To confirm that the resin conjugated with **32** was specifically bound to the 46 kDa protein, we performed competitive binding analyses using the free active compound (**18b**). As a result, the addition of the free form of compound **18b** into the HT-29 lysate clearly competed with the **32**-immobilized resin for the binding to the 46 kDa protein (**Fig. 18**). The bound 46 kDa proteins were then subjected to LC/MS/MS analysis as the specific binding partner of trametinib. MEK1 and MEK2 were the major proteins bound to **32**, with less extensive binding to **33**, and negligible binding to the negative control resin.[15] Western blot analysis using anti-MEK antibody also revealed that MEK1 and MEK2 proteins were strongly detected at the 46 kDa position in the pull-down extract of the **32**-conjugated resin. Further evidence that trametinib specifically binds to MEK1 and MEK2 and that its binding pocket was the same as PD0325901 (**34**) (**Fig. 19**) was provided by experiments using PD0325901 (**34**); **34** competed with **32**-immobilized resin for the binding to MEK1 and MEK2.[15] PD0325901 is an allosteric MEK1/2 inhibitor discovered by Pfizer, which was in Phase 2 clinical trials at the time of our studies.[28]

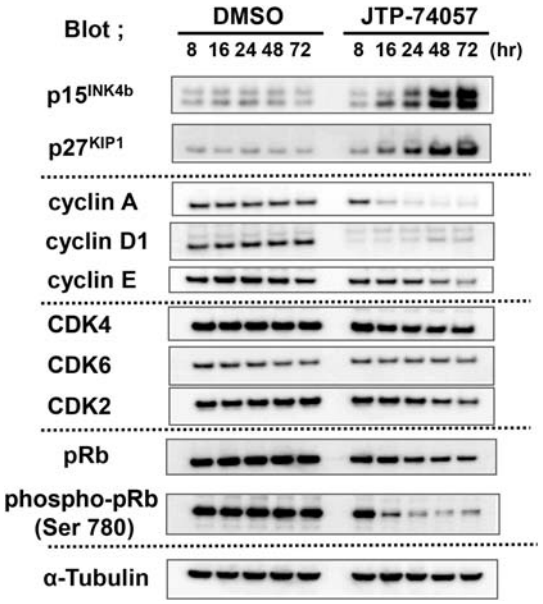

Fig. 16 Effect of trametinib (**1**) on cell-cycle-related protein expression in HT-29 cells. Expression levels of various cell-cycle-related proteins with 10 nM trametinib (**1**, JTP-74057) treatment were assessed by Western blot analysis. DMSO was used as a control. The representative data was shown from 2 to 3 independent experiments.

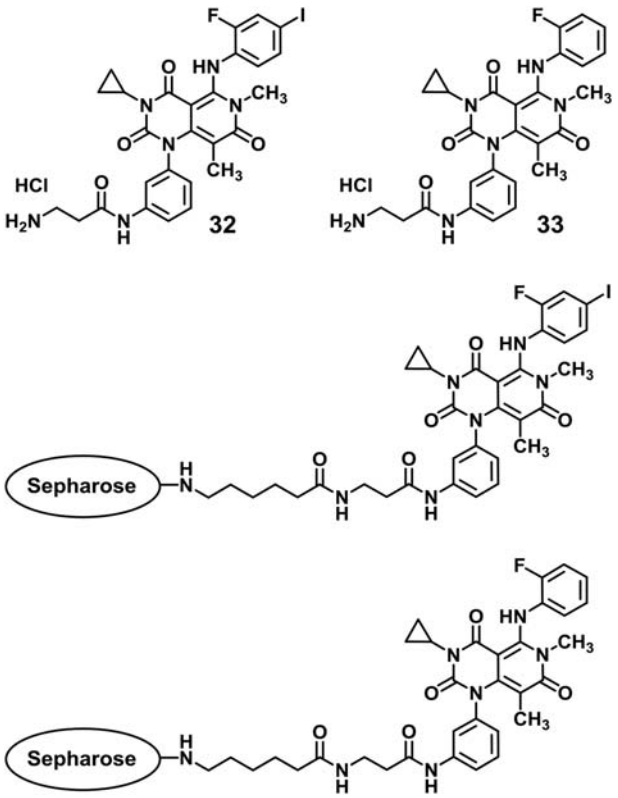

Fig. 17 Structures of trametinib derivatives and chemical affinity probes.

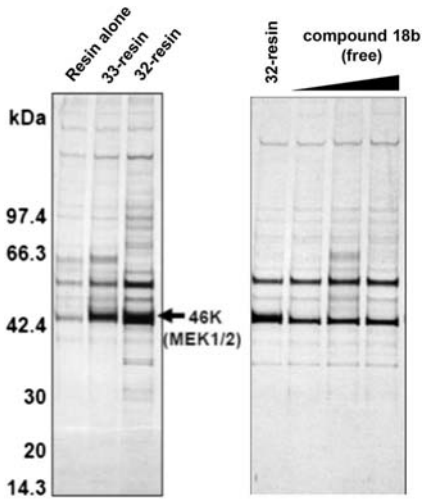

Fig. 18 Drug-affinity chromatography. HT-29 cell lysates were incubated with negative control resin (resin alone), **33**-conjugated resin, or **32**-conjugated resin and the bound proteins were extracted by pull-down assays, then subjected to SDS-PAGE analysis (left). The 46 kDa protein was competed by adding increasing concentrations of free compound **18b** (right).

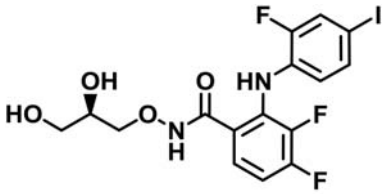
8.02.6.2 MEK Inhibitory Activity of Trametinib

Once we had identified MEK1 and MEK2 as the binding target of trametinib (**1**), we examined the inhibitory activity of trametinib (**1**) against MEK1/MEK2 kinase activity. The inhibitory activity of trametinib (**1**) was determined by measuring the phosphorylation of ERK2, substrate of MEK, by phosphorylated MEK1 or MEK2. Unexpectedly, the IC_{50} value of trametinib (**1**) in this assay platform was 290 nM, unreasonably weak compared with the cell growth inhibitory activity, which was in the subnanomolar concentration range (Fig. 20). The same discrepancy was seen for PD0325901(**34**), whose IC_{50} value was determined as 120 nM (cell growth



PD0325901 (**34**)

Fig. 19 Structure of PD0325901.

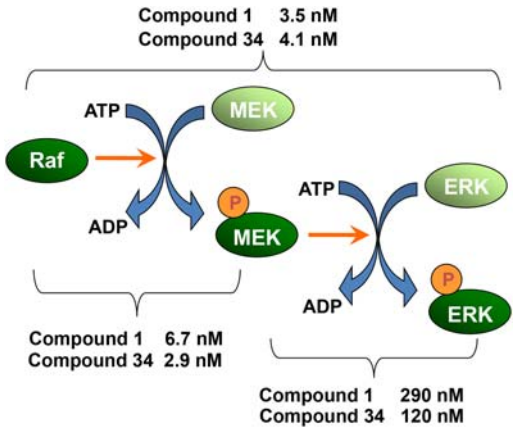


Fig. 20 Inhibitory activities (IC_{50} values) in Raf, MEK single kinase assay or Raf/MEK/ERK cascade kinase assay.

inhibition IC_{50} was 3.4 nM) (Fig. 20). Then, we employed a cascade kinase assay, which consist of active Raf, unphosphorylated (i.e., inactivated) MEK1 or MEK2 and unphosphorylated ERK2.[15] Under these conditions, trametinib (**1**)'s IC_{50} value was determined as 3.5 nM in the B-Raf–MEK1–ERK2 cascade kinase assay (Fig. 20). The IC_{50} value of PD0325901 (**34**) was 4.1 nM in the same cascade assay. Further analysis revealed that trametinib (**1**) and PD0325901 (**34**) inhibited MEK1 phosphorylation by active Raf with the IC_{50} values of 6.7 and 2.9 nM, respectively.[15] Taken together, our results demonstrated that trametinib (**1**) favorably binds to unphosphorylated MEK1/MEK2, resulting in the block of phosphorylation and activation by upstream molecule Raf. Trametinib (**1**) also had an ability to inhibit kinase activity of phosphorylated MEK1/MEK2 even though its activity was considered to be weaker than blockade of activation of MEK1/MEK2 protein by Raf.

Selectivity of trametinib (**1**) over several kinases was examined using a kinase panel study. Trametinib (**1**) did not show inhibitory activity up to 10 μM over the other 98 kinases examined (Table 15). We also retrospectively examined the kinase inhibitory activity of the lead compound (**2**) using a subset of the kinase panel. However, the lead compound (**2**) did not show MEK1 inhibitory activity even at 10 μM because of using phosphorylated MEK1 in this platform, implying that we would not have been able to identify this lead structure if we had conducted our HTS screening campaign using the phosphorylated MEK1 kinase assay platform. The choice of phenotypic screening might be considered an example of serendipity in this trametinib discovery story.

8.02.6.3 Pharmacological Characterization of Trametinib

Trametinib (**1**) is the MEK1/MEK2 selective inhibitor with a nanomolar or subnanomolar range of activity. Here, we provide a summary of the pharmacological activity of trametinib (**1**). Table 16 shows the antiproliferative effects of trametinib (**1**) using 10 human colorectal cancer cell lines. Trametinib (**1**) exhibited strongest IC_{50} values against HT-29 and COLO205 cells, which are known to bear the gain-of-function mutation in B-Raf protein. The cell lines bearing a K-Ras mutation showed a wide range of sensitivity to trametinib. In contrast, COLO320 DM cells, bearing the wild-type gene in both B-Raf and K-Ras, were found to be resistant to trametinib even at 10,000 nM.[2] Trametinib (**1**) also inhibited the growth of normal human lung fibroblasts (NHLF) with the IC_{50} values of 31 nM, which is more than 50-fold weaker than the IC_{50} values in B-Raf mutant, HT-29 and COLO205 cells. 5-Fluorouracil (5-FU), a standard-of-care colon cancer drug, inhibited within a narrow range of IC_{50} values regardless of the mutation status of cell line, whereas the antitumor effect of trametinib seemed to be highly dependent on the mutation status of cell line. Consistent with this, Western blot analysis of the phosphorylation level of ERK1/2 revealed that constitutive ERK phosphorylation was detected in all cell lines except of COLO320 DM and it was inhibited by trametinib treatment (Fig. 21).

NHLF	Normal cell	31 ± 9.8	6.7 ± 2.1

Various human colorectal cancer cell lines or human normal lung fibroblasts (NHLF) were treated with various concentrations of trametinib (**1**) or 5-FU for 72 h. Viable cell number was determined by sulforhodamine B assay.

As mentioned in the earlier section, trametinib induced the expression of CDK inhibitors $p15^{INK4b}$ and $p27^{KIP1}$, and we examined the expression level of $p15^{INK4b}$ and $p27^{KIP1}$ in these cell lines after treatment with trametinib. As shown in Fig. 21, both $p15^{INK4b}$ and $p27^{KIP1}$ were upregulated in the HT-29, COLO205, HCT-15, HCT116, and LoVo cells, whereas either $p15^{INK4b}$ or $p27^{KIP1}$ was upregulated in the LS-174T, SW480, SW620, and T84 cells. Most importantly, the resistant cell line, COLO320 DM cells, showed no induction of $p15^{INK4b}$ or $p27^{KIP1}$ by trametinib treatment, suggesting that upregulation of either $p15^{INK4b}$ or $p27^{KIP1}$ is a prerequisite for growth inhibition by trametinib.[2] Also, our phenotypic HTS campaign leading to the discovery of trametinib was considered to be the assay monitoring a potential pharmacodynamic biomarker of an MEK inhibitor; fortunately, we selected appropriate cells in which $p15^{INK4b}$ can be upregulated as a consequence of MEK inhibition.

In vivo antitumor efficacy of trametinib (**1**) was determined using a nude mouse xenograft model as mentioned earlier. Single oral dosing of trametinib at 1 mg/kg was administered to nude mice bearing HT-29 xenografts. The phosphorylation of ERK1/2 was completely inhibited in the established tumor within 1 h after the dosing, and this effect was diminished by 24 h after the dosing.[2]

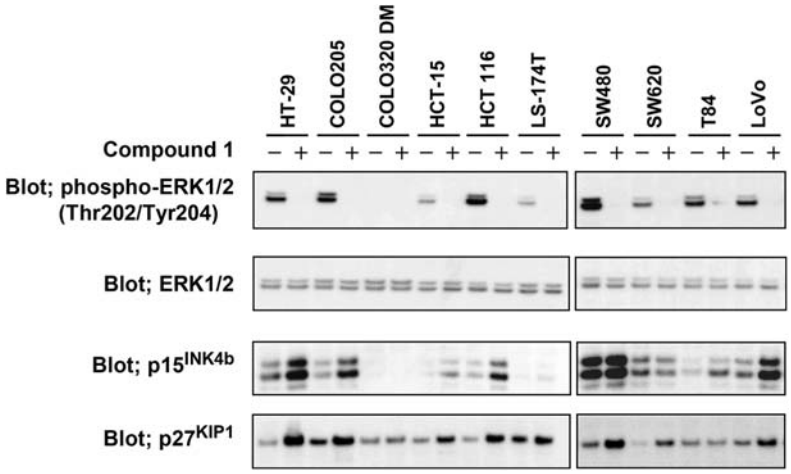

Fig. 21 Effect of trametinib (**1**) on phosphorylation of ERK1/2 and expression of $p15^{INK4b}$, and $p27^{KIP1}$ in various colorectal cancer cell lines. Ten colorectal cancer cell lines were treated with or without compound **1** at 100 nM (in case of HT-29, 10 nM). After 2 h (ERK1/2) or 24 hours ($p15^{INK4b}$, $p27^{KIP1}$), cells were lysed and phospho-ERK1/2, ERK1/2, $p15^{INK4b}$ or $p27^{KIP1}$ were detected by Western blot. The representative data are shown from 2 to 3 independent experiments.

As shown in Fig. 13, administration of 1 mg/kg of trametinib resulted in complete suppression of tumor growth in the HT-29 xenograft model. The antitumor effect of trametinib was also evaluated in another B-Raf mutant cell line, the COLO205 xenograft model. In this case, complete tumor regression was observed in 4 out of 6 mice in which the tumor degenerated to the point that tumor volume was not measurable at a dose of 1 mg/kg, where only complete growth suppression of tumor was observed in the HT-29 xenografts (Fig. 22).[2]

Despite the fact that trametinib inhibited the proliferation of HT-29 and COLO205 cells with comparable IC_{50} values in vitro, COLO205 tumors were much more sensitive to trametinib treatment than HT-29 tumors in vivo. To address this issue, apoptosis induction by trametinib was analyzed in vitro using HT-29 and COLO205 cells. Although trametinib induced apoptosis both in HT-29 and COLO205 cells, COLO205 cells were found to be more sensitive to trametinib than HT-29 in terms of apoptosis induction (data not shown).[2] Since it has been reported that HT-29 cells, but not COLO205 cells, have a mutation in PIK3CA, encoding a catalytic subunit (p100α) of phosphatidylinositol 3-kinase (PI3K) in addition to B-Raf mutation, excess activation of the PI3K–Akt pathway would occur in HT-29 cells concomitantly with MAPK pathway activation. Indeed, a combination treatment of trametinib with an Akt inhibitor, API-2, effectively induced apoptosis at lower concentrations in HT-29 cells (data not shown).[2]

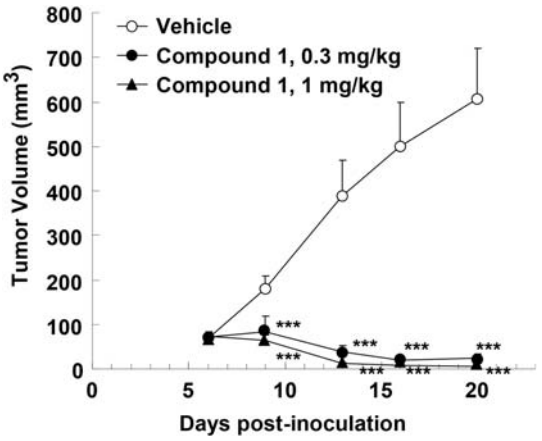

Fig. 22 Antitumor effect of trametinib (**1**) in nude mice bearing COLO205 xenografts. COLO205 cells were inoculated subcutaneously into the right flank of nude mice, and compound **1** or vehicle (10% PEG400, 10% cremophor EL) was administered orally once daily for 14 days starting from 7 days after the inoculation. Tumor volumes were measured twice a week. The results are expressed as mean ± SD ($n=6$). $^{***}P<.001$ versus vehicle (Dunnett's test).

8.02.7 Polymorphism Study

Next we performed the crystalline polymorphism study on trametinib. Several initial batches of trametinib had a melting point (mp) of 180°C and showed acceptable oral bioavailability. However, a new crystal form emerged unexpectedly after several preparations of this compound. This form had a very high mp of 300°C, and exhibited almost no oral exposure. (This polymorph proved to be the most stable after thorough polymorphism study.) In this kind of situation, one of the strategies commonly employed is preparing salts with different molecular packing motifs from that of a parent molecule. One can expect the increase of aqueous solubility. However, we were trapped in a difficult situation because this compound was almost neutral and did not form stable salts with hydrochloric acid or sulfuric acid, for example. The sodium salt could be obtained utilizing weakly acidic NH proton, however, this salt immediately turned into the parent free form upon contact with water. We next searched for stable solvates. Trametinib formed a variety of solvates with Class 3 solvents. For example, solvates with ethanol, 1-propanol, 2-propanol, formic acid, and acetic acid were easily prepared by recrystallization conditions. Although most solvates partially desolvated under reduced pressure, no desolvation occurred in the case of the acetic acid solvate under reduced pressure at 60°C for 3 h. We confirmed the ratio of trametinib to acetic acid to be 1:1 by NMR, elemental analysis, and X-ray. We prepared several lots of acetic acid solvates for biological testing. Our biologist colleagues told us this solvate smelled strong upon opening the lid of a vial. We checked the stability once again and found under more rigorous conditions this solvate had lost acetic acid partially (reduced pressure, 60°C, 48 h, 8% loss; 80°C, 60 h, 60% loss). We abandoned further work with the acetic acid solvate and were in a deadlock once again. One day, my colleagues brought me an NMR spectrum and said "Might this be the one we are looking for?" That was a DMSO solvate. The NMR spectrum clearly showed the ratio of trametinib to DMSO was exactly 1:1. Although data had been collected before the polymorphism study of trametinib had been performed, my coworker hesitated because none of us had ever heard of a "DMSO solvate" as a drug substance. Due to the high boiling point of DMSO (b.p. DMSO, 189°C; AcOH, 118°C) desolvation of this solvate had not been observed even under rigorous drying conditions. We were delighted to observe that the DMSO solvate of trametinib also passed the stability test (80°C, open air, 3 days; 60°C, 75% RH, 3 weeks, etc.). As shown in the X-ray crystal structure in Fig. 23, the unit cell contains two molecules of both trametinib and DMSO, and a hydrogen bond is formed between the oxygen atom of DMSO and the nitrogen of the acetamide moiety of trametinib. Oral exposure was restored as expected. DMSO is a Class 3 solvent, so there's no safety concern. We selected trametinib DMSO for development. Later, trametinib DMSO became the first FDA approved drug of this solvate.

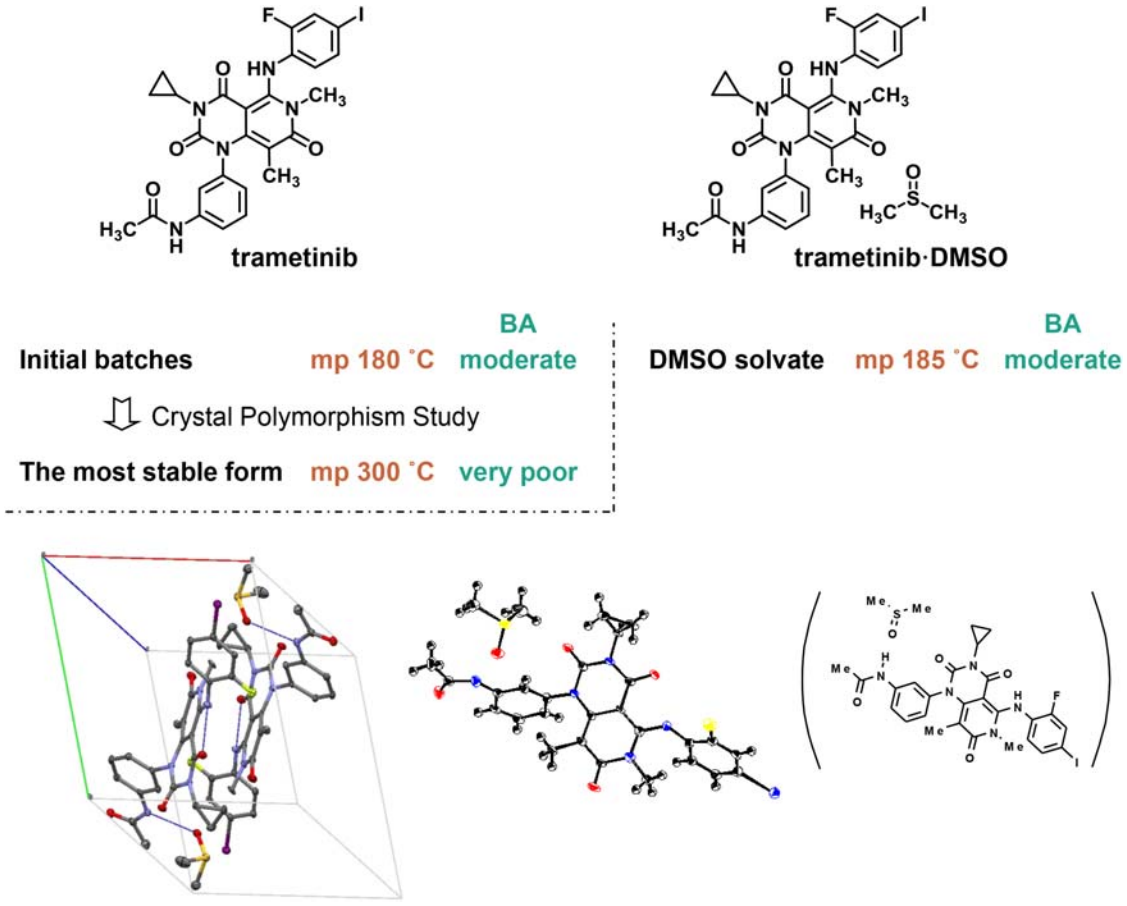

Fig. 23 Crystal polymorphism study of trametinib.

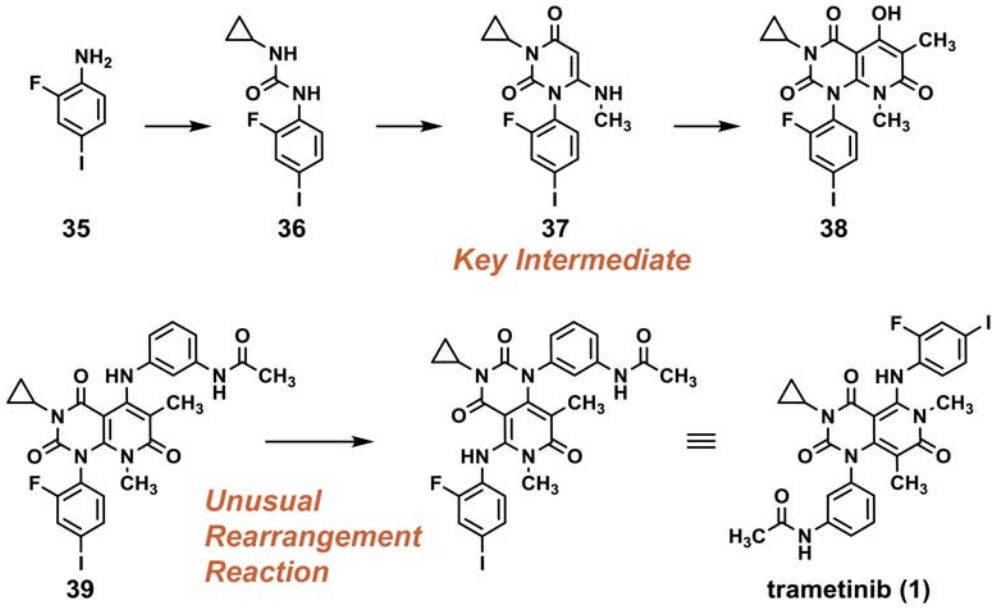

Fig. 24 Synthetic plan of trametinib.

8.02.8 Synthetic Studies

The synthetic plan for trametinib is outlined in Fig. 24. We employed the unusual rearrangement reaction mentioned earlier for the final step. The synthesis of the key intermediate **37** regioselectively without chromatographic purification was an important issue.

Key intermediate **37** could be conveniently prepared if the chloride **41** was obtained regioselectively (Fig. 25). However chlorination of **40** with phosphoryl chloride produced a mixture of the two regioisomeric chlorides **41** and **42**, with a predominant formation of undesired **42**. We tried to vary the reaction conditions by changing the amount of added water or base. But the ratio of **41** and **42** was always c.1:2. When we separated pure chlorides **41** and **42**, and reacted each of them separately under the chlorination conditions, both pure **41** and **42** gave a mixture of **41** and **42** in the same ratio. This outcome clarified that this chlorination reaction proceeded under thermodynamic control, and we abandoned this approach.

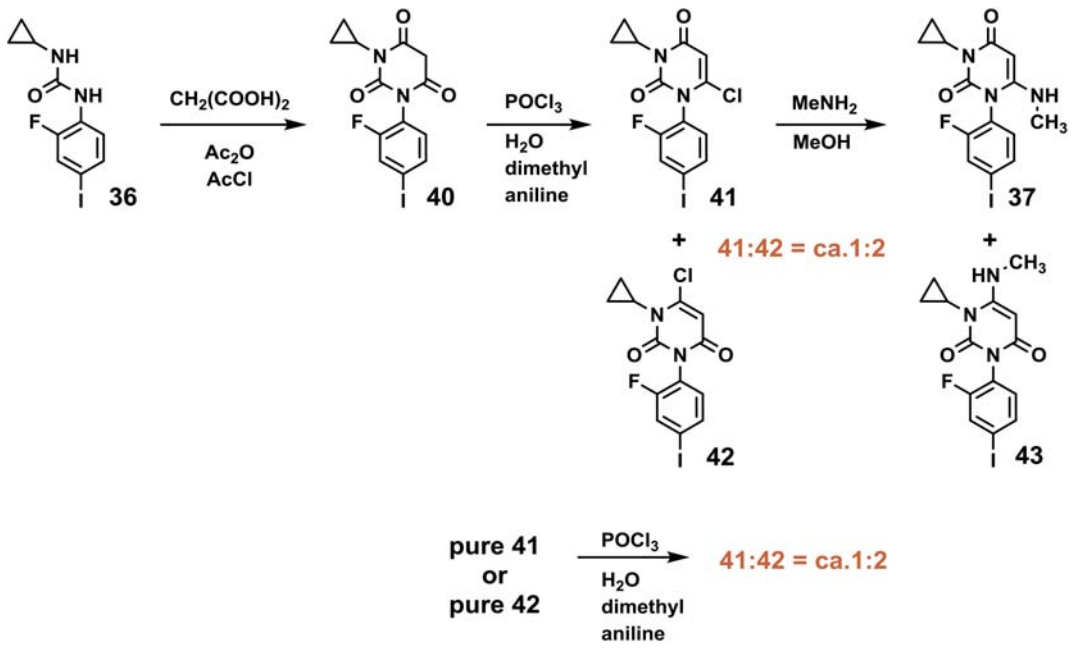

Fig. 25 Preparation of key intermediate-1.

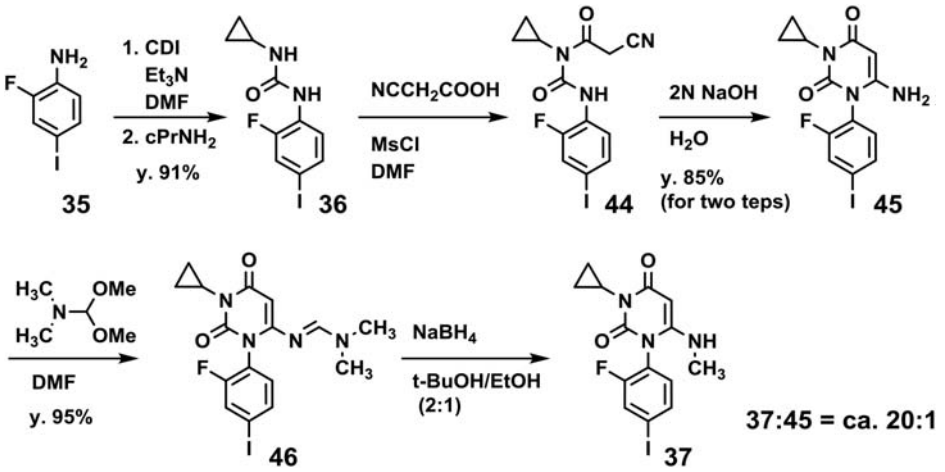

Fig. 26 Preparation of key intermediate-2.

We next investigated an alternative route to synthesize key intermediate **37**, which employed the reduction of the amidine **46** as a key step (Fig. 26). Urea **36** was obtained in high yield by treatment of 2-fluoro-4-iodoaniline (**35**) subsequently with carbonyldiimidazole and cyclopropyl amine. In this reaction, the issue of deiodination of iodo-aniline mentioned before ("SAR Study-1" section) was not present, because this reaction did not require high temperature. Condensation of urea **36** with cyanoacetic acid to give **44** was accomplished using mesyl chloride as an activating reagent. This reaction also proceeded by using acetic anhydride, acetyl chloride, or tosyl chloride, but mesyl chloride gave the best results. Ring-closure reaction of **44** to give **45** smoothly proceeded in a warm alkaline solution in good yield. Direct mono-methylation of the primary amine in **45** was not possible due to the enamine-like character of this compound. However, amine **45** reacted with *N*,*N*-dimethylformamide dimethyl acetal on the primary nitrogen, and gave a high yield of the amidine **46**. Reduction of **46** with sodium borohydride gave the desired mono-methylated **37** and reduction side-product **45**.[29,30] Ratio of **37**:**45** was sensitive to the solvent system employed for reduction reaction. For example, reduction of **46** in methanol gave undesired **45** as a major product (**37**:**45** = 1:1.3). We finally found that the best solvent system for this reduction reaction was *tert*-butanol/ethanol = 2:1, which gave the key intermediate in high selectivity of **37**:**45** = c.20:1.

Subsequent ring-closure reaction of **37** with methylmalonic acid gave **38** in good yield by using **37** purified by column chromatography (Fig. 27). However, crude **37** gave various yields of **38** depending on the lot used. A closer look clarified that the reaction yield was very low when the reduction was quenched by acetic acid whereas quenching with citric acid gave high yield. We speculated that crude **37** contained boric acid (or its derivatives) and quenching the reaction with acetic acid interfered the next ring-closure reaction. This kind of small finding might not seem important, but was a real enjoyment for us chemists when working on the large scale process development. Tosylation of **38** afforded **47**. Thermal reaction of **47** with the substituted aniline gave a high yield of **39**. Finally, trametinib was obtained employing the unusual rearrangement reaction of **39** as mentioned before.

The synthetic route to trametinib is summarized in Fig. 27. The 10-step sequence required no chromatography, and resulted in an overall yield of 34% of trametinib. The unusual rearrangement reaction to trametinib proceeded in very high yield. One of the desirable features of this route is only the final compound is biologically highly active, so the other compounds do not require special handling. This synthetic route was refined at GSK and was performed conveniently on a 40 kg scale.

8.02.9 Addendum

MEK inhibitors such as Pfizer's compound are known to bind an allosteric pocket adjacent to the ATP-binding pocket. And these compounds are classified as type III inhibitors.[31–33] We speculate that trametinib also binds the same allosteric pocket (see "Target Identification of Trametinib" section).[15]

The compounds with an iodo-substituent on the aniline ring exhibited high potency as explained in the text. This is due to halogen bonding between iodine and the backbone carbonyl of the enzyme, and has been reviewed.[34]

8.02.10 Conclusion

In conclusion, starting from an initial lead **2** identified by a cellular high-throughput screen to identify the compounds that increase $p15^{INK4b}$ and SAR studies to improve antiproliferative activity against cancer cells culminated in the discovery of **1**, trametinib (JTP-74057, GSK1120212), a highly potent, selective, and orally active MEK inhibitor. Trametinib displays remarkable potency

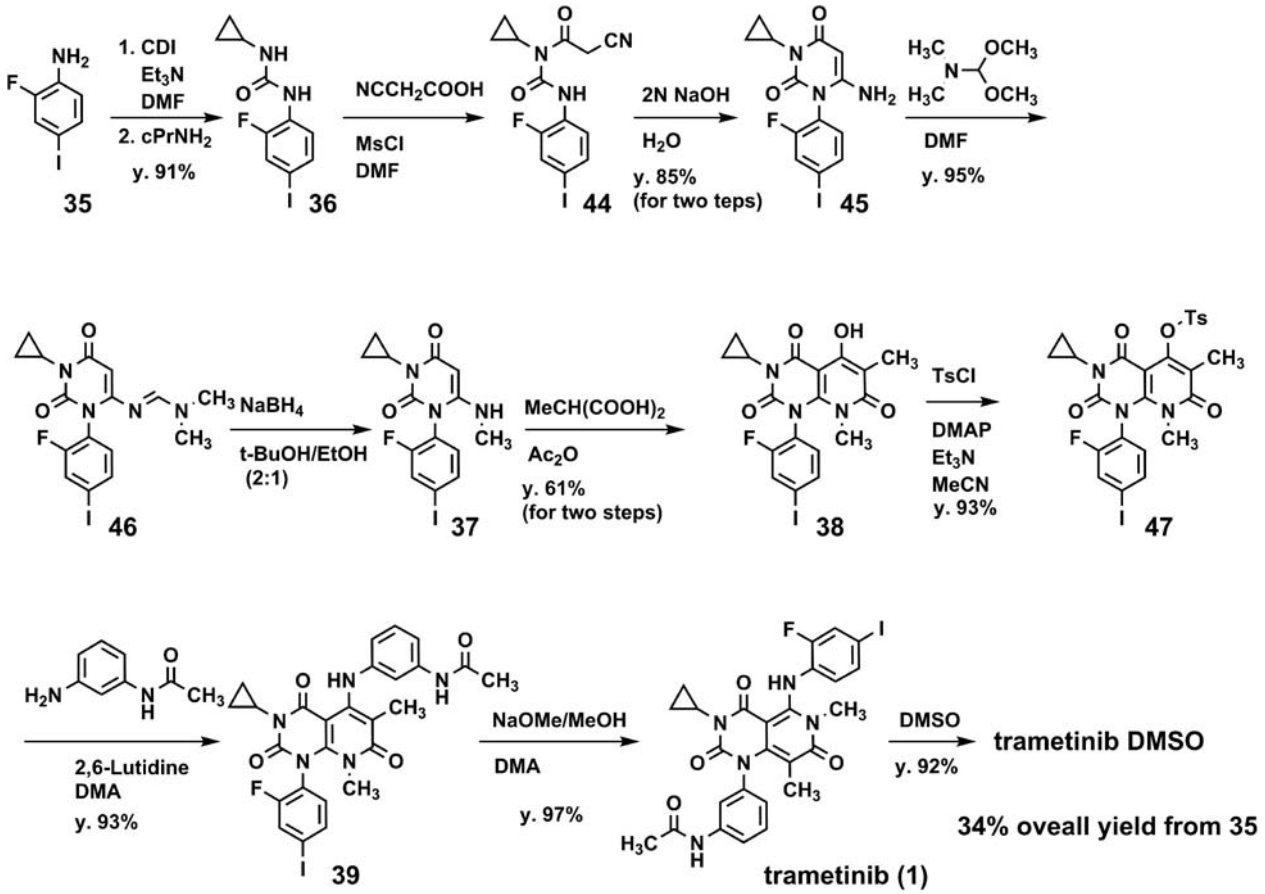

Fig. 27 Synthetic route to trametinib.

in antiproliferative cellular assays and excellent in vivo activity. Trametinib is a new structural class of MEK inhibitor possessing the unique pyrido[4,3-*d*]pyrimidine core. The synthetic route to trametinib featuring unusual rearrangement reaction is concise and highly efficient. Inhibition of the MEK–ERK pathway offers a very promising therapeutic strategy for cancers with activating mutants Ras and Raf. Trametinib is now widely available for use as a single-agent or in combination with the Raf inhibitor, dabrafenib, in the treatment of patients with unresectable or metastatic melanoma with a BRAF V600E or V600K mutation. The research and development of trametinib is still being extensively continued, including not only the melanoma therapy in combination with novel immunotherapies targeting the activation of antitumor immune response, but also the treatment options for the other solid tumors and leukemia. As of Oct. 2015, around 300 references in the literature could be found in PubMed regarding the research on trametinib/GSK1120212/JTP-74057, and over 100 clinical trials for trametinib, both active and completed studies, are listed in the ClinicalTrials.gov. Trametinib, discovered by a unique strategy of the phenotypic screening followed by extensive medicinal chemistry and the target identification by chemical biology methods, has opened up a new horizon for melanoma therapeutic options as well as for a combination therapeutic strategy for malignant tumors using more than two molecular targeting drugs.

8.03.1 Introduction

8.03.1.1 Preamble

Tumor hypoxia (deprivation of oxygen in tumor cells) is arguably one of the best validated targets for oncology drug development.[1] Tumor hypoxia has been demonstrated to occur in a wide range of human tumors and is a driver of tumor progression through adaptive responses and resistance to therapy through reduction in proliferation and failure to fix radiation-induced DNA damage. Despite being the subject of drug discovery efforts for over four decades, hypoxia is one of the least successfully drugged oncology targets. In this age of "targeted therapy," why have we failed to capitalize on this opportunity? In this article, we background the case for targeting hypoxic tumor cells and explore a recent drug discovery campaign to develop a drug targeted against hypoxic cells in solid tumors. We aim to give insight into the difficulties presented by this ubiquitous target and how specific tools have been developed to increase the chances of success.

8.03.1.2 Hypoxia

Tumor hypoxia arises as a result of an imbalance between supply and demand for oxygen. The supply of oxygen is diffusion limited in small, avascular tumors, and in larger tumors, oxygen supply is compromised by disordered and dysfunctional tumor vasculature.[2,3] This deficiency is exacerbated by increased metabolic demand within tumors, and collectively, this imbalance results in pathophysiological hypoxia. However, the target is not a simple binary proposition. The depth of hypoxia varies greatly, and the spatial and temporal distribution of hypoxia is highly heterogeneous, both within individual tumors and between tumors of the same type, even in the same patient (**Fig. 1A**).[8] This complexity has been complicated by considerable ambiguity in the literature around definitions of "normoxia" and "hypoxia." This ambiguity stems from the various measurement systems used to report hypoxia and semantic variations (**Fig. 1B**).[9] Three commonly used units for oxygen concentration are shown on the *x*-axis of **Fig. 1B**. While normoxic conditions used in most cell culture experiments have around 20% oxygen (measured in the humidified gas phase and assumed to be in equilibrium with culture medium), the level of oxygen in peripheral "normal" tissues is considerably lower, typically in the range of 3–7%. Fine-needle measurements of oxygen tension in tumor tissue made using an Eppendorf oxygen electrode

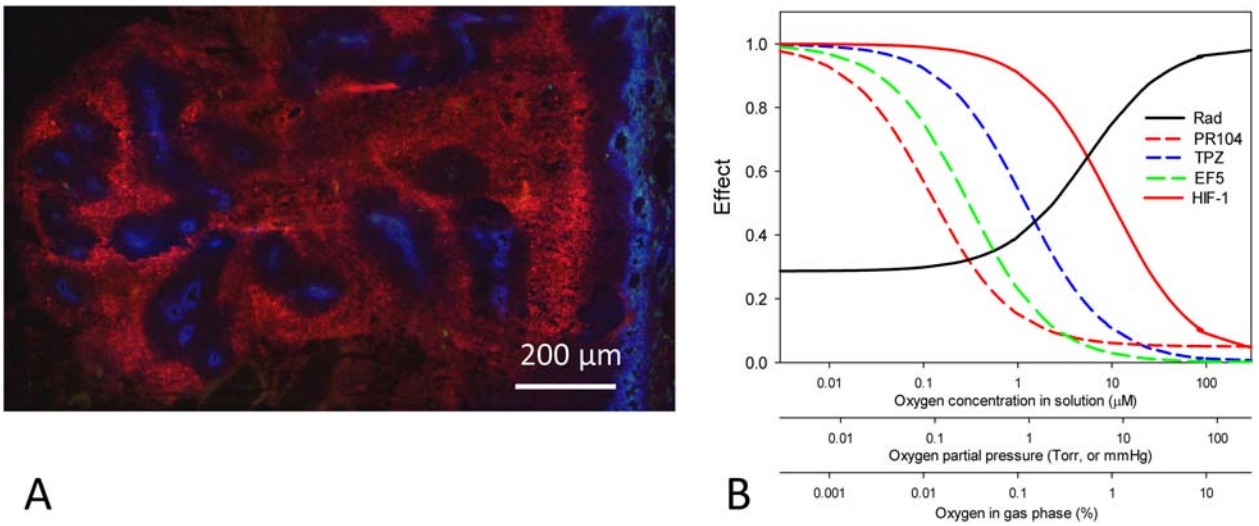

Fig. 1 (A) Detection of hypoxic cells in a SiHa human cervical carcinoma xenograft grown subcutaneously in nude mice. Hypoxic marker EF5 (60 mg kg^{-1}) was administrated intraperitoneally 1.5 h, and blood vessel perfusion marker Hochest33342 (40 mg kg^{-1}) was administered intravenously 2 min before the mice were euthanized. Frozen sections (8 μm) were immunostained for the hypoxic marker (EF5, *red*) and perfused blood vessels identified by Hochest33342 fluorescence (*blue*). (B) Oxygen detection and response. Schematic representation of quantitative oxygen dependencies for ionizing radiation, bioreductive activation of prodrugs and imaging agents, and biological responses to hypoxia. The curves are based on representative oxygen sensitivity parameters for clonogenic cell killing by ionizing radiation (Rad),[4] tirapazamine (TPZ),[5] and PR-104A.[6] Also shown is the binding of 2-nitroimidazole etanidazole pentafluoride (EF5) to intracellular proteins.[7] Biological responses to hypoxia are time and cell type dependent; an indicative relationship shown here is based on acute stabilization of HIF1 in HT1080 cells.[7] Modified and redrawn from Wilson, W. R.; Hay, M. P. Targeting Hypoxia in Cancer Therapy. *Nature Rev. Cancer* **2011**, *11*, 393–410.

are regarded as the gold standard and have identified a wide range of oxygen tensions within solid tumors.[8] The oxygen concentration for half-maximal effect (K_{O_2}) for radiation-induced cell killing is ~4 μM,[10] and cells below ~1 μM (0.1%) (Fig. 1) are considered radiobiologically resistant. Nitroimidazole-based probes[11] are activated at relatively low oxygen tensions with K_{O_2} values ~0.5 μM (0.05%) and report radiobiological hypoxia (Fig. 1). In contrast, the identification of the role of hypoxia-inducible factor-1 (HIF-1)[12] in the cellular response to low oxygen tensions has provided another measure of hypoxia where HIF-mediated response has a higher K_{O_2} of ~10 μM (1%).[7] A variety of endogenous markers, such as carbonic anhydrase IX (CA IX)[13] and osteopontin,[14] that are regulated by HIF-1 report this higher range of oxygen tension. Hypoxia also varies in temporal sense with "cycling hypoxia"[15] resulting changes in vessel perfusion on a timescale from minutes to hours.[16,17] Cycling hypoxia is considered to be of particular importance in the development of an aggressive phenotype.[18]

The identification of the molecular signaling pathways mediated by HIF-1 and their roles in the adaptive response to hypoxia have increased understanding of the role of hypoxia in tumor progression.[12,19] Hypoxia plays a role in the suppression of cell death responses[20,21] including immune suppression,[22,23] initiation of angiogenesis[24] and vasculogenesis,[25] and activation of a glycolytic shift in metabolism,[26,27] and hypoxia enhances invasion[28] and metastasis.[29–31] Hypoxia also promotes genomic instability through increased production of reactive oxygen species (ROS)[32] and suppression of DNA repair processes.[33,34]

Despite the expansive growth in our understanding of the molecular consequences of hypoxia in the last decade and the consequent implications for therapy, most of the initial understanding of the impact of hypoxia came from radiotherapy studies. While early clinical studies demonstrated radiosensitivity was influenced by blood flow,[35,36] it was not until the work of Gray that hypoxia was implicated in radioresistance.[37,38] Studies using Eppendorf oxygen electrodes in accessible tumors, such as head and neck squamous cell carcinoma (HNSCC) and cervical carcinoma, revealed a significant incidence of hypoxia in these tumors.[8] These studies indicated hypoxia could be related to resistance to radiotherapy impacting on local tumor control and overall survival.[39–42] Further evidence that hypoxia impacts treatment outcomes is accruing, not only particularly in the head and neck cancer setting where radiotherapy or chemoradiotherapy is the definitive treatment[43–46] but also in other tumor sites.[21,46–49] The pathophysiological conditions present in tumors that lead to hypoxia such as poor perfusion, large and variable distances between capillaries,[3] and high interstitial pressures[50] can also limit the diffusion of chemotherapeutic agents.[51] In addition, these physiological responses to hypoxia can promote chemoresistance,[52,53] although it should be noted that, in some instances, these changes may result in increased sensitivity to chemotherapy.[1]

The high incidence of tumor hypoxia, its influence on tumor progression, and treatment outcome clearly implicate hypoxia as a validated prospect for a "targeted therapy" approach. However, drug development targeting hypoxia has an extensive and somewhat checkered history.

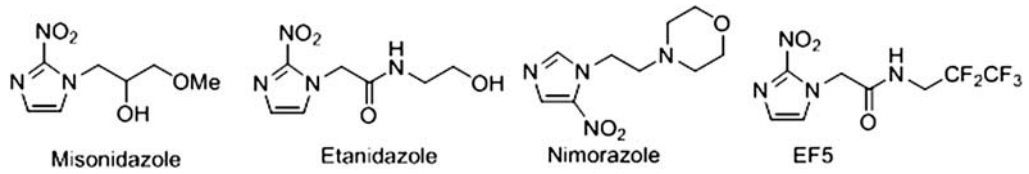

Fig. 2 Nitroimidazole oxygen-mimetic radiation sensitizers and imaging agents.

8.03.1.3 Drug Development in the Context of Hypoxia

Initial efforts to ameliorate the impact of tumor hypoxia on therapy focused on the modification of tumor oxygen levels. Fractionated radiation schedules allowed partial reoxygenation between fractions,[54] while increased oxygen delivery to tumors was achieved with hyperbaric oxygen[55] or carbogen breathing.[56–58] Drug discovery efforts based on small-molecule oxygen mimetics have an extensive history.[59] Electron-affinic nitroimidazoles were intended to mimic oxygen and "fix" radiation damage in hypoxic tumor cells.[59–61] Leading candidates such as misonidazole[62] and etanidazole[63] (Fig. 2) were trialed extensively with fractionated radiotherapy but were ultimately unsuccessful.[64–66] A less electron-affinic 5-nitroimidazole radiosensitizer, nimorazole, was shown to be well tolerated.[67,68] Nimorazole has shown activity in combination with radiotherapy for head and neck cancer[69] and is in clinical use in Denmark. Although the clinical experience with these modalities has provided mixed results, when taken together in a meta-analysis, these interventions to modify hypoxia have been shown to provide benefit,[70] further strengthening the case for the therapeutic targeting of hypoxia. Importantly, retrospective analysis of hypoxia in these tumors, based on a hypoxic gene expression signature, showed that benefit is restricted to patients with more hypoxic tumors.[43] This points to the importance of stratifying patients based on tumor hypoxia in the clinical development of hypoxia-targeted agents.[71] Prospective trials evaluating nimorazole in conjunction with hypoxia markers are currently in progress (ClinialTrials.gov identifiers, NCT01880359 and NCT01950689).

Theoretically, these attempts to modify hypoxia could restore tumor radiosensitivity of fully oxygenated cells. A new approach evolved where hypoxia-activated prodrugs (HAPs) were designed to directly kill hypoxic tumor cells.[1,72–75] This approach also had the potential to leverage the presence of hypoxic cells to release cytotoxins that could diffuse to adjacent tumor cells and lead to increased tumor cell kill.

From a design perspective, HAPs may be characterized as containing a bioreductive trigger unit that deactivates or masks a cytotoxic effector unit through a physical or electronic linker unit.[76] This concept covers a large number of chemically diverse prodrugs linked by a common mechanism of activation (Fig. 3A). One-electron reduction of the bioreductive trigger unit by reductase enzymes may be reversed in the presence of oxygen leading to the formation of superoxide and the parent prodrug.[77] This redox cycling is relatively nontoxic because of detoxification of the superoxide by superoxide dismutase and reduction of the resulting H_2O_2 by catalase, glutathione peroxidase, and peroxiredoxins. In the absence of oxygen, the initial radical may then rearrange or fragment to a reactive species that mediates cytotoxicity or may be further reduced to activate the effector molecule. This concept has been the subject of extensive drug design efforts producing a wide range of exploratory HAPs, and these can be categorized in six chemical classes: nitroaryl, nitroheteroaryl, quinone, metal complex, aliphatic N-oxide, and heteroaryl N-oxide compounds (Fig. 3B).[1,74] It is worthwhile to note that most, if not all, of the HAP compounds violate structural alert rules generally espoused within the drug development community.[78] Furthermore, the idea that metabolism is necessary for activity requires special consideration and needs to be explicitly addressed in drug design in this context (section "Measuring Extravascular Drug Transport").

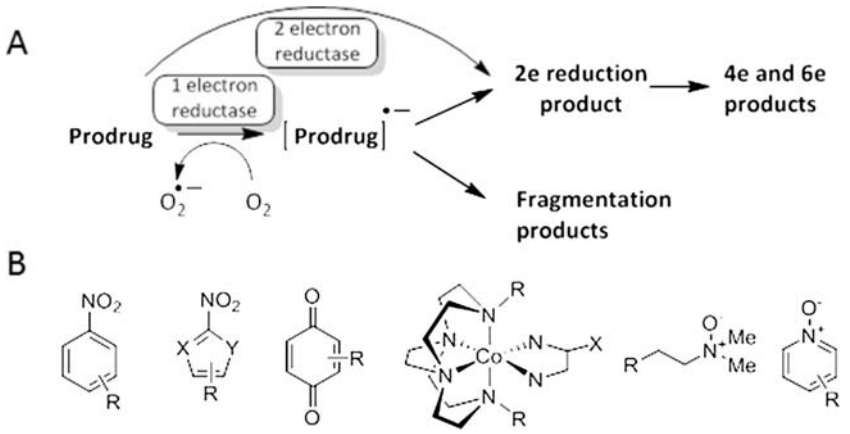

Fig. 3 (A) A general mechanism of activation for HAPs. (B) Chemical classes explored as HAPs.

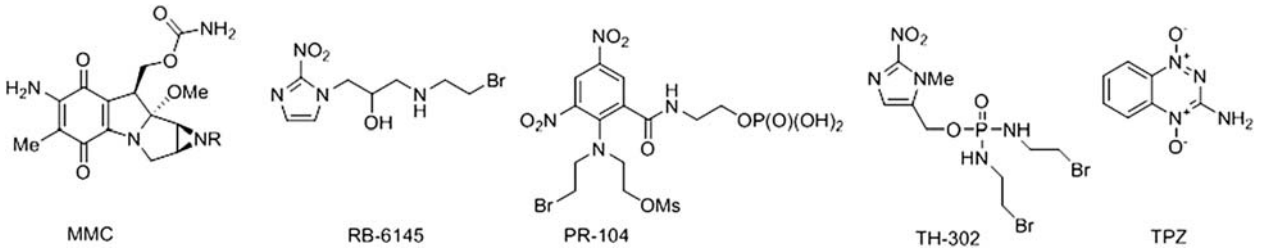

Fig. 4 Hypoxia-activated prodrugs.

The earliest demonstration of a potential HAP approach came with the observation that mitomycin C (Fig. 4) was activated by bioreduction[79,80] and that one-electron reduction of quinones could result in redox cycling in the presence of oxygen.[81,82] Although mitomycin C and related quinones (porfiromycin, apazaquinone)[83,84] can act as HAPs, they are also susceptible to two-electron activation that compromises their hypoxic selectivity and, in the case of apazaquinone (aka EO9) that is activated by the two electron reductase DT-diaphorase,[85] this provides a therapeutic targeting strategy.[86]

Evolving from known electron-affinic radiosensitizers such as misonidazole,[62] a variety of nitroimidazoles and related nitroheterocycles were explored as HAPs[87–91] culminating in the identification of RB-6145.[92] Unfortunately, preclinical development was curtailed by the observation of induced blindness in animal studies that was related to ablation of hypoxic tissue within the retina.[93]

Early work identifying nitroreduction as an electronic switch leading to the activation of nitrogen mustards[94–96] led to a structure–activity exploration of dinitrobenzamide mustards[95,97–100] culminating in the identification of PR-104 that is the phosphate prodrug of HAP PR-104A.[101] Nitroreduction of PR-104A to hydroxylamine and amine compounds, which can be catalyzed by P450 oxidoreductase (POR)[102] and other diflavin reductases[103] under hypoxia, results in the activation of the mixed bromomesylate mustard to generate DNA cross-links.[104] PR-104 demonstrated single-agent activity and synergistic activity in combination with radiation and chemotherapy in multiple xenograft models.[101] Observations of single-agent activity in some xenografts suggested unexpected activation under aerobic conditions.[105,106] The aldo-keto reductase isoform 1C3 (AKR1C3) was identified as the enzyme responsible for aerobic (oxygen-insensitive) activation of PR-104A activation.[105] Phase I clinical trials demonstrated dose-limiting hematologic toxicity,[107,108] with enteritis and liver failure also observed at the very high doses achievable in leukemia patients.[109] AKR1C3 expression in myeloid progenitor cells was suggested as a contributor to toxicity.[110] Preclinical studies suggest possible utility in cancers with high AKR1C3 expression,[111–113] although these also suggest that AKR1C3 is not the sole determinant of monotherapy activity and that a broader understanding of predictive biomarkers would thus be required for further clinical development.

A similar approach is being pursued by Threshold Pharmaceuticals in their development of TH-302 (evofosfamide). Based on early work on nitroheterocyclic prodrugs of phosphoramidate mustards,[114,115] a nitroimidazole prodrug of bromoisophosphoramide mustard was identified as a HAP.[116] Reduction of the nitroimidazole trigger unit initiates fragmentation and release of the phosphoramide.[117] TH-302 displays marked hypoxic selectivity *in vitro*[116–118] and impressive preclinical activity as a single agent[119] or in combination studies in a variety of tumor xenograft models.[117,120] Unfortunately, positive indications from two phase II clinical studies[121,122] were not replicated in phase III trials in pancreatic cancer in combination with gemcitabine (NCT01746979) and in sarcoma with docetaxel (NCT01440088).

8.03.1.4 Tirapazamine

Tirapazamine (3-amino-benzotriazine 1,4-dioxide, TPZ, **1**) was identified from an antimicrobial collection prepared by Bill Lee at Stanford Research Institute International (Palo Alto, CA) and characterized as a HAP by Martin Brown at Stanford University.[123] It was the first example of an N-oxide HAP and has been the subject of extensive research for three decades.[124–126] TPZ displays considerable hypoxic selectivity *in vitro*, typically from 50- to 300-fold when measured by either clonogenic survival or inhibition of proliferation.[127–129] TPZ undergoes bioreductive metabolism by one-electron reductases, for example, POR,[130,131] inducible nitric oxide synthase,[132] and undefined nuclear reductases,[133] to generate relatively nontoxic 1-oxide **2** and minor amounts of nor-oxide **3** (Fig. 5). Direct two-electron reduction to 1-oxide **2** or four-electron reduction to nor-oxide **3** does not contribute to cytotoxicity. An intermediate radical **4** was proposed to act as the oxygen sensor and to mediate cytotoxicity.[134,135] In the absence of oxygen, the reducing radical **4** may undergo protonation (**5**) and subsequent rearrangement to produce an oxidizing radical.[136,137] The identity of this radical species has been the subject of considerable debate with the formation of hydroxyl radical benzotriazinyl (BTZ) radical **6** or aryl radical **7** proposed. Kent Gates and colleagues have proposed the formation of hydroxyl radical[136] and demonstrated a fingerprint of DNA damage by TPZ that mimics that seen for hydroxyl radical.[138] In isotope-labeling studies of a related but considerably more electron-affinic benzotriazine dioxide (BTO) analog of TPZ, they present evidence for the formation of hydroxyl radical.[139] In contrast, Bob Anderson and colleagues at the University of Auckland have used pulse radiolysis and electron paramagnetic resonance (EPR) studies to explore possible radical species generated after the protonation of the initial oxidizing radical **4**. They have demonstrated the presence of several species including an oxidizing BTZ radical **6**[137,140] and minor contributions from aryl radical proposed as **7**.[141] Critically, they did not observe evidence for the production of hydroxyl radical from TPZ.

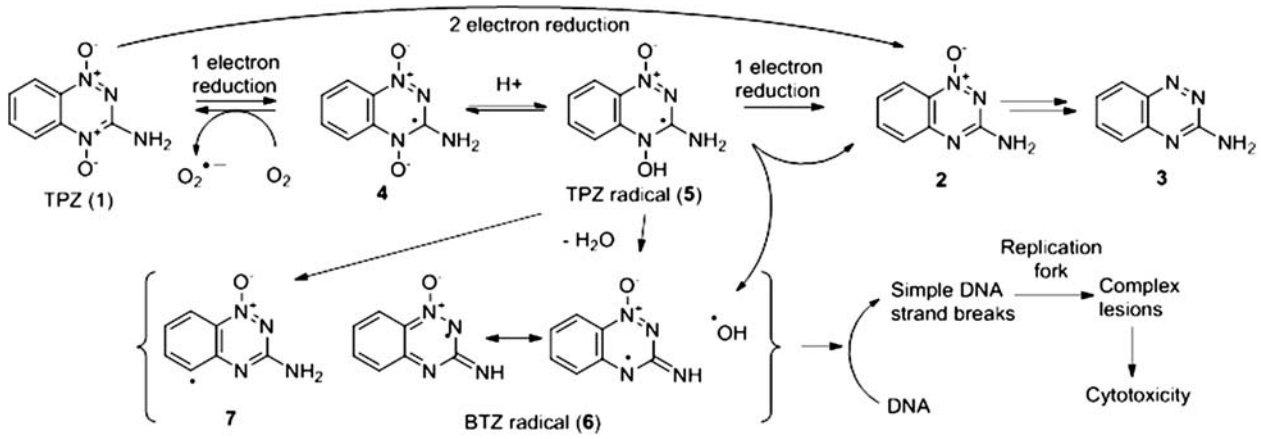

Fig. 5 Bioreductive mechanism of TPZ activation.

Analog studies with a variety of 3-substituted BTO analogs demonstrated that a variety of radical species are produced after rearrangement of the initial reducing radical and that the product distribution is subject to electronic influences,[141] while EPR studies with related quinoxaline 1,4-dioxides show formation of hydroxyl radical is promoted by increased electron affinity.[142] While discussion on the exact nature of the radicals that mediate TPZ cytotoxicity is ongoing,[143,144] this had not hindered the advancement of TPZ or the pursuit of improved analogs.

A distinctive feature of TPZ and other members of the class is the oxygen sensitivity of the initial radical. The K_{O_2} of TPZ is approximately 1–3 μM[5] and this is approximately 10- to 30-fold higher than nitroaryl and nitroimidazole HAPs (**Fig. 1B**).[128] It has been suggested that this oxygen sensitivity complements the oxygen dependence of external beam radiotherapy[5] and allows N-oxide HAPs such as TPZ to kill hypoxic cells at intermediate oxygen concentrations, thus targeting the most important subpopulation of radioresistant tumor cells.[4,5]

Bioreduction results in complex DNA damage as observed by using comet assay[145,146] or γH2AX induction[147,148] and includes clustered DNA single-strand breaks, double-strand breaks, and covalently bound topoisomerase complexes.[149] Consequently, this damage is repaired by multiple repair processes including homologous recombination repair (HRR) of replication fork-associated double-strand breaks.[150,151]

TPZ demonstrated additional cell killing in tumor xenograft models in combination with both single-dose radiation[152] and fractionated radiation.[153,154] In preclinical studies, TPZ displayed synergistic activity in combination with cisplatin[155,156] through hypoxia-dependent inhibition of the repair of cisplatin-induced DNA cross-links.[157] Preclinical pharmacology studies revealed TPZ was converted predominantly to the corresponding 1-oxide **2** and small amount of the nor-oxide **3** after i.p. or i.v. injection.[158,159] Large single doses of TPZ induced weight loss, hyperactivity, and tremors, while myelotoxicity was observed with fractionated daily dosing.[160]

TPZ has been the subject of extended clinical investigation with variable results. Evidence of activity was seen in early-stage trials, and this has validated the concept of hypoxia targeting to some degree. However, disappointing results in phase III trials have compromised TPZ's advance to registration.[126,161,162] Initial trials revealed TPZ was well tolerated up to 390–450 mg m^{-2} as a single agent.[163] Dose reductions were required in combination with chemotherapy, and TPZ was used at 260 mg m^{-2} in combination with cisplatin.[164] TPZ induced nausea and vomiting, diarrhea, weight loss and muscle cramps, reversible hearing loss, and tinnitus.[126,162] Clinical evaluation has focused on non-small cell lung cancer (NSCLC),[165–168] cervical carcinoma,[169–174] and HNSCC and more recently on the potentiation of chemoradiotherapy, particularly cisplatin and radiation.[175,176] Indications of activity in the randomized phase III CATAPULT I trial in advanced NSCLC where TPZ, in combination with cisplatin, provided significant increases in response rates and overall survival compared with cisplatin alone[167] were supplanted by a superior combination of etoposide and cisplatin in the NSCLC CATAPULT II trial.[166] In the head and neck setting, a phase II trial suggested that TPZ, in combination with cisplatin chemoradiotherapy, was efficacious with a trend in favor of the TPZ arm for increased locoregional control and failure-free survival over 5-fluorouracil (5-FU) plus chemoradiotherapy.[175] However, this effect was only seen in patients with hypoxic tumors as defined by ^{18}F-misonidazole PET imaging, and the converse was also seen; the 5-FU–chemoradiotherapy combination was considerably less effective for patients with hypoxic tumors.[46,177] Unfortunately, TPZ did not significantly improve overall survival or local tumor control in a large, randomized phase III trial[176] where poor radiotherapy quality control[178] and failure to select patients with hypoxic tumors for TPZ treatment reduced the power of the study. A retrospective analysis of treatment compliance identified a trend in favor of TPZ for time to locoregional failure (HR 0.74, 95% CI 0.53–1.04, $P=0.067$).[178] Further analysis of the hypoxia imaging data from the phase I and II trials also considered the impact of human papillomavirus (HPV) status and suggested further stratification on the basis of HPV p16 status, with hypoxic, p16-negative patients most likely to benefit from the addition of TPZ to chemoradiation therapy.[179] Unfortunately, this observation came too late to influence the conduct of the phase III TPZ trials, and TPZ development has been halted (personal communication, Prof. J. M. Brown).

8.03.2 Building a Toolset for Bioreductive Drug Discovery

8.03.2.1 Introductory Remarks

In 2003, we entered into collaboration with Prof. Martin Brown at Stanford University on an NIH-funded program grant to develop a second-generation BTO analog of TPZ. By this time, TPZ was well advanced in clinical evaluation and, although positive clinical results were documented, a series of problems that limited the activity of TPZ as a HAP were becoming apparent. TPZ had relatively low aqueous solubility and required extended infusion times in the initial monotherapy study.[159,163] TPZ demonstrated significant toxicities that limited its therapeutic ratio. Perhaps the most significant limitation was that TPZ was substantially less selective for hypoxic cells in three-dimensional culture models[180] or tumor xenografts[181] than for those in monolayer cell culture. These observations provided real opportunities for the development of an improved analog as a "fast follower." This campaign was run in an academic drug discovery environment with emphasis on development of improved tools for lead optimization rather than "brute-force" screening of analogs.

8.03.2.2 Structure–Activity Toolset

As we embarked on the discovery program for a second-generation TPZ analog, we turned to the literature to understand the scope of existing structure–activity relationships (SAR). TPZ had been identified from a library of antimicrobial agents, but we were surprised at the limited number of BTOs evaluated,[123,127,182,183] given the extensive preclinical and clinical studies on TPZ. Even the patent literature on the class was relatively terse.[184] Initial studies had demonstrated that increased electron affinity gave increased hypoxic cytotoxicity *in vitro* and increased toxicity *in vivo* and that *in vitro* hypoxic selectivity was maximal for TPZ itself.[123,127] Addition of strongly basic diethylaminoalkyl side chains linked through the 3-amino position (**8**; **Fig. 6**) provided increases in hypoxic cytotoxicity and selectivity *in vitro*, but did not translate into increased activity against hypoxic cells *in vivo*, at least in part due to reduced drug exposure (reduced drug half-life at maximum tolerated dose (MTD)).[182] In a subsequent study, the use of electron-withdrawing substituents at the 7-position to increase electron affinity, and consequently hypoxic cytotoxicity, was combined with solubilizing dialkylaminoalkyl side chains to provide BTO analogs (e.g., **9**) with increased *in vitro* hypoxic potency relative to TPZ but reduced hypoxic selectivity and reduced *in vivo* activity. Notably, several analogs bearing 3-alkyl substituents (**10**, **11**) displayed improved potency and selectivity *in vitro*, and this translated to comparable efficacy to TPZ *in vivo* in a fractionated radiation model.[183]

Our first objective was to prepare a toolset of compounds that would allow us to more closely define the SAR for cytotoxicity and hypoxic selectivity and understand the possibilities and limitations around BTO synthesis. To this end, we prepared a set of 34 3-amino BTOs **12** with a variety of substituents on the benzo ring (X = NEt_2, NMe_2, OMe, Me, F, Cl, CF_3, $MeSO_2$, and *n*-$BuSO_2$) that provided compounds spanning a wide range of electron affinity and steric interaction and a modest range of lipophilicity.[129] We utilized a two-step synthesis starting from appropriately substituted nitroanilines **13** (**Fig. 7**). These were condensed with cyanamide under acidic conditions to form the intermediate guanidines that were then cyclized under strongly basic conditions in an Arndt cyclization[185] to produce the corresponding benzotriazine 1-oxides **14**.[186] This process was conducted as a melt and produced a significant exotherm to drive the reaction to completion. Although effective for a wide range of analogs, this sequence is really only suitable on a millimolar scale. These 1-oxides **14** could be oxidized to the corresponding 1,4-dioxides **12** in modest yields. We surveyed a range of oxidants and found that peracetic acid or, preferably, pertrifluoroacetic acid provided the best conversion to products. This reaction was always a compromise with extensive conversion being associated with complex by-product mixtures and difficult chromatographic separations. In practice, we settled for lower conversion and a relatively simple purification of starting material and product. Preparation of 5-substituted compounds has been proved to be difficult with compounds only ever isolated in very low yields, presumably due to steric interference at the peri N-4 position. Although the two-step procedure was less efficient than the direct condensation[187] that provides 1,4-dioxide **12** directly from nitrofuroxan **19** (benzo[*c*][1,2,5]oxadiazole 1-oxide), it provides access to a wider range of compounds, including monosubstituted analogs with unequivocal regioisomeric identification. In addition, this route also provides the corresponding 1-oxides **14** that are the primary metabolites in this class and thus useful as standards in mechanistic and pharmacological studies. We were also able to convert 3-amino-1-oxides **14** to the corresponding chlorides **15** and install 3-aminoalkyl side chains (e.g., **17**) (section "BTOs With Improved EVT"). Alternately, we could convert **14** to iodides **16** and use Pd-mediated cross-coupling reactions[188,189] to access 3-alkyl BTOs and 3-aryl BTOs **18** in subsequent studies (section "Exploring 3-Alkyl BTOs: Role of H bonding on EVT"). This was more efficient than the alternative Bamberger triazine synthesis of 3-alkyl triazines **23**,[190] which still required a difficult oxidation step to give triazine dioxides **18**.[183]

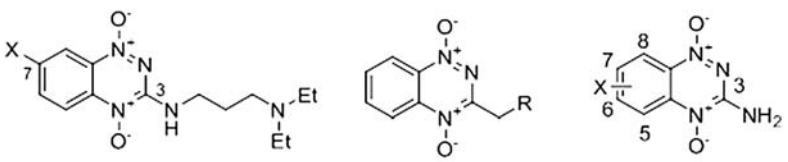

Fig. 6 TPZ and related BTO analogs.

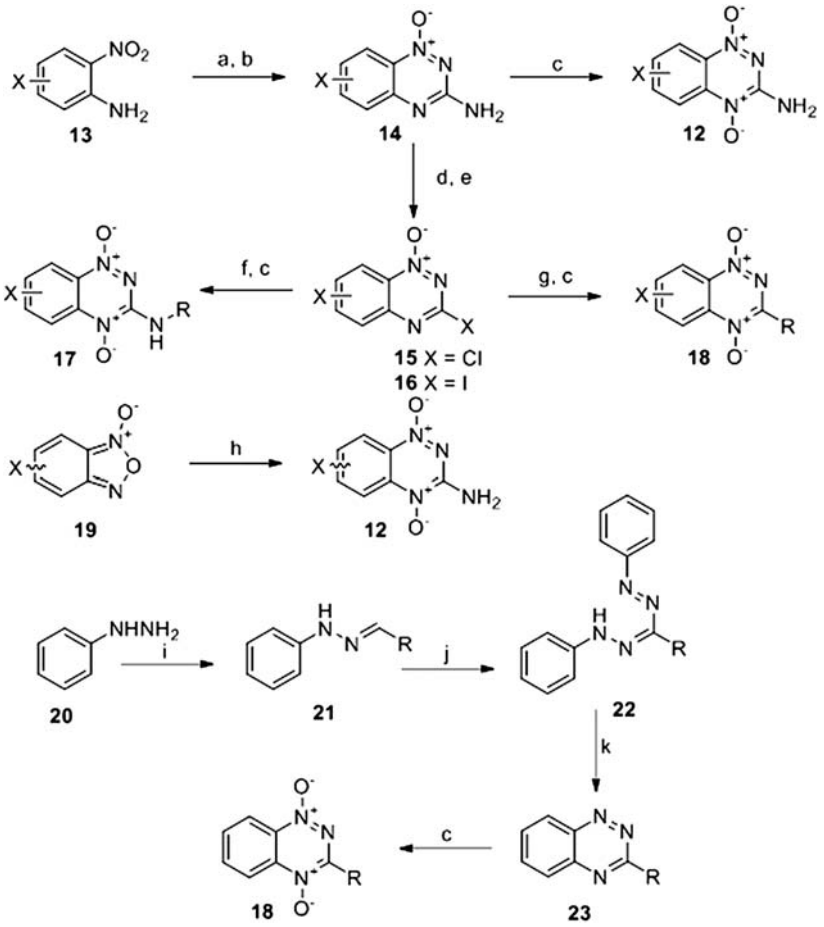

Fig. 7 Synthesis of BTO analogs. Reagents: (a) NH_2CN, HCl; (b) aq. NaOH; (c) CH_3CO_3H or CF_3CO_3H, DCM; (d) $NaNO_2$, CF_3CO_2H; (e) DMF, $POCl_3$; (f) RNH_2, DME; (g) Stille or Suzuki reaction; (h) Na_2NCN, MeOH; (i) RCHO, EtOH; (j) Aniline, $NaNO_2$, HCl, HOAc; (k) $BF_3 \cdot HOAc$.

We determined the lipophilicity of a subset of 12 compounds as octanol/water partition coefficients (P) at pH 7.4 and were able to train predictive software (Advanced Chemistry Development Inc., Toronto, Canada) to reliably predict the lipophilicity as ($\log P$) of BTO compounds going forward. The SAR set spanned a limited range of $\log P$ from -1.38 to 0.84. These BTOs were generally less soluble than TPZ, and this did preclude determination of aerobic cytotoxicity for some compounds, but otherwise did not limit the study. The compounds spanned a wide range of electron affinity with one-electron reduction potentials [$E(1)$], measured by pulse radiolysis, covering the range from -671 to -240 mV. This spans the zone of electron affinity for efficient bioreduction by mammalian enzymes (approximately –450 to -300 mV). We found $E(1)$ values correlated with the Hammett sigma substituent parameter with 5- and 8-substituted BTOs best described by σ_m and 6- and 7-substituted BTOs described by σ_p. The electron affinity correlated with aerobic, but not hypoxic, toxicity as determined by clonogenic survival of murine SCCVII tumor cells consistent with increased aerobic metabolism and cytotoxicity mediated by ROS formed by redox cycling of the radical anion. This toolset of BTOs also allowed us to confirm that the sulforhodamine B proliferation-based assay of cytotoxicity was a suitable surrogate for the "gold standard" clonogenic survival assay with excellent correlation of IC_{50} (drug concentration over 4 h exposure to reduce cell density of either murine SCC VII or human HT29 colon carcinoma cells to 50% of controls) against C_{10} (drug concentration over 1 h exposure to reduce clonogenic survival by one log). This provided a considerable streamlining of the discovery campaign.

8.03.2.3 Measuring Extravascular Drug Transport

The next component required to underpin our campaign was an *in vitro* system to evaluate extravascular drug transport (EVT). Early evidence for the limited EVT of TPZ had been gathered in multicellular tumor spheroids (MTS)[180] or tumor xenografts.[181] MTS are 3-D cell cultures that grow as spheres with many features of the extravascular compartment of tumors including diffusion-limited hypoxia and gradients of nutrients, pH, and proliferation as a function of distance from their boundary.[191–193] In order to investigate TPZ transport further, we used multicellular layer (MCL) cultures (Fig. 8A), an alternative *in vitro* 3-D model of the extravascular compartment developed in our laboratory.[194,195] Cells are grown on a semipermeable support membrane to a thickness of ~100–400 μm, which is approximately the distance between the capillaries in many tumors. MCLs are used in diffusion chambers

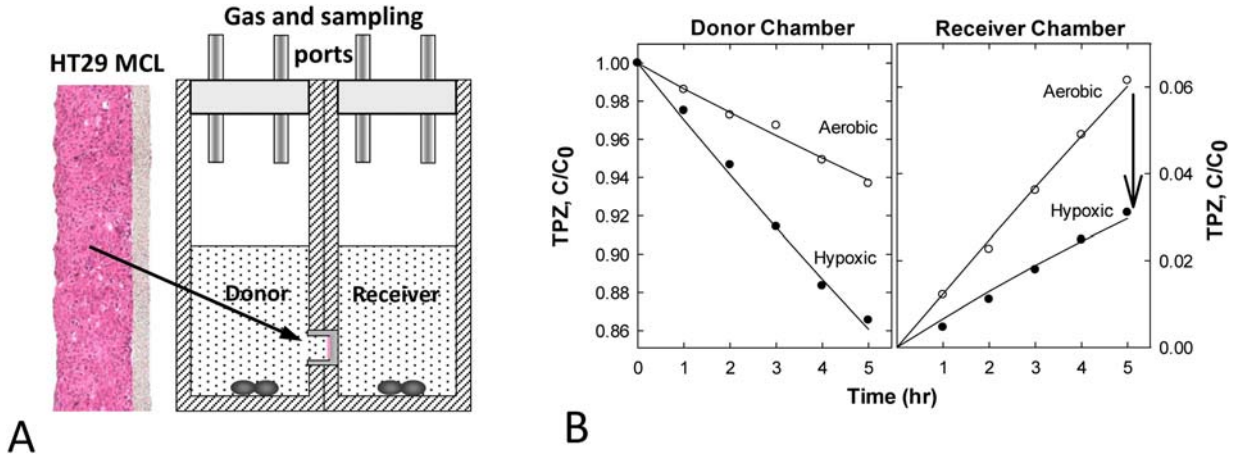

Fig. 8 (A) MCL cultures and diffusion chamber apparatus. Drug is introduced to the donor chamber and measured in both chambers as a function of time. (B) Measured TPZ concentrations in donor and receiver chambers. Clear demonstration that TPZ penetration is lower under hypoxia is shown by decreased concentrations (normalized to the initial concentration, C_0) in the receiver chamber (indicated by *arrow*). The lower concentrations in the donor chamber under hypoxia reflect metabolic consumption in the MCLs, which limit penetration. Adapted and redrawn from Pruijn, F. B.; Patel, K.; Hay, M. P.; Wilson, W. R.; Hicks, K. O. Prediction of Tumour Tissue Diffusion Coefficients of Hypoxia-Activated Prodrugs from Physicochemical Parameters. *Aust. J. Chem.* **2008**, *61*, 687–693.

(Fig. 8A) to study the rate of drug transport by measuring drug concentrations in culture medium on each side of the MCL using compound-specific analytic techniques such as high-performance liquid chromatography (HPLC) and liquid chromatography/mass spectrometry. We, and others, had previously used MCLs to demonstrate that TPZ transport under anoxia is hindered by rapid bioreductive metabolism (Fig. 8B).[196–198] In addition, these studies enable quantitation of the key parameters that determine drug transport in tumor tissue: the diffusion coefficient and rates of cellular uptake, binding, and irreversible metabolism.

Parameters are fitted using a reaction–diffusion equation to describe transport in the MCL:

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - M \tag{1}$$

where C is the free drug concentration, x is the distance diffused through the MCL, t is time, M is the rate of drug reaction, and D is the drug diffusion coefficient. M generally has the form

$$M = k_{\text{met}}C + k_{\text{f}}C - k_{\text{r}}C_{\text{b}} + \cdots \tag{2}$$

where k_{met} is the rate constant for first-order metabolism and k_{f} and k_{r} are forward and reverse rate constants for first-order binding (e.g., reversible binding to macromolecules when binding sites are in excess). Other terms including higher-order reaction can be added as required[195,199] as can explicit intracellular and extracellular compartments.[200]

For BTO analogs, D may be estimated using aerobic MCLs to suppress bioreductive metabolism and the parameters for M estimated using hypoxic MCLs, either directly or by scaling k_{met} determined in single-cell suspensions to MCL cell density[198] (see section "Developing a Spatially Resolved-PK–PD Model" and Ref. 201 for further details).

We were able to measure the diffusion coefficients for a training set of structurally diverse BTOs and to develop an algorithm to predict D in MCLs (D_{mcl}) from physicochemical parameters: MW, log$P$ 7.4, and number of H-bond donors (HD) and acceptors (HA).[202,203]

$$\log(D_{\text{mcl}}) = a + b\log\text{MW} + \frac{c}{1+\exp\left(\frac{\log P_{7.4} - x + y\cdot\text{HD} + z\cdot\text{HA}}{w}\right)} \tag{3}$$

These parameters can be interpreted using simple expressions in 1-D geometries to predict concentrations in the effect compartment (i.e., cells distant from the drug source) with high spatial and temporal resolution. Particularly useful in the drug development context are the T_{90} and the penetration half distance ($X_{1/2}$) in a plane region (Fig. 9). The T_{90} is the time to reach 90% concentration at a distance of L from the source in a slab of thickness $2L$:[204]

$$T_{90} = 0.9\frac{L^2}{D} \tag{4}$$

(which is related to the characteristic diffusion time for compounds that undergo no reaction). $X_{1/2}$ for compounds that are consumed by first-order metabolism is given by

$$X_{1/2} = \ln(2)\sqrt{\frac{D}{k_{\text{met}}}} \tag{5}$$

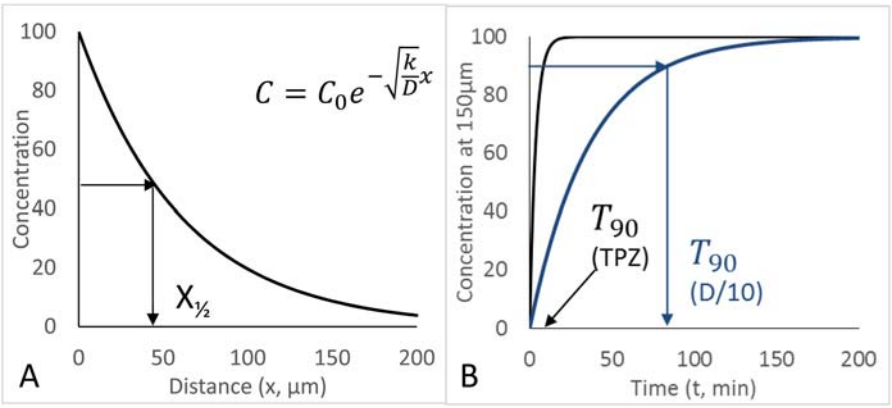

Fig. 9 Representations of drug EVT. (A) Penetration half distance ($X_{1/2}$) for TPZ in anoxic HT29 tumor tissue ($D=4\times10^{-7}$ cm^{2}s^{-1}, $k=0.58$ s^{-1}) is 45 μm. (B) The T_{90} for TPZ in well-oxygenated tissue at a distance $L=150$ μm is 8.4 min. The T_{90} for a compound with 10-fold lower effective diffusion coefficient is also shown in *blue* ($D=4\times10^{-8}$ cm^{2}s^{-1}).

where k_{met} is derived directly at tissue cell density from MCL studies. Other useful derived transport parameters such as the penetration distance for compounds that undergo near-zero-order consumption (e.g., O_2) can also be calculated.[38,205,206]

Generally, the diffusion coefficients of most low-MW drugs are sufficient to allow rapid equilibration in the extravascular compartment unless they react intra- or extracellularly. Taken alone, irreversible metabolism will generally limit drug penetration distance with little effect on the time to reach steady state, while reversible uptake or binding will substantially increase the equilibration time,[195,207] which can be estimated by T_{90}. For example, TPZ is expected to reach peak concentrations rapidly in hypoxic tissue but at a substantially lower concentration than in plasma. The relatively low diffusion coefficient of TPZ in HT29 MCLs (4.0×10^{-7}cm^2 s^{-1}) results in $T_{90}=8.4$ min at 150 μm under aerobic conditions but when combined with high rate of bioreductive metabolism ($k_{met}=0.58$ min^{-1} at HT29 MCL cell density) results in a predicted $X_{1/2}$ of 45 μm at steady state for planar diffusion into hypoxic tissue (Fig. 9).

The importance of distinguishing the mechanisms of drug consumption leading to reduced penetration or delayed equilibration is further outlined by simple simulations of free drug concentrations in the effect compartment (150 μm from a blood vessel where drug plasma concentration decays with a half-life of 30 min) (Fig. 10). The flux of drug through MCLs can be described well by three different EVT models: simple diffusion, diffusion with metabolism, and diffusion with reversible binding (Fig. 10A). However, the predicted concentration–time profiles at a distance of 150 μm into a plane tissue slab are very different for the three EVT models (Fig. 10B).

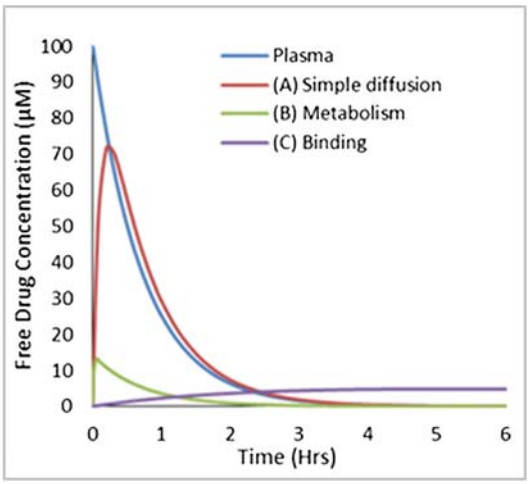

Fig. 10 Simulation of free drug concentrations at 150 μm from a blood vessel for a drug with a plasma half-life of 30 min illustrates how diffusion kinetics differ depending on the mode of drug consumption. Transport parameters were derived from the three models fitted to a single set of hypothetical MCL data. The intercapillary region is approximated by diffusion into a plane slab from both sides, and this is intermediate between radial inward and radial outward diffusions. The cases are simple diffusion ($D=2.5\times10^{-7}$ cm^{2}s^{-1}), irreversible metabolism ($D=5\times10^{-7}$ cm^{2}s^{-1}, $k_{met}=0.95$ s^{-1}), and reversible binding ($D=5\times10^{-7}$ cm^{2}s^{-1}, $k_f/k_r=200$). Modified and redrawn from Wilson, W. R.; Hicks, K. O. Measurement of Extravascular Drug Diffusion in Multicellular Layers. *Br. J. Cancer* **1999**, *79*, 1623–1626.

The earlier-mentioned transport models can generally be distinguished by fitting the concentration–time profile in the donor and the receiver chamber. This approach clearly demonstrated that for TPZ, the EVT impediment for anoxic MCLs compared with that for oxic MCLs is due to metabolic consumption, rather than a change in D under anoxia. Therefore, EVT could be modeled for subsequent analogs by measuring D in oxic MCLs and the kinetics of metabolic consumption in single-cell suspensions under anoxia and scaling the derived metabolism rate constant (k_{met}) to MCL cell density using MCL flux data. The latter strategy enabled sampling of the cell population over time to determine clonogenicity and hence development of pharmacokinetic/pharmacodynamic (PK–PD) models relating exposure to cytotoxicity (see section "Developing a Spatially Resolved-PK–PD Model").

In view of these considerations, it was hypothesized that improving the transport properties of BTOs had potential to improve *in vivo* activity and selectivity. This could be achieved by either increasing the drug diffusion coefficient (D) or decreasing bioreductive metabolism (k_{met}). However, the difficulty with the latter approach is that reductive drug metabolism in tumor cells is essential for hypoxic cytotoxicity. Consequently, the challenge for BTO analog development is to optimize the rate of metabolism, rather than minimize it.

8.03.2.4 Developing a Spatially Resolved-PK–PD Model

To achieve this optimization, we developed a detailed spatially-resolved (SR)-PK–PD model for TPZ transport, metabolism, and cytotoxicity[5,198,208] in tumor tissue. The cytotoxicity of TPZ could be related to its metabolism as a function of drug concentration and time of HT29 cells.[198] Drug concentrations in the extracellular medium were measured by HPLC, and cell survival (clonogenicity) was measured by plating cells from the same sample. Using a simple chemical kinetic scheme, cell killing was related to the intracellular concentration of cytotoxic metabolite that is in turn related to the rate of metabolism of parent drug. In general, this gives the form

$$\log \text{cell kill} = -\log \text{SF} = \gamma k_{met} C^m T^n \tag{6}$$

where SF is the cell surviving fraction and γ, m, and n are fitted parameters. The transport and PD models were then used to predict the concentration, and hence cell killing, at each point in hypoxic MCLs, and good agreement between measured and predicted average cell killings was observed.[198] From this equation, useful parameters for drug development may be calculated—the CT_{10} that is the area under the concentration–time curve providing 1 log cell kill and the M_{10} ($=k_{met} \times CT_{10}$) that is the amount of metabolism required to produce 1 log cell kill and is a measure of the efficiency by which bioreductive BTO metabolism produces cytotoxicity.

While a penetration problem was confirmed to result in decreased cell kill for large hypoxic 3-D cultures, it was not immediately obvious that this would translate to an analogous problem in HT29 tumor xenografts used for drug screening, where there is a continuous gradient of oxygen concentration. Hypoxia most commonly occurs in tumors as small focal regions at large distances from the capillaries (**Fig. 1A**). It follows from Fick's first law with reaction that distance can exacerbate the penetration problem for a fixed-size metabolic sink. In addition, both oxygen and drug concentrations in tumors can be affected by known aspects of tumor structure and function such as heterogeneity in intercapillary distances, vessel diameters, blood flow rates, and extraction of compound from the tortuous, leaky microvascular network.[209] We developed an *in silico* SR-PK–PD model for TPZ in a mapped microvascular network using Green's function method that had been used for simulating oxygen distribution (**Fig. 11**).[201,208–211]

To simulate bioreductive drug action, additional parameters for TPZ PK–PD were included (see Ref. 201 for details): the oxygen dependence of metabolism and cytotoxicity described by the oxygen concentration required for half-maximal suppression of TPZ activity ($K_{O_2} \sim 1.2$ μM O_2)[5]and TPZ plasma pharmacokinetics in mice that was generally first order at high doses for TPZ and BTO analogs.[208] The distribution of TPZ in this microvascular network was simulated with the free drug concentration in mouse plasma (determined by PK of total drug and estimation of free fraction by equilibrium dialysis) as the input[208] allowing the calculation of surviving fraction at each point. The model predicted heterogeneous distribution for TPZ due to the complex 3-D structure with a range of intercapillary distances and oxygen concentrations (**Fig. 11**). The model clearly predicted less cell killing in the microregion than the theoretical maximum attainable if TPZ was homogenously distributed at the same concentration as in plasma (see Refs. 201,208 for more details). Simulating improved transport over a realistic range of diffusion coefficients indicated a five- to sixfold increase in hypoxic cell kill in addition to radiation alone, and a similar increase in hypoxic selectivity compared to that for well-oxygenated zone was possible (**Fig. 12**).

By using tumor cell survival in Green's function model as the efficacy endpoint, the predictions of the model could be directly compared with the results of the clonogenic survival assays after tumors were excised from mice treated with TPZ combined with radiation (see Refs. 201,208,212 for methodology). Good agreement was seen between predicted and observed hypoxic cell killings for TPZ. We extended this SR-PK–PD evaluation to a set of 15 structurally diverse BTO analogs and found there was a strong correlation between model-predicted and measured hypoxic cell killings ($R^2 = 0.89$), but a poor correlation when the model did not include EVT ($R^2 = 0.32$). This result provided the confirmation that explicit consideration of EVT was vital for a BTO analog discovery campaign and further that the model would allow us to efficiently identify BTO analogs with improved *in vivo* activity. We have gone on to extend the correlation as more compounds have become available in the program (**Fig. 13**), and it is gratifying to note that the correlation has not changed significantly. We have also developed a modified model for TPZ in a second tumor xenograft (SiHa cervical carcinoma).[6]

With these considerations in mind, we designed an analog screening algorithm with additional decision points based on parameters derived from 3-D cultures and SR-PK–PD modeling (**Fig. 14**).

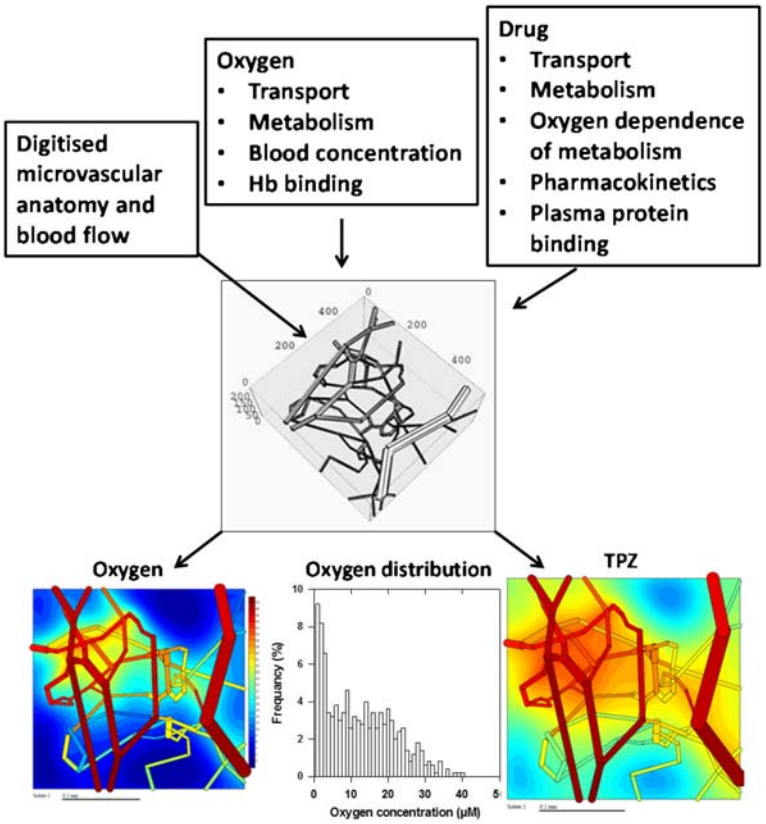

Fig. 11 Simulation of oxygen and TPZ distribution in the 3-D SR-PK–PD model in the digitized, mapped rat R3230Ac microvascular network from Ref. 209. The lower images show the simulated oxygen and TPZ concentrations for an input of 50 μM of each. This model reproduced key features of the dysfunctional vasculature in tumors resulting in oxygen distributions typical of tumors. Predictions of cell killing based on simulated drug distributions are shown in **Fig. 12**. Modified and redrawn from Hicks, K. O. Introducing Drug Transport Early in the Design of Hypoxia Selective Anticancer Agents Using a Mathematical Modelling Approach. 8.03.3 Drug Discovery Campaign to Identify a Second-Generation TPZ Analog

8.03.3.1 Design Criteria

Having assembled the tools to conduct our campaign, we defined our objectives based on the limitations that impaired TPZ activity and the requirements to advance a second-generation BTO into clinical development:

- Increased aqueous solubility relative to potency
- Improved EVT
- Improved hypoxic selectivity *in vivo*
- Improved therapeutic index in preclinical models
- An unencumbered patent position

TPZ has only modest aqueous solubility (9 mM in phosphate-buffered saline) necessitating lengthy infusions, so BTOs with increased solubility and/or potency would be advantageous.

Metabolism in hypoxic cells had been demonstrated to limit the EVT and hypoxia-selective cytotoxicity of TPZ in tumors as discussed earlier. Thus, BTOs with improved EVT would be expected to display increased hypoxic selectivity *in vivo*, and we hypothesized these compounds should also display an improved therapeutic index. We considered normal tissue toxicity to be less affected by poor EVT, and so any improvement in EVT was likely to improve the therapeutic index of a BTO through increased tumor cell killing. Patents held by Sanofi Winthrop covered the core benzotriazine 1,4-dioxide motif with a considerable range of substituents on the benzo ring and amino, alkyl, and aryl substituents at the 3-position. We adopted two strategies to secure a patent position: a selection invention approach based on the identification of generically defined BTOs with unexpectedly good activity and a search for BTO structures outside the definitions of the Sanofi Winthrop patents.[184] We limited our exploration to benzotriazines because the obvious isostere strategy around 2-cyano-quinoxaline 1,4-dioxides had been explored.[213–215]

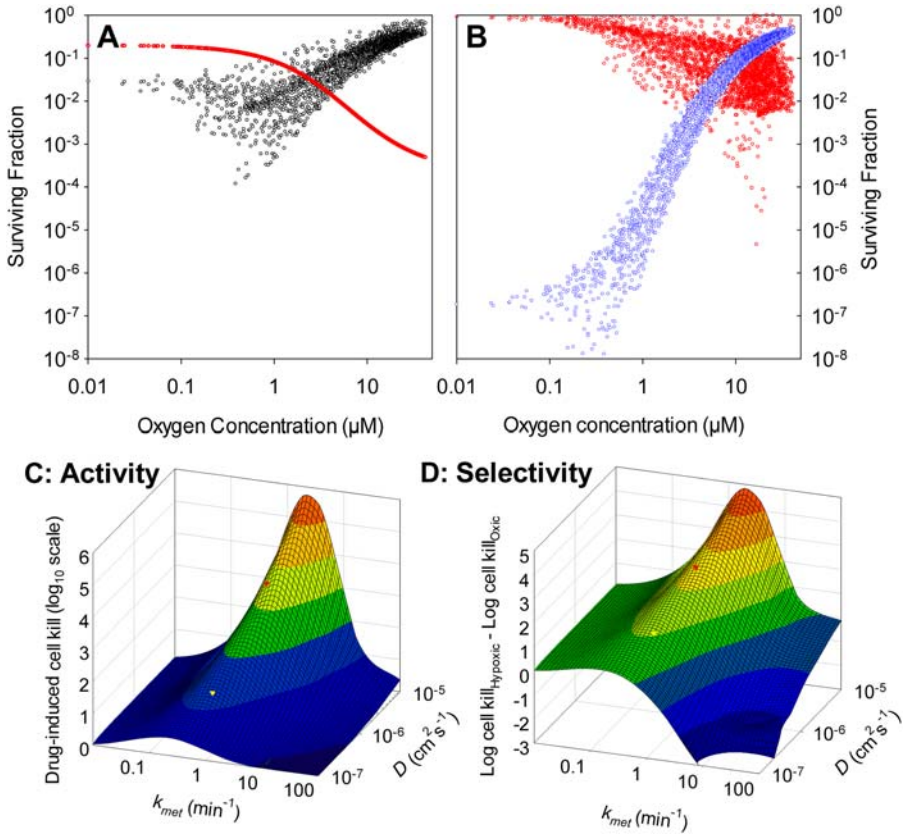

Fig. 12 (A) Predicted cell kill by TPZ (*black*) and radiation (*red*) plotted as a function of oxygen concentration simulated in the microvascular network model. (B) A hypothetical BTO analog with a fivefold higher *D* (*blue*) shows improved cell killing in the hypoxic region, while a fivefold increase in k_{met} (*red*) results in little killing of hypoxic cells and a loss of hypoxic selectivity. Lower graphs show drug-induced hypoxic cell kill in addition to radiation (C) and hypoxia selectivity (D) for hypothetical BTO analogs over a wide range of diffusion coefficients with the same relationship between cell kill and bioreductive metabolism as for TPZ. The figures show that for each diffusion coefficient, there is an optimum rate of metabolism above which tumor penetration becomes limiting and below which potency is lost. Modified and redrawn from Hicks, K. O.; Pruijn, F. B.; Secomb, T. W.; Hay, M. P.; Hsu, R.; Brown, J. M.; Denny, W. A.; Dewhirst, M. W.; Wilson, W. R. Use of Three-Dimensional Tissue Cultures to Model Extravascular Transport and Predict *in vivo* Activity of Hypoxia-Targeted Anticancer Drugs. *J. Natl. Cancer Inst.* **2006**, *98*, 1118–1128.

8.03.3.2 DNA Targeting

While we were developing the methodology for the PK–PD model, we took the opportunity to explore a DNA-targeting approach to improve the activity of a TPZ analog. TPZ had been demonstrated to kill tumor cells by causing a variety of DNA damage including base damage, single-strand breaks, and double-strand breaks.[136,216] Evidence from Martin Brown's lab suggested that only the fraction of TPZ activated by nuclear reductases contributed to hypoxic cell killing[133,217] and that cytoplasmic activation was unproductive metabolism. Further, it was hypothesized that this unproductive metabolism, especially in the mitochondria,[218] was responsible for observed clinical toxicities such as tinnitus, reversible hearing loss, and muscle cramping[162] through redox cycling and the formation of ROS. This evidence, in conjunction with previous reports of DNA targeting of bioreductive agents,[219–221] suggested that such a targeting approach might provide solutions to several of the design criteria. We expected the DNA-targeted BTOs to be more potent than TPZ and increasing the production of toxic radicals close to the target (DNA) might improve the therapeutic index of BTO analogs. We prepared a prototype, SN26955 (**24**) (Fig. 15), which linked a 9-aminoacridine unit to TPZ via the 3-amino group to explore this hypothesis.[222] BTO **24** was a moderately strong DNA binder ($K_{DNA} = 14.3 \times 10^4\ M^{-1}$) and displayed increased formation of single- and double-strand breaks leading to increased hypoxic cytotoxicity *in vitro* compared to TPZ while retaining similar hypoxic selectivity. However, this increased activity *in vitro* did not translate into hypoxic cell killing *in vivo*, and this was postulated to result from poor EVT.

