod (**24**) was as effective as mycophenolate in preventing and treating established nephritis in NZBW F1 mice.[122] Moreover, in advanced disease laquinimod (**24**) was more effective than mycophenolate in prolonging survival. Subsequently, a phase IIa trial in patients with lupus nephritis was conducted using two different doses of laquinimod (**24**) 0.5, 1 mg or placebo. All patients received standard of care with mycophenolate mofetil and corticosteroids. The results favored the laquinimod (**24**) arms with 64% of the patients having a renal response at 24 weeks in the 0.5 mg dose arm versus 50% in 1 mg dose arm versus 33.3% in the placebo arm.[123] Cardiovascular side effects have also plagued the laquinimod (**24**) trials for MS, so the future of its development for SLE remains unclear.

Paquinimod (*N*,5-diethyl-4-hydroxy-1-methyl-2-oxo-*N*-phenylquinoline-3-carboxamide, **25**) is the other quinolone derivative used in SLE. It was successful in preventing disease in MRL/*lpr* mice[124] to a degree comparable to mycophenolate. In a proof of concept study that did not address efficacy to a significant extent, it was also given in SLE patients and was relatively well tolerated; mild-to-moderate side effects such as arthralgias and myalgias were observed in patients who received higher doses.[124]

Overall, the quinoline derivatives may be effective in a variety of autoimmune diseases, but a lot is yet to be learned-regarding their mode of action. The side-effect profile and especially cardiovascular toxicity remains a significant barrier to the full clinical deployment of these compounds decades after their initial introduction as immunomodulatory medications.

5.15.7 Conclusion and Future Directions

Extensive basic science work in vitro and in animal models has uncovered much of the immunopathology of SLE. Treatment options have largely though remained static with an emphasis in global immunosuppression with extensive use of corticosteroids. The development of new agents follows two trends: the first one is to block easily accessible surface molecules and circulating mediators. This approach using biologics has been very effective in rheumatoid and psoriatic arthritis but in the case of SLE has had modest success, such as with belimumab or no effect such as with epratuzumab or abatacept. The second approach targets intracellular enzymes and other factors using small molecules that penetrate the cell membrane. As discussed earlier and shown in **Table 1**, various agents show promise. The problem of selectivity does remain though given that most of the targets are generally expressed in a variety of cells and tissues.

A major hurdle to move these drugs from preclinical studies to the clinic is the appropriate design of trials. SLE trials have been difficult to conduct not only because of the rarity of the disease but also its heterogeneity. This has been to a degree improved but not resolved, by the use of novel outcome measures, BICLA (a BILAG-based measure) and SRI (a SLEDAI-based measure). The second hurdle is the use of background immunosuppressive therapies in SLE. The introduction of new therapies should not only improve outcomes but also decrease the side effects (immune-suppressive and metabolic) of current therapies. Corticosteroid and other immunosuppressives sparing strategies should therefore be taken into account when designing clinical trials with novel agents The Biomarkers in lupus disease (BOLD) study design (https://www.clinicaltrials.gov/ct2/show/NCT00987831) is one example where patients without life threatening disease are taken off major immunosuppressives, and thus the drug in question can be examined in a more thorough way for effectiveness and toxicity.

In conclusion, several novel small molecules discussed earlier show promise in becoming effective treatments for SLE, either alone or more likely in combination with traditional disease-modifying agents and corticosteroids.

Table 1 Emerging small-molecule treatments for SLE

Target	*Compound*	*Stage of development in SLE*
Jak/STAT	Tofacitinib (**1**)	Positive mouse studies
	Solcitinib (**4**)	Early human study stopped because of lack of biologic effect
	Stattic (**3**)	Positive mouse studies
Syk	Fostamatinib (**6**)	Positive mouse studies; clinical development for ITP
ROCK	Fasudil (**8**)	Positive mouse studies; clinical development for vascular diseases
CaMKIV	KN-93 (**9**)	Positive mouse studies
Calcineurin	Tacrolimus	Successful trials in nephritis
	Dipyridamole (**10**)	Positive mouse studies
mTOR	Rapamycin	Effective in case series
	N-acetyl cysteine (**12**)	Positive early studies in patients
PI3K	AS605240 (**13**)	Positive mouse studies
	AS252424 (**14**)	Human in vitro trial
	CDZ173	Clinical trial in Sjogren syndrome
Btk	Ibrutinib (**15**)	Positive mouse studies
	PF-06250112 (**16**)	Positive mouse studies
	MSC2364447C	Ongoing phase Ib trial
HDAC	Vorinostat (**17**)	Positive mouse studies
	Givinostat (**18**)	Effective in systemic juvenile rheumatoid arthritis
	Trischostatin-A (**16**)	Positive mouse studies
Proteasome	Bortezomib (**19**)	Effective in case series
	Carfilzomib (**20**)	Positive mouse studies
	Delanzomib (**21**)	Positive mouse studies
	ONX 0914 (**22**)	Positive mouse studies
S100A9 (?)	Laquinimod (**24**)	Pilot study in SLE; long-term toxicity risk unclear
	Paquinimod (**25**)	Pilot study in SLE

5.16.1 General Characteristics of IBD

There are two major types of inflammatory bowel disease (IBD): ulcerative colitis (UC) and Crohn's disease (CD). These are chronic inflammatory diseases affecting the gastrointestinal (GI) tract. The general characteristics of UC and CD are summarized in Table 1.[1–5]

The exact causes of IBD are currently not fully understood. IBD is likely due to a combination of genetic variations and alterations in the bacterial flora, which can subsequently drive a dysregulated immune response resulting in chronic intestinal inflammation.

Scientific evidence suggests that UC is associated with an atypical Th2 response mediated by natural killer T (NKT) cells producing interleukins 5 and 13. Interleukin 13 is of particular importance because it exerts cytotoxic functions against epithelial cells, including induction of apoptosis and alteration of the protein composition of tight junctions.[1] In addition, NK T cells upon activation may be directly cytotoxic to epithelial cells.[2]

CD is characterized by T lymphocytes producing the signature cytokines IFN-γ and IL-17, respectively. Recent studies have identified T cells that produce both IFN-γ and IL-17.[3] Also, these dual Th17/Th1 cells can be converted into nonclassic Th1 cells. These T lymphocytes, which produce mainly IFN-γ, may also be involved in the pathogenesis of CD.[4,5]

When considering the characteristics of IBD, it becomes clear that suppression (during active disease) or prevention (acute flares of IBD) related to an exaggerated immune response is critical when considering new therapeutic approaches for IBD. This article will primarily address recent small-molecule approaches, which have resulted in drugs that have entered clinical trials for CD and/or UC. Secondarily, we will discuss certain novel small-molecule approaches that have shown efficacy in animal models of IBD. Finally, we will summarize results with some natural product-derived small molecules, which could have future utility for the treatment of IBD.

5.16.2 Small-Molecule Approaches for IBD: Drugs in Clinical Trials

During the past 5 years, several small-molecule drugs have entered clinical trials for IBD. These drugs have actions against various targets such as Janus kinase (JAK1 and JAK3 inhibitors), sphingosine 1 phosphate (S1P), alpha 4 integrin, C-C chemokine receptor type 9 (CCR9), and IL-17.

5.16.2.1 S1P Receptor Modulators

S1P is formed intracellularly by the phosphorylation of sphingosine, a process that is controlled by two sphingosine kinases: SK1 and SK2. S1P is then exported out of cells where it can act on five specific receptors (S1P receptor 1 (S1PR1) to S1PR5).[6] *Fingolimod* (Gilenya, Novartis AG) is a sphingosine analog that is phosphorylated primarily by SK2 to form phosphorylated fingolimod, which is an agonist at all of the S1PRs except for S1PR2. It is a functional antagonist, which prevents lymphocyte egress from lymphoid organs and induces immunosuppression. Fingolimod is an approved drug for relapsing-remitting multiple sclerosis (MS).[6,7] It has shown efficacy in various murine models of IBD.[8–12]

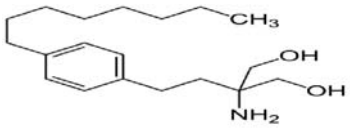
Fingolimod has unique pharmacokinetic properties. Its absorption is slow, reaching peak concentrations 8–36 h after oral administration. It has a large volume of distribution (1116–1737 L) and a clearance of about 123–383 mL min^{-1}, resulting in

Table 1 General characteristics of IBD

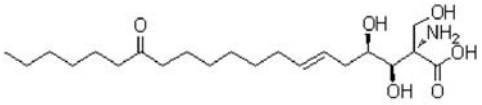
Ulcerative colitis	*Crohn's disease*
Disease is limited to colon	Disease throughout GI tract (ileum is a common site)
Continuous disease	Discontinuous disease (skip lesions)
Disease affects the mucosa and submucosa	Disease is transmural (affects all layers including the muscularis propria)
Classified as an atypical Th2 disease with a Th17 component (increased IL-13 and IL-17)	Classified as a transitional Th17 to Th1 disease (increased IL-17 and IFN-γ)

a long elimination half-life of about 108 h (4.5 days).[13] Since it is given once a day, seemingly it takes about 4 weeks to reach steady-state concentration, with 11–19-fold accumulation in tissues compared to first-dose administration.

Fingolimod belongs to the class of organic compounds known as phenylpropylamines. These are compounds containing a phenylpropylamine moiety, which consists of a phenyl group substituted at the third carbon by a propan-1-amine. It is derived from myriocin (ISP-1), a metabolite of the fungus *Isaria sinclairii* broth.[14] The structures of these compounds are shown here.

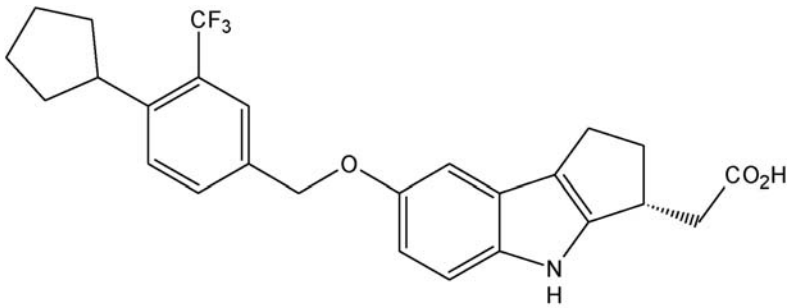


Fingolimod (FTY720) [Compound1]



Myriocin [Compound 2]

APD-334 (Arena Pharmaceuticals) is a potent functional antagonist of S1PR1.[15] APD-334 is an orally available agonist of the S1P1 receptor. S1P1 receptors have been demonstrated to be involved in the modulation of several biological responses, including lymphocyte trafficking from lymph nodes to the peripheral blood. This compound (structure shown in the succeeding text) has entered phase 2 clinical trials for UC (see **Fig. 1**).



ADP-334 [Compound 3]

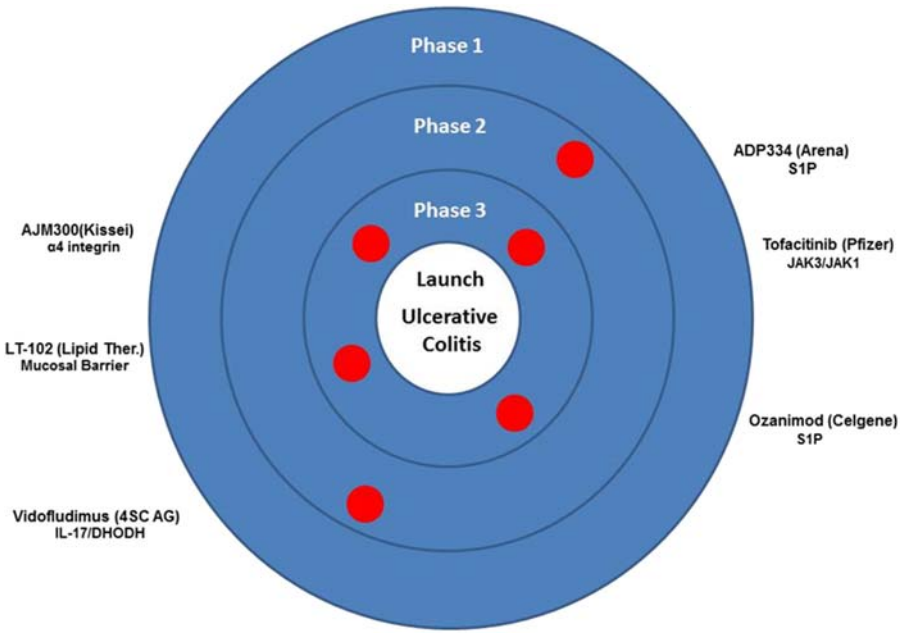


Fig. 1 This figure shows drugs that are currently in clinical trials for the treatment of ulcerative colitis (UC). The red circles within the figure show the phase of development that the drug is currently in as an UC therapeutic agent. The applicable drug, drug target, and relevant company are indicated parallel to the red circles within the figure.

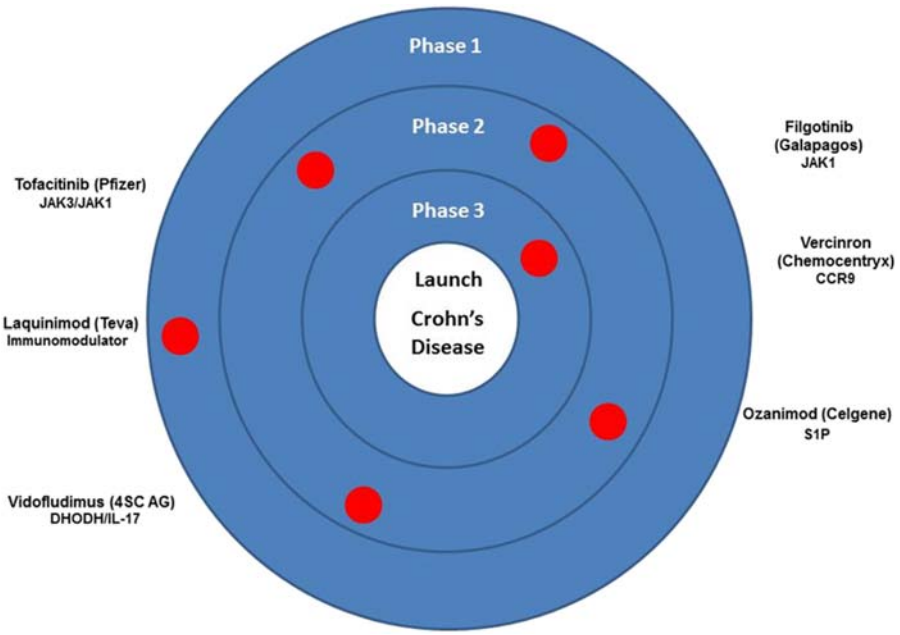

Fig. 2 This figure shows drugs that are currently in clinical trials for the treatment of Crohn's disease (CD). The *red circles* within the figure show the phase of development that the drug is currently in as a CD therapeutic agent. The applicable drug, drug target, and relevant company are indicated parallel to the *red circles* within the figure.

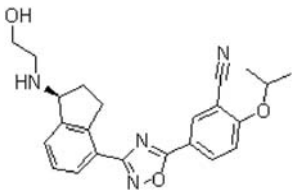
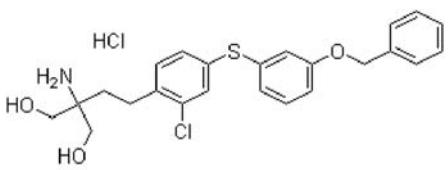
Ozanimod (RPC1063) is another S1PR1 modulator. It was discovered by Receptos (a spin-off company from Scripps Research Institute) and is currently being developed by Celgene.[6] Ozanimod has advanced to phase 3 clinical trials for UC patients (Fig. 1), as well as phase 2 clinical trials for CD (Fig. 2).



Ozanimod [Compound 4]

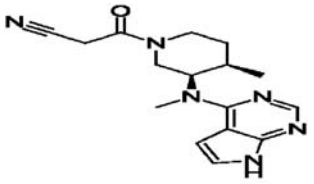
KRP-203 (Kyorin Pharmaceutical) is a S1P receptor 1, 4, 5 prodrug. Specifically, KRP-203, 2-amino-2-(2-(4-(3-benzyloxyphenylthio)-2-chlorophenyl)ethyl)-1,3-propanediol hydrochloride, is an immunosuppressant that has been identified as an agonist for S1PR1 and appears to behave similarly to fingolimod, by sequestering lymphocytes in lymphoid tissues.[16] It was effective in dextran sulfate sodium (DSS) and IL-10 knockout mouse models of IBD.[7] This compound progressed to phase 2 clinical trials. However, clinical development of the drug has apparently been discontinued in Europe and Japan.



KRP-203 [Compound 5]

5.16.2.2 JAK Inhibitors

In Nov. 2012, the Food and Drug Administration (FDA) approved *tofacitinib* (Xeljanz, Pfizer), which is a JAK inhibitor for the treatment of rheumatoid arthritis (RA). Oral tofacitinib is indicated for the treatment of active RA, in adult patients who had inadequate responses to methotrexate and/or other DMARDs. Tofacitinib is primarily a JAK1/JAK 3 inhibitor.[17] Therefore, this drug would block the production of various key cytokines (IL-2, IL-6, IFN-γ, and IL-17), which have been implicated in the pathogenesis of IBD.[17,18]

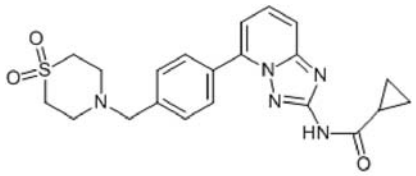


Tofacitinib [Compound 6]

Tofacitinib has shown good clinical results in a phase 2 UC trial. Specifically, Pfizer reported positive phase 2 (OCTAVE trials) results in patients with moderate to severe UC. Tofacitinib has now entered phase 3 trials (Fig. 1). In contrast, the phase 2 clinical results with tofacitinib in CD patients were not as positive. Therefore, tofacitinib is being tested in a larger phase 2B trial for CD (Fig. 2).[19]

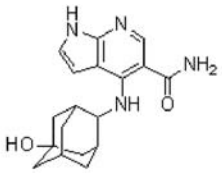
Filgotinib (Galapagos NV) is a selective JAK1 inhibitor in clinical development for CD. It is currently in a phase 2 clinical trial, which is evaluating efficacy as both an induction and maintenance therapy.[20]

Filgotinib belongs to the class of compounds known as *n*-phenylbenzamides. These are benzamides that are N-linked to a phenyl group via the carboxamide group. The structure of filgotinib is shown in the succeeding text.



Filgotinib [Compound 7]

Peficitinib (Astellas Pharma) is another JAK1 inhibitor that was in clinical development for IBD.[18] However, phase 2 clinical trials for UC have been discontinued. It is interesting that unlike filgotinib, the clinical testing of this compound focused on UC (instead of CD) patients.



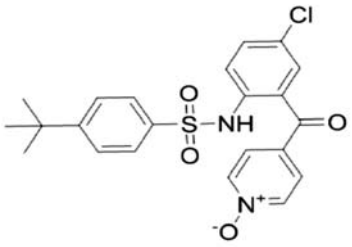
Peficitinib (ASP 015K) [Compound 8]

5.16.2.3 CCR9 Antagonists

CCR9 is a chemokine receptor expressed on memory/effector CD4 + T cells and selectively binds the chemokine CCL25. Inhibition of the CCR9/CCL25 interaction has been proposed as a therapeutic approach for CD.[21] CCR9 is a tissue-specific lymphocyte trafficking molecule that selectively attracts T lymphocytes to the intestine.

Vercirnon is an oral small-molecule CCR9 antagonist. It is a selective antagonist of the CCR9 and is being developed by GlaxoSmithKline under license from ChemoCentryx Inc. for the potential treatment of intestinal inflammatory diseases, including CD and celiac disease. Vercirnon may hasten the elimination of inflammatory T cells from the intestines, thus potentially speeding

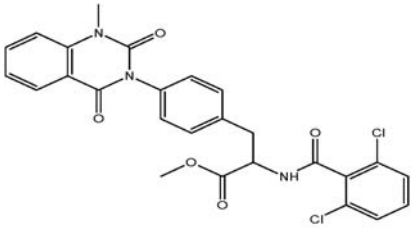
clinical recovery by reducing the longevity of flare-ups associated with IBD.[22] This drug has advanced to phase 3 clinical trials for CD.[23] The chemical structure of vercirnon is shown in the succeeding text.



Vercirnon (GSK-1605786; CCX282-B, Vercimon, Traficet-EN) [Compound 9]

5.16.2.4 Alpha (α)-4 Integrin Antagonists

AJM300 is an orally active small-molecule inhibitor of the α-4 integrin. Similarly to vedolizumab (Entyvio, Millennium Pharmaceuticals, Inc.), which is a marketed α4β7 integrin antagonist, the pharmacological goal of this approach is to block lymphocyte trafficking (via adhesion molecules) into the inflamed intestine. This compound showed efficacy in a murine IL-10-deficient T-cell transfer model of colitis.[24] AJM300 showed efficacy as an induction therapy for patients with active UC, in a phase 2a clinical trial.[25] As indicated in **Fig. 1**, AJM300 has entered phase 3 clinical studies in Japan, for the treatment of UC. Safety issues (i.e., progressive multifocal leukoencephalopathy (PML)) may be a potential concern with this pharmacological approach.[26] However, PML was not reported to be a problem in the aforementioned phase 2a clinical trial.[25]



AJM300 [Compound 10]

5.16.2.5 Immunomodulator Drugs

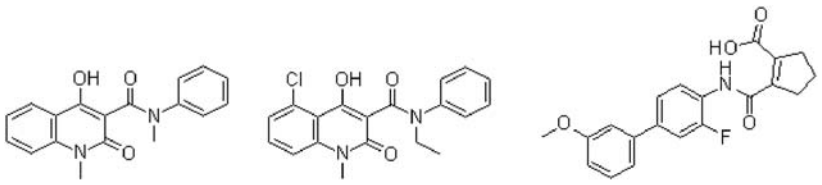
Laquinimod is an interesting orally active small-molecule immunomodulatory drug. This drug is being developed by Teva Pharmaceuticals for the treatment of various autoimmune diseases. Using an IL-10-deficient mouse model of colitis, investigators showed that laquinimod ameliorated colitis. The reduction in colonic inflammation was associated with a restoration of colonic barrier function, as well as a decrease in NF-kB signaling.[27] A recent phase 2 study demonstrated the efficacy and safety of this drug in CD patients. Laquinimod is currently in phase 3 trials for the treatment of moderate to severe CD.[28]

Laquinimod is the successor of Active Biotech's failed experimental immunomodulator linomide (Roquinimex). *Linomide* is a quinoline derivative immunostimulant that increases NK cell activity and macrophage cytotoxicity. It also inhibits angiogenesis and reduces the secretion of TNF-α. Linomide had been investigated as a treatment for some cancers (including as adjuvant therapy after bone marrow transplantation in acute leukemia) and autoimmune diseases, such as multiple sclerosis and recent-onset type I diabetes. Several trials of this drug have been terminated due to serious cardiovascular toxicity.[29]

Previous preclinical publications by the lead author demonstrated that vidofludimus (a novel immunomodulatory from 4SC AG) has a dual mechanism of action. Specifically, vidofludimus can (1) reduce colonic IL-17 production by inhibiting STAT3 and NF-kB activation and (2) act as a DHODH (dihydroorotate dehydrogenase) inhibitor, which attenuates T-cell expansion in the colon.[30,31] This compound was effective in mouse DSS and TNBS models, as well as a rat model of TNBS-induced colitis.[30,31] Vidofludimus showed good efficacy and safety in an initial phase 2A European IBD clinical trial, involving both CD and UC

patients.[32] This clinical trial showed an 88.5% response rate for patients with IBD.[32] Further clinical testing of vidofludimus is anticipated in 2016.

The structures of these three immunomodulatory drugs are shown in the succeeding text.



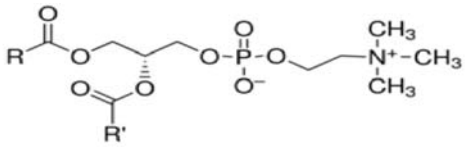
Linomide (Roquinimex) [Compound 11]

Laquinimod [Compound 12]

Vidofludimus [Compound 13]

5.16.2.6 Mucosal Barrier Enhancer Drug

LT-102 is an interesting small-molecule compound that is under development for IBD by Lipid Therapeutics. Essentially, it is a retarded-release phosphatidylcholine-rich phospholipid agent. In this regard, the mucus layer coating the GI tract is predominantly composed of water, glycoproteins, lipids, other proteins, and nucleic acids.[33] Phospholipids, although minor constituents of the GI mucus, are indispensable for the maintenance of an intact barrier function where they play a role in establishing the hydrophobic surface by virtue of their amphipathic nature.[34] Phosphatidylcholine (PC), the major mucus phospholipid, has been found to be substantially reduced in the mucus of patients with UC compared with patients with CD and healthy controls, independent of the state of inflammation.[35] A lack of PC could result in a reduction in surface hydrophobicity, enabling the invasion of luminal noxious agents. However, by virtue of being integrated in the plasma membranes of enterocytes, PC also participates in various potential pro-inflammatory pathways including tumor necrosis factor-α (TNF-α) signaling, activation of NF-kB cytokine expression, and mitogen-activated protein kinase.[36] Based on its inherent structural role in the colonic mucosa, it has been hypothesized that PC reconstitution (by LT-102) in the colonic mucus of patients with UC could help to restore the structure and density of the mucus, improving the barrier function and preventing inflammation in UC.[37] The goal of this phosphatidylcholine agent is to improve mucosal barrier function in patients with mild/moderate UC. According to a company release statement, LT-102 will enter phase 3 trials for UC in 2016.[38]



R, R' = fatty acid residues

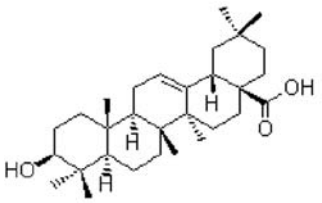
L-α-Phosphatidylcholine (LT-102) [Compound 14]

5.16.3 Novel Small-Molecule Approaches for IBD: Preclinical Results

5.16.3.1 Synthetic Triterpenoids

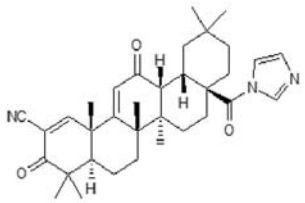
Synthetic triterpenoids (like *CDDO-Im/CDDO imidazolide*, Geisel School of Medicine, Dartmouth College) can inhibit activation of the STAT3 and NF-kB pathways.[39,40] Interestingly, synthetic triterpenoids also upregulate the expression of nuclear factor E2-related factor 2 (Nrf2), which positively regulates the levels of important antioxidant enzymes like heme oxygenase-1 (HO-1).[41] Previous results from the lead author's laboratory showed that CDDO-Im could effectively inhibit colonic STAT3 activation and attenuate various parameters of acute DSS-induced colitis in mice.[42] Another synthetic triterpenoid (*CDDO-Me/bardoxolone*) suppressed the development of colitis-associated cancer (CAC) in mice.[43] As a whole, these data suggest that synthetic triterpenoids could be an interesting therapeutic approach in patients with IBD. However, a phase 3 clinical trial (by Reata Pharmaceuticals) evaluating bardoxolone for the treatment of chronic kidney disease was terminated, when drug-treated patients were found to have a higher rate of heart-related adverse events.[44] In a more recent phase 2 study for patients with pulmonary arterial hypertension, the drug was relatively well tolerated with no serious adverse events.[45] Nevertheless, with regard to the potential development of any synthetic triterpenoids for IBD, safety considerations would be a top priority during ongoing clinical trials.

From a chemical perspective, compounds belonging to the most potent molecules of oleanolic derivatives include 2-cyano-3,12-dioxooleana-1,9(11)-dien-28-oic acid (CDDO) and its C-28 methyl ester, CDDO-Me. Both compounds have enone functions in their A- and C-rings and an electron-withdrawing nitrile group at the C-2 position in the A-ring.[46] A chemical feature shown to be essential for the activity of the synthetic triterpenoids focuses on the electron-withdrawing nitrile group that activates the A-ring enone, thereby allowing it to serve as an acceptor of a Michael addition to covalently, but reversibly, bind activated sulfhydryl groups of cysteine residues in protein targets.[47] Relevant chemical structures are shown in the succeeding text.



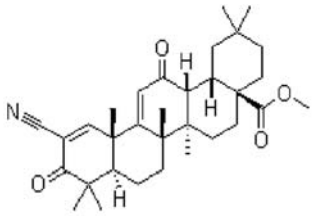
Oleanolic acid (Oleanic acid)

[Compound 15]



CDDO Im

[Compound 16]



Bardoxolone methyl (CDDO-Methyl ester)

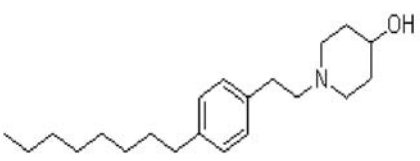
[Compound 17]

5.16.3.2 ROR-γT Inhibitors

Retinoic acid-related orphan nuclear receptor gamma T (ROR-γT) is the key transcription factor for IL-17 expressing cells. Importantly, ROR-γT expression is upregulated in various animal models of colitis.[48] Recent data showed that various parameters of TNBS-induced colitis were improved by treatment with VPR-7 (a specific small-molecule ROR-γT inverse agonist, discovered by Visionary Pharmaceuticals).[48] Theoretically, VPR-7 could also block the transcription of possible pro-inflammatory receptors (IL-23R) cytokines (IL-17 and IL-21) and chemokines (CCL20) putatively involved in the pathogenesis of IBD.[48,49] Development of ROR-γT inhibitors may be an interesting approach for IBD (particularly as a maintenance therapy), as recent data suggest that Th17 cells (due to plasticity) can be converted to atypical Th1 cells during the pathogenesis of IBD.[4,5] Various pharmaceutical companies have focused on ROR-γT as a therapeutic target during the past 5 years. In this regard, Lycera and Merck previously announced an agreement (in 2011) to develop an alliance targeting ROR-γT for the treatment of autoimmune disease.[50]

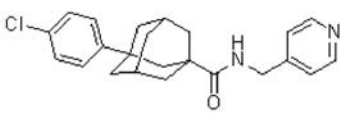
5.16.3.3 Sphingosine Kinase Inhibitors

As mentioned earlier, sphingosine kinase (SK) catalyzes the formation of S1P from sphingosine. SK inhibitors like ABC294640 (discovered by Apogee Biotechnology and being developed by RedHill Biopharma) have shown efficacy in rodent models of colitis and colitis-associated cancer.[51–53] The potential utility of SK inhibitors as drugs for IBD was discussed in previous papers.[54,55] Selective small-molecule inhibitors of SK1, like *RB-005* and analogs (originally discovered by Queens College, The City University of New York), would be interesting compounds to test in IBD models.[56] RB-005 is selective inhibitor of SK1 over SK2. The hydroxyl group in the heterocyclic ring is important for inhibition of SK1 by RB-005. Replacement of the 4-OH group with a 4-methyl group yields a moderate inhibitor of both SK1 and SK2, whereas the 3-OH region isomer is a selective but less potent SK1 inhibitor.[57] The structure of RB-005 is shown in the succeeding text.



RB-005 (1-(4-octylphenethyl) piperidin-4-ol)

[Compound 18]



ABC294640

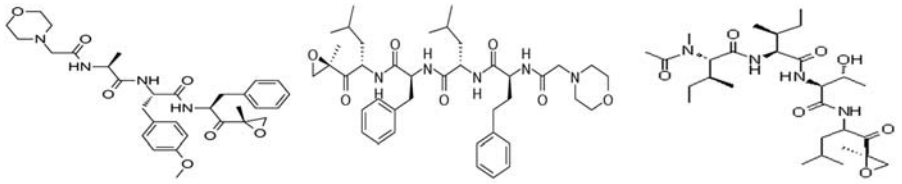
[Compound 19]

5.16.3.4 Immunoproteasome Subunit Inhibitors

Exposure of cells to pro-inflammatory cytokines (IFN-γ, IL-1β, and TNF-α) causes the replacement of constitutive catalytic proteasome subunits with immunoproteasome subunits. These immunoproteasome subunits (low molecular mass polypeptide (LMP)2 (b1i), multicatalytic endopeptidase complex-like-1 (b2i), and LMP7 (b5i)) have been implicated in the pathogenesis of colitis.[58,59]

Of note, a novel small-molecule LMP7-selective inhibitor (*PR-957*, or *ONX-0914*, which was originally discovered by Proteolix Inc.) strongly reduced the symptoms of DSS-induced colitis in mice, following IV administration of the compound.[59] Interestingly, treatment with PR-957 also attenuated the expression of key cytokines (IL-6, TNF-α, IL-23, and IL-17) associated with this colitis.[60] Some previous review papers have discussed the potential utility of immunoproteasome subunit inhibitors for the treatment of chronic inflammatory diseases like IBD.[54,61]

Carfilzomib (PR-171, discovered by Proteolix Inc. and developed by Onyx Pharmaceuticals) is an approved drug for multiple myeloma. It is a modified tetrapeptidyl epoxide and an analog of epoxomicin (see structures in the succeeding text).



PR-957 (ONX-0914) [Compound 20]

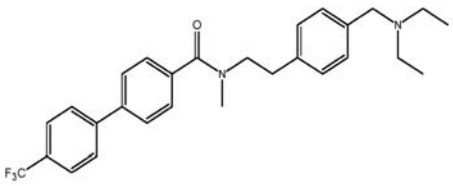
Carfilzomib (PR-171) [Compound 21]

Epoxomicin [Compound 22]

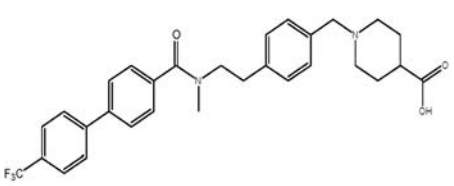
It is also a selective proteasome inhibitor. Carfilzomib irreversibly and selectively binds to *N*-terminal threonine-containing active sites of the 20S proteasome, the proteolytic core particle within the 26S proteasome. This 20S core has 3 catalytic active sites: the chymotrypsin, trypsin, and caspase-like sites. Inhibition of the chymotrypsin-like site by carfilzomib (particularly the β5i subunit) is the most effective target in decreasing cellular proliferation, ultimately resulting in cell cycle arrest and apoptosis of cancerous cells. At higher doses, carfilzomib reportedly will also inhibit both the trypsin- and caspase-like sites.[62]

5.16.3.5 Melanin-Concentrating Hormone (MCH) Receptor 1 Antagonists

MCH is a peptide that is produced in both the brain and the GI tract.[63] Previous work from the lead author's laboratory showed that two small-molecule MCH receptor 1 antagonists (DABA-821 and DABA-822, originally discovered by Procter & Gamble Pharmaceuticals, Inc.) attenuated various parameters of TNBS-induced colitis in mice.[64] However, DABA-822 was not effective in mice with established colitis due to IL-10 deficiency.[65] Further studies with specific MCH receptor 1 antagonists are needed in other animal models of IBD, in order to better understand the true clinical potential of this pharmacological approach.[66–68] The structures of these DABA compounds are shown here.



DABA-821 [Compound 23]

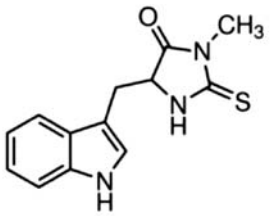


DABA-822 [Compound 24]

5.16.3.6 Receptor-Interacting Protein Kinase 1 (RIP1 and RIP3) Inhibitors

A recent review paper suggested that receptor-interacting protein kinase 1 (RIP1 and RIP3) played a role in the control of apoptosis and inflammatory cytokine production, independent of the traditional role in necrosis.[69] Liu and colleagues found that necrostatin 1 (a specific inhibitor of RIP1 and RIP3) attenuated various parameters of acute DSS-induced colitis in mice.[70] Other investigators have suggested that the development of RIP kinase 1 inhibitors may be an effective pharmacological approach for the treatment of

IBD.[71] Necrostatin 1 was originally discovered by academic investigators at Tufts University. The structure of necrostatin1 is shown in the succeeding text.



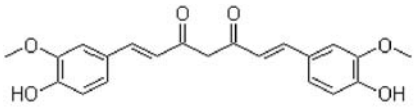
Necrostatin 1 or 5-(1H-indol-3-ylmethyl)-3-methyl-2-thioxo-4-Imidazolidinone [Compound 25]

5.16.4 Natural Product-Derived Small-Molecule Approaches for IBD

An excellent review article recently summarized various botanical drugs, which may be potentially used in the treatment of IBD.[72] When considering this approach, it is important to remember that the development of natural products as primary therapies for IBD would likely require the isolation of an individual active component from the plane extract. An example is curcumin.[72]

5.16.4.1 Curcumin

Curcumin is the main active component of *Curcuma longa* (Zingiberaceae), commonly known as turmeric. Several pharmacological activities have been reported for curcumin, including antioxidant, antimicrobial, anticancer, and anti-inflammatory properties.[73] It has three vital functionalities central to its biological activities including an aromatic *o*-methoxy phenolic group, α, β-unsaturated β-diketo moiety, and a seven-carbon linker (see structure in the succeeding text). Extensive research in the last two decades has provided evidence for the role of these different functional groups in its crucial biological activities.



Curcumin (Diferuloylmethane) [Compound 26]

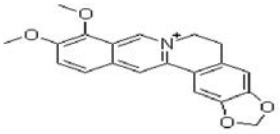
Curcumin has demonstrated efficacy in different experimental models of colitis.[74–77] The anticolitis mechanism of action for curcumin may be related to the inhibition of p38 MAPK and/or NF-kB.[72,77] Of note, clinical studies have shown that curcumin has demonstrated some evidence of efficacy for the treatment of IBD.[72,78] A very recent clinical study showed that curcumin plus mesalamine therapy was superior to the combination of placebo and mesalamine for inducing remission in patients with mild/moderate UC.[79] Other postulated mechanisms of actions for curcumin are due to its ability to scavenge free radicals and modify multiple signaling pathways (especially MAPK and ERK), thereby affecting the expression of different proteins implicated in the intestinal inflammatory cascade, like MPO, COX-2, iNOS, or LOX.[80]

5.16.4.2 Berberine

Berberine is an interesting compound, which is derived from various plants. It is an alkaloid isolated mainly from *Hydrastis canadensis*. Berberine is also found in many other plants. It is relatively toxic parenterally but has been used orally for various parasitic and fungal infections and as antidiarrheal agent.[81] Berberine belongs to the class of organic compounds known as protoberberine alkaloids and derivatives. These are alkaloids with a structure based on a protoberberine moiety, which consists of a 5,6-dihydrodibenzene moiety fused to a quinolizinium and forming the 5, 6-dihydrodibenzo (a, g) quinolizinium skeleton (see the structure in the succeeding text).

Berberine inhibits both NF-kB and STAT3 pathways.[82] The lead author (and others) proposed that these two intracellular pathways could be important in the pathogenesis of IBD and CAC.[54,83] Numerous studies have shown berberine to

be effective in rodent models of IBD.[82,84–87] This compound would appear to be an interesting candidate for future testing in IBD patients.

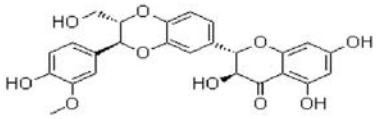


Berberine (5,6-Dihydro-9,10-dimethoxybenzo[g]-1,3-benzodioxolo[5,6-a]quinolizinium) [Compound 27]

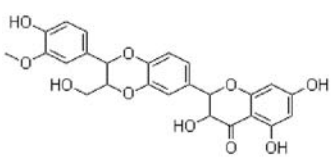
5.16.4.3 Silibinin

Silymarin is an extract of milk thistle seeds. Silymarin's primary constituents are the flavonolignan isomers silybins A and B, isosilybins A and B, silychristin (also known as silichristin), silydianin (also known as silidianin), and their flavonoid precursor, taxifolin. In the literature, the mixture of the silybins A and B is often referred to as silibinin. These compounds exist as equimolar mixtures as trans diastereoisomers. These diastereomers have very similar ^{1}H and ^{13}C NMR spectra and have no characteristic signals for facile identification of the individual isomers.[88] A number of other chemically related compounds have been found in the fruits including dehydrosilybin, desoxysilychristin, desoxysilydianin, silandrin, silybinome, silyhermin, and neosilymermin. The common feature of these compounds is a flavonolignan skeleton ($C_{25}H_{22}O_{10}$, MW 482). Basically, flavonolignan nucleus consists of the dihydroflavonol taxifolin linked to coniferyl alcohol moiety through an oxeran ring. The oxeran ring is responsible for the biological activity of silymarin, and opening of this ring results in loss of activity. Only silybins and isosilybins contain the 1,4-dioxane ring system in their structure. Silybin and isosilybin have the same trans conformation of C-2, C-3, and C-7′ and C-8′. Silybin is considered the major and most active component in silymarin.[89]

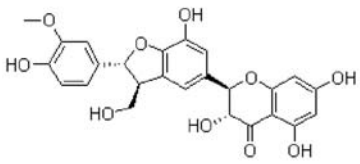
These compounds are known for their antioxidant and anti-inflammatory properties.[90] Human clinical trials have investigated milk thistle or silymarin primarily in individuals with hepatitis or cirrhosis, although small studies have been reported about individuals with acute lymphoblastic leukemia, prostate cancer, breast cancer, and hepatocellular carcinoma.[91] With relevance to this article, silibinin was effective in a rat model of hapten-induced colitis.[92] The chemical structure of silibinin and other silymarin constituents is shown in the succeeding text.



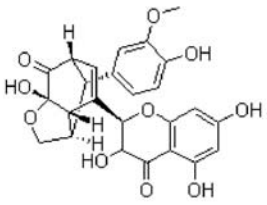
Silibinin (Silybin) [Compound 28]



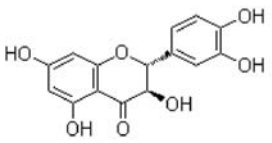
Isosilybin (Isosilibinin) [Compound 29]



Silychristin (Silicristin) [Compound 30]



Silydianin (Silidianin) [Compound 31]



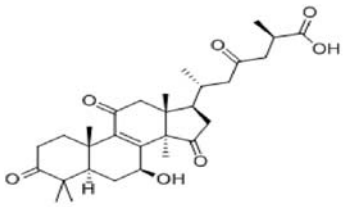
Taxifolin [Compound 32]

5.16.4.4 Triterpene Ganoderic Acid C1 (GAC1)

Ganoderic acid C1 (GAC1) is a triterpenoid that has been isolated from *Ganoderma lucidum* (*reishi*), which is the lingzhi mushroom.[93] There are many ganoderic acids that have been isolated and characterized, of which ganoderic acid A and ganoderic acid B are the best characterized. GAC1 belongs to the class of compounds known as tirucallane and euphane triterpenoids with

a structure based on either the tirucallane or the euphane skeleton. These compounds are obtained by backbone rearrangement of a dammarane-based precursor molecule.[94]

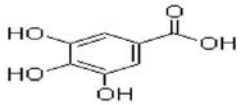
GAC1 decreased TNF-α production by macrophages from CD patients. It also decreased pro-inflammatory cytokine production (TNF-α, IL-17, and IFN-γ) by inflamed colonic biopsied from CD patients. These effects were related to inhibition of the NF-kB pathway.[93] GAC1 should undergo future testing in animal models of IBD.



Ganoderic Acid C1 (GAC1) [Compound 33]

5.16.4.5 Gallic Acid

Gallic acid is a phenolic compound also known as 3,4,5-trihydroxybenzoic acid. It is found both as a free state and as a constituent of tannins, namely, gallotannin. Gallic acid and its derivatives are present in nearly every part of the plant, such as bark, wood, leaf, fruit, root, and seed.[95] Gallic acid has been shown to effectively suppress DSS-induced colitis in mice. Intriguingly, the anticolitis effect was attributed to the suppression of colonic NF-kB and STAT3 activation.[54,96] Here is the structure of gallic acid.



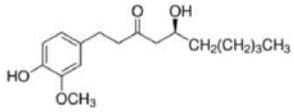
Gallic acid (3, 4, 5-Trihydroxybenzoic acid; Pyrogallol-5-carboxylic acid) [Compound 34]

5.16.4.6 Diallyl Sulfide

Diallyl sulfide (di-2-propenyl sulfide, DAS) belongs to the class of organosulfur compounds known as dialkylthioethers, containing a thioether group that is substituted by two alkyl groups. Diallyl sulfide is found in animal foods, *Allium* species (garlic oil), Japanese horseradish (*Wasabia japonica*), and black mustard (*Brassica nigra*) powder and cooked beef. Diallyl sulfide has antioxidant and anti-inflammatory activities. Like other natural product-derived compounds cited in this article, the compound inhibits inflammatory signaling mediated by NF-kB and STAT3.[97,98] This small-molecule compound was also effective after oral administration for attenuating DSS-induced colitis in mice.[98]

Diallyl sulfide (Allyl sulfide) [Compound 35]

5.16.4.7 6-Gingerol



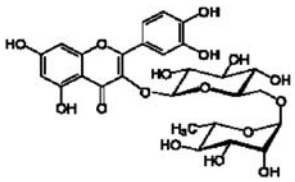
6-Gingerol [Compound 36]

Gingerols are phenolic compounds in ginger (*Zingiber officinale Roscoe*, *Zingiberaceae*). Gingerols are the most abundant pungent compounds in fresh roots, and several gingerols of various chain lengths (n6 to n10) are present in ginger, with the most abundant being 6-gingerol.[99] These compounds have antioxidant and anti-inflammatory activities.[100] 6-Gingerol, a pungent ingredient of ginger, has a wide array of pharmacologic effects. 6-Gingerol has been tested in the murine DDS-colitis model. Two separate

laboratories demonstrated the efficacy of 6-gingerol against this colitis. One group attributed the anticolitis activity to activation of adenosine monophosphate-activated protein kinase (AMPK) activity.[100,101]

5.16.4.8 Rutin

Rutin (rutoside or quercetin-3-*O*-rutinoside) is a flavonoid contained in many plants. The major sources of rutin for medical use include buckwheat, Japanese pagoda tree, and *Eucalyptus macrorhyncha*. It is thought to be an antioxidant, a free radical scavenger, and an iron-chelator working similarly to the antioxidant mechanism of 5-ASA.[102,103] After oral administration, rutin is hydrolyzed in the GI tract to release quercetin, which is responsible for many of the actions of rutin. The structure of rutin is shown here.



Rutin (quercetin-3ß-D-rutinoside) [Compound 37]

Animal studies suggest rutin has anti-inflammatory activity against TNBS-induced colitis in rats, as well as T-cell transfer colitis in mice.[104,105]

The inhibitory effects of natural products on the expression of pro-inflammatory cytokines (e.g., tumor necrosis factor-α (TNF-α)), intercellular adhesion molecule expression and pro-inflammatory mediators (such as inducible nitric oxide synthase (iNOS) and cyclooxygenase 2 (COX2)), master transcription factors (such as nuclear factor-kB (NF-kB)), and reactive oxygen species (ROS) (summarized earlier) and their utmost safety profile suggest that they have encouraging potential for the treatment of IBD. However, randomized controlled clinical investigations in large cohorts of patients are needed to fully evaluate the clinical potential of these compounds. It is possible that some of these natural products may find utility as adjunct therapies in IBD patients. In this regard, clinical trials that examine the efficacy of natural products in combination with traditional IBD drugs (e.g., 5-aminosalicylate derivatives and corticosteroids) are eagerly anticipated in the future.

5.16.5 Summary: Small-Molecule Compounds for IBD Therapy

Over the last decade, some degree of success has been achieved in developing biological drugs (monoclonal antibodies) for treating patients with IBD. Recently, new small-molecule inhibitors have also been developed for chronic inflammatory diseases like IBD. It is anticipated that over the next 5 years, some of the small-molecule drug approaches described in this article will find utility for the treatment of IBD. In this regard, the results of relevant and ongoing clinical studies are eagerly awaited in 2016.

5.17.1 Introduction

Since their introduction into clinical medicine over 70 years ago, perhaps no drugs have had more impact on both quantity and quality of human life than antibiotics.[1] Formerly fatal bacterial infections could now be cured relatively rapidly and completely in the majority of cases. Yet very soon after antibiotics were introduced, resistance to these drugs was observed in a number of pathogens.[2] The pharmaceutical industry was able to keep ahead of this resistance issue by a combination of discovery and development of new agents/novel classes and modifications of old ones. However, as we move into the early 21st century, the bacteria are steadily gaining ground such that occasional clinical isolates are now observed that are essentially untreatable.[3–6] There is increasing discussion of the possibility of returning to a pre-antibiotic era with increased incidence of mortality due to previously curable infections.

Antibiotic resistance genes are located both on the bacterial chromosome and, increasingly, on transmissible extrachromosomal elements.[7] Important resistant clones such as methicillin-resistant *Staphylococcus aureus* (MRSA) USA300,[8] *Escherichia coli* ST131,[9] and *Klebsiella pneumoniae* ST258[10] have disseminated rapidly worldwide in recent years. This spread has been facilitated by a combination of factors including interspecies gene transmission, poor sanitation and hygiene in communities and hospitals, and the increasing frequency of global travel. Diseases that formerly would have remained isolated are now just a plane ride away from the rest of the world.

[a]Data from Center for Disease Dynamics, Economics & Policy http://resistancemap.cddep.org/ except where noted.

Key recent examples of notable resistance spread are summarized on a topline level in **Table 1**.[11,13] These examples include antibiotic-resistant *Neisseria gonorrhoeae*, which emerged in Vietnam in 1967, then spread to the Philippines, and finally to the United States and other parts of the world where it is becoming a major health concern.[14–16] The New Delhi metallo-β-lactamase-1 (NDM-1) enzyme, first reported in 2008, has now spread worldwide.[17] A study found NDM-1-producing bacteria (including *Shigella boydii* and *Vibrio cholera*) in 2 (4%) of 50 drinking water samples and 51 (30%) of 171 seepage samples in New Delhi, India, indicating the possibility of acquiring resistance outside healthcare facilities.[18] Finally, increasing rates of resistance to colistin and polymyxin B, often treatments of last resort for Gram-negative organisms, are being reported from countries around the world, including South Korea, Italy, Greece, and Saudi Arabia.[19] The recent discovery of the plasmid-encoded *mcr-1* gene, conferring colistin resistance, in animals and humans in China is a truly disturbing finding and this gene has since been found in other areas of the world as well.[20] Moreover, there is some evidence of cross-resistance to colistin and host antimicrobial peptides that are part of the body's immune response.[21] More detailed descriptions of these examples along with others are found here.

Other factors influence the continued spread of antibiotic resistance in the world today. The sheer breadth of antibiotic usage is itself an important driver: these drugs are among the most commonly purchased and are widely available in a number of countries without a physician's prescription. As a result worldwide antibiotic consumption continues to increase, exerting constant selective pressure for expanded resistance. There have been attempts at antibiotic stewardship in recent years by curbing the unnecessary use of these drugs and some successes have been achieved in recent years.[22] However, the usage trends remain of concern, and certainly more needs to be done to preserve the utility of these valuable agents. In this article, recent resistance trends for major antibacterial,

antifungal, and antiviral agents will be described as well as additional updates on selected key pathogens. For bacteria, we have divided the discussion into updates for selected drug classes and updates on selected key pathogens.

5.17.2 Antibacterial Resistance

5.17.2.1 Selected Drug Classes

5.17.2.1.1 β-Lactam resistance

β-Lactam antibiotics represent one of the oldest, and currently most prescribed classes of antibacterial agents in clinical use (Fig. 1).[23] The β-lactams include penicillins (**1**), cephalosporins (**2**), carbapenems (**3**), and monobactams (**4**), all of which are originated from natural products. Most pathogenic bacteria are intrinsically susceptible to at least one of the β-lactam subgroups, although serious resistance to these drugs has emerged in all bacterial species. The β-lactams are bactericidal agents that kill bacteria by interrupting peptidoglycan (cell wall) biosynthesis. Their targets are penicillin-binding proteins (PBPs) that exhibit transglycosylase/transpeptidase or carboxypeptidase activities in both Gram-positive and Gram-negative bacteria.[24] The PBPs are found anchored in the cytoplasmic membrane but are extracytoplasmic; in Gram-negative bacteria, they extend into the periplasmic space. Thus, access to the killing targets for β-lactams is somewhat more facile than for other antibiotics that must enter the cytoplasm.

Penicillins such as penicillin G (**5**) and cloxacillin (**6**) were initially developed to treat infections caused by Gram-positive bacteria, but as Gram-negative bacteria became more prominent, broad-spectrum penicillins such as amoxicillin (**7**) and antipseudomonal penicillins such as piperacillin (**8**) were introduced. Cephalosporins with activity against methicillin-susceptible staphylococci (MSSA) included the early agents like cefazolin (**9**), but have recently been displaced by the "anti-MRSA cephalosporins" ceftobiprole (**10**) and ceftaroline (**11**). The early cephalosporins were followed by the introduction of "expanded-spectrum" cephalosporins cefotaxime (**12**), ceftazidime (**13**), and cefepime (**14**) with potent activity against Gram-negative bacteria. The monobactam aztreonam (**15**) has dedicated anti-Gram-negative activity similar to ceftazidime, but with less potency against current *Pseudomonas aeruginosa* strains. Carbapenems, such as imipenem (**16**) and meropenem (**17**), are considered to be the most potent of the β-lactams, with broad-spectrum activity encompassing MSSA, the streptococci, enteric bacteria, nonfermentative bacteria, and anaerobes.[23]

Because β-lactams are found commonly in the environment,[25] it was not unexpected that β-lactam resistance determinants were identified in ancient sources.[26] Resistance can be due to any or all of the three major factors: (a) modification of an essential PBP target; (b) decreased concentration of the antibiotic at the target site due to increased efflux or decreased penetrability; and (c) enzymatic inactivation of the β-lactam. In the staphylococci, the major β-lactam resistance determinant is conferred by the *mecA* gene that encodes PBP2a, a PBP with low affinity for almost all β-lactam antibiotics with the exception of the recently introduced ceftobiprole and ceftaroline. It is assumed that the *mecA* gene was originally introduced into MRSA from environmental isolates of *Staphylococcus sciuri*.[27] Decreased cellular β-lactam concentrations are important in Gram-negative bacteria, where defective outer membrane proteins can limit the amount of β-lactam that can enter the periplasmic space where the PBPs are located, or where efflux mechanisms serve to pump out intact β-lactam molecules. However, the most common β-lactam resistance mechanism is enzymatic hydrolysis of the β-lactam ring by β-lactamases. Before penicillin was introduced for use in the military during World War II, resistance due to the production of a penicillin-inactivating enzyme had been reported in a strain of "*Bacillus coli*" (or *E. coli*) that had not been exposed to penicillin.[28] Similar penicillin-inactivating activity was soon recognized in staphylococcal clinical isolates from patients treated with the drug.[29] Today β-lactamases are found in $>80\%$ of staphylococcal clinical isolates[30] and are the most frequent β-lactam resistance determinant identified in Gram-negative bacteria. To date more than 2100 unique, naturally occurring β-lactamases have been identified (Bush, personal communication). The most important classes include the penicillinases in staphylococci and many enteric bacteria, the chromosomal AmpC cephalosporinases in Gram-negative bacteria, the extended-spectrum β-lactamases (ESBLs), and the carbapenemases, which encompass those with serine at the active and those that are zinc-containing metallo-β-lactamases (MBLs).[31]

Epidemiological studies show that penicillins are still effective therapeutic agents against some Gram-positive bacteria, including β-hemolytic streptococci.[32–34] Ampicillin (**18**) retains $>90\%$ susceptibility among *Enterococcus faecalis* worldwide,[35,36] but has little useful activity against vancomycin-resistant strains, especially *Enterococcus faecium*.[37] Among the staphylococci, MSSA is usually susceptible to the penicillinase-stable penicillins such as cloxacillin and to cephalosporins such as cefazolin and carbapenems,[38,39] but, with the exception of ceftaroline and ceftobiprole, β-lactams are not effective against MRSA.[40] The "anti-MRSA cephalosporins" generally exhibit susceptibility against $>85\%$ of isolates at their respective susceptible breakpoints (minimum inhibitory concentrations, or MICs <1 μg mL^{-1} for ceftaroline[41,42] and <2 μg mL^{-1} for ceftobiprole[43]). However, recent studies have identified a set of MRSA isolates in Switzerland, the Asia-Pacific region and Africa with MICs for these cephalosporins elevated two- to fourfold higher than the susceptibility breakpoints in strains with missense mutations in PBP2a.[42,43] Susceptibility to penicillin in *Streptococcus pneumoniae* varies by geographic location, with susceptibility as low as 42.9% in Japan[40] to 91% in Europe.[44] Recent increases in penicillin susceptibility in Europe and the United States have been attributed to the introduction of the 13-valent pneumococcal conjugate vaccine.[44,45]

β-Lactamase-mediated resistance is a major factor in the Gram-negative bacteria. Most enteric and nonfermentative bacteria produce a species-specific AmpC-type cephalosporinase that can be produced constitutively at high enzyme concentrations, or that can be induced by β-lactam antibiotics.[46] AmpC enzymes have escaped onto high copy plasmids that ensure elevated levels of these enzymes that confer resistance to many penicillins and cephalosporins, as well as carbapenems when combined with a porin defect. In addition, production of the ESBLs has ensured resistance to almost all β-lactam antibiotics with the exception of the

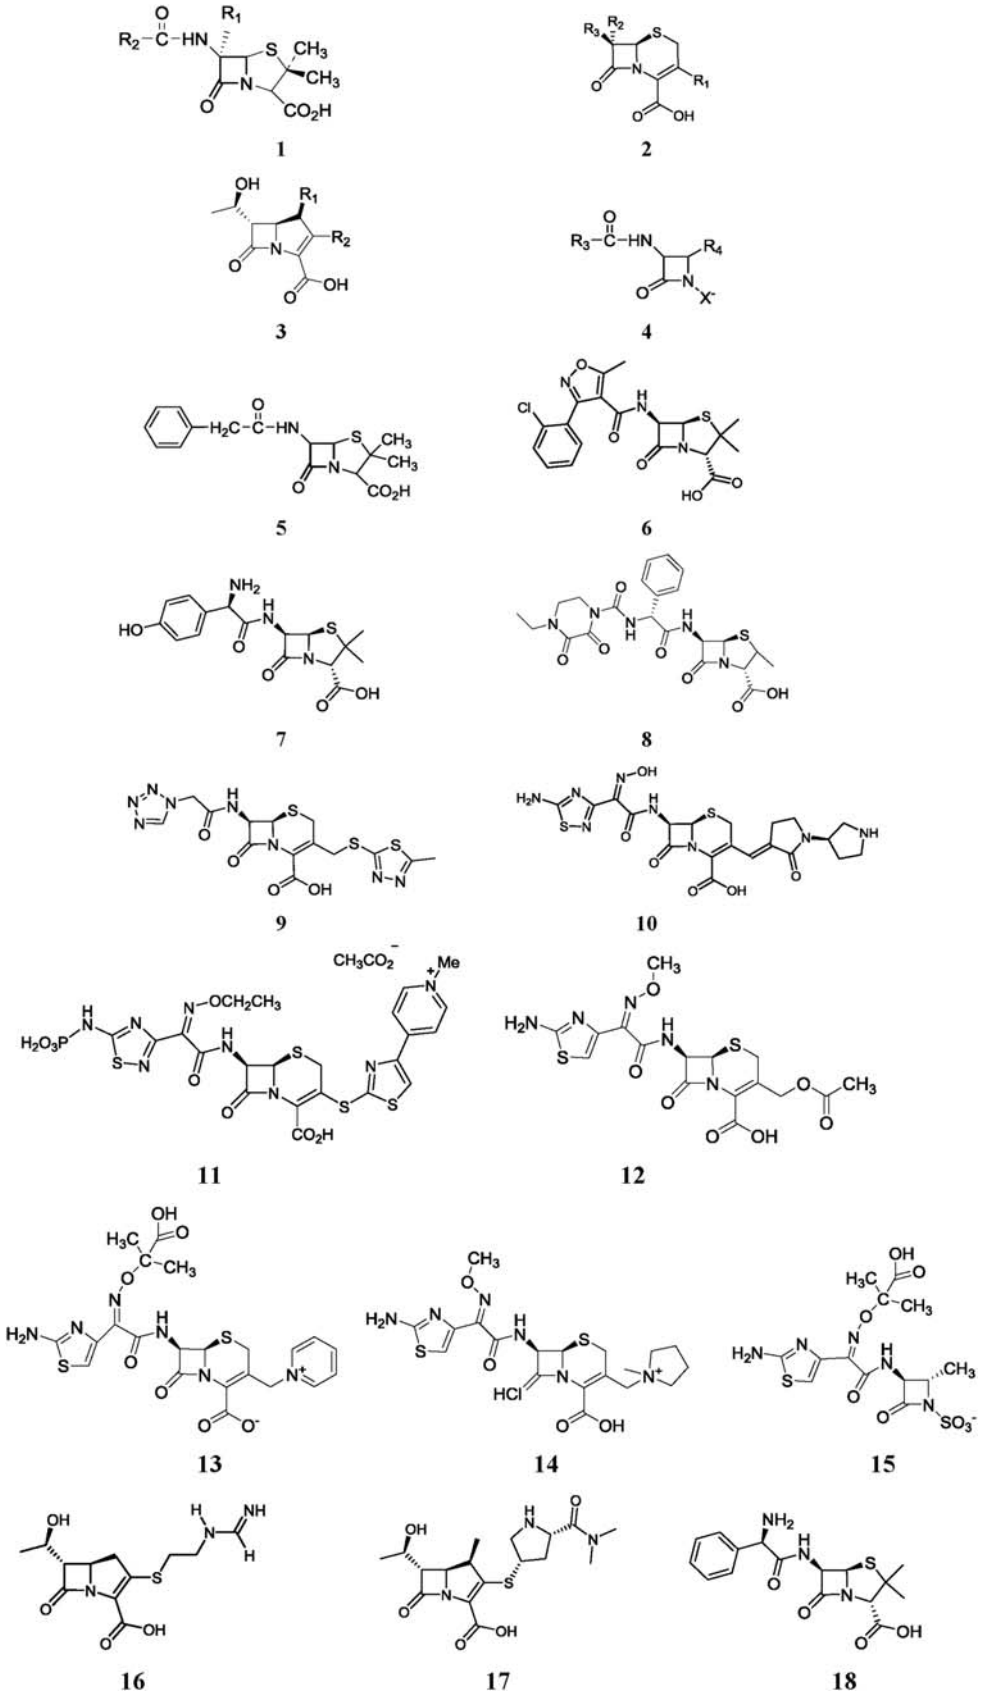

Fig. 1 β-Lactam antibiotics: **1** penicillins, **2** cephalosporins, **3** carbapenems, **4** monobactams, **5** penicillin G, **6** cloxacillin, **7** amoxicillin, **8** piperacillin, **9** cefazolin, **10** ceftobiprole, **11** ceftaroline, **12** cefotaxime, **13** ceftazidime, **14** cefepime, **15** aztreonam, **16** imipenem, **17** meropenem, **18** ampicillin.

carbapenems.[47] These enzymes are usually found on mobile elements that can be readily transferred among the enteric and nonfermentative bacteria. Cephalosporin resistance due to ESBL-producing Enterobacteriaceae isolated from healthy individuals ranges from 2% in the Americas to 46% in the Western Pacific region.[48] In Japan, $<5\%$ of *K. pneumoniae* isolates from complicated urinary tract infections (UTIs) produce ESBLs,[49] compared to China (60%) and Thailand (71.4%) for similar isolates.[50] These latter rates are similar to southern European countries like Greece and Bulgaria where 70–75% of invasive *K. pneumoniae* isolates exhibit resistance to expanded-spectrum cephalosporins (European Centre for Disease Prevention and Control, 2015). ESBL-related resistance in *E. coli* is similar to that seen for *K. pneumoniae* for the Asia-Pacific region, but is generally less in European isolates; Greece and Bulgaria report 21.0% and 40.4% cephalosporin resistance in invasive *E. coli* isolates, respectively (European Centre for Disease Prevention and Control, 2015). Notably, ESBL-producing isolates usually retain full susceptibility to carbapenems.[50] Unfortunately, the latter have become the latest to fall victim to the critical β-lactamase-related resistance mechanisms in Gram-negative pathogens, as plasmid-encoded serine and zinc-containing MBLs have emerged capable of hydrolyzing virtually all β-lactams and especially carbapenems.[51] These enzymes usually travel with other resistance determinants to create Gram-negative pathogens that are multidrug-resistant (MDR).[52] Further information about these β-lactamases is discussed in Section **β-Lactamase Inhibitor Resistance** in this article.

5.17.2.1.2 β-Lactamase Inhibitor Resistance

In an attempt to circumvent the hydrolytic activity of the β-lactamases, novel β-lactamase-inactivating molecules were introduced in combination with β-lactamase-labile penicillins (**Fig. 2**).[53] The first of these inactivating agents was clavulanic acid (**19**), a potent suicide inhibitor of the penicillinases that was combined with amoxicillin (**7**) in an orally bioavailable form and with ticarcillin (**20**) for nosocomial infections. Sulfone-containing β-lactams soon followed, with sulbactam (**21**) combined with ampicillin (**18**), and tazobactam (**22**) combined with piperacillin (**8**). These inhibitors serve to acylate the active site serine of class A penicillinases, with limited hydrolysis of the inhibitor occurring before the enzymes are rendered inactive.[53] They are not effective inhibitors of the AmpC cephalosporinases or of carbapenemases.[54] Resistance to the β-lactamase inhibitor (BLI) combinations has been due largely to the emergence of enzymes inherently resistant to the action of the inhibitors, or to the production of multiple β-lactamases in an organism. To a lesser extent, mutational changes leading to a previously susceptible enzyme becoming resistant to the inhibitor have been seen particularly in TEM and SHV penicillinase variants that have decreased affinities for clavulanic acid or tazobactam.[53] In ESBL-producing *E. coli* UTI isolates from the Asia-Pacific area (2010–13), susceptibility to piperacillin–tazobactam was 88–92%, but only 53–65% of similar ESBL-producing *K. pneumoniae* isolates were susceptible.[50] In studies of US and European pneumonia isolates (2009–12), susceptibility to piperacillin–tazobactam was 29.5% in *Acinetobacter* spp., 72.9% in *P. aeruginosa*, 84.4% in *K. pneumoniae*, and 90.4% in *E. coli*.[55]

New BLI combinations have recently emerged. Tazobactam has been combined with the antipseudomonal cephalosporin ceftolozane (**23**) to provide increased coverage of *P. aeruginosa* and to inhibit some ESBL-producing enteric bacteria.[56,57] Resistance in the enteric bacteria is usually due to the inefficiency of tazobactam to inhibit AmpC cephalosporinases, some ESBLs and the carbapenemases. In *P. aeruginosa*, the primary resistance mechanism that has been identified in vitro is the result of multiple mutations affecting the structure and high-level expression of the AmpC enzyme.[58] Susceptibility to ceftolozane–tazobactam has been reported to be 94–97% in *P. aeruginosa* and 98–100% in *E. coli*, even in ESBL-producing isolates.[56,57] Lower susceptibility occurs in *K. pneumoniae* with 86–89% susceptibility for all isolates, and 44% in isolates with an ESBL phenotype.[57]

Avibactam (**24**) is a novel non-β-lactam diazabicyclooctane BLI[59] that has been approved for marketing in combination with ceftazidime (**13**), but that is also in development with ceftaroline (**11**) and aztreonam (**15**).[54] Unlike the other BLIs, its main mechanism of action is to form reversible covalent bonds with the active site serine in those β-lactamases that utilize serine to facilitate β-lactam hydrolysis.[60,61] Its activity expands the spectrum from the previous BLIs by inhibiting not only the narrow-spectrum

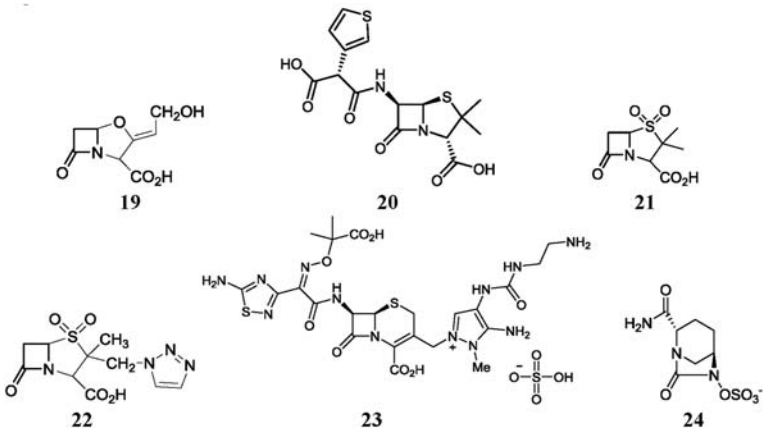

Fig. 2 β-Lactamase inhibitors (BLIs): **19** clavulanic acid, **20** ticarcillin, **21** sulbactam, **22** tazobactam, **23** ceftolozane, **24** avibactam.

penicillinases, but also AmpC cephalosporinases, ESBLs, serine carbapenemases, and some OXA β-lactamases[61]; MBLs are not inhibited.[62] In addition to its β-lactamase inhibitory activity, it binds to essential PBPs in both Gram-positive and Gram-negative bacteria, leading to enhanced synergistic antibacterial activity when avibactam is combined with other cell wall active agents.[63] MICs for ceftazidime, ceftaroline, and aztreonam are frequently decreased up to 128-fold in MDR enteric bacteria when avibactam is present.[64] Ceftazidime susceptibility in a set of 34,062 Enterobacteriaceae isolates increased from 75.6% to 99.5% when tested with avibactam; a subset of non-MBL-producing isolates that were not susceptible to meropenem exhibited 91.4% resistance to ceftazidime, but only 2.3% resistance after the addition of avibactam.[62] In *P. aeruginosa*, the addition of avibactam to ceftazidime increases ceftazidime susceptibility from 84.0% to 96.3%.[65] Resistance to the combination reported from clinical isolates has often been due to mechanisms related to the accompanying β-lactam. In historical *P. aeruginosa* patient isolates, resistance to the ceftazidime–avibactam combination has been observed as a result of permeability barriers and efflux mechanisms.[66] Among recent French carbapenem-nonsusceptible Enterobacteriaceae, the highest MIC for ceftazidime when tested with avibactam was 4 $\mu g\,mL^{-1}$, occurring in porin-deficient *K. pneumoniae* isolates. A novel aztreonam–avibactam resistance mechanism observed in a set of *E. coli* isolates producing the NDM MBL is an insertion in PBP3, thus leading to resistance to an accompanying cephalosporin or monobactam, not to the BLI.[67] Only future use will determine whether the new BLI combinations will select for resistance more frequently than their predecessors.