Concern that the DNA binding of SN29655 might be limiting its diffusion[223] led us to design a series of analogs of SN29655 in which we modulated the DNA-binding affinity though modification of the chromophore or the basicity of the amine side chain.[224] We hypothesized that a "minimal" DNA chromophore would provide improved EVT characteristics[207] while retaining increased hypoxic potency and selectivity. We prepared a series of BTO analogs linked by amines of varying basicity to 4-quinoline, 1-phenazine, and 4-acridine carboxamides. The DNA-binding affinity of the compounds ranged over 5200-fold and correlated strongly with hypoxic cytotoxicity, but not selectivity. All compounds were selectively cytotoxic against hypoxic cells with several

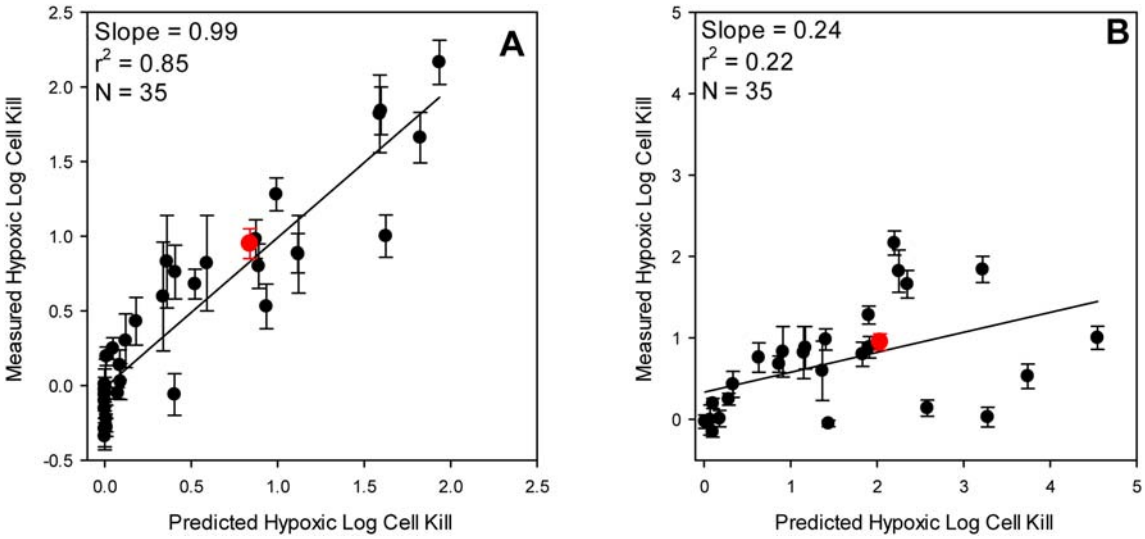

Fig. 13 (A) Correlation between hypoxic cell killings predicted by the SR-PK–PD model in the tumor microvascular network and cell killing observed in HT29 tumor xenografts for all analogs tested. (B) A similar correlation with cell kill predicted using the microvascular network with the same oxygen gradient but assuming the extravascular compartment has a homogenous drug concentration (tissue drug concentrations equal to those in plasma). Hypoxic log cell kill is defined as in the text. This updates the previously reported correlation[208] with the addition of 19 further compounds. TPZ is in *red*. Adapted and redrawn from Hicks, K. O. Introducing Drug Transport Early in the Design of Hypoxia Selective Anticancer Agents Using a Mathematical Modelling Approach. In *New Challenges for Cancer Systems Biomedicine*; D'Onofrio, A., Cerrai, P., Gandolfi, A., Eds.; Springer: Italy, 2012; pp 337–354.

acridine 4-carboxamides (e.g., **25** and **26**; Fig. 15) with reduced DNA-binding affinity ($K_{DNA} = 0.75$ and 3.3×10^4 M^{-1}, respectively) displaying excellent hypoxic selectivity (HCR, 87 and 124, respectively). The 4-acridine carboxamide BTO **26** was demonstrated to increase the free radical-induced production of both single- and double-strand breaks under hypoxia compared with TPZ itself.[225] Plasmid DNA was damaged by hydroxyl radicals generated from the radiolysis of water, and potentiation of single- and double-strand breakages was measured in the presence of TPZ and DNA-targeted BTO analogs. BTO **26** was able to increase single-strand breaks by 18-fold, and double-strand breaks were increased by 110-fold. In addition, targeting a 1-oxide BTO was seen to potentiate single-strand breakage, but not double-strand breakage, compared to TPZ. This study supported the hypothesis that nuclear localization increases productive metabolism and hypoxic potency. While DNA targeting of BTO analogs demonstrated increased hypoxic potency and selectivity, it became apparent that even with a moderate DNA-binding unit, metabolism would compromise EVT. The impact of a binding component on the model for diffusion can be seen in Fig. 9B. We attempted to offset this metabolic liability by preparing less-electron-affinic BTO analogs (e.g., **27**), and although addition of the 6-Me group halved k_{met}, this was still some ninefold higher than for TPZ.[208] Thus, metabolism and diffusion liabilities found in DNA targeting dominated the micro-pharmacokinetic properties of these BTOs that were predicted to be inactive *in vivo*, defeating this approach to increasing the therapeutic index of BTO analogs.[208]

These early studies provided additional insight into the requirements for successful bioreductive drug design and demonstrated the power of using an integrated screening model to include diffusion and metabolism parameters along with *in vitro* cytotoxicity, allowing early predictions of *in vivo* hypoxic selectivity.

8.03.3.3 BTOs With Improved EVT

Our next endeavor was to expand upon previous SAR studies from Martin Brown's group where a 3-amino-linked side chain bearing a basic amine was used to increase aqueous solubility.[182,183] As noted in section "Structure–Activity Toolset," strongly basic diethylaminoalkyl side chains (e.g., **8**) increased solubility, hypoxic toxicity, and selectivity *in vitro*, but did not translate into increased activity against hypoxic cells *in vivo*. Further increases in *in vitro* hypoxic potency were obtained by adding electron-withdrawing substituents at the 7-position (e.g., **9**) to increase electron affinity; however, these analogs displayed reduced hypoxic selectivity *in vitro* and reduced *in vivo* activity.[183] We had previously observed the addition of an electron-donating 6-methyl substituent had provided a BTO analog **12** (X = 6-Me) with reduced *in vitro* hypoxic potency and similar hypoxic selectivity to TPZ[129] but which had demonstrated a dramatic fourfold increase in killing hypoxic cells *in vivo* compared to TPZ,[208] despite extremely low aqueous solubility. We sought to build on this observation while directly addressing EVT in our design criteria and exploring the SAR around EVT (Fig. 16).

We prepared a series of 6-substituted BTO analogs bearing a variety of 3-aminoalkylamines to explore the impact of lipophilicity and amine pK_a on EVT. The electron-donating 6-substituents were designed to offset the increase in electron affinity due to the 3-

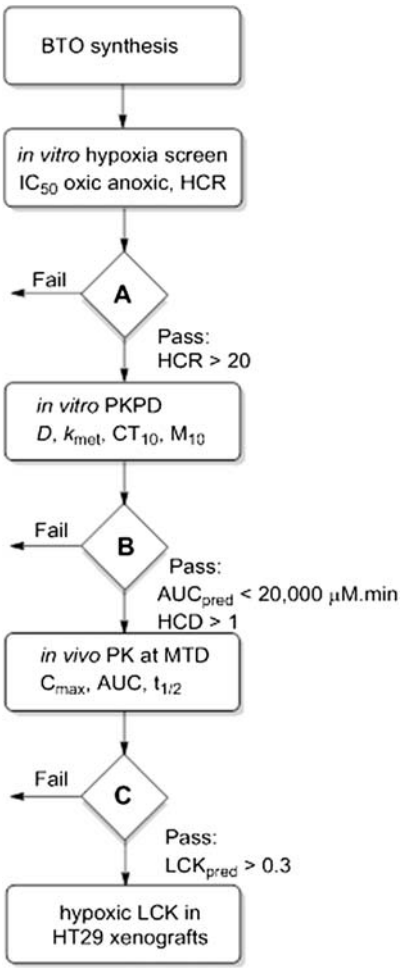

Fig. 14 SR-PK–PD model-guided algorithm for bioreductive drug design. Definitions: HCR, hypoxic cytotoxicity ratio, IC_{50}(oxic)/IC_{50}(anoxic); D, tissue diffusion coefficient (see Eq. 3); k_{met}, first-order rate constant for metabolism in anoxic cell suspensions scaled to cell density in MCLs; CT_{10}, the area under the concentration–time curve providing 10% surviving fraction; M_{10}, amount of drug metabolized for 10% surviving fraction; AUC_{pred}, predicted area under the plasma concentration–time curve required to give 1 log cell kill of HT29 tumors in addition to that produced by a single 20 Gy dose of gamma radiation (μM min); HCD, *in vivo* hypoxic cytotoxicity differential = $LKC_{hypoxic}/LCK_{oxic}$, [log cell kill in the radiobiologically hypoxic region (< 4 μM O_2)]/[log cell kill in aerobic region (> 30 μM O_2)]; MTD, maximum tolerated dose of drug given i.p. to CD-1 nu/nu mice (μmol kg^{-1}); C_{max}, maximum plasma drug concentration (μM); AUC, area under the plasma drug concentration–time curve (μM min); $t_{1/2}$, terminal drug half-life (min); LCK_{pred}, predicted log cell kill of hypoxic tumor cells in addition to radiation; drug given at 75% of MTD 5 min after irradiation of HT29 tumors; hypoxic cell killing was determined as [log(clonogens/g of tumor for radiation only)] − [log(clonogens/g of tumor for radiation plus drug)].

aminoalkylamino group and so optimize the rates of bioreductive metabolism in hypoxic tissue (Fig. 16). The 43 BTO analogs prepared were evaluated using our screening strategy based on the SR-PK–PD model (sections "Measuring Extravascular Drug Transport" and "Developing a Spatially Resolved-PK–PD Model"). We measured, or estimated by calculation, the key *in vitro* PK–PD parameters (D, k_{met}, CT_{10}, and M_{10}) (see Fig. 14 for definitions) for HT29 cells and used the model to calculate the AUC_{pred} required

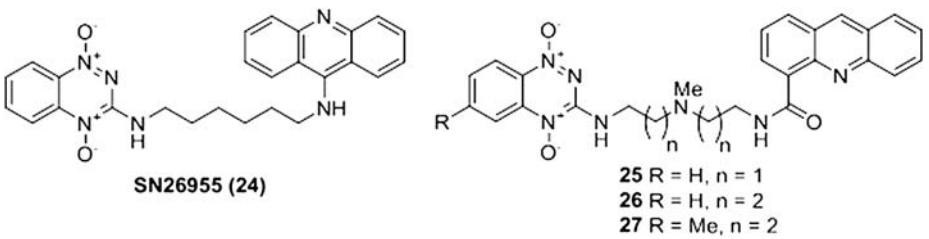

Fig. 15 DNA targeting of BTOs.

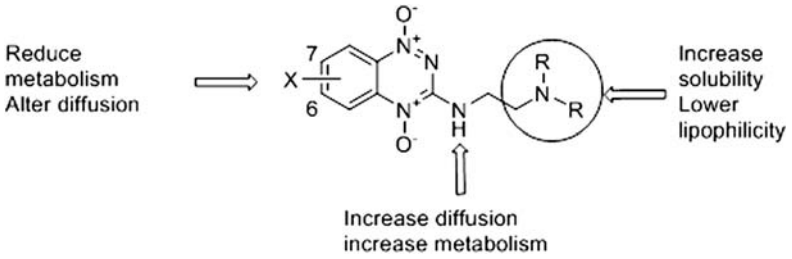

Fig. 16 Structural influences on EVT.

to give 1 log hypoxic cell kill in tumors and the HCD where HCD = [LCK (hypoxic)]/[LCK (oxic)]. These parameters were used to prioritize compounds for initial *in vivo* evaluation of toxicity and pharmacokinetic profile to obtain plasma AUC, C_{max}, and $t_{1/2}$ values that were used in the PK–PD model to calculate the log hypoxic cell killing (LCK_{pred}) predicted in HT29 xenografts. We selected those compounds for which the LCK_{pred} was >0.5. We also used the one-dimensional EVT parameter $X_{1/2}$ to provide a convenient indicator of EVT.

It became readily apparent that the addition of the solubilizing side chain compromised EVT primarily through increased electron affinity, shown by an increase in the $E(1)$ values of 60 mV for **30** (−396 mV)[226] over TPZ (−456 mV),[129] and a consequent elevation of k_{met}. Thus, BTO analogs bearing side chains with pK_a values of 8.5 and higher (**28**–**30**) showed increased hypoxic potency while maintaining *in vitro* hypoxic selectivity as a consequence of significantly increased hypoxic metabolism (k_{met}) (Table 1). Only the near-neutral morpholide **31** displayed lower hypoxic potency and hypoxic metabolism compared to TPZ. Whereas the more basic analogs had much lower $X_{1/2}$ values, the morpholide was similar to TPZ. When translated into AUC_{pred}, only morpholide **31** gave a similar value to TPZ with the more basic amines requiring much higher AUC_{pred} values, and a similar pattern was observed with the predicted hypoxic selectivity parameter HCD. This clearly suggested that simply adding solubilizing side chains would compromise EVT and that this needed to be offset by a reduction in electron affinity and/or an increase in lipophilicity. We sought to explore both arms of this hypothesis.

Addition of electron-donating 6-methyl substituents lowered electron affinity (the $E(1)$ of **32** (−440 mV)[226] was 44 mV lower than **30**) and generally increased $X_{1/2}$ values through reduced hypoxic metabolism (lower k_{met} values), but again, only examples with weakly basic morpholine side chains, for example, **33**, had improved $X_{1/2}$ relative to TPZ. Although more lipophilic alkyl substituents (Et, iPr, and tBu) did increase lipophilicity and diffusion coefficients within a homologous series, modest gains were accompanied by compromised aqueous solubility. This prompted us to consider 6-alkoxy BTO analogs where a stronger

electronic influence was expected to dampen hypoxic metabolism. Indeed, the $E(1)$ of **34** was down to -500 mV,[226] and this reduced electron affinity was reflected in lowered hypoxic potencies relative to 6-H (**30**) and 6-alkyl analogs (**32**). The more polar alkoxy substituents lowered lipophilicity and gave lower diffusion coefficients. This was balanced by low rates of hypoxic metabolism and generally resulted in similar or improved EVT properties compared to TPZ, for example, **34** and **35**. However, in examples where a weakly basic amine was present, for example, **35**, the rates of hypoxic metabolism were so low that they compromised hypoxic potency, leading to a high required drug AUC_{pred}.

The application of the screening algorithm (Fig. 14) predicted that, with the exception of the morpholide **31**, the unsubstituted BTO analogs would likely be inactive at decision point B (AUC_{pred} values over 20,000 μM min and HCD values significantly less than those for TPZ). The addition of the 6-Me group improved the AUC_{pred} and HCD values for all analogs resulting in most passing the criteria for advancement to *in vivo* testing, with the exception of several weak bases where a loss in potency compromised the AUC_{pred}. A similar pattern emerged for other 6-alkyl and 6-alkoxy analogs explored with excellent EVT being compromised by very low potency in the case of weak bases, for example, **35**, leading to a very high AUC_{pred} requirement in these instances.

Although a total of 18 compounds passed the threshold at decision point B, we elected to triage 11 lipophilic analogs because of close structural similarity to analogs that failed because of high *in vivo* toxicity. We determined the MTD and plasma PK data for the remaining seven BTOs and found they were better tolerated than TPZ, but within homologous series, increases in lipophilicity and electron affinity were accompanied by increased toxicity. Although half of the analogs gave increased AUC values compared to TPZ, when compared as a ratio of injected dose, the AUC values ranged from 70% to 200% of that for TPZ. In particular, more lipophilic amines with strongly basic side chains displayed a considerable PK liability. The plasma PK data were used in the SR-PK–PD model to predict active compounds ($LCK_{pred} > 0.5$), and these BTOs were evaluated against HT29 xenografts. A single dose of BTO was given i.p. 5 min after a high dose (20 Gy) of radiation, which was designed to sterilize the oxic compartment of the tumor. Drug activity was assessed by an *ex vivo* clonogenic survival assay comparing drug alone, radiation alone, and the combination. The additional cell kill observed over radiation alone represents the killing of hypoxic tumor cells (LCK) for the BTO (Fig. 17). All BTOs were sufficiently soluble to administer as solutions, and none displayed any single-agent activity as expected on mechanistic grounds. We had included several BTOs predicted to fail on the basis of low LCK_{pred} values to confirm the robustness of the SR-PK–PD model, and these did not display any activity. Six of six compounds predicted to be active on the basis of LCK_{pred} did in fact display significant hypoxic cell killing *in vivo* with two compounds **33** and **34** displaying superior activity to TPZ, while of three BTOs with borderline LKC_{pred}, two were inactive and one was active.

Overall, there was good agreement between LCK_{pred} and the LCK observed in HT29 tumors (correlation coefficient, $R^2 = 0.78$, $P < 0.001$). This was a gratifying confirmation of the previous model validation conducted with a different set of BTO analogs.[208] Perhaps of more significance was the observation that three of the six active BTOs identified would not have been selected for *in vivo* evaluation if the usual criteria of increasing *in vitro* hypoxic potency ($IC_{50} < 5$ μM) and selectivity (HCR > 71) compared with those for TPZ had been applied. Conversely, if these *in vitro* selection criteria had been applied to the 43 BTOs in the study, then only 14 of 43 candidates would have qualified but, based on PK–PD modeling, only three would have been found to be active against hypoxic cells *in vivo*. This exercise provides further evidence for the value of optimizing EVT parameters *in vitro* and combining these data with PK data using the PK–PD modeling to identify active compounds for *in vivo* evaluation. The structural evolution of the BTOs through this EVT optimization (Fig. 18) demonstrates that relatively small structural changes have a dramatic effect and that improving EVT is necessary, but not sufficient, for improved *in vivo* activity. With further validation of the SR-PK–PD and the identification of two BTOs **33** and **34** with superior activity to TPZ against hypoxic cells *in vivo*, we moved to a lead optimization phase where we wished to increase the potency of the BTOs and secure a composition-of-matter intellectual property position.

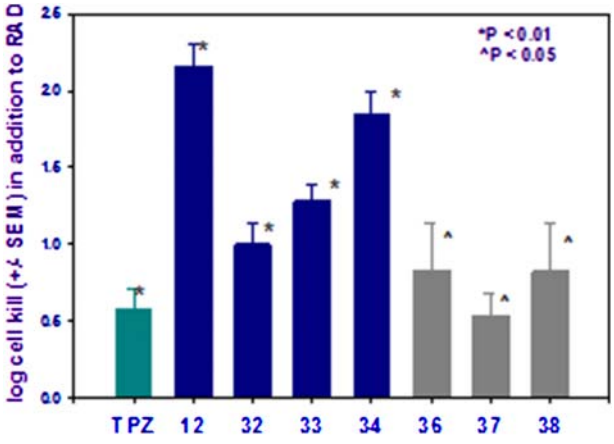

Fig. 17 Activity of representative 3-amino alkyl BTOs against hypoxic cells in HT29 tumor xenografts in CD-1 nude mice by *ex vivo* clonogenic assay. Drugs were administered i.p. at 75% of MTD 5 min after 20 Gy of radiation. Significance compared to LCK for RAD alone. Compound 12 (6-Me-BTO).

8.03.3.4 Exploring 3-Alkyl BTOs: Role of H Bonding on EVT

During our initial exploration of a series of solubilized BTO analogs, much of the gains in *in vivo* activity could be ascribed to increased drug plasma concentrations at equivalent toxicity rather than clear increases in EVT compared to TPZ (e.g., **34**). Hence, we sought to build on early BTOs[183] where the 3-amino group was replaced with a 3-alkyl substituent.[227] These analogs would allow us to further explore the impact of the H-bond donors (HD) on EVT with an expectation, based on the strong dependence of diffusion coefficient on HD described earlier (section "Measuring Extravascular Drug Transport"), that removing HD would increase EVT. We fully expected that a balancing act would be required with the influences of each structural modification having multiple consequences (Fig. 19).

Rather than using the low-yielding Bamberger condensation of 3-alkyl diphenylformazans **22** (Fig. 7)[190] and oxidation of the resultant 3-alkyltriazines **23**,[183] we elected to use palladium-mediated cross-coupling reactions to install alkyl and aryl groups at the 3-position. Thus, conversion of 3-NH_2-BTO 1-oxides to the corresponding chlorides **15** provided key intermediates to access 3-alkyl- and aryl-substituted BTOs **18** using Pd-mediated Stille and Suzuki reactions, respectively (Fig. 7).[188,189,227] Modification of a 3-allyl side chain using ozonolysis with a reductive workup provided access to a series of alcohols that could be further elaborated with solubilizing basic amine side chains. Based on the relatively weak electron donation of alkyl substituents ($\sigma_p = -0.17$) compared to 3-NH_2 ($\sigma_p = -0.66$), we anticipated 3-alkyl BTOs would also demonstrate increased hypoxic metabolism and potency. Consequently, we also prepared a series of 3-ethyl BTO analogs bearing an electron-donating alkyl or alkoxy side chain at the 6- or 7-position to modulate the electron affinity of the BTO and to provide a handle for solubilizing functionality. We processed the 43 analogs prepared through the PK–PD model as described in the preceding text. While simple 3-alkyl BTOs (e.g., **10** and **11**; Table 2) did show dramatically improved diffusion coefficients, this positive effect on EVT was negated by strong increases in hypoxic metabolism driven by elevated electron affinity; $E(1)$ values ranged from -376 to -327 mV compared with -456 mV for TPZ. BTOs **10** and **11** did display improved EVT, but $X_{1/2}$ values for other analogs were generally lower than for TPZ, and this translated into predictions of poor *in vivo* activity. BTOs **10** (SR4895) and **11** (SR4941) had been previously identified as active *in vivo*,[183] and we confirmed **10** and **11** as having similar activity to TPZ against hypoxic cells in HT29 tumor xenografts (Fig. 21). The addition of electron-donating side chains at the 6- and 7-positions resulted in lowered electron affinity and hypoxic metabolism with the 6-position being more influential (e.g., **42** vs. **44**; Table 2). The consequent reduction in hypoxic metabolism, combined with increased diffusion provided by the 3-ethyl substituent, provided a series of compounds (e.g., **40**, **41**, **42**, and **44**) with generally improved EVT ($X_{1/2}$: 42–156) compared to TPZ ($X_{1/2}$: 45). However, the aqueous solubility of these neutral analogs was no better than for TPZ. We added a variety of basic amine side chains that provided increased aqueous solubility at the expense of EVT due to

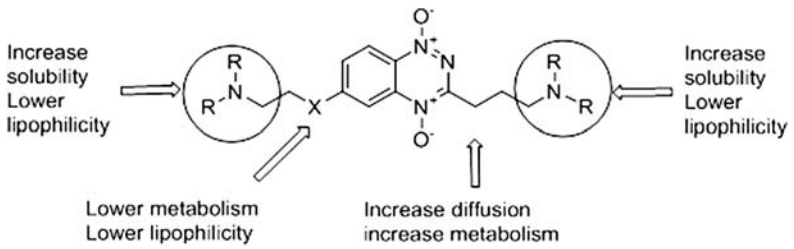

Fig. 19 Design for increasing potency and diffusion.

Hypoxia-Selective 3-Alkyl 1,2,4-Benzotriazine 1,4-Dioxides: The Influence of Hydrogen Bond Donors on Extravascular Transport and Antitumor Activity. *J. Med. Chem.* **2007**, *50*, 6654–6664.

increased hypoxic metabolism. A compromise was found where the near-neutral morpholine side chains (e.g., **43** and **45**) gave adequate aqueous solubility with minimal impact on hypoxic metabolism, leading to increased EVT relative to TPZ. Interestingly, the morpholides **43** and **45** had larger diffusion coefficients compared to the corresponding alcohols, **42** and **44**, respectively, despite being less lipophilic, emphasizing the strong, negative influence of HD on diffusion.

A total of 14 out of 43 3-alkyl BTOs qualified for *in vivo* evaluation, but eight neutral analogs were triaged because of poor aqueous solubility. While improving EVT is necessary to identify improved TPZ analogs, the additional requirement for BTOs to display good macro PK characteristics is clearly illustrated in the analog series in Fig. 20. Although these compounds possess excellent EVT characteristics and were predicted to be active on the basis of their AUC$_{pred}$ and HCD, the negative effect of increasing lipophilicity and amine pK_a on both host toxicity and AUC acts to undermine the potential efficacy of **47**.

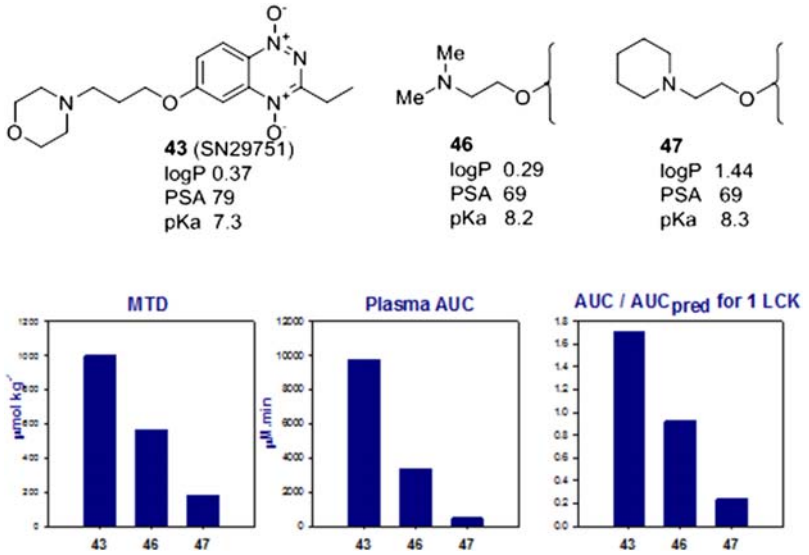

Fig. 20 Influence of amine lipophilicity and pK_a on host toxicity and drug exposure. MTDs were determined for single i.p. injections of drug to CD-1 nude mice and were defined as the highest dose that did not cause drug-related deaths, body weight loss of more than 15%, or severe morbidity in a group of six animals over 28 days. PK measurements were determined at 75% of MTD for each BTO.

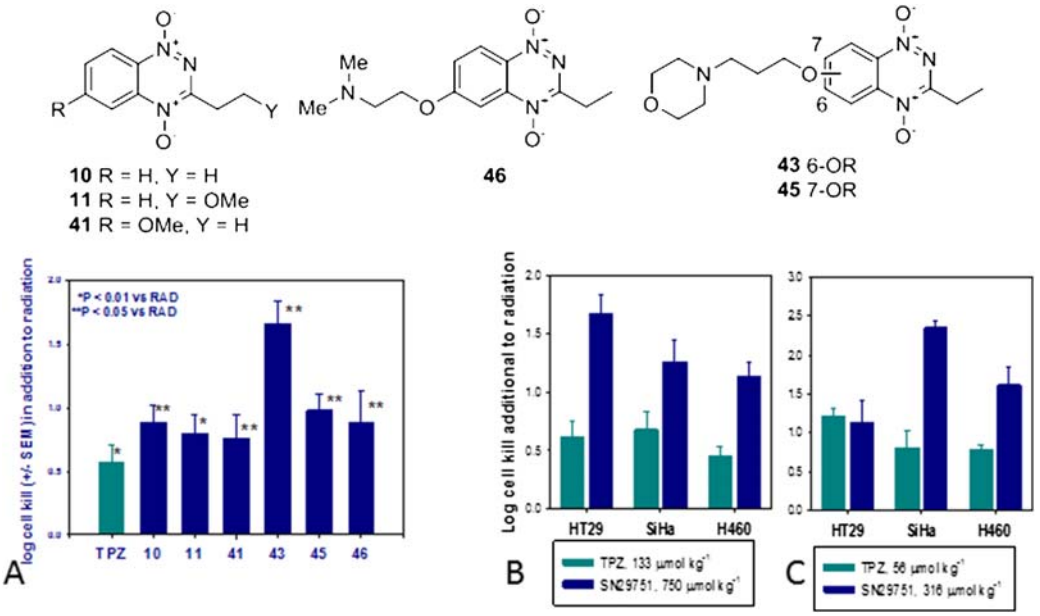

Fig. 21 (A) Activity of representative 3-alkyl BTOs against hypoxic cells in HT29 tumor xenografts in CD-1 nude mice by *ex vivo* clonogenic assay. Drugs were administered i.p. at 75% of MTD 5 min after 20 Gy of radiation. Significance compared to LCK for radiation alone. (B) Single-dose radiation (15 Gy for SiHa, 20 Gy for HT29, and H460 tumor xenografts), with compounds administered 5 min after irradiation. (C) Fractionated radiation (8×2.5 Gy), with compounds administered 30 min before each radiation dose.

All compounds predicted to be active on the basis of the full PK–PD prediction were found to show similar or improved activity against hypoxic cells in HT29 tumor xenografts (Fig. 21), demonstrating the predictive power of the SR-PK–PD modeling approach. In particular, BTO **43** (aka SN29751) demonstrated approximately threefold greater log cell kill of hypoxic cells than TPZ.

One can rationalize the design elements that led to increased EVT and increased *in vivo* activity of **43** (Fig. 22). Replacement of the 3-NH_2 group of TPZ with a 3-ethyl group (**10**) leads to a higher tissue diffusion coefficient and reflects the importance of minimizing HD for improved EVT. The concomitant increase in electron affinity and thus bioreductive metabolism would preclude efficient tissue penetration, but this is offset by the electron-donating 6-alkoxy side chain (**41**), which provides further significant increase in EVT. However, the low aqueous solubility of **41** suggested the addition of a weakly basic morpholine group (**43**) that increases aqueous solubility, albeit with a reduction in EVT due to reduced diffusion.

Further *in vivo* evaluation of SN29751 demonstrated impressive activity against SiHA and H460 tumor xenografts in combination with single dose of radiation (Fig. 21B) and modest activity against HT29 tumor xenografts and excellent activity against SiHa and H460 xenografts in combination with fractionated radiation (Fig. 21C).[212] The exceptional activity of BTO **43** led us to successfully pursue a selection invention patent strategy to protect BTO **43**.[228] This patent provided coverage of BTO **43**, but was not broad enough to be commercially appealing so we continued exploring the patent landscape around TPZ.

8.03.3.5 Designing Novel Analogs

Having demonstrated that the combination of chemical design and an SR-PK–PD model-guided approach could deliver BTOs with significantly superior killing of hypoxic tumor cells *in vivo* compared to TPZ, we tried to identify an intellectual property position that did not overlap with patents from Sanofi Winthrop around benzotriazine 1,4-dioxides[184] and AstraZeneca around isosteric 2-cyanoquinoxaline 1,4 dioxides.[215] Careful examination of the Sanofi Winthrop patents revealed an opportunity to exploit; no account had been made for an extended central chromophore with an alicyclic ring system fused to the benzotriazine core, despite

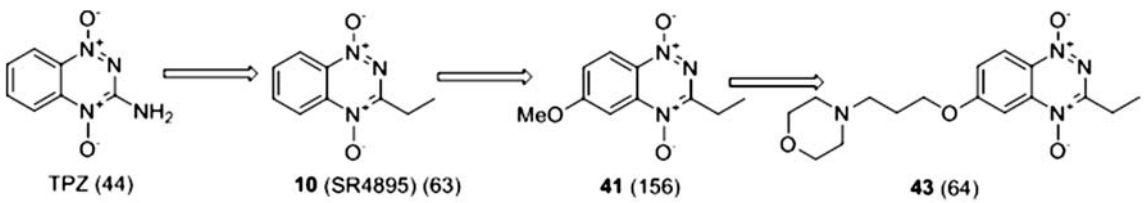

Fig. 22 Influence of structure on EVT (as $X_{1/2}$) for 3-alkyl BTOs.

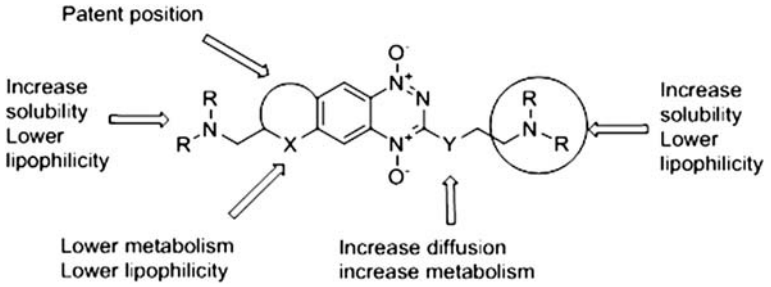

Fig. 23 Design for novel TTO analogs.

fused aryl and heteroaryl cores and cycloalkyl substituents being generically covered. This provided an opportunity to exploit, and we set out to explore the potential of such fused chromophore systems using our SR-PK–PD model-guided approach. The potential for the alicyclic ring to contribute to increases in EVT through increased lipophilicity and reduced electron affinity was countered by recognition that the extended ring system would reduce aqueous solubility, thus requiring a solubilizing group (Fig. 23). With this balancing act constraining design, we sought to explore a wide range of tricyclic systems (tricyclic triazine 1,4-dioxides (TTOs)) that could provide compounds with improved *in vivo* efficacy.

Our first step was to prepare a simple example of a TTO to validate the concept. This example consisted of a fused cyclopentyl ring system (7,8-dihydro-6*H*-indeno[5,6-*e*][1,2,4]triazine). 5-Indanamine was readily converted to the corresponding 6-nitro-5-indanamine and further elaborated using our methodology developed for benzotriazine analogs (Fig. 24). Condensation of the appropriate nitroaniline **48** with cyanamide and Arndt cyclization under strongly basic conditions provided triazine 1-oxides **49**. Diazotization in trifluoroacetic acid followed by chlorination of the intermediate phenol provided triazine 3-chlorides **50**. Displacement of the chloride with various amines installed a series of 3-aminoalkyl side chains, and 1-oxides **52** were oxidized to TTOs **53** with pertrifluoroacetic acid with an excess of trifluoroacetic acid to prevent oxidation of aliphatic amine side chains.

Our prototypical TTO (**61**) looked a promising candidate based on *in vitro* data and demonstrated that the fused alkyl ring could act to lower electron affinity and provide increased lipophilicity, offsetting the impact of the polar, solubilizing side chain to give improved EVT compared to TPZ (Table 3). Modeling predictions based on *in vitro* data suggested a modest PK requirement and potentially a selective compound *in vivo*. However, **61** proved to be relatively toxic *in vivo* and displayed low AUC (988 μmol min) (Fig. 26); PK–PD modeling predicted no *in vivo* activity and the compound was shelved. Although a disappointing result, **61** did provide a starting point for further optimization (Fig. 25).

Our first task was to improve on the PK profile of **61**. We explored a variety of solubilizing amine side chains to vary the pK_a and lipophilicity in order to further define an SAR for *in vivo* toxicity and to increase the *in vivo* drug exposure, that is, to maximize AUC_{actual}/AUC_{pred}. We prepared a series of 20 analogs of **61** with side chain variations that provided wide range of pK_a and lipophilicity. Again, weakly basic amines such as morpholine (e.g., **62**) provided the best EVT, primarily due to low hypoxic metabolism and

modest impact on diffusion (Table 3). More lipophilic amines (e.g., **63**) did not always provide improvements in EVT because of increased hypoxic metabolism. We advanced 12 TTO analogs into MTD testing and found a similar relationship between pK_a and lipophilicity and *in vivo* toxicity and PK parameters to that observed with earlier BTOs (Fig. 26). The reduction in AUC for the more lipophilic analogs undermined any increases in potency and resulted in PK–PD model predictions of inactivity. In summary, from the group of 20 TTOs, we were able to predict and confirm *in vivo* activity in 2/2 TTOs, both of which carried a morpholine side chain. However, the *in vivo* hypoxic LCK was modest (**62**, LCK 0.68 ± 0.14) and provided no benefit over TPZ (LCK 0.59 ± 0.15), so further exploration was required.

We explored the diversity of the fused ring substituents where the heteroatoms would further modulate the electron affinity of the TTOs (Fig. 25). We expanded the range of tricyclic variants with the fused ring selected from simple cycloalkyl (e.g., cyclopentyl, cyclohexyl, and cycloheptyl) and substituted cyclopentyl to isomeric dihydrofurans, tetrahydropyrans, dioxolane, and substituted pyrrolidine and piperidine rings fused at either the 6,7- or 7,8-position (Fig. 24).[229] We combined these ring systems with neutral 3-aminoalkyl or weakly basic pK_a 3-aminoalkylamine substituents (pK_a 7.4–8.5) to reduce the impact of the amine side chain on EVT. In general terms, the cycloalkyl–TTO analogs displayed increased lipophilicity, and the position of the fused ring did not alter its influence of the ring on EVT parameters. In the case of fused oxygen or nitrogen containing rings, the position of the heteroatom was important with a stronger influence on electron affinity and consequently hypoxic

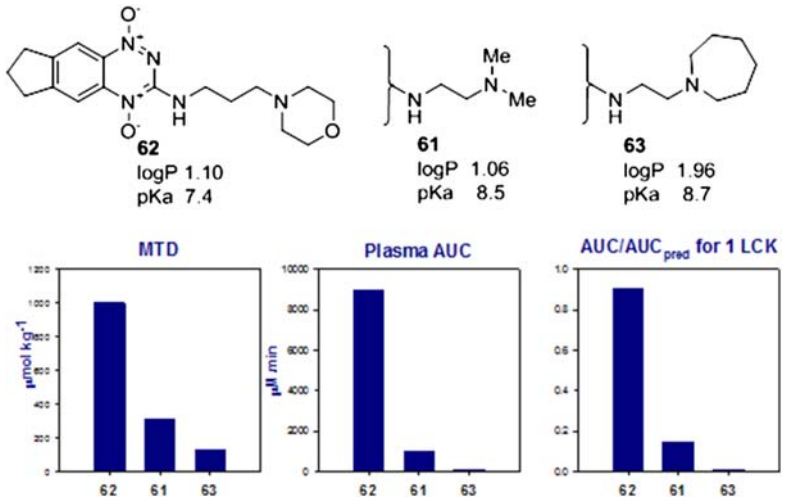

Fig. 26 Influence of amine lipophilicity and pK_a on host toxicity and drug exposure. MTDs were determined for single i.p. injections of drug to CD-1 nude mice and were defined as the highest dose that did not cause drug-related deaths, body weight loss of more than 15%, or severe morbidity in a group of six animals over 28 days. PK measurements were determined at 75% of MTD for each BTO.

potency and metabolism, when at the "6" position rather than the "7" or "8" positions (BTO ring numbering). The heteroatom also reduced lipophilicity significantly, and this factor dominated corresponding reductions in hypoxic metabolism resulting in a negative impact on EVT across the board. The low hypoxic potency and metabolism contributed to high AUC_{pred} values, and the modest diffusion parameters contributed to low predicted *in vivo* hypoxic selectivity (HCD). While this was disappointing, we consoled ourselves with the wide array of novel compounds that provided strategic support for the composition-of-matter patent needed to secure the TTOs.

In an effort to increase hypoxic potency without compromising EVT, we next explored 3-alkyl substituents combined with a limited number of fused chromophores (cyclopentyl, dihydrofuran, and piperidine) (Fig. 25). 3-Amino triazine 1-oxides **49** were converted to 3-iodides **51** by diazotization with *tert*-butyl nitrite in THF followed by iodination with diiodomethane (Fig. 24). Stille reactions of various triazine 3-iodides **51** gave the corresponding 3-ethyl analogs **54**, while Heck reactions with allyl alcohol provide a series of 3-propanals **56** that were further elaborated to tricyclic 1-oxides bearing 3-propanols **57** and various 3-propylamine side chains **58** that were oxidized to the corresponding TTOs **59** and **60**, respectively.

We explored different topologies with the solubilizing functionality attached via either the 3-alkyl substituent or the fused ring (Fig. 25). The fused rings were selected to best balance the effect of the 3-alkyl substituents on electron affinity. These compounds were generally more lipophilic and displayed higher diffusion coefficients than TPZ with only the polar influence of the dihydrofuran ring outweighing the removal of the 3-NH bond donor on diffusion. The greatest effect on EVT was seen for compounds with a fused cyclopentyl ring and an amine side chain linked via a 3-alkyl substituent. Compounds bearing weakly basic amines (e.g., **64** and **65**) displayed exceptionally high diffusion coefficients (Table 3), which more than offset accompanying increases in hypoxic metabolism. PK–PD modeling predicted modest AUC_{pred} requirements and increased *in vivo* hypoxic selectivity. In contrast, the presence of a more basic, more lipophilic amine (e.g., **66**) compromised EVT through strongly increased hypoxic metabolism, and this undermined the PK–PD predictions with a reduction in expected hypoxic selectivity *in vivo*, despite exceptional hypoxic selectivity *in vitro*. We investigated the animal toxicity of a series of these promising TTOs and again found a trend between lipophilicity, amine pK_a, and MTD and consequently AUC (Fig. 27). The weakly basic morpholide **64** displayed the least host toxicity and best AUC and increasing lipophilicity (**65**), and amine pK_a (**66** and **67**) increased host toxicity resulting in drastically reduced drug exposures. The predicted activity of **64** was confirmed with a hypoxic LCK of 1.4, approximately 2.5-fold greater than TPZ.

The combination of the lipophilic, electron-donating cyclopentyl ring with a 3-aminoalkylamino side chain in BTO **61** provided modestly increased EVT and excellent hypoxic selectivity, which suggested excellent *in vivo* potential (Fig. 28). However, the combination of increased lipophilicity with a moderately basic amine side chain undermined this potential, and BTO **61** was predicted inactive on the basis of the very low AUC achieved. Reducing the amine pK_a provided increased diffusion and a reduction in hypoxic metabolism to suggest excellent EVT. However, the potential was only partially realized with **62** displaying modest hypoxic cell killing *in vivo* due to relatively low potency. By increasing the potency and diffusion through removal of the 3-NH- group (**64**), a modest decrease in EVT was observed, but the increased metabolism led to increased hypoxic cell killing with **64** showing excellent *in vivo* activity (see section "Mechanism of DNA Damage").

8.03.3.6 Summary

In total, we prepared 281 BTO and TTO analogs, including 43 low-solubility compounds for the SAR "toolset" study (Fig. 29). Fifty-six compounds were immediately triaged because they were not sufficiently soluble to allow the determination of their HCR. We

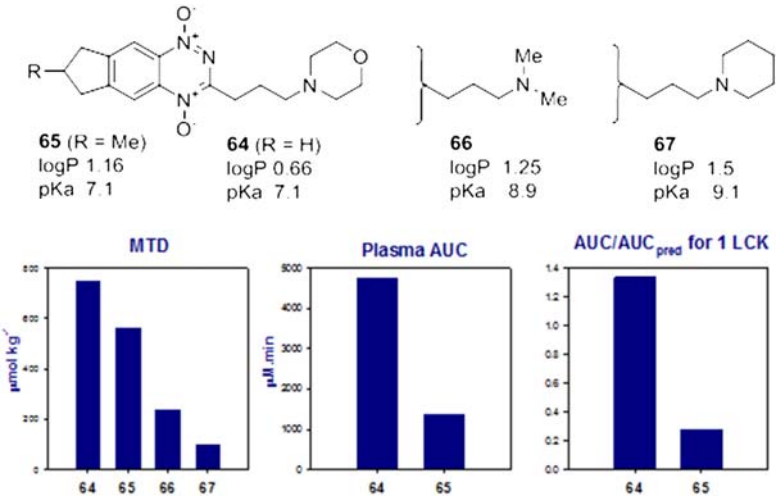

Fig. 27 Influence of amine lipophilicity and pK_a on host toxicity and drug exposure. MTDs were determined for single i.p. injections of drug to CD-1 nude mice and were defined as the highest dose that did not cause drug-related deaths, body weight loss of more than 15%, or severe morbidity in a group of six animals over 28 days. PK measurements were determined at 75% of MTD for each BTO.

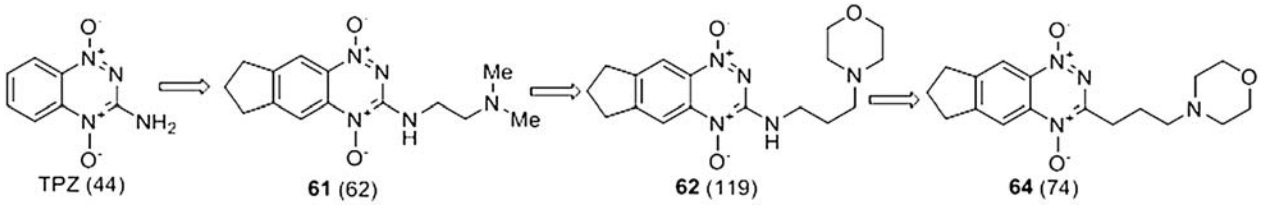

Fig. 28 Influence of structure on EVT (as $X_{1/2}$) for TTOs.

had set a relatively low threshold to advancement through checkpoint A (HRC > 20 in both HT29 and SiHa cells), and a majority of compounds (182) passed through this checkpoint. We evaluated 173 of these compounds for clonogenic survival and metabolic consumption in HT29 cells under anoxic conditions to determine the first-order rate constant for metabolism, k_{met}. The tissue diffusion coefficients were calculated from physicochemical properties (MW, log *D*, and the number of HD and HA) using an established relationship for a "training" set of BTOs measured in 3-D MCLs.[203] These values were used in the PK–PD model to calculate the *in vivo* HCD and the AUC required to achieve a hypoxic LCK of 0.5 at checkpoint B. The filters used at this checkpoint required compounds to have an HCD > 1 and AUC_{pred} of less than 20,000 μM min, twice that of TPZ at its MTD in CD-1 nude mice. We determined the PK at 75% of MTD for 123 compounds; 115 actives and eight compounds predicted to be inactive that were to act as negative controls. These PK data were then used in a second iteration of the PK–PD model to identify compounds with LCK_{pred} greater than 0.3. As noted earlier, a number of lipophilic, basic amines, which passed the checkpoint for LCK_{pred}, were rejected on the basis of low MTD values precluding attainment of the requisite AUCs. Eighteen BTOs, which were predicted active, along with 12 of 32 compounds predicted inactive, were evaluated against HT29 tumor xenografts in combination with radiation. Sixteen of eighteen were found to have statistically significant activity, and one of the false positives had a statistically insignificant hypoxic LCK of 0.60 ± 0.36. In contrast, 12/12 compounds predicted to be inactive were found to be inactive, despite displaying appreciable hypoxic selectivity *in vitro*. Analysis showed that neither *in vitro* hypoxic potency as IC_{50} ($r^2 = 0.07$ and $P = 0.16$) nor selectivity as $\log_{10}$ HCR ($r^2 = 0.02$ and $P = 0.47$) correlated with hypoxic LCK.[212] This campaign efficiently identified active BTOs and TTOs by explicitly considering micro-PK parameters along with systemic PK relative to toxicity with SN29751 (**43**) designated as a lead BTO and SN30000 (**64**) as a lead TTO.

8.03.4 Characterization of SN30000

8.03.4.1 Preamble

The identification of SN30000 as a lead analog of TPZ based on its ability to kill hypoxic tumor cells in an *ex vivo* clonogenic assay brought us into a new phase of the discovery campaign. We sought to characterize the activity of SN30000 in comparison with TPZ to confirm it for clinical development.

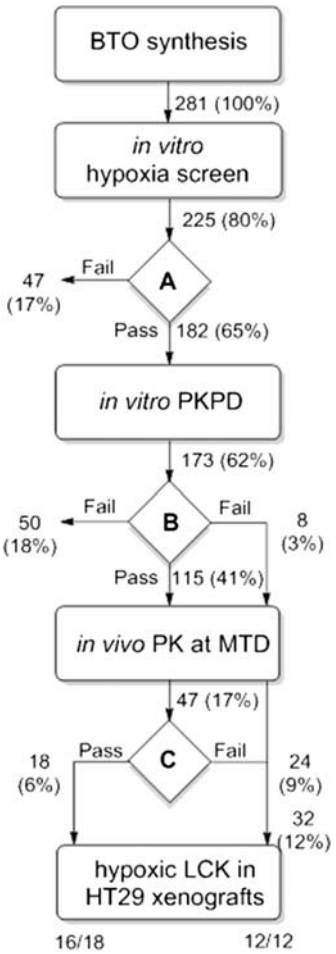

Fig. 29 PK–PD-guided lead optimization of BTO analogs.

8.03.4.2 Synthesis Optimization

We needed to prepare gram quantities of SN30000 to support a more in-depth biological evaluation, and this provided an opportunity to optimize the synthesis before transferring to the pilot plant for Chemistry, Manufacturing and Controls (CMC) development.

Our initial synthesis of SN30000 started from the commercially available 5-aminoindane **68** that was protected as the acetamide **69** and nitrated with KNO_3 in H_2SO_4 (Fig. 30). These initial nitration conditions gave all possible nitro isomers, which could be separated by column chromatography. Although producing both 6-nitro and 4-nitro isomers **70** and **71**, which could be elaborated to linear and angular TTOs, respectively, the modest yield (~25%) of the desired 6-nitro-5-acetamide **70** was unsatisfactory. Optimization of the nitration conditions identified milder conditions as a viable alternative. The use of $cHNO_3$ in acetic acid with careful temperature control gave an excellent yield of **70** with only ~9% of **71** after an aqueous workup. Rather than isolate the 6-nitro isomer at this stage, we carried the mixture through hydrolysis of the acetamides and crystallized 6-nitro-5-aminoindane **72** in 73% yield for the two steps. The original condensation of **72** with excess cyanamide was carried out as a melt with addition of cHCl initiating an exothermic reaction to generate the intermediate guanidine. This could be cyclized in the presence of 7 M NaOH to give indanotriazine 1-oxide **73** that was purified using column chromatography. Although we could carry out this procedure on a 100 g scale, concerns about controlling the exothermic reaction led us to develop a milder condensation procedure. We conducted the reaction using 4 M HCl in dioxane added slowly to a solution of **72** in dioxane with a fourfold excess of cyanamide at 80°C giving **72** in a final concentration of 0.5 M. The reaction proceeded smoothly and went to completion in ~1 h at 100°C. The mixture was cooled, petroleum ether added, and the mixture stood at room temperature overnight before the solvent was decanted from the resulting precipitate. After washing with ether, the solid was dried under a stream of nitrogen and then suspended in water, treated with 7 M NaOH and stirred at 100°C for several hours. On completion of the reaction, the mixture was cooled and diluted with water and the resulting precipitate filtered to provide 1-oxide **73** in yields of 92–94%. The anhydrous Sandmeyer reaction was initially carried out with diiodomethane, but this was replaced with iodine when we scaled this reaction up. Diazotization of **73** with *tert*-butyl nitrite in the presence of CuI and iodine gave the 3-iodide **74** in moderate to good yields (58–79%) after an aqueous

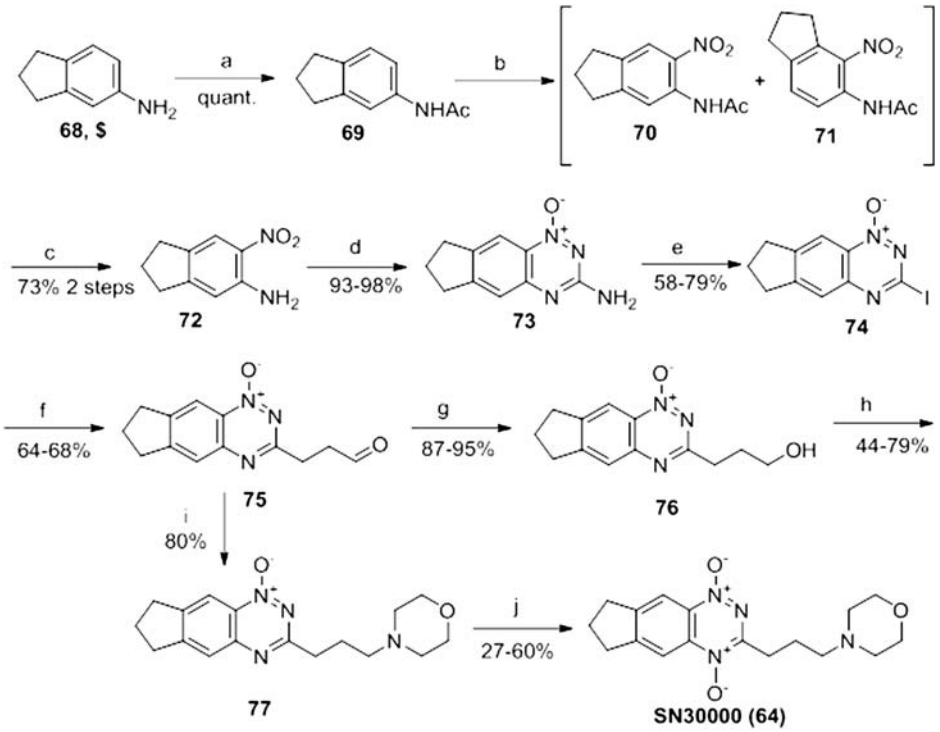

Fig. 30 Synthesis of SN30000. Reagents: (a) Ac_2O, dioxane; (b) $cHNO_3$, HOAc; (c) aq. HCl; (d) NH_2CN, HCl in dioxane, then aq. NaOH; (e) tBuONO, I_2, CuI, THF; (f) allylOH, $Pd(OAc)_2$, $Bu_4N^+Cl^-$, $NaHCO_3$, THF; (g) $NaCNBH_3$, EtOH; (h) MsCl, Et_3N, DCM, then morpholine; (i) $NaBH(OAc)_3$, morpholine, DCM, EtOH; (j) 70% H_2O_2, $(CF_3CO)_2O$, DCM.

workup and filtration of the organic fraction through a short plug of alumina. Careful control of reaction time and temperature and exclusion of moisture eliminated the formation of 3-H and 3-OH by-products. Standard Heck conditions were used to install the alkyl side chain to provide aldehyde **75** in moderate yields (64–68%) with only an aqueous workup and filtration through a plug of silica required for purification. Installation of the terminal morpholine could be accomplished either directly, via a reductive amination to give **77**, or stepwise by reduction to the alcohol **76**, mesylation and displacement with morpholine. In our hands, the stepwise approach was more convenient with $NaCNBH_3$-mediated reduction proceeding well (87–95%), and the subsequent conversion to the morpholide using standard conditions provided the morpholide **77** that was purified by crystallization as the HCl salt in moderate yields (47–79%). The direct reductive amination of **75** using $NaCNBH_3$ was accomplished in poor to low yields (15–52%) on a small scale, and we elected not to pursue this reaction for scale-up. The critical step in the synthesis was the final oxidation of 1-oxide **77** to 1,4-dioxide SN30000. Over several years, we had explored a wide range of oxidants and conditions to oxidize a wide variety of BTOs. We had settled on the oxidation with preformed pertrifluoroacetic acid added to a solution of 1-oxide in dichloromethane at room temperature as the most effective. BTOs with aliphatic amine side chains were protected by addition of trifluoroacetic acid, and reactions were only run to partial completion to avoid the complex mixtures that were produced if more forcing conditions were used. In our initial synthesis of SN30000, we typically isolated ~10% recovered starting 1-oxide and ~50% of SN30000. Obviously, this necessitated a chromatographic purification, and although we could isolate SN30000 in high purity and moderate yields (47–60%) at a 10 g scale, we sought to eliminate the chromatographic step. Despite our best efforts, we were unable to identify conditions to drive reactions to completion or to isolate SN30000 products without chromatography. When we used an acid/base partitioning step, followed by filtration of the organic fraction through an alumina plug, and crystallization of the hydrochloride salt, we suffered from lower yields (~27–56%) of SN30000 with significant levels (1–7%) of the starting 1-oxide **77** present.

We transferred the synthesis to our CMC contractor at Onyx Scientific Ltd, Sunderland, the United Kingdom, and were gratified that the scale-up was achieved without major changes to the synthetic route. The first five steps were scaled without note to provide 5 kg quantities of iodide **74**. However, several key modifications were made in the pilot plant to achieve a robust, scalable Good Manufacturing Practice (GMP) synthesis. The first of these was to use the reductive amination of aldehyde **75** with $NaBH(OAc)_3$ that provided **77** directly in 80% yield. An optimized oxidation procedure was defined using preformed pertrifluoroacetic acid added to a solution of 1-oxide **77** in DCM/HOAc, and the mixture was stirred for up to 4 days to effect maximum conversion to the product. Extensive crystallization trials were conducted on SN30000 to establish a purification process. In the final analysis, a relatively simple crystallization from EtOAc with subsequent slurrying of the precipitate in EtOAc gave the free base of **64** in acceptable purity with the major contaminant being the starting 1-oxide **77**. Further crystallization of the hydrochloride salt from EtOAc provided GMP grade SN30000.

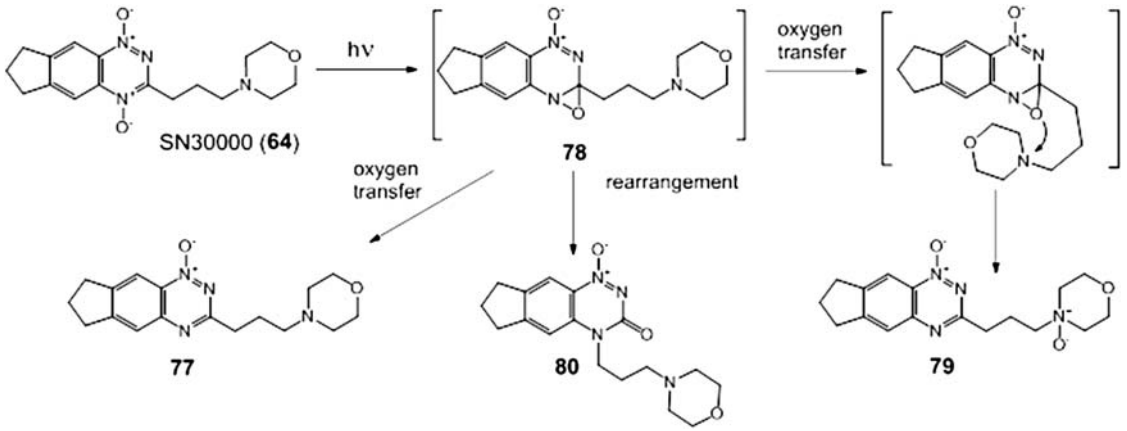

Fig. 31 Photolytic rearrangement of SN30000.

Some of the difficulties encountered in the purification and isolation of SN30000 were ascribed to the instability of the compound. SN30000 was found to unstable during silica gel chromatography. Although the compound did display an exothermic decomposition by differential scanning calorimetry, extensive testing for explosivity concluded that SN30000 was not an explosion risk. However, SN30000 did display significant photosensitivity, decomposing under ambient light to produce several products. Photolysis of solutions of SN30000 under UV or visible light produced predominantly the side chain N-oxide **79** via intramolecular oxygen transfer from the intermediate oxaziridine **78** (Fig. 31).[230] A small amount of a rearrangement product 3-keto BTO **80** and traces of 1-oxide **77** were also detected, presumably from intermolecular oxygen transfer. The photolysis products were shown to be less cytotoxic *in vitro* and less toxic to mice than SN30000.[230] The practical resolution of this problem was to store and formulate SN30000 and solutions in amber vials, and this has proved to be satisfactory.

8.03.4.3 SN30000 Is an Improved TPZ Analog

SN30000, while mechanistically similar to TPZ, is a quantitatively improved analog where the optimization of physicochemical parameters leads to improved micro and systemic pharmacokinetic properties and results in increased activity against hypoxic cells both *in vitro* and *in vivo*. Although SN30000 has a higher MW, it has an approximately fivefold increase in aqueous solubility by virtue of a weakly basic amine side chain (Table 4). Elevation of electron affinity [$E(1)$] raises the rate of hypoxic metabolism (k_{met}) and hypoxic potency, while removal of HD increases diffusion (D) (Fig. 32), producing improved EVT ($X_{1/2}$) compared to TPZ. SN30000 is more potent than TPZ under anoxia as measured by IC_{50} (proliferation assay) against a panel of eight cell lines (Fig. 33A). SN30000 is also more selective for anoxia than is TPZ in both the proliferation assay (Fig. 33B) and by clonogenic survival (Fig. 33C). Importantly, the potencies of SN30000 and TPZ were highly correlated in this panel,[212] supporting the view

Table 4 Physicochemical properties of TPZ and SN30000 and PK–PD parameters for prediction of hypoxic cell killing in HT29 xenografts in CD-1 male nude mice at 75% of MTD

Parameter (units)	*TPZ*	*SN30000*
Physicochemical properties		
MW (Da)	178	367
Solubility (mM) Culture medium (37°C)	8.9	48.5
E(1) (mV)	-456 ± 8	-401 ± 8
Log *P*, pH 7.4	-0.34 ± 0.02	0.50 ± 0.05
pK_a (Calculated)	NA	7.1
HD, HA	2, 6	0, 7
PK–PD parameters		
k_{met} (min^{-1})	1.30 ± 0.04 (74)	1.53 ± 0.21 (8)
D ($\times 10^{-6}$ $cm^2 s^{-1}$)	0.40 ± 0.02 (12)	1.26 ± 0.11 (6)
$X_{1/2}$	45	74
Dose (75% of MTD) (μmol kg^{-1})	133	562
C_{max} (μM)	61.7 ± 0.1	85.1 ± 7.8
$AUC_{p\infty}$ (μM h)	49	79
$t_{1/2}$ (min)	27.9	32.1

Values are means and SEM (number of determinations in parentheses).

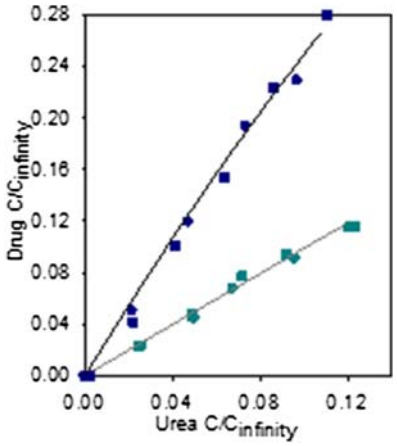

Fig. 32 Diffusion of TPZ (*cyan symbols*) and SN30000 (*blue symbols*) through HT29 MCLs. *Symbols* represent the drug concentration in the receiver compartment after diffusion through the MCL. Concentrations are expressed as fractions of the expected concentration at equilibrium and plotted against the ^{14}C-urea internal standard (instead of time) to account for differences in MCL thickness. Two replicate experiments are shown (with different symbols) for each compound. Redrawn from Hicks, K. O.; Siim, B. G.; Jaiswal, J. K.; Pruijn, F. B.; Fraser, A. M.; Patel, R.; Hogg, A.; Liyanage, H. that the two compounds have a common mechanism of action. In addition, both show a similar DNA repair profile in a panel of repair mutant lines.[151]

When administered to mice as a single i.p. dose, SN30000 was better tolerated than TPZ, gave increased peak plasma concentrations, and had an increased plasma half-life (Table 4).[212] When administered as a single dose at 75% of the MTD, SN30000 gave increased hypoxic cell kill in combination with a single dose of radiation determined by *ex vivo* clonogenic survival (Fig. 34A). This effect was consistent in three xenograft models (HT29, SiHa cervical carcinoma, and H460, non-small cell lung carcinoma), and a similar, but somewhat attenuated, response was seen in a fractionated radiation experiment where radiation and drug were given twice daily for 4 days in the same xenograft models (Fig. 34B). No activity was seen with SN30000 alone in any of the xenograft models, and this is consistent with selective killing of the hypoxic subpopulation. SN30000 also showed significant activity in combination with fractionated radiation in a growth delay endpoint at doses of 176 or 263 μmol kg^{-1} ($P = 0.0058$ and 0.0004, respectively, log-rank test) (Fig. 34C). SN30000 in combination with radiation also provided a significant growth delay of H460 tumor xenografts compared to radiation alone in nude rats.[231]

It is important to note that SN30000 is not universally active in all tumor models. It did not provide significant additional clonogenic cell killing in DLD-1 breast cancer xenografts when combined with radiation.[118] This points to the importance of identifying predictive biomarkers to support its clinical development.

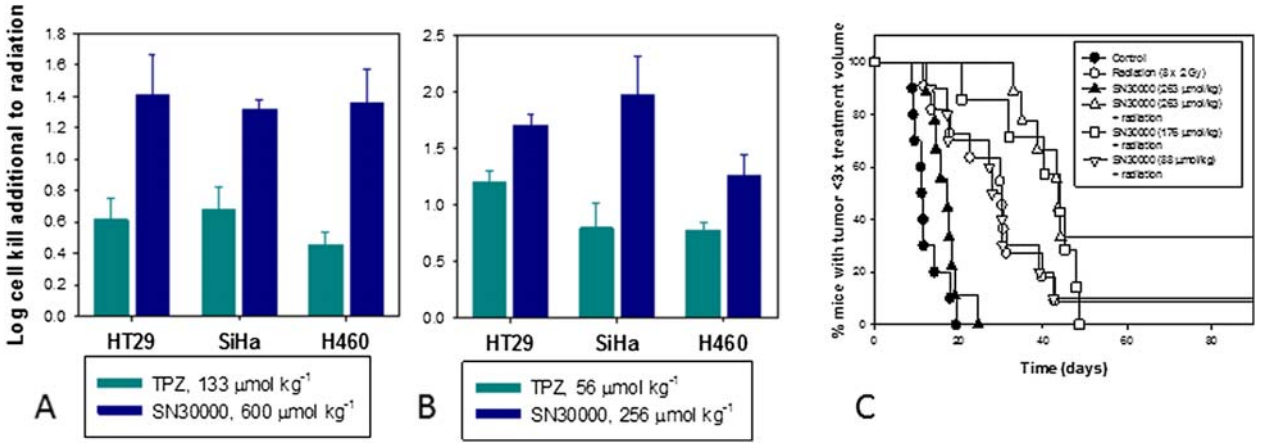

Fig. 34 Activity of TPZ and SN30000 against hypoxic cells in human tumor xenografts in combination with radiation. Comparison of cell killing by tumor excision and clonogenic assay 18 h after the end of treatment (mean and SEM for five mice). (A) Single-dose radiation (15 Gy for SiHa, 20 Gy for HT29, and H460 tumor xenografts), with compounds administered 5 min after irradiation. (B) Fractionated radiation (8×2.5 Gy), with compounds administered 30 min before each radiation dose. (C) SN30000 alone and 30 min before each dose of fractionated radiation (8×2 Gy) against SiHa xenografts by tumor regrowth assay. Modified and redrawn from Hicks, K. O.; Siim, B. G.; Jaiswal, J. Pharmacokinetic/Pharmacodynamic Modeling Identifies SN30000 and SN29751 as Tirapazamine Analogues With Improved Tissue Penetration and Hypoxic Cell Killing in Tumors. *Clin. Cancer Res.* **2010**, *16*, 4946–4957.

Building on studies demonstrating that SN30000 and pentafluorinated etanidazole (EF5) were reduced by the same reductases[148], PET imaging studies in H460 xenografts in rats also suggested that ^{18}F-EF5 was a suitable biomarker for hypoxia (see section "Predictive Biomarkers and Response Biomarkers for SN30000").[231]

8.03.4.4 Mechanism of DNA Damage

SN30000 qualitatively displays the same mechanism of activation and interaction with DNA as TPZ. It is reduced by POR to form a radical anion **81** (Fig. 35) that is reducing in nature and cannot oxidize DNA. In the presence of oxygen, this radical anion is oxidized back to SN30000 with concomitant formation of superoxide. The radical anion may be protonated (**82**), and elimination of water provides an oxidizing radical, which mediates DNA damage with production of 1-oxide **77**. Pulse radiolysis and EPR studies have identified the benzodiazinyl (BDZ) radical **83** (equivalent to the BTZ radical **6** for TPZ (Fig. 5)) as the main radical species involved in the oxidation of DNA, although formation of a minor amount of a more potent aryl radical **84** was also observed.[232] Notably, no evidence was seen for the formation of hydroxyl radical that has been proposed[136] as the main species

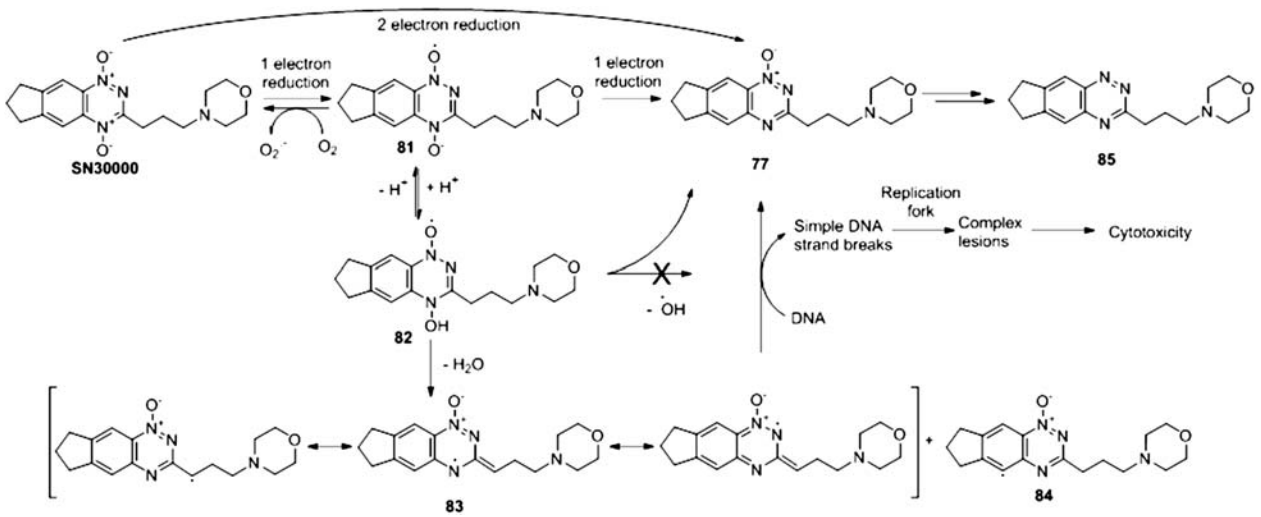

Fig. 35 Bioreductive activation of SN30000.

effecting DNA damage for TPZ (see section "Tirapazamine"). The BDZ radical **83**, formed by one-electron oxidation of 1-oxide **77** with selenite radical, was shown to react with 2-deoxyribose at a greater rate than TPZ. SN30000 was also shown to cause double-strand breaks in DNA plasmids after reduction by POR at approximately twice the rate of TPZ. This increased reactivity was ascribed to the higher reduction potential of the BDZ radical formed from SN30000 compared with the corresponding BTZ radical **6** derived from TPZ and also from a contribution to DNA damage from the highly reactive aryl radical **84**.[232] SN30000 and TPZ were not metabolized under oxic conditions, but metabolism of both was highly correlated ($r^2 = 0.87$ and $P < 0.001$) across a diverse panel of 14 tumor cell lines under anoxia.[148] Manipulation of POR levels resulted in similar changes in SN30000 and TPZ metabolism and DNA damage as measured by γH2AX formation. Small amounts of the nor-oxide **85** have been observed *in vitro* and *in vivo*, mimicking the bioreduction of TPZ.[148,212]

8.03.4.5 Predictive Biomarkers and Response Biomarkers for SN30000

A central issue for clinical development of SN30000, as for other HAPs, is the identification of predictive biomarkers (companion diagnostics) that can be used to enrich for potentially responsive tumor subtypes in early-phase clinical trials; once clinically validated, these biomarkers could ultimately be used for identification of individual tumors in a personalized medicine context. Discovery and validation of predictive biomarkers for HAPs are challenging given that determinants of sensitivity are multifactorial, encompassing hypoxia, expression of the one-electron reductases that activate the prodrug, and intrinsic (cell-autonomous) sensitivity to the active cytotoxin.

An interesting possibility is that 2-nitroimidazole probes that bind covalently in hypoxic cells, such as pimonidazole and EF5, might be activated by the same one-electron reductases as SN30000 and might thereby act as dual reporters of hypoxia and SN30000 reductases. In support of this hypothesis, metabolic activation of SN30000 (and TPZ) strongly correlated with covalent binding of EF5 in a genetically diverse panel of 14 human tumor cell lines under anoxia.[148] The same study varied hypoxic fraction in HCT116 xenografts by manipulating the respiratory gas and demonstrated that EF5 binding (assessed by flow cytometry) predicted sensitivity of individual tumors to SN30000-induced DNA damage (γH2AX formation). Further evidence that EF5 and SN30000 are activated by the same reductases was provided by a subsequent study in which overexpression of members of the diflavin reductase family (POR, MTRR, NOS3A, and NDOR) resulted in similar activation of both substrates under anoxia.[233] It is noteworthy that binding of EF3, a close analog of EF5, showed differences in maximal binding within small fragments from HNSCC biopsies incubated under hypoxia,[234] suggesting that interpatient variations in one-electron reductase activity may be important. The reported association between avidity for the PET probe ^{18}F-FMISO and sensitivity to TPZ in HNSCC[46,179] may thus reflect the ability of 2-nitroimidazole PET probes to act as dual reporters for both hypoxia and activity of BTO-activating reductases. These observations suggest PET imaging with ^{18}F-labeled 2-nitroimidazole probes currently in clinical use such as FMISO, FAZA, and HX4[235] can provide a mechanistically well-matched companion diagnostic for clinical development of SN30000. However, new hypoxia imaging modalities such as oxygen-enhanced MRI[236] may also have utility if variation in reductase expression emerges as less important than variation in the extent and depth of hypoxia between tumors.

While functional imaging clearly has potential for identifying SN30000-responsive tumors, profiling of molecular determinants of sensitivity offers a complementary approach with the flexibility to explore all three classes of biomarkers (hypoxia, reductases, and intrinsic sensitivity). Expression of a hypoxia-responsive mRNA expression signature has been shown in a retrospective study to identify HNSCC patients who benefit from the hypoxia-selective radiosensitizer nimorazole (**3**) in combination with radiotherapy.[43] If validated in prospective studies currently in progress, this will provide strong motivation for the use of gene expression signatures to identify hypoxic tumors in other settings. Multiplexing with mRNAs for SN30000 reductases would be a logical extension but will obviously require identification of the reductases involved. The well-studied one-electron reductase POR was the first enzyme shown to be capable of metabolic activation of SN30000 when overexpressed in hypoxic tumor cell lines.[148,237] As noted earlier, other members of the diflavin reductase family (MTRR, NOS2A, and NDOR1) also activate SN30000 when overexpressed.[233] The endoplasmic reticulum-associated flavoreductase FOXRED2 also reduces both SN30000 and TPZ in a hypoxia-dependent manner.[238] However, such studies do not establish a role for these reductases at endogenous levels of expression in human tumors. In fact, knockout of *POR* with zinc finger nucleases in two human tumor cell lines (HCT116 and SiHa) had little effect on their ability to metabolize SN30000 to its 1-oxide **77**, its anti-proliferative activity, or clonogenic cell killing under anoxia,[237] suggesting the existence of additional reductases.

As a first step toward identifying the reductases involved, we recently used genome-wide lentiviral short hairpin (sh) RNA libraries (82,017 barcoded shRNAs targeting 16,019 genes) to knock down expression of genes that confer SN30000 sensitivity.[239] Surprisingly, screening for SN30000 resistance by deep sequencing of shRNA barcodes in surviving populations identified *POR* as the only gene consistently selected in a HCT116 cell line with a single copy of the *POR* gene. Specificity was confirmed by demonstrating a correlation between the extent of selection of the four POR shRNAs and the extent of knockdown by lentiviruses expressing each shRNA. Further, no such enrichment of these shRNAs was found when the screen was repeated using a *POR*-null (biallelic knockout) HCT116 clone. Further screens using a focused shRNA library encompassing all flavoreductase genes, with high clonal representation, also identified POR as the sole screening hit in both PANC-1 and HT29 cells, again with no such selection of POR shRNAs in the *POR* null line. The shRNA screens thus identified POR as the most important single determinant of SN30000 sensitivity in hypoxic human tumor cell lines. The same study examined the quantitative relationship between POR expression and SN30000 activation, both in a series of HCT116 clones and in a diverse panel of human cell lines. This demonstrated a substantial non-POR contribution, suggesting nonspecific "leakage" of electrons from multiple flavoreductases that individually make too

small a contribution to be enriched in the screens. What is not yet clear is whether this background activation is sufficient to provide hypoxic-selective killing in tumors. This study[239] also extended a previous immunohistochemical (IHC) evaluation of POR expression in human tumors,[103] demonstrating wide variance in expression between individual HNSCC tumors. Importantly, it was also shown that POR expression is more spatially homogenous than the endogenous hypoxia marker CA IX, suggesting that POR is relatively uniformly expressed in hypoxic and oxic zones. Thus, the sampling problems that confound assessment of tumor hypoxia by IHC[240,241] are likely to be less of a constraint in evaluating POR expression. These findings identify POR as requiring evaluation as a predictive biomarker in clinical trials of SN30000 and other HAPs. Although specificity of the POR antibody used in these studies has been thoroughly validated,[103,239] it is noteworthy that a quantitative targeted proteomic assay for POR proteotypic peptides is also available.[237] Given the potential for multiplexing large numbers of proteotypic targets by mass spectrometry, this platform presents a further attractive option for biomarker evaluation in the clinic.

The third class of predictive biomarkers, namely, the gene products that influence intrinsic sensitivity to the free radical cytotoxin(s) arising from one-electron reduction of SN30000, may be more difficult to identify using forward genetic screens (such as shRNA libraries) in a bulk culture format given that the most likely pathways (e.g., DNA damage response/repair and free radical detoxification) are likely to confer sensitivity rather than resistance when knocked down. Such genes are difficult to identify by deep sequencing of bulk cultures because of stochastic loss of shRNAs at low surviving fraction, even if they are neutral with respect to drug sensitivity. Studies with cell lines in which HRR genes such as *BRCA1*, *BRCA2*, *PALB2*, *XRCC3*, and *Rad51d* are mutated, knocked out, or knocked down demonstrate that this pathway is important in the repair of DNA lesions induced by TPZ and SN30000.[118,150,151] In addition, HRR is suppressed by chronic hypoxia through multiple mechanisms,[34] so it may play a role in enhancing SN30000 sensitivity in hypoxic tumor cells. However, the synthetic lethality induced by HRR loss is less pronounced for TPZ and SN30000 than for HAPs of DNA cross-linking agents such as PR-104A and TH-302,[118,151] so it is not yet clear whether HRR status will be an important determinant of sensitivity. A more complete view of determinants of intrinsic sensitivity may require use of arrayed RNA interference reagents or more powerful forward genetic screens in bulk cultures such as high-representation CRISPR/Cas9 libraries able to quantify loss of fitness[242] and resistance. In addition, CRISPR libraries that use Cas9 constructs engineered to drive gene expression[243] have exciting potential for gain-of-function genetic screens to identify pathways that modulate intrinsic sensitivity.

Although current SN30000 biomarker development is in the discovery phase, any predictive biomarker (or set of biomarkers) will ultimately need to be validated in phase II/III clinical studies. In the absence of that validation, the choice of tumor types for initial exploration of SN30000 in the clinic needs to be driven by evidence that hypoxia limits outcomes with the current standard of care and information about potential determinants of sensitivity at a population level. The case is perhaps strongest for combination with (chemo)radiotherapy for the treatment of advanced HNSCC where there is compelling evidence that hypoxia determines outcome.[42,43,70] Recent evidence identifies the HPV-negative subset as a distinct molecular subtype[244] with relatively poor chemoradiation outcomes[245] and evidence shows improved local tumor control when TPZ is combined with cisplatin and radiotherapy for treatment of hypoxic tumors.[179] Increased hypoxia in recurrent tumors within the radiation field because of suppression of angiogenesis[246] also suggests possible applications in the treatment of recurrent squamous cell carcinomas and brain tumors (the latter potentially exploiting the high blood–brain barrier permeability of SN30000).

During clinical development, response biomarkers that provide early readout of clinical activity also have high value. This aspect of SN30000 development has not yet been explored thoroughly. Hypoxia- and reductase-dependent inductions of γH2AX by SN30000 have been documented[148] and would assist in confirming mechanism, although the requirement for sampling the tumor post-treatment would limit utility. A small but significant reduction in ^{18}F-EF5 specific uptake values was observed 24 h after SN30000 treatment of H460 tumors in athymic rats, accompanied by increased apoptosis in regions distant from the blood vessels,[231] although it is not clear whether the loss of metabolic viability of hypoxic cells will typically be fast enough post-SN30000 for this to be a useful early response marker in the clinic. The distinction between predictive and response biomarkers becomes blurred when one considers use of hypoxia imaging during fractionated radiotherapy to assess residual hypoxia and thus determine whether administration of HAP should be continued. Preclinical studies to address this question would be highly informative.

8.03.5 Summary

We have successfully conducted a drug discovery campaign to identify an improved TPZ analog SN30000, and a backup compound SN29751, using an SR-PK–PD model-guided approach. The use of the PK–PD modeling in our discovery algorithm allowed us to ignore the misdirection provided by *in vitro* hypoxic potency and selectivity data and to successfully and efficiently predict compounds with increased *in vivo* hypoxic selectivity compared to TPZ. A key focus during this investigation was the improvement in EVT through optimization of diffusion and metabolism properties of the BTOs. We have also uncovered, although not completely defined, the SAR for *in vivo* toxicity and AUC for BTO analogs, at least in murine models. In this campaign, we have predicted and confirmed the activity of 16 BTO analogs from a pool of 280 BTO compounds with only one incorrect prediction.

We have demonstrated that SN30000 has the improved properties we sought as design targets at the outset of our campaign. In particular, we have improved both solubility and potency with SN30000 being approximately fivefold more soluble than TPZ and having increased hypoxic potency against a panel of human tumor cell lines. SN30000 displays improved EVT compared to TPZ as a consequence of increased diffusion, which more than offsets a small increase in hypoxic metabolism. These properties translate to

increased predicted hypoxic selectivity *in vivo* that, when combined with the lower toxicity of SN30000, results in SN30000 displaying increased killing of hypoxic cells *in vivo* in a range of human tumor xenograft models in combination with radiation.

SN30000 has undergone preclinical development including CMC studies where a GMP synthesis has been developed and preclinical formulation and toxicology studies in rats have been completed. SN30000 and its backup compound SN29751 are both protected by patents. The search for suitable biomarkers for hypoxia and competent reductases is well advanced, and SN30000 is ready to advance to clinical evaluation.

Acknowledgments

The authors would like to acknowledge the team who contributed to the discovery and development of SN30000. At the Auckland Cancer Society Research Centre (ACSRC), we thank Dr. Robert Anderson, Dr. Adrian Blaser, Dr. Swarna Gamage, Dr. Francis Hunter, Dr. Ho Lee, Dr. Karin Pchalek, Dr. Frederik Pruijn, Dr. Sujata Shinde, Dr. Bronwyn Siim, Dr. Jingli Wang, Dr. Shanjing Yang, Jane Botting, Annie Fraser, Alison Hogg, Sisira Kumar, Sarath Liyanage, and Rita Patel for their contributions to the design, synthesis, and evaluation of the compounds. We would particularly like to acknowledge Prof. Bill Denny (ACSRC), Prof. Martin Brown (Stanford University), and Dr. Thorsten Melcher (J&J Innovation) for their strong support of the program. We thank Prof. Timothy Secomb (University of Arizona) for his continuing developmental support of Green's function PK–PD modeling capabilities and Prof. Secomb and Prof. Mark Dewhirst (Duke University) for the use of the digitized tumor networks. We also would like to thank the Cancer Research UK Centre for Drug Development, and their contractors, for major contributions to GMP synthesis of SN30000 (Dr. Nigel Westwood and the team at Onyx Scientific Ltd, Sunderland, the United Kingdom), formulation (Prof. Gavin Halbert and the Cancer Research UK Formulation Unit at Strathclyde), and GLP toxicology (Dr. David Edwards and Sequani Ltd, Ledbury, the United Kingdom).

8.04.1 The Ubiquitin Proteasome System

Protein homeostasis is the dynamic process by which a cell regulates protein turnover to maintain the balance of protein levels required for proper growth and development.[1,2] While early work implicated lysosomal degradation as largely responsible for this function, it was later shown to be insufficient in explaining variations in protein stability or degradation rates under changing physiological conditions. Further work showed that, along with lysosomal activity, a significant subset of protein turnover is regulated by the collection of enzymes and proteases of the ubiquitin proteasome system (UPS).[3] The ground-breaking work of Ciechanover[4] and Wilkinson[5] identified the role of ubiquitin (Ub), a 76 amino acid protein of unknown function when originally isolated, as a post-translational modifier of proteins which plays a critical role in the quality control mechanism of the UPS. Mediated by a series of enzymes (E1, E2, E3), a Ub chain is covalently linked to a substrate which enables recognition by the proteasome, the large proteolytic complex responsible for protein degradation.[6,7] Following removal of the Ub chain, the protein is processed by the proteolytic core of the proteasome and the resulting peptide fragments are available for use in the synthesis of new protein (**Fig. 1**).[8]

The UPS plays a key role in a diverse array of cellular functions from cell cycle control and transcription to development[9–12] and aberrations within this pathway have been implicated in a number of diseases.[3] Moreover, cancer cells exist in a heightened state of cellular stress and rely on the machinery of the UPS to a greater extent than normal cells making this an area of focus for therapeutic intervention.[10,13] Early efforts to impact targets within this pathway focused on inhibition of the proteasome. Validation of this approach was realized with the approval of the small molecule proteasome inhibitor bortezomib (VELCADE®, Millennium Pharmaceuticals, Inc. a wholly owned subsidiary of Takeda Pharmaceuticals, Ltd.) as an effective treatment for multiple myeloma and mantle cell lymphoma.[8,10,12,14,15] Further work in this area resulted in the approval of the proteasome inhibitors carfilzomib (Kyprolis®, Amgen)[16–18] and the orally bioavailable ixazomib (NINLARO®, Takeda).[16,19] These molecules act by disrupting protein homeostasis and increasing proteotoxic stress within the cell which results in the induction of apoptosis.[10,13] The effectiveness of this treatment in multiple myeloma may be due to the fact that the myeloma cells express increased levels of the pro-survival transcription factor NF-kB and proteasome inhibition stabilizes the endogenous inhibitor of NF-kB (Ik-B).[10,11,20] Further research, however, suggests a greater contribution from activation of the unfolded protein response (UPR) and the induction of pro-apoptotic UPR genes.[21] While transformative for the treatment of multiple myeloma and mantle cell lymphoma, therapeutic application of proteasome inhibitors has so far only been approved in these particular cancer types while showing no success in the solid tumor setting.[10,22] Targeting other components within the UPS is a potential strategy to improve outcomes across a wider variety of tumor types and many of these targets have been the subject of extensive reviews.[9,10,12] This article will describe our efforts toward the identification of inhibitors of two targets within this pathway: the Nedd8-activating enzyme (NAE) and the ubiquitin-activating enzyme (UAE).

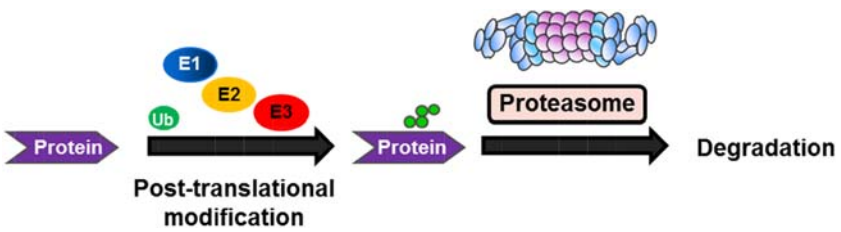

Fig. 1 Overview of the ubiquitin proteasome system (UPS).

8.04.2 UAE and NAE

Within the UPS, E1-activating enzymes initiate the process of modifying a protein with Ub or a ubiquitin-like (Ubl) modifier. In the context of the UAE pathway, activation of Ub occurs in an ATP-dependent fashion by way of a three-step mechanism (Fig. 2).[23] In Step 1, ATP and Ub bind UAE and react to form an adenylate between the C-terminal glycine of Ub and the adenosine monophosphate (AMP) of ATP. The resulting AMP-Ub adduct undergoes nucleophilic attack by the catalytic cysteine of UAE to form a Ub-Cys thioester (Step 2) after which an additional adenylation step occurs and a second equivalent of AMP-Ub binds UAE (Step 3).

The resulting ternary complex is now poised to transfer Ub from the catalytic cysteine of the E1 to one of its corresponding E2-conjugating enzymes (aka Ubc, Ub-conjugating enzyme) (Fig. 3).[24]

Transfer of Ub (as the single protein or as a poly-Ub chain) to a lysine residue of a substrate is mediated by an E3 Ub-protein ligase[12,23,25] whose function is to bring the protein in close proximity to the E2-Ub species (Fig. 4). The manner in which Ub transfer occurs is dependent on the class of E3 ligase involved in the process. For HECT-domain E3 ligases, Ub is first transferred to a conserved cysteine residue of the E3 and then to the substrate. Other E3s (U-box proteins, monomeric RING finger E3s, and multisubunit E3 complexes that contain a RING finger protein) mediate transfer directly from the E2 to the substrate protein.[12,26] Proteins tagged with a poly-Ub chain linked through lys-48 (K48) on Ub are targeted for degradation by the proteasome. In addition to this function, the UAE pathway plays a role in a variety of other cellular signaling processes including DNA repair, autophagy, histone function, receptor internalization, and protein localization.[3,11,27] These different functions are dependent upon whether a protein is mono- or poly-ubiquitinated along with which amino acid residue ubiquitination occurs. Poly-ubiquitination at Lys48 (K48) of the Ub protein results in degradation of the substrate by the proteasome. Poly-ubiquitination at an alternate lysine residue (i.e., Lys63) or mono-ubiquitination manifests in one or more of the aforementioned cellular functions.[3,9,11]

Subsequent to the discovery of UAE, seven other E1-activating enzymes were identified which share a similar homology and employ similar activation mechanisms to that described earlier. Importantly, however, each E1 employs different components within their corresponding activation pathways to impart specificity of function to modified substrates.[28] Of these, the pathway initiated by NAE is responsible for modifying the cullin family of proteins[29] with the Ubl modifier nedd8 (neural precursor cell-expressed, developmentally downregulated protein 8).[30] The cullin proteins act as a core scaffold for a subclass of Ub E3's, the cullin-RING ligases (CRLs) and posttranslational modification of the cullins with nedd8 is required for ligase activity (Fig. 5). Numbering in the hundreds, this set of E3 ligases is involved in regulating the ubiquitination of proteins which have important

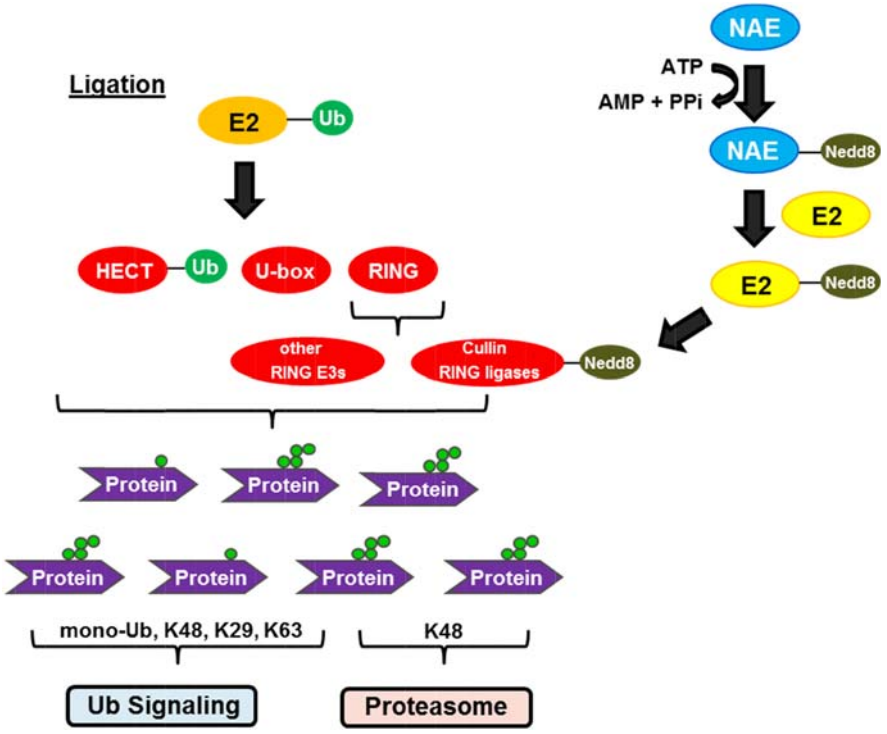

Fig. 5 The Nedd8-activating enzyme (NAE) pathway.

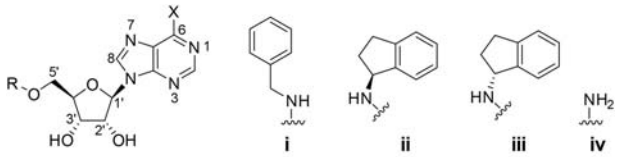
roles in cellular processes associated with cancer cell growth and survival pathways.[15,26] As a target upstream of the proteasome, inhibition of NAE would be expected to disrupt cancer cell protein homeostasis more selectively than inhibition of proteasome activity with potential differences in clinical efficacy.[15]

8.04.3 The Discovery of Pevonedistat (MLN4924/TAK-924)

Efforts toward a small-molecule inhibitor of NAE began with a high-throughput screen from which a series of N-6 substituted adenosine derivatives was obtained as weak, micromolar inhibitors of NAE. Following up on this, a diverse set of N6 (purine numbering



Compound	R	X	NAE IC_{50} (nM)

5	$(OH)_2P=O$	ii	120

Fig. 6 Early SAR: follow-up of a high-throughput screen.

system) amine analogs was generated where SAR indicated a preference for benzyl amine substituents (Fig. 6). In particular (*S*)-1-aminoindane provided one of the most active inhibitors (**2**), albeit with low micromolar activity, against the target. Recognizing that AMP (**4**) is known to be a weak inhibitor of NAE as a result of product inhibition,[31] a 5′-*O*-phosphate group was appended to compound **2** to provide the first submicromolar inhibitor of NAE within this series (**5**).

While potent in a biochemical assay, compound **5** showed no activity when evaluated in a cellular assay measuring NFκB activity, a transcription factor and downstream substrate of the NAE pathway. As alluded to in the Introduction, the protein IκB is the endogenous inhibitor of NFκB[32] and IκB protein levels are dependent on the NAE activation pathway (Fig. 7). Upon stimulation of cells by the cytokine TNFα, IκB is phosphorylated by the IκB kinase (IKK). Downstream of NAE, the neddylated CRLs SCF-βTRCP is the E3 responsible for ubiquitination of phospho-IκB resulting in its subsequent degradation by the proteasome.[33] By blocking the degradation of IkB, NAE inhibition prevents the NFκB transcription factor from entering the cell nucleus and exerting its activity.

Medicinal chemistry efforts to address cell potency revealed that replacement of the phosphate with the neutral sulfamate group greatly improved biochemical potency and yielded the first cell active compounds (compounds **6** and **7**, Fig. 8). Despite favorable enzyme and cell potency, however, a screen against other E1's showed that these adenosine sulfamate derivatives lacked desirable selectivity over UAE and the SUMO-activating enzyme (SAE).

Furthermore, compounds of this type exhibited an inherent chemical instability wherein the sulfamate moiety was displaced by intramolecular cyclization with N3 of the adenine ring (Fig. 9). Mitigating this degradation event and improving selectivity over other E1s were initial SAR goals within this series.

Initial attempts were made to reduce the leaving group ability of the sulfamate via replacement with either a sulfamide (**8**) or sulfonamide (**9**). While this afforded compounds with greater chemical stability and improved selectivity over UAE and SAE, compounds of this type generally resulted in a decrease in on-target cellular potency (Fig. 10).

Alternatively, attempts were made to reduce the nucleophilicity of the adenine N3 by substituting at N6 with electron withdrawing groups (e.g., acyl (**10**), sulfonamide (**11**), and urea (**12**)). This resulted in diminished selectivity over other E1's along with a reduction in cellular potency (Fig. 11). Replacement of the electron donating nitrogen linkage with carbon (phenethyl

compound **13**) mitigated the cyclization event and afforded a compound with very good biochemical/cell potency. While this molecule exhibited excellent selectivity over SAE, it displayed only modest selectivity over UAE. Variations on this theme in the form of the conformationally rigidified phenethylene (**14**) and phenylacetylene (**15**) were potent but not selective.

In addition to exploring side-chain modifications, SAR around the adenine ring was investigated in order to address selectivity/stability (Fig. 12). While removal of the N3 nitrogen (imidazo-pyrimidine **16**), resulted in a compound with diminished cellular potency, the corresponding pyrrolo-pyrimidine **17** (N7 removal) displayed excellent activity against NAE and afforded an improvement in selectivity over both UAE and SAE. Separately, the impact of the removal of the hydroxyl groups on the ribose moiety was explored. From this effort, it was found that the 3′-OH was required for potency (**20**) whereas 2′-deoxy compounds retained potency and showed improved selectivity (**19**, **21**). Replacement of the ribose moiety with the cyclopentane also afforded potent analogs (**18**, **22**) and eliminated the anomeric center within the molecule. In particular, the combined removal of N7 and the 2′-OH with the cyclopentane modification afforded compound **23** which was potent, selective, and cell active. However, the molecule was still prone to internal cyclization.

14		1	4	26	62
15		0.3	0.3	3	35

*mouse UAE

Fig. 11 Efforts to mitigate undesired cyclization: N6 modification. *Mouse UAE.

Another approach to address the cyclization event was to prevent alignment of the leaving group and the nucleophile. The "nonnatural" anti configuration of the cyclopentane ring was explored by generating the methylene sulfamate epimer at the 4′-position of compound **23** (compound **24**, Fig. 13). It was not known whether compounds with an anti configuration would retain activity. Surprisingly, this stereoisomer maintained excellent potency and, gratifyingly, the anti configuration prevented the internal cyclization between the sulfamate moiety and the purine-like base.

Importantly, these compounds unexpectedly proved potent in both biochemical and cell assays and exhibited very good selectivity over UAE and SAE (Fig. 14). A survey of N-6 substituents (**25–30**) confirmed that the compound substituted with the (*S*)-aminoindane was preferred over, for example, benzyl, α-methylbenzyl, and the opposite (*R*)-amino indane isomer (Fig. 14). Compound **24** was ultimately selected as the clinical candidate (pevonedistat).

8.04.4 Pevonedistat In Vitro and In Vivo Evaluation

The selectivity of pevonedistat within a cellular setting is demonstrated by Western blot analysis. A dose titration of the inhibitor in HCT116 cells prevented the formation of the thioester formed between the E2-conjugating enzyme (Ubc12) associated with NAE and the Nedd8 protein whereas thioesters associated with either UAE (Ubc10-Ub) or SAE (Ubc9-SUMO) activity remain uninhibited at up to 3 μM of compound throughout a 24-h incubation period (Fig. 15A). Further evidence of target engagement was observed with the corresponding decrease in neddylated cullin proteins following a similar dose response. Over the same time frame, substrates of CRLs were stabilized (e.g., NRF2, CDT-1, and p27), and markers of apoptosis (cleaved caspase and cleaved

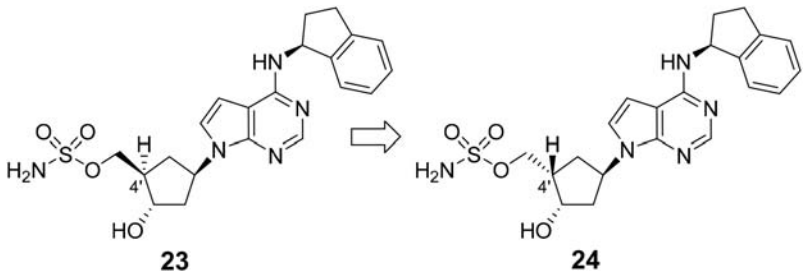

Fig. 13 A compound epimeric at the 4′-position does not undergo internal cyclization.

poly (ADP-ribose) polymerase (PARP)) were evident (Fig. 15B). This is consistent with average cell viability LD_{50} in an ATPLite assay of approximately 80 nM in HCT116 cells at 72 h.

To illustrate activity in vivo, nude mice bearing HCT116 xenografts were given a single subcutaneous injection of pevonedistat (Fig. 16). A dose-dependent pharmacodynamic response was observed with a decrease in levels of neddylated cullins with a maximal response around 2 h and returning toward baseline at 24 h. The converse is observed with levels of substrate, such as CDT1 and NRF2, increasing and giving a maximum response between 2 and 5 h and returning toward baseline at 24 h.[15]

To evaluate the effect on tumor growth, nude mice bearing subcutaneous xenografts derived from human HCT116 tumor cells were administered pevonedistat by subcutaneous injection on a variety of schedules and doses (Fig. 17).[15] Tumor growth inhibition was assessed by measuring tumor volume and comparing with control. Antitumor activity was similarly assessed in severe combined immunodeficient (SCID) mice bearing LY10 human tumor xenografts.[34] These and additional studies demonstrated that pevonedistat effectively suppressed tumor growth at doses and schedules that were well tolerated and supported advancement into human clinical trials.[35,36]

One of the most intriguing aspects of the NAE effort which required extensive follow-up was the stark difference in potency observed upon replacement of the phosphate moiety with a sulfamate. A crystal structure of pevonedistat bound to NAE in the presence of the Nedd8 protein suggested no clear interaction that could explain this dramatic potency shift (Fig. 18A). A breakthrough

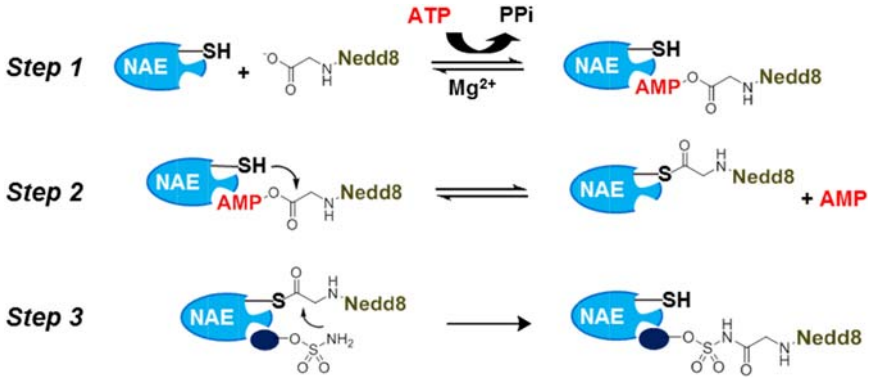

Fig. 19 The mechanism of "substrate-assisted inhibition."

observation was realized when a crystal structure was obtained in the presence of ATP: cocrystallization of MLN4924 with NAE/Nedd8/ATP revealed continuous electron density between the nitrogen of the sulfamate and the C-terminus of the Nedd8 protein showing that a *covalent bond had formed between the inhibitor and the Ubl* (Fig. 18B).[14] This covalent adduct, incorporating all the recognition elements intrinsic to the Nedd8 protein, binds noncovalently to the adenylation active site normally occupied by ATP and Nedd8 and acts as an inhibitor of the enzyme.[14,37]

Termed "substrate-assisted inhibition," the extensive set of experiments performed to elucidate the mechanism of adduct formation are described by Soucy[15] and Brownell.[14] From this work, it was determined that the first two steps of the activation pathway take place to form the singly loaded NAE-Nedd8 thioester (Fig. 19). At this point, instead of formation of the subsequent ternary complex, the inhibitor effectively competes for the ATP-binding site (Step 3) whereupon Nedd8 is transferred to the nitrogen nucleophile of the sulfamate resulting in a stable adduct that is tightly bound to the enzyme.

8.04.5 The Discovery of TAK-243 (MLN7243)

With the success of the NAE program and the knowledge gained from elucidating the mechanism of action of pevonedistat, attention was turned toward investigating UAE as a potential oncology target. Since UAE is upstream of the proteasome and impacts a greater number of substrates than NAE, it is hypothesized that inhibition should result in distinct biological outcomes thereby warranting clinical investigation.

Compounds from the adenosine sulfamate series provided an attractive starting point for the UAE program. As exemplified by **7** and **15** (Fig. 20), this chemotype displayed excellent biochemical potency against multiple E1s. Initial efforts were focused on obtaining UAE selective inhibitors and it was observed that substitution with an indole (**31**) diminished activity against SAE. Furthermore, the change from nitrogen to carbon linkage at the C6 position significantly mitigated the cyclization event that was problematic early on in the NAE campaign.

SAR exploration around the indole ring with electron-withdrawing and electron-donating groups afforded a set of UAE inhibitors with varying degrees of selectivity over NAE and SAE. From these data (Fig. 21), substitution at the six position on the indole moiety afforded compounds with optimal potency and selectivity albeit with some limitation to the size of substituent that could be accommodated (compare potency of **33** with **35**).

During the course of SAR exploration, it was realized that certain compounds within this series inhibited protein synthesis (as determined by incorporation of [(**35**)*S*]-methionine into proteins within cells). A change from ribose to cyclopentane eliminated

this undesired activity with little variation in the overall SAR (data not disclosed). From this effort, compound **38**, which displayed comparable biochemical potency and a similar selectivity profile to its corresponding ribose derivative, was selected as a tool molecule to probe in vivo effects of UAE inhibition (Fig. 22). In addition to excellent enzyme potency, compound **38** displayed reasonable on-target cellular activity (Ubc10-Ub: 520 nM). The Ubc10-Ub assay monitors the formation of the thioester formed between the catalytic cysteine of one of the E2 enzymes associated with UAE (Ubc10) and Ub and therefore provides a direct readout of UAE inhibition. Despite favorable on-target in vitro activity, the compound failed to have meaningful impact on pharmacodynamic markers in vivo (i.e., inhibition of polyubiquitination and subsequent stabilization of substrate proteins in vivo).

In light of this, an effort was made to identify alternative chemotypes suitable for evaluating the in vivo impact of UAE inhibition. A variety of scaffolds which placed N9 of the adenosine sulfamate series exo to the ring system was investigated (Fig. 23). Synthesis of several different 5,6 and 6,6 ring systems resulted in compounds with excellent potency against the target. An overlay of the crystal structures of compound **39** and the pyrazolo-pyrimidine **40** illustrates the conservation of key hydrogen bond interactions and the position of the hydrophobic moieties between the two scaffolds. The hydroxyl substituents on the cyclopentane rings of both compounds interact with an aspartic acid residue (Asp470) in the active site. In addition, a hydrogen bond to the backbone nitrogen of Val520 is maintained in both structures. While SAR around several different chemotypes was extensively explored, the pyrazolo-pyrimidine scaffold (as represented by compound **40**) became the main focus of the program and the remainder of this article will detail efforts around this particular scaffold.

Structure–activity relationships around the adenosine sulfamate series showed that both the 2′- and 3′-hydroxyl groups on a cyclopentane were optimal for potency against UAE. This trend was further explored within the pyrazolo-pyrimidine series. In the example where Ar = Ph (Fig. 24, compounds **40–42**), SAR showed that the 2′-hydroxyl group is required for optimum biochemical potency against UAE. Compounds with larger hydrophobic groups (**43–49**) resulted in greater potency against both UAE and NAE relative to their unsubstituted phenyl counterparts. In general, compounds with a 2′-hydroxyl group showed better cellular potency than those without this functional group as evaluated in an assay measuring the inhibition of protein polyubiquitination (K48 cell assay). As discussed in the introduction, UAE catalyzes the reaction that appends a chain of Ub molecules (linked through the lys48 (K48) residue of the Ub protein) to a substrate. An inhibitor's ability to prevent this from taking place provides a downstream readout of UAE target engagement. Overall, compounds within the pyrazolo-pyrimidine series showed excellent selectivity over SAE while selectivity over NAE proved more challenging.

Fig. 25 SAR around naphthyl ring substitution.

Following up on the improvement in potency observed with the increase in aryl hydrophobicity, SAR of variously substituted naphthyl derivatives on the pyrazolo-pyrimidine scaffold was explored (Fig. 25). Substitution with fluorine at either C4 (**46**) or C5 (**47**) of the naphthyl substituent afforded excellent biochemical and cellular potency as did a CHF_2 group at C6 (**48**). A chlorine substituted at C4 provided a compound with activity similar to its fluorinated counterpart (compare compounds **46** and **49**) as did switching to an electron donating methyl group (**50**). While these examples illustrated that substitution at most positions around the naphthyl ring was well tolerated, substitution at the 2-position deviated from this trend. The 2-methyl derivative **52** and the 2,4-dichloro compound **51** showed greatly diminished cellular potency. Interestingly, these compounds displayed a meaningful difference in potency between UAE and NAE and provided a path forward to explore selectivity over NAE within this series.

Toward this end, a series of substituted naphthyl derivatives was synthesized with increasing steric bulk at the 2-position (Fig. 26). In particular, the isopropoxy substituted naphthyl compound **55** afforded a molecule that was still quite potent against UAE (3 nM) in the biochemical assay but was not active against NAE (>1000 nM). The favorable impact on selectivity appeared to be specific to the naphthyl group. 2-Methoxynaphthyl compound **54** showed >100-fold selectivity over NAE where the effect was not nearly as pronounced for the corresponding 2-methoxyphenyl compound (**56**, ~fivefold selective in the biochemical assay).

Despite favorable selectivity, compounds such as **55** showed dramatically diminished cellular activity and, while further refinement could have overcome this, the question was raised as to whether or not selectivity over NAE was necessary to identify a suitable clinical candidate. As discussed in the Introduction, there is an overlap in the function of NAE and UAE. NAE controls a subset of E3 ligases (the CRLs)[26] that are directly involved in ubiquitination (which, of course, requires UAE activity). Inhibition of UAE prevents the activation of Ub and obviates the function of all E3's including cullin-dependent E3's. Therefore, it was hypothesized that the phenotype of a *dual* UAE/NAE inhibitor would be identical to that of a UAE *selective* inhibitor. The phenotype of NAE selective inhibition, established during the NAE program with pevonedistat, exhibited DNA re-replication and the accumulation of cells in the

S-phase of the cell cycle as observed by fluorescence-activated cell sorting (FACS) analysis (Fig. 27B).[15] Inhibition and phenotype analysis with a *selective* UAE inhibitor (compound not shown) resulted in cell cycle arrest in the G2 phase (Fig. 27C). A *dual* UAE/NAE inhibitor (compound **46**) exhibited this same G2 arrest phenotype (Fig. 27D) and confirmed the dominant UAE phenotype of inhibition over that of NAE inhibition.

A possible explanation for the difference in phenotype lies in the substrates which are modified within each pathway. The replication licensing factor CDT1, following DNA replication, is ultimately ubiquitinated and degraded in an NAE (CRL)-dependent manner to ensure replication occurs only once within a cell cycle. When NAE is inhibited CDT1 cannot be degraded and remains active thereby inducing the DNA re-replication phenotype observed. Presumably, this would occur upon UAE inhibition as well since there is an overlap in function of NAE and UAE which should also lead to the stabilization of CDT1. However, UAE inhibition also results in the stabilization of the protein geminin, the endogenous inhibitor of CDT1. Stabilization of both geminin and CDT1 would prevent the cellular imbalance observed resulting from NAE inhibition and therefore prevent the re-replication phenotype.[38] To summarize this observation: An NAE inhibitor inhibits only NAE activity. A UAE inhibitor inhibits both UAE and NAE function regardless of its activity against NAE.

8.04.6 Selection of the Development Candidate

Having established the dominant UAE phenotype, selectivity for UAE over NAE was not considered critical to moving forward and focus was directed toward in vivo evaluation of potent UAE inhibitors regardless of NAE inhibition. Along with exploration of SAR around the naphthyl moiety, considerable effort was focused on other variously substituted aryl and heteroaryl substituents. This work identified a clear preference for compounds with meta-substituted phenyl substituents as exemplified by a comparison of compound **61** (which was ultimately selected as the clinical candidate) with the corresponding ortho (**62**) and para (**63**) compounds that showed diminished biochemical and cellular potency (Fig. 28).

8.04.7 Profile of the Clinical Candidate

Compounds that displayed potent on-target cellular activity were further profiled in vitro in advance of in vivo evaluation. In addition to excellent activity in the K48 polyubiquitination assay, TAK-243 (**61**) displayed excellent cytotoxicity as determined in an ATPlite assay in HCT116 cells (Fig. 29A). Furthermore, the compound inhibited the formation of the Ubc10-ubiquitin thioester adduct with an IC_{50} of 50 nM thereby preventing the downstream transfer of Ub to protein substrates. This leads to the stabilization of short-lived proteins such as c-jun and c-myc and the induction of ER (endoplasmic reticulum) stress as indicated by the stabilization of ATF and GADD34 (Fig. 29B). The accumulation of cleaved PARP signified the induction of an apoptotic response (Fig. 29C). A crystal structure of TAK-243 bound to UAE (in the presence of Ub and ATP) revealed the formation of a covalent adduct formed between the sulfamate moiety of the compound and C-terminal glycine of Ub (Fig. 29D).

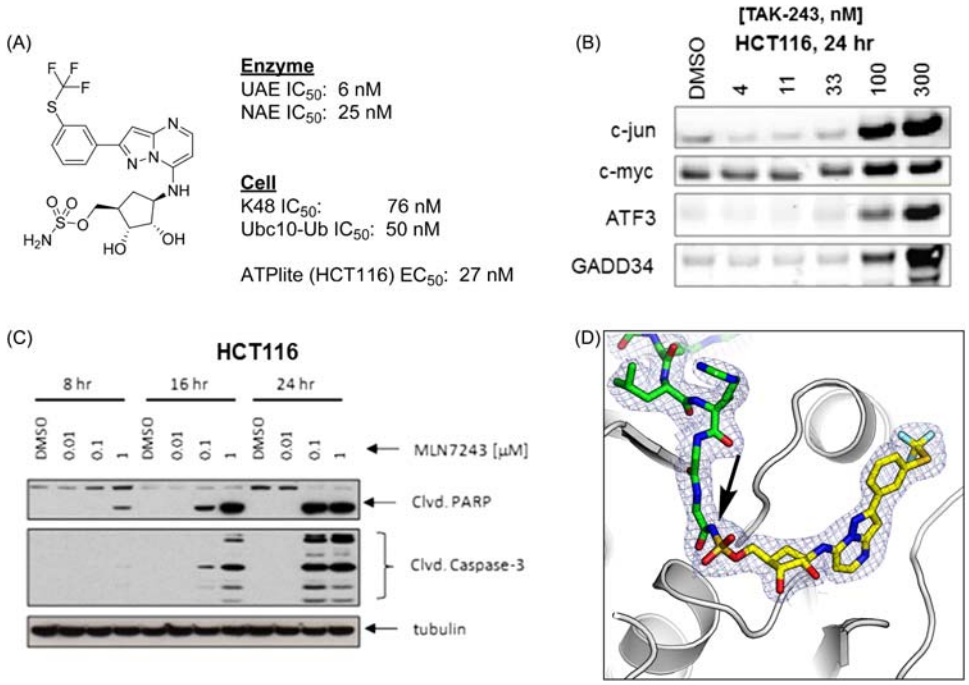

Fig. 29 (A) In vitro profile of TAK-243. (B) Western blot analysis of proteins stabilized as a result of UAE inhibition. (C) Western blot analysis of apoptotic markers cleaved PARP (HCT116 cells). (D) Crystal structure of TAK-243 (*arrow* indicates the bond between the sulfamate of the inhibitor and ubiquitin).

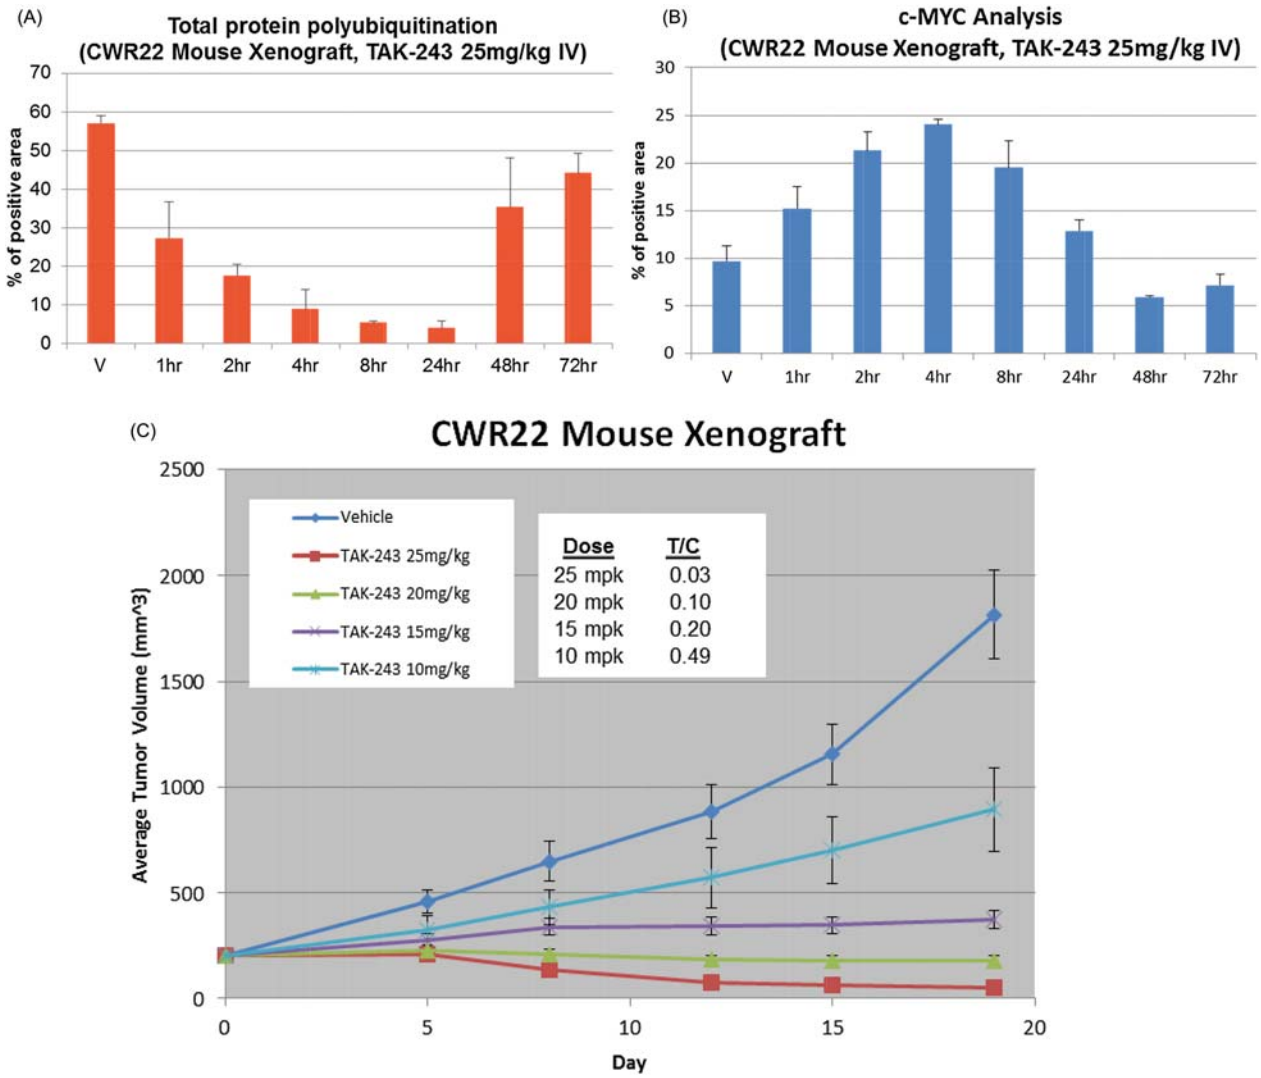

Fig. 30 (A) PD response in CWR22 tumor samples: levels of polyubiquitinated protein conjugates decreases over time. (B) Accumulation of c-Myc as a result of UAE inhibition. (C) 21-day efficacy study in CWR22 mouse xenografts (IV dose, twice weekly, MTD is 25 mpk).

In vivo, TAK-243 displayed a robust and durable pharmacodynamic response. For example, immunohistochemistry analysis of tumor samples from a cell-line-derived CWR-22 xenograft (prostate cancer model) showed a very good correlation between the loss of poly-ubiquitinated proteins (Fig. 30A) and the stabilization of the protein c-myc that persisted out to 24 h (Fig. 30B). This translated into excellent antitumor activity in the same model treated with TAK-243 on a clinically relevant twice weekly dosing schedule (Fig. 30C).

TAK-243 also showed antitumor activity in a patient-derived colon adenocarcinoma model following the same twice weekly dosing schedule (Fig. 31A) and tumor samples from both treated and untreated animals were analyzed by immunohistochemistry. The clear presence of inhibitor-Ub adduct (Fig. 31B) and the loss of polyubiquinated proteins (Fig. 31C) in treated samples provided confidence that tumor growth inhibition was driven by target engagement. In addition to the nonclinical efficacy studies described herein, TAK-243 exhibited broad antitumor activity across a variety of cell-line derived and primary tumor xenograft models. These data supported the initiation of a phase I dose escalation clinical trial (C33001) in solid tumors.

The clinical success of proteasome inhibition afforded validation that disruption of the UPS is a valid approach to the treatment of cancer. Building on this knowledge, attention was turned to other targets within the UPS in order to impact protein quality control in a different and potentially more selective fashion. TAK-924 and TAK-243 represent the first E1-activating enzyme inhibitors to enter the clinic. These mechanism-based inhibitors form a covalent adduct in situ that is tight-binding, ATP competitive, and reversible. The adduct takes advantage of the strong protein–protein interactions native to the E1 and its corresponding Ub or Ubl to bind noncovalently to the enzyme. This leads to durable pharmacodynamic responses and broad in vivo efficacy in nonclinical models. In addition to potential clinical benefit, intervention with small molecules affords tools to better understand the molecular mechanisms and interactions involved in the complex array of processes within the UPS and enable development of the next generation of chemotherapeutic agents.

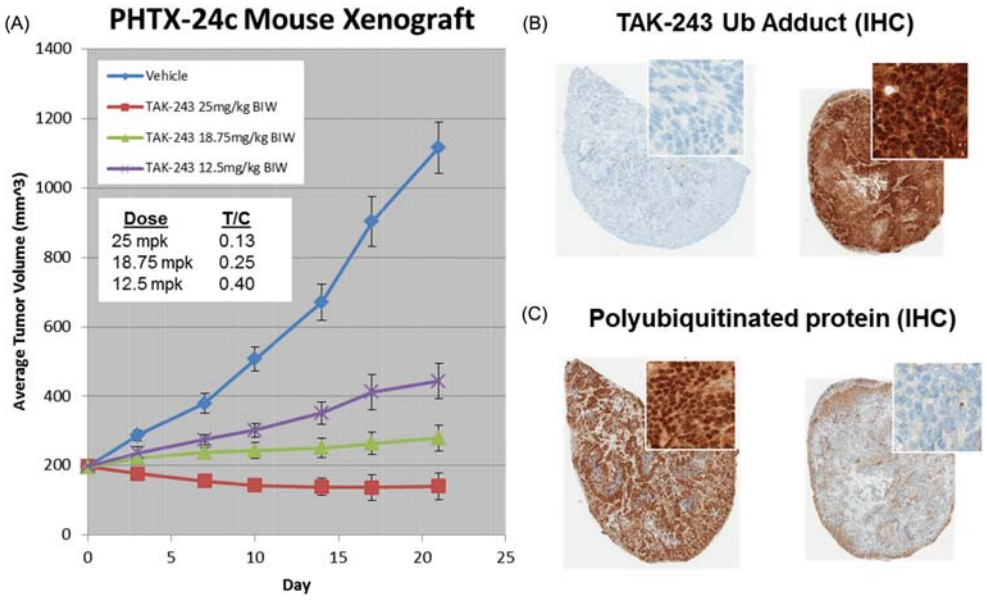

Fig. 31 (A) Twenty-one day efficacy study in PHTX-132Lu xenografts (IV dose, twice weekly). Efficacious response was seen at the maximum tolerated dose of the compound (25 mpk), at ¾ MTD (18.75 mpk) and at ½ MTD (12.5 mpk). (B) and (C) IHC (immunohistochemistry) analysis of treated tumor samples (PHTX-24c, 16 h post-single IV dose of 25 mpk) showing the detection of inhibitor-Ub adduct (B) and the loss of polyubiquinated proteins (C).

8.05.1 Introduction

8.05.1.1 Rationale for p97 Inhibition as a Cancer Target

8.05.1.1.1 Nononcogene addiction pathways

The occurrence of oncogenic mutations that either hyper-activate tumor cell growth pathways or inactivate tumor suppression pathways is a key step in the conversion of healthy tissue to a malignant lesion. Several oncogenic driver mutations have been successfully targeted to produce antitumor therapies but these therapies suffer from short response duration and rapid development of resistance. Tumor cells exist in a highly stressed environment and frequently become dependent upon a number of fundamental biological pathways in order to adapt to the stress of the tumor environment, and dependence on these pathways is called nononcogene addiction (**Fig. 1**).[1] Recently these pathways have become interesting targets for anticancer therapy. One reason to target these nononcogenic pathways is the recognition of heterogeneity in the oncogenic driver mutations within individual tumors that can rapidly render individual oncogene targeted therapies inactive (**Fig. 1**).[2] By targeting the underlying nononcogenic addiction pathways one could provide effective therapies where the number or heterogeneity of oncogenic mutations has caused the tumor mass to become resistant to targeted therapies. One key nononcogenic pathway cancer cells rely on is the control of protein homeostasis. Many tumor cell types require high levels of proteasome activity and efficient mechanisms for dealing with unwanted, incorrectly translated or misfolded proteins to prevent lethal levels of proteotoxic stress from accumulating.[1b]

8.05.1.1.2 p97 and protein homeostasis

The highly abundant protein p97, also called Valosin-containing protein (VCP) or cdc48 in yeast, serves multiple cellular functions through interaction with a variety of cofactor proteins. One main function of p97 is to act as a key regulator of protein homeostasis by sitting at the junction of two important pathways that cells use to deal with proteotoxic stress, the ubiquitin proteasome pathway

[a]Current address: FLX Bio, South San Francisco, CA, United States.

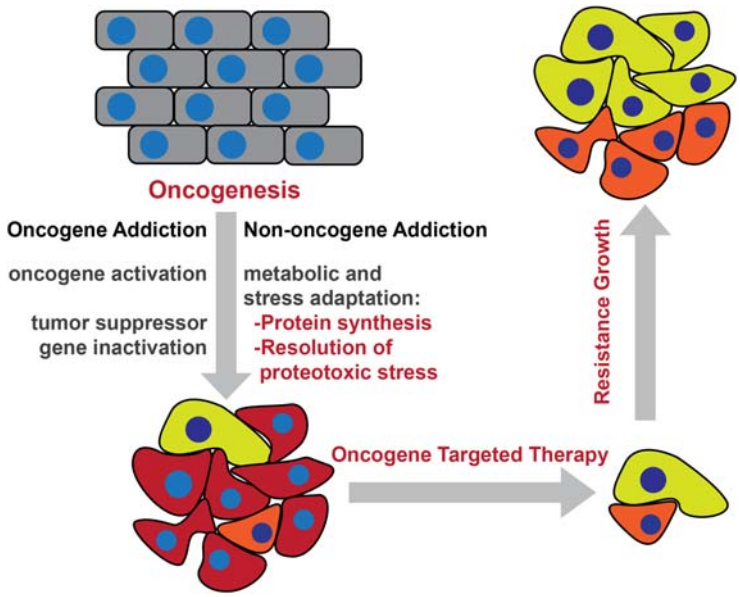

Fig. 1 Interaction of oncogenic and nononcogenic factors in the transformation of normal tissue to cancerous lesions that are heterogeneous and susceptible to targeted agent resistance.

Fig. 2 Domains of p97 protein.

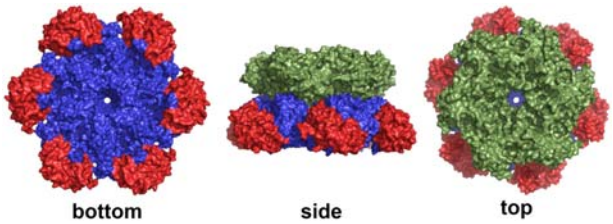

Fig. 3 Cryo-electron microscopy images of the p97 hexamer.[5]

and the autophagy lysosome pathway.[3] The protein p97 is a member of the AAA+ family of ATPases. This a heterogeneous group of ATPases that act as mechanoenzymes by converting the chemical energy of ATP to generate force that is used to translocate and remodel protein/protein, protein/nucleic acid, or protein/membrane complexes.[4] Six p97 protein monomers with each monomer containing three protein subdomains (Fig. 2) combine to form a homohexamer (Fig. 3). Recently a cryo-electron microscopic image of the hexamer has been published.[5]

The N-terminal domain is responsible for binding cofactor proteins which help to direct p97 to different processes within the cell. The D1 domain binds tightly to ADP and interactions between D1 sites on adjacent monomers are important for hexamer formation. The D2 domain is responsible for the majority of the ATP hydrolysis activity of p97.[6] An important function of p97 is to extract polyubiquitinated (poly-Ub) proteins from the endoplasmic reticulum (ER) and other organelles and deliver them to the 26S proteasome for degradation (Fig. 4). Previous work has shown that knockdown of p97 interrupts this process leading to increases in poly-ubiquitinated proteins and buildup of mis-folded proteins in the ER which leads to an induction of the unfolded protein response (UPR) resulting in apoptotic cell death.[7] Given p97's critical role in protein homeostasis, inhibition of its ATPase activity was hypothesized to result in preferential killing of cancer cells that have a high protein synthesis burden.[8] Therefore, several groups have put forth efforts in discovering small molecule inhibitors of p97. This review will cover published medicinal chemistry efforts directed at finding new inhibitors of the ATPase activity of p97.

8.05.1.2 Mass Screening and Initial Hit to Lead Efforts

8.05.1.2.1 HTS screen and hit triage

To better understand the role of p97 cellular functions, there was a desire to discover a compound that could rapidly block the ATPase activity of p97 and enable the study of the downstream effects of this inhibition. A robust biochemical assay was developed

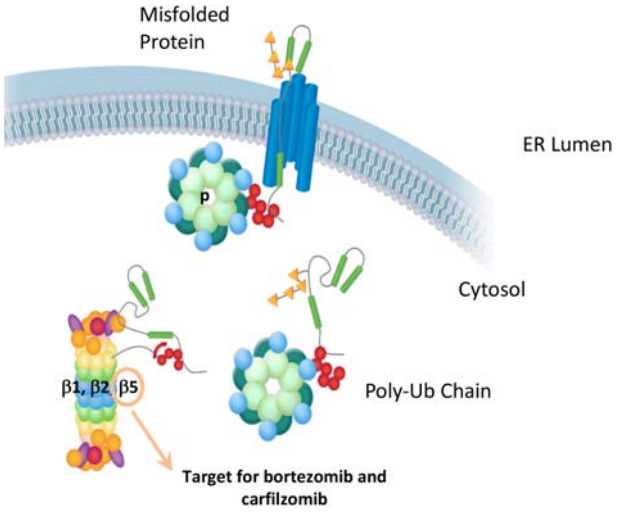

Fig. 4 Role of p97 in processing of misfolded proteins.

that measured recombinant p97 ATPase activity via a luminescent readout of ADP generated from hydrolysis of ATP.[9] This assay was used to screen over 234,000 compounds from two compound libraries (Maybridge HitFinder Collection and the National Institutes of Health Molecular Libraries Small Molecule Repository) at concentrations of 8–10 μM. From the initial 959 mass screen hits (hit rate of 0.4%), 759 hits were retested in triplicate yielding 333 active compounds of which 54 compounds inhibited p97 ATPase activity by more than 50% at $\leq$8 μM. Retesting of these compounds in a 10-point titration yielded only 5 compounds with IC_{50} values under 10 μM. Subsequent retesting of selected compounds resulted in a group of 28 compounds with measurable IC_{50}s in the ATPase assay, several with IC_{50} concentrations in the single-digit micromolar range. This collection of 28 compounds was assessed in a cellular assay that measured the ability of compounds to inhibit the p97 dependent degradation of a fluorescently labeled protein substrate (Ub^{G76V}-GFP).[7] Results from this assay were used to prioritize a group of the 10 most potent compounds (**1**–**10**) for assessment of the selectivity of their interactions with p97 in cells vs. other AAA+ ATPases and other enzymes involved in the UPS (Table 1). This was accomplished by comparing the compounds' ability to inhibit Ub^{G76V}-GFP degradation to that of two luciferase labeled proteins whose degradation was known to be independent of p97; ODD-Luc (oxygen-dependent degradation domain of HIF1a which requires ubiquitination but not p97 activity) and Luc-ODC (luciferase fused to the ubiquitin-independent degradation domain of ornithine decarboxylase) whose degradation is proteasome dependent but ubiquitin and p97 independent. Of the molecules assessed, compounds **1** (DBeQ) and **2** were 10-fold weaker at inhibiting the p97 independent degradation of Luc-ODC or Luc-ODD than the p97 dependent degradation of Ub^{G76V}-GFP (Table 1).

It is interesting to note that many of these compounds determined to have nonselective activity at the cellular level also contained reactive functionality or other structural features found in compounds that often are identified as hits in HTS. Such compounds sometimes referred to as pan assay interfering compounds[10] generally have a poor track record in hit to lead efforts. These include structures such as ketones, chloro-ketones (**3**, **4**, **6**, **8**), Michael acceptor functionality (**7**, **9**), and hydrazine functionality (**10**).

Subsequent biochemical studies determined that **1** was a reversible and competitive inhibitor at the ATPase D2 site of p97 with an IC_{50} of 2.3 μM while only weakly inhibiting the closely related ATPase NSF (<25% inhibition at 100 μM). On the basis of these findings of selective p97 inhibition in both biochemical and cellular contexts, **1** was chosen as the lead molecule from this mass screening effort. Although the previously described p97 inhibitor Eeyarestatin (**11**)[11] inhibited the degradation of the p97 reporter Ub^{G76V}-GFP it did not inhibit the ATPase activity of purified p97. Although compound **11** has been shown to interact with p97 with μM affinity through surface plasmon resonance, gene expression data suggest that it lacks cellular specificity.[12] Furthermore, compound **11** has also been shown to interact with ataxin 3 [11]and Sec61.[13] Analogs of the 2-anilino-thiazole class such as 3-(2-((4-hydroxyphenyl)amino)thiazol-4-yl)phenol (compound **12**) with submicromolar p97 inhibitory potency had also previously been described in the literature (Fig. 5).[14] However, this series of compounds has also been reported to be active against other enzymes, such as neuropeptide Y5 receptor and sphingosine kinase with a similar potency. Despite its advantage in biochemical selectivity, DBeQ was hampered by its micromolar inhibitory potency and poor physicochemical properties including very low aqueous solubility.

8.05.1.2.2 Hit to lead investigations

To discover improved inhibitors of p97 structure activity relationship (SAR) studies were initiated in a joint effort between the University of Kansas and Cal Tech. These efforts focused on both DBeQ (**1**) and the somewhat weaker 2-aryl quinazoline analog (**2**) that had also been identified in the HTS. Changes to the 2 and 4 substituents on the quinazoline core as well as the addition of substituents on the phenyl ring of the quinazoline were investigated.[15] Using an "analog by catalog" approach, commercially

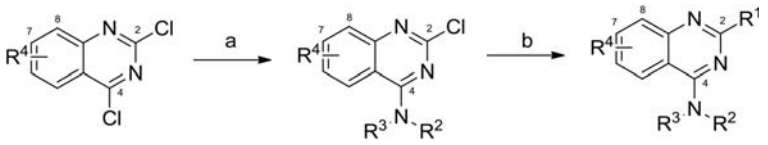
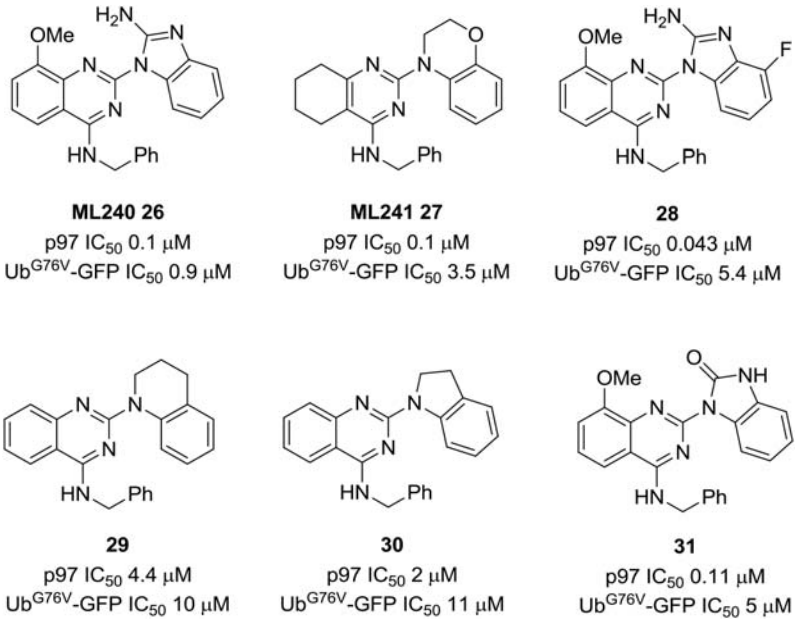
available quinazoline analogs were assayed for their ability to block p97 ATPase activity in both the biochemical and cell-based assays described above (Table 2). A few compounds were found with modestly improved biochemical potency, but their cell-based potency was less than that of DBeQ. Importantly, this early effort showed that the SAR was not flat and identified a number of molecules with substantially reduced potency. Methylation of the 4-*N*-benzyl nitrogen (**19**) resulted in a significant loss of activity. Compounds having a 7-chloro substituent (**15** and **16**) showed significantly decreased potency while compound **25** with an 8-methoxy substituent had improved biochemical potency. Overall none of the commercially available analogs tested showed a significant improvement over **1**. Directed synthesis of analogs investigated a range of amino-aromatic functionality at the 2-position of the quinazoline (P2). The best of these functionalities were combined with small changes to the quinazoline core. These compounds were prepared by a simple two-step procedure as shown in Scheme 1. The 4-position amine could be selectively introduced through reaction of the desired amine of dichloroquinazolines or analogous tetrahydroquinazoline. Subsequent reaction of the aminochloroquinazoline with a second amine under microwave conditions resulted in the target compounds. Substitution of the P2 position with bicyclic heterocycles with the 1-N linked benzimidazole and benzomorpholino ring systems is the most potent. Compounds **26** (ML-240) and **27** (ML-241) were identified as probe compounds because they both had biochemical ATPase IC_{50}s of approximately 0.1 μM. However **26** was more potent than **27** at inhibiting p97 activity within cells as evidenced by the cellular Ub^{G76V}-GFP assay (IC_{50} 0.9 vs. 3.5 μM). This difference translated into more potent effects in inducing tumor cell death. Substitution of the benzimidazole aromatic ring of **26** resulted in some compounds such as **28** with improved biochemical potency but decreased cell-based potency. Explorations of other heterocyclic functionality (i.e., **29** to **31**) at the P2 position failed to yield superior analogs and were not pursued further.



Scheme 1 General synthetic route to DBeQ analogs. Conditions: (a) R_2R_3NH, Et_3N, MeCN, rt 16 h; (b) R_4R_5NH, MeCN microwave irradiation, 180°C, 1 h.



Like compound **1**, **26** was shown to inhibit p97 in an ATP-competitive manner. The selectivity of ML240 against 174 kinase ATP sites was assessed by measuring their ability to inhibit the binding of a reactive ATP acyl phosphate probe (Kinative assay, ActivX, San Diego, CA) (Fig. 8). Compound **26** inhibited labeling of only three of 170 kinase domains by greater than 50% when tested at 20 μM: PIP5K3, JAK1 JH2, and DNAPK.[16] ML240 was also assessed against 43 CNS relevant targets and found to be inactive at all except for 5HT5a with an affinity of 2.5 μM.

Despite being the most potent p97 inhibitor so far reported, **26** had low aqueous solubility (0.32 μg/mL) at pH 6.2 in aqueous PIONS buffer, high plasma protein binding in both human and mouse (>99.6% in a high throughput dialysis assay) and low stability in mouse hepatocytes (<1% remaining at 1 h). Together, these properties decreased the likelihood that it would be useful for establishing an in vivo proof of concept (POC) for a p97 inhibitor in mouse tumor models.

8.05.2 Discovery of CB-5083

8.05.2.1 Lead Development Efforts

8.05.2.1.1 Changes in p97 biochemical assay

As efforts got underway at Cleave Biosciences to discover more potent and drug-like p97 inhibitors a new version of the p97 biochemical ATPase assay was instituted. The new assay used a lower p97 protein concentration relative to the ATP concentration used in the earlier version of the assay.[17] These changes had two desirable effects: (1) use of less p97 protein per assay well and (2) increasing the dynamic range of the assay to allow differentiation of more potent inhibitors of p97. The changes in concentrations and IC_{50}s of DBeQ and ML240 are listed in Table 3. These changes in the assay allowed for the differentiation of more potent compounds.

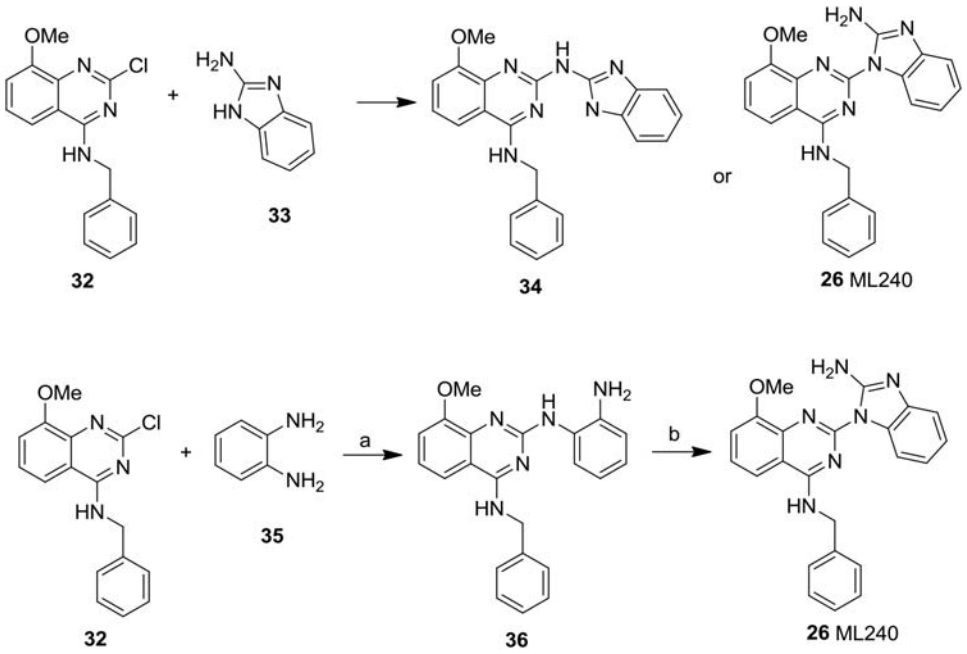
Anderson[17]	0.020	20	1,000	7.0	0.82

8.05.2.1.2 Alternative synthesis of ML240

Compound **26** was prepared by condensation of chloro-pyrimidine **32** with 2-aminobenzimidazole **33**. However, it was never unambiguously determined whether the coupling took place on the nitrogen of the imidazole or on the 2-amino group which would produce compound **34**. An alternative synthesis of **26** was carried out by condensation of chloropyrimidine **32** with 2,3-diaminopyrimidine **35** using Hartwig–Buchwald conditions, followed by condensation of **36** with cyanuric bromide and resulted in the unambiguous production of **26** validating the original structural assignment.[15,18]

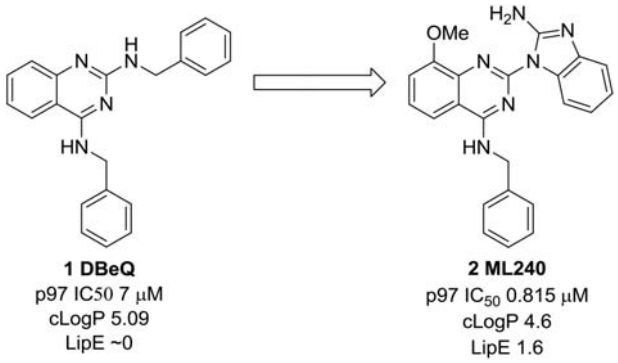


Reagents and conditions: (A). $Pd(OAc)_2$, BINAP, Cs_2CO_3, dioxane, 100°C; (B). BrCN, MeCN, H_2O, rt.

8.05.2.1.3 Guiding principles used in lead development of 26 (ML240)

Throughout the work leading to CB-5083, significant attention was paid to changes that led to both improvements in biochemical potency and improvements in physical properties. A guiding principle was to focus on those changes that resulted in increases in biochemical potency without disproportionately increasing calculated log P (cLogP). One way to quantify the contribution of lipophilicity to increases in target potency is the metric lipophilicity efficiency (LipE).[19] This is calculated by the equation $LipE = pIC_{50} - cLogP$. Analysis of the hit to lead work that produced ML240 determined that significant improvements in p97 biochemical potency could be achieved while simultaneously decreasing cLogP as evidenced by increased LipE (**Scheme 2**).

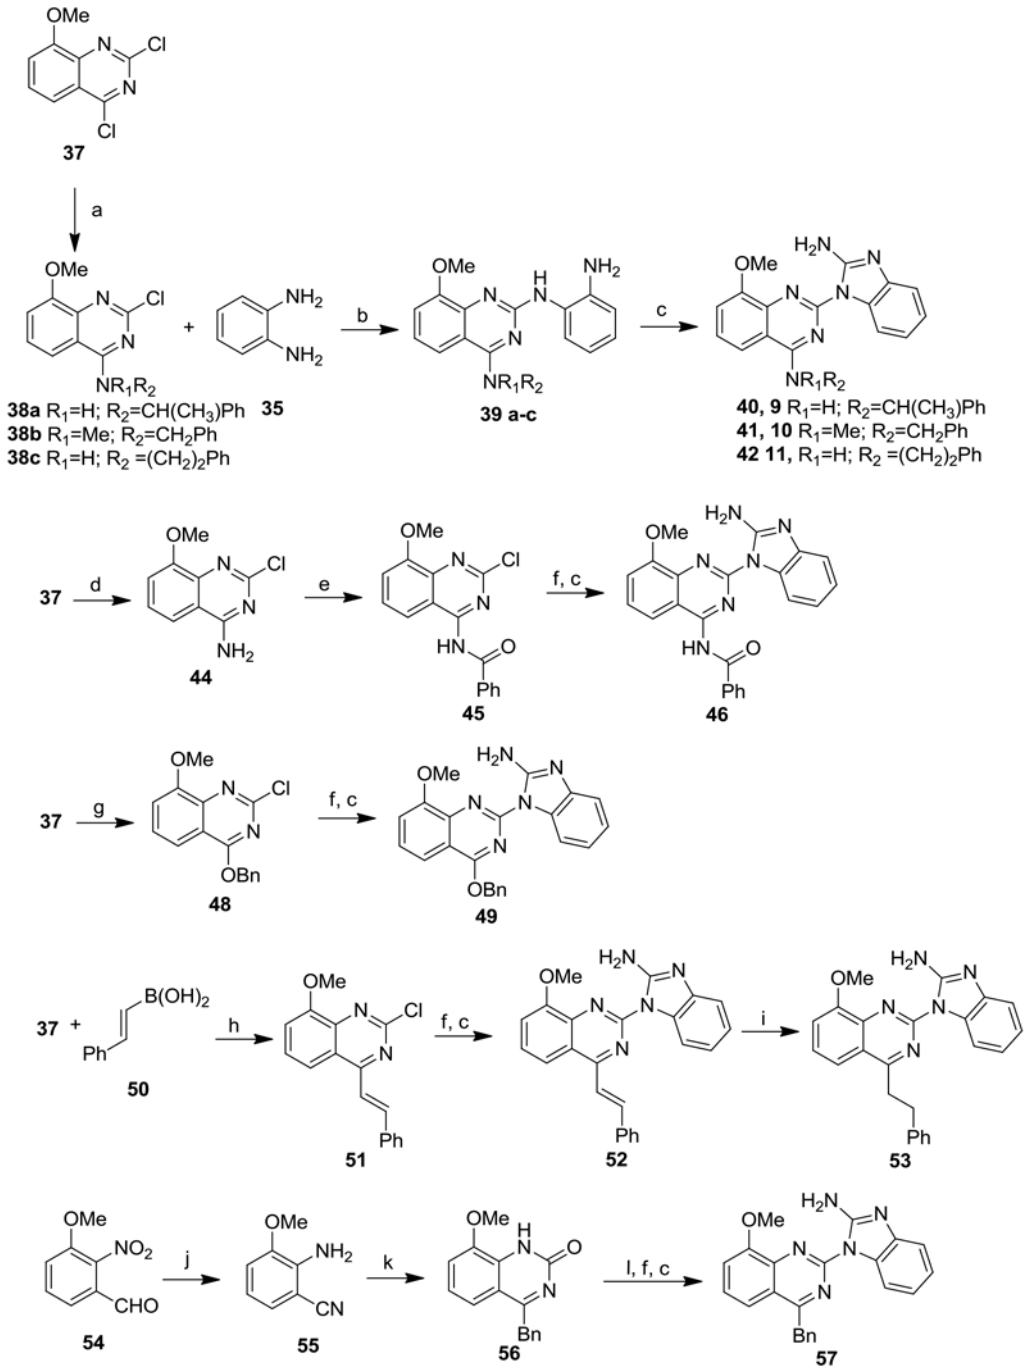
Since p97 is a highly expressed intracellular target it stands to reason that efficient cellular penetration of inhibitors is needed for good cellular activity. Control of polar surface area (PSA) would also play a role making p97 inhibitors with good cellular potency.



Scheme 2 Improvement in both potency and physical properties.

8.05.2.1.4 Investigation to changes of the N-benzyl substituent of ML240

Investigation of the importance of the 4-*N*-benzyl functionality found in ML240 was undertaken. A variety of synthetic methods were used to assess alternatives to this functionality (Scheme 3). Various amines were regioselectively added to the 4-position of the 2,4-dichloroquinazoline **37** producing the corresponding 4-amino-2-chloro quinazolines 38a-c which were converted in two steps to the target compounds **40**–**42**. Similarly the dichloroquinazoline **37** could be reacted with ammonia and the resulting 4-aminoquinazoline was acylated and converted to target **46**. Target **49** was prepared by substituting the benzyl alcohol anion for the amine. Coupling of compound **37** and boronic acid **50** resulted in **51** which was converted in three steps to target compound



Scheme 3 Generalized routes to synthesize ML240 *N*-benzyl analogs. 57	CH_2Ph	>5.0	4.6

53. Addition of the phenyl Grignard reagent to compound **53**, pyrimidine formation, and addition of the 2-amino-benzimidazole resulted in target compound **57**. All of the changes to the *N*-benzyl group resulted in complete loss of p97 inhibitory activity consistent with the earlier studies that this group was absolutely crucial for activity. Substitution on the aromatic ring also led to a loss in the binding activity. Taken together these findings discouraged further exploration in this region of the molecule and efforts were focused on other regions of the molecule (Table 4).

8.05.2.1.5 Benzimidazole analogs

The lack of toleration to changes to the 4-*N*-benzyl substituent shifted focus to the 2-benzimidazole functionality found in ML240. A systematic survey of simple changes to the 2-substituents on the benzimidazole, the necessity of the phenyl ring of the benzimidazole system, and the nature of the linkage to the 4-*N*-benzyl pyrimidine system was investigated.

The syntheses of these analogs are outlined in Schemes 4 and 5. Selective acylation at the 2-amino position of **58** (Scheme 4) and coupling resulted in compound **59**, the N-acylated version of **ML-240**. The *N*-monomethyl and *N*,*N*-dimethylated derivatives **60** and **61**, respectively could be prepared from key intermediate **36** as could the 2-hydroxy derivative **62** which also likely exists in solution as its tautomer, the 2-benzimidazolone. The cyclohexyl-imidazole analog was prepared in three steps from 2-chlorocyclohexanone **64** by condensation with acetyl-guanidine, condensation of the resulting *N*-acyl imidazole, and removal of the acetyl group resulted in the desired cyclohexyl imidazole analog **65**. The dimethyl-imidazole analog **68** was prepared in a similar way. Taking advantage of the known procedure to selectively prepare 1-*N*-BOC-benzimidazole allowed the preparation of compound **70** whose spectroscopic properties were distinct from **26** (ML-240) and consistent with the symmetry of the molecule.

The C-linked benzimidazole **74** could be prepared via the 2-bromomethyl-pyrimidine derivative **72** followed by coupling with the benzimidazole and installation of the 4-*N*-benzyl group. The two substituent analogs **76a** and **76b** could be simply prepared by coupling the readily available 2-substituted benzimidazoles with key intermediate **32** using palladium-catalyzed conditions.

Introduction of the acetyl group on the 2-position nitrogen of **26** led to a complete loss of potency, however introduction of one or two methyl groups to this nitrogen resulted in compounds **60** and **61** with somewhat improved potency, albeit with increases in cLogP over 5. This was a direction that was not further explored. However it was found that introduction of a replacement of the 2-amino functionality of the benzimidazole with a hydroxyl group (compound **62**) led to a loss in potency. Presence of only a hydrogen at the two position of the benzimidazole led to a complete loss of activity. However introduction of a methyl substituent (compound **76a**) or methoxy substituent (compound **76d**) led to compounds with p97 biochemical IC_{50}s under 200 nM while maintaining or somewhat increasing LipE compared to **26**. Interestingly the 2-ethyl-substituted benzimidazole derivative **76c** was completely inactive. Replacement of the phenyl ring of the benzimidazole of **26** with either a cyclohexyl ring as in compound **65** or 4,5-dimethyl substituents (compound **68**) resulted in a complete loss of activity as did connecting to the pyrimidine ring through the 2-nitrogen of the benzimidazole (compound **70**) or a C-linkage to the 1-nitrogen of the benzimidazole (compound **74**) (Table 5).

8.05.2.1.6 Exploration of other fused pyrimidine cores

In parallel with attempts to improve potency through manipulation of the substituent at the 2-position of the benzimidazole, efforts were underway to explore pyrimidine cores with reduced lipophilicity and/or aromaticity. Introduction of additional polar functionality through the 8-alkoxy substituent of the quinazoline ring and replacement of the phenyl ring of the quinazoline with heterocyclic or saturated carbocyclic functionality on the quinazoline ring were studied. A variety of these alternative fused 4-*N*-benzyl-2-chloro pyrimidines were prepared as outlined in Scheme 6. These intermediates were used to prepare final

compounds with P2 benzimidazole substituents having either amino, methyl, or methoxy at the 2-position of the benzimidazole ring system by methods outlined previously.

An attempt was made to decrease lipophilicity by introducing polar functionality to the 8-alkoxy substituent on the pyrimidine ring. Removal of the methyl group from compound **32** followed by introduction of methoxy-ethyl functionality gave intermediate **78**. The pyrimidine diols **79a**[20] and **79b**[21] were converted to their respective dichlorides which were converted

Notes: All experiments to determine IC_{50} values were run with at least duplicates at each compound dilution and all IC_{50} values were averaged when determined in two or more independent experiments.

to their respective 4-*N*-benzyl-2-chloro derivatives **80a** and **80b**. The cyclohexanone carboxylate **81** was used to readily prepare the tetrahydroquinazoline **82**, which was selectively converted to compound **83**.

The *N*-benzyl-4-pyridinone **84** was readily converted to the pyrimidine dichloride **85**. To avoid the problem of selectively removing the *N*-benzyl group of the fused piperidine nitrogen at the end of the sequence in the presence of the *N*-benzyl group at the 4-position of the pyrimidine, a protecting group switch was implemented on **85**. Reaction of **85** with acetyl chloride effected removal of the *N*-benzyl group which was quickly replaced with the Boc protecting group giving compound **86** which was converted to the 4-*N*-benzyl-2-chloropyrimidine **87**. The 2-chloropyrimidine derivatives were converted to the 2-benzimidazole-pyrimidine target compounds **88–98** using the methodology previously described.

A variety of pyrimidinyl-benzimidazoles with small substituents in the 2-position of the benzimidazole were evaluated (Table 6). The introduction of the methoxy-ethoxy group at the 8-position of the quinazoline ring system (compounds **88–90**) led to decreases in potency for all 2-benzimidazole substituents that were assessed. Replacement of the 8-methoxy-phenyl ring of the quinazoline of ML240 resulted in a significant decrease in potency. Replacement of the phenyl ring of the quinazoline with a thiophene resulted in compound **91** with a significant decrease in potency, whereas replacement with a thiazole ring system resulted in compound **92** with only slightly decreased potency and a cLogP of 4.5 one of the lowest so far calculated. However replacement of the methoxy-substituted phenyl ring with a fused cyclohexyl ring resulted in our first compounds with potency below 100 nM. Compound **94** with a 2-methyl-benzimidazolyl or compound **95** with a 2-methoxybenzimidazolyl substituent in the two position of the tetrahydroquinazoline had p97 IC_{50}s of 98 and 76 nM, respectively. Introduction of a nitrogen atom into the saturated ring resulted in significant losses of potency across compounds **96–98**. Twenty percent to fifty percent improvements in LipE values were observed for some compounds. Although compound **92** was somewhat less potent than **26**, reductions in

Notes: All experiments to determine IC_{50} values were run with at least duplicates at each compound dilution and all IC_{50} values were averaged when determined in two or more independent experiments.

CLogP led to increased LipE values. While this was a promising trend it was also recognized that **92** had five aromatic rings. It has been noted that increased numbers of aromatic rings correlate with decreased solubility.[22] For this reason focus shifted to compounds **93–98** having a nonaromatic ring fused to the pyrimidine core. The tetrahydropyrimidines **94** and **95** represented the first compounds under 100 nM in the p97 biochemical assay. Although these compounds suffered from modest increases in cLogP, they also had somewhat increased LipE values. Compound **98** having a piperidine ring fused to the pyrimidine ring resulted in a compound with reduced potency but also significantly reduced cLogP which also led to a modest increase in LipE. Compound **95** was the first compound we had made that had a p97 inhibitory potency significantly under 100 nM and so was selected for more detailed study.

8.05.2.1.7 Evidence of p97 inhibition in cellular assays and in vivo

Expected consequences of p97 inhibition would be a buildup of polyubiquitinated proteins as they are not chaperoned by p97 to the 26S proteasome and hence they are not degraded. In addition the buildup of mis-folded proteins in the ER causes accumulation of C/EBP homologous protein (CHOP), a protein associated with activation of the UPR. Immunofluorescence assays were developed to look for changes to intracellular levels of both of these proteins.[17] Treatment of cells with compound **95** resulted in a dose-dependent increase in both of these cellular markers of p97 inhibition (Fig. 6).

Poly-UB and CHOP accumulation occurred after treatment of A549 tumor cells with varying concentration of compound **95**. These elevations occurred at similar concentration which led to cell death at 72 h (IC_{50} 3.9 μM) suggesting that this mechanism was the route of cellular toxicity. The dose–response curve for CHOP was shifted to the right compared to the 6 h accumulation numbers for poly-UB. This is consistent with the fact that CHOP accumulation occurs as a consequence of poly-ubiquitinated proteins accumulating in the ER. After oral administration (300 mg/kg) to mice bearing A549 tumors increases in poly-UB in tumor lysates were observed by a western blot assay (Fig. 7A). Repeated treatment with compound **95** (300 mg/kg) over 32 days caused a 79% inhibition in tumor growth similar to that caused by the maximum tolerated dose regimen of taxol (Fig. 7B).

The specificity of the interaction of compound **95** with the D2 ATPase site of p97 was assessed using an ATP probe which was attached to a biotin label (ActivX, San Diego, CA) (ref). The probe irreversibly labels lysines in the ATP binding sites found in kinases and ATPases. After trypsin digestion of a lysate from A549 cells the peptide fragments were passed through a streptavidin column to capture those peptide fragments from the ATP sites labeled with biotin. The abundance of the labeled versus unlabeled sites was quantified by mass spectral detection (Fig. 8). Labeling of the proteins existing in the cellular lysates of A549 tumor cells in the presence or absence of **95** was assessed by measuring the abundance of labeled peptide signals after tryptic digest and purification. Compound **95** selectively inhibited labeling at the D2 site of p97 by 65% but did not prevent the labeling of any other ATPase sites from >130 different ATPases including the p97 D1 site. This specific interaction with the D2 domain of p97 is consistent with its ability to inhibit the ATPase activity of p97 since the D2 region has been shown to be primarily responsible for the ATPase activity of p97.

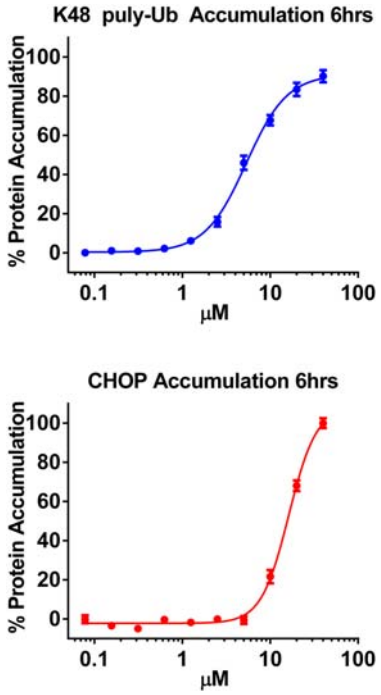

Fig. 6 Accumulation of Poly-Ub and CHOP caused by compound **95**.

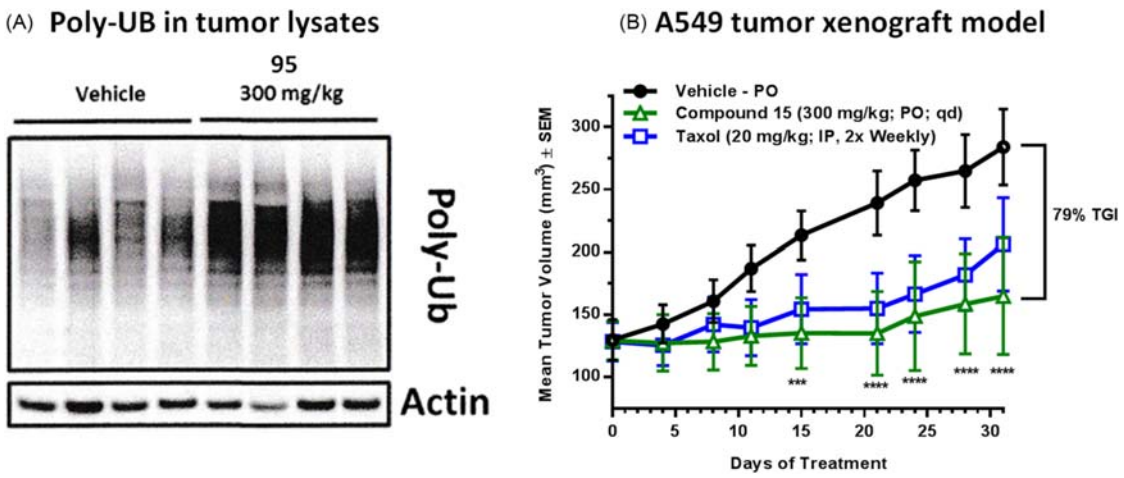

Fig. 7 In vivo effects of compound **95** (A) Poly-UB in tumor lysates (B) A549 tumor xenograft model.

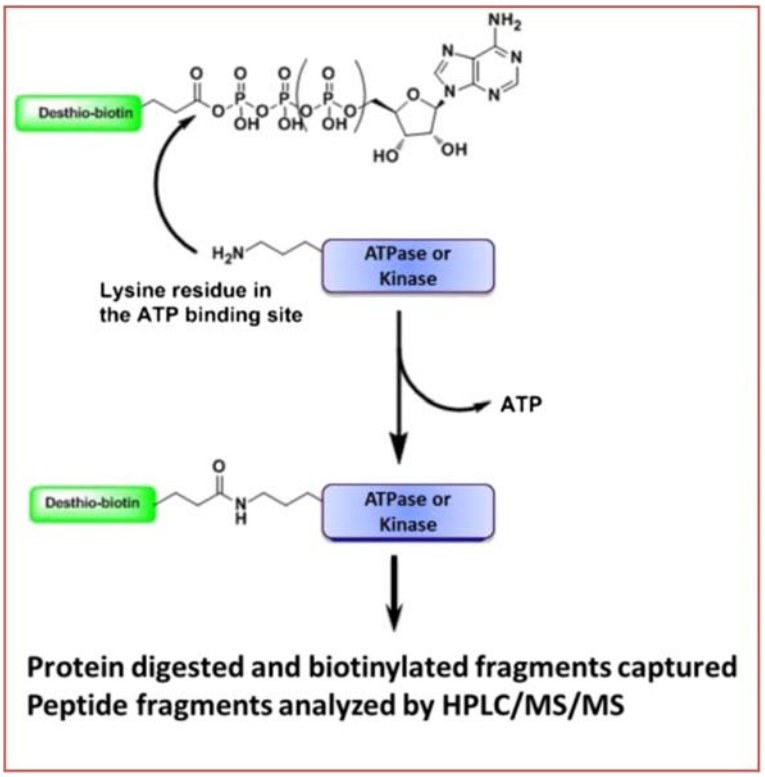

Fig. 8 Mechanism of ATP site labeling and detection.

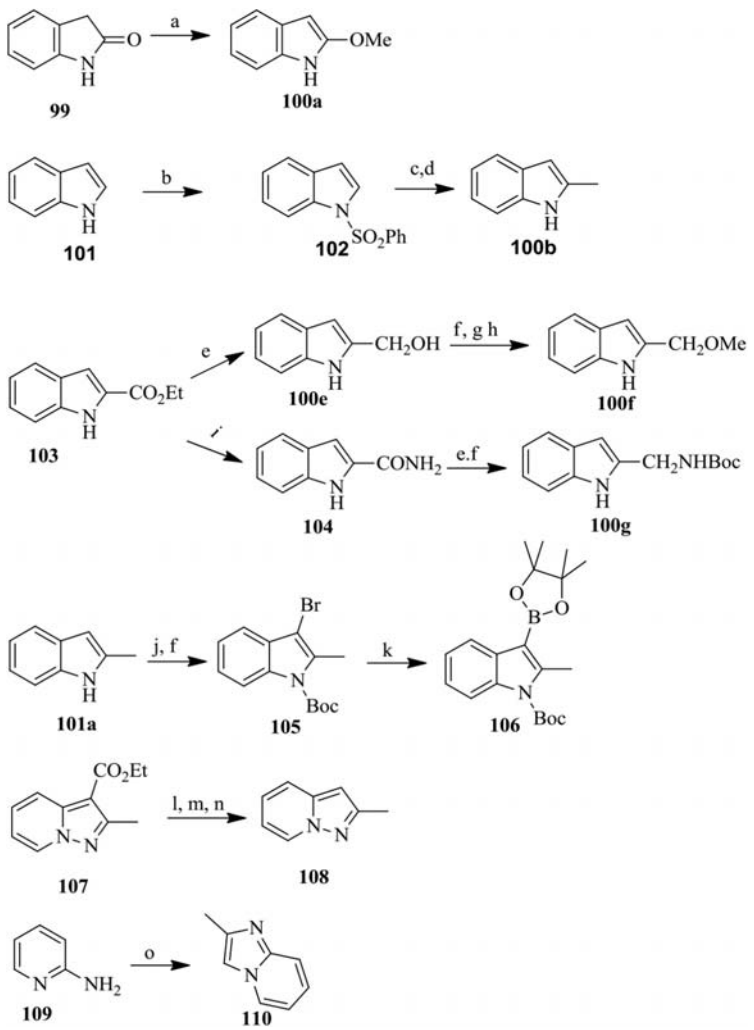
Together these studies demonstrated that blockade of p97 ATPase activity at the D2 site could cause significant increases in poly-ubiquitinated proteins and markers of ERAD induction and prevent tumor growth increases at a tolerable dose in mice. The data provided to our knowledge the first in vivo validation of the p97 D2 site as a potentially druggable anticancer target. While compound **95** provided the first in vivo POC for p97 it was also realized that additional improvements in potency would be needed in order to produce a viable drug candidate.

8.05.2.2 Candidate Seeking Efforts

Next attention was turned to constructing molecules that replaced the benzimidazole with other 5–6 heterocyclic systems attached to saturated fused pyrimidine cores. A variety of 2-substituted 5,6 ring heterocycles that could be obtained commercially or be prepared as in Scheme 7 were assessed.



Scheme 7 Synthesis of 2-substituted 5,6 heterocyclic systems. Reagents and conditions: (a) $PhSO_2Cl$, NaH, THF; (b) n-BuLi, MeI, THF, −40°C; (c) NaOH; H_2O, EtOH, 40°C; (d) Me_3OBF_4, $CHCl_3$, rt; (e) $LiAlH_4$, THF, 0°C; (f) $(Boc)_2O$, DAMP, TEA, DCM, rt; (g) MeI, NaH, THF, 0°C; (h) TFA, DCM, 0°C; (i) NH_3, THF, rt; (j) Br_2, DMF; (k) 2-isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane, *n*-BuLi, THF, −78°C; (l) NaOH, MeOH, H_2O, reflux; (m) NBS, $NaHCO_3$, DMF, 0°C; (n) *n*-BuLi, THF, −78°C; (o) $MeCOCH_2Br$, EtOH, dioxane.

Methylation of the oxindole **99** by trimethyl tetrafluoroborate gave the 2-methoxy indole **100a**. Lithiation of the sulfonamide-indole **102** with *n*-butyl lithium occurred at the two position of the indole to ultimately produce 2-methylindole **101a** after removal of the sulfonamide group. Reduction of ester **103** to 2-hydroxymethyl indole **100c** and methylation of this compound gave 2-methoxymethyl indole **100f**. Conversion of ester **103** to the amide followed by reduction and Boc protection resulted in **100g**. To facilitate coupling at the indole at the three position the 2-methyl, 3-boronate protected indole **106** was prepared by bromination of indole **101a** followed by protection to give **105**. Halogen lithium exchange was affected by *n*-butyl-Li and the anion at the three position of the indole was quenched with the diborolane ester which gave the 3-indolyl boronate ester **106**. The known ester **107** was converted to bromide which was lithiated and then protonated to give the 2-methyl imidazopyridine **108**. 2-Amino-pyridine (**109**) was condensed with bromoacetone to produce the methyl-imidazopyridine **110**.

The indole **100** could be efficiently coupled to chloropyrimidine **83** via Pd-mediated Hartwig–Buchwald-type coupling. It was necessary to use cesium carbonate as the base for efficient coupling. Suzuki coupling between chloropyrimidine **83** and the 3-indolyl boronate ester **106** gave compound **119**. Palladium-catalyzed Heck-type coupling of **108** and **110** with **83** gave target compounds **120** and **121**. Condensation of the protected dihydropyridine fuses pyrimidine **87** with 2-methyl indole (**100b**) followed by deprotection to give target compound **122**.

Replacement of the indole analog **112** where the 3-nitrogen of compound **95** was replaced with a CH resulted in a twofold improvement in p97 inhibitor potency. Not surprisingly this compound suffered from acid instability due to the enolic nature of the methyl ether. Subsequently it was found that an indole having methyl group in this position as in compound **113** imparted similar potency. Compound **113** had similar LipE suggesting that the increase in potency was largely due to increased lipophilicity. Further elaboration of these two positions of the indole did not lead to further improvement in potency or physical properties

(compounds **114–118**). Investigation of alternative 5,6-heterocyclic cores (compounds **119–121**) resulted in compounds having reduced potency. To explore the effect of the introduction of a heteroatom into the saturated ring of the fused pyrimidine the tetrahydro-pyridine **122** was prepared. Although this compound had reduced potency compared to the tetrahydro-quinazoline **113** it also had significantly decreased cLogP resulting in an increase in LipE. This compound also had the best mouse bioavailability properties so far seen ($F = 44\%$). Because of this a more detailed investigation of substitution on the six-membered ring of the indole was undertaken (**Table 7**).

The target compounds in **Table 8** were prepared by condensation of the substituted indoles with fused pyrimidine **87** as previously described. Attempts to couple seven-substituted indoles using the Buchwald-type conditions were unsuccessful likely due to steric issues. As shown in **Table 8** substituents at the 5 or 6 position of the indole nucleus resulted in an almost complete loss of activity. However substituents at the 4 position were better tolerated with the 4-cyano substituted indole derivative **134** having slightly better potency compared to the unsubstituted derivative **122**. Although with a slightly lower cLogP the 4-nitrile imparted a slightly higher cLogP relative to the unsubstituted compound and thus compound **134** also enjoyed a slightly higher LipE value (3.3 vs. 2.9) compared to **122**. Given that the 4-halogen-substituted analogs **131** and **132** were tolerated but had decreased potency and that the trifluoromethyl analog **133** had decreased potency, we hypothesized that the increased potency of **134** was due to the carbonyl-like nature of the nitrile rather than solely to its electron withdrawing effect. To further explore this possibility the nitrile in the 4 position of the indole of **134** was replaced with a carboxylic acid giving **135** which had both increased potency and decreased lipophilicity giving an LipE of 6.6. However unlike compound **134**, which had modest activity in the cell titer glow viability assay, compound **135** as well as the 4-tetrazole isostere **136** were completely inactive in the cellular assay. A possible explanation for this is that the zwitterionic nature of **135** and **136** inhibited efficient cellular penetration preventing activity. However when an amide was placed in the 4 position of the indole (compound **137**) both biochemical and cellular potency were significantly increased and a good LipE was achieved. However substitution of the amide nitrogen (compounds **138**, **139**, and **140**) resulted in significant decreases in biochemical and cellular potency. Based on the good profile of the 4-amido-2-methyl indole analog **137**, investigation of this P2 substituent on a variety of other fused pyrimidine cores was undertaken.

Additional fused pyrimidine cores with nitrogen and oxygen in alternative positions of the ring fused to the pyrimidine were prepared as shown in **Scheme 8**. Reaction of *N*-benzyl pyrimidinone ester **141** with urea under basic conditions resulted in pyrimidine diol **142**. Chlorination and removal of the benzyl protecting group resulted in **143**. Protection of the basic amino group with the BOC group and selective addition of the methyl phenyl group to the four position of the pyrimidine gave compound **144**. Attempts to make tetrahydropyrano pyrimidines were complicated by the fact that the pyran would not survive the forcing conditions used to form the pyrimidine diol. In a milder two-step procedure vinylogous carbamates **146** were formed and treated with trichloro acetyl isocyanate, and cyclization with ammonia in methanol resulted in pyrimidine diols **147**. Chlorination and installation of the aminomethyl phenyl functionality produced the pyrano pyrimidines **148** (**Scheme 9**).

Attempted coupling of 4-amido-2-methylindole with chloropyrimidines resulted in a mixture of products from coupling through both the amide and indole nitrogens. As shown in **Scheme 10**, target compounds **149–153** could more efficiently be prepared by first coupling 4-cyano-2-methylindole with the fused 2-chloropyrimidines followed by conversion of the cyano functionality to the amide. In the case of piperidino-pyrimidines the Boc protecting group was removed before conversion of the nitrile

to the amine. The regiochemical assignment of the *N*-benzyl and indole positions at the 4 and 2 position of the pyrimidine was confirmed by X-ray crystallography of the dihydrate of compound **152** (Fig. 9).

Of the 4-amido-2-methylindole analogs prepared, the tetrahydroquinazoline analog **149** had the greatest inhibitory potency (IC_{50} of 6 nM) against the ATPase activity of p97. However this compound had an increased cLogP resulting in a reduced LipE relative to the piperidino analog **137**. Likely because of its improved biochemical potency compound **149** was the first compound we observed that had activity against A549 cancer cells in the submicromolar range. The 7-aza-fused piperidine analog **151** was weaker than the 6-aza analog **137** in both the biochemical and cellular assays. The 6-oxo-pyrano-pyrimidine analog **152** had good

biochemical potency and had submicromolar IC_{50} in the cellular assay. Its combination of good in vitro potency and reduced cLogP resulted in the highest lipE (5.2) observed in this effort. Compound **152** showed both greater biochemical and cellular potency than the 7-oxo analog **153** with compound **152** showing similar submicromolar cellular potency to **149** (Table 9).

The pharmaceutical properties of the two most potent p97 inhibitors **149** and **152** are compared in Table 10. Both compounds exhibited good solubility in acidic aqueous media (pH 2 as found in the stomach) while compound **152** is somewhat more soluble at the slightly higher pH as found in the lower intestinal tract where most drug absorption occurs. Both compounds showed good Caco2 intestinal cell permeability with favorable AB/BA asymmetry suggesting good absorption after oral dosing with little likelihood of the inhibition of uptake from the intestine by efflux transporters. Both compounds showed reasonable stability in mouse liver microsomes.

With these favorable in vitro ADME characteristics both compounds were taken into in vivo PK/PD studies. Both compounds were administered orally as a suspension in 0.5% methylcellulose at a dose of 150 mg/kg; plasma and tumor samples at multiple time points (2, 6, 16, and 24 h) were harvested for PK/PD analysis (Fig. 10). **152** had an approximately twofold higher exposure in both plasma and tumor compared to **149**. Compound **152** also achieved a more sustained PD effect of polyubiquitin accumulation in tumor, especially at later time points. Anti-tumor activity of the two compounds was assessed in an HCT116 tumor xenograft model at their maximum tolerated doses and schedules. Oral administration of **152** was administered every day (qd), whereas **149** was administered every other day (q2d). Both **152** and **149** showed anti-tumor activity in this study (Fig. 11).

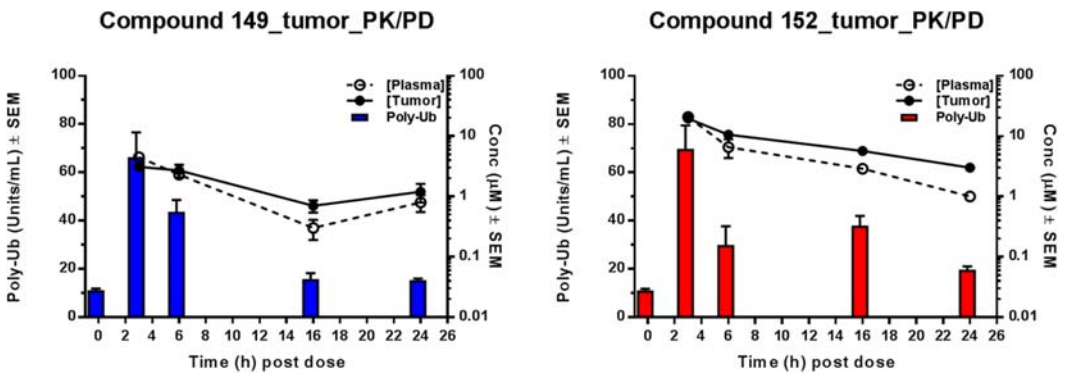

Fig. 10 PK/PD comparison of **149** and **152**.

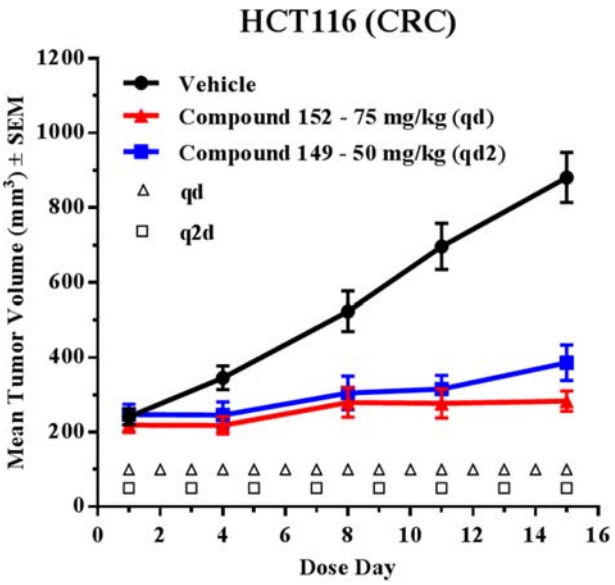

Fig. 11 Comparison of maximum tolerated doses of compounds **149** and **152** in a tumor xenograft study.

Selectivity of **152** for other ATPase and kinase sites was assessed using the irreversible ATP probe as shown in Fig. 8.[16] Compound **152** inhibited 97% of probe binding to the D2 ATPase region of p97 in cellular lysates of A549 tumor cells while not interacting with the D1 ATPase region or the ATPase region of over 135 other ATPase sites. In addition **152** was assessed against 387 kinases (Proqinase Screen) at 5 μM concentration. Only three kinases had >50% inhibition at this concentration and only DNAPK had significant activity at concentrations under 1 μM (IC_{50} 0.519 μM).No DNAPK cellular effects were observed. In addition **152** had no significant interactions with 77 GPCRs and ion channels.

Based on its good biochemical selectivity, as well as its PK and tolerability profile compound **152** (CB-5083) was selected for further preclinical development and is currently being evaluated in clinical trials.

8.05.3 Further Evaluations of CB-5083 and Analogs

8.05.3.1 LipE and Cell Penetration

An important part of the optimization process leading to the discovery of **CB-5083** was improvement in cellular potency. As shown in Fig. 12 in the early part of the program p97 biochemical potency increased and there was a general trend to increased cellular potency. However as the biochemical potency increased beyond 30 nM there was a less pronounced increase in cellular potency with increasing biochemical potency. Previously we had hypothesized that poor cellular permeability owing to the zwitterionic nature of biochemically potent analogs **135** and **136** was responsible for their lack of cellular activity. This led us to explore the relationship between LipE and cellular potency.

The LipE metric allowed plotting of a value derived from a combination of biochemical potency and cLogP against cellular potency. In Fig. 13 the pEC_{50} of A549 cell viability against LipE of p97 analogs under 30 nM is plotted. This reveals a parabolic relationship wherein all of the most potent analogs ($pEC_{50}>6$) were concentrated in the LipE range between approximately 4 and 5.5. Those analogs having a LipE value less than 4 and having a higher cLogP relative to their biochemical potency were challenged to exhibit good cellular potency because of poorer solubility in cellular media. Alternatively for compounds with LipE values greater than 5.5 all had cLogP values below 2.5. This greater polarity likely inhibited good cellular penetration required to achieve intracellular compound levels sufficient to effectively inhibit abundant p97 protein. Many of the compounds with lower cellular potency having LipE between 4 and 5.5 had PSA's ≥ 110 A^2 which also likely would inhibit there efficient penetration into the cell.

8.05.4 Summary of p97 Inhibitors Reported From Competitors' Efforts

8.05.4.1 2-(Cyclohexylmethylamino)pyrimidines

The alkylsulfanylpyrimidine **154** was discovered through a mass screening effort at Nerviano pharmaceuticals, and a medicinal chemistry program was set up to identify the key structural features responsible for activity and to improve the biological profile of this class of compounds.[23] Extensive SAR studies produced the amide **155** with improved p97 biochemical potency. However

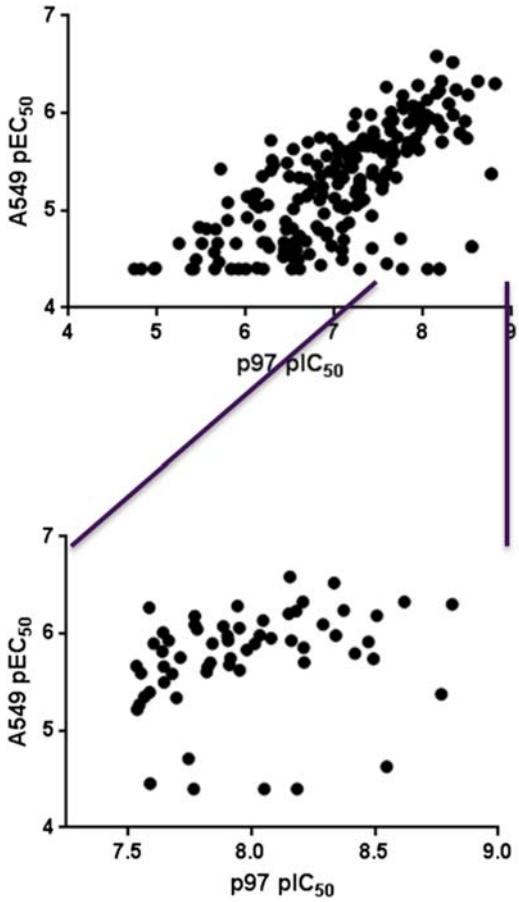

Fig. 12 Correlation of biochemical and cellular potency.

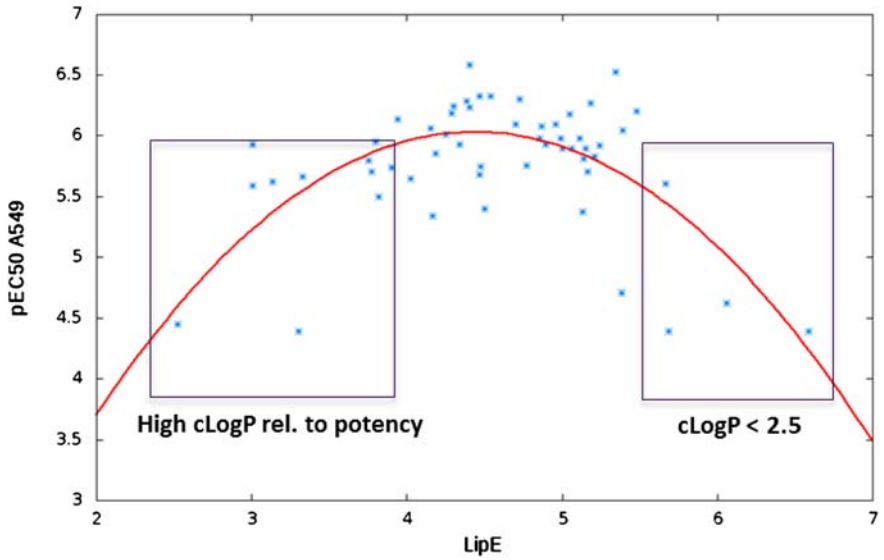

Fig. 13 Correlation of LipE with A549 pEC_{50}.

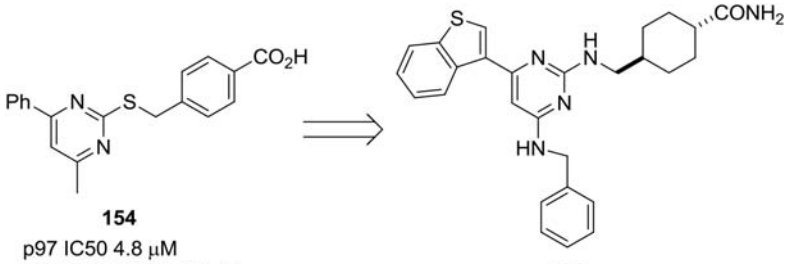
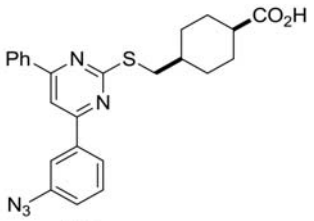
compound **155** had only modest potency in an HCT116 cellular assay but did show evidence of p97 inhibition in these cells through increases in poly-UB and CHOP protein biomarkers.



154
p97 IC50 4.8 μM
HCT-116 IC50 > 20 μM

155
p97 IC50 0.074μM
HCT-116 IC50 5.4 μM

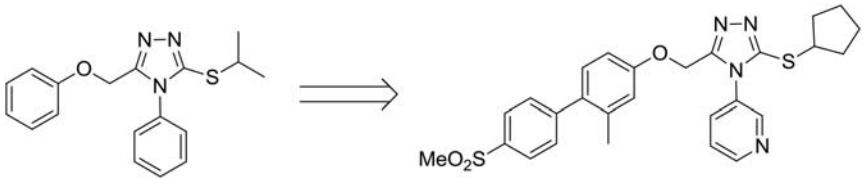


156
p97 IC50 0.879 μM

As part of these efforts compound **156** was prepared as a photoaffinity label. It was found to label Asp479 which is near the D2 site of p97 consistent with the competitive nature of these inhibitors.

8.05.4.2 Alkylsulfanyl Triazoles

A group at Nerviano and Genentech used HTS of over 1 million compounds to identify the 1,2,4-alkylsulfanyl 1,2,4-triazole **157**.[24] It was able to inhibit p97 ATPase activity with an IC_{50} of 2.69 μM but was devoid of antiproliferative effects up to a concentration of 20 μM. The biochemical potency was unaffected by altering ATP concentration in assay conditions suggesting a mechanism of noncompetitive inhibition with respect to this substrate. Moreover, serial dilution experiments and mass spectrometric analysis of p97 upon incubation with a molar excess of the inhibitor indicated that it possesses reversible binding properties.



157 **158**

A comprehensive investigation of the SAR of this series led to the discovery of **158** with improved biochemical potency and submicromolar cellular potency (p97 IC_{50} 0.024 μM; HCT-116 IC_{50} 0.38 μM).

Compound **158** (NMS-873) was shown to be selective against a handful of other AAA ATPases (NSF, SPATA5, VPS4B, and cdc6), HSP90, as well as a panel of 50 kinases. No activity was detected at concentrations up to 10 μM. Like the original lead **157** the potency of p97 inhibition by compound **158** was not affected by increased ATP concentration. The compound was shown to be rapidly cleared by human liver microsomes (Cl_{int} = 422 mL/min/kg) and showed only modest exposure and bioavailbility after oral dosing in mice. Perhaps this explains why no in vivo activity has been reported with this compound (**Table 11**).

It has been hypothesized that noncompetitive or allosteric inhibitors of p97 would be advantageous because they would be less affected by the high intracellular concentration of ATP. However a comparison of biochemcial and cellular potency between the competitive inhibitor compound **152** and the allosteric inhibitor **158** suggests this may not be the case. In both cases there is an approximate fivefold shift between biochemical potency and cell viability for both compounds and similar shifts for the CHOP and Poly-UB markers of activity. These results do not suggest an advantage for the allosteric modulator over the competitive inhibitor in terms of activity under cellular conditions.

158[24]	Allosteric at D1/D2	0.055	3.3	2.68	4.69	1.86

8.05.4.3 Compounds Discovered by U. Pittsburgh/UCSF Collaboration

A collaboration led by groups at the University of Pittsburgh and the University of California, San Francisco has recently reported the discovery of two other series of p97 inhibitors.

8.05.4.3.1 5-N-(3-(1H-indol-2yl)-phenyl-piperidines

The 5-trifluoromethyl indole derivative **159** was identified as a p97 inhibitor with modest potency.[25] A number of analogs were prepared to invesitgate the effect of changes to the 5-position substituent on the indole. The most potent analog in a p97 biochemical assay was a 5-nitro compound **160**. Interestingly the authors found that the pentafluorosulfanyl group (compound **164**) was not a good replacement for the trifluoromethyl group found in the original lead. Somewhat surprisingly the trifluoromethoxy group (compound **163**) was found to be a superior replacement for the trifluoromethyl group. No cellular activity is reported for these compounds. Recently a cryo-electron microscopy derived image of the 5-fluoro derivative **165** bound between the D1 and D2 ATPase regions in p97 has been published.[5] This structure may be useful for further optimization of this series (Table 12).

8.05.4.3.2 N-5-indolyl-carboxamides

The indolyl-pyrazine carboxamide **166** was discovered in the same mass screen as the previous series.[26] A small series of analogs was prepared as shown in Table 13. The most potent of these was the pyridine carboxamide **166**. Other changes to the aminopyrizine core or the 2-indolyl substituent led to a loss of potency. Compound **166** appears to be an allosteric modulator as its potency appears to increase with higher ATP concentrations.

8.05.5 Summary and Future Directions

Several lines of evidence point to the AAA+ ATPase, p97, as a potenitally interesting target for the development of novel anticancer therapies. Mass screening of an NIH compound library against p97 ATPase activity and subsequent hit triage identified DeBQ (**1**) as the most promising hit from this effort. Subsequent hit to lead efforts identified **26** (ML240) as a compound with submicromolar potency. Further lead development and candidate seeking efforts identified **152** (CB-5083) as a first-in-class potent and selective

cLogP 2.7
LipE 5.2

Potency and LipE were also shown to play a role in determining cellular potency likely by influencing target affinity and cell permeability. Other efforts have resulted in the discovery of an additional series of competitive inhibitors (i.e., **155**) and a related photoaffinity label suggested a binding mode for these compounds. Three series of allosteric modulators have also been explored (i.e., **158** (NMS-873), **165**, and **167**). An image of **165** bound to p97 derived using cryo-EM techniques produced a structure that may be useful for further optimization of this series of allosteric modulators.

Most of the efforts to optimize p97 inhibitors so far published have measured ATPase inhibiton of the protein in the absense of cofactor proteins that are known to play a key role in mediating the translocation of various substrates. Recently Chou and coworkers have demonstrated that the ATPase inhibitory potency is differentially affected by various p97 cofactor proteins.[27] Since these cofactor proteins influence the substrates affected by the mechanical activity of p97, identifying compounds that can selectively inhibit specific p97-cofactor complexes could be an important new direction in the search for p97 inhibitors with differential cellular and therapeutic effects.

Acknowledgments

The authors would like to acknowledge Ronan LeMoine for leading the in vivo pharmacology efforts and providing the reported xengraft and PK/PD data. We would also like to acknowledge Ray Deshaies for his leadership in the p97 field as well as helpful discussions and Laura Shawver for her helpful comments on this manuscript.

8.06.1 Introduction

The receptor tyrosine kinase mesenchymal epithelial transition factor (MET) and its endogenous ligand, hepatocyte growth factor (HGF), are implicated in cellular processes relevant to cancer such as cell proliferation, survival, motility, migration, and invasion.[1] Amplification of the MET gene, overexpression of MET, activating mutations, and cross-talk are some of the mechanisms of deregulation that have been found in human cancers.[2] The strong association between the amplification of signaling via the MET/HGF pathway in some human cancers makes it an ideal target for the development of corrective therapeutics targeting both its growth factor, HGF, and the kinase activity of the MET receptor.[3]

Several monoclonal antibodies directed against HGF are currently at different stages of clinical development.[4] Although anti-HGF monoclonal antibodies have been shown to reduce tumor burden in animal models and in early clinical trials, their use will likely be limited to HGF-driven cancers. Ligand-independent activation of the MET/HGF pathway represents another important mechanism of tumorigenesis; therefore, direct inhibition of MET kinase activity should provide a more general approach, addressing both ligand-dependent and ligand-independent MET deregulation.[5] Toward this objective, several small molecule inhibitors of the MET receptor kinase with different binding modes (classes Ia, Ib, II, and other) have been described and have progressed to the clinic.[6] This chapter will outline our contribution to the discovery and the preclinical development of a best-in-class MET kinase inhibitor, **AMG 337** (Fig. 1).[7]

8.06.2 Discussion

The first effort toward the discovery of an MET receptor kinase inhibitor at Amgen resulted in the evaluation of **AMG 458** (Fig. 1) as a potential development candidate.[8] **AMG 458** is representative of a class II-type kinase inhibitor, which adopts an extended conformation, projecting past the gatekeeper residue into a distal hydrophobic pocket.[9] Although this compound displayed good enzymatic inhibition, it was only marginally selective[10] over off-target kinases,[11] confounding the evaluation of its pharmacological activities (Fig. 2). Furthermore, it exhibited a pronounced loss of potency when evaluated in a cellular assay that measured

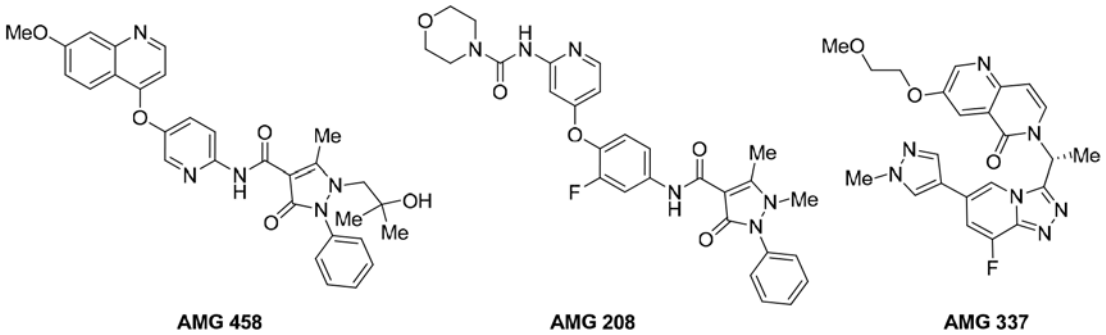

Fig. 1 Class Ib and II MET inhibitors nominated as clinical candidates by Amgen.