5.17.2.1.3 Aminoglycoside resistance

Aminoglycosides (Fig. 3; **25**) were among the first antibiotics to be developed as antibacterial drugs with the discovery of streptomycin by Waksman in the early 1940s.[68] This class of drugs has been widely utilized for decades due to broad-spectrum activity encompassing staphylococci and Gram-negative bacteria,[69] but also mycobacteria.[70] Aminoglycosides act by binding to the aminoacyl tRNA site (A-site) of the bacterial ribosome,[71] resulting in the cessation of protein synthesis. They are generally considered to be bactericidal agents,[72] although cidality is often enhanced in the presence of β-lactam antibiotics.[73] The most frequently used agents are gentamicin (**26**), tobramycin (**27**), and amikacin (**28**). They have been utilized for treatment of a variety of bacterial infections including sepsis, skin and soft tissue infections (SSTIs), serious infections of the respiratory tract, serious bone and joint infections, intraabdominal infections (IAIs) (including peritonitis), postoperative infections (including postvascular surgery), ophthalmic disease, the management of cystic fibrosis (CF) with inhaled tobramycin, and tuberculosis (TB) (streptomycin [**29**]) (https://dailymed.nlm.nih.gov/dailymed/search.cfm?startswith=amikacin&x=14&y=12). Because of the potential for ototoxicity[74] and nephrotoxicity,[75] as well as the increasing resistance seen for all antibiotics, aminoglycosides are currently not utilized as frequently

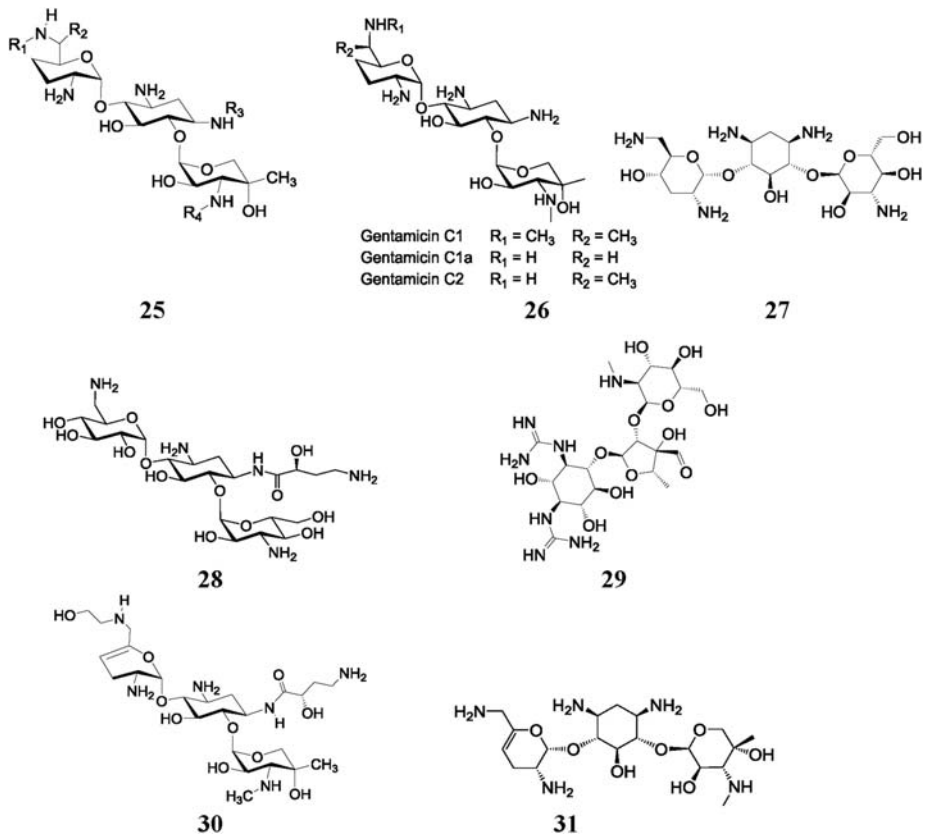

Fig. 3 Aminoglycoside antibiotics: **25** aminoglycosides, **26** gentamicin, **27** tobramycin, **28** amikacin, **29** streptomycin, **30** plazomicin, **31** sisomicin.

as other drugs such as the β-lactams, unless the appearance of aminoglycoside susceptibility in highly resistant Gram-negative bacteria suggests that an aminoglycoside may be a reasonable therapeutic option. Encouraging results have recently been reported for the investigational aminoglycoside plazomicin (**30**), a semisynthetic aminoglycoside based on sisomicin (**31**), designed to avoid common aminoglycoside resistance mechanisms, particularly those related to aminoglycoside-modifying enzymes (AMEs).[76] This novel aminoglycoside is currently under development for the treatment of serious antibiotic-resistant infections caused by enteric bacteria.[77]

Aminoglycoside resistance can be caused by three major mechanisms. Production of AMEs is the most common, occurring in both staphylococci and Gram-negative bacteria. Enzymes that modify specific drugs either by N-acetylation, O-adenylation, or O-phosphorylation can cause aminoglycoside inactivation.[78] Multiple AMEs may exist in a single bacterial strain, with two or three AMEs frequently appearing in aminoglycoside-resistant Enterobacteriaceae or *Acinetobacter* spp.[78] Plazomicin evades most AMEs, except for an uncommon chromosomal acetylase that inactivates plazomicin and gentamicin,[76] and has been identified only in *Providencia stuartii*.[78] In staphylococci, a limited number of AMEs may be produced alone or in combination[76,79,80] resulting in resistance to amikacin and tobramycin, but generally showing lower MICs for gentamicin and plazomicin. A second common aminoglycoside resistance mechanism is alteration of the ribosomal binding, often through 16S rRNA methyl transferases (RMTs) in the Enterobacteriaceae.[78,81] Both AMEs and RMTs can be found on transferable elements that may be circulated among species, thus increasing the proliferation of resistance. Dissemination may be due to both clonal spread and plasmidic transfer of mobile resistance determinants. RMTs may travel on the same plasmids as ESBL-encoding genes[82] or quinolone resistance proteins[83] and are often associated with insertion sequences.[83] One of the most disconcerting appearances of these methylases has been the identification of RMTs in highly antibiotic-resistant Gram-negative pathogens that produce the NDM-1.[84] A third aminoglycoside mechanism, primarily in Gram-negative bacteria, involves decreased penetration and/or increased efflux. Membrane alterations that affect aminoglycoside permeability are infrequently encountered in most enteric bacteria with the exception of the Proteae, which typically have an outer membrane that impedes the aminoglycoside entry[85] (including plazomicin[78]). In *P. aeruginosa*, aminoglycosides often exhibit higher MICs as a result of hyperproduction of the MexXY efflux pump,[86] whereas in *Acinetobacter baumannii*, increased expression of the AdeB efflux system may contribute to reduced sensitivity to plazomicin.[87]

In recent surveillance studies, aminoglycoside susceptibilities have remained relatively steady from 2009 to 2012 among the Enterobacteriaceae in both the United States and Europe, with amikacin resistance usually $<10\%$ and gentamicin resistance $<20\%$[55] except for ESBL-producing *Klebsiella* spp. where resistance was as high as 39% (amikacin) and 46% (gentamicin). These data contrast with historical data collected in 2001 from intensive care patients in which aminoglycoside resistance ranged from 2.2% to 5.4% in *Klebsiella* spp. with confirmed ESBLs.[88] Aminoglycoside susceptibility in *P. aeruginosa* ranged from 87% to 96% in the United States ($n=1439$) and from 75% to 89% in Europe and the Mediterranean region ($n=1250$) in patients hospitalized with pneumonia from 2009 to 2012.[55] In *Acinetobacter* spp., amikacin and gentamicin susceptibility is lower than in pseudomonal isolates, with 41–49% amikacin susceptibility and 30% gentamicin susceptibility in US patients, and 32–35% amikacin susceptibility and 28% gentamicin susceptibility in European/Mediterranean patients.[55] Interestingly, susceptibility to aminoglycosides in nonfermentative bacteria has not changed dramatically for pseudomonal isolates since the period 1997–2001, when 76–89% susceptibility was reported for gentimicin, tobramycin, or amikacin in a global collection of *P. aeruginosa* isolates[89]; however, slightly higher aminoglycoside susceptibilities were observed in a similar older collection of *Acinetobacter* isolates that reported 48–62% susceptibility to the three aminoglycosides tested.[89]

5.17.2.1.4 Quinolone resistance

Quinolones (Fig. 4; **32**) represent a class of potent, broad-spectrum antibiotics with good bioavailability that has enabled both oral and intravenous formulations.[90] These drugs target the essential bacterial enzymes DNA gyrase and topoisomerase IV, which are involved in DNA replication and recombination and control the topology of the bacterial chromosome.[91] Initially used mainly in the treatment of UTIs, newer generations of fluoroquinolones were optimized to gain sufficient antibacterial activity for the treatment of systemic Gram-negative infections as well as Gram-positive respiratory tract infections.[92] Although antibacterial activity gains were achieved for newer quinolones against Gram-positive pathogens, ciprofloxacin (**33**), introduced in 1987, still remains

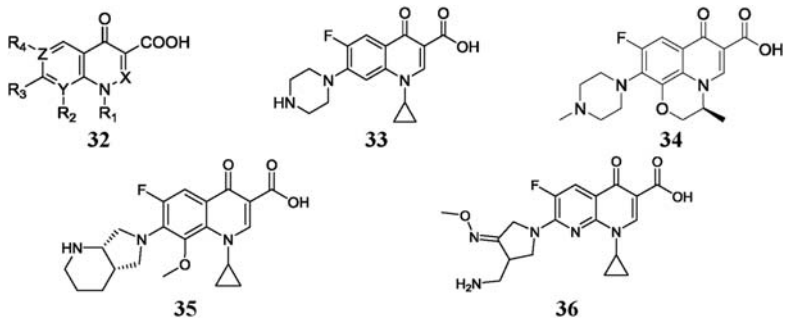

Fig. 4 Quinolone antibiotics: **32** quinolones, **33** ciprofloxacin, **34** levofloxacin, **35** moxifloxacin, **36** gemifloxacin.

the most active against Gram-negative pathogens. Additional clinical indications now include SSTIs, IAIs, sexually transmitted diseases, bone and joint infections, and gastrointestinal infections, and in recent years several quinolones have been explored for the treatment of TB.[93]

Not surprisingly, the growing popularity of these drugs led to increased usage, particularly in the 1990s, and subsequently to resistance development that was first chromosomally mediated through target-based mutations and/or mutations that affect drug accumulation (permeability or efflux) in the bacterial cell.[91,94] Target-based mutations are found in the *gyrA* and *parC* genes encoding DNA gyrase and topoisomerase IV enzymes, respectively. More recently, the emergence of several mechanisms of plasmid-mediated resistance has occurred as well.[95] A key plasmid-encoded gene designated *qnr* has been discovered that encodes a protein that can bind to and protect both DNA gyrase and topoisomerase IV from inhibition by quinolones.[96] Most *qnr* genes are found on multidrug resistance plasmids linked to genes for ESBLs, AmpC β-lactamase, and resistance to aminoglycosides, sulfonamides, trimethoprim, and other antimicrobial agents, thus adding to treatment issues in patients infected with these organisms. Changes in quinolone resistance over the past decade for several clinical indications are captured here.

The overall resistance rate of ciprofloxacin for outpatient *E. coli* urinary isolates in the United States and Canada during 2003–04 was reported to be 5.4%, though some areas reported rates in excess of 20%.[97] A similar study performed in 2003–06 in nine European countries including Russia and Brazil found that the ciprofloxacin resistance rate for *E. coli* isolates in the healthy women having uncomplicated lower UTIs was 8.3%, although again higher rates (up to 13.6%) were observed in several areas.[98] A more recent (2010–12) Korean study reported ciprofloxacin resistance in *E. coli* isolates from women having community-acquired acute pyelonephritis was 20.0%,[99] while a second study showed similar (22.5%) ciprofloxacin resistance in *E. coli* isolates from women with community-associated acute pyelonephritis.[100] Most studies have indicated that prior exposure to quinolones is a significant risk factor for the development of quinolone resistance in uropathogenic *E. coli*.[100,101] Of additional concern is the high association of quinolone resistance with ESBL production in Enterobacteriaceae in UTI patients, which limits treatment options.[102]

Pneumococcal resistance to β-lactam and macrolide antibiotics has led to increased use of quinolones such as levofloxacin (**34**), moxifloxacin (**35**), and gemifloxacin (**36**) for the treatment of patients with community-acquired pneumonia. As the use of quinolones has increased, fluoroquinolone-resistant *S. pneumoniae* has emerged in many countries.[103] Quinolone resistance rates for *S. pneumoniae* in North America remain low (<2%).[104] In Europe, pneumococcal resistance to quinolones was reported to be 5.2% in 2012 (European Centre for Disease Prevention and Control); however, rates were much lower (<0.7%) in two German multicenter studies (MOXIAKTIV Study and German CAPNETZ surveillance study).[105,106] In Asia, the Asian Network for Surveillance of Resistant Pathogens (ANSORP) also showed relatively low resistance rates of 1.7% and 0.4% for levofloxacin and moxifloxacin, respectively, with highest rates of levofloxacin resistance at 6.5% and 4.6% in Taiwan and Korea, respectively.[107]

Haemophilus influenzae and *Moraxella catarrhalis* have largely remained highly susceptible to quinolones.[108] For other respiratory pathogens isolated from healthcare-associated pneumonia, such as Enterobacteriaceae, *P. aeruginosa*, and *A. baumannii*, quinolone resistance rates have been substantially higher with isolates frequently MDR. A prospective surveillance study by the ANSORP from 2008 to 2009 also showed high ciprofloxacin resistance in *K. pneumoniae* (31.2%), *P. aeruginosa* (30.1%), and *Acinetobacter* spp. (80.7%) in Asian countries.[109]

5.17.2.1.5 Macrolide resistance

The macrolides (Fig. 5; **37**) and ketolides (**38**) represent a class of antibiotics with antibacterial activities against most Gram-positive and selected Gram-negative as well as atypical pathogens including penicillin-resistant microorganisms.[110] Macrolides belong to the polyketide class of natural products that reversibly bind to the 50S subunit of the bacterial ribosome blocking protein synthesis, thereby preventing bacterial growth and replication. These drugs are primarily bacteriostatic, but at higher concentrations can be bactericidal.[111] Erythromycin (**39**), clarithromycin (**40**), and azithromycin (**41**), the most extensively used examples, have proven useful in a variety of clinical indications including both upper and lower respiratory tract infections as well as skin and skin structure and ophthalmic infections. The introduction of clarithromycin and azithromycin provided both increased pathogen coverage and a significant improvement in adverse event profiles when compared with the first macrolide agent, erythromycin. However, as might be expected, widespread usage led to the development of resistance including a global increase in macrolide-resistant *S. pneumoniae*, thus limiting their effectiveness. By 2005, 29.5% of *S. pneumoniae* strains isolated in the United States were found nonsusceptible to macrolides.[112]

Solithromycin (**42**), a next-generation oral and intravenous fluoroketolide currently in Phase 3 clinical development, has been reported to possess improved effectiveness against macrolide-resistant bacteria because of the ability to bind to three sites on the bacterial ribosome, as opposed to one or two for the current macrolides. This binding to three ribosomal sites is also expected to limit resistance development (http://www.cempra.com/products/Solithromycin-cem-101/). In vitro and in vivo studies have shown potent activity against *S. pneumoniae* as well as an extended spectrum of activity against community-associated-MRSA (CA-MRSA), enterococci, *Mycobacterium avium* and in malaria. It is also active against atypical bacteria such as *Legionella*, *Chlamydia*, *Mycoplasma*, and *Ureaplasma* and against gonococci and other organisms that cause genitourinary tract infections. It is 8–16 times more potent than azithromycin and is active against azithromycin-resistant strains.

Soon after the introduction of erythromycin into clinical use in the 1950s, bacterial resistance to this antibiotic was reported for the first time in staphylococci.[113] In addition to ribosomal mutations, there are three major gene-encoded mechanisms by which bacteria become resistant to macrolides: rRNA methylases, efflux, and inactivating enzymes[114,115] that include esterases, lyases, phosphorylases, and transferases. The cluster of macrolides with two other classes, lincosamides and streptogramin B, has been

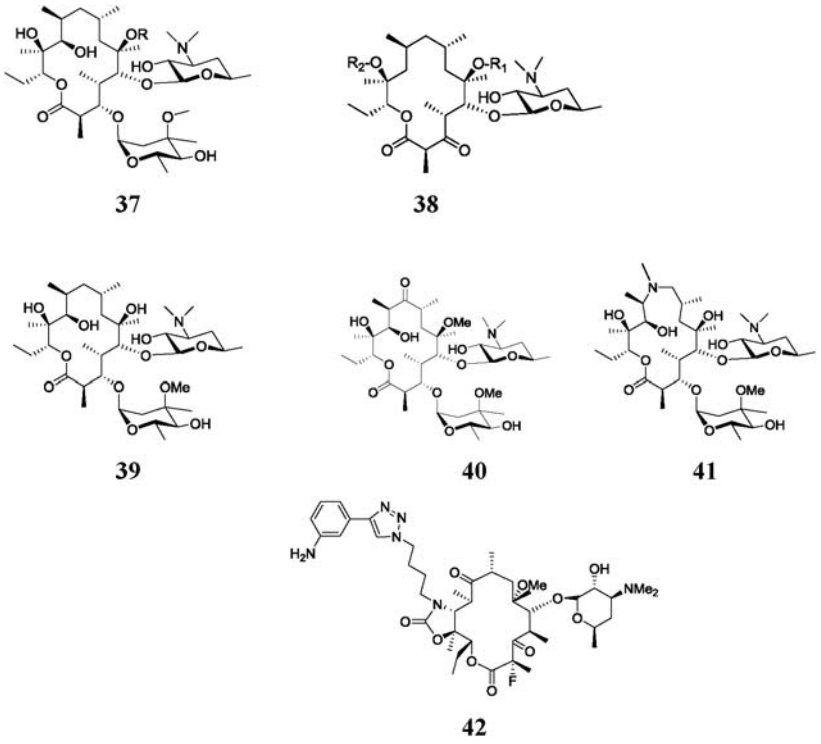

Fig. 5 Macrolide antibiotics: **37** macrolides, **38** ketolides, **39** erythromycin, **40** clarithromycin, **41** azithromycin, **42** solithromycin.

designated the macrolide–lincosamide–streptogramin B (MLS) antibiotics, and resistance to these drugs is termed MLS resistance.[116] More than 60 MLS resistance genes have been identified to date.

Erythromycin resistance is widespread in MRSA, with 87.9% erythromycin resistance reported for these isolates (compared with 8.2% for MSSA).[117] Due to the apparent inability of ketolides to act as inducers of methylase production, they maintain good in vitro activity against *S. aureus* strains with inducible methylase, but lose activity against strains constitutively producing ermA or ermC methylase.[118] With regard to pneumococci, even though macrolide MICs typically increase along with those of penicillin, ketolides remain consistently active irrespective of penicillin susceptibility. In contrast, 71% of penicillin-nonsusceptible pneumococci were nonsusceptible to erythromycin and azithromycin.[119] Macrolides have poor activity against *Enterococcus* spp. with ketolides exhibiting better activity. However, neither demonstrated activity against erythromycin- or vancomycin-resistant *E. faecalis* and *E. faecium*.[120,121] *Listeria monocytogenes* and *Corynebacterium* spp. showed susceptibility to macrolides and ketolides, with the latter having superior activity compared with macrolides.[121–123] In regard to Gram-negative pathogens, *P. aeruginosa*, Enterobacteriaceae, and *Acinetobacter* are intrinsically nonsusceptible to macrolides and ketolides. However, both classes were active against *H. influenzae* and *M. catarrhalis* and their in vitro activities were not affected by the presence of β-lactamase production or by ampicillin susceptibility.[121,123]

5.17.2.1.6 Tetracycline resistance

Tetracycline (Fig. 6; **43**) antibiotics have been widely used in the treatment of bacterial infections for more than 60 years. These drugs inhibit bacterial growth by inhibiting protein synthesis through binding to the bacterial 30S ribosomal subunit, preventing aminoacyl-t-RNA binding to the ribosomal A-site and subsequent addition of amino acids to the growing polypeptide chain. Because of the widespread use of tetracyclines over many years, resistance developed in many pathogens leading to limitations in their utility. Efforts to identify new analogs in this class that could overcome bacterial resistance issues resulted in the discovery of the glycylcyclines (**44**),[124] exemplified by tigecycline (**45**), which was approved by the USA Food and Drug Administration (FDA) in 2005 and by the European Medicines Agency in 2006 for the treatment of adults with complicated IAIs and complicated skin and skin structure infections (cSSSI).[125,126] Tigecycline also received FDA approval for the treatment of community-acquired bacterial pneumonia in adults.[127] This drug offers expanded broad-spectrum coverage of such problem pathogens as MRSA, vancomycin-resistant enterococci (VRE), *A. baumannii*, and ESBL-producing Gram-negative strains.[128] It is also active against anaerobes and "atypical" bacteria including *Mycoplasma*, *Legionella*, and *Chlamydia* species. Tigecycline exhibits a low MIC against *Clostridium difficile* in vitro and may be able to affect the pathogenesis of the disease in a mouse model of *C. difficile* infection (CDI).[129]

In vitro susceptibility data for tigecycline against Gram-positive organisms was collected between 2004 and 2009 from the Tigecycline Evaluation and Surveillance Trial[130] and indicated that activity was maintained against the organisms tested, including MRSA and other antibiotic-resistant pathogens.[131] Tigecycline has continued to maintain this in vitro antibacterial activity against MSRA

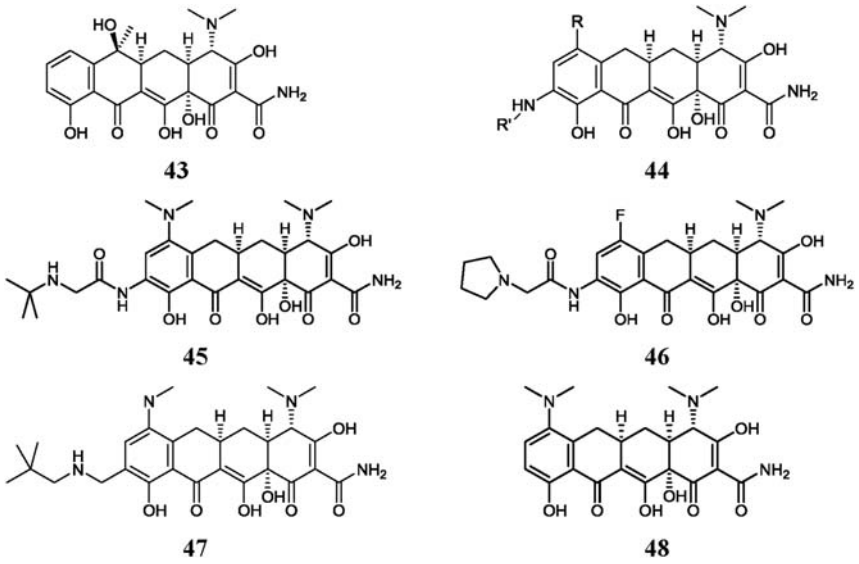

Fig. 6 Tetracycline antibiotics: **43** tetracyclines, **44** glycylcyclines, **45** tigecycline, **46** eravacycline, **47** omadacycline, **48** minocycline.

into 2012.[132] In vitro activity against Gram-negative organisms has also continued independent of ESBL phenotype or resistance to other antimicrobials.[133] For example, 97.9% of ESBL-producing *Klebsiella* spp. and 98.2% of imipenem nonsusceptible strains remained susceptible to tigecycline (minimum inhibitory concentrations for 90% of the isolates tested, MIC_{90}, 0.5/1.0 mg L^{-1} for both subsets) in data through 2009. Another study of European blood culture isolates from 2004 to 2009 showed no decline in tigecycline susceptibility against Gram-negative organisms.[134] A more recent survey indicates that tigecycline has maintained this excellent broad-spectrum pathogen coverage through 2014.[135] However, it is not active against *P. aeruginosa* and *Proteus* spp., *Morganella* and *Providencia* species.[136]

Tigecycline is often considered as a drug of last resort against MDR *A. baumannii*. However, increasing resistance has been observed following growing usage of the drug to treat infections caused by this pathogen, primarily due to efflux mediated by the resistance-nodulation-cell division (RND)-type transporters AdeABC, AdeFGH, and AdeIJK. Other resistance mechanisms may contribute as well.[137] Comparative evaluation of the tigecycline resistance rates reported worldwide has been difficult due to differences in vitro susceptibility methodologies used, with broth microdilution being considered the reference method. The high concentrations of manganese in Mueller–Hinton agar have been associated with increased MICs determined by both Etest® and disk diffusion.[138] Since the concentration of manganese in human serum is much lower than levels found in standard bacterial media, tigecycline MICs in media with low manganese content are considered more clinically relevant.

Because tigecycline has broad-spectrum antibacterial activity against both Gram-positive and Gram-negative pathogens, there has been some confusion in how to best position the drug for clinical usage.[139,140] There have been multiple clinical investigations of tigecycline for the treatment of both community-acquired and hospital-acquired infections. Despite some resistance observed for *A. baumannii*, the drug possesses good tissue distribution and effective levels of activity against most current MDR pathogens. There is even a case for its use in *A. baumannii* infections, since most isolates show MICs of ≤ 2 μg mL^{-1} and can be resistant to almost all other antibiotics, but a susceptibility breakpoint for *Acinetobacter* spp. has not yet been adequately established for the reasons discussed earlier. Despite the apparent positive microbiology data, there are several issues that must be considered prior to clinical use. Tigecycline is bacteriostatic against Gram-negative bacteria, and while good clinical successes have been reported by some investigators, others have reported high clinical failure rates.[141] Also, standard tigecycline doses can result in serum concentrations that are below the MICs of most Gram-negative pathogens, making it risky for use in bloodstream infections. Warnings of increased mortality have been raised by meta-analyses based on heterogeneous infections encompassing ventilator-associated pneumonia (VAP), hospital-acquired pneumonia, diabetic foot infections, and infections by MDR bacteria.[142,143]

Two other tetracycline derivatives are in late stages of clinical development. Eravacycline (**46**) (in Phase 3) is a synthetic fluorocycline antibacterial agent that is structurally similar to tigecycline with two modifications to the D-ring of its tetracycline core: a fluorine atom replaces the dimethylamine moiety at C-7 and a pyrrolidineacetamido group replaces the 2-tertiary-butyl glycylamido at C-9.[144] Eravacycline is two- to fourfold more potent than tigecycline versus Gram-positive cocci and two- to eightfold more potent than tigecycline versus Gram-negative bacilli. This drug demonstrates broad-spectrum antimicrobial activity against Gram-positive, Gram-negative, and anaerobic bacteria with the exception of *P. aeruginosa*. Omadacycline (**47**), representative of another class of tetracycline analogs, the aminomethylcyclines that are C-9 derivatives of minocycline (**48**),[145] is also in advanced clinical development (III3). Both of these compounds are reported to have advantages against isolates with current tetracycline resistance mechanisms.[146,147]

5.17.2.1.7 Glycopeptide resistance

Vancomycin (Fig. 7; 49), first isolated in 1957, is a cell wall antibiotic that inhibits a late stage of peptidoglycan biosynthesis by binding to the D-ala-D-ala termini of murein monomers, blocking the activity of glycosyltransferase leading to inhibition of the incorporation of the murein monomers to the growing peptidoglycan chain. This prevents further transpeptidation and continued cell wall synthesis. Vancomycin is a tricyclic glycopeptide consisting of seven-membered peptide chains forming the tricyclic structure with attached disaccharide composed of vancosamine and glucose. It has a relatively high molecular weight of 1485 similar to that of

Fig. 7 Glycopeptide antibiotics: **49** vancomycin, **50** avoparcin, **51** dalbavancin, **52** oritavancin, **53** televancin.

daptomycin and possesses a bactericidal mechanism of action with the exceptions of enterococci, where it is bacteriostatic, and MSSA, where it is only slowly bactericidal, sometimes leading to poorer clinical outcomes.[148]

The drug has an impressive spectrum of activity against Gram-positive aerobic pathogens including staphylococci (including both MSSA and MRSA), streptococci, enterococci, and pneumococci as well as *Corynebacterium*, *Listeria*, *Bacillus* spp., *Clostridia*, and oral Gram-positive anaerobes. Strains of *Leuconosoc*, *Lactobacillus*, *Pediococcus*, and *Erysipelothrix* possess inherent resistance to vancomycin. Even after many decades of use, vancomycin remains an inexpensive first-line agent for MRSA and MRSE infections, including bacteremia, endocarditis, pneumonia, cellulitis, and osteomyelitis. In addition, it is used to treat serious Gram-positive infections among patients who are allergic to β-lactam antibiotics.[149]

Due to the widespread emergence of MRSA and MRSE in the 1970s, vancomycin usage increased dramatically, which led to the subsequent appearance of vancomycin resistance among enterococci by the mid-1980s and patient treatment failures.[150] In the late 1990s, staphylococcal strains with intermediate susceptibility to vancomycin (VISA), vancomycin-resistant *S. aureus* (VRSA),[150–152] and vancomycin-resistant *S. epidermidis*[153] were reported. Fortunately, the occurrence of these difficult-to-treat staphylococci remains rare. Typically, MICs of vancomycin against *S. aureus* are ≤ 2 μg mL^{-1} and it has been repeatedly shown that clinical failures in patients with endocarditis, bacteremia, and pneumonia occur when the *S. aureus* isolates causing these infections have MIC of ≥ 2 μg mL^{-1}.[154,155] However, even within the range of MICs below 2 μg mL^{-1}, high failure rates have been observed in patients infected with strains that have vancomycin MICs of 1.5 μg mL^{-1}.[156] A phenomenon designated "vancomycin creep" has been described in recent years, denoting a slow but steady increase in vancomycin MIC observed over time from values of 0.5–0.75 μg mL^{-1} to levels of 1.25–1.5 μg mL^{-1}.[157] In some parts of the world, however, this phenomenon does not seem to occur.[158]

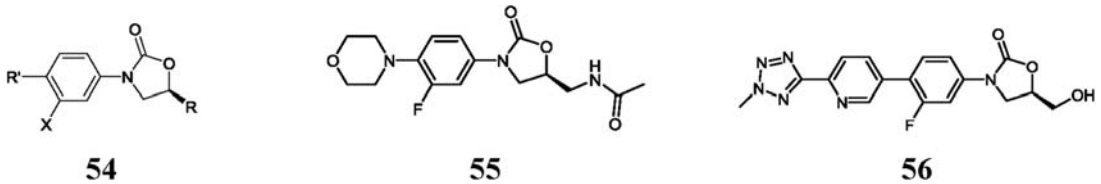
VRE isolates were first encountered in England and France in 1986 followed by isolation of VRE *E. faecalis* in the United States in 1987.[159–161] In Europe, the rise of VRE was mostly in the community and the selective pressure was believed to derive from transmission from animals and animal food products to humans through the use of the glycopeptide antibiotic avoparcin (**50**) as a growth promoter in livestock.[162] In contrast, in the United States the predominance of VRE was in the hospital setting, believed to be due to the increasing use of vancomycin.[163] A rapid spread of VRE occurred in US hospitals in the 1990s, followed by a VRE increase in Europe in the 2000s. Changes in the D-Ala-D-Ala peptidoglycan precursors to D-Ala-D-Lac or D-Ala-D-Ser resulted in significant decreases in vancomycin binding affinities to bacterial cell wall, allowing for cell survival.[164] Currently *E. faecium* displays more resistance, with the more pathogenic *E. faecalis* lagging behind. Eight phenotypic variants of acquired glycopeptide resistance in enterococci have been described (VanA, VanB, VanD, VanE, VanG, VanL, VanM, and VanN), as well as one intrinsic resistance (VanC). VanA is responsible for most human VRE disease around the world, principally in *E. faecium*.

Around the world, rates of VRE are at their highest in the United States, with 35.5% of enterococcal hospital-associated infections resistant to vancomycin from 2009 to 2010, ranking as the second most common cause of nosocomial infections.[165] In Europe, VRE is much less prevalent (4% in 2013), but on the rise. However, prevalence depended on the country, ranging from less than 1% (France, Spain, Sweden) to greater than 20% (Greece, Ireland, Portugal, United Kingdom).[166] Infections often target the immunosuppressed, causing bacteremia, IAIs, UTIs, SSSIs, and other clinical manifestations. Due to the multiple resistance mechanisms found in VRE, treatment options are often limited.

Three other glycopeptide antibiotics have been approved since 2009.[167,168] Dalbavancin (**51**) inhibits the late stages of peptidoglycan synthesis by mainly impairing transglycosylase activity, while oritavancin (**52**) and telavancin (**53**) anchor in the bacterial membrane by the lipophilic side chain linked to their disaccharidic moiety and disrupt membrane integrity leading to bacteriolysis. The long half-lives of oritavancin and dalbavancin allow for infrequent dosing compared to vancomycin and televancin. Televancin was approved in 2009 for cSSSI, and in 2013 for hospital-acquired and ventilator-associated bacterial pneumonia caused by *S. aureus*.[169] Dalbavancin was approved in 2014 for the treatment of acute bacterial skin and soft tissue infection (ABSSSI) caused by certain susceptible bacteria such as *S. aureus* (including MSSA and MRSA) and *Streptococcus pyogenes*.[170] Oritavancin was approved for ABSSSI in 2014.[171] A recent study of skin and soft tissue clinical isolates from the United States and Europe showed 97.9–100% susceptibility for staphylococci, streptococci, and enterococci with MIC_{90} values ranging from 0.008 to 0.5 μg mL^{-1}.[172]

5.17.2.1.8 Oxazolidinone resistance

Oxazolidones (Fig. 8; **54**) represent one of only three novel antibacterial structural classes (the others are fidaxomicin and daptomycin) approved by the FDA in the last 30 years. Linezolid (**55**) was approved in 2000 and is available both intravenously and orally for several clinical indications, including infections caused by VRE, nosocomial pneumonia, CAP, and both uncomplicated and complicated SSSIs.[173] A second oxazolidinone, tedizolid (**56**), was approved by the FDA in 2014 for the treatment of ABSSSI caused by certain susceptible bacteria including *S. aureus* (both MSSA and MRSA), various *Streptococcus* species (including *S. pyogenes* and *S. agalactiae*),



54 **55** **56**

Fig. 8 Oxazolidinone antibiotics: **54** oxazolidinones, **55** linezolid, **56** tedizolid.

and *E. faecalis*.[174] This second-generation oxazolidinone derivative has been reported to be 4- to 16-fold more potent against staphylococci and enterococci compared to linezolid. Mechanism of action data indicates that oxazolidinones interact with the 50S ribosomal subunit and inhibit the initiation phase of translation by binding at the A-site of the peptidyl transferase center. This leads to interference with the binding of the amino acyl moiety of the incoming aminoacyl tRNA.[175] Crystal structure data of linezolid bound to the *Haloarcula marismortui* 50S subunit supports this inhibition mechanism of competition with the incoming A-site substrates.[176]

The spontaneous frequency of resistance to oxazolidinones is quite low compared to other antibiotics, probably due to the necessity of mutating multiple copies of the 23S rRNA gene target. The frequency of linezolid resistance in staphylococci and enterococci has been reported to be $<10^{-9}$, while tedizolid was found to possess an even more impressive mutation frequency, $\sim$16-fold lower mean spontaneous mutation than linezolid.[177] Linezolid resistance was first seen clinically in *E. faecium* infections in patients from two early compassionate use programs, and soon after its launch in 2000 additional resistant staphylococci and enterococci strains were identified. Analyses of linezolid-resistant mutants indicated a limited spectrum of mutations in the 23S rRNA along with mutations in ribosomal proteins L3 and L4.[178]

Another mechanism of resistance, mediated by the *cfr* gene, was originally identified in veterinary staphylococcal isolates as early as 1997.[179] This gene encodes a methyltransferase that abolishes drug binding and confers resistance to a set of structurally diverse compounds that target the peptidyl transfer region including phenicols, lincosamides, oxazolidinones, pleuromutilins, streptogramin A, and 16-membered macrolides. The *cfr* gene was discovered to be often associated with additional antibiotic resistance genes, including *erm* (resistance to macrolides, lincosamides, and streptogramin B), *lsaB* (reduced susceptibility to lincosamides), and *fexA* (resistance to phenicols).[180] Strains carrying *cfr* in combination with ribosomal mutations also have been observed. However, MIC values for tedizolid were reported to be unchanged against strains that carried the *cfr* gene compared with two- to eightfold increases for linezolid, suggesting better clinical effectiveness against these *cfr* isolates.[181]

In regard to clinical linezolid resistance, the 2009 LEADER study reported no significant increases in rates between 2004 and 2009 among six groups of Gram-positive organisms, with resistance rates in the United States for *S. aureus* 0.15%, coagulase-negative staphylococci 1.47%, and enterococci 0.49%.[182] A similar 2010 study that included isolates from Canada, Europe, Latin America, and the Asia-Pacific regions reported stable linezolid resistance rates for coagulase-negative staphylococci, streptococci, and enterococci.[183] Increases in the rate of resistance have, however, been observed in local outbreaks of linezolid-resistant strains. For example, a Spanish multicenter surveillance program showed that the frequency of linezolid resistance among coagulase-negative staphylococci increased from 1.6% in 2008 to 8% in 2010.[184] In the most recent data update from LEADER 2014, susceptibility testing of $>$6000 Gram-positive pathogens demonstrated excellent linezolid activity and a sustained susceptibility rate of 99.78% overall (99.62–99.83% during 2008–13).[185] There were 15 nonsusceptible isolates, 8 of which (8/15 (53.3%)) carried *cfr*. Even though these numbers are very low, the increase in the presence of *cfr* in linezolid nonsusceptible isolates is a concern and merits monitoring in the future due to its transmissible properties.[186] However, it is encouraging that the linezolid-resistant and nonsusceptible rate (0.22%) is essentially the same as in 2005 (0.24%). Linezolid MIC distributions have remained stable without evidence of "MIC creep" in these studies.

In regard to tedizolid, nearly 7000 Gram-positive clinical isolates collected from multiple US and European sites as part of the Surveillance of Tedizolid Activity and Resistance Program in 2011 and 2012 were assayed for in vitro susceptibilities.[187] MIC_{90} values were 0.25 μg mL^{-1} for *S. epidermidis* and beta-hemolytic streptococci and 0.5 μg mL^{-1} for *S. aureus*, other CoNS, and enterococci. Of 16 isolates with elevated tedizolid or linezolid MIC values (intermediate or resistant isolates), 10 had mutations in the genes encoding 23S rRNA, 5 had mutations in the genes encoding ribosomal proteins L3 or L4, and 5 carried the *cfr* multidrug resistance gene. Overall, tedizolid showed excellent activity against Gram-positive bacteria and was at least fourfold more potent than linezolid against wild-type and linezolid-resistant isolates.[187]

5.17.2.1.9 Colistin resistance

Colistin (**57**) belongs to the family of polymyxins (Fig. 9), cationic polypeptides with broad-spectrum activity against Gram-negative bacteria, including most current MDR isolates. The two polymyxins currently in clinical use are polymyxin B (**58**) and

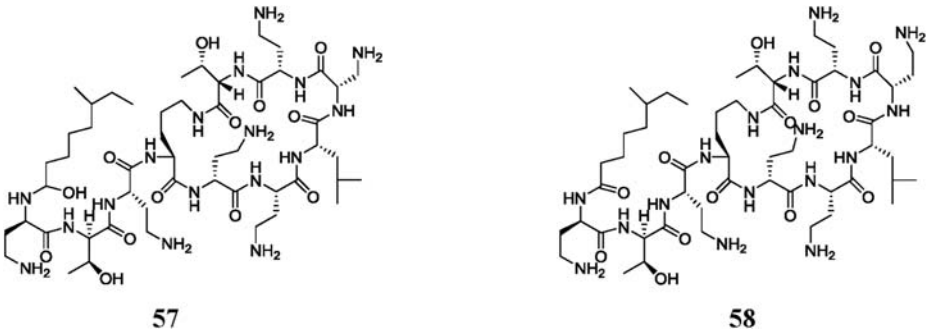


Fig. 9 Polymyxin antibiotics: **57** colistin, **58** polymyxin B.

colistin (polymyxin E), which differ only by one amino acid and have similar biological activity. The initial target of polymyxins is the lipopolysaccharide (LPS) content of the bacterial outer membrane. Polymyxins bind selectively to LPS, and consequently are active against only Gram-negative bacteria.[188,189] It is generally believed that the polymyxins kills bacteria through membrane lysis, first crossing the outer membrane and then destroying the physical integrity of phospholipid bilayer of inner membrane.[189]

Colistin was used clinically from the late 1950s into the 1970s, and then rarely until the 2000s, when it was revived as a last resort for treating MDR Gram-negative infections with few other treatment options. However, because it was originally developed decades ago, there was little information about dosing regimens with regard to both efficacy and adverse effects. Toxicity was the main reason use declined, as serious nephrotoxicity and neurotoxicity was often seen after parenteral administration and safer alternatives became available.

The mechanism of resistance to polymyxins is modification of lipid A, resulting in reduction of polymyxin affinity.[190] Until recently, all reported polymyxin resistance mechanisms were chromosomally mediated, involving modulation of two component regulatory systems (e.g., pmrAB, and phoPQ and its negative regulator mgrB in the case of *K. pneumoniae*). However, *mcr-1*, a plasmid-mediated gene that confers colistin resistance in *E. coli* and *K. pneumoniae*, was recently identified in isolates cultured from animals and patients in China.[20] The *mcr-1* gene was found to encode a phosphoethanolamine transferase able to cationically modify the lipid A moiety of LPS with phosphoethanolamine, leading to reduced electrostatic interaction between colistin and LPS.[191] Following this discovery, this gene has been shown to be present outside of China, in other parts of Asia, Europe, Africa, and South America, and in other Enterobacteriaceae species. Additional studies have found that it is more widespread than initially believed and has been around since the 1980s.[192] A major concern is that the *mcr-1* gene has already established itself in highly antibiotic-resistant Enterobacteriaceae, including carbapenem-resistant strains carrying an NDM-5 resistance plasmid.[193] Such an isolate possesses a pandrug-resistant phenotype where even colistin and the new β-lactam–BLI combination ceftazidime–avibactam are rendered ineffective.

5.17.2.1.10 Trimethoprim resistance

Trimethoprim (Fig. 10; **59**) is a completely synthetic drug belonging to the diaminopyrimidine group of compounds, and is a competitive inhibitor of the enzyme dihydrofolate reductase (DHFR).[194] In the folic acid biosynthetic pathway, DHFR catalyzes the NADPH-dependent reduction of dihydrofolate acid to the active coenzyme tetrahydrofolate. Trimethoprim can be considered as a structural analog of folic acid, therefore, through inhibition of DHFR, affects DNA synthesis and replication leading to the death of the bacterial cell. The folate biosynthetic pathway has been recognized for more than 60 years as an outstanding target for the development of antibacterial compounds[195] although resistance soon emerged when a single folate antagonist was used therapeutically.

Sulfamethoxazole (**60**) also interferes with folate biosynthesis by competing with *p*-aminobenzoic acid to block the biogenesis of dihydrofolate. The combination trimethoprim–sulfamethoxazole (SXT) has been used clinically since the 1960s for the treatment of MRSA and UTIs. Recent clinical practice guidelines recommend SXT as first-line therapy for uncomplicated UTIs, SSTIs, and CA-MRSA infections.[196,197] No significant changes in the rates of susceptibility among CA-MRSA clinical isolates were reported over a 10-year period despite a significant increase in usage of SXT, although decreased susceptibility was observed for *E. coli* and *Proteus* species.[198] There was also no evidence for selection of isolates with increased resistance to other antibiotics correlating with this increased SXT use. However, this drug combination has been associated with the spread of resistant microorganisms on a population level through selection of a transferable class 1 integron, resulting in MDR Enterobacteriaceae in the intestinal flora of children.[199]

While intrinsic resistance to TMP has limited the useful spectrum, the emergence of resistance threatens to reduce the bacterial spectrum even further. Low-level resistance to trimethoprim can occur through chromosomal mutations in the *folA* gene that encodes DHFR.[200,201] Because the drug is synthetic, enzymes that degrade or modify it would not be expected in nature. High-level resistance occurs by a bypass mechanism through the action of an acquired gene that is a drug-nonsusceptible variant of a chromosomal DHFR. These plasmid-mediated DHFRs emerged in Gram-negative bacteria within several years of the clinical introduction of the drug.[202] These acquired alternative DHFR genes were first classified into two distinct gene families, *dfrA* and *dfrB*.[203] Currently six plasmid-mediated families have been reported, with relatively few *dfr* determinants originating from Gram-positive sources.[7,204]

Iclaprim (**61**), a next-generation diaminopyrimidine, is a potent and selective inhibitor of DHFR that was resulted from a rational design approach based on TMP structural information.[205,206] It has been shown to have good antibacterial activity against Gram-positive pathogens that are susceptible to TMP. Iclaprim inhibits bacterial DHFR in a manner similar to TMP but possesses higher affinity due to increased hydrophilic interactions with the protein.[207] It exhibits some activity against TMP-resistant isolates, but lower than that against TMP-susceptible strains. Iclaprim has been shown to be rapidly bactericidal and to possess a low potential for resistance development when used as monotherapy without the synergistic combination of

Fig. 11 Daptomycin.

a sulfonamide agent.[208] Iclaprim completed Phase 3 clinical trials for the treatment of complicated SSTIs but was denied approval until additional clinical data demonstrate efficacy and safety. New Phase 3 trials are currently in progress.

5.17.2.1.11 Daptomycin resistance

Daptomycin (Fig. 11; **62**) is a bactericidal lipopeptide antibiotic active against a wide range of Gram-positive clinical pathogens. The mechanism of action involves perturbation of the cell membrane in a calcium-dependent manner, interacting with its target mostly at the bacterial division septum.[209,210] Although daptomycin was first discovered in the late 1980s, it did not gain FDA approval until 2003. The drug is approved in the United States for the treatment of cSSSI at a 4 mg kg^{-1} day^{-1} dose and for treatment of bacteremia and right-sided endocarditis caused by *S. aureus* at 6 kg^{-1} day^{-1}. Because daptomycin represents a new antibiotic class and targets membranes, widespread resistance has been slow to emerge.

Most *S. aureus* isolates remain susceptible to daptomycin, but there are reports of resistance to the drug. Although resistance mechanisms are still not completely understood, current data suggest that they are complex and multifactorial involving mutational changes.[210,211] Risk factors for selection of these isolates appear to include infections with high bacterial loads such as endocarditis, catheter-related bacteremia, or an undrained abscess and/or exposure to vancomycin.[212] In *S. aureus*, the mechanism of resistance can involve electrostatic repulsion of the drug–calcium complex via an increase in the positive charge of the bacterial cell surface,[213] although other causes have been implicated.[214] Enterococci are intrinsically more resistant to daptomycin compared with staphylococci (Clinical Laboratory Standards Institute MIC breakpoint of ≤ 4 vs. ≤ 1 μg mL^{-1}). Genes involved in daptomycin resistance in enterococci appear to encode either regulatory systems that control cell-envelope homeostasis and stress response or those involved in cell membrane phospholipid metabolism.[215,216] In particular, the LiaFSR three-component regulatory system that controls cell-envelope response to antimicrobial and host defense peptide stress[217] and is analogous to the vraSR regulatory system in *S. aureus* has been implicated. Mutation to this system has been identified in daptomycin-nonsusceptible *E. faecalis*.[218] Transmissible resistance has not been observed for daptomycin to date.

5.17.2.2 Selected Key Pathogens

5.17.2.2.1 Carbapenem-resistant Enterobacteriaceae

Carbapenems (reviewed in section "Antibacterial resistance") are the most potent broad-spectrum β-lactam antibiotics active against Gram-negative organisms. Due to slow or negligible hydrolysis by the majority of β-lactam-hydrolyzing enzymes, this class has been used successfully against MDR Gram-negative organisms since their introduction in the early 1980s, often as a last line of defense. Their utility, however, has been eroding due to increased resistance, especially in the Enterobacteriaceae. Isolates have become MDR; mortality rates associated with carbapenem-resistant Enterobacteriaceae (CRE) infections are as high as 65% in patients with hematologic malignancies.[219] Carbapenemases, the major resistance factors, were known to be produced by the Gram-positive bacilli in the 1960s,[220] but were first detected in Enterobacteriaceae in the mid-1980s[221]; however, there was no significant detection of these enzymes for more than 20 years.[222] These first carbapenemases known were all chromosomally encoded, with any dissemination due to clonal spread. Transferable imipenem resistance due to an MBL was first noted in Japan in *P. aeruginosa*,[223] signaling the beginning of an era when carbapenemases became mobile among Gram-negative bacteria. Widespread carbapenemase production in the Enterobacteriaceae began to be reported in the early 2000s after the first carbapenem-resistant *K. pneumoniae* carrying a new carbapenemase, KPC, was reported in 2001.[224] In addition to carbapenemase production, carbapenem resistance can be caused by increased levels of other β-lactamases such as ESBLs or the AmpC cephalosporinases, accompanied by porin defects leading to decreased penetration of the drug.[225] The National Healthcare Safety Network reported in 2008 that among the nosocomial pathogens reported during 2006–07 from 463 hospitals throughout the United States, 10–11% of all *K. pneumoniae* isolates causing central line-associated bloodstream infections or UTIs were resistant to

carbapenems.[226] From 2005 onward, there were reports of KPC-producing strains in multiple countries with notable nationwide outbreaks in Israel, Greece, and Italy.[227–229]

As of 2014, areas with endemic KPC enzymes are China, Israel, Greece, Italy, Poland, Colombia, Argentina, Brazil, and some states in the United States. In India, the NDM family of MBLs is identified in 75–88% of CRE, often appearing with other carbapenemases such as KPC or OXA enzymes in as many as 19% of the isolates.[230,231] In Turkey OXA-48 carbapenemases are prevalent. It has become evident that without stringent infection control measures these organisms can rapidly become endemic. In New York City 38% of *K. pneumoniae* isolates produced a KPC enzyme in 2006; after stricter infection control measures were implemented, this number was reduced to 29% in 2009, indicating improvement, but not eradication of these pathogens.[232] There are limited treatment options today for CRE, although the avibactam-BLI combinations and some of the newer investigational drugs such as plazomicin and eravacycline have potentially useful antibacterial activity against many of these isolates. Overall, it is clear that CRE have become a challenge to our healthcare systems due to their rapid spread, poor treatment options, and often severe outcomes.[233]

5.17.2.2.2 *Antibiotic-resistant* N. gonorrhoeae

The World Health Organization (WHO) estimated in 2008 that 106 million new gonorrhea cases occur among adults annually worldwide causing significant morbidity and socioeconomic consequences globally.[234] Previously relatively easily treatable, the prevalence of *N. gonorrhoeae* strains with resistance to most antimicrobial agents, including sulfonamides, penicillins, earlier cephalosporins, tetracyclines, macrolides, and fluoroquinolones is now increasing.[235] In most countries, the only options for first-line empirical antibiotic monotherapy are currently the extended-spectrum cephalosporins, oral cefixime (**Fig. 12**; **63**), and particularly, the more potent injectable ceftriaxone (**64**).[236] The dual-antimicrobial treatment regimens with ceftriaxone and azithromycin introduced in the United States and Europe[237,238] appear currently to be highly effective. Recent gonorrhea treatment failures with the extended-spectrum cephalosporins cefixime and ceftriaxone and the emergence of gonococcal strains exhibiting high-level clinical resistance combined with resistance to nearly all other available antimicrobials are quite troubling. Resistance to azithromycin has been reported in Asia and Canada at rates $\leq 5\%$, but emerges more rapidly where there is frequent use of this drug.[235] There is a significant contribution of drug efflux pumps in clinical isolates of *N. gonorrhoeae* that express extensively drug-resistant or MDR phenotypes.[239] Furthermore, gonococcal strains with decreased susceptibility or resistance to both ceftriaxone and azithromycin have already been observed around the world.

Future therapy might not be affordable for lower economic-level individuals where the highest gonorrhea burdens are often found. From a global public health perspective, new antimicrobials for effective monotherapy or for inclusion in a new combination regimen are desperately needed. Some other currently marketed or late stage drugs with potential for use include tigecycline and eravacycline, solithromycin, dalbavancin, and delafloxacin (**65**).[235] Older antimicrobials have also been considered for future empirical monotherapy of gonorrhea.[236] These include the injectable carbapenem ertapenem (**66**),[240] oral fosfomycin (**67**),[241] and the injectable aminoglycoside gentamicin, which has been used as first-line treatment in Malawi for more than 20 years without any reported emergence of in vitro resistance.[242] However, it is important to note that *N. gonorrhoeae* has developed resistance to all antimicrobials introduced as first-line therapy over the last 70 years; for more sustainable future treatment, combination therapies or new compounds with truly novel mechanisms of action are needed.

5.17.2.2.3 *Clostridium difficile*

C. difficile is recognized as the major cause of healthcare antibiotic-associated diarrhea[243] and is correlated with antibiotic therapy, particularly with broad-spectrum agents that disrupt the protective intestinal microbiota allowing acquired or resident *C. difficile* to colonize the gastrointestinal tract and infect the host. CDI has significantly increased in incidence across the United States, Canada, and Europe over the last decade, adding a large financial burden on healthcare systems.[244–247] The emergence of highly virulent

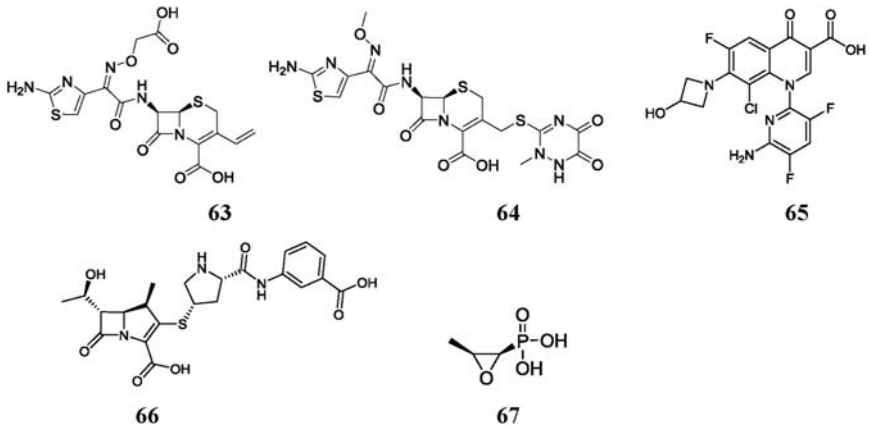

Fig. 12 Antibiotics for the treatment of *Neisseria gonorrhoeae* infections: **63** cefixime, **64** ceftriaxone, **65** delafloxacin, **66** ertapenem, **67** fosfomycin.

strains, particularly ribotype RT027, has led to severe infections characterized by a high recurrence rate recurrences, increased mortality, and less responsiveness to traditional therapies.[243,248] These strains have spread globally over recent years[249,250] including into previous low-risk populations such as young individuals, healthy peripartum women, antibiotic-naive patients, or those with no recent healthcare exposure.[251–253] Paralleling the increased CDI incidence, increased morbidity and mortality was observed and associated with the emergence and spread of the hypervirulent type RT027 strain. CDI caused by RT027 is characterized by increased severity, being refractory to traditional therapy and greater risk of relapse.

Antibiotic resistance has played a key role in driving this current epidemic. The emergence and spread of *C. difficile* RT027 has been correlated with the widespread use of fluoroquinolones and the acquisition of fluoroquinolone resistance, since this resistance was not observed in ancestral strains of the same type.[254] Antibiotic resistance rates vary considerably in different studies, often dependent on locations and antibiotic usage. Recent data extrapolated from 30 studies published between 2012 and 2015 indicate that resistance to clindamycin (Fig. 13; **68**) and cephalosporins is very common in *C. difficile* clinical isolates (55% and 51%, respectively), as is the resistance to erythromycin and fluoroquinolones (47%).[255] Most of the strains tested for susceptibility to second-generation cephalosporins such as cefotetan (**69**) and cefoxitin (**70**) were resistant (79%), whereas resistance to expanded-spectrum cephalosporins such as ceftriaxone and cefotaxime is present in a lower number of isolates (38%). For quinolones, resistance to ciprofloxacin was widespread in *C. difficile* (99% of the strains tested), while resistance to fourth-generation fluoroquinolones such as moxifloxacin and gatifloxacin (**71**) was observed in 34% of the tested strains.[255]

Ribosomal methylation is the most widespread mechanism of *C. difficile* resistance to MLS antibiotics. ErmB erythromycin ribosomal methylases commonly mediate resistance, while other *erm* genes are rarely detected in *C. difficile* isolates.[256–258] Quinolone resistance is due to alterations in the quinolone resistance determining region (QRDR) of either the GyrA or GyrB DNA gyrase subunits.[259–261]

Metronidazole (**72**) is considered first-line treatment for mild to moderate CDI.[262,263] However, although resistance rates remain low, treatment failures are observed.[264] Vancomycin is used as the first-line antibiotic for moderate to severe CDI.[263] Although resistance to this drug is not common, a number of strains with reduced susceptibility (MICs $>$ 2–16 μg mL^{-1}) have recently been reported. The clinical significance of reduced susceptibility to vancomycin is not clear, since the fecal concentration of drug can be over 2 mg mL^{-1}.[265] Since there has been an increased rate of treatment failure and infection recurrence with either vancomycin or metronidazole treatment, other therapy options have been investigated.[264] Rifamycins, in particular rifaximin (**73**), have recently

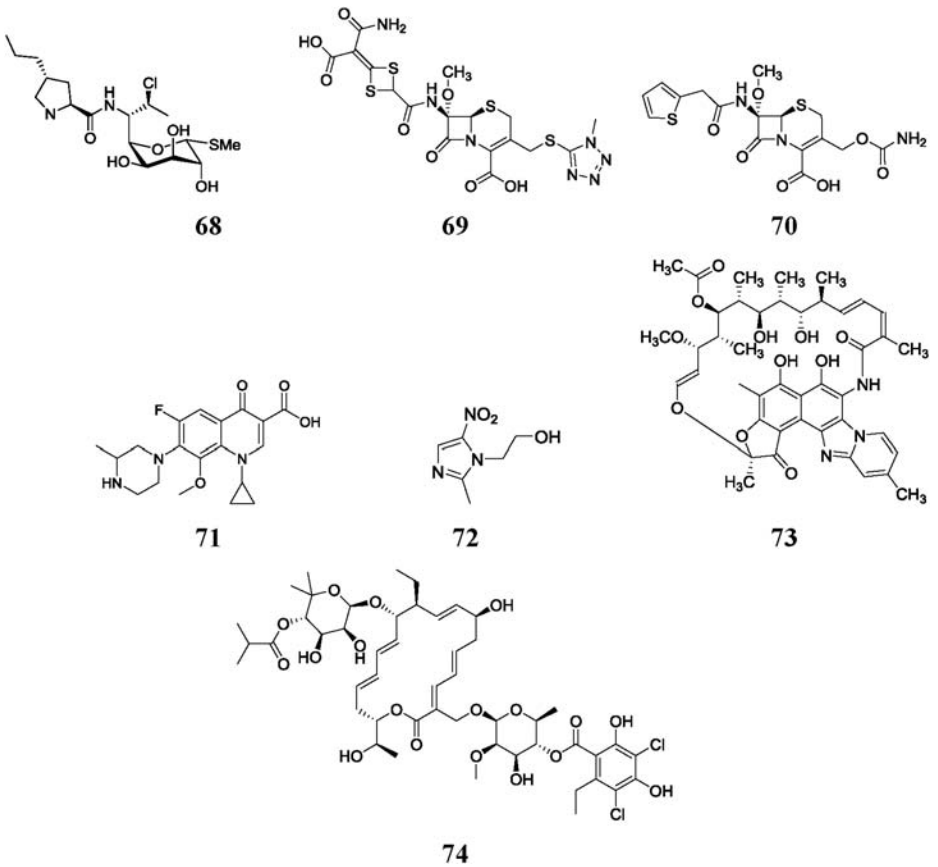

Fig. 13 Antibiotics for the treatment of *Clostridium difficile* infections: **68** clindamycin, **69** cefotetan, **70** cefoxitin, **71** gatifloxacin, **72** metronidazole, **73** rifaximin, **74** fidaxomicin.

been suggested for treatment of relapsing CDI,[266] while fidaxomicin (**74**) is a bactericidal narrow-spectrum macrocyclic antibiotic that is used for the management of CDI with high risk for recurrences.[267] Both rifamycins and fidaxomycin inhibit bacterial transcription but with different RNA polymerase target sites. Fidaxomicin provides cure rates not inferior to vancomycin and is associated with a significantly lower rate of recurrence of CDI.[268] It also has a minimal impact on the composition of the gut microbiome, in particular Bacteroides species,[12] despite high local concentration in the gut and feces.

5.17.2.2.4 *Multidrug-resistant* Acinetobacter

Acinetobacter spp. are strictly aerobic, nonfermentative, Gram-negative organisms frequently isolated in soil and water that can exist as part of normal skin flora. There has been a significant increase in the incidence of infections caused by *A. baumannii* in recent years. Most of the nosocomial outbreaks by this microorganism have occurred in intensive care units, where there is substantial use of antimicrobial agents that select for the emergence of MDR strains. There has been a large increase in *A. baumannii* resistance to all antimicrobial agents in recent years. For example, resistance to ceftazidime is >85% and to ciprofloxacin is >90%.[269] About 63% of *Acinetobacter* are considered MDR to at least three different classes of antibiotics and approximately 2% of healthcare-associated infections are caused by this organism with the proportion higher among critically ill patients on mechanical ventilators (about 7%).[270] The result is an estimated 12,000 healthcare-associated *Acinetobacter* infections in the United States each year with nearly 7000 (or 63%) MDR, and about 500 deaths are attributed to these infections.

Resistance to β-lactams occurs in several ways, including upregulation of inherent chromosomal AmpC and carbapenemase (bla_{OXA-51}) genes by insertion sequences, OXA carbapenemases, and NDM carbapenemases.[271] The presence of a specific IS element ISAba1 upstream of the naturally occurring *ampC* gene generates promoter sequences that enhance expression, providing resistance to broad-spectrum cephalosporins. The most common ESBLs identified in *A. baumannii* are the PER-, GES- and VEB-type β-lactamases. Despite wide dissemination among Enterobacteriaceae, only a few KPC-type β-lactamases have been identified in *A. baumannii*.

Quinolone resistance in *A. baumannii* arises by a single mutation in the *gyrA* gene, resulting in high-level resistance clinically. This is due to the fact that *A. baumannii* also has some intrinsic resistance due to decreased permeability or constitutive expression of efflux pumps.[272] Plasmid-mediated *qnr* genes have not been identified in this organism. Tigecycline has shown good antibacterial activity against *A. baumannii* with successful clinical outcomes.[273] Two mechanisms of resistance to colistin have been reported in *A. baumannii*: alterations of the lipid A component of LPS resulting from mutations in the PmrAB two-component system,[274] and complete loss of LPS production resulting from mutations in the *lpxA*, *lpxC*, and *lpxD* genes encoding the enzymes that catalyze the first steps in LPS biosynthesis.[275]

In a recent study, 5477 *A. baumannii* and other relevant Gram-negative organisms (collected 2007–11) were tested for susceptibility to tetracycline, doxycycline (**Fig. 14**; **75**), and other broad-spectrum antimicrobial agents.[276] *A. baumannii* strains were highly resistant to all agents tested with the exception of minocycline (79.1% susceptible) and colistin (98.8% susceptible).

5.17.2.2.5 *Methicillin-resistant* Staphylococcus aureus

S. aureus continues to be one of the most common bacterial pathogens in the world and causes a broad spectrum of diseases in both community and hospital settings.[277] More recently, highly virulent CA-MRSA strains such as USA300 have emerged. Over time treatment of *S. aureus* infections has become more challenging, with an increasing frequency of MDR isolates, particularly in MRSA. Clinical isolates with reduced susceptibility to glycopeptides, particularly vancomycin, have been reported.[278] However, unlike for MDR Gram-negative pathogens, there are now a number of treatment options available for MRSA infections.

Overall rates of *S. aureus* bacteremia appear to have stabilized over the past 20 years while the contribution MRSA has fluctuated.[277,279] Since 2005 many regions have seen significant reductions in rates of MRSA bacteremia, usually correlated with improvements in infection control procedures. These reductions were especially evident in the United Kingdom, where rates of MRSA bacteremia were halved between 2004 and 2011.[280] The United States has also seen such reductions.[281] While *S. aureus* has traditionally been the leading cause of SSTIs, its importance has been magnified in the past 15 years with the emergence of a worldwide epidemic of CA-MRSA SSTIs.[282,283] Recent US data suggest that the MRSA SSTI incidence may have peaked around 2007–08; for example, the proportion of all community-onset SSTIs due to MRSA in the US military health system declined from 62% to 52% from 2005 to 2010, although overall *S. aureus* SSTI rates did not change.[284]

The increased prevalence of cardiac device implantations has led to an increased incidence of cardiac device *S. aureus* infections.[285] The impact of these infections is high and those due to MRSA are generally, but not invariably, associated with higher mortality rates than those caused by MSSA.[286] *S. aureus* is an important cause of pneumonia in both community and hospital settings. In particular, *S. aureus* has consistently been shown to be one of the most common pathogens in healthcare-associated infections (HCAP). A recent study found MRSA as the cause of 28% of VAP cases in 31 US community hospitals,[287] and patients

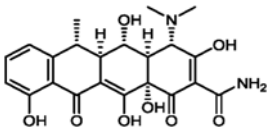

Fig. 14 Doxycycline.

with MRSA VAP tend to incur increased costs of care compared to patients with MSSA pneumonia.[288] Fortunately, the overall incidence of MDR pathogens, including MRSA, is relatively low in patients with HCAP[289] and rates are lower in most parts of Europe compared with the United States.[290] *S. aureus* is becoming a common pathogen in CF patients, an increasing proportion of which are MRSA. *S. aureus* may form biofilms in the airways of patients with CF,[291] contributing to the persistence of colonization and antibiotic failure.

The worldwide emergence of methicillin-resistant staphylococci (MRSA and MRSE) in the 1970s brought vancomycin to the forefront for treatment of staphylococcal infections. The drug remains as first-line therapy for methicillin-resistant coagulase-negative and coagulase-positive staphylococcal infections, including bacteremia, endocarditis, pneumonia, cellulitis, and osteomyelitis.[292] Vancomycin exhibits slower bactericidal activity against MSSA compared to β-lactams, and this slow activity may contribute to the worse clinical outcomes seen with cases of MSSA bacteremia and pneumonia treated with vancomycin.[293] In 2002, the first vanA-mediated vancomycin-resistant strain was reported and, since that time only 13 isolates have been reported in the United States,[294] with a few others in India, Iran, and Brazil.

One more recent treatment option is daptomycin,[209] for which no *S. aureus* MIC "creep" (such as reported for vancomycin) has been observed since its approval for clinical use.[157] In fact, daptomycin MIC distributions have changed little for any of the Gram-positive pathogens for which it is approved[295] and the MIC_{90} remains 0.5 μg mL^{-1} among staphylococci. However, there have been reports of emergence of daptomycin-nonsusceptible *S. aureus* isolates during unsuccessful therapy with the drug.[296,297] *S. aureus* nonsusceptibility to daptomycin appears to be multifactorial, involving alterations to both cell membrane and cell wall through adaptations in metabolic and stress response regulatory pathways.[298]

Clinical infections with *S. aureus*, especially MRSA, will likely remain both common and serious, with waves of increasing antimicrobial resistance.[299] Over the past 20 years, two clear shifts in the epidemiology of *S. aureus* infections have occurred: first, growth in the number of healthcare-associated infections such as those associated with prosthetic device procedures, and second, an epidemic of community-associated SSTIs driven by strains with particular virulence factors.[277] Further epidemiology shifts are probable in the future, with MRSA maintaining its role as a key human pathogen.

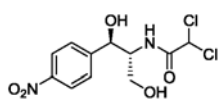
5.17.2.2.6 *Multidrug-resistant* Pseudomonas aeruginosa

P. aeruginosa is an important pathogen frequently involved in a variety of healthcare-associated infections, especially in critically ill or immunocompromised patients. Intrinsic antibiotic resistance is a particular problem with *P. aeruginosa* due to a combination of reduced cell wall permeability and the ability to acquire and express multiple resistance mechanisms including porin deletions and overexpression of efflux pumps.[300,301] Although the prevalence of *P. aeruginosa* in the last two decades has remained relatively stable, the incidence of antibiotic-resistant strains has increased dramatically.[302,303] *P. aeruginosa* infections caused by resistant isolates are associated with higher mortality, increased morbidity, and extensive resource utilization and associated costs. These MDR isolates make effective treatment much more challenging and limited available treatment options can lead to inappropriate empiric therapy often associated with poor clinical and economic outcomes.[304]

P. aeruginosa currently shows resistance to the following antibiotics at varying levels: penicillins, including those combined with BLIs; early cephalosporins; piperacillin; piperacillin and tazobactam; cefepime; ceftazidime; aminoglycosides; the quinolones; and the carbapenems, as well as colistin and fosfomycin. Therefore, monitoring resistance trends for *P. aeruginosa* becomes important for choosing the optimal antibiotic, as this organism has become one of the leading causes of pneumonia. Carbapenem resistance in *P. aeruginosa* is mostly attributable to porin (OprD) deficiency, often combined with derepressed expression of the chromosomal AmpC cephalosporinase, and more rarely to carbapenemases—mainly the IMP, VIM, SPM, and GIM MBLs.[305] NDM-1-producing *P. aeruginosa* isolates were first reported in 2011, with two strains recovered from Serbia.[306] NDM-1-positive *P. aeruginosa* isolates have since been identified in India, Italy, Egypt, and Slovakia.[305] A *P. aeruginosa* isolate producing both the IMP-18 MBL and the KPC-2 serine carbapenemase has been reported from Puerto Rico.[307] With regard to aminoglycoside resistance, the first 16S rRNA methylase, RmtA, recovered in *P. aeruginosa* was identified in 2003 in a clinical isolate from Japan.[308] Fluoroquinolone resistance in *P. aeruginosa* is mainly related to the MexAB–OprM RND-type efflux system, whose expression is constitutive. This system also confers reduced susceptibility to chloramphenicol (Fig. 15; **76**), tetracyclines and β-lactams.[309] The emergence of colistin-resistant *P. aeruginosa* isolates associated with modifications of the lipid A component of LPS has been reported worldwide.[310] Several two-component regulatory systems, such as PmrAB, PhoPQ, ParRS, CprRS, and ColRS, are involved in resistance to polymyxins in *P. aeruginosa*.[311]

5.17.2.2.7 *Mycobacterium tuberculosis*

Tuberculosis (TB) continues to be the world's leading cause of death by a single infectious agent. The WHO estimates that in 2014, 9.6 million people became ill with active TB and 1.5 million died from the disease, including 140,000 children.[312] Most new cases



75

Fig. 15 Chloramphenicol.

of TB occur in Asia and Africa (58% and 28%, respectively). South Africa is particularly affected, as TB represents the single largest cause of mortality with nearly 9% of all deaths in 2013,[313] and TB continues to be a major killer of human immunodeficiency virus (HIV)-infected individuals in Africa and elsewhere around the world causing 400,000 of the 1.2 million HIV deaths reported in 2014.[312]

Antibiotic treatment regimens are available, but the emergence of drug-resistant TB complicates efforts to control the epidemic fully. In 2014, 3.3% of these cases resulted from MDR tuberculosis (MDR-TB) and extensively drug-resistant tuberculosis (XDR-TB) strains.[314] MDR-TB are resistant to both of the first-line drugs of standard TB treatment isoniazid (**Fig. 16**; **77**) and rifampicin (**78**), while XDR-TB are resistant to isoniazid, rifampin, at least one fluoroquinolone, and any of the second-line injectable treatments (amikacin, capreomycin [**79**], kanamycin [**80**]).[315] Other drugs considered to be in first-line combination therapy are ethambutol (**81**) and pyrazinamide (**82**).[316] The cost of treating these resistant TB strains can be as much as 25 times higher and take three times longer than for drug-susceptible strains.[317] In 2014, there were 480,000 new cases of MDR-TB with especially significant incidence in Eastern Europe and central Asia. Approximately 9.7% of MDR-TB cases are caused by XDR-TB strains globally, with the highest rates of XDR-TB among MDR-TB cases occurring in Belarus (29%), Lithuania (25%), Latvia (19%), and Georgia (15%) in 2014.[312] In the United States in 2014, the proportional incidence of MDR-TB remains relatively low at 1.3%, and overall TB incidence in the United States remained approximately 3.0 cases per 100,000 persons during 2013–15.[318]

Drug resistance to *Mycobacterium tuberculosis* (MTB) generally results from inadequate drug treatment of active TB caused by lack of patient compliance, inadequate drug levels, drug shortages, or other factors. New antibiotic regimens with novel drugs are needed that can potentially shorten the current treatment course of 6 months or more. Treatment of MDR- or XDR-TB strains can take 18 months and cost more than $150,000 in the United States. With the increased toxicity of second-line agents, patient compliance over the entire treatment period can be even more challenging. Treatment of patients in less developed countries is often beyond the means of governments, ensuring that MDR- and XDR-TB strains will remain with us and possibly increase in incidence in the future.

Recent years have seen the first regulatory approvals for new TB drugs bedaquiline and delamanid, in more than 40 years.[319] Bedaquiline (**83**) is a diarylquinoline that was granted accelerated approval for the treatment of MDR-TB by the US FDA in Dec. 2012,

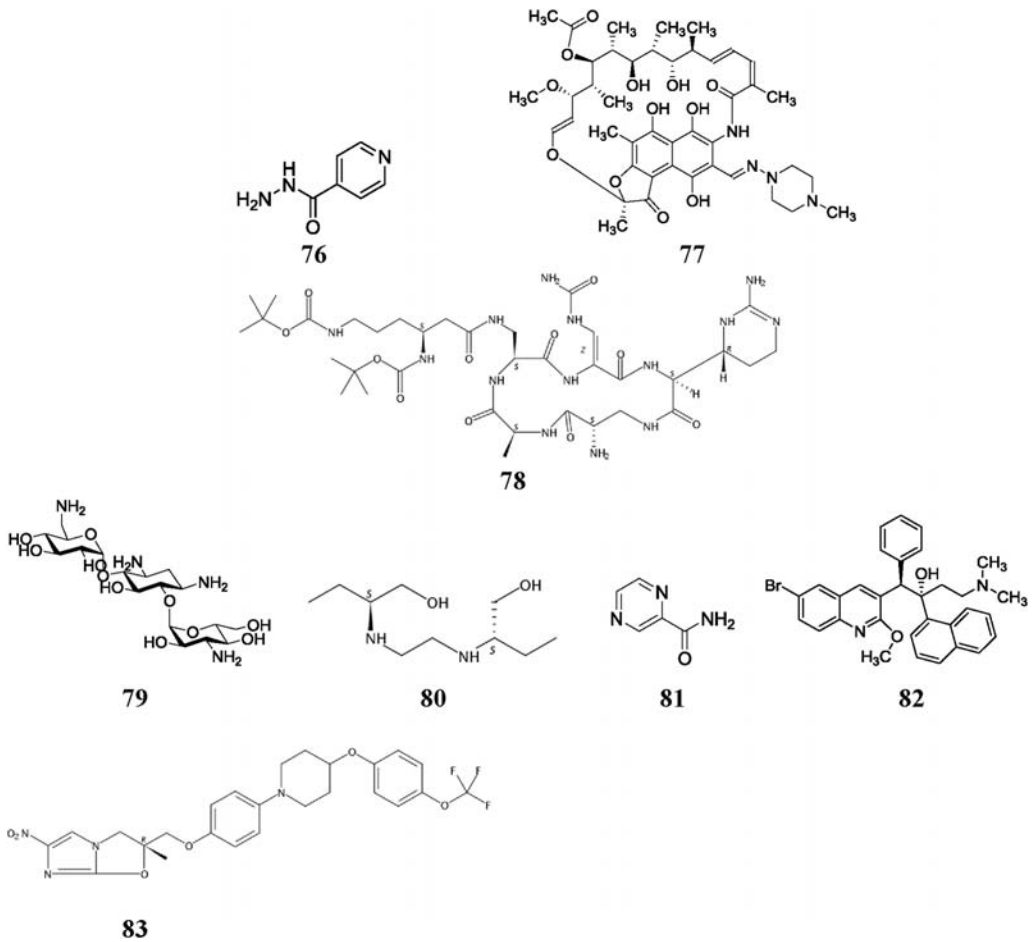


Fig. 16 Antibiotics for the treatment of *Mycobacterium tuberculosis*: **77** isoniazid, **78** rifampicin, **79** capreomycin, **80** kanamycin, **81** ethambutol, **82** pyrazimide, **83** bedaquiline.

based on data generated by Phase 2b trials. This is the first new drug approved specifically for TB. Bedaquiline has a unique mechanism of action that targets the proton pump for ATP synthase.[320] Delamanid (**84**), a nitro-dihydro-imidazooxazole, is an orally dosed prodrug whose primary metabolites likely kill mycobacteria by blocking the synthesis of mycolic acids and disrupt cell wall synthesis.[321,322] Nitroimidazoles also appear to kill the TB bacteria by poisoning them with nitric oxide, which the drugs release when metabolized. Delamanid received its first global approval for the treatment of MDR-TB in the European Union (EU), for use in combination with optimized background therapy, and also has been granted orphan drug status in both the EU and Japan.[323]

5.17.3 Antifungal Resistance

Candida species and *Aspergillus* are the key pathogenic fungi whose incidence and resistance trends have been carefully monitored. Over the past decade, decreases in bacterial causes have led to *Candida* becoming the most common cause of healthcare-associated bloodstream infections in many US hospitals.[324] *Candida* spp. are becoming increasingly resistant to current antifungal drugs (Fig. 17) such as the azole fluconazole (**85**) and the echinocandin glucan synthetase inhibitor caspofungin (**86**); however, overall resistance rates are relatively low compared with what has been observed for bacteria. Fluconazole resistance in particular has remained relatively constant over the past 20 years.[325,326]

A 2016 publication described 1846 fungal clinical isolates from 31 countries. Echinocandin resistance in *Candida* spp. ranged from 0.0% to 2.8% (highest for anidulafungin [**87**] vs. *C. glabrata*), and fluconazole resistance was noted among 11.9% and 11.6% of the *C. glabrata* and *Candida tropicalis* isolates, respectively.[327] Other US studies have followed the development of echinocandin resistance in *Candida* species, particularly *C. glabrata*. The majority of these resistant isolates have specific mutations in one of two "hot spot" regions of the FKS1 or FKS2 genes, which encode a subunit of the 1,3-β-D-glucan synthase target protein.[328,329] There is also evidence that many echinocandin-resistant *C. glabrata* isolates are also resistant to fluconazole.[330] One recent study reported several significant findings. First, despite a decreasing number of *C. glabrata* candidemia, the level of echinocandin resistance remained steady or has increased. Second, elevated MIC values and echinocandin resistance are caused by an increasing number of distinct mutations in *C. glabrata*, primarily in the FKS1 and FKS2 genes. Third, MDR among *C. glabrata* isolates was high (>3%) and may indicate future problems with this pathogen.[328]

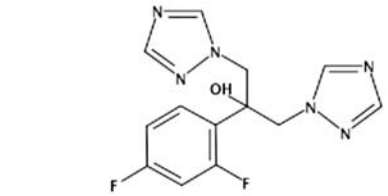
Other studies showed that immunocompromised patients, particularly those undergoing bone marrow or organ transplants, were found to develop *Candida* infections after receiving micafungin (**88**) prophylaxis. The rate of echinocandin-resistant *C. glabrata* increased from 4.9% to 12.3% and fluconazole-resistant isolates from 18% to 30% over a 10-year period through 2010.[331] Echinocandin resistance among US *C. glabrata* isolates is a concern, especially in light of the fact that one-third of those isolates may be MDR. Because treatment options for fungal infections remain limited, this potential new resistance trend needs to be closely monitored.

Azole resistance in *Aspergillus fumigatus* has become an issue in recent years. It has been known that in patients with chronic exposure to azoles, such as those with chronic pulmonary aspergillosis, resistance to this class of agents can occur. The first reports came from isolates collected from patients who had been treated with itraconazole in the 1990s in the United States and Sweden (**89**).[332] As seen with *Candida* species, resistance in *Aspergillus* can be due to point mutations in the CYP51A gene, which encodes the enzyme responsible for the demethylation of lanosterol in the final step in ergosterol biosynthesis. Rates of azole resistance in the United Kingdom were reported to have increased from 5% to 7% to up to 20% from 2004 to 2009, with these isolates primarily coming from patients with chronic pulmonary aspergillosis combined with long-term azole exposure.[333,334]

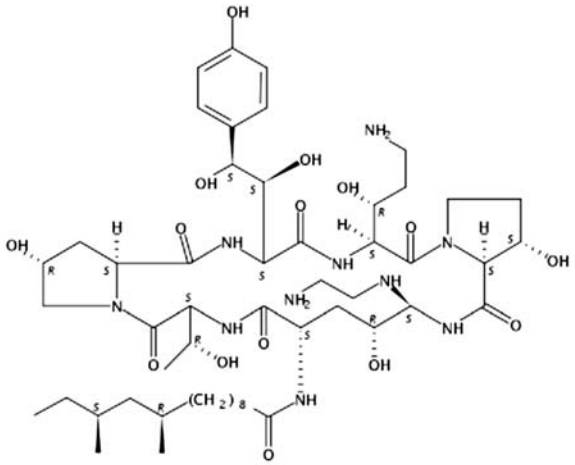
Fluconazole inhibits the fungal cytochrome P450 enzyme 14α-demethylase. Selectivity occurs since the mammalian demethylase activity is much less sensitive to fluconazole than fungal demethylase. This inhibition prevents the conversion of lanosterol to ergosterol, an essential component of the fungal cytoplasmic membrane, with consequent accumulation of 14α-methyl sterols. Of note, in documented invasive aspergillosis, azole-resistant *A. fumigatus* isolates have been reported in patients without previous azole exposure with tandem repeats in the promoter region of CYP51A, in addition to point mutations found within this gene. Environmental isolates with these changes have also been recovered, including the indoor environment of hospitals and areas in direct proximity to the medical centers along with areas where azole fungicides are used in agriculture.[335,336] The rise in azole resistance rates in *A. fumigatus* isolates in the United States and in other countries around the world and the discovery of mechanisms of resistance associated with environmental exposure are causes for concern.[337] Even more troubling is the appearance of multidrug *Candida* infections resistant to both echinocandins and fluconazole, leaving few treatment options other than amphotericin B (**89**). Such limited treatment options for infections due to resistant isolates may be associated with a higher probability of treatment failure.[338,339]

5.17.4 Antiviral Resistance

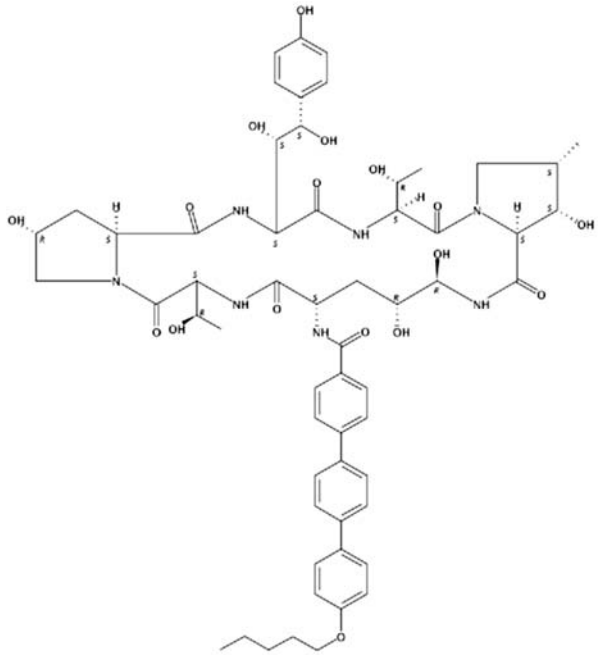
By comparison with the antibacterials and antifungals, antiviral drug discovery took longer to gain momentum as the dogma in the early days was that because viruses are obligatory parasites their replication could not be blocked selectively. Initial antiviral treatments were not specific and were mostly derived from the development of polymers (including polyanions). Antiviral development was also influenced by the emergence of interferon therapy and by research on innate and acquired immunity. Additionally, synthetic polyanions initially thought to act as direct-acting antiviral agents (DAAs) were later discovered to induce interferon. Since the first antiviral treatments were nonspecific, had low selectivity, and were frequently targeting cellular factors, they were not prone



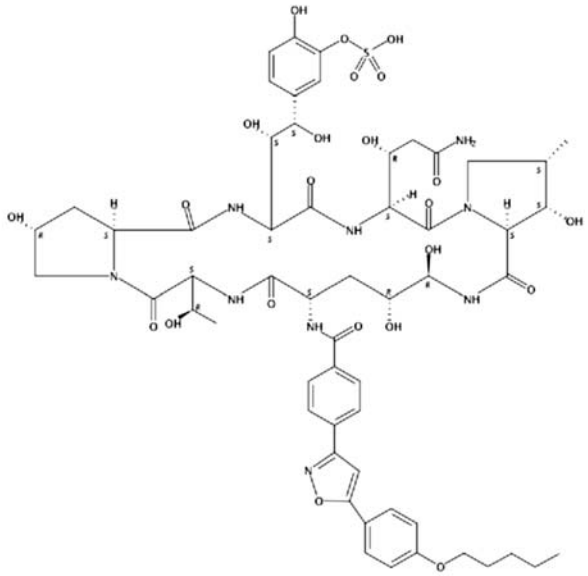
84



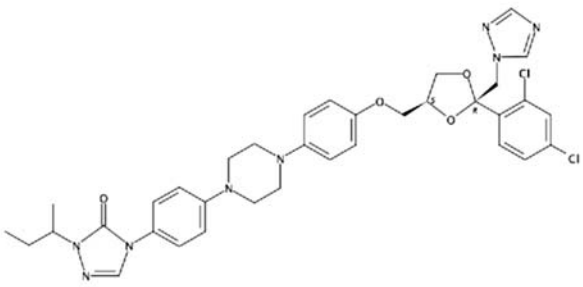
85



86

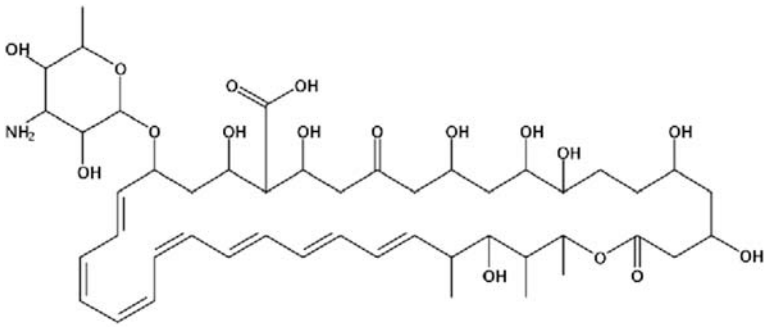


87



88

Fig. 17 Antibiotics for the treatment of fungal infections.



89

Fig. 17 (*continued*).

to resistance. With the development of DAAs targeting specific viral gene products, better selectivity was achieved but at the cost of selective pressure against the less genetically stable viral targets. This led to the emergence of drug resistance to viral pathogens, in particular those with high genetic variability arising from low polymerase fidelity or from high levels of viral genome recombination. The discovery of acyclovir, the first selective antiviral, as a treatment for herpes simplex infection stimulated a further quest for novel antiviral agents with narrow selectivity and high activity.[340]

As the number of DAAs in clinical usage increased, so resistance emerged. This emergence was also more pronounced for lethal diseases such as acquired immunodeficiency syndrome (AIDS), as treatment to prevent patient health worsening or death was obviously urgent, and initial regimens provided suboptimal antiviral effects. For long-term treatments, patient fatigue or side effects led to reduced treatment adherence, suboptimal drug levels, and a consequent increase in the development of resistance. Overall, resistance to antiviral drugs has emerged as one of the most important barriers to efficacy in the treatment of chronic infections.[341] This section discusses only the resistance issues encountered with the most frequently used drugs, focusing on the last 10–15 years and the major pathogens HIV, hepatitis B virus (HBV), hepatitis C virus (HCV), and influenza.

5.17.4.1 Human Immunodeficiency Virus

HIV is a lentivirus, a member of the Retroviridae family. Two types of HIV, HIV-1 and HIV-2, were discovered in the early 1980s and were rapidly identified as the causative agents of AIDS.[342–344] HIV-1 is found worldwide, and HIV-2 is mostly prevalent in sub-Saharan Africa. HIV has a unique viral cycle characterized by an RNA-to-DNA step executed by an unusual polymerase, the reverse transcriptase (RT), offering an opportunity for the development of nucleoside analogs able to target viral replication relatively specifically. Additionally, and in contrast to retroviruses discovered previously, a function map of the HIV genome was quickly established after discovery and sequencing, allowing the identification of potential targets and leading to intensified drug development.

The drugs currently approved to treat HIV target the viral proteins RT, protease (PR), and integrase (IN), all three of which generated from the pol polyprotein, as well as the envelope gene product (ENV). All current antiretroviral drugs (ARVs) are DAAs, and representatives from several classes are usually combined to treat HIV infection for life, as no curative treatment is available. The well-established high mutation rate of HIV is linked to its error-prone polymerase, the RT. Although frequently deleterious for the viruses, some mutations are fit enough to allow transmission of drug-resistant isolates, one of the modern challenges for HIV treatment.[341] Consequently, screening for HIV drug resistance before the start of a new regimen is now standard of care in most developed countries.

Modern antiretroviral regimens are adjusted to the presence or potential emergence of resistance mutations by preferentially selecting drugs with higher minimum (trough) plasma concentrations (C_{min}) that largely exceed the antiviral activity (EC_{95}). These properties are captured by their inhibitory quotient (IQ), the ratio of the clinical drug concentration (such as C_{min}) to the EC_{95} ($IQ = C_{min}/EC_{95}$).[345–348] The IQ can be advantageously modified by adjustment of the drug dosage when available for clinical use.[349] The most commonly used ARVs, their respective HIV targets, and their resistance profiles are described here.

5.17.4.1.1 HIV reverse transcriptase

HIV RT inhibitors were the first class of drug to be developed. These drugs bind directly to the HIV RT, an RNA-dependent DNA polymerase, blocking its function in viral replication. Early drugs were derivatives of natural nucleosides and included examples with simple chemical modifications such as zidovudine, zalcitabine, didanosine, and stavudine. With limited selectivity between the viral and cellular polymerases, many had significant side effects, but they played a key role in delaying AIDS for some patients, allowing for the discovery of new drugs.[350] Next generations of RT inhibitors were further developed, are mostly in use today and discussed here.

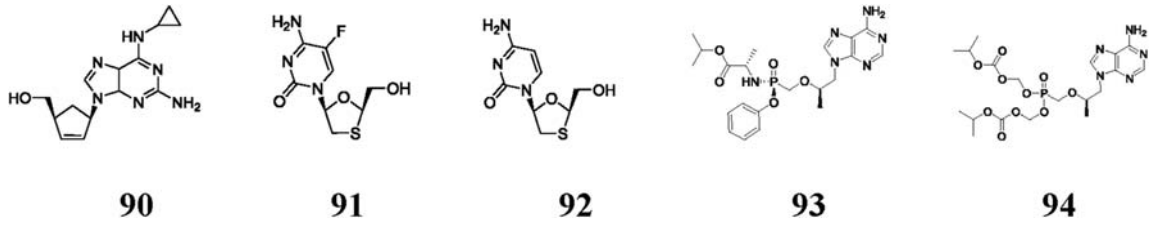


Fig. 18 HIV nucleoside RT inhibitor (NRTI).

5.17.4.1.1.1 Nucleoside RT inhibitors

Drugs in the nucleoside reverse transcriptase inhibitor (NRTI) class were designed as derivatives of natural nucleosides or nucleotides (Fig. 18). All are phosphorylated by cellular host enzymes to produce their triphosphate analogs. The most frequently used drugs in this class include abacavir (**90**), emtricitabine (**91**), lamivudine (LAM) (**92**), and tenofovir (TFV). For each, the active metabolite can inhibit RT by incorporation into viral DNA, causing a termination of DNA chain elongation. The most recent NRTI to be FDA-approved is TFV alafenamide (**93**), a novel prodrug of TFV, with more selective safety and pharmacokinetics (PK) properties than the current tenofovir prodrug, TDF (**94**).[351] The resistance barrier to NRTIs is usually low, as a single point mutation can render the virus less susceptible or drug-resistant, such as M184V or K65R (reviewed in Ref. [352]). Resistance can also be conferred through accumulation of multiple mutations, such as the Q151M complex or thymidine analog mutations, as well as insertion multiple residues at position T69.

5.17.4.1.1.2 Nonnucleoside RT inhibitors

Nonnucleoside reverse transcriptase inhibitors (NNRTIs) do not originate from natural products but from synthetic screening libraries. Unlike NRTIs, NNRTIs act as allosteric inhibitors by reducing the catalytic activity of RT without binding the polymerase catalytic pocket.[353] Interestingly, the NNRTI binding site is not observed crystallographically in the absence of ligand. Current NNRTIs (Fig. 19) are only active against HIV-1. Drugs in this class are very potent, and include nevirapine, delavirdine, and efavirenz (**95**). Etravirine (**96**) and rilpivirine (**97**) are second-generation NNRTIs, which were designed to be active against HIV strains with mutations that confer resistance to the most commonly prescribed first-generation NNRTIs such as K103N, although their IQ is lower than some of the first-generation drugs in this class.

5.17.4.1.2 HIV protease

HIV PR plays a central role in the viral cycle, as it is responsible for the processing of all the viral products produced in the gag-pol polyprotein, including auto-processing to generate the free PR. The enzyme has different levels of activity against the several substrate sequences it needs to cleave, allowing coordinated cuts in specific order, important for the production of viral PARTICLES with optimal infectivity.

5.17.4.1.2.1 Protease inhibitors

Protease inhibitors (PIs) are early examples of peptido-mimetic drugs. Their structures were based on tetrapeptides, mimicking amino acid residues around the cleavage sites (P2–P1–P1′–P2′) in the enzyme substrates (gag and pol products). First-generation PIs were very hydrophobic, with an entropy-based binding to the PR heavily relying on desolvation. These properties led to fast emergence of resistance.[354] Moreover, high structural similarities between the first-generation PIs and their extensive use led to the emergence of HIV-1 isolates with cross-resistance to all members of this class,[355] leading to their combination in attempts to obtain better antiviral activity. An important outcome was the observation of improved PK wherein one PI (ritonavir, which irreversibly inhibits CYP3A) boosted the PK properties of the others.[356] This led to the extensive use of boosted-PIs in the clinic,[357] allowing higher drug systemic exposures through an increased IQ and better antiviral activity against isolates with PR resistance-associated mutations such as D30N, M46I, G48V, I50V, V82A, I84V, N88S, and L90M.[358] Second-generation PIs (Fig. 20) such as lopinavir (**98**), atazanavir (**99**), and darunavir (**100**) were developed to reduce serum binding, resistance to

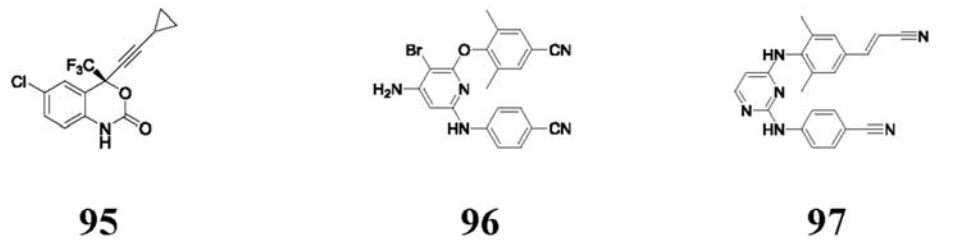

Fig. 19 HIV nonnucleoside RT inhibitors (NNRTIs).

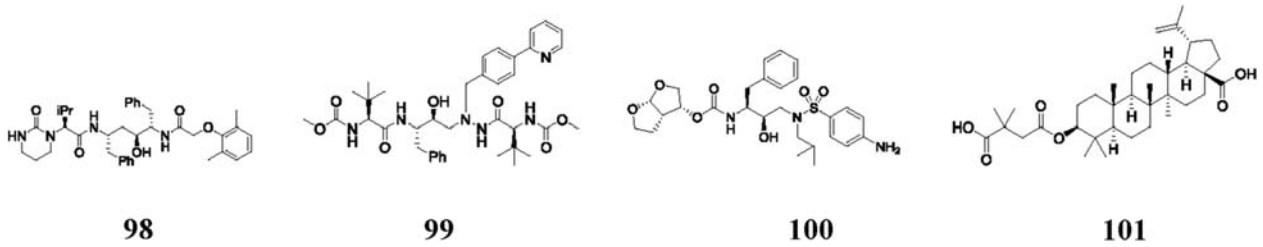

Fig. 20 HIV protease inhibitors and maturation inhibitors.

some primary mutations, and adverse metabolic profiles such as elevation of serum lipids, and these are currently the most commonly prescribed agents, although they still require boosting to achieve high IQs.[359]

5.17.4.1.2.2 Gag maturation inhibitors

A second locus involved in HIV resistance to PIs was identified outside of the PR gene, with mutations emerging in the gag polyprotein precursor, close to cleavage sites.[360] This discovery led to the development of a novel class of gag-pol polyprotein maturation inhibitors, with beviramat (Fig. 20; **101**) as the prototypical example. Bevirimat has not reached FDA approval, but analogs are being investigated in clinical studies.

5.17.4.1.3 HIV integrase

HIV IN is also produced from the gag-pol polyprotein. After penetration of the HIV preintegration complex into the cell nucleus, IN catalyzes the integration of viral DNA into host DNA. Although several inhibitory modes have been identified, only one resulted in FDA-approved drugs, known as integrase strand transfer inhibitors (INSTIs). Currently, three INSTIs are available (Fig. 21): raltegravir (RAL) (**102**), elvitegravir (EVG) (**103**), and dolutegravir (DTG) (**104**). INSTIs bind to the IN active site, preventing the DNA strand transfer step essential for the HIV replication. EVG retains activity against some IN mutants (such as L74M, G140S, Y143R/H/C) that are resistant to RAL.[361] Similarly, DTG retains activity against IN mutants that are resistant to EVG and RAL (such as T66I, E92Q, N155H).[362,363]

5.17.4.1.4 HIV envelope (ENV)

HIV ENV is produced as a highly glycosylated precursor polyprotein, gp160. The gp160 is then processed by the cellular enzyme furin into two subunits, the surface (SU) subunit gp120 and the transmembrane (TM) subunit gp41. Mature functional ENV consists of a trimer of gp120/41 (SU/TM) heterodimers. The viral envelope controls entry into selected permissive target cells. Entry inhibitors preventing envelope functioning have been the focus of intense research, such as small molecules or peptides[364]; the few entry inhibitors FDA-approved are described here.

5.17.4.1.4.1 Fusion inhibitors

The TM protein gp41 contains a fusion peptide at its NH_2-terminal end, allowing fusion of the virus and cell membranes. The fusion peptide contains two helical heptad repeat regions that control the fusion process, and adopts a triple helix secondary structure, allowing conformational changes enabling membrane fusion. Exploration of peptidic analogs of the triple helix led to the approved drug T-20 (enfuvirtide; Fig. 22) (**105**).[365] The drug needs to be injected, limiting its attractiveness in comparison to oral treatments, but has been frequently used in salvage therapy.

5.17.4.1.4.2 Cellular receptor antagonists

Before fusion, HIV needs to bind to cells expressing the CD4 protein, which is used as a receptor by the virus. Along with CD4, a coreceptor is necessary for initiation of fusion process. Either of the chemokine receptors CCR5 or CXCR4 can serve as coreceptor, and the interaction triggers conformational changes in the gp120/gp41 envelope glycoprotein complex leading to the fusion of the virus with cell membranes. Maraviroc (MVC) (Fig. 22; **106**) is an antagonist of CCR5 and is active against HIV strains that depend upon CCR5 for cell entry (the large majority) but not those that depend on CXCR4.[366] Consequently, it is only recommended for

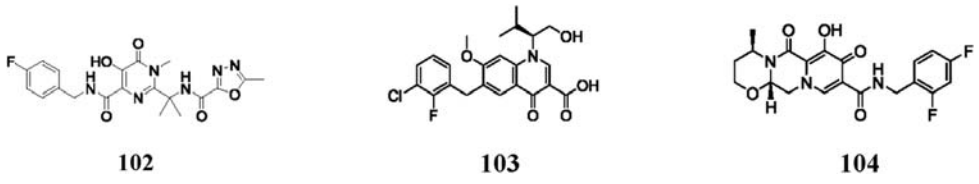

Fig. 21 HIV integrase strand transfer inhibitors (INSTIs).

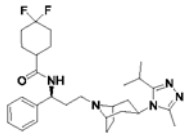

[acetyl]-YTSLIHSLIEESQNQQEKNEQELLELDKWASLWNWF-[NH_2]

105 **106**

Fig. 22 HIV entry inhibitors.

treating HIV infections with CCR5-tropic viruses.[341] Although resistance data to MVC is limited, resistance has been associated with mutations in the V3 loop of gp120 such as positions 308, 316, and 323. Substitutions outside the V3 loop may also contribute to reduced susceptibility and could be classified as resistant mutations.[367]

5.17.4.1.5 Drug combinations

Antiviral drug resistance emerged rapidly when ARVs were used alone early in the AIDS epidemic. This led to the exploration of combinations of multiple drugs, which initially showed a significantly increased reduction of HIV viral load, preventing damage to the immune system and significantly lowering the risk of developing AIDS. The approach was widely adopted in clinical practice, and combinations of three ARVs from at least two different classes became the standard of care (initially defined as highly active antiretroviral therapy, HAART, and later as combination antiretroviral therapy, cART). Consistent HIV treatment with cART led to better adherence to the regimen, improved drug steady-state levels, and sustained viral suppression in the majority of the patients. A large diversity of ARVs are currently available and several have been formulated as fixed-dose combinations, administered as single tablets once daily, that enable adherence.[368] These efforts have resulted in clinical efficacy rates for chronic viral suppression of above 90%, consequently reducing the incidence of drug resistance. However, management of HIV infection still requires lifelong therapy as the regimens are not curative.[369]

5.17.4.2 Hepatitis B Virus

HBV is a double-stranded DNA virus of the Hepadnaviridae family and is the causative agent of chronic hepatitis B (CHB). Currently, the only two drug classes approved for treatment CHB are a finite course of interferon and continuous therapy with oral nucleos(t)ide analogues. Treatment response to interferon varies, but the host and viral factors that contribute to differences in treatment response are not fully elucidated. Given that interferon is not a DAA, no resistance mutations have been established against interferon and only direct-acting pol/RT inhibitors will be discussed here.

While treatment of CHB often results in suppression of HBV DNA levels in the serum, current regimens are rarely effective at eliminating the viral genetic reservoir covalently closed circular DNA (cccDNA), which remains in the nucleus of infected hepatocytes and allows for an increase of viral load after cessation of treatment. The cccDNA reservoir is established early during the course of CHB infection. Current DAAs against HBV inhibit the transcription of RNA from viral DNA and thus do not target the established cccDNA reservoir (reviewed in Ref. [370]). This viral reservoir, along with the long half-life of infected hepatocytes, creates a lifelong risk of viral rebound if treatment is suspended. Because of the need for long-term treatment of patients with CHB, antiviral resistance is an important consideration for therapy.

5.17.4.2.1 Nucleos(t)ide reverse transcriptase inhibitors

The HBV polymerase is a multifunctional protein encoding four domains, including an RT and RNase H domain. The pol/RT domain of HBV shares structural homology to that of HIV,[371] and this similarity is reflected by the overlapping antivirals used in HIV and HBV therapy. There are currently five oral antivirals available for treatment of CHB. Unlike HIV therapy, antivirals for HBV are routinely prescribed as monotherapy.

Nucleos(t)ide reverse transcriptase inhibitors (N[t]RTIs) approved for treatment of CHB (Fig. 23) include nucleosides (LAM (**92**) and telbivudine (LdT) (**107**)), phosphonate analogs (adefovir (ADV) (**108**) and TDF (**94**)), and entecavir (ETV) (**109**), a nucleoside analog with a carbocyclic replacement for the ribose ring.[372] The first antiviral to be approved for the treatment of HBV was LAM, marketed in 1998. Increased suppression of viral DNA was achieved with LAM compared to interferon treatment; however, rates of resistance mutations in the pol/RT (rtM204V/I/S) were as high as 20% after 1 year, to 70% through 5 years of treatment.[373] Beginning with ADV in 2002 and through the 2000s, several novel agents were approved, with varying levels of resistance development. Unlike LAM, resistance to ADV is typically associated with two mutations (rtA181T/V, rtN236T) leading to a higher barrier to resistance. Despite this, rates of resistance were as high as 29% after 5 years of treatment.[374,375] Initial studies with LdT demonstrated increased rates of HBV DNA suppression compared to LAM. Unfortunately, like ADV, rates of resistance were high with 25% of subjects developing LdT resistance mutation (rtM204I/V, rtA181T/V) after only 2 years of treatment.[376]

The third-generation CHB antivirals ETV and TDF are characterized by higher potency, low rates of resistance, and rates of HBV DNA suppression over 90% after 5 years in treatment-naïve patients. In N[t]RTI-naïve patients, resistance to ETV is low, with 1.2% of patients with resistance after 5 years.[377,378] Resistance to ETV requires the rtL180M + rtM204V/I LAM-associated resistance

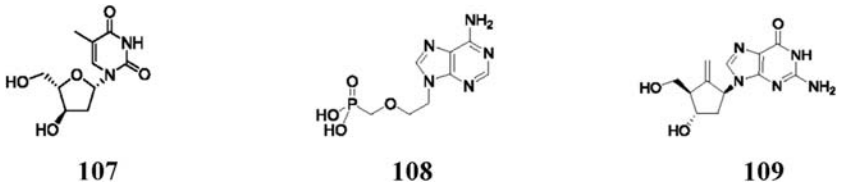

Fig. 23 HBV nucleos(t)ide reverse transcriptase inhibitors (N[t]RTI).

mutations as well as additional ETV-specific substitutions (rtI169 T, rtS184G, rtS202G/I, or rtM250V). Unfortunately, treatment-experienced patients that have developed resistance or compensatory mutations to other antivirals have a lower barrier to resistance development to ETV. Conversely, despite the structural similarity of TDF and ADV, no clinical antiviral resistance has been detected in treatment-naïve patients through at least 6 years of treatment.[379] TDF was also effective in patient populations with preexisting resistance mutations, although the time to viral suppression may be slower in ADV experienced patients.[380–383] TDF can therefore be used in patient populations who have failed previous treatments with other N[t]RTIs. Due to the high rates of resistance, the first- and second-generation antivirals LAM, ADV, and LdT have been replaced in the American Association for the Study of Liver Diseases and the European Association for the Study of the Liver treatment guidelines by third-generation agents that have lower rates of resistance even with long-term therapy.[384,385]

5.17.4.2.2 New viral targets

Although antiviral therapeutics with no known associated resistance mutations are available, the rate of clearance of the viral cccDNA reservoir is low and new viral targets must be identified to achieve a CHB cure. Multiple pathways to cccDNA clearance have been envisioned, including direct targeting of the cccDNA (histone modification, siRNA), activation of the immune system (TLR agonists, therapeutic vaccines), and inhibition of viral spread (capsid inhibitors, egress inhibitors) (reviewed in Ref. [386]).

5.17.4.3 Hepatitis C Virus

Discovered in 1989 as a causative agent of hepatitis, HCV is a single-stranded positive enveloped virus and the only member of the Hepacivirus genus, which constitutes at least seven distinct genotypic variants. Infection can result in acute hepatitis, but over 70% of infections establish chronic HCV that can lead to cirrhosis and hepatocellular carcinoma.[387] In contrast to other chronic viral infections such as HIV and HBV, HCV does not have a viral reservoir and elimination of viral replication can result in a complete cure, or sustained virologic response (SVR).

The first therapies for HCV, based on a 24-week regimen of interferon and the guanosine analog ribavirin, achieved approximately 55% SVR.[388] Greater understanding of the viral enzymes encoded by HCV (including the NS3/4A proteinase, NS5B polymerase, and multifunctional NS5A protein) were afforded by the development of replicon systems for in vitro study and allowed for direct targeting of viral processes by DAAs.[389] Since the introduction of HCV-specific DAAs into clinical practice in the 2010s, SVR rates have steadily risen to as high as 100% in some patient populations (reviewed in Ref. [390]). In general, DAAs with or without ribavirin are now the recommended therapy for most patients.[391,392] Four classes of DAAs are currently approved for chronic HCV, including nucleotide analogues and nonnucleotide NS5B inhibitors, NS5A inhibitors, and NS3/4A proteinase inhibitors. Mutations associated with drug resistance to HCV are referred to as resistance-associated variants (RAVs), and are briefly discussed here.

5.17.4.3.1 Nucleotide analogue NS5B inhibitors

Nucleotide analogues against HCV target the viral RNA-dependent RNA polymerase NS5B, and the only approved drug as of 2016 is the uridine analogue sofosbuvir (Fig. 24; **110**). Viruses with the S282T sofosbuvir resistance substitution within the highly conserved NS5B active site have lower viral fitness. Additionally, resistance to sofosbuvir is rarely seen prior to treatment and is not stable in the viral population after treatment cessation.[393–395] Few mutations have been determined to confer resistance clinically (L159F, S282T, and L320F), and the occurrence of these substitutions varies by genotype (reviewed in Ref. [396]).

Fig. 24 HCV NS5B inhibitors.

5.17.4.3.2 Nonnucleotide NS5B inhibitors

Many nonnucleotide NS5B inhibitors are in development, but dasabuvir (Fig. 24; **111**) is the only approved example. This class of drugs has a lower barrier to resistance than nucleotides and is therefore used in combination therapy, as in the Viekira Pak™. Established resistance-associated sites include C316, M441, Y448, and S556. Mutations at these positions have limited impact on viral fitness, allowing them to persist off treatment.[397,398]

5.17.4.3.3 NS5A inhibitors

Although it lacks any known enzymatic activities, the viral protein NS5A is required for HCV replication, modulates the cellular immune response, and alters the membranous environment via unknown mechanisms. Daclatasvir (Fig. 25; **112**) was the first NS5A inhibitor approved for HCV treatment and was followed by additional NS5A-targeted antivirals including ledipasvir (**113**), ombitasvir (**114**), and elbasvir (**115**), with additional examples currently in development. This drug class is characterized by high potency, perhaps due to the inhibition of multiple NS5A-dependent steps of the HCV replication cycle. Amino acids that can harbor resistance mutations (including M28, Q30, L31, and Y93) are located at the NS5A dimer interface, suggesting that one consequence of drug binding is to block dimerization.[389,392]

Polymorphic sites with preexisting resistance to NS5A inhibitors are common and are detected in upwards of 10% of patients prior to treatment.[399] When a patient develops resistance to NS5A on treatment, the mutation often becomes fixed in the viral population. This may be due to a high viral fitness levels, additional compensatory mutations, or a barrier to reversion back to wild type (reviewed in Ref. [390]).

5.17.4.3.4 NS3/4A protease inhibitors

The NS3 protein encodes multiple enzymatic components including the N-terminal proteinase responsible for cleavage of the viral polyprotein, and the C-terminal helicase and NTPase. At the C-terminal end, the covalently bound NS4A acts both to target the viral proteinase to cellular membranes and as a cofactor to the viral PR. The first approved NS3/4A inhibitors (Fig. 26) telaprevir (**116**) and boceprevir (**117**) act by binding directly to the catalytic serine of NS3. Additional drugs in this class include paritaprevir (**118**) and grazoprevir (**119**).

5.17.4.3.5 Drug combinations

Due to the prevalence of some RAVs in viral populations, combination therapies with or without ribavirin or interferon are the preferred treatment options for both treatment-naïve and treatment-experienced patients and lead to higher overall SVR rates. A number of combination therapies are approved for treatment and the recommended regimens are determined by viral genotype, preexisting RAVs, and presence of cirrhosis. For example, commonly prescribed combination therapies include ledipasvir/sofosbuvir, ombitasvir/paritaprevir/ritonavir/dasabuvir, and grazoprevir/elbasvir.[391,392]

5.17.4.4 Influenza

Influenza viruses are negative-sense, single-stranded, segmented RNA viruses of the orthomyxovirus family. Of the three types of influenza viruses (A, B, and C), Influenza A viruses are the major cause of influenza symptoms in humans. Influenza B and C viruses are less common, cause milder symptoms, and do not result in pandemics.

The high error rate of the viral polymerase as well as the inclusion of eight genome segments makes influenza uniquely primed for the development of antiviral resistance mutations.[400] In addition to mutation, reassortment of gene segments during coinfections with multiple influenza viruses leads to the rapid acquisition of new genes. This allows for rapid spread of resistance mutations, and is also typically the origin of novel pandemics.

While vaccination is the most effective method for prevention of influenza epidemics, antivirals are used as treatment in severe cases as well as to prevent spread of the disease in closed populations or early in the course of pandemics when vaccines are unavailable.[401] Currently, only two classes of influenza antivirals are approved: adamantanes and neuraminidase inhibitors (NAIs).

5.17.4.4.1 M2 inhibitors (adamantanes)

The first antiviral drugs developed for treatment of influenza were the adamantane class of compounds (Fig. 26; **120**), targeted against the viral protein M2. This protein is only found in influenza A virus, so the class is ineffective against influenza B. The M2 protein is a transmembrane ion channel responsible for both the release of viral RNA from the virion after entry as well as regulating viral maturation. Adamantane-based antivirals block M2 function by binding to the pore of the channel to displace a water molecule, resulting in disruption of the pH-sensing residues of the transmembrane domain.[402] Two adamantane-based antivirals are approved for use: amantadine and rimantadine.

Three dominant adamantane-resistant mutations (S31N, V27A, L26F) have been observed clinically and additional mutations (A30T, G34E) have been reported to confer resistance in vitro.[403] A single point mutation is sufficient to confer resistance to both marketed adamantanes, and all mutations are naturally occurring variations at the drug binding site. In vitro and animal studies demonstrated that adamantane resistance does not decrease viral fitness,[404,405] allowing resistance to become fixed in currently circulating influenza viruses.

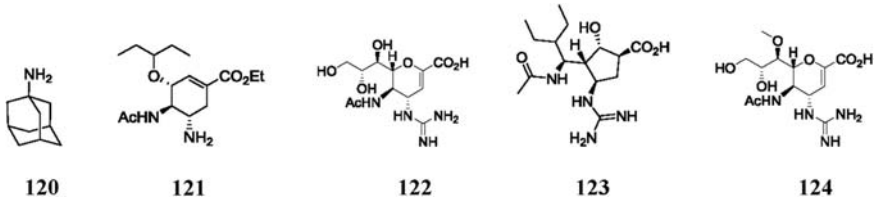
Resistance to adamantanes rose rapidly in the early 2000s, with resistance mutations detected in nearly all currently circulating H3N2 influenza. The prevalence of adamantane resistance in H1N1 influenza was rare in the 2007–08 seasonal strain, but the 2009 pandemic H1N1 that remains the dominant H1N1 in circulation has resistance rates of over 99%. Due to the high prevalence of resistance to adamantanes in circulating influenza A viruses, this class of antiviral drugs is not recommended for treatment by Centers for Disease Control and Prevention (CDC) guidelines.[406,407]

5.17.4.4.2 Neuraminidase inhibitors

Along with hemagglutinin, the neuraminidase of influenza makes up one of two glycoproteins on the surface of the viral envelope. It is required for cleavage of sialic acid from the cell surface during the release of progeny virions from infected cells and is highly conserved across influenza and B viruses, making it an attractive antiviral target. NAIs are structural analogs of the natural substrate of neuraminidase, sialic acid, and bind directly to the enzymatic site.[406] Two NAIs (Fig. 27), oseltamivir (**121**) and zanamivir (**122**), are currently widely approved for treatment of influenza, with an additional two, peramivir (**123**) and laninamivir (**124**), available in selected countries. Peramivir shares structural similarities to both oseltamivir and zanamivir, while laninamivir is similar to zanamivir.[408]

Resistance to NAIs can occur either through mutations at the highly conserved active site of the neuraminidase or to the surrounding structural amino acids. The H274Y mutation (N1 numbering) is the only one considered to have proven clinical resistance by the WHO and confers complete resistance to oseltamivir, with reduced susceptibility to zanamivir. A number of additional substitutions detected in clinical isolates have been implicated in antiviral resistance (E119G, E119V, R224K, R292K, N294S), with others often associated with the H274Y mutation (I222R, I222V, S246N) (reviewed in Ref. [408]).

As with the adamantanes, drug resistance to NAIs was detected soon after the introduction of treatment in the early 2000s. While most frequently detected in children or immune-compromised adults, resistance has also been found in patients without previous exposure to influenza antivirals. Although NAI resistance occurs at lower levels than that to adamantanes, prevalence can reach up to 100%, as was seen with oseltamivir resistance in the 2007–08 H1N1 seasonal strain. Currently, resistance to all NAIs remains low, at less than 10% globally.[406]



120 121 122 123 124

Fig. 27 Influenza inhibitors.

Table 2 Infectious disease threats as defined by the Centers for Disease Prevention and Control in 2013[12]

CDC threat level	*Pathogen*	*Recent status*
Urgent	Carbapenem-resistant Enterobacteriaceae (CRE)	Endemic in many US states and in many countries worldwide Treatment options becoming more limited New agents in late development may provide protection against many CRE
	Clostridium difficile	Cephalosporin, fluoroquinolone, clindamycin, erythromycin resistance common Increased treatment failures with vancomycin and metronidazole
	Neisseria gonorrhoeae	Strains identified with resistance to most available antimicrobials New antibiotics effective as monotherapy or in combinations needed Late stage investigational agents are in development
Serious	MDR *Acinetobacter*	Significant increase in the incidence of *Acinetobacter* infections Large increase in resistance to all antimicrobial agents in recent years New antibiotics effective as monotherapy or in combinations urgently needed
	Extended-spectrum β-lactamase-producing (ESBL) Enterobacteriaceae	Steady increase in rates in United States since 2000 Treatment options becoming more limited as multidrug resistance is common Carbapenems and new β-lactamase inhibitor combinations often effective
	MDR *Pseudomonas aeruginosa*	Prevalence of infections has remained relatively stable Incidence of multidrug-resistant strains has increased dramatically in recent years
	Drug-resistant tuberculosis	TB now the most prevalent infectious disease in the world Incidence of TB has been relatively stable in United States in recent years but increasing in other parts of the world MDR and XDR remain a concern Important global cause of death per year
	Methicillin-resistant *Staphylococcus aureus* (MRSA)	Rates of bacteremia and SSTIs have stabilized in recent years A leading cause of healthcare-associated infections especially involving devices Resistance rates for linezolid, daptomycin, and other new anti-Gram-positive antibiotics remain very low[416]
	Vancomycin-resistant enterococcus (VRE)	High rates in United States, prevalence still relative low elsewhere[339] Limited treatment options, especially for *Enterococcus faecium*
	Drug-resistant *Streptococcus pneumoniae*	Despite vaccine availability, invasive pneumococcal disease (IPD) remains a problem worldwide[417] IPD mortality has not changed significantly in the past decades[159]
	Fluconazole-resistant *Candida*	Fluconazole resistance has remained relatively low and constant over the past 20 years
Concerning	Vancomycin-resistant *Staphylococcus aureus* (VRSA)	14 cases in four states 2002–15 Still rare in occurrence Cases mainly in patients with other underlying conditions Many newer anti-Gram-positive agents effective

Initial in vitro and animal studies on drug resistance mutations in the neuraminidase gene determined that resistance had a detrimental effect on viral replication, with viruses encoding H274Y being highly attenuated.[409] Recent in vitro work suggests that the H274Y compensatory mutations R194G and V234M/R222Q can increase viral fitness while maintaining resistance to oseltamivir.[410] These permissive mutations may account for the high frequency of resistance seen in seasonal influenza in 2007.[410,411]

5.17.4.4.3 New influenza antivirals

The rapid development of antiviral resistance in influenza viruses could potentially be overcome through the use of combination therapies, much as for HIV and HCV therapy. Given the high frequency of adamantane resistance and the relative paucity of influenza antiviral classes, new drugs are necessary to provide an effective combination therapy. Research into the design of M2 or NA inhibitors with higher thresholds of antiviral resistance is underway, although far from market approval.[412] The many other viral enzymes of influenza make attractive antiviral targets, including the three components of the viral polymerase (PB1, PB2, and PA) (reviewed in Ref. [413]). Indeed, one polymerase inhibitor (favipiravir) is licensed for limited use in Japan.[414] The nucleoside analog ribavirin has demonstrated inhibition of influenza in vitro; however, clinical results have been inconclusive. In addition to DAAs, multiple therapeutic antibodies and host-targeting drugs are in preclinical and early clinical trials for use in influenza treatment.[415]

5.17.5 Conclusions

Antimicrobial resistance is a critical threat that affects agents in all areas of infectious disease. **Table 2** lists the most important threats described by the CDC in 2013.[12,159,416–418] Many of these threats have only increased in severity, whereas others such as MDR-*S. pneumoniae* and fluconazole-resistant *Candida* spp. remain virtually unchanged. Somewhat optimistically, for some threats such as those posed by the ESBL-producing Enterobacteriaceae, treatment options are improving.

Drug discovery efforts and adaptiveness over the past few decades, in all antimicrobial fields, have been up to the challenge of fighting emerging resistant strains. Drug combinations played a key role in constraining resistance. However, the need for innovation is still there, since new drug combinations will be limited by the diversity of drugs available.

Overall, resistance is still a major challenge to our antimicrobial armamentarium, and needs to be monitored on a continuing basis.[182,419–427]

5.18.1 Introduction

Remarkable progress has been made in the treatment of hepatitis C virus (HCV) infection since the 2007 edition of *Comprehensive Medicinal Chemistry* when the optimal therapy was a combination of pegylated interferon-α-2a (PEG-IFN-2α) administered subcutaneously once weekly and ribavirin (**1**) taken twice daily orally for 48 weeks.[1–5] This drug regimen was poorly tolerated, with essentially all patients experiencing side effects so severe that many were unable to complete the course of therapy, with some refusing to start therapy based on the anticipated ordeal.[3,6–9] In addition, cure rates were low, of the order of 40–50% for genotype (GT) 1 virus, which proved to be the most challenging for this therapeutic regimen.[4] In 2014, the first direct-acting antiviral drug combinations were approved, providing regimens able to cure HCV infection in GT-1-infected patients after 8–24 weeks of therapy depending on clinical background, with the convenience of oral dosing and a marked reduction in the side effects that are associated with the use of PEG-IFN-α and **1**.[10] Nevertheless, therapy continues to evolve toward the development of oral regimens capable of treating all genotypes of HCV infection, and for the first time in history, we are in a position to be able to cure a chronic virus infection solely with small-molecule inhibitors.[11–16]

The development of combinations of direct-acting antiviral agents (DAAs) for the treatment of HCV has been described as a medical triumph based on the high cure rates in GT-1-infected patients, a circumstance subtended by the elegant medicinal chemistry associated with the design and development of effective drug candidates.[14–17]

The HCV genome is encoded by a single strand of positive RNA composed of approximately 9600 nucleotides that was first characterized in 1989 by the cloning of a cDNA from an infected patient, the first virus to be identified using molecular biology techniques.[18–21] The genetic organization of the ~3000 residue polyprotein that was encoded by the viral RNA (captured in Fig. 1) was quickly mapped, providing the first glimpse of potential targets for drug discovery including the NS3 serine protease, the NS3 helicase, and the NS5B RNA-dependent RNA polymerase (RdRp).[22–29] The structural and nonstructural proteins and the 5′- and 3′-untranslated regions were subsequently defined more precisely and the mode and order of cleavage of the polypeptide determined, as summarized in Fig. 2.[30–32] These developments set the stage for drug discovery programs, which initially were focused on the NS3 protease and NS5B RdRp since biochemical assays were readily recapitulated in vitro and were aided considerably by the availability of structural information for these enzymes by X-ray crystallographic analysis.[33–37] However, a major impediment to rapid progress was the lack of a cell culture system that would allow demonstration of target engagement by lead inhibitors under the more authentic circumstances associated with a complex cellular milieu. This situation changed in 1999 with the development of the first subgenomic replicon based on a genotype 1b sequence, with subsequent advances broadening these systems to include replicons that encompassed the full genomes and extending to genotype 1a and 2a viruses.[38–43] The development of replicons facilitated the implementation of phenotypic screening, an approach that led to the identification of the first HCV NS5A inhibitors that were optimized into a clinically important drug class that has taken its place as a mainstay of therapy when used in combination with NS3 and/or NS5B RdRp inhibitors.[44–46] Careful study and optimization of cell culture systems ultimately culminated in the identification of fully replicating systems that extended the interrogation of the virus life cycle to include the processes of entry, uncoating, assembly, and release of virions.[47–51] These developments have led to the current circumstance where a combination of in vitro assays, replicons, and infectious viruses have been utilized to identify and/or characterize small-molecule inhibitors of all of the structural and nonstructural proteins of HCV and the HCV internal ribosome entry site (IRES).

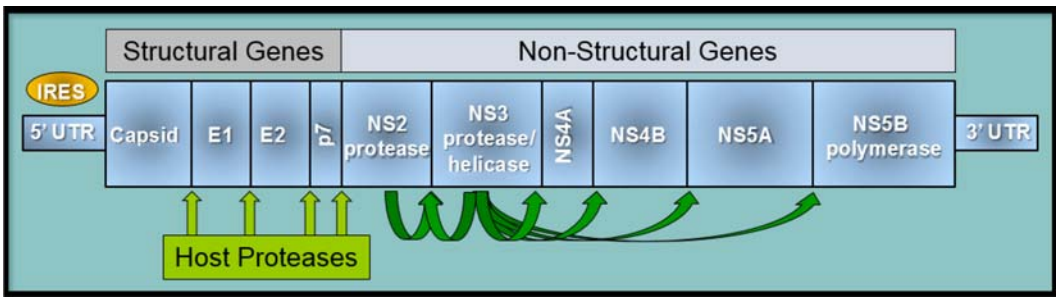

Fig. 1 Genetic organization of HCV depicting the untranslated regions, the structural and nonstructural genes, and the sites of cleavage in the polypeptide by host cell and viral proteases.

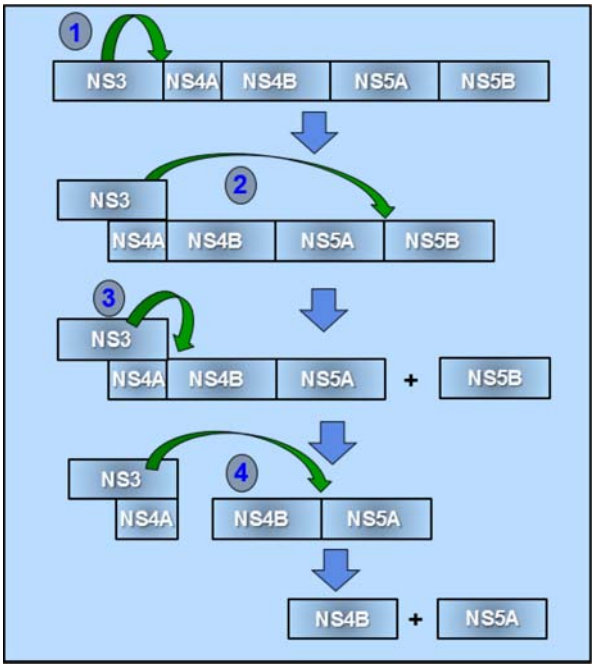

Fig. 2 Order of cleavage of the HCV nonstructural proteins by the NS3 protease.

The need for combinations of DAAs to treat HCV was anticipated based on the experience with human immunodeficiency virus-1 (HIV-1) drug development, setting the stage for a considerable effort that was expended across both the pharmaceutical industry and academia, which focused on developing antiviral agents acting by complementary mechanisms. More recently, the scientific basis for combination therapy has been articulated based on studies that assessed virus replication rates in vivo in the context of the frequency of errors of reproduction attributed to the limited fidelity of the HCV NS5B RdRp.[52–57] These analyses estimated that the average individual infected with HCV produces up to 10^{12} virions per day, 10–100-fold higher than the reproduction rate of HIV-1, and that the fidelity of reproduction is one base error incorporated for every 10 genomes that are synthesized. Taken together, these figures predict that 91% of the virus is reproduced faithfully, while 8.7% of the genomes produced incorporate a single mutation that equates to a daily production of 87 billion virus particles (data summarized in Table 1). Viruses with two mutations are estimated to be produced at a rate of 4.2 billion per day, while triply mutant viruses constitute only 0.013% of the daily output, although that still represents 130 million virus particles in the average infected individual. These calculations suggest that with a genome composed of $<10{,}000$ RNA bases, every possible single mutant is produced every day and predict that the use of drug monotherapy will lead to the rapid emergence of resistant virus. This was indeed observed in practice in early clinical trials with NS3, NS5A, and NS5B RdRp inhibitors, which were administered for up to 14 days as monotherapy.[58–63]

While the first DAAs to be approved, the NS3 protease inhibitors telaprevir (**2**) and boceprevir (**3**), were licensed for use in combination with PEG-IFN-α and ribavirin (**1**), the approval of the nucleoside-based NS5B RdRp inhibitor sofosbuvir (**4**) and the NS3 protease inhibitor simeprevir (**5**) set the stage for the use of DAAs in combination (Figs. 3 and 4).[64–68] This was formalized in 2014 with the regulatory approval of the combination of the NS3 protease inhibitor asunaprevir (**6**) and the NS5A inhibitor daclatasvir (**7**) for the treatment of GT-1b infection in Japan in July.[69] Further advances came in Nov. 2014 with the licensing by the Food and Drug Administration (FDA) of a fixed-dose combination comprising 400 mg of sofosbuvir (**4**) with 90 mg of the NS5A inhibitor ledipasvir (**8**), marketed as Harvoni™.[70] Shortly thereafter, Viekira Pak™, a fixed-dose combination of 12.5 mg of the NS5A inhibitor ombitasvir (**9**), 75 mg of the NS3 protease inhibitor paritaprevir (**10**), and the cytochrome P450

Table 1 Estimated kinetics of HCV reproduction in vivo

Number of mutations	*% of viruses produced daily*	*Virions produced per day*
0	91	910×10^9
1	8.7	87×10^9
2	0.42	4.2×10^9
3	0.013	0.13×10^9

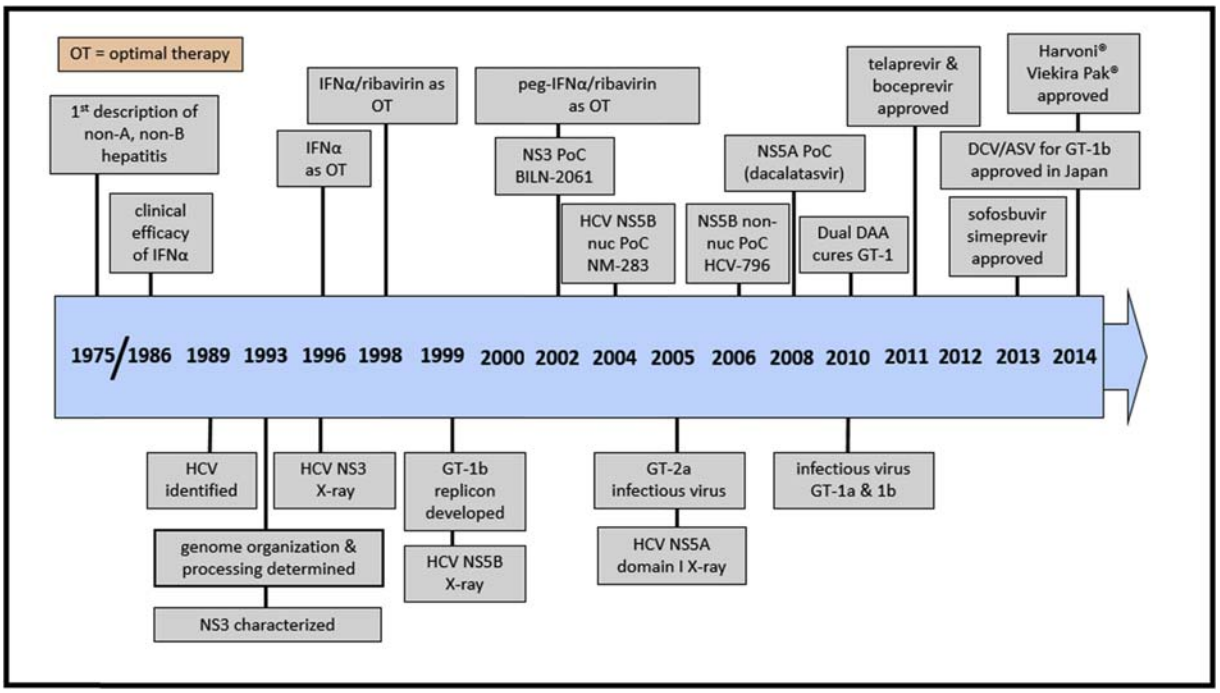

Fig. 3 Timelines for HCV drug approvals and key developments in biochemical pharmacology.

inhibitor ritonavir (**11**) taken quaque die (QD) along with the allosteric NS5B inhibitor dasabuvir (**12**) (which is administered on a bis in die (BID) schedule of 250 mg), was approved for the treatment of GT-1 infection (Fig. 4).[71] For those with GT-1a infections or cirrhosis, adding ribavirin (**1**) at doses of 1 or 1.2 g BID based on body weight to Viekira Pak™ improved cure rates.[71] A fixed-dose combination of 50 mg of the NS5A inhibitor elbasvir (**13**) and 100 mg of the NS3 protease inhibitor grazoprevir (**14**) has completed phase 3 clinical trials in patients infected with GT-1, GT-4, and GT-6 HCV, and a new drug application (NDA) for the marketing of Zepatier TM was approved by the FDA on Jan. 28, 2016.[72] However, achieving this level of clinical success with DAAs has been arduous, relying upon the development of a large number of compounds examined preclinically and clinically, with many failing for reasons of either poor efficacy or unacceptable levels of toxicity.[73] It has been estimated that 712 individual drug candidates were examined between 1995 and 2014 from which 12 drugs had been marketed, while 588 failed and 112 remain in development, statistics that translate to an overall success rate at the end of 2015 of just 2%.[74]

5.18.1.1 Inhibitors of HCV Core (Capsid) Protein Function

The HCV core or capsid protein is composed of approximately 177 residues in its mature form and is cleaved from the 191 residue precursor protein by removal of the C-terminal transmembrane residues that form the signal sequence for the E1 protein (Fig. 5).[75–77] Little is known about the specific three-dimensional structure of the core protein, although about half of the protein adopts an α-helical conformation, and the basic functional unit appears to be a dimer that is disulfide-linked via Cys128.[75–78] The protein has been divided into two domains with the hydrophilic domain D1 composed of residues 1–117, while the remainder of the protein is more hydrophobic and designated as domain D2. Within D1, there are three clusters of basic residues, designated as BD1 (AAs 2–23), BD2 (AAs 38–74), and BD3 (AAs 101–121). Domain D1 is involved in both RNA binding and oligomerization, with the first 82 residues of the protein highly disordered but capable of forming ordered nucleocapsid-like particles in the presence of structured RNA. The D2 domain mediates association with the endoplasmic reticulum and lipid droplet membranes and contains two regions that form amphipathic helices—helix I (AAs 119–136) and helix II (AAs 148–164)—that are separated by a hydrophobic loop.[75] The process of HCV capsid assembly and release involves complex choreography between viral (core, E1, E2, p7, NS2, NS3, NS4A, NS5A, and NS5B) and host cell proteins, with roles for diacylglycerol *O*-acyltransferase (DGAT), the mitogen-activated protein kinase-regulated cytosolic phospholipase A2, endosomal sorting complex required for transport, microsomal triglyceride transfer protein, apolipoprotein E, and the assembly of very-low-density lipoprotein documented, but many others remain to be identified.[77]

While therapeutic intervention with agents targeting some of these host cell processes has been described, direct inhibitors of core protein have focused on identifying compounds that interfere with dimerization.[75,76,79,80] An in vitro assay was developed that assessed the binding of an FLAG-tagged core protein to an immobilized glutathione S-transferase (GST)–core protein construct, in which the core protein of each partner was identical and composed of residues 1–106 to avoid the precipitation and aggregation problems associated with full-length protein.[76] The protein–protein interaction was assessed by fluorophore-labeled antibodies

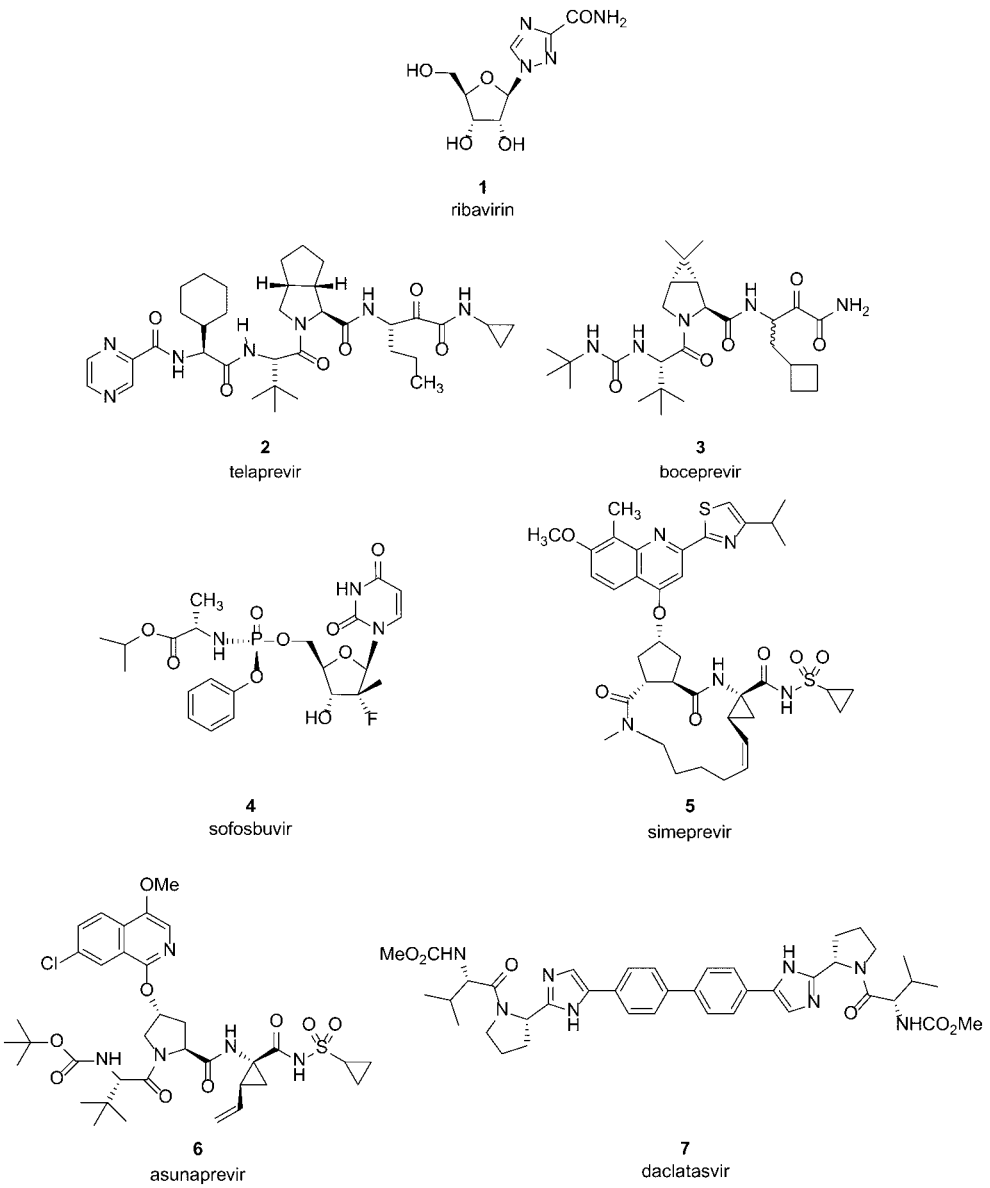

Fig. 4 The structures of drugs approved to treat HCV infection.

against GST and the FLAG tag, and this assay was used as the basis for a high-throughput screen.[76,78] SL175 (**15**), a 15-amino acid peptide that represents residues 92–106 of the core sequence, inhibited protein association in this assay with an IC_{50} of 21.9 μM, while a control peptide composed of the reverse sequence was inactive (Fig. 6).[76,79] SL175 (**15**) was shown to bind to a core protein fragment comprising residues 1–106 with a K_d of 1.9 μM using a fluorophore-tagged derivative of the peptide, and this molecule was displaced by unlabeled SL175 (**15**) with an IC_{50} of 18.7 μM.[76,79] The core 1–106 protein association assay was used to screen for additional small-molecule inhibitors, leading to the identification of the racemic pyrido[4,3-*b*]indole derivative SL209 (**16**) as a lead, $IC_{50} = 1.4$ μM.[76,80] This compound demonstrated antiviral activity in a GT-2a virus replication assay with EC_{50} values of 2.3 and 3.2 μM when viral RNA levels were determined early and late, respectively, using a real-time reverse transcriptase polymerase chain reaction (RT-PCR) assay.[76,80] The EC_{50} values determined for **16** are well separated from the concentration at which cytotoxicity toward the host cell was evident, reported as a CC_{50} value of 127 μM, consistent with an effect on the virus rather than the host cell. Further studies with SL209 (**16**) attempted to exploit the dimeric nature of the core protein by preparing symmetrical dimeric inhibitors that demonstrated markedly enhanced potency, results that catalyzed the synthesis of the asymmetrical triazole derivative **17**, which blocked core association with an $IC_{50} = 92$ nM (Fig. 6).[81] However, the potency of **17** in the virus replication assay was comparable with **16** with EC_{50} values of 1.4 and 1.1 μM, measured early and late, respectively, and a CC_{50} of > 100 μM.[81] A member of this series was shown to interfere with HCV NS3 helicase association with an oligomeric form of the core protein and to block the production of infectious virus but not the replication of a subgenomic replicon, consistent with an inhibitory effect on virus

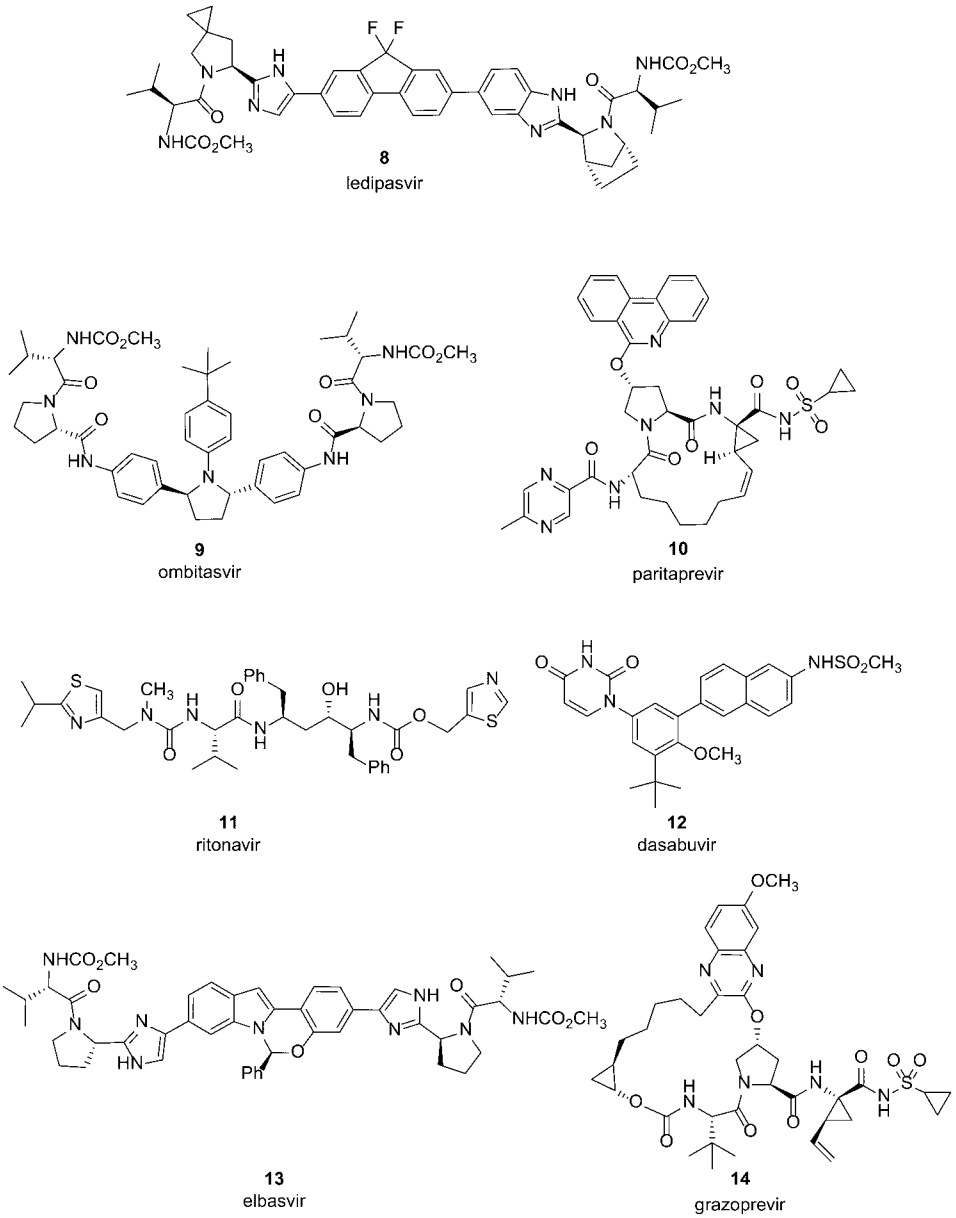

Fig. 4 (*continued*).

assembly.[82] The biotinylated analog SL209 (**18**), which inhibited core dimerization with an IC_{50} of 2.8 μM and virus replication with an EC_{50} value of 3.2 μM, was utilized as an affinity probe to screen lysates of HCV-infected cells and recombinant HCV proteins.[83] When lysates were passed over SL209 (**18**) bound to streptavidin-coated agarose beads, core protein was pulled down along with NS3, NS5A, and NS5B, proteins known to associate with core; however, neither NS5A nor NS5B adhered to the SL209-coated beads in the absence of core protein. While intracellular labeling studies with SL209 (**18**) were consistent with the core protein as the target, the precise mode of action of this compound remains to be determined since the in vitro experiments could not distinguish between an effect on capsid assembly and an effect on capsid disassembly.

5.18.1.2 Inhibitors of HCV Entry: E1 and E2

HCV entry into hepatocytes is mediated by the viral E1 and E2 surface glycoproteins interacting with multiple host cell proteins, but the precise mechanism and sequence of events are complex and not fully understood.[77,84–86] The most coherent current view suggests that the first step of the entry process involves a low-affinity association between the virus particle and the basolateral membrane of hepatocytes that is mediated by interactions with highly sulfated heparan sulfate proteoglycans (HSPGs), the LDL

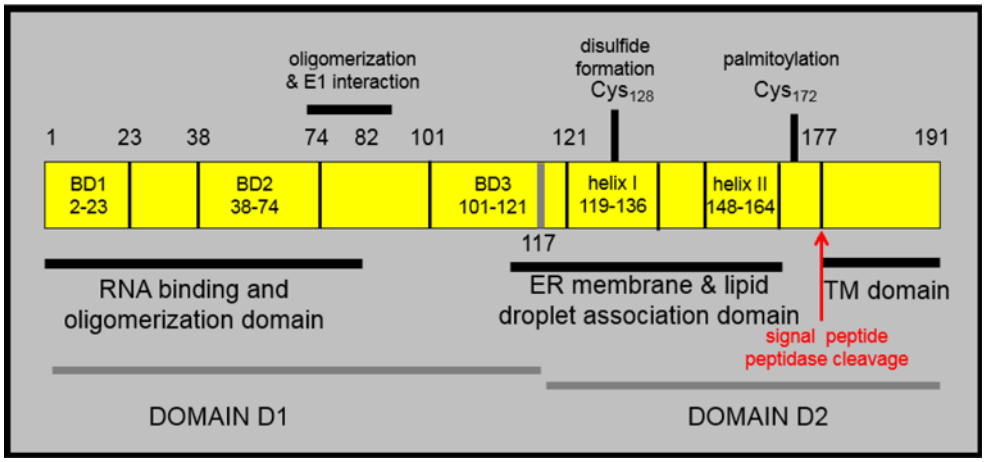

Fig. 5 Structural features of the HCV core protein.

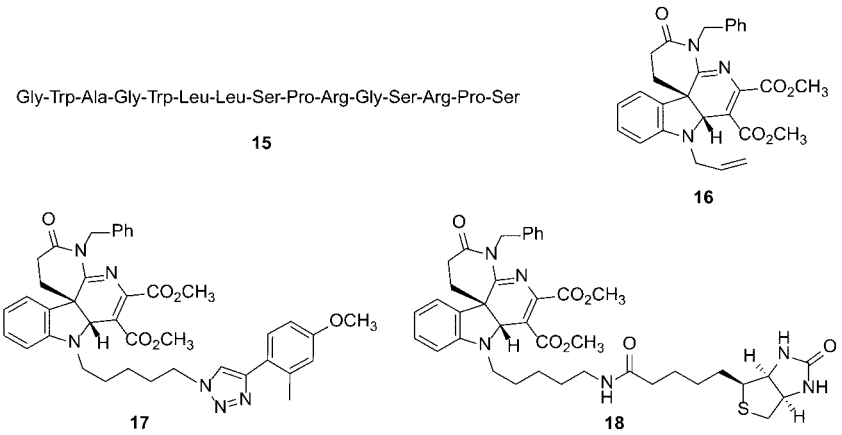

Fig. 6 HCV core protein inhibitors.

receptor, and the scavenger receptor class B type 1 (SR-B1).[77] SR-B1 may stimulate the dissociation of lipoproteins from the virus particle to expose the CD81 binding domain of the E2 glycoprotein. An important step in the entry process is the lateral migration of the CD81-bound particles to tight junctions where claudin 1 (CLDN1) is located; CLDN1 is believed to interact with CD81 to form a complex competent for clathrin-mediated endocytosis. Occludin has also been implicated in this step of the process but its precise function is unknown. The movement of the HCV particles to tight junctions and the interaction of CD81 with CLDN1 are facilitated by the activation of several intracellular signaling pathways triggered by CD81 engagement, a repertoire that includes the receptor tyrosine kinases epidermal growth factor receptor (EGFR) and the ephrin type-A receptor 2 (EphA2). This leads to activation of Rho and Ras GTPases, which promote remodeling of actin and the cell membrane, thereby facilitating migration of the HCV particle to tight junctions. After endocytosis, the virus particle is trafficked to an endosomal compartment containing the Ras-related protein Rab5A where the lipoprotein content of the virus may be further modified by SR-B1 and Niemann–Pick C1-like 1 protein (NPC1L1), a mediator of cholesterol absorption, as a prelude to membrane fusion. The low pH of the endosomal compartment triggers a conformational rearrangement of the HCV E1 and E2 glycoprotein heterodimer that leads to the formation of a trimeric fusion spike and exposure of the fusion peptide, resulting in convergence of the viral and endosomal membranes to release the viral RNA into the cytosol.

The identification of host factors involved in the entry process provides a rational basis for the selection and study of potential sites for intervention. The EGFR inhibitor erlotinib (**19**) inhibits HCV pseudoparticle (HCVpp) entry and HCV cell culture (HCVcc) infection in human hepatoma Huh7.5.1 cells with EC_{50} values of 0.45 and 0.53 μM, respectively, while dasatinib (**20**), a potent EphA2 inhibitor, blocks HCVpp entry and HCVcc infection with EC_{50} values of 0.53 and 0.50 μM, respectively.[87,88] Both compounds were effective only when present during in the early stages of infection, blocked cell-to-cell transmission, and interacted synergistically with a range of DAAs, data consistent with an inhibitory effect on the entry process.[87,89] Erlotinib (**19**) (Fig. 7) demonstrated antiviral activity in the chimeric urokinase plasminogen activator–severe combined immunodeficiency (uPA-SCID) mouse model of HCV infection, reducing viremia by 90% compared with the placebo control group.[87] The

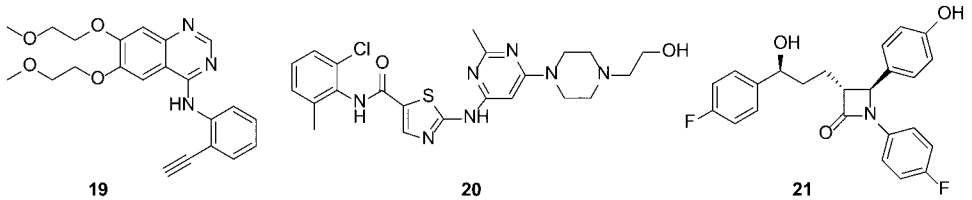

Fig. 7 Structure of the EGFR inhibitor erlotinib (**19**), dasatinib (**20**), and ezetimibe (**21**).

determination of a role for NPC1L1 in HCV entry prompted evaluation of the cholesterol absorption inhibitor ezetimibe (**21**), and this compound was shown to dose-dependently interfere with infection of all of the major genotypes in an HCVcc assay if added at the time of inoculation with virus but not at later time points.[90] In the uPA-SCID mouse model, pretreatment with ezetimibe (**21**) for 2 weeks delayed the establishment of HCV GT-1b infection.[90] A single clinical observation has described the resolution of a chronic HCV GT-1b infection unresponsive to multiple treatments with PEG-IFN-α and ribavirin (**1**) after several months of therapy with **21** in combination with a 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor.[91]

Intervention at the entry step mediated by SR-B1 has been probed with ITX-5061 (**22**), which half-maximally prevents infection of Huh7 hepatoma cells by an HCV GT-2a chimeric virus at a concentration of 0.1 nM, a profile preserved in an unidentified analog that is associated with reduced p38 mitogen-activated kinase (p38 MAPK) and UDP glucuronosyltransferase 1, polypeptide A1 (UGT1A1) inhibition (Fig. 8).[92–95] ITX-5061 (**22**) interacts synergistically with IFN-α, ribavirin (**1**), and HCV NS3 and NS5B RdRp inhibitors to inhibit GT-2a virus infection of Huh7.5.1 cells.[95] Resistance mapping experiments identified an Asn415Asp change in the E2 protein as a mutation that conferred >1000-fold resistance, $EC_{50} > 20$ μM, compared with an EC_{50} value of 20 nM for the wild-type Jc1-Luc virus used in these experiments.[95] ITX-5061 (**22**) exhibits 10-fold lower activity toward the Gly451Arg mutant that shows a reduced dependence on SR-B1 for entry, data that taken together with the results described in the preceding text are consistent with SR-B1 as the pharmacological target. When administered to subjects with low HDL levels at doses of 150 and 300 mg daily for 6 weeks, ITX-5061 (**22**) was associated with a 20% increase in HDL levels in plasma, an effect also observed in wild-type and human apoA-1 transgenic but not in SR-B1$^{-/-}$ mice.[96] Although this result demonstrated a clinical effect, in a phase 2a clinical trial conducted in HCV-infected subjects administered with 150 mg of ITX-5061 (**22**) per day for 3, 14, and 28 days, no significant effect on viral load was observed, with the exception of one patient in the 28-day arm who experienced a 1.49 $\log_{10}$ IU mL^{-1} reduction in viremia from a baseline value of 5.58 $\log_{10}$ IU mL^{-1} to 4.09 $\log_{10}$ IU mL^{-1}.[97] There was no clearly apparent reason why ITX-5061 (**22**) failed to demonstrate an antiviral effect in this study, a particularly perplexing outcome considering that genetically humanized SR-B1$^{-/-}$ mice exhibited reduced HCV infectivity consistent with a role for this protein in virus entry.[98] Structurally disparate SR-B1 antagonists have been described, including ITX-4520 (**23**), which inhibits both GT-1a and GT-2a HCV infectious viruses with EC_{50} values of 1.5 nM, but these compounds do not appear to have been advanced into development.[99,100]

The advent of cell culture infectious HCV and the development of pseudoparticles facilitated the implementation of phenotypic screening campaigns, which have identified several classes of HCV entry inhibitors. EI-1 (**24**), identified using a pseudoparticle assay, inhibits a GT-1a/2a and GT-1b/2a Rluc HCVcc with EC_{50} values of 24 and 12 nM, respectively, with an excellent therapeutic index based on a CC_{50} of >50 μM toward the host Huh7.5 cell line.[101] The results of time of addition experiments are consistent with inhibition of virus entry at a post-attachment step prior to endosomal acidification, and **24** prevents cell-to-cell spread of virus in vitro. Resistance mapping studies identified Val719Phe and Val719Gly substitutions in a residue located in the transmembrane region of the carboxy terminus of the E2 protein that conferred a 50- to 90-fld shift in the EC_{50}.[101] Resistance to the HCV entry inhibitor **25**, which prevents HCV infection in vitro with EC_{50} values of 30 nM toward a GT-1b/2a chimeric virus and 40 nM toward a GT-2a virus, also maps to the E2 protein with a Pro687Ser substitution that is 20-fold less sensitive.[102] This compound rapidly inactivates infectious HCV while allowing the release of only noninfectious particles and prevents the fusion of the viral and endosomal membranes. However, the precise modes of action of both **24** and **25** will require further experimentation, with studies directed toward developing a deeper understanding of the role and function of the enigmatic E1 and E2 proteins, optimally aided by analyses of the solid-state structures of these proteins in complex with an inhibitor.[103–107]

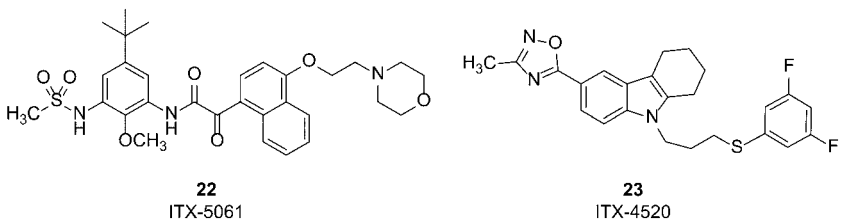

Fig. 8 SR-B1 inhibitors.