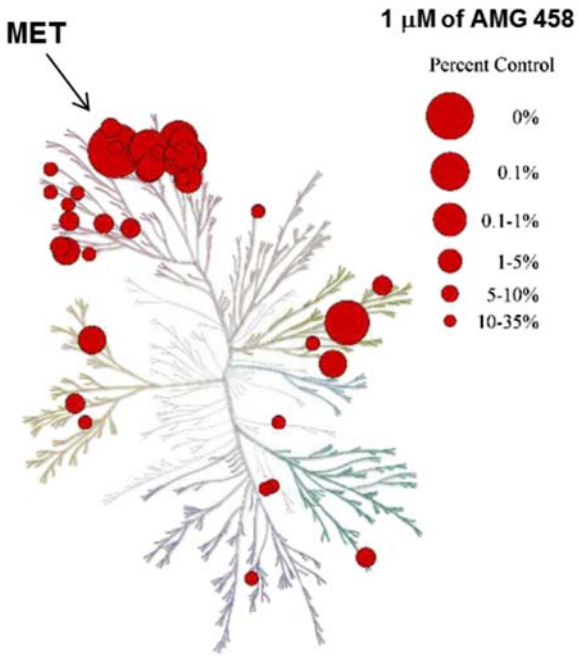

Fig. 2 KINOMEscan of **AMG 458**.

inhibition of MET autophosphorylation (Table 1). **AMG 458** achieved good oral exposure and displayed moderate unbound clearance in rodent, resulting in >50% target inhibition (HGF-induced phosphorylation of MET in mouse liver) for up to 12 h at a single oral dose of 30 mg/kg (Table 1). Ultimately, **AMG 458** was evaluated in a MET-dependent xenograft model, the NIH-3 T3/TPR-Met model derived from NIH3T3 cells transfected with human TPR-Met, an oncogenic form of MET.[12] When administered orally q.d. or b.i.d., **AMG 458** induced dose-dependent tumor growth inhibition with approximate ED_{50} of 12 mg/kg and an ED_{90} of 34 mg/kg. Unfortunately, preclinical analysis of the metabolic fate of **AMG 458** identified the formation of methoxyquinoline thioether glutathione adducts in vitro and in vivo, which halted its further development.[13]

In an attempt to mitigate the concerning metabolic fate of **AMG 458** and improve its overall properties the hinge binder moiety was targeted first. This effort led to the identification of **AMG 208** (Fig. 1), another class II MET inhibitor that progressed into Phase I clinical trials.[14] Although **AMG 208** exhibited evidence of antitumor activity in humans with manageable toxicity,[15] the identification of more potent and selective[16] inhibitors was desirable to fully harness the potential of MET inhibition.

This objective, coupled with a report from Sugen Inc. in 2005[17] describing several potent, selective low molecular weight MET inhibitors (Fig. 3), provided an alternative path to design selective inhibitors with the requisite properties to maintain prolonged inhibition of MET (>50% inhibition for 12–24 h) in a mouse PD model to achieve robust antitumor activity at low doses in MET-driven xenograft models.[18]

To evaluate this new family of MET inhibitors, three novel analogs (**2**–**4**) were prepared and evaluated for their inhibition of MET kinase activity.[19] Since compound **2** had the greatest activity and showed complete selectivity (>25 μM) over a panel of 25 kinases,[20] it was investigated further (Table 2).

[b]LipE = pIC_{50} − cLogP.

In order to understand the origin of the potency and selectivity of this series, compound **2** was co-crystallized with MET (Fig. 4).[21] Contrary to **AMG 458**, which extended deep into the hydrophobic pocket behind the gatekeeper residue typical of a class II inhibitor, compound **2** presented a different binding mode. This class Ib binding mode only occurs with movement of the activation loop, allowing the inhibitor to wrap around Met1211. Additionally, the inhibitor interacted with the hinge residue (Met1160) of the kinase via the phenol portion of the molecule. The core had a favorable pi-stacking interaction between

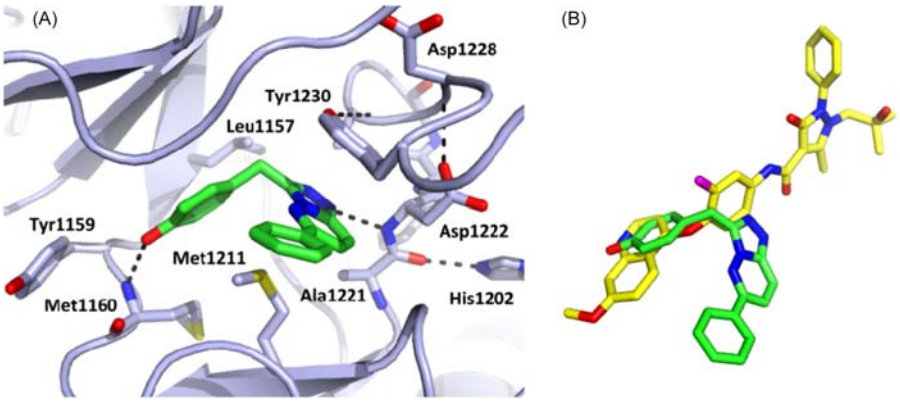

Fig. 4 (A) Co-crystal structures of triazolopyridazine **2** *(green)* and MET. (B) overlay with **AMG 458** analog *(yellow)*.

Tyr1230 and the triazolopyridazine portion of the inhibitor. Although compound **2** represented an attractive starting point, this compound exhibited moderate to high intrinsic clearance (RLM $Cl_{int} = 160$ μL/min/mg and HLM $Cl_{int} = 63$ μL/min/mg).

The overlay of the structures of a close analog of **AMG 458**[22] and compound **2** bound to the catalytic domain of MET revealed an overlap between the *p*-hydroxyphenyl moiety of compound **2** and the quinoline ether portion of **AMG 458** (Fig. 4B). Based on this analysis, hybrid compound **5** was prepared, replacing the phenolic structural alert[23] of **2** with the methoxyquinoline of **AMG 458**.[19]

Compound **5**, a member of the "*O*-linked series," displayed excellent biochemical and cellular potencies and importantly, an attractive selectivity profile comparable to compound **2**.[24] Compound **5** was co-crystalized with MET to confirm its binding mode.[25] As shown in Fig. 5, the predicted binding conformation was verified, with the methoxyquinoline of compound **5** bound to the hinge region and the triazolopyridazine moiety pi-stacking with Tyr1230.

While compound **5** represented a step in the right direction, its microsomal clearance across species was also moderate to high (RLM $Cl_{int} = 416$ μL/min/mg and HLM $Cl_{int} = 88$ μL/min/mg). In order to address this issue, metabolite identification studies were performed. The studies revealed that the C6-phenyl ring was prone to metabolism (Fig. 6). Incubation of triazolopyridazine **5** with rat and human liver microsomes in the presence of NADPH qualitatively yielded C6-phenylarene oxidation product as one of the major metabolites. Also identified in the study were metabolites arising from oxidative cleavage at the benzylic ether carbon (**7** and **8**).

Guided by analysis of the co-crystal structure, various groups were introduced onto the C6 arene in an attempt to mitigate the oxidative liability observed at the C-6 position of the triazolopyridazine.

Introduction of fluorine on the phenyl ring was investigated in an effort to block the observed metabolic activation and to modulate π-stacking interactions[26] with the anticipation of increased potency (Table 3). Both *para* and *meta* substitutions (**10** and **11**) were potent in the enzyme assay with ~3× shift in the cellular assay. The *ortho*-substituted fluorine analogue **12** was not as well tolerated, presumably due to the steric interaction with the triazolopyridazone core, which would rotate the C6-aryl group out of the optimal planar arrangement. In addition, both the 3,4-difluoro (**13**) and the 3,5-difluoro (**14**) analogs were potent against MET kinase activity, but again showed a reduced potency in the cellular assay. Interestingly, the trifluoro analogue **15** was potent in the biochemical and cellular assay with $IC_{50} < 10$ nM. The co-crystal structure of **5** also indicated that the *para*-position of the C-6 phenyl substituent projected toward solvent; therefore, polar functionality could be incorporated at this position to improve physicochemical properties. The introduction of a methylcarboxamide in compound **16** afforded a compound with improved cellular

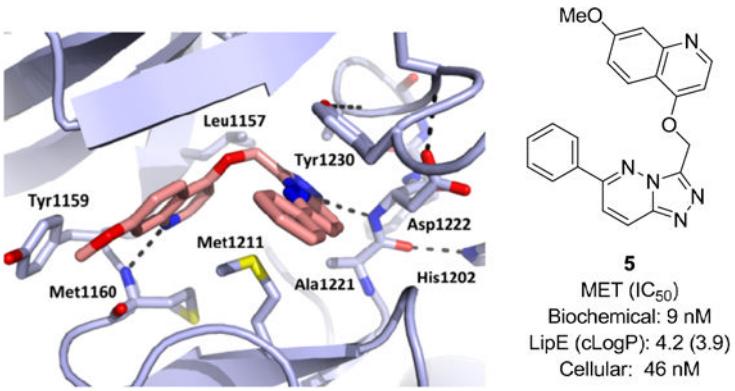

Fig. 5 Co-crystal structure of triazolopyridazine **5** and MET.

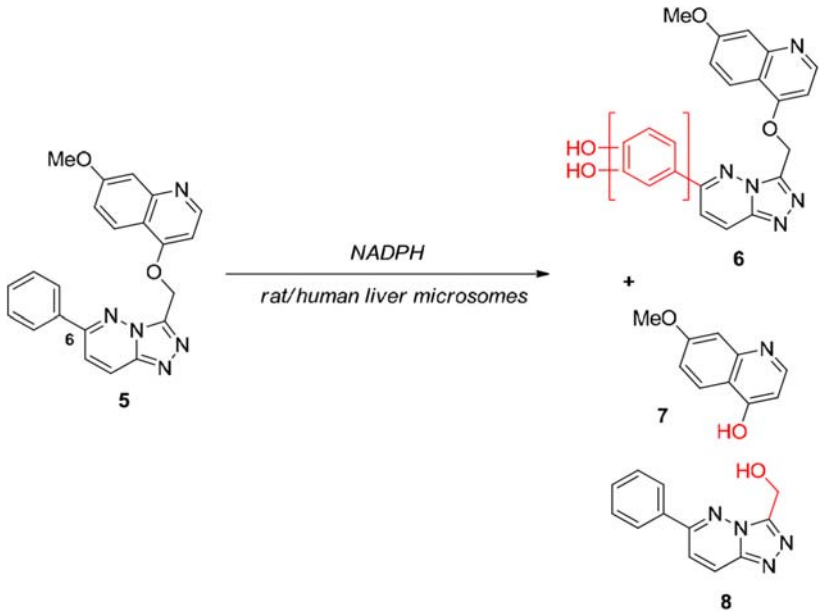

Fig. 6 Identification of metabolic liabilities.

potency compared to compound **5**. The cellular potency of **16** could be further improved by incorporation of a fluorine atom *ortho* to the amide with compound **17**. In addition to substituted phenyl rings, five-membered heterocycles were also explored. Methylisothiazole **21** and *N*-methylpyrazole **23** were found to be optimal groups that led to desirable pharmacokinetic properties while maintaining 1 and 5 nM cellular activity, respectively.

Selected analogs from Table 3 were evaluated in rat pharmacokinetic studies (Table 4). Compound **5**, trifluoro analog **15**, methylisothiazole **21**, and the methyl pyrazole **23** demonstrated low in vivo clearance and moderate oral bioavailability. Both fluorobenzamide analog **17** and methylthiophene **20** were rapidly cleared in vivo and were not pursued further (data not shown).[19]

Although compounds such as **15** and **23** represented valuable leads based on their respective unbound clearance, this series suffered from significant CYP 3A4 time-dependent inhibition (TDI).[27] The absence of a corrective effect on TDI upon introduction of fluorine on the C6 phenyl (compounds **13** and **14**) or a heterocycle (compound **21**) was indicative of a different mechanism of inactivation (Table 5).[28] Therefore, the second major metabolic pathway observed with this series, yielding the formation of hydroxyquinoline **7** and alcohol **8** (Fig. 6) was considered as an alternative mechanism. While increasing the steric hindrance around the ether moiety did not reduce TDI (**24** and **25**), converting the oxygen tether to a nitrogen atom proved to be beneficial, as evidenced by compound **26**. Unfortunately, this change also led to a much weaker inhibition of MET.

Examination of the co-crystal structure of compound **5** revealed that the bent geometry of the tether was critical to allow the inhibitor to properly wrap around Met1211. This favored conformation would be disrupted in compound **26** with a repulsive clash between the −NH of the tether and the hydrogen present on the quinoline at C5 (represented in *red* in Fig. 7). It was hypothesized that the proper binding conformation could be restored by replacing the C5−CH of the quinoline with a nitrogen, as shown with naphthyridine **27**. This change restored the potent inhibition of MET kinase activity and led to the "*N*-linked triazolopyridazine series" described in Table 6.[28]

As anticipated, compound **27** showed improved potency compared to **26** and furthermore, compound **27** showed reduced TDI liability (Table 6). The SAR observed previously at the C6 position in the *O*-linked series translated well to the *N*-linked scaffold, leading to compound **30**. Also, compounds in this series showed reduced unbound clearance when compared to the *O*-linked analogues (Table 7).

To evaluate the properties of this series in vivo, compound **30** was dosed in a mouse PD model. Compound **30** was administered at 30 mg/kg by oral gavage and HGF-induced MET phosphorylation was quantified at various time points thereafter. Sustained inhibition of MET was achieved, with > 50% of inhibition measured 12 h after a single oral dose. Based on this encouraging profile, compound **30** was further characterized; however, low aqueous solubility (HCl/PBS/SIF: > 200/3/13 μg/mL) and the associated dose limiting absorption hampered its progression.

While compound **30** represented a significant overall improvement compared to **AMG 458** with regard to potency and selectivity, the structural and physicochemical properties of this series were not optimal for solubility. To address this limitation while maintaining the remarkable potency and selectivity of these class Ib inhibitors, polarity was introduced and efforts were made to reduce the sp2 character of the compounds. In the process of identifying heterocyclic replacements of the triazolpyridazine and the naphthyridine, optimization of the tether to the hinge binder was explored.

As evidenced by the dramatic improvement in potency moving from **26** to **27**, the two heterocyclic systems that comprise the class Ib inhibitors form a close interaction that can either enforce the desired binding conformation or disrupt it. With this knowledge, the tether and the two heterocyclic systems were optimized in concert to maximize, through favorable intramolecular contact, a conformation similar to the bound conformation. The replacement of the triazolopyridazine with a more polar and less saturated triazolopyridone provided **32**.[29] While this change preserved key features of the triazolopyridazine, both the tether and the hinge binding moiety needed to be altered to obtain the optimal conformation. Guided by structure-based design, a simple methylene tether was incorporated, projecting an unsubstituted quinoline toward the hinge residue in a manner reminiscent of earlier compounds (**2**, **3**, and **4**). The encouraging potency (610 nM) and improved solubility (HCl/PBS/SIF: $>200/>200/60$ μg/mL) of compound **32** warranted further optimization (**Table 8**).

Efforts to improve the potency of the triazolopyridone scaffold were informed by the SAR developed during the optimization of the *O*- and *N*-linked series described above. As mentioned previously, the coplanar arrangement of the C6 substituent and the heterocyclic core was crucial for maintaining potency through the pi-stacking interaction with Tyr1230. For the triazolopyridone scaffold, a methylisothiazole substituent was anticipated to be uniquely suited to provide the required planarity due to a nonbonding intramolecular interaction of the isothiazole sulfur atom with the proximal carbonyl of the triazolopyridone.[30] Indeed, the introduction of the methylisothiazole as in compound **33** provided an increased potency in the biochemical assay (21 nM); however, greater improvement in potency was still required.

As shown in **Fig. 8A**, the inhibitor also interacted with the carbonyl of Arg1208 with dual hydrogen bonding interaction and possessed the desired pi-stacking interaction with Tyr1230. However, the sp3 hybridized carbons present in the triazolopyridone **33** would likely not be optimal and thus unsaturation was re-introduced to test this hypothesis (**34**). Although the introduction of the methyl isothiazole (**33**) and the unsaturated core (**34**) imparted enhanced potency in comparison to **32**, both changes led to a dramatic decrease in solubility (HCl/PBS/SIF for compound **33**: $43/2/<1$ μg/mL) and **34**: $80/<1/5$ μg/mL).

Further exploration of this scaffold, informed by the co-crystal structure, led to the introduction of a methyl group on the tether that was intended to fill the small lipophilic pocket defined by the side chains of Val1092, Leu1157, Ala1226, and Lys1110 (**35**). Although the substitution of the benzylic position did not drastically increase potency or solubility, it was hypothesized that introduction of a chiral center would be beneficial for selectivity and could reduce oxidative metabolism of the benzylic carbon through increased steric bulk. Lastly, the addition of the methoxy group on the quinoline (see 8B for overlay) gave **36**, which maintained potency while providing a handle for the introduction of solubilizing groups as represented by compound **37** (HCl/PBS/SIF: 37/9/40 μg/mL). Combining previously described SAR with the discovery of the optimal C6-methylisothiazole, the potency of the triazolopyridone scaffold was improved >1000-fold from the initial compound (**32**), with the synthesis of only 35 compounds in this series.

Concurrent to efforts focused on replacement of the triazolopyridazine with a triazolopyridone core, a second replacement was also investigated. As learned through inhibitors **2** and **4**, removal of the N5 atom ($X=N \rightarrow X=CH$) led to a significant loss in potency (**Table 2**). However, the introduction of a fluorine atom at the C8 position, potentially filling a small cleft within the active site,[32] increased the potency as evidenced upon comparison of compounds **38** and **39**.[33] This new series, which contained an 8-fluorotriazolopyridine moiety tethered via a methylene unit to a quinoline, afforded a molecule with encouraging inhibitory activity.

The 8-fluorotriazolopyridine series underwent rapid optimization, incorporating the same set of C6-heterocycles as described previously. As shown in **Table 9**, a coplanar pyrazole (**40**) or isoxazole (**41–43**) was beneficial for proper binding. A bis-fluoro group (**40–41**) or a methyl substituent (**42–43**) at the benzylic position was tolerated and filled the same small lipophilic pocket described previously. Geminal dimethyl, cyclopropyl, and ethyl substituents were not tolerated in this space and the stereochemistry of the methyl substituent required the (*S*)-enantiomer for good potency. Lastly, the combinations of chiral substitutions, the planar C6 ring, and the methoxy side chain improved the potencies to 2 nM in our biochemical assay and 3 and 6 nM in our cellular assay, respectively, shown by compounds **42** and **43**.

In order to understand the clearance mechanism for this series, metabolic profiling experiments were conducted. The major metabolic pathway for these compounds was mediated by glutathione *S*-transferase (GST), displacing the aromatic fluorine at the C8 position with glutathione (GSH). Metabolism by GSH conjugation as the primary clearance mechanism for a drug can be problematic due to the existence of multiple GST isoforms in the human population as well as for the potential of GSH depletion leading to oxidative stress if the drug is dosed at high and/or repeated doses.[34] As a means to triage compounds before progressing them into more resource intensive studies, an in vitro assessment was conducted to determine the extent of GSH conjugation.[35]

Using the in vitro GSH conjugation assay, it was observed that two remote components of the core were playing an important role in affecting the reactivity with GSH (**Fig. 9**). For compound **41**, the electron-withdrawing nature of the fluorines on the benzylic carbon, combined with the electron deficiency of the methylisoxazole, acted to increase the amount of GSH conjugation significantly. The electron donating capability of the heterocycle attached at the C6 position modulated the extent of GSH displacement, with the more electron-donating pyrazole group showing reduced incorporation of GSH even in combination with the benzylic fluorines (**40**).[36] The extent of GSH displacement was greatly decreased with removal of the fluorines present on the bridging carbon (**41** → **42** → **43**).

Since inhibitor **43** showed the best overall profile with respect to potency and GSH conjugation, its metabolic fate was further investigated by incubation with NADPH in liver microsomes. Analysis by LC–MS revealed that **43** displayed differing metabolic profiles across species, which could present complications for further advancement (**Fig. 10A**). Incubation of **43** in monkey and human liver microsomes showed oxidation of the tether methyl group (M4) as the major pathway of biotransformation; however,

this metabolite was below the detection limit in mouse, dog, and rat liver microsomes. The major metabolite in mouse liver microsomes was demethylation of the methoxyquinoline (M1). This metabolite was also present in rat and dog liver microsomes in addition to metabolites resulting from oxidation of the methylisoxazole (M2) and the triazolopyridine ring (M3). While it was certainly possible to progress this compound forward, the complication of predicting human PK in light of the observed species differences in metabolism made compound **43** less desirable.

One hypothesis for potentially altering the metabolism of **43** was to introduce an alternative metabolic soft spot. Thus inhibitor **44**, bearing an ethoxymethoxy solubilizing group on the quinoline, was synthesized and showed similar potency to compound **43** (Table 10). Compound **44** was also incubated with NADPH in the presence of the liver microsome panel. The introduction of the ethoxymethoxy solubilizing chain provided an alternative site of metabolism that was the major site in all species. The primary metabolites formed after incubation of **44** with mouse, rat, dog, monkey, and human liver microsomes were demethylation of the ethoxymethoxy side chain (M6) and subsequent oxidation to acid M7 (Fig. 10B).

The parallel lead optimization efforts on the triazolopyridone and 8-fluorotriazolopyridine scaffolds culminated in compounds **37** and **44** (Table 10). These two compounds demonstrated single-digit nanomolar potency in both biochemical and cellular assays. Their favorable rat PK showed that both compounds could achieve robust exposure levels above the measured IC_{50} in the cellular assay since the PK in mouse was generally similar to rat.[37] The promising potency and PK attributes of **37** and **44** led to their characterization in a mouse PD model.

Despite only modest improvement in solubility from naphthyridine **30**, compound **37** showed outstanding efficacy and extended coverage in a mouse PD model. It displayed >90% inhibition of HGF-induced phosphorylation of MET at 10 mg/kg up to 12 h, with an associated unbound plasma concentration of 20 nM, providing 11-fold coverage of the cellular IC_{50}. Furthermore, it also achieved unbound coverage of the cellular IC_{50} for up to 24 h. 8-Fluorotriazolopyridine **44**, while demonstrating excellent in vitro potency, excellent solubility, and nearly identical PK to **37**, did not show the same extended inhibition of MET activity in the PD model. As mentioned previously, extended inhibition of MET in a mouse PD model was required for robust tumor growth inhibition. The more robust PD response provided by **37** made this molecule seem more attractive at the outset, but upon further investigation, it was determined that the triazolopyridone scaffold exhibited TDI of CYP3A4 and undesirable solubility. Compound **44** did not exhibit TDI liabilities, but as stated above, did not meet the efficacy requirements for advancement. Thus the team devised a means to combine these two scaffolds in order to identify a molecule that fulfilled the potency and efficacy requirements without the risk of TDI.

In order to merge sustained efficacy with mitigated TDI liability, two key design elements derived from **37** to **44** were hybridized to afford compound **45**. First, it was hypothesized that the superior efficacy of compound **37** in the PD time-course model was a result of the favorable U-shaped binding mode that is reinforced by a key intramolecular interaction between the carbonyl of the pyridone (in *orange*) and the hydrogen of the quinoline as shown in Fig. 11A. The second consideration was eliminating the CYP3A4 TDI while maintaining the superior efficacy of compound **37**. Upon juxtaposition of **37** and **44**, the CYP3A4 TDI activity was attributed to the triazolopyridinone ring of **37**, since both series shared the quinoline hinge-binding element. Accordingly, the 8-fluorotriazolopyridine portion of **44** (in *green*, Fig. 11C) was combined with a naphthyridinone ring system to afford **45**, in which the direction of the internal H-bond interaction, exhibited by **37**, had been reversed (in *orange*, Fig. 11B). This new scaffold was found to maintain single-digit nanomolar inhibition of MET phosphorylation (MET biochemical IC_{50} 3 nM, cellular IC_{50} 9 nM) and furthermore did not show TDI.

A co-crystal of **45** within the catalytic domain of unphosphorylated MET was obtained[38] indicating that the inhibitor adopts the desired U-shaped binding mode around Met1211 (Fig. 12A and B). Furthermore, the hypothesis that the naphthyridinone carbonyl and H-5′ of the 8-fluorotriazolopyridine ring would participate in an intramolecular H-bond to reinforce the optimal binding mode was confirmed by the 3.3 Å distance between these two moieties. The naphthyridinone nitrogen atom N-1 participates in a single-point hydrogen bond with linker residue Met1160, while N-1′ of the 8-fluorotriazolopyridine interacts with the backbone −NH of Asp 1222. Additionally, a face-to-face π-stacking interaction is observed between Tyr1230 and the 8-fluorotriazolopyridine ring system. A two-point binding contact between hydrogens on C-7′ and C-4″ and the lone pairs of the Arg1208 carbonyl group is also apparent. Confirmation that the (*R*)-enantiomer is preferred by the protein was demonstrated by the methyl substituent filling

a small, lipophilic pocket in MET, defined by the side chains of Val1092, Leu1157, Ala1226, and Lys1110.[39] Finally, the fluorine atom at the 8′-position fills a small cleft within the active site, where it sits perpendicular to the backbone carbonyl of Asn1209.[40]

The synthesis of **45** required the individual construction of coupling partners **49a** and **53a** (Scheme 1). Stille cross-coupling of 5-chloro-2,3-difluoropyridine (**46a**) and commercially available isoxazole stannane **47** yielded intermediate **48a**, which was treated with hydrazine to form pyridyl hydrazine **49a**. Coupling partner **53a** was prepared as a racemic mixture in two steps from naphthyridinone **50a** through alkylation with ethyl 2-bromopropanoate (**51**) followed by hydrolysis of the resultant ester (**52a**) under acidic conditions. Acid **53a** underwent HATU-mediated amide coupling with hydrazine **49a**, after which cyclization under dehydrative conditions provided the racemic 8-fluorotriazolopyridine product in 52% yield over two steps. Finally, separation of racemic **45** by chiral chromatography afforded the active (*R*)-enantiomer of **45**.[41]

Alternatively, an enantioselective synthesis of compound **45** was achieved via preparation of a chiral acid coupling partner **55** (Scheme 2).[42] Mitsunobu reaction between naphthyridinone **50a** and (*S*)-methyl lactate (**54**), followed by ester hydrolysis afforded compound **55** in high yield and >95% *ee*.[43] HATU-mediated amide coupling of **49a** with **55**, followed by cyclization under dehydrative conditions yielded **45** in high yield and with complete retention of enantiomeric excess.

Having identified a structurally unique scaffold with nanomolar inhibition of MET phosphorylation without TDI liability, compound **45** was further characterized. The solubility of **45** (0.01 N HCl, PBS, SIF: 172, 34, 55 μg/mL) was superior to compounds **30** and **37** and the associated plasma-free fraction (f_u) was high across species relative to compounds **30**, **37**, and **44** (Table 12). Naphthyridone **45** demonstrated low intrinsic clearance in rat, mouse, and human liver microsomes, consistent with the low to moderate in vivo clearance observed in male Sprague-Dawley rats. While **45** showed similar total clearance (Cl) to compounds **30**, **37**, and **44** in rat, i.e., 0.38 L/h/kg vs. 0.19, 0.57, and 0.56 L/h/kg, respectively, the unbound clearance (Cl_u) was significantly improved for **45** compared to **30**, **37**, and **44**. The unbound clearance for compound **45** was 1.9 L/h/kg, vs. 26, 26, 31 L/h/kg for compounds **30**, **37**, and **44**, respectively, which could be advantageous for lowering human dose requirements. Furthermore, compound **45** demonstrated both a reasonable bioavailability and half-life for further in vivo testing. In the mouse PD assay,

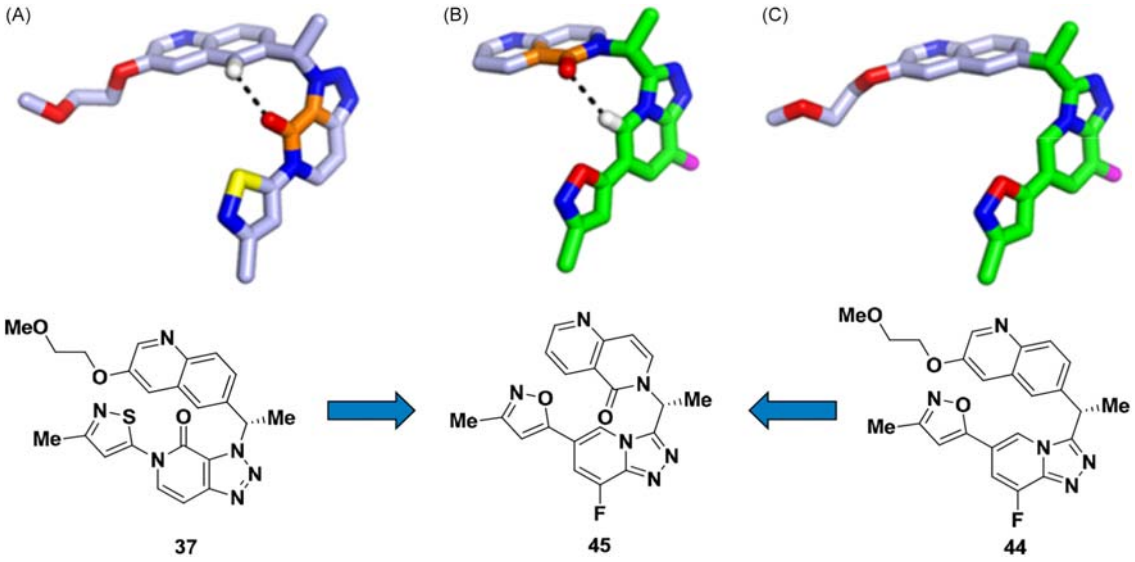

Fig. 11 Origin of the naphthyridinone series, represented by hybrid **45**.

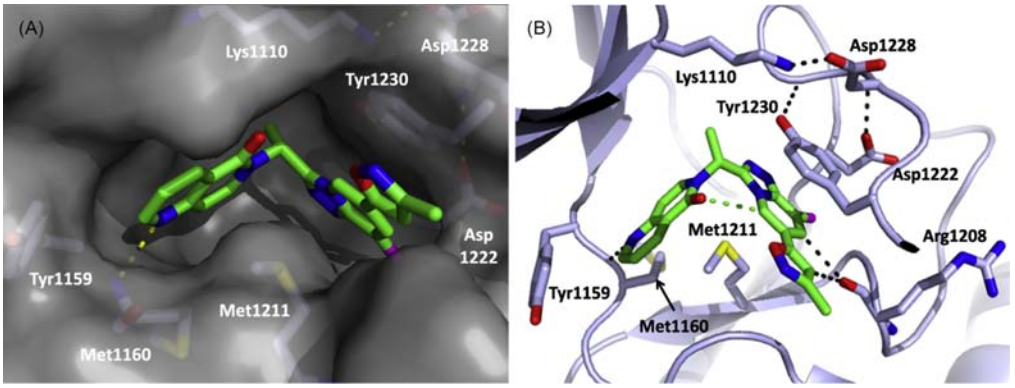

Fig. 12 Co-crystal structure of MET and naphthyridinone **45**.

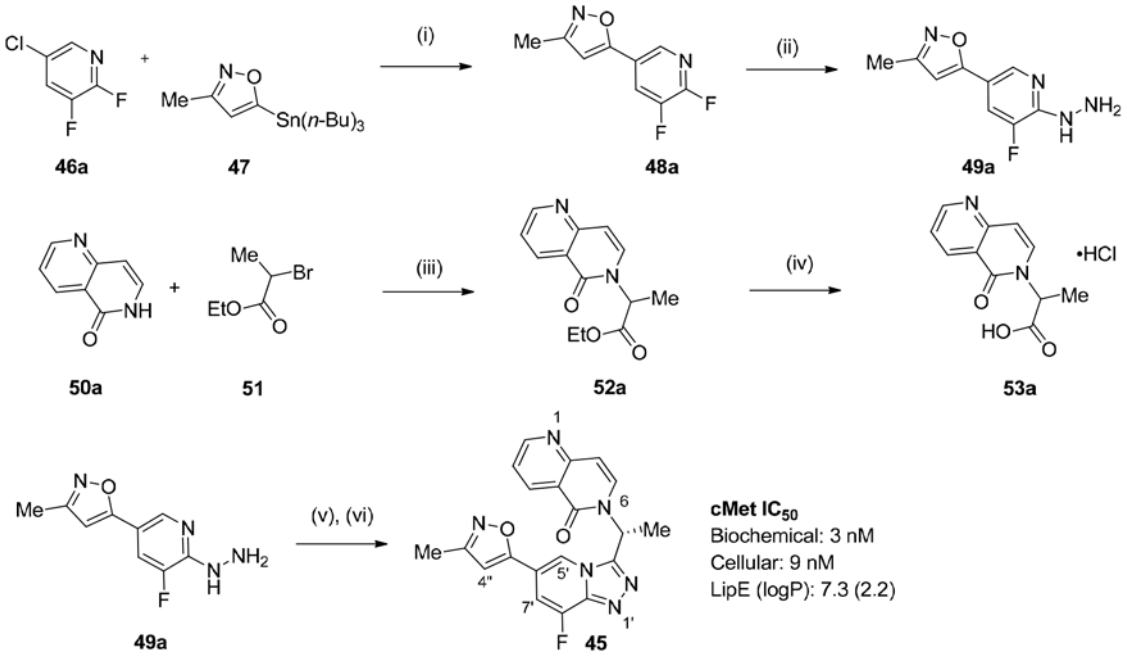
compound **45** was dosed orally at 10 mg/kg and showed 91% inhibition of MET phosphorylation for 9 h with an associated unbound plasma concentration of 193 nM, covering both the cellular IC_{50} and IC_{90} (Fig. 13). Despite the improvements in solubility and the lack of TDI for compound **45**, a more efficacious molecule was necessary in order to achieve the required >50% inhibition of MET at the 24 h time point in the mouse PD assay.

In order to further explore the SAR around lead compound **45**, a general synthetic method was developed to allow for rapid preparation of naphthyridinone analogs substituted at the C-3 position. Substitution at this position had proved pivotal for improving physicochemical properties, metabolism, and potency in compounds **37** and **44**. In addition, variation at the C-6′ position was also important; since both the 3-methylisoxazole and the *N*-methyl pyrazole were good partners with the 8-fluorotriazolopyridine core (Table 9). Finally, since removal of the fluorine substituent at the 8-position had not been investigated with the more potent naphthyridone scaffold, variation of this substituent was also included in the SAR.

The modified synthesis of naphthyridinone analogs began with a Suzuki reaction between 5-chloro-2,3-difluoropyridine (**46a**) or 5-bromo-2-fluoropyridine (**46b**) and 3-methyl-5-(tributylstannyl)isoxazole (**47**) or a Stille reaction with 1-methyl-4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-1H-pyrazole (**60**), yielding fluoropyridine intermediates **48b–d** (Scheme 3). **48b–d** were combined with hydrazine in *i*-PrOH and warmed to afford hydrazines **49b–d**. Naphthyridinones substituted at the C-3 position were derived through an annulation reaction between commercially available ethyl 5-bromo-2-methylnicotinate (**56**) and 1,3,5-triazine (**57** under basic conditions producing 3-bromo-1,6-naphthyridin-5(6*H*)-one (**58**) in 91% yield).[44] Substitution of bromine was achieved by heating with NaOMe/MeOH or $MeOCH_2CH_2ONa/MeOCH_2CH_2OH$ in the presence of 3,4,7,8-tetramethyl-1,10-phenanthroline and CuI as catalysts to provide naphthyridinones intermediates **50b,c**. Exposure of **50b,c** and (±)-ethyl 2-iodopropanoate (**59**) to Cs_2CO_3 in THF at elevated temperature generated racemic ethyl esters **52b,c**, which were converted to the corresponding carboxylic acids **53b,c** through treatment with an aqueous solution of HCl. HATU-mediated coupling of the carboxylic acids **53a–c** with hydrazines **49a–d** yielded the hydrazide intermediates, which underwent dehydrative cyclization with DEAD, $TMSN_3$, and PPh_3 to give triazolopyridines **45**, **61–68** after chiral separation.[45]



Scheme 1 Synthesis of naphthyridinone **45**. [a]Reagents and conditions: (i) $Pd(OAc)_2$, X-Phos, 1,4-dioxane/water, 100°C, 18 h, 60%; (ii) NH_2NH_2, *i*-PrOH, 65°C, 3 h, 90%; (iii) Cs_2CO_3, THF, 60°C, 3 h, quantitative; (iv) aq. Fig. 13 Compound **45** inhibited HGF-induced phosphorylation of MET over time in the mouse liver PD assay after oral administration at 10 mg/kg (10 mL/kg dose volume, formulated in 2% hydroxypropyl methylcellulose 1% Tween 80 in water, pH 2.2 adjusted with methanesulfonic acid). Data represent the mean ± standard deviation ($n = 3$ mice per group). Statistical significance was determined by ANOVA followed by Bonferroni/Dunn post hoc test. $^*p < 0.0001$ compared to HGF control. *Red circles* represent the mean terminal unbound concentration of **45** in the plasma ± standard deviation ($n = 3$ mice per group).

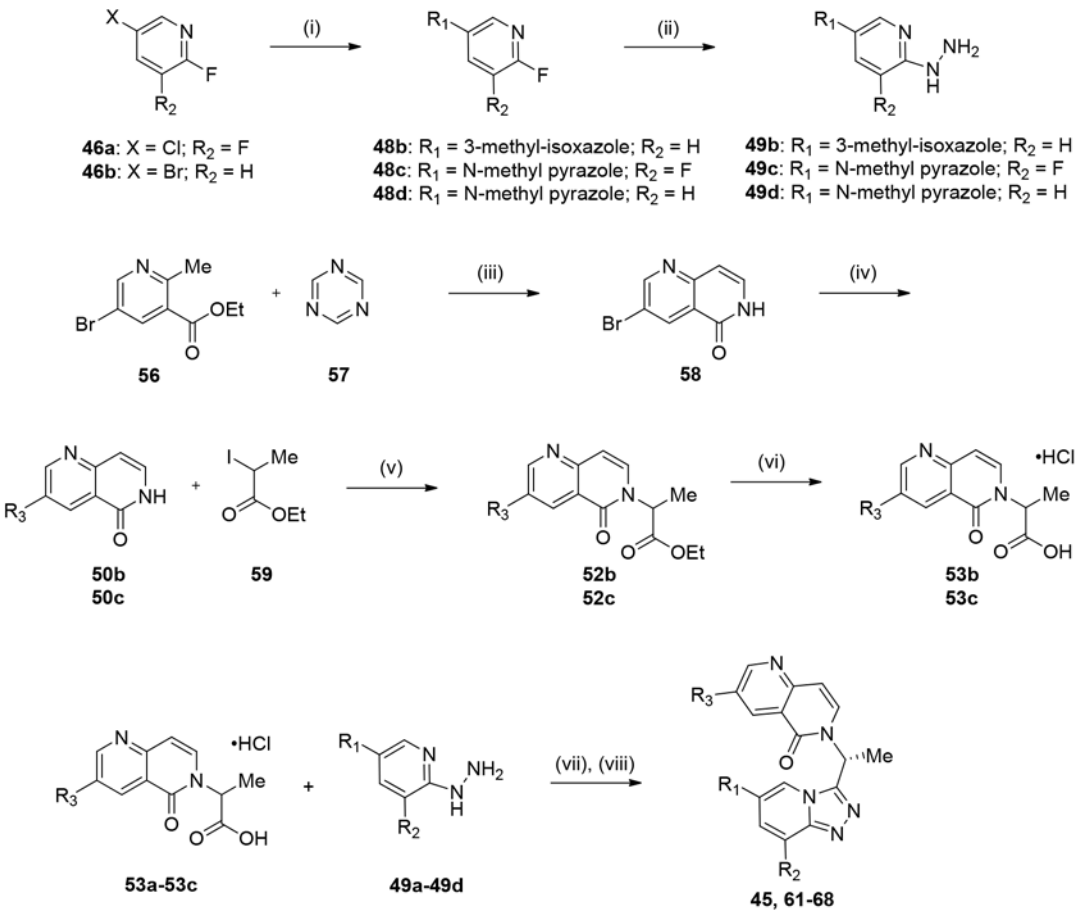

Scheme 3 Synthesis of naphthyridinones (**45**, **61**–**68**). [a]Reagents and conditions: (i) for **48b**: 3-methyl-5-(tributylstannyl)isoxazole (**47**), $Pd_2(dba)_3$, $P(t\text{-}Bu)_3{\bullet}BF_4$, CsF, 1,4-dioxane, 90°C, 12 h, 66%; for **48c**: 1-methyl-4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-1*H*-pyrazole (**60**), $Pd(OAc)_2$, X-Phos, K_3PO_4, 1,4-dioxane/water, 100°C, 45 min, 81%; for **48d**: 1-methyl-4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-1*H*-pyrazole (**60**), $PdCl_2$(dppf), Cs_2CO_3, 1,4-dioxane/water, 90°C, 3 h, 87%; (ii) NH_2NH_2, *i*-PrOH, for **49b**: 60°C, 2 h, 96%; for **49c**: 65°C, 3 h, 97%; for **49b**: 60°C, 48 h, 98%; (iii) *t*-BuOK, DMSO, 80°C, 1 h, 91%; (iv) 3,4,7,8-tetramethyl-1,10-phenanthroline, CuI, for **50b**: MeONa, MeOH, 130°C, 24 h, 89% (75% pure); for **50c**: *t*-BuONa, $MeOCH_2CH_2OH$, 124°C, 21 h, 85% (v) Cs_2CO_3, THF, for **52b**: DMF, 70°C, 18 h, 40%; **52c**: THF, 60°C, 90 min, 53%; (vi) aq. HCl, for **53b**: 80°C, 10 h, 85%; for **53c**: THF, 65°C, 4 h, 78%; (vii) for HATU, Hunig's base, MeCN or DMF, 23°C, 1–3 h, 23–92%; (viii) PPh_3, $TMSN_3$, DEAD, THF, 23°C, 1–3 h, 20–73%; then chiral separation.

Modification of the C6′ position with a variety of heterocycles provided SAR consistent with that observed for the scaffolds represented by **30** and **44**. Biochemical and cellular potencies were maintained across multiple variations made within the naphthyridinone series with LipE[46] values ranging from 7.0 to 7.9 (Table 11). C-6′ substitution with methylisoxazole (**45**, **61**–**63**) and methylpyrazole (**64**–**68**) appeared interchangeable with respect to potency. The addition of methoxy (**61**, **65**, and **67**) or methoxyethoxy (**62**, **63**, **66**, and **68**) groups at the C-3 position of the naphthyridinone, installed for the purposes of improving solubility, was also well tolerated and maintained or slightly increased the potency (2–3 ×) in the biochemical assay when compared to the unsubstituted naphthyridinones **45** or **64**. Finally, replacement of the C8 fluorine with hydrogen showed a slight decrease in potency (4–6 ×), but only in the analogs containing a pyrazole at C6′ (**65** vs. **67** and **66** vs. **68**).

The metabolic stability and pharmacokinetic properties of **45**, **61**–**68** were evaluated and low microsomal clearance was observed across species for all compounds (Table 12). The free fraction in rat, mouse, and human plasma was relatively high, consistent with data collected for compound **45**. No obvious differentiation was observed based upon respective unbound clearance (Cl_u) and oral bioavailability (%F) for the inhibitors shown in Table 12. One consideration was the consistent cross-species metabolism demonstrated by inhibitors containing a methoxyethoxy group (**62**, **63**, and **66**) in contrast to inhibitors with an undecorated naphthyridine or a methoxy group. When inhibitors **63** and **66** were incubated with NADPH in the presence of liver microsomes, their metabolic profiles were relatively consistent across species, showing demethylation of the $MeOCH_2$-CH_2O-side chain and subsequent oxidation to the acid.[47] Consequently, compounds **62**, **63**, and **66** were selected for advancement into a PD time-course study as a means to determine which of these promising compounds would provide extended duration of coverage over the IC_{50} for MET inhibition.

[a]In vitro (*RLM*, rat liver microsomes; *MsLM*, mouse liver microsomes; *HLM*, human liver microsomes).
[b]Plasma unbound fraction (f_u) were measured using equilibrium dialysis; Concentration = 5 μg/mL.
[c]In vivo experiments with male Sprague-Dawley rats (n=3).
[d]*iv*, 0.25 mg/kg (DMSO).
[e]*po*, 2 mg/kg (2% HPMC 1% Tween 80 in water, pH 2.2 adjusted with methanesulfonic acid).

Unlike compounds **45** and **62**, compounds **63** and **66** exhibited extended inhibition of MET activity in mice, achieving >90% inhibition of HGF-induced phosphorylation of MET for at least 12 h at a dose of 10 mg/kg (Fig. 14). Furthermore, compounds **63** and **66** maintained approximately 50% inhibition over a 24 h period.[48] Based on these results, **63** and **66** were selected as structurally diverse candidates for PK profiling in a second preclinical species.

Compounds **63** and **66** showed low clearance and moderate volumes of distribution at steady-state, with comparable half-lives following IV administration to beagle dogs (Table 13). After oral dosing at 10 and 30 mg/kg, the exposure increased proportionally to dose for both inhibitors and the oral bioavailability for **63** and **66** was also comparable. Overall, both compounds had reasonable dog *iv* and *po* PK properties.

Ultimately, **66** was advanced and evaluated in an MET-dependent xenograft model (Fig. 15). Following oral administration (*q.d.*) of **66** at 0.1, 0.3, 1, 3, and 10 mg/kg over 22 days, dose-dependent tumor growth inhibition was observed with an ED_{50} of 0.3 mg/kg and an ED_{90} of 0.8 mg/kg with no adverse effect on body weight.[49] This represents a more than 40–43 × improvement over the tumor growth inhibition (ED_{50} and ED_{90}) results provided by the original clinical candidate **AMG 458**.

Illustrated by the graph of unbound plasma concentration of **66** over time, doses covering the cellular IC_{90} for at least 12 h (3 and 10 mg/kg) resulted in >90% tumor growth inhibition. Compound **66** did not suffer from CYP3A4 TDI, exhibited good solubility in its hydrate form (0.01 N HCl/PBS/SIF: 174/77/>200 μg/mL) and displayed exquisite selectivity against a panel of 402 tyrosine and serine/threonine kinases (Fig. 16).[50] These attributes, when coupled with its long half-life in rat and dog, its predictable metabolism and good human dose projection, led to the selection of compound **66** as the clinical candidate designated **AMG 337**.

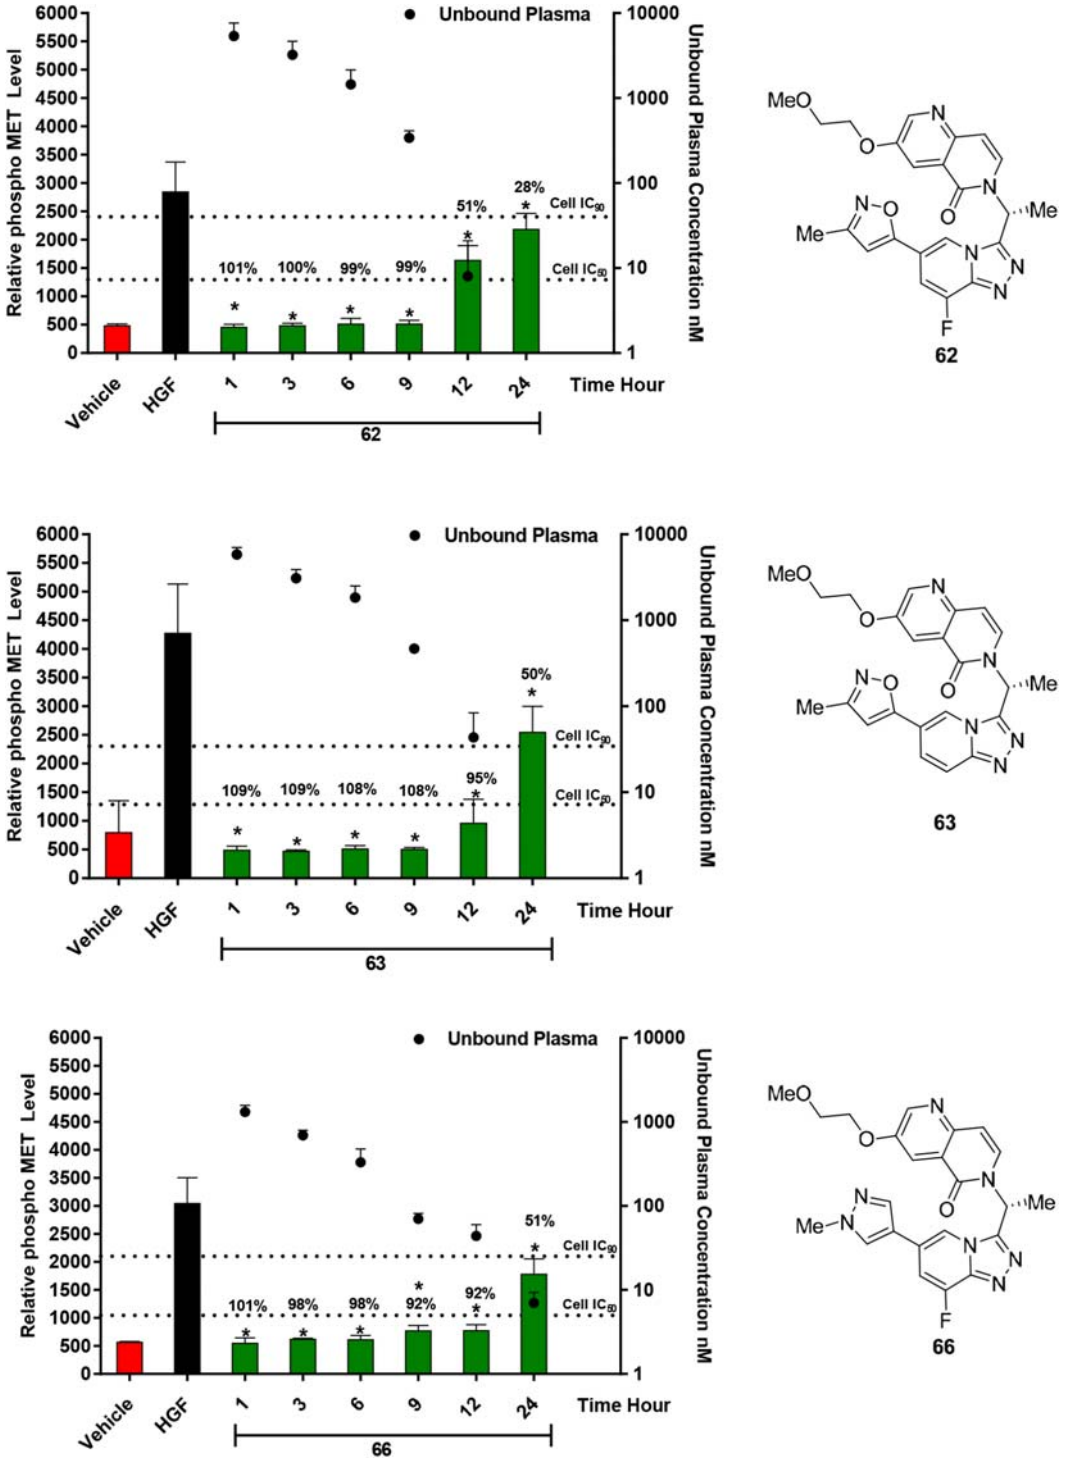

Fig. 14 The effect of **62**, **63**, and **66** on HGF-induced phosphorylation of MET over time in the mouse liver PD assay after oral administration at 10 mg/kg (10 mL/kg dose volume, formulated in 2% hydroxypropyl methylcellulose 1% Tween 80 in water, pH 2.2 adjusted with methanesulfonic acid). Data represent the mean ± standard deviation ($n=3$ mice per group). Statistical significance was determined by ANOVA followed by Bonferroni/Dunn post hoc test. *$p<0.0001$ compared to HGF control. *Red circles* represent the mean terminal unbound concentration of compound **62**, **63**, or **66** in the plasma ± standard deviation ($n=3$ mice per group).

AMG 337 was dosed once daily in patients with advanced solid tumor, escalating from 25 to 400 mg to access safety, tolerability, and PK. No accumulation was observed over the 28 days of dosing, and the observed half-life ranged from 4.6 to 6.9 h, supporting a QD dosing regimen with a median T max of 2–3 h. For all doses, the cellular IC_{50} and IC_{90} were covered for up to 24 h. The MTD was determined to be 300 mg.[51]

8.06.3 Conclusion

A thorough analysis of the bound structures of our inhibitors throughout the optimization process enabled the selection of ideal scaffolds and substitutions leading to two advanced series of MET receptor kinase inhibitors, represented by compounds **37** and **44**. The combination of both series, guided by the exploitation of an intramolecular hydrogen bond to favor the active conformation, and a careful analysis of metabolism across species led to the discovery of **AMG 337 (66)**. This exquisitely potent and selective MET inhibitor, demonstrated a sustained inhibition of MET phosphorylation in a mouse liver pharmacodynamic model and strong tumor growth inhibition in an MET-dependent mouse efficacy model. The favorable clinical pharmacokinetics and tolerability of **AMG 337** warranted its progression into Phase II trials.

8.07.1 Introduction

8.07.1.1 The DNA Damage Response

The DNA within our cells is constantly under attack from endogenous sources, environmental mutagens, and carcinogens with tens of thousands of DNA damage events occurring every day.[1,2] Many different mechanisms have evolved to deal with the different forms of DNA damage thus evoking different repair mechanisms and signaling pathways which include cell-cycle arrest, regulation of DNA replication, and the repair or bypass of DNA damage.[3] The collective term for these various responses is DNA damage response (DDR). Five major repair pathways exist within human cells: base excision repair which repairs the DNA single-strand breaks (SSBs) primarily generated from the processing of modified bases and abasic sites[4]; homologous recombination repair (HRR) which is a relatively efficient and accurate repair pathway for DNA double-strand breaks (DSBs) but which relies upon the presence of undamaged sister chromatid DNA[5]; nonhomologous end-joining (NHEJ) which also repair DNA DSBs but are not dependent on the presence of replicated DNA[6]; nucleotide excision repair which deals with modified nucleotides and UV-induced damage[7]; and mismatch repair which deals with replication errors such as mismatch base-pairing and nucleotide insertions/deletions.[8] Whilst DNA SSBs are the most common form of DNA damage with an estimated 20,000 events at least per cell per day, the less common DNA DSBs are the most cytotoxic lesions due to the issues associated with accurate chromosome segregation during cell division. The formation of DNA DSBs is the primary driver for cytotoxicity for ionizing radiation (IR) and a number of approved cancer chemotherapies, such as topoisomerase I and II inhibitors (e.g., camptothecin, irinotecan, etoposide, doxorubicin, etc.), and can also be induced by targeting specific DDR pathways (such as inhibition of poly(ADP-ribose) polymerase (PARP) with the approved drug olaparib). The increased number of DNA DSBs induced by these therapies results in a pause of the cell cycle to allow repair of the accumulated damage; however, should this damage reach a sufficient threshold, or persist for long enough, programmed cell death (apoptosis) is triggered. Cells in the S-phase, that is, during DNA synthesis, are more sensitive to DNA damaging agents due to the vulnerable structure of DNA. Opportunities to interfere with the repair of DNA DSBs may,

therefore, result in increased levels and/or duration of DNA damage and consequently may potentiate the cytotoxicity of DSB inducing agents. The DDR of cancer cells differ in three important aspects to those of normal cells.[9] Firstly, most (if not all) cancer cells will have lost one or more DDR pathways thereby resulting in an increased dependency on those remaining pathways. Secondly, cancer cells have increased levels of replication stress compared with normal cells as a result of oncogenic drivers, loss of cell-cycle checkpoints, and increased levels of intrinsic reactive oxygen species (ROS).[10,11] Finally, cancer cells have increased levels of endogenous DNA damage as a result of factors associated with increased proliferation, such as increased transcription and increased metabolic and replication stress. These key differences between cancer cells and normal cells mean that cancer cells are more sensitive to exogenous DNA damage and support the hypothesis that targeting DDR pathways may cause greater effects in cancer cells thus providing a therapeutic margin to exploit in the clinic.

8.07.1.2 Ataxia-Telangiectasia Mutated Kinase

Ataxia-telangiectasia mutated (ATM) kinase is a member of the phosphatidylinositol 3-kinase (PI3K)-related kinase (PIKK) family of atypical serine/threonine protein kinases (also comprising ATR, DNAPKcs, mammalian target of rapamycin (mTOR), SMG1, and the nonenzymatic TRRAP)[12] and plays a central role in the DDR by regulating the detection and repair of DNA DSBs.[13,14] ATM derives its name from a rare human autosomal recessive disorder ataxia-telangiectasia (A-T) that results from mutations in the *ATM* gene. A-T patients suffer a variety of symptoms amongst which are immunodeficiency, extreme radiosensitivity, and a predisposition to cancer. Cells from A-T patients have been shown to have abnormal cell-cycle arrest in the G_1, S, and G_2 phases, and show hypersensitivity to IR.[15] Like other PIKK family members, ATM is a large protein (350 kDa) comprising 3056 residues and containing a kinase domain with a relatively high degree of similarity to the lipid kinase PI3K.[16] Recruitment of the inactive dimeric form of ATM to the site of a DNA DSB is mediated by the DNA-end tethering MRE11-RAD50-NBS1 (MRN) complex and results in the autophosphorylation of ATM on serine 1981.[17,18] This autophosphorylation event activates ATM leading to dimer dissociation and subsequent phosphorylation of nearby histone variant H2AX on serine 139 (γH2AX) thereby initiating the assembly of DDR components at the breakage site to facilitate DNA repair, cell-cycle arrest, and/or cell death.[19,20] ATM directly phosphorylates p53 on serine 15, Mdm2, and Chk2 thus stabilizing p53 by preventing its Mdm2-mediated ubiquitinylation and degradation.[21–23] Upon activation and accumulation in the nucleus, p53 acts as transcription factor to drive the expression of genes involved in G_1/S cell cycle checkpoint activation and apoptosis.[24] ATM-mediated Chk2 phosphorylation induces degradation of the phosphatase Cdc25A which would otherwise promote S-phase progression through activation of Cdk2 that is needed for DNA synthesis.[25] In addition, hundreds of substrates are phosphorylated in an ATM-dependent manner, demonstrating the complexity of the ATM-mediated DDR pathways.[26] Loss of ATM activity has been shown to increase the sensitivity of virtually all cells to IR whereas upregulation of ATM signaling has been observed in different cancers leading to both chemoresistance and radioresistance.[27–29] Small molecule inhibitors of ATM have been shown to recapitulate the phenotype of A-T cells thus affecting the ability of the cells to mount a cytoprotective response to DNA damage and mouse models in which ATM has been knocked out have also been shown to have increased radiosensitivity and a predisposition to developing cancer.[30] In addition to its key role in coordinating the DDR response to DNA DSBs, growing evidence suggests a role for ATM in signaling and protecting against oxidative stress through its activation by surface cysteine residue oxidation.[31] This activity has been linked to ATM's vascular-protecting function at regions of highly fluctuating oxidative conditions during pathoneoangiogenesis.[32] The central role of ATM in coordinating repair pathways in response to induced DNA DSBs highlights this protein as a highly attractive pharmacological target to sensitize tumor cells to both chemotherapy and radiotherapy.[33,34] The benefit of ATM inhibition may not only reside in the enhancement of DNA DSB cytotoxicity but there may also be the opportunity to exploit the concept of synthetic lethality.[35,36]

8.07.1.3 Inhibitors of ATM Kinase

The promise of ATM inhibition to provide a potentially meaningful treatment for cancer patients has resulted in the identification and disclosure of a number of ATM inhibitors with differing profiles and properties (Fig. 1).[16,37] Wortmannin (**1**) was the first reported inhibitor of ATM enzyme ($IC_{50} = 0.15\ \mu M$) although it also inhibits a number of other PIKK enzymes (DNAPK $IC_{50} = 0.016\ \mu M$, ATR $IC_{50} = 1.8\ \mu M$) and its primary activity resides against PI3K ($IC_{50} = 0.003\ \mu M$). Wortmannin (**1**) sensitizes cells to IR but concentrations above those required to inhibit ATM are required for optimal radiosensitization. A549 lung

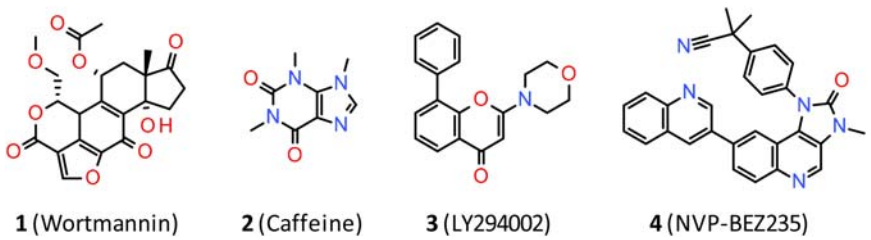

Fig. 1 Structures of nonselective ATM inhibitors in the public domain.

adenocarcinoma cells treated with both wortmannin (**1**) and IR displayed S-phase and G_2-phase abnormalities observed with ATM deficient cells.[38] Caffeine (**2**) has also been reported as a relatively weak and nonspecific ATM inhibitor with an in vitro IC_{50} of 200 μM against the ATM enzyme and weak activity against a number of PIKK enzymes (ATR $IC_{50}=1100$ μM, DNAPK $IC_{50}=10{,}000$ μM).[39] The discovery of LY294002 (**3**), developed by Eli Lilly from the naturally occurring flavonoid quercetin, provided a significant step forward in the understanding of the PIKK enzymes.[40] LY294002 (**3**) is an ATP competitive inhibitor with modest potency against a variety of PI3K and PIKK enzymes (PI3Kα,β,γ,δ $IC_{50}=0.55$, 16, 12, and 1.6 μM, respectively; mTOR $IC_{50}=2.5$ μM; DNAPK $IC_{50}=2.5$ μM); however, activity against ATM is surprisingly limited.[41] Crystallographic studies of LY294002 (**3**) bound to the ATP-binding site of PI3Kγ have revealed that the inhibitor forms a key interaction from the oxygen of the morpholine unit to the hinge region of the kinase.[42] More recently the dual PI3K/mTOR inhibitor NVP-BEZ235 (**4**), taken into clinical studies by Novartis, has been shown to inhibit ATM and a number of other PIKKs in addition to PI3K and mTOR (ATM $IC_{50}=0.007$ μM; DNAPK $IC_{50}=0.005$ μM; PI3Kα,β,γ,δ $IC_{50}=0.004$, 0.075, 0.005, and 0.007 μM, respectively; mTOR $IC_{50}=0.021$ μM).[43] The ability of NVP-BEZ235 (**4**) to block both the HRR and NHEJ DSB repair pathways through simultaneous inhibition of both ATM and DNAPK has been shown to result in the radiosensitization of a number of cancer cells; however, its clinical development appears to have been halted.[44,45]

Whilst the identification of pan PI3K/PIKK inhibitors has undoubtedly advanced the biological understanding of these important targets, the development of selective agents has allowed researchers to further probe the biology of individual proteins (Fig. 2). KU-55933 (**5**) was one of the first potent and selective inhibitors of ATM to be reported and was developed following the extensive structure–activity relationship (SAR) studies performed on chemical scaffolds related to the pan-PI3K and pan-PIKK inhibitor LY294002 (**3**).[46] KU-55933 (**5**) is an ATP-competitive, potent inhibitor of ATM enzyme ($IC_{50}=0.013$ μM) with impressive selectivity over the closely related enzymes DNAPK ($IC_{50}=2.5$ μM), ATR ($IC_{50}>100$ μM), mTOR ($IC_{50}=9.3$ μM), and PI3K ($IC_{50}=16.6$ μM).[47] Whilst structural data for ATM is not currently available, docking simulations using homology models of ATM combined with observed SAR suggest that KU-55933 (**5**) binds to ATM in an analogous fashion to that observed for LY294002 (**3**) in PI3Kγ (i.e., the morpholine oxygen binding to the kinase hinge). KU-55933 (**5**) was shown to sensitize HeLa cells to the cytotoxic effects of topoisomerase I and II inhibitors and to IR; however, the utility of KU-55933 (**5**) in vivo has been limited by its poor physicochemical properties, in particular low aqueous solubility and low oral bioavailability. Optimization of KU-55933 (**5**) has resulted in the discovery of second generation ATM inhibitors, such as KU-60019 (**6**) and KU-59403 (**7**), in which polar substituents have been appended to tricyclic core resulting in moderately improved potency and aqueous solubility.[48,49] KU-60019 (**6**) and KU-59403 (**7**) are potent inhibitors of ATM enzyme ($IC_{50}=0.006$ μM and 0.003 μM, respectively) whilst retaining high selectivity over ATR, DNAPK, mTOR, and PI3K (>270-fold and >300-fold, respectively). Cellular potency was also improved with KU-60019 (**6**) and KU-59403 (**7**) giving effective chemosensitization at a concentrations of 3 μM and 1 μM, respectively, whereas concentrations of 10 μM were required to observe similar effects with KU-55933 (**5**). When dosed at 50 mg kg^{-1} i.p., KU-59403 (**7**) showed tumor concentrations considered above those required to deliver effective chemosensitization for 4 h. Whilst administration of KU-59403 (**7**) alone did not result in any significant antitumor efficacy, when dosed at either 12.5 or 25 mg kg^{-1} i.p. bis in die, twice daily (BID) for 5 days, in combination with etoposide, a dose-dependent increase in tumor growth delay was observed. A similar dosing schedule combining KU-59403 (**7**) with irinotecan has also been shown to be effective without any obvious unacceptable adverse effects on the animals (as measured by body weight loss). KU-60019 (**6**) has been reported to radiosensitize human glioma cells in vitro and significantly reduce migration, invasion, and growth.[50] Glioblastoma multiforme (GBM) is the most common and lethal primary brain tumor in adults where current treatment (surgery followed by fractionated radiotherapy and treatment with temozolomide) provides a median survival of just 12–15 months.[51] The poor survival is attributed to an intrinsic radioresistance and chemoresistance with around one third of GBM tumors containing p53 mutations

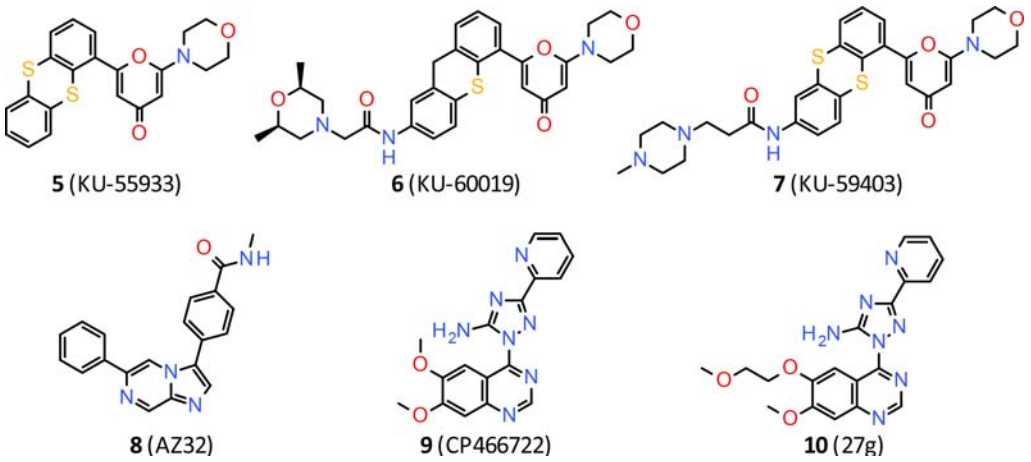

Fig. 2 Structures of selective ATM inhibitors in the public domain.

and ~80% harboring other cell-cycle checkpoint deficits. The clear unmet medical need for treating GBM combined with the potential for ATM inhibitors to radiosensitize GBM cells makes this an exciting opportunity to demonstrate the clinical benefit of small molecule ATM inhibition. KU-60019 (**6**) has low blood–brain barrier (BBB) penetration and therefore only low concentrations of compound are observed in brain tissue following systemic administration; however, when dosed intercranially (through the use of minipumps) and combined with radiation, KU-60019 (**6**) has shown a significant increase in the survival of mice bearing human orthotopic gliomas.[52] More recently, AstraZeneca has disclosed AZ32 (**8**), a specific inhibitor of ATM possessing good BBB penetration in mouse. AZ32 (**8**) is a potent inhibitor of ATM enzyme ($IC_{50} < 0.006$ μM) with moderate potency against ATM in cell ($IC_{50} = 0.31$ μM) and good selectivity over ATR (ATR cell $IC_{50} > 23$ μM) whilst also possessing high permeability in MDCK cell lines overexpressing MDR1 (P_{app} A–B $= 33.7 \times 10^{-6}$ cm s^{-1}, efflux ratio = 0.4).[53] Following an oral dose of 200 mg kg^{-1} in mice AZ32 (**8**) achieves free brain concentrations in excess of the cellular IC_{50} for approximately 22 h. When combined with IR, this dose of AZ32 (**8**) results in a significant increase in survival of mice bearing orthotopic gliomas. The quinazoline CP466722 (**9**) was identified following a screen of 1500 compounds from the Pfizer compound library and shown to be a moderately potent inhibitor of ATM in cells ($IC_{50} = 0.37$ μM). CP466722 (**9**) does show activity against a number of additional kinases including PI3K and PIKK enzymes (significant activity against 106 out of 451 kinases when tested at 3 μM); however, little activity against either ATR or DNAPK was observed in cells.[54] CP466722 (**9**) has low aqueous solubility (28 μM) and high clearance with a short half-life in mice (CL = 160 mL h^{-1}, $t_{1/2} = 1$ h) and was, therefore, unsuited for further in vivo assessment. Optimization of this scaffold identified 27 g (**10**) which although showing slightly reduced ATM potency ($IC_{50} = 1.2$ μM), displays increased selectivity when tested against a panel of diverse kinases (significant activity against 41 out of 451 kinases when tested at 3 μM), reduced propensity for oxidative metabolism and improved in vivo pharmacokinetics in mouse ($t_{1/2} = 19$ h).[55] Similar efficacy was observed for both CP466722 (**9**) and 27 g (**10**) when evaluated at 10 μM in a clonogenic assay in which MCF7 cells were treated with compound and irradiated with increasing doses of IR (0, 2, and 4 Gy).

Despite the emergence of small molecule inhibitors of ATM with encouraging selectivity profiles there remains a clear need to develop molecules with increased potency and selectivity combined with physiochemical and pharmacokinetic properties suitable for in vivo target validation. Such developments in compound activity and properties will be vital to provide compounds suitable for the clinical evaluation of ATM inhibition.

8.07.2 Discovery of Novel, Potent, and Selective ATM Inhibitors With Oral Bioavailability

A directed screen of approximately 15,000 compounds from the AstraZeneca compound collection was initiated to identify compounds with the ability to inhibit the phosphorylation of ATM on serine 1981 in HT29 cells following irradiation. Analysis of the data generated identified the quinoline carboxamide hit **11** (Fig. 3A) as a moderately potent inhibitor of ATM in cells ($IC_{50} = 0.82$ μM) but with selectivity for ATM over ATR, as measured by inhibition of pCHK1 in HT29 cells following treatment with 4-nitroquinoline 1-oxide ($IC_{50} = 4.4$ μM). Compound **11** was shown to be a potent inhibitor of ATM enzyme ($IC_{50} = 0.008$ μM) with moderate to good selectivity over closely related enzymes (>10-fold selective for ATM over DNAPK and PI3Kα and >100-fold selective over mTOR, PI3Kβ, and PI3Kγ).[56] Compound **11** also showed encouraging selectivity when assessed

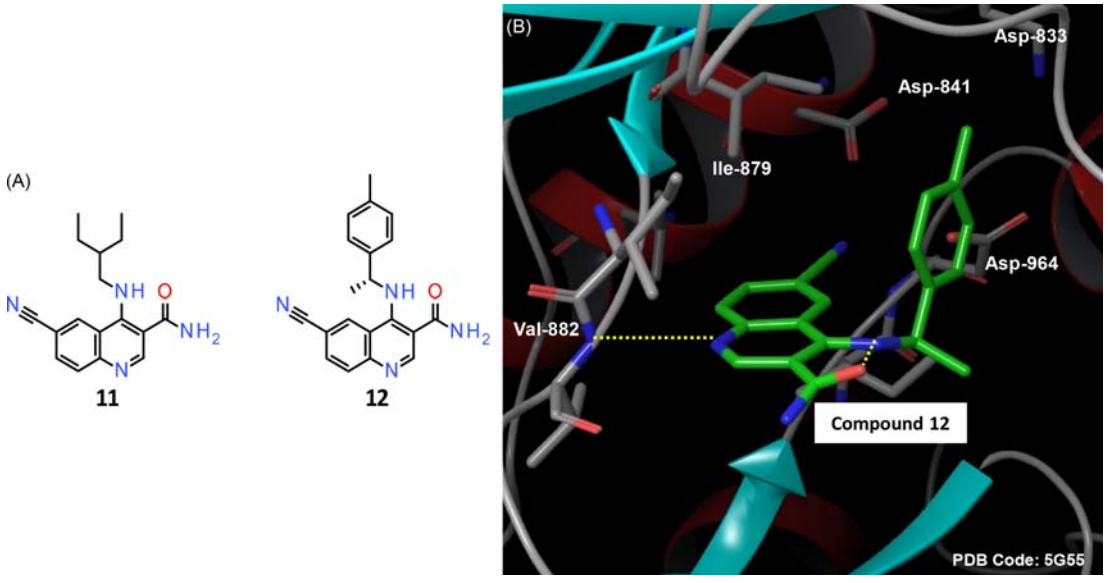

Fig. 3 (A) Structure of screening hit **11** and closely related PI3K inhibitor **12**. (B) X-ray structure of **12** bound into PI3Kγ (PDB code: 5G55).

against a diverse panel of kinases with only 8 of the 124 kinases tested showing >50% inhibition when tested at 1 μM. Despite the encouraging selectivity profile, the physicochemical properties of **11** were considered suboptimal with low aqueous solubility (19 μM), high intrinsic clearance (CL_{int}) in hepatocytes (rat $CL_{int}=74$ μL min^{-1} 10^6 $cells^{-1}$, human $CL_{int}=74$ μL min^{-1} 10^6 $cells^{-1}$), and activity against the hERG (human ether-a-go-go related gene) ion channel ($IC_{50}=2.3$ μM) all requiring optimization.[57,58] However, it was considered that the relatively high lipophilicity of this hit ($\log D_{7.4}=3.5$) may, in part, be responsible for these properties and, therefore, an optimization campaign was undertaken with the goal of increasing ATM cellular potency and selectivity whilst simultaneously optimizing physicochemical and pharmacokinetic parameters.

The use of X-ray crystal structure data to inform the optimization of small molecule kinase inhibitors is well documented but unfortunately no crystal structure of ATM exists; however, structural data is available for the closely related kinases PI3Kγ and mTOR.[59] Examination of existing near neighbors of **11** within the AstraZeneca collection highlighted compound **12** (Fig. 3A) a closely related compound with known activity against PI3K (PI3Kα enzyme $IC_{50}=0.0055$ μM). Structural data for **12** bound into the active site of PI3Kγ exists and, given the relatively high levels of homology between the ATP-binding sites of ATM and PI3K, it was felt that this data may be informative. Close inspection of the structure (Fig. 3B) shows the quinoline nitrogen forming a key interaction with the hinge region of the kinase as well as suggesting an opportunity to build out from both the C4 and C6 positions of this scaffold, thereby offering the potential to position substituents deeper into the binding pocket in an attempt to pick up additional constructive interactions with the protein surface. An internal hydrogen bonding interaction between the 4-amino substituent and the 3-carboxamide substituent can also be observed, presumably helping to organize the molecule in a bioactive conformation. Although **12** does not have appreciable activity against ATM in cells ($IC_{50}>30$ μM) we hypothesized that a similar binding mode may be adopted by **11** when bound into ATM and as such the optimization of both the 4-amino and 6-cyano susbstituents was prioritized.

SAR exploration quickly established that significant improvements in both ATM cellular potency and selectivity could be achieved by replacing the 6-cyano substituent with an aromatic group, in particular the 3-pyridyl isomer exemplified in **13** (Table 1). The positioning of the pyridine nitrogen appears key to maintain potency and selectivity with closely related analogs showing a significant reduction in both parameters; however, the lipophilic nature of **13** results in poor physicochemical properties, in particular, poor aqueous solubility and high turnover in hepatocyte incubations. Substitution on the pyridyl ring was tolerated when *para* to the quinoline core and it was appreciated that this might provide an opportunity to modulate lipophilicity through

the introduction of small polar functionality. Unfortunately, those substituents that retained the desired potency and selectivity profile, such as the methoxymethyl substituent present in **14**, had little observed impact on the physicochemical properties or on hERG affinity, although some improvements in metabolic stability were observed.

In parallel with the optimization of the 6-substituent, high throughput chemistry approaches were utilized to vary the 4-amino substituent with the intent of reducing the lipophilicity of the molecule. Such a design strategy resulted in the identification of **15** which, although showing a slight reduction in potency and selectivity when compared to **13**, shows a highly significant reduction in lipophilicity ($\Delta \log D_{7.4} = 2.1$) (Table 1). The concept of lipophilic ligand efficiency (LLE) has been widely reported in the literature and is routinely used within the Medicinal Chemistry community as a measure of compound quality to limit the optimization of less productive lipophilicity-driven interactions between inhibitor and protein.[60,61] When comparing the LLE (ATM Cell pIC_{50}–$\log D_{7.4}$) of **13** and **15**, a clear improvement is observed. The reduced lipophilicity of **15** results in dramatically improved physicochemical properties (i.e., increased metabolic stability and improved aqueous solubility) thereby validating the design strategy. Interestingly, the reduction in lipophilicity appears to have little impact on hERG affinity suggesting that reducing lipophilicity per se will not be sufficient to remove this potential liability. A range of bespoke chiral amines with metabolically stable functionality and relatively low lipophilicity is available within AstraZeneca as a result of a forward-looking Strategic Reagent Initiative program and the incorporation of such amines into the quinoline carboxamide scaffold resulted in the identification of compounds such as **16** and **17**.[62] Whilst the incorporation of these specific chiral amines has resulted in a slight increase in lipophilicity compared to **15**, this is more than compensated by an increase in ATM potency thus resulting in an improved LLE. The impact of this increased lipophilicity on both solubility and metabolic stability has been relatively minor resulting in compounds with a more attractive balance of properties. Whilst there still appears to be little correlation between lipophilicity and hERG affinity in this series it is interesting to note that the chiral pyrazole containing amine incorporated into **17** does appear to reduce hERG activity. The chirality of these amines is important for the biological activity with the majority of the ATM potency appearing to reside in a single enantiomer; however, the exact stereochemistry of the preferred enantiomer was found to vary depending on the amine introduced. Docking simulations utilizing an homology model of ATM were unable to adequately rationalize this observation. The combination of SAR understanding from both the 4-amino and the 6-substituent resulted in the identification of compound **18**, a potent and selective ATM inhibitor with promising physicochemical properties although still possessing activity against hERG. Compound **18** was selected for further profiling and given the external identifier of AZ31.

AZ31 (**18**) is a potent inhibitor of ATM enzyme ($IC_{50} = < 0.0012$ μM) with excellent selectivity over closely related enzymes (>500-fold selective over DNAPK and PI3Kα and >1000-fold selective over mTOR, PI3Kβ, and PI3Kγ). When tested against a diverse range of kinase targets AZ31 (**18**) inhibited 0 out of 126 kinases by >50% when tested at 1 μM. Assessment of permeability using Caco2 cells showed AZ31 (**18**) to have reasonable permeability (P_{app} A–B $= 5.2 \times 10^{-6}$ cm s^{-1}) and in vivo pharmacokinetic evaluation showed the compound to have low to moderate clearance combined with reasonable bioavailability in both rat and dog (CL = 18 and 50 mL $min^{-1}kg^{-1}$, $F = 46\%$ and 31% in rat and dog, respectively). AZ31 (**18**) showed good exposure in mice with an oral dose of 100 mg kg^{-1} quaque, once a day (QD) of AZ31 (**18**) giving unbound plasma exposures in excess of the ATM cell IC_{50} for approximately 24 h. The efficacy of AZ31 (**18**) was assessed in HT29 tumor-bearing immunocompromised mice following oral administration at 100 mg kg^{-1} QD, in combination with IR (2 Gy delivered on each of days 1–5 of the study) (Fig. 4A). Whilst AZ31 (**18**) treatment alone gave no benefit and IR alone gave only a modest benefit, the combination of AZ31 (**18**) and IR produced a significant reduction of tumor growth highlighting the radiosensitizing effect of ATM inhibition in this in vivo model. The ability for AZ31 (**18**) to potentiate the effect of DNA DSB inducing chemotherapy was also assessed in an SW620 (colorectal cancer cell line) xenograft model. Significant reduction in tumor growth was observed following oral administration of AZ31 (**18**) at 100 mg kg^{-1} QD combined with irinotecan dosed at 50 mg kg^{-1} Q7D i.p. (Fig. 4B). Interestingly in this model the regrowth of tumors was observed following the cessation of treatment; however, a second round of combination treatment again drives tumor regression. No monotherapy effect was seen in this model for AZ31 (**18**) and monotherapy efficacy for irinotecan was modest.

Brief examination of the SAR at other positions around the quinoline core uncovered that the incorporation of a fluorine into the 7-position reduces hERG affinity whilst having only a minor reduction of ATM potency, exemplified by **19** (Table 1). However, solubility was reduced in this instance. Substituents larger than fluorine appeared to result in a much more significant reduction in ATM potency; however, combination of the 7-fluoro with the pyrazole containing 4-amino substituent gave rise to compounds such as **20** which are potent, selective ATM inhibitors with significantly reduced hERG affinity when compared with AZ31 (**18**). Substitution at either the 2- or 8-positions was not tolerated, which is consistent with such groups disrupting the hydrogen bond between the quinoline nitrogen and the hinge region of the kinase. Substitution at the 5-position also leads to a significant reduction in potency and it was postulated that this substitution pattern will interfere with the internal hydrogen bond formed between the 4-amino and 3-carboxamide motifs. The importance of this internal hydrogen bond was also supported by the observation that potency is significantly reduced, or completely removed, when replacing the 4-amino substituent with a 4-alkoxy substituent, or when removing the 3-carboxamide motif. These observations support the original hypothesis concerning the similar binding mode of the quinoline carboxamide scaffold in ATM and PI3K.

Compound **20** retains the excellent enzyme potency and selectivity observed for AZ31 (**18**) (**20**: ATM enzyme $IC_{50} = < 0.0006$ μM with >500-fold selectivity over DNAPK and PI3Kα and >1000-fold selective over mTOR, PI3Kβ, and PI3Kγ) with 3 out of 386 kinases inhibited by >50% when tested at 1 μM against a diverse panel of kinases. The permeability of **20** was good (Caco-2 P_{app} A–B $= 14 \times 10^{-6}$ cm s^{-1}) and reasonable in vivo pharmacokinetic profiles were observed in rat and dog (CL = 13 and 13 mL $min^{-1}kg^{-1}$, $F = 29\%$ and 71%, respectively). Good oral exposure in mouse was observed with a dose of 50 mg kg^{-1} BID of **20** giving unbound plasma exposures in excess of the ATM cell IC_{50} for approximately 24 h. The

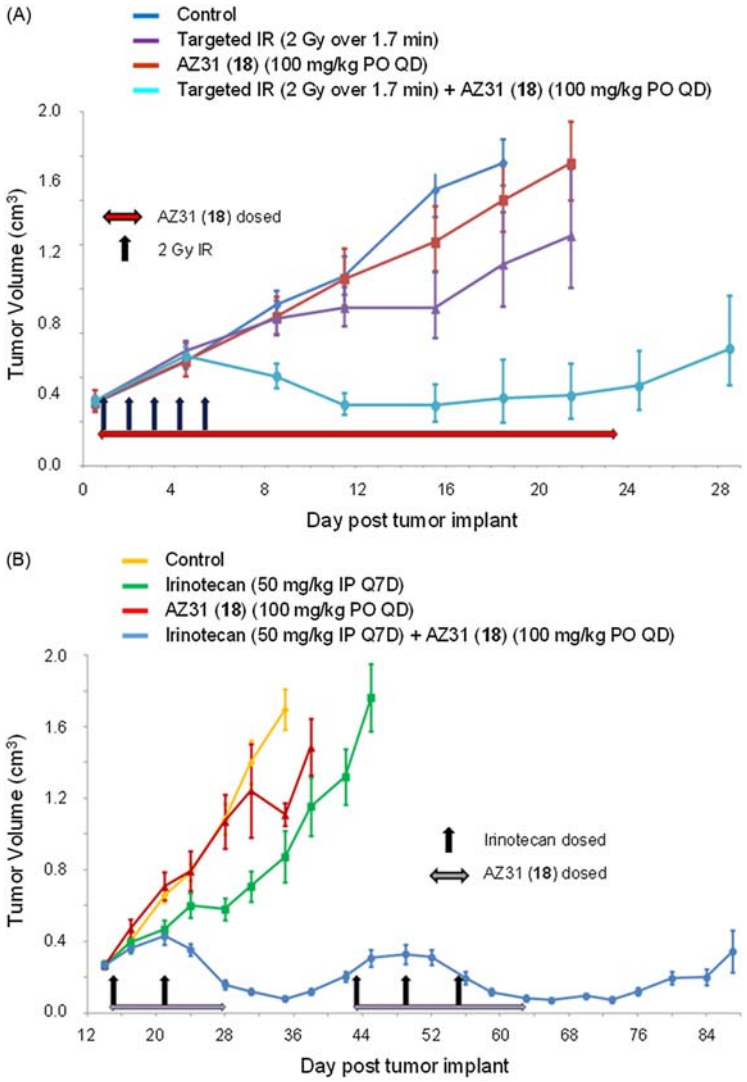

Fig. 4 (A) AZ31 (**18**) potentiates the efficacy of IR in an HT29 xenograft model. (B) AZ31 (**18**) potentiates the efficacy of irinotecan in an SW620 xenograft model.

efficacy of **20** was explored in SW620 tumor-bearing immunocompromised mice following oral administration at 50 mg kg^{-1} BID (dosed on days 2–4 of a weekly cycle) in combination with irinotecan dosed at 50 mg i.p. Q7D (Fig. 5). This combination schedule was tolerated and gave a significant tumor growth reduction following a 3-week regimen which was found to be statistically significant and greater than the reduction observed with irinotecan treatment alone and highlights that continuous inhibition of ATM is not required for efficacy in this model. This observation may allow the opportunity to further increase the therapeutic margin of an ATM inhibitor, combined with a DNA DSB inducing agent, in the clinic through the careful selection of an appropriate schedule.

8.07.3 The Importance of Predicting Dose to Man and Maximum Absorbable Dose

The failure of candidate drugs during clinical trials as a result of unsuitable drug metabolism and pharmacokinetic properties (DMPK) has been highlighted as one of the major reasons for attrition within the clinical development of new therapies and as a result significant attention is placed on these parameters during candidate optimization and final selection.[63–65] One of the key parameters to consider during candidate selection is the predicted dose required to achieve the clinical exposures necessary to elicit a desired biological response. Many methods of predicting clinical doses exist including the method described by McGinnity et al. which takes into account the human pharmacokinetic parameters of clearance and volume of distribution as well as protein binding, gut absorption, bioavailability, and dosing interval. This method has been validated using a number of marketed drugs

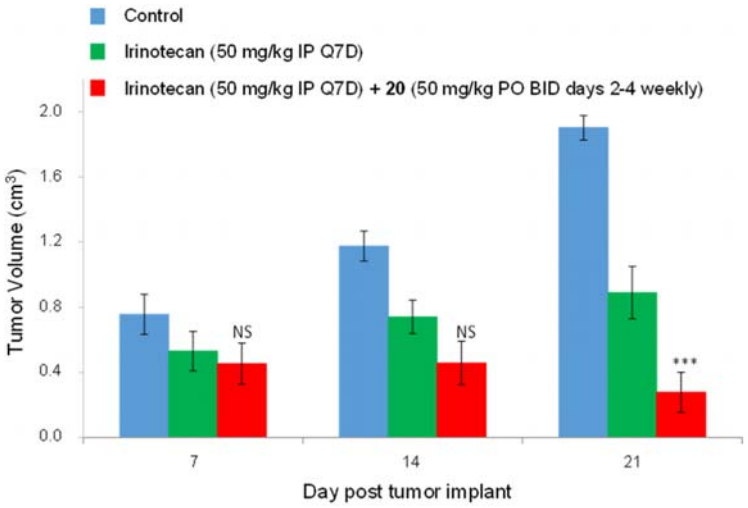

Fig. 5 Compound **20** potentiates the efficacy of irinotecan in an SW620 xenograft model.

and assumes that efficacy will be observed if unbound plasma concentrations exceed a defined threshold (defined by in vitro or in vivo measures of biological potency) for a defined period.[66] As a result many companies, including AstraZeneca, routinely use predicted clinical dose as an optimization parameter and to assist candidate selection.[67] In addition to identifying candidate drugs with low predicted clinical dose, it is important to understand the developability of the selected candidate. Oral administration remains the preferred route of administration for many new therapies due to ease of use for the intended patients, but poor absorption characteristics for an orally administered candidate will require significant investment in formulation approaches thus adding significant cost and time to the clinical development program; for such compounds the developability would be considered low. In extreme cases poor absorption characteristics may actually prevent the candidate from achieving sufficient clinical exposure to properly test the intended biological hypothesis. One of the parameters that has recently come to prominence when looking to assess the developability of a compound is the maximum absorbable dose (D_{abs}).[68–70] Values for D_{abs} can be predicted using computational simulation software such as GastroPlus from easily measured in vitro parameters, such as aqueous solubility and permeability, combined with knowledge of intestinal surface area and transit times. D_{abs} has been shown to correlate well with in vivo bioavailability for cases where solubility is moderate to good. For compounds with poor aqueous solubility it is important to assess solubility in media which better mimics the small intestinal lumen. In order to minimize the risk of being unable to test a biological hypothesis in the clinic and to simplify clinical development, where possible AstraZeneca has adopted the approach of selecting compounds with a low predicted clinical dose (<50 mg) and a significant margin between the predicted clinical dose and the D_{abs} ($D_{abs} > 10$ times the clinical dose).

Several methods exist for the prediction of human pharmacokinetics and subsequent predicted clinical efficacious dose including allometry-based methods and more complex physiologically based pharmacokinetic (PBPK) models.[71,72] The use of PBPK modeling for AZ31 (**18**) predicted relatively low clearance in human; however, the relatively modest volume of distribution predicted for this neutral compound resulted in only a modest predicted half-life ($\sim$6 h). This, when combined with other key parameters, predicted that a dose of 430 mg QD would be required to achieve a free plasma concentration in excess of the determined ATM IC_{50} for 24 h (thereby replicating the level and duration of target engagement observed at efficacious doses in the preclinical efficacy studies). It was also appreciated that these predicted parameters would result in relatively narrow margin for AZ31 (**18**) between predicted maximum concentration (C_{max}), when corrected for protein binding, and hERG affinity which could also introduce further risk during development. An analogous modeling approach suggests that despite a low predicted clearance for **20**, the low volume of distribution will result in a half-life of $\sim$4 h. This relatively short half-life means that a dose of either 700 mg QD or 88 mg BID would be required to deliver the duration and extent of target engagement believed necessary for clinical efficacy. Whilst successful candidates have progressed with higher clinical doses than these, the relatively low differential between the predicted doses and the predicted D_{abs} (AZ31 (**18**) $D_{abs} = 2000$ mg; **20** $D_{abs} = 530$ mg) was a cause of concern and highlighted the potential for further optimization to identify a candidate with lower predicted efficacious clinical dose and an increased margin between predicted dose and predicted D_{abs}. When considering the factors important in predicting both human pharmacokinetics and clinical doses it is important to realize that different parameters can have a greater or lesser impact; for example, whilst increasing potency (once corrected for protein binding changes) will always reduce dose predictions in a proportional manner, the increase of predicted half-life can have a much more profound influence (especially in those cases where the predicted half-life is significantly shorter than the required duration of biological target engagement). Compounds AZ31 (**18**) and **20** are predicted to have relatively short half-lifes in man and therefore, when considering opportunities to reduce the predicted clinical dose of these compounds, the optimization of human half-life was considered a promising strategy. The relatively low metabolic turnover of these compounds suggests that a strategy to increase the volume of distribution (V_{ss}) would constitute

a more profitable strategy for increasing predicted half-life than one of further reducing clearance. Many studies have been reported in an attempt to accurately describe the molecular properties that influence V_{ss} and one of the more dominant parameters is often ionization state, with acid compounds tending to show low V_{ss}, neutral compounds showing moderate values, and bases often showing significantly higher values.[73] Therefore, a strategy to incorporate basic substituents into an ATM inhibitor could be regarded as a sensible strategy to reduce human dose predictions.

8.07.4 The Discovery of AZD0156: A First in Class Potent, Selective and Orally Available ATM Inhibitor Suitable for Clinical Evaluation

8.07.4.1 Identification of a Scaffold With Increased Permeability

Thorough SAR exploration of both the 4- and 6-substituents of the quinoline carboxamide scaffold has resulted in a wealth of data to aid SAR understanding and a detailed retrospective analysis of the data highlighted the potential to incorporate a basic substituent in 6-position, exemplified by **21** (Fig. 6). Compound **21** is a highly potent inhibitor of ATM in cells ($IC_{50} = 0.0086$ μM) with excellent selectivity over ATR ($IC_{50} > 30$ μM) and provides evidence that a basic substituent in this region can provide a constructive interaction with the protein. However, despite the promising levels of potency and selectivity observed, the permeability of **21** was low and a significant efflux liability was observed (MDCK-MDR1 P_{app} A–B $= 0.8 \times 10^{-6}$ cm s^{-1}, efflux ratio = 28). Given the reasonably high lipophilicity of **21** ($\log D_{7.4} = 2.8$), the low permeability was presumed to be driven by a combination of the number of hydrogen bonding groups (in particular hydrogen bond donating groups) and the presence of a basic center. These data suggest that it would be a significant challenge to identify a basic compound from the quinoline carboxamide scaffold that would have the required permeability profile without increasing lipophilicity to a level likely to severely compromise aqueous solubility and metabolic stability (i.e., $\log D_{7.4} > 3$); therefore, it was considered essential that a new, inherently more permeable scaffold be found to facilitate continued optimization.

Examples in which aromatic rings have been removed from a template and replaced with a "pseudo-ring" system constrained by internal hydrogen bonding are well known and indeed this is a commonly used strategy when looking to "scaffold hop" to different templates or to reduce either the lipophilicity or aromatic content of a scaffold.[74] However, it was appreciated that the quinoline carboxamide scaffold already contains such a "pseudo-ring" between the 4-amino substituent and the 3-carboxamide substituent, and that the contribution of these motifs to the overall number of hydrogen bond donors is likely to contribute significantly to the relatively poor permeability of this scaffold. Therefore, we proposed a strategy in which the "pseudo-ring" is replaced by an appropriate covalently bonded cyclic system that would ensure the substituents are correctly positioned to maintain potency whilst simultaneously reducing the hydrogen bond donor count. A number of possible tricyclic systems with the potential to fulfill these desired criteria can be conceived but knowledge gained from the screening of existing internal equity suggested that the imidazo[5,4-c]quinolin-2-one scaffold, such as that present in **22**, was both synthetically tractable and known to have activity against related PIKK kinases (Fig. 6). Indeed, the dual PI3K/mTOR inhibitor NVP-BEZ235 (**4**), which is also known to be a potent inhibitor of a number of PIKK enzymes including ATM, contains this same imidazo[5,4-c]quinolin-2-one scaffold thus providing further evidence of the ability of this scaffold to inhibit ATM, whilst at the same time highlighting the challenge of achieving the required level of selectivity.

Comparison of quinoline carboxamide **15** with the analogous imidazo[5,4-c]quinolin-2-one **22** shows that ATM potency is broadly maintained (**15**: ATM cell $IC_{50} = 0.95$ μM, **22**: ATM cell $IC_{50} = 0.36$ μM); however, the selectivity of **22** against closely related kinases is significantly reduced and indeed **22** appears to have greater affinity for ATR than for ATM (**22**: ATR cell $IC_{50} = 0.087$ μM). Pleasingly, imidazo[5,4-c]quinolin-2-one **22** does show the anticipated increase in permeability, alongside a concomitant reduction in efflux, when compared to quinoline carboxamide analog **15** (**22**: MDCK-MDR1 P_{app} A–B $= 30 \times 10^{-6}$ cm s^{-1}, efflux ratio = 1.5, Caco2 P_{app} A–B $= 60 \times 10^{-6}$ cm s^{-1}, efflux ratio = 0.6; **15**: MDCK-MDR1 P_{app} A–B $= 4.8 \times 10^{-6}$ cm s^{-1}, efflux ratio = 10, Caco2 P_{app} A–B $= 15 \times 10^{-6}$ cm s^{-1}, efflux ratio = 4.5). This improved permeability is achieved with only a modest increase in lipophilicity ($\Delta \log D_{7.4} = 0.3$) thus supporting the hypothesis that the imidazo[5,4-c]quinolin-2-one is an inherently more permeable scaffold whilst also highlighting the key role that the number of hydrogen bond donors plays in limiting permeability for the quinoline carboxamide scaffold. Despite the subtle increase in lipophilicity, **22** retains good stability in hepatocyte incubations (rat $CL_{int} = 9.4$ μL min^{-1} 10^6 $cells^{-1}$, human $CL_{int} < 4.9$ μL min^{-1} 10^6 $cells^{-1}$), although aqueous solubility is reduced (12 μM) and some affinity for hERG is still apparent ($IC_{50} = 11$ μM).

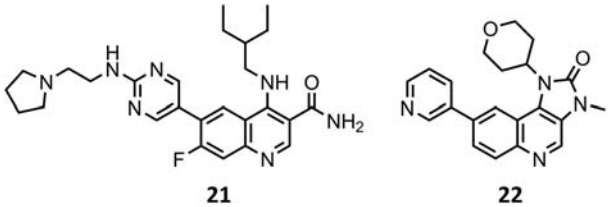

Fig. 6 Structures of **21** and **22**.

8.07.4.2 Achieving ATM Selectivity With Imidazo[5,4-c]quinolin-2-one Based Compounds

Initial SAR exploration of this new scaffold highlighted a high degree of similarity between the 8-position of the imidazo[5,4-c]quinolin-2-one core and the analogous 6-position in the quinoline carboxamide scaffold. This observation is exemplified by **23** in which the introduction of the methoxymethyl substituted pyridine motif in the 8-position has both improved ATM potency and importantly reestablished a high level of selectivity for ATM over ATR (Table 2). Compound **23** remains stable in human hepatocyte incubations and continues to show high levels of permeability and low levels of efflux. The aqueous solubility of **23** remains low. The incorporation of a fluorine in the 7-position of the imidazo[5,4-c]quinolin-2-one scaffold, **24**, again highlights similarity in the SAR between this scaffold and the quinoline carboxamides with a slight reduction in potency observed but, in this instance, an improvement in aqueous solubility. However, divergent SAR was observed when comparing the 4-amino substituent of the quinoline carboxamide scaffold with the analogous 1-position of the imidazo[5,4-c]quinolin-2-one core. The introduction of previously optimized chiral substituents into the imidazo[5,4-c]quinolin-2-one scaffold, exemplified by **25**, failed to deliver the anticipated improvement in potency and a reduction in LLE was observed. Following a detailed exploration of this position it was found that small cyclic alkyl groups, such as the methoxycyclobutyl motif in **26**, are amongst the most favored substituents. Compound **26** showed good pharmacokinetic properties in rat with good bioavailability (>100%) and low to moderate clearance (22.5 mL min^{-1} kg^{-1}); however, as anticipated for a neutral compound the V_{ss} was relatively low (0.98 L kg^{-1}) and therefore resulted in a modest half-life (2.7 h). Compound **26** provides a relatively potent and highly selective start point with excellent permeability from which to explore the introduction of basic substituents intended to increase pharmacokinetic half-life through the modulation of V_{ss}.