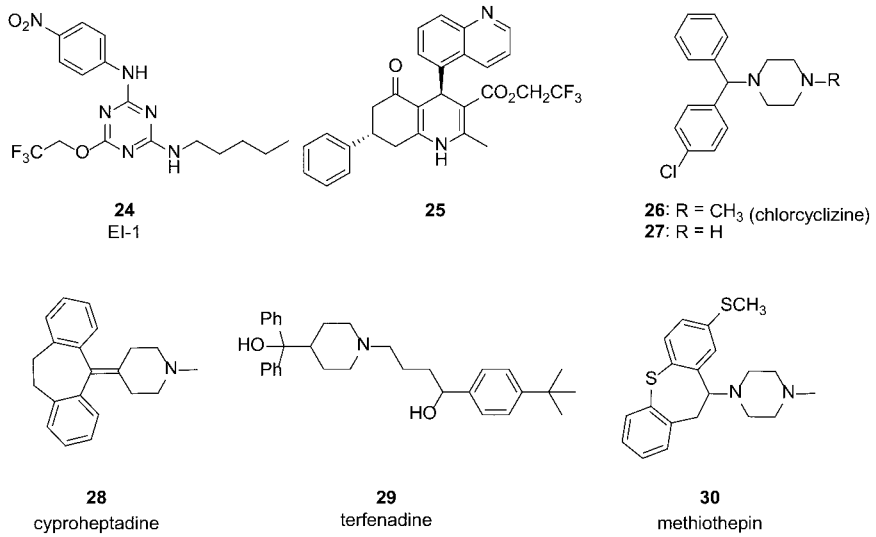

Fig. 9 HCV entry inhibitors.

The HCV entry inhibitors **26–29**, which share some common structural features and mechanistic attributes, were discovered using phenotypic screens (Fig. 9).[108–110] The antihistamine agent chlorcyclizine (**26**) and its major in vivo metabolite norchlorcyclizine (**27**) are potent HCV entry inhibitors in cell culture with EC_{50} values ranging from 2.3 to 44 nM, activity that is insensitive to the absolute configuration at the chiral center.[108–110] Cyproheptadine (**28**) inhibits infectious GT-1a and GT-2a viruses with EC_{50} values of less than 1 μM, while terfenadine (**29**) and the 5-HT_2 antagonist methiothepin (**30**) were identified as modestly potent inhibitors of HCV infectivity using assays designed to detect inhibitors of the interaction of E2 with CD81.[108–112] Attempts to probe the mode of action of chlorcyclizine (**26**) by the development of resistant virus in vitro were unsuccessful, leading to the conclusion that the compound may act by interfering with a host cell target; however, as a potential complicating factor, it has been noted that lipophilic amines can interfere with endosomal maturation.[108,109] In a chimeric mouse model infected with either a GT-1b or GT-2a virus, chlorcyclizine (**26**) administered at daily IP doses of 50 mg kg^{-1} for 4 weeks (GT-1b) and 10 mg kg^{-1} for 6 weeks (GT-2a) suppressed viremia by 1.5 to 2 $\log_{10}$IU mL^{-1}, with rebound occurring only after cessation of drug dosing.[109]

However, against the backdrop of the failure of the SR-B1 antagonist ITX-5061 (**22**) and JTK-652 (a pyrrolopyridazine derivative of undisclosed structure and entry inhibition mechanism) to demonstrate significant antiviral activity in HCV-infected patients, the potential for inhibitors of HCV entry to emerge as clinically relevant therapeutic agents remains to be determined.[97,113]

5.18.1.3 Inhibitors of the Ion Channel Activity of p7

HCV p7 is a small hydrophobic protein composed of 63 residues that include three helical segments embedded in the membrane domains, residues 2–14 (H1), 19–32 (H2), and 40–52 (H3) (Fig. 10).[114–117] The p7 protein is predicted to adopt an overall topology that projects the N- and C-termini into the ER lumen with the cytoplasmic loop composed of residues 33–39, which incorporates a dibasic Lys–Gly–Arg motif. The p7 protein has been shown to be critical for virus propagation in vitro and in vivo in chimpanzees and plays a crucial role in virus infectivity and capsid assembly but not replication.[118–122]

In vitro, p7 oligomerizes into hexamers and heptamers, with the N-terminus helical domains forming the pore of an ion channel that selectively conducts cations (Ca^{2+}, K^+, Na^+, and H^+) across an artificial membrane.[114–117,123–128] Using single-particle electron microscopy that mapped a detergent-solubilized, cross-linked, hexameric channel from GT-1b virus to ~16 Å resolution, a flower-shaped architecture was observed in which the N- and C-termini sequences projected like petals into the ER lumen.[124] Nuclear magnetic resonance (NMR) studies have provided deeper insight into channel structure and function, with improved detail revealing the three helical segments and confirming the flower-shaped hexamer structure, data that have facilitated analysis of

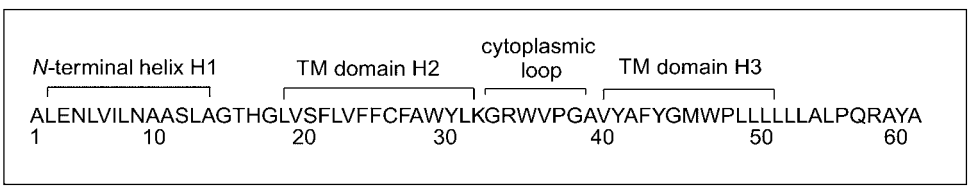

Fig. 10 Structure of HCV p7 with the N-terminal helix, the transmembrane (TM) domains, and the cytoplasmic loop demarcated.

the interaction of p7 with inhibitors.[125–128] The channel from GT-5a virus exhibited some difference from that of the GT-1b protein, adopting an overall funnel architecture, with H1 forming the narrow conical region and H2 the wide cylindrical element of the pore, whereas H3 faced the lipid membrane.[127] Ile6 was suggested to form the hydrophobic filter that prevents water from passing through the channel, while Asn9, conserved in all HCV genotypes with the exception of GT-2, was proposed as a selectivity filter that recruits cations and removes the associated water molecules and is located close to the funnel exit. A second key polar residue is Arg35, located at the wide end of the funnel, which has been hypothesized to associate with anions at the entrance to the pore and interfere with their passage.

The ion channel function of p7 has led to its classification as a member of the viroporin family that includes the Vpu protein of HIV-1, the picornavirus 2B protein, and the influenza M2 proton channel. Indeed, HCV p7 can substitute for the influenza M2 channel in a cell-based assay where it facilitates the transport of hemagglutinin to the cell surface.[115] The cation-conducting properties of p7 have formed the basis for the development of assays to facilitate the identification of inhibitors, with further advances assisted by structural information derived from detailed NMR analyses.[125–128] The influenza M2 inhibitors amantadine (**31**) and rimantadine (**32**) have been characterized as modestly potent inhibitors of HCV p7 channel activity in vitro that show genotype dependency; however, both compounds exhibit poor antiviral activity in cell culture assays (**Fig. 11**).[125,130–132] The antiviral effects of amantadine (**31**) have been studied clinically since the original observation of a beneficial effect, but more recent studies have concluded that the benefit is minimal at best.[133–135] Nevertheless, amantadine (**31**) has been shown to associate with the p7 hexamer by NMR, binding to a hydrophobic pocket between the pore and lipid-facing helices defined by Phe20, Val25, and Val26 from H2 and Leu52, Val53, and Leu56 from H3, with six of these symmetrically distributed within the hexamer.[127] This is concordant with resistance data that have associated changes at Phe20 with modulating sensitivity to inhibition by amantadine (**31**), with a Leu substitution found in GT-1b and GT-2a strains more sensitive to **31**, leading to consideration of this region as a binding site that modulates channel function by an allosteric mechanism.[136]

Other inhibitors of p7 ion channel function in vitro include the iminosugar *N*-nonyl-deoxynojirimycin (**33**), which also expresses antiviral activity via α-glucosidase inhibition, and the acyl guanidine BIT225 (**34**), which also inhibits HIV-1 Vpu function.[136–139] Resistance to **33** maps to a Phe25Ala change that suggested an inhibitory effect on proper channel oligomerization.[136] BIT225 (**34**) has been evaluated clinically where a preliminary study evaluated a dose of 400 mg BID in conjunction with PEG-IFN-α and ribavirin (**1**), with the result that the observed decline in viremia was enhanced by 10-fold compared with the control group administered with PEG-IFN-α and ribavirin (**1**) alone.[117,139] The quinazoline LDS25 (**35**) was one of several compounds identified as a potent p7 inhibitor based on a structure-guided drug design exercise that used the solution structure of monomeric GT-1b protein to develop a model of a heptameric channel.[128] This exercise was part of a broader effort to more precisely define the binding site for adamantine (**31**) and rimantadine (**32**), information that would be useful for in silico compound screening.[128] Twelve of the hits identified in this fashion inhibited GT-1b p7 ion channel activity with IC_{50} values of ~250 nM, considerably more potent than rimantadine (**32**), IC_{50} = 40 μM. LDS25 (**35**) is reported to demonstrate antiviral activity in cell culture with an EC_{50} value of ~300 nM.[117,128]

The challenges associated with identifying and characterizing HCV p7 inhibitors preclinically have impeded progress toward this target, and although clinical evaluation of BIT225 (**34**) is ongoing, the potential for a p7 inhibitor to be approved as a component of combination therapy against a rapidly evolving clinical landscape remains to be determined.[117]

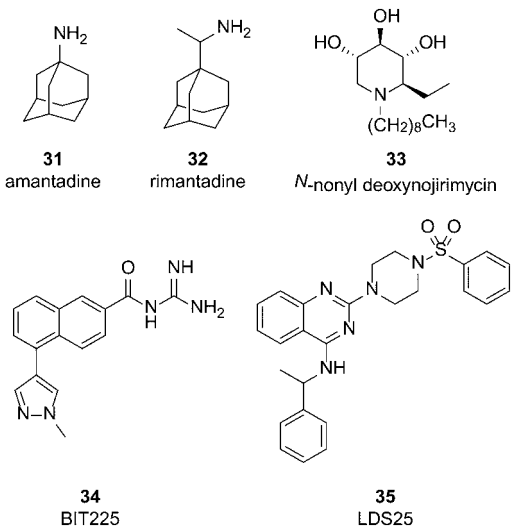

Fig. 11 HCV p7 ion channel inhibitors.

5.18.1.4 HCV NS2 Protease Inhibitors

The HCV NS2 cysteine protease is a 217-residue peptide that is essential for viral replication, cleaving the viral polypeptide at the NS2–NS3 junction in a fashion that is dependent on the presence of the NS3 protein.[140–142] NS2 forms complexes with both structural (E1, E2, and p7) and nonstructural (NS3 and NS5A) proteins that contribute to a central role in virion assembly, although the precise function and choreography of these interactions remain to be determined.[140,141,119] In addition, NS2 interacts with several host cell proteins that allow the virus to modulate the cellular environment in its favor. Biochemical studies have revealed that the N-terminal hydrophobic region anchors the peptide in the endoplasmic reticulum membrane via three putative transmembrane domains and that residues His143, Glu163, and Cys184 are associated with proteolytic catalysis.[140,141] HCV NS2 protease is, however, unusual in that in the crystalline form, the postcleavage protein (residues 94–217) assembles as a dimer that shows little resemblance to other viral proteases, with two composite active sites in which Cys184 from one monomer combines with His143 and Glu163 from the other.[143] Experimental data are consistent with the protease functioning as a dimeric species, and once cleavage has occurred, Leu217 in the C-terminus associates with the active site residues of the dimer to stabilize the enzyme in an inactive configuration, thereby regulating the function of the protease during viral replication.

Inhibitors of the HCV NS2 protease have been explored only sparsely.[140,141] As a cysteine protease, NS2 is sensitive to inhibition by the thiol modifiers *N*-ethylmaleimide and iodoacetamide but, surprisingly, not the *trans*-configured epoxide E-64 (**36**), which has been utilized as a general inhibitor of cysteine proteases (Fig. 12).[140,141,144,145] However, the *cis*-disposed epoxy bis-amide **37** has been characterized as a modestly potent inhibitor of autoproteolysis of the GT-2a JFH1 NS2–NS3, $IC_{50} = 93$ μM, while the prototype **38** is inactive.[146] This provided a matched pair of compounds with which to explore effects in a cell-based assay where **37** was active in a subgenomic replicon system only when processing of the polyprotein was dependent on NS2 autoprotease activity, determined by comparison of NS2–NS5 and NS3–NS5 constructs.[146] Epoxide **38** was inactive both in this context and toward a transient GT-2a chimeric infectious clone, whereas **37** reduced replication to 15% of control at a concentration of 90 μM.

The HCV NS2 protease inhibitors that have been described to date have not been the subject of attempts to refine these leads into more potent and specific agents, a reflection of the difficulties associated with this protein as a therapeutic target. As a consequence, the current understanding of the biochemical pharmacology of the NS2 protease and its inhibition is immature and with several very effective drug combinations already approved as HCV therapeutics, this circumstance seems unlikely to change.

5.18.1.5 HCV NS3 Protease Inhibitors

The HCV NS3 serine protease has been extensively explored as a drug target since its original identification and characterization, facilitated by the development of biochemical assays suitable for screening and further enhanced by the solving of solid-state structures that have been exploited in rational drug design.[24–27,32–34,147] This protease comprises the first 181 residues of the 631-residue bifunctional NS3 protease/helicase and is characterized by an extended and exposed substrate-binding groove that is largely shallow and featureless, originally viewed as providing limited opportunity for optimizing drug–target affinity.[32–34] The catalytic activity of the native enzyme is poor in comparison with mammalian serine proteases with a $K\text{cat}/K\text{m} = 30$–$2000\ M^{-1}\ s^{-1}$ for peptide-based substrates (versus a $K\text{cat}/K\text{m} = 10^{15}\ M^{-1}\ s^{-1}$ for thrombin); however, NS3 is markedly stimulated by association with NS4A, a cofactor that increases $K\text{cat}/K\text{m}$ values to 10,000–55,000 $M^{-1}\ s^{-1}$.[147–151] The catalytic triad of the enzyme is composed of His57, Asp81, and Ser139 that in the solid state lie in a cleft between two β-barrel subdomains and is deployed in a chymotrypsin-like fold.[31,32] The enzyme is further stabilized by coordination of a Zn^{2+} ion by Cys97, Cys99, Cys145, and His149, a structural element of importance to the cleavage of the polyprotein by NS2. The central portion of the NS4A cofactor, residues 21–32, adopts a β-strand structure that associates with the N-terminal β-barrel of the protease, thereby favoring the correct folding of NS3. The hydrophobic α-helix located at the amino terminus of NS4A anchors the complex to the membrane, while the acidic carboxy terminal region of the protease interacts with the helicase domain. Substrate specificity is relatively low, governed primarily by recognition of Cys at the cleavage site, a small residue at P1′, and an acidic amino acid at P6.[31,32] In addition to processing the viral polyprotein, the NS3 protease also acts on several host cell substrates that provide the virus with a measure of control over the host cell immune response. Mitochondrial antiviral-signaling protein (MAVS, formerly known as CARDIF, VISA, and IPS1) and Toll/interleukin-1 receptor (TIR) domain-containing adaptor inducing IFN-β (TRIF) are the two host substrates that have been characterized most thoroughly, and both are involved in the induction of an innate immune response.[152–155]

The biochemical properties and structural features of the NS3 protease are such that the identification of lead small-molecule inhibitors using high-throughput screening protocols was unsuccessful, focusing drug design on substrate-based approaches. An

Fig. 12 HCV NS2 protease inhibitors.

important discovery toward that objective was the observation that the NS3 enzyme was subject to product inhibition by the carboxylic acid products of cleavage, providing a basis for the optimization of product-based peptides into potent inhibitors.[156–158] The hexapeptide **39**, which is derived from the NS4A–NS4B junction, inhibited the protease with a K_i of 600 nM, a potent but challenging lead template from which to design more drug-like molecules based on the size, the polyacidic nature of the molecule, and the presence of the Cys at the C-terminus (**Fig. 13**).[157] The latter problem was solved initially in an elegant fashion in the context of the more potent analog **40**, $K_i = 40$ nM, in which the P2 glutamate residue is substituted by a cyclohexylalanine (Cha) moiety and the P3 Met residue is elaborated to 3,3,-diphenylalanine (Dif).[158] Capitalizing on the known but underappreciated H-bond-donating properties of an alkyl difluoride and the similarity in shape, size, and molecular electrostatic potential compared with a thiol moiety, a difluoro-Abu P1 residue was examined.[159,160] This afforded **41** as a compound with potency comparable with **40** that was superior to the simple Abu analog **42**, indicative of effective functional mimicry of the thiol moiety.[161,162] The keto acid **45** is a smaller, slow-binding analog of the more potent aldehyde **43** and keto acid **44** and displays a K_i of 17 μM and a K_i* of 27 nM. These inhibitors take advantage of the electrophilicity of the keto carbonyl of **45**, the *Si*-face of which reacts with the hydroxyl of the catalytic Ser139 to form a covalently bound, tetrahedral intermediate, as observed in the cocrystal structure. In the P1 pocket, the CF_2H moiety makes hydrophobic contacts with Val132, Leu135, and part of the side chain of Lys136, while the hydrogen atom is oriented toward the backbone amide oxygen of Lys136, confirming the bioisosteric mimicry of the cysteine thiol moiety.[159,162] In addition, one of the fluorine atoms is in contact with the *para*-hydrogen atom of Phe154 at the base of the pocket.

As the understanding of the activity and SARs associated with substrate-based inhibitors of NS3 evolved, two avenues for drug discovery were pursued that focused on optimizing either activated ketone-containing peptide derivatives or carboxylic acid-based product inhibitors. The former approach led to the approval of the first HCV NS3 protease inhibitors telaprevir (**2**) and boceprevir (**3**), which were licensed in May 2011, although both were taken on a TID dosing schedule in combination with PEG-IFN-α and ribavirin (**1**).[64,65,163–165] The discovery of telaprevir (**2**) has its origins in the tetrapeptidic aldehyde **46**, a modestly potent inhibitor of NS3, $K_i = 12$ μM (**Fig. 14**).[166–169] Further optimization of **46** to the α-keto amide **47**, $K_i = 0.22$ μM, took advantage of interactions with the S′ subpockets of the enzyme. Both **46** and **47** incorporate large aromatic-containing moieties attached via a 4-hydroxy proline at P2 that project beyond the substrate-binding groove of the enzyme, frequently designated as P2* elements. However, further modification focused on fused bicyclic rings at this site, culminating in the discovery of **48**, $K_i = 0.04$ μM. Subsequent adjustments to the structure systematically optimized the bicycloproline, P4, and ketoamide moieties to arrive at telaprevir (**2**), $K_i = 0.007$ μM.[166,167,170] Telaprevir (**2**) undergoes facile racemization at the P1 residue in vivo to afford a diastereomeric mixture with 30-fold weaker potency, an observation that prompted a study of the deuterated analog **49**.[171,172] This compound sought to take advantage of the kinetic isotope effect associated with deuterium and its design was based on the hypothesis that proton removal was the rate-determining step in racemization. Compound **49** was characterized as a twofold more potent NS3 inhibitor than telaprevir (**2**) and exhibited slower racemization at P1 in phosphate buffer and human plasma, producing only 10% of the epimer over 1 hour compared with 35% for the parent drug. Consistent with increased stability, the AUC of **49** following oral dosing to rats was 13% higher than for telaprevir (**2**), suggestive of slower racemization at P1 in vivo.[171]

By way of contrast, boceprevir (**3**) was developed as the racemate at P1 due to the facility with which racemization at P1 occurred, particularly in biological assays.[173] Optimization charted a similar pathway of truncation from an undecapeptide-based lead inhibitor, initially to the pentapeptide derivative **50**, K_i* = 15 nM, which like telaprevir relies upon the α-ketoamide

motif to react with the serine hydroxyl of NS3 (Fig. 15).[173–176] The introduction of a *gem*-dimethylcyclopropylproline at P2, which was observed to interact closely with the CH_3 of Ala156 in the cocrystal structure, coupled with modification of the amide terminus provided **51**, $K_i^* = 15$ nM, with measurable inhibitory activity in a replicon assay, $EC_{90} = 100$ nM, but poor PK properties in rats. The latter was addressed by further truncation at the P′ side of the scissile bond mimic and modification of the P3 moiety to give **52**, $K_i^* = 25$ nM and $EC_{90} = 400$ nM. The final structural adjustments were made at P1, P3, and the amino terminus by combining optimal elements identified from the extensive SAR studies that had been conducted, leading to boceprevir (**3**), $K_i^* = 15$ nM and $EC_{90} = 350$ nM, which demonstrated oral bioavailability in the mouse, rat, dog, and cynomolgus monkey.[173–176]

The alternative pathway focused on optimizing peptidic carboxylic acid derivatives and resulted in the discovery of BILN-2061 (**53**), a macrocyclic tripeptide-based inhibitor that was the first NS3 protease inhibitor to demonstrate antiviral activity following oral dosing to HCV-infected subjects (Fig. 16).[177–181] A 200 mg dose of **53** administered twice daily orally as a solution in PEG 400 and ethanol for 2 days to eight GT-1-infected subjects resulted in a rapid reduction in viremia, amounting to 2–3 $\log_{10}$ IU mL^{-1} in all patients, with most achieving undetectable levels of HCV RNA by 48 hours after the first dose of drug.[177]

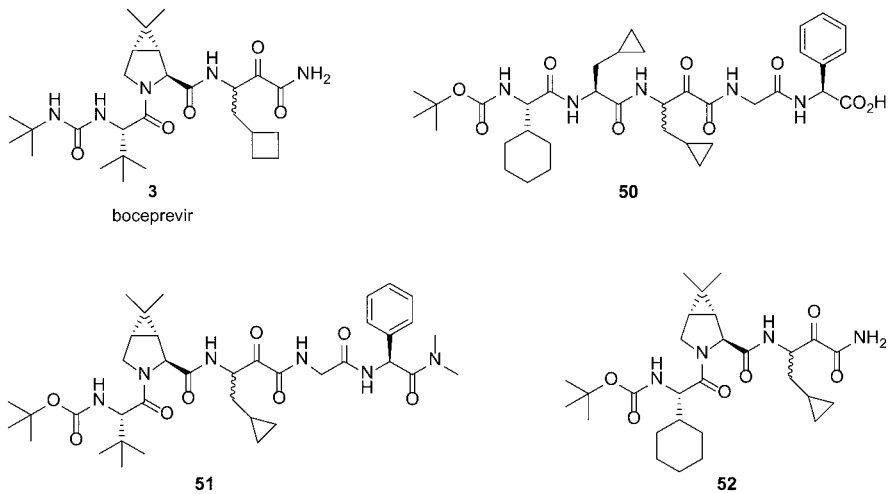

Fig. 15 HCV NS3 protease inhibitors boceprevir (**3**) and precursor molecules **50–52**.

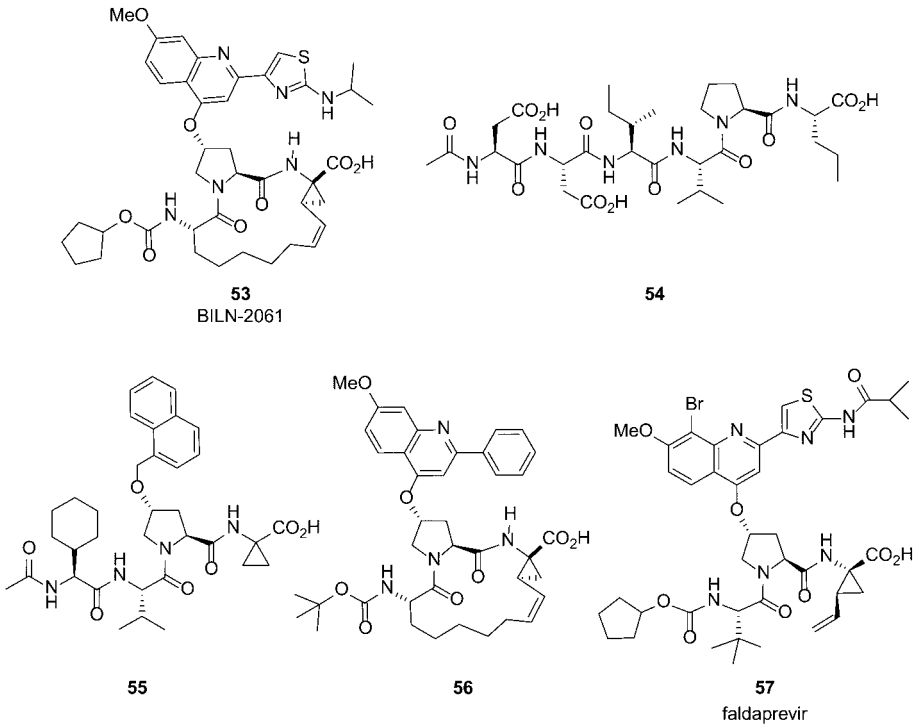

Fig. 16 HCV NS3 protease inhibitors **53–57**.

The origin of **53** was the polyacidic hexapeptide **54**, $IC_{50} = 150$ μM, for which systematic SAR studies established that the installation of 1-aminocyclopropane-1-carboxylic acid at P1 enhanced potency by threefold, while the introduction of a large lipophilic P2* element at the 4-position of the P2 proline produced a more dramatic 350-fold enhancement.[181] A combination of these SAR observations gave potent inhibitors in the context of a platform that facilitated truncation to afford the tetrapeptide **55**, which contains only a single acidic moiety and which inhibited NS3 with an IC_{50} value of 3.5 μM. Further optimization of **55** relied upon systematic variation of each amino acid residue, aided by NMR analysis of representative inhibitor–protease complexes that revealed an extended β-strand conformation of the inhibitor that placed P1 and P3 proximal.[182–184] This is a common binding mode for protease substrates and provided the inspiration to link the P1 and P3 elements as a means of preorganizing the bound conformation and improving the negative entropic aspect of the binding event.[185] The interest in this approach was heightened by the observation that when free in solution, the P1 moiety of unconstrained inhibitors adopted a conformation different to that recognized by the protease, while the P2–P3 amide existed as a *cis–trans* mixture. These studies reinforced the potential for enhanced potency in macrocycle-based inhibitors, an anticipation that was realized in the context of **56**, which inhibited NS3 with an IC_{50} of 11 nM, 30-fold more potent than a structurally similar acyclic analog.[178–180,186] An X-ray cocrystal structure of **56** bound to NS3 illuminated the key drug–target interactions, which included H bonds between the P1–P2 amide NH and the backbone carbonyl of Arg155 and between the P2–P3 carbonyl oxygen atom and the NH of Ala157.[178–180] At the C-terminus, one of the oxygen atoms of the carboxylic acid was bound in the oxyanion hole of the protease, interacting with the backbone NHs of Gly137 and Ser139, while the other interacted with the NH of the imidazole of His57. In addition, there appeared to be a bifurcated H bond between the carboxylate moiety and the side-chain OH of Ser139. The methoxyphenyl group of the P2* quinoline interacted with the guanidinium moiety of Arg155 in a π-stacking-type interaction that helped to stabilize the salt bridge association between Arg155 and Asp168 of the enzyme.[187] This provided an understanding of the emergence of resistance associated with Arg155Gln and Asp168Val—mutations in which disruption of the salt bridge removes the conformational constraint on these residues leading to a steric clash with the P2* moiety of the inhibitor.

The fully optimized molecule BILN-2061 (**53**) inhibited NS3 with IC_{50} value of 3.0 nM, which translated efficiently into potent antiviral activity in a replicon ($EC_{50} = 1.2$ nM), while dosing to rats demonstrated an oral bioavailability of 42%.[178,179,181] These data provided the basis for advancing BILN-2061 (**53**) into clinical trials, but development was terminated as a consequence of the occurrence of cardiac toxicity in rhesus monkeys.[188] Myocytic vacuolation and mitochondrial swelling resulted in left ventricular dysfunction after 28 days of exposure, and cardiac effects were observable after three or more doses of drug, a toxicity profile found to be common to two other macrocycle-based NS3 inhibitors. This led to a refocus on nonmacrocyclic alternatives from which faldaprevir (**57**) emerged as a candidate that successfully completed phase 3 clinical trials in conjunction with PEG-IFN-α and ribavirin (**1**) before development was halted for business reasons in June 2014.[189–191] Faldaprevir (**57**) is a slow-binding inhibitor of NS3 with K_i values of 2.6 and 2.0 nM toward GT-1a and GT-1b proteases, respectively, that translate into potent antiviral effects in

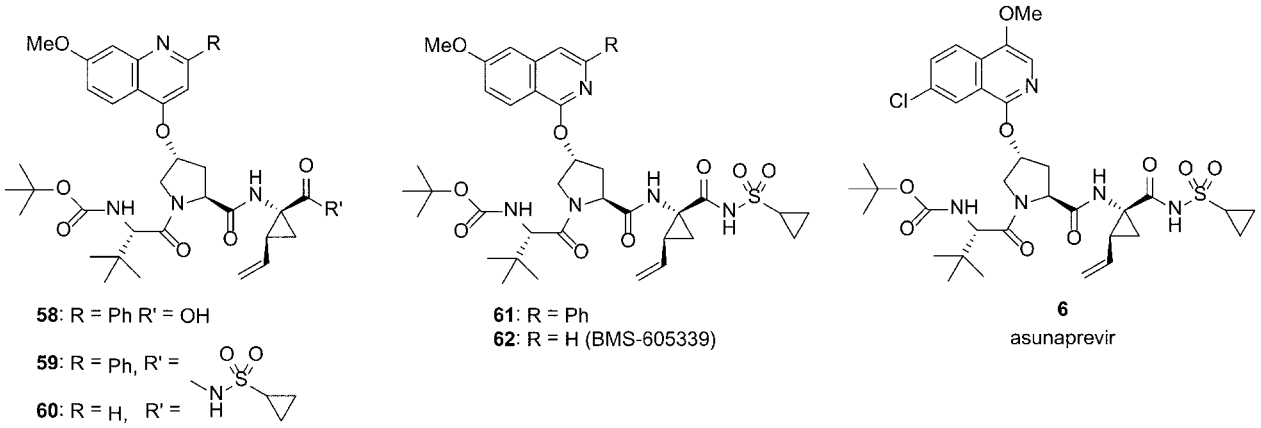

Fig. 17 HCV NS3 protease inhibitors **58–62** and asunaprevir (**6**).

replicons with EC_{50} values of 6.5 and 3.1 nM for GT-1a and GT-1b, respectively (Fig. 16).[189,190] The cocrystal structure of **57** bound to NS3 revealed an interesting halogen bonding interaction between the bromine atom and the backbone carbonyl of Asp79.[191,192] In addition, the sulfur atom of the thiazole heterocycle engaged in a close chalcogen interaction with the pendent acyl oxygen atom (the S to O distance is 2.87 Å, almost 0.5 Å less than the 3.32 Å sum of the van der Waals radii of S and O), which stabilizes the observed topology in an overall planar arrangement.[191,193]

A significant advance in the optimization of carboxylic acid-based NS3 inhibitors came with the advent of the cyclopropyl acylsulfonamide moiety, which was designed to enhance potency by preserving the acidic nature of the C-terminus motif while allowing access to the small but well-defined S1′ pocket that is lined, in part, by the side chains of Phe43, Val55, and Gly58.[194,195] The effectiveness of this approach is amply illustrated by comparing the enzyme and replicon inhibitory data for the matched pairs **58** and **59** (Fig. 17), results that reflect a 50–100 potency gain in the acylsulfonamide (Table 2).[194] An X-ray cocrystal structure revealed the origin of the enhancement, with the acylsulfonamide nitrogen atom rather than the oxygen atom engaging the catalytic His57 in a salt bridge interaction—a regiochemistry supported by electrostatic potential calculations, which favor residence of the charge on nitrogen—while the carbonyl oxygen atom accepts a H bond from the NH of Gly137.[194] Both sulfonamide oxygen atoms interact closely with the oxyanion hole with each accepting a H bond, one from Gly137 and one from Ser139, while the cyclopropyl ring is an optimal fit in the small, lipophilic S1′ pocket.

In this series, oral bioavailability in rats demonstrated a remarkable sensitivity to the identity of the P2* heterocycle, most effectively illustrated by comparing the rat exposure data following intraduodenal (ID) dosing of the quinolines **59** and **60** with their matched isoquinoline partners **61** and **62**, respectively (Table 2).[194] The ratios of AUC and liver levels measured at 4 hours after dosing **59** and **61** are ~10-fold in favor of the isoquinoline **61**, an advantage that is amplified to 100–600-fold for the simpler-substituted 6-methoxy isoquinoline BMS-605339 (**62**) compared with **60**. An in-depth evaluation of BMS-605339 (**62**) in a series of preclinical studies revealed an overall profile that supported advancing this compound into phase 1 clinical trials.[194] A single ascending dose study conducted initially in healthy volunteers and subsequently in subjects infected with HCV GT-1 demonstrated a dose-related increase in plasma exposure accompanied by a dose-dependent reduction in viremia, with a mean maximal decline of 1.8 $\log_{10}$IU mL^{-1} following a single oral dose of 120 mg.[194] However, mild bradycardia, PR interval prolongation, and junctional rhythm disturbances that were observed in two subjects resulted in further development being halted. Asunaprevir (**6**), which differs from BMS-605339 (**62**) by structural changes only to the isoquinoline P2* moiety and adds only a single chlorine atom to the molecular formula, was identified as a second clinical candidate that exhibits similar in vitro potency to **62**, a more hepatotropic in vivo disposition in rats (Table 2) and an improved cardiac profile, the result of rigorous triaging of candidate compounds through a Langendorff isolated perfused heart preparation.[195]

Table 2 In vitro antiviral activity and in vivo rat PK parameters for NS3 inhibitors **58–62** and asunaprevir (**6**)

	In vitro profiling		*Rat PK data following dosing of 15 mg kg^{-1} ID*

6	1	6	1.90	67.41

The advantages offered by the cyclopropyl acylsulfonamide moiety have resulted in this structural element being prominently deployed in many clinically evaluated NS3 inhibitors that explore a range of interesting drug design principles. Sovaprevir (**63**) is an acyclic protease inhibitor that incorporates a succinic acid moiety as the P3–P4 element and was advanced into clinical trials (Fig. 18).[196] However, development of this compound was halted in favor of the P1–P3 macrocycle neceprevir (**64**), which incorporates the same P2* moiety as simeprevir (**5**) and demonstrates activity toward a broader range of HCV genotypes.[197] The design of simeprevir (**5**) relies upon the use of a *trans*-disposed cyclopentane dicarboxylic acid as a mimic of the P2 proline that is constrained within a 14-membered macrocycle linking P1 to P3.[198–201] Although this compound does not contain functionality that projects into P4, it is a potent, time-dependent NS3 inhibitor with K_i values estimated at 0.5 and 0.4 nM toward GT-1a and GT-1b proteases, respectively, which translates into potent inhibition in cell-based assays, $EC_{50} = 28$ and 25 nM in GT-1a and GT-1b replicons, respectively.[200,202] Resistance studies mapped virus escape to mutations at Asp168 with a Val or Ile substitution at this position associated with ~2000-fold reduced sensitivity to simeprevir (**5**), while Gly or Asn substitutions exhibited a less than 10-fold shift in the EC_{50} values.[203] In the cocrystal structure with NS3, the thiazole moiety of simeprevir (**5**) adopts a coplanar arrangement with the quinolone ring that juxtaposes the sulfur atom with the quinolone nitrogen atom.[201] This is the result of an attractive interaction between these two atoms, which are just 3.0 Å apart (less than the sum of the respective van der Waals radii), that stabilizes the observed conformation.[193,201] Simeprevir (**5**) gained regulatory approval in Japan in Sep. of 2013, in the United States in Nov. 2013, and by the European Commission in May 2014 with an indication for the treatment of HCV GT-1 infection to be used in conjunction with PEG-IFN-α and ribavirin (**1**).[67,204]

Two other protease inhibitors that are based on a P1–P3 macrocyclic tripeptidic acylsulfonamide backbone but incorporate different structural elements at P2* and P4 are danoprevir (**65**) and paritaprevir (**10**).[205–212] Danoprevir (**65**) (Fig. 18) is a potent

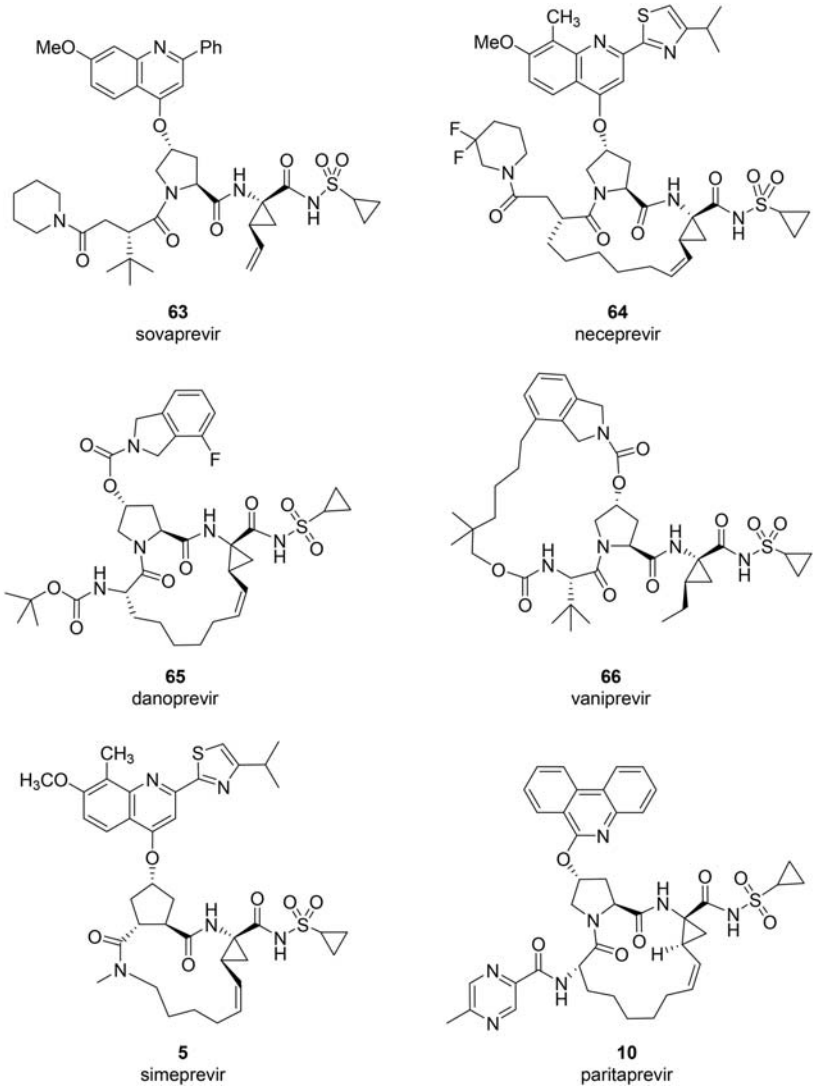

Fig. 18 HCV NS3 protease inhibitors **63–66**, simeprevir (**5**), and paritaprevir (**10**).

NS3 inhibitor, $IC_{50} = 0.2–3.5$ nM dependent upon genotype, that exhibits a slow off rate from the enzyme and displays potent antiviral activity in replicons, $EC_{50} = 1.6$ nM (GT-1b) and 20 nM (GT-2 and GT-3).[205–207] Danoprevir (**65**) deploys a carbamate moiety at P2* that was initially derived by probing a virtual library of potential targets based on an acyclic tetrapeptide carboxylic acid core and synthesizing representative examples of those with the most promising scores.[205] Subsequent optimization focused on identifying compounds that reduced the peptidic nature of the molecules while combining potent antiviral activity in replicons with good liver exposure in rats following oral dosing, with the latter varying markedly within the chemotype. A 30 mg kg^{-1} dose of danoprevir (**65**) administered orally to rats and cynomolgus monkeys provided liver levels of drug at 12 hours that exceeded the replicon EC_{50} values, with levels 10-fold higher in the rat than the monkey.[205,207] In a 14-day monotherapy study in HCV-infected subjects, 200 mg doses of danoprevir (**65**) administered on a BID and TID schedule were associated with declines in viremia of 3.2 $\log_{10}$ and 3.9 $\log_{10}$ IU mL^{-1}, respectively.[208,209] Virus rebound was observed in ~20% of the patients, with sequencing revealing an Arg155Lys mutation as the predominant change that reduced susceptibility by over 400-fold.[210] Since danoprevir (**65**) is metabolized by CYP 3A4, a PK-boosting strategy by coadministration with the potent CYP 3A4 inhibitor ritonavir (**11**) has been pursued for more advanced clinical studies.[208]

The design parameters and preclinical challenges that subtend the discovery and development of paritaprevir (**10**) have not been described in detail.[211] However, the compound is a potent antiviral agent in GT-1a, GT-1b, GT-2a, GT-3a, GT-4a, and GT-6a HCV replicons, with EC_{50} values ranging from 0.09 nM (GT-4a) to 19 nM (GT-3a) in the absence of human serum, while in GT-1a replicons, the EC_{50} value shifts by 17–25-fold in the presence of human serum.[211,212] Resistance mapping studies in vitro identified Asp168Val as a key mutation, conferring 96- and 159-fold reduced susceptibility toward GT-1a and GT-1b replicons, respectively, and this mutation, along with Arg155Lys, was observed in a 3-day monotherapy study.[212] Since paritaprevir (**10**) is metabolized primarily by CYP 3A4, it, like danoprevir (**65**), is coadministered with ritonavir (**11**) to boost the C_{trough} of the drug and minimize the emergence of resistant virus.[211,212]

Vaniprevir (**66**) and grazoprevir (**14**) are the result of an examination of an alternative macrocyclization topology that takes advantage of the proximity of the P2* moiety to elements that bind in the S4 pocket in cocrystal structures, a design principle explored by modeling studies.[213–215] The seminal study examined the concept in the context of tripeptidic carboxylic acids incorporating a quinoline heterocycle at P2*, from which **67** emerged with the optimal linker length and point of attachment to the quinoline, inhibiting a GT-1b protease with a K_i of 8.5 nM and active in a GT-1b replicon, $EC_{50} = 1.15$ μM.[213] In this molecule, the P4–P2* linker occupies the site occupied by Glu628 of the C-terminus of the helicase domain in the X-ray of the full-length protein, an observation that was instrumental in the original design concept. Installation of the cyclopropyl acylsulfonamide terminus to give **68** improved intrinsic potency by more than 500-fold, $K_i = < 0.016$ nM, accompanied by a 170-fold increase in replicon inhibitory activity, $EC_{50} = 6.7$ nM. However, **68** demonstrated poor plasma and liver exposure in rats following oral dosing, a shortcoming only partially resolved by rearranging the P3 substituent to that of a *tert*-butyl moiety. These results prompted the examination of an isoquinoline P2* heterocycle, with the prototype **69** preserving the in vitro profile of **68**, $K_i = 0.07$ nM, $EC_{50} = 4.5$ nM, but demonstrating a 36-fold higher plasma $AUC_{0-4\ h}$ and 4.75-fold higher liver levels 4 hours after a single 5 mg kg^{-1} oral dose, recapitulating observations in the acyclic series.[194,213]

Further optimization of this chemotype focused on variation of the P2* moiety, which enabled additional probing of linker length, level of saturation, and substitution in conjunction with modifications to P3 and P1.[214] While saturation of the linker had no effect on potency, saturation of the P1 vinyl moiety led to a 10-fold reduction in potency but increased liver levels after oral dosing to rats. Interestingly, saturation of both the linker and the P1 vinyl moiety restored potency toward the sentinel GT-1b virus and led to improved liver levels, but activity toward a GT-2a replicon was modest (EC_{50} ~ 100 nM), stimulating additional optimization in pursuit of a broader inhibitory profile. This was accomplished by the installation of a gem-dimethyl substituent on the linker proximal to the P3–P4 carbamate, a modification leading to the identification of vaniprevir (**66**), which exhibits improved GT-2a inhibition ($EC_{50} = 9–15$ nM).[214–216] Vaniprevir (**66**) exhibited high liver concentrations 24 hours after an

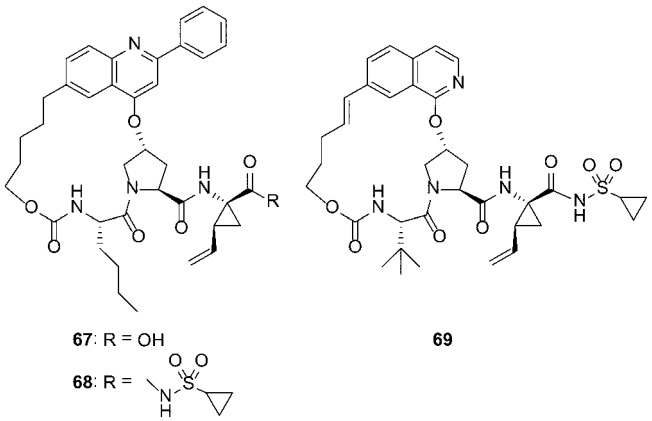

Fig. 19 HCV NS3 protease inhibitors **67–69**.

oral dose of 5 mg kg^{-1} to rats (400 nM), dogs (600 nM), and rhesus monkeys (200 nM), although plasma exposure was not sustained in the rat and rhesus monkey.[216] In addition, a 10 mg kg^{-1} dose administered to chimpanzees afforded a liver concentration of 31 μM. In patients chronically infected with GT-1 HCV and administered doses of vaniprevir (**66**) ranging from 25–700 mg BID to 125 and 600 mg QD for 8 days, viral load declined by 1.8 to 4.6 $\log_{10}$ IU mL^{-1}.[217] Plasma and liver levels of the drug were determined in a cohort of three treatment-experienced subjects administered with 300 or 600 mg on a BID schedule, with liver biopsy samples taken at 6 or 12 hours after the final dose.[218] Liver levels ranged from 84.6 to 169 μM at 6 hours and 29.4 to 54 μM at 12 hours, concentrations well above the replicon EC_{50}s of 2.9 to 27 nM, with liver/plasma ratios ranging from 20 to 280. These data are consistent with transporter-mediated hepatic uptake of vaniprevir (**66**), and the results contrast markedly with the profile of telaprevir (**2**), which demonstrates a hepatotropic disposition in preclinical species but a very different profile in HCV-infected patients where liver/plasma ratios were <1 and absolute drug concentrations in the liver were much lower at $\sim$7 ng g^{-1}.[219]

The antiviral activity of vaniprevir (**66**) was diminished toward replicons harboring resistant mutations that arose during combination therapy, with EC_{50} values of 350 nM for Arg155Lys, 430 nM for Asp168Tyr, and 200 nM for Ala156Thr, while the K_i toward a GT-3a enzyme was 54 nM, over 100-fold higher than for a GT-1b protease.[217,220–223] This provided focus for subsequent studies that led to the identification of grazoprevir (**14**), a molecule with an improved antiviral profile that inhibits a GT-3a protease with a K_i of 0.7 nM, while the three mutant proteases described in the preceding text are inhibited with K_i values ranging from 0.07 to 5.3 nM.[215,221] The optimization campaign leading to grazoprevir (**14**) was directed toward topological modifications of the P2* heterocycle that would increase contact with the GT-3a protease. This approach relied upon building into a conserved region of the protease in a fashion that also reduced contact of the P2* element with the Arg155–Asp168 salt bridge, which when compromised by mutations leads to conformationally more mobile side chains that sterically interfere with inhibitor binding. The topology of the P2*–P4 linker was also altered to avoid polymorphisms unique to GT-3a in this region of the protease, a design exercise that provided a compound with a significantly improved antiviral profile.[215,221–225] Grazoprevir (**14**) has completed phase 3 clinical studies as a fixed-dose combination with the NS5A inhibitor elbasvir (**13**), and an NDA was filed on 28 May 2015 seeking approval for marketing to treat of GT-1, GT-4, and GT-6 infection, which was granted in Jan. 2016.[223]

grazoprevir

The simultaneous incorporation of both a P4–P2* and a P1–P3 macrocycle was explored in the context of MK-6325 (**70**) (Fig. 20).[226] This compound demonstrated subnanomolar IC_{50} values toward proteases representative of GT-1 to GT-6a and those with mutations at Arg155, Ala156, and Asp168, a profile that translated into potent antiviral activity in replicons, with EC_{50} values ranging from 0.4 nM (Arg155Lys) to 5.5 nM (Ala156Thr). This analog, which incorporates a methyl substituent in the cyclopropylsulfonamide moiety, exhibited a liver concentration of 20 μM in rats 24 hours following a 5 mg kg^{-1} oral

dose and 9.9 μM in dogs 24 hours after a 3 mg kg^{-1} dose, although oral bioavailability in both species was poor at 8% and 12%, respectively.

Irreversible inhibition of NS3 protease by targeting a reactive cysteine, Cys159, in the substrate-biding groove remote from the catalytic site and proximal to the S4 pocket, inspired the design of tripeptidic inhibitors that incorporate a Michael acceptor with low intrinsic chemical reactivity, as exemplified by **71** (Fig. 20).[227] A structure-based design approach suggested that a D-Ala P3 moiety would provide the necessary conformational bias to help present the acrylamide element of **71** to Cys159, a residue highly conserved in NS3 sequences. Compound **71** potently inhibited HCV NS3 protease activity with an IC_{50} of 2 nM, whereas the saturated propylamide homologue was a much weaker inhibitor, IC_{50} of 1.15 μM, and **71** poorly inhibited a protease incorporating a Cys159Ser mutation, $IC_{50} = 1.8$ μM. In an HCV replicon assay, **71** half-maximally inhibited luciferase activity at a concentration of 6 nM, while the propylamide analog was inactive, collective data that are consistent with a covalent mechanism of action. Adduct formation was confirmed by mass spectrometric and X-ray crystallographic analysis of the complex of **71** with the wild-type enzyme. Despite the presence of an unsubstituted acrylamide moiety, **71** demonstrated good discrimination with respect to inhibition of a panel of mammalian proteases and was not overtly reactive with glutathione.

Boronic acid derivatives are an established class of serine protease inhibitor that have been shown by X-ray cocrystal structural data to form a covalent adduct in which the catalytic serine hydroxyl adds to the boron to afford a stable tetrahedral intermediate.[228,229] Peptide-based boronic acid derivatives were examined for their potential as a platform for NS3 inhibitor design with the P1-phenethyl-substituted pentapeptide derivative **72** a representative example, $K_i = 8$ nM (Fig. 21).[230–232] The introduction of a para-CF_3 substituent gave **73**, which exhibited improved NS3 protease inhibition, $K_i = 2$ nM, while reducing affinity for human leukocyte elastase by twofold, $IC_{50} = 3.5$ μM, and chymotrypsin by 200-fold, $IC_{50} = 16$ μM.[232] The most successful boron-based NS3 protease inhibitor was PHX-1766 (**74**), which demonstrated potent ($IC_{50} = 8$ nM; $K_i = 0.05$ nM), selective, and reversible inhibitory activity toward GT-1, GT-2a, and GT-3a proteases.[233,234] This compound retained activity against the most common resistance mutations at Ala156, Arg155, and Asp168, although replicon EC_{50} values have not been reported. PHX-1766 (**74**) was advanced into phase 1 clinical studies where doses of 50–1000 mg were administered to normal healthy volunteers (NHVs) to establish the safety and exposure of the compound. This was followed by a study conducted in 6 HCV-infected patients, which assessed single doses of 100 and 500 mg QD and 250 mg BID and a multiple-dose study of 400 and 800 mg BID administered to 7 subjects.[234] However, plasma levels at trough in the 800 mg BID dose group were only threefold higher than the in vitro IC_{50} of 8 nM, and the observed reduction in viral load, 1.5 $\log_{10}$ IU mL^{-1} after 6 days of dosing, was considered to be a modest antiviral effect when compared with contemporary inhibitors. As a consequence, further development of PHX-1766 (**74**) was abandoned.[234]

An interesting variation on the boronic acid motif that has been explored focused on several series of cyclic α-amino oxaborole derivatives, with **75** and **76** as representative examples.[235,236] NS3 inhibitory activity exhibited some sensitivity to the size of the oxaborole ring, with the 6-membered homologue severalfold weaker than the prototypical 5-membered example, although a 7-membered ring largely retained activity; however, substitution of the ring was poorly tolerated.[235] The isoquinoline-based inhibitor **75** inhibited GT-1a NS3 protease with an $IC_{50} = 120$ nM but was poorly active in a replicon system. The binding mode

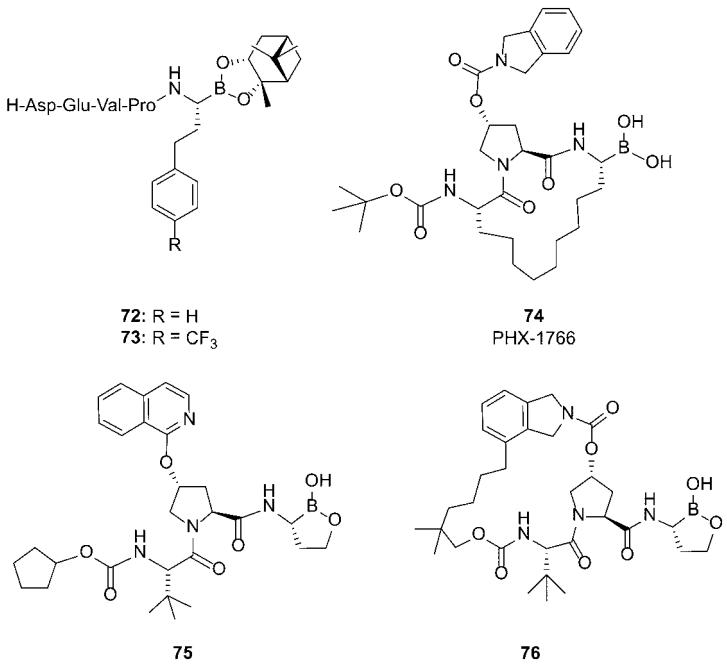

Fig. 21 Boron-based HCV NS3 protease inhibitors **72–76**.

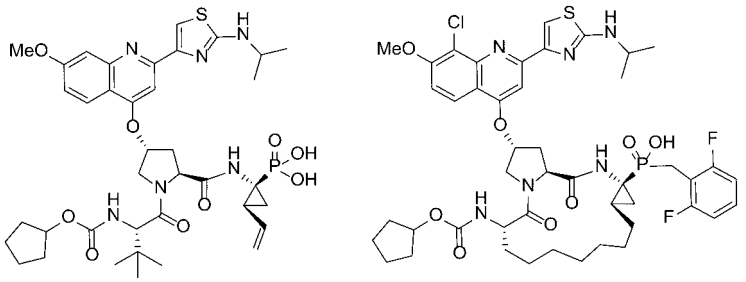

Fig. 22 Phosphorus-based HCV NS3 protease inhibitors **77**–**78**.

was confirmed by an X-ray cocrystal structure that revealed a covalent bond between the boronic acid and the hydroxyl moiety of Ser139 while the intramolecular boron–oxygen bond was cleaved. An X-ray cocrystal of **75** with a Ser139Ala mutant protease revealed a similar overall binding topography, but in this structure, the oxaborole ring remained intact.[235] The formation of the observed adduct with the wild-type enzyme was proposed to proceed by addition of the serine hydroxyl to the cyclic oxaborole followed by hydrolytic cleavage of the ring.[236] This cyclic α-amino oxaborole P1 moiety was subsequently incorporated into more potent macrocycle-based NS3 protease inhibitor chemotypes exemplified by **76**, which hybridizes the boronic acid motif with the macrocyclic ring system found in vaniprevir (**66**). This compound inhibits a GT-1a NS3 protease with an IC_{50} value of 43 nM, displays a binding mode analogous to **75**, and is active in GT-1a and GT-1b replicons with EC_{50} values of 780 and 520 nM, respectively, representing an improvement over the acyclic series.[236] However, these values are several hundredfold weaker than those recorded for vaniprevir (**66**), which was used as the control, $EC_{50} < 1$ nM.

Phosphonic acids are another C-terminus motif that have been probed, designed to take advantage of the observation of product inhibition and interact with the catalytic elements of the protease.[237] This concept was explored initially in the context of the acyclic tripeptide **77**, which inhibited NS3 protease activity with an IC_{50} of 900 nM, threefold more potent than the corresponding carboxylic acid (**Fig. 22**). However, **77** exhibited poor potency in a replicon assay, $EC_{50} = 92$ μM, and further optimization focused initially on structural modifications of the phosphonic acid to a phosphinic acid, designed to allow the introduction of lipophilic moieties that would help mask the overtly acidic polarity.[238,239] Further optimization took advantage of P1–P3 macrocycles and culminated in the identification of GS-9256 (**78**), which inhibited a GT-1b NS3 protease activity with an IC_{50} of 4 nM, exhibited rapid association and slow dissociation kinetics, and was potently active in a replicon, $EC_{50} = 20$ nM.[239,240] The 2,6-difluoro substitution was determined to be important for membrane permeability, while the introduction of the chlorine atom to the P2* isoquinoline heterocycle improved oral bioavailability in the dog to 21%, an eightfold improvement over the unsubstituted congener.[239] GS-9256 (**78**) was advanced into clinical trials where single doses of 150, 300, and 450 mg administered to HCV GT-1-infected subjects were associated with reductions in viremia of 1.8, 2.4, and 2.8 $\log_{10}$ IU mL^{-1}, respectively. However, in a phase 2a clinical trial evaluating GS-9256 (**78**) in combination with an NS5B polymerase inhibitor with and without PEG-IFN-α and ribavirin (**1**), bilirubin elevation was seen in all patients, leading to discontinuation of the compound.[241–243]

An interesting approach to serine protease inhibitor design, discovered originally in the context of trypsin inhibitors, relies upon the incorporation of two metal-binding elements appropriately disposed to combine with the catalytic histidine and serine side chains to create a tetrahedral coordination site that can bind a Zn^{2+} ion.[244–246] This kind of metal-binding motif is presented by *bis*-benzimidazolemethane derivatives, and a library screening campaign identified **79** as a lead inhibitor that inhibited full-length NS3 protease activity with a K_i of 200 nM in the presence of Zn^{2+} ion (**Fig. 23**).[247,248] In the presence of EDTA, which sequesters the

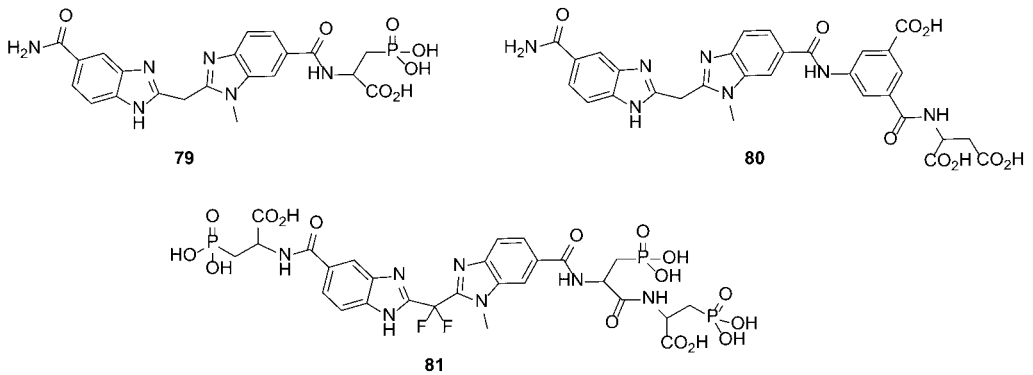

Fig. 23 Zn^{2+}-dependent HCV NS3 protease inhibitors **79**–**81**.

metal, the K_i increased by over 800-fold to 167 μM, providing an index for the effect of stabilization of the complex by the Zn^{2+} ion. Structure–activity studies directed toward finding replacements for the polar phosphonate moiety were only partially successful with **80**, the most potent compound identified from the initial survey, $K_i = 1$ μM in the presence of Zn^{2+}.[247] The highly charged nature of **79** proved to be of importance since partial masking of the charge led to compounds with reduced potency. Polyacidic compounds, exemplified by the tri-phosphonoalanine derivative **81**, which displayed K_i values of 27 nM and 1 μM in the presence and absence of Zn^{2+} ion, respectively, exhibited the optimal potency.[248] These findings appear to reflect the natural substrate selection process, which relies upon multiple acidic residues proximal to the cleavage site, although the SARs developed for this bis-benzimidazolemethane series exhibited some divergence in the presence and absence of Zn^{2+} ion, suggestive of different binding modes dependent on the conditions.

The ring strain associated with a pyrrolidine-5,5-*trans*-lactam presents a chemically reactive carbonyl moiety with some analogy to the well-known β-lactams that interact with serine-containing penicillin-binding proteins.[249] Pyrrolidine-5,5-*trans*-lactams react with serine proteases as mechanism-based inhibitors that engage with the catalytic serine hydroxyl, and the inherent chemical reactivity can readily be modulated by the lactam nitrogen substituent where sulfonylation or acylation enhances electrophilicity.[249] The design of this chemotype was inspired by a family of euphane triterpene-based serine protease inhibitors for which activity is dependent on an unusual trans γ-lactone moiety, with modification to the pyrrolidine-5,5-*trans*-lactam core providing vectors suitable for both derivatization and modulation of carbonyl electrophilicity. This chemical platform has been exploited in the design of inhibitors of a range of mammalian and viral proteases, including HCV NS3.[249–256] In order to identify lead inhibitors of HCV NS3 protease, the amine moiety of **82** (**Fig. 24**) was coupled with a series of carboxylic acid derivatives to provide a library of 200 amides; however, none of these compounds demonstrated significant inhibitory activity, necessitating a more refined analysis of the design priniciples.[250] To improve recognition by the protease, the pyrrolidine amine was acylated with the tetrapeptide Ac-EDVV, which mimics the NS5A-5B cleavage sequence—a modification that gave a time-dependent inhibitor that exhibited a modest IC_{50} of 19 μM after incubation with the enzyme for 18 hours. Systematic SAR studies focused initially on separation of the pyrrolidinone diastereomers, which revealed similar overall inhibitory activity, although the α-isomer was found to react with the protease more rapidly. The next phase of optimization examined truncation of the peptide element to afford **83**, which inhibited NS3 activity with an IC_{50} value of 20 μM after 18 hours of incubation. A cocrystal of **83** with a truncated NS3 protease bound to the NS4A cofactor provided key insights to guide further structural modification, despite being solved at a modest 2.6 Å resolution.[252] It was established that the lactam moiety had reacted covalently with Ser139 and that the ethyl substituent was projecting into the S1 pocket of the enzyme. In addition, the carbamate nitrogen atom was proximal to the carbonyl of Ala157, although beyond H-bonding distance, and the *tert*-butyl moiety was close to the S4 pocket. Further modification focused on optimization of the P1 ethyl group to a spirocyclobutane, while the sulfonyl moiety was replaced with a less electrophilic acyl group. This design exercise afforded **84** as a compound with modest potency in a replicon assay, $EC_{50} = 9$ μM, improved plasma stability, and reasonable clearance in the dog following IV administration.[252,253] Further adjustments were required to more effectively balance the biochemical and replicon properties, affording GW0014 (**85**), which demonstrated an EC_{50} of 1 μM in a replicon, a moderated K_{obs}/I value of 270 $M^{-1}s^{-1}$, and reasonable IV PK in the dog.[255] Although human leukocyte elastase and human cytomegalovirus protease inhibitors derived from this chemotype were developed that exhibited oral bioavailability in the dog, no oral PK data were described for any of the HCV NS3 inhibitors, and more advanced molecules have not been described.[249]

Fragment-based drug design (FBDD) has evolved into an effective strategy for ligand discovery and optimization that relies upon the identification of compact, efficient molecules that bind weakly to specific sites of interest on target proteins.[257,258] This is followed by structural elaboration that, when practiced optimally, takes advantage of insights provided by X-ray crystallographic and isothermal titration calorimetry data in a fashion that allows for the careful optimization of ligands while paying close attention to maintaining a high ligand-binding efficiency index. The application of FBDD to the identification of inhibitors of HCV NS3 activity has provided a compelling example of the power of this approach to identify functionally useful and mechanistically novel molecules that, in this case, act via a unique allosteric mechanism.[259] The screening campaign to identify ligands that bind to NS3

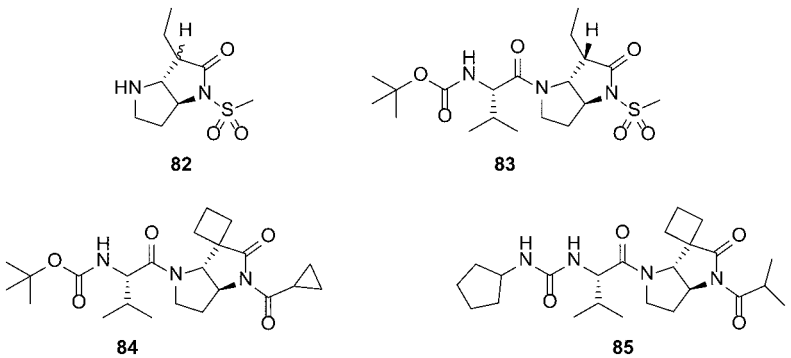

Fig. 24 Pyrrolidine-5,5-*trans*-lactam-based HCV NS3 protease inhibitors **82–85**.

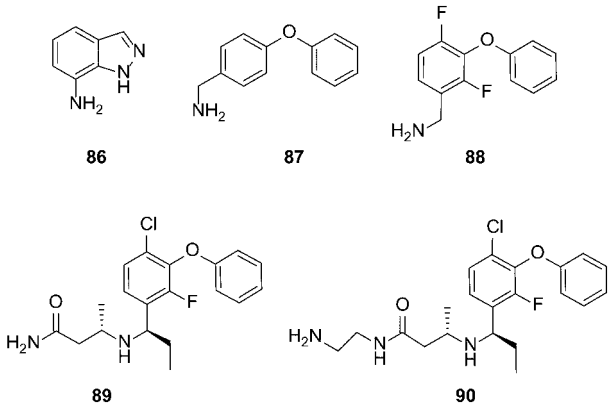

Fig. 25 Optimization of HCV NS3 protease inhibitors **86–90** by fragment-based drug design.

utilized a full-length GT-1b protease/helicase enzyme comprising residues 3–631 with a fragment, residues 21–32, of the NS4A cofactor incorporated at the amino terminus. In this structure, the active site of the protease was occupied by the C-terminus of the helicase domain, a construct that, by definition, would focus on the identification of compounds binding to allosteric sites. Crystals of the NS3 protein construct were soaked for up to 10 days with a total of 176 fragments, presented to the protein as cocktails of 4 compounds that were screened at an individual concentration of 50 mM before the complex was subjected to X-ray crystallographic analysis. Two compounds, **86** and **87**, were found to occupy a hydrophobic site located at the interface of the protease and helicase domains (Fig. 25). These ligands were within van der Waals contact of residues Met485, Val524, Cys525, Glu526, and Val630 from the helicase domain and Val78, Asp79, Arg155, His57, and Asp81 of the protease domain, the latter two residues being functional elements of the catalytic triad. (Note that Arg155, Met485, Val524, and Glu526 are proximal to the region occupied by the typically large P2* element of the more conventional tripeptide-based active site ligands.) Although the indazole **86** showed no significant inhibition of protease activity at a concentration of 5 mM, the benzyl amine **87** weakly inhibited the enzyme, reducing activity by 55% at 500 μM, a result that encouraged further study. Moving the aminomethyl moiety to the *meta* position relative to the ethereal oxygen atom allowed engagement of the acid side chain of Glu628, while the addition the two *ortho* fluorine atoms afforded **88**, which exhibited detectable enzyme inhibition, $IC_{50} = 20$ μM, and represented a favorable increase in ligand efficiency (LE), defined as the log of the IC_{50} value divided by the heavy atom count of the inhibitor, from 0.30 to 0.38 kcal per heavy atom.[259] Further optimization included the introduction of an ethyl substituent at the benzylic position, designed to limit the rotational freedom of the amine-containing side chain, which, in this context, engaged the NS3 protein via H bonds to Glu628, mediated via a bound H_2O molecule, and the carbonyl moiety of Cys525. Elaboration of the phenyl substitution pattern and the amine moiety led to the primary amide **89**, which inhibited NS3 protease activity with an IC_{50} of 100 nM and exhibited promising antiviral activity in a GT-1b replicon, $EC_{50} = 400$ nM. The key interactions between **89** and the full-length NS3 are depicted in Fig. 26, with the primary amide adding to the binding energy and efficiency by engaging the NH of Cys525 and the C=O of Leu517 in H-bonding interactions. The absolute configuration of the CH_3 in the propionamide element was found to be critical, since inversion reduced binding affinity by over 250-fold. Extension of the primary amide of **89** with functionality designed to probe interactions with Asp79, Thr519, and Leu522 gave **90**, which displayed an IC_{50} of < 10 nM, a K_d of 22 nM, and an EC_{50} in a GT-1b replicon of 8 nM.[259]

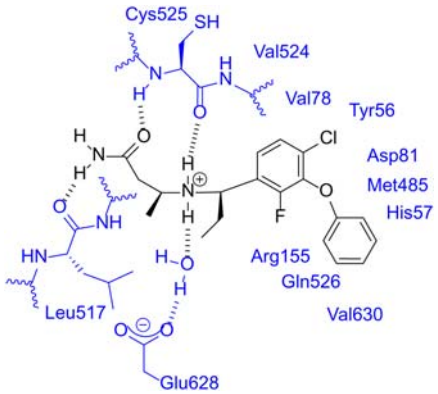

Fig. 26 Key interactions between **89** and the full-length HCV NS3 protein.

Isothermal titration calorimetry data indicated a trend toward reduced conformational flexibility of the protein in the presence of this class of inhibitor, while sedimentation analysis revealed that the NS3 protein populates two conformations in solution, attributed to the closed form observed in the X-ray and an extended, open form in which the helicase C-terminus vacates the protease active site to allow entry of substrate. These data suggested a mode of action in which the compounds interfere with articulation of NS3 between the closed inhibited state and the protease competent open form by stabilizing the auto-inhibited conformation.[259]

Passaging of **89** in increasing drug concentrations for 39 days resulted in the isolation of resistant viruses that upon sequencing revealed Met485Val and Val630Leu mutations in the helicase domain, both of which interact with the phenyl ether ring of the inhibitor. Full-length NS3 protein incorporating these mutations exhibited reduced sensitivity to **89**, with an X-ray cocrystal with the Val630Leu mutant protein clearly demonstrating the effects of the smaller binding pocket that results from the larger side chain presented by the leucine substitution upon inhibitor binding. An analysis of available NS3 sequences indicated 75–96% conservation of identity of the key residues in the binding pocket, suggestive of broad genotype inhibition. This was confirmed experimentally using hybrid proteins incorporating sequences from GT-1a, GT-2a, GT-3a, GT-4, GT-5, and GT-6, which revealed preservation of the activity of **89** toward all but GT-2a, for which inhibition was substantially compromised, and GT-4, where inhibitory activity was modestly reduced. These results are in accord with the sequence differences in the binding pocket, with the Val630Met mutation expressed by GT-2a and the Leu517Phe associated with GT-4 anticipated to compromise inhibitor binding.[259] While **89** offers a unique approach to NS3 protease inhibition and presents an interesting antiviral profile, further studies with this compound have not been described.

The successful development of potent and clinically effective HCV NS3 protease inhibitors offers a compelling example of contemporary drug discovery in which significant advances in the understanding of inhibitor design were based on a combination of developing fundamental structure–activity relationships in conjunction with iterative analyses of X-ray cocrystallographic structures to guide optimization. This class of HCV inhibitor has had a significant impact on HCV drug discovery and development and has taken its place as an important component of therapeutic drug regimens that are curative.

5.18.1.6 HCV NS3 Helicase Inhibitors

The HCV NS3 helicase, which resides in the C-terminus domain of NS3, has proved to be a challenging target for drug discovery, with few well-characterized inhibitors and no clinically relevant compounds described in the literature.[260,261] The HCV helicase is composed of three domains that allows it to traverse RNA or single-stranded DNA from the 3′ to 5′ direction, with energy derived from adenosine triphosphate (ATP) hydrolysis. The role of helicase in HCV replication has not been precisely defined, but it is thought that it may either unwind the duplex RNA formed when the NS5B polymerase duplicates the single-stranded genome or modulate the conformation of viral RNA to facilitate processing by the NS5B RdRp. The helicase is essential for viral replication since mutation of the Asp in the DECH motif, which abrogates ATP hydrolytic function, gave virus incapable of establishing an infection in chimpanzees.[261,262] Inhibitors of the binding of ATP to kinases have proved to be a successful approach to drug discovery, but the ATP-binding site in HCV helicase has been recalcitrant to the identification of potent and selective inhibitors.

A strategy that integrated biophysical and structural approaches was used to characterize and triage low-molecular-weight fragments that bound to a conserved lipophilic pocket in the enzyme.[263] This pocket was identified by a combination of in silico and bioinformatic analyses that initially characterized 8 potential binding sites. After high-throughput screening (HTS) failed to identify an inhibitor lead, a 1000-member fragment library was screened using a saturation transfer difference (STD) NMR assay, which identified an indole-3-acetic acid derivative that bound to the targeted site. An initial round of optimization afforded **91** (**Fig. 27**), an inhibitor of NS3-mediated RNA duplex unwinding with an $IC_{50} = 14\ \mu M$, that was cocrystallized with NS3 helicase in order to characterize the binding mode. The X-ray structure suggested that substitution at the 6-position of the indole ring would be beneficial, a fruitful hypothesis since the 3,5-diaminophenyl derivative **92** was the most potent inhibitor of the series, $IC_{50} = 3\ \mu M$, accompanied by only a modest reduction in ligand efficiency.[263] In the cocrystal structure of **92** bound to helicase, the diaminophenyl moiety projected into solvent, but one of the amines interacted with the backbone carbonyl of Trp501 by donating a H bond, while the 2-methoxy-5-nitrobenzene moiety bound closer to the lipophilic pocket when compared with **91** but still maintained a productive $\pi - \pi$ interaction with Trp501.

Two series of acridones, represented by the optimized compounds **93** and **94**, have been described as HCV helicase inhibitors, with **93** half-maximally inhibiting helicase-mediated unwinding of a double-stranded DNA substrate at a concentration of 8.6 μM, while the IC_{50} value for **94** was 110 μM.[264,265] Both compounds exhibited antiviral activity in a replicon assay, with EC_{50} values of < 1 and 6.7 μM for **93** and **94**, respectively; however, the precise mode of action of these compounds in the cell-based assay remains to be determined.

The symmetrical *bis*-amide **95** inhibits HCV helicase-mediated strand separation of both RNA and DNA duplexes with IC_{50} values ranging from 0.7 to 5 μM but lacked virus selectivity, also inhibiting helicases from dengue virus, Japanese encephalitis virus, and humans.[266,267] SARs indicated the importance of the benzimidazole NH and the phenyl ring at the two position, while mechanistic studies suggested that **95** inhibits helicase-mediated ATP hydrolysis by competing with RNA binding to the protein.[266,267]

HCV NS3 helicase inhibitor design has been challenging, and the molecules that have been described to date that interfere with the function of this enzyme lack inherent intrinsic potency. Thus, the potential of this approach as an antiviral strategy remains unfulfilled.

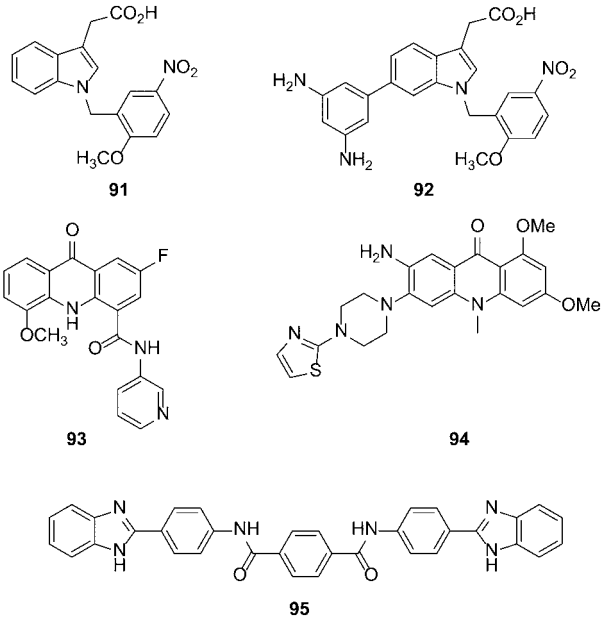

Fig. 27 HCV NS3 helicase inhibitors **91**–**95**.

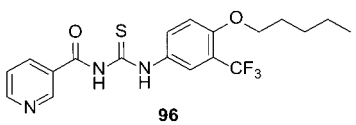
5.18.1.7 HCV NS4A Inhibitors

The HCV NS4A protein is a 54-residue cofactor for NS3 that catalyzes protease activity by increasing the K_{cat} and K_{cat}/K_m and promotes the binding of peptide-based inhibitors.[268,269] Inhibitors of NS4A function have been identified using replicon-based screening, with the acylated thiourea derivative ACH-806 (GS-9132, **96**) an optimized molecule that was advanced into clinical trials.[270–273] ACH-806 (**96**) is a potent inhibitor of HCV replication in GT-1a and GT-1b replicons, EC_{50} values = 10–50 nM that does not directly inhibit NS3 protease and interacts synergistically with protease and polymerase inhibitors.[270,271] The selection of replicons resistant to ACH-806 (**96**) led to the isolation of cell lines with EC_{50} values 10- to 20-fold higher than for the wild-type parent, with Cys16Ser and Ala39Val mutations in NS3 shown to confer 12- to 14-fold resistance when reverse engineered into replicons. These replicons retained replicative capacity comparable with wild-type and remained sensitive to a direct inhibitor of protease and both a nucleoside and nonnucleoside NS5B polymerase inhibitor. The mutations mapped to the amino terminus of NS3 and these residues are in close contact (4.1–7.3 Å) with NS4A. In more detailed mechanism of action studies, ACH-806 (**96**) had no effect on polyprotein processing or NS5B polymerase activity but reduced the amount of NS3 and NS4A in replicons, attributed to an accelerated degradation that resulted in an altered composition of the replication complex.[272,273] ACH-806 (**96**) treatment led to the appearance of a 14 kDa protein determined to be a dimer of NS4A, while an analog containing an azide photoaffinity element selectively labeled NS4A. These observations were interpreted as a scenario in which ACH-806 (**96**) binds to NS4A to promote dimer formation, thereby reducing its association with NS3 and compromising protease function and leading to the degradation of both proteins and the formation of defective replication complexes. The antiviral activity of ACH-806 (**96**) was determined to be dependent on the presence of the thiourea moiety since comparison of a matched thiourea/urea pair revealed the latter to be inactive, although NS4A dimer association did not appear to rely upon the formation of a disulfide bond.[272]

ACH-806 (**96**) was advanced into clinical trials where a dose of 300 mg BID was administered to 10 GT-1-infected subjects for 5 days in a proof-of-concept study.[272] A reduction in viremia was detected by day 2 and all patients experienced a >0.5 $\log_{10}$IU mL^{-1} decline in viral load by day 5, with a mean change of -0.91 $\log_{10}$IU mL^{-1}. However, reversible kidney toxicity was observed in this study, detected by increased creatinine levels in treated subjects and attributed to renal tubular dysfunction, toxicity concerns that prevented further development of the compound, which was terminated in Feb. 2007.[272]



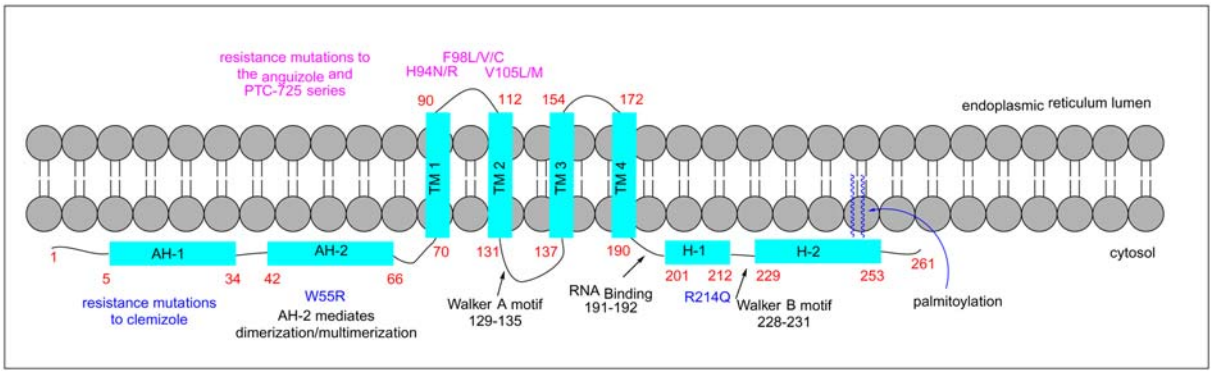


Fig. 28 Topology of the HCV NS4B protein with demarcation of the transmembrane domains in accord with Gouttenoire et al.[274] Key residues are noted, including those associated with resistance to small-molecule inhibitors.

5.18.1.8 HCV NS4B Inhibitors

HCV NS4B is a hydrophobic 261-residue protein whose integration into the endoplasmic reticulum (ER) membrane is predicted by four putative transmembrane domains located in the central region of the protein, with a topology that projects the N- and C-terminal regions toward the cytosol (Fig. 28).[274–277] More recent studies suggest that the N-terminus can translocate to the endoplasmic reticulum (ER) lumen, while the precise location of the transmembrane domain boundaries is not clear, with those shown in Fig. 28 based on those proposed in a review article.[274] NS4B is a critical component of the HCV replication complex that appears to oligomerize and has been shown to induce the formation of the membranous web that acts as a platform for viral replication. It associates with the viral nonstructural proteins and viral RNA in the replication complex as well as with several host cell proteins.[274–278] NS4B appears to express enzymatic activity, binding to and hydrolyzing both ATP and guanosine triphosphate (GTP) as well as catalyzing the formation of ATP and adenosine monophosphate (AMP) from two molecules of adenosine diphosphate (ADP), described as an adenylate kinase activity.[279] However, the enigmatic role(s) of NS4B in virus replication initially limited the utility of specific biochemical assays designed to identify lead inhibitors, directing screening campaigns toward a phenotypic approach. The seminal description of such a strategy identified leads by using a cell line expressing NS4B to screen for compounds capable of reversing its antiapoptotic activity, with hits triaged by discarding those that induced death in cells not expressing NS4B.[280] Several active series were identified that were confirmed to bind to purified NS4B using an assay that evaluated quenching of the fluorescence of tryptophan residues upon compound association, with measured K_d values ranging from 0.31 to 10 μM. The profile of the triazino[5,6-*b*]indole **97** (Fig. 29), one of 12 examples of this chemotype disclosed, was examined in some detail, demonstrating antiviral activity in an HCV GT-1b replicon with an EC_{50} value of 1.13 μM. Resistance mapped to Lys52Arg, Gly120Val, and Ala210Ser in the NS4B protein, although these were not confirmed by reverse engineering the mutations into replicons.[278,280] Several aminothiophenes related to **98**, EC_{50} = 700 nM, were also claimed but it was the pyrazolopyrimidine anguizole (**99**), EC_{50} = 630 nM, that attracted further attention.[280–284]

Initial studies related to anguizole (**99**) focused on a modified imidazo[1,2-*a*]pyridine core, with optimization designed to enhance potency and divest of the problematic furan and thiophene rings that can be associated with metabolic activation.[282] A critical element for enhancing potency was the presence of a H-bond acceptor in the amide moiety, fulfilled by the piperazinamide carbonyl in **100**, a potent inhibitor of GT-1a and GT-1b replication in replicons, EC_{50} values = 0.81 and 5.4 nM, respectively.[282] The *trans*-hydroxyl substituent of **100** (Fig. 30) was introduced to the cyclohexane ring to improve metabolic stability, inspired by biotransformation studies of the parent unsubstituted cyclohexane that indicated this to be a metabolic hot spot. Resistance mapping for earlier compounds in the series had identified His94Asn/Arg, Phe98Leu, and Val105Leu/Met in NS4B as mutations conferring reduced sensitivity to inhibition, and **100** was 5- to 160-fold less active in stable and transiently transfected replicons incorporating the individual changes, although mutations associated with resistance to NS3, NS5A, and NS5B inhibitors remained

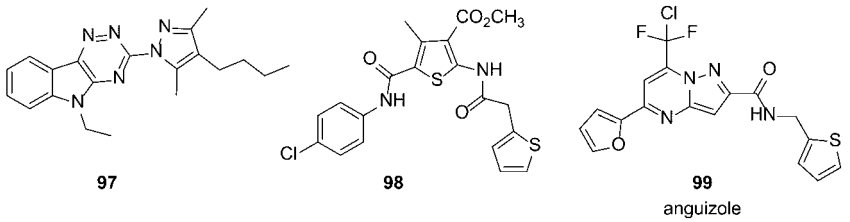

Fig. 29 HCV NS4B inhibitors **97**–**99**.

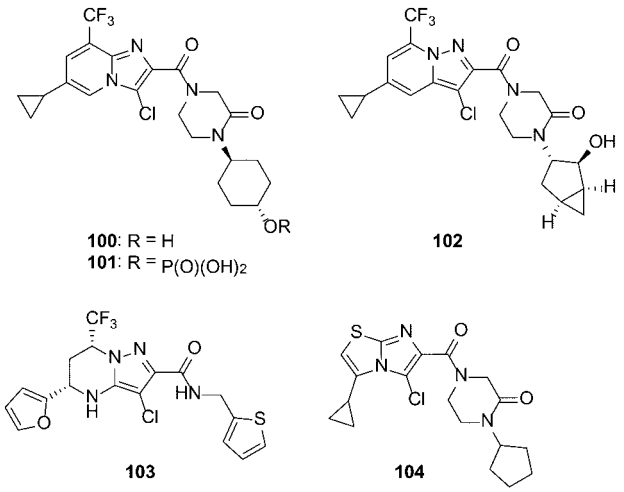

Fig. 30 HCV NS4B inhibitors **100–104**.

fully sensitive. All of these mutations reside in the endoplasmic reticulum lumen-facing loop located between transmembrane (TM) domains I and II (Fig. 28), dependent on the precise boundaries of transmembrane domain I (*vide infra*).[274] Of particular note, residue 94 of NS4B of wild-type GT-2a virus is Thr, while both residues 98 and 105 are Leu, providing a potential explanation for the poor antiviral activity toward this genotype.

Although **100** demonstrated good oral exposure in rats and dogs following a 5 mg kg^{-1} dose, higher doses failed to achieve the exposure margins required by safety studies, despite the evaluation of several formulations.[282,283] This problem was successfully addressed by the phosphate prodrug **101,** which was used to establish efficacy in the PXB mouse model of GT-1a HCV infection. In this model, oral doses of 10 and 30 mg kg^{-1} of **101** administered on a BID schedule for 7 days were associated with a reduction in viremia of 4 $\log_{10}$ IU mL^{-1} by day 4, superior to a clinically effective NS5B inhibitor used as the control.[283,284] However, a 7-day toxicological evaluation of **101** in rats revealed an adverse cardiovascular finding that led to termination of the compound, providing a clear focus for the profile of a replacement compound. An initial survey probed the effect of isosteric variation of the core heterocycle using a binding assay that was developed with a tritiated NS4B inhibitor from an earlier series, with inhibitory activity confirmed in a GT-1b replicon.[282,283] After consideration of the lipophilic ligand efficiency and binding efficiency index of lead inhibitors, a pyrazolo[1,5-*a*]pyridine core was selected as a vehicle that offered the optimum combination of physical and antiviral properties.[283–286] Variation in the amide terminus modulated lipophilicity, antiviral activity, and PK properties from which **102** was identified as a compound meeting the targeted profile.[283] The binding of **102** to NS4B and the antiviral activity in replicons were found to be quite sensitive to the configuration of the [3.1.0]bicyclohexanol moiety. In GT-1a and GT-1b replicons, the EC_{50} values recorded for **102** were 0.6 and 0.3 nM, respectively, and 5 and 38 nM for GT-1b replicons harboring His94Asn and Val105Met mutations, respectively. PK studies with **102** revealed low to moderate clearance in the mouse, rat, dog, and cynomolgus monkey and >90% oral bioavailability, with exposure margins for safety evaluation achieved without resort to a prodrug moiety. In a humanized mouse model of HCV infection in which **102** was administered over 7 days, viremia declined by 3 $\log_{10}$ IU mL^{-1}, but sequencing of virus at the end of the dosing period revealed several resistance mutations in the NS4B protein including Asn56Ile and Asn99His, which had not been observed with in vitro studies. While the overall profile of **102** appears to be encouraging, the fate of the molecule has not been disclosed.

A high-throughput screen using a GT-1b replicon identified the racemate of AP80978 (**103**) as an HCV inhibitor with an EC_{50} of 1.78 μM that was resolved by chiral chromatography to identify the active species shown, EC_{50} = 0.63 μM, with the absolute configuration determined by analysis of a single crystal X-ray structure.[287] This compound bears a significant structural resemblance to anguizole (**99**) and exhibits a similar antiviral profile, with poor activity toward a GT-2a replicon (EC_{50} > 25 μM) and resistance mapping to Phe98Val and Phe98Leu mutations in NS4B that increase EC_{50} values to >20 μM.

The imidazo[1,2-*a*]pyridine-based NS4B inhibitor **100** provided inspiration for the design of a series of imidazo[2,1-*b*]thiazole derivatives giving rise to **104**, which half-maximally inhibited a GT-1b replicon at a concentration of 16 nM.[288] This compound was profiled in transient replicons harboring single mutations in NS4B known to confer resistance to anguizole-like compounds, with His94Arg (EC_{50} = 4 μM), Phe98Cys (EC_{50} = 27.1 μM), and Val105Met (EC_{50} = 27.3 μM) all showing significantly reduced sensitivity. However, mutations in the amino (His3Arg, EC_{50} = 1.1 μM) and carboxy (Gln26Arg, EC_{50} = 350 nM) termini of NS4B also compromised the potency of **104**. Replicons with mutations associated with resistance to NS3, NS5A, and NS5B inhibitors remained sensitive, and combination studies between **104** and representatives of these mechanistically different HCV inhibitors revealed synergistic antiviral interactions.[288]

The precise mode of action of anguizole (**99**) and related compounds remains obscure, although studies have revealed an inhibitory effect of the compound on vesicle aggregation induced by a peptide derived from the NS4B AH2 domain.[281,290] This observation was attributed to interference of anguizole (**99**) with the AH2 of the full-length protein associating with the membrane,

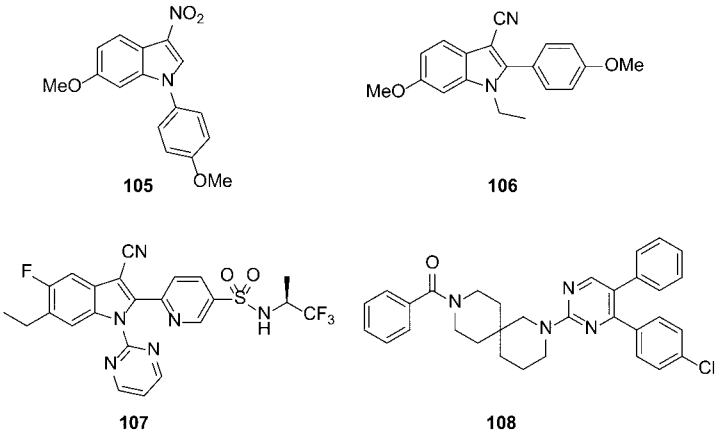

Fig. 31 HCV NS4B inhibitors **105–108**.

but no effect was observed on the multimerization of NS4B. However, more recent studies conducted in cell-based settings have provided evidence that the AH2 domain of NS4B is a mediator of both multimerization and the correct subcellular localization of the protein, in addition to an interaction with NS5A, and that anguizole (**99**) interferes with all of these events.[291]

Another series of NS4B inhibitors originated with the indole **105** (Fig. 31), identified as a weakly potent inhibitor of HCV replication in a GT-1b replicon, $EC_{50} = 50$ μM, that was optimized to **106**, $EC_{50} = 4.1$ μM, after an initial survey of SARs.[292] A refined and more potent compound was used to probe the mode of action by developing resistant virus, which mapped to a Phe98Cys change in NS4B. These studies facilitated the identification of PTC-725 (**107**) as an advanced molecule with moderate oral bioavailability in mice, rats, dogs, and cynomolgus monkeys and liver to plasma ratios of 15 in mice and 23 in rats.[293–296] This compound inhibits GT-1a and GT-1b replicons with EC_{50} values of 7 and 1.7 nM, respectively, but is much less potent toward JFH1 GT-2a infectious virus, $EC_{50} = 2.2$ μM.[296] More detailed resistance mapping studies confirmed Phe98Cys and also identified Phe98Leu and Vla105Leu, along with His94Arg, as sensitivity determinants for **107**, data that were rationalized based on these residues being present in transmembrane domain I and localized proximally on the same face of a helical wheel representation of residues 93–109.[296] Interestingly, immunofluorescence studies indicated that PTC-725 (**107**) did not affect subcellular localization of NS4B in replicons.

Using a radioligand displacement assay that monitored the association of a tritiated NS4B inhibitor related to **100** to purified GT-1b protein immobilized on resin via an FLAG–His-tagged sequence, 28 DNA-encoded combinatorial libraries of small molecules were screened in an effort to identify structurally novel binders that might offer the potential to be optimized into compounds demonstrating inhibitory activity toward GT-2a virus.[297] A chemotype based on a 2,9-diazaspiro[5.5]undecane core was identified that after several cycles of optimization resulted in the characterization of GSK0109 (**108**), which displayed a K_i of 46 nM in the biochemical assay and was active in a GT-1b replicon, $EC_{50} = 20$ nM. Although this molecule exhibited more modest activity in GT-1a ($EC_{50} = 803$ nM) and transient GT-3a, GT-4a, and GT-5a replicons, it showed no significant activity toward two GT-2a transient replicons at concentrations of 10 μM. As a result of this profile, which is analogous to the anguizole-based series of inhibitors, this chemotype was not pursued further.[297]

The piperazinone **109** (Fig. 32) is representative of another class of NS4B inhibitor that was optimized from a screening lead discovered using a GT-1b replicon assay.[298] Compound **109** is a potent antiviral agent, exhibiting EC_{90} values of 22 and 6 nM

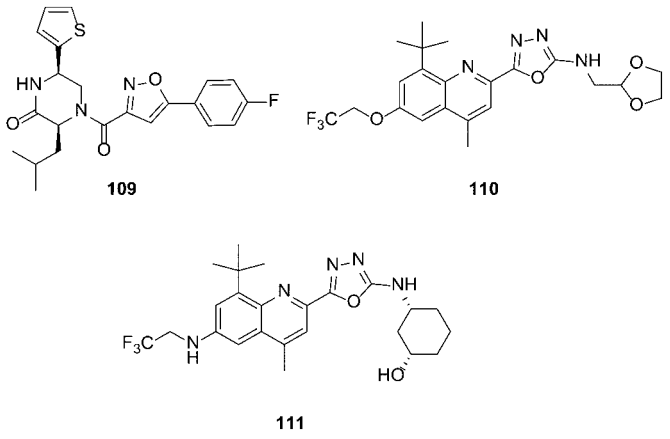

Fig. 32 HCV NS4B inhibitors **109–111**.

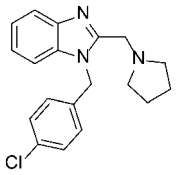
in GT-1a and GT-1b replicons, respectively.[298] While specific resistance mapping studies were not conducted, this compound was inactive in a GT-2a replicon, although a Leu98Phe mutation partially restored sensitivity to an analog in the series. However, the antiviral profile fell short of the sought-after pan-genotypic inhibitor, resulting in diminished interest in further pursuit of the chemotype.

The absence of GT-2a activity with NS4B inhibitors provided a key focal point for the optimization of a series of quinolone-based compounds derived from the early lead **110,** which inhibits GT-1a and GT-1b replicons with EC_{50} values of 0.9 and 1.3 nM, respectively.[299] This compound binds to NS4B with a K_d of 31 nM; retains activity toward a GT-1b His94Asn mutant virus, $EC_{50} = 54$ nM; and exhibits modest potency in a GT-2a replicon, $EC_{50} = 3.6$ μM. Optimization studies sought to reduce the Log *D* to 3.5 while improving GT-2a inhibition on the path to a goal of achieving a lipophilic ligand efficiency (LLE; pIC_{50}—Log *D*) value of 4.5 using a screening tier that evaluated activity in GT-1a, GT-1b, GT-1b His94Asn, and GT-2a replicon assays. The *tert*-butyl substituent in **110** improved potency in GT-1b and GT-2a replicons by fourfold compared with the CF_3 analog, while systematic exploration of the SAR associated with the amide moiety arrived at **111** as a potent GT-1a and GT-1b inhibitor, EC_{50} values = 0.08 and 0.10 nM, respectively. This compound was inhibitory toward the His94Asn/Ser mutants and GT-2b and GT-4a viruses while inhibiting GT-2a JFH, GT-3a, and GT-6a replicons with EC_{50} values of 3.0–3.7 nM.[299] While the antiviral properties and preliminary PK profile of **111** in rats appear to be promising, further studies with **111** have not been forthcoming.

An analysis of HCV NS4B binding to RNA using a microfluidic affinity assay demonstrated an associative interaction, $K_d = 3.4$ nM, corroborated using an RNA filter binding assay with recombinant NS4B protein.[300] The interacting elements were mapped to the 3′-terminus of negative strand viral RNA and to an arginine-rich motif located in the last 71 residues of the C-terminus of NS4B that projects from the cytosolic side of the membrane. The microfluidic affinity assay offered a screening capability with which to identify potential inhibitors of the NS4B–RNA interaction, with 104 active hits identified from a library of 1280 compounds and 110 compounds that showed some discordance between replicate experiments.[300–302] These 214 compounds were tested at a lower concentration in a secondary assay, a triage that left 18 confirmed hits of which 5 demonstrated specificity for NS4B and were evaluated in replicons. This screening cascade distilled the hits to the histamine H_1 receptor antagonist clemizole (**112**) as an inhibitor of GT-1b replication, $EC_{50} = 8$ μM, with activity extending to GT-2a infectious virus. Resistance mapping using the GT-1b replicon identified Trp55Arg and Arg214Gln mutations in NS4B that reduced potency by 2.25- and fivefold, respectively. The Trp55Arg protein demonstrated a fourfold increased affinity for RNA ($K_d = 0.75$ nM) comparable to the Arg214Gln mutant where the K_d was determined to be 0.6 nM, providing an understanding of the mode of resistance.[300–302] Clemizole (**112**) exhibited a synergistic interaction with the NS3 protease inhibitors telaprevir (**2**) and boceprevir (**3**) and was additive in conjunction with ribavirin (**1**), PEG-IFN-α, and both a nucleoside and a nonnucleoside NS5B polymerase inhibitor.[302] A clinical trial in subjects chronically infected with HCV and naive to therapy was conducted between July 2009 and Aug. 2010 but the results have not been disclosed.[303]



112

Screening leads for which resistance maps to the NS4B protein have been optimized into compounds demonstrating impressively potent antiviral activity in replicons. However, despite the expenditure of considerable effort that has led to several compounds being evaluated in advanced preclinical studies, there are no examples of NS4B inhibitors that have demonstrated clinical efficacy and the full potential of this class of antiviral agent remains to be determined.

5.18.1.9 HCV NS5A Inhibitors

HCV NS5A inhibitors are characterized by remarkable potency in cell-based assays where refined compounds typically express subnanomolar EC_{50} values toward a broad range of genotypes, and this class has assumed prominence as an important component of clinically effective drug combination regimens.[304–312] Despite this, the precise mode of action of NS5A inhibitors remains enigmatic since the protein does not express enzymatic activity. However, NS5A is critically involved in both virus replication and assembly and also plays a key role in modulating the host cell environment to favor the virus, leading to its designation as a master regulator protein.[313–317] The NS5A protein is structurally organized into three domains, with domain I incorporating an amphipathic helix (residues 5–25) that mediates association with the membrane and a Zn^{2+}-binding motif (**Fig. 33**). Protein constructs derived from domain I crystallize as dimers, with one interfacial arrangement forming a U-shaped domain in which the interior is rich in basic amino acids, leading to the proposal that this motif binds RNA, although all three domains appear to be involved in viral RNA recognition.[318–323] Concordant with the crystal structural data, NS5A dimerization has been shown to be important for virus replication in vitro.[324] Domain I contains a segment that binds to NS5B, while the 4 serine residues that are subject to phosphorylation, including the conserved Ser222, reside in the segment intervening between domains I and II. Phosphorylation of NS5A has been proposed as a mechanism to regulate the activities of the protein at different stages of the virus life cycle,

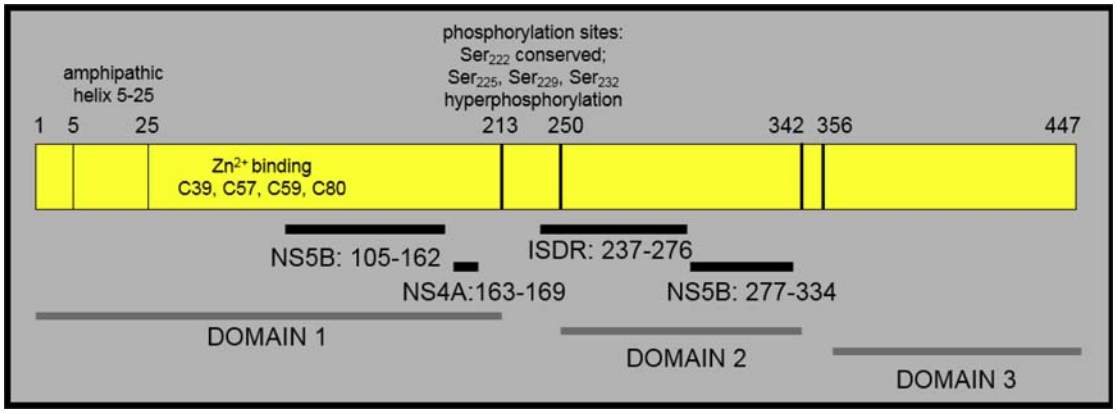


Fig. 33 Structural organization of the HCV NS5A protein, with protein interaction sites and residues that are phosphorylated noted. ISDR = interferon sensitivity-determining region.

with the basally phosphorylated protein (referred to as P56) involved in replication. Hyperphosphorylation (to generate P58) may disrupt this function and the lipid kinase phosphatidylinositol 4-kinase IIIα has been implicated as playing an important role in this respect.[325–328] Domain II contains a second sequence that interacts with NS5B and a region that is believed to be involved in countering the effects of interferon on the host cell, although this function is somewhat controversial.[329–334] Domain III contributes to HCV replication but is also associated with an essential role in virion assembly.[77,335,336]

The initial disclosure of HCV inhibitors for which resistance mapped to the NS5A protein claimed a series of C-5-arylated iminothiazolidinones.[44,45,337] These compounds were discovered using a dual-replicon assay screen format that evaluated for inhibition of HCV and bovine viral diarrhea virus (BVDV) in a single well with host cell cytotoxicity also determined, allowing for a rapid and rigorous triaging of hit compounds. The prototype lead, BMS-858 (**113**), inhibited a wild-type GT-1b replicon with an EC_{50} value of 0.5 μM ($CC_{50} > 5$ μM) while the homologue BMS-824 (**114**) was 100-fold more potent ($EC_{50} = 5$ nM) (Fig. 34).[45,337] Resistance mapping with BMS-858 (**113**) identified a Tyr93His change in the NS5A protein that conferred at least 10-fold reduced sensitivity that was amplified with BMS-824 (**114**) for which the EC_{50} value was > 5 μM, representing greater than 1000-fold reduction in inhibitory activity. Studies with BMS-824 (**114**) identified additional mutations in NS5A associated with resistance, mapped to Leu31Val (60x) and Gln54Leu (9x) changes, with the combination 354-fold less sensitive to the inhibitory effect of the compound.[45] Additional studies revealed that BMS-824 (**114**) exhibited poor inhibition of a GT-1a replicon ($EC_{50} > 5$ μM), while evaluation of GT-1a/1b hybrid replicons confirmed that sensitivity mapped to the N-terminus of NS5A. These NS5A inhibitors altered the phosphorylation state of NS5A, preventing the formation of the P58 hyperphosphorylated form without affecting its stability—a profile that was, interestingly, mimicked by a NS3 protease inhibitor but not an inhibitor of the NS5B RdRp.

The exploratory optimization of this series of NS5A inhibitors took an interesting turn when it was discovered that BMS-824 (**114**) was chemically unstable, completely degrading under the assay conditions but, remarkably, without a significant effect on the potency of replicon inhibition.[338–340] Detailed studies using a biogram-based analysis of extracted fractions of compound that had been incubated in cell culture assay medium for 48 hours identified several degradation products, with two high-molecular-weight species equating with potent replicon inhibition.[339] These compounds were determined to be dimers (**115**) using spectroscopic methodologies that established the connectivity to be at C-5 of the iminothiazolidinone heterocycle.[339] A

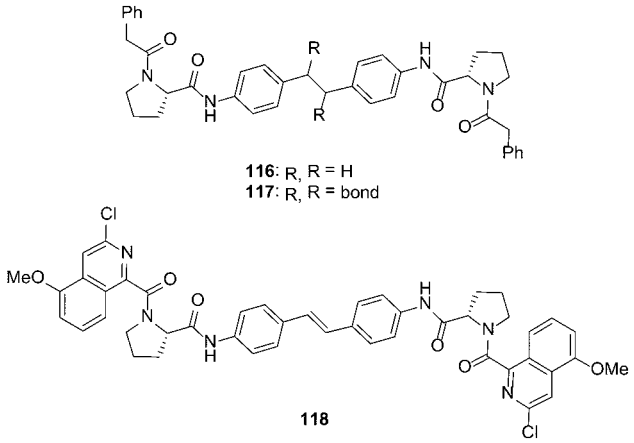

Fig. 35 Dimeric HCV NS5A inhibitors **116–118**.

radical-mediated mechanism of dimerization was proposed that was attributed to an initial abstraction of the C-5 H-atom by molecular oxygen, which is a diradical in the ground state, with the resultant radical stabilized by the captodative properties of the C-5 methine substituents.[340,341] Based on the somewhat nebulous SARs associated with the iminothiazolidinone *N*-substituents in contrast to the precise requirement exhibited by the amino acid moiety, which was restricted to alanine and proline and was highly sensitive to absolute configuration, it was hypothesized that the inhibitory pharmacophore was defined by the bibenzyl **116**.[340] This compound demonstrated an EC_{50} value of 30 nM in the GT-1b replicon, while the more planar, unsaturated stilbene precursor **117** (Fig. 35) was almost 350-fold more potent, $EC_{50} = 86$ pM. Confirmation that **116** and **117** preserved the NS5A-inhibiting activity of the original lead molecules was obtained by testing **117** in the GT-1b Tyr93His mutant replicon where the EC_{50} value was determined to be more than 10,000-fold higher at 4 μM.[338,340] The symmetry inherent to this pharmacophore elegantly complemented that subsequently observed in the crystal structures of the domain I proteins and the observation that HCV replication depends upon NS5A dimerization.[318–320,324]

While **117** was a potent inhibitor of GT-1b replication, the compound was inactive toward a GT-1a replicon, necessitating further structural manipulation in order to broaden the antiviral spectrum. These studies sought to concomitantly address the liabilities associated with the stilbene moiety, which offered the complication of facile *cis–trans* isomerization, and the embedded anilines, where concern revolved around the possible safety issues associated with the potential for unmasking to occur in vivo. Optimization was broad-based and studied the effects on structural manipulation of both the stilbene core, viewed as a scaffold on which to deploy the peripheral structural elements, and the phenylacetic acid moiety, which was determined to be a critical and sensitive modulator of potency.[338,342–346] The key breakthrough in expanding the genotype inhibition to encompass GT-1a was made with the synthesis and profiling of the isoquinolinamide **118**, a balanced inhibitor with EC_{50} values of 19 and 7 nM toward GT-1a and GT-1b replicons, respectively.[344] This discovery inspired an examination of α-substituted phenylacetic acid derivatives, with the substituents designed to mimic the H-bond-accepting capability of the isoquinoline heteroatom while also relaxing the conformational constraint imposed by the fused heterocyclic ring system. A series of mandelic acids productively probed the installation of an α-hydroxyl substituent but it was dimethylamine and methylcarbamate moieties that emerged as the preferred elements. These substituents conferred broad genotype inhibition when examined in the context of the alkynes **119** (Fig. 36), which exhibited EC_{50} values of ~8 and <4.6 nM toward GT-1a and GT-1b replicons, respectively, and **120**, which displayed EC_{50} values of 26 and 0.013 nM toward GT-1a and GT-1b, replicons, respectively.[343–345] The potentially problematic anilide moiety was addressed by replacing it with a benzimidazole heterocycle, as in **121**, which preserved the H-bond acceptor and donor properties but modified the topological presentation of the terminal phenylglycine moieties.[346] This change compromised potency, particularly toward GT-1a, $EC_{50} = 108$ nM, although potent GT-1b inhibition was maintained, $EC_{50} = 0.055$ nM. The final steps that culminated in the discovery of daclatasvir (**7**) involved replacing the diphenyl alkyne core of **121** with a biphenyl moiety, which recapitulates the linear topology, accompanied by deannelation of the benzimidazole ring to compensate for the reduced distance between the termini, affording **122**. These modifications produced a potent and balanced inhibitor of GT-1a and GT-1b replicons, $EC_{50} = 28$ and 6.7 pM, respectively, but **122** demonstrated poor oral bioavailability in rats, prompting truncation of the phenyl ring to an isopropyl moiety, explored in the context of the D-valine derivative **123**. However, this structural change had a dramatically deleterious effect on inhibition of both HCV genotype replicons, with EC_{50} values of 1.24 μM and 1.22 nM toward GT-1a and GT-1b, respectively.[347] This was addressed with a final structural adjustment, inverting the stereo-configuration of the valine moiety of **123** to that of the natural amino acid, which afforded daclatasvir (**7**) as a potent HCV inhibitor that demonstrated antiviral activity toward a broad range of genotypes in replicons and also inhibited replicating GT-2a virus.[46,338,347]

The initial clinical study with daclatasvir (**7**) evaluated single oral doses of 1, 10, and 100 mg in GT-1-infected patients and revealed a significant reduction in viremia at all dose levels.[46,63] Notably, the decline in viral load was more rapid than had been observed with either HCV NS3 protease or NS5B RdRp inhibitors, subsequently attributed to an inhibitory effect of daclatasvir

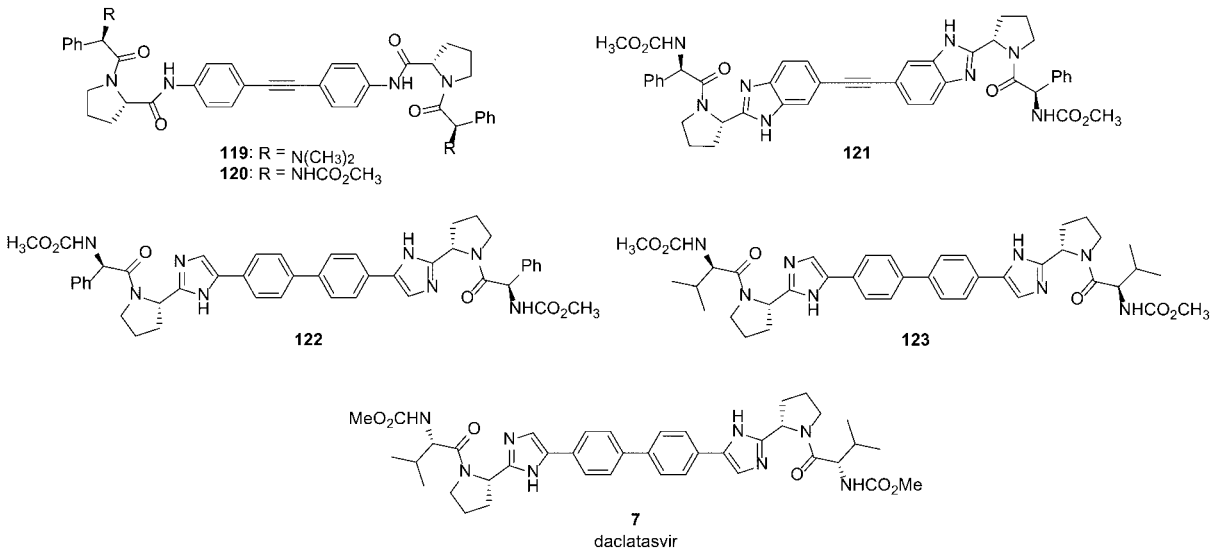

Fig. 36 Symmetrically dimeric HCV NS5A inhibitors **119–123**, precursors to daclatasvir (**7**).

(7) on virion assembly and/or production in addition to interfering with virus replication.[348] This effect was not detectable in the initial replicon screen but was subsequently observed in studies of replicating virus and indicates that although daclatasvir (7) appears to act by binding to domain I of NS5A, the interaction compromises the activity of the protein in virion assembly.[349,350] A careful analysis of the clinical data led to a revision of the half-life of the virus in plasma to approximately 45 minutes, significantly lower than the 2.7 hours originally estimated.[52,348]

Evidence of the binding of NS5A inhibitors to the protein was probed with the biotinylated compounds **124** and **125** and the photoaffinity probes **126** and **127**.[46,350–352] The biotin derivative **124**, based on natural proline, inhibited HCV GT-1b replication in a replicon with an EC_{50} value ranging from 33 to 150 nM, an activity that was sensitive to the Tyr93His mutation, $EC_{50} \geq 10$ μM.[46,338,350,352] The (*R*,*R*)-isomer **125** is inactive, $EC_{50} > 10$ μM, SARs that mirror that of symmetrical NS5A inhibitors.[46,352] An attempted pull-down experiment using **124** in which GT-1b replicons were lysed, incubated with the probe, and then passed over streptavidin beads failed to enrich a bound protein. However, when **124** was incubated in GT-1b replicons for 18 hours before passing the cell lysate over streptavidin beads, HCV NS5A was selectively pulled down, while the inactive diastereomer **125** was ineffective. This indicates that the association of **124** with NS5A occurs during formation of the replication complex. Most intriguingly, when **124** was incubated in replicons harboring the Tyr93His resistance mutation, NS5A protein was still enriched in pull-down experiments. This observation indicated that resistance mutations do not lead to exclusion of the inhibitor from the binding site but rather that the NS5A protein appears to be capable of restoring function in the presence of a bound molecule.[352] Direct binding of daclatasvir (7) to the NS5A protein has been demonstrated using an in vitro microscale thermophoresis assay, which indicated that drug binding prevented the association of the protein with RNA, while ledipasvir (8) has also been shown to bind to NS5A protein.[349,353] Binding models for the interaction of NS5A inhibitors with the dimeric form of the protein have been proposed based on an analysis of structure–target interactions, the location of resistance mutations, and structure–activity relationships associated with the core and proline elements, which are thought to be proximal to Leu31 and Gln54, while the valine cap moiety is believed to associate with Tyr93.[352–355] Although the symmetry of daclatasvir (7) complements that of the crystal structure of domain I of NS5A, symmetry is not required and unsymmetrical binding modes have also been contemplated.[354] Interestingly, and in contrast to the results with the biotin derivative **124** (Fig. 37), in the

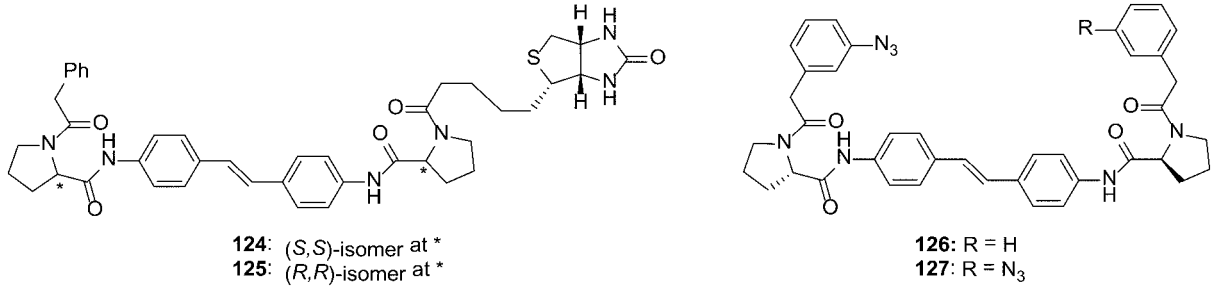

Fig. 37 HCV NS5A biotin-based and photoaffinity probes **124–127**.

microscale thermophoresis assay, daclatasvir (**7**) binds less effectively to NS5A protein incorporating Leu31Val and Tyr93His mutations, while ledipasvir (**8**) has been shown to bind less effectively to protein incorporating a Tyr93His mutation.[349,353] Studies with the photoaffinity probes **126** and **127**, EC_{50} values of 7 and 55 nM toward GT-1b replicons, respectively, provided additional insight into drug–target interactions: Photolysis of the monoazide **126** in replicons selectively labeled NS5A, whereas a similar experiment conducted with the symmetrical homologue **127** resulted in the labeling of bands corresponding to both dimers and to higher-order multimers, indicative of a more complex drug–target interaction.[352] Using NS5A fluorescently labeled at either the N- or C-terminus, active inhibitors have been shown to disrupt the intramolecular and intermolecular proximity of both domain I and domain III by altering the conformation of the protein.[356] This results in the formation of large aggregates of NS5A with altered subcellular distribution.[350,351] The collective data have been interpreted to suggest of a mode of action in which the binding of an inhibitor to an oligomeric form of NS5A is able to disrupt its function, providing an explanation for the remarkable potency and stoichiometry of inhibition; it has been estimated that the NS5A protein exceeds inhibitor concentration by several thousand-fold.[309,350–353,357]

The NS5A inhibitor pharmacophore defined by daclatasvir (**7**) has been explored extensively in the literature, with structural modifications focused primarily on the 4,4′-di(1*H*-imidazol-5-yl)-1,1′-biphenyl core scaffolding element that appears to project the dipeptide-based cap moieties in a spatial arrangement that complements the dimeric domain I of NS5A.[309,354,355] These studies have revealed some latitude in functionalization of the proline ring, exemplified by ledipasvir (**8**) and GSK2336805 (**128**) (Fig. 38).[358,359] However, the methoxycarbonyl valine moiety is largely invariant in those compounds that retain potent and

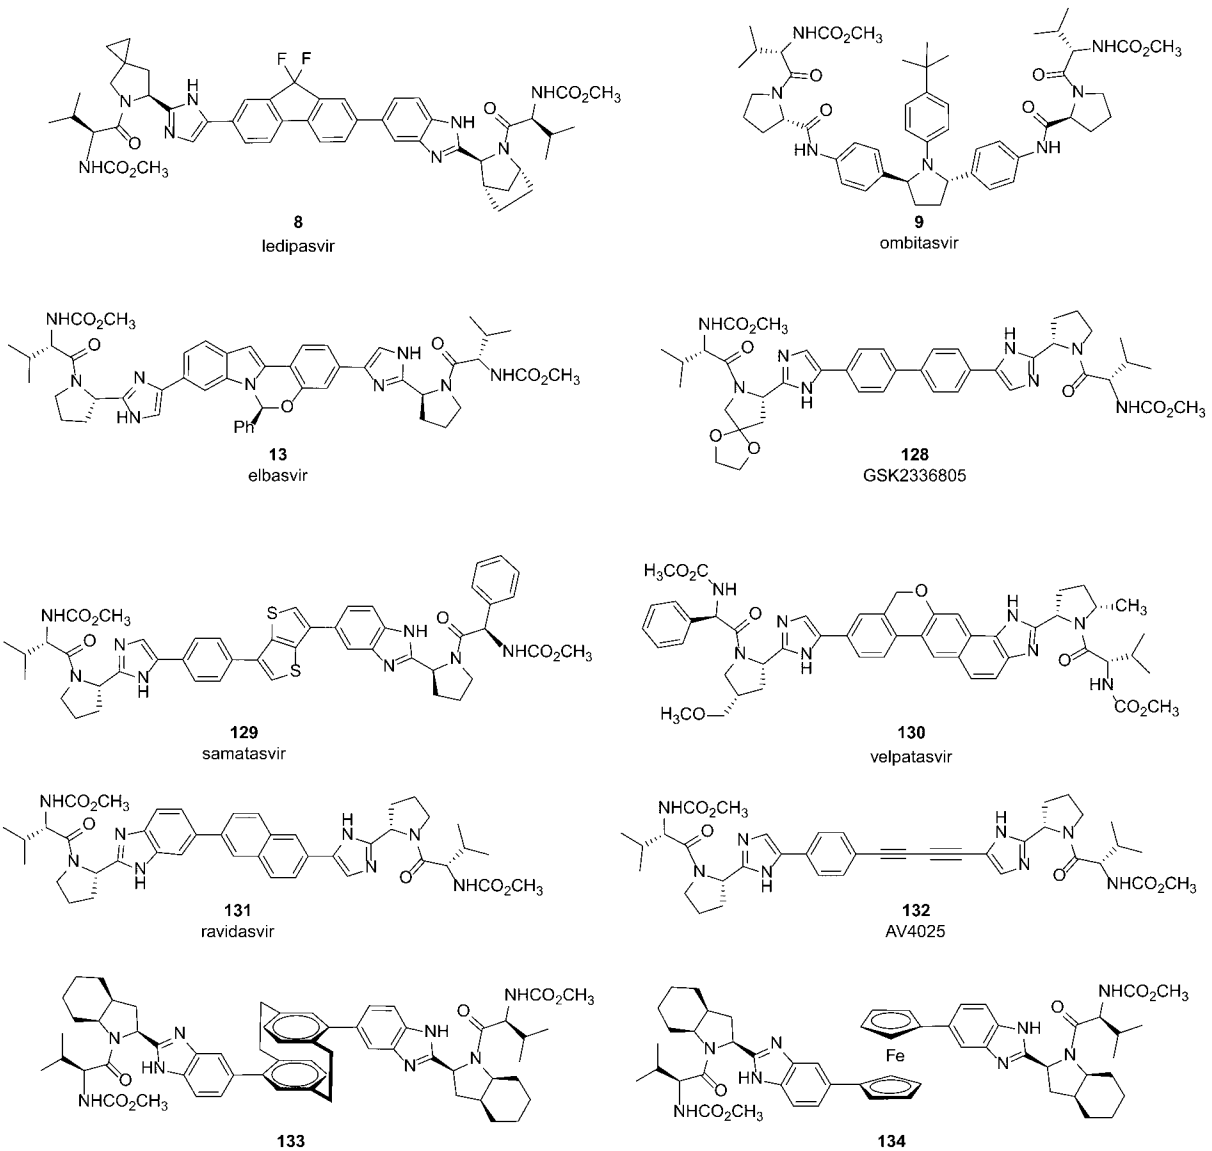

Fig. 38 HCV NS5A inhibitors ledipasvir (**8**), ombitasvir (**9**), elbasvir (**13**), and **128–134**.

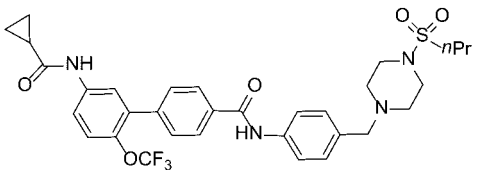
balanced inhibitory activity toward a broad range of genotypes although the phenylglycine moiety that was discovered with **120**–**122**, antecedents of daclatasvir (**7**), is exploited effectively in samatasvir (**129**) and velpatasvir (**130**).[360,361] Both of these molecules combine asymmetrical caps with unsymmetrical core elements that incorporate a benzimidazole heterocycle as one of the H-bond donor/acceptor elements that in the case of **129**, presumably compensates for the increased length of the molecule imposed by the changes to the scaffold. Ravidasvir (**131**) and AV4025 (**132**) are also assembled on asymmetrical cores that effectively project the key methoxycarbonyl valine–proline moieties; a benzimidazole and imidazole-naphthyl pharmacophore is exploited in **131**, while the buta-1,3-diyne moiety of **132** recapitulates the linear geometry of a phenyl ring, although with a slightly extended reach.[309,362] Other interesting cores that have been explored include the *N*-phenylated pyrrolidine in ombitasvir (**9**), the substituted indole moiety in elbasvir (**13**), the cyclophane in odalasvir (**133**), and the ferrocene in **134**, although very little has been disclosed about the specific antiviral profiles of the latter two compounds.[363–365]

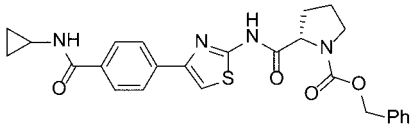
Several additional chemotypes for which resistance was mapped to NS5A have been discovered by phenotypic screening, but the antiviral activity of these compounds has generally been restricted to the GT-1b virus strain utilized in the original screen.[309] Prominent examples include AZD-7295 (A-689, **135**), which was evaluated clinically, and GL-100953 (**136**) and its homologue **136**, which exhibited improved GT-1b inhibitory activity but not GT-1a inhibition (**Fig. 39**).[304,308,309,359,366] AZD-7295 (**135**) inhibits GT-1b replication with an EC_{50} value of 7 nM but activity toward a chimeric GT-1a replicon was significantly weaker, $EC_{50} = 1.24$ μM, while the EC_{50} value for **137** in a GT-1b replicon is 400 pM; however, this compound is essentially inactive toward GT-1a virus, $EC_{50} > 50$ μM.

The screening hit **138** (**Fig. 40**), which inhibited a GT-1b replicon with an EC_{50} value of 18 nM but was 100-fold less active in a GT-1a replicon, $EC_{50} = 1.8$ μM, was elaborated into a series of quinazoline-based HCV inhibitors.[367,368] A prototype molecule, **139**, demonstrated improved potency toward a GT-1a replicon, $EC_{50} = 170$ nM, while maintaining GT-1b inhibition, $EC_{50} = 16$ nM. In this molecule, the *iso*-propyl moiety exerts a significant influence on potency and is optimal, with the cyclopropyl and *iso*-butyl homologues >100-fold weaker toward the GT-1b replicon and 50-fold less active toward GT-1a virus.[367] Further elaboration afforded **140**, which exhibited more a balanced inhibitory profile, $EC_{50} = 45$ and 7 nM toward GT-1a and GT-1b, respectively, with this enantiomer 4- to 13-fold more potent than the (*R*)-isomer.[368] The homologue **141**, although a little less potent than **140**, possessed adequate solubility to be administered IV to a chimpanzee infected with HCV GT-1b virus.[368] Five 2.5 mg kg^{-1} doses of **141** were infused at 8 hour intervals, with viremia falling by 1.65 $\log_{10}$ IU mL^{-1} over 32 hours. Sequencing of the virus at the end of the experiment identified resistance mutations emerging in the NS5A gene, notably Leu28Met and Tyr93Cys + Lys26Arg. Reverse engineering of the Tyr93Cys mutation into a GT-1b replicon resulted in a 900-fold increase in the EC_{50} value for **141**, implicating NS5A as the drug target. However, this chemotype bears some structural resemblance to AZD-2836 (**142**), for which resistance initially mapped to NS5A, but subsequent experiments and reverse genetic engineering studies were far less definitive.[366] The structurally related compound AL-9 (**143**) has been shown to interfere with HCV replication by inhibiting the host cell enzyme phosphatidylinositol 4-kinase IIIα (PI4KIIIα), $IC_{50} = 570$ nM, with fivefold selectivity over the β-isoform.[369] Kinase inhibition correlated with replicon potency, and it was shown that cells exposed to **143** had reduced plasma membrane levels of phosphatidylinositol 4-phosphate. AZD-2836 (A-831, **142**) was advanced into clinical trials but was subsequently abandoned due to low plasma levels following oral dosing that were attributed to the poor pharmaceutical properties of the compound.[366]

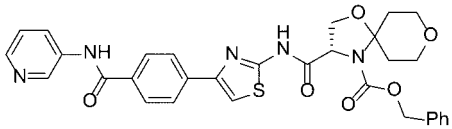
Adding to the biochemical complexity and intrigue associated with the inhibition of HCV NS5A, further experiments with the biotinylated probe **124** have led to the identification of molecules that modulate the protein in an allosteric fashion that resensitizes resistant viruses to restore full inhibition by daclatasvir (**7**).[370] That **124** bound to both wild-type and Tyr93His NS5A in replicons with similar affinity and was competed out in both circumstances by an NS5A inhibitor with similar EC_{50} values led to the



135



136



137

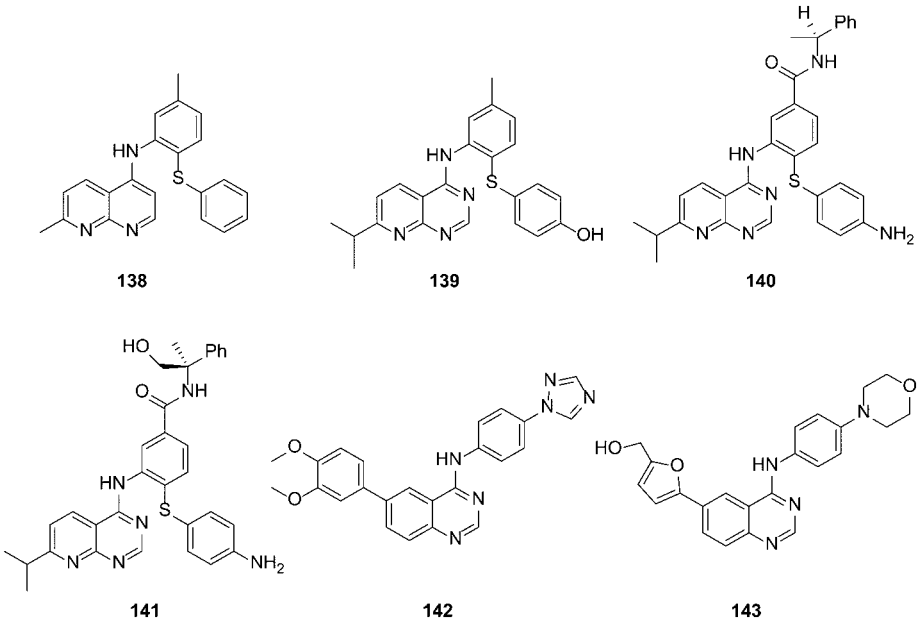

Fig. 40 HCV NS5A inhibitors **138–142** and the phosphatidylinositol 4-kinase IIIα inhibitor **143**.

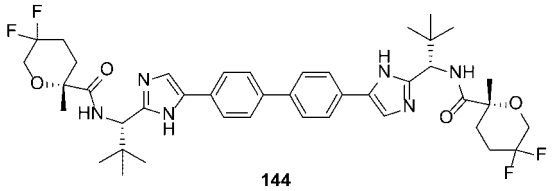
hypothesis that the binding of a second molecule to NS5A at an adjacent site may be capable of restoring inhibition by bound **7**. Using a Tyr93Asn GT-1a replicon to screen weakly active and inactive compounds structurally related to **7** that would restore inhibition, the tert-butyl glycine derivative **144** was identified as a synergistic inhibitor. The EC_{50} value for **7** toward the Tyr93Asn GT-1a replicon was 339 nM, over 10,000-fold higher than the half-maximal inhibition of wild-type replicon, $EC_{50} = 0.033$ nM, while the synergist **144** was poorly active in both replicons, EC_{50} values of 214 nM (wild-type) and 215 nM (Tyr93Asn). However, in the presence of 40 nM of **144**, a concentration of 0.13 nM of **7** is required to half-maximally inhibit replication of the Tyr93Asn GT-1a replicon, representing a 2600-fold increase in sensitivity. As might be anticipated, the interaction between **7** and **144** is reciprocal in nature with the EC_{50} value for **144** measured as 7 nM in the presence of 1.37 nM of **7**. In HCV elimination studies conducted in GT-1a replicons, synergist **144** was an effective replacement for either an NS3 protease or an NS5B polymerase inhibitor in triple-drug combinations. Moreover, the combination of **7** and **144** resulted in a higher genetic barrier to the emergence of resistance in GT-1a replicons and mapping experiments revealed that linked substitutions, including Met28Thr-Gln30Arg and Met28Thr-Ser38Phe, were required for a resistant phenotype. Studies in vivo in chimeric mice in which the liver is largely replaced with normal human hepatocytes that support an HCV infection, combination therapy with close analogs of **7** and **144** delayed the emergence of resistant virus compared with monotherapy with the individual drugs.[370] The model proposed to explain both the high potency of NS5A inhibitors, and the phenomenon of cooperativity between **7** and **144** suggested that in the replication complex, the protein functions in an oligomeric form and that the individual monomers communicate with each other in a fashion in which changes in one dimer are transmitted to adjacent dimers. Thus, the conformational changes associated with accommodation of bond inhibitors by resistant NS5A protein are communicated throughout the oligomeric chain in a manner that allows a second inhibitor molecule to bind with restoration of inhibition.

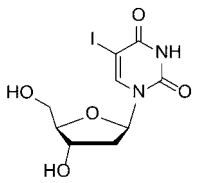


The discovery and development of HCV NS5A inhibitors represents a compelling example of the value of phenotypic screening to identify and optimize important and mechanistically interesting antiviral agents. In the absence of screening leads, the poor understanding of NS5A function and an inability to develop a useful biochemical assay basically rendered this protein in the class of undruggable targets, with no apparent rational or practical approach to the design inhibitors de novo. While the mechanistic underpinnings of daclatasvir (**7**) and related compounds remain as enigmatic as the function of the NS5A protein, this class of HCV antiviral agent has developed into an important contributor to the clinical landscape since all of the approved HCV combination therapies include a drug from this class.

5.18.1.10 HCV NS5B Inhibitors

5.18.1.10.1 Background

Viral polymerases represent a classic target for antiviral drug discovery, with nucleoside analog synthesis a universal design strategy that originates with the demonstration that idoxuridine (**145**) selectively inhibits herpesvirus replication.[371–376] Nucleoside analogs rely upon metabolic activation to an unnatural nucleoside triphosphate or triphosphate analog that is incorporated into the growing oligomeric chain to block elongation in either an obligate (no 3′-OH) or nonobligate fashion.[371–375] However, host toxicity with nucleoside analogs is an ever-present and frequently unpredictable concern, and nucleoside-based inhibitors of the HCV NS5B RNA-dependent RNA polymerase (RdRp) have not been an exception.[377–380] However, the HCV RdRp offers multiple opportunities for intervention since two major allosteric inhibitor binding regions have been characterized.[377,381–386] The thumb domain, where closing of the fingers is required to initiate polymerase activity, contains two sites where inhibitor ligands have been characterized. The palm site region, sometimes referred to as the primer grip site, is adjacent to the active site of the enzyme and presents an extended pocket to which several structurally diverse inhibitor chemotypes have been shown to bind. Inhibitors that bind at both thumb and palm domains block initiation of viral RNA polymerization, while nucleoside analogs primarily act by interfering with elongation of the growing RNA chain after incorporation.



145
idoxuridine

The HCV NS5B polymerase is composed of ~590 amino acids and incorporates the GDD motif that is a hallmark of viral RNA polymerases at residues Gly317, Asp318, and Asp319.[377] Initial studies focused on characterization of the biochemical and kinetic properties of the polymerase as a prelude to developing assays suitable for screening for lead inhibitors, while X-ray crystallographic studies of apo GT-1b proteins from which the C-terminal membrane-binding domain had been deleted revealed key molecular details of the enzyme.[29,35–37,386–391] In the solid state, the apoprotein adopted the shape of a right hand in common with several classes of polymerase enzyme, with loops from the fingers subdomain associated with the thumb subdomain in what is the closed and active form of the enzyme, while the palm domain contained the catalytic elements of the active site (**Fig. 41**).[35–37,389–391] The key active site residues Asp318 and Asp319 combine with Asp220 and the carbonyl oxygen atom of Thr221 to coordinate the two metal ions, either Mg^{2+} or Mn^{2+}, with the former likely to be the physiological relevant element that catalyzes the polymerization reaction. These metal ions coordinate with the α- and β-phosphate moieties of the incoming nucleotide, as determined from X-ray structures of ternary complexes of the enzyme with dinucleotide primers and nucleoside diphosphates as substrate mimics.[389–392] The priming dinucleotide is stabilized by salt bridge interactions between Arg386 and Arg394 located on the primer grip helix and

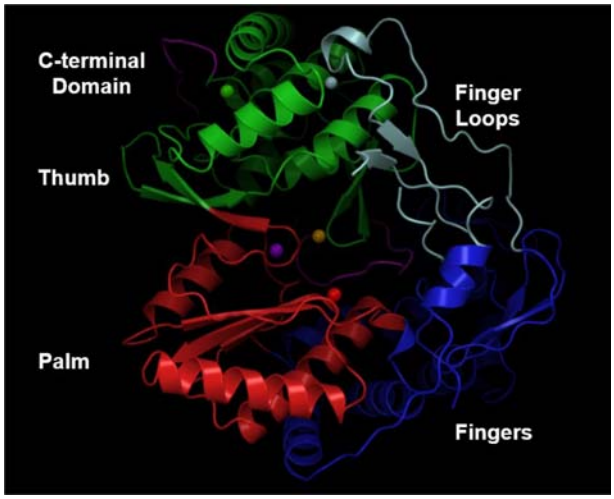


Fig. 41 Domain structure and location of inhibitor binding sites in HCV NS5B RdRp. The palm (red), thumb (green), fingers (blue), and C-terminal (magenta) domains and finger loops (cyan) are shown in cartoon representation. Locations of the active site (red), thumb site I (cyan), thumb site II (green), and palm sites I (magenta) and II (yellow) are denoted with colored spheres. Image generated with the PyMOL Molecular Graphics System (Version 1.7.6 Schrödinger, LLC) using coordinates in the Protein Data Bank, entry 1C2P.[35]

the 5′-phosphate of the primer.[392] The ternary complex structures reveal that the selectivity of NS5B for ribonucleotide triphosphates resides in the establishment of a H-bonding network in which the OH of Ser282 engages both the 2′-hydroxyl of the substrate and the carboxylate of Asp225 in H-bonding interactions, further stabilized by an interaction of the 2′-*O* atom with the side-chain amide NH of Asn291. Mutation of Ser282 to Thr282 of NS5B leads to resistance to 2′-CH_3-based nucleoside analogs, attributed to a steric clash of this moiety with the CH_3 of Thr282. Analysis of ternary complexes representing the primed initiation and elongation states of the enzyme has suggested a mechanism of function that is initiated by entry into the active site of both the 3′-nucleotide of the viral RNA template and the nucleotides that will form the primer. The dinucleotide primer is generated de novo by the initial phosphoryl transfer reaction but the primed complex is thought to be unstable until the dinucleotide primer is extended by an additional 1–3 bases. This results in the β-loop of the finger domain and the C-terminus residues of NS5B that are bound into the active site cavity being expelled, thereby allowing the enzyme to transition into its fully processive elongation state.[392]

5.18.1.10.2 Nucleoside inhibitors of HCV NS5B RdRp activity

The first HCV-inhibiting nucleoside analog to be advanced into clinical trials was 2′-*C*-methylcytidine (NM-107, **146**) that was developed as valopicitabine (NM-283, **147**), a valine ester prodrug designed to improve oral bioavailability (**Fig. 42**).[393–396] NM-107 (**146**) was discovered as an inhibitor of a range of RNA viruses in cell culture that included BVDV (EC_{50} = 670 nM), the closest flavivirus to HCV that was used as a surrogate in the early days of drug discovery before the advent of HCV replicons, yellow fever virus (EC_{50} = 3.1 μg mL^{-1}), and West Nile virus (98% inhibition at 5 μg mL^{-1}). In a GT-1b HCV replicon, NM-107 (**146**) was modestly potent, EC_{50} = 270 nM, and although synergistic when combined with IFN-α, the combination with ribavirin (**1**) was antagonistic.[393,396,397] Resistance to BVDV was mapped to a Ser405Thr mutation in the viral polymerase that is equivalent to a Ser282Thr change in HCV NS5B.[396] Daily administration of **147** to chimpanzees chronically infected with GT-1b HCV at a dose of 8.3 and 16.6 mg kg^{-1} each to 2 animals for 7 days resulted in mean reductions in viremia measured at day 7 of 0.83 and 1.05 $\log_{10}$IU mL^{-1}, respectively, with no significant change in the placebo control group.[396] In a phase 1 clinical trial, a dose of 800 mg of **147** administered QD for 15 days to subjects chronically infected with HCV produced a 0.73 $\log_{10}$IU mL^{-1} decline in viral load, while combination of this dosing regimen with PEG-IFN-α-2b afforded more than a 2 $\log_{10}$IU mL^{-1} reduction in viremia in 93% of the patients after 4 weeks of therapy. Although this compound established proof of concept for nucleoside-based inhibitors of NS5B RdRp in a clinical setting, development was halted by the FDA on 13 July 2007 due to gastrointestinal toxicity that could not be obviated by codosing with an antiemetic, and the compound was subsequently abandoned.

Both 2′-*C*-methyladenine (**148**) and 2′-*C*-methylguanine (**149**) inhibit HCV replication in replicons with EC_{50} values of 0.25 and 3.5 μM, respectively, with conversion to the active triphosphate determined to be a limitation for **149** (**Fig. 43**).[398–400] The phosphoramidate prodrug **150** of the 5′-monophosphate of **148** failed to significantly improve potency in a replicon, EC_{50} = 0.25 μM, but application of the same ProTide prodrug technology to **149** led to **151**, which exhibits >10-fold enhanced antiviral activity, EC_{50} = 0.28 μM.[401–404] The activity of **151** was further improved by modification of the guanosine base to afford INX-08189 (**152**), which inhibits HCV replication in a GT-1b replicon with an EC_{50} of 10 nM.[405–408] Administration of a single 3 mg kg^{-1} oral dose of **152** to rats revealed that the liver concentration of 2′-*C*-Me-GTP was equivalent to the EC_{90} in replicons and further increased in proportion to doses ranging from 5 to 300 mg kg^{-1}.[408] The complex sequence of intracellular metabolism of **152** has been elucidated and relies upon carboxylesterase cleavage of the ester moiety to initiate the cascade of prodrug unmasking reactions, with the released acid **153** reacting intramolecularly at phosphorus to eject β-naphthol and generate the unstable cyclic acyl phosphoramidate **154** (**Scheme 1**).[403,404,409,410] This is believed to hydrolyze spontaneously to the phosphonamide **155,** which is processed, at least in part, by histidine triad nucleotide-binding protein 1 (Hint1) to afford the monophosphate **156**.[409] The monophosphate **156** is a substrate for adenosine deaminase-like protein 1 (ADAL1), which metabolizes the base to the guanine moiety to afford 2′-*C*-methylguanine monophosphate (**157**). Sequential phosphorylation of **157** by guanylate kinase and nucleoside-diphosphate kinase (NDPK) is believed to complete metabolism to **158**, the active triphosphate species (**Fig. 44**).

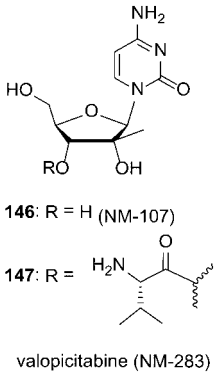

Fig. 42 HCV NS5B inhibitor NM-107 (**146**) and its prodrug valopicitabine (**147**).

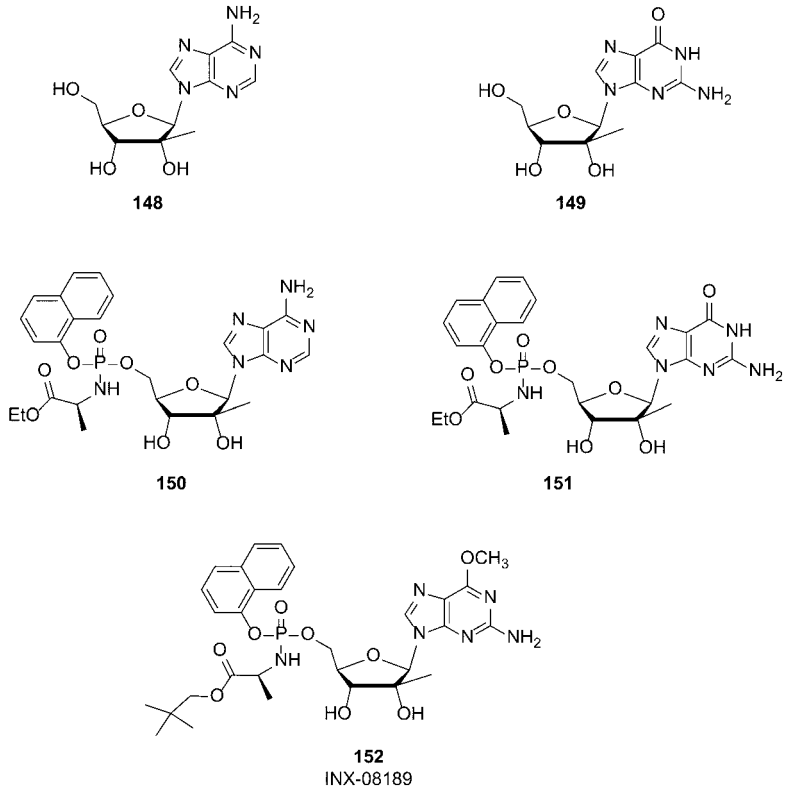

Fig. 43 Nucleoside-based HCV NS5B inhibitors **148–152**.

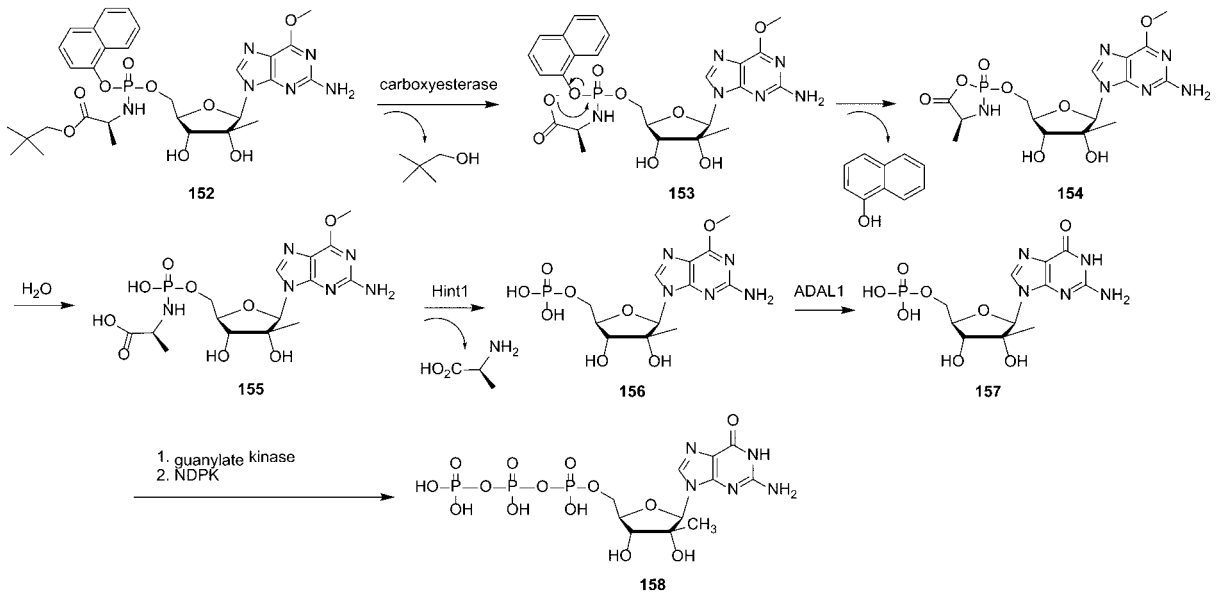
Since the resolved isomers of INX-08189 (**152**) exhibited equivalent antiviral activity in vitro, this compound was advanced into clinical trials as a mixture of diastereomers at the phosphorus center where daily doses of 9–200 mg for 7 days were associated with dose-dependent reductions in viremia ranging from 0.64 to 4.25 $\log_{10}$IU mL^{-1}.[402] However, development of this compound was terminated in Aug. 2012 after the observation of unexpected cardiac toxicity in a phase 2 clinical trial in combination with daclatasvir (**7**), manifested as an ST-segment and T-wave abnormalities on the surface ECG, with one patient suffering a rapidly progressive heart failure that was ultimately fatal.[379,411]



Scheme 1 Intracellular metabolism of INX-08189 (152) to generate 2′-*C*-methylguanine triphosphate (158).