8.07.4.3 Optimization of Basic Imidazo[5,4-c]quinolin-2-ones

Combining the newly acquired SAR understanding of the imidazo[5,4-c]quinolin-2-one scaffold with the detailed understanding of the quinoline carboxamide SAR resulted in the design of compound **27** containing a basic chain similar to that contained in **21**. Compound **27** shows a significant increase in ATM potency again suggesting that a basic center in this region is able to form a constructive interaction with the protein; furthermore, **27** displays excellent levels of selectivity for ATM over ATR (Table 3). The incorporation of a polar, ionizable group results in a large reduction in log $D_{7.4}$ and a dramatic increase in aqueous solubility but has a negative impact on permeability. However, the inherently more permeable nature of the imidazo[5,4-c]quinolin-2-one scaffold means that despite this impact the permeability of **27** remains moderate. Compound **27** is stable in hepatocyte incubations and has only modest activity against the hERG ion channel. The reduced lipophilicity of **27**, combined with the increased ATM potency, results in a clear improvement in compound quality (as measured by LLE). The influence of hydrogen bond donors on permeability has already been established and so a further improvement in permeability was sought through the removal of the NH linking the basic chain to the core. A range of different linkers were investigated with the replacement of the NH by oxygen (exemplified by **28**) found to be well tolerated and give a significant improvement in permeability. Although the LLE for **28** is considerably lower than that for **27** the overall balance of properties was considered advantageous. Further exploration of oxygen linked basic chains highlighted the importance of the linker length with the three carbon chain present in **29** proving optimal; in addition, the reduced hERG activity and high aqueous solubility of basic compounds such as **29** negates any benefit offered by the incorporation of the 7-fluoro substituent thus allowing its removal and thereby providing an additional increase in ATM potency. Compound **29** is an extremely potent and selective inhibitor of ATM with good solubility, moderate turnover in human

hepatocytes, and moderate to good permeability. Pharmacokinetic evaluation of **29** in rat showed low to moderate clearance (19.5 mL $min^{-1}kg^{-1}$) and good bioavailability (50%). Pleasingly, the basic nature of **29** had the desired impact by increasing V_{ss} (5.7 L kg^{-1}) and therefore gave an increased half-life (~5 h). The higher V_{ss} predicted for **29** in man offsets the predicted moderate to high predicted clearance resulting in a predicted half-life of ~15 h. The longer predicted half-life of **29**, combined with the much improved potency means that the predicted clinically efficacious dose is now extremely low (<10 mg) with a large margin to the predicted D_{abs} (>3000 mg). This dramatic reduction of predicted dose and large differential between predicted dose and D_{abs} means that compounds such as **29** can be considered to carry a significantly reduced risk, when compared to compounds such as AZ31 (**18**) or **20**, if progressed to the clinic. Significant exploration of the basic substituent highlighted the ability to replace the dimethylamino motif with other simple bases, such as azetidine, pyrrolidine, and piperidine; however, closely related bases such as morpholine were largely inactive highlighting the restricted nature of the SAR in this position.

In the quinoline carboxamide series the SAR for different regions of the molecule was found to be broadly additive, to establish if the same might be true in the imidazo[5,4-c]quinolin-2-one scaffold a number of compounds were designed which combined preferred groups identified in different regions. These studies showed the SAR to again be broadly additive in nature thereby helping inform future design and resulted in the identification of a number of potent and selective molecules with encouraging physicochemical properties. Amongst these compounds, **30** was identified as a subnanomolar inhibitor of ATM in cells, with >10,000-fold selectivity over ATR, good solubility, and low turnover in human hepatocytes. Compound **30** was considered to possess an extremely attractive balance of properties and was consequently selected for further profiling and given the internal/external identifier AZD0156.[75]

8.07.4.4 Profile of AZD0156

AZD0156 (**30**) is an exceptionally potent inhibitor of ATM with excellent selectivity over closely related targets in both enzyme and cell based assays (Table 4). When screened at 1 μM against a panel of 397 kinases AZD0156 (**30**) showed excellent general kinome selectivity with activity above 65% inhibition observed for only 5 kinases (HASPIN: 67%; JAK1(JH2domain-pseudokinase): 67%; LRRK2: 87%; mTOR: 93%; PIK4CB: 70%). A stable crystalline form of AZD0156 (**30**) was identified and shown to have good aqueous solubility. AZD0156 (**30**) has high levels of unbound drug in rat, dog, and human plasma, is permeable with good pharmacokinetics in both rat and dog, and does not inhibit any of the five major isoforms of human cytochrome p450 at the

concentrations tested (Table 5). Detailed in vitro metabolite identification studies have suggested that the major route of metabolism in man will be FMO mediated *N*-oxidation of the basic dimethylamino moiety. Independent synthesis of this *N*-oxide has allowed detailed profiling and shown it to be a potent and selective ATM inhibitor (ATM cell $IC_{50}=0.005\ \mu M$, ATR cell $IC_{50}=10\ \mu M$), albeit significantly less potent that AZD0156 (**30**). Whilst the potential for this metabolite to contribute to efficacy is appreciated, metabolic conversion of AZD0156 (**30**) to the *N*-oxide in hepatocyte incubations is relatively low ($\leq 10\%$ in rat, dog, and human hepatocytes), and only low levels were detected in rat and dog in in vivo studies ($<10\%$ of parent by AUC).

The ability of AZD0156 (**30**) to potentiate the efficacy of DNA DSB inducing agents was assessed in vitro by combining with either SN-38 (the active agent of the topoisomerase I inhibitor irinotecan) or olaparib (a PARP inhibitor which indirectly induces DNA DSBs by trapping PARP on DNA).[76] In SW620 cells the IC_{50} for SN-38 is reduced when combined with AZD0156 (**30**) (Fig. 7A) thereby showing that AZD0156 (**30**) can potentiate the efficacy of SN-38. A similar effect was observed on the IC_{50} of olaparib when combined with AZD0156 (**30**) in FaDu cells (Fig. 7B) demonstrating that AZD0156 (**30**) can potentiate the efficacy of olaparib. AZD0156 (**30**) shows good exposure in mice thereby allowing the in vivo assessment of ATM inhibition in mouse xenograft models. When combined with irinotecan dosed at 50 mg kg^{-1} i.p. Q7D, AZD0156 (**30**) dosed orally at 20 mg kg^{-1} QD (on days 2–4 of a weekly cycle) showed clear synergy and caused tumor regression in an SW620 xenograft model in immunocompromised mice (Fig. 8A). No appreciable efficacy was observed in this model when AZD0156 (**30**) was dosed as a monotherapy. The addition of AZD0156 (**30**), dosed orally at 5 mg kg^{-1} QD (on days 1–3 of a weekly cycle), to olaparib, dosed orally at

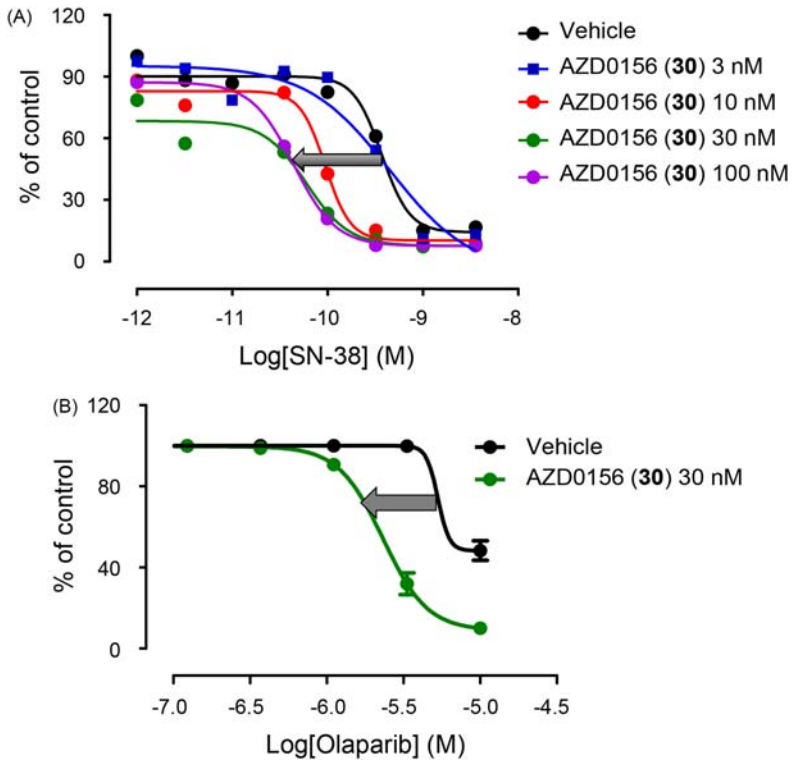

Fig. 7 (A) AZD0156 (**30**) potentiates the in vitro efficacy of SN-38 (IC_{50} shift on addition of AZD0156 (**30**) highlighted by *gray arrow*). (B) AZD0156 (**30**) potentiates the in vitro efficacy of olaparib (IC_{50} shift on addition of AZD0156 (**30**) highlighted by *gray arrow*).

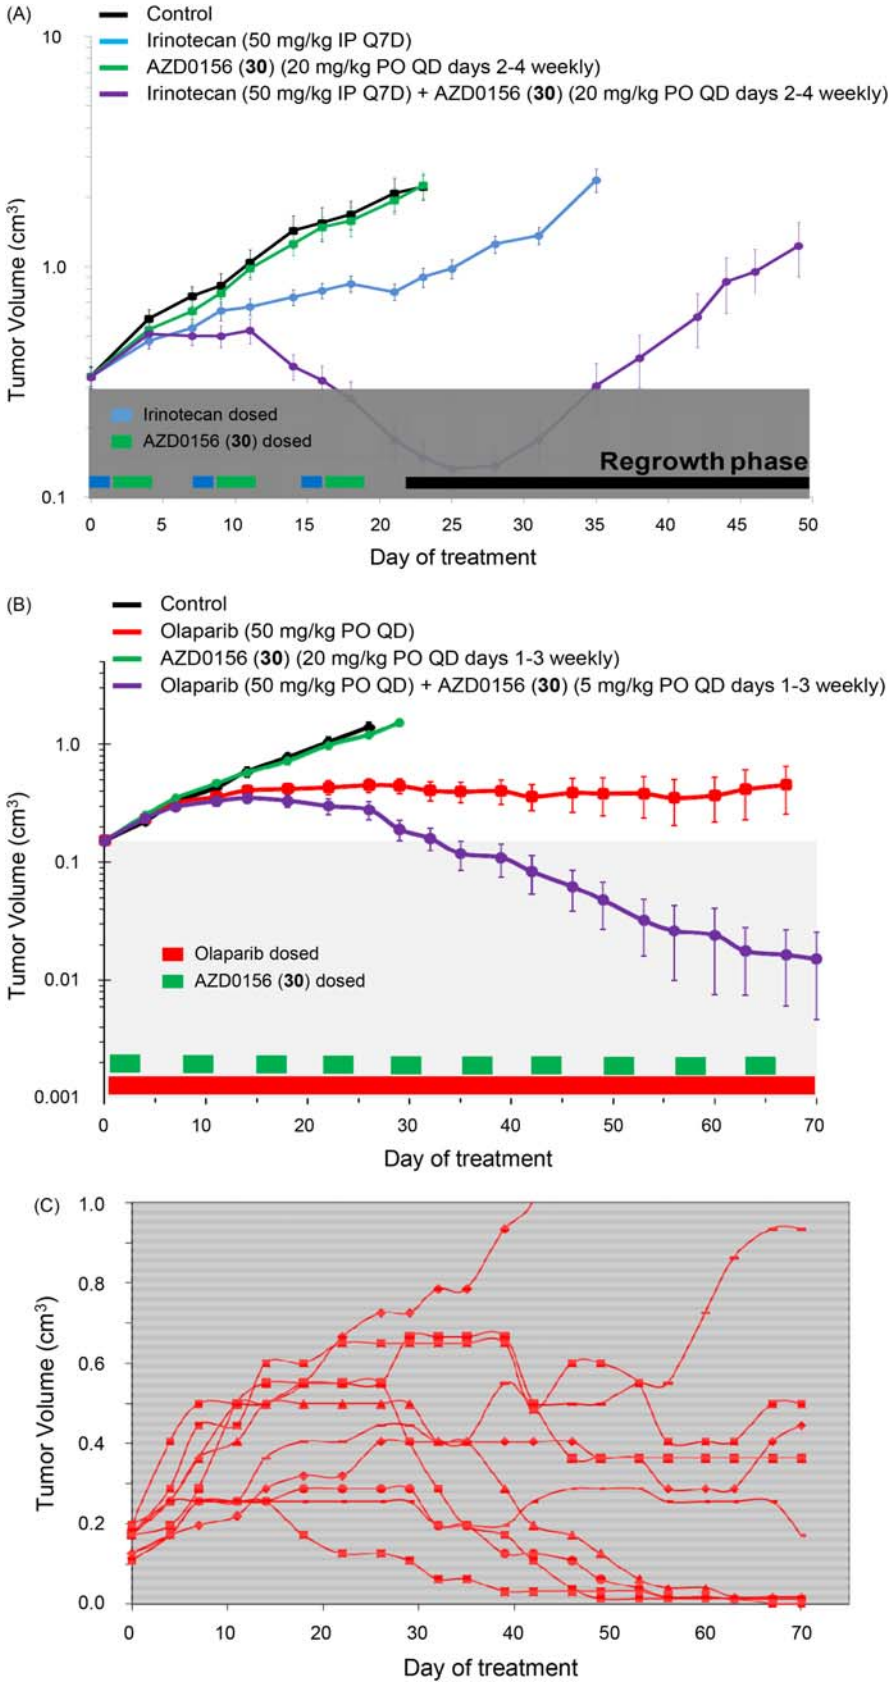

Fig. 8 (A) AZD0156 (**30**) potentiates the efficacy of irinotecan in an SW620 xenograft model. (B) AZD0156 (**30**) potentiates the efficacy of olaparib in a HBCx-10 patient derived tumor xenograft model. (C) 4 out of 10 mice show tumor regressions in a HBCx-10 patient derived tumor xenograft model following treatment with olaparib (50 mg kg^{-1} PO QD). (D) 9 out of 10 mice show tumor regressions in a HBCx-10 patient derived tumor xenograft model following treatment with olaparib (50 mg kg^{-1} PO QD) and AZD0156 (**30**) (5 mg kg^{-1} PO QD days 1–3 weekly).

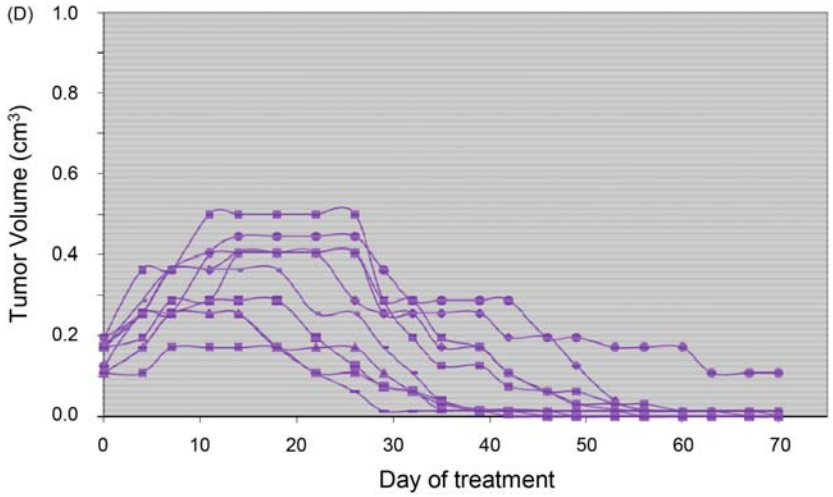

Fig. 8 (*continued*).

50 mg kg^{-1} QD, also resulted in clear synergy and tumor regression when examined in immunocompromised mice bearing HBCx-10 patient derived tumors (Fig. 8B). HBCx-10 is a ductal adenocarcinoma with mutated Brca2, mutated TP53, no HER2 overexpression and no PR/ERα overexpression (i.e., it is triple-negative) which is sensitive to monotherapy treatment with olaparib when used as a mouse xenograft model.[77] The impact of the combination is arguably more apparent when examining the tumor growth in individual animals from the study. For mice treated with olaparib alone a range of effects were observed with 4 out of 10 mice showing tumor regression (Fig. 8C). However, 9 out of 10 mice treated with a combination of AZD0156 (**30**) and olaparib showed tumor regression clearly highlighting the ability of ATM inhibition to sensitize tumors to olaparib treatment (Fig. 8D).

PBPK based modeling suggests that AZD0156 (**30**) is likely to have a half-life of ~10 h in man and is predicted to give good oral bioavailability. Early estimates of the efficacious clinical dose, based on achieving unbound concentrations in excess of the cellular ATM IC_{50} for 24 h, are low (<10 mg) and show an excellent margin to the predicted D_{abs} (>4000 mg), thereby suggesting that AZD0156 (**30**) has a relatively low risk of being unable to achieve concentrations in the clinic suitable to test the biological hypothesis. Toxicological evaluation of AZD0156 (**30**) in both rats and dogs supported progression to the clinic and AZD0156 (**30**) is currently being evaluated in a Phase I clinical trial in combination with olaparib.

8.07.5 Conclusion

Targeting the DDR of cancer cells provides an exciting opportunity to treat cancer by exploiting the inherent differences between cancerous and normal cells. As a key regulator of the response and repair of cytotoxic DNA DSBs, ATM provides an attractive pharmacological target. Previous disclosed ATM inhibitors have hinted at the potential for ATM inhibition to enhance the efficacy of both radiotherapy and DSB-inducing chemotherapies but limitations in either their potency, selectivity, or pharmacokinetic properties have restricted their utility. A focused screen of compounds in the AstraZeneca compound collection, followed by an iterative optimization campaign, resulted in the identification of novel, potent, selective, and orally available ATM inhibitors such as AZ31 (**18**) and **20**. Such compounds have played an important role in helping to validate the potential of ATM inhibition to potentiate both IR and chemotherapy in disease relevant in vivo models. Candidate selection strategies focused on identifying compounds with a low predicted clinically efficacious dose and high developability, highlighted opportunities to further improve compound profiles to reduce DMPK risks. In particular, the potential to increase pharmacokinetic half-life, thereby significantly reducing clinical dose, was appreciated and a strategy of increasing V_{ss} was adopted. To allow the successful optimization of V_{ss} a more permeable scaffold was required and knowledge of the likely bioactive conformation, alongside an understanding of the molecular properties contributing to permeability, resulted in the discovery of potent and selective compounds from an imidazo[5,4-c]quinolin-2-one scaffold. Introduction of basic substituents to this permeable scaffold led to further improvements in potency and pharmacokinetic properties resulting in compounds with low predicted dose and high predicted developability. The discovery of AZD0156 (**30**), an extremely potent and selective ATM inhibitor with good physicochemical properties and preclinical pharmacokinetics, has allowed more detailed in vivo target validation and has now entered clinical trials.

One of the key challenges facing the successful clinical development of ATM inhibitors will be to understand how best to combine with the variety of DSB inducing agents, and which patients will respond best to such combinations. As the use of AZD0156 (**30**) further develops our understanding of the biology and potential of ATM inhibition additional opportunities for

rational combinations, or even for monotherapy treatment, may well emerge.[78] The potential for ATM inhibition to combine with radiotherapy is also an area of active research and the importance of the BBB in the potential to treat patients with brain tumors (such as GBM) will need to be established to ensure that clinical agents with suitable profiles can be developed. The biology of ATM is known to include its activation by ROS and the emergence of high-quality ATM inhibitors will allow more detailed investigations into these areas and may uncover the potential for ATM inhibition outside of cancer therapies. For example, recent publications suggest that ATM inhibition may have therapeutic potential in Huntingdon's disease.[79]

The identification and subsequent clinical development of AZD0156 (**30**) will provide a significant step forward in the understanding of targeting both ATM and the DDR in general and has the potential to provide a therapy that will make a significant improvement in the life of patients.

Acknowledgments

The author would like to acknowledge the contributions of all the members of the project team responsible for the discovery and profiling of AZD0156 (**30**) and in particular the contributions of Bernard Barlaam, Nicola Colclough, Elaine Cadogan, Richard Ducray, Giles Ouvry, Philip MacFaul, Gareth Hughes, Phil Jewsbury, and Martin Pass.

8.08.1 Introduction

The c-Met oncoprotein is a kinase and belongs to the receptor tyrosine kinase (RTK) superfamily activated by its physiological ligand hepatocyte growth factor (HGF).[1] HGF binding results in a dimerization of the c-Met followed by consecutive autophosphorylation, which in turn activates multiple signaling cascades involved in cell survival, motility, migration, proliferation, and angiogenesis (e.g., the PI3K/Akt and MAPK/ERK pathways).[2] During embryonic development, c-Met activation followed by mesenchymal–epithelial transition is of utmost importance for cell motility and, as a consequence, organ morphogenesis. Therefore, it is not surprising that knockout of c-Met or its physiological ligand HGF is embryonically lethal.[3,4]

c-Met is typically expressed in a variety of epithelial tissues, and HGF expression is predominantly detected on tissues of mesenchymal origin.[5]

The physiological role of c-Met is not completely understood, but it was reported that following tissue damage, upregulation of both c-Met and HGF is associated with cell motility and tissue regeneration.[6,7]

Under physiological conditions, c-Met is strictly regulated during embryonic development and tissue homeostasis with physiologically relevant expression levels in differentiated tissue like liver and lung.

Molecular analyses of cancer patient samples revealed different dysregulations of c-Met function, as a result of overexpression, mutational activation, or amplification.[8] These alterations are observed in many types of cancer, including liver and lung cancer.[9] In addition, activating point mutations of c-Met are ultimately responsible for certain forms of hereditary and sporadic papillary renal carcinoma.[10] Furthermore, c-Met activation by its various mechanisms is associated with rapid tumor growth, metastasis, invasiveness, and induction of angiogenesis. Retrospective studies indicated a correlation between poor patient prognosis and overexpression of c-Met or HGF.[11]

c-Met was initially described in 1984 by Copper et al.[12], but it took almost two decades to realize the relevance as a promising target in oncology and identify suitable modulators of this important oncogene. Besides monoclonal antibodies against the physiological ligand (HGF) or the c-Met receptor, multiple small-molecule c-Met inhibitors are described in the literature.[13] In principle, two different types of c-Met inhibitors are described in the literature: highly selective c-Met inhibitors and inhibitors where c-Met is only a component in a more polypharmacological profile. Though many spectrum-selective kinase inhibitors provide a pharmacologically relevant c-Met component like staurosporine, XL-880, and XL-184, the polypharmacological nature of these inhibitors is often regarded as a double-edged sword. On the one hand, there is certainly a beneficial pharmacological component associated to the inhibition of multiple cancer-related kinases, but on the other hand, the applicability of multispecific kinase inhibitors like staurosporine is often hampered by the simultaneous interaction with toxicologically relevant targets, ultimately leading to an unacceptably narrow therapeutic index.

The first reasonably selective c-Met inhibitor described in the literature was crizotinib back in 2006. Since the first publications of crizotinib (PF-02341066),[14] many scientists became interested and tried to identify proprietary ligands for this highly relevant proto-oncogene. As a result, highly potent and selective c-Met inhibitors like PF-04217903,[15] SGX-523,[16] and JNJ-38877605[17] were identified (Fig. 1).

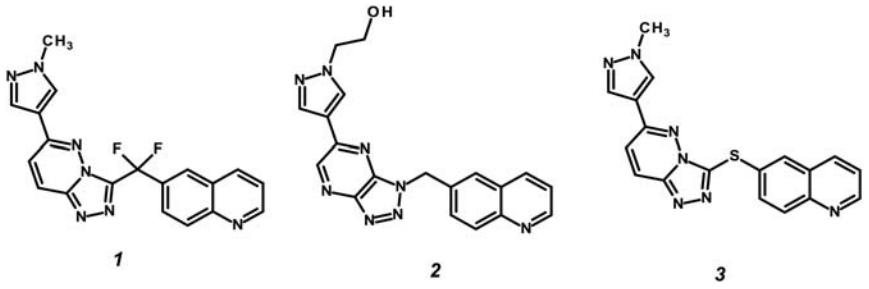

Fig. 1 Monospecific c-Met inhibitors: (**1**) JNJ-38877605, (**2**) PF-04217903, and (**3**)SGX-523.

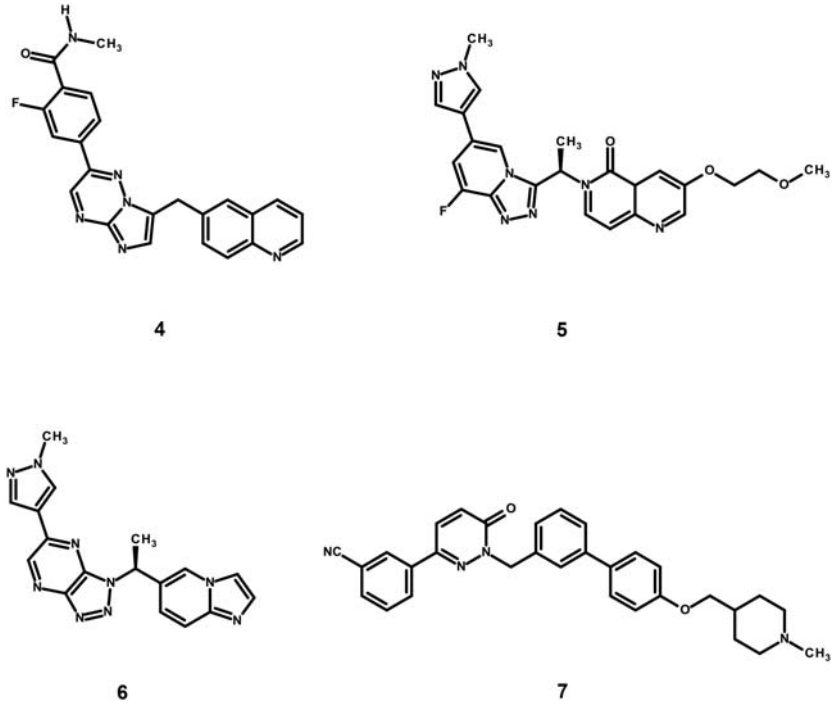

Fig. 2 Monospecific c-Met inhibitors: (**4**) capmatinib (INCB-28060), (**5**) AMG-337, (**6**) savolitinib (AZD6094), (**7**) and tepotinib (MSC2156119/EMD 1214063).

A number of clinical studies were performed to evaluate the safety and efficacy profile of agents inhibiting c-Met activity. These agents span a panel of diverse therapeutic modalities and include ligand-dependent activation of c-Met (monoclonal antibodies binding against HGF like ficlatuzumab (SCH-900105/AV-299)[18] or rilotumumab (AMG102))[19] and ligand-dependent c-Met activation by monoclonal one-armed antibodies against the c-Met receptor like onartuzumab[20] and selective small-molecule tyrosine kinase inhibitors like savolitinib (AZD6094),[21] AMG-337,[22] capmatinib (INCB-28060),[23] or tepotinib (MSC2156119)[24] shown in Fig. 2.

8.08.2 Discussion

Our c-Met program started with an internal high-throughput screening campaign of approximately 350 k compounds against the kinase domain of the c-Met receptor (hit rate ~ 0.5 %). Besides multiple well-known and spectrum-selective kinase inhibitors, thiadiazinone **8** (Fig. 3) was identified as an uncommon structural class. This HTS hit, originally synthesized for a phosphodiesterase

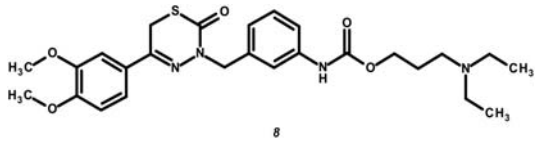

Fig. 3 Initial hit molecule, thiadiazinone **8**.

Table 1 PDE activities of two representative carbamates

inhibitor project, was identified as a potent inhibitor of c-Met (*in vitro* IC_{50} (c-Met) = 35 nM and cellular IC_{50} (c-Met) = 795 nM, Table 1).

Supportive x-ray structures of c-Met in complex with multiple thiadiazinones incl. compound **8** were rapidly available (Fig. 4—PDB-ID: 4R1Y). Details from these x-ray structures revealed the essential binding interactions and guided the subsequent compound optimization process. Similar to other selective c-Met kinase inhibitors like JNJ-38877605, PF-04217903, AZD6094 (volitinib), or AMG-337, thiadiazinone **8** is bound in the ATP pocket of c-Met in a U-shaped binding mode. The most important structural features are the interaction of the carbamate carbonyl with the backbone nitrogen of Met1160 within the hinge region, the benzylic bend, which arranges the residues, and a carbonyl interaction of the pyridazinone to Asp 1222 of the DFG motif, which probably contributes to the overall potency and selectivity of the ligand. Another H-bond is formed to a side chain of Asn1164, and

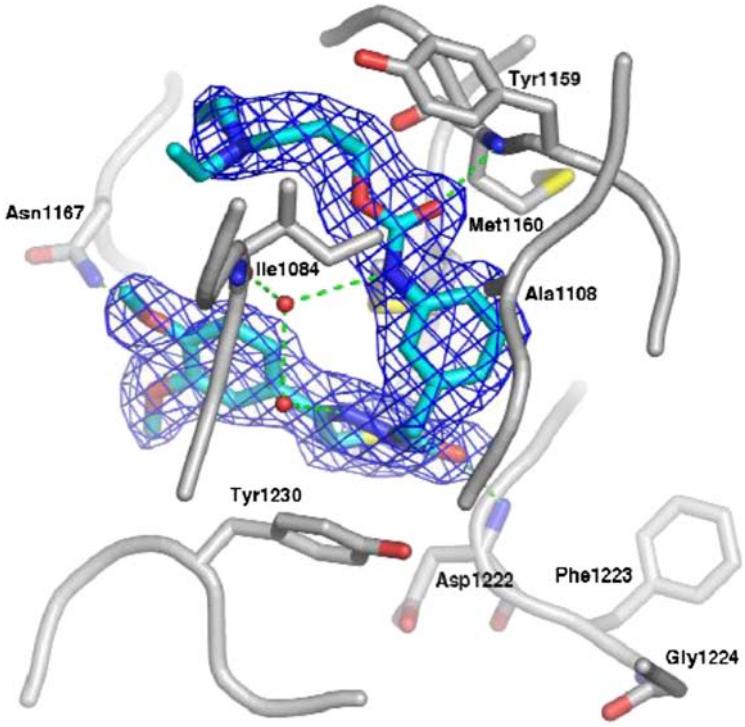

Fig. 4 The x-ray structure of the binding pocket of c-Met kinase in complex with thiadiazinone **8** with at 2.0 Å resolution (PDB-ID: 4R1Y). The inhibitor and neighboring protein side chains are depicted as stick model, colored according to the chemical type ($C_{(inhibitor)}$, cyan; $C_{(protein)}$, gray; O, red; N, blue; S, yellow). Hydrogen bonds are indicated as green dotted lines.

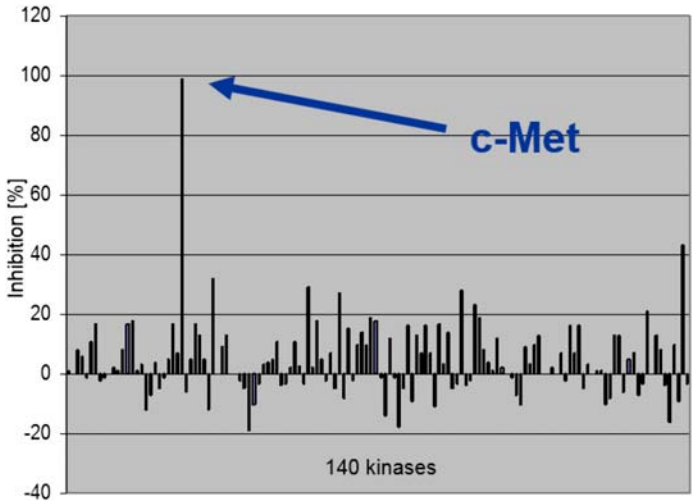

Fig. 5 Kinase profiling of thiadiazinone 8 against 140 kinases at 10 μM.

there are additional hydrophilic interactions from the carbamate NH group, bridged by a water molecule, to the main chain carbonyl of Ile1084 (from the glycine-rich loop). In addition, one of the methoxy groups of the 3,4 dimethoxy phenyl moiety is in close proximity to Asn1167, potentially contributing to the overall potency of the ligand. Furthermore, the binding of thiadiazinone **8** is supported by hydrophobic interactions involving Ala1108, Tyr1159, Met1211, and Tyr1230 (Fig. 4).

In addition to promising enzymatic and cellular c-Met potency, the physicochemical parameters of thiadiazinone **8** are within acceptable ranges including solubility of more than 100 μg ml^{-1} and a logD of 2.5. Kinase profiling activities, depicted in Fig. 5, revealed that thiadiazinone **8** is a highly selective c-Met inhibitor; however, unwanted off-target activities, that is, phosphodiesterase inhibition, were observed (PDE3 $IC_{50} \sim 1500$ nM, PDE4 $IC_{50} \sim 60$ nM)[25].

Subsequent evaluation of the pharmacokinetic profile of **8** revealed an oral bioavailability of less than 5% and a clearance of larger than 6 l h^{-1} kg^{-1}, which is considered to be suboptimal and focus of improvement. Retrospectively, one could argue based on binding efficiency considerations that the molecular weight was slightly too high to qualify thiadiazinone 8 (514.7 g mol^{-1} with a BEI value of 14.5) as an attractive starting point for an optimization program. However, it quickly became evident that molecules with reduced molecular weight, like thiadiazinone **13** (429.5 g mol^{-1} with a BEI value of 17.8), provided a comparable activity profile with an improved PK profile (Table 2).

8.08.2.1 Optimization of Aryl Substitution Pattern: Reduction of PDE Activity

Approximately 30 different aromatic substitution patterns covering electron donating and electron withdrawing substituents and different heterocycles and sterically demanding residues were synthesized[26] and tested. The resulting structure–activity relationship, in line with the binding model built from the cocrystal structure, suggested that a wide variety of substitution patterns and heterocycles are tolerated without significantly impacting biochemical activity. One caveat is that the coplanarity of the aryl moiety with the thiadiazinone ring cannot be compromised. For example, ortho substituents like the exemplified compound **11** are considerably less potent compared with meta- or parasubstitution patterns of compounds **9** and **10** (Table 3).

One of our first optimization efforts was to remove the unwanted off-target, PDE activity. According to literature, methoxy phenyl but especially the 3,4 dimethoxy phenyl residue present in compounds **8** and **13** were described as well-known PDE recognition motives.[27] Based on initial reassuring data that, for example, 4-chloro phenyl **12** demonstrated a significantly reduced PDE activity, our first optimization effort was dedicated to the identification of alternative substituents preferably in the meta- or paraposition without significant PDE activity.

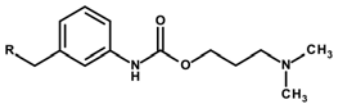
Contribution of the observed interaction between one of the methoxy groups of **8** and Asn1167 to the overall binding was not mandatory to maintain affinity. On the contrary, there was a slight tendency toward an improved affinity for the monosubstituted methoxy phenyl derivatives **9** and **10**. However, the goal to identify a potent c-Met inhibitor without a pronounced PDE activity on any of the PDE isoenzymes was achieved by replacing the 3,4-dimethoxyphenyl substituent by a 3,5-difluorophenyl residue, which resulted in cpd **14** with an increased biochemical and cellular potency. The overall improvement is immediately evident by calculating molecular descriptors of the overall compound quality like the binding efficiency index (BEI). This simple optimization of the substitution pattern improved the BEI value from 14.5 to 17.8 and in addition provided a compound with a comparable or even reduced IV clearance and increased oral bioavailability in mice compared with thiadiazinone **8**.

8.08.2.2 Identification of Bioisosteric Core Replacements: Address Chemical Instability

Despite the improvements in potency, the thiadiazinone series was limited due to chemical instability. Repeated evidence showed that under harsh conditions (high temperatures or anhydrous acidic conditions), the thiadiazinone ring decomposes potentially liberating CSO. This chemical instability negatively affects not only chemical accessibility and the synthetic yields but also shelf life and may cause potential issues in long-term assays. Therefore, the strategy was to identify suitable bioisosteres[28] as potential thiadiazinone replacements with high priority. With the exception of the acylpyrazolines, which were already identified as additional hit matter in the high-throughput screening, approximately 20 additional five- and six-membered heterocycles and annelated bicyclic ring systems were synthesized. The properties of the four most active bioisosteres are described in Table 4.

c-Met cocrystal structures of representatives of every lead structure class could be obtained, which provided valuable insights into the binding conformation of the bioisosteric thiadiazinone replacements. All four thiadiazinone core replacements, namely, pyridazinones[29] **15**, acylpyrazolines[30] **16**, benzoxazolones[31] **17**, and thiadiazolinones **18**, share the already-discussed essential pharmacophoric features like a hydrogen bond acceptor in a defined orientation and a coplanar extended aromatic moiety in the ribose pocket. As anticipated, the core replacements also show a comparable and overlapping structure–activity relationship in our enzymatic assay (Table 4).

Table 4 Selection of bioisosteric thiadiazinone replacements



Cpd	R	c-Met biochem IC_{50} (nM)	c-Met cell IC_{50}(nM)	Stability PBS buffer pH 7.4	Stability SGF pH 1.2	Stability human plasma	BEI
15		14	400	89	88	100	18.5
16		165	3100	73	91	46	15.9
17		110	2500	100	87	87	18.8
18		43	1300	100	85	83	17.1

Despite its slightly reduced potency, one particularly interesting modification from a bioisosteric point of view is the compound class of acylpyrazolines **16**. This compound class was initially identified during the HTS run and was elaborated in parallel to the optimization activities around the thiadiazinone class. The compound class of the acylpyrazolines provides all required pharmacophoric features. The reduction of the ring size and insertion of the carbonyl into the side chain (Fig. 6), which forms the important Asp 1222 interaction to the c-Met protein, result in a comparable binding mode and structure–activity relationship.

The structure–activity relationship on c-Met for all bioisosteric compound classes was assessed to be widely comparable to the parental thiadiazinones and could therefore easily transferred from one compound class to the other. Extended stability tests in standard media were done for all potential bioisosteric core replacements. These stability tests revealed a significant plasma instability for the series of acylpyrazolines around compound **16** (Table 4). Although the decomposition product was not elucidated, it was hypothesized that amidases present in the plasma might be responsible for the clearance of the amide bond. This instability in combination with a suboptimal pharmacokinetic behavior *in vitro* and *in vivo* profile led to the decision to deprioritize the acylpyrazoline series. The most promising bioisosteric replacement, pyridazinone **15**, turned out to be equipotent in the biochemical and cellular c-Met potency (14 and 400 nM, respectively) compared with the thiadiazinone **14** (6 and 340 nM, respectively). In addition, based on a slightly more favorable ratio between enzyme and cell potency, the decision was made to focus our optimization efforts on this novel compound class.

The chemical accessibility for pyridazinones is excellent and offers the opportunity to independently optimize the different moieties of this scaffold in acceptable overall yields. Starting from the commercially available benzaldehydes, the synthesis followed a four-step synthetic protocol where the pyridazinone ring is formed by condensing the respective benzaldehyde with glyoxylic acid in the presence of hydrazine. The regioselectivity between oxygen and nitrogen alkylation of the following benzylation step was

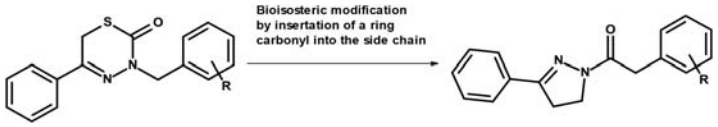


Fig. 6 Bioisosteric modification.

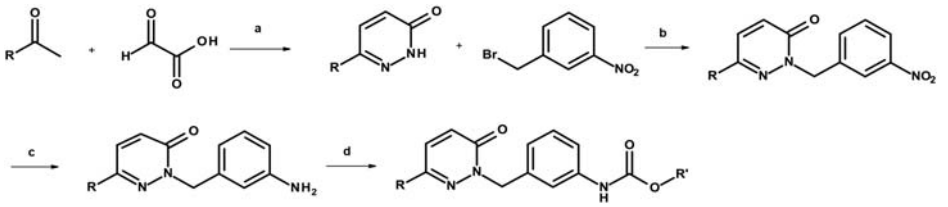

Scheme 1 Synthesis of carbamate derivatives. Reagents and conditions: (A) hydrazine hydrate, AcOH, 95 °C, (B) K_2CO_3, acetonitrile, 80 °C; (C) H_2, RaNi, THF; (D) ClCOOR', pyridine, dichloromethane, rt.

highly dependent on the base that is used. The use of potassium carbonate allows for the regioselectivity to favor nitrogen alkylation and only traces of the undesired benzylether could be detected under these conditions. The subsequent hydrogenation of the aryl nitro moiety does not affect the core fragment but could potentially interfere with sensitive substituents in the R residue. The final carbamate formation was performed under standard conditions in high yields. The whole synthesis including specific protocols has been published recently (**Scheme 1**).[24.a]

This versatile synthetic route allows for the optimization of the solubilizing moiety in the last step of the synthesis via *in situ* generation of a suitable chloroformate followed by the preparation of the respective carbamate. In contrast to the thiadiazinones, which were regularly found to decompose under anhydrous HCl conditions during hydrochloride salt formation, the pyridazinones turned out to be stable under acidic conditions and allow for the more convenient purification method of hydrochloride salt crystallization.

The influence on enzymatic potency of modifications in the solubilizing anchor is marginal, but this part of the molecule was exploited to optimize secondary parameters like solubility.

8.08.2.3 Final Optimization, Selection, and Characterization of a Putative Clinical Candidate

With the exception of compounds containing rigidified modifications like piperidine **25**, significant reduction of biochemical c-Met potency and BEI value was not observed for a variety of solubilizing anchor moieties (**Table 5**). The binding efficiency index turned out to be in a comparable range between 17.5 and 20.5. However, the c-Met activity of compounds bearing a basic amine turned out

Table 5 Influence of different carbamates on activity and solubility

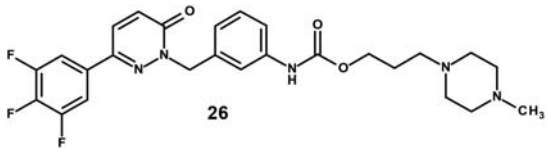

Fig. 7 Structure of pyridazinone carbamate 26.

to be superior compared to neutral modifications like compound **19** or **20**. In particular, derivatives with three methylene units between the carbamate and the basic center represent the optimum in biochemical and cellular c-Met potency in particular (**22** and **24**). Besides the cellular potency, the compound selection for further optimization was mainly driven by solubility considerations.

The optimization of the linker and solubility anchor followed by fine-tuning of the substitution pattern of the aryl residue attached to the pyridazinone ring led to the introduction of a third fluorine atom in the paraposition and finally to the identification of carbamate **26** (Fig. 7), which provided a favorable physicochemical and pharmacodynamic *in vitro* profile.

Carbamate **26** is a highly potent inhibitor of c-Met with IC_{50}'s in the single-digit nanomolar range on the isolated enzyme and 50 nM in A549 cells. Kinase profiling of **26** on a panel of 80 kinases revealed that the compound is a highly selective c-Met inhibitor, which seems to be a conserved feature of this compound class expected to stabilize an inactive conformer of the c-Met protein.

In addition to the pharmacological profiling (Table 6) and structural information provided by cocrystal structures, valuable additional biophysical insights like binding constants and residence times were provided by surface plasmon resonance (SPR) measurements. The residence time of the piperazine carbamate **26** on the c-Met receptor was measured to be 12.6 min with a Kd of 0.5 nM (Table 16). The overall quality of this particular c-Met inhibitor is underlined by a favorable physchem profile of solubility and stability (Table 7). The favorable overall *in vitro* profile justified a more in-depth *in vivo* characterization of compound **26**. Therefore, a broader pharmacokinetic and pharmacodynamics *in vivo* profiling of carbamate **26** and initial safety assays were performed in parallel.

The *in vitro* and *in vivo* PK profile of **26** is summarized in Tables 8 and 9, respectively. The intrinsic clearance in human hepatocytes is lower than 0.28 l h^{-1} kg^{-1}. There are no concerning CYP inhibition data, although this compound is mainly metabolized by the same CYP that it is inhibiting (CYP3A4). The compound showed reasonable plasma protein binding in the range of 98 % and some residual PgP substrate properties. No reactive metabolites have been found by glutathione adduct trapping. In mice, the compound is sufficiently stable, and no hints of instability have been observed in dog, monkey, or human plasma. Interestingly, for unknown reasons, the compound seems to be highly unstable in rat plasma. With the exception of rats, the *in vivo* PK profiles in three different species showed good to very good clearance, half-life values, and oral bioavailability. Allometric scaling based on these results predicts that **26** will be a low-clearance drug in humans with a long half-life and a good oral bioavailability.

PK/PD studies using compound **26** were performed to demonstrate a dose-dependent target engagement *in vivo* (Fig. 8) and to guide the optimal dosing and scheduling regimes. These PK/PD studies indicated that a single application of 50 mg kg^{-1} of compound **26** is sufficient to inhibit the kinase activity of c-Met almost completely for 2 days *in vivo*, whereas doses of 25 mg kg^{-1} resulted in a transient and incomplete target engagement (Fig. 8).

In addition to these PK/PD studies, an *in vivo* efficacy testing in a xenograft model using HS746T, a c-Met amplified gastric cancer cell line, was performed in CD1 mice (Fig. 9). Compound **26** was given orally once daily at doses of 25, 50, and 100 mg/kg. Impressively, in line with the expectations based on the target coverage in the PK/PD studies, complete regression could be achieved in this gastric cancer model by using 50 mg/kg/d or higher doses of cpd. 26. The durability of the response is reflected by the fact that no tumor regrowth was observed, for at least 20 days, even when the treatment was stopped. Comparable activities could be achieved by using autocrine c-Met-dependent tumor cell lines like U87MG glioblastoma cells or mouse fibroblasts transfected with the clinically relevant fusion protein TPR-Met.

In parallel to the extensive pharmacokinetic and pharmacodynamic characterization, piperazine **26** was characterized in the first set of relevant safety assays. Unfortunately, it turned out that the compound showed a significant hERG activity of ~50 nM in our cellular patch clamp assay. The *in vitro* hERG activity was also visible in a ventricular wedge assay where piperazine 26 significantly increased the refractory period and reduced the force of contraction at physiologically relevant concentrations. In addition to a significant risk for QT prolongation (delayed ventricular repolarization), the piperazine **26** also showed a dose-dependent, direct, and inverse cardiovascular side effect on heart rate and blood pressure. Furthermore, based on histological studies, it became evident that compound **26** induced phospholipidosis in rats in various tissues like liver and lung, and after intravenous application, a dose-dependent hemolysis was observed. This effect might be due to the amphiphilic nature of this particular compound, induced

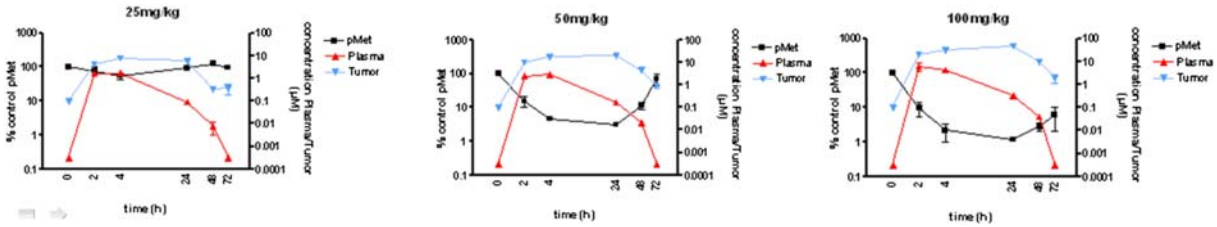

Fig. 8 Concentration/time curves and degree of target coverage after single application of 25 mg kg^{-1}, 50 mg kg^{-1}, and 100 mg kg^{-1} of carbamate **26** in a PK/PD experiment (cell line).

by a strong basic head group (calculated bpKa of 8.1) in combination with a rather lipophilic residual structure on the one hand forming micelles and on the other hand potentially interfering with membrane integrity. Compound **26** also induces the formation of micronuclei in the presence of metabolic activation by S9 mix (genotoxicity potential). The capability of alkyl carbamates to induce micronuclei, by the formation of an epoxide as a reactive intermediate after metabolic activation, is described in the literature for some carbamates like ethyl carbamates. [32] Taken altogether, these findings led to the disappointing conclusion that the therapeutic safety index of this compound does not justify further development and the optimization of the pyridazinones had to be continued with a focus on safety aspects.

8.08.2.4 Back to the Bench! Identification of Bioisosteric Carbamate Replacements

It was suspected that some of the undesired safety-related properties of the compound, that is, the positive micronucleus test, QT prolongation, and observed hemolysis could be attributed to the carbamate/linker/solubility anchor region of the molecule. Therefore, a broad screen for alternative groups that could act as potential carbamate replacements was conducted.

Initially, closely related linear bioisosteric analogs, like amides, retroamides, ureas, and retrocarbamates, were synthesized, but it quickly became evident that these analogs share the same liabilities and may even add additional complications. For example, urea derivatives led to reduced permeability due to an increased number of hydrogen bond donors.

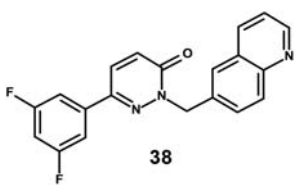
Therefore, another approach was evaluated where several five-membered heterocycles, with a hydrogen bond acceptor as the hinge-binding element, were designed and docked into the pyridazinone carbamate cocrystal structure. In alignment with the docking results, it became evident that the nitrogen acceptor that interacts with Met1160 has to be located in the 2-position of the heterocyclic carbamate bioisostere. Interestingly, one of the first compounds synthesized, a 5-methyl-[1,2,4]oxadiazol-3-yl derivative, demonstrated a significant inhibition of c-Met (IC_{50}: 23 nM), which is comparable to the corresponding alkyl carbamates **19** and **27** (c-Met IC_{50} of 4 and 7 nM, respectively). Unfortunately, oxadiazole pyridazinone **28** lacked cellular potency, which fostered the decision to discontinue the oxadiazole series. As expected by our virtual docking results, the isomeric oxadiazole **29** was less active in the biochemical and cellular assay, probably because the nitrogen in the 2-position, serving as the hinge-binding element, was absent or sterically shielded by the methyl group, potentially causing a repulsive steric interaction of the methyl substituent with the hinge region of the c-Met protein, which consequently led to a nonoptimal positioning of the donor nitrogen. Additional evidence for this hypothesis was derived from the matched molecular pair of the two thiazole isomers **32** and **33** and their inverted isomer **34**. Although the biochemical activity of thiazole **32** was already in a reasonable range of 20 nM, the search for alternative ring systems was continued in order to avoid potential metabolic liabilities of thiazoles. Based on thiazole **32** and by applying the well-known bioisosterism of sulfur, C=C and N=C bonds,[33] six-membered ring compounds **35**, **36**, and **37** were prepared. It became evident that, besides the obligatory hydrogen bond acceptor and its acceptor qualities, a certain coplanarity was found to be essential for an optimal interaction of the hydrogen bond acceptor with the backbone N-H of Met1160. Based on the available cocrystal structures of all five- and six-membered heterocycles, the presence of a CH-π interaction between the H-atom next to the hinge acceptor pointing toward the π-system of Tyr1159 was identified as an additional ligand/receptor interaction, contributing to the overall affinity. The lacking CH-π interaction is the anticipated explanation for the reduced affinity of only 4200 nM for pyridazine **37**.

In addition to biarylic modifications, a few annelated heterobicyclic systems were synthesized, providing a hydrogen bond acceptor and a polarizable C-H donor. As an example, quinoline **38** depicted in Fig. 10 was found to be a reasonably potent c-Met inhibitor. The biochemical c-Met activity of quinoline **38** (45 nM) was comparable to phenyl oxadiazole **28**, phenyl thiadiazole **32**, or even phenyl pyrimidine **36**. The properties of quinolines, however, are controversially discussed in the literature. Even severe side effects like a potential risk of neurotoxicity, mutagenicity, and a tendency to form reactive metabolites are described in the literature. Especially in the absence of superiority in any particular property, these considerations in combination with a limited access to versatile building blocks led to the deprioritization of this particular class.

From a holistic perspective,[34] parasubstituted phenyl pyrimidines demonstrated the best overall profile including biochemical and cellular potency and physicochemical properties, providing all necessary pharmacophoric features like a near coplanarity of the six-membered heterocycle with the phenyl group and the presence of a polarized hydrogen alpha to the nitrogen in close proximity to Met1160. Therefore, pyrimidine derivative **36** was chosen as the most promising inhibitor for further derivatization.

8.08.2.5 Optimization of Pyrimidine Substituents: Introduction of Solubility

In the next optimization cycle, different smaller and more sterically demanding substituents including acids, bases, and additional aromatic systems were introduced to the paraposition of the pyrimidine ring. All compounds tested so far suffered from a significant



38

Fig. 10 Quinoline **38** as exemplified heterobicyclic hinge binder.

split between the biochemical and the cellular autophosphorylation assay of about a factor of 100. In the majority of the cases, the limited aqueous solubility (<1 μg ml^{-1} in a PBS buffer at pH 7.4 for methylpyrimidine derivative **36**) was expected to be the reason for the rather weak activity in the cellular A549 assay ($IC_{50} \sim 0.55$ μM).

The BEI values (approximately 21) for pyrimidine derivatives bearing a small substituent like methyl (compound **36**) or amino (compound **39**) were assessed to be reasonably attractive. Small substituents in the paraposition of the pyrimidine like alkyl, amino, hydroxyl, halogen, or carboxylic acids (**36** and **39–42**) did not show a significant improvement in cellular activity (**Table 10**). Sterically more demanding aromatic substituents like methyl pyrazole or smaller modified chains like cpds **43–47** demonstrated a significantly improved cellular potency and a reduced drop-off between the biochemical and the cellular assay of ~ 10. In analogy to the structure–property relationships in the carbamate class around compound **26**, the introduction of a basic anchor fragment, attached to the pyrimidine, increased the solubility and the amphiphilic character of the inhibitor, which ultimately led to an improved cellular potency and reduces the split between the biochemical and cellular assay. In addition to a larger set of

parasubstituted pyrimidines, a significantly lower number of metasubstituted pyrimidines were synthesized and tested for their ability to inhibit the activity of the c-Met kinase. Although meta- and paramodified aminoalkoxy pyrimidines offered the advantage of a lower drop-off between the cellular and biochemical activity values, the parasubstituted aminoalkoxy pyrimidine **47** demonstrated a superior biochemical and cellular potency compared with the corresponding isomer **46**.

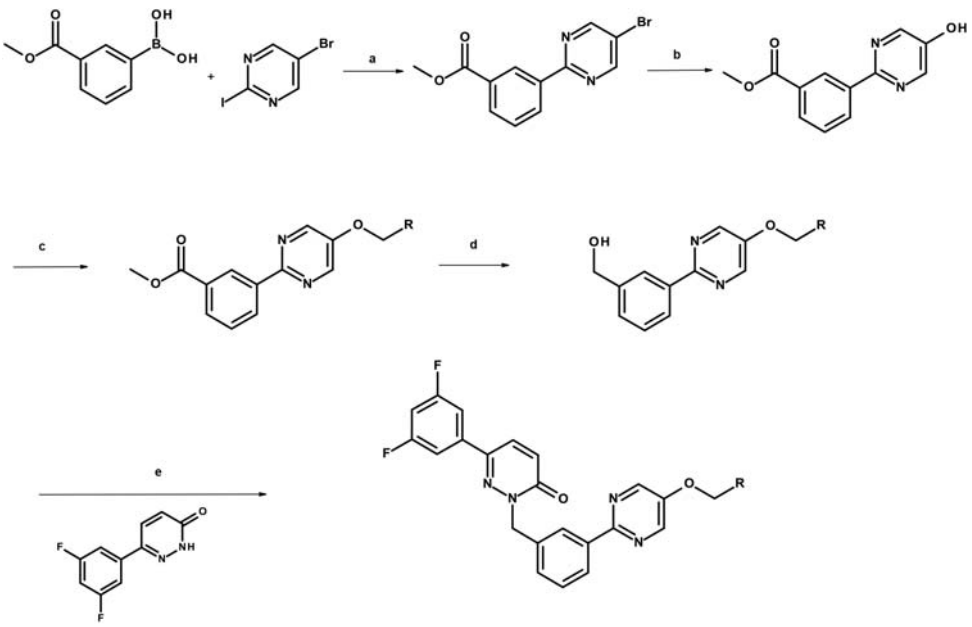
A reasonable potency and a favorable physicochemical profile are regarded as a prerequisite for an attractive lead structure. However, the main complication for the discontinued carbamate series including compound **26** was the unfavorable safety profile incl. hERG activity and *in vitro* formation of micronuclei in the presence of metabolic activation by S9 mix. In order to get the first impression of the safety profile of the pyrimidine series, a set of representative compounds were tested in the micronucleus test assay and in the cellular hERG patch clamp assay. As expected, pyrimidines did not induce the formation of micronuclei in general. The inherent hERG activity of nonsubstituted pyrimidines was negligible, but depending on the lipophilicity and basicity of the solubilizing anchor, compounds like diaminopropyloxy pyrimidine **47** showed a residual hERG activity in the patch clamp assay[35] of around 6 μM. In contrast to the initially elaborated carbamate **26**, which turned out to be equipotent in the cellular c-Met autophosphorylation and the hERG patch clamp assay (both IC_{50}'s ~ 50 nM), even pyrimidines containing a basic anchor like **47** provided an initial hERG safety window of ~100 on a cellular level.

Based on these results and despite the fact that the clogP value of the cellular active compounds **43–47**, ranging between 3.8 and 4.1, is still regarded to be tendentially on the higher side, it was concluded that amino alkyloxy pyrimidines including compound **47** provided a more balanced profile. These modifications are offering a reasonable cellular potency in combination with an acceptable physicochemical and safety profile and therefore should be regarded as a blueprint for further derivatives. Multiple synthetic routes offer the access to para-alkoxy-substituted pyrimidinyl pyridazinones and are extensively described in the literature. One exemplified approach to access pyrimidine derivatives with a basic solubility anchor connected to the pyrimidine nucleus by an ether bridge is shown in **Scheme 2**.

Synthetic route A offered the advantage that the diversification step for the introduction of alkyl ethers was designed to be the ultimate step. The synthetic sequence and the involved chemistry came with certain flexibility as described in **Scheme 3** for the synthesis route B and allowed for multiple rearrangements in order to perform the diversifying step in the aryl pyridazinone part in the penultimate or ultimate step (**Scheme 3**). An additional advantage of this flexible synthesis was that the route could be adopted according to the prerequisites and limitations of the compounds to be synthesized. This especially became important for rather harsh synthetic conditions in the presence of labile substituents in the phenyl pyridazinone moiety.

N,*N*-dimethylamino-propoxy pyrimidine **47** had significantly improved cellular activity (**Table 11**) compared with pyrimidines without a basic moiety like alkyl, amino, hydroxyl, halogen, or carboxylic acids (**36** and **39–42**). This compound was regarded as an advanced lead and therefore extensively profiled in physicochemical and DMPK-related assays. The favorable overall physicochemical and stability profile of compound **47** is summarized in **Table 12**. Despite the relatively high clogP value of 4.1, the *N*,*N*-dimethylamino-propoxy pyrimidine **47** is surprisingly soluble.

The overall *in vitro* PK profile of pyrimidine **47** is summarized in **Table 13** and does not reveal any significant liabilities. Although the *in vitro* microsomal clearance in rodents is regarded suboptimal (**Table 13**), the intrinsic clearance in human hepatocytes and human microsomes is lower than 0.28 l h^{-1} kg^{-1} and lower than 10 μl min^{-1} mg^{-1}, respectively. CYP inhibition studies for compound **47** showed that only CYP2C9 was inhibited with an IC_{50} of 6.7 μM, whereas all other CYP isoenzymes (2C19, 1A2,



Scheme 3 Synthesis of pyrimidine derivatives via route B (detailed synthetic procedures are described in reference 24a and 24d). Reagents and conditions: (A) 1 mol % $PdCl_2(PPh_3)_2$, $KHCO_3$, toluene/water/methanol (1:1:2), 80 °C; (B) 1.2 eq. bis(pinacolato)diboron, 3 eq. 2D6, and 3A4) are inhibited with IC_{50} values higher than 20 μM. Plasma protein binding in human plasma was concentration dependent and measured in a range of 97.4–99.06% at concentrations of 0.3 and 10 μM. The highly permeable pyridazinone **47** does not form reactive metabolites, which was tested by glutathione adduct trapping,[36] and in contrast to the observations for carbamate **26** in our plasma stability assay, pyrimidine **47** turned out to be stable in plasma of all species.

8.08.2.6 Fine-Tuning of the Phenyl Pyridazinone Substitution Pattern

Although the overall profile of the difluorophenyl pyridazinone **47** was reassuring, the relatively high lipophilicity in combination with a pronounced amphiphilic character reminded us of the phospholipidosis and hemolysis issue observed for the highly lipophilic carbamate with a pronounced molecular dipole. In order to further understand the SAR and reduce the safety risk, 40 additional molecules were synthesized with different substitution patterns and aryl/heteroaryl variations of the pyridazinone were synthesized with the focus of significantly reducing calculated logP/logD. This set of compounds was not only fully characterized with a special focus on the biochemical and cellular potency but also keeping an eye on the respective physicochemical and DMPK profile. A representative set of compounds including some key parameters are summarized in Table 14. Compared to the initial difluorophenyl residues, the majority of the modifications did not result in an improved biochemical or cellular potency (as in **48**, **49**, and **50**). The only compounds, combining a reduced lipophilicity with an improved biochemical and cellular activity, were 4-cyanophenyl- or 3-cyanophenyl pyridazinones **51** and **52** offering a factor of 3 in cellular and biochemical potency while lowering the measured logD value by 0.6. One potential explanation for the significantly improved potency of the cyano isomers **51** and especially for **52** could be derived from the integration of the cyano group into the water network interacting with multiple water molecules in the x-ray structure depicted in Fig. 11.

4-Cyanophenyl- and 3-cyanophenyl-derived pyridazinones **51** and **52** seem equally qualified for further optimization. While there was no striking difference to rationally favor one cyano substitution pattern over the other, due to the limited pharmacological and physicochemical profile, the metasubstituted compound was picked for further derivatization merely because of a slightly more favorable *in vitro* DMPK profile.

8.08.2.7 Final Selection of the Solubilizing Anchor Led to the Identification of Tepotinib

The last optimization cycle was dedicated to the identification and final selection of an appropriate solubilizing anchor for the 3-cyano phenyl substitution, balancing the need for a pronounced solubility and potency against a pronounced amphiphilic nature, its potential safety implications, and the associated pharmacokinetic profile of the respective compounds. Only a small set of meta-cyanophenyl-derived pyrimidines were synthesized based on our experience accumulated during the optimization of the solubilizing anchor in the carbamate series. Along with a small set of additional modifications not discussed in this communication,

the main focus was on morpholines and piperidines described in Table 15. The dimethylaminopropyl-derived compound **52** already had acceptable pharmacokinetic properties in mice; the morpholino derivative **53** demonstrated an improved clearance but had somewhat lower cellular potency. Finally, the methylpiperidine derivative **7** (MSC2156119, also known as EMD 1214063 or tepotinib) combined very high biochemical and cellular potency of <1 nM and 6 nM, respectively, with suitable pharmacokinetic properties. The relatively high BEI values of more than 18.3 and the measured logD value of 1.4 were even more reassuring and increased the confidence that **7** should be regarded as a clinical candidate.

Shortly after the structure-guided rational design and the final selection of tepotinib **7**, selected compounds, representing important milestones or decisions in the compound optimization process, were selected and tested for their biophysical binding characteristics (k_{on}, k_{off}, and residence time) by solid plasmon resonance (SPR)[37]. Their key characteristics are summarized in Table 16.

It turned out that the residence time of tepotinib **7** was prolonged by orders of magnitude compared with even structurally closely related compounds, and serendipitously, a compound with a very long residence time of >1000 min was picked.

8.08.3 Characterization of Tepotinib

One of the very first characterizations after the final selection of tepotinib **7** was to confirm the anticipated binding conformation by solving a cocrystal structure of **7** in complex with c-Met. The resulting complex had a resolution of 1.2 Å (Fig. 11, PDB-ID: 4R1V), proving the assumed U-shaped binding mode, and was well in line with our expectations based on earlier cocrystal structures and our in-depth understanding of the underlying structure–activity relationship of this particular pyridazinone compound class.

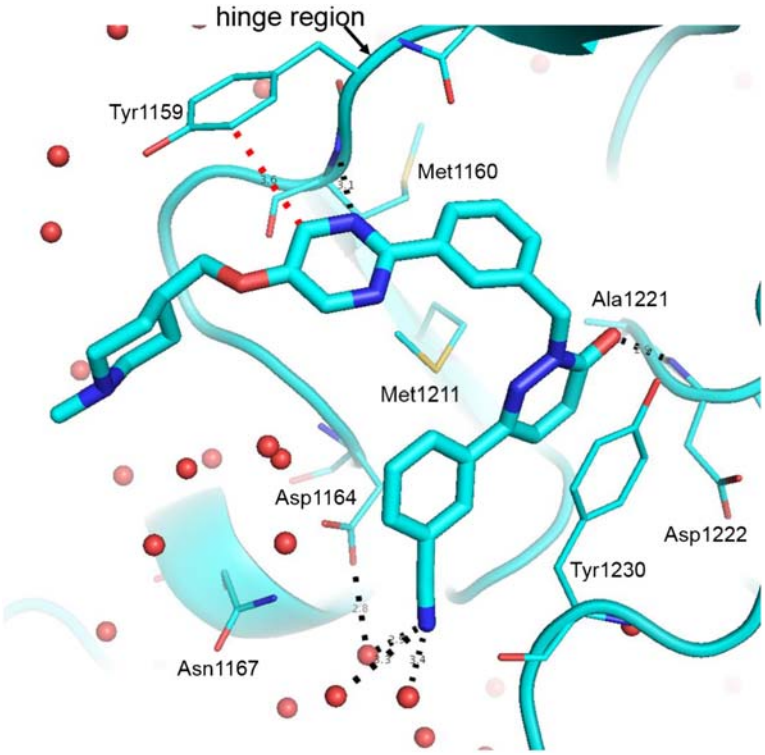

Fig. 11 The x-ray structure of the binding pocket of c-Met kinase in complex with tepotinib 7 with at 1.2. Å resolution (PDB-ID: 4R1V). Important ligand/protein interactions are shown as dashed lines, namely, the interaction between the pyrimidine nitrogen and the backbone of Met1160 (black), the pyridazinone O-atom and Asp1222 (black), and multiple interactions from the cyano group of the cyano phenyl toward different water molecules building a water cluster (black). Another potentially important interaction is calculated with the software tool ViewContacts[34] and visualized as dashed red line describing a close proximity (3.6 Å) and potential interaction of a CH–π interaction between the pyrimidine 3-CH-atom and the side chain of Tyr1159.

[a]not reliably measurable due to the very long residence time. KD for tepotinib **7** is estimated to be < 100 pM

As expected, tepotinib is a class I ATP competitive inhibitor bound in the already-known binding mode to c-Met with the pyrimidine nitrogen as a hinge binder toward Met1160 and a nonclassical CH-π interaction between the pyrimidine and Tyr1159. In addition, the interaction between the pyridazinone O-atom and Asp1222 was visible and potentially contributes to the overall selectivity of this particular compound class. Although one could have expected a direct interaction between the cyano group of the meta cyano phenyl residue and Asn1167, the recognized interaction is water mediated by a cluster of three water molecules embedded into the overall water network and connected to Asp1164. These contacts may serve as an explanation for the significantly improved biochemical activities of the cyano-substituted phenyl residues compared with other substituents like fluoro or chloro. In summary, the following residues can be found in the vicinity of the ligand with a maximum distance of 3.9 A: Ile1084, Ala1108, Leu1140, Leu1157, Pro1158, Tyr1159, Met1160, Lys1161, Gly1163, Asp1164, Arg1208, Met1211, Ala1221, Asp1222, Ala1226, and Tyr1230.

A broad kinase profiling of tepotinib **7** was conducted at concentrations of 100 nM and 10000 nM. At a concentration of 100 nM (Fig. 12), **7** was not able to inhibit more than 30% of the activity of any kinase (besides c-Met) out of 284 kinases tested. In a second screening campaign at 10 μM (more than 1000-fold above the c-Met IC_{90} of MSC2156119), only 5 out of 242 kinases were

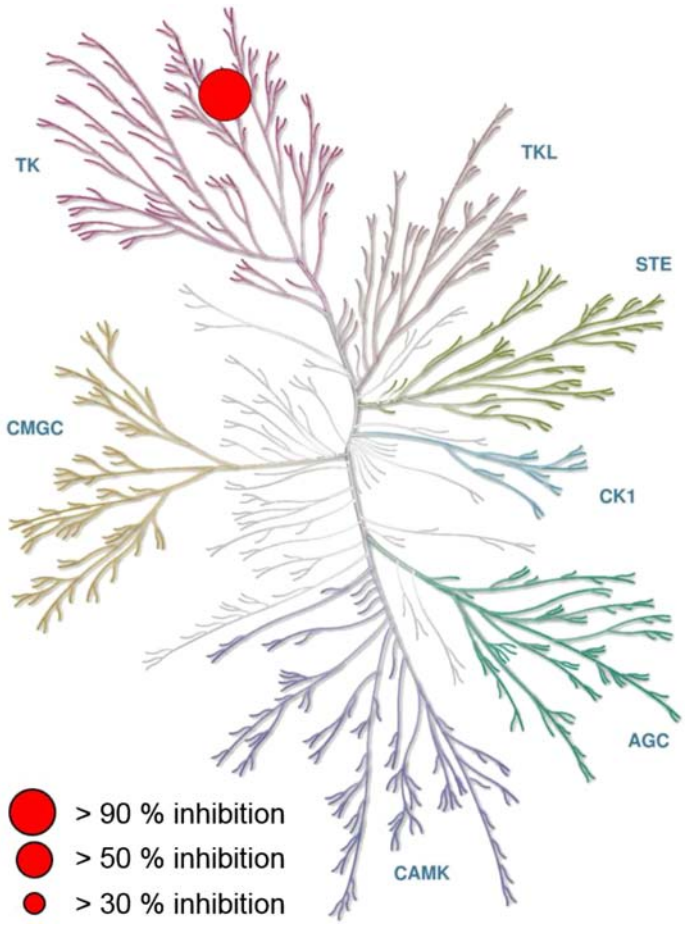

Fig. 12 Graphic representation of a percentage of inhibition of 284 kinases at a concentration of 100 nM of **tepotinib 7**.

inhibited by tepotinib with more than 50% (IRAK4, TrkA, Axl, IRAK1, and Mer). The IC_{50} determinations for the 5 kinases resulted in values ranging from 615 to 2272 nM. These activities are considered not to be relevant, because it is unlikely that MSC2156119 will achieve the pharmacologically relevant inhibitory free concentration of these kinases *in vivo*.

8.08.4 Pharmacokinetic Characterization of Tepotinib

The overall pharmacokinetic *in vitro* profile of tepotinib is summarized in Table 17. As it is symptomatic for this compound class, the microsomal clearance in rodents is pronounced, whereas **7** (MSC2156119) only showed a negligible intrinsic clearance in human microsomes and hepatocytes with $<10\ \mu l\ min^{-1}\ mg^{-1}$ and $<0.28\ L\ h^{-1}\ kg^{-1}$, respectively. All CYP P450 inhibition IC50s are equal or higher than 30 μM, and the CYP phenotyping revealed that tepotinib is mainly metabolized by CYP 3A4 without any evidence for reactive metabolites or metabolic intermediates evaluated by glutathione adduct trapping. **7** showed a human plasma protein binding of about 94% and was stable in plasma of mice, rats, dogs, and humans. According to CaCo2 studies, tepotinib can be considered as a highly permeable compound.

The *in vivo* pharmacokinetic properties of **7** were determined in regulatory (mono) PK studies in 4 preclinical species using solutions in solutol HS15/ethanol/water and suspensions in 0.25% aqueous methocel for *IV* and *PO* administration, respectively (Table 18). The *IV* clearance (CL) was moderate to high, in part even exceeding the liver blood flow in the respective species. The results may suggest elimination of **7** via hepatic *and* extrahepatic pathways at least in rats and dogs. The considerably lower clearance in monkeys is assumed to be due to a lower contribution of extrahepatic elimination. The volume of distribution at steady state (V_{ss}) was consistently high across all species indicative of pronounced distribution of **7** into organs and tissues. The *IV* plasma half-life ($t_{1/2}$) was moderate in rodents and longer in nonrodents. The oral bioavailability (F) from methocel suspension ranged from slightly more than 20% in dogs and monkeys up to 55% in rats despite the high clearance of **7** in the latter species. This is, however, well in line with the aforementioned assumption of extrahepatic elimination pathways.

Taken altogether, tepotinib **7** exhibits an overall acceptable pharmacokinetic profile with intermediate to high clearances, large volumes of distribution, medium to long plasma half-lives, and moderate oral bioavailability in the preclinical species tested. Based on various allometric scaling approaches (also considering, e.g., *in vitro* CL_{int} values as correction factors), a moderate clearance, a high volume of distribution, and consequently a long plasma half-life were predicted for humans.

8.08.5 Pharmacodynamic Characterization of Tepotinib

As described previously in the literature[24.b,24.c], the c-Met-related pharmacology of tepotinib was extensively studied *in vitro* and *in vivo*. First of all, cellular activity of tepotinib was investigated in HGF-stimulated A549 lung cancer cells using a capture ELISA assay format. Cells were serum-starved for 12 hto reduce background tyrosine phosphorylation, preincubated with test compounds for 30–45 min, and then stimulated with 100 ng ml^{-1} recombinant human HGF (R&D Systems) for 5 min. Reactions were stopped on ice by adding detergent-containing lysis buffer including a protease and phosphatase inhibitor cocktail. c-Met was captured on white ELISA plates using an antibody against its extracellular domain (R&D Systems), and total tyrosine phosphorylation was detected with a biotin-coupled version of the antiphosphotyrosine antibody pY99 (Santa Cruz), streptavidin-HRP (Amersham

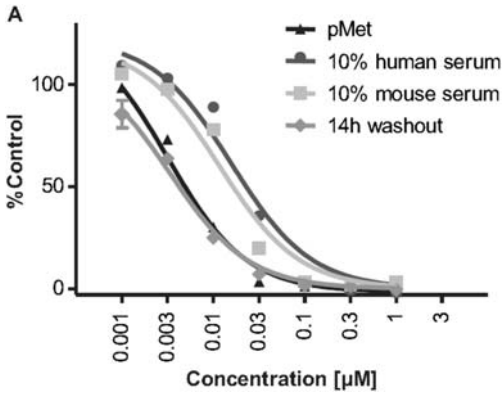

Fig. 13 Inhibition of HGF-induced c-Met phosphorylation by tepotinib **7** in A459 cells testing different conditions (triangles: standard (serum-free) conditions, squares: in the presence of 10% mouse serum, circles: in the presence of 10% human plasma, diamonds: standard (serum-free) conditions), after removal of tepotinib by 3x washing and 14 hrs incubation in fresh serum-free medium.

Biosciences), and a subsequent chemiluminescence reaction. Under these conditions, tepotinib inhibited the HGF-induced c-Met tyrosine phosphorylation with an IC_{50} of 6 nM and an efficacy of 100% (Fig. 13: triangles).

To address the effect of serum protein binding and metabolizing enzymes in serum on the activity of tepotinib, a similar cellular c-Met phosphorylation assay was conducted in the presence of 10% mouse serum or 10% human serum. Higher serum concentrations could not be used as they suppressed the HGF-induced c-Met phosphorylation, likely by binding of the added HGF to serum proteins or HGF inactivation by serum proteases. In the presence of murine or human serum, the IC_{50} values of tepotinib **7** were only shifted by a factor of ~2–5 as compared with serum-free conditions, likely reflecting the impact of serum protein binding on the effective free inhibitor concentration. This 2–5-fold IC_{50} shift was less dramatic than expected, based on the 96.9% plasma protein binding of tepotinib.

The sustainability of cellular c-Met inhibition was assessed by removing the tepotinib-containing supernatant after 30–45 min of incubation and washing cells. After a period of ~14 hrs in serum-free medium without inhibitor, HGF-induced c-Met tyrosine phosphorylation was measured using the capture ELISA assay. Despite the removal of the inhibitor-containing supernatant and extensive washing of the cells, a short incubation period with tepotinib was sufficient to block HGF-induced c-Met phosphorylation for at least 14 hrs reflected by unchanged IC_{50} values suggesting cellular retention and long-lasting activity of tepotinib. This observation supports the assumption that tepotinib has sustained pharmacological activity due to an extended residence time on c-Met. These effects were confirmed in additional models with high ligand-independent c-Met activation by c-Met gene copy number amplification and/or exon 14 skipping, like MKN-45 or Hs746T gastric cancer cells (data not shown).

Additional evidence for the long-lasting pharmacological effects of tepotinib came from autoradiograms of tumor-bearing mice after single oral dose application of ^{14}C-labeled tepotinib depicted in Fig. 14. Even after 24 and 48 h, the radioactivity is still detectable in target-expressing tissues like liver or the subcutaneously grafted tumor (Hs746T) suggestion, a long residence time of tepotinib, and a sustained c-Met inhibition.

The correlation between drug concentrations in plasma and tumor at various time points after a single application of tepotinib was studied in an *in vivo* PK/PD experiment (Fig. 15). In addition, a number of biomarkers downstream of the c-Met signaling pathway were analyzed to further characterize the mode of action (Fig. 16).

For these preclinical PK/PD studies, the levels of tyrosine phosphorylated c-Met in Hs746T gastric cancer xenografts were evaluated after a single oral application of tepotinib either by Western blotting or by immunohistochemistry with a phosphorylation site-specific antibody (Y^{1234}/Y^{1235}). The degree of target inhibition was then correlated with plasma and tumor levels of tepotinib.

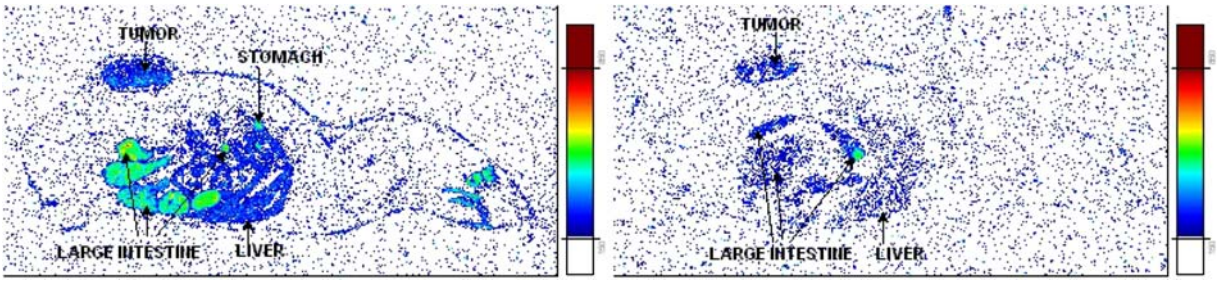

Fig. 14 Distribution of drug-related [^{14}C] radioactivity after single oral administration of 6 mg/kg [^{14}C]-tepotinib to tumor-bearing (Hs746T) nude mice (left 24 hrs and right 48 hrs).

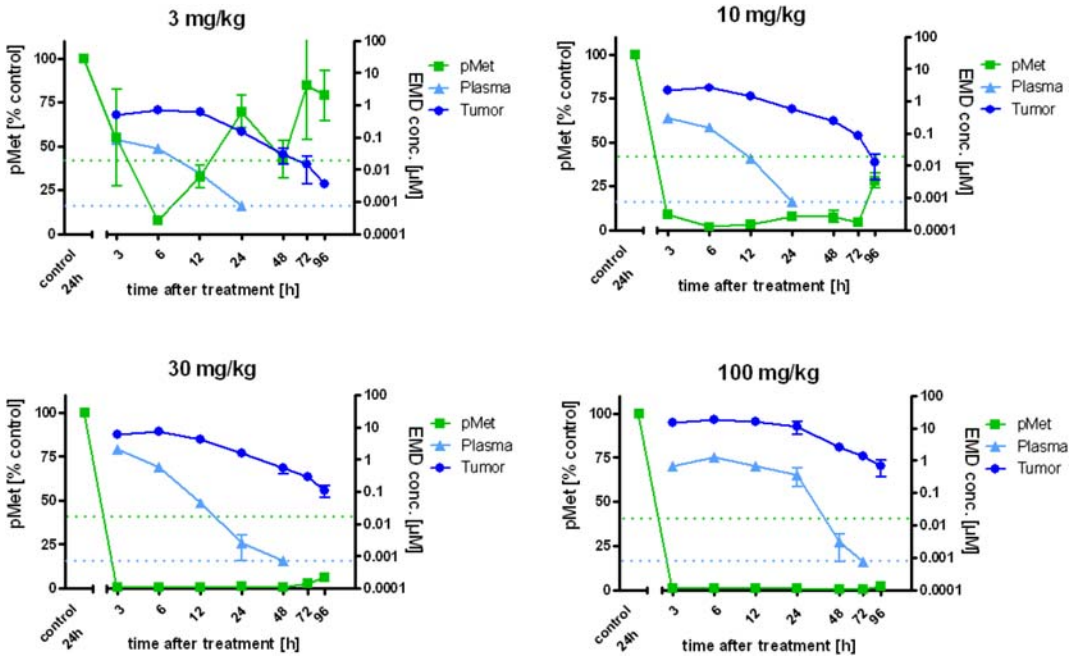

Fig. 15 Correlation of c-Met tyrosine phosphorylation (green squares) and drug concentrations in plasma (blue triangles) and tumor tissue (blue circles) following a single administration of 3, 10, 30, and 100 mg kg^{-1} of tepotinib. The dotted blue line indicates the detection limit for tepotinib, and the dotted green line marks the cellular IC_{50} of tepotinib for the inhibition of c-Met tyrosine phosphorylation in the presence of serum proteins.

In agreement with the PK study results, the relatively high volume of distribution (V_{ss} (mouse) ~ 8.2) of tepotinib led to compound concentrations in tumor tissue always higher than the corresponding plasma concentrations and remaining well above the cellular IC_{50} for considerable amount of time. The oral application of 30 and 100 mg kg^{-1} of tepotinib resulted in tumor concentrations of ≥ 100 nM and almost undetectable levels of phospho-c-Met for at least 4 days (Fig. 15). Even a daily dose of 10 mg kg^{-1} was sufficient to inhibit c-Met more than 90% for up to 3 days. Only a dose of 3 mg kg^{-1} was not able to block c-Met autophosphorylation for a sustained period of time. Altogether, the quantitative PK/PD data confirmed the sustained presence of tepotinib in the target tissue and a strong, long-lasting inhibition of c-Met *in vivo*.

Immunohistochemical studies utilizing tumor samples from PK/PD experiments confirmed a time- and dose-dependent inhibition of c-Met phosphorylation and suggest a tepotinib-induced cell cycle arrest and induction of apoptosis in Hs746T xenografts judged by decreased expression of cyclin D1 and increased levels of p27 and cleaved caspase-3 (Fig. 17).

Additional studies using targeted proteomic approaches and mRNA gene expression analysis aimed to identify pharmacodynamic biomarkers that could be detected in plasma and would therefore not require sequential tumor biopsies that are difficult to obtain in a clinical setting. Among several candidate biomarkers, the inhibition of IL-8 and VEGF secretion from tumor cells by tepotinib was considered most robust and worth to explore in the clinic.

Considering the strong constitutive activation of c-Met signaling in tumor cells with a c-Met gene amplification, the working hypothesis discussed in the literature (poster AACR 2006)[38] was that a sustained target coverage of greater than 90% is required to induce a therapeutically meaningful effect. Based on the generated PK/PD data, this would translate to an expected minimal efficacious dose of 3–10 mg kg^{-1} d^{-1} PO for c-Met-amplified tumor models, like Hs746T gastric or EBC-1 lung cancer xenografts.

Based on this hypothesis, c-Met-amplified human Hs746T and EBC-1 tumors were grafted onto mice and, depending on the cell line, treated with different daily doses of tepotinib, which should lead to a sustained > 90% target inhibition throughout the treatment period. As expected, in case of HS746T tumor-bearing mice, a daily dose of 10 mg kg^{-1} tepotinib **7** for 10 days resulted in an impressive complete response rate of 80% (tumors not detectable anymore in 8/10 animals) (Fig. 18), without any impact on body weights. In general, oral daily doses of up to 200 mg/kg tepotinib were well tolerated without any body weight changes, confirming the clean off-target profile of tepotinib and suggesting that even sustained c-Met inhibition is not associated with any acute toxicity in mice.

To assess the durability of response, c-Met amplified EBC-1 lung tumor xenografts were treated with doses of 6 and 15 mg kg^{-1} for 5 days followed by 2 days of drug holiday. This schedule was chosen for convenience reasons, only.

When the vehicle-treated control group reached the predefined maximal tumor volume at day 32, the treatment was stopped for all animals with the purpose to determine tumor growth delay. In the 6 mg kg^{-1} dose group, tumor growth reduction was observed during the treatment period, but 20 days after discontinuing the tepotinib treatment, tumors nearly reached the predefined maximal volume. In contrast, the 15 mg kg^{-1} dose of tepotinib applied PO using the 5 days on/2 days off schedule did result in an

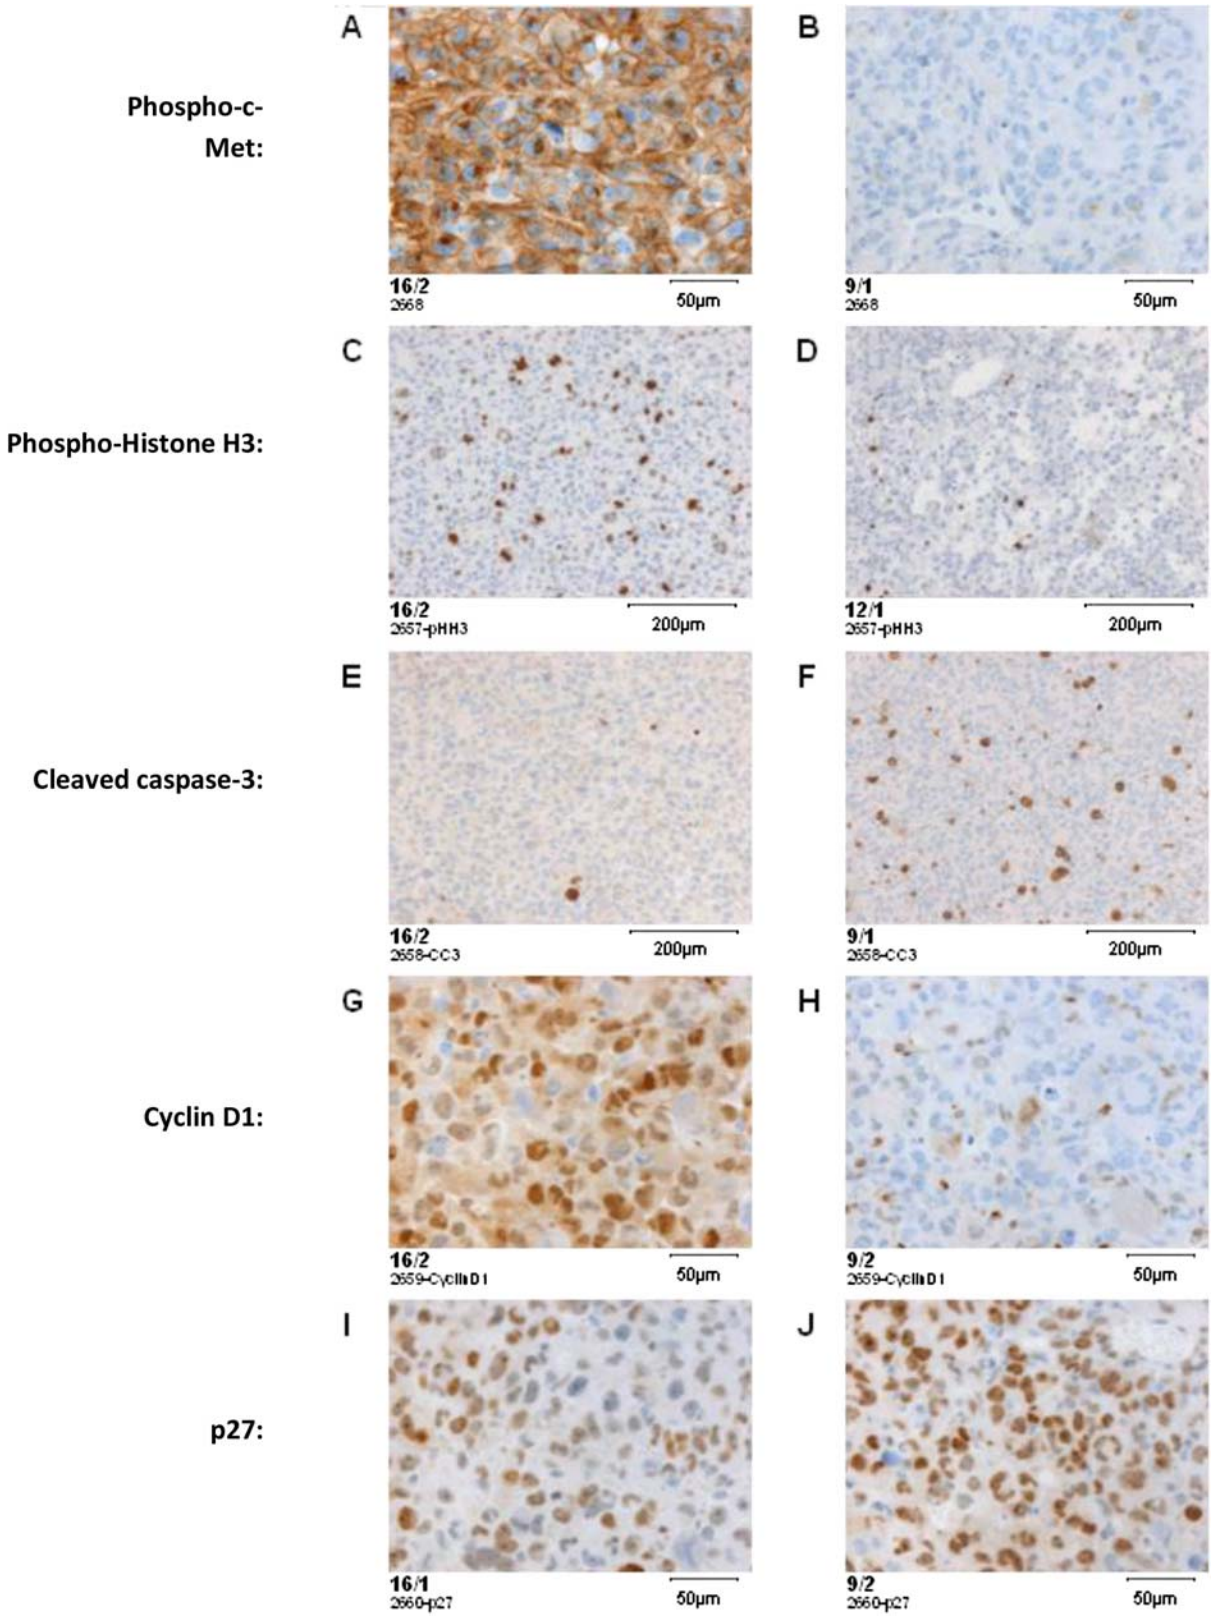

Fig. 16 Immunohistochemical analysis of phospho-Met (A, B)(Y^{1234}/Y^{1235}), phospho-histone H3 (C, D), cleaved caspase-3 (E, F), cyclin D1 (G, H), and p27 (I, J) levels in Hs746T xenografts treated for 24 (B, F, H, J) or 48 hrs (D) with vehicle (A, C, E, G, I) or 30 mg/kg of tepotinib as a single dose.

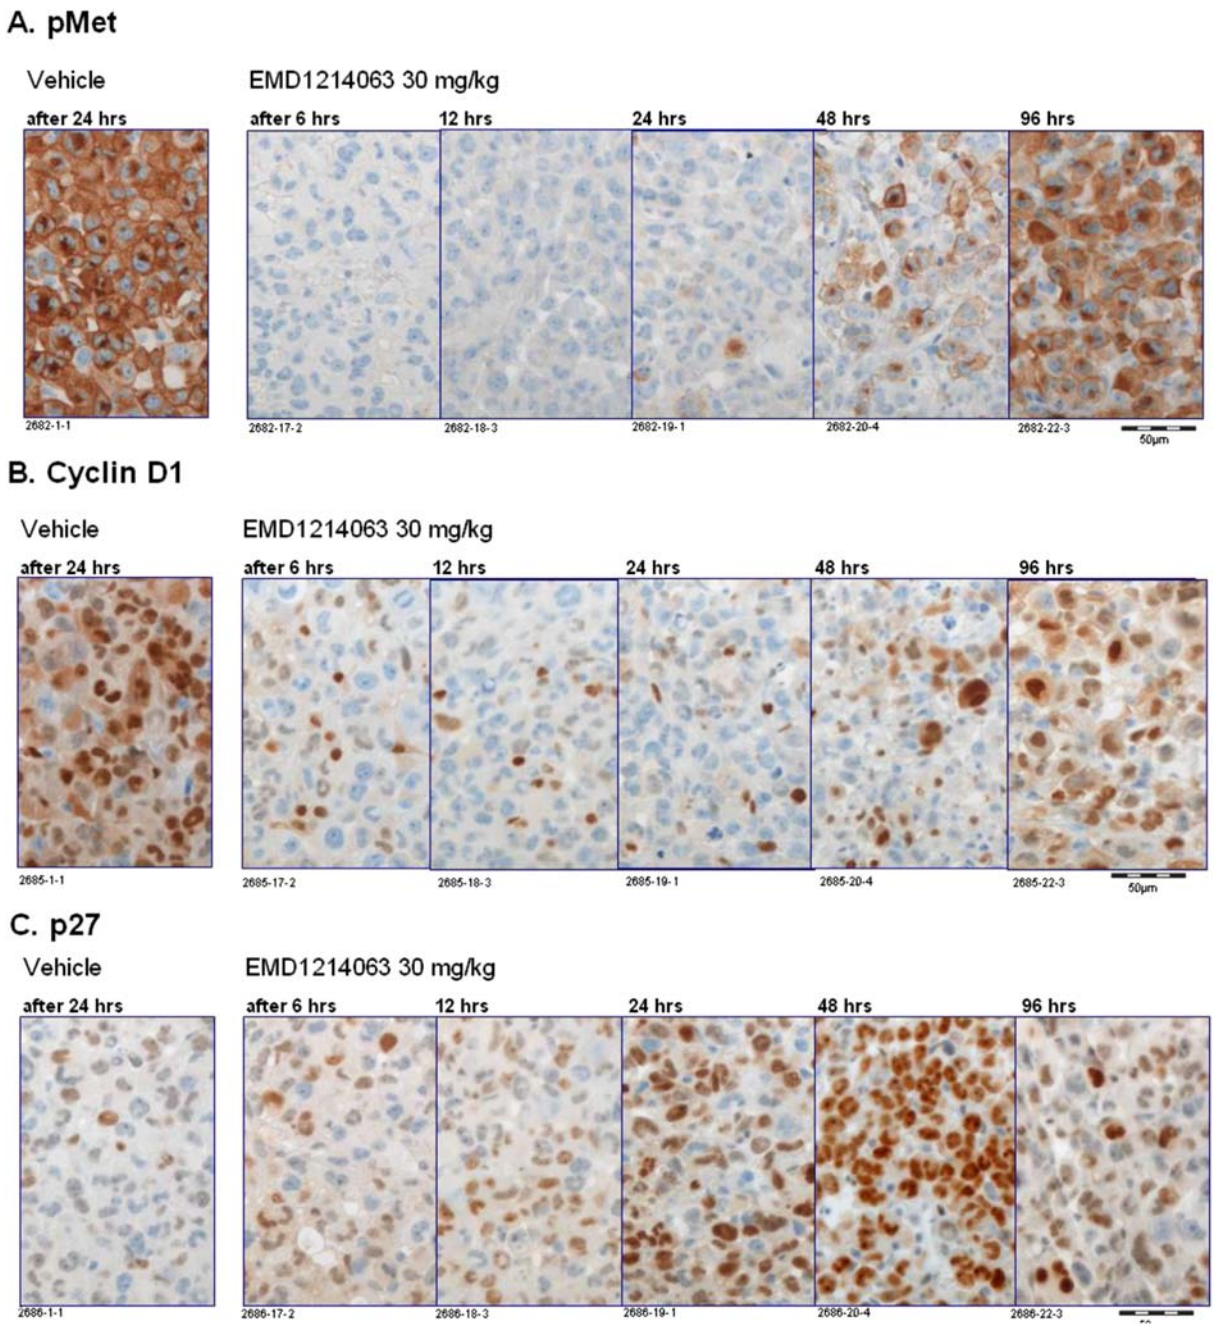

Fig. 17 Immunohistochemical analysis of phospho-Met (A), cyclin D1 (B), and p27 (C) levels in Hs746T xenografts different times after treatment with a single dose of 30 mg/kg of tepotinib (EMD1214063).

impressive complete response rate of 100% during the entire observation period of 84 days, well beyond the tepotinib treatment period of 32 days (Fig. 19). Again, all treatment regimens were well tolerated in mice without any body-weight changes.

In addition to highly oncogene addicted c-Met amplified tumor models, tepotinib was also very efficacious in autocrine models like KP-4 pancreatic tumors that secrete large amounts of HGF that permanently activate the coexpressed c-Met receptor and in genetically engineered murine tumors that express the constitutively active intracellular TPR-Met fusion protein (data not shown). The fact that murine HGF does not fully cross-react with human c-Met has initially limited further characterization of tepotinib in models where c-Met is activated by paracrine HGF stimulation. Therefore, genetically engineered mice were generated that express human HGF and allowed to study a larger variety of human tumor models that do express c-Met.

Based on its good preclinical safety profile, tepotinib could be well combined with standard of care chemotherapy and other targeted therapies, like small-molecule EGFR or PI3K pathway inhibitors (data not shown).