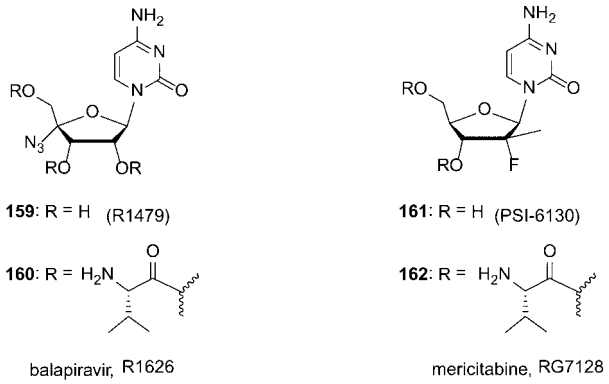


Fig. 44 Nucleoside-based HCV NS5B inhibitors **159–162**.

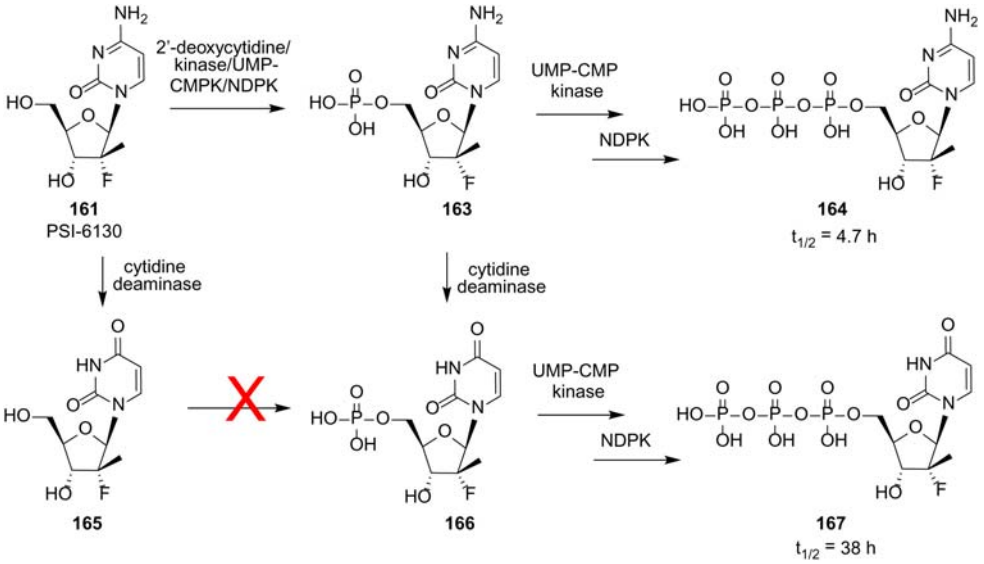
R1479 (**159**) is a 4′-azido cytidine derivative that is an effective although modestly potent inhibitor of HCV replication in a GT-1b replicon, $EC_{50} = 1.28\ \mu M$, for which antiviral activity was not significantly improved by the preparation of prodrugs of the monophosphate derivative.[412–414] R1479 (**159**) was advanced into clinical trials as the trivaline ester prodrug **160** (R1626, balapiravir), which improved drug absorption in the gut.[415] HCV-infected subjects were treated with doses of 1500, 3000, and 4500 mg of **160** administered on a BID regimen for 14 days, which produced viral load reductions of 1.2, 2.6, and 3.7 $\log_{10}$-IU mL^{-1}, respectively.[416] A subsequent study evaluated a 1500 mg BID dose of **160** administered for 28 days in conjunction with PEG-IFN-α and ribavirin (**1**) and resulted in a 5.2 $\log_{10}$IU mL^{-1} reduction in viremia.[417] While these patients subsequently continued with PEG-IFN-α and ribavirin (**1**) therapy for 44 weeks, high relapse rates were seen at 72 weeks, and this compound was discontinued after a phase 2 clinical trial revealed an unacceptable benefit-to-risk ratio.[418,419]

The presence of a 2′-hydroxyl on the ribose ring is not an essential recognition element for nucleoside-based inhibitors of HCV NS5B.[376,420,421] 2′-Deoxy-2′-fluoro-2′-*C*-methylcytidine (PSI-6130, **161**) is an active antiviral agent in HCV replicons, $EC_{50} = 1.3\ \mu M$, that is not cross-resistant with R1479 (**159**) and was formulated as the bis-valine ester **162** (RG7128, mericitabine) for clinical development, a modification designed to improve the poor pharmacokinetic properties associated with the parent drug.[422–426] In early clinical trials in patients infected with GT-1, GT-2, or GT-3 viruses, a dose of 1500 mg BID of **162** for 14 days was associated with a reduction in viremia of 2.7 $\log_{10}$IU mL^{-1} while QD doses of 750 mg and 1500 mg were less effective, reducing viral load by 2.1 and 1.5 $\log_{10}$IU mL^{-1}, respectively.[427] A 4-week clinical trial in which a 1500 mg BID dose of **162** was added to a regimen of PEG-IFN-α and ribavirin (**1**) for 4 weeks produced a maximal mean viral load reduction of 5.1 $\log_{10}$IU mL^{-1}, with no evidence of the emergence of resistance.[427,428] These studies set the stage for longer trials of the combination therapy, explored in context of 8-week, 12-week (PROPEL), and 24-week (JUMP-C) phase 2b regimens in which doses of 500 or 1000 mg BID of **162** with PEG-IFN-α and **1** were compared with a combination of PEG-IFN-α and **1** with a placebo control.[429,430] In the shorter studies, there was no difference in SVR across the drug regimens, while in the longer study, **162** improved SVR to 56.8% compared with 36.5% with placebo, although relapse rates in the two groups were similar, results anticipating combination studies with direct-acting antiviral agents.[429–431] However, the clinical development of **162** was apparently abandoned in Jan. 2015.

A comprehensive analysis of the intracellular metabolism of **161** identified a complex, bifurcated pathway that resulted in the production of the fluorinated uridine triphosphate **167**, a potent inhibitor of the HCV NS5B enzyme that has a much longer intracellular half-life than the cytidine triphosphate derivative **164** (Scheme 2).[432,433] Conversion of **161** to the uridine **165** by cytidine deaminase was observed in vitro but the latter compound is not metabolized to the monophosphate **166** in hepatocytes, providing an explanation for the absence of antiviral activity with **165** in cell-based assays. However, the monophosphate **163** is also a substrate for cytidine deaminase, generating **166**, which, analogous to **163**, is phosphorylated sequentially by cytidine monophosphate (UMP-CMP) kinase 1 and NDPK to afford the active triphosphate **167**.

In order to circumvent the metabolic block preventing **165** from being converted to the active species **167**, phosphoramidate-based prodrugs of **165** were explored, with optimization of the prodrug elements guided by antiviral potency in a subgenomic replicon assay.[409,434] The result of this process was the identification of PSI-7851 (**168**) (Fig. 45) as a potent inhibitor of replication, $EC_{90} = 0.52\ \mu M$.[434] PSI-7851 (**168**), which was subsequently renamed GS-9851, was advanced into clinical trials as the mixture of diastereomers at phosphorus after preclinical profiling established that oral administration of this compound to rats and dogs resulted in the formation of high levels of the triphosphate in the liver.[434,435] In phase 1 clinical studies, **168** was well tolerated with dose-related effects on viral load observed: 3 daily doses of 400 mg effected a mean maximal reduction in viremia of 1.95 $\log_{10}$IU mL^{-1} compared with 0.09 $\log_{10}$IU mL^{-1} in the placebo group.[377,436,437] Resolution of **168** identified the *Sp* diastereomer **4** (PSI-7977, sofosbuvir) as the preferred species, $EC_{90} = 0.42\ \mu M$, while the *Rp* diastereomer was over 10-fold less active, $EC_{90} = 7.5\ \mu M$.[434] Sofosbuvir (**4**) exhibits pan-genotypic inhibitory activity in replicons expressing GT-1 to GT-6 sequences, with EC_{50} values ranging from 14 to 110 nM, and a high genetic barrier to resistance, with 16-fold reduced sensitivity to replicons expressing the Ser282Thr mutation.[435,66] In a phase 2 clinical study, a 400 mg daily dose of **4** administered as monotherapy for 14 days to GT-1-infected subjects resulted in a decline in viral load of 5.0 $\log_{10}$IU mL^{-1}.[377]



Scheme 2 Intracellular metabolism of PSI-6130 (161).

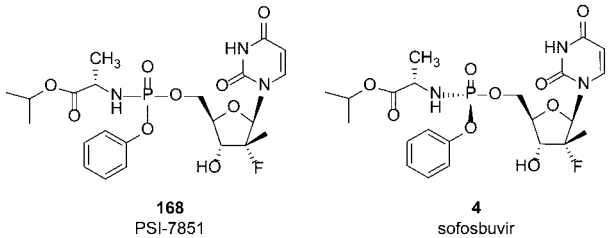


Fig. 45 Nucleoside-based HCV NS5B inhibitors **168** and sofosbuvir (**4**).

2′-Fluoro-2′-C-methyl guanosine (**169**) is a modestly potent HCV inhibitor in a subgenomic replicon, $EC_{90} = 56–69$ μM, while the adenosine homologue is inactive with an EC_{90} value of > 100 μM (Fig. 46).[438–440] However, not only was triphosphate derived from **169** a potent inhibitor of wild-type GT-1b, GT-2a, GT-3a, and GT-4a NS5B polymerase activity with IC_{50} values ranging from 1 to 4.7 μM, but also it inhibited the Ser282Thr mutant polymerase with only twofold reduced sensitivity, $IC_{50} = 9.2$ μM, an improved profile compared with the pyrimidine-based triphosphate **167**.[377,440] Based on the premise that the initial

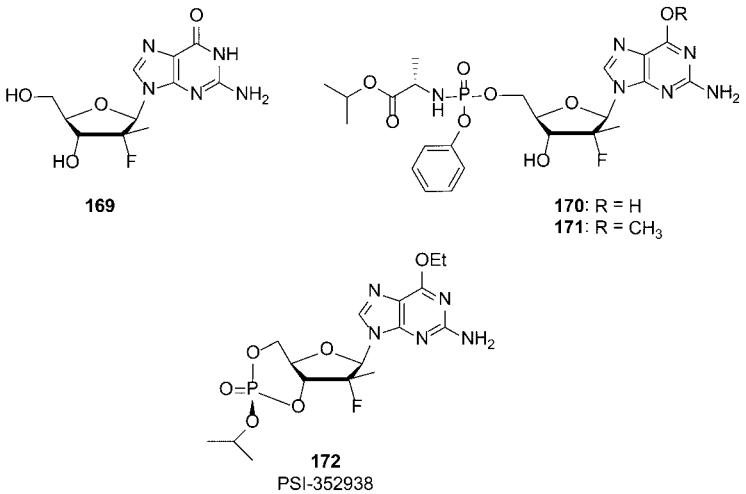

Fig. 46 Nucleoside-based HCV NS5B inhibitors **169–172**.

phosphorylation of the 5′-alcohol was limiting cellular production of the triphosphate of **168**, the phosphoramidate prodrug **170** was prepared and evaluated.[439] This compound offered significantly increased potency in cell-based assays with an EC_{90} of 0.75 μM in a GT-1b wild-type replicon. Further optimization focused on the C-6 substituent of the guanine base, with small alkoxy and alkylamine substituents offering improved potency. The observation that more lipophilic compounds were more cytotoxic precipitated a focus on the methoxy analog **171**, $EC_{90} = 0.02$ μM, as an optimal compromise.[439] The *Sp* diastereomer of **171**, isolated initially by crystallization, was the more potent, $EC_{90} = 8$ nM, offering a threefold advantage over the *Rp* isomer, $EC_{90} = 27$ nM, a structure–activity relationship that mirrors observations with **168**. The metabolic activation pathway for the *Sp* diastereomer of **171** was determined to be analogous to that elucidated for **152,** and the compound afforded high levels of the triphosphate of **169** in primary human hepatocytes.[377,439,440] However, although this compound was selected for clinical development, it appears to have been abandoned in favor of the cyclic phosphate analog PSI-352938 (**172**).[377,441,442] PSI-352938 (**172**) is the thermodynamically more stable *Rp* (*cis*) isomer and inhibits a GT-1b replicon with an EC_{90} value of 1.37 μM, while the *Sp* (*trans*) diastereomer is twofold more potent, $EC_{90} = 0.69$ μM.[441] However, **172** was able to deliver higher levels of the triphosphate metabolite of **169** in primary human hepatocytes than in replicon cells, and high levels of triphosphate were measured in the livers of rats following oral administration of the drug.[441,443,444] The metabolic pathway unmasking **172** has been elucidated and is initiated by CYP 3A4-mediated removal of the *iso*-propyl ester moiety with other CYP enzymes being incompetent, a mechanism that may underlie the modest replicon potency since the parent cell lines only poorly express this enzyme.[444] Ring opening of the cyclic phosphate is mediated by phosphodiesterases 2A1, 5A, 9A, and 11A4, all of which are expressed in the liver, with the next step the removal of the 6-ethoxy moiety of the guanine base by ADAL1 to afford the monophosphate of **169**. The final steps of activation are sequential phosphorylation of the monophosphate of **169** by guanylate kinase 1 and NDPK to give the triphosphate.[444] In a multiple ascending dose study in which GT-1-infected subjects were administered with 100, 200, and 300 mg of **172** daily for 7 days, mean viral load declined by 4.31, 4.65, and 3.94 $\log_{10}$ IU mL^{-1}, respectively, measured at the end of the study, with no viral breakthrough observed.[376] This reflects a high genetic barrier to resistance in which multiple mutations in the NS5B gene are required for virus escape.[445] Clinical development of **172** was focused on combination with sofosbuvir (**4**), but this compound was abandoned after a phase 2a trial in which liver enzyme elevation of greater than threefold was observed in a monotherapy arm of the study, reflective of hepatotoxicity.[378,380]

5.18.1.10.3 Nonnucleoside inhibitors of HCV NS5B RdRp activity

Lead nonnucleoside HCV NS5B polymerase inhibitors that act via an allosteric mechanism were discovered by high-throughput screening campaigns, and structural studies have provided further details on modes of binding in the thumb and palm regions described in the preceding text.[377] The thumb domain contains two distinct sites, designated as thumb sites I and II, that are separated by approximately 15 Å. The palm domain has also been classified into 2 main sites based on inhibitor binding, but these form part of an extended, contiguous binding site that is ~15 Å long and ~20 Å wide and demonstrates considerable conformational plasticity.[377] Perhaps not surprisingly given its size, HCV NS5B inhibitors that have been characterized as interacting with the palm site represent multiple structurally diverse themes.

5.18.1.10.4 Thumb site I nonnucleoside inhibitors of HCV NS5B RdRp activity

Prototypical ligands for thumb domain I are represented by the indoles deleobuvir (**173**) and JTK-109 (**174**), while filibuvir (**175**), lomibuvir (**176**), and radalbuvir (**177**, GS-9669) are ligands that bind to thumb site II (Fig. 47).[377,386–338,446–449] Thumb domain site I of HCV NS5B is located 30 Å away from the active site of the enzyme and X-ray crystallographic structures reveal that in the apo enzyme, this binding site is occupied by a short α-helix, located at the tip of the N-terminal loop of the enzyme, that serves to connect the fingers and thumb domains.[450,451] Thumb domain I inhibitors interfere with this interaction, thereby preventing the enzyme from articulating correctly during viral RNA synthesis. However, thumb domain I is proximal to a GTP-binding site and inhibitors that act at this domain indirectly compromise GTP association.

The benzimidazole-based thumb domain I inhibitor leads **178** and **179** were discovered independently by high-throughput screening campaigns, and both demonstrated modest enzyme inhibitory potency, IC_{50} values = 14 and ~10 μM, respectively, and neither were active in HCV replicons (Fig. 48).[452,453] In both cases, the minimum pharmacophore was deduced to be the embedded *N*-alkyl-1*H*-benzo[*d*]imidazole-5-carboxylic acid, with initial SAR studies directed in complementary directions that led to the identification of BILB 1941 (**180**), which is based on a more lipophilic indole core, and the benzimidazole JTK-109 (**174**) as clinical candidates.[447,454,455] Both compounds were profiled as potent antiviral agents in HCV replicons with EC_{50} values of 153 and 84 nM for **180** toward GT-1a and GT-1b replicons, respectively.[455,456] JTK-109 (**174**) inhibited GT-1a and GT-1b replicons with EC_{50} values of 62 and 320 nM for GT-1a and GT-1b, respectively, although this compound was poorly active in replicons based on GT-2a and GT-2b sequences.[447] Moreover, both compounds were the result of drug discovery campaigns that optimized for both intrinsic antiviral potency and oral exposure, with a specific focus on liver exposure where concentrations of both were ~10-fold higher than in plasma following oral administration to rats.[447,455]

In the case of BILB 1941 (**180**), the optimized spirocyclobutane moiety was confirmed using parallel synthesis methodology starting from a *gem*-dimethyl substituent that functioned to provide a distinct stereo-orientation by taking advantage of the Thorpe–Ingold effect and favoring an L-shaped topology that complements the enzyme binding site.[457–459] Resistance to **180** mapped to changes at Pro495, Pro496, and Val499 in the thumb region, residues that are proximal to the aromatic ring of the indole core.[451] Clinical evaluation of **180** established proof of concept for this inhibitory mechanism with doses of 10–450 mg administered on a TID schedule for 5 days to GT-1-infected subjects.[456] A robust antiviral response was observed only in the

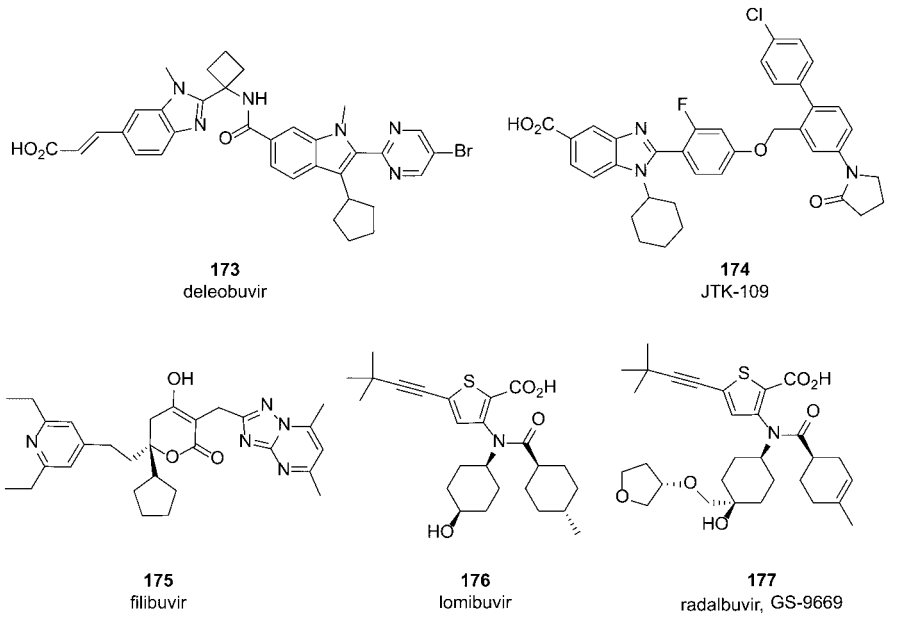

Fig. 47 Nonnucleoside-based HCV NS5B inhibitors **173–177**.

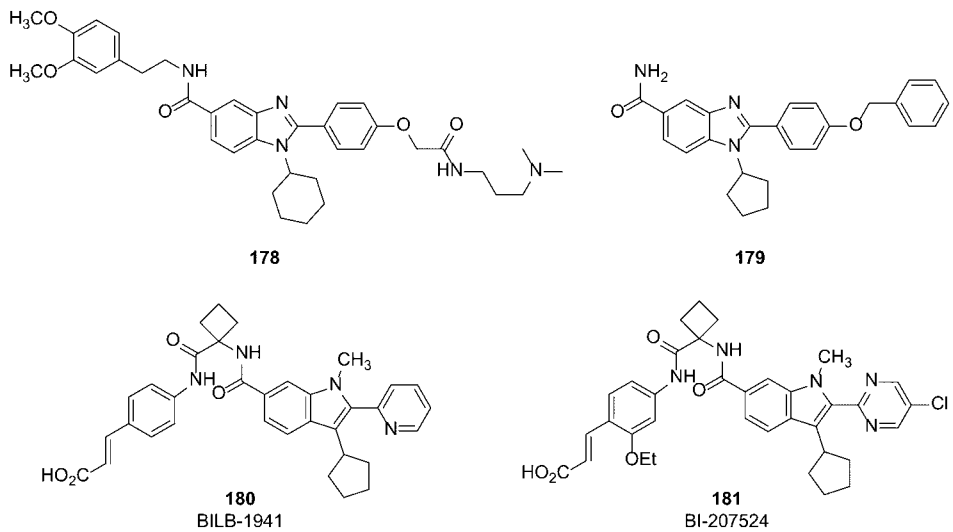

Fig. 48 Nonnucleoside-based HCV NS5B inhibitors **173–177**.

450 mg dose cohort, with 4 of 5 patients experiencing a >1 $\log_{10}$ IU mL^{-1} decline in viremia. However, at this dose, GI intolerance in 4 of the subjects and liver enzyme elevation in the remaining patient prevented further dose escalation and development of this compound was abandoned.[457,458] Follow-up studies were focused on identifying compounds with improved potency, and BI-207524 (**181**), a compound with a less acidic carboxylic acid moiety by virtue of the *ortho*-ethoxy substituent, fulfilled the improved targeted antiviral criteria with EC_{50} values of 29 and 11 nM for GT-1a and GT-1b replicons, respectively, while maintaining the PK profile of **180**.[460,461] Unfortunately, development of this compound was precluded by the observation that the embedded aniline, a genotoxin, was released in vitro in both rat and human liver microsomes.[461,462] While the genotoxicity problem was addressed by replacing the aniline with a 2-aminopyridine, compounds in this class failed to achieve antiviral and PK profiles predictive of reasonable doses in humans, necessitating further optimization, ultimately arriving at deleobuvir (**173**) in which the anilide is replaced by a benzimidazole ring.[446] The design of **173** relied upon extensive NMR and computational studies of conformational preferences of **180** that illuminated the role of the individual substituents and identified potential sites for rigidification as an approach to optimizing complementarity with the protein binding site. This analysis, which carefully assessed key rotatable bonds, also suggested that the role of the pyridyl moiety of **180** was to influence the orientation of the cyclopentyl ring, a critical element of the pharmacophore.[446,463] The orientation of the amide carbonyl attached to the indole

ring is also of importance since the oxygen atom establishes a H-bonding interaction with the guanidinium moiety of Arg503. However, attempts to influence conformation of the amide to that in the bound state (which is as depicted in **173** and **178–181**) by installing an *ortho*-CH_3 or introducing a nitrogen atom into the phenyl ring of the core heterocycle of a benzimidazole series were associated with poorer inhibition, despite achieving the desired control of the preferred topology.[446] Ultimately, a focus on modulating the conformation of the anilide element of **180** and **181** precipitated the idea of exploiting benzimidazole as an anilide isostere, leading to the identification of deleobuvir (**173**). This compound inhibited a GT-1b NS5B RdRp with an IC_{50} value of 50 nM; was active in both GT-1a and GT-1b replicons with EC_{50} values of 23 and 11 nM, respectively; and was active toward representative GT-2a, GT-2b, GT-3a, GT-4a, GT-5a, and GT-6a replicons, with EC_{50} values of <100 nM.[446,464] Resistance mapping experiments identified mutations in the thumb domain, with reduced sensitivity associated with changes at Pro495, Pro496, and Val499 and with the Pro495Leu variant 120- to 310-fold resistant.[464,465] In a phase 1b clinical trial conducted in GT-1-infected subjects, doses of 100, 200, 400, 800, or 1200 mg of **173** administered TID for 5 days to those without cirrhosis were associated with a dose-dependent reductions in viral load that ranged from 0.4 to 3.8 $\log_{10}$ IU mL^{-1}, with the maximal effect seen at the 800 mg dose.[377,465] Subjects with cirrhotic livers received doses of 400 or 600 mg TID for 5 days and had mean HCV RNA reductions of approximately 3.0 $\log_{10}$ IU mL^{-1}. Although deleobuvir (**173**) was advanced into phase 3 clinical trials in combination with the NS3/4A inhibitor faldaprevir (**57**), development was abandoned in early 2014 after a preliminary analysis of the data revealed a higher rate of premature drug discontinuations that compromised drug efficacy.[466] A similar fate befell JTK-109 (**174**), which was advanced into phase 2 clinical studies but abandoned late in 2003 for reasons that have not been disclosed.[377]

Further evolution of this chemotype focused on indole derivatives, which allowed for simultaneous 1,2,3-trisubstitution to probe the effects of structural constraint between the core heterocycle and the 2-aryl substituent.[377] The acetamide **182** (**Fig. 49**) inhibited a C-terminus truncated NS5B polymerase with an IC_{50} value of 26 nM and was active in a GT-1b replicon, $EC_{50} = 800$ nM.[450] A cocrystal structure of **182** with the NS5B protein revealed the key drug–target interactions and provided a rational basis for further structural exploration. The carboxylic acid moiety formed a salt bridge with the guanidinium of Arg503, with the proximal His428 imidazole adding to the positive electrostatic potential in this region, while the cyclohexyl and phenyl rings occupied adjacent hydrophobic pockets in the thumb domain. An initiative focused on surveying carboxylic acid isosteres was embarked upon based on the premise of solving the problem of acyl glucuronide formation in vivo, a metabolite that can be problematic from a toxicity perspective.[467,468] However, this tactic also allows extension of the pharmacophore into the region probed by the amino acid amide moieties of **173**, **180**, and **181** while preserving acidic functionality at this important site. The success of this approach is exemplified by the acyl-*N*,*N*-dimethylsulfamide **183**, which inhibits the N-terminal truncated GT-1b enzyme with an IC_{50} of 4 nM and is active in a GT-1b replicon with an EC_{50} value of 120 nM.[467]

The construction of a ring between the indole heterocycle and the 2-phenyl substituent was explored by several groups as a means of conferring conformational constraint to the core and providing some control over the topological vectors explored by substituents extending from the bridging element.[469–474] These studies gave rise to MK-3281 (**184**) as a compound with potent in vitro

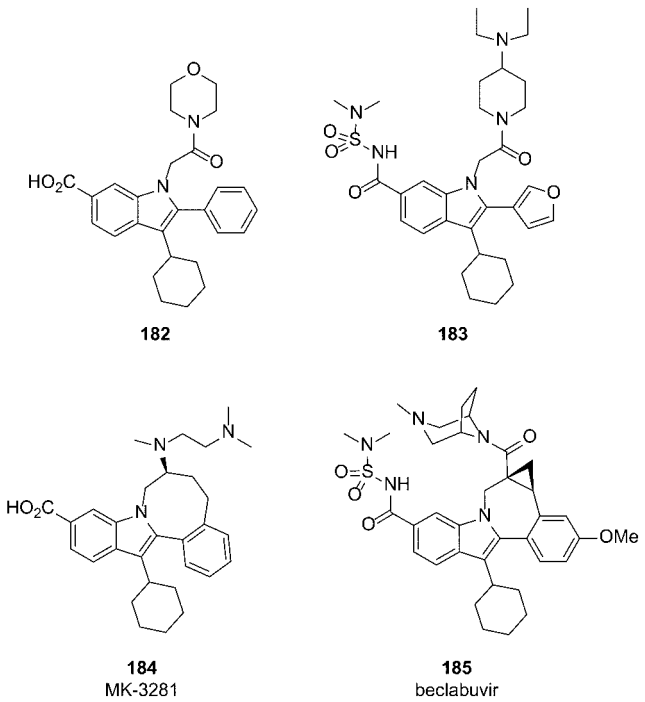

Fig. 49 Nonnucleoside-based HCV NS5B inhibitors **182–185**.

activity, $IC_{50} = 6$ nM toward a GT-1b enzyme, with EC_{50} values of 28, 38, and 37 nM in GT-1a, GT-1b, and GT-3a replicons, respectively, that was six- to ninefold more potent than its enantiomer.[473] However, MK-3281 (**184**) was a weaker inhibitor of GT-2a and GT-2b replication, $EC_{50} = 2$ and 1.8 μM, respectively. In a cocrystal structure of **184** with a GT-1b polymerase, the dihedral angle between the phenyl and indole rings was measured at 46°, the carboxylic acid moiety engaged Arg503, and the amine-containing side chain projected into solvent, leading to the suggestion that the poorer activity of the enantiomer could be attributed to unfavorable steric interactions between enzyme and ligand. This compound demonstrated oral bioavailability in rat, dog, and cynomolgus monkeys, with liver levels in the rat fivefold higher than plasma levels.[473] In vivo antiviral activity was demonstrated in HCV-infected chimeric mice following a dose of 50 mg kg^{-1} administered intraperitoneally twice a day for 4 days, which led to a mean decrease in viremia of 3.13 ± 0.7 $\log_{10}$ IU mL^{-1}. A 10 mg kg^{-1} dose was associated with reduced efficacy, with a mean decrease in viremia of 1.4 ± 0.25 $\log_{10}$ IU mL^{-1}. MK-3281 (**184**) was evaluated in a phase 1b clinical trial where a dose of 800 mg BID for 7 days as monotherapy resulted in a decrease in viral load of 1.28 $\log_{10}$ IU mL^{-1} in GT-1a-infected subjects and 3.75 $\log_{10}$ IU mL^{-1} in those infected with GT-1b virus.[376] Development of **184** was, however, suspended for reasons that have not been disclosed.

Beclabuvir (**185**) resulted from extensive optimization of a tetracyclic chemotype that traces its origins to the benzodiazepinone **186**, a potent GT-1b enzyme inhibitor, $IC_{50} = 70$ nM, that prevents replication of a GT-1b replicon with an EC_{50} value of 240 nM.[474–476] The exocyclic amide **187** (**Fig. 50**) offered comparable potency with balanced GT-1a and GT-1b replicon inhibition, EC_{50} values = 404 and 359 nM, respectively.[476] The acyl-*N*,*N*-dimethylsulfamide **188** provided an optimized solution to metabolic modification of the carboxylic acid of **186** by glucuronidation and improved antiviral potency by twofold, EC_{50} values for GT-1a and GT-1b replicons of 119 and 148 nM, respectively. A focus on structural modification of the morpholine ring required considerable iterative evolution through a series of heterocycles in order to circumvent pregnane X receptor transactivation while preserving potency and PK properties compatible with oral delivery.[476,477] The site of the bridge in the bicyclic piperazine moiety of **185** was determined to be important since the isomer in which the bridge is proximal to the tertiary amine demonstrated higher clearance and poorer exposure in rats.[476] The absolute configuration of the cyclopropyl moiety in **185** was also important with selection based on a significant 15- to 30-fold advantage for the more active enantiomer in potency in replicons. Beclabuvir (**185**) was active in cell culture, inhibiting GT-1a and GT-1b HCV replicons with EC_{50} values of 3 and 6 nM, respectively, with similar activity toward GT-3a, GT-4a, and GT-5a replicons, although GT-2a and GT-6a replicons were less potently inhibited.[476,478] The PK characteristics of **185** in rat, dog, and cynomolgus monkey revealed a hepatotropic disposition, with liver to plasma ratios ranging from 1.6 to 60, and plasma levels in all species were ≥10-fold above the protein binding-adjusted EC_{50} values after a single, orally administered dose. Interestingly, beclabuvir (**185**) is metabolized by CYP 3A4 to the desmethyl derivative **189**, which is a major circulating metabolite that exhibits an antiviral profile similar to the parent drug but exhibits much lower oral bioavailability.[479] Mechanistic studies revealed that **185** is a time-dependent, noncompetitive NS5B inhibitor that interacts with resistant mutants in a fashion that is indicative of a two-step inhibition process.[480] For the Pro495Leu variant, the rates of association with and dissociation from the enzyme are similar to wild-type, but the second step leading to the final tight-binding complex is significantly faster, indicating that this mutation results in a less stable initial complex. In contrast, the Leu30Ser mutant shows seven- to 10-fold higher association/dissociation kinetics but the forward and reverse rates of final complex formation are comparable to the wild-type enzyme.[480] In a phase 1b clinical trial conducted in HCV GT-1-infected subjects, a single 300 mg oral dose of **185** resulted in a mean 2.5 $\log_{10}$-IU mL^{-1} decline in viral load measured at 24 hours post dose.[481]

Conformational constraint in which the acyl-*N*,*N*-dimethylsulfamide element is linked back to the core via a macrocyclic ring has been explored as an approach to simultaneously addressing the metabolism issues associated with simple carboxylic acids while improving drug–target interactions by favoring the bound topology of the acyl-*N*,*N*-dimethylsulfamide moiety.[482–484] Macrocycle motifs that linked the acyl-*N*,*N*-dimethylsulfamide to the indole *N* atom or to the 2-phenyl substituent provided lead compounds **190** and **191**, respectively, which demonstrate sub-micromolar EC_{50} values in a GT-1b replicon (**Fig. 51**). However, early compounds from this series displayed poor in vivo PK profiles, leading to a focus on a third topological design in which macrocyclization linked the acyl-*N*,*N*-dimethylsulfamide to an amide moiety projecting from the bridged ring that was originally explored

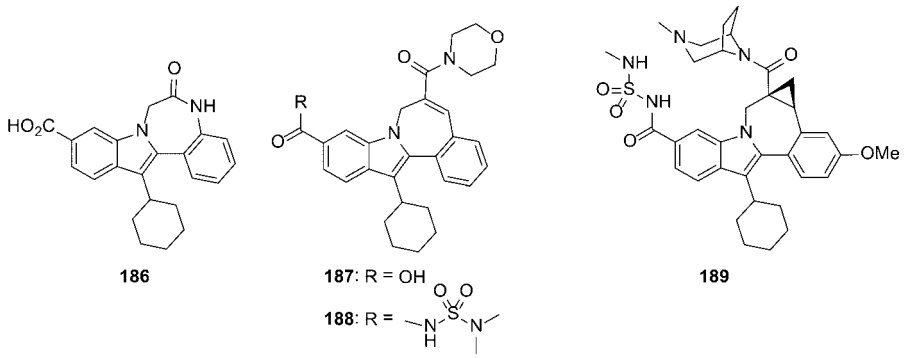

Fig. 50 Nonnucleoside-based HCV NS5B inhibitors **186–189**.

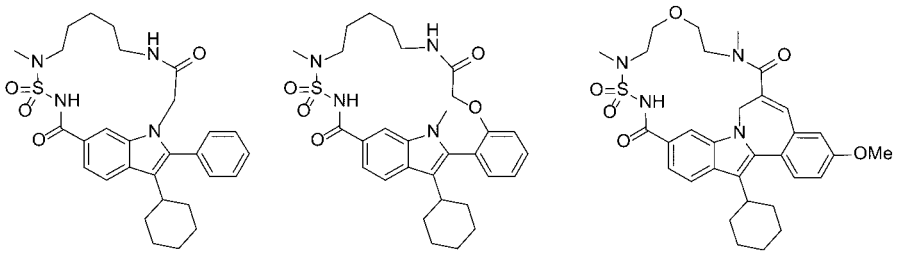


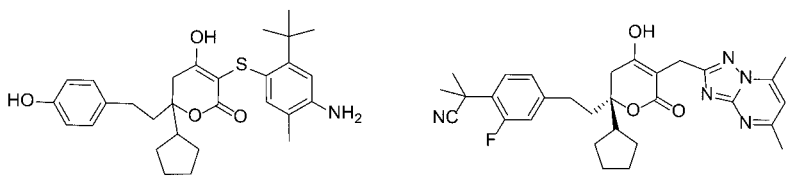
190: EC_{50} = 430 nM **191**: EC_{50} = 180 nM **192** TMC647055

Fig. 51 Nonnucleoside-based HCV NS5B inhibitors **190–192**.

with **184**, **185**, and **188**.[482–484] TMC647055 (**192**) emerged from this effort as an optimized compound after careful examination of the linker length and composition of the bridge olefin.[484,485] A 16- or 17-membered macrocycle provided higher potency than either a 15- or 18-membered ring, while the amide moiety attached to the bridge was important for potency since reduction to the amine was associated with a 25-fold increase in the IC_{50} value. The identity of the bridge motif was particularly influential on the PK profile since the unsaturated analog exhibited lower bioavailability and reduced liver levels, while the cyclopropane analogous to beclabuvir (**185**) was associated with higher clearance in vivo. TMC647055 (**192**) inhibits GT-1a, GT-1b, GT-3a, GT-4a, and GT-6a replicons with EC_{50} values ranging from 27 to 113 nM but is markedly less potent toward GT-2a and GT-2b replicons with EC_{50} values >10 μM.[484,485] The NS5B Pro495Leu mutation conferred a 370-fold reduction in sensitivity in a GT-1b background, while the EC_{50} values for Leu392Ile and Val494Ala were nine- and threefold higher, respectively. Phase 1 clinical trials with **192** examined escalating doses of 300, 1000, and 1250 mg BID in NHVs and doses of 500 and 1000 mg BID were selected for the phase 1b study in HCV-infected subjects who were administered with the drug for 6 days. Exposure was twofold higher in the HCV-infected individuals and mean trough concentrations after oral dosing exceeded the EC_{50} values measured in GT-1a and GT-1b replicons. In GT-1a-infected subjects, the median maximal decline in viremia was 1.4 $\log_{10}$ and 2.4 $\log_{10}$ IU mL^{-1} at the 500 and 1000 mg dose, respectively, while in GT-1b-infected subjects, the median maximal decline in viremia was 3.3 $\log_{10}$ and 3.4 $\log_{10}$ IU mL^{-1}, respectively. Preliminary phase 2 studies of **192** in combination with the NS3 protease inhibitor simeprevir (**5**) have been completed, with antiviral effects superior to the individual drugs although the emergence of Arg155Lys in the NS3 protein was observed in GT-1a-infected subjects, reducing sensitivity to simeprevir (**5**) by 30-fold.[484] Ongoing trials evaluating combinations of TMC647055 (**192**) and simeprevir (**5**) include the CYP 3A4 inhibitor ritonavir (**11**) in order to offset the induction of CYP 3A4 by **192**, which promotes its own metabolism.

5.18.1.10.5 Thumb site II nonnucleoside inhibitors of HCV NS5B RdRp activity

The discovery of filibuvir (**175**) has its genesis with the HTS hit **193** (Fig. 52), a modestly potent NS5B inhibitor, $IC_{50} = 0.93$ μM, that is derived from a series of HIV-1 protease inhibitors.[486] An X-ray cocrystal structure of **193** with a genotype 1b BK strain ΔC21 C-terminal truncated NS5B polymerase protein identified the binding site in the thumb domain. The key drug–target interactions were revealed to be a direct H bond between the enol and the backbone NH of Ser476 in conjunction with three additional H-bonding interactions, all of which were mediated by H_2O molecules: the enol moiety with the NH of Tyr477, the lactone C=O with the guanidinium of Arg501, and the phenol with the NH of Leu497.[486] The phenol ring occupied a hydrophobic pocket, while the aniline ring appeared to make limited contact with the protein. The optimization of **193** focused on enhancing potency while retaining the sulfide linker, with structural modifications guided by X-ray cocrystal data; however, while the initial iterations improved potency by 30-fold, this was not accompanied by demonstrable antiviral activity in a replicon. Subsequent studies probed replacing the aniline moiety with fused heterocycles and modifying the phenol ring, changes that led to compounds with antiviral activity in replicon screens.[487] Substituting the sulfur atom with a CH_2 led to a 10-fold increase in replicon potency in a matched pair comparison, attributed to reduced acidity of the enol, with the added benefit of improved PK properties. Compound **194** emerged as an advanced prototype that inhibited GT-1a and GT-1b polymerases with IC_{50} values of 3 and 70 nM, respectively;



193 **194**

Fig. 52 Nonnucleoside-based HCV NS5B inhibitors **193** and **194**.

was active in a GT-1b replicon with an EC_{50} value of 15 nM; and demonstrated favorable oral bioavailability and clearance in rats.[487,488] However, development of **194** was abandoned due to potent CYP 2D6 inhibition, $IC_{50}=300$ nM, and the identification of a more stable polymorph during the scale-up process that was associated with 80-fold lower solubility.[448,488] The CYP 2D6 inhibition was determined to be associated with the cyano moiety attached to the fluorophenyl ring, an important structural element since it engaged the NH of Leu497 of NS5B in a direct H-bonding interaction, replacing the H_2O that mediated this interaction with the phenol **193**. A focus on modifications of the cyano phenyl moiety led to the identification of filibuvir (**175**) as a compound meeting criteria for advancement into clinical trials.[448,489] Preclinical profiling of **175** in a panel of chimeric subgenomic reporter replicons incorporating polymerase proteins from GT-1a and GT-1b clinical isolates revealed potent in vitro antiviral activity toward 95.8% of the strains, with an overall mean EC_{50} value of 0.59 nM.[489] In vitro resistance mapping studies identified Met423Thr as a mutation conferring 760-fold reduced susceptibility. In phase 1 clinical trials, antiviral efficacy with **175** was established at doses of 100, 300, and 450 mg BID and 300 mg TID for 8 days that were associated with mean maximal reductions in viremia of 0.97, 1.84, 1.73, and 2.13 $\log_{10}$ IU mL^{-1}, respectively.[490] Viral breakthrough was observed in almost half of the patients, mapped to changes of Met423 to Ile, Thr, or Val, although a small number of subjects harbored virus with mutations at Arg422 and Met426 that were also associated with reduced susceptibility in vitro.[490,491] Although **175** was advanced into phase 2b clinical trials where it was studied in conjunction with PEG-IFN-α and **1**, development was abandoned in Mar. 2013 for strategic reasons.[379]

The second major chemotype that binds to the thumb site II domain is a series of carboxylic acid derivatives that originated in two screening hits, the substituted phenylalanine **195**, $IC_{50}=1.8$ μM, and the thiophene carboxamide **196**, $IC_{50}=14$ μM (**Fig. 53**).[492–496] While optimization of both chemotypes was investigated, advancing the potency of the thiophene-based series, particularly in the replicon, was more facile and guided by NMR and X-ray cocrystal structure data.[494–498] Replacing the amide of **196** with a CO_2H enhanced potency by threefold and further optimization afforded VCH-759 (**197**) for which the presence of an *N*-alkyl substituent enhanced potency, particularly in replicons.[496] The key drug–target interactions between the NS5B enzyme and **195** and analogs of **197** were determined to be direct H-bonding interactions between the CO_2H moieties and the backbone N–H atoms of Ser476 and Tyr477, thus acting as functional isosteres of the acidic enol moiety of **193** and **194** and the intermediary H_2O molecule.[494,498,499] VCH-759 (**197**) exhibits antiviral activity in a GT-1b replicon, $EC_{50}=150$ nM, with major resistant mutations identified as Leu419Met and Met423Thr, which conferred eight- to 20-fold reduced susceptibility.[500] VCH-759 (**197**) was evaluated in phase 1 clinical trials where the maximal effect was observed at a dose of 800 mg BID, which reduced viremia by 2.46 $\log_{10}$ IU mL^{-1}.[377,501]

Further structural refinement afforded lomibuvir (**176**) that exhibits higher potency in replicons; EC_{50} values of 23 nM (GT-1a), 5–12 nM (GT-1b), and 4.6 μM (GT-2a); and good preclinical oral bioavailability in the rat and dog.[377,502] In a phase 1b clinical trial, lomibuvir (**176**) was administered to GT-1-infected subjects at a dose of 750 mg on a BID regimen for 3 days, which resulted in a 3.7 $\log_{10}$ IU mL^{-1} reduction in viral load.[377,379] However, development of **176** was halted in Mar. 2013 after results from a phase 2 clinical trial evaluating combination therapy with ribavirin (**1**) and telaprevir (**2**) suggested that the efficacy and safety profile of the combination would not be competitive with other drug regimens in development at that time.[380]

Radalbuvir (**177**) exhibits high-affinity binding to wild-type GT-1b polymerase, $K_D=1.35$ nM, which translates into potent HCV inhibition with EC_{50} values of <11 nM toward GT-1 and GT-5 replicons.[449,503] However, GT-2a, GT-2b, and GT-3a replicons are significantly less susceptible to **177**, with EC_{50} values of ≥ 30 μM, while GT-4a is more sensitive, $EC_{50}=348$ nM. The resistance profile for radalbuvir (**177**) is different to the other thumb site II inhibitors **175** and **176**, with selective pressure producing mutations primarily at Ile482Leu in GT-1a replicons and at Arg422Lys and Leu419Met in GT-1b replicons, while the Met423Thr is only threefold less susceptible.[503,504] Detailed mechanism of action studies has revealed that in order for binding by radalbuvir (**177**) to the polymerase to result in potent enzyme inhibition, both the β-loop and C-terminus regulatory elements must be present, suggesting that the compound stabilizes the full-length protein in a closed, inactive conformation that is dependent on intramolecular interactions mediated by the regulatory elements.[505] In a phase 1b clinical trial conducted in GT-1a- and GT-1b infected individuals, radalbuvir (**177**) was administered at doses ranging from 50 to 500 mg on either a BID or QD regimen.[504] Mean maximal reductions in viremia ranged from 2.18 $\log_{10}$ to 4.02 $\log_{10}$ IU mL^{-1} with doses of 100 mg BID associated with 3.4 $\log_{10}$ and 3.47 $\log_{10}$ IU mL^{-1} declines in viremia in GT-1a and GT-1b patients, respectively.

5.18.1.10.6 Palm site (primer grip) nonnucleoside inhibitors of HCV NS5B RdRp activity

Palm domain binding site inhibitors present a structurally diverse group of allosteric NS5B inhibitors that have been categorized based on their binding location, either palm site region I or II. The most prominent clinically evaluated palm site I HCV NS5B inhibitors are dasabuvir (**12**), setrobuvir (**198**), and IDX375 (**199**), while nesbuvir (HCV-796, **200**) and tegobuvir (**201**) are representative of inhibitors acting at palm site II that have demonstrated clinical efficacy (Fig. 54).[506–512]

5.18.1.10.7 Palm site I nonnucleoside inhibitors of HCV NS5B RdRp activity

The first palm site I inhibitor to be characterized was the benzo-1,2,4-thiadiazine **202**, discovered by high-throughput screening, which inhibited HCV polymerase with an IC_{50} of 100 nM and demonstrated antiviral activity in a GT-1b replicon, $EC_{50}=550$ nM (Fig. 55).[513,514] Preliminary SAR studies indicated the importance of the quinolone *N*-substituent since its absence or contraction to a methyl group resulted in an inactive compound, while the expansion of the side chain to the branched derivative **203** retained activity.[513–515] Resistance mapping studies with **202** identified Met414Thr as a key mutation that reduced susceptibility by 4 orders of magnitude.[516] Mode of action studies with **202** determined it to be an inhibitor of the initiation of RNA synthesis with no effect on elongation, potentially the result of the formation of a ternary complex composed of the inhibitor, the enzyme, and the RNA template.[517] The introduction of polarity into the *N*-alkyl side chain was generally detrimental to potency, while activity was preserved with an *N*-benzyl substituent but, interestingly, not the *N*-phenethyl homologue.[514,518] Substitution on the quinolone ring was largely restricted to small atoms or groups at C-5 and C-6, with C-6 more tolerant; substituents at C-7 led to reduced potency, while a fluorine was acceptable at C-8 but not NO_2. The enol moiety was critical for potency with a range of modifications or deletion leading to inactive compounds. *N*-Methylation of the benzo-1,2,4-thiadiazine was detrimental, attributed to the disruption of an intramolecular H-bonding interaction that stabilized the overall planar conformation observed in the cocrystal (a 20° twist between thiadiazine and quinolone rings). The cyclopropyl derivative **204** (SB-711845) was identified as a clinical candidate based on its in vitro inhibitory potency, $IC_{50}=49$ and 10 nM toward GT-1a and GT-1b enzymes, respectively; activity in a GT-1b replicon, $EC_{50}=38$ nM; and a preclinical PK profile that revealed low clearance and >35% oral bioavailability when dosed as a suspension in rat, dog, and monkey.[514] However, the potency of **204** in a replicon assay in the presence of 45 mg mL^{-1} of human serum albumin (HSA) and 1 mg mL^{-1} of alpha-1-acid glycoprotein (AAG) was significantly reduced, EC_{50} value of

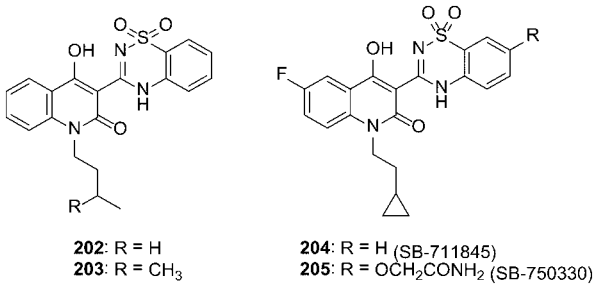

Fig. 55 Palm site nonnucleoside HCV NS5B inhibitors **202–205**.

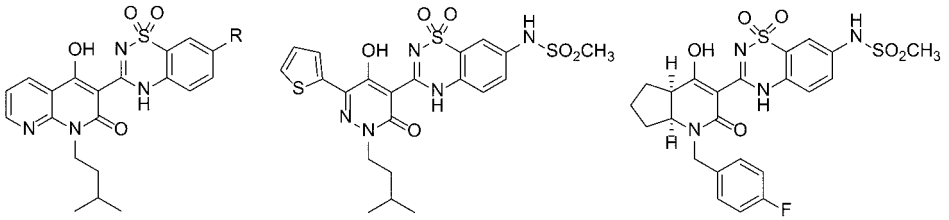

Fig. 56 Palm site I nonnucleoside HCV NS5B inhibitors **206–209**.

13 μM, providing a focus for further optimization that probed the effects of substitution of the benzo-1,2,4-thiadiazine ring.[518] Polar moieties at C-7 were found to be beneficial and SB-750330 (**205**) was selected as a second clinical candidate. This compound was 20-fold more potent in a GT-1b replicon than **204**, $EC_{50}=2$ nM, attributed to the oxyacetamide moiety more effectively occupying the pocket and the amide C=O engaging a side-chain NH of Asn291 in a H-bonding interaction, while potency in presence of HSA and AAG was also improved, $EC_{50}=1.48$ μM.[518]

Although neither of these compounds progressed into advanced clinical trials, the antiviral activity and favorable PK properties of this chemotype attracted considerable attention, and SARs associated with this class of NS5B inhibitor have been extensively explored.[515] The advantage of a sulfonamide substituent at C-7 of the benzo-1,2,4-thiadiazine was demonstrated in the context of the matched pair of naphthyridones **206** and **207** where the addition of this C-7 substituent conferred potent antiviral activity in GT-1a and GT-1b enzyme assays, IC_{50} values for **207** = 2 and 6 nM, respectively (Fig. 56).[519] Of particular importance was the enhanced GT-1a inhibition associated with **207** (since **206** exhibited only modest activity, $IC_{50}=310$ nM), which translated into potent antiviral activity in a GT-1a replicon, $EC_{50}=3$ nM. The importance of the sulfonamide moiety was recognized in a series of pyridazinones that formed the basis of an extensive set of studies where the focus was on optimizing potency and oral bioavailability.[520–523] Compound **208** potently inhibited replication of GT-1a and GT-1b replicons with respective EC_{50} values of 22 and 5 nM and demonstrated good metabolic stability in rat liver microsomes, $t_{1/2}=60$ minutes.[522] After oral administration of a single 3 mg kg^{-1} dose to rats, liver levels of **208** were ~1 μg g^{-1} at 4 hours post dose, over 240-fold higher than the concentration in plasma, while at 12 hours post dose, liver levels were ~40 ng g^{-1}, 64-fold higher than in plasma and 24-fold above the EC_{50} value for the GT-1b replicon.[522] However, the oral bioavailability of **208** in cynomolgus monkeys was poor despite good IV PK, attributed to poor absorption from the gastrointestinal tract due to the high polar surface area (PSA) of the molecule and P-gp-mediated efflux, necessitating further optimization. Fused pyridinones were explored as a vehicle for reducing PSA, with **209** characterized as a compound with good permeability in vitro, favorable PK properties in rats and monkeys, and potent antiviral activity in a GT-1b replicon, $EC_{50}=16$ nM.[524] However, despite being a potent inhibitor of a GT-1a enzyme, $IC_{50}<25$ nM, this compound was considerably less active in a GT-1a replicon, $EC_{50}=550$ nM, providing a key objective for the next phase of optimization of this chemotype.[508]

A cocrystal structure of **209** bound to GT-1b HCV NS5B revealed the key drug–target interactions (Fig. 57), providing an explanation for the beneficial effect of the sulfonamide moiety, which formed two direct H-bonding interactions with the enzyme

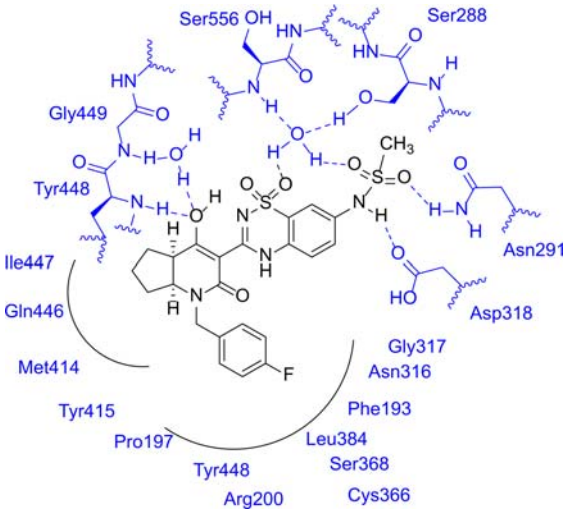

Fig. 57 Key drug–target interactions between **209** and the HCV NS5B GT-1b polymerase enzyme.

and one through the intermediacy of a H_2O molecule.[508,522] The structure also suggested that potency might be improved by probing the third dimension around the cyclopenta[*b*]pyridin-2-one ring by incorporating a bicyclic ring system designed to more effectively fill this pocket of the enzyme. Since the pocket is of a defined size, the preparation of only a limited series of target molecules was necessary in order to examine the concept and the preferred stereochemistry of the bicyclic ring system was quickly established as favoring the (2*S*,7*R*)-enantiomers found in setrobuvir (**198**).[508] Setrobuvir (**198**) was characterized as a potent inhibitor of the replication of GT-1b HCV, EC_{50} 3 nM, but the activity toward GT-1a is more variable with reported EC_{50} values ranging from 8 to 52 nM.[377,510,525–527] This has been attributed to the presence of Phe at residue 415 of the GT-1a RdRp that reduces susceptibility but which is Tyr in GT-1b sequences. Nevertheless, setrobuvir (**198**) is 7- to 30-fold more potent than the prototype **209**, confirming the design premise. Resistance development studies with setrobuvir (**198**) identified Met414Thr (EC_{50} = 470 nM), Met314Leu (EC_{50} = 300 nM), Gly554Asp (EC_{50} = 634 nM), and the dual combination of Met414Thr with Gly554Asp (EC_{50} = 20 μM) as mutants with reduced sensitivity.[509] Preclinical efficacy was established in HCV-infected chimpanzees, with a single dose of 30 mg kg^{-1} administered orally to two GT-1a-infected animals producing reductions in viremia amounting to 0.5 and 1.5 log_{10} IU mL^{-1}. A multiple-dose study in which two GT-1b-infected chimpanzees were administered with 30 mg kg^{-1} doses of **198** daily for 4 days resulted in a maximal viral load decline of 2.1 and 2.6 log_{10} IU mL^{-1}.[509] One animal maintained viral suppression throughout the dosing period, while the second experienced rebound beginning on day 2; sequencing of the viral RNA in each animal revealed the presence of the Gly544Asp mutation. In a phase 1b clinical study, doses of 200, 400, and 800 mg of setrobuvir (**198**) were administered orally on a BID dosing regimen for 3 days to subjects chronically infected with GT-1 and the effect on viremia compared with a placebo control.[528] At the end of the treatment period, viral load was reduced by 2.1, 2.2, and 2.9 log_{10} IU mL^{-1} in the 200, 400, and 800 mg cohorts, respectively, with GT-1b-infected subjects experiencing greater efficacy (range: 2.7 to 3.1 log_{10} IU mL^{-1}) than GT-1a-infected patients (range: 1.3 to 2.7 log_{10} IU mL^{-1}); no viral breakthrough was observed during therapy. Although setrobuvir (**198**) was advanced into combination trials with PEG-IFN-α and ribavirin (**1**), development of this compound appears to have been halted in early 2015.

IDX375 (**199**) is a palm site I inhibitor that combines a tetramic acid moiety with an unusual benzo[*c*][1,5,2]diazaphosphinine 1-oxide heterocycle that was formulated as its choline salt for clinical studies.[510,529] This compound expresses relatively balanced GT-1a and GT-1b inhibition in replicons with EC_{50} values of ~6.2 and 2.3 nM, respectively, and IC_{50} values of 30 and 18 nM toward the respective polymerase enzymes. IDX375 (**199**) is not overtly cytotoxic to a range of cell lines but its spectrum of inhibitory activity is restricted since it is much less active toward GT-2a, GT-3a, and GT-4a polymerases. In PK profiling, **199** exhibited 16–42% oral bioavailability in preclinical species, and the compound was successfully advanced through IND toxicology studies. In a small phase 1b study of **199** conducted in three HCV-infected subjects administered with two 200 mg doses, plasma exposure was fourfold higher than in NHVs and viral load declined by 0.5–1.1 log_{10} IU mL^{-1}.[528]

The second major class of palm site I inhibitor that has been evaluated in clinical studies originated with the high-throughput screening lead **210**, a dihydrouracil derivative that provided the template from which dasabuvir (**12**) and ABT-072 (**211**) were identified (**Fig. 58**).[506,513,530] Compound **210** inhibited GT1-a and GT-1b polymerases with IC_{50} values of 0.58 and 0.36 μM, respectively, but was inactive toward GT-2a, GT-2b, and GT-3a enzymes.[530] Mechanistic studies indicated that the compound was not interfering with RNA binding, and testing against a panel of mutant polymerases revealed reduced susceptibility to enzymes with mutations in the palm site I pocket. The Cys316Tyr mutant exhibited 100-fold resistance, while Met414Thr and Thr448Tyr were 24- and 41-fold less susceptible, respectively, but changes in the thumb region—Met423Thr and Pro495Ala—conferred only a fivefold reduced sensitivity. Details of the optimization of **210** to arrive at dasabuvir (**12**) and ABT-072 (**211**) have not been shared but both compounds were advanced into clinical trials and the preclinical profile of dasabuvir (**12**) has been described in some detail.[377,506] The in vitro biochemical and antiviral profiles of dasabuvir (**12**) and ABT-072 (**211**) are summarized in **Table 3** and reveal potent inhibition of GT-1 polymerases and replicons, with modest eight- to 17-fold shifts in the presence of 40% human serum, but much weaker activity toward GT-2a, GT-2b, GT-3, and GT-4a RdRp enzymes.[506,531,532] Both compounds exhibited high membrane permeability and their preclinical PK profiles indicated good oral exposure in rat and dog and preferential distribution to the liver.[531,532] In dose-ranging phase 2a clinical trials, dasabuvir (**12**) and ABT-072 (**211**) were evaluated briefly as monotherapy followed by 12 weeks of combination therapy with PEG-IFN-α and ribavirin (**1**).[533] ABT-072 (**211**) at doses of 100, 300, and 600 mg QD was associated with reductions in viremia ranging from 1.07 to 1.57 log_{10} IU mL^{-1} after 3 days, while administration of dasabuvir (**12**) at doses of 400 and 800 mg BID for 3 days produced mean maximum decreases in viral load of 1.08 and 0.97 log_{10} IU mL^{-1}, respectively. After completion of the study, SVR_{24} was achieved in 50%, 25%, and 86% of the subjects receiving

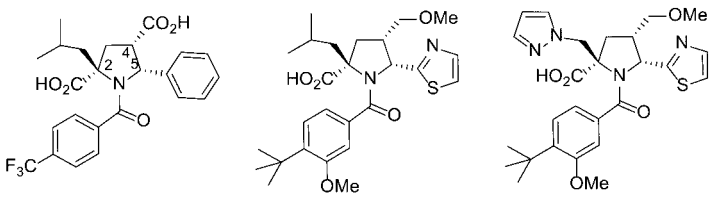
ABT-072 (**211**) and in 63% of both cohorts administered with dasabuvir (**12**), which compared with 9% in the placebo control group receiving PEG-IFN-α and ribavirin (**1**) alone.

There are many additional chemotypes that either bind to palm site I or bind in a fashion that is partially overlapping with it. The pyrrolidine diacid **212** (Fig. 59) available synthetically via a [3 + 2] cycloaddition between imines of amino acid esters and *tert*-butyl acrylate was deconvoluted from a combinatorial library mixture of 168 racemic compounds that inhibited a truncated GT-1b HCV NS5B enzyme, with the pure compound active in the biochemical screen with an $IC_{50} = 700$ nM.[534] The active enantiomer was determined to be as depicted in **212**, and further optimization was focused on modulating physical properties in an effort to identify compounds active in replicons.[535] The 2-carboxylate was demonstrably of importance since the ester was inactive and the primary amide over 10-fold less potent, leading to a focus on the C-4 and C-5 positions, which were explored via the preparation of combinatorial arrays of racemic compounds. These studies identified a 2-linked thiazole as the preferred C-5 element and replicon activity was initially detected with C-4 amide derivatives. Refinement of this structure was aided by X-ray cocrystallographic structures, which identified H bonds between the C-2 carboxylate and the NH of Gly449 and the benzamide C = O and the NH of Tyr448 as the key drug–target interactions. Further optimization focused on manipulating the benzamide substitution pattern while reducing polarity at C-4 in order to enhance membrane permeability, an enterprise that identified **213** as a homochiral compound displaying good oral bioavailability (59%) and low clearance (5 mL $min^{-1} kg^{-1}$) in the rat.[536] This compound inhibited a full-length GT-1b NS5B enzyme with an $IC_{50} = 440$ nM, potency that translated effectively into antiviral activity in a GT-1b replicon, $EC_{50} = 390$ nM, and was selected for clinical development.[537] However, this compound was subsequently replaced with GSK625433 (**214**), a more potent inhibitor that exhibited EC_{50} values of 290 and 3 nM in GT-1a and GT-1b replicons, respectively, and a modest three- to fourfold shift in potency in the presence of 40% human serum.[538] The difference in potency between the GT-1a and GT-1b enzymes was ascribed to the Tyr415Phe mutation in GT-1a that removes a water-mediated H bond between the phenol moiety and the thiazole nitrogen atom. GSK625433 (**214**) was also much less active toward GT-2a, GT-3a, GT-3b, and GT-4a enzymes, while resistance mapping experiments conducted in a GT-1b replicon identified Met414Thr and Ile447Phe as mutations with 83- and 170-fold reduced susceptibility, respectively.[538] Although GSK625433 (**214**) was advanced into clinical studies, development was terminated for reasons unknown.[539]

5.18.1.10.8 Palm site II nonnucleoside inhibitors of HCV NS5B RdRp activity

Nesbuvir (**200**) is a potent inhibitor of GT-1a and GT-1b replication in replicons, EC_{50} values = 5 and 9 nM, respectively, and of NS5B enzymatic activity with IC_{50} values ranging from 20 to 140 nM for GT-1a and 10 to 40 nM for GT-1b.[511] Representative GT-2, GT-3, and GT-4 polymerases were less susceptible with IC_{50} values of 1700, 220, and 570 nM, respectively. Resistance was mapped to mutations within palm site II, specifically changes at Cys316 and Ser365 that conferred substantial changes in sensitivity. Mutation of Cys316 to Asn, Phe, and Tyr was associated with 73-, 130-, and 167-fold changes, respectively, while Ser365Ala and Ser365Thr enzymes are, respectively, 41- and 212-fold less sensitive to inhibition. These residues are proximal to nesbuvir (**200**) in a cocrystal structure where the oxygen atom of Ser365 was observed to engage the N–H of the benzamide moiety in a H-bonding interaction, while larger side chains at Cys316 sterically interfere with the association of the core benzofuran heterocycle to the enzyme.[540,541] Indeed, the Cys316Asn mutation reduces the affinity of **200** for an NS5B enzyme construct by 2 orders of magnitude from a K_i value of 70 nM to 7 μM.[542,543] The Cys316Asn mutation occurs in 11–13% of GT-1b clinical samples isolated



212 **213** **214** GSK625433

Fig. 59 Nonnucleoside HCV NS5B inhibitors **212–214**.

from DAA-naive subjects, although prevalence can be higher, potentially limiting the therapeutic efficacy of nesbuvir (**200**) in some patient populations.[544–546] In a phase 1b clinical trial, nesbuvir (**200**) was administered to HCV-infected patients at doses of 50, 100, 250, 500, 1000, and 1500 mg twice daily for 14 days as monotherapy, with the highest dose associated with a maximal fall in viremia (on day 4) of 1.4 $\log_{10}$ IU mL^{-1}.[511,547] However, viral rebound was observed, and by day 14, viral load was only 0.7 $\log_{10}$ IU mL^{-1} below baseline, coincident with the emergence of a Cys316Tyr mutation in the NS5B protein. In a subsequent phase 2 study of nesbuvir (**200**) administered at 500 mg BID in conjunction with PEG-IFN-α and ribavirin (**1**), serum ALT concentrations increased to three times the upper limit of normal in 13 of 162 patients after 8 weeks of dosing compared with ~1% of patients in the control group receiving only PEG-IFN-α and ribavirin (**1**).[511,548] Two patients who were described in some detail developed severe symptoms of liver toxicity after more than 15 weeks of dosing at which point therapy was suspended and both went on to recover. Notably, neither patient had detectable HCV RNA in their serum 6 months after the end of treatment.[546] The specter of hepatotoxicity, however, in a patient population already managing a liver insult presented a significant problem and clinical development of nesbuvir (**200**) was abandoned in 2008.[511,549]

The identification of the palm site II inhibitor GSK2485852 (**215**) relied upon a computer-aided drug design approach that sought to hybridize the unique chemical properties of a boronic acid moiety with the antiviral attributes of nesbuvir (**200**) in a fashion that would overcome some of the limitations of this compound associated with its resistance profile.[550–552] The site of installation of the boronic acid functionality on the nesbuvir (**200**) template was guided by the principle of placing this structural element proximal to the incoming nucleoside triphosphate where it was anticipated to interfere with RNA processing or modulate the conformation of the protein.[550] This analysis suggested the hydroxyethyl side chain as the optimal location, and a series of compounds were prepared that installed a boronic acid-containing moiety at the sulfonamide *N* atom. Biological evaluation was guided by an initial focus on introducing potent antiviral activity toward the Cys316Asn and Cys361Tyr mutant viruses with subsequent studies directed toward improving PK properties. GSK2485852 (**215**) was identified as a compound meeting the targeted antiviral criteria with EC_{50} values of 3 and 1.7 nM toward WT GT-1a and GT-1b replicons, 1.9 nM toward the GT-1b Cys316Asn mutant, and 3.2 and 1.4 nM in GT-1a and GT-1b Cys316Tyr mutants, respectively (Fig. 60).[550,553] This molecule takes full advantage of the unique properties of the boronic acid since replacing it with carboxylic, sulfonic, and phosphonic acid moieties resulted in compounds with markedly inferior profiles in replicons. Kinetic analysis of the interaction of GSK2485852 (**215**) with a GT-1b Cys316Asn mutant NS5B indicated a 40-fold slower dissociation rate compared with nesbuvir (**200**) and preservation of the initiation inhibitory mechanism observed with the prototype. X-ray cocrystallographic structures with WT GT-1a, Cys316Tyr GT-1a, and Cys316Asn GT-1b NS5B enzymes revealed the molecular basis for the potent antiviral activity toward these viruses.[550] Interestingly, association of **215** with the RdRp protein did not depend on covalent bond formation between the boronic acid and the protein, perhaps surprising based on the chemical reactivity of this moiety, but rather, a network of H-bonding interactions with Met414 and Tyr488 in addition to bound H_2O molecules. GSK2485852 (**215**) exhibited potent antiviral activity toward GT-3a, GT-4a, and GT-5a chimeric replicons with EC_{50} values close to that of the wild-type GT-1b replicon, while a GT-2a replicon was somewhat less sensitive but still half-maximally inhibited at a drug concentration of <10 nM.[553] Although GSK2485852 (**215**) was advanced into clinical trials where a single orally administered 420 mg dose resulted in 1.33 $\log_{10}$ IU mL^{-1} decline in viremia, development was terminated in Aug. 2012 due to poor human PK properties associated with rapid metabolism and the observation of an undisclosed toxicity on repeat dosing.[380,550,554]

The HCV inhibitor tegobuvir (**201**) was developed using a phenotypic approach to lead identification based on the BVDV inhibitor **216**, and SAR optimization was guided by replicon inhibitory activity.[512,555–557] The *ortho*-fluoro substituent on the 2-phenyl ring of tegobuvir (**201**) was found to be important for conferring HCV inhibition but SARs for inhibition of the two viruses were found to be divergent, although molecules with dual activity were identified.[512,556,557] Tegobuvir (**201**) inhibited GT-1a and GT-1b replicons with EC_{50} values of 13.8 and 0.8 nM, respectively, but chimeric replicons incorporating GT-2 to GT-6 polymerase sequences were much less susceptible to inhibition, EC_{50} values of >100 nM, with sensitivity traced to a Cys445Phe mutation present in the latter genotypes.[558,559] Resistance mapped to mutations in the NS5B polymerase, most notably Cys316Tyr, Tyr448-His, Tyr452His, and Cys445Phe, which when individually reverse engineered into a GT-1b replicon conferred 7- to 36-fold reduced sensitivity. However, tegobuvir (**201**) presented an interesting mechanistic conundrum since it failed to inhibit NS5B enzymatic activity in biochemical assays and biophysical analyses failed to detect binding of the compound to the protein.[512,558,560] A Western blot analysis of HCV nonstructural proteins in a GT-1b replicon exposed to tegobuvir (**201**) revealed two NS5B species, with the size of the unnatural band correlating with inhibitor potency. Mass spectrometric analysis of the additional protein indicated a mass

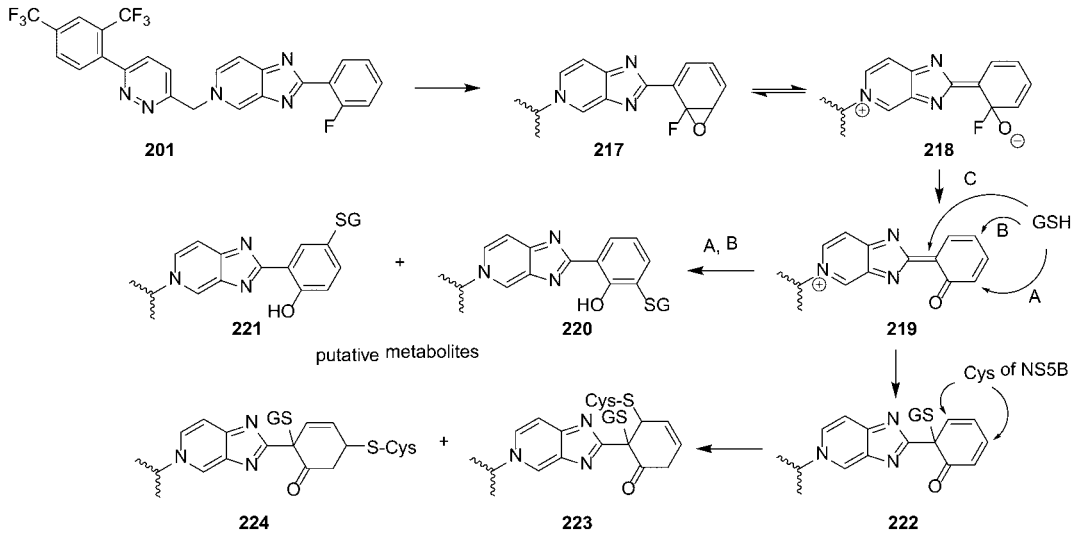

Scheme 3 Proposed mechanism of bioactivation and HCV NS5B inhibition by tegobuvir (201).

increase of 820 Da, a difference that correlated with the molecular weight of a tegobuvir (**201**) metabolite that involved the addition of glutathione (GSH) coupled with the loss of fluorine, leading to the hypothesis that a metabolite of **201** was responsible for the antiviral acitivity.[560] This was corroborated by the observation that CYP inhibitors abrogated the activity of tegobuvir (**201**), narrowed to CYP 1A1 when it was observed that expression of this enzyme in HeLa cells carrying HCV replicons restored inhibitory activity.[558,560] The mechanism proposed to account for these observations is summarized in **Scheme 3** and relies upon an initial metabolic activation of the fluorophenyl ring to the epoxide **217**. Epoxide **217** is thought to undergo ring opening and loss of fluoride via **218**, a process assisted by the extended electronic interaction with the dihydropyridine ring, to afford the highly reactive electrophile **219**. Addition of GSH to **219** via path A or B followed by rearomatization affords the suspected metabolites **220** or **221**, while addition of GSH to the exocyclic double bond (path C) does not allow rearomatization of the ring but rather preserves electrophilicity, allowing **222** to react with a Cys of HCV NS5B to afford the putative adducts **223** or **224**.[560] The identity of the amino acid residue reacting with **222** has not been identified but speculation has implicated Cys366 since this has been shown to be susceptible to modification by soft electrophiles and sulfenylating agents that inhibit NS5B polymerase.[561–563]

In a phase 1 clinical trial conducted in HCV GT-1-infected subjects who were administered with 40 or 120 mg of tegobuvir (**201**) on a BID schedule for 8 days, viremia declined by 1.61 and 1.95 $\log_{10}$ IU mL^{-1}, respectively.[241,377] In a follow-up phase 2 study, dosing of tegobuvir (**201**) was restricted to 40 mg BID due to concerns over QT prolongation, and this dosing regimen was examined in combination with the NS3 protease inhibitor **78** (75 mg BID) with and without ribavirin (**1**) or PEG-IFN-α for 28 days at which point all patients were switched to **1** and PEG-IFN-α.[377] In the dual DAA therapy arm, viral load declined by a median 4.1 $\log_{10}$ IU mL^{-1} but significant breakthrough was observed and only 13% of the cohort achieved RVR, while all patients receiving quadruple therapy achieved RVR.[241,377] Although tegobuvir (**201**) was the subject of several additional clinical studies in combination with other DAAs, development of the compound was ended in 2013.[564]

An interesting variation on the structure of tegobuvir (**201**) that was designed to address the hERG liability associated with this compound focused on reducing basicity.[565] This approach was studied in the context of the imidazopyridazine **225** (**Fig. 61**), which has a calculated pK_a for the core scaffold that is 3.6 units lower than the identically substituted imidazopyridine. Systematic SAR studies that examined all elements of the molecule identified the phenol ether **226** as an optimized compound, $EC_{50} = 22$ and 3 nM toward GT-1a and GT-1b replicons, respectively. The ester **227** was prepared as part of the SAR survey and found to exhibit comparable antiviral activity to **226** but several attempts to prepare the corresponding carboxylic acid by saponification always resulted in isolation of **226**. This suggested that under the assay conditions, **227** was converting to **226**, a thesis confirmed by analysis of the replicon supernatant, and the compound was determined to be unstable in biological media but stable in aqueous medium at pH 2 or 7. This fortuitous finding proved to be useful since the PK of **226** was less than optimal, with 33% and 12% oral bioavailability in

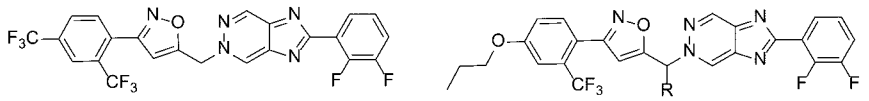

Fig. 61 Palm site II nonnucleoside HCV NS5B inhibitors **225**–**227**.

the rat and dog, respectively. However, administering **227** resulted in a significant increase in the plasma exposure of **226**, with F = 80% and 51% in the rat and the dog, respectively; moreover, the ester exhibited improved exposure on dose escalation. Plasma exposure was further enhanced by manipulating the identity of the ester moiety, which acts as a traceless prodrug moiety.[565]

5.18.1.11 HCV Internal Ribosome Entry Site (IRES) Inhibitors

The initiation of HCV polyprotein translation relies upon an IRES that extends from position 40 to 372 of the 5′ untranslated region of the viral RNA and is well conserved across virus genotypes.[566] This region of the viral genome adopts a highly structured fold that is defined by two major domains, labeled II and III, that contain the structural elements responsible for recognizing and recruiting the two initiation factors eIF2 and eIF3 and the 40S ribosome.[567–569] Flexible interconnecting linkers intervene between these domains and between domain III and domain IV where the AUG start codon is located in a stem loop structure at positions 342–344.[567–569] The earliest approach to targeting the HCV IRES relied upon antisense technology and ISIS-14803, a 20-unit phosphorothioate oligodeoxynucleotide designed to complement nucleotides 330–349 of the HCV IRES, inhibited HCV protein expression and replication in cell culture, and was active in a mouse model of HCV infection.[570,571] ISIS-14803 was evaluated in a phase 1 clinical trial where it was administered to subjects chronically infected with HCV as a 2 hr IV infusion at doses of 0.5, 1, and 2 mg kg^{-1} three times per week for 4 weeks with a 7-day washout period following the first dose.[572] However, plasma viral RNA was not reduced in the majority of the patients with just 3 of the 20 treated individuals experiencing transient reductions of 1.2–1.7 $\log_{10}$ IU mL^{-1} that persisted for up to 32 days. A follow-up phase 2 study conducted in GT-1-infected subjects evaluated doses of 0.5, 1, 2, and 3 mg kg^{-1} administered IV or subcutaneously 3 times a week for 4 weeks and produced a qualitatively similar result with only limited efficacy observed in 11 of 24 patients, while 17 subjects experienced ALT flares, a profile that that led to the development of the compound being terminated.[573,574]

The design of small molecules that target the various forms of RNA is an underexploited approach to drug discovery and an area of considerable contemporary interest where the focus is on developing a deeper understanding of the structure of RNA motifs and specifically the kinds of interactions that can be taken advantage of with small molecules.[575,576] The observation from cryoelectron microscopy studies that domain II of the HCV IRES induces a conformational change in the 40S ribosomal subunit once it is bound to elements of domain III, an event that is important for initiating translation, provided the basis of a high-throughput screen that sought small molecules binding to domain IIa.[577,578] A 29-mer derived from **228** (**Fig. 62**), which represents the stem loop of domain IIa, was prepared along with a 33-mer structured RNA used as a control and compounds selectively binding to **228** were identified using mass spectrometry. The 2-aminobenzimidazole **229** was characterized as an initial lead that bound to the 29-mer RNA with a K_d of 100 μM and exhibited a threefold selectivity compared with binding to the control RNA.[578] An optimization campaign found that introducing a second basic amine moiety at C-6 of the core improved affinity, and further refinement involved the introduction of conformational constraint. This design process arrived at **230**, a racemic mixture of *cis* and *trans* diastereomers, that bound to the 29-mer RNA with a K_d of 0.72 μM, representing a 25-fold improvement over the lead. Compound **230** exhibited antiviral activity in a subgenomic replicon, reducing HCV RNA levels with an EC_{50} value of 5.4 μM without overt cytotoxicity, $CC_{50} > 100$ μM. Mapping of the binding site using protection against RNase-mediated degradation of a larger 40-mer RNA identified uridine-55 and cytosine-56, residues in the bulge of **228**, as the ligand-binding region. Subsequent NMR studies with an analog of **230** binding to a 38-mer RNA that encompassed the sequence defined by **227** determined that inhibitor association with the bulge resulted in a structural reorganization of the RNA.[579] This study revealed that in the presence of the small-molecule ligand, the helical regions adjacent to the binding site adopted a coaxial structure that in the fuller IRES would be expected to orient the domain II apical loop away from the ribosomal E-site where eIF5 binds to the 40S

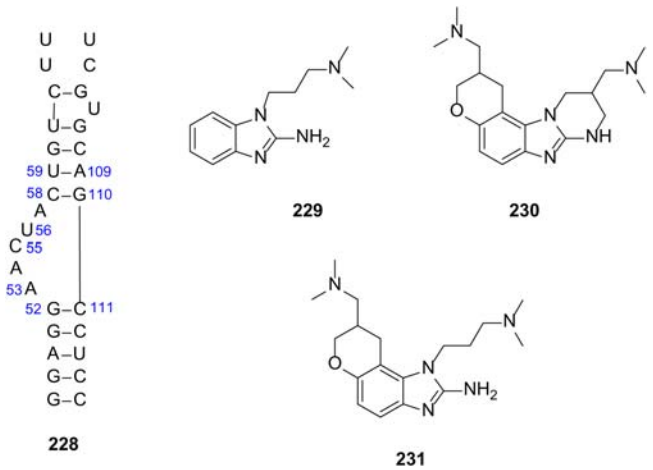

Fig. 62 Structure of a stem loop of domain IIa of the HCV IRES (**228**) and HCV IRES inhibitors **229–231**.