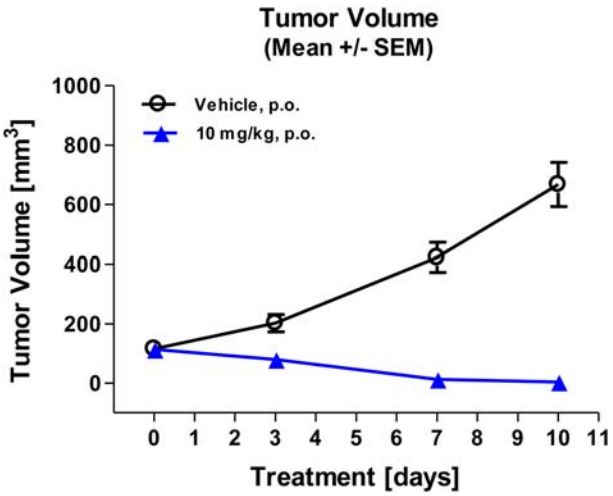

Fig. 18 Inhibition of the growth of Hs746T gastric cancer xenografts by a 10-d oral treatment with 10 mg kg^{-1} d^{-1} tepotinib.

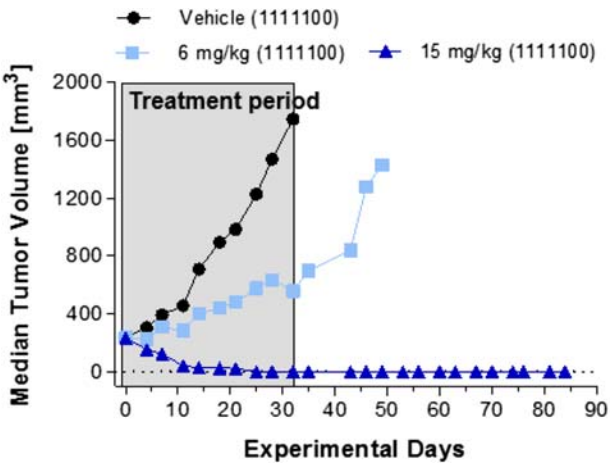

Fig. 19 Tumor growth inhibition of EBC-1 lung xenografts in nude mice treated with 6 and 15 mg kg^{-1} PO using a 5 days on/2 days off schedule. The treatment period is highlighted by a gray box.

In preclinical studies, high c-Met expression, c-Met gene amplification, exon 14 skipping, and c-Met and HGF coexpression were identified as a potentially predictive biomarker for the response of tepotinib.

Together with more extensive PK/PD studies in other tumor models, a comprehensive set of efficacy studies in regular xenografts and patient-derived primary tumor models, more detailed PK characterizations, and a robust preclinical safety package formed the basis for the human dose prediction and combined with phase I data for a selection of an optimal biologically active dose for phase II studies.

8.08.6 Summary and Conclusion

In summary (Fig. 20), the rationally guided compound optimization of our internal c-Met inhibitor program, started from an attractive singleton identified in a HTS run of 350 k compounds and led to the identification of tepotinib (**7**). The interesting thiadiazinone carbamates chemical series came from an internal phosphodiesterase program and demonstrated a high degree of kinase selectivity in combination with a significant inhibitory activity on c-Met kinase activity of around 30 nM. Though the binding efficiency index was only 14.5, the compound had a reasonable physicochemical profile and good solubility. Evaluating the biochemical and cellular structure–activity relationship that was regularly supported by cocrystal structures of c-Met in complex with various compounds from different classes, led to the identication of pyridazinone carbamates as a first generation of pharmacologically active and apparently attractive c-Met inhibitors. While this class of first-generation inhibitors including compound **26** had to be discontinued because of their unfavorable toxicological profile (phospholipidosis, QT prolongation, and direct cardiovascular side effects), the structural insights and the accumulated understanding of the pharmacological and toxicological structure–

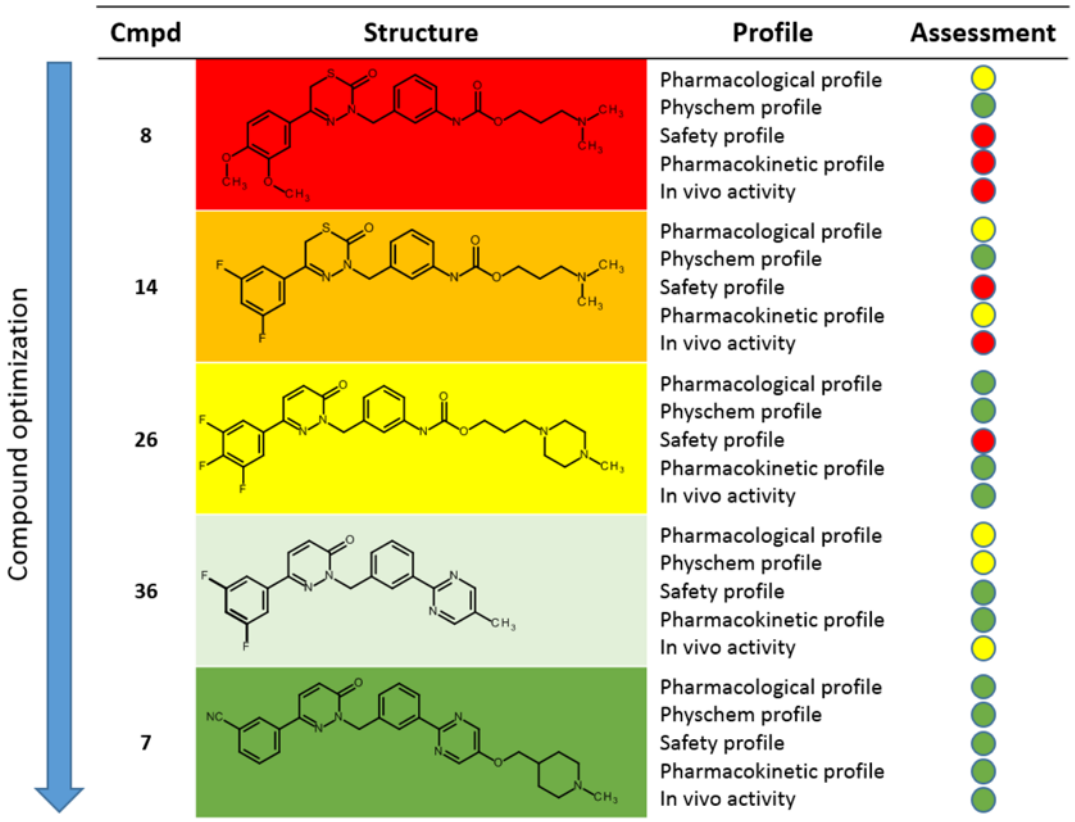

Fig. 20 A simplified graphic representation of the compound optimization process and some profile considerations.

activity relationship paved the way for a more holistic and finally successful compound optimization approach. The first milestone on the journey from an initial HTS hit toward a clinical candidate was the optimization of the substitution pattern of the aryl ring in order to diminish the residual PDE activity, followed by the switch from the chemically somewhat labile thiadiazinones toward the chemically more stable pyridazinones. The most valuable modification was the identification of the pyrimidine hinge binder as a potent and superior bioisostere of the toxicologically questionable alkyl carbamate. This modification is retrospectively regarded as the major breakthrough in the overall optimization process. This observation and the associated profile of the compounds are again underlining the reputation of pyrimidines as one of the preferred heterocycles used regularly in medicinal chemistry.[39] Subsequent fine-tuning of the solubilizing anchor and the aryl substitution pattern seems somehow trivial, but it was guided by the general compound quality considerations to identify a compound providing a balanced drug profile. Though many compounds consisting of combinations of different substructural motives, like pyridazinones, thiadiazinones, benzoxazolones, or carbamates, oxadiazoles and pyrimidines demonstrated significant *in vitro* potency on the c-Met kinase in combination with a reasonable pharmacokinetic and physicochemical profile; the most impressive *in vivo* efficacy was achieved by combining the pyridazinone core with pyrimidine moieties.

Tepotinib **7** demonstrated outstanding *in vivo* activity in multiple HGF-dependent and HGF-independent xenograft models, which may potentially be explained by the extraordinary residence time of more than 15 hoin combination with a pronounced PK/PD disconnect initially observed in cellular washout experiments. This explanation is also supported by a long-lasting target inhibition in our PK/PD *in vivo* experiments and by the sustained tumor concentration observed in autoradiographic *in vivo* experiments using tumor-bearing mice. Tepotinib offers a promising pharmacological *in vitro* and *in vivo* profile including the significant modulation of relevant downstream markers in combination with a favorable toxicological profile without the aforementioned concerning safety signals seen for the pyridazinone carbamate around compound **26**. Tepotinib **7** (MSC2156119) is an exquisitely selective and highly potent c-Met inhibitor with a reassuring pharmacokinetic and pharmacodynamic profile. Tepotinib **7** is currently evaluated in clinical phase II proof-of-concept studies in EGFR-inhibitor-resistant, c-Met overexpressing NSCLC and in c-Met overexpressing hepatocellular cancer in order to evaluate the potential of monospecific c-Met inhibitors in these particular oncological applications.

8.08.7 Supplementary Material

Experimental details including assay protocols and synthetic procedures are mainly described in references (24a–d) and (29)–(31).

8.09.1 Introduction

Alzheimer's disease (AD) is a chronic, progressive, ultimately fatal neurodegenerative disease, and is the most common cause of dementia.[1] Predominantly a disease of the elderly, AD is a leading cause of death in the United States[2] and is increasing in incidence globally as the population ages.[3] In 2015, there were an estimated 46 million patients with dementia worldwide, and the estimated cost for caring for these individuals was US$ 818 billion.[4] By 2050 the global incidence of AD is projected to nearly triple,[4] and estimates place the annual cost of patient care at >US$ 1 trillion in the United States alone,[5] creating an unsustainable healthcare burden.

Initial symptoms of AD usually manifest as short-term memory loss. As the disease progresses there is a worsening of cognitive function, decreased ability to perform activities of daily living, and profound personality and behavioral disturbances.[1] In the latter stages of the disease patients typically require constant care, placing a significant burden on family members and caregivers. Current treatments—the acetylcholinesterase inhibitors and the *N*-methyl-D-aspartate receptor antagonist memantine—provide modest, temporary symptomatic benefit but do not impact the underlying disease pathogenesis.[6] Consequently, there is an urgent need to develop disease-modifying therapies that alleviate the profound patient, caregiver, and socioeconomic burden of the disease.

Invariant histopathological hallmarks in postmortem AD patient brains are extracellular neuritic plaques composed primarily of aggregated amyloid β (Aβ) peptides and intracellular neurofibrillary tangles composed primarily of hyperphosphorylated tau protein.[7] The disease progresses over the course of decades with the occurrence of pathological changes in the brain antecedent to the emergence of cognitive symptoms. The temporal relationship between biomarkers of AD pathophysiology—amyloid positron emission tomography (PET) imaging, tau PET imaging, cerebrospinal fluid (CSF) $A\beta_{42}$, CSF Tau, and structural MRI—suggests that amyloid accumulation occurs early in the disease process while accumulation of Tau tangles occurs later and correlates more closely with neuron loss and clinical symptoms of cognitive decline.[8,9]

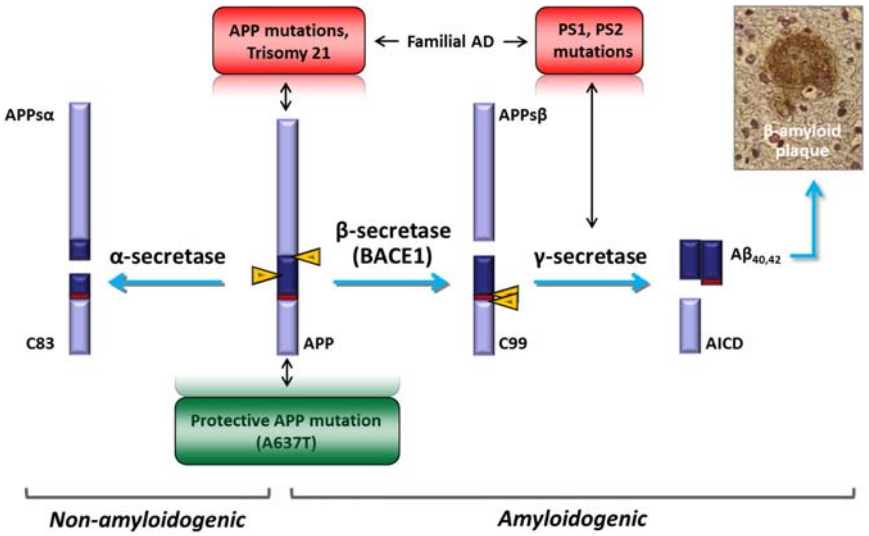

Fig. 1 Schematic representation of the amyloidogenic and nonamyloidogenic pathways of amyloid precursor protein (APP) processing. In the amyloidogenic pathway, APP is cleaved by BACE1 to produce soluble APPβ (APPsβ) and C99. The C99 fragment is further cleaved by γ-secretase to release amyloid β fragments, primarily $A\beta_{40}$ but also $A\beta_{42}$, which is highly prone to aggregation, and the APP intracellular domain (AICD). In the nonamyloidogenic pathway, APP is cleaved by α-secretase to produce soluble APPα (APPsα) and C83, which itself is subsequently cleaved by γ-secretase to produce nonaggregating species.

According to the amyloid hypothesis of AD, the aberrant accumulation of Aβ peptides, particularly $A\beta_{42}$, either as soluble oligomeric species or as plaques, is causative of the impaired neurotransmission, neuroinflammation, neuronal cell death, and ultimately dementia that is characteristic of the disease.[10–12] The Aβ peptides are produced from the transmembrane amyloid precursor protein (APP) by two sequential proteolytic cleavages that constitute a minor APP processing pathway (Fig. 1).[13] The first committed step in Aβ peptide synthesis is the cleavage of APP at its β-site by β-site APP cleaving enzyme 1 (BACE1), also known as β-secretase, resulting in shedding of the APP ectodomain APPsβ. The remaining membrane-bound C-terminal fragment C99 is subsequently processed by γ-secretase (GS), affording not only multiple isoforms of the Aβ peptides, predominantly $A\beta_{40}$, but also minor amounts of the $A\beta_{42}$ isoform that is highly prone to aggregation[14] and is the principal component of the neuritic plaques characteristic of AD.[15] The majority of APP is processed by α-secretase-mediated cleavage within the Aβ domain yielding a membrane-bound C-terminal fragment that is subsequently processed by GS leading to nonamyloidogenic products.

Although aspects of the etiology of AD remain poorly understood, several lines of genetic, biochemical, and biomarker evidence support the amyloid hypothesis.[16–18] Early-onset autosomal dominant familial AD is associated with mutations in APP and in the GS components presenilin-1 and -2, and all of these mutations increase total Aβ and/or the proportion of Aβ species with a greater propensity to aggregate. APP gene trisomy as occurs in Down syndrome is associated with increased Aβ production, amyloid deposition, and AD. Conversely, a rare APP mutation (A673T) was recently identified that is associated with reduced risk of developing AD and with improved cognitive function in the elderly (see below).[19] The highest known risk factor for late-onset sporadic AD is the presence of the APOE gene allele APOE4, which is associated with increased amyloid accumulation.[20] Finally, recent studies support reduced levels of $A\beta_{42}$ in the CSF, indicative of reduced $A\beta_{42}$ clearance, and the presence of amyloid aggregates in the brain as prognostic biomarkers for AD.[8,9]

Inhibition of BACE1 is widely regarded as the most promising therapeutic approach for development of a disease-modifying AD therapy.[21,22] First cloned and characterized in 1999, BACE1 is a transmembrane aspartyl protease.[23–27] In the brain, BACE1 is preferentially expressed in neurons which produce the majority of Aβ in the CNS,[23,24,28] and BACE1 expression and activity is increased in the brains of AD patients.[29–31] The enzyme is highly expressed in the nervous system early in development, and is subsequently downregulated.[32] In mature animals there is broad, low level BACE1 expression and secretion of Aβ across a variety of cell types and tissues.

Validation of BACE1 as a prime therapeutic target for AD has been provided by extensive genetic studies performed in mice. Bace1 knockout (KO) mice do not produce Aβ confirming that BACE1 is the major enzyme responsible for Aβ production in vivo.[33] Furthermore, Bace1 heterozygous mice obtained by crossing Bace1 KO mice with transgenic mice that overexpress human APP harboring familial AD mutations have reduced plaque deposition and improved cognitive function compared to Bace1 homozygous APP transgenic mice.[34–36] The rare protective APP mutation A673T mentioned above provides human genetic validation of BACE1 as an important AD therapeutic target.[19] This mutation occurs two amino acid residues C-terminal to the BACE1 cleavage site, reduces the rate of BACE1-mediated APP processing and Aβ peptide production by 40%,[19] and results in Aβ species that are less prone to aggregation compared to Aβ derived from wild-type APP.[37,38] The presence of the A673T variant is associated with five- to sevenfold reduced risk of developing AD and improved cognitive function in the elderly.[19] Conversely, the APP mutation A673V

that occurs at the position identical to the A673T variant leads to increased BACE1-mediated APP processing and Aβ production, and individuals homozygous for this mutation develop early-onset AD.[39]

Despite the progression of multiple drug candidates into long-term clinical trials, amyloid-centric approaches have failed to provide clear clinical benefit to date, and this has been cited as evidence against the validity of the amyloid hypothesis.[40] However, limitations of the drug candidates tested, of their mechanisms of action, or of clinical trial designs confound this viewpoint. The majority of these agents targeted Aβ synthesis with small molecule GS inhibitors or modulators, or targeted Aβ directly with antibodies, but in clinical trials they produced at best modest effects on CSF Aβ levels or brain amyloid plaques due to dose-limiting side effects and/or inadequate target engagement.[41] In one such trial, although the Aβ antibody solanezumab failed to meet its Phase 3 clinical endpoints, prespecified post-hoc analyses demonstrated that patients with mild AD had a modest but significant slowing of cognitive decline.[42] In the same trials, patients with moderate AD showed no benefit. These results suggest that intervention earlier in the disease process may be beneficial, and additional Phase 3 trials with solanezumab are currently underway to test this hypothesis.

BACE1 inhibitors are among the newer agents to target amyloid reduction as a therapeutic approach to AD, and they appear capable, with proper design and safety profiling, of effecting a more profound lowering of CNS Aβ than earlier approaches. The most advanced agent targeting this mechanism is verubecestat (MK-8931), currently in Phase 3 clinical trials in patients with mild-to-moderate AD and in patients with early stage, prodromal AD. Beginning with initiation of our BACE1 inhibitor program and chronicling a number of strategies and approaches, this article describes the discovery of verubecestat, which is uniquely positioned to provide a robust test of the amyloid hypothesis.

8.09.2 BACE1 Characteristics and Drug Discovery Challenges

Mature BACE1 is a 501 amino acid single transmembrane domain aspartyl protease that belongs to the pepsin family of proteases.[43] The catalytic domain contains two signature hexapeptide motifs each bearing an aspartic acid residue that forms a catalytic dyad intimately involved in substrate proteolysis. An additional structural aspect of BACE1 is a β-hairpin loop that forms a mobile flap over the active site. A crystal structure of the BACE1 apo protein (**Fig. 2**) shows a water molecule bound to the catalytic aspartates and the flap in a partially closed conformation.[44]

BACE1 is initially synthesized as a zymogen that is converted to its mature form through the action of furin convertases in the Golgi. During maturation BACE1 undergoes several posttranslational modifications and its intracellular localization is influenced by a number of regulatory proteins. Posttranslational modifications of BACE1 include disulfide cross-linking, glycosylation, acetylation, phosphorylation, and palmitoylation; the regulatory roles of many of these modifications are not well understood.[23,43] The transmembrane domain of BACE1 orients the catalytic domain to project into the lumen of intracellular organelles, proximal to the APP β-cleavage site. Typical of most aspartyl proteases, an acidic pH near 5 is optimal for BACE1 catalytic activity.[24] Accordingly, the majority of APP processing by BACE1 occurs in endosomes and in the trans-Golgi network where the lumenal pH is maintained in the acidic range (pH 5–6).[43]

At the outset of our discovery program there were two major considerations that had the potential to pose significant obstacles. Since there was no precedent for the development of brain-permeable inhibitors of aspartyl proteases, first was the need to discover inhibitors sufficiently small and with suitable physicochemical properties to be brain penetrant in order to inhibit brain BACE1, and hence directly lower brain-derived Aβ levels. Precedent for aspartyl protease inhibitor drug development was established by the marketed HIV protease inhibitors and the renin inhibitor aliskiren.[45,46] However, these agents tend to be large peptidomimetic structures with physicochemical properties that confer poor permeability and P-glycoprotein (Pgp) efflux susceptibility that limits oral bioavailability and brain penetration.

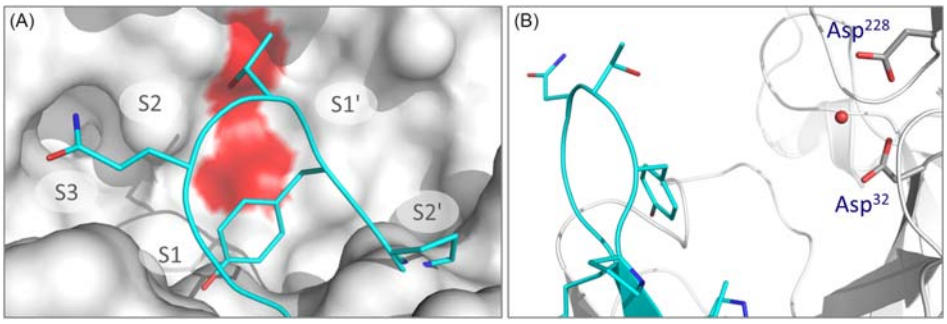

Fig. 2 (A) X-ray structure of the active site of the BACE1 apo protein showing the surface of the protein in *gray* with the surface of the two catalytic aspartates in *red*. A β-hairpin loop, shown as a *blue ribbon* with side chains, forms a flap in front of the aspartates; unless explicitly stated, the flap is omitted from X-ray views for clarity. (B) View of the active site of BACE1 apo structure from the prime side showing that the two catalytic aspartates are bound to a water molecule.

The second challenge was to achieve adequate selectivity over other human aspartyl proteases with relatively small, low molecular weight (MW) BACE1 inhibitors. Analysis of the substrate specificity of BACE1 versus the aspartyl proteases cathepsin D (CatD), cathepsin E (CatE), pepsin, renin, and napsin A suggested that the challenge of achieving selectivity over these enzymes might be readily surmountable.[47] In particular, we considered sufficient selectivity for BACE1 over the lysosomal enzyme CatD to be paramount since loss of function of this aspartyl protease had been shown to cause neurodegeneration, blindness, and postnatal lethality in mice.[48] Given those findings, new compounds that we prepared during lead optimization were routinely counterscreened against CatD. At the outset of our program, we implemented a selectivity criterion of >100-fold for BACE1 over CatD based on K_i values to be acceptable for compound advancement. After the discovery of verubecestat, reports emerged of CatD-mediated toxicity in animals with competitors' BACE1 inhibitors that highlighted the importance of achieving adequate selectivity for BACE1 over CatD.[49–51] Notably, inhibitor pK_a has been shown to be a key determinant of CatD-mediated toxicity, whereby basic inhibitors have lower selectivity in cells due to lysosomal accumulation compared to that measured in cell-free enzyme assays.[51] During the course of the work described herein, preclinical safety data generated from chronic animal studies with a number of our weakly basic lead compounds that had BACE1/CatD selectivity ratios in the hundreds of fold and CatD affinity in the single digit micromolar range were devoid of findings that were ascribed to CatD inhibition. Based on these internal observations, and lacking knowledge of the CatD-mediated toxicity of competitors' inhibitors prior to the discovery of verubecestat, we did not significantly modify the CatD selectivity criterion that remained in place for the duration of the work described in this article.

Shortly after BACE1 was discovered, a close homolog designated as BACE2 was also identified.[52,53] Unlike BACE1, BACE2 is expressed mainly in the periphery and has very low expression levels in the CNS. In addition, heterologous expression studies indicate that the preferred sites of APP cleavage by BACE2 are 19–20 residues C-terminal to the BACE1 cleavage site, affording distinct cleavage products.[54–56] Consequently BACE2 does not significantly contribute to Aβ production in vivo. This was confirmed by studies of brain tissue or cultured neurons derived from Bace1 KO mice in which Aβ production is almost completely suppressed, and by the demonstration that Bace2 KO mice produce normal levels of Aβ.[33,57,58] At the outset of our efforts, the effects of BACE2 loss of function had not been reported. Recent studies have established a role of BACE2 in pigmentation in rodents. BACE2 processes the melanosome structural protein PMEL17 and Bace2 KO mice display fur hypopigmentation.[58] Additionally, BACE2 has been shown to process the pancreatic β-cell proteins Tmem27 and islet amyloid polypeptide, and inhibition of BACE2-mediated processing of these substrates has been proposed to be of benefit in Type 2 diabetes.[59,60] At the commencement of our drug discovery efforts it was anticipated that selectivity for BACE1 over BACE2 would be very difficult to achieve due to the high active site sequence homology between the two enzymes.[47,52,53] This was indeed the case, and as our program evolved, the relatively benign or possibly beneficial phenotypes related to BACE2 loss of function that emerged mitigated concerns related to lack of inhibitor selectivity for BACE1 over BACE2.

At the time BACE1 was first characterized, it was reported that Bace1 KO mice were viable, healthy, and lacked an overtly negative phenotype, thus mitigating concerns of toxicity mediated by BACE1 inhibition.[33,57] This view has evolved as more recent data generated with Bace1 KO mice and/or BACE1 pharmacological inhibition has revealed potential adverse consequences of inhibiting BACE1-mediated processing of substrates unrelated to APP.[21,28,61] The best characterized of these substrates are members of the neuregulin 1 (NRG1) family, NRG1 type I and NRG1 type III. Bace1 KO mice show reductions in peripheral nerve myelination[32,62] and in muscle spindle formation,[63] which has been ascribed to loss of BACE1-mediated processing of NRG1 type III and NRG1 type I, respectively. Importantly, these as well as other phenotypes observed in homozygous Bace1 KO mice are not seen in Bace1 heterozygous mice, and are not recapitulated in adult wild-type mice administered BACE1 inhibitors, thus supporting a greater impact of BACE1 activity in early development and the need to achieve substantial (>50%) inhibition of BACE1 for these phenotypes to manifest even in early development. This latter assertion is further supported by the observation that Bace1 is expressed at markedly higher levels in the developing mouse CNS relative to adult mice.[32]

In sum, while appropriate safety monitoring of clinical trials is essential, the available data does not preclude the possibility that substantial long-term pharmacological BACE1 inhibition in AD patients could be a safe approach to disease modification. A recent review of the known BACE1 biology emphasized that BACE1 inhibitor clinical trials not only need to address the degree of BACE1 inhibition required for disease modification in AD, but also balance this with achieving a safe therapeutic window to potential BACE1-mediated adverse effects.[61]

8.09.3 BACE1 Inhibitor Lead-Finding Strategies

8.09.3.1 Overview

We assigned high priority to development of BACE1 inhibitors for disease modification, and from the outset we invested significant resources in support of multiple hit finding approaches to identify tractable inhibitor lead series. Like most organizations in this highly competitive area, we conducted high-throughput screening (HTS), and we also pursued parallel synthesis and screening of targeted libraries. Unfortunately, neither of these approaches delivered viable leads. In addition, we were able to leverage substantial capabilities and expertise in the areas of protein X-ray crystallography, structure-based design, and fragment screening which were established at Schering-Plough during the 1990s. Accordingly, shortly after the initial reports of the characterization of BACE1 had appeared in the literature, we commenced BACE1 protein production and crystallization efforts. This positioned us to conduct a fragment screen and characterization of screening hit binding modes by X-ray crystallography in 2001–2002. These

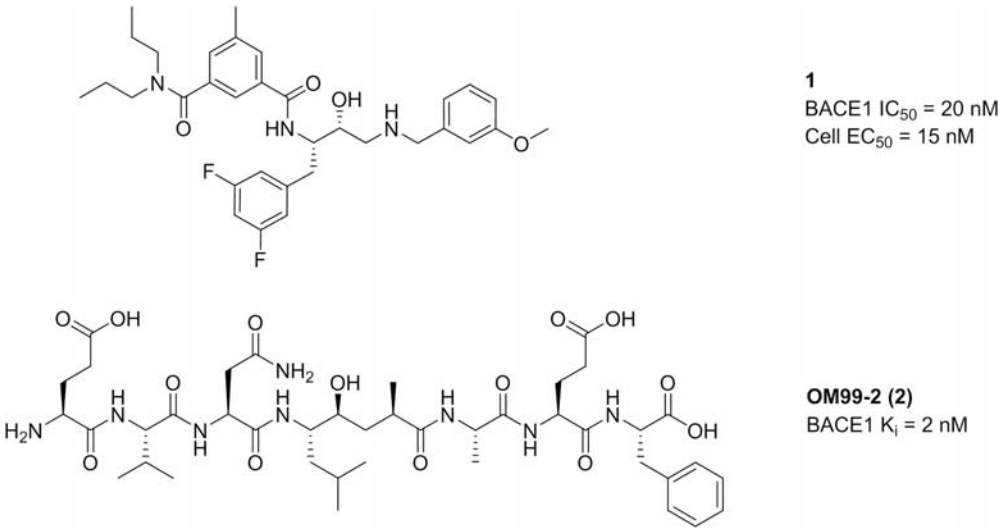

Fig. 3 Structures of hydroxyethylamine peptidomimetic BACE inhibitor **1**,[64,65] and of substrate-based peptidomimetic inhibitor OM99-2.[66,67]

fragment screening hits were of critical importance to the success of the program and their discovery and early structure-driven optimization efforts are described in Section "Fragment Screening: Discovery of New Inhibitor Chemotypes."

Also at about this time, the first potent inhibitors containing the hydroxylethylamine (HEA) peptidomimetic transition state isostere were published in the patent literature, exemplified by **1** from Elan/Pharmacia (Fig. 3).[64,65] These structures followed publication by Ghosh and Tang in 2000 of an X-ray structure of a peptidomimetic substrate-based inhibitor, the homostatine OM99-2 (**2**), bound to BACE1, which established that the enzyme was amenable to crystallography and structure-based design.[66,67] An attractive property of HEA analogs such as **1**, in addition to their high BACE1 affinity, was their cell potency indicative of their intrinsic cell penetration properties.[65] Consequently, to jump-start our program, we employed a scaffold-hopping approach to the development of novel inhibitors as described in Section "Hydroxyethylamine-Based Peptidomimetic Inhibitors," in parallel with our fragment-based approach.

8.09.3.2 BACE1 and CatD in vitro Assays

Throughout our program two key in vitro assays that we used to evaluate the BACE1 potency of inhibitors were variants of a cell-free enzymatic assay, and a cell-based functional assay that measured inhibition of $A\beta_{40}$ secretion in response to a BACE1 inhibitor. The initial enzymatic assay utilized a soluble form of BACE1 and an 18mer peptide substrate possessing the familial AD Swedish mutation (KM → NL).[68] A refined version of the assay that was used to determine K_i values employed a lower BACE1 enzyme concentration and a 12mer substrate that retained the KM → NL substitution (BACE1 $K_m = 8\ \mu M$).[69] Both peptide substrates were fluorescently labeled to enable measurement of BACE1-mediated substrate hydrolysis in the presence of a BACE1 inhibitor through time-resolved fluorescence resonance energy transfer (HTRF) methods.

The cell-based assay employed HEK-293 cells stably transfected to express human APP containing the familial AD Swedish (K670N/M671L) and London (V717I) mutations.[68] These mutations result in increased APP processing and increased secretion of $A\beta_{40}$ and $A\beta_{42}$ into the culture medium. Quantification of Aβ peptide secretion in response to a BACE1 inhibitor was determined by Aβ antibody capture methods and the potency of an inhibitor to reduce Aβ secretion was expressed as an IC_{50}.

The CatD enzymatic counterscreen assay employed human liver CatD and a fluorogenic 12mer peptide substrate to measure proteolytic activity in the presence of an inhibitor by fluorescence resonance energy transfer methods.[69]

8.09.3.3 Hydroxyethylamine-Based Peptidomimetic Inhibitors

Using **1**[64,65] as a starting point, our initial goal was to develop brain penetrant, patentable inhibitors that lowered CNS Aβ levels following systemic administration to rodents. Inhibitor **1** engages in a number of specific interactions with BACE1 (Fig. 4), and our initial approach was to minimize disruption of these interactions to avoid significant loss of affinity. In addition to hydrogen bonding interactions between the HEA transition state isostere and the catalytic dyad, the amine hydrogen of **1** is within hydrogen bonding distance of the Gly^{34} carbonyl and the hydrophobic S2′ pocket is occupied by the methoxyphenyl group. In the nonprime region, the difluorophenyl group makes hydrophobic contacts with the S1 pocket and the amide hydrogen engages in a hydrogen bond with Gly^{230}. The isophthalamide spans the S2 and S3 pockets with its distal amide carbonyl picking up a hydrogen bond to Thr^{232}. Docking studies based on an X-ray cocrystal structure of **1** bound to BACE1 suggested that the enzyme could accommodate the steric demand of a cyclic amine motif formed through introduction of a two- or three-atom bridge linking the methylene

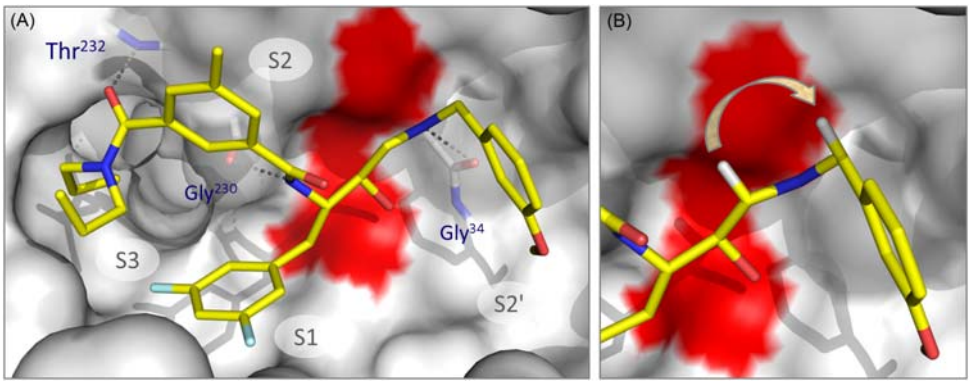

Fig. 4 (A) X-ray structure of hydroxyethylamine **1** bound to BACE1 showing key interactions of the structure with the enzyme. (B) Close-up view of hydroxyethylamine portion of **1** showing the potential for cyclization around the amine.

carbons flanking the secondary amine nitrogen. Furthermore, modeling suggested that conformational constraint imposed by such a cyclic amine would not disrupt the key interactions of the HEA transition state isostere with the catalytic dyad and might provide an ideal vector into the S2′ pocket.

Implementation of this design strategy by Cumming et al. and by Iserloh et al. proved to be successful, with potent piperazine- and pyrrolidine-based inhibitors such as **3** and **4** (Fig. 5A) identified through this approach.[70–73] The piperazine core in particular was useful not just for SAR development, but also for generation of high specific activity radiolabeled material for ex vivo studies, for example, compound ^{35}S-**5**. X-ray cocrystal structures of these inhibitors confirmed that their binding mode relative to **1** was highly conserved, as shown for **3** in Fig. 5B. In addition, the sulfonyl group of the piperazine sulfonamide of **3** was engaged in a hydrogen bond with the backbone amide NH of Thr^{72} in the flap that was not present with **1** (Fig. 5C).[70]

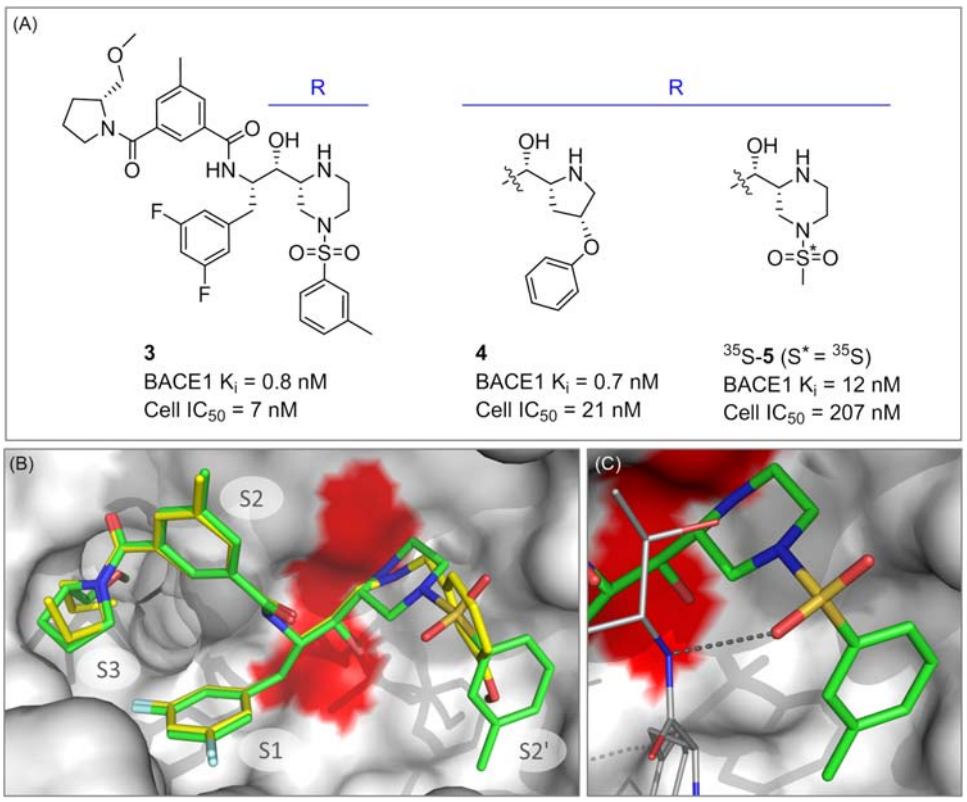

Fig. 5 (A) Structures of optimized cyclic amine peptidomimetic BACE inhibitors **3** and **4** and of radioligand ^{35}S-**5**. (B) Overlay of the X-ray structures of acyclic hydroxyethylamine **1** (*yellow*) and piperazine sulfonamide **3** (*green*) showing their well-conserved binding modes. (C) Close-up view of the hydrogen bonding interaction between one of the sulfonyl oxygens of piperazine sulfonamide **3** and backbone NH of Thr^{72} in the flap.

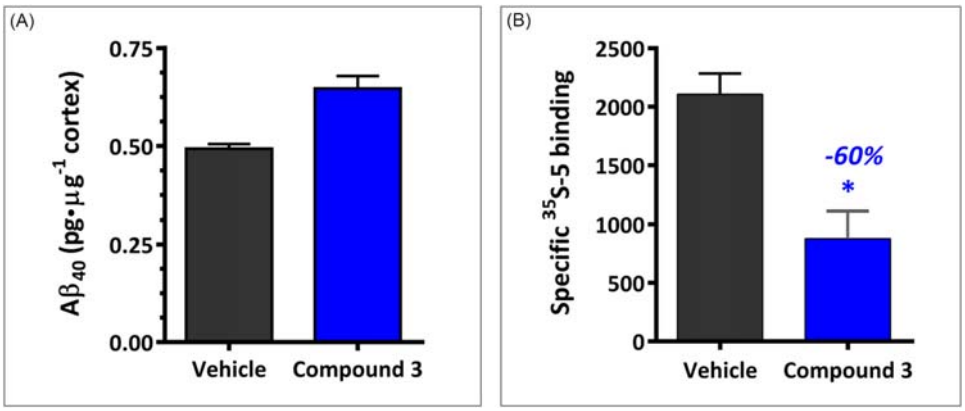

Fig. 6 (A) Lack of effect of subchronic administration of piperazine sulfonamide **3** (300 mg kg^{-1} SC, BID, 5 days) on brain $A\beta_{40}$ levels in TgCRND8 mice. Plasma levels of $A\beta_{40}$ were completely suppressed. (B) Ex vivo binding of ^{35}**S-5** to brain slices from TgCRND8 mice following subchronic treatment with piperazine sulfonamide **3**.

Of the novel cyclic amine containing HEA inhibitors that were identified, **3** was among the most potent in regard to its activity in the cell-based assay and was assessed for its potential to lower Aβ levels in vivo.[70] The in vivo model we initially employed was transgenic CRND8 mice (TgCRND8), which overexpress the human APP gene containing the Swedish (K670N/M671L) and Indiana (V717F) familial AD mutations. These mice produce high levels of Aβ peptides and develop very aggressive plaque pathology in the brain accompanied by deficits in learning and memory acquisition commencing at approximately 3 months of age.[74] Disappointingly, acute subcutaneous administration of **3** at doses of 30–300 mg kg^{-1} to TgCRND8 mice had no effect on cortex $A\beta_{40}$ levels, although profound inhibition of plasma $A\beta_{40}$ levels was observed at each dose. While compound **3** is a substrate for Pgp, which would be expected to limit its CNS exposure, brain binding studies of **3** by equilibrium dialysis of mouse brain homogenates were consistent with unbound levels of **3** in the brain being at or above its cell IC_{50} value. Subchronic administration of **3** to TgCRND8 mice (subcutaneous doses of 300 mg kg^{-1} twice daily for 5 days) completely suppressed plasma Aβ levels but did not cause reduction of brain Aβ levels (Fig. 6A).[70] Brain slices from these mice were subjected to ex vivo binding studies with the labeled inhibitor ^{35}**S-5**, which indicated that approximately 60% BACE1 occupancy had been achieved during the study (Fig. 6B). The lack of brain Aβ inhibition after subchronic administration of **3** was particularly striking, leading us to conclude that high brain BACE1 occupancy was necessary to elicit brain Aβ reduction (see Section "In Vivo Validation and Development of a High-Throughput Rat PD Assay").

From these experiments and from additional SAR exploration with peptidomimetic cyclic amines, we concluded that the challenges to achieve adequate oral bioavailability and brain penetration with an HEA inhibitor were likely insurmountable. At about the time these results were generated, prosecution of the fragment-derived iminoheterocycle series had provided tool compounds that inhibited centrally derived Aβ production in vivo as described in Section "In Vivo Validation and Development of a High-Throughput Rat PD Assay," and we abandoned our efforts on the HEA series in order to focus exclusively on the fragment-derived series.

8.09.3.4 Fragment Screening: Discovery of New Inhibitor Chemotypes

8.09.3.4.1 Fragment screening and hit triage

Soon after the purification and cloning of BACE1 was reported in the literature, an efficient *E. coli* expression and protein refolding system were developed in-house by Wang et al. that provided large quantities of the purified BACE1 catalytic domain for inhibitor cocrystallization studies.[75] To enable protein NMR-based fragment screening, Wang et al. adapted this expression system to generate homogenously ^{15}N-labeled BACE1 catalytic domain for detection of weak binders by ^{1}H-^{15}N HSQC NMR spectroscopy.[75,76] A virtually complete assignment of backbone NMR resonances corresponding to the catalytic domain of human BACE1 was determined to facilitate a detailed analysis of fragment hit binding.[77] At this early stage, gram amounts of purified BACE1 protein were produced to ensure that screening by NMR and structural studies to inform hit triage and optimization would not be limited by protein availability.

NMR screening of a 10,000-member fragment library was conducted in the laboratory of Wang et al. by screening compounds as mixtures of 10 against ^{15}N-labeled BACE1.[76] Active mixtures were deconvoluted by NMR to identify the active single compound(s), which were confirmed by repeating the NMR experiment with a compound solution freshly prepared from solid sample. This campaign required several months to complete and afforded active site-directed weak binders from multiple distinct chemical classes represented by structures **6–11** in Fig. 7. By comparing their BACE1 chemical shift perturbations with those induced by OM99-2, it was confirmed that each of these hits bound in the BACE1 active site. Affinity of these hits was in the micromolar to millimolar range as determined by NMR titration experiments.[76] Hit follow-up was conducted through efforts to generate X-ray cocrystal structures with the initial hits, and by NMR screening of near neighbors to identify additional candidates for X-ray

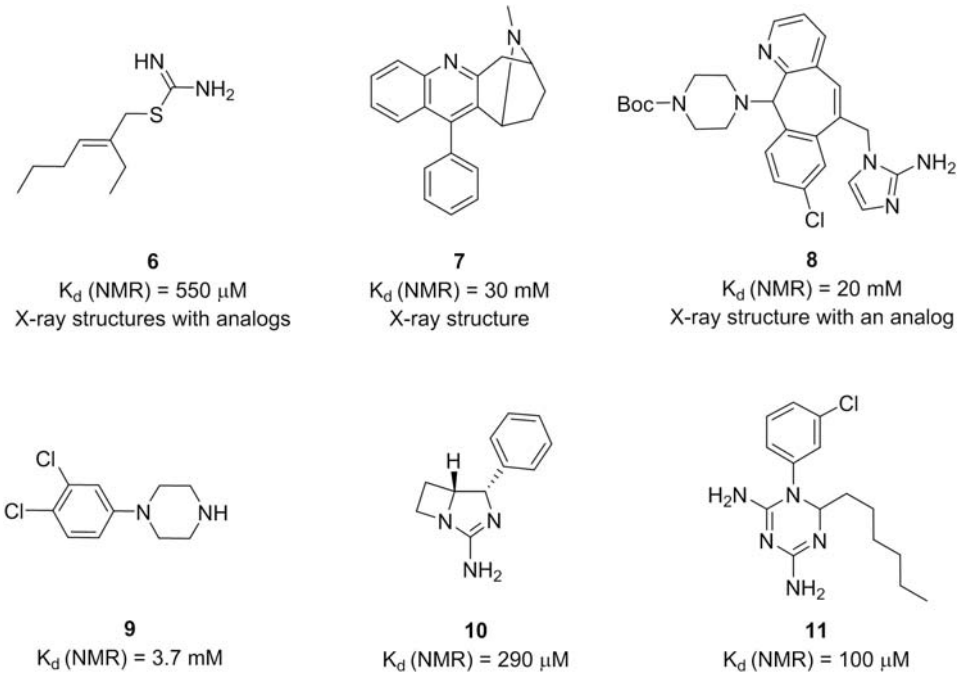

Fig. 7 Structures of representative active site-directed weak binders of BACE1 identified through ^{1}H-^{15}N HSQC NMR screening of a 10,000-member fragment library.[76]

crystallography. Of the initial structural classes that were discovered by Wang et al.,[76] three of these afforded X-ray cocrystal structures, either with the initial hits—isothiourea **6**, tropylquinoline **7**, and fused azatricycle **8**—or with analogs thereof. Enabled by detailed information on their binding modes, synthetic chemistry effort was applied to each of these chemotypes; however, it was the isothiourea class that provided a path to a viable lead series.

Chemical shift changes in the HSQC NMR spectra of isothiourea **6** indicated that this ligand interacted with the catalytic dyad as well as with Ile^{118} and Gly^{230} in S1 and Gly^{34} in S1′.[76] Due to the potentially attractive nature of its binding interactions that were similar to those of OM99-2, this hit was prioritized for additional follow up. To identify a higher affinity analog, a high concentration biochemical assay and NMR spectroscopy were employed in tandem to screen about 200 isothioureas that were available in our compound collection.[76] Screening of these isothioureas at high concentrations in the enzymatic assay resulted in the identification of analog **12** as a weak BACE1 inhibitor (IC_{50} approximately 200 μM) that had higher affinity than initial screening hit **6** as determined by NMR titration experiments (NMR K_d 15 μM vs. 550 μM). Chemical shift perturbations were consistent with binding of **12** to the catalytic dyad, and to the S1 and S3 pockets (Fig. 8).

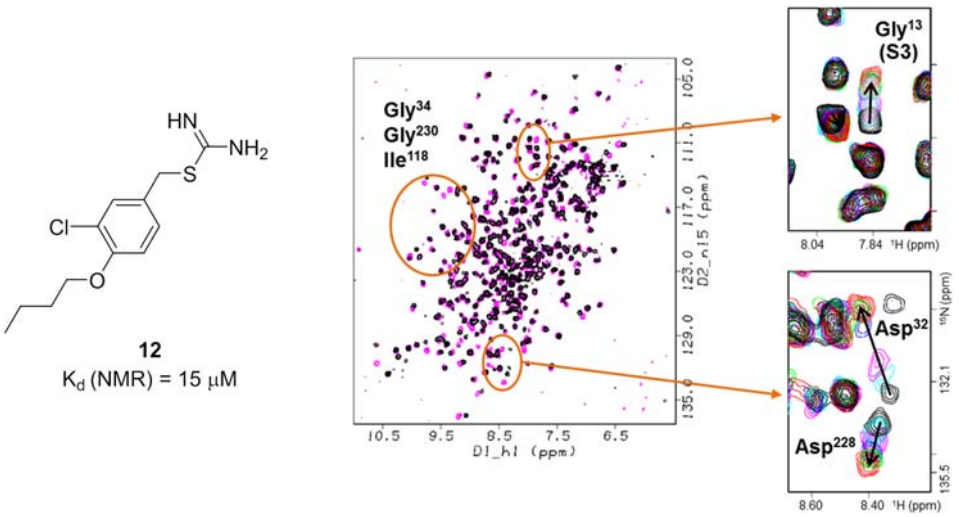

Fig. 8 Concentration-dependent HSQC NMR chemical shift perturbations observed in ^{15}N-labeled BACE1 induced by binding of isothiourea **12** to the active site.

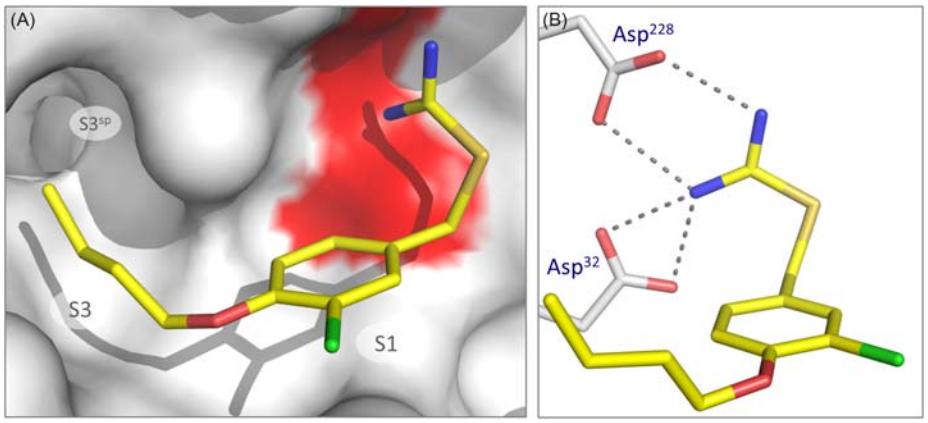

Fig. 9 (A) X-ray cocrystal structure of isothiourea **12** bound to BACE1. (B) Detailed view highlighting the unique hydrogen bonding network of the amidine moiety with the catalytic dyad.

Details of this binding mode were confirmed by a high-resolution X-ray cocrystal structure (Fig. 9) in which the amidine of **12** was engaged in a hydrogen bonding network directly with the active site Asp^{228} and Asp^{32} residues, an interaction that was at the time unprecedented for an aspartyl protease.[76] This binding mode was also unique among the other fragment chemical classes for which we were able to generate X-ray structures in BACE1, with tropylquinoline **7** and an analog of fused azatricycle **8** each interacting with the aspartates through one or two bridging water molecules. In addition to direct interactions with the catalytic dyad, the phenyl and butoxy groups of **12** made hydrophobic contacts with the S1 and S3 pockets, respectively, with the butyl group extending toward a narrow channel near S3, termed the $S3^{sp}$ subsite.

In addition to providing the initial high-resolution X-ray cocrystal structure of **12** that was inspirational for inhibitor design efforts described below, the ability to generate cocrystals of **12** with BACE1 was critical for rapid generation of crystal structures of new inhibitors through soaking experiments. This allowed crystal structures of inhibitors bound to BACE1 to be solved with cycle times synchronous with data generated from the NMR and enzymatic activity assays, enabling structural information to inform inhibitor design and SAR development in real time. This was especially critical for interpreting SAR in the early stages of the project when multiple binding modes were observed.

8.09.3.4.2 Iminoheterocycle scaffold design and validation

With detailed knowledge of the binding mode of **12** in hand, careful consideration was given to its development into a progressible lead series. At the outset we sought to replace the isothiourea moiety itself due to concerns related to its potential toxicity and hydrolytic instability. To achieve this, two approaches were pursued in parallel. The first approach employed by Wang et al. involved targeted NMR screening of low MW heterocyclic isosteres that contain an amidine moiety required for interaction with the catalytic dyad.[76] This effort identified planar aromatic heterocycles such as 2-aminopyridine **13** as low affinity BACE1 inhibitors (Fig. 10A). The X-ray cocrystal structure of **13** bound to BACE1 confirmed the hydrogen bonding network between the aminopyridine and the

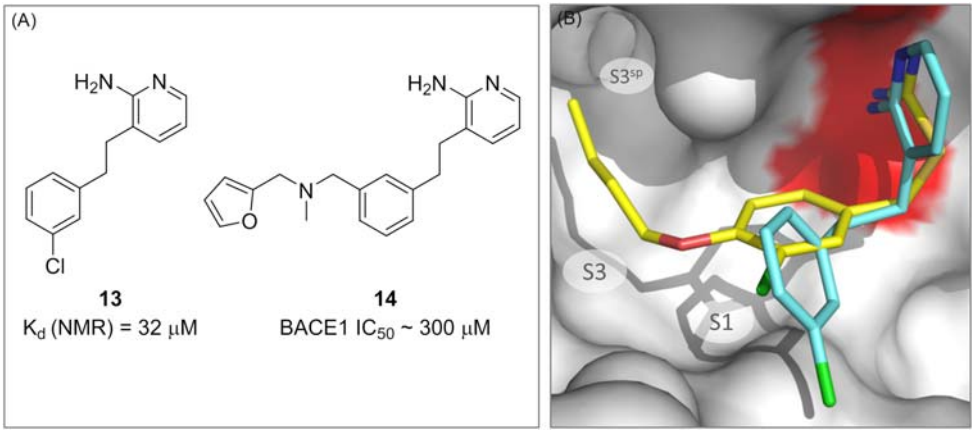

Fig. 10 (A) Structures of low affinity 2-aminopyridine BACE1 inhibitors **13** and **14**. (B) Overlay of X-ray crystal structures of isothiourea **12** (*yellow*) and 2-aminopyridine **13** (*blue*) bound to BACE1 confirming that the aminopyridine moiety of **13** recapitulates the catalytic aspartate interactions seen with isothiourea **12**.[76]

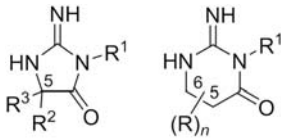

Fig. 11 Generic structures of cyclic acyl guanidines **15** and **16** designed from isothiourea fragment screening hit **12**.[69]

catalytic dyad, and revealed that the chlorophenyl group was positioned near the S1 pocket but oriented roughly perpendicular to the corresponding phenyl group of **12** (Fig. 10B). Enabled by this structural information, we conducted a focused SAR exploration designed to gain affinity by exploiting interactions in the S1–S3 region. Identification of more potent analogs with measurable biochemical activity proved challenging, with **14** being notable in that it displayed weak enzymatic inhibitory activity (Fig. 10A). An X-ray cocrystal structure of **14** bound to BACE1 confirmed that the phenyl group bound in S1 and that the furanyl group bound deep in $S3^{sp}$.[76]

In the second approach Zhu et al. pursued de novo design of heterocyclic scaffolds that preserved key features of the isothiourea **12** necessary for its BACE1 affinity.[69] We hypothesized that the basicity of the isothiourea ($pK_a \sim 9$) was important for driving enthalpic interactions with the catalytic dyad. Computational analysis suggested that the catalytic dyad is doubly deprotonated when bound to the protonated amidine of **12**. This led Zhu et al. to propose that the pK_a value of a designed inhibitor should be greater than the endosomal compartment (pH ~5-6), the native environment of active BACE1 in vivo. In addition to presenting the amidine motif in its protonated form, modulating the pK_a of the inhibitor in a weakly basic range was also expected to enhance blood–brain barrier permeability through interconversion of the protonated and unprotonated forms. A second design criterion was to restrict the number of hydrogen bond donors in the unprotonated form of the scaffold to the two essential for interaction with the catalytic dyad, as the number of hydrogen bond donors is inversely correlated with brain penetration.[78] These lines of reasoning led Zhu et al. to consider the 5-membered cyclic acyl guanidine **15** and its 6-membered congener **16** (Fig. 11) that were expected to possess pK_a values in the desirable range. For **15**, the importance of disubstitution of C5 was appreciated at the outset to prevent tautomerization to an aromatic system and substantial loss of basicity, a concern that does not attend the 6-membered analog **16**, which offers two sp^3 carbons for potential substitution.[69]

Zhu et al. initially focused on the 5-membered iminohydantoins due to their synthetic accessibility.[69] Regioisomeric iminohydantoins **17** and **18**, differing in which ring nitrogen is substituted, were both considered to be potentially viable scaffolds (Fig. 12A). Docking experiments on the des-chloro versions of these designed putative ligands yielded binding poses similar to that of isothiourea **12**, with the amidine motif of the core hydrogen bonded to the catalytic dyad and the chlorophenyl substituent placed in the S1 pocket (Fig. 12B), and both prototype scaffolds were prioritized for synthesis. Once in hand, NMR experiments revealed that the N3-substituted isomers **17** and **19** produced significant BACE1 chemical shift perturbations, whereas the N1-substituted isomers **18** and **20** did not. We were initially surprised by this result, but pK_a measurements demonstrated that the N1-substituted analog **20** is substantially less basic (pK_a 4.2) than the N3-substituted variant **19** (pK_a 7.2), with the latter possessing a weakly basic pK_a in a desirable range for a CNS-active drug.[69]

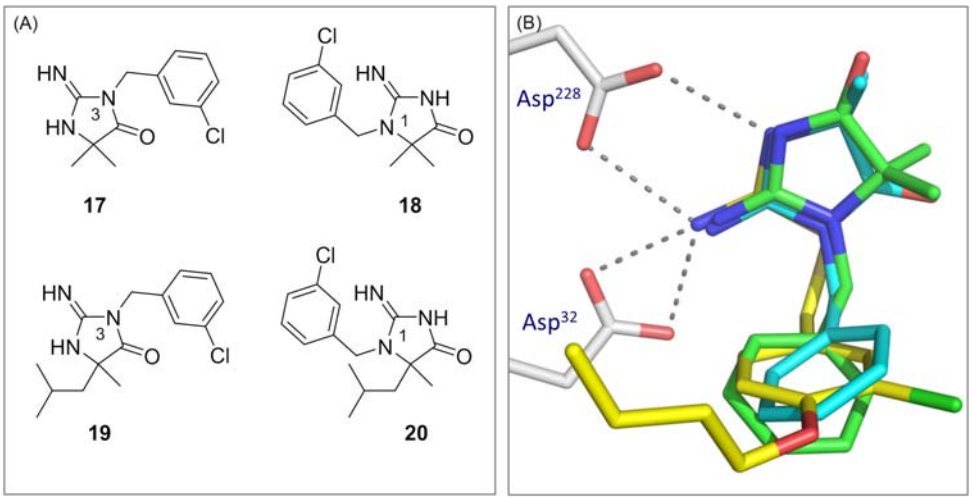

Fig. 12 (A) Structures of designed N3- and N1-substituted iminohydantoins **17**–**20**. (B) Models of the des-chloro analogs of **17** (*blue*) and **18** (*green*) overlaid with isothiourea **12** (*yellow*) showing conservation of the hydrogen bonding network with the catalytic dyad and consistency of binding in S1.

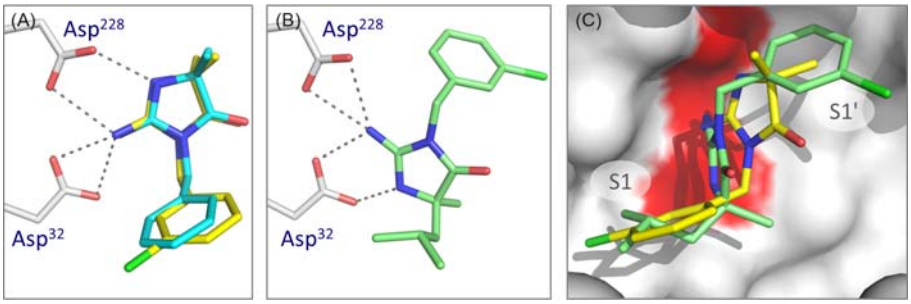

Fig. 13 X-ray crystal structures of designed iminohydantoin fragments bound to BACE1. (A) Overlay showing the excellent agreement between the structure of compound **17** (*yellow*) and of the docked conformation of the des-chloro analog used for modeling (*blue*). (B) Binding of compound **19** to the catalytic dyad. (C) Compounds **17** (*yellow*) and **19** (*green*) overlayed showing 180 degree flip of binding modes.

Gratifyingly, an X-ray cocrystal structure of N3-substituted iminohydantoin **17** confirmed the predicted binding mode (Fig. 13A).[69] This structure revealed the extensive hydrogen-bonding network between the amidine and the catalytic dyad, with the ligand participating in a bidentate interaction with Asp^{228}, similar to that of isothiourea **12**, and the chlorophenyl substituent occupying the S1 pocket. Interestingly, however, an X-ray cocrystal structure of the other N3-substituted iminohydantoin **19** revealed that the modest change of methyl to isobutyl at C5 resulted in a binding mode in which the iminohydantoin core is flipped 180 degree in the active site (Fig. 13B and C). In this binding mode, the hydrogen-bonding requirements of the ligand amidine motif and the catalytic dyad remain satisfied but with the Asp^{32} now engaged in the bidentate interaction, while the chlorophenyl substituent occupies S1′ and the isobutyl group projects into S1.[69] The flipped binding modes of **17** and **19** reinforced early on the challenges of prosecuting fragments, and highlighted the importance of timely X-ray cocrystal structures for interpretation of emerging SAR and for informing prospective modeling studies.

Comparison of the binding modes of iminohydantoins **17** and **19** with aminopyridine **14** highlighted a perceived key advantage of the nonplanar iminohydantoin scaffold. The sp^3 center of the iminohydantoin ring provides direct, favorable trajectories toward the prime and nonprime pockets adjacent to the catalytic dyad. On the other hand, the planar aminopyridine scaffold defines vectors that are perpendicular to the enzyme specificity pockets and thus requires incorporation of additional rotatable bonds to orient the substituents toward these pockets. This is shown clearly in an overlay of the X-ray structures of iminohydantoin **19** and of aminopyridine **14** bound to BACE1 (Fig. 14). Whereas there is only one rotatable bond from the iminohydantoin core to the S1 substituent, there are three from the 2-aminopyridine core. Based on this analysis the iminohydantoin scaffold was considered an inherently more efficient design, and given the limited resources available at the time, the aminopyridine series was deprioritized.

8.09.3.4.3 Iminohydantoin hit-to-lead prosecution

Having accomplished biophysical validation of the designed iminohydantoin scaffold as a novel aspartyl protease binding motif, the team was faced with the daunting prospect of developing this scaffold into potent, selective BACE1 inhibitors with CNS drug-like properties. Both binding modes displayed by **17** and **19** presented opportunities for affinity gains based on the disposition of the 3- and 5-substituents in the active site. However, the unpredictability of binding modes coupled with reliance on NMR for SAR development posed significant challenges. To advance the program as rapidly as possible, Zhu et al. adopted a strategy of targeting a relatively large number of analogs through parallel synthesis and identifying promising structural modifications by medium-throughput BACE1 NMR chemical shift perturbation analysis.[69] Promising analogs were further triaged in the enzymatic

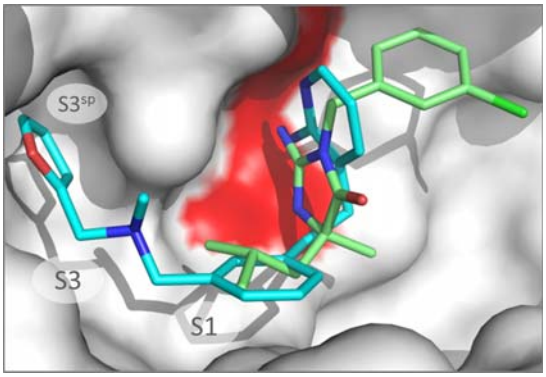

Fig. 14 Overlay of the X-ray structures of iminohydantoin **19** (*green*) and of 2-aminoypyridine **14** (*blue*) bound to BACE1, showing the additional rotatable bonds required to reach the S1 pocket required by the nonoptimal, planar aminopyridine scaffold.

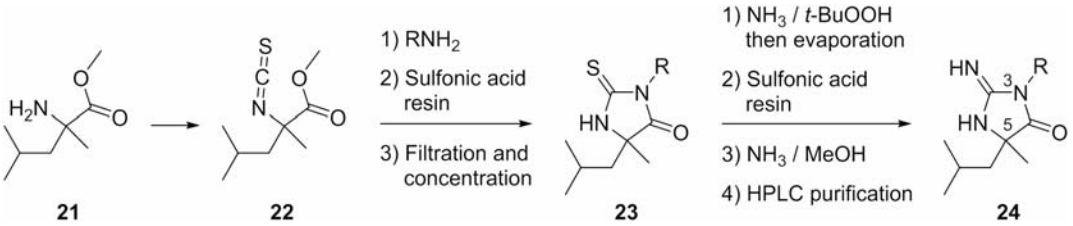

Fig. 15 Parallel synthetic method for rapid expansion of SAR in N3-substituted iminohydantoin series. Synthesis of analogs **24** proceeded via isothiocyanate **22** and thiohydantoin **23**.

HTRF assay and through determination of BACE1 cocrystal structures, with the initial goal of identifying functionally active BACE1 inhibitors with well-understood binding characteristics.

Starting from α,α-disubstituted amino acids like **21**, parallel synthesis chemistry allowed ready access to N3-modified analogs of the core while incorporating more targeted modifications at the 5-position represented by **24** (Fig. 15). Influenced by the structure of OM99-2 bound to BACE1 in which the inhibitor P1 leucine side chain binds in a position similar to the isobutyl group of **19**, the 5-isobutyl group was selected as a preferred substituent for our parallel synthesis libraries. Fig. 16 highlights the most important hits that were identified via this strategy, represented by benzyl ureas **25** and **26**[69] and piperidine analogs **27** and **28**.[79] The benzyl urea series preceded the piperidine series and was the focus of our early optimization efforts; its evolution will be discussed in depth.

NMR experiments allowed us to quickly determine that analogs of **19** in which the phenyl group bore a variety of substituents at the meta and para positions consistently produced BACE1 chemical shift perturbations. Moreover, para-substituted benzyl ureas exemplified by **25** and **26** emerged as the first inhibitors with micromolar potency in the enzymatic assay. Generally phenyl ureas were up to an order of magnitude more potent than the corresponding alkyl ureas as shown by the comparison of **25** and **26**.[69]

X-ray crystallography again revealed how structural changes influence binding modes in unpredictable ways, with the BACE1 cocrystal structures of **25** and **26** showing very different binding modes (Fig. 17). Analogous to the original iminohydantoin

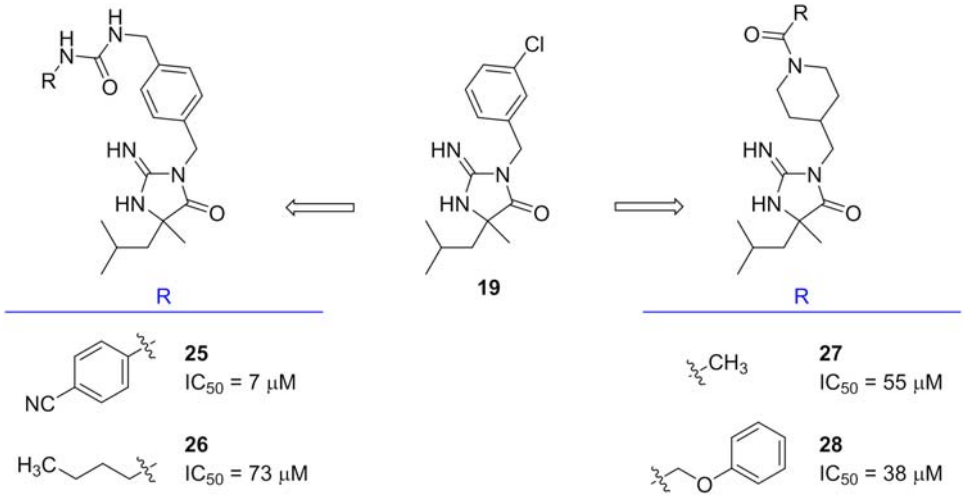

Fig. 16 Structures of N3-modified iminohydantoins **25**–**28** identified through parallel synthesis as modifications of the original designed ligand **19**.

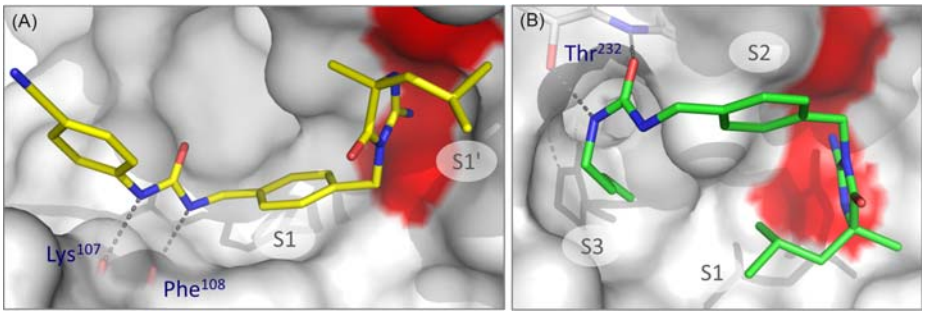

Fig. 17 X-ray crystal structures of N3-benzyl urea-substituted iminohydantoins bound to BACE1 showing the 180 degree flip seen in their binding poses as well as key interactions each makes with the enzyme. (A) Bound structure of compound **25**. (B) Bound structure of compound **26**.

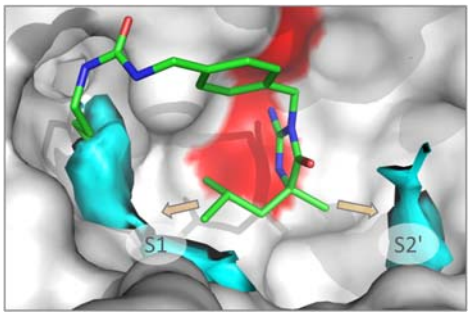

Fig. 18 Hydrophobic surface map of the BACE1 active site (*blue*) with iminohydantoin **26** bound showing trajectories from the C5 substituents into and toward the lipophilic S1 and S2′ subsites.

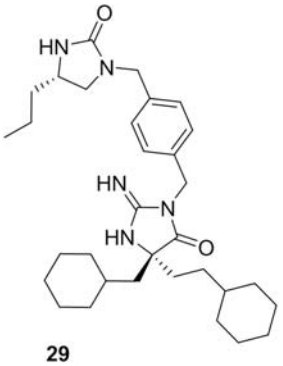
inhibitors **17** and **19**, the two structures were flipped by 180 degree depending on their substituents. In the X-ray cocrystal structure of the more potent phenyl urea **25**, the isobutyl group occupies the S1′ pocket and the benzyl moiety binds near S1 with the cyanophenyl substituent projecting toward the protein surface (Fig. 17A). The two urea hydrogens participate in hydrogen bonding interactions with backbone carbonyls of Lys[107] and Phe[108]. On the other hand, the cocrystal structure of the less potent analog **26** shows that the isobutyl group occupies the S1 pocket and the benzyl group projects toward the nonprime sites, with the urea participating in two hydrogen bonding interactions with Thr[232] and providing a vector for the butyl group to penetrate into the S3 pocket (Fig. 17B).[69]

Careful consideration of the two binding modes led Zhu et al. to deprioritize phenyl urea **25** for further SAR studies. Despite having greater potency, its reliance on the urea hydrogen bonding interactions for affinity was considered a liability for CNS penetration, and a path for designing out this undesirable feature seemed unclear. Instead, Zhu et al. decided to focus on optimization of the binding mode represented by butyl urea **26**.[69] The binding mode afforded by **26** not only possessed one fewer essential hydrogen bond donor but also offered opportunities for optimization of the isobutyl group in S1 and by building from the 5-methyl substituent to capitalize on binding in S2′. Both of these subsites are relatively hydrophobic (Fig. 18), and a significant portion of our optimization effort utilized lipophilic groups to reach these regions.

Iterative design cycles based on this strategy resulted in cyclic urea **29** that provided our first iminoheterocyclic BACE1 inhibitor with affinity under 100 nM (Fig. 19).[69] This result was important because it demonstrated that it was possible to generate potent BACE1 inhibitors based on the iminoheterocyclic scaffold. On the other hand, the focus on structure-based affinity-driven optimization had introduced a number of drawbacks, including a high MW, a high c log *P*, a potency shift in the cellular assay relative to intrinsic affinity, poor oral pharmacokinetic (PK) properties, and lack of selectivity over the related aspartyl protease CatD. The poor properties of **29** were also reflected by the modest ligand efficiency (LE) value of 0.25, which was essentially identical to the optimized examples in the peptidomimetic series.

The deficiencies in the profile of **29** prompted us to reevaluate our strategy. To identify a more lead-like starting point Zhu et al. pursued a minimum pharmacophore approach with the intent of defining less lipophilic, lower MW, more highly ligand efficient



29
BACE1 K_i = 71 nM (LE 0.25)

Mouse plasma f_u < 0.1%
cLogP = 7.5

Fig. 19 Structure and profile of optimized N3-elaborated iminohydantoin **29**.

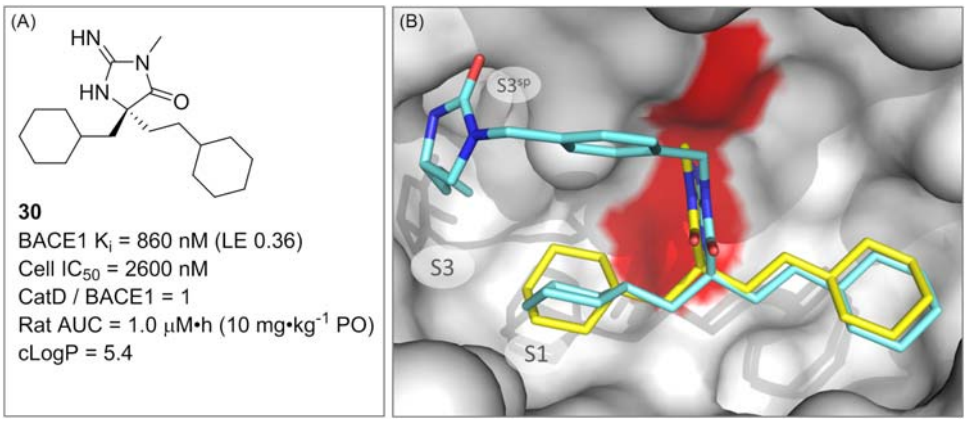

Fig. 20 (A) Structure of truncated N3-methyl iminohydantoin **30**. (B) Overlay of X-ray structures of N3-elaborated iminohydantoin **29** (*blue*) and the racemate of N3-methyl iminohydantoin **30** (*yellow*) bound to BACE1.

scaffolds that could subsequently be reoptimized with control of physicochemical parameters into more desirable property space. Toward this end, it was apparent from the crystal structures of **29** and its analogs that the phenylene motif did not engage in productive interactions with BACE1, but merely served to link the N3-position of the iminohydantoin core to the urea moiety that bound in the S3 pocket. The suboptimal nature of this N3-substituent was confirmed by its truncation to a methyl group in compound **30** (Fig. 20A), which showed only a relatively modest loss of affinity with a substantial increase in LE (LE 0.39) and a significant reduction of c log*P* and cellular potency shift.[69] The conserved binding mode of **30** relative to **29** presented the opportunity to reoccupy the S3 pocket from the substituent residing in S1 in a more efficient manner by exploiting the contiguity of the S1 and S3 pockets (Fig. 20B). This strategy was attractive due to the relative hydrophobicity of this region of the enzyme, and was reminiscent of the approach that was successfully applied to the discovery of the renin inhibitor Aliskiren.[46]

Initial forays in this area by Caldwell et al. resulted in the identification of inhibitors exemplified by **31**, which were bound as intended with the cyclopentyl group extending into the S3 pocket (Fig. 21A).[80] However, while CatD selectivity was significantly increased, improvement of BACE1 affinity was difficult to achieve. A more potent subclass of inhibitors represented by aminoquinoline **32** was discovered by derivatizing the S1 amino group with hydrogen bond acceptor-containing groups. We were surprised to find that in the binding mode of **32** and related amides and ureas, the S3 subsite was unoccupied, and the nitrogen substituent instead occupied a narrow hydrophobic surface extending from S1 toward a solvent-exposed region defined by Lys^{107}, Phe^{108} (which forms a hydrogen bond between its carbonyl and **32**), and Ile^{110} (Fig. 21B).[80] While inhibitors such as **32** had improved affinity and selectivity over CatD, they remained highly lipophilic and deficient with respect to cellular potency and PK properties, and therefore, efforts on this subseries were abandoned.

While the S1–S3 approach applied directly to **30** failed to provide a progressible path to more optimized inhibitors, we were simultaneously exploring direct replacement of the cyclohexylmethyl and cyclohexylethyl substituents of this scaffold. Major emphasis was placed not only on further reduction of lipophilicity, but also on decreasing the number of rotatable bonds to achieve entropically driven affinity gains and improvement of oral PK properties. In the course of these efforts, a series of analogs was generated in which the alkyl substituents were replaced by phenyl directly attached to the iminohydantoin core. In addition to satisfying the design criteria above, our interest in a phenyl substituent was further bolstered by a structure-based rationale arising from comparison of the flap configurations of BACE1 seen in X-ray structures with peptidic inhibitor OM99-2 and with the racemate of **30** (Fig. 22). With OM99-2, the flap is in a relatively closed conformation and places the aryl side chain of Tyr^{71} toward the prime side of the enzyme. With iminohydantoin **30**, the flap position is more reminiscent of the BACE1 apo structure in that it is more open with the Tyr^{71} side chain residue oriented toward the nonprime side of the enzyme. This leaves a relatively open space more proximal to the aspartates than S2′, which we subsequently termed the F′ subsite.

Based on this analysis, we reasoned that replacement of the prime-side binding cyclohexylethyl group of **30** with a phenyl moiety directly attached to the C5 position of the iminohydantoin core would project that group into the F′ site. To that end, we synthesized racemic C5-phenyl iminohydantoins **33–36** and prochiral diphenyl iminohydantoin **37** (Fig. 23A). With the exception of C5-benzyl analog **36**, these variants retained a similar level of micromolar affinity for BACE1 versus the racemic version of **30** (BACE1 $K_i = 1.4$ μM). To our surprise, however, when racemic **33** was soaked with BACE1, the (*S*)-enantiomer with the phenyl group in F′ was not observed in the X-ray structure as designed; instead the (*R*)-enantiomer was observed with the phenyl group bound in S1 (Fig. 23B). In addition, there was a notable and unexpected shift of the iminohydantoin core itself, with the C5 position moving 1.4 Å toward the nonprime side to place the S1 phenyl group in a position corresponding to that of the cyclohexyl group of **30**. For each of the other racemic analogs **34–36**, binding of the (*R*)-enantiomer was observed exclusively, placing the phenyl group in the S1 pocket in the same region as **33**. Prochiral diphenyl analog **37** also bound with its core and pro-(*R*) phenyl group was similarly positioned.[69] This profound preference for S1 phenyl occupancy and accompanying unpredicted shift in binding pose of the core again highlights the importance of X-ray crystallography for key insights into inhibitor binding.

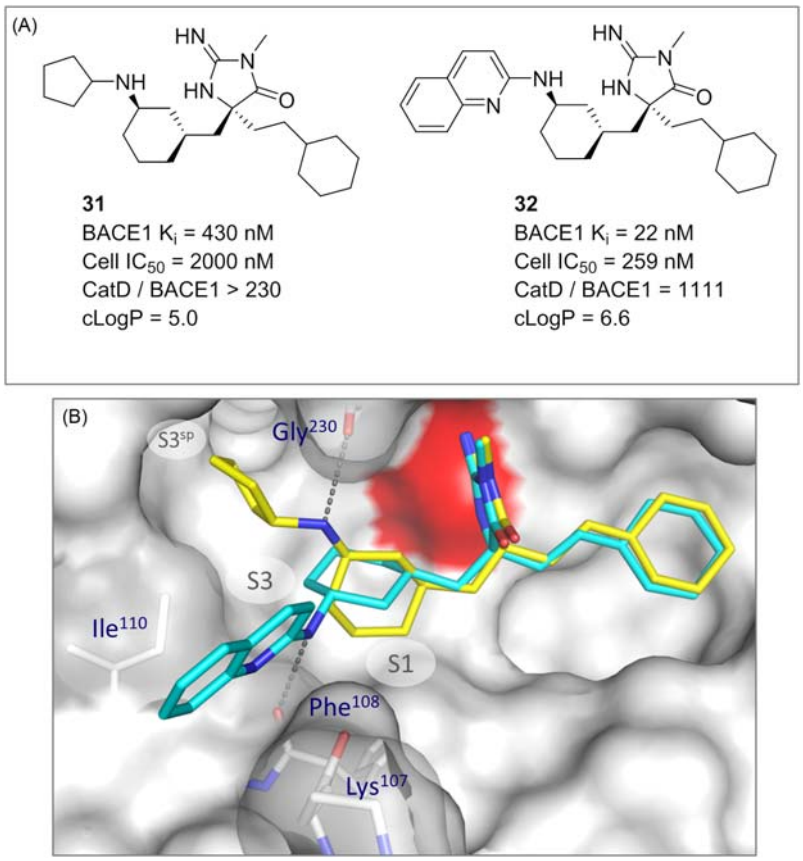

Fig. 21 (A) Structures of S1 aminocyclohexane-derived iminohydantoins **31** and **32**. (B) Overlay of X-ray structures of **31** (*yellow*) and **32** (*blue*) bound to BACE1 showing the different trajectory induced by derivatization of the S1 aminocyclohexane with a hydrogen bond acceptor group as in **32**.

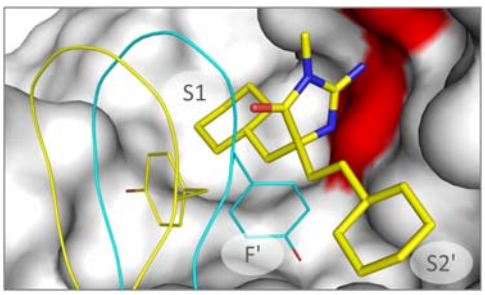

Fig. 22 Comparison of the flap positions in X-ray structures of the racemate of iminohydantoin **30** (*yellow*) and of OM99-2 (*not shown*) bound to BACE1. The flaps are represented as ribbons with their Tyr^{71} side chains displayed, and they are colored by compound—the flap from the iminohydantoin X-ray is *yellow* and the flap from OM99-2 is *blue*. In the OM99-2 structure, the flap is in a relatively closed position with Tyr^{71} oriented on the prime side. In the iminohydantoin structure, the flap is in a more open conformation with the Tyr^{71} side chain moved to the nonprime side. We termed the open space left by that flap movement in the iminohydantoin structure as the F' subsite.

The discovery of diphenyl iminohydantoin **37** by Zhu et al. was a key breakthrough for our program.[69] This low MW compound, of MW just slightly less than of the original isothiourea hit **12**, had single digit micromolar affinity and retained high LE (Fig. 24A). Its c log*P* of 1.9 was much more favorable in comparison with **30;** it had a minimal shift in cellular potency and displayed greater than 20-fold selectivity over CatD. The compound also achieved high plasma exposures and was brain penetrant following oral administration to rats. The X-ray cocrystal structure of **37** demonstrates that the pro-(*R*) phenyl occupies the S1 pocket in analogy to the racemic C5-phenyl iminohydantoins above. In addition, the flap is in a well-organized, partially closed conformation with the Tyr^{71} aromatic ring providing an edge–face interaction with the S1 phenyl group of **37** and the phenol of Tyr^{71} donating a hydrogen bond to the carbonyl of Lys^{107} (Fig. 24B). The pro-(*S*) phenyl substituent projects toward but does not occupy the

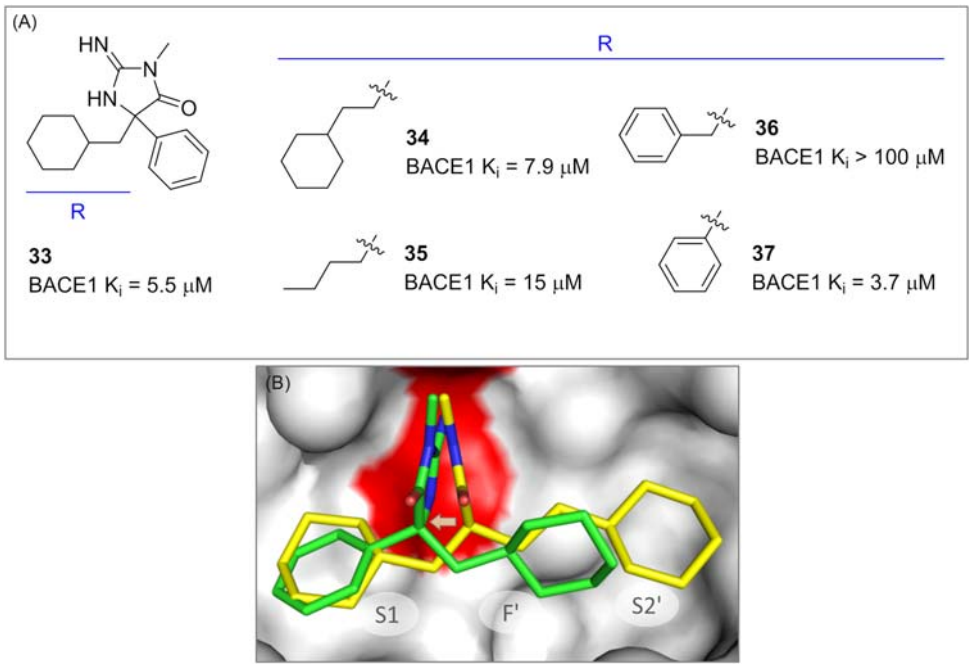

Fig. 23 (A) Structures of C5-phenyl iminohydantoins **33**–**37**. (B) Overlay of the X-ray structures of racemic C5-phenyl iminohydantoin **33** (*green*) and the racemate of C5-bis(cyclohexylalkyl) iminohydantoin **30** (*yellow*) bound to BACE1 showing the C5-phenyl group of **33** in S1 and the resulting 1.4 Å shift in its core binding pose.

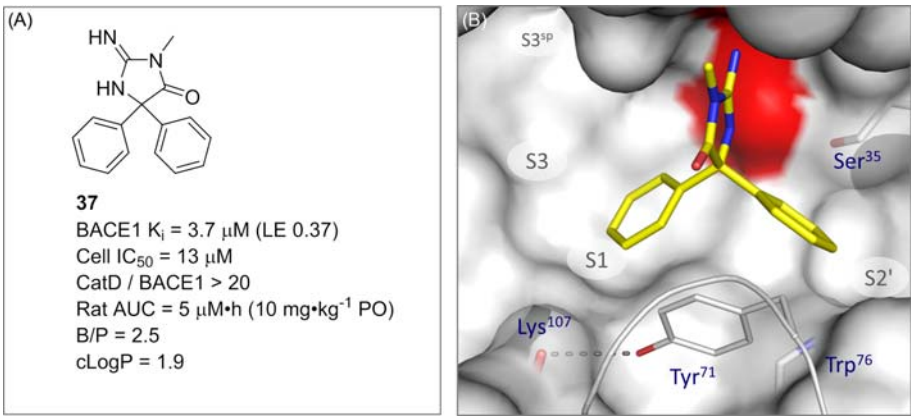

Fig. 24 (A) Structure and profile of C5-diphenyl iminohydantoin **37**. (B) Key aspects from the X-ray structure of **37** bound to BACE1 showing the pro-(*R*) phenyl group in the S1 pocket.

S2′ pocket, and instead engages in hydrophobic interactions with the Ser^{35}, Trp^{76}, and Tyr^{71} of the flap. Remarkably, scientists at Wyeth independently discovered **37**, which we learned upon publication of their patent application a few months after our disclosure[81] of the structure of **37** in a patent application. A subsequent publication by the Wyeth group confirmed that they discovered **37** via HTS in contrast to our fragment-based approach.[82]

8.09.4 Lead Optimization

8.09.4.1 Iminohydantoins: S3 Occupancy

With compound **37** in hand as an attractive lead-like starting point the team considered approaches to higher affinity analogs while maintaining desirable overall properties. In silico docking experiments suggested that the meta positions of either the pro-(*R*) or

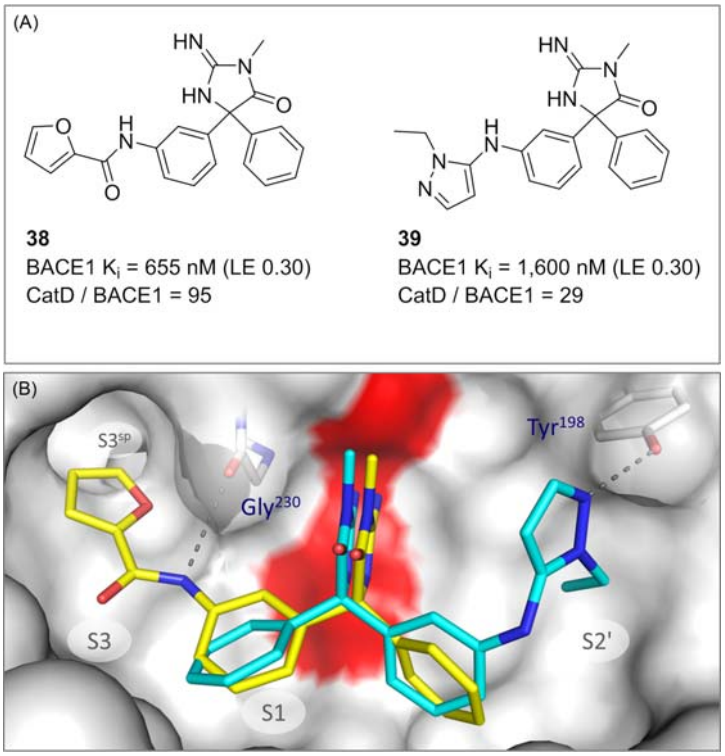

Fig. 25 (A) Structures of racemic *meta*-amino-substituted diphenyl iminohydantoins **38** and **39**. (B) Overlay of X-ray structures of **38** (*yellow*) and **39** (*blue*) bound to BACE1 showing their occupancy of S1/S3 and S1/S2′, respectively.

pro-(*S*) phenyl groups of **37** provided favorable vectors toward S3 and S2′, respectively, and multiple structural motifs were prioritized for evaluation. One of these incorporated a nitrogen linker at the meta position as exemplified by furan carboxamide **38**[83] and diarylamine **39**[84] (Fig. 25A). Both of these compounds afforded affinity gains, and X-ray cocrystal structures with BACE1 showed that the binding modes of **38** and **39** were distinct, binding in S3 and S2′, respectively, in general support of our binding hypotheses (Fig. 25B). Furan carboxamide **38** bound with the furanyl group occupying the S3 pocket and the amide hydrogen engaged in a hydrogen bond with the Gly^{230} carbonyl. On the other hand, pyrazole derivative **39** bound with the pyrazole ethyl group in S2′ and with a pyrazole nitrogen accepting a hydrogen bond from Tyr^{198}. Neither of these N-linked chemotypes received further resourcing due to the emergence of the more promising biaryl series (vide infra), although knowledge of the binding mode of **38** later proved to be pivotal to the discovery of our lead clinical candidate verubecestat as discussed in Section "Discovery of Verubecestat."

In a second structural presentation that was prioritized for synthesis, Cumming et al. incorporated an aryl group directly attached to the meta position of the pro-(*R*) phenyl of **37** to form a 3-biaryl motif that reached into S3 and potentially $S3^{sp}$.[85] Introduction of an additional phenyl substituent as in **40** increased c log*P* by approximately two log units, but this could be mitigated by substitution of the biaryl motif with polar groups or by incorporation of a more polar heterocycle in place of phenyl (Fig. 26A). Pursuit of this approach paid immediate dividends. 3-Pyridyl derivative **41** and 3-methoxyphenyl analog **42** showed substantial gains in affinity over **37** with maintenance of good LE, which was in contrast to biphenyl analog **40** which showed essentially no gain in affinity. In the X-ray cocrystal structure of **41**, the (*R*)-enantiomer in fact bound with the pyridyl group in S3 (Fig. 26B),[85] which was an important confirmation of our design as we had considered that the (*S*)-enantiomer could have bound with the biaryl group displayed in S2′ as observed for **39**. The nitrogen of the S3 pyridyl in **41** was positioned at the entrance of $S3^{sp}$ within hydrogen bonding distance of an ordered water molecule. The X-ray cocrystal structure of the more potent methoxyphenyl analog **42**[86] was virtually superimposable with that of **41**, the only significant difference being occupancy of $S3^{sp}$ by the methoxy group with accompanying displacement of the ordered water molecule, clearly highlighting the benefit of $S3^{sp}$ occupancy to affinity. A more extensive scan of substituted aryl and heteroaryl groups in S3 reinforced these findings, namely that analogs bearing an S3 moiety that hydrogen bond to or displace the water molecule in $S3^{sp}$ showed gains in affinity over the simple C5-diphenyl parent **37**, whereas those that cannot (e.g., analogs **43** and **44** of **41** and **42**, respectively, Fig. 26A), showed essentially no benefit to affinity.[85] These results were an early highlight of the importance of optimal interactions in $S3^{sp}$ that again became important later as part of the discovery of verubecestat.

At this stage, optimization efforts continued in two complementary directions—further optimization of substitution about the iminohydantoin core while simultaneously expanding our effort into development of additional new iminoheterocycle cores.

8.09.4.2 Iminohydantoins: Advanced Lead Optimization

Further optimization of the iminohydantoin series by Cumming et al. examined potential replacements for the phenyl group bound in F′ in the analogs above, with the intent of identifying alternative moieties with lower MW and/or c log*P*.[87] As part of this effort, we were able to successfully incorporate structural information gleaned from earlier SAR development around N3-piperidine-substituted iminohydantoins **27** and **28** (Fig. 16). In that effort, we explored C5 variations in combination with a nonoptimized C5-butyl group to allow this core to find its own optimized pose, for example, general structure **45** (Fig. 27A). This approach was informed by the multiple binding modes observed within the active site during our preliminary exploration of the iminohydantoins (Section "Fragment Screening: Discovery of New Inhibitor Chemotypes"). With the N3-piperidine series, a small sampling of aromatic, heteroaromatic, and saturated cyclic C5 variants in combination with the C5 *n*-butyl group all showed generally flat SAR with affinities in the 1–5 μM range. To understand any changes in binding that had occurred, we obtained crystal structures of a number of these analogs bound to BACE1. While in most cases the compounds bound with the (*R*) configuration, as seen earlier for N-methyl analogs **33–36** (Fig. 23), C5-cyclopropyl analog **46** unexpectedly bound in the (*S*) configuration to display the cyclopropyl group in the F′ subsite (Fig. 27B).[87] Most interestingly, overlay of **46** and the S1-binding C5-phenyl analog **47** in this subseries suggested that the combination of these two C5 modifications should be favorable in the context of S1–S3 biaryl subseries.

Cumming et al. returned to the N3-methyl iminohydantoin core to test this hypothesis, and gratifyingly the first analogs **48** and **49** (Fig. 28A) showed slightly improved or similar BACE1 affinity and cell Aβ lowering potency versus the analogous F′ phenyl analogs **41** and **42** (Fig. 26A).[85] An overlay of the X-ray structures of S3 methoxyphenyl analogs **42** and **49** showed that the inhibitor binding modes with C5-phenyl and C5-cyclopropyl were well conserved. The flap maintained the same conformation as well, but moved in closer to the C5-cyclopropyl analog, with the Tyr^{71} side chain shifting by 1.3 Å between the two structures (Fig. 28B). A more extensive set of F′ analogs showed that, among a fairly broad set of variants, including other cycloalkyl groups as well as alkyl and heteroaryl moieties, the cyclopropyl was unique in imparting the improved potency.[85] Given the half-log improvement in LE due to the lower MW of the F′-cyclopropyl analogs, we continued significant optimization of this scaffold.

(B) Overlay of X-ray structures of **46** (*yellow*) and **47** (*blue*) bound to BACE1 suggesting that phenyl and cyclopropyl cosubstitution at C5 should be favorable.[87]

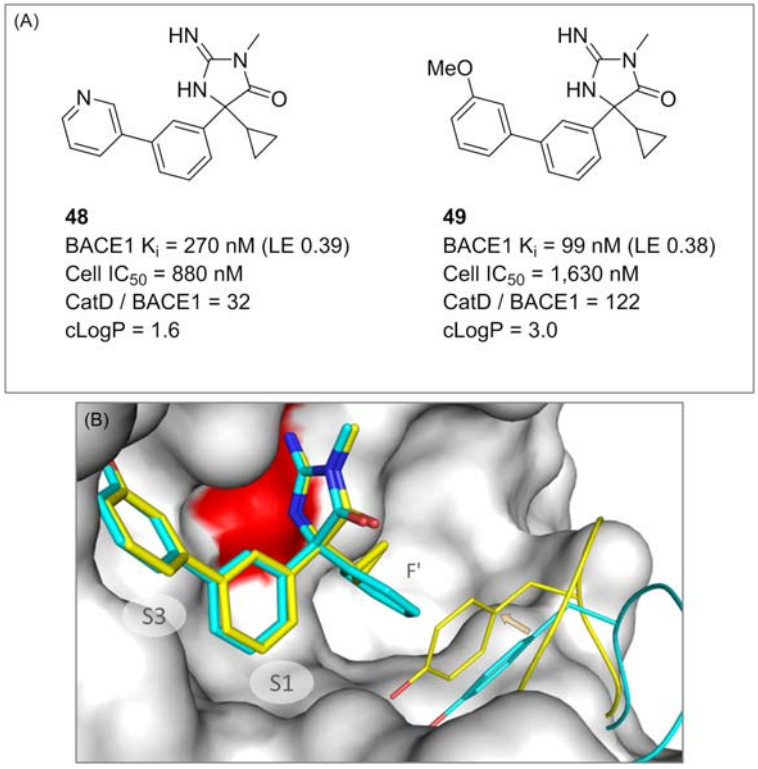

Fig. 28 (A) Structures of early C5-cyclopropyl, C5-biaryl iminohydantoins **48** and **49**. (B) Overlay of the X-ray structures of F'-cyclopropyl analog **49** (*yellow*) and F'-phenyl analog **42** (*blue*) bound to BACE1 showing the conserved binding mode between the modifications as well as movement of the flap (ribbon, colored to match inhibitor structure) with Tyr^{71} 1.3 Å closer to F'-cyclopropyl analog **49**.