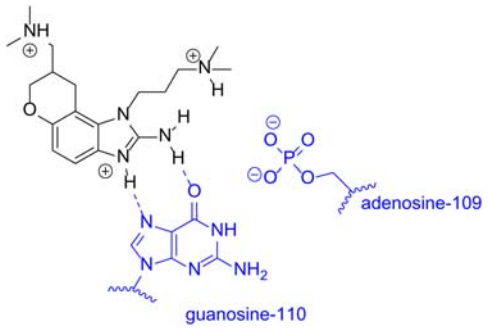

Fig. 63 Key interactions between **231** and elements of domain IIa of the HCV IRES.

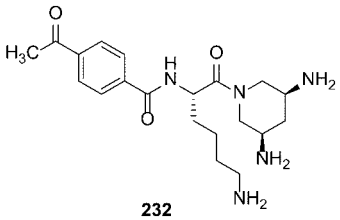
subunit. X-ray crystallographic studies of the native domain IIa revealed an L-shaped structural motif that plays a key role in positioning the domain II hairpin into the ribosomal E-site. In the presence of inhibitor **231**, which binds into a deep cavity, domain II is stabilized in a more linear architecture that prevents it from associating with the ribosomal E-site.[569,580–582] The inhibitor **231** associates with the heterocycle of the guanine of the cytosine-58–guanosine-110 base pair via H-bonding interactions and engages adenosine-53, which forms the ceiling of the binding pocket (Fig. 63).[569,582] In addition, the guanosine-52–cytosine-111 base pair, which forms the floor of the binding cavity, is involved in stacking interactions with the heterocycle of **231**, while the protonated dimethylamine side chain attached to the benzimidazole core interacts with the phosphate moiety of adenosine-109. The essential nature of guanosine-110 in ligand recognition was confirmed by analyzing two double mutants in which the crucial cytosine-58–guanosine-110 base pair was replaced by either a guanosine58–cytosine-110 or uridine-58–adenosine-110 base pair, with neither undergoing a conformational change in the presence of **231**.[582]

In contrast to the observations with the benzimidazoles **229–231**, the substituted lysine derivative **232** appears to act in a complementary fashion by competing with structurally important Mg^{2+} ions to stabilize the domain IIa RNA in the L-shaped conformation, with speculation suggesting that this interaction interferes with ribosome release.[569,583] Compound **232** was identified using an RNA-binding screen similar to that described earlier in the text, and no change in conformation of the RNA using a FRET assay was detected, in contrast to the observations with **229–231**.[583] In a cell-based replicon assay, **232** inhibited HCV IRES-mediated translation of a luciferase reporter at low micromolar concentrations that were not overtly toxic to the host cell line.



232

The residues that surround the binding site of **230** are >99% conserved across 1600 HCV clinical isolates, with adenosine-109 and cytosine-111 completely conserved and only three residues within domain IIa, adenosine-57, cytosine-104, and guanosine-107, exhibiting polymorphisms. These observations suggest that IRES inhibitors may be have a high genetic barrier to the emergence of resistance since mutations would be expected to compromise IRES function.[582] However, while these HCV IRES inhibitors are mechanistically interesting and provide some insight into approaches to productively targeting RNA, as HCV inhibitors in cell-based assays, they offer limited potency and thus remain prototypes that require considerable additional optimization if they are to be transformed into potential drug candidates.

5.18.2 Drug Combinations in Clinical Trials

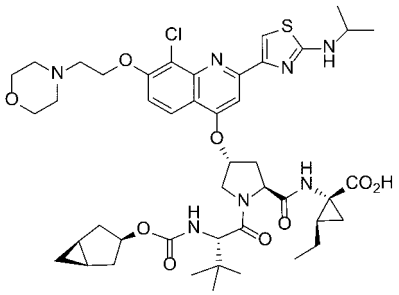
The drug discovery programs that began in the decade after the identification and characterization of HCV in 1989 developed in parallel with the evolution of HCV therapy from poorly effective daily doses of INF-α alone to weekly subcutaneous administration of PEG-IFN-α along with daily oral doses of ribavirin (**1**). This combination offered improved but still far from ideal cure rates (~50%) and with the burden of a significant incidence of unpleasant side effects over the 24–72 weeks of therapy associated with each drug. These early drug discovery efforts were hampered by the lack of a convenient cell culture system that supported HCV replication and the only animal model available was the chimpanzee, which could not be used routinely because of the expense. The advent of subgenomic replicons in 1999 represented a crucial advance that catalyzed drug discovery initiatives by providing a cell-based system that assessed the antiviral activity of candidate compounds in a more relevant environment while generating a target for plasma concentrations in vivo.[38] The impediment presented by the dearth of animal models was

circumvented by advancing compounds directly into clinical trials, where the efficacy of inhibitors could typically be assessed after just a few days of dosing to chronically infected subjects. Preclinical profiling of candidate compounds generally assessed PK parameters in several species and demonstrated liver exposure, typically in rats, with human dosing projections based on attaining plasma and/or liver levels that exceeded the replicon EC_{50} value. During much of the early period of DAA discovery and development, it was not clear if DAA combinations would be sufficient to cure HCV in the absence of the immune stimulation contributed by PEG-IFN-α and the indirect antiviral effects associated with **1**, particularly in difficult-to-treat populations.[584,585] There were also a large number of failures along the way with many of the early DAAs; indeed, almost all of the molecules that provided clinical proof of concept for a specific mechanism of action were terminated because of either preclinical or clinical toxicity or efficacy issues, the sole exception being the NS5A inhibitor daclatasvir (**7**).[73,74] It was estimated that by Mar. 2015, 712 candidate drugs had been considered for the treatment of HCV infection, of which 588 had failed, 12 had achieved marketed status and 112 were still in development.[74] However, the issues encountered by the pioneering molecules were of value in as much as they provided follow-on compounds with a clearer path toward clinical success.

Clinical trials with the early HCV DAAs **2** and **3** were by necessity studies of these drugs as add-on therapy to PEG-IFN-α and ribavirin (**1**), with both drugs approved based on improving response rates in GT-1-infected naive and experienced subjects from 45–55% to 65–75%.[586–589] However, therapy was still based on 48 weeks of treatment, the DAAs were administered on a TID schedule and each brought an additional tolerability burden, with **2** associated with a significant occurrence of rash and pruritus (35–59%), while **3** resulted in a worsening of anemia and a higher incidence of thrombocytopenia.[590,591] The first step toward DAA-only therapy was a small, 13-day clinical trial evaluating the combination of danoprevir (**65**) and mericitabine (**162**) in treatment-naive subjects and null responders.[592] The highest dose tested resulted in a 5.1 $\log_{10}$ IU mL^{-1} reduction in viral load measured on day 14 and all of these patients then continued on PEG-IFN-α and ribavirin (**1**) for 46 weeks. However, a key turning point in the development HCV DAAs occurred in 2012 with the publication of the results of a small phase 2a clinical study evaluating the combination of the NS3 inhibitor asunaprevir (**6**) and the NS5A inhibitor daclatasvir (**7**) in GT-1-infected subjects who either had failed to respond to PEG-IFN-α and ribavirin (**1**) (null responders) or experienced an initial reduction in viral load but ultimately failed therapy.[593] This study evaluated the combination of **6** and **7** with and without PEG-IFN-α and **1** for 24 weeks in what was considered to be the most difficult patient population to treat. All patients in the cohort of 10 receiving the quadruple therapy achieved SVR_{12} and 9 achieved SVR_{24}, while in the dual-therapy arm, 4 of 11 patients achieved SVR_{12} and SVR_{24}. Two of these subjects were infected with GT-1b virus and two were infected with a GT-1a strain, while the remaining seven patients, all of whom experienced viral breakthrough during therapy, were infected with GT-1a virus. The rapid emergence of resistance in the GT-1a-infected subjects can be attributed to the lower genetic barrier to resistance of this genotype that frequently requires only a single base pair change in order to code for a different amino acid, while genotype 1b generally requires two changes.[594–596] These results were important because they demonstrated for the first time that a chronic HCV infection could be cured without the use of immune stimulation by PEG-IFN-α and/or the inclusion of ribavirin (**1**) and were described as *a watershed moment in the treatment of hepatitis C*.[597] This clinical trial set the stage for what subsequently became an extensive study of DAA combinations that were evaluated in a wide range of patient populations extending to genotypes beyond GT-1 and including patients with and without cirrhosis, the renally impaired, those coinfected with HIV-1, and those in the post-liver transplant setting in addition to evaluating the effects of shortening the duration of therapy.

Whereas the combination of **6** and **7** would require a third agent to enhance efficacy in the treatment of GT-1a infections, the results with GT-1b-infected subjects provided the basis for a focus on phase 2 and phase 3 clinical trials in Japan where GT-1b is the predominant infecting strain, studies that ultimately led to this being the first DAA combination to achieve regulatory approval that occurred in July 2014.[69,598,599] In combination with the NS5B inhibitor beclabuvir (**185**), **6** and **7** effect high rates of cure (≥87%) in noncirrhotic and cirrhotic patients, while the combination of **7** with sofosbuvir (**4**) is an effective treatment of GT-1, GT-2, and GT-3 infections in subjects who are naive to or experienced with therapy, HIV-1-coinfected subjects, and those in the post-liver transplant patient population.[600–604]

The combination of sofosbuvir (**4**) and ledipasvir (**8**) is associated with >90% cure rates in GT-1 infections against a range of background conditions that include those naive to therapy or previously treated, those with or without cirrhosis, and subjects who are coinfected with HIV-1.[605–610] In a phase 2a clinical study conducted in therapy-naive GT-1-infected patients without cirrhosis, intensifying this dual-combination therapy to include either the NS5B inhibitor radalbuvir (**177**) or vedroprevir (GS-9451, **233**), a potent inhibitor of GT-1 HCV NS3 protease, resulted in 19 of 20 subjects achieving SVR_{12} in each arm after just 6 weeks of therapy.[611–614]



233
vedroprevir (GS-9451)

The fixed-dose combination of sofosbuvir (**4**) and ledipasvir (**8**) is an effective therapy for GT-4 infections, but GT-2 and GT-3 infections require the addition of ribavirin (**1**) in order to achieve high SVR_{12} rates, although GT-2 and GT-3 infections can be treated effectively with sofosbuvir (**5**) and ribavirin (**1**) alone.[70,615,616] However, 12 weeks of therapy of a fixed-dose combination of sofosbuvir (**4**) and velpatasvir (**130**) provided SVR_{12} rates of 95 to >99% in HCV genotypes 1–6, providing a well-tolerated pan-genotypic drug regimen.[617–620] In patients with advanced cirrhosis or those who had failed previous therapy, the SVR_{12} rates ranged from 89 to 91%, while for those with decompensated cirrhosis, the cure rates were 83% in the absence of **1** and 94% when this drug was included in the regimen.

Viekira Pak™ was developed for the treatment of GT-1 infections and is associated with high rates of cure in treatment-naive and treatment-experienced patients with and without cirrhosis, those coinfected with HIV-1, and those in a post-liver transplant setting where SVR_{12} rates are in excess of 85%.[71,621–625] Cirrhotics fare better with the addition of ribavirin (**1**) to the regimen and this therapy is also effective in those infected with GT-4, where SVR_{12} rates in excess of 95% were achieved in a phase 2b clinical trial conducted in experienced patients and those naive to therapy.[626]

There are several additional drug combinations in advanced clinical studies or that have completed phase 3 trials that are designed to be effective against all genotypes and that, if successful, will add to the available options to treat HCV infection.[564,627,628]

5.18.3 Conclusion

The advent of combination antiretroviral therapy in 1995 had a significant impact on mortality due to HIV-1 infection, with a rapid and marked decline in death rates following the approval of the first protease inhibitors that were combined with existing nucleoside analogs.[629,630] By 2007, HCV infection had surpassed HIV-1 as a cause of mortality in the United States.[631] Predictions of morbidity and mortality as a consequence of HCV infection in the absence of effective therapy suggested a continuous rise in the incidence of serious complications arising from the disease that would peak between 2030 and 2035 before subsiding.[632–634] This analysis estimated 38,600 cases of end-stage liver disease, 3200 liver transplant referrals, and 36,100 deaths that would occur annually during the peak years. The successful development of orally acting DAAs that are well tolerated and lead to high rates of cure of HCV infection after 8–24 weeks of therapy has the potential to significantly alter the course of these predictions and reduce the significant morbidity and mortality that was anticipated in their absence.[15,635,636] However, many questions remain concerning the precise outcome of curing HCV infection for individual patients as a fuller understanding of the effects of chronic infection on the liver and the potential for fibrosis and cirrhosis to reverse as well as the outcome of the insult placed on extrahepatic sites becomes more apparent from experience.[637] While the DAA combinations that have been approved or are in late stages of clinical testing offer high rates of cure are well tolerated and cost-effective, the scope of the epidemic is presenting a significant financial challenge for health authorities to manage.[638–642] Nevertheless, the development of DAAs that cure chronic HCV infection with well-tolerated drugs administered orally on convenient dosing schedules represents a medical triumph that has its roots firmly in the basic science and intellectual creativity associated with contemporary drug design and development.[11–16]

5.19.1 Human Immunodeficiency Virus

The advent of highly active antiretroviral therapy (HAART) for human immunodeficiency virus (HIV) infection has transformed acquired immune deficiency syndrome (AIDS) from a fatal disease to a manageable, long-term, chronic condition.[1] As treatment regimens have improved, the life expectancy of HIV patients has increased dramatically.[2,3] This transformation represents one of the great accomplishments of medicinal chemistry, and indeed of biomedical research, in the last century. When the first antiretrovirals for HIV were used clinically, it quickly became clear that single agents were inadequate for long-term suppression of the virus due to rapid emergence of HIV strains resistant to the drugs being administered. But greater understanding of the viral life cycle subsequently enabled the discovery of antiretroviral agents whose combination suppressed resistance and led to long-term control over viral replication (see Chapter 50017).[4] Much of the history of this momentous accomplishment was detailed in the previous iteration of *Comprehensive Medicinal Chemistry*, published in 2007, including the development of nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and entry inhibitors, as well as newer areas of research including integrase and maturation inhibitors.[5] In this update, new medicinal chemistry research in these and other drug classes is described. This work has led to more powerful, better-tolerated, and simplified treatment regimens for HIV patients. In addition, recent strategies and efforts aimed at true eradication or cure of HIV are reviewed.

5.19.1.1 HIV Life Cycle and Drug Targets

The life cycle of HIV is both one of the most complex and most well-studied processes in virology (Fig. 1). Researchers have attempted to target nearly every step in the process with small-molecule drugs. The life cycle commences with a mature HIV virion binding to a CD4 cell via the CD4 receptor and co-receptors CCR5 and CXCR4. This initial binding has been targeted by entry inhibitors such as maraviroc. This is followed by fusion to the cell membrane, a process targeted by fusion inhibitors (enfuvirtide), and uncoating of the viral capsid releasing the viral RNA. Reverse transcription of this RNA to viral DNA (targeted by both NRTIs and NNRTIs), formation of the preintegration complex, and translocation to the nucleus is followed by integration of the viral DNA to the host genome by the viral integrase [targeted by both integrase strand-transfer inhibitors (INSTIs) and noncatalytic integrase inhibitors (NCINIs)]. Transcription of the viral DNA to new viral RNA and proteins is followed by assembly as new immature virus. After budding and release, the viral protease cleaves the polyprotein to form the mature Gag protein (targeted by PIs), and the resultant mature HIV virions are ready to infect new cells.[6,7]

5.19.1.2 Current Regimens—Evolution of Treatment Guidelines 2006 Versus 2014

The last decade has seen significant improvements in both individual agents and clinical regimens for HIV, and these are reflected in a comparison of the treatment guidelines published by the International Antiviral Society—USA Panel from 2006[9] versus 2014[10] (Tables 1 and 2). In both sets of recommendations, treatments with two NRTIs plus a third agent with a different mechanism were preferred. In 2006, three nucleoside combinations were included along, with two NNRTIs and four PIs. Choices were based on many factors, including the side effect profile of the drugs involved as well as the viral genotype of the patient to determine which drug combinations would prove most effective.

In 2006, the side effect profile for many of the individual agents and regimens were daunting and likely played a role in limiting adherence. The choice of third agent (NNRTI or PI) was nuanced: NNRTIs showed higher tolerability, but a greater propensity for development of resistance, whereas PIs showed worse tolerability, but a significantly stronger resistance profile. Also, although some agents were dosed once daily (QD), several recommended agents were twice daily, resulting in many different complicated regimens. Taken together, the combination of side effects and complicated dosing protocols for many of the better regimens in 2006 limited overall efficacy.

By 2014, several agents with the least favorable tolerability profiles, dosing schedules and efficacy were dropped from the recommended list. These include the NNRTI nevirapine, the PIs lopinavir, fosamprenavir and saquinavir, and the nucleoside combination zidovudine/lamivudine. In addition, each recommendation now constitutes a complete regimen containing two NRTIs and a third agent; overall, the recommendations are considerably simplified.

The biggest change in the recommendations was the inclusion of INSTIs as a new third agent class. Regimens containing the three approved INSTIs raltegravir, elvitegravir, and dolutegravir show good efficacy with generally improved tolerability compared with

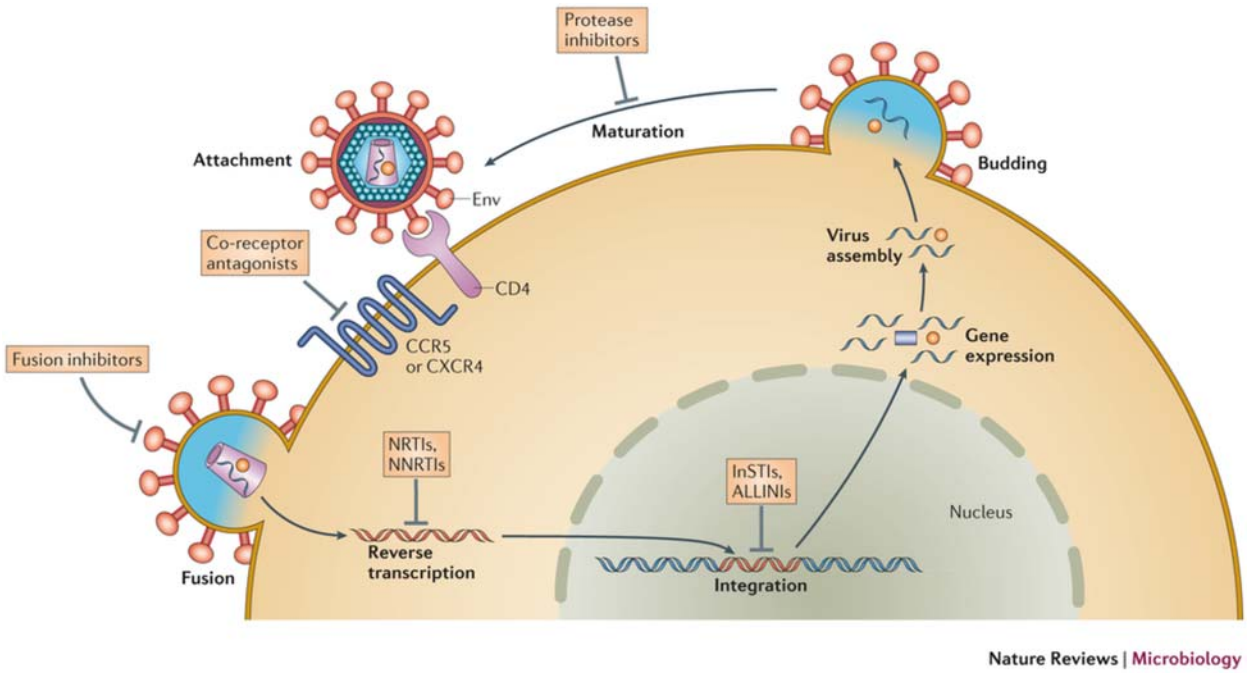

Fig. 1 The HIV life cycle and drug targets.[8] http://www.nature.com/reprints/permission-requests.html.

Table 1 Recommended components of initial antiviral therapy taken from the 2006 International Antiviral Society recommendations[7]

Component	*Considerations*	*Major toxic effects and cautions*	*Resistance considerations*
NRTIs	Well tolerated	Baseline renal function should be evaluated	M184V and K65R
Tenofovir disoproxil fumarate (TDF)/ emtricitabine	Efficacy > zidovudine/lamivudine or stavudine/lamivudine Spares thymidine analogs Fixed dose, QD	before initiating Use with caution or avoid in patients with renal dysfunction	
Zidovudine/lamivudine	Most extensive clinical trial data set and Phase IV experience supporting use Standard-of-care comparator in many trials Fixed dose, BID	Headache, nausea Anemia Liopatrophy	M184V and thymidine-analog-associated mutations
Abacavir/lamivudine	Supportive clinical trial data Spares thymidine analogs Fixed dose, QD	Hypersensitivity syndrome in 5–8% of persons (greater risk in person with the HLA-B5701 genotype)	M184V and K65R
NNRTIs	Efficacy proven in controlled trials	CNS toxic effects may be limiting	Single-step high-level resistance occurs with treatment failure with cross-resistance to nevirapine
Efavirenz	Standard-of-care comparator in many trials Fixed dose	Teratogenic in the first trimester of pregnancy	
Nevirapine	Efficacy proved in controlled trials Safe to fetus	Rash Hepatotoxicity Hypersensitivity syndrome Avoid in women with > 250 CD4 cell mL^{-1} and men with > 400 CD4 cells mL^{-1}	Single-step high-level resistance occurs with treatment failure with cross-resistance to efavirenz
Ritonavir-boosted protease inhibitors	Substantial clinical trial data set and Phase IV experience supporting	Gastrointestinal adverse events Hyperlipidemia	Protease inhibitor mutations are rare in treatment failure if virus is fully susceptible at baseline
Ritonavir-boosted Lopinavir	efficacy Heat-stable formulation available QD or BID for treatment naive BID for treatment experienced	Lipodystrophy Insulin resistance	
Ritonavir-boosted Atazanavir	Decreased potential for hyperlipidemia than with other protease inhibitors QD	Hyperbilirubinemia (UGT1A1-28 alleles and T3435C polymorphism in MDR1 gene) Avoid concomitant antacid use (separate dosing times) Do not use concomitant proton pump inhibitors	Limited data on resistance mutations in previously antiretroviral-naive patients
Ritonavir-boosted Fosamprenavir	No food restrictions	Rash	Limited data on resistance mutations in previously antiretroviral-naive patients
Ritonavir-boosted Saquinavir	Lower lipid effects(?) Soft-gel formulation is less effective than ritonavir-lopinavir	Gastrointestinal toxic effects with soft-gel formulation; incidence diminished with hard-gel formulation	Limited data on resistance mutations in previously antiretroviral-naive patients

Table 2 Initial antiviral regimens taken from the 2014 International Antiviral Society recommendations[8]

Regimen type	*Combination*	*Considerations*
INSTI plus 2 NRTIs	Dolutegravir plus tenofovir disoproxil fumarate (TDF)/ emtricitabine	Dolutegravir associated with modest increases in creatinine levels
	Dolutegravir plus abacavir/lamivudine	
	Elvitegravir/cobicistat/TDF/emtricitabine	Cobicistat is associated with modest increases in creatinine levels; has similar drug interactions to ritonavir
	Raltegravir plus TDF/emtricitabine	Raltegravir is taken twice daily
NNRTI plus 2 NRTIs	Efavirenz/TDF/emtricitabine	Efavirenz is associated with CNS side effects
	Efavirenz plus abacavir/lamivudine	Efavirenz is associated with CNS side effects
	Rilpivirine/TDF/emtricitabine	Rilpivirine-based therapy is not recommended in patients with baseline viral load > 100,000 copies mL^{-1}
Ritonavir-boosted PI plus 2 NRTIs	Atazanavir plus TDF/emtricitabine	Atazanavir is associated with nephrolithiasis, cholelithiasis, and chronic kidney injury
	Atazanavir plus abacavir/lamivudine	Atazanavir is associated with nephrolithiasis, cholelithiasis, and chronic kidney injury
	Darunavir plus TDF/emtricitabine	

PI-based regimens. Notably, nearly all the recommended third agents are dosed QD (with the exception of raltegravir), though PIs still require a boosting agent. Four of the 10 regimens are available as single-tablet regimens (STRs)—a simplification that can lead to improved adherence.

The other significant change that occurred between 2006 and 2014 is the recommendation to begin HIV treatment as soon as the patient is diagnosed and not wait for the immune system to show signs of failure (low CD4 counts).

5.19.1.3 Adherence and Resistance

The development of viral resistance has long been recognized as the main obstacle for the long-term suppression of HIV.[11] Maintaining viral suppression and inhibiting resistance require both potent drug combinations and high levels of adherence, and in the early days of HIV treatment this was difficult due to complicated and poorly tolerated regimens.[12]

Over the last 10 years, improvements in the efficacy and tolerability of HIV agents have led to both higher levels of adherence and viral suppression. Further, as the regimens have improved it has been recognized that complete adherence may no longer be necessary to maintain suppression. In 2007, near perfect levels (95% and up) of adherence to prescribed regimens were required to achieve the highest levels of viral suppression.[13] However, a 2015 study showed that somewhat lower levels of adherence (85–90%) with newer agents can still be associated with high levels of viral suppression.[14] This is likely due in part to improved overall characteristics of the individual agents and regimens (more potent compounds, longer half-lives, higher individual barriers to resistance, and better tolerability). Further, there is now significant evidence that simplification to STRs leads to higher adherence and better outcomes as well.[15,16]

5.19.1.4 Integrase Inhibitors

The discovery and development of INSTIs has led to one of the most significant changes to HIV treatment over the past decade—INSTIs have become the third agent of choice for most of the currently recommended HIV regimens. Prior to 2007, nearly all naive HIV patients were treated with a triple combination containing two NRTIs and either a PI or an NNRTI. Though these regimens are efficacious for many patients, they have limitations—patients on NNRTI-based regimens tend to develop viral resistance more quickly, and patients on PI-based regimens are subject to more frequent and severe adverse events. In addition, development of resistance to the NNRTI- and PI-based regimens was still causing some patients to fail therapy. In this context, researchers were eager to discover new antivirals targeting other parts of the viral life cycle. Indeed, efforts targeting many vital aspects of the life cycle were undertaken, and out of these efforts INSTIs have emerged with the best combination of efficacy and tolerability. Three INSTIs have been approved for the treatment of HIV: raltegravir (**1**, 2007), elvitegravir (**2**, 2012), and dolutegravir (**3**, 2014). Due to their great efficacy and relatively good tolerability they have rapidly become the first choice of regimens. Indeed, a recent meta-analysis of 48 clinical studies suggests that regimens containing INSTIs are superior to others.[17]

5.19.1.4.1 Raltegravir

Raltegravir (**1**) was the first FDA-approved INSTI, and its discovery has been described extensively.[18–20] High-throughput screening campaigns led to the identification of diketo acids like **4** (Fig. 2). These compounds are divalent cation binders and were found to bind to and inhibit HIV integrase and, subsequently, HCV NS5B. A collaboration between Integrated Research Biotech Model

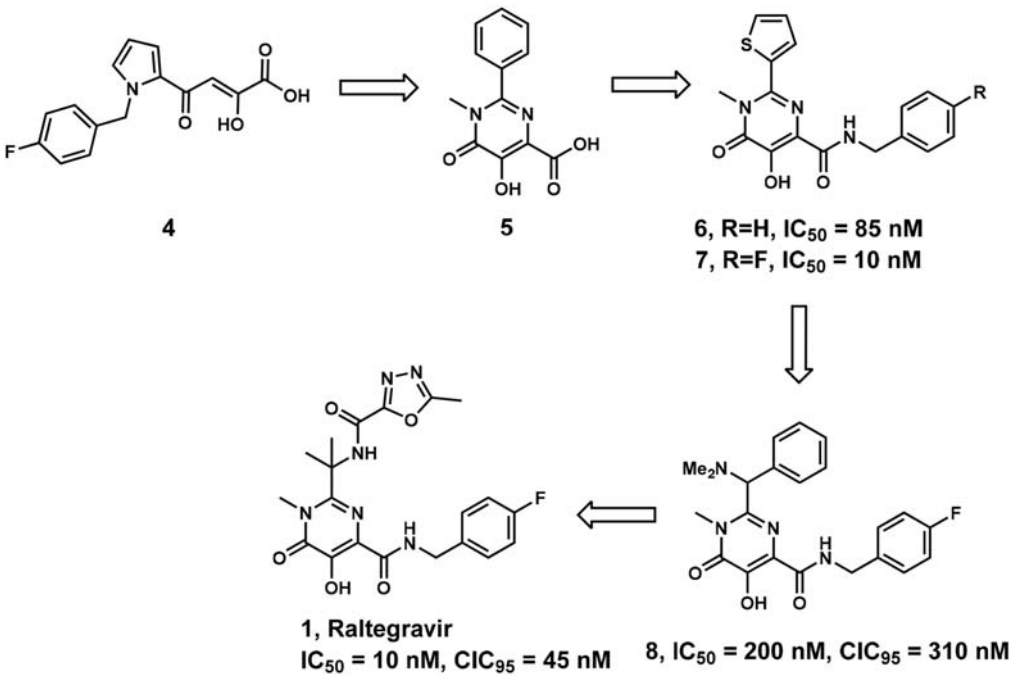

Fig. 2 Discovery of raltegravir.

(IRBM) in Rome and Merck West Point found a suitable replacement for the diketo acids in dihydroxypyrimidine **5**. Though this compound lacked cell-based activity, it was further optimized by the addition of a 4-fluorobenzylamide giving compound **7** with a biochemical potency of 10 nM. The addition of a basic substituent at the 2-position of the core gave the first compound with cell-based activity (**8**, $CIC_{95} = 310$ nM). Finally, an extensive investigation of the 2-position was undertaken with an eye toward finding the optimal level of plasma protein binding. High protein binding led to unacceptably high potency shift under high serum conditions. Lower levels led to higher clearance in animals. The methyl-oxadiazole analog **1** provided for optimal protein binding and became raltegravir.

Clinical studies with raltegravir show impressive response rates. In naive patients in combination with tenofovir disoproxil fumarate (TDF)/emtricitabine, twice daily administration led to a higher suppression rate compared to the NNRTI efavirenz: virologic suppression was observed in 86.1% of patients in the raltegravir group compared with 81.9% in the efavirenz group.[21] In the same combination context, Phase III studies established that twice daily administration of raltegravir was more efficacious than QD: 89% of patients on the twice daily regimen responded versus 83% of patients in the QD cohort.[22] In a study of multidrug-resistant HIV patients, twice daily raltegravir (400 mg) added to regimens containing an average of four other antiretrovirals brought 53.3% of patients to full suppression (<50 copies mL^{-1}).[23] Raltegravir was approved in 2007.

5.19.1.4.2 Elvitegravir

The discovery of elvitegravir (EVG) began with a different divalent cation-binding motif—the monoketo acid **9** (Fig. 3). Though this compound had only weak integrase activity (1.6 μM) and no measurable cellular activity, it was found that potency could be improved dramatically with the addition of two halogens on the benzyl group and an ethanol moiety attached to the pyridine (**10**). Further exploration of the SAR in this series revealed that the addition of an isopropyl group to the ethanol side chain or the attachment of a methoxy group to core each increased cellular potency significantly (10- and 4-fold, respectively). Combination of these motifs gave EVG with a cellular potency of 0.9 nM.[24] EVG shows high potency against many wild-type HIV strains with potencies below 1 nM in most cases. In vitro resistance selection experiments demonstrated that selection pressure with EVG can lead to single-point mutants with >30-fold resistance (T66I and E92Q).[25]

Elvitegravir was co-formulated with the booster cobicistat (COBI) to allow for QD dosing, and when combined with the NRTIs TDF and FTC in Phase III studies, the four-drug regimen was found to be equally as effective (noninferior) as the NNRTI-based regimen EFV/FTC/TDF,[26] as well as the PI-based regimen ATZ/RTV + FTC/TDF.[27] In addition, significantly lower rates of neurological side effects were observed for the EVG-based regimen as compared to the EFV-based regimen, and lower rates of bilirubin abnormalities as compared with the ATZ-based regimen. The EVG combination showed a higher incidence of nausea compared with the EFV combination. EVG/COBI/FTC/TDF was approved by the FDA in 2012 as the first STR containing an integrase inhibitor.[28]

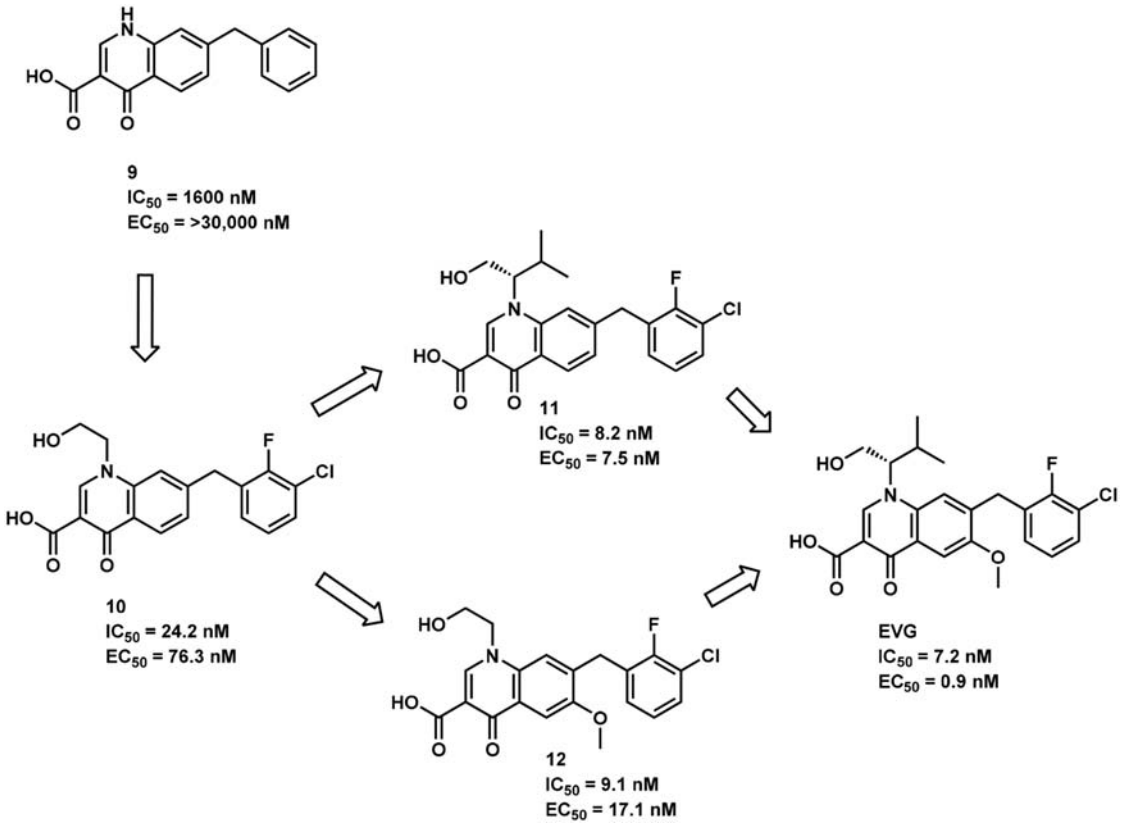

Fig. 3 Discovery of elvitegravir.

5.19.1.4.3 Dolutegravir

An extensive analysis of known integrase inhibitor scaffolds including raltegravir, elvitegravir, and others based on quinolones provided the basis for the discovery of dolutegravir (DTG, Fig. 4). Using data from foamy virus integrase crystal structures as a guide, a pyridine scaffold was incorporated to orient the divalent metal-binding motif and lipophilic tail optimally (compound **13**, $IC_{50} = 10$ nM).[29] Cyclization to bicycle **14** resulted in an increase in wild-type potency (1.6 nM), but this compound shows a significant loss in potency to the known integrase mutant Q148K (22-fold change).[30] At the same time, it was found that hemiaminal **15** showed good wild-type potency (3.8 nM) with only a small Q148K shift (2.1). This compound suffered from low bioavailability in

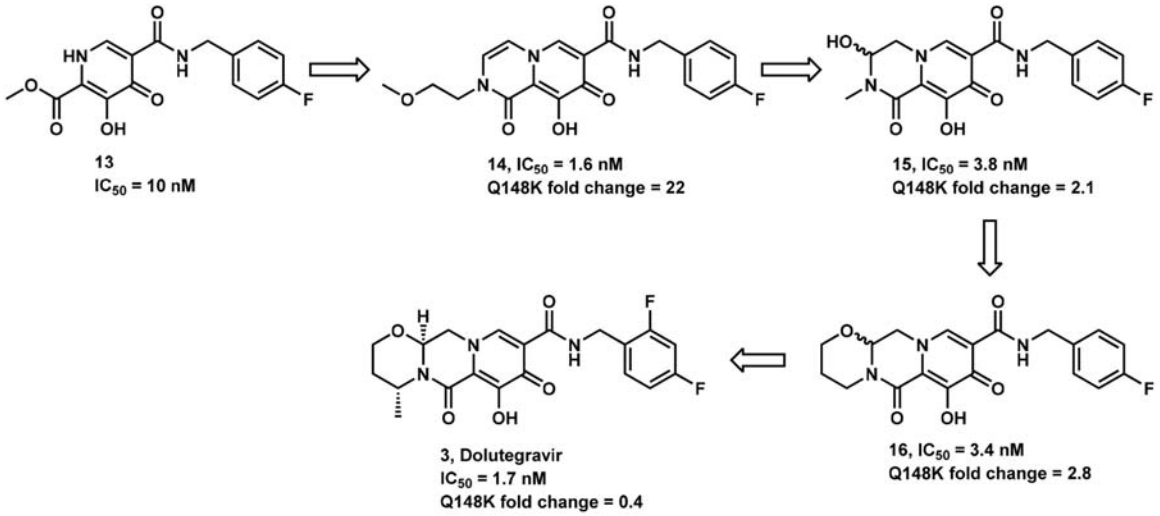

Fig. 4 Discovery of dolutegravir.

Table 3 Activity of DTG and RAL against RAL-resistant HIV strains

		Fold change	
Patient # (week at RAL failure)	*Genotype*	*DTG*	*RAL*
1 (8)	Y143K	1.26	10.5
1 (8)	E138K and Q148K	3.01	50.12
2 (24)	T97A and Y143C	1.72	45.3
3 (24)	V72I, Y143R, and T206S	1.92	72.41
4 (24)	G140S and Q148H	10.39	327.84

rat as well as stereochemical instability. The addition of a third ring gave racemate **16**, a compound with good potency (3.4 nM) and small Q148K shift (2.8) and very good pharmacokinetics profile in rats ($t_{1/2} = 17$ h, $F(\%) = 51$). Investigation of different substitutions around the aminal ring afforded monomethyl analog **3**, which became dolutegravir. This compound showed excellent potency against WT virus as well as Q148K, and pharmacokinetic profiles in preclinical studies suggestive of a QD profile in humans.[31]

DTG shows a significantly improved resistance profile compared with first-generation integrase inhibitors, maintaining significant potency against many of RAL-resistant clinical isolates (Table 3).[32]

In a large Phase III trial, QD DTG (50 mg) regimens achieved noninferiority to twice daily raltegravir regimens (400 mg twice daily).[33] Frequency and severity of adverse events were similar in both groups. In another trial, the combination of DTG with abacavir and lamivudine was shown to provide a superior level of viral suppression compared with efavirenz-TDF–FTC (88% vs. 81%), though this difference was primarily due to a greater number of discontinuations in the efavirenz group.[34] Similarly, DTG regimens have shown superiority over darunavir regimens—also primarily due to fewer discontinuations.[35] Further, the improved resistance profile of DTG has been demonstrated in a clinical trial of treatment-experienced patients in which DTG was shown to provide effective viral suppression for 75% of patients with preexisting RAL and EVG mutations when given twice daily.[36] The improved resistance profile for DTG has been attributed to the kinetics of enzyme inhibition; DTG has much longer k_{off} rates than first-generation integrase inhibitors RAL and EVG.[37] DTG has recently been approved as part of a STR with abacavir and lamuvidine, and this is currently the only unboosted, STR containing an integrase inhibitor.[38]

5.19.1.4.4 Other clinical- and preclinical-stage integrase inhibitors

Work on new integrase inhibitors continues. Cabotegravir, discovered concurrently with dolutegravir,[39] has a very long human half-life and is being investigated clinically as a long acting injectable in combination with the NNRTI rilpivirine (Fig. 5).[40] Bictegravir (GS-9883), a new INSTI shows a longer human half-life and improved resistance profile compared to currently approved INSTIs.[41] In a 10-day Phase I study, QD bictegravir showed a >2 $\log_{10}$ viral load reduction at doses at or above 25 mg day^{-1}, and the compound is being studied in Phase II in combination with tenofovir alafenamide (TAF) and emtricitabine.[42] MK-8970, a prodrug of RAL, shows improved bioavailability in the colon, effectively lengthening the time absorption that takes place, and thus has potential for QD dosing.[43] PF-47765480, containing an N-hydroxyl-amide chelator, showed good potency and an improved

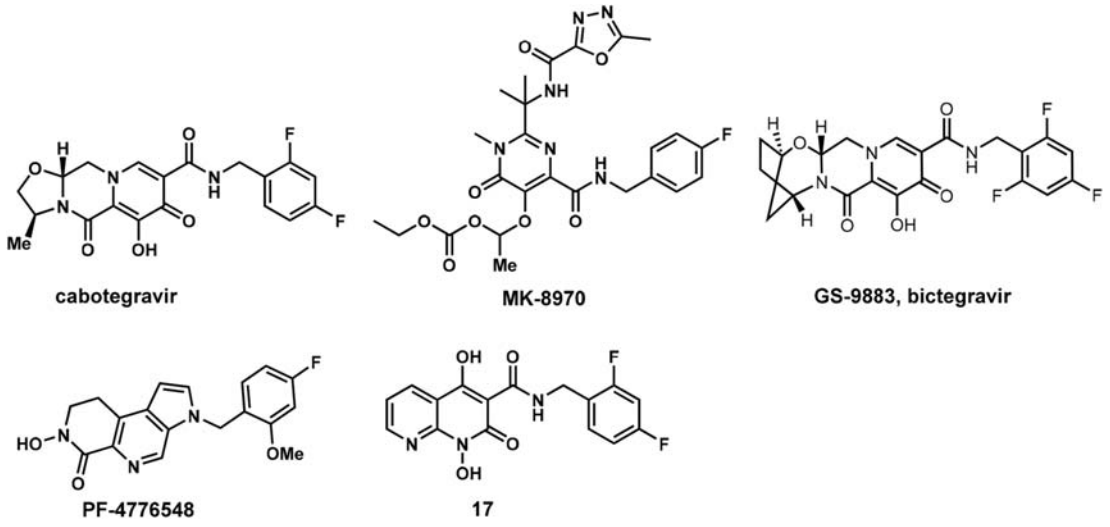

Fig. 5 Structures of recent clinical- and preclinical-stage INSTIs.

resistance profile compared to RAL and EVG. However, a human PK study using a microdose of the compound revealed higher than expected human clearance and a short human half-life (2.8 h).[44] An N-hydroxyquinolone series exemplified by **17** has also been reported to exhibit single-digit nanomolar potencies and improved coverage of some RAL-resistant mutants.[45]

5.19.1.5 Nucleoside Reverse Transcriptase Inhibitors

Since the regulatory approval of the first nucleoside analog zidovudine (AZT) in 1987 as a monotherapy for HIV, nucleoside or NRTIs have been established as the backbone for therapeutic regimens for the treatment of HIV infection.[46–48] NRTIs mimic endogenous 2′-deoxy-nucleosides and nucleotides and require intracellular phosphorylation by host cell kinases[49,50] to form their respective active triphosphate metabolites, which are incorporated by and inhibit reverse transcription. Each of the approved antiretroviral NRTIs (**Fig. 6** and **Table 4**) lack the 3′-hydroxyl moiety and thus cause obligate chain termination of the viral reverse transcripts. The standard of care for the treatment of HIV, known as HAART, includes combinations of three or more drugs of which two are typically NRTIs owing to their high genetic barrier to resistance, potent activity, and in general long intracellular persistence, which translates to lower dosing frequency. Limitations of NRTI's, however, include drug-drug interactions,[51] emergence of resistance,[52,53] and especially adverse events,[54] which have had the greatest impact on guidelines for current HAART.[55]

A majority of the adverse events observed with NRTIs, especially pertaining to AZT, zalcitabine (ddC), stavudine (d4T), and didanosine (ddI), have been associated with inhibition of mitochondrial DNA polymerase gamma (mtDNA).[56] The thymidine-based NRTIs stavudine (d4T) and AZT have both been associated with lipoatrophy.[57,58] AZT has also been associated with myopathy, cardiomyopathy, and anemia, all of which are attributed to indirect depletion of mitochondrial DNA through inhibition of thymidine phosphorylating enzymes, affecting endogenous mitochondrial thymidine triphosphate concentrations.[59] As well as causing lipodystrophy, stavudine has also been associated with peripheral neuropathy[60] and as a result is no longer considered an appropriate treatment for patients. The cytidine-based NRTI zalcitabine (ddC), while highly potent,[61] has a short half-life requiring three times daily dosing, and has also been associated with adverse events resulting from depletion of mitochondrial DNA.[62] The sale and distribution of ddC has been discontinued. Didanosine (ddI) has been associated with short-term toxicities including lactic acidosis, pancreatitis, peripheral neuropathy,[54] and myocardial infarction,[63] as well as with noncirrhotic portal hypertension in patients on long-term therapy.[64]

Modern antiretroviral therapies have shifted away from NRTIs that exhibit high potential for mitochondrial toxicity and have moved toward the use of TDF, 3TC, emtricitabine (FTC), and abacavir (ABC), which exhibit improved safety profiles. TDF and FTC are the two NRTIs that are preferred for first-line combination regimens by virtue of their potent and durable efficacy and established long-term safety in combination therapies.[65–69] TDF is a bis(isopropyloxycarbonyloxymethyl) ester prodrug of tenofovir (TFV), employed to improve oral bioavailability of the parent, and is the most widely prescribed antiretroviral drug worldwide. While it has a favorable safety profile, long-term TDF therapy has been associated with renal adverse events[70] as well as bone density loss,[71,72] in small patient populations. These adverse events are attributed to the high plasma exposures of TFV, a consequence of the low plasma stability of the prodrug moiety. TFV accumulation in renal proximal tubule cells due to transport by human OAT1 has been implicated in the renal insufficiency observed.[73] A prodrug of TFV, tenofovir alafenamide (TAF, vide infra), which has improved plasma stability to mitigate this toxicity, has recently received regulatory approval.

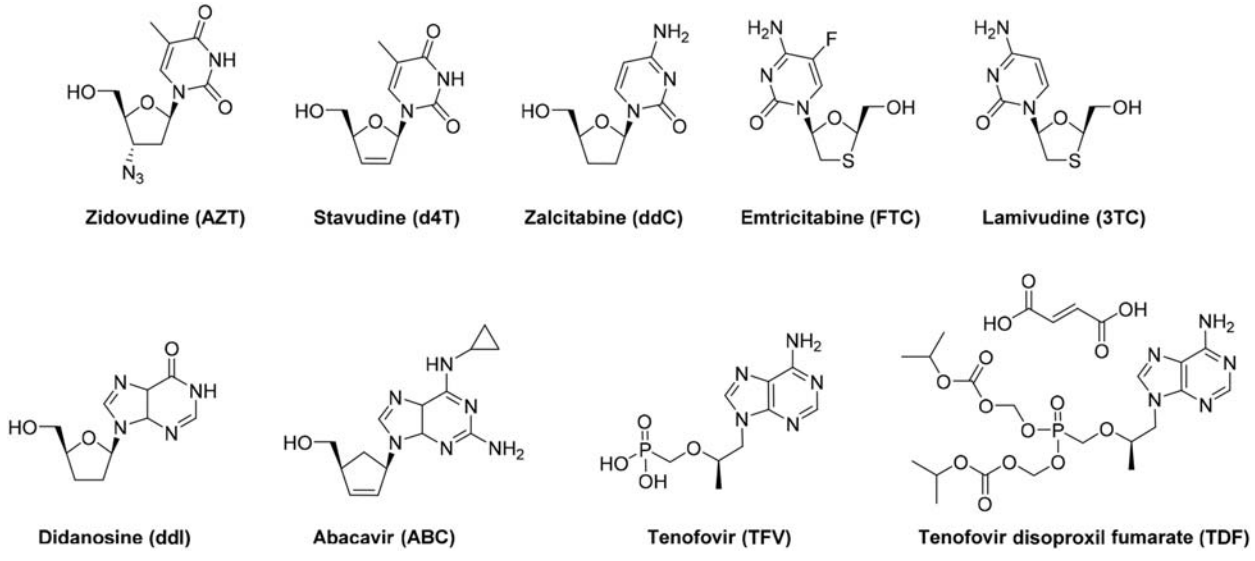

Fig. 6 Structures of approved pyrimidine- and purine-based NRTIs.

Table 4 FDA-approved NRTIs

Drug	Approval year	Dosage (mg)	Dose frequency[a]	F%[b,47]	Plasma $t_{1/2}$ (h)[48]	Intracellular TP $t_{1/2}$ (h)[c,48]	Resistance mutations[52]	Adverse effects[54]
AZT	1987	300 200	bid tid	75%[82]	0.5–3	7[83]	Q151M	Dyslipidemia, myopathy, anemia, nausea, and rash
ddI	1991	250–400 125–200	qd bid	30–42%	1.5	24[84]	K65R, L74V, and Q151M	Lipoatrophy, dyslipidemia, lactic acidosis, pancreatitis, distal sensory polyneuropathy, and hepatic steatosis
ddC	1992	0.75	tid	>80%[85]	1–3[86]		Q151M	Lactic acidosis, pancreatitis, peripheral neuropathy, myocardial infarction, and portal hypertension
d4T	1994	30–40	bid	99%[87]	1.2	7[84]	V75T and Q151M	Lipoatrophy, dyslipidemia, lactic acidosis, pancreatitis, DSPN, and hepatic steatosis
3TC	1995	300 150	qd bid	86–87%	5–7	22[83]	M184VI and K65R	Negligible
ABC	1998	600 300	qd bid	83%	1.54	21[79]	M184V, K65R, L74V, and Q151M	Hypersensitivity, hepatotoxicity, and heart disease
TDF	2001	300	qd	25–39%	~17	>60[88]	K65R and K70E	Renal insufficiency and bone loss
FTC	2003	200	qd	93%	10	39[89]	M184VI and K65R	Skin discoloration

[a]qd, once daily; bid, twice daily; tid, three times daily.
[b]*F*%, oral bioavailability.
[c]Terminal half-life in PBMCs.

FTC is a fluorinated cytidine analog featuring an oxathiolane replacement for the ribose ring. Importantly, the FTC conformation is in the unnatural L-enantiomeric form, which is more potent and less toxic than the S-antipode and provides an excellent selectivity profile.[74] FTC is relatively well tolerated in patients with side effects that include headache, insomnia, diarrhea, nausea, vomiting, rash as well as hyperpigmentation on the palms and/or soles.[75,76]

Lamivudine (3TC) is closely related in structure to FTC but lacks the 5-fluoro substitution on the cytidine base, and the two have very similar profiles. Compared to FTC, 3TC is slightly less potent in in vitro assays, has a shorter serum and intracellular half-lives, and has lower bioavailability which translates to a moderately higher dose.[74,77] ABC is a diaminopurine-based nucleoside with a cyclopentene in place of the ribose ring.[78]

ABC is a prodrug that undergoes intracellular metabolism to the monophosphate by adenosine phosphotransferase followed by further enzymatic conversion of the cyclopropyl diaminopurine to guanosine to afford carbovir monophosphate.[79] ABC causes a hypersensitivity reaction in approximately 8% of treated patients, related to histocompatibility complex class 1 human leukocyte antigen 57.1 haplotype.[80] Genetic testing is available to prescreen patients that may be predisposed to this hypersensitivity. ABC has also been associated with an increased risk of myocardial infarction.[63]

In therapeutic practice, the resistance profiles of the NRTIs discussed above are weighed against their potential side effects. The most common resistance mutations include M184V/I, arising from FTC and 3TC use, as well as thymidine analog mutations (TAMs)—see Chapter 50017.[52,53] Although the prevalence of M184V/I mutants is high their fitness is greatly reduced,[81] and FTC and 3TC are still used in first-line treatment with TDF or ABC.

5.19.1.5.1 Tenofovir alafenamide

TAF is the phenoxy isopropyl L-alaninate phosphoramidate prodrug of TFV (Fig. 7), and the first reports of synthesis and isolation appeared in 2001.[90,91] The EC_{50} of TAF in MT-2 cells is 0.005 μM, compared to 5 μM for the parent TFV and 0.05 μM for TDF, and it has been shown to more efficiently load lymphoid cells and tissues as compared to TDF.[92] The improved pharmacology of TAF is

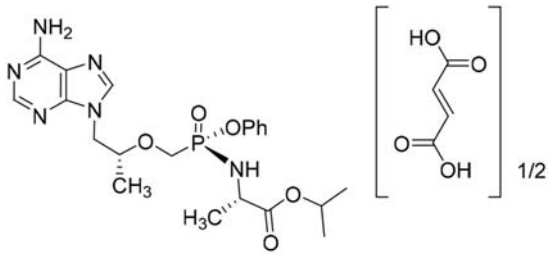

Fig. 7 Structure of tenofovir alafenamide (TAF) in the hemifumarate form.

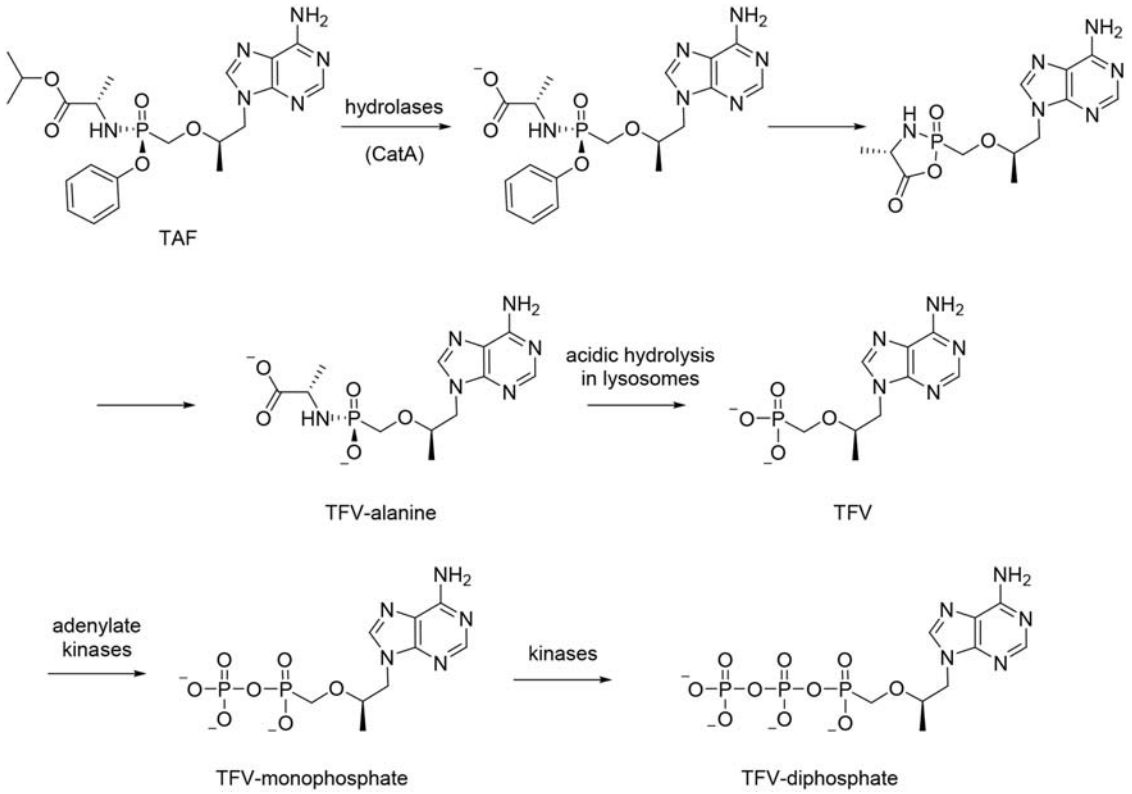

Fig. 8 Mechanism of the intracellular activation of TAF.

attributed to its distinct mechanism of activation (Fig. 8). In peripheral blood mononuclear cells (therapeutically relevant target cells of HIV-1 infection), intracellular metabolism of TAF begins with the hydrolysis of the ester moiety by hydrolases localized in lysosomes.[93–96] The serine protease cathepsin A, which is highly expressed in lymphoid tissue,[97] has been established as primarily responsible for this initial bond cleavage. The metastable carboxylate metabolite then spontaneously cyclizes to expel phenol, and subsequent hydrolysis of the cyclic acyl phosphate affords the TFV-alanine metabolite. Chemical or enzymatic cleavage of the alanine reveals the parent TFV, which is anabolized to the active TFV-diphosphate. As for TDF, the fact that TFV is a phosphonic acid precludes any metabolism to an uncharged species (such as a nucleoside), and consequently the intracellular half-life is enhanced.

In addition to exhibiting higher intracellular concentrations of TFV-diphosphate, TAF shows greater stability in human plasma, resulting in lower parent TFV plasma exposures as compared to TDF and thereby reducing the potential for renal and bone toxicity. Furthermore, TAF does not interact with OAT1 or OAT3 and exhibits no OAT-dependent cytotoxicity and thus is unlikely to actively accumulate in renal proximal tubules.[98] TAF has been evaluated in combination with other direct-acting antiviral agents (Fig. 9). The first TAF-based combination regimen, Genvoya (elvitegravir (E), 150 mg/cobicistat (C), 150 mg/emtricitabine (FTC) 200 mg/TAF 10 mg), was approved by the FDA in Nov. 2015 for the treatment of HIV-1 infection. The efficacy of E/C/FTC/TAF provided noninferior virological suppression as compared to the standard of care E/C/FTC/TDF, and both regiments maintained a high barrier to resistance.[99,100] Patients receiving E/C/FTC/TAF had significant improvements in serum creatinine, renal tubular proteinuria, and bone mineral density as compared to E/C/FTC/TDF.[99,100] In March 2016, a STR containing rilpivirine (R) with FTC/TAF was approved as the second TAF-based STR.[101]

Additional clinical studies with TAF are ongoing. The beneficial resistance profile of darunavir and the safety profile of TAF make for an attractive combination that in a Phase II clinical study has been shown to provide comparable efficacy to the E/C/FTC/TAF regimen.[102] Subdermal implants containing TAF for long-acting HIV prophylaxis have also been reported.[103]

5.19.1.5.2 Investigational NRTIs

The currently approved NRTIs have demonstrated efficacy and a high degree of safety in long-term treatments and will continue to play an important role for HAART in the future. However, some limitations in the safety, resistance, and pharmacology of these NRTIs remain, and several investigational alternatives are currently in development (Fig. 10). Apricitabine (ATC) is the natural (−)-enantiomer 2′-deoxy-3′-oxa-4′-thiocytidine analog of 3TC.[104] It is less active than the unnatural (+)-enantiomer but has an improved toxicity profile.[105] While it is less potent than other NRTIs, it maintains broad activity against HIV-1 resistance mutants

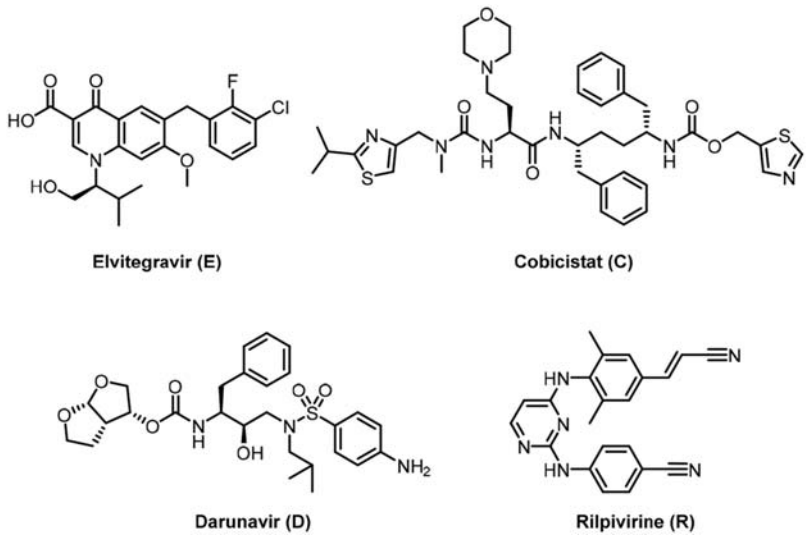

Fig. 9 Structures of antiretrovirals being evaluated in combination regimens with TAF.

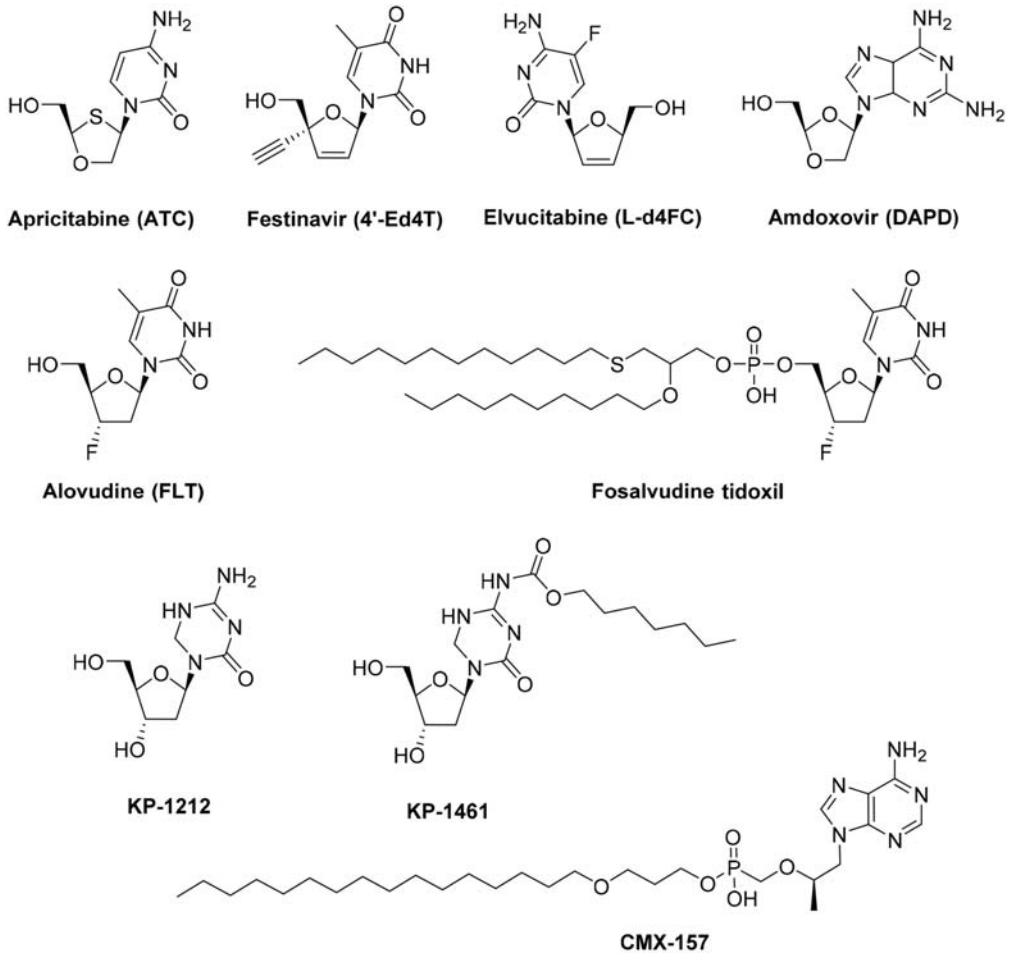

Fig. 10 Structures of investigational NRTIs in clinic trials.

which provides a potential advantage for the treatment of NRTI-experienced patients who failed prior therapies.[106] The efficacious dose of ATC is 800 mg twice daily and it is currently in the final stages of Phase III clinical development.

Festinavir (4′-Ed4T, BMS-986001) is a d4T analog with a 4′-ethynyl substitution[107] that exhibits an EC_{50} of 250 nM in MT-2 cells.[108] The 4′-ethynyl substitution confers selectivity against incorporation by host mitochondrial DNA and has a significantly improved in vitro toxicity profile as compared to d4T.[109] Festinivir has reached Phase II clinical development.

Elvucitabine (L-d4FC) is of the unnatural L-nucleoside configuration, with a dideoxy ribose ring and a 5-fluoro cytidine base. While highly potent, L-d4FC shows in vitro cytotoxicity despite having little effect on mitochondrial DNA.[110,111] Observations of hematological toxicity in the clinic limits the dose[112] and lower $CD4^+$ cell recovery was observed as compared to 3TC.[113] Elvucitabine has reached Phase II clinical evaluation, but there have been no recent developments reported.

Amdoxovir (DAPD) is a diaminopurine (DAP) dioxolane prodrug that is converted to the corresponding guanosine base (DXG) through the action of adenosine deaminase. DXG has an EC_{50} of 85 nM in MT-2 cells and has little effect on mitochondrial DNA.[114] Notably, DAPD retains the activity of M184V and TAMs resistance mutants.[115,116] Amdoxovir has reached Phase II clinical evaluation.

Alovudine (FLT) is a 3′-deoxy-3′-fluorothymidine analog that has comparable potency to AZT, but maintains activity against NRTI-resistant mutants including TAMs.[117] FLT does affect mitochondrial DNA[118] and has been shown to cause hematopoietic toxicity,[119] which restricts doses to levels that only achieved moderate suppression of viral load in a Phase II clinical study.[120] The development of FLT has been discontinued. In order to overcome the dose limitations, the phospholipid prodrug fosalvudine tidoxil was investigated. In a Phase II study for 14 days, a 40 mg dose provided a 1.00 $\log_{10}$ reduction in viral titer with no dose-dependent adverse effects.[121] The long-term potential for toxicity of fosalvudine tidoxil has yet to be addressed and there have been no recent developments reported.

KP-1212 is a deoxycytidine analog with a 5-aza-5,6-dihydro cytidine-modified base. The 3′-hydroxyl group enables stable incorporation by reverse transcriptase and the trizazinone base efficiently base-pairs with both G and A which increases the rate of random transitional mutations in the viral genome and leads to clearance of the virus.[122] KP-1212 is a substrate for mitochondrial DNA polymerase γ,[123] which potentially can lead to long-term mitochondrial toxicity; however, this toxicity has not been observed thus far in in vitro cell-based assays.[122] KP-1461 is the N^4-heptyloxycarbonyl prodrug of KP-1212, designed to enhance oral bioavailability. In a Phase IIa study, KP-1461 was dosed orally at 1600 mg twice daily and was generally well tolerated, but it did not significantly affect viral load or CD4 lymphocyte count.[124] However, alteration of the mutation spectrum of HIV consistent with the mechanism of action of KP-1461 was observed.[125]

CMX-157 is the hexadecyloxypropyl prodrug of TFV designed to mimic natural phospholipids, and exhibits excellent potency with an $EC_{50} < 1$ nM in MT-2 cells.[126] The prodrug moiety enhances gastrointestinal absorption and cell permeability as compared to TFV, and provides a plasma-stable prodrug that is well tolerated in rats and monkeys.[127] CMX-157 is currently being developed in Phase II clinical trials assessing safety, tolerability, and pharmacokinetics.

5.19.1.6 Nonnucleoside Reverse Transcriptase Inhibitors

Early NNRTIs were plagued by the rapid development of resistance.[128] The discovery of TMC-125 (etravirine) came from an effort to develop new NNRTIs that retained activity against many of the strains known to be resistant to earlier generations of NNRTIs, and began with a healthy dose of good fortune.[129,130] Though many varied types of chemical scaffolds were known to inhibit HIV reverse transcriptase, iminothiourea **18** was one of the first to retain appreciable activity against many of the known single mutant-resistant strains (Fig. 11). After a problematic liability in the metabolism of **18** (oxidative cyclization to a thiadiazole) became apparent, an attempt to synthesize the cyano-guanidine analog **19** resulted in the unexpected formation of amino-triazole **20**. This compound retained nearly all of the activity of the thiourea lead, including its potency against many single-point mutants. Specific removal of one of the nitrogens in the core led to amino-pyrimidine **21**, which had greater potency, and the addition of a second cyano group (as well as swapping methyls for chlorines) gave the exquisitely potent compound **22**. This compound retained low nanomolar potency against many single mutants and even had some activity versus some problematic double mutants. Finally, the addition of bromine atom on the core further improved the resistant mutant profile, giving TMC-125 (etravirine). Etravirine showed good efficacy, even in treatment-experienced patients,[131] and was approved by the FDA in 2008.