A scan of S3 substituents with the cyclopropyl iminohydantoin core clearly revealed the direct relationship between c log*P* and cell potency shift, with a c log*P* of 2.5 or less required for a cellular potency shift versus enzymatic K_i of less than 10-fold. In most cases, control of c log*P* was achieved with a substituted pyridyl moiety as the S3 group, the impact of which is clearly seen when comparing 3-chlorophenyl analog **50** (c log*P* 3.8, cell shift 40-fold) with 3-chloro-5-pyridyl analog **51** (c log*P* 2.4, cell potency shift sevenfold) (Fig. 29). Based on this analysis, we fixed the S3 substituent as 3-pyridyl and next sought to examine the effects of occupancy deeper into the relatively narrow $S3^{sp}$ pocket given that our earlier SAR showed that the organized water in that pocket could be displaced by methoxy, as well as by chloro and cyano, all of which were essentially equipotent. To that end, a larger, linear

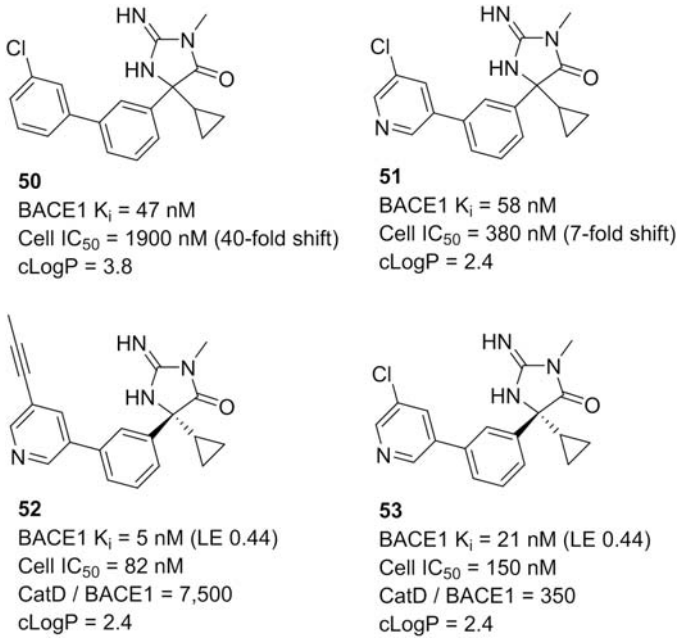

Fig. 29 Structures of C5-cyclopropyl iminohydantoins with substituted pyridyl groups in S3 with analog **52** showing the benefit to BACE1 affinity and selectivity over CatD imparted by deeper occupancy of $S3^{sp}$.[85]

propynyl group on as S3 pyridyl moiety using resolved core provided **52**, which showed a fourfold improvement in BACE1 affinity and a 20-fold improvement in selectivity over CatD versus the corresponding resolved chloro analog **53** (Fig. 29).[85] Both of these resolved analogs possessed excellent LE.

An X-ray crystal structure of **52** bound to BACE1 showed that the propynyl group projected deeper into $S3^{sp}$ as designed where it engaged in a favorable hydrophobic interaction with Ala^{335} (Fig. 30).[85] In CatD, this residue is replaced with a larger and more polar aspartate residue that would not be expected to accommodate the propynyl group. This difference in residues is reflected in the significant increase in selectivity seen with **52**, which is achieved both through improved BACE1 affinity and through decreased affinity for CatD. Propynyl analog **52** represented our most optimized iminohydantoin BACE inhibitor; it was one of the only compounds in that series to have cellular potency less than 100 nM, although it was still 16-fold shifted from its potency against purified enzyme, and it possessed excellent plasma exposure ($AUC_{0-6h} = 18$ μM h) following a single 10 mg kg^{-1} oral dose in a rat PK screen, albeit with only modest CNS exposure.

8.09.4.3 Core Modification: Ring Expansion to Iminopyrimidinone

In parallel with optimization of the S1–S3 and F′ substituents in the iminohydantoin series, we also sought to design and explore other novel iminoheterocycle cores that could similarly engage the BACE1 catalytic dyad while simultaneously opening additional

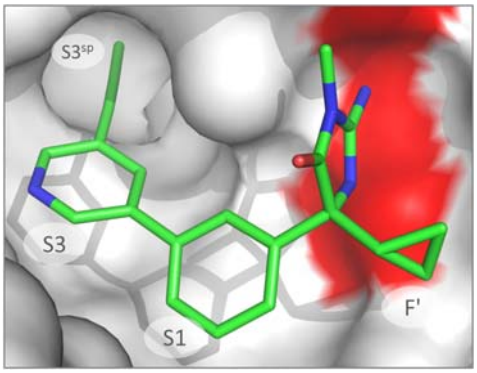

Fig. 30 X-ray structure of optimized iminohydantoin **52** bound to BACE1. In the $S3^{sp}$ site of CatD, there is an Asp residue in place of the Ala^{335} of BACE1, resulting in both steric and electrostatic differences that are less favorable to binding of the propynyl group of **52**.

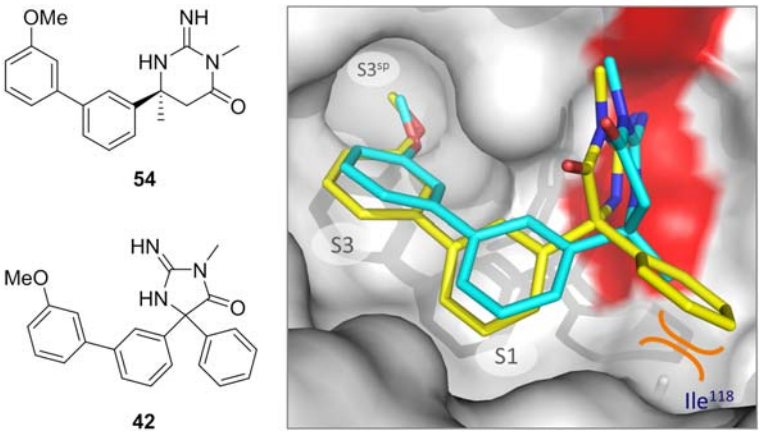

Fig. 31 Overlay of the modeled docking pose of iminopyrimidinone **54** (*blue*) versus the X-ray structure of iminohydantoin **42** (*yellow*) bound to BACE1 showing the difference in trajectory toward the prime side of the enzyme and the potential for close contact with Ile^{118} from larger C5-substituents on the iminopyrimidinone core.[86]

SAR opportunities and potentially offering unique physicochemical properties. To that end, one direction we pursued early in our program was ring expansion of the five-membered iminohydantoin core to a six-membered iminopyrimidinone ring (e.g., general structure **16**, Fig. 11).[86] This new core offered two important points of differentiation. First, in terms of SAR, incorporation of a second sp^3 center not only provided an additional site for exploration, but modeling suggested that this change would introduce nonplanarity into the ring in contrast to the planar iminohydantoin, and this change in molecular shape would potentially alter the trajectories of substituents into both the prime and nonprime sides. Particularly noteworthy for prospectively docked iminopyrimidinone **54** was the prime-side facing substituent pointing more directly to the protein backbone versus iminohydantoin **42** (Fig. 31), suggesting a preference for smaller substituents at that position, while changes to the conformation of the S1–S3 biaryl were more subtle. The second change induced by ring expansion was to increase the basicity of the amidine center of the iminopyrimidinone, which could be beneficial in reducing the cellular potency shift seen with the iminohydantoins since more basic analogs could favor increased partitioning into acidic endosomal compartments where BACE1 processes APP. Since this was an endemic issue with the iminohydantoins, the change was particularly attractive.[86]

Analogs **54–59** (Fig. 32A) were among the earliest examples made in this series to test the design elements described above, with the C6 methyl and phenyl groups designed to plumb the effects of trajectory changes toward the nonprime side, and the biaryl substituents to enable facile comparison with the iminohydantoin series.[86] As anticipated by modeling, the C6-methyl iminopyrimidinones were significantly more potent than their C6-phenyl counterparts and, importantly for this novel core, were roughly equipotent to the analogous iminohydantoins (cf. iminohydantoins **41** and **42**, Fig. 26). An X-ray crystal structure of compound **54** bound to BACE1 agreed well with the modeling result above (Fig. 32B). Notably, the C6-methyl group was positioned 3.6 Å from Ile^{118}, favorable for a hydrophobic interaction but a distance that would not tolerate the larger phenyl substituent without significant perturbation of the binding mode. In terms of effects of core basicity, when comparing matched sets of biaryl substituents, the increased basicity of the iminopyrimidinone core translated to substantially lower or no cell potency shift versus the corresponding iminohydantoins (e.g., threefold for S3 methoxyphenyl iminopyrimidinone **54** vs. 14–16-fold for the analogous iminohydantoins **42** and **52**) despite similar or higher c log*P* values for the iminopyrimidinones.[86] It is worth noting that we later learned that the iminopyrimidinone core was independently identified by the Astex/AstraZeneca collaboration through their fragment-based discovery and hit optimization approach.[88]

A rat PK screen on these initial iminopyrimidinone analogs described by Stamford et al. clearly identified the 3-cyanophenyl substituent of **58** as preferred for further SAR development, with a single oral 10 mg kg^{-1} dose producing a plasma of $AUC_{0\text{-}6h}$ of 8.6 μM h, versus a dose-matched AUC_{0-6h} of less than 1 μM h with the other two S3 analogs.[86] Fixing the distal cyanophenyl substituent, we examined a large number of mono- and bicyclic heteroaryl groups (Fig. 33) as replacements for the proximal phenyl group, from which several SAR trends stand out. First, thienyl variants, and in particular the 2,4- and 2,5-isomers **60** and **61**, respectively, were the only modifications that improved on the affinity conferred by phenyl while maintaining essentially no cellular potency shift as well as imparting similar selectivities over CatD.[86] Many heteroaryl groups conferred affinity similar to that of phenyl, though those whose heteroatoms would face the carbonyl of Gly^{230} in the S1 pocket (e.g., 2,6-pyridyl **62** and 2,5-furanyl **63**) were significantly less potent. Several benzothienyl modifications **64–66** were also examined that afforded alternate trajectories into S3 and/or differentiated filling of the open S1–S3 pockets. While at best slightly more potent than P1 phenyl, they offered no advantage given their increased MW, reflected in lower LE, and in fact they showed increased cell potency shifts due to their higher c log*P* values.[89]

With the 2,4- and 2,5-thienyl regioisomers identified as conferring the most affinity in the initial biaryl iminopyrimidinone analogs, and seeking further affinity and cell potency gains, we turned our attention to modifications in S3. The most profound improvements in affinity and cell potency were obtained by replacement of the cyanophenyl moiety by the

3-propyn-1-yl-5-pyridyl moiety, affording analog **67** (Fig. 34).[86] In particular, **67**, with single digit nanomolar affinity and comparable cell potency, proved to be an important tool compound as described in the next section. In fact this compound, along with its progenitors iminopyrimidinone **60** and iminohydantoin **52**, helped to establish a new paradigm for characterizing in vivo pharmacodynamic (PD) effects for our program.

8.09.4.4 In Vivo Validation and Development of a High-Throughput Rat PD Assay

The discovery of **52**, **60**, and **67** over the course of a few months marked a watershed for the program. These compounds proved to be critical tools for characterizing inhibitor-mediated in vivo pharmacology and paved the way for the development of a high-throughput PD assay that drove optimization of the in vivo properties of subsequent generations of inhibitors.

Upon discovery of **60** as the first inhibitor in the series with a K_i value less than 100 nM combined with essentially equipotent cell activity, high Caco-2 permeability, oral bioavailability, and reasonable brain penetration, this compound was profiled in the TgCRND8 mouse model. As was discussed in the context of peptidomimetic inhibitor **3** in Section "Hydroxyethylamine-Based Peptidomimetic Inhibitors," an advantage of this model is that large amounts of Aβ are produced in the brains of these mice and it was well established that orally administered GS inhibitors caused profound reductions of brain Aβ levels in these mice.[90] Single acute oral doses of **60** up to 200 mg kg^{-1} in TgCRND8 mice failed to elicit significant reduction of cortex $Aβ_{40}$ levels despite causing complete ablation of plasma $Aβ_{40}$ levels, a result that was reminiscent of studies with peptidomimetic **3**. Notably, mouse brain homogenate binding studies suggested that free brain levels of roughly 70 nM were attained at the 200 mg kg^{-1} dose, a value similar to the in vitro potency of the compound. Gratifyingly, subchronic administration of **60** (200 mg kg^{-1} PO, 5 days, BID) resulted in somewhat higher exposure and a modest 30% reduction of brain $Aβ_{40}$ levels (Fig. 35). This was important as it was

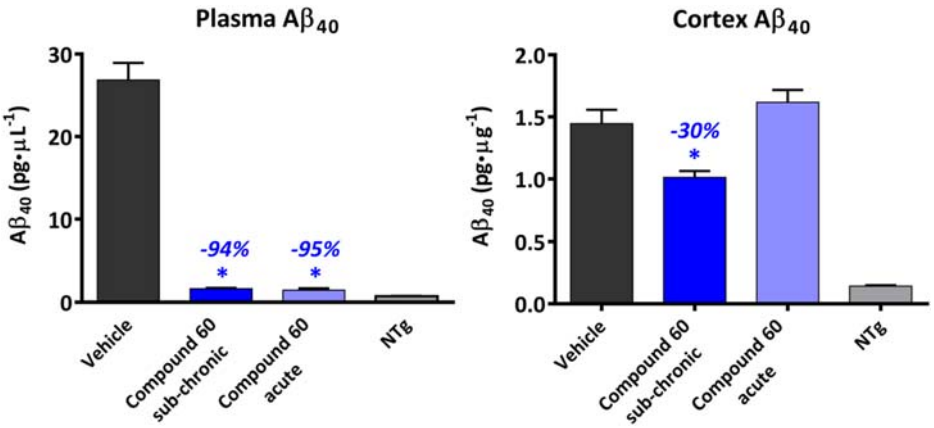

Fig. 35 Comparison of the effects on $Aβ_{40}$ in plasma and cortex in TgCRND8 mice following subchronic (5 days, BID) and acute, single dose administration of 200 mg kg^{-1} PO of compound **60**. The $Aβ_{40}$ levels in plasma and cortex of nontransgenic mice (NTg) are included for comparison.

the first demonstration of brain Aβ lowering by a BACE1 inhibitor in our program, and furthermore at that time there were no reports from any source of inhibitors that lowered brain Aβ despite the intensive efforts of many groups over several years.

Given the challenges that we had experienced in developing inhibitors with potent central activity up to this point, and having identified **60** as novel, nonpeptidic inhibitor with favorable drug-like attributes including central activity after subchronic oral dosing, it was of interest to assess its impact on disease modification upon chronic dosing in TgCRND8 mice. Hyde et al. therefore designed a study to determine the effects of **60** (100 mg kg^{-1} day^{-1}) formulated in diet on total brain Aβ levels, amyloid plaque deposition, and cognitive function in TgCRND8 mice.[91] Dosing was commenced in preplaque animals at 6 weeks of age and continued for 6 months. At multiple time points during dosing, independent groups of mice that received **60** had statistically significant reductions in cortical $Aβ_{40}$ and $Aβ_{42}$ levels of 26-37% relative to age-matched vehicle controls (Fig. 36A). At the 6-month time point, a 35% reduction in mature plaque density as defined by Thioflavin S positive area was also observed in the cortex of treated mice. In the Morris water maze, a model of learning and memory, mice treated with **60** for 6 months did not show benefit to their efficiency of finding the hidden platform; however, evidence of improved performance relative to age-matched controls and performance similar to that of age-matched nontransgenic controls was evident in the probe trial component of the water maze (Fig. 36B). Moreover, through the duration of the study, **60** was well tolerated and no overt compound-related safety concerns were identified at the termination of the study. These results were exciting because they were the first demonstration that partial chronic BACE1 inhibition via pharmacological intervention could realize disease modification in an AD model.[91]

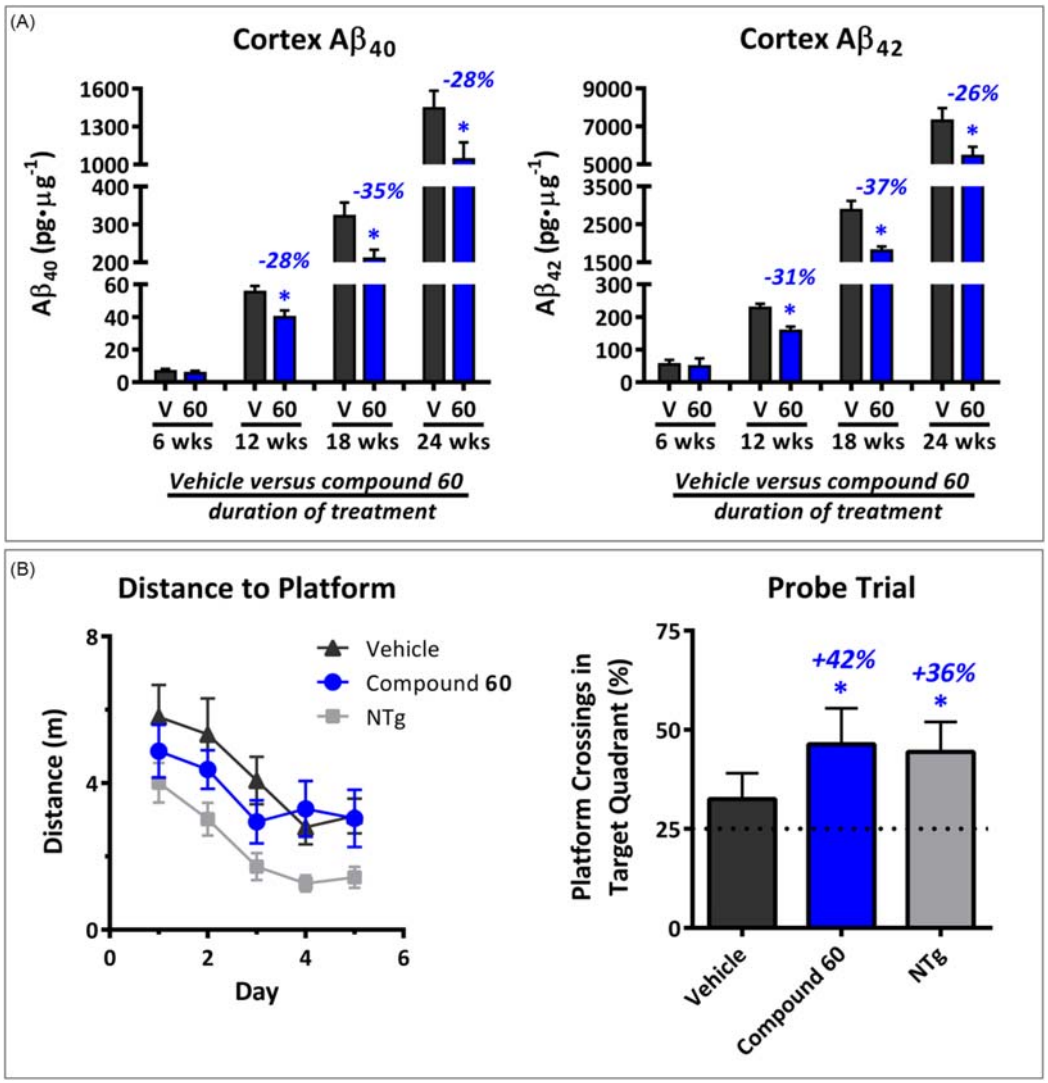

Fig. 36 (A) Effects on cortical $Aβ_{40}$ and $Aβ_{42}$ in TgCRND8 mice over time as a result of chronic dosing with 100 mg kg^{-1} day^{-1} in diet of compound **60**. (B) Performance of TgCRND8 mice in the Morris water maze cognition model following 6 months of treatment with 100 mg kg^{-1} day^{-1} in diet of compound **60** relative to age-matched TgCRND8 and nontransgenic (NTg) controls treated with vehicle.[91]

While the positive outcome of the chronic study conducted by Hyde et al. provided tremendous impetus to the program, the lack of potency of **60** and related inhibitors with respect to acute cortex Aβ reduction in TgCRND8 mice, as well as the low throughput of the assay, presented significant obstacles for SAR development. The striking differential potency between the plasma and central compartments in TgCRND8 mice could not be explained by differences in potency between peripheral and CNS BACE1; a number of inhibitors including **60** were essentially equipotent in reducing Aβ production by cultured TgCRND8 mouse neuronal cells and HEK293 cells. At this stage we pursued two parallel avenues that significantly shaped our strategy to identify more centrally potent inhibitors. First we sought to understand fundamental parameters of BACE1 in vivo biology that may be contributing to the weak central potency. Second, concerned that the weak central potency may be dependent on the overexpression of the human FAD APP-Swedish mutant gene in TgCRND8 mice, we invested in the development of an acute PD assay in nontransgenic rats.

As a framework to investigate the first avenue, we advanced the hypothesis that BACE1 may be rate limiting for Aβ production in the periphery, but not in the CNS; therefore higher enzyme inhibition in the brain relative to the periphery might be required to achieve central Aβ reduction. To interrogate this hypothesis, Hyde et al. determined brain Aβ levels and inhibitor activity were determined in wild-type Bace1 heterozygous (Bace1 HET) mice which have 50% of the BACE1 levels of wild-type mice.[92] Interestingly, Bace1 HET mice showed approximately 50% reduction of $A\beta_{40}$ in the plasma consistent with a 50% reduction of peripheral enzyme activity. In contrast, no significant reduction in brain or CSF Aβ levels was observed in Bace1 HET mice in comparison with Bace1 wild-type mice (**Fig. 37A**). This suggests that BACE1 is rate limiting for Aβ production in the periphery but not in the CNS, possibly because BACE1 in the brain is not saturated with its substrate APP. This observation is also consistent with the hypothesis that a higher degree of brain BACE1 inhibition is required to reduce brain Aβ levels relative to the degree of peripheral BACE1 inhibition required to reduce peripheral Aβ. Moreover, oral administration of doses at or above 100 mg kg^{-1} of compound **67** to Bace1 HET

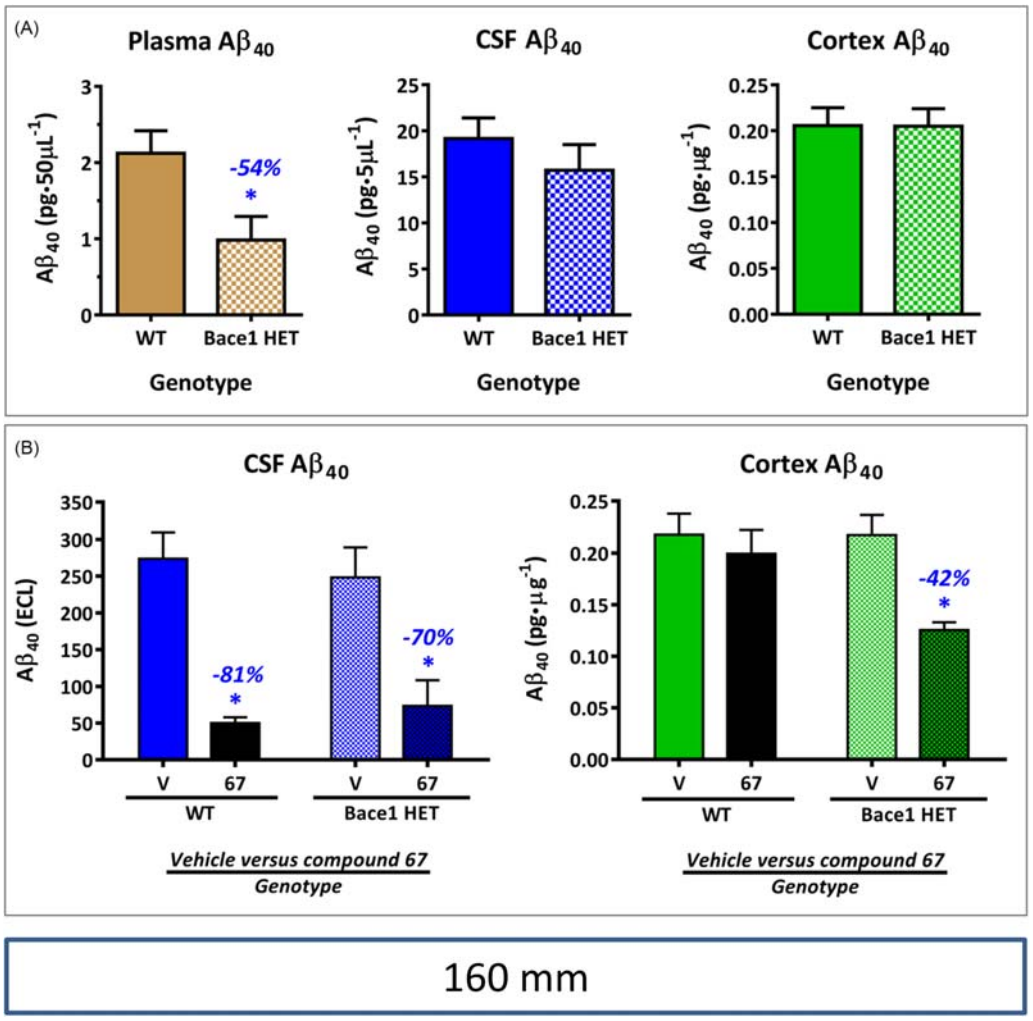

Fig. 37 (A) Levels of $A\beta_{40}$ in plasma, CSF, and cortex in wild-type (WT) and Bace1 heterozygous mice (Bace1 HET). (B) Effects of acute treatment with 200 mg kg^{-1} PO of compound **67** on $A\beta_{40}$ levels in CSF (expressed as electrochemiluminescence, ECL) and cortex of wild-type and of Bace1 heterozygous mice.

mice elicited significant reduction of cortex $A\beta_{40}$ (cf. Fig. 37B for 200 mg kg^{-1} dose of **67**), presumably due to combined genetic and pharmacological ablation of BACE1 activity, whereas no cortex $A\beta_{40}$ reduction was observed in Bace1 wild-type mice treated with the same doses of **67**. From these studies it was inferred that very high BACE1 occupancy (much greater than 50%) is necessary to achieve significant acute brain Aβ reduction. This conclusion was also supported by subchronic studies with the peptidomimetic inhibitor **3** described in Section "Hydroxyethylamine-Based Peptidomimetic Inhibitors."

In pursuit of the second avenue that impacted program strategy, that is, development of a PD assay in nontransgenic rats, sensitive immunoassays were developed to quantify Aβ levels in rats. In addition to our concern that the TgCRND8 mouse may be inherently less sensitive to BACE1 inhibition, the dynamics of Aβ production and turnover in nontransgenic rats was more likely to be similar to Aβ dynamics in the human sporadic AD population. Due to their larger size compared with mice, use of rats would also enable reliable, routine sampling of CSF to determine changes in CSF Aβ levels in response to BACE1 inhibitor treatment, providing a surrogate for brain Aβ inhibition that could be translated into human clinical studies as a primary biomarker for proof of activity. Use of CSF Aβ levels as a surrogate biomarker for brain Aβ inhibition was also supported by studies with GS inhibitors in Tg mice overexpressing APP[93,94] and in non-Tg rodent species[95,96] that published contemporaneously with our ongoing efforts.

In assessing our tool compounds in nontransgenic rats, Hyde et al. showed that acute oral administration of **60** at doses up to 100 mg kg^{-1} caused a dose-dependent reduction in CSF Aβ levels but, in contrast, did not affect cortex $A\beta_{40}$ levels across this dose range (Fig. 38A).[92] Plasma $A\beta_{40}$ levels were profoundly reduced at each dose tested. The higher affinity analogs **52** and **67** had similar profiles—they were more potent in reducing CSF Aβ levels across a similar dose range, but failed to elicit significant brain Aβ reduction after a single oral dose. Gratifyingly, multiple oral doses of **67** (as few as three doses of 100 mg kg^{-1} separated by 12 h) elicited robust cortical $A\beta_{40}$ reduction possibly related to the accumulation (~twofold) of **67** that was observed under the multiple dosing conditions (Fig. 38B).[92] Contrastingly, the structurally similar pyrazole analog **68** (Fig. 38C),[97] which has properties comparable to those of **60**, failed to impact CSF Aβ levels following a single oral dose, despite essentially complete ablation of plasma $A\beta_{40}$ levels, demonstrating that dramatic changes to the plasma Aβ pool occurred independently of the CSF Aβ pool in rats (Fig. 38D). Combined with the observation of direct brain activity of **67**, this result provided confidence that changes in CSF Aβ levels were a sensitive measure of changes in brain-derived Aβ in response to a BACE1 inhibitor, consistent with conclusions drawn from studies with GS inhibitors.

The outcomes of these studies conducted in the laboratory of Hyde et al.[92] had significant implications for our medicinal chemistry program. The profiles of optimized inhibitors identified to date highlighted the challenges of achieving free brain concentrations sufficient to drive the high degree of brain BACE1 inhibition necessary for significant brain Aβ inhibition. Inspection of the in vitro potency, permeability, and physicochemical properties profiles of these leads failed to provide insight into a set of parameters that could predict robust brain activity at acceptable doses to guide further SAR development. While Caco-2 cell efflux ratios of these leads were modest, it was later unambiguously determined that in a cell line overexpressing Pgp the compounds are Pgp efflux substrates which likely restricted their brain exposure and PD activity. Nevertheless, we were encouraged that inhibitors such as **67** had demonstrated significant brain activity given that at the time of these discoveries, 6-7 years after the discovery of BACE1, there remained no reports in the public domain of centrally active BACE1 inhibitors despite enormous industry-wide efforts. Consequently, new target synthesis continued to be guided by structure-based design and directed to ligand efficient inhibitors that occupied properties space (c log*P*, PSA, MW) represented by the current leads. In addition, an acute rat CSF Aβ screen was implemented early in our compound evaluation protocol to provide a rapid read on central PD activity for multiple compounds per week to identify compounds of high interest and to guide future optimization efforts.

8.09.4.5 Iminopyrimidinones: Advanced Optimization of the P1-P3 Biaryl Series

With an eye toward further improvement of the profile of the biaryl iminopyrimidinones, Stamford et al. pursued additional SAR around the S1 2,5-thienyl moiety. In analogy to the 2,4-thienyl series, in which introduction of an S3 propynylpyridine substituent imparted benefits in BACE1 affinity and cell-based potency, we prepared the analogous 2,5-thienyl regioisomer **69** (Fig. 39).[86] While this compound showed slightly less affinity for BACE1 than 2,4-isomer **67**, it offered the opportunity for introduction of small, flap-facing substituents at the 3-position of the thiophene to potentially impart affinity gains. To that end, 3-chlorothienyl analog MBi-1 (**70**) showed significant improvements in affinity and cellular activity, with only a modest increase in cell potency shift despite its higher c log*P*. In the acute rat CSF screen established as discussed above, MBi-1 inhibited CSF $A\beta_{40}$ by 66% 3 h after a single 10 mg kg^{-1} oral dose, an effect similar to that of the positive control **67** dosed at 30 mg kg^{-1} orally in the same experiment. Based on this potent CSF $A\beta_{40}$ PD response, MBi-1 was subjected to more in-depth profiling.[86]

MBi-1 showed favorable PK properties in rats with oral bioavailability of 69%, a plasma terminal half-life of 3 h, and an average brain/plasma ratio of 3. These results were anticipated by its good permeability and low efflux ratio in Caco-2 cells (P_{app} 153 nm s^{-1}, AP/BL 2.4) as well as its low intrinsic clearance in rat hepatocytes (4.9 μL min^{-1}million $cells^{-1}$). CSF and cortex $A\beta_{40}$ levels were reduced in a dose-dependent manner 3 h after rats were administered single oral doses of MBi-1 across the dose range of 0.3–30 mg kg^{-1}, with ED_{50} values for CSF and cortex of 4 and 6 mg kg^{-1}, respectively. The unbound plasma concentration of 15 nM at the ED_{50} was significantly lower than that of **67** (~200 nM), and the substantially improved acute CSF and cortical $A\beta_{40}$ potency of MBi-1 may be due to a combination of intrinsically higher BACE1 affinity and improved brain uptake.[86]

In an X-ray structure of compound MBi-1 bound to BACE1, the chlorinated thienyl group caused the flap to move into a more closed conformation relative to the isomeric thienyl analog **67** with Tyr^{71} of the flap repositioned toward the prime side and in proximity with the iminopyrimidinone C5 methylene group, inducing a pocket to accommodate the chloro group (Fig. 40).

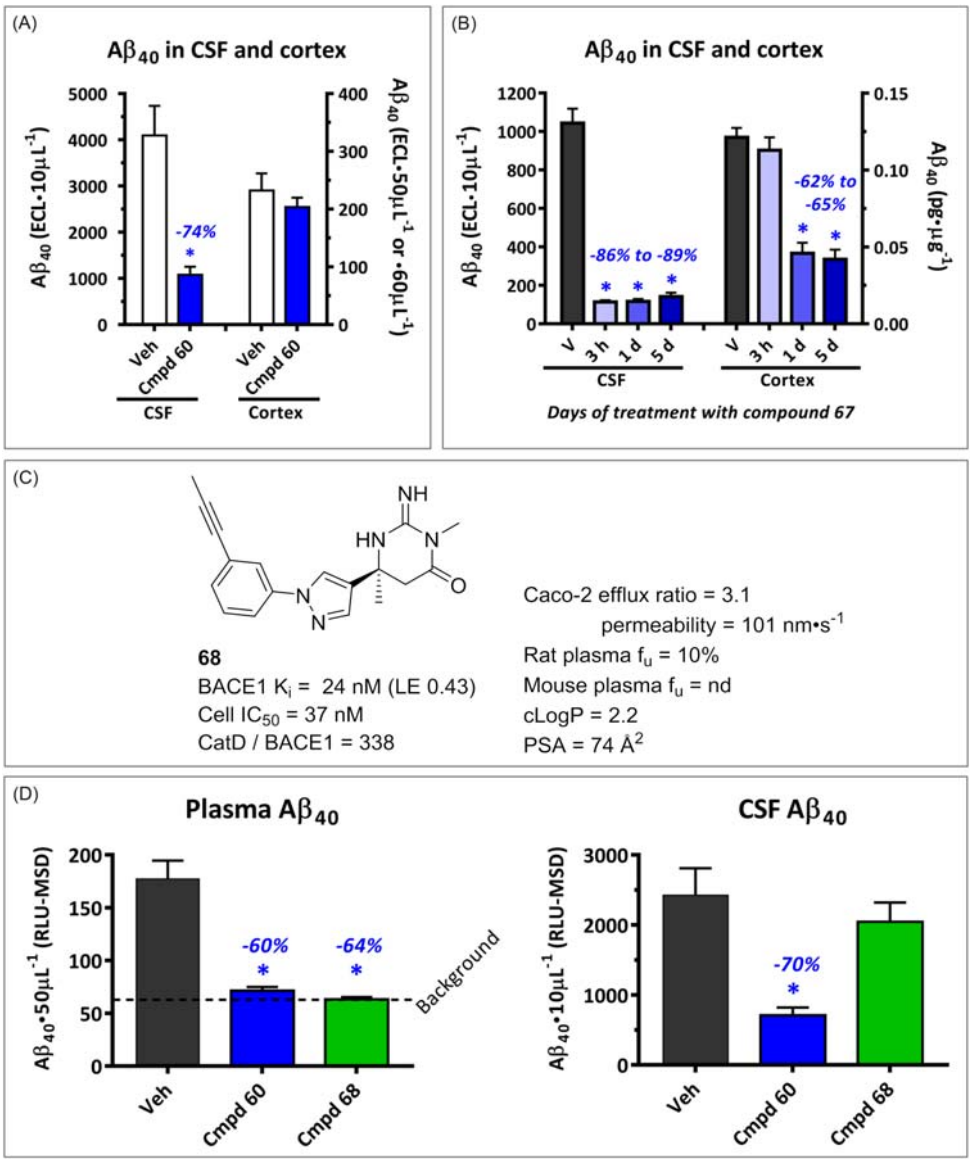

Fig. 38 In vivo studies in nontransgenic rats. (A) Effects of single dose treatment with 100 mg kg^{-1} PO of compound **60** on CSF and cortex $A\beta_{40}$ levels; plasma $A\beta_{40}$ levels were also profoundly reduced. (B) Effects of single and multiple dose (BID) treatment with 100 mg kg^{-1} PO of compound **67** on CSF and cortex $A\beta_{40}$. (C) Structure and profile of pyrazole tool compound **68**. (D) Comparison of the effects of single doses of compounds **60** (100 mg kg^{-1} PO) and **68** (80 mg kg^{-1} PO) on plasma and CSF $A\beta_{40}$ levels (expressed as relative luminescence units—mesoscale diagnostics, RLU-MSD), clearly demonstrating that effects in these two pools are distinct.

Fig. 39 Structures of S1 2,5-thienyl biaryl iminopyrimidinones **69** and MBi-1 (**70**).

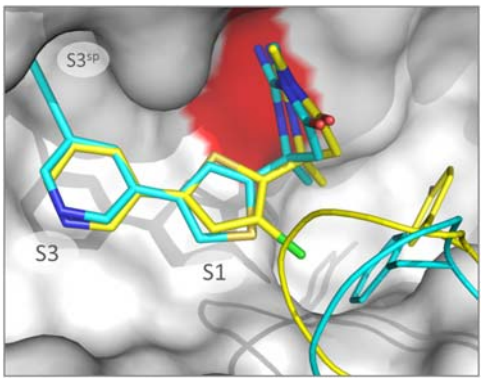

Fig. 40 Overlay of X-ray crystal structures of S1 thienyl biaryl iminopyrimidinone **67** (*blue*) and MBi-1 (*yellow*) showing the dramatic change in flap conformations (shown as ribbons, colored to match inhibitors) induced by the 3-chloro substituent of MBi-1.

While the selectivity of MBi-1 over CatD was similar to that of its des-chloro precursor **69**, its selectivity over a number of other human aspartyl proteases (pepsin, CatE, and renin) was moderate to high (260-, 350-, and >10,000-fold, respectively). Typical of compounds in this series, compound MBi-1 was not selective over BACE2 ($K_i < 1$ nM).[86]

While the profile of MBi-1 represented a high point of discovery in the S1–S3 binding class of inhibitors with respect to its PK/PD profile, the compound was considered unsuitable for progression. Despite its improved in vivo potency on an exposure basis, its CatD affinity and selectivity were considered to be inadequate. Furthermore, the propynyl pyridine moiety was susceptible to oxidative metabolism and formation of glutathione adducts, raising potential safety concerns. Nevertheless, the discovery of MBi-1 validated our molecular design and compound triaging strategy. The molecular properties of MBi-1, including MW (373), log*D* (1.8), and pK_a (7.5), all fall well within those considered optimal for CNS drugs. Substantial advances in addressing CatD selectivity and metabolism concerns were later achieved through more profound structural changes to the S1–S3 binding biaryl motif, leading to the discovery of verubecestat as discussed in Section "Discovery of Verubecestat."

8.09.4.6 Structural Differentiation: Occupancy of S2′

Beyond the S1–S3 filling approaches, we also sought to identify more structurally differentiated approaches to development of BACE inhibitors to derisk unforeseen structure-based toxicity or other issues that might arise as endemic in the S1–S3 biaryl series. From the crystal structures of **60** and other biaryl iminopyrimidinones, we had clearly seen that the biaryl moiety adopted a pseudoaxial conformation (Fig. 41A). Mandal et al. hypothesized that stabilization of this presumably higher energy bioactive conformation might offer an avenue for further structural modification of the iminopyrimidinone core, particularly if done in combination with occupancy of S2′, which we had not significantly reinvestigated since our earlier work with the cyclohexylalkyl substituents.[98] By analyzing the X-ray structures of **60** and analogs Mandal et al. also recognized that there was sufficient room in the active site for ring fusion at the C5-C6 of the iminopyrimidinone core that could enable occupancy of S2′ (Fig. 41B). Combining those observations, energetic calculations with a five-membered ring fused to C5-C6 of **60** predicted a modest 0.9 kcal mol^{-1} stabilization of the pseudoaxial conformation, and further modeling suggested that the nitrogen atom of a 3,4-fused pyrrolidine (e.g., general structure **71**, Fig. 41C) would offer a favorable vector for facile SAR development in S2′.[98] It should be noted that there

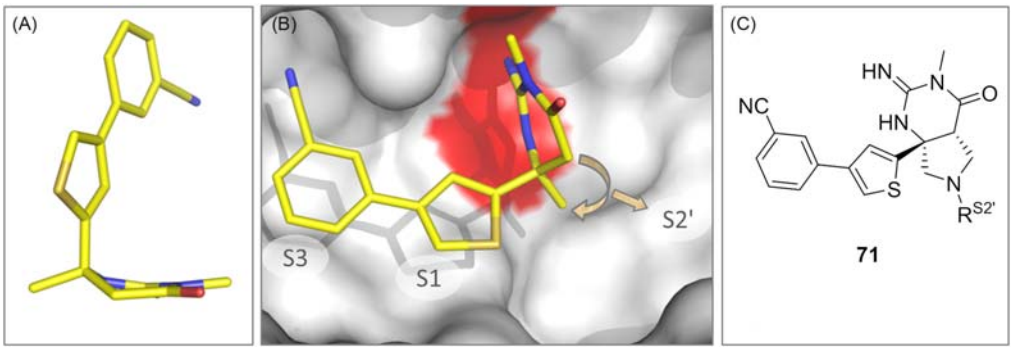

Fig. 41 (A) Structure of biaryl iminopyrimidinone **60** oriented to highlight the pseudoaxial conformation of the core biaryl substituent. (B) X-ray cocrystal structure of **60** and BACE1 showing potential to fuse a ring to the core and grow into the S2′ subsite. (c) Generic structure of designed fused pyrrolidine iminopyrimidinone **71**.

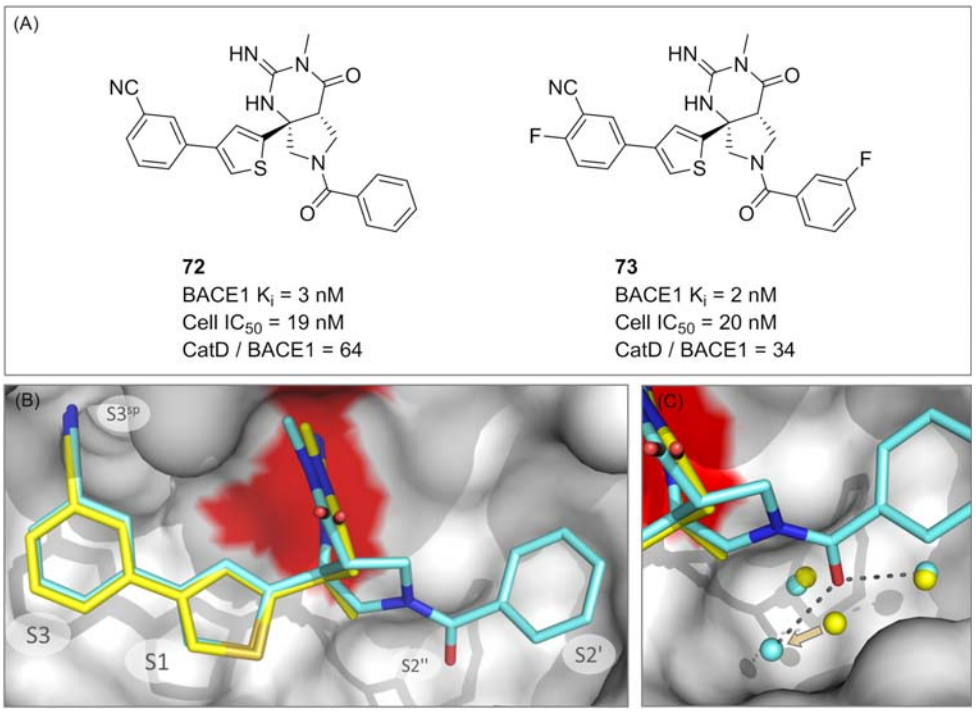

Fig. 42 (A) Structures of early fused pyrrolidine analogs bearing benzamide substituents. (B) Overlay of X-ray structures of fused pyrrolidine **72** (*blue*) and its prime-side unsubstituted progenitor **60** (*yellow*) bound to BACE1 showing the highly conserved binding mode of the nonprime side and core after introduction of the fused pyrrolidine ring. (C) Close-up view of the prime side subsites showing the 1.8 Å difference in the position of one of the waters in the S2″ pocket upon binding of benzamide **72**. Waters are colored to match the inhibitors.

are several conserved water molecules in this subsite that are part of a hydrogen bonding network with the protein backbone, and the effects of occupancy of this region were unknown when we initiated these efforts.

To our satisfaction, we found that benzamide **72** and several close analogs, for example, fluorinated compound **73**, showed a more than 10-fold improvement in intrinsic affinity over **60** with a modest improvement in cellular activity and retention of selectivity over CatD (Fig. 42A). The X-ray structure of **72** bound to BACE1 showed that the binding mode of the core and biaryl nonprime side of the molecule was highly conserved with that of **60** and that the benzamide projected into S2′ as designed (Fig. 42B). Interestingly, whereas modeling suggested that one of the conserved water molecules in a pocket near the S2′ subsite, termed the S2″ pocket, might be displaced by the benzamide carbonyl, the water instead rearranged to accommodate a hydrogen bond to that carbonyl (Fig. 42C). Unfortunately, while these initial examples validated the design of the fused pyrrolidine imino-pyrimidinones in terms of their potency and selectivity, their PK properties in rat were substantially eroded from their nonfused precursor. This may be due to their relatively high rat hepatocyte clearance and/or susceptibility to Pgp efflux as manifested by analog **73** (rat hepatocyte clearance = 46 μL $min^{-1}10^6$ $cells^{-1}$, Caco-2 efflux ratio = 17).[98]

To mimic interactions of the carbonyl oxygen with the conserved water in the S2″ site while replacing the benzamide moiety, which were hypothesized to be detrimental to the PK properties in the series, Mandal et al. explored a series of N2-pyridyl and N2-pyrimidinyl analogs.[98] These modifications, in combination with small substituents around the heteroaryl rings as exemplified by analogs **74**–**76** (Fig. 43A), were generally well tolerated and recapitulated the affinity, cell potency shift, and CatD selectivity profile of the benzamides. An X-ray structure of 3-methoxypyridyl analog **74** bound to BACE1 showed that the pyridyl nitrogen did in fact replicate the hydrogen bonding interaction of benzamide **72** with a water in the S2″ site (Fig. 43B). Unexpectedly and in contrast, introduction of a methoxy group at the 6-position of the pyridine in analog **75** caused a large shift of the pyridine ring of more than 1 Å toward S2″, embedding the methoxy group deep in that subpocket and displacing two of the conserved water molecules from that region (Fig. 43C). This modification was accompanied by high BACE1 affinity and similar CatD selectivity. This change in binding pose was replicated with *N*-pyrimidine analogs, with 5-fluoro-6-methoxypyrimidine analog **76** also showing promising affinity, cell potency, and CatD selectivity.[98]

Unfortunately, **76** showed only modest activity in the rat CSF assay, lowering Aβ levels by 45% following a 30 mg kg^{-1} oral dose, and was similar to many of the analogs in this series.[98] This inferior in vivo PD response relative to the earlier nonfused pyrrolidine lead MBi-1 is driven at least in part by its poor CNS penetration, to which the relatively high MW and PSA values for these compounds (e.g., MW = 478 and PSA = 117 $Å^2$ for **76**) likely contributed. In addition, like many related structures in this initial effort, **76** showed time-dependent inhibition of CYP3A4, which was likely due to bioactivation of the heteroaryl ring and generation of a reactive intermediate which we had observed for a related analog.[98]

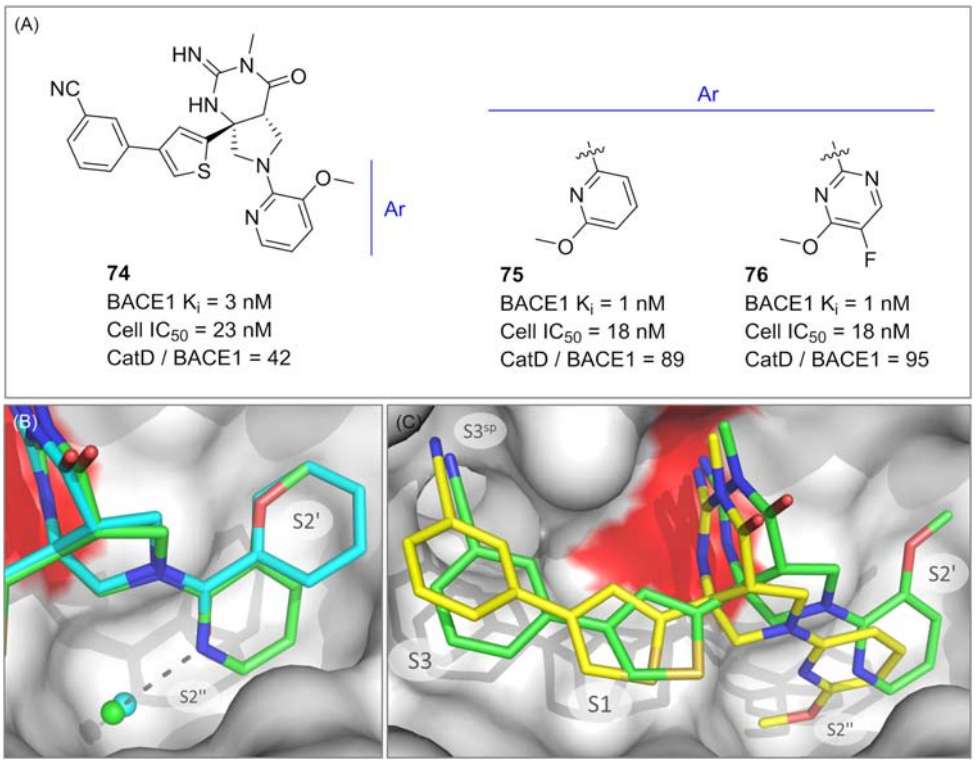

Fig. 43 (A) Structures of N-heteroaryl fused pyrrolidine analogs **74**–**76**. (B) Detail of the S2″ region from an overlay of the X-ray crystal structures of benzamide **72** (*blue*) and N-pyridyl analog **74** (*green*) bound to BACE1 showing that the pyridine nitrogen of **74** recapitulated the positioning and hydrogen bonding interactions with a conserved water in that subsite. Waters are colored to match inhibitors. (C) Overlay of the X-ray crystal structures of N-pyridyl analogs **74** (*green*) and **75** (*yellow*) showing the significant change in pose induced by binding of the 6-methoxy group deep into S2″ with analog **75**.

Given our interest in the structural diversity represented by this new series, Mandal et al. pursued a strategy to rescue the profile of these molecules.[99] First, this involved truncation of the S3 cyanophenyl to reduce the relatively high MW of in the series. The anticipated loss of affinity could then be addressed through further modification of the S1 and S2″ binding motifs. In parallel, to mitigate time-dependent CYP3A4 inhibition, we examined fully substituting the pyrimidine ring as a route to block oxidation of the pyrimidine and/or direct the metabolic pathway to the newly introduced substituent itself. Gratifyingly, the combination of these two modifications in cyanothiophene **77** provided an analog with only a modest loss in affinity, albeit with an increase in LE over its biaryl predecessor due to its lower molecule weight (Fig. 44). In addition, truncated cyanothiophene **77** possessed a modest cellular potency shift, only a slight erosion of CatD selectivity, and importantly, a significantly attenuated time-dependent inhibition of CYP3A4 (preincubation $IC_{50} = 18$ μM vs. 2 μM for **76**). Though lower in MW, the cyano group on the S1 thienyl of **77** contributed to a PSA that was equivalent to the biaryl analogs, and the compound showed a similar level of CSF Aβ40 lowering activity (−47%) in the acute rat PD screen following an orally administered dose of 30 mg kg^{-1}. Although we examined additional SAR beyond methyl at the four-position of the pyrimidine ring, other modifications offered no benefit or eroded the potency and selectivity of the resulting analogs.[99]

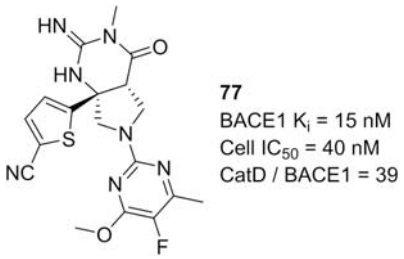

Fig. 44 Structure of unoptimized truncated fused pyrrolidine iminopyrimidinone **77**.

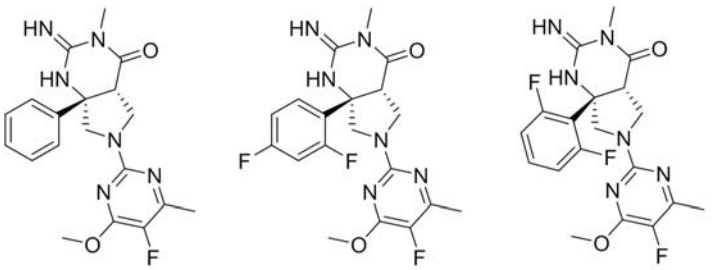

Fig. 45 Structures of S1 phenyl fused pyrrolidine iminopyrimidinone analogs **78**, MBi-4 (**79**), and **80**.

Along with optimizing the S2″ binding substituent, Mandal et al. also reexamined SAR in the S1 pocket in the truncated subseries since we anticipated there would be no particular benefit to keeping the S1 thiophene that had been incorporated as the best moiety to properly display S3 substituents in the S1–S3 biaryl iminopyrimidinone series. To that end, we initially returned to an S1 phenyl group as well as a set of its fluorinated variants (Fig. 45), all of which possessed roughly 20 Å^2 lower PSA than the S1 cyanothiophene. The unsubstituted baseline phenyl analog **78** was roughly equipotent to cyanothiophene analog **77**, and introduction of an *ortho*- or *para*-fluorine to the phenyl ring, or combination thereof as in 2,4-difluorophenyl analog MBi-4 (**79**), resulted in a several-fold improvement in affinity to give single-digit nanomolar BACE1 inhibitors. Interestingly, introduction of a second ortho fluorine as in 2,6-difluoro analog **80** completely ablated any gain in affinity, with this and other analogs containing the bis-*ortho*-fluorophenyl at best equipotent to the unsubstituted analog **77**.[99]

To understand these subtle differences in SAR, X-ray structures of selected compounds were again useful. The crystal structure of 2,4-difluorophenyl analog MBi-4 bound to BACE1 indicated that the improvement in affinity for the 2-fluoro and 4-fluoro bearing analogs could be due to electrostatic interactions with Tyr^{71} of the flap and/or with Trp^{115} in the distal part of S1 (Fig. 46A). It is interesting to note that the 2,4-difluoro moiety avoided a flipped conformation in which the *ortho*-fluoro pointed not toward the flap but instead toward the backbone of the protein. That it did not bind in that latter conformation presaged a potential reason for the reduced affinity of the 2,6-difluoro-substituted analog **80**. In the X-ray obtained of the racemate of compound **80** bound to BACE, the second *ortho*-fluorine is oriented toward the protein backbone and is only 3.1 Å from the Gly^{230} carbonyl, potentially representing a weakly negative interaction (Fig. 46B). Also from these crystal structures, regardless of fluorine substitution on the S1 phenyl, the binding mode of the molecules is well conserved with excellent overlap of the S2″ pyrimidine and fused iminopyrimidinone core.[99]

Encouragingly, all of these initial S1 phenyl and fluorophenyl analogs were slightly to significantly more selective over CatD than cyanothiophene **77**, and they all showed only a slight or no time-dependent inhibition of CYP3A4.[99] We explored some additional expansion of the S1 SAR to include 2-chlorophenyl analogs such as **81**, in analogy to the chlorothiophene present in MBi-1, as well as benzothiophene **82** (Fig. 47). The 2-chloro analogs offered no benefit in in vitro profile over their 2-fluoro counterparts and in fact demonstrated inferior oral PK profiles in rats. The S1 benzothiophene analog **82** had equal affinity with other high affinity

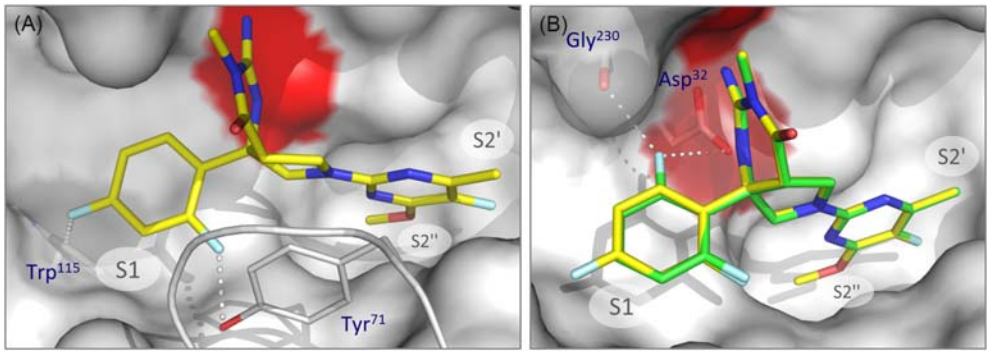

Fig. 46 (A) X-ray crystal structure of S1 2,4-difluorophenyl-fused pyrrolidine iminopyrimidinone MBi-4 (*yellow*) bound to BACE1 showing interactions of the ortho and para fluoro substituents that may be beneficial to affinity. (B) Overlay of X-ray structures of S1 2,6-difluorophenyl fused pyrrolidine analog **80** (*green*) and MBi-4 (*yellow*) showing the well-conserved binding modes and showing interactions of the additional ortho fluoro substituent in **80** that may be deleterious to affinity.

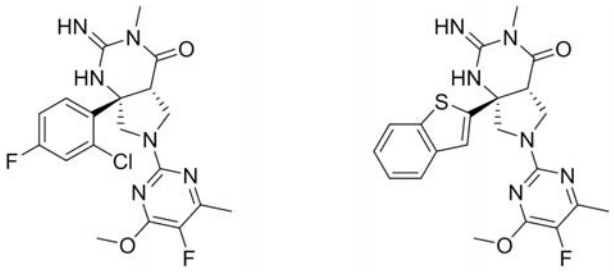

Fig. 47 Structures of S1 2-chlorophenyl and S1 benzothiophene fused pyrrolidine iminopyrimidinones **81** and **82**.

analogs against BACE1, but showed a much larger cellular potency shift owing to the significantly higher c log*P* (e.g., 3.3 for **82** vs. 2.6 for 2,4-difluorophenyl analog MBi-4). In addition, CatD selectivity attained with the benzothiophene modification was much lower than that of the other S1 modifications.

Ultimately, 2,4-difluorophenyl analog MBi-4 was chosen for more in-depth characterization given its excellent overall balance of affinity, cell potency, and selectivity. This compound exhibited high clearance and low-to-moderate oral bioavailability in rats, dogs, and monkeys, which was attributed to high hepatic extraction and plasma instability of the compound in these species. In contrast, MBi-4 had low intrinsic clearance in human hepatocytes and was stable in human plasma, supporting a prediction of once-daily dosing in humans.[99]

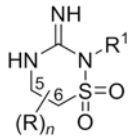
In addition to its lack of CYP3A4 inhibition, MBi-4 did not inhibit or induce cytochrome P450 enzymes involved in xenobiotic metabolism, suggesting a low risk for perpetrating drug-drug interactions. The compound is a potent inhibitor of BACE2 (K_i 2.7 nM) and in a patch clamp assay inhibited the hERG channel with an IC_{50} of 1.9 μM. Additionally MBi-4 did not have significant activity against a diverse panel of receptors, enzymes, and ion channels with the exception of weak affinity for the histamine H2, melatonin MT1, and motilin receptors with K_i values in the micromolar range.[99]

In the rat PD assay, MBi-4 lowered $A\beta_{40}$ levels in the CSF and cortex with ED_{50} values of 5 and 13 mg kg^{-1}, respectively, which compared favorably with the nonfused pyrrolidine biaryl iminopyrimidinone lead MBi-1. Importantly, the similar $A\beta_{40}$ ED_{50} values were achieved with comparable unbound plasma concentrations—the unbound plasma EC_{50} values for CSF $A\beta_{40}$ for MBi-4 and MBi-1 were 30 and 15 nM, respectively. The PK/PD profile of MBi-4 was also determined in nonhuman primates. In cynomolgus monkeys, $A\beta_{40}$ lowering was achieved in the CSF (35%) and cortex (58%) 4 h after a single 10 mg kg^{-1} oral dose. This was an important result as it showed that changes in CSF Aβ levels were indicative of effects in the cortex in a primate species and thus built confidence that CSF $A\beta_{40}$ would be an effective biomarker of brain Aβ inhibition in patients in a clinical setting. Interestingly, the PD effect in cortex was more pronounced than in CSF. This is not unexpected in an acute dose setting since levels in the cortex are a direct measure in the compartment where $A\beta_{40}$ is produced, whereas levels of $A\beta_{40}$ in the CSF are in part dependent on the kinetics of its transit to the CSF compartment. This temporal effect was confirmed in a dose–response time course study of CSF Aβ lowering in cisterna magna ported monkeys with maximal CSF $A\beta_{40}$ inhibition occurring at 12–24 h after a single oral dose, which was significantly delayed relative to the timing of peak plasma and CSF concentrations of MBi-4.[99]

As the culmination of research in the fused pyrrolidine series, MBi-4 represented an advanced lead that was structurally differentiated from the S1–S3 spanning biaryl iminopyrimidinone represented by MBi-1. Compound MBi-4 was positioned for clinical development, supported by its preclinical safety profile and favorable human dose projections derived from PK/PD data in preclinical species to achieve significant central Aβ reduction at steady state under a QD dosing regimen. However, further development of this series was suspended in light of the emergence of a superior inhibitor class, namely the iminothiadiazinane dioxide diaryl amide series described in Section "Discovery of Verubecestat." Compounds from this new series, which ultimately delivered verubecestat, were substantially more potent in vivo and offered the potential for a lower dose and a superior therapeutic window to enable testing of a much greater dose–response range for central Aβ inhibition in the clinic.

8.09.4.7 From Acyl Guanidines to Sulfonyl Guanidines: Discovery of Iminothiadiazinane Dioxides

MBI-1 and MBi-4 represented successful optimization efforts that followed from our overarching strategy to balance improvements in potency and profile against unproductive increases in MW, number of rotatable bonds, PSA, or other characteristics that can erode the overall drug-like nature of molecules and result in issues later in development. These two structurally differentiated iminopyrimidinones were important lead compounds for the program. However, both structures were highly engineered, and small alterations to their structure often resulted in significant erosion to different aspects of their profiles, whether be it cell potency, selectivity, off-target, or PD activity.



83

Fig. 48 Generic structure of the novel iminothiadiazinane dioxide core **83**.

While we continued to explore SAR of the iminopyrimidinone series, we simultaneously pursued the discovery of novel catalytic dyad binding motifs. To that end Scott et al. and Gilbert et al. sought to replace the iminopyrimidinone acyl group with a sulfonyl group as in the unprecedented iminothiadiazinane dioxide core **83** (Fig. 48).[100,101] Beyond the subtle, possibly beneficial effects on inhibitor profiles that this change could bring, such as we had observed in the progression from iminohydantoin to iminopyrimidinone, we were attracted to the novel intellectual property space offered by the iminothiadiazinane dioxide motif. This had become a priority as we anticipated increased competition in this chemical space in the years since the initial disclosure of cyclic acylguanidines in 2005–2006 by us and others.

The iminothiadiazinane dioxide motif was evaluated in the context of both the S1–S3 biaryl presentation exemplified by **84** and **85** and the fused pyrrolidine S1-S2′ display as in analogs **86** and **87** (Fig. 49).[100,101] With respect to calculated properties in comparison with the corresponding iminopyrimidinones, replacement of the carbonyl group by the sulfonyl group imparted somewhat higher PSA and lower c log*P* values, although these remained within CNS drug-like ranges. We also anticipated that introduction of the sulfonyl group would result in reduced basicity relative to identically substituted iminopyrimidinones, although the unreliability of calculated pK_a values created uncertainty in predicting the magnitude of this effect, and the impact on inhibitor profiles was unclear. In addition, the change to an sp^3 sulfonyl from an sp^2 carbonyl would make the monocyclic iminothiadiazinane core of **84** and **85** less rigid, and importantly, modeling simulations suggested that the bioactive pseudoaxial disposition of the biaryl motif was close to the minimum energy conformation. Furthermore, in silico docking experiments suggested that the increased

Fig. 49 Structures of thiadiazinane dioxide S1–S3 biaryl analogs **84** and **85** and S1-S2″ fused pyrrolidine analogs **86** and **87**.

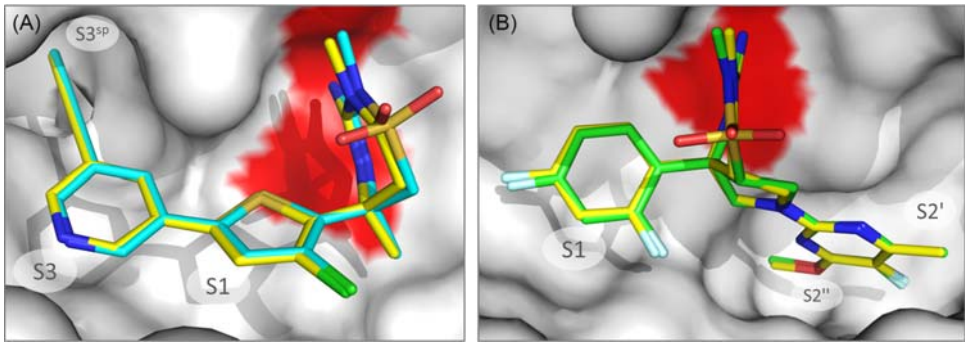

Fig. 50 (A) Overlay of X-ray structures of S1–S3 biaryl iminothiadiazinane dioxide **85** (*blue*) and of iminopyrimidinone MBi-1 (*yellow*) bound to BACE1. (B) Overlay of X-ray structures of S1-S2′ fused pyrrolidine iminothiadiazinane dioxide **86** (*green*) and of iminopyrimidinone MBi-4 (*yellow*) bound to BACE1. Both sets of overlays show excellent conservation of binding modes between the iminothiadiazinane dioxide and iminopyrimidinone cores.

steric demand of the sulfonyl group in both the monocyclic and fused bicyclic cores would not cause unfavorable interactions with BACE1.[100]

Upon synthesis and testing of the biaryl thiadiazinane dioxide analogs **84** and **85**, we were gratified to find that they possessed single-digit nanomolar BACE1 binding affinities that compared favorably to the corresponding iminopyrimidinone analogs (i.e., **67** and MBi-1 with BACE1 K_i values of 8 and 2 nM, respectively). Notably, the X-ray cocrystal structure of **85** bound to BACE1 confirmed that the thiadiazinane dioxide core was a good surrogate for the iminopyrimidinone as the overlay with MBi-1 showed that the two inhibitors were virtually superimposable (**Fig. 50A**). Introduction of the tetrahedral sulfonyl group did not cause a significant change in the conformation of the core nor did it alter the trajectory of the biaryl substituent into the S1-S3-S3^{sp} pockets. Generally with respect to BACE1 affinity and CatD selectivity, the iminothiadiazinane dioxide and iminopyrimidinone biaryl analogs exhibited very similar SAR.[100] On the other hand, fused pyrrolidine iminothiadiazinane dioxide **86** prepared by Gilbert et al. had about a 10-fold lower affinity than MBi-4 despite a similarly near-superimposable binding mode in an X-ray structure with BACE1 (**Fig. 50B**).[101]

The measured pK_a values for **85** and **86** were significantly less basic than those of the corresponding iminopyrimidinones, and this probably accounts for the magnified cellular potency shifts observed for these analogs. In the case of the fused pyrrolidine subseries explored by Gilbert et al., affinity and, to some extent, cell potency could be rescued by modification of the pyrimidinyl substituent to the (methoxymethyl)pyridyl group present in **87**. Despite the ability to achieve such improvements, the pyrrolidino-fused analogs displayed weak central PD activity in rats when screened with oral doses up to 30 mg kg^{-1} even though they possessed high cell permeability and brain penetration, and achieved unbound plasma concentrations similar to their iminopyrimidinone counterparts.[101] Although we lack understanding of the reasons for the poor PD activity of the fused pyrrolidine analogs, it is possible that their reduced basicity alters their intracellular distribution leading to reduced BACE1 inhibition in vivo.

In a comparison of the iminothiadiazinane biaryl analogs **84** and **85** it is important to note that the magnitude of the pK_a and related cell shifts was highly dependent on the 6-aryl substituent with the chlorothienyl analog **85** (pK_a 6.6) having the weaker basicity and greater shift between its K_i and cell IC_{50} values. Despite the reduced cellular potency, **85** robustly reduced $A\beta_{40}$ levels in the CSF and cortex of rats by 82% and 53%, respectively after a single oral dose of 10 mg kg^{-1}. On an exposure basis comparing unbound plasma concentrations of **84** and **85** for the observed PD activity in that study, the latter compound was substantially more potent (120 nM for **84** vs. 7 nM for **85**). This is presumably due to its enhanced CNS penetration imparted by its increased permeability and reduced susceptibility to efflux relative to **84** as indicated by a comparison of their permeabilities and efflux ratios in the Caco-2 bidirectional assay. Not only did the greater potency of the chlorothienyl analog **85** relative to **84** recapitulate the rank order of potency for the thiophene isomers in the iminopyrimidinone series (i.e., MBi-1 >**67**), but **85** was also appreciably more potent in vivo than its iminopyrimidinone counterpart MBi-1. The superior in vivo potency of **85** clearly validated the iminothiadiazine dioxide catalytic dyad binding motif as a viable scaffold with superior properties to the iminopyrimidinone, and also served to highlight the profound and unpredictable impact on in vivo activity that subtle changes in physicochemical properties such as pK_a, PSA, and log D can impart. In addition, representative iminothiadiazinane dioxide analogs showed enhanced hydrolytic stability under weakly basic conditions compared to analogous iminopyrimidinone derivatives, highlighting an additional advantage of the iminothiadiazinane dioxide core.[100]

8.09.5 Discovery of Verubecestat

8.09.5.1 S1–S3 Spanning Diaryl Amides: Rationale

While the increased potency of **85** relative to MBi-1 was an advantage, it nonetheless did not meet criteria for advancement due to deficiencies it had in common with MBi-1 such as inadequate CatD selectivity (47-fold) and concerns about the metabolic lability

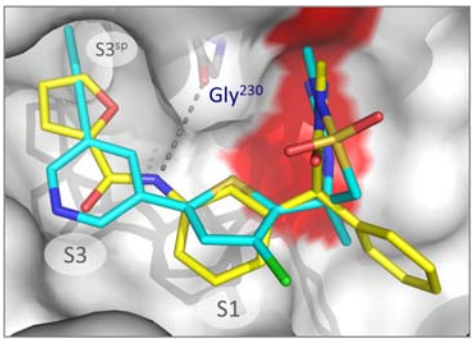

Fig. 51 Overlay of the X-ray cocrystal structures of diaryl iminohydantoin **38** (*yellow*) and biaryl iminothiadiazinane **85** (*blue*) bound to BACE1.

of the propynyl pyridine moiety. To remedy these deficiencies, Scott et al. pursued more profound structural variations of the S1–S3 spanning biaryl motif.[100] Among those explored was a series of diaryl carboxamide analogs inspired by iminohydantoin **38** (Fig. 25) which, despite its weak BACE1 affinity, caught our attention because it possessed some intrinsic selectivity for BACE1 over CatD. Overlay of the X-ray structures of **38** and of **85** bound to BACE1 showed that the furanyl moiety of **38** was positioned deeply in $S3^{sp}$, not dissimilar to the propynyl moiety of **85** (Fig. 51). In addition, the amide hydrogen of **38** was within hydrogen bonding distance of the Gly^{230} carbonyl of the enzyme.[100]

Recognizing that the trajectory of the carboxamide substituent into the S1–S3 pockets from the iminohydantoin core of **38** may not have been optimal and could contribute to the weak BACE1 affinity of this compound, Scott et al. prepared a series of iminopyrimidinone and iminothiadiazinane dioxide diaryl amides, exemplified by **88** and verubecestat (**89**, MK-8931), respectively (Fig. 52). To our satisfaction, both compounds were high affinity BACE1 inhibitors with potent cell-based activity. Surprisingly, these analogs were extremely selective for BACE1 over CatD, exhibiting selectivity ratios of $>10{,}000$-fold. Consistent with the trend observed with the biaryl analogs **85** and MBi-1, the iminothiadiazinane analogs were significantly less basic than the corresponding iminopyrimidinones, manifesting in this case as unexpectedly large differences in their permeabilities, efflux ratios, and in vivo profiles. The iminothiadiazinane verubecestat had much greater permeability and a lower efflux ratio than the iminopyrimidinone **88**, and this translated into a substantial difference in in vivo potency. In rats, verubecestat potently reduced $A\beta_{40}$ levels in the CSF and cortex with ED_{50} values of $<10\ mg\ kg^{-1}$ 3 h after oral administration, corresponding to unbound plasma EC_{50} values of <100 nM. In contrast, the CSF and cortex $A\beta_{40}$ ED_{50}s of **88** were $\geq 30\ mg\ kg^{-1}$ 3 h following oral administration, which corresponded to unbound plasma levels of ≥ 190 nM.[100]

8.09.5.2 Verubecestat Cocrystal Structure, in vitro Profile, and Key SAR

In the X-ray cocrystal structure of verubecestat bound to BACE1 (Fig. 53), the S1–S3 phenyl picolinamide group projects pseudoaxially from the iminothiadiazinane core, with the fluorophenyl group occupying the S1 pocket. The flap-facing fluoro substituent is accommodated in a region created by positioning of the flap Tyr^{71} toward the prime side allowing the flap to be in a well-defined, rather closed position similar to the MBi-1 cocrystal structure with BACE1. The fluoropyridyl moiety occupies the S3 pocket and extends into $S3^{sp}$. As was observed with the iminohydantoin analog **38**, the amide NH of the inhibitor is within hydrogen bonding

distance of the Gly^{230} carbonyl oxygen. The two aryl rings of the inhibitor are in a trans, near-coplanar configuration with the pyridyl nitrogen *syn* to the amide hydrogen.[100]

Key SAR highlights related to verubecestat are shown in Fig. 54. The 6-desfluoro analog **90** is about fivefold less potent, demonstrating that the fluoro substituent on the S1 phenyl group of verubecestat provides enhancement of affinity similar to that observed for the similarly positioned chloro substituent of **85**. Replacement of the pyridyl group in the diaryl carboxamide by phenyl results in about a 10-fold loss of affinity (e.g., MBi-3 (**91**) vs. **92**), which we attributed to a change in the conformational bias about the pyridyl—carbonyl bond caused by loss of the internal hydrogen bond between the pyridyl nitrogen and the amide NH. The absence of the internal hydrogen bond also has a significant impact on permeability and efflux susceptibility in Caco-2 cells, again underscored by comparison of MBi-3 and **92**, presumably due to the impact of unmasking of the amide hydrogen bond donor on solvation and recognition by Pgp. The combination of these effects had a dramatic impact on the ability of the compounds to lower CNS $A\beta_{40}$ in the rat PD assay, with MBi-3 having a very similar profile as verubecestat but **92** having no effect on $A\beta_{40}$ at a matched dose. It should be noted that with all of the aforementioned modifications, selectivity over CatD remained high; all of the analogs in Fig. 54 had selectivities for BACE1 versus CatD of >7500-fold.[100]

The high selectivity of verubecestat and its analogs for BACE1 over CatD can be ascribed to differences between the S1, S3, and $S3^{sp}$ pockets of the two enzymes. In particular, the S3 and $S3^{sp}$ pockets of CatD are smaller than the corresponding pockets of BACE1. Overlay of a CatD crystal structure with the verubecestat/BACE1 cocrystal structure reveals that the fluoropyridine moiety of verubecestat is too large to occupy the smaller S3 and $S3^{sp}$ pockets of CatD (Fig. 55). Presumably, rotation of the pyridyl group of verubecestat to alleviate these steric clashes within S3 and $S3^{sp}$ of CatD would be disfavored due to the disruption of the preferred near-planar picolinamide conformation of the inhibitor.[100]

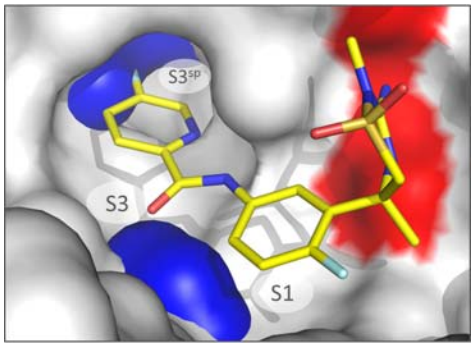

Fig. 55 X-ray cocrystal structure of verubecestat in BACE1 overlayed with CatD X-ray structure with CatD residues Phe[131] in S1, and Ala[13] and Asp[323] in S3/S3[sp] highlighted in *blue*.

In addition to its lack of CatD inhibition, verubecestat was essentially inactive against the human aspartyl proteases CatE and pepsin with K_i values greater than 100 μM and was a weak inhibitor of renin ($K_i = 38$ μM). Not surprisingly, verubecestat was a potent inhibitor of the BACE1 homolog BACE2 ($K_i = 0.38$ nM) which, based on the known biology of BACE2 and the lack of overt issues associated with BACE2 inhibition on chronic dosing, did not preclude development of the compound. Verubecestat had no significant activity when screened against a diverse panel of enzymes, receptors, ion channels, and transporters. Verubecestat is not an inhibitor or inducer of cytochrome P450 isozymes 3A4, 2D6, 2C9, or 2C19 and is not expected to elicit drug-drug interactions in a therapeutic setting. The compound is an inhibitor of the I_{KR} channel encoded by hERG ($IC_{50} = 2.2$ μM); this was shown to be of no consequence in Phase 1 clinical trials at supratherapeutic doses.[100]

8.09.5.3 Verubecestat Synthesis

The discovery synthesis of verubecestat developed by Scott et al. is shown in Fig. 56.[100] The route installed the S1 substituent in the first step through diastereoselective addition to the ketimine and allowed for extensive SAR exploration in S3 since that substituent was introduced in the penultimate step through amide coupling.

The synthesis began with addition of the conjugate base of sulfonamide **93** to ketimine **94** to afford the chiral amino sulfonamide **95** with good diastereoselectivity and moderate yield, establishing the lone stereocenter of verubecestat. Following a two-step deprotection of the sulfinamide and *para*-methoxybenzyl groups under acidic conditions to afford **96**, the iminothiadiazinane

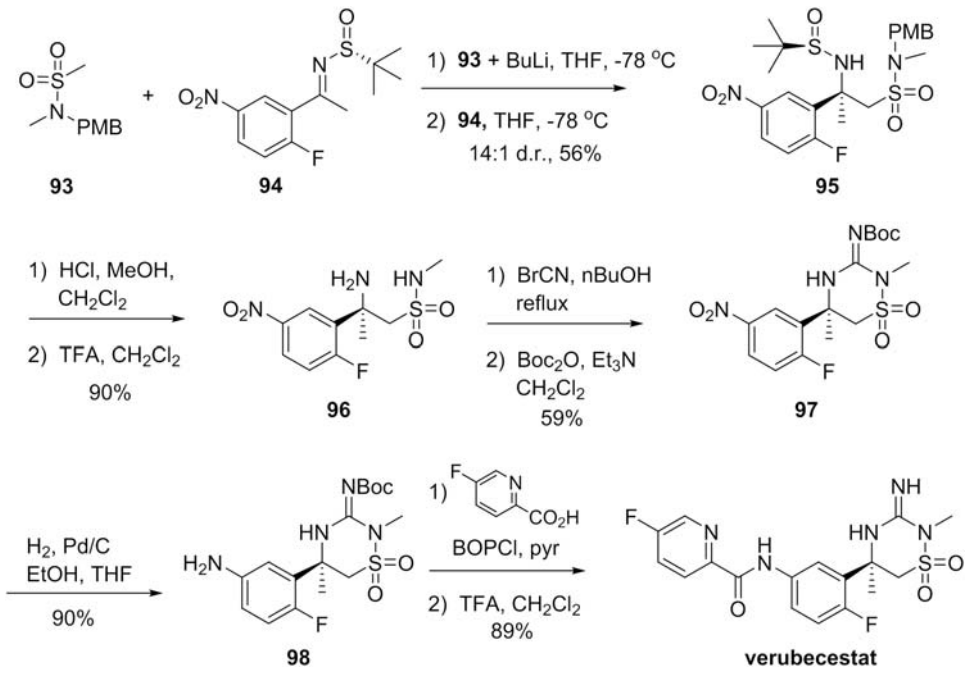

Fig. 56 Discovery synthesis of verubecestat.

dioxide core was formed using cyanogen bromide and the imino group was protected as a *tert*-butyl carbamate to afford **97**. Reduction of the nitrophenyl moiety to the corresponding aniline **98** was followed by amide coupling with 5-fluoropyridine carboxylic acid and removal of the imino protecting group to afford verubecestat which was crystallized as the free base, the physical form selected as the development form.

8.09.5.4 PK/PD Profile of Verubecestat in Preclinical Species

Preclinical PK parameters of verubecestat were determined in rats, dogs, and monkeys. Verubecestat had moderate oral bioavailability of 45% in rats and high bioavailability of $\geq$95% in dogs and monkeys. Across the preclinical species, total clearance was low to moderate and the volume of distribution was moderate to high. This translated to terminal half-lives of verubecestat of 2, 5, and 10 h in rats, monkeys, and dogs, respectively. Allometric scaling of PK parameters from the three preclinical species was consistent with once-per-day dosing in humans. In vitro, verubecestat had high permeability of 28.6×10^{-6} cm s^{-1} in LLC-PK-1 cells and was demonstrated to be a Pgp substrate with an efflux ratio of 11 in the same cell line overexpressing human MDR-1. Human plasma protein binding was relatively low (55%) and was similar to that observed in preclinical species (50-64%). Verubecestat also had low turnover in human hepatocytes, building confidence that a once-per-day dosing regimen would be supported in humans.[100]

The PK/PD profile of verubecestat was determined as described by Kennedy et al. in rats and monkeys.[102] Single oral doses of verubecestat were administered to rats to define the duration and dose dependence of its effects on plasma, CSF, and cortex Aβ_{40} levels. Acute oral administration of verubecestat (10 or 30 mg kg^{-1}) to rats elicited substantial CSF and cortical Aβ_{40} reduction, with peak effects on Aβ_{40} levels occurring 3–6 h after dosing and diminishing rapidly thereafter. The maximal reduction of CSF and cortical Aβ_{40} was delayed relative to the peak total concentrations of verubecestat in plasma, brain, and CSF, which were observed $\leq$1 h after dosing.[92] This lag is likely attributable to multiple factors (e.g., the time required for turnover of preexisting Aβ) and is consistent with previous studies.[49,103]

Oral administration of verubecestat across the dose range of 1–100 mg kg^{-1} to rats caused dose-dependent reductions in plasma, CSF, and cortical Aβ_{40} (**Fig. 57**), and additional doses as low as 0.03 mg kg^{-1} were effective in lowering Aβ_{40} in plasma. Maximal Aβ_{40} reductions of >90% were achieved in all three compartments. The ED_{50} values for reduction of plasma, CSF, and cortical Aβ_{40} were 0.03, 5, and 8 mg kg^{-1}, respectively, corresponding to unbound plasma EC_{50} values of 1, 48, and 78 nM, in the respective compartments. The enhanced potency in the periphery relative to the CSF and brain is consistent with the combined effects of BACE1 being rate limiting for Aβ production in the periphery but not in the CNS, and the Pgp efflux susceptibility of the compound restricting its CNS exposure.[102]

To establish the PK/PD response of verubecestat in nonhuman primates, Kennedy et al. determined a time course of the acute effects of verubecestat on plasma and CSF Aβ_{40} levels in cisterna magna cannulated cynomolgus monkeys via serial sampling over 24 h (**Fig. 58A**).[102] Single oral doses of verubecestat (3 or 10 mg kg^{-1}) reduced CSF Aβ_{40} with peak reductions of 72% and 81%, respectively observed 12 h postdose. The reduction of CSF Aβ_{40} was sustained at near-maximal levels for 24 h. Verubecestat elicited similar effects on CSF sAPPβ levels in this study. Plasma Aβ_{40} levels were inhibited to the limit of detection of the assay at 24 h at both dose levels. Consistent with the PK/PD relationship observed in rats, peak effects on CSF Aβ_{40} levels significantly lagged verubecestat peak plasma and CSF concentrations. The duration of the PD effect in cynomolgus monkeys is also consistent with the sustained plasma and CSF levels over the time course of the experiment; at 24 h unbound plasma and CSF levels were 24 and 14 nM, respectively, for the 3 mg kg^{-1} dose and thus exceeded the in vitro K_i value. The CSF-to-unbound plasma concentration of verubecestat was significantly less than unity at each time point of the serial sampling in accord with the observation that in vitro and in vivo verubecestat is a Pgp substrate.[100,102] In a separate study in cynomolgus monkeys, verubecestat elicited a profound 72% reduction in cortex Aβ_{40} 4 h after an oral dose of 10 mg kg^{-1} (**Fig. 58B**). CSF Aβ_{40} levels were reduced by 60% in this study, an effect similar in magnitude to that seen in the serial CSF sampling studies.[102] The observation that the potency of verubecestat for cortical versus CSF Aβ reduction was minimally shifted in rats and not shifted in monkeys despite the efflux susceptibility of the compound

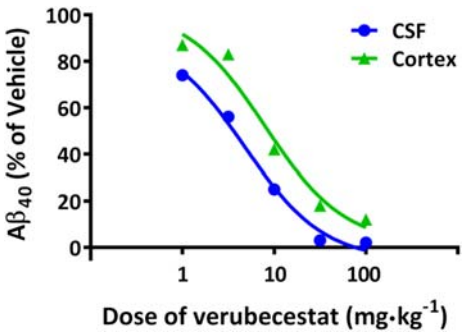

Fig. 57 Acute CSF and cortex Aβ_{40} dose–response study of verubecestat in Sprague–Dawley rats (3 h after 1, 3, 10, 30, or 100 mg kg^{-1} PO administration).

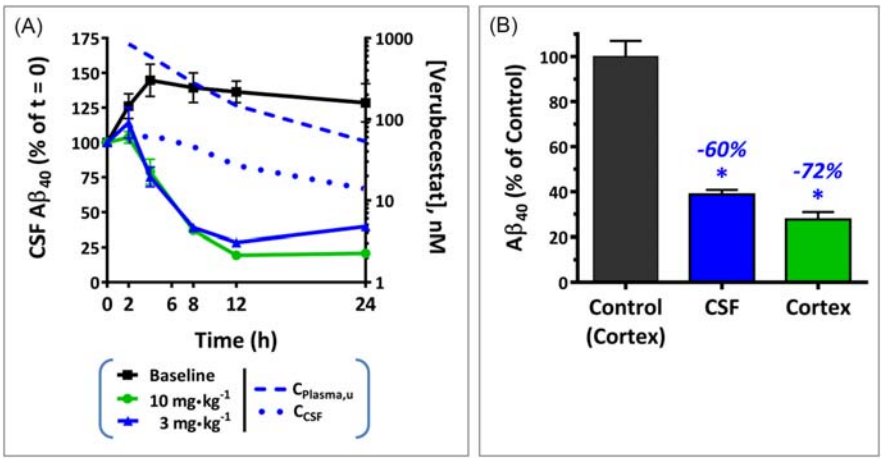

Fig. 58 (A) Time course of CSF $A\beta_{40}$ levels in cynomolgus monkeys orally dosed with 3 and 10 mg kg^{-1} of verubecestat. Unbound plasma and CSF concentrations of verubecestat are indicated for the 3 mg kg^{-1} dose. (B) Acute effect of verubecestat (10 mg kg^{-1} PO) on CSF and cortex $A\beta_{40}$ in cynomolgus monkeys.

was important because it provided added confidence that in the clinic CSF Aβ biomarkers would be a reliable measure of brain Aβ inhibition.

Inhibition of brain and CSF Aβ under conditions of chronic verubecestat administration was also investigated. Once-daily oral doses of verubecestat administered to monkeys at the suprapharmacological doses of 10, 30, and 100 mg kg^{-1} for 9 months afforded substantial (up to >90%) reductions of CSF $A\beta_{40}$, $A\beta_{42}$, and sAPPβ levels and cortex $A\beta_{40}$ and sAPPβ levels, demonstrating that the acute effects of verubecestat on central Aβ biomarkers were maintained after chronic administration. Similar effects were observed in rats under chronic dosing conditions, with profound reductions of cortex $A\beta_{40}$ observed after 3 months of once-daily oral doses of 25, 75, and 200 mg kg^{-1}.[102]

8.09.5.5 Human Dose and PK/PD Projections

Allometric scaling of PK parameters from rats, dogs, and monkeys in conjunction with data from PD studies in cynomolgus monkeys was used to generate human dose projections. The human target steady-state trough plasma concentration was set to the level required to produce 75% lowering of the clinical biomarker CSF $A\beta_{40}$, which projected to a once-daily oral dose of 35 mg. The relatively low QD dose reflected the favorable projected half-life (11 h) and oral bioavailability (75%).[100,102] The physical properties of the crystalline free base form of the compound that was selected for development were highly favorable. Verubecestat has aqueous solubility of 1.6 mM and at the projected human dose of 35 mg was classified as a BCS class 1 substance.[100]

It should be noted that the targeted 75% reduction of CSF $A\beta_{40}$ was not arbitrary, but rather it reflected significant consideration of the magnitude of Aβ lowering that could be both required and practically achieved to affect disease modification in symptomatic or prodromal AD patients. On the lower end of inhibition, chronic administration of **60** to young, preplaque TgCRND8 mice modestly reduced Aβ levels (~30%), yet produced some evidence of cognitive changes (Section "**In Vivo Validation and Development of a High-Throughput Rat PD Assay**").[91] Similarly, experiments that crossed Bace1 KO mice with TgPDAPP mice (Section "**Introduction**") showed that 20% lowering of central Aβ was safe, inhibited plaque deposition, and improved the cognitive phenotype relative to Bace1 homozygous wild-type/TgPDAPP mice.[34–36] The report of the human APP mutation A673T that partially inhibits Aβ production (~40% reduced Aβ) and protects against AD was published early in the verubecestat development program and was timely in that it provided human validation of the benefit of lifelong modest Aβ inhibition against a backdrop of failed amyloid-based clinical trials.[19] We recognized, however, that the modest levels of Aβ inhibition in subjects with this mutation were present from conception and might not reflect the degree of Aβ inhibition required for disease modification through pharmacological intervention in clinical settings of established disease in adults.

Considering the upper end of central Aβ inhibition, as indicated from chronic dosing in rats and monkeys, the preclinical safety profile of verubecestat offered the potential to interrogate a broad dose–response range for Aβ lowering. Practically, the clinical target of 75% CSF Aβ reduction at steady state represented the upper end of the dose–response curve; modeling predicted that disproportional increases in doses would be required to achieve statistically greater levels of Aβ reduction. Therefore, given our desire to balance maximizing the probability of efficacy with the need to guard against any mechanism-based issues that might attend a high degree of chronic BACE1 inhibition in humans, we ultimately focused on 75% inhibition as a robust level of Aβ lowering prior to the initiation of clinical trials, with the intention of also targeting a lower dose that would test a more modest degree of CSF Aβ reduction.[102] The ability to interrogate essentially a full dose–response curve for Aβ inhibition with verubecestat was in stark contrast to the GS inhibitors and anti-Aβ antibodies where dose-limiting side effects in the clinic limited the degree of Aβ lowering that could be tested.

8.09.6 Clinical Evaluation

Design of clinical trials for disease-modifying therapies for AD evolved significantly since iminoheterocycle BACE inhibitors were first disclosed in 2005. In fact, at the end of that same year, the Alzheimer's Association Roundtable hosted a conference with attendees from academia, industry, and the FDA, as well as patients and caregivers, to discuss on how best to clinically assess disease modification.[104] Compounds discussed at that meeting were a GS inhibitor (semagacestat, Eli Lilly),[105] a GS modulator (*R*-flurbuprophen, Myriad),[106] a monoclonal antibody (AB001, a second generation version of AN1792, Elan),[107] and an agent to promote Aβ clearance (Alzemed, Neurochem).[108] At that time, all of the well-characterized BACE1 inhibitors in the literature were of peptidic or peptidomimetic origin and, as discussed in Section "**Hydroxyethylamine-Based Peptidomimetic Inhibitors**," did not have profiles that offered promise for clinical development. Significant focus at that meeting was on the use of CSF Aβ and phosphorylated tau as biomarkers, and on the potential of amyloid imaging with PET tracers to be a more sensitive biomarker than MRI measurements of brain volume for detecting early stages of AD.[104]

To that point, researchers have long believed that earlier intervention could be more beneficial to patients, though the infrastructure to properly diagnose and recruit people with mild cognitive impairment and presymptomatic (prodromal) AD has only recently been in place and is still developing.[109–112] In particular, a longitudinal study reported in 2010 by Avid Radiopharmaceuticals definitively connected amyloid imaging using their tracer AV-45 with postmortem presence of plaque in the brain.[113] This study, in conjunction with an additional longitudinal study and earlier reports,[8,114] led to FDA approval of AV-45 the following year. Also, in 2010, Jack et al. published a hypothetical model of biomarker changes in the context of disease progression, later refined in 2013 (**Fig. 59**).[9] This model codified the perspective that changes in Aβ significantly precede both changes in other biomarkers and functional decline, supported by amyloid imaging using another agent, Pittsburgh compound B.[8]

To build the foundation for long-term verubecestat Phase 3 outcome trials, an extensive series of Phase 1 studies to assess safety, PK, and resulting Aβ PD effect of verubecestat was conducted in healthy volunteers and AD patients. In healthy volunteers, single oral doses up to 550 mg and multiple oral doses up to 250 mg once per day for 14 days elicited dose-dependent reductions of the three BACE1-dependent biomarkers, CSF $A\beta_{40}$, $A\beta_{42}$, and sAPPβ, with >90% maximal reductions achieved at the top doses in both of the studies (**Fig. 60**).[102] The compound was generally well tolerated, and concentrations in both plasma and CSF were increased in a dose-proportional manner. As had been observed preclinically in monkeys, CSF levels of verubecestat were lower than the unbound plasma concentrations, consistent with its susceptibility to Pgp-mediated efflux.

In patients with mild-to-moderate AD, oral doses of 12, 40, and 60 mg once per day for 7 days were also generally well tolerated and once again resulted in dose-dependent reductions of the three biomarkers. Maximal reduction of CSF $A\beta_{40}$ and $A\beta_{42}$ of >80% was observed at both the 40 and 60 mg doses (**Fig. 61**). Importantly, the PD activity of verubecestat was consistent between the healthy volunteers and AD patients, showing that there was no dramatic effect of the presence of disease on safety or on the ability of BACE1 inhibition to lower central Aβ.[102]

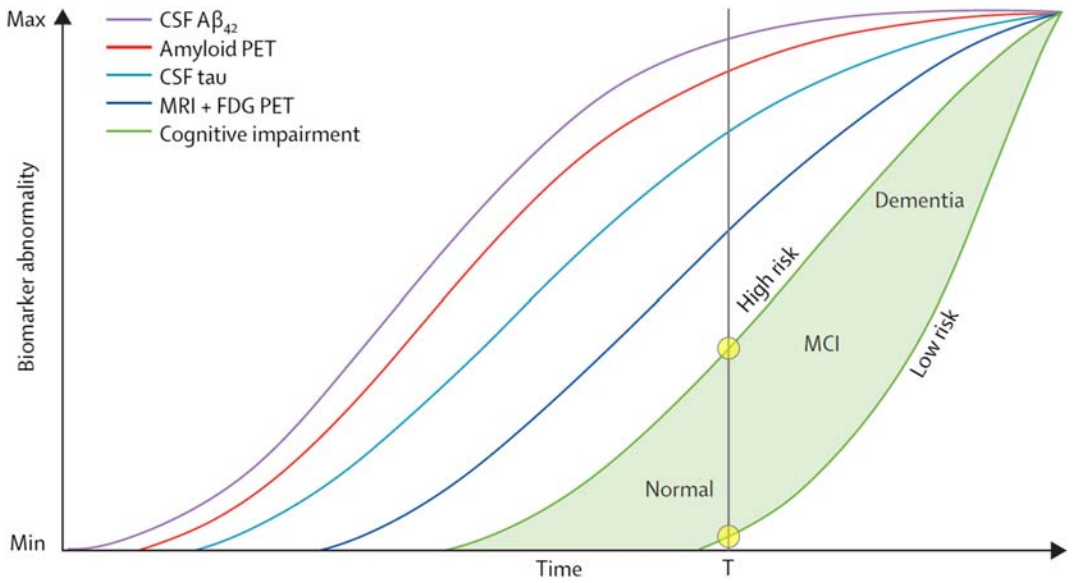

Fig. 59 Hypothetical model developed by Jack et al. of biomarker changes over time in Alzheimer's disease onset and progression.[9] The *y*-axis reflects the severity of the biomarker abnormality. CSF Aβ42 (*purple*) is the earliest biomarker to show abnormalities, followed by amyloid PET imaging (*red*), CSF tau (*light blue*), and finally MRI and fluorodeoxyglucose (FDG) PET imaging (*dark blue*). Actual cognitive impairment is represented as a range (*green*) between those at high risk and at low risk based on genetic factors, comorbidities, or lifestyle. The *vertical gray line* represents the expected degree of biomarker changes and the risk for manifestation of cognitive impairment at a particular point in time.