5.19.1.6.1 Rilpivirine

Further work in the diaminopyrimine series resulted in the discovery of rilpivirine (TMC278).[132] Rilpivirine shows even greater potency against wild-type and mutant strains of HIV than efavirenz or etravirine, and this enhanced activity has been attributed to a new specific interaction between the vinyl-extended cyano group and Trp229. It is speculated that some of the improved activity against resistant strains may derive from additional torsional freedom in the bonds to the aniline ring in TMC278 compared to

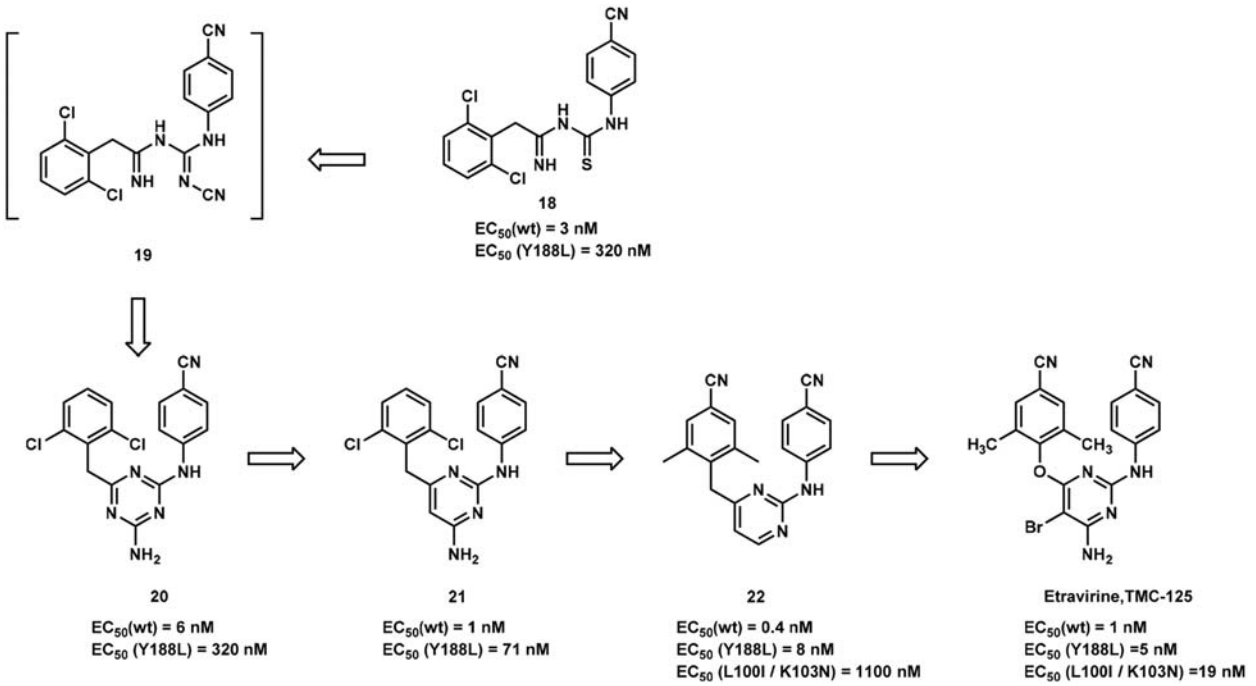

Fig. 11 Optimization of diaryltriazines to TMC-125 (etravirine).

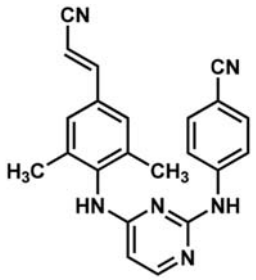
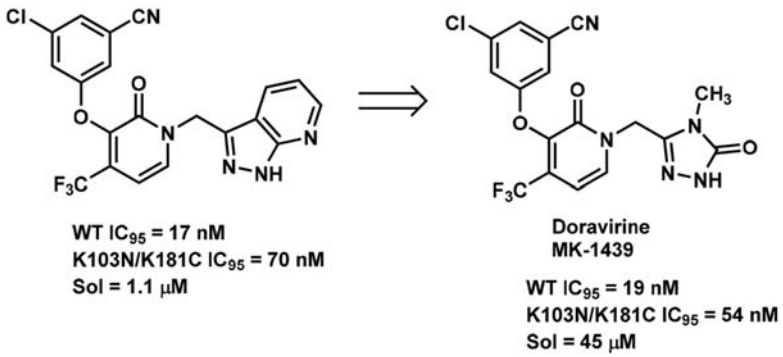
previous analogs. In vitro studies for rilpivirine suggest that it has a higher genetic barrier and a more robust resistance profile than either efavirenz or nevirapine.[133]



Clinical studies show rilpivirine has comparable efficacy to efavirenz with better tolerability (reduced incidences of several adverse events—neurological events, rash, and lower lipid elevations).[134,135] Though patients with high viral load ($>500{,}000$ copies mL^{-1}) showed higher rates of virologic failure than efavirenz, rilpivirine regimens showed superiority in patients with lower initial viral loads ($<100{,}000$ copies mL^{-1}) with fewer adverse events and discontinuations.[136] Rilpivirine dosing is limited to 25 mg by a hERG interaction at higher doses.[137] Rilpivirine was approved by the FDA in 2011. It is included in multiple STRs and is also being studied as a long-acting injectable treatment in combination with the second-generation integrase inhibitor cabotegravir.[138]

5.19.1.6.2 Doravirine

Recent work on NNRTIs with pyridone cores led to the discovery of doravirine (MK-1439).[139] Early compounds in this series showed much improved activity against NNRTI-resistant strains such as K103N/Y181C, but poor pharmacokinetics. Optimization of both the heterocycle and substituents on the pyridone core led to doravirine.



Doravirine shows improved potency against both wild-type HIV as well as key resistant strains (Table 5), and also lacks the dose-limiting hERG liability of rilpivirine.

Currently in Phase III studies, doravirine (100 mg QD) shows comparable efficacy to efavirenz (600 mg QD) and a significantly improved tolerability profile with only half as many patients experiencing a CNS-related adverse event (22.2% for doravirine vs. 43.5% for efavirenz). The most common CNS adverse events were dizziness (doravirine 9.3% and efavirenz 27.8%) and abnormal dreams (doravirine 5.6% and efavirenz 16.7%).[140]

5.19.1.7 Protease Inhibitors

PIs have historically been one of the most important and widely used third agents contained in HIV regimens. Though they have generally have had more onerous side effect profiles than NNRTIs, they exhibit a stronger barrier to resistance. Darunavir, approved by the FDA in 2006, is the newest PI to reach the market, and it, along with atazanavir (approved in 2003, and described extensively in Comprehensive Medicinal Chemistry II) have become the PIs of choice for modern HIV regimens.

5.19.1.7.1 Darunavir

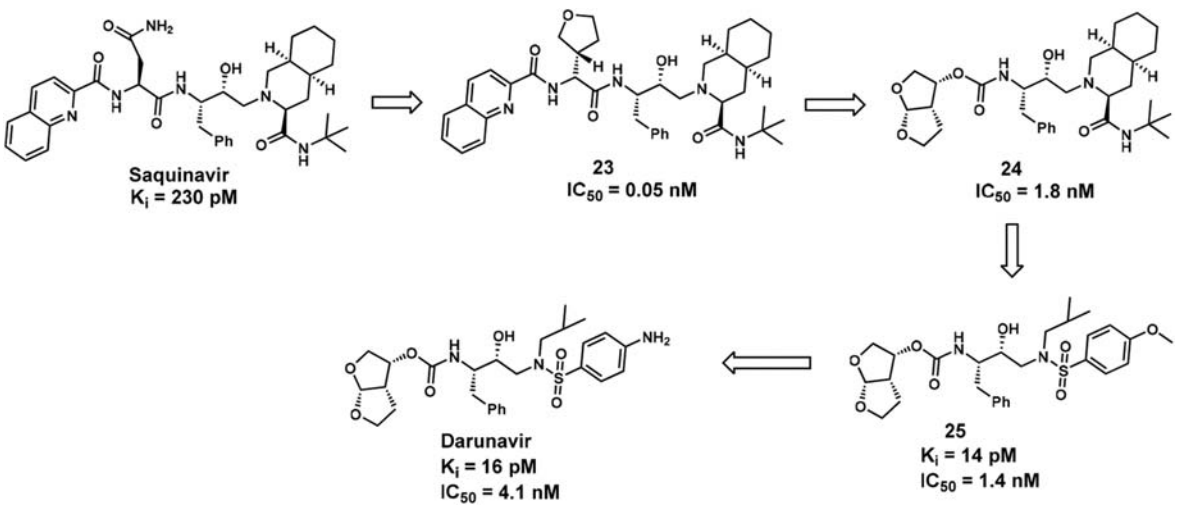


Table 5 Resistance profiles of NNRTIs

	Spread IC95 (μM) with 50% NHS			
Compound	*WT*	*K103N*	*Y181C*	*K103N/Y181C*
Efavirenz	0.039	1.4	0.089	3.2
Rilpivirine	0.036	0.044	0.120	0.37
MK-1439	0.019	0.042	0.025	0.054

The discovery of darunavir came out of an effort to improve both the pharmacokinetic properties and the resistance profile of existing PIs. Starting from the crystal structure of the known PI saquinavir, researchers sought to improve PK properties by reducing the peptidic character of the molecules (by removing amides and other hydrogen bond donors) and further improve the resistance profile by increasing contacts with the backbone of the enzyme.[141,142] Initial replacement of the P2-asparagine with a tetrahydrofuran led to the highly potent compound **23**. Removal of the quinolinyl-amide led to a significant loss of potency ($IC_{50} = 160$ nM), but optimization of the THF moiety led to the discovery of bis-THF **24**, and the recovery of much of the potency. The bis-THF motif (in the proper *R,S,R* stereochemistry) was shown to improve binding through two new hydrogen bonds to backbone residues Asp29 and Asp30. In the context of this motif, reoptimization of the remainder of the molecule led to the discovery of *p*-methoxyphneylsulfonamide as a potent element for P2 binding. Compound **25** (TMC-126), containing both of these pieces, showed extraordinary potency against WT (14 pM) and much improved potency against many PI-resistant strains. The oxygen atom of the methoxy group was shown to make two more important hydrogen bonds including one to the backbone. Finally, replacement of the methoxyphenyl with aniline provided darunavir, a compound with significantly improved pharmacokinetics compared with **25**. A crystal structure of darunavir bound to HIV-PI clearly shows the backbone hydrogen bonds believed to be responsible for its improved potency and resistance profile (Fig. 12).

A clear advantage of darunavir over the earlier PIs saquinavir and nelfinavir can be seen in comparing their potencies against both wild-type HIV strains and multidrug-resistant strains (Table 6).[143]

Early Phase II studies showed that darunavir boosted with ritonavir provided a much greater response in protease-experienced patients than control PIs (45% vs. 10% reaching <50 viral copies mL^{-1}), with 9% of darunavir-treated patients discontinuing treatment due to an AE- or HIV-related event (compared to 5% in the PI control arm) and 8% of darunavir patients discontinuing as a result of virologic failure (compared to 67% of PI control patients).[144]

More recent clinical data shows that darunavir regimens are superior to lopinavir regimens[145] as well as atazanavir regimens,[146] though in both cases the improvement is primarily a result of fewer discontinuations due to adverse events. Lower rates of

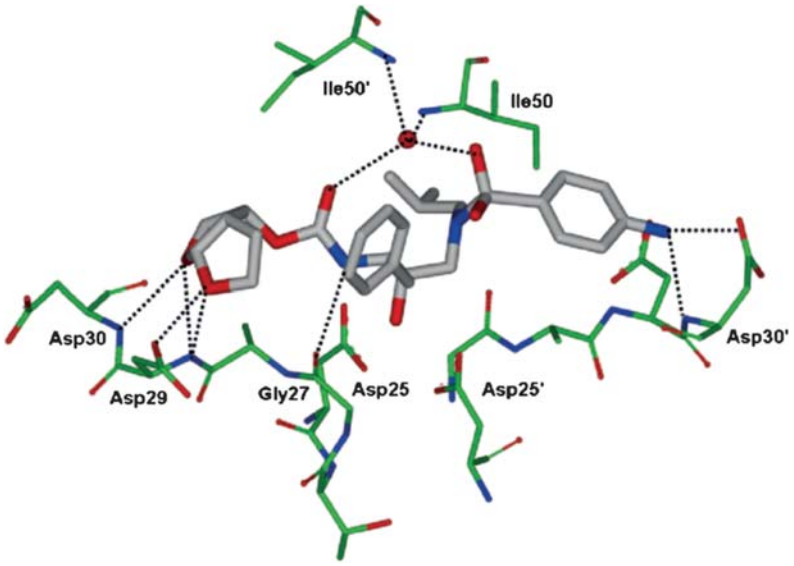

Fig. 12 Crystal structure of darunavir bound to HIV protease showing key hydrogen bonds including backbone hydrogen bonds to both the bis-THF moiety and the aniline nitrogen.

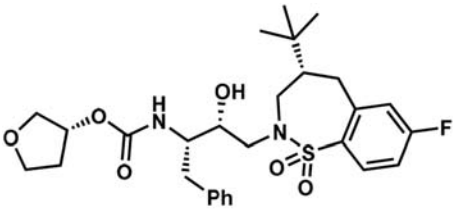
gastrointestinal side effects, lipid level increases, and hyperbilirubinemia in the darunavir arms appeared to contribute to its statistical superiority.

5.19.1.7.2 Other protease inhibitors

Beyond darunavir, newer PI research has led to compounds like brecanavir, an extremely potent PI[147] which was studied clinically and ultimately abandoned due to difficulty in developing an effective oral formulation (Fig. 13). The addition of a third fused THF (**26**) was shown to result in an excellent antiviral profile against both wild-type and drug-resistant strains.[148] TMC310911, a newer PI from Tibotec, shows further improvements in resistance profile compared with darunavir. It retains activity (less than a fourfold potency shift) for 71% (879/1233) of a large set of clinical isolates which show decreased susceptibility to DRV and early PIs.[149]



27
K_i = 0.26 nM

Additional structural diversity in the PI class is seen in compounds like cyclic sulfonamide **27**,[150] as well as PI's containing heterocyclic cores[151] including benzodiazapenes[152] and other nonpeptidomimetic alternatives.[153] Somewhat weaker activity has been seen with macrocyclic approaches.[154]

5.19.1.8 Other Mechanisms

5.19.1.8.1 Attachment inhibitors

HIV attachment inhibitors are a class of anti-HIV compounds that prevent HIV entry. The process by which HIV gains entry into uninfected cells is a sequential series of events initiated by the binding of the viral surface glycoprotein gp120 to the host cell CD4 receptor. Upon binding, gp120 undergoes a conformational change that helps promote a cascade of events involving gp41-promoted pore formation and membrane fusion. Distinct from fusion inhibitors such as enfuvirtide, which inhibit gp41-mediated fusion, and CCR5 antagonists such as maraviroc, which inhibit the binding of the essential cofactor CCR5, attachment inhibitors appear to stabilize a conformation of gp120 that inhibits binding of CD4 and prevents attachment to CD4 cells. The exact mechanism of action remains a subject of investigation.[155]

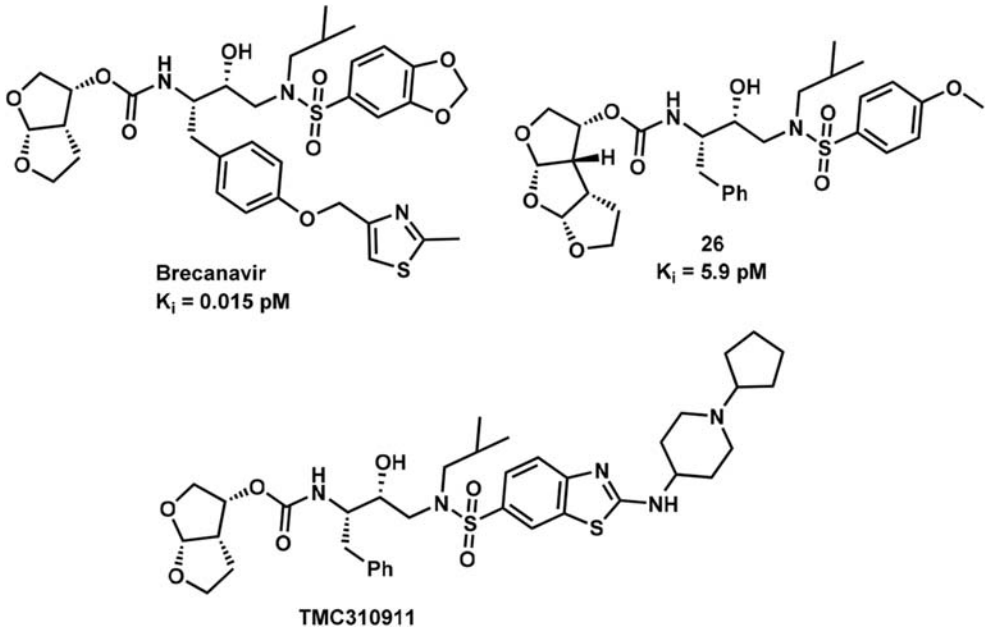


Fig. 13 Newer HIV protease research has led to compounds with further enhanced profiles.

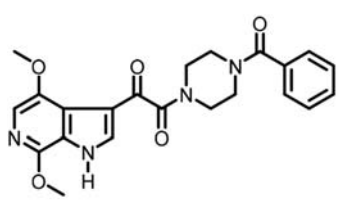
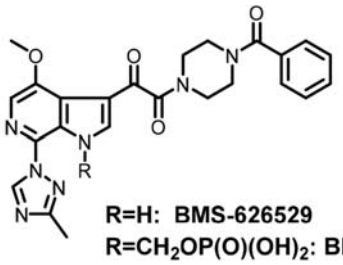


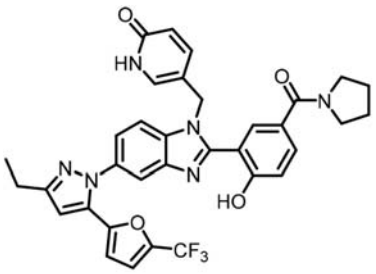
BMS-488043



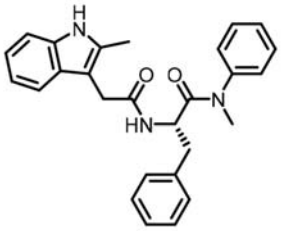
R=H: BMS-626529
R=$CH_2OP(O)(OH)_2$: BMS-663068

Initial proof of concept for targeting gp120 to prevent virus entry was provided by positive results in clinical trials of PRO542, a tetravalent CD4-IgG_2 fusion protein.[156] Small-molecule gp120 inhibitors were identified from a broad cell-based anti-HIV screen. Evaluation of BMS-488043 in HIV-1-infected subjects provided oral proof of concept for this class, albeit with modest antiviral potency. A next generation compound was sought to address limited oral bioavailability, suboptimal pharmacokinetics and insufficient inhibitory potency in the context of gp120 heterogeneity. BMS-626529 displays improved potency against a broader spectrum of HIV-1 viruses than its predecessor. BMS-663068 (fostemsavir) entered clinical development as the phosphonooxymethyl prodrug of BMS-626529, successfully addressing the low solubility and poor intrinsic dissolution properties of the active parent molecule.[157] In early-stage clinical trials, fostemsavir has demonstrated good antiviral activity and found to be well tolerated. It is currently in late-stage clinical evaluation. The FDA has granted Breakthrough Therapy Designation to fostemsavir in part due to the novel mechanism of action and its efficacy in treatment-experienced HIV patients.

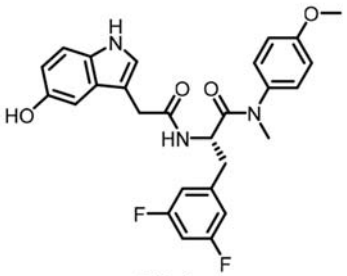
5.19.1.8.2 Capsid inhibitors



BI-060



PF-3450074



GS-2

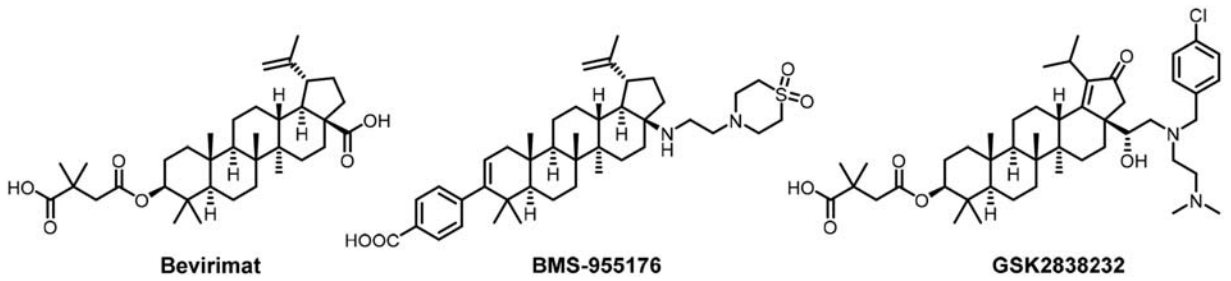
In recent years, significant advances have been made in understanding the role of the HIV-1 capsid protein (CA) in the HIV life cycle. In addition to its key role in virus maturation, it is becoming increasingly apparent that the capsid protein has important functions during the early stages of infection. Capsid protein is now associated with impacting the kinetics of virus uncoating, recognition by restriction factors, and nuclear import and integration.[158] As such, there has been increasing attention toward targeting CA as a novel mechanism of intervention.

Multiple CA small-molecule binding sites have been identified on both NTD and CTD domains. The most notable inhibitors described thus far are shown below. BI-060 was discovered by BI to bind at the NTD site I, inhibiting the ability of CA to form higher order multimeric species necessary for proper core formation, and established proof of concept for potent anti-HIV activity through capsid binding.[159] Although less potent, PF-3450074 may provide a more intriguing starting point for potential drug discovery. Also binding the Capsid NTD, it does so at an orthogonal site 2, with drastic mechanistic consequences. Current evidence suggests that PF-3450074 and the more potent analog GS-2 possess a unique multimodal antiviral mechanism involving potent early-stage (nuclear import block) and late-stage (improper capsid assembly) effects on virus replication.[160] To date, no capsid inhibitors have been evaluated in human clinical trials.

5.19.1.8.3 Maturation inhibitors

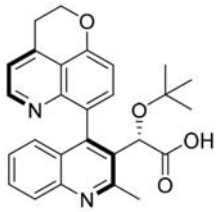
The first-generation maturation inhibitor, bevirimat, demonstrated efficacy in HIV-infected subjects in early-phase clinical trials. Maturation inhibitors of this class target the Gag polyprotein, inhibiting the action of HIV protease at its last cleavage event between capsid (CA) protein p24 and SP1. This mechanism of action constitutes the inhibition of a single cleavage event, and stands in contrast to PIs, which directly target the active site of the viral protease. Due to naturally occurring polymorphisms in Gag, ~50% of patients exhibited reduced viral susceptibility to bevirimat, thus limiting its potential clinical utility.[161] Work toward a maturation inhibitor with improved virologic profile has been ongoing with BMS and GSK both reporting second-generation compounds. BMS-955176 possesses improved potency, antiviral spectrum, and Gag polymorphic coverage.[162] In a proof-of-concept study, 10 days of BMS-955176 monotherapy at 40 mg QD resulted in maximum median declines in HIV-1 RNA of

$\sim$1.70 $\log_{10}$c mL^{-1}.[163] Further evaluation of BMS-955176 in Phase II trials is ongoing. GSK2838232 displays an improved virologic profile with a reported MT4 $IC_{50} < 1$ nM that appears not to be affected by the presence of human serum.[164] GSK2838232 was advanced into human clinical trials.



5.19.1.8.4 Noncatalytic integrase inhibitors

NCINIs bind to the viral integrase in an allosteric pocket within the catalytic core domain. The most advanced NCINI is BI 224436 (**28**). This compound, a stable atropisomer bearing a carboxylic acid that binds the peptide backbone in the integrase dimer cleft, shows high potency, a low serum shift, and a long half-life in rat pharmacokinetics (8.8 h). The discovery of this compound relied on structure-based drug design and X-ray crystallography of the catalytic core domain of integrase.[165] The upper tricyclic quinoline motif stacks against the protein and provides improved metabolic stability. Contrary to initial hypotheses surrounding the antiviral mechanisms of NCINIs, these compounds do not derive their potency by blocking integration. Instead, NCINIs promote improper integrase oligomerization during viral particle formation, leading to defective virion production.[166] Compound **28** was progressed into Phase I clinical studies.



28

5.19.1.9 Simplified Regimens and Nonstandard Regimen Research

To improve adherence and outcomes, researchers have long sought to simplify regimens. Some simplification has occurred naturally as the dosing frequency of preferred individual agents has moved more and more to QD administration. Further, as the potency of the preferred agents has increased, the tablet sizes have gone down, and more agents have been combined into single tablets. The convergence of these two trends has allowed for the creation of STRs—three or more medicines constituting complete HIV regimens, co-formulated into single pills. Since 2006, five STRs for QD administration have been approved by the FDA (**Table 7**).[167]

Although standard regimens have long contained two nucleosides and a third agent, clinical researchers have continued to investigate innovations beyond this convention. The motivations behind this research are twofold—to find effective regimens for patients resistant to certain drugs classes (NRTIs, NNRTIs, and others), and to find regimens with better tolerability profiles. In one case, researchers investigated the addition of a fourth agent for patients with high viremia.[168] This study showed no benefit to patients with four drugs over three. Much of the research in this area involves regimens which are either nuc sparing[169] or

Table 7 Approved single-table regimens for HIV

Generic names	*Brand name*	*FDA approval date*
Efavirenz, emtricitabine, and tenofovir disoproxil fumarate	Atripa	Jul. 12, 2006

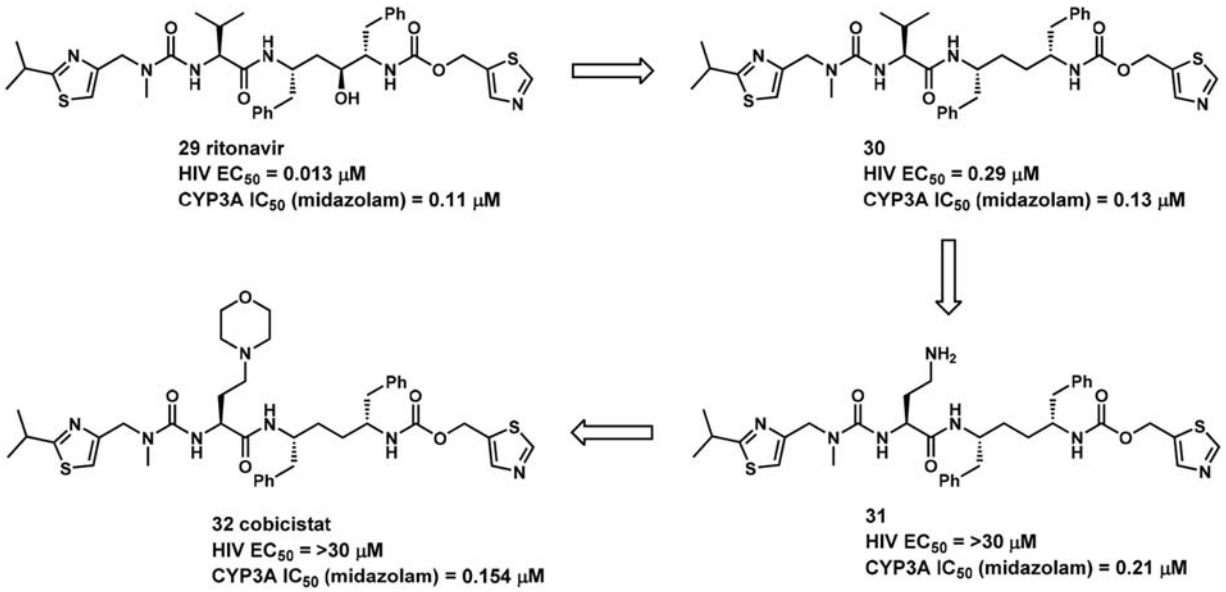
Rilpivirine, emtricitabine, and tenofovir alafenamide	Odefsey	Mar. 1, 2016

both nuc- and protease sparing.[170,171] Currently, evidence supports the use of these simpler nuc-sparing regimens in patients failing standard regimens. However, evidence for the use of nuc-sparing regimens in naive patients is more sparse.[172] And none are currently recommended for first-line therapy.

5.19.1.10 Boosters and Cobicistat

Ritonavir, a first-generation PI, was originally approved in 1996 and used in combination with two NRTIs for several years until it was gradually replaced by more efficacious and better-tolerated PIs such as fosamprenavir and lopinavir, and more recently by atazanavir and darunavir.[173] However, since it was recognized as a potent irreversible CYP3A4 inhibitor, its use as a "boosting" agent for other PIs has continued.[174] Due to concerns for generation of resistance—especially at this lower dose—ritonavir's use a booster is limited to PI-based regimens.

In this context, the need for a CYP3A4 inhibitor, or booster, without HIV protease inhibition was recognized. A booster without protease activity could be used to enhance the pharmacokinetics of drugs with other mechanisms (such as INSTIs). An effort to discover an agent of this type was undertaken and resulted in the discovery of cobicistat. Starting from the structure of ritonavir, removal of the central hydroxyl group of ritonavir led to >20-fold reduction in HIV protease activity without affecting CYP3A inhibition.[175] Further, it was found that the addition of polar groups at P2, as exemplified by **31**, gave compounds with little or no remaining HIV protease activity.[176] When **31** was shown to have poor permeability and bioavailability, alternative basic groups at P2 with fewer hydrogen bond donors were shown to give acceptable pharmacokinetics. This led to cobicistat (COBI) **32**, a CYP3A inhibitor (or pharmacoenhancer) devoid of HIV protease activity.[177]



In a Phase II clinical study, 150 mg of COBI was shown to produce a strong pharmacokinetic boosting effect on EVG, allowing for the latter to be dosed QD.[178] The four-drug combination of EVG/COBI and TDF/FTC was studied in multiple Phase III trials. This combination showed noninferiority to EFV/TDF/FTC with fewer of the CNS-related side effects that are characteristic of EFV-containing regimens (abnormal dreams and dizziness), and a larger increase in serum creatinine.[179] Further, EVG/COBI/TDF/FTC showed noninferiority to the protease-based regimen ATZ/RTV/TDF/FTC, with fewer reports of abnormal liver function tests.[180] EVG/COBI/TDF/FTC was approved by the FDA in 2012 as the first integrase-containing STR.[181] In 2015, the four-drug combination of EVG/COBI/TAF/FTC (containing the newer low-dose NRTI TAF in place of TDF) was approved by the FDA.[182] Further, COBI has been shown to effectively enhance the pharmacokinetics of the PIs darunavir and atazanavir.[183] These fixed-dose combinations have also been approved by the FDA and STR-containing darunavir/cobicistat/TAF/FTC is also being studied clinically.[184] If approved, this would be the first protease-containing STR.

5.19.1.11 Preexposure Prophylaxis (PreP)

In 2010, clinical studies were published showing that a combination of TDF and FTC was effective in preventing HIV infection in humans—both in men who have sex with men,[185] as well as by heterosexual transmission.[186] These data were supported by subsequent monkey studies.[187] Though seen as controversial due to its perceived potential to reduce compliance with other HIV prevention strategies, TDF/FTC was approved as an HIV preventative in 2012.[188] In addition, the integrase inhibitor cabotegravir, formulated as a long-acting injectable suspension, is also being evaluated for PreP.[189]

5.19.1.12 HIV Cure

Although current HIV treatments can effectively deter resistance emergence, reduce viral load, and are better tolerated than older treatments, HIV patients are aging and new cases continue to emerge. As a result, a significant amount of scientific effort has focused on approaches toward HIV cure, with the ultimate goal of pathogen eradication.

The pursuit of HIV cure has been approached from several angles, and this section focuses on the two dominant paradigms. The first strategy, known as the "kick-and-kill" approach, is designed to tackle the problem of viral latency. HIV infects multiple cell types, integrating copies of proviral DNA into the host. When infected cells undergo transition into a dormant state, viral latency is achieved. Patients who discontinue HAART will nearly always experience a rapid and strong viral rebound that is presumed to originate from viral propagation out of this latent reservoir. The first strategy seeks to "kick" this latent reservoir of infected cells into an active state with a small molecule or biologic, and then to "kill" them with further therapy. In this way, purging the viral reservoirs could lead to viral eradication or sustained viral control by the host immune system.

Even in the absence of a complete cure, it is desirable for patients to reduce the frequency of dosing associated with HAART. Lowering the total amount of drug in the body could benefit patients on life-long therapy.[190] This alternative to "kick and kill" for managing care is referred to as "functional cure."

5.19.1.12.1 Kick and kill

Epigenetic control of DNA transcription has been shown to contribute to many pathogenic states, including HIV. Because integration of proviral HIV DNA occurs in many cell types, one "kick" approach involves removing epigenetic regulators that block viral transcription in latently infected cells. The most well-studied targets in this area are histone deacetylases (HDACs)—zinc-containing metalloproteins that catalyze the removal of acetyl groups from lysine residues of histones, which is a process known to downregulate the transcription of select genes, and which may contribute to the latency of integrated HIV. Small-molecule HDAC inhibitor (HDACi) research in the context of oncology has served to provide momentum for this approach.

HDACi's which have been tested in vitro or in vivo for latency reversal are shown in **Fig. 14**. **33–36** have all been tested in multiple in vitro models.[195,196] To avoid the known off-target liabilities of the hydroxamic acid class, the macrobicyclic depsipeptide Romidepsin (**37**) was also investigated.[191] Romidepsin is a prodrug that undergoes disulfide bioreduction to provide a free thiol that coordinates to the zinc atom in the active site of HDACs.[192–194]

Despite their potential to deliver the clinical "kick," there is evidence that HDACi's may lead to latent reservoir reseeding. A further concern is the potential for HDACi's to produce undesirable side effects due to nonspecific epigenetic effects.

In latency reversal models of HIV in $CD4^+$ T cells derived from patients, Vorinostat (**33**)[195] and Romidepsin (**37**)[192] have both shown latency reactivation with proviral transcription, but belinostat (**34**), gavinostat (**35**), and panobinostat (**36**) have not yet demonstrated efficacy.[196]

Vorinostat (**33**), the most advanced hydroxamic acid-based HDACi, has been tested in HIV patients.[197] Though there was a 4.8-fold increase in viral mRNA production (potential evidence of a "kick"), concerns regarding reservoir reseeding remained.[198] Although HDAC inhibitors may achieve the "kick" portion of latency reversal approach, a "kill" is also needed. Activation of the innate and adaptive immune systems of the host may aid this process. TLR7 agonists such as compounds (**38–40**) can stimulate the release of interferon and immunomodulatory cytokines, and awaken the innate immune system. Thus, TLR7 agonists are being pursued as potential components of an HIV cure.

SAR studies revealed two important factors governing the potency of TLR7 agonists (**Table 8**).[199] First, a basic amine on the distal portion of the molecule was critical for achieving a potent minimal effective concentration (MEC, defined as the minimal agonist concentration requires threefold stimulation of IFNα over baseline). Thus, **39** displayed greater MEC potency than **38**. Additionally, **39** was more selective for stimulation of IFN-α relative to TNF-α. Second, the addition of a lipophilic n-butoxy side chain led to GS-

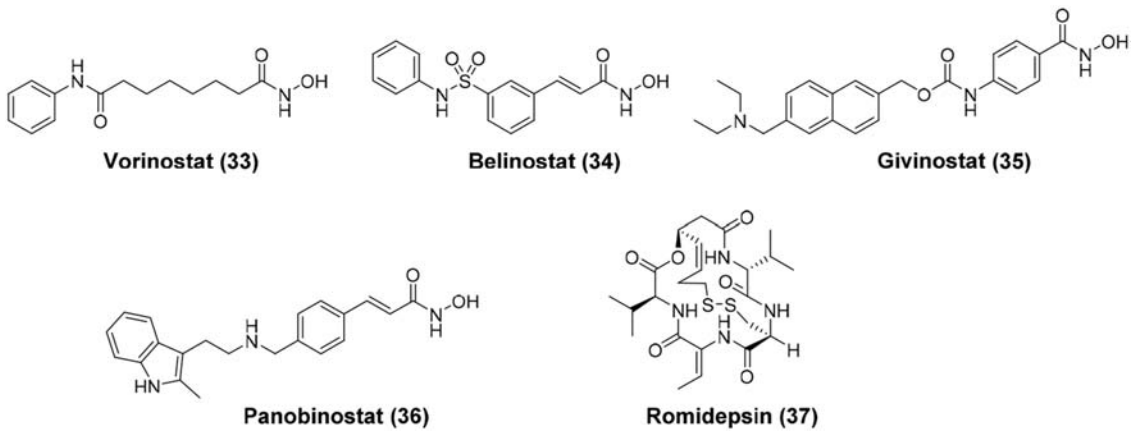


Fig. 14 HDAC inhibitors.

9620 (**40**), which showed further increased potency and also favorable pharmacodynamics in cynomolgus monkeys. GS-9620 is currently in a Phase I clinical trial in HIV-infected patients.[200]

One challenge with modulation of the innate or adaptive immune system is the activation of unwanted pathways during the "kick" process. Indeed, antiviral IFNα-based therapies are associated with undesirable side effects. Thus, some research has been directed toward agents that affect a "kill" without activating the latent infected cells (i.e., no "kick"). A high-throughput screen for CD4/8T-cell killing agents that do not broadly activate the immune system revealed disulfiram (antabuse) (**9**) as a candidate molecule (Table 9).[201] While the precise mechanism of HIV "killing" is unknown, evidence suggests the inhibition of PTEN, which is important in the regulation of the Akt pathway.[202] The human metabolism of disulfiram (**9**) is complex, making it difficult to assess whether biological activity derives from the parent or metabolite(s).[203] Disulfiram (**41**) and its primary thiocarbamic acid metabolite (**42**) are both active in a latency reversal assay, but the S-oxide metabolite (**43**) and thioester analog (**44**) are both inactive (Table 9). Disulfiram (**41**) was tested in HIV-infected adults, and although latency reversal was observed, there was no statistically significant change in the size of the viral reservoir.[204]

HDAC inhibitors can act at the level of chromatin remodeling and epigenetic control, functionally close to the production of viral mRNA. Disulfiram is believed to act further upstream, at the level of PTEN signaling in the cytosol.[202] The TLR7 receptor is yet further upstream, expressed in the early endosomal compartment, and activates immunity in response to pathogen-associated molecular patterns. Another target in the "kick and/or kill" strategy, protein kinase C (PKC), lies even farther upstream. PKC is a cell-membrane-associated enzyme capable of T-cell activation via the NF-kB pathway when stimulated by small molecules.[205] Exploration of PKC activation has spanned multiple cell classes including primary $CD4^+$ T cells, J-Lat cells, and QVOA patient cell isolates.

One PKC activator, phorbol-12-myristate-13-acetate (PMA, **45**), showed some activity in three different models of latent cellular activation, reaching full activation in J-Lat clone cells (Table 10). The natural product prostratin (**46**) can also induce virus from latently infected primary $CD4^+$ T cells.[205] As with **45**, the response to **46** across cell types was highly variable. The macrolide

[b]J-Lat clone cell lineages: 5A8, 6.3, 8.4, and 11.1.
[c]QVOA cells are HIV patient-derived cells.

bryostatin-1 (**47**) and related analogs can also engage PKC via binding to the diacetylglycerol-binding region.[205] Bryostatin-1 (**47**) exhibited extreme variability in primary CD4$^+$ T cells depending on the specific model, but failed to activate QVOA cells.

Because calcium regulation is important within the PKC activation pathway, PKC activators such as PMA (**45**) have been paired with the calcium ionophore ionomycin (**48**). In the Greene and Siliciano versions of the HIV latent CD4$^+$ T-cell assay, the combination of **45** and **48** gives more robust activation than for either compound alone (**Table 4**).

5.19.1.12.2 Direct-acting antivirals for functional cure

Several HIV targets have been investigated specifically due to their unusual PK/PD potential—they may provide more effective treatments with less frequent dosing regimens. Among targets of this type are tat and rev (**Fig. 15**).

HIV tat regulates the transcription of integrated proviral DNA.[206] One of its functions is to bind a DNA segment called the trans-activation region (TAR) to enable viral DNA transcription. When tat binds to TAR a feedback signaling loop is initiated, amplifying the transcription of full-length viral mRNA. Dehydrocortistatin A (dCA, **49**), a synthetic analog of the natural product cortistatin A (**50**), binds to the TAR-binding domain of tat (**Fig. 15**) suppressing the formation of p24 (HIV capsid protein) with an EC_{50} of 0.7 pM[207] and thereby repressing the feedback trans-activation loop. In contrast to the "kick" approach, which aims to reverse latency, **49** *promotes* latency. Hence, in a separate experiment, CD4$^+$-HeLa cells infected with HIV were treated with **49** for a period of 60 days, followed by cessation of treatment. No viral rebound was observed for up to 27 days postcessation, in contrast to the rebound seen with current HAART.[208] This phenomenon has been attributed to long-term silencing of key HIV-transcriptional systems.[207,209] Notably, HIV-infected cells treated with **49** were resistant or even recalcitrant to "kick" reactivation by the HDAC

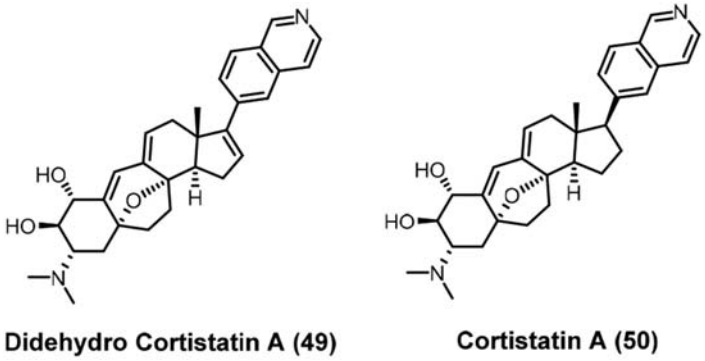

Fig. 15 Selected small molecules targeting HIV tat.

inhibitor **33**, the PKC activator **46,** or the PKC activator combination of **45** and **48**. To provide further evidence that the silencing effect of **49** is mediated via inhibition of the TAR domain of HIV-tat, the introduction of a plasmid containing the *Tat* gene into silenced HIV-infected cells was shown to result in a rapid rebound in viremia.[209] Taken together, these studies suggest dCA (**49**) administration could help achieve a "functional cure" alone or in combination with other therapies by reducing therapeutic dosing frequency.

HIV-tat is responsible for transcription activation, leading to the production of full-length 9 kB viral mRNA. The next stage in the viral life cycle requires both partial and complete splicing to the 4 and 2 kB viral mRNAs that encode select viral proteins. Regulation of this splicing is directed by the HIV rev protein, which binds to the rev response element (RRE) present on 4 and 9 kB viral mRNA transcripts. Rev also coordinates the export of viral mRNA by binding directly to cap-binding-complex (CBC) proteins.[210] Tetracycle **51** (IDC16) was found to disrupt the action of HIV-rev by controlling splicing factors.[211] However, IDC16 is nonspecific in its binding to RNA and DNA, giving rise to cytotoxicity. ABX-464 (**52**) was devised as a less planar version of **51** and retained the favorable disruption of rev in HIV-infected macrophages while imparting lowered cytotoxicity (**Table 11**).[211] In a humanized mouse model of HIV, mice were virally suppressed either with HAART or **52**. When therapies were removed, viral rebound was rapid in mice treated with HAART, but delayed (sometimes by greater than a month) in those treated with **52**. ABX-464 (**52**) is currently in Phase II clinical trial as part of a "functional cure" approach toward HIV.

The field of HIV cure research is growing, and clinical work has begun. Key to the "kick-and-kill" approach will be increased understanding of the interactions between HIV and the host immune system. Combination therapy has evolved as STRs have emerged for HAART, and combinations could play a valuable role in the "kick-and-kill" strategy as well. This may also be true for "functional cure" regimens, which could allow patients the option of less frequent dosing.

5.19.2 Hepatitis B Virus

Hepatitis B virus (HBV) is a DNA virus that targets hepatocytes and causes a chronic liver infection which, like that of hepatitis C virus (HCV), slowly causes liver damage and can eventually lead to liver fibrosis, cirrhosis, and hepatocellular carcinoma (HCC).[212] Although HBV is a small and relatively simple virus,[213] the search for effective treatments has been surprisingly difficult. This is likely due to an unusual viral life cycle, which involves a long-lived covalent, circular closed DNA (cccDNA) genetic template, as well as the virus's apparent ability to dampen the host immune response.[214] In this section, current treatment regimens, the life cycle of HBV and efforts to develop improved small molecule and biologic treatments are described.

There are approximately 240 million chronically infected HBV patients worldwide,[215] for whom current treatment options are quite limited and based on interferon- and nucleoside-based regimens.[216] Both approaches lead to improvements in disease severity (HBV DNA reductions and often ALT normalization) in many patients, with nucleoside regimens well tolerated and effective for long-term viral suppression, but neither leads to significant rates of cure (defined as S-antigen seroconversion or HBsAg loss) (**Table 12**); indeed, no currently approved HBV regimen leads to HBsAg loss in >10% of patients. As a consequence of this limited efficacy, patients are generally not recommended for treatment until the severity of disease becomes problematic (increased ALT levels and/or detectable fibrosis or cirrhosis).

5.19.2.1 HBV Replication Cycle and Potential Drug Targets (New Section)

In contrast to HIV, HBV is a small and relatively simple DNA virus. The virus consists of viral DNA and the viral polymerase enclosed within an icosahedral nucleocapsid composed of core antigen protein (HBcAg). The surface of the nucleocapsid is covered by

surface antigen (HBsAg). The replication cycle commences when HBV binds the sodium-taurocholate cotransporting polypeptide (NTCP) receptor on a hepatocyte (Fig. 16). After receptor-mediated endocytosis, the nucleocapsid is released into the cell. This is followed by import into the nucleus, after which viral DNA (in the form of relaxed-circular DNA or rcDNA) is converted by the covalently attached viral polymerase to the stable viral genetic template—covalently closed circular DNA or cccDNA. Transcription of cccDNA, which may be aided by host transcription factors as well as viral proteins such as HBcAg and HBx, leads to the formation of three classes of mRNAs which include genome-length pregenomic and precore RNAs (coding for core protein, the viral polymerase, and e-antigen) and subgenomic mRNAs (coding for S antigens and HBx protein). After translation to form viral proteins (core, polymerase, eAg, sAg, and X), pregenomic RNA and polymerase are encapsidated. Reverse transcription to form the viral DNA

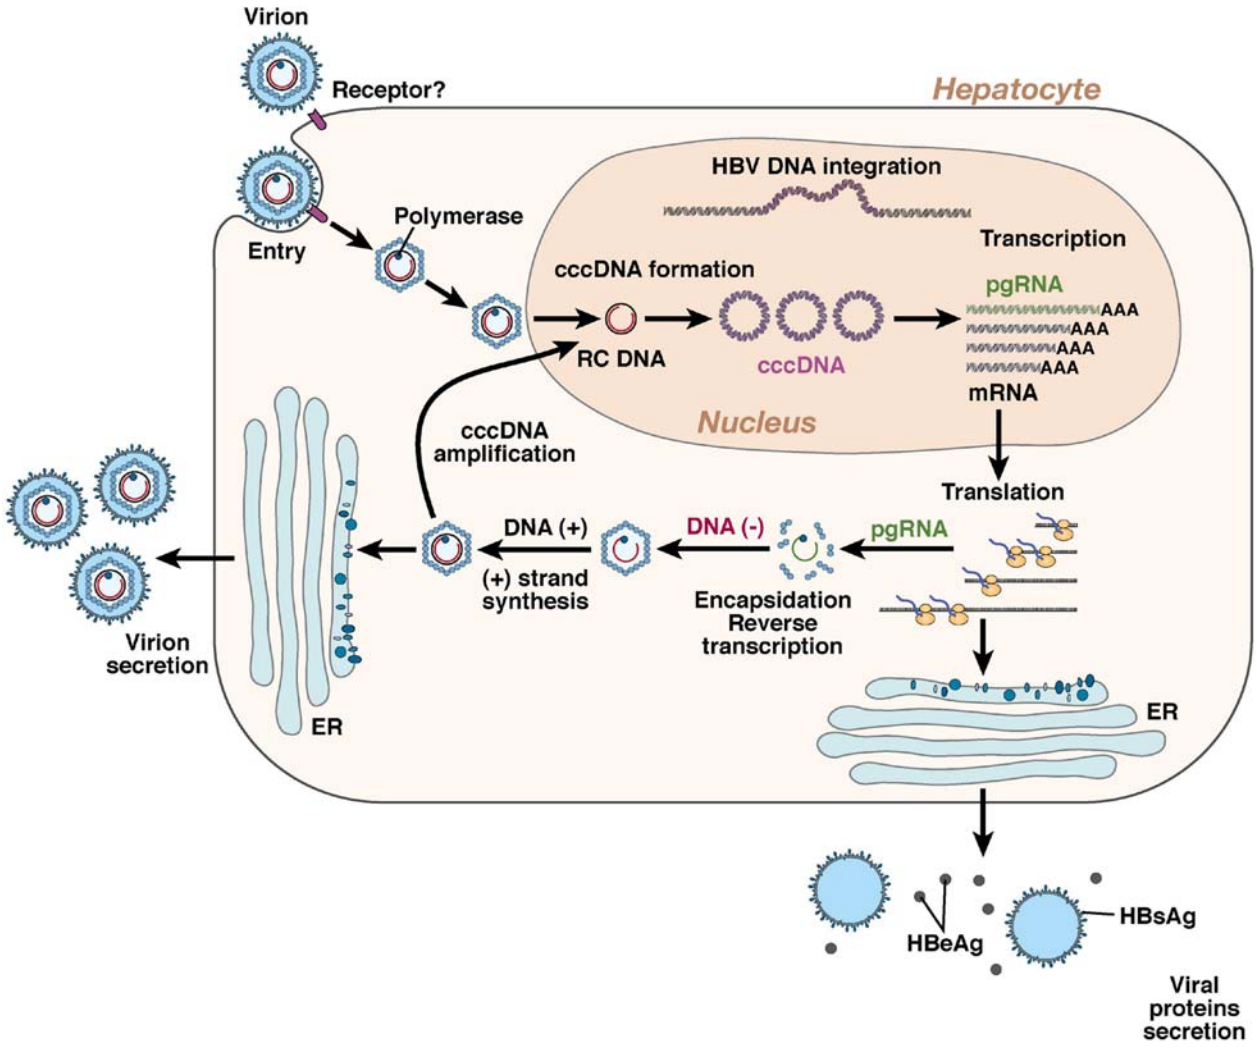

Fig. 16 The HBV replication cycle.[220]

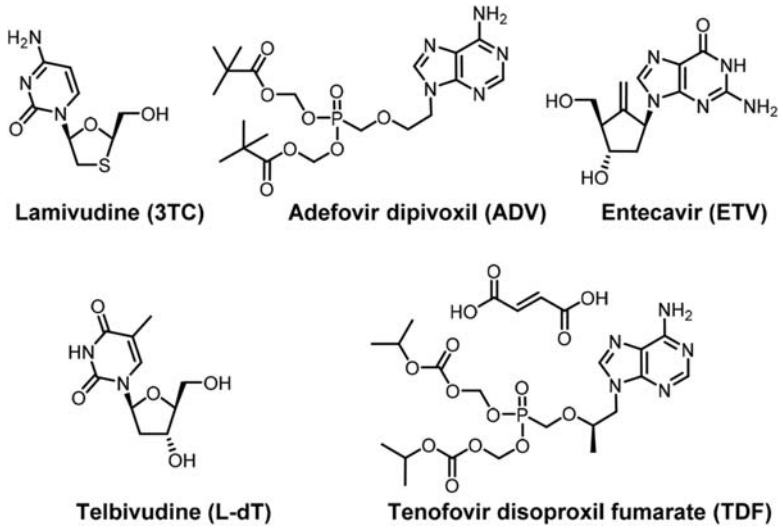

Fig. 17 Structures of approved nucleoside HBV reverse transcriptase inhibitors.

occurs inside the nucleocapsid, and this immature virion can either be recycled back to the nucleus for potential cccDNA amplification or enveloped with sAg and secreted as an infectious virion.[218,219]

5.19.2.2 Nucleoside Reverse Transcriptase Inhibitors

Nucleoside or nucleotide reverse transcriptase (RT) inhibitors have become widely used for the treatment of chronic HBV infection.[221–224] There are five approved anit-HBV nucleoside or nucleotide therapeutics: lamivudine (3TC), adefovir dipivoxil (ADV), entecavir (ETV), telbivudine (L-dT), and TDF (Fig. 17 and Table 13). These agents undergo phosphorylation to their active triphosphate (ETV, 3TC, and L-dT) or diphosphate (ADV and TDF) metabolites which are then incorporated by the viral polymerase and inhibit phases of reverse transcription. 3TC inhibits (+)RNA-dependent (−)DNA synthesis,[225,226] whereas ADV and TDF inhibit both priming of RT and (+)RNA-dependent (−)DNA synthesis.[227–230] ETV and L-dT interact with priming, (+)RNA-dependent (−)DNA synthesis, and subsequent (−)DNA-dependent (+)DNA synthesis.[231–233] The goal of HBV treatment with nucleoside or nucleotide agents is to achieve sustained viral suppression of HBV replication without the emergence of resistance, and thereby to decrease the risk of liver cirrhosis and HCC.

[f]Adefovir terminal elimination half-life.

3TC was the first HBV RT inhibitor to be approved by the FDA (in 1998). It inhibits HBV replication with an EC_{50} of approximately 10 nM in HepG2 2.2.15 cells,[240,241] and is dosed orally at 100 mg QD and is well tolerated with negligible adverse effects. The drawback of 3TC therapy is the rapid onset of resistance, with only a single mutation sufficient to compromise efficacy significantly.[242] Thus, other antivirals with higher barriers to resistance are prescribed preferentially.[234] The related 5-fluoro analog, emtricitabine (FTC, not shown), is also potent against HBV[241] and has an excellent safety profile. FTC, has been evaluated as both monotherapy[243] and in combination with TDF,[244,245] for the treatment of HBV. In both combination studies, FTC/TDF treatment resulted in higher rates of viral suppression than TDF alone. However, rates of e- or s seroconversion were low and not improved with combination therapy.

ADV, the bis-(pivaloylmethyl) ester prodrug of adefovir designed to improve oral absorption, was approved in 2002 for the treatment of HBV. The parent adefovir inhibits HBV replication with an IC_{50} of 0.7 μM in HepG2 cells.[246] ADV exhibits an EC_{50} of 0.1 μM in HepG2 2.2.15 cells[227] and is dosed orally at 10 mg QD. ADV has been associated with renal toxicity at higher (30 mg) or more frequent doses; while the 10 mg dose has minimal effects, close monitoring of renal function is required.[222] While improved compared to 3TC, ADV still has a low genetic barrier with high-level resistance occurring from a single mutation.[234,242] The resistance profile coupled with the potential for renal toxicity has led to a decrease in use of ADV.

ETV is a 2′-deoxyguanosine nucleoside analog featuring a cyclopentyl ring with an exocyclic olefin replacement for the oxygen of the ribose moiety, and was approved in 2005 for the treatment of chronic HBV infection. ETV is a highly potent and selective inhibitor of HBV with an EC_{50} of 3.75 nM in the HepG2 2.2.15 cells, and is dosed orally QD at 0.5 or 1.0 mg in treatment-naive or -experienced patients, respectively.[247,248] Unlike the other approved anti-HBV nucleoside inhibitors, ETV is a nonobligate delayed chain terminator,[249] which reduces the potential for subsequent excision.[232] ETV is well tolerated, and has a very high genetic barrier with a very low incidence of resistance that requires three point mutations.[234,250,251] ETV is currently prescribed as a first line of therapy for the treatment of HBV.[221,223]

L-dT is the unnatural L-isomer of thymidine approved for the treatment of HBV in 2006. L-dT has selective anti-HBV activity with an EC_{50} of 0.19 μM in HepG2 2.2.15 cells, and is dosed orally at 600 mg once daily.[252] L-dT has an excellent safety profile and has been implicated in the suppression of mother-to-child transmission of HBV during pregnancy.[253] While the barrier to resistance is higher than 3TC, resistance to L-dT can still develop through a single point mutation[234,242] and thus it is not recommended as a first-line therapy.

TDF is the most recent RT inhibitor to be approved for the treatment of HBV (2008). It shows comparable clinical efficacy to ETV and is also prescribed as a first-line agent.[221,223,254] TDF is the bis(isopropyloxycarbonyloxymethyl) ester prodrug of the parent nucleotide TFV. The ester prodrug is required for adequate oral absorption. TFV-diphosphate is a potent competitive inhibitor of HBV polymerase ($K_i = 0.18$ μM), and TDF inhibits HBV replication with an EC_{50} of 0.02 μM in HepG2 2.2.15 cells.[227] TDF is dosed orally at 300 mg QD, and while generally well tolerated, TDF therapy has been associated with renal adverse events[255] as well as bone density loss,[256,257] in some patients. Despite this potential for toxicity, discontinuation of therapy with TDF was less prevalent than with ETV therapy.[254] Remarkably, TDF shows a very high barrier to resistance and no resistance mutations have been identified after up to 6 years of treatment.[258]

5.19.2.2.1 Investigational HBV RT inhibitors

Even with the success of existing anti-HBV nucleoside and nucleotide therapeutics, efforts have continued to identify novel RT inhibitors that may have additional benefits as compared to the existing agents (**Fig. 18**). TAF is the orally bioavailable isopropylalanilyl phenyl ester prodrug of TFV and was approved in 2015 for the treatment of HIV (vide supra). TAF exhibits greater stability in human plasma than TDF and leads to much lower exposure of the parent TFV in plasma. As a result, TAF shows lower potential for renal and bone toxicity. TAF also provides efficient delivery of the active metabolite TFV-diphosphate to hepatocytes, where the prodrug is primarily activated by carboxylesterase 1.[259] TAF is safe and well tolerated, with similar efficacy to TDF even at much lower doses (from 8 to 120 mg),[260] and is currently being evaluated in Phase III clinical trials.

Besifovir is the dipivoxil prodrug of a novel acyclic guanine phosphonate nucleoside analog which features a cyclopropyl group in the backbone. Besifovir is a potent and selective anti-HBV agent with an EC_{50} of 50 nM in HepG2 2.2.15 cells.[261] Besifovir is currently being evaluated clinically at once daily oral doses of 90 or 150 mg, and has demonstrated good safety profile with carnitine depletion noted as the most common side effect.[262] No virological breakthrough has been observed over 2 years of treatment and the efficacy is comparable to ETV. Besifovir is in Phase III clinical trials.

Pradefovir is a prodrug of adefovir that was designed to be selectively activated in the liver to improve the therapeutic index as compared to ADV.[263,264] The prodrug is oxidatively cleaved by CYP3A4 in hepatocytes.[265] Pradefovir has demonstrated good efficacy as compared to ADV and appears to be well tolerated up to 48 weeks of administration.[266] Pradefovir is currently being evaluated in Phase II clinical trials.

CMX-157 is the hexadecycloxypropyl phospholipid prodrug of TFV and is in development for the treatment of HBV as well as for HIV (vide supra). It inhibits HBV replication with an EC_{50} of 1.6 μM in HepG2 2.2.15 cells.[267] The prodrug is designed to mimic natural phospholipids and improves oral bioavailability and cell permeability as compared to the parent TFV. Like TAF, the prodrug is stable in plasma and is intended to reduce the potential for renal and bone toxicity by lowering plasma

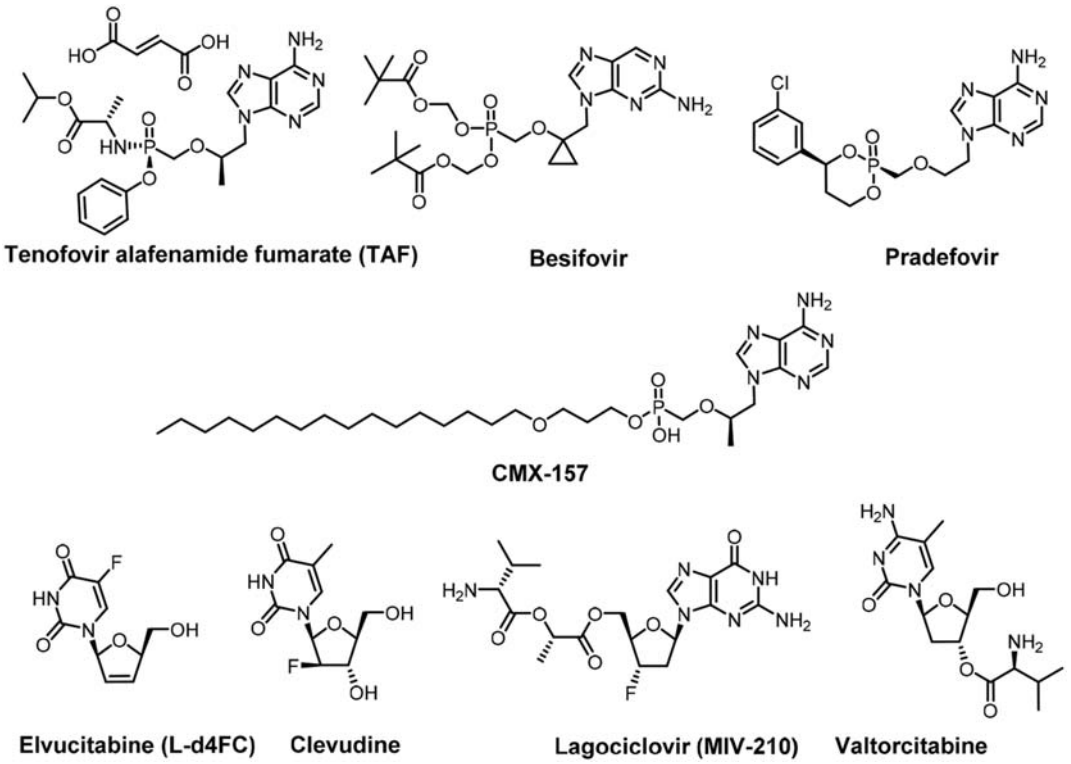

Fig. 18 Structures of investigational nucleoside HBV reverse transcriptase inhibitors.

exposure of the parent TFV. CMX-157 is currently being evaluated for safety, tolerability, and pharmacokinetics in Phase I clinical trials.

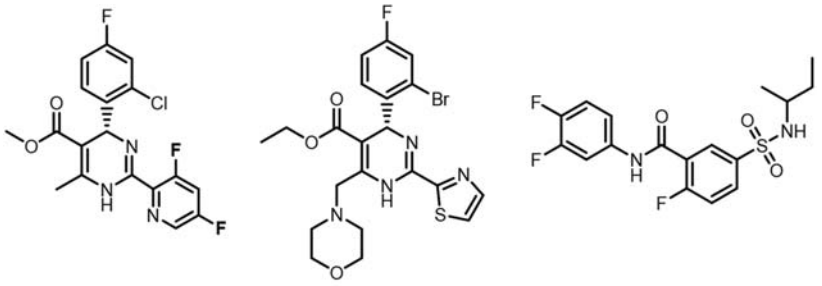
Elvucitabine (L-d4FC) is a 5-fluoro cytidine dideoxy ribose L-nucleoside that has also been explored clinically for the treatment of both HIV (vide supra) and HBV. L-d4FC inhibits HBV replication with an EC_{50} of 2-8 nM in HepG2 2.2.15 cells.[268–270] At oral doses up to 100 mg L-d4FC was well tolerated, without apparent drug-related adverse events, and showed potent antiviral activity in patients with hepatitis B infection.[271–274] L-d4FC has reached Phase II clinical development; however, there have been no recent reports of its clinical progress.

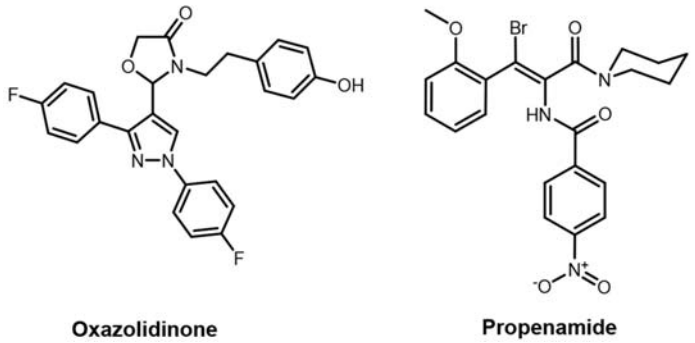
Clevudine (L-FMAU) is a 2′-fluoro-5-methyl-β-L-arabinofuranosyl uracil analog that exhibits an EC_{50} of 0.1 μM against HBV in HepG2 2.2.15 cells.[275] L-FMAU was launched in several Asian countries; however, in the United States, it was associated with the onset of myopathy in Phase III clinical trials[276] and its development was discontinued. Additionally, Lagociclovir[277] and Valtorcitabine[278] are two further investigational anti-HBV nucleosides that reached Phase II clinical evaluation, but whose development has recently been discontinued.

5.19.2.3 Capsid Assembly Inhibitors

Beyond NRTIs, the mechanism that has elicited the most interest from small-molecule drug discovery groups has been capsid inhibition. Capsid modulators are believed to act by changing the kinetics of capsid assembly, resulting in malformed or noninfectious particles.[279] Further, because the core protein is involved in multiple parts of the viral life cycle, it is believed that capsid assembly modulators can affect HBV infection in more ways that simply reducing viral load. It has been reported that capsid inhibitors, in addition to causing misassembly of the capsid, also cause improper packaging of RNA and interfere with the establishment of new cccDNA.[280] At least four classes of small molecules have been shown to interfere with the viral capsid assembly process: heteroaryldihydropyrimidines (HAPs), phenyl sulfonamides, oxazolidinones,[281] and propenamides.[282] Of these the most extensively studied are the HAPs, which were discovered in the late 1990s. An important early HAP lead is BAY-41,[283,284] which showed activity in cellular assays as well as in an HBV transgenic mouse model. Later the more potent GLS-

4[285] was disclosed, and this analog has completed Phase I clinical studies.[286] More recent work on the HAP chemotype includes bicyclic variants.[287]





The sulfonamide class of capsid modulators originated from a high-throughput screening effort resulting in compounds, such as DRV-23, with sub-micromolar potency in cellular assays.[288] Optimization of this class has continued, and one compound, NVR-3-778 (structure not disclosed) has entered clinical trials. The first human clinical proof of concept for this mechanism was established with this compound: oral administration of 600 mg twice daily for 28 days led to a 1.7 log reduction of HBV DNA in the plasma of chronically infected patients.[289]

5.19.2.4 Immunomodulators

A coordinated action of both the innate and adaptive immune response is understood to be a requirement for effective host control of viral infection.[290] Pattern recognition receptors such as the Toll-like receptors (TLRs) serve as first responders in signaling and activation of the innate immune system and additionally provide a link to adaptive immune system T- and B-cell responses.[291] Of particular relevance as a therapeutic target for the treatment of HBV infection, TLR7 has been identified as a member of this receptor class with single-stranded RNA of viral origin as its native ligand.[292]

A family of pteridinone TLR7 receptor agonists including **53**, **54**, and **55** was reported, and their properties described in terms of immunomodulatory activity, selectivity versus other TLRs, and the resulting induction of antiviral cytokines such as IFN-α and TNF-α in assays characterizing the in vitro response of peripheral blood mononuclear cell culture (PBMC) assays. Compound **55** (GS-9620) exhibited an IFN-α MEC of 3 nM and a selectivity ratio of 100 for the observed IFN-α/TNF-α response. Appending the pyrrolidine ring onto the scaffold conferred higher potency and selectivity as compared to related compound **55** (**Fig. 19**).[293]

Compound **55** is highly soluble at low pH and is rapidly metabolized in mouse, rat, dog, monkey, and human hepatic microsomes (with a human microsomal $t_{1/2}$ of 30.5 min). Compound **55** was tested in both chimpanzee and woodchuck efficacy models for HBV. In chimpanzees, every-other-day dosing at 1 mg kg^{-1} for 4 weeks followed by a 1 week rest and then 4 weeks at 2 mg kg^{-1} led to a mean maximal HBV viral reduction of 2.2 logs.[294] In a WHV[295] woodchuck efficacy study, sustained antiviral response to compound **55**, including long-term sAg loss and s-antibody seroconversion was reported in animals treated with dose regimens of 2.5 mg kg^{-1} every other day for 9 weeks as well as in animals receiving 5 mg kg^{-1} weekly for 8 weeks.[296]

In human Phase Ib clinical trials recently reported for compound **55**, chronically infected HBV patients received 0.3, 1, 2, or 4 mg as either a single dose or with a second dose repeated 7 days later. Dose-dependent peripheral mRNA expression of interferon-stimulated gene 15 was detected, although no clinically significant reductions in plasma HBV DNA levels were observed in treatment-naive patients, and no clinically significant HBsAg reduction was observed for either treatment naive or virally suppressed

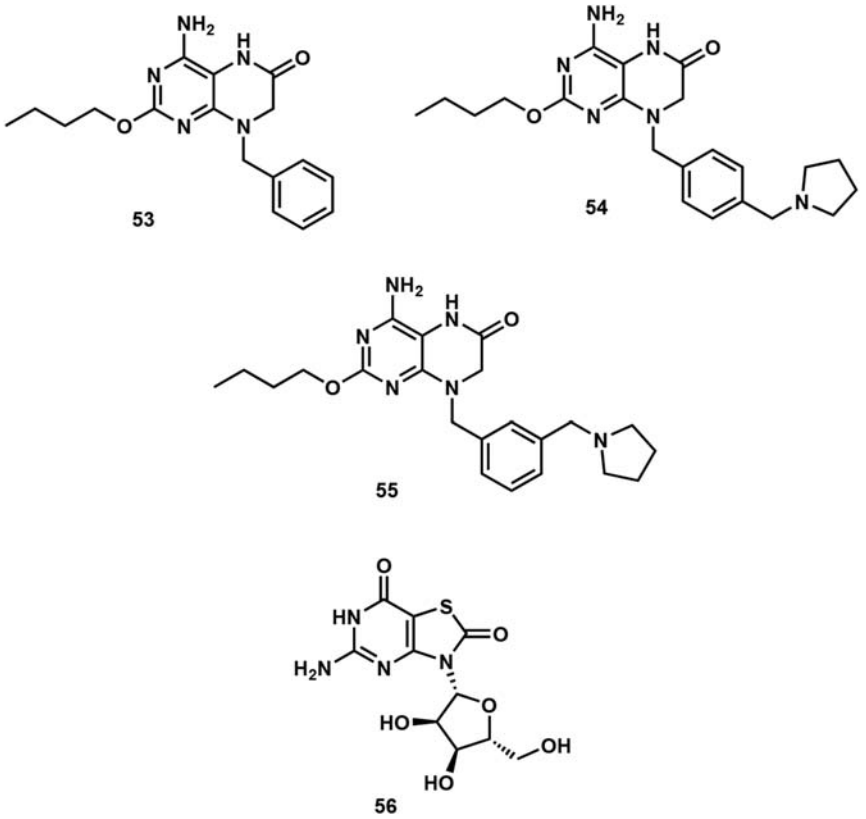


Fig. 19 Immunomodulators for HBV.

subjects.[297] Compound **55** is currently the subject of Phase II clinical trials examining longer dosing durations in chronically infected HBV patients.[298]

Another immunomodulator under examination for its potential to treat HBV is RG-7795 (formerly ANA-773), a prodrug of the nucleoside analog isatoribine (**56**). The prodrug moiety for **56** remains undisclosed, but its active metabolite has been characterized for TLR7 agonism, as well as for in vitro activation of the innate and adaptive immune response.[299] Following earlier clinical trials for the treatment of HCV, its efficacy in the context of virally suppressed, chronically infected HBV patients is the subject of Phase II clinical trials.[300]

5.19.2.5 Biologics-Based Approaches: RNAi and Entry Inhibition

Though nucleoside polymerase inhibitors have provided durable viral suppression and improved outcomes for HBV patients, a cure has remained elusive. Beginning in the early 2000s, some researchers turned their attention to biologic-based approaches. Foremost among these is the use of small-interfering RNAs (siRNAs) to block viral transcription. One early report showed that siRNA reduced viral DNA, RNA, and antigens in vitro (up to 80%) and when delivered by plasmid was also active in a mouse model.[301] Soon after, another group showed that siRNA delivered in liposomes elicited a >1.0 log reduction in viral DNA in a mouse model of HBV.[302] Adenovirus delivery of siRNA was also shown to reduce HBV gene expression and replication to near undetectable levels for at least 26 days in mouse.[303] Still it was recognized that for RNAi silencing to become an effective HBV treatment in humans, several limitations needed to be addressed. These include poor siRNA stability, difficulties in cellular uptake, and off-target effects.[304]

Several groups are actively pursuing this line of research,[305] and the most advanced siRNAs for HBV are ARC-520 and ARC-521—both designed to address the difficulties in delivery that generally plague siRNA therapy. The novel delivery method in both cases involves a siRNA conjugated to a cholesterol derivative (for liver targeting), coinjected with a hepatocyte-targeted endosomolytic polymer (which facilitates siRNA escape from endosomes).[306–308] In Phase II clinical trials in HBV patients, ARC-520 administration was recently reported to result in a mean viral DNA reduction in plasma of 2.2 logs, with a mean maximal HBsAg reduction of 1.1 logs in eAg-positive patients.[309]

In addition to drugs targeting transcription, agents which block viral entry have also been pursued. The most effective and well studied of these is myrcludex B, a lipopeptide that targets the critical entry host factor NTCP.[310] In HBV infected uPA/SCID mice, myrcludex B was shown to block viral spread and hinder amplification of cccDNA.[311] Myrcludex B was recently reported to be in clinical trials in combination with pegylated interferon-alpha-2a.[312]

5.19.3 Conclusion

The results of decades of drug discovery and development for treatments of HIV and HBV have greatly improved the lives of millions of patients. Medicinal chemistry research directed at HIV has resulted in many classes of effective drugs that, in proper combinations, lead to a long-term suppression of HIV. The newest of these drugs are more potent, result in fewer side effects, have longer half-lives, and are often combined into convenient STRs. In addition to ever more effective oral antivirals, treatments requiring less frequent dosing including once-monthly injectables are being tested. Efforts are now intensifying toward the even greater challenge of discovery of a safe and effective curative approach.

HBV research is at a less advanced stage. Though several nucleoside- and interferon-based treatments are in common use and can improve liver function, few patients achieve cure (sAg seroconversion), and no other classes of HBV drugs have yet been approved. Current work on HBV includes direct-acting antivirals (capsid inhibitors), immunomodulators (TLR7), and biologics that block viral translation (RNAi). If an HBV cure is to be found, it may require the combination of several of these approaches.