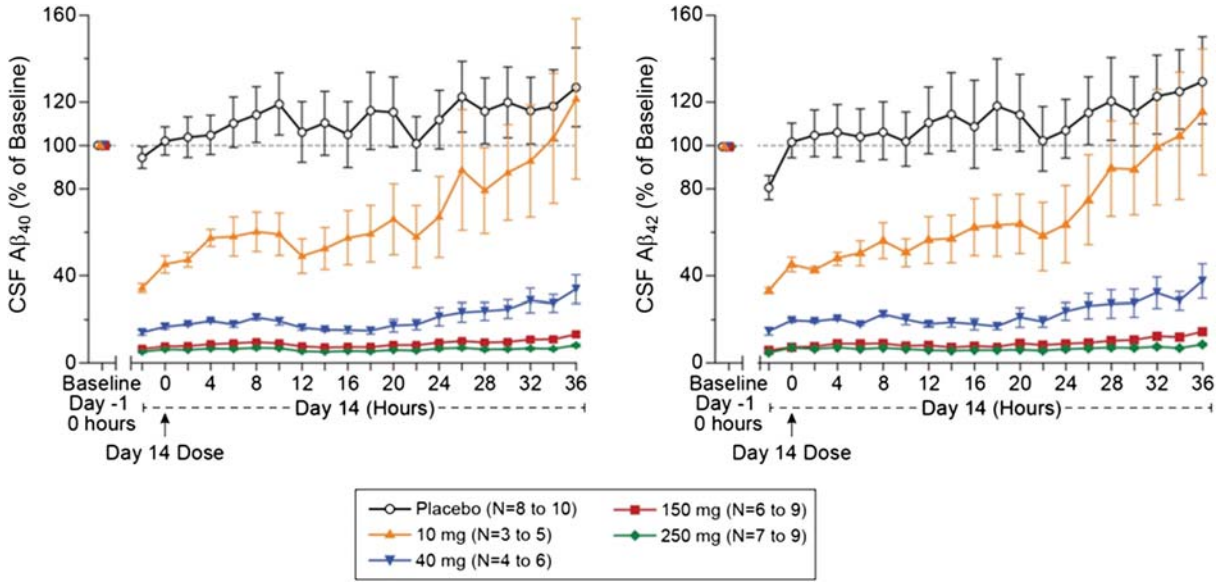

Fig. 60 Dose-dependent reduction of CSF $A\beta_{40}$ and $A\beta_{42}$ in healthy, nonelderly adults following 14 days of once-daily oral doses of 10, 40, or 150 or 250 mg of verubecestat. Day 14 CSF samples were obtained every 2 h from an indwelling lumbar catheter starting 2 h before the last dose. Baseline levels of CSF $A\beta_{40}$ and $A\beta_{42}$ were determined from a sample collected via lumbar puncture prior to the start of verubecestat treatment.

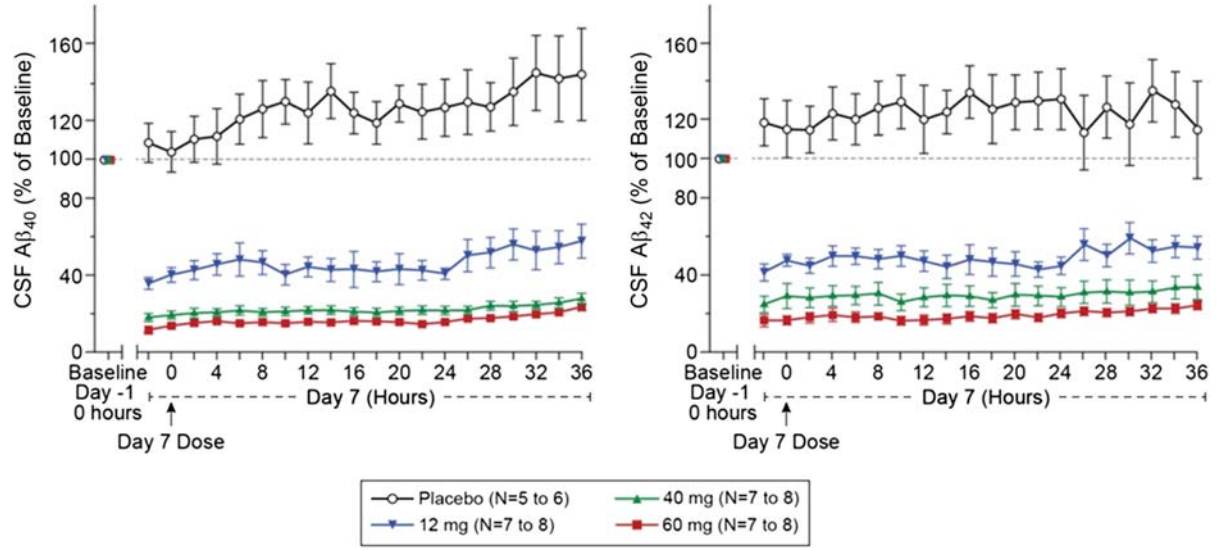

Fig. 61 Dose-dependent reduction of CSF $A\beta_{40}$ and $A\beta_{42}$ in Alzheimer's patients following 7 days of once-daily oral doses of 12, 40, or 60 mg of verubecestat. Day 7 CSF samples were obtained every 2 h from an indwelling lumbar catheter starting 2 h before the last dose. Baseline levels of CSF $A\beta_{40}$ and $A\beta_{42}$ were determined from a sample collected via lumbar puncture prior to the start of verubecestat treatment.

Verubecestat was advanced into two Phase 3 trials, the first BACE inhibitor to reach this milestone, and each study is enrolling patients at a different stage of the disease. One of the trials, designated EPOCH (NCT01739348),[115] is investigating verubecestat in mild-to-moderate AD. The second trial, known as APECS (NCT01953601),[116] is investigating verubecestat in earlier stage prodromal AD patients. As part of its adaptive design, the EPOCH trial included an initial Phase 2 arm in which a cohort of 400 patients was evaluated for 3 months to test the safety of verubecestat and enable initiation of the longer term Phase 3 trials. The doses for this cohort—12, 40, and 60 mg—mirrored those used in the Phase 1 study in AD patients described above. Ultimately, the 12 and 40 mg doses were selected for continuation into the two Phase 3 trials supported by modeling of the extensive Phase 1 data set, which projected that 95% of the patients receiving the 12 mg dose would have CSF $A\beta_{40}$ reductions in the 50–75% range and that 95% of those on the 40 mg dose would have 80–90% CSF $A\beta_{40}$ lowering. Importantly, these two patient populations would be largely nonoverlapping, with one testing partial and the other testing near full inhibition.[102]

The EPOCH trial is a randomized, placebo controlled, double-blind efficacy, and safety trial of verubecestat in approximately 1960 subjects with mild-to-moderate AD. The duration of the trial is 18 months with cognitive and functional primary outcome measures. Cognitive function will be assessed as change from baseline in the Alzheimer's Disease Assessment Scale Cognitive Subscale score,[117] while functional outcome will be measured via the Alzheimer's Disease Cooperative Study—Activities of Daily Living score.[118] Secondary outcome measures include additional functional and cognitive assessments [change from baseline scores in Clinical Dementia Rating Scale-Sum of Boxes (CDR-SB),[119] Mini Mental State Examination,[120] and Neuropsychiatric Inventory[121]] and biomarker changes comprising changes in brain amyloid load, CSF total tau, and hippocampal volume. EPOCH was fully enrolled by late 2015, and primary trial completion is scheduled for Jul. 2017 with a 4-year extension phase.

The APECS trial is a Phase 3, randomized, placebo-controlled, double-blind clinical trial to study the efficacy and safety of verubecestat in approximately 1500 subjects with prodromal AD. An inclusion criterion for the trial is a positive amyloid imaging PET scan using [^{18}F]flutemetamol tracer or positive CSF tau/Aβ42 ratio. This trial is 24 months in duration with the primary efficacy outcome measure of change from baseline in the CDR-SB score. As with the EPOCH trial, secondary outcome measures include additional cognitive and functional assessments, and changes from baseline in total hippocampal volume and CSF total tau. The estimated primary completion date of the APECS trial is Jul. 2019.

With no disease-modifying therapy of any mechanism yet approved by the FDA or other health agencies, the regulatory landscape continues to evolve even as clinical trials of verubecestat and other agents are in progress. In 2013, the FDA issued guidance that improved cognition and daily function would be required for regulatory approval of disease modification for early-stage disease.[122] Interestingly, Eli Lilly recently announced that, in an ongoing Phase 3 trial in mild AD patients with the anti-Aβ monoclonal antibody solanezumab, measures of cognition will be the sole primary endpoint, with functional changes specified as secondary endpoints.[123] The reason for this change was not clear, but has a logical basis since function is largely intact and changes slowly in the early stages of the disease. Thus drug effects on function may be difficult to detect. Despite FDA guidance to the contrary, this change may also reflect a gambit that it will be difficult to deny approval to a compound that shows significant improvements in cognition even in the absence of significant effects on functional outcome. If successful, this precedent could have broad implications for the development of disease-modifying agents in the AD field.

8.09.7 Conclusions

The discovery of verubecestat was the pinnacle of our BACE inhibitor discovery program, and it was achieved through the confluence of many factors. Key among these were access to novel starting chemical matter from the use of emerging screening technologies, early adoption of structure-based drug design, a strategy focused on optimization of drug-like properties beneficial for CNS penetration, placement of a high-throughput in vivo assay high in the research funnel, and, more generally, close collaboration between the many functions that drive drug discovery. An important facet of our medicinal chemistry strategy was repeated innovation around the aspartyl protease binding motif as well as around exploration of the adjacent binding sites, coupled with a willingness to walk away from potency in favor of overall properties of the molecules. The 12-year pathway from the start of the program to initiation of Phase 3 featured many avenues of exploration, some more fruitful than others, as well as a number of unexpected discoveries. In this article, we have attempted to capture a number of these aspects of our efforts and especially our decision making at key points. Taken together, they highlight the importance of risk-taking and perseverance in prosecution of the most challenging of drug targets.

Verubecestat entered Phase 3 in 2013, the first BACE inhibitor to achieve this milestone, and is one of only two compounds that have advanced to this stage in the clinic. In 2016 Eli Lilly and AstraZeneca announced the progression of the inhibitor LY3314814/AZD3293, which was discovered at AstraZeneca (**99**, Fig. 62), representing the second Phase 3 entrant.[124,125] In retrospect, beyond these two molecules, it is striking that all of the disclosed structures of BACE inhibitors that have entered the clinic or have demonstrated robust preclinical Aβ lowering in large animal species contain iminoheterocycle-based aspartyl protease binding motifs (additional representative examples **100–105** are shown in Fig. 62). In addition to the shared amidine moiety that makes the key interactions with the catalytic dyad, these structures all possess an aryl group that occupies the S1 subsite. To that end, while all of these structures have additional substituents that occupy either the S3 subsite, the S2′ subsite, or both, benzyl amidine **106** is a representation of a common structural element contained in all of the depicted compounds.

The privileged nature of substructure **106** embodied in inhibitors, first disclosed by Schering-Plough, Wyeth, and AstraZeneca/Astex in 2005–2006, is reflected in the patent analysis in Fig. 63.[132,133] A search on this key structural element shows that beginning in 2009, several years after those initial disclosures, there were an increasingly large number of research groups employing this structural element. At the peak from 2011 through 2014, there were 20–40 applications per year claiming BACE1 inhibitors containing this structural motif. It is a remarkable coalescence around a single structural element, and reflects the complexity and difficulty in obtaining high-quality chemical matter for this target. Ultimately, our efforts and those of everyone in the field are directed to improving the lives of patients. Verubecestat and iminoheterocycle BACE inhibitors in general represent a breakthrough in the ability to target BACE1, definitively test the amyloid hypothesis, and, most importantly, offer patients hope for development of a disease-modifying therapy for AD.

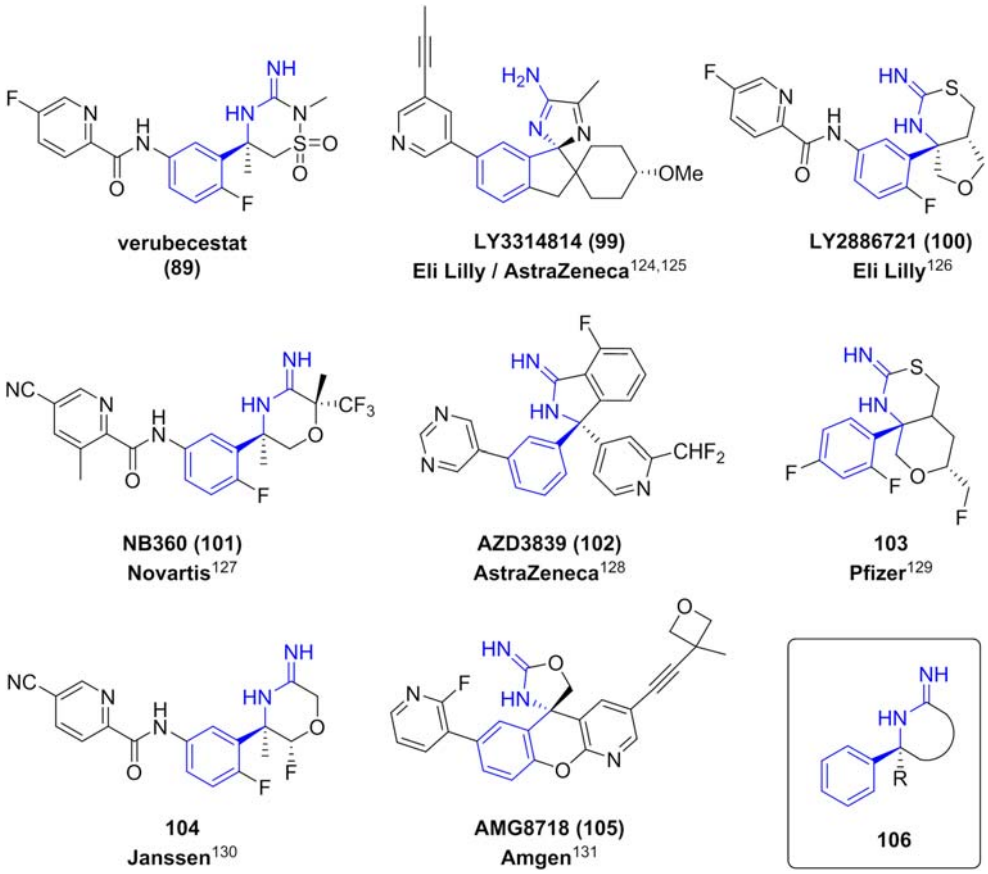

Fig. 62 Structures of the two BACE inhibitors that have progressed to Phase 3 clinical trials, verubecestat and LY3314814 (**99**), as well as a representative selection of structurally diverse compounds **100**–**105**[126–131] from other companies that have entered clinical or advanced preclinical development. The common structural element **106** is present in all of these compounds and is highlighted in *blue* within each structure.

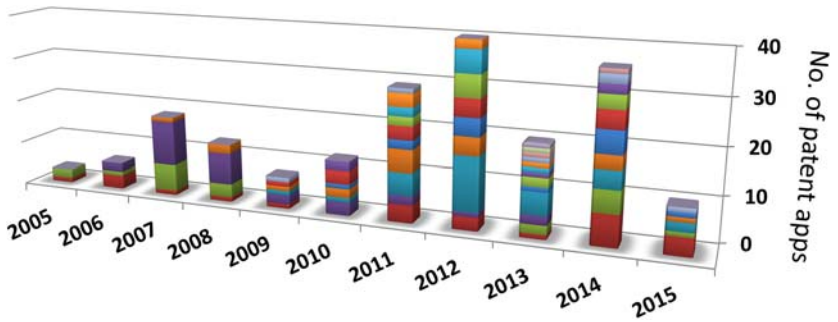

Fig. 63 Number of patent applications that claim BACE inhibitors containing key structural element **106** beginning from first disclosure of the iminoheterocycle binding motif in 2005 through 2015. In each year, the columns are colored by research group.

SERAPHIN Study with an endothelin receptor antagonist in pulmonary arterial hypertension

8.10.1 Introduction

The present case study summarizes key aspects of the drug discovery program that led to the discovery of macitentan (Opsumit®, ACT-064992, Fig. 1), a potent, orally active dual endothelin receptor antagonist (ERA) that is an approved long-term treatment for patients with pulmonary arterial hypertension (PAH). Starting from the structure of known ERAs, we focused on optimizing three key properties: in vitro potency on both endothelin (ET) receptors, in vivo efficacy in hypertensive Dahl salt-sensitive (Dahl-S) rats, and in vivo liver safety in a rat model of bile salt transport interference. The results and processes outlined later illustrate how our approach may be successfully applied to other drug discovery programs.

8.10.1.1 Biology and Pharmacology of the ET System

Discovered in 1988, endothelin-1 (ET-1) is a 21-amino acid peptide produced by endothelial and other cells, which is considered one of the most potent vasoconstrictors known. ET-1 release by endothelial cells is polarized toward the tissue, where it acts in a paracrine/autocrine fashion on neighboring cells. In addition to causing vasoconstriction, ET-1 stimulates cell proliferation, fibrosis and inflammation, smooth muscle and cardiomyocyte hyperplasia and hypertrophy, extracellular matrix deposition, and aldosterone and catecholamine production.[1–3]

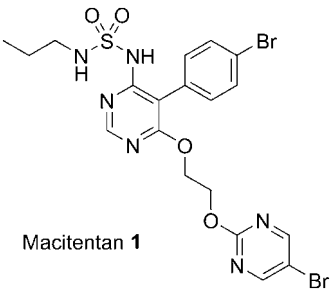
ET-1 binds to two homologous G protein-coupled receptors, ET_A and ET_B. Both receptor subtypes activate Gq protein-mediated signaling pathways causing phospholipase Cβ activation and protein kinase C activation, which lead to increases in cytosolic calcium levels. In vascular smooth muscle cells the activation of ET receptors followed by increases in cytosolic calcium promotes cytoskeletal contraction and cellular proliferation as seen in pulmonary arteries of patients suffering from PAH, a devastating disease characterized by increased pulmonary endothelial ET-1 release.[4–6]

Under physiological conditions, ET_A receptors predominate on vascular smooth muscle cells and mediate vasoconstriction, whereas endothelial ET_B receptors may mediate vasodilation, through nitric oxide release, and hemodilution.[7,8] In various cardiovascular diseases, we and others have observed that endothelial ET_B-mediated vasodilation is lost, while ET_B receptors are upregulated in the smooth muscle cell layers of blood vessels and contribute to vasoconstriction.[9,10] Therefore, in pathology both ET_A and ET_B receptors mediate the detrimental effects of ET-1, be it vasoconstriction or cell proliferation and inflammation.[2,9,11,12]

These observations suggest that dual ET receptor antagonism might provide superior efficacy and safety compared to ET_A-selective receptor antagonism. Indeed, in animal models of pulmonary hypertension and models of chronic heart failure, dual receptor antagonism was necessary to significantly increase survival.[1,13,14] Safety might also be improved with dual ERAs, as chronic stimulation of unantagonized ET_B receptors could explain some secondary effects of ET_A-selective antagonists, such as increased cell proliferation[15] and exaggerated fluid retention.[16,17] Clinical trials have showed increased clinical worsening in idiopathic pulmonary fibrosis in patients treated with an ET_A-selective antagonist but not with dual ERAs.[18–20]

As mentioned earlier, the key role of ET-1 in the pathophysiology of PAH was suggested by extensive preclinical research, and dual ET receptor blockade was first validated as a therapeutic strategy by the positive clinical trials of bosentan **2** in PAH patients (Fig. 7).[13] Since then, other ERAs have been approved for this indication: sitaxentan **26** (Fig. 6, IC_{50} ET_A 1.4 nM, ET_B 9.8 μM, voluntarily withdrawn in 2010 based on the observation of a risk of potentially life-threatening idiosyncratic liver injury),[21,22] ambrisentan **19** (Fig. 5, K_i ET_A 1 nM, ET_B 195 nM),[23] and macitentan **1** (Fig. 1). PAH and the major etiologies of PAH are associated with elevated ET-1 synthesis or elevated plasma ET-1 concentrations.[1,24] In idiopathic or secondary PAH, increased ET-1 immunostaining was seen in the plexiform lesions and the endothelial cells of pulmonary arteries characterized by medial thickening.[4] ET receptors, ET_B receptors in particular, were upregulated in the interstitium and the media of pulmonary arteries in different forms of pulmonary hypertension.[25,26] Overexpression of ET-1 was also observed in the right ventricle of rats with pulmonary hypertension, suggesting a local effect of endogenous ET-1 on cardiac remodeling.[27]

Therefore, contribution of both ET_A and ET_B receptors to the remodeling effects of ET-1 (including inflammation, proliferation, hypertrophy, fibrosis) combined with the wide tissue distribution of the ET system, its upregulation in pathological situations, and its local autocrine/paracrine activity, make the tissue ET system an important factor in promoting pulmonary vascular structural damage and cardiac hypertrophy. These key features of the ET system were the basis for compound profiling as we wanted a compound exhibiting a better efficacy and safety profile compared to existing ERAs.



Macitentan **1**

8.10.1.2 Project Goals

The ERA program was the first drug discovery project initiated at Actelion Pharmaceuticals Ltd after its foundation in December 1997. The goal of this project was to discover and develop a more potent and efficacious ERA that would not be limited by the safety signals observed with bosentan. With receptor binding IC_{50} values of 45 and 202 nM at ET_A and ET_B, respectively, bosentan **2** markedly reduced the arterial blood pressure in animal models of hypertension. In Phase II and Phase III clinical trials, bosentan was best dosed at 125 mg twice daily. At this dose, however, about 11% of patients treated with bosentan **2** showed a transient, dose-dependent increase in serum liver aminotransferase levels of >3 times the upper limit of normal.[28–30] In view of these data, we aimed at identifying a novel dual ERA for the treatment of patients with PAH that was more potent and more efficacious than bosentan **2**, could be administered to patients once daily, and had no liver liability.

8.10.1.3 Compound Profiling and Selection Cascade

The assays that served to specifically assess the key properties of potency, in vivo efficacy, and liver safety formed the cornerstones of our compound profiling cascade (Table 1). In vitro assessment of ET_A and ET_B blockade was performed by measuring the inhibition of binding of ^{125}I-labeled ET-1 to membranes of Chinese hamster ovary (CHO) cells expressing the human recombinant ET_A or ET_B receptor.[32,33] As mentioned earlier, bosentan showed IC_{50} values of 45 and 202 nM at ET_A and ET_B, respectively. The potency on ET_A and ET_B was further assessed in an ex vivo functional inhibition assay using isolated aorta and trachea rings, respectively.[34] In these tests, bosentan showed pA_2 values of 6.78 and 6.47. As animal and human data suggested that optimal efficacy on blood pressure reduction and safety with respect to edema formation is obtained with dual ERAs[1,2,9,11–14,16,17] we prioritized compounds with the ability to block both ET_A and ET_B receptors.

Beyond this classical in vitro assessment, compounds more potent than bosentan were tested in vivo in hypertensive rats to assess the efficacy profile of the new chemical structures. We selected the Dahl-S rat model, which is a model of systemic hypertension associated with increased vascular ET production and hence a good responder to ET receptor blockade.[35,36] Selected compounds were administered orally at a dose of 3 mg kg^{-1} to hypertensive Dahl-S rats, and arterial blood pressure and heart rate (HR) were recorded using a telemetry device implanted in the animal. The area between curves (ABC) calculated between the period before and after the treatment served as efficacy measure and was compared to that of bosentan.

In this model, both ET receptors contribute to the maintenance of elevated blood pressure, with a predominant role of ET_A receptors. To confirm ET_B receptor blockade in vivo, we also tested the effect of selected compounds on plasma levels of ET-1, which is a biomarker for ET_B receptor engagement as these receptors, within the pulmonary circulation, mediate clearance of ET-1.[31,37,38]

In parallel, compounds with an in vivo efficacy superior to that of bosentan were also tested in vivo in a model relevant for hepatic safety. Mechanistic studies by Fattinger et al.[39] suggested that the hepatotoxicity observed in patients treated with bosentan is mediated by its ability to inhibit the hepatic bile salt excretion pump (BSEP) leading to intrahepatic cholestasis, and proposed increases in plasma bile salt concentrations as a marker for in vivo hepatic BSEP inhibition. Therefore we screened in vivo in rats for compounds that did not increase plasma bile salts, as a surrogate for hepatotoxicity.

Thus the pharmacological characterization of the compounds was designed to encompass the desired properties of a new ERA: dual blockade of ET receptors, high efficacy, and improved liver safety in vivo.

8.10.1.4 Identifying Starting Points for Our Discovery Program

In view of the large number of known ERAs,[40–46] we decided to start our drug discovery program from a selection of published ERAs rather than to search for novel scaffolds with a high-throughput screening campaign. We therefore tried to categorize the various

Table 1 Key experiments of the compound profiling and selection cascade

ERAs according to their structures and analyze the existing data on potency and efficacy as a preparation for the selection of viable starting points. Our analysis of the known ERAs is briefly sketched in the following paragraphs.

8.10.1.5 Competition, Structures of Known ERAs

Based on the importance and the ubiquity of the ET system in the body,[47] ERAs were expected to be effective treatment options for a large variety of cardiovascular diseases, such as hypertension,[48–50] heart failure,[51] renal failure,[52,53] myocardial infarction, subarachnoid hemorrhage, and cerebral vasospasm as well as proliferative diseases such as fibrosis[25] and cancer.[54] These attractive opportunities triggered a vast number of activities throughout the pharmaceutical industry and academia to identify small molecule ERAs with diverse selectivity profiles. The majority of industrial programs focused on the discovery of either ET_A-selective or dual ET_A/ET_B receptor antagonists, and only a limited number of publications disclose ET_B-selective compounds.[40–46]

In the following paragraphs, some of the most prominent approaches leading to ERAs are summarized to reveal the basis of our own efforts that culminated in the discovery of macitentan. While a few of the early projects involved peptidomimetic approaches, the majority of discovery programs focused on identifying small molecule ERAs.

8.10.1.5.1 Peptidomimetic ERAs

Fig. 2 summarizes the peptide-based ERAs. All of these molecules were studied in vivo following parenteral administration. From the early efforts to optimize cyclic peptides that were isolated from *Streptomyces misakiensis* that inhibited the ET receptors, two prominent analogs, BQ-123 **3**[55] and BQ-788 **4**[56] emerged (Fig. 2). While the cyclic peptide **3** is a highly potent and selective antagonist of the ET_A receptor, the linear tripeptide **4** specifically blocks the ET_B receptor. Over the years, both molecules have been used in a number of pharmacological studies in animals and humans.[57–69]On the other hand, the cyclic peptide TAK-044 **6** represents a dual ERA that has also been studied in humans as a potential i.v. drug in indications such as hypertension, myocardial infarction, and acute renal failure.[70–73] The peptidomimetic IRL3630 **5** was discovered by elaborating a rational approach that identified key amino acids of the natural ligand ET-1 responsible for its high receptor affinity. Studies in guinea pigs showed that bolus injections of **5** were able to suppress the respiratory resistance changes induced by ET-1.[74–77]

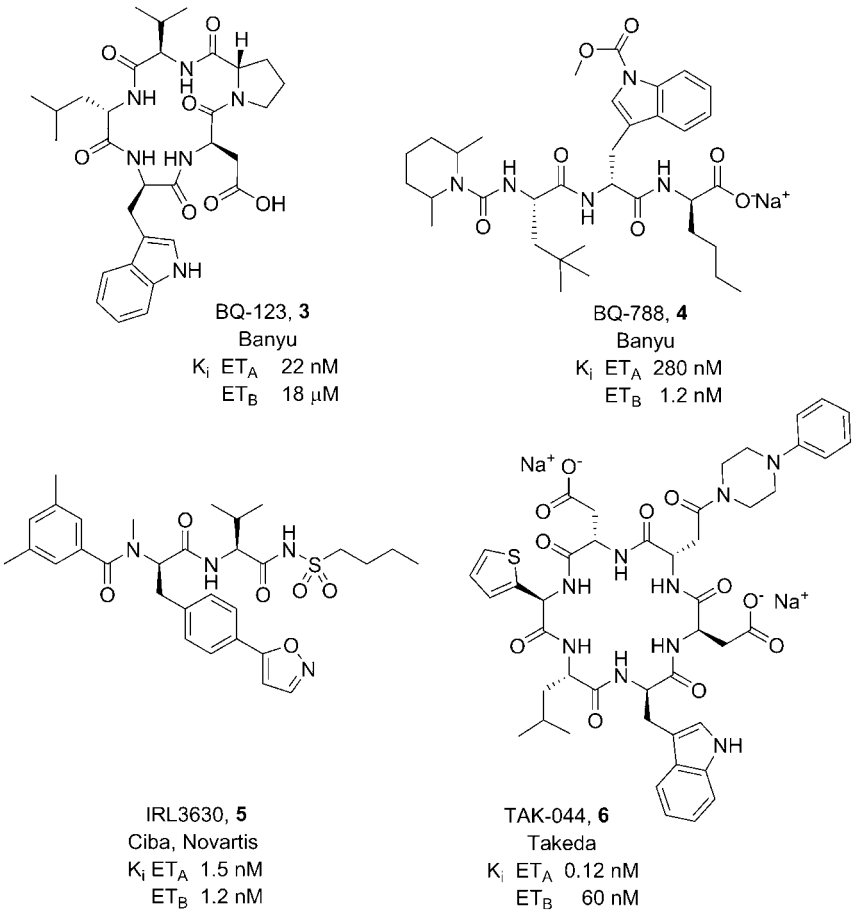

Fig. 2 Structure of peptidic and peptidomimetic ERAs.

8.10.1.5.2 Small molecule ERAs

A quick inspection of the structures of the known small molecule ERAs suggests that an acidic function is mandatory to obtain high affinity. In addition, a general structure of ERAs can be drawn as depicted in Fig. 3.[42] Depending on the nature of the acidic function and the core, this generalized scheme allows the small molecule ERAs to be subdivided into three classes. In the first class of compounds, a carboxylic acid is attached to a 5 to 10 membered heterocyclyl or heteroaryl template, which is further substituted with two aromatic rings and an optional substituent (eg, enrasentan **7**, atrasentan **9**, fadosentan **17**). In the second class of ERAs the carboxylic acid is attached to an alkoxy chain that bears aromatic substituents (eg, ambrisentan **19**). A third class of ERAs is characterized by an acidic aryl sulfonamide bound to a more linear core structure such as an acetic acid or a biphenyl moiety (eg, sitaxentan **26**). Finally, a fourth class of ERAs consists of acidic aryl sulfonamides that are attached to a pyrimidine bearing up to three additional substituents (eg, bosentan **2**).

8.10.1.5.2.1 Carboxylic acids bound to a cyclic core

Examples of the first class of ERAs are shown in Fig. 4. It is interesting to note that although the structures in Fig. 4 are closely related, they were discovered by several independent approaches.

Scientists at SmithKline Beecham worked on the indane carboxylic acids such as enrasentan **7**.[41,78,79] Enrasentan showed IC_{50} values of 1 and 111 nM on ET_A and ET_B, respectively, and was studied in Phase II clinical trials in patients with chronic heart failure (ENCOR study) and in patients with left ventricular systolic dysfunction.[80,81] A close analog of enrasentan, the di-acid **8**, showed a similar potency profile and was particularly suitable for i.v. administration.[82–84]

Abbott's design of ERAs was based on replacing the indane moiety of enrasentan by a pyrrolidine.[85,86] This allowed for a much easier structure–activity relationship (SAR) investigation of the space opposite to the carboxylic acid. Hence, exploring the substituent attached to the pyrrolidine nitrogen led to the identification of the ET_A-selective atrasentan **9** (IC_{50} ET_A 0.31 nM, IC_{50} ET_B 191 nM)[85,86] as well as a number of highly ET_B-selective antagonists such as **10**.[87,88] Atrasentan **9** was well tolerated in healthy subjects and Phase II and III clinical studies focused on its use in diabetes and chronic kidney disease[53,89] as well as prostate cancer.[90,91]

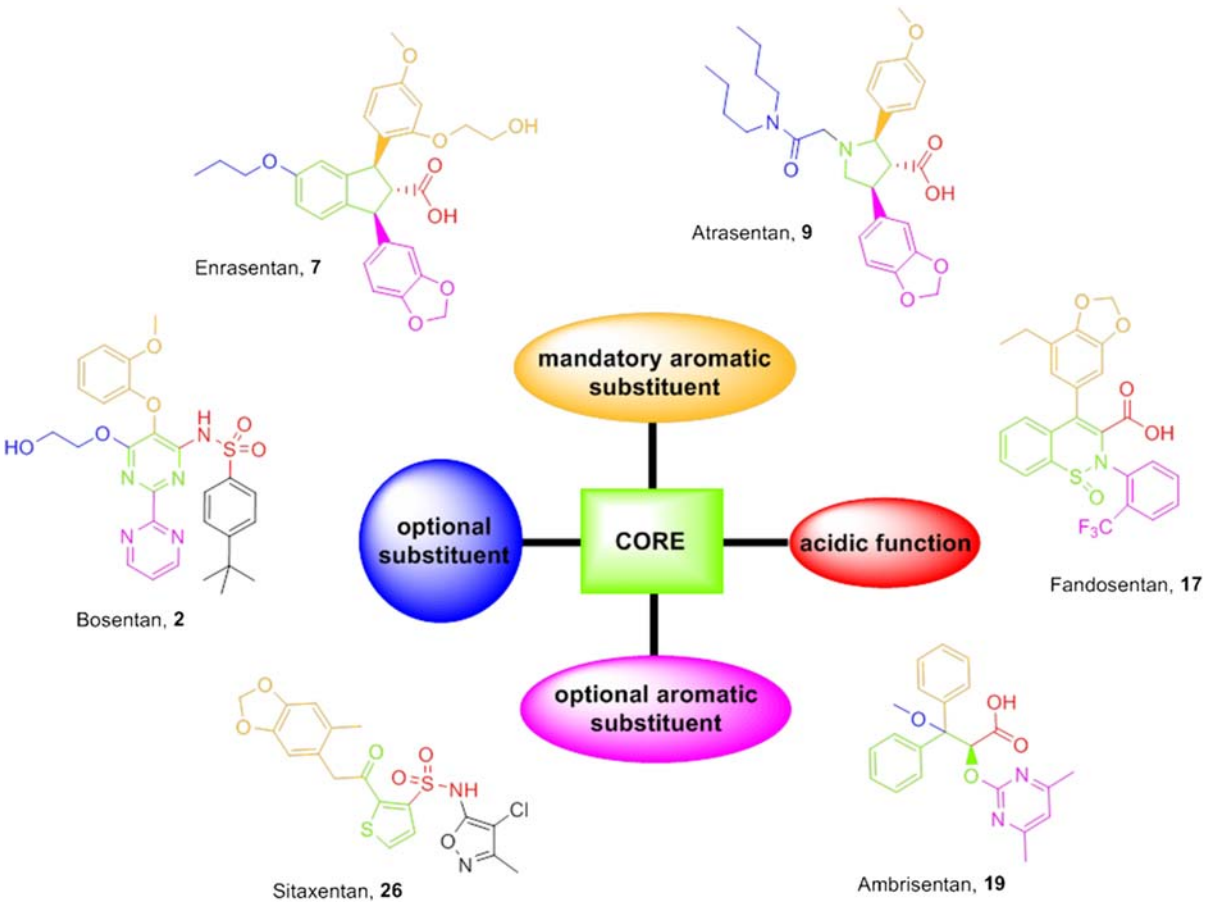

Fig. 3 General structure of endothelin receptor antagonists and a few structures of ERAs for illustration. For a superposition of the structure of ambrisentan **19** with the scaffold of enrasentan **7** see Riechers et al.[23]

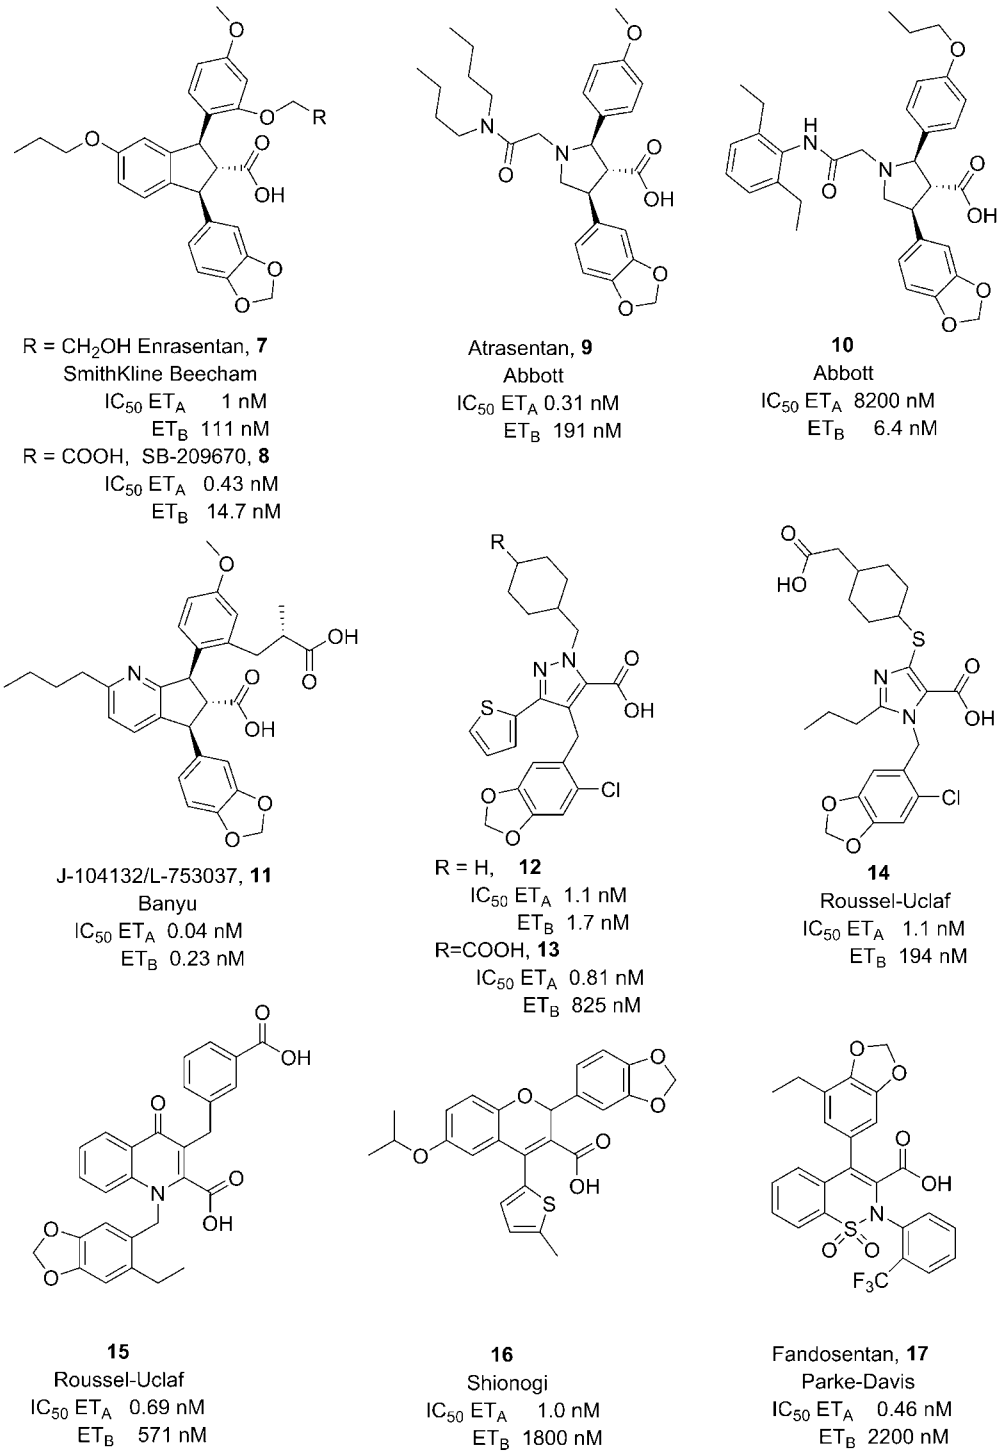

Fig. 4 Structures of ERAs containing a carboxylic acid attached to an aliphatic or aromatic ring.

Efforts by a research team at Banyu Pharmaceuticals were aimed at reducing the lipophilicity of enrasentan. Introduction of a nitrogen to the indane scaffold furnished highly potent ERAs such as J-104132/L-753037 **11**.[92] Interestingly, in contrast to the related di-acid **8**, this compound was well suited for oral dosing.[93] As part of a collaboration with Merck & Co., the cyclopentanopyridine **11** was studied in patients with congestive heart failure.[94]

Researchers at Hoechst Marion Roussel discovered highly potent ET_A-selective (eg, **13**) and dual ERAs (eg, **12**) by optimizing a series of pyrazol-5-ols that were identified by screening their in-house compound library for ET receptor binding.[95,96] Further

investigations led to imidazole-5-carboxylic acid derivatives such as **14**, which showed efficacy in blocking the ET-1 induced pressor response in the rat.[97] In the same high-throughput screening, a series of 6-substituted quinolones was found to be active on ET_A and ET_B. Superposition of these quinolones with **8** led to the design of compounds such as **15**, a potent and orally active selective ET_A receptor antagonist.[98]

Based on the observation that angiotensin II receptor blockers and ERAs share structural features, scientists at Shionogi modified their chromene-based angiotensin II receptor antagonists to yield highly potent orally available ET_A-selective ERAs such as **16**.[99]

The benzothiazine-3-carboxylic acid fandosentan **17**, discovered by Parke-Davis, represents one of the last examples of ERAs consisting of a carboxylic acid attached to a hetero-aromatic core structure. Fandosentan was characterized as a potent ET_A receptor-selective antagonist with good oral bioavailability in rat and dog and promising pharmacological effects in hypoxia induced pulmonary hypertension in the lamb.[100] However, no clinical data have been reported.

8.10.1.5.2.2 Carboxylic acids attached to an acyclic core

Representatives of the second class of small molecule ERA are shown in **Fig. 5**. Important contributions by BASF/Knoll started from a high-throughput screening hit originally designed as an herbicide and resulted in the discovery of the diphenylpropionic acid derivatives darusentan **18** and ambrisentan **19**.[23] While darusentan did not meet the primary endpoints in Phase III clinical trials for the treatment of patients with resistant systolic hypertension, and was discontinued for the treatment of hypertension, myocardial infarction, and congestive heart failure,[101–105] ambrisentan **19** is an approved treatment for PAH (marketed in the United States by Gilead as Letairis® and in Europe by GlaxoSmithKline as Volibris®).[106]

Rhône-Poulenc Rorer's phenoxyphenylacetic acid derivative **20** was discovered by optimizing two lead structures identified in-house. Although this potent and orally active compound was selected as a development candidate, no clinical data are available.[107]

8.10.1.5.2.3 Arylsulfonamides bound to a biphenyl or acetic acid core

The selection of compounds compiled in **Fig. 6** illustrates the third class of small molecule ERAs wherein an aryl sulfonamide is attached to either a biphenyl or an acetic acid core. Several of these aryl sulfonamides are based on benzene sulfonamide **21**, which was identified as a 69 μM screening hit at Bristol-Myers Squibb. First SAR studies led to the identification of the orally active dansyl sulfonamide **22**, which showed an ET_A-binding IC_{50} value of 150 nM.[108] Replacing the central naphthaline by a biphenyl moiety followed by further optimization culminated in the discovery of the two highly potent and selective ET_A receptor antagonists BMS193884 **23** and edonentan **24**,[109,110] which were both studied in Phase II clinical trials with congestive heart failure patients.[111]

Zeneca's approach to optimize the dansyl sulfonamide **22** ultimately furnished zibotentan (ZD-4054) **25**,[112,113] an ET_A-selective antagonist that was primarily investigated for the treatment of prostate cancer.[114–117]

Medicinal chemists at Immuno Pharmaceuticals, a subsidiary of Texas Biotechnology Corporation, based their discovery program on replacing the benzene sulfonamide in **7** by a thiophene sulfonamide.[118] Extensive preclinical studies eventually led to selecting sitaxentan (TBC 11251) **26** for clinical development in heart failure and pulmonary hypertension.[21,119,120] The compound is a highly ET_A-selective antagonist with IC_{50} values of 1.4 nM and 9.8 μM at ET_A and ET_B, respectively, exhibited excellent bioavailability of 60–100% in rats and dogs and prevented acute hypoxia-induced pulmonary hypertension in rats at 15 mg kg^{-1} p.o. dosing. Sitaxentan was marketed as Thelin®, but was voluntarily withdrawn in 2010 based on the observation of a potentially life-threatening risk of idiosyncratic liver injury.[22] Meanwhile, drug discovery efforts continued and TBC3711 **27** was selected for clinical development on the basis of its high potency and ET_A selectivity, and its carefully optimized pharmacokinetics (PK) properties. TBC3711 **27** is among the most selective ET_A receptor antagonists tested in humans, was well tolerated, and showed an oral bioavailability of $>80\%$ and a half-life of 6–7 h in healthy volunteers.[121]

Detailed SAR studies aimed at improving the weak affinity that α-phenoxyphenylacetic acid-based angiotensin II receptor antagonists showed for the ET receptors led to the discovery of L-754142 **28**. This most prominent representative, wherein an arylsulfonamide is bound to an acetic acid core antagonized both ET receptors with high potency, and in the rat inhibited the big-ET-1

induced pressor response with an ED_{50} of 0.56 mg kg^{-1} p.o. and a long duration of action.[122,123] Compounds related to **28** have been reported by Merck KGaA (**29**),[124] Pfizer (**30**),[125] and Shionogi (PABSA, **31**).[126]

8.10.1.5.2.4 Arylsulfonamides bound to a pyrimidine core

A few examples of ERAs incorporating an aryl sulfonamide attached to a pyrimidine core are compiled in **Fig. 7**. Researchers at Roche discovered that compound **32**, prepared in the context of an antidiabetic program, inhibited ET receptors in vitro and

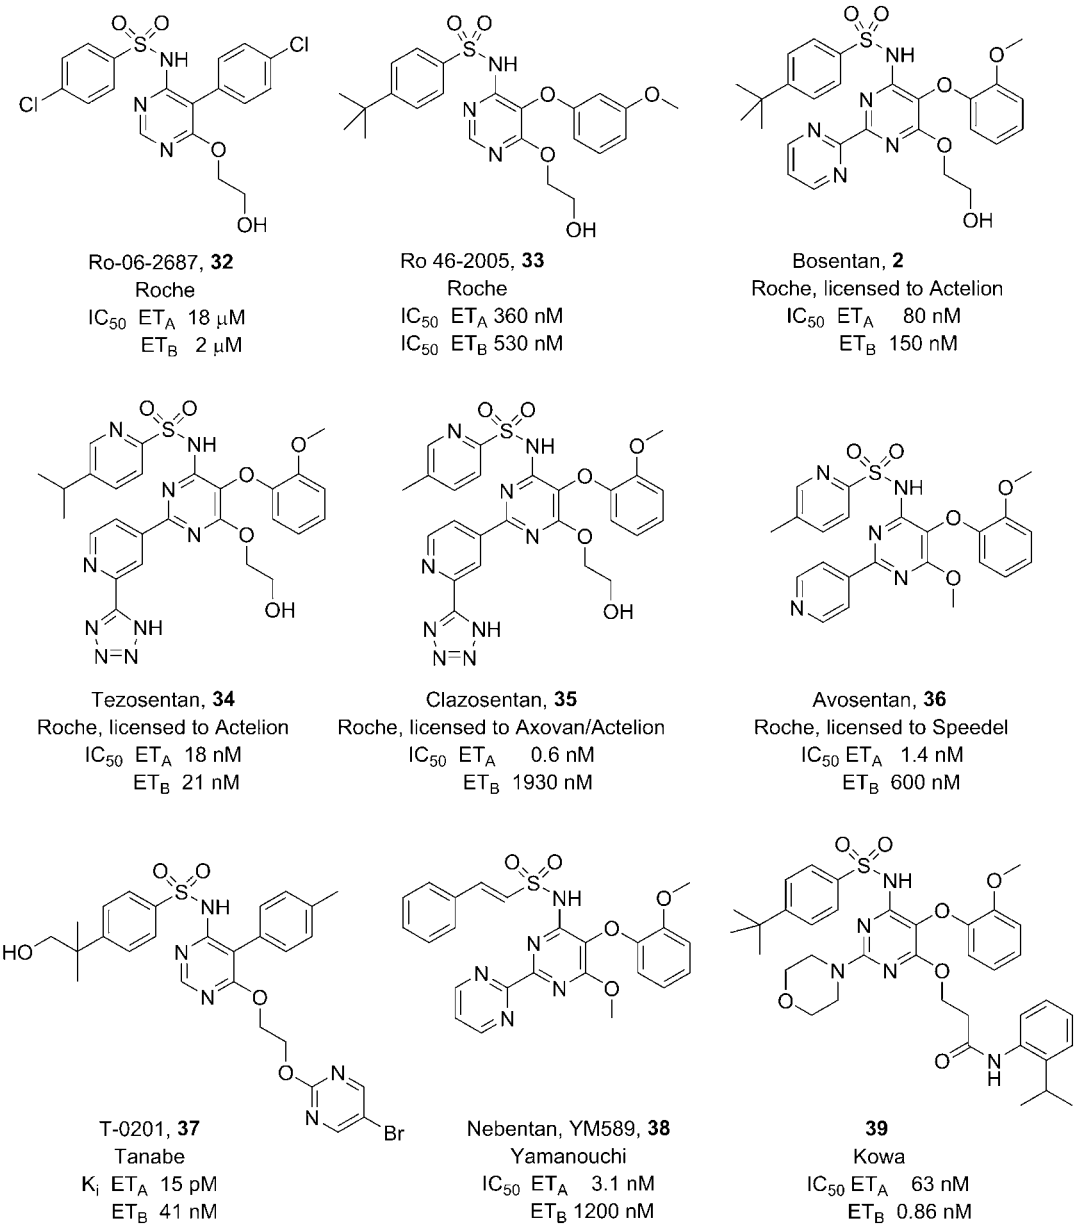

Fig. 7 Structures of ERA incorporating an aryl sulfonamide attached to a pyrimidine.

antagonized the ischemia-induced renal vasoconstriction in the rat. Preliminary optimization of this lead structure led to the identification of Ro 46-2005 **33**, the first orally available small molecule dual ERA.[32,127] In-depth SAR work performed at Roche resulted in the discovery of several compounds with reported clinical history. The orally available dual ERA bosentan **2**[34,128] was studied in a number of cardiovascular and fibrosis indications and was approved under the tradename Tracleer® for the treatment of PAH.[29,30,129,130] The ET_A-selective avosentan **36**[131,132] underwent clinical testing in patients with diabetic nephropathy but was stopped due to intolerable side effects (fluid retention).[133] The 5-isopropyl-2-pyridine sulfonamide tezosentan **34**[134] is a highly potent dual ERA designed for i.v. application. Phase III clinical studies in acute heart failure patients were discontinued due to low probability of achieving significant efficacy.[135–137] Interestingly, the 5-methyl-2-pyridine analog clazosentan **35** is highly selective for the ET_A receptor[138] In patients with aneurysmal subarachnoid hemorrhage, clazosentan reduced the risk of angiographic vasospasm and occurrence of rescue therapy but did not affect new cerebral infarction and mortality.[139,140] Basing their drug discovery efforts on the structure of pyrimidine **33**, additional proprietary ERAs were found by research teams at Tanabe, Yamanouchi, and Kowa. Although promising preclinical data have been published for T-0201 **37**,[141–143] nebentan **38**,[144–146] and Kowa's morpholine derivative **39**,[147] no clinical development has been reported for these three compounds.

8.10.2 Medicinal Chemistry Efforts Leading to the Discovery of Macitentan

8.10.2.1 Selected Starting Points

As a result of our analysis of known ERAs, we decided to select one lead structure from each of the five sub-classes outlined in section "Competition, Structures of Known ERAs" as starting points for our medicinal chemistry efforts. The five lead compounds were selected on the basis of their ability to block both the ET_A and the ET_B receptor and their efficacy in vivo, eg, blockade of the ET-1-induced pressor response. Hence, the structures of IRL3630 **5**,[76] pyrazole **12**,[96,148] ambrisentan **19**,[23] L-754142 **28**,[123] and bosentan **2**[34] (Fig. 8) were considered attractive representatives for a peptidomimetic, a carboxylic acid attached to a heterocycle, a carboxylic acid attached to an alkyl scaffold, an aryl sulfonamide attached to an acetic acid core, and an aryl sulfonamide attached to a pyrimidine, respectively.

In the following paragraph we briefly summarize our strategies to modify the five selected compounds to discover novel ERAs. We also show how results from first analogs we prepared influenced a further shortlisting of the approaches.

To get rid of the peptide-like nature of compound **5**, an approach similar to the one reported for substance P antagonists was undertaken.[149,150] Hence, a set of IRL3630 (**5**, Fig. 8) analogs was prepared wherein, eg, a malonic acid (**40**), an amino-piperidine moiety (**41**), or an aromatic ring (**42**) replaced part of the lead compound's peptide backbone (Fig. 9). Unfortunately, all prepared examples showed considerably lower in vitro potency when compared to the original IRL series. In addition, the synthesis of some of these analogs turned out to be much more cumbersome than expected. Similarly, attempts to modify the scaffolds of compounds **12** and **28** led to analogs with significantly lower affinity for the ET receptors. For instance, corresponding analogs of compound **28** incorporating a sulfonylurea scaffold rather than a sulfonylamide showed IC_{50} values >1 μM at both ET_A and ET_B. On the other hand, analogs of pyrazole **12** that were based on alternative heteroaromatic core structures showed IC_{50} values >10 μM. In the series of ambrisentan **19** analogs, our approach was based on introducing a ring between the carbon of the methoxy group and one of the phenyl rings to rigidify the compound's scaffold (Fig. 10). In addition, patent literature around **19**[151] suggested that the oxygen of the methoxy group could be replaced with a nitrogen. These two modifications led to the general structure **43** as a proposal for novel ERAs. Compound **44** (as racemate), which was among the very first examples prepared in this novel class, showed IC_{50} values of 12 and 184 nM at ET_A and ET_B, respectively, and reduced the mean arterial blood pressure (MAP) after oral administration of 30 mg kg^{-1} to hypertensive Dahl-S rats. These observations confirmed the viability of this approach. A comparison of the structures of bosentan **2** with that of Tanabe's clinical candidate **37** (Fig. 11) prompted us to attach the 5-bromo-pyrimidine moiety present in **37** to the ethylene glycol side chain of bosentan. Although the resulting compound **45** was rather large (Mw = 707), its high affinity for both the ET_A and ET_B receptors (Fig. 11) made this approach very attractive for further exploration.

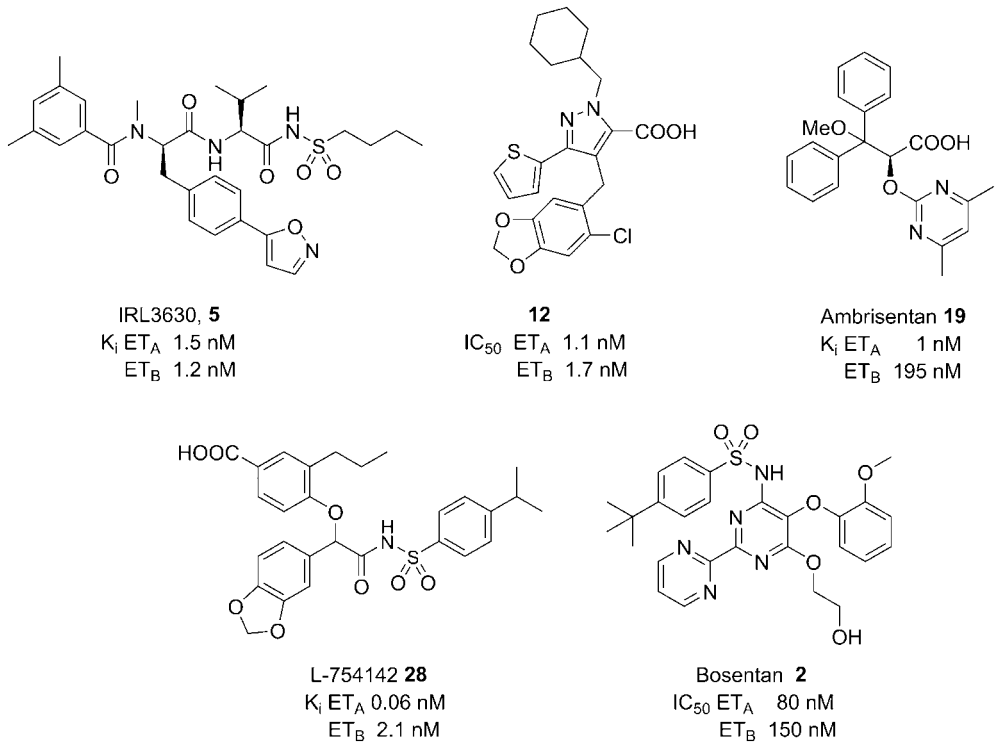

Fig. 8 Structures and published potencies of the ERAs IRL3630 **5**,[76] pyrazole **12**,[96] ambrisentan **19**,[23] L-754142 **28**,[123] and bosentan **2**[128] selected as starting points for our medicinal chemistry program.

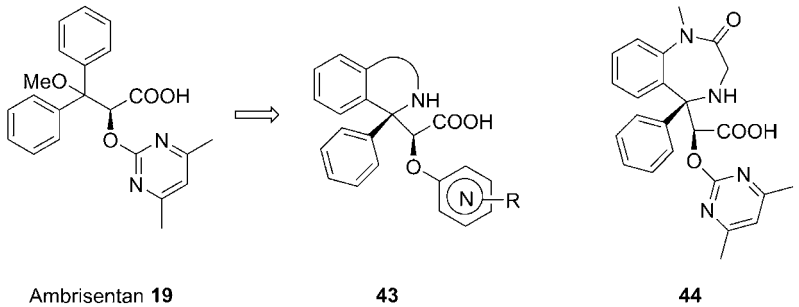

Fig. 10 Introducing an additional ring to the structure of ambrisentan **19** delivered novel ERAs such as tetrahydro-benzo[e][1,4]diazepin-2-one **44**.

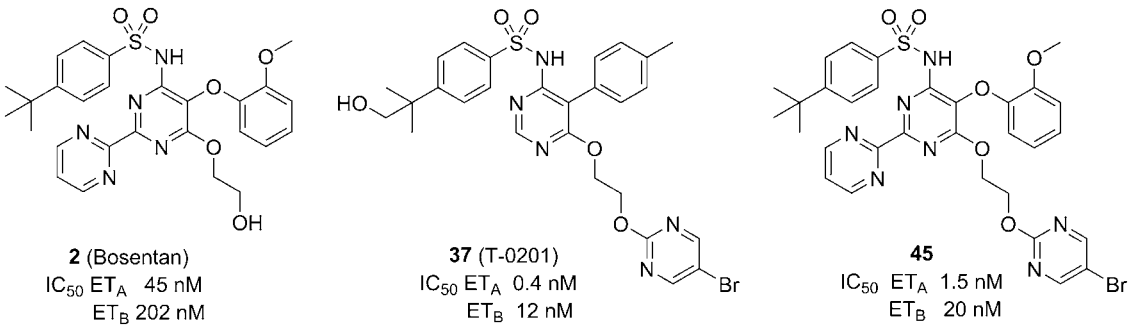

Fig. 11 Structure and in vitro activity of bosentan **2**, T-0201 **37** and a first bosentan analog **45** incorporating the 5-bromo-pyrimidine moiety of **37**.

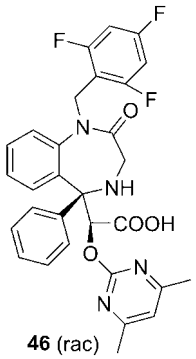
As a result of these early evaluations, further investigation of analogs of compounds **2** and **19** clearly appeared warranted, while additional efforts to explore compound **5**, **12**, and **28** analogs seemed less attractive and were therefore suspended.

8.10.2.2 Progress of the Project

Optimization of the pyrimidine and the benzodiazepinone series occurred in parallel and followed an analogous approach. These efforts culminated in the discovery of macitentan **1** (Fig. 1) and compound **46** (Fig. 12) as best representatives of the pyrimidine and benzodiazepinone series, respectively. For both compound classes, detailed SAR analyses have been published previously[33,152] and the following discussion, therefore, focuses on the discovery process from a more conceptual perspective using exemplary SAR data only.



46 (rac)

Fig. 12 Structure of compound **46**, one of the best benzodiazepinone derivatives. This compound showed IC_{50} values of 17 nM and 565 nM on ET_A and ET_B, respectively, and was efficacious in vivo.[152]

Close to 2000 pyridimine and about 400 benzodiazepine derivatives were prepared in the course of our medicinal chemistry program. ET-1 binding competition IC_{50} values on ET_A and ET_B were measured for each of these compounds. About 400 compounds were at least as potent as bosentan and were thus characterized in the functional assays using rat aorta and trachea rings. As shown in Fig. 13, plotting aorta pA_2-values against ET_A IC_{50} values showed a clear relationship between the two parameters (Spearman correlation coefficient $\rho = 0.66$) demonstrating that functional potency obtained from rat tissue correlates with the binding affinity measured on the human ET_A receptor. As expected, the aorta pA_2 values did not correlate with the compound's potency at the ET_B receptor ($\rho < 0.1$), confirming that the endothelium-denuded aorta responds to ET_A receptor modulation only. Analogous results were obtained when trachea pA_2 values were compared with ET_A ($\rho = 0.2$, negligible correlation) and ET_B ($\rho = 0.48$, relationship, Fig. 14) IC_{50} values. However, for both the pyrimidine and the benzodiazepinone class the correlation between the pA_2 and the corresponding IC_{50} value showed significant scattering and a considerable number of compounds deviate more than a factor of three from the correlation line. Unfortunately, there is not enough data available to allow us to determine whether the observed scattering is due to differences in the affinity of our compounds for the rat and human ET receptors. In addition, although we suspected that physicochemical properties of the compound influence its functional potency, we were unable to identify any specific physicochemical parameter that explained the observed behavior. For instance, plotting aorta pA_2 values against clog*P* or clog $D_{7.4}$ (data not shown) did not reveal any relationship between the two parameters ($\rho < 0.1$). As a consequence, we applied the thresholds for the IC_{50} and pA_2 values for compound advancement more leniently as we progressed with our discovery program.

For about 300 of the 400 compounds tested on aorta and trachea rings, the functional potency on ET_A was at least as high as that of bosentan (pA_2 value > 6.8). These compounds were further profiled in vivo by measuring their effect on blood pressure in hypertensive Dahl-S rats. For illustration, the MAP and HR recordings after oral administration of 3 mg kg^{-1} of bosentan and macitentan

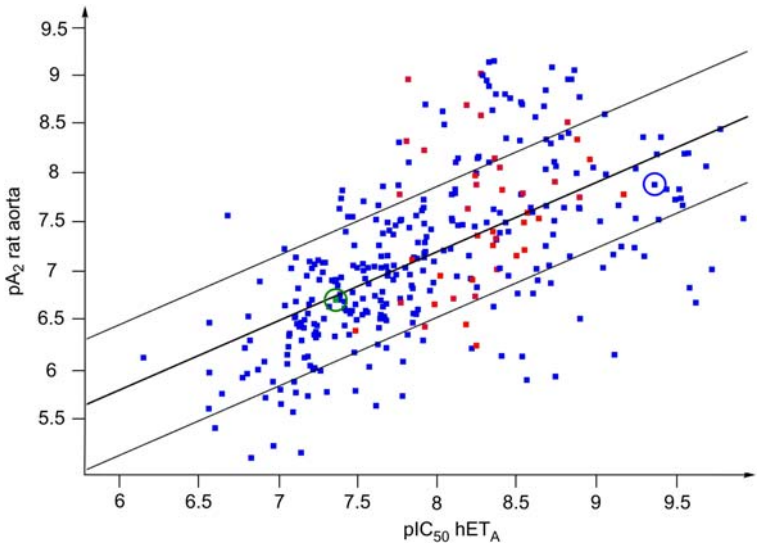


Fig. 13 Correlation of ET_A pIC_{50} and aorta pA_2 values of pyrimidine derivatives (*blue*), benzodiazepinone derivatives (*red*), bosentan **2** (*green circle*), and macitentan **1** (*blue circle*); linear correlation with standard deviation is shown.

are shown in Fig. 15. None of the tested compounds showed an effect on HR. A quick glance at the MAP recordings in Fig. 15 is sufficient to note that macitentan is significantly more efficacious than bosentan in this model of hypertension. A more accurate ranking of the compounds was based on the calculated ABC values of the MAP recordings. Most of the highly efficacious compounds (ABC $\geq$500 mmHg h) displayed a pA_2 value greater than that of bosentan. The data also demonstrated that a high pA_2 value is necessary but not sufficient for a compound to show oral activity. This observation came as no surprise, as oral activity depends, of course, not only on the functional potency but is influenced by many more factors such as compound dissolution, absorption, metabolic stability, tissue distribution, clearance, etc. Hence, while the pA_2 values helped to prioritize compounds for in vivo testing in the beginning, the overall progress of the project was clearly driven by the emerging in vivo efficacy data.

The examples compiled in Tables 2–8 illustrate the observed in vivo SAR and demonstrate how the early availability of in vivo data shaped the discovery process.

As mentioned in section "Selected Starting Points," compound **45**, which combined the structure of bosentan with the 5-bromopyrimidine moiety of T-0201 **37**, showed high potency at the ET_A and ET_B receptor. However, with a molecular weight of 707 this compound is rather large. First efforts therefore aimed at reducing the molecule's size while keeping its favorable potency profile. To this end, stepwise reduction of the sulfonamide moiety was investigated. While removing the *tert*-butyl group at the benzene sulfonamide to give compound **47** (Table 2) led to a moderate decrease in affinity, a further reduction of this moiety to a methyl group (compound **48**) not unexpectedly resulted in a more pronounced potency loss. To our surprise, however, a rather short alkyl chain such as a propyl group (compound **49**) largely restored the compounds' affinity, in particular for the ET_A receptor. Inserting a nitrogen between the alkyl chain and the sulfur to yield sulfamide derivatives further improved the potency on both ET receptors (eg, compounds **50** and **51**). Most importantly, compounds **50** and **51**, incorporating a much smaller sulfonamide/sulfamide moiety when compared to bosentan clearly displayed superior in vivo efficacy. The two compounds showed an ABC of −177 and −232 mmHg h, respectively, while bosentan at the same dose reached an ABC of −88 mmHg h only. Based on

the in vivo efficacy of sulfamide **51** and the more general observation that the sulfamides showed higher potency on ET_B when compared to the corresponding sulfonamide analogs, the sulfamide class was explored in more detail.

The series of benzyl sulfamide derivatives compiled in Table 3 illustrate the optimization of the 2-substituent at the core pyrimidine. As evident from compounds **53** and **54**, replacing the pyrimidine in **52** by a pyridine or a morpholine, respectively, delivered potent compounds but brought no advantage with respect to molecular weight and in vivo efficacy. On the other hand, replacing

the pyrimidine in position 2 by a methoxy group (compound **55**) not only reduced the molecular weight but also the affinity of the compound for the ET receptors. Interestingly, however, omitting the 2-substituent completely to give compound **56** largely maintained its potency on the ET receptors as well as its in vivo efficacy.

The examples given in Table 4 exemplify the in vitro and in vivo SAR of the 5-substituent at the core pyrimidine. The 3-methoxyphenoxy analog **57** of compound **56** was not only more potent on ET_A but also more efficacious in the Dahl-S rat hypertension model. Adding a chloro substituent in position 6 of the phenol moiety (compound **58**) or replacing the 3-methoxy-phenoxy substituent with a 4-chloro- (**59**) or 4-bromo- (**60**) phenyl ring did not affect the potency on ET_A but further improved the compound's in vivo efficacy.

The compounds in Table 5 have been selected to shed light on the in vivo SAR of the 5-substituent attached to the pyrimidine at the ethylene glycol. Even though all four compounds in Table 5 have comparable affinities for the ET_A and the ET_B receptor and similarly high aorta pA_2 values, their efficacy in reducing the MAP in hypertensive Dahl-S rats is clearly different. At an oral dose of 3 mg kg^{-1}, the derivatives incorporating a bromine (**60**) or a methylthio substituent (**63**) were significantly more active than bosentan, while the nearly equipotent cyclopropyl (**61**) and methoxy (**62**) analogs had only a small effect.

Taken together, the compounds in Tables 2–5 demonstrate that in cases where the in vitro potency profiling did not allow compounds to be distinguished, the in vivo efficacy data served as a valuable basis for SAR development and compound prioritization and thus contributed to a rapid progress of the discovery program.

As a last key profiling step, the potential to change plasma bile salt concentrations in Wistar rats was assessed after i.v. administration of those approximately 40 compounds that were clearly more efficacious than bosentan in the Dahl-S rat hypertension model (ABC $\geq$ 500). Due to the limited number of compounds tested in this assay, no detailed SAR could be established. Nevertheless, while all of the tested benzodiazepine derivatives induced changes in plasma bile salt levels, several pyrimidine derivatives showed no activity in this assay (Fig. 16). This observation and the fact that the benzodiazepines often had to be dosed 10 times higher to achieve an in vivo efficacy comparable to that obtained with pyrimidine derivatives, reduced the attractiveness of the benzodiazepinone derivatives. Based on the results of the bile salt experiment, the data of additional standard safety assessments, as well as the properties outlined in section "Preclinical Properties of Macitentan" later, macitentan was eventually selected as a preclinical candidate.

8.10.3 Preclinical Properties of Macitentan

Macitentan was selected based on its potent dual ET_A and ET_B receptor antagonism, its high in vivo efficacy, and, when compared to bosentan **2**, its reduced risk of interaction with bile salt transport. This section summarizes the results of more detailed physicochemical and mechanistic studies and shows how structural properties translated into in vivo efficacy. Macitentan will be compared with the two other ERAs approved for the therapy of PAH, bosentan **2** and ambrisentan **19**.

8.10.3.1 From Physicochemistry to Primary Cell Pharmacology: The Distinct Profile of Macitentan

Macitentan's in vivo efficacy in hypertensive Dahl-S rats was clearly superior to that of bosentan **2** (see previous section and Refs. 33,155) and ambrisentan **19**.[9,152] To explain this marked difference a series of physicochemical, molecular, and cell biological studies comparing macitentan **1**, bosentan **2**, and ambrisentan **19** were carried out. These studies uncovered a distinct profile for macitentan in terms of acidity, lipophilicity, conformational flexibility, binding mode, target dissociation kinetics, and antagonistic efficacy.[31,153,154,156] In the following sections we describe how the physicochemical and conformational profile of macitentan affects binding mode and binding kinetics, and leads to increased antagonistic efficacy despite a target affinity similar to those of bosentan **2** and ambrisentan **19**.

8.10.3.1.1 Distinct physicochemical and conformational properties of macitentan

Key structural and physicochemical properties of macitentan **1**, bosentan **2**, and ambrisentan **19** are compiled in Table 6. Macitentan and its sulfamide analogs have pK_a values of around 6.2. This weak acidity is unique among the known ERAs, which being either carboxylic acids or aryl sulfonamides have pK_a values at least one unit lower, as is the case for ambrisentan ($pK_a = 3.5$) and bosentan ($pK_a = 5.1$). In fact, the acidic function in ERAs had so far been thought to be essential for target binding, allowing for a charge–charge interaction with positively charged Arg^{326} (ET_A) or Arg^{343} (ET_B), as shown for bosentan.[157] Also its high lipophilicity distinguishes macitentan ($\log D_{7.4} = 2.9$) from bosentan ($\log D_{7.4} = 1.3$) and ambrisentan ($\log D_{7.4} = -0.4$). Thus early on in the development of macitentan, its low acidity and high lipophilicity suggested a potentially different receptor binding mode involving different binding forces.

Molecular modeling of ERAs binding to their target requires a notion of the relevant antagonist conformation. In the cases of bosentan **2** and ambrisentan **19**, molecular flexibility is low and conformational variation is therefore limited. This is in contrast to macitentan, whose structure allows considerable conformational variation. Nuclear magnetic resonance (NMR) studies in aqueous solution performed to elucidate the conformation of macitentan under physiological conditions indicated that macitentan is present in a compact conformation characterized by pyrimidine π–π-stacking (Fig. 17). This conformation allows an unparalleled and precise occupation of a hydrophobic pocket in the modeled ET_A receptor.[154]

8.10.3.1.2 Distinct receptor interaction forces for macitentan as compared to other ERAs

Comparison of macitentan **1** and bosentan **2** binding to a common ERA binding site in the ET_A receptor using molecular modeling suggested potentially different binding modes of the two molecules, characterized by the differential involvement of three amino acids (Fig. 18). Site-directed mutagenesis of these three proposed key interaction amino acid residues (Arg^{326}Gln, Leu^{322}Ala, and Ile^{355}Ala) affected macitentan and bosentan binding in opposing ways.[154]

Macitentan binding was not affected after exchanging charged Arg^{326} for an uncharged Gln residue, while bosentan and ambrisentan binding was essentially lost. The exchange of Leu^{322} for Ala abolished macitentan binding, but had no effect on bosentan and ambrisentan binding. Mutating Ile^{355} to Ala abolished bosentan binding, but not macitentan binding. In conjunction with the ET_A model, these data suggest that macitentan in its compact conformation binds via a tight hydrophobic fit (Leu^{322}) to a subpocket within the ET binding site without necessity for charge–charge interaction (Arg^{326}) and without contact to the peripheral Ile^{355}. The more extended bosentan molecule uses obligatory charge–charge interactions (Arg^{326}) and does not fully occupy this subpocket (no contact to Leu^{322}), but protrudes from it (Ile^{355}-interaction). Also ambrisentan requires the electrostatic interaction with Arg^{326}

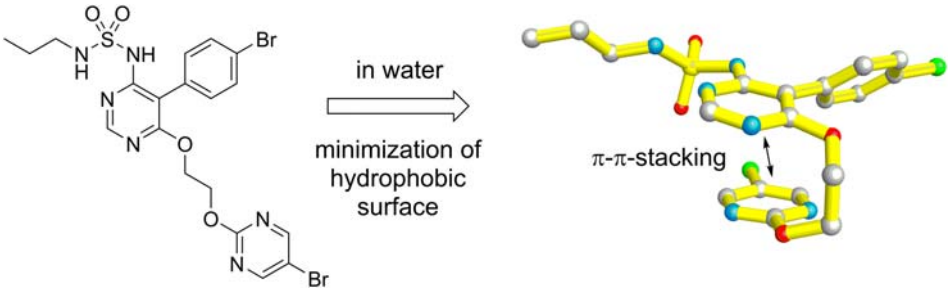

Fig. 17 Conformation of macitentan in water. Compact conformation of macitentan in aqueous solution as proposed by molecular modeling and corroborated by 2D NMR spectroscopy. Ball colors are: carbon, *gray*; nitrogen, *blue*; oxygen, *red*; sulfur, *yellow*; bromine, *green*. Hydrogens have been omitted for reason of clarity.

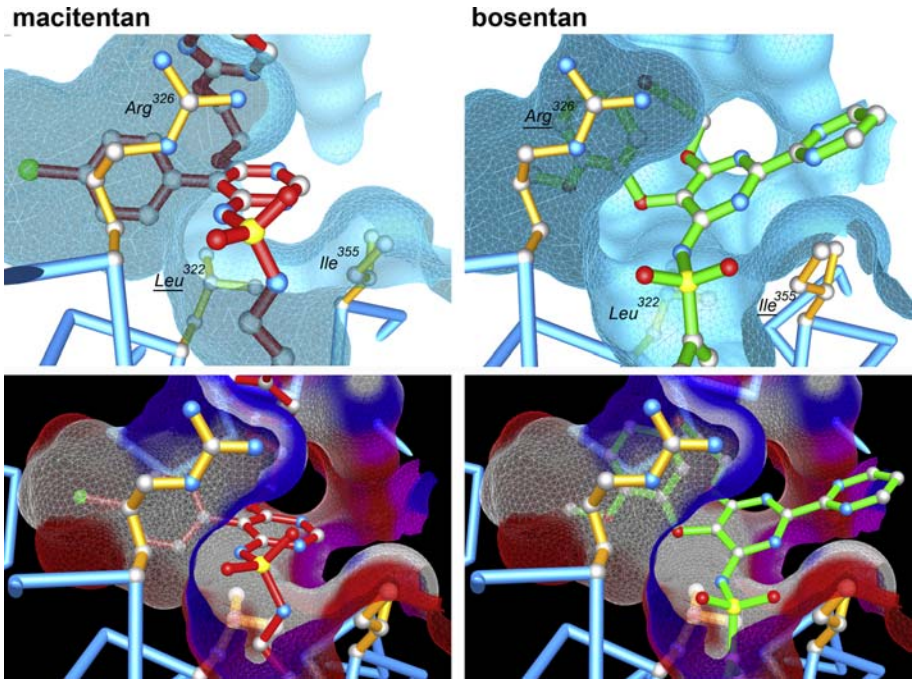

Fig. 18 Macitentan (*left*) and bosentan (*right*) interacting with the ET_A receptor as proposed by mutational experiments and molecular modeling. Three amino acids, Leu^{322}, Arg^{326}, and Ile^{355}, differentially contribute to macitentan and bosentan interaction, causing a hydrophobic and an electrostatic interaction mode, respectively. The same perspectives of the complexes are shown, one of them including polar surface distribution (*red*: H–bond acceptor; *blue*: H–bond donor; *pink*: H–bond acceptor and donor; *white*: lipophilic). Amino acid residues essential for ERA binding are underlined. Reproduced from Gatfield, J.; Mueller Grandjean, C.; Bur, D.; Bolli, M. H.; Nayler, O. Distinct ETA Receptor Binding Mode of Macitentan as Determined by Site Directed Mutagenesis. *PLoS One* **2014**, *9*, e107809.

for binding, indicating similar charge-dependent binding forces for the acidic ambrisentan and bosentan molecules but not for the less acidic macitentan molecule. In conclusion, the macitentan binding mode is characterized by a good hydrophobic fit and a lack of charge–charge interaction at the target receptor and therefore is distinct from that of other more acidic ERAs.

8.10.3.1.3 From a distinct binding mode to sustained target blockade and higher antagonistic efficacy in primary human target cells

It is increasingly realized that in vivo efficacy depends not only on (1) antagonist affinity for the target and (2) in vivo exposure but also on (3) the ability of the antagonist to avoid direct competition with the sometimes highly concentrated natural agonist for target binding. Most (70%) of the newly Food and Drug Administration (FDA)-approved antagonists avoid competition by a variety of mechanisms,[158,159] and probably the most prominent mechanism is slow kinetics of dissociation from the target. Slow target dissociation and thus long receptor occupancy half-life lead to insurmountable antagonism, ie, the inability of the natural agonist, even at very high concentrations, to activate an antagonist-occupied receptor.[160] The evolution of angiotensin II receptor blockers

over the past 20 years illustrates that an increase in receptor occupancy half-life and insurmountability is paralleled by an increase in clinical efficacy.[159,161,162]

Different binding modes of antagonists can affect ligand–receptor binding kinetics and several examples are known where a tight hydrophobic fit between ligand and a receptor pocket leads to increases in receptor occupancy time,[163,164] while charge–charge interactions in ligand–receptor pairs with less tight fit are associated with rapid dissociation kinetics.[165] Therefore, we performed second messenger signaling studies with human primary pulmonary arterial smooth muscle cells (PASMC) to determine the dissociation kinetics and the surmountability profiles of macitentan, bosentan, and ambrisentan. All three compounds were highly potent antagonists of ET-1 signaling at low ET-1 concentrations ($K_b = 0.1–1$ nM; see **Table 6**). Interestingly, however, their receptor occupancy half-lives, as determined by washout assays, were very different. Bosentan and ambrisentan displayed very short half-lives (1 min) at ET receptors in PASMCs. In contrast, macitentan displayed a ~20-fold increased receptor occupancy half-life of 17 min, which is probably sufficient to withstand a locally released wave of the highly unstable para/autocrine ET-1 peptide. The extremely short receptor occupancy half-lives observed for ambrisentan and bosentan are typical of diffusion-controlled drug–target interaction, which occurs (i) in the absence of conformational changes in target or drug and (ii) for binding events with rapid solvation/desolvation of target and drug.[166]

Since many antagonists with longer receptor occupancy half-lives display higher antagonist efficacy,[158,161,162,164,167] ie, insurmountability, we performed curve shift assays to assess competitivity profiles of macitentan, ambrisentan, and bosentan (**Fig. 19**). The distinctly slower target dissociation of macitentan indeed translated into an insurmountable mode of antagonism as evidenced by the inability of even very high ET-1 concentrations to efficiently activate the macitentan-blocked ET receptors in PASMCs, the relevant therapeutic cell type. This more efficient mode of antagonism places macitentan, in contrast to bosentan and ambrisentan, into the class of modern and efficacious drugs that are resistant to competition by the natural ligand.

In summary, based on its specific structure and conformation and its unique physicochemical properties, macitentan displays a distinct binding mode, which leads to slow target dissociation kinetics and, most importantly, to highly efficacious insurmountable antagonism of ET-1 signaling in PASMCs.

8.10.3.2 Tissue Distribution in Animal Models of PAH

Macitentan possesses physicochemical properties (eg, log $D_{7.4}$) that favor partitioning into tissue more than other ERAs, such as bosentan and ambrisentan.[31] Such properties, in addition to its binding mode, could explain the greater efficacy achieved in vivo, as macitentan could access more receptors in the cardiovascular tissue. We therefore investigated its tissue distribution using microautoradiography. We were interested in two aspects: first, the difference in distribution between a healthy animal and a diseased one (for this we selected the bleomycin rat model of pulmonary fibrosis associated with pulmonary hypertension) and second, we wanted to compare the distribution of macitentan with that of bosentan. We first observed that administration of radiolabeled ^{14}C-macitentan showed a greater distribution of drug into the lung of bleomycin-treated rats as compared to healthy rats. This might be attributed to a greater permeability of the damaged lung. Second, we observed that the distribution of labeled macitentan into the general lung tissue of pulmonary hypertensive rats was superior to that of ^{14}C-bosentan.[156] This greater pulmonary distribution was confirmed by quantitative tissue analysis using high-pressure liquid chromatography. We also observed a greater distribution of macitentan compared to bosentan in the right ventricle, the target organ in pulmonary hypertension, on which ERAs can exert direct antihypertrophic activity.

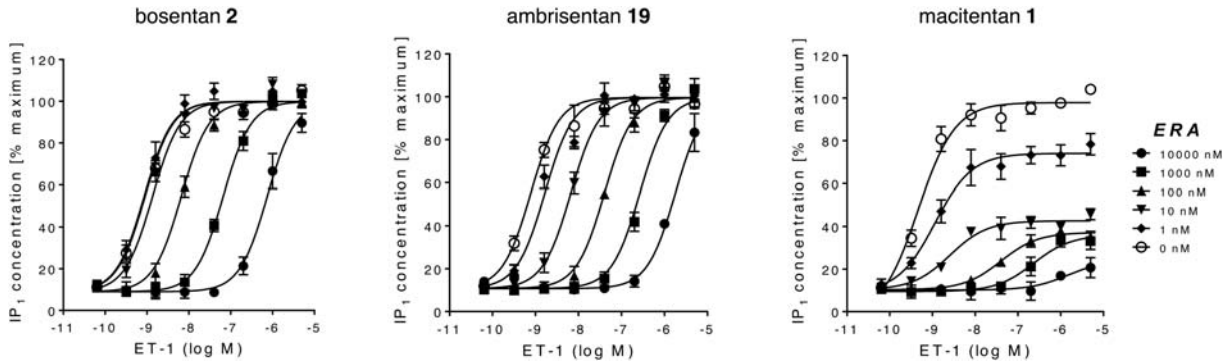

Fig. 19 Effect of bosentan 2, ambrisentan 19, and macitentan 1 on ET-1-induced IP_1 accumulation in human PASMC. Cells were pre-incubated with dilution series of antagonists followed by the addition of a dilution series of ET-1. After 20 min of stimulation, cells were lysed and the IP_1 content was determined. Raw data from four independent experiments were normalized, and average values ±SEM are shown. IP_1, inositol-1-phosphate. Reproduced from Gatfield, J.; Mueller Grandjean, C.; Sasse, T.; Clozel, M.; Nayler, O. Slow Receptor Dissociation Kinetics Differentiate Macitentan from Other Endothelin Receptor Antagonists in Pulmonary Arterial Smooth Muscle Cells. *PLoS One* **2012**, *7*, e47662.

8.10.3.3 In Vivo Efficacy and Comparison With Other ERAs

In vivo data generated during the drug discovery phase showed that single-dose administration of macitentan in conscious hypertensive rats equipped with telemetry triggered a long-lasting decrease in blood pressure, which was superior in terms of amplitude and duration of action to that achieved with bosentan. We confirmed this efficacy profile in rat models of pulmonary hypertension using double telemetry technology to simultaneously measure systemic and pulmonary arterial blood pressure. Macitentan dose-dependently induced a long-lasting decrease in pulmonary blood pressure without increasing HR and, importantly, without decreasing systemic blood pressure (Fig. 20).

This highlights one of the beauties of dual ET receptor antagonism: only vascular beds where the ET system is activated will respond to an ERA. Hence, in healthy vessels, where no dysregulation of the ET system is found, no vascular response occurs, reflecting the minor role of ET in the regulation of vascular tone in physiology. Consequently, in normotensive rats with no activation of the ET system, macitentan, like bosentan,[168] had no effect on systemic blood pressure up to the highest dose tested. On the other hand, macitentan was able to reduce systemic arterial blood pressure in hypertensive Dahl-S and DOCA-salt rats because both Dahl-S and DOCA-salt rats have increased expression of vascular ET-1.[49] In the monocrotaline model of pulmonary hypertension, pulmonary dysregulation of the vascular ET system is observed,[169] and associated with an increase of local pulmonary pressure, whereas the systemic blood pressure of these animals remains in the physiological range.[31] Likewise, in patients with PAH during the phase III study, macitentan decreased pulmonary vascular resistance while no noticeable effect on systemic blood pressure was observed.[170]

The sustained duration of action of macitentan (eg, up to 48 h at a dose of 10 mg kg^{-1}) in hypertensive rats was attributed to its pharmacokinetic properties, including a half-life of 2–5 h, and the formation of the active metabolite M6 (also known as ACT-132577, Scheme 1) with an even longer half-life of 8.4 h in the rat.[31] Metabolite M6 is also a dual ERA, approximately eightfold less potent than macitentan on ET_A and twofold less potent on ET_B receptors. On the basis of these characteristics, M6 may contribute to the in vivo efficacy of macitentan.[31]

To investigate whether macitentan was able to achieve a greater pharmacological effect than other ERAs, a study was designed in which Dahl-S hypertensive rats were given a maximally effective dose of macitentan on top of maximally effective doses of either ambrisentan (used as an ET_A-selective receptor antagonist) or bosentan (dual ET_A/ET_B receptor antagonist).[155] In both cases, macitentan was able to further decrease blood pressure when given on top of the other ET receptor antagonist; conversely, these compounds were not able to cause additional blood pressure reduction when given on top of macitentan. The add-on effect of macitentan on top of bosentan (Fig. 21) or ambrisentan suggests that macitentan is able to achieve a more effective blockade of ET-1-mediated effects in vivo, probably by additional blockade of ET_B receptors (vs. ambrisentan), superior tissue distribution, and an increased receptor occupancy half-life (vs. ambrisentan and bosentan).[9,155]

Finally, chronic studies were initiated to investigate the effect of macitentan on pulmonary artery and cardiac remodeling in rat models of pulmonary hypertension. Chronic administration of macitentan dose-dependently inhibited pulmonary vascular and right ventricular remodeling and, in contrast to bosentan, prolonged survival (Fig. 22). Indeed, we observed that in rats treated with doses of antagonists exerting similar hemodynamic effects on the pulmonary vasculature, macitentan was superior to bosentan in preventing remodeling of the right ventricle.[9] Therefore the improvement of survival observed with macitentan could be attributed to a superior cardiac protection compared to bosentan. These results were indeed encouraging and supported a clinical program aimed at demonstrating an effect of macitentan on hard endpoints such as morbidity and mortality.

8.10.4 Macitentan in Humans

The following sections illustrate how preclinical properties translated into efficacy and safety in humans. To clearly outline the advances made with macitentan, key observations with the benchmark bosentan are summarized at the beginning of the following sections, where appropriate.

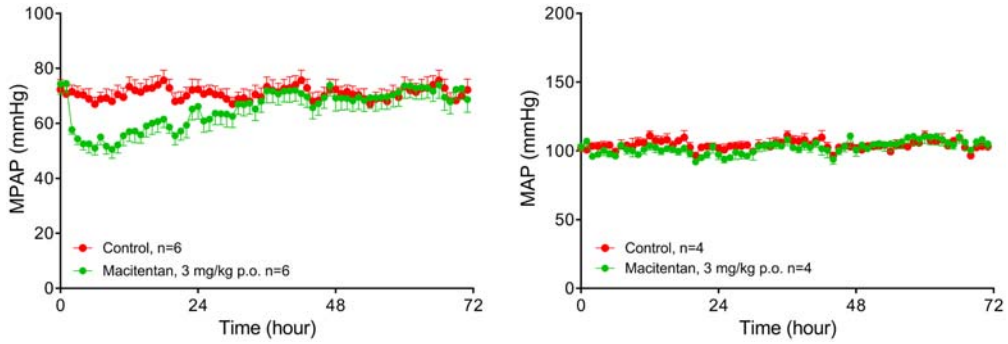

Fig. 20 Concomitant telemetry traces showing mean pulmonary arterial pressure (MPAP, *left*) and systemic arterial pressure (MAP, *right*) in conscious pulmonary hypertensive rats (Sugen/hypoxia model). Single oral administration of macitentan is followed by a selective and sustained decrease in pulmonary pressure without significant change in systemic pressure.

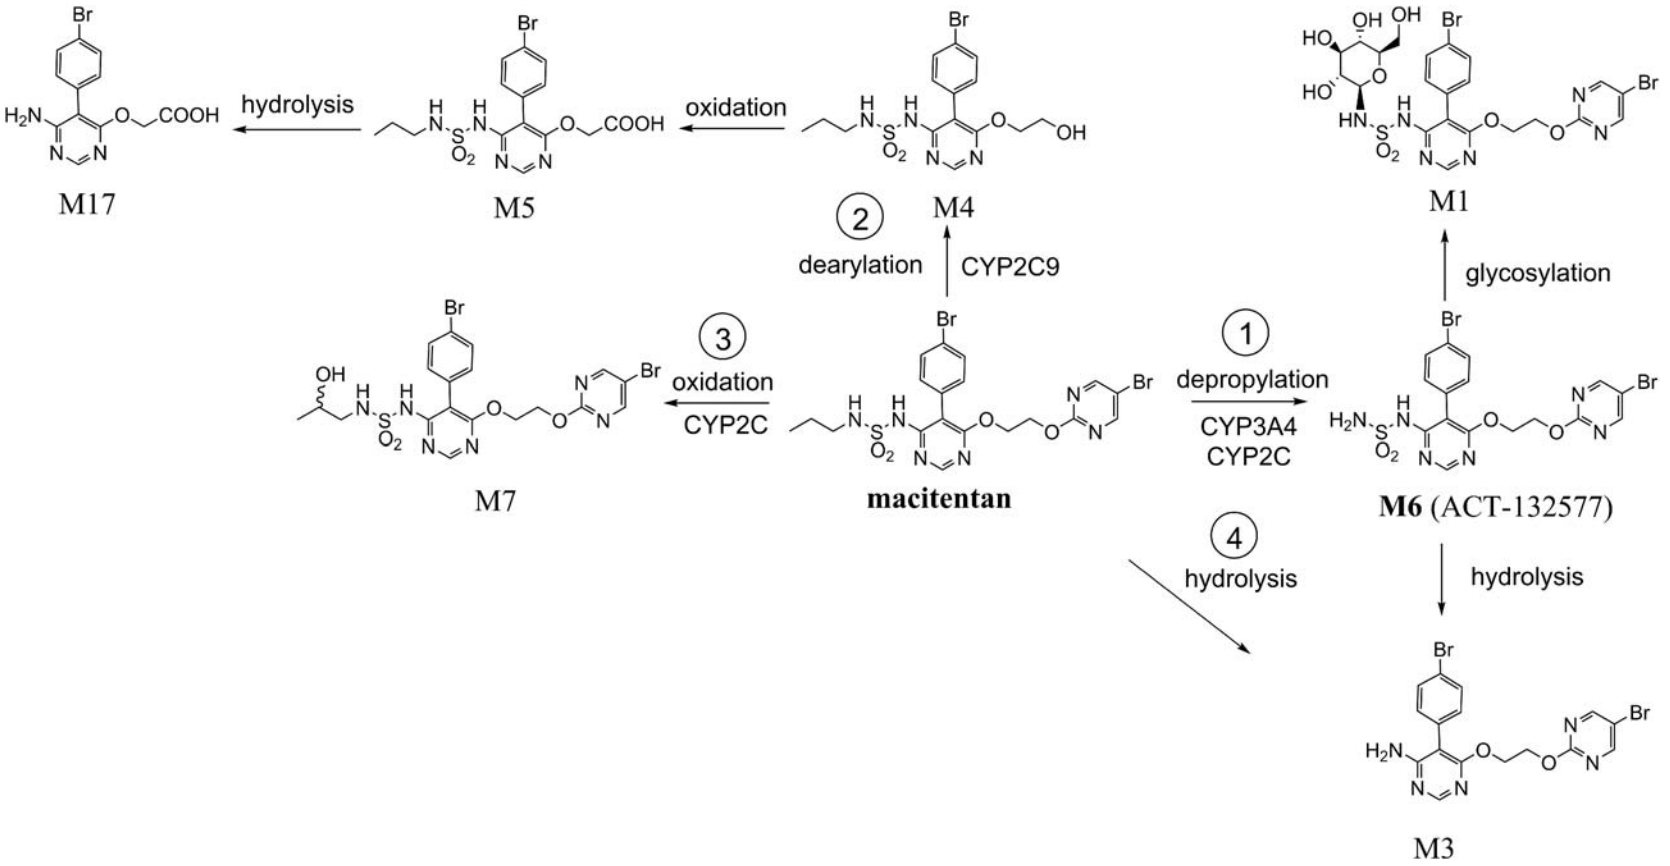

Scheme 1 The four metabolic pathways of macitentan in humans. Metabolite M6 is pharmacologically active with similar potency to macitentan. Metabolites M3 and M4 are significantly less active, while M5 is inactive.[171] Pharmacological activity of M1, M7, and M17 was not determined.

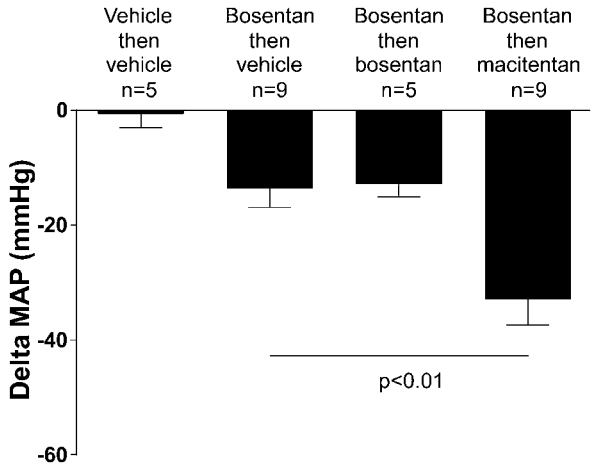

Fig. 21 Effect on mean arterial pressure (Delta MAP) after oral administration of either macitentan (30 mg kg^{-1}) or bosentan (100 mg kg^{-1}) on top of a maximally effective dose of bosentan (100 mg kg^{-1}) to hypertensive Dahl-S rats. Reproduced from Iglarz, M.; Bossu, A.; Wanner, D.; Bortolamiol, C.; Rey, M.; Hess, P.; Clozel, M. Comparison of Pharmacological Activity of Macitentan and Bosentan in Preclinical Models of Systemic and Pulmonary Hypertension. *Life Sci.* **2014**, *118*, 333–339.

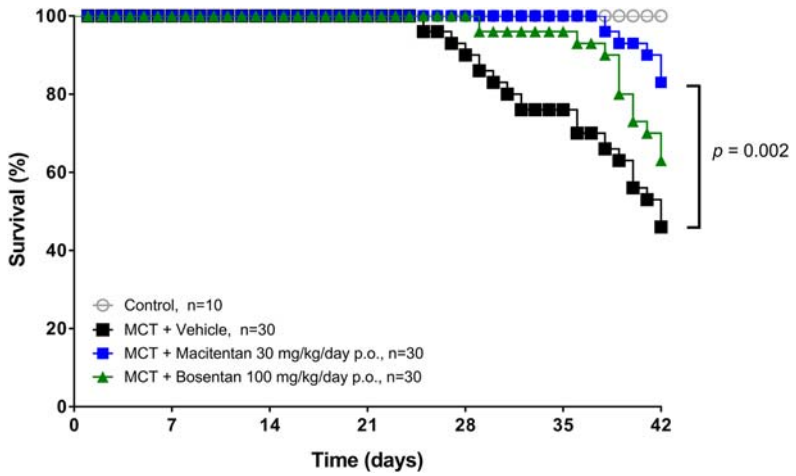

Fig. 22 Survival curve of control and monocrotaline (MCT)-induced pulmonary hypertensive rats ($n=30$/group except $n=10$ in control). Rats were treated with macitentan, bosentan, or vehicle just after MCT administration. Only macitentan significantly improved survival ($p<0.002$ vs. vehicle-treated MCT on day 42).

8.10.4.1 Pharmacokinetics

The maintenance dose of bosentan for the treatment of PAH is 125 mg b.i.d. Bosentan is rapidly absorbed after oral dosing and reaches peak plasma concentrations of 1317 ng mL^{1} within 3 h after a single dose.[172] Steady-state is reached after 3–5 days and plasma concentrations are then about 50% compared to single-dose data, likely because bosentan induces its own metabolism. Its volume of distribution at steady-state is 30 L, ie, approximately body water volume, indicating reasonable penetration into tissues. Hepatic disposition is mediated by OATP1B1 and OATP1B3 as evidenced by the sensitivity of bosentan PK to concomitant organic anion-transporting polypeptide (OATP) inhibitors.[173] Bosentan plasma exposure was increased by about 30- to 48-fold in the presence of cyclosporine A[174] or lopinavir/ritonavir.[175] In contrast, inhibition of metabolism by the CYP3A4 inhibitor ketoconazole led to an only about twofold increase in bosentan exposure.[176] OATP-mediated hepatic uptake is therefore considered the rate-limiting step in overall clearance. Despite a fairly low plasma clearance of 17 Lh^{-1}, bosentan has a terminal half-life of only 5.4 h and needs to be given twice daily. Bosentan undergoes extensive metabolism catalyzed by CYP3A4 and CYP2C9 to yield three metabolites, one of which retains activity on ET receptors and may contribute to about 20% to the overall pharmacological effect. Bosentan metabolites are mostly excreted via the bile while renal elimination is a minor excretion pathway.[177]

Conceptually, pharmacokinetic optimization of a drug can be achieved in several ways. Drug clearance could be reduced either by increasing the drug's stability toward metabolizing enzymes and/or by modifying its hepatic disposition profile, ie, by decreasing

drug concentrations in liver cells. Bosentan exhibits an intrinsic metabolic clearance (CL_{int}) with human liver microsomes of only 15 μL min^{-1} mg and thus offered little room for improvement. The corresponding value for macitentan is in fact about 150 μL min^{-1} mg and macitentan, therefore, is not an obviously superior candidate over bosentan. Decreasing OATP affinity was another option to reduce drug clearance by limiting entry into hepatocytes. This approach, however, created a dilemma as it was believed that ET receptor binding relies on the interaction of a negative charge of the antagonist with Arg326.[157] In the case of ambrisentan, this negative charge is provided by a carboxylic acid while bosentan contains an aromatic sulfonamide. The negative charge makes them, however, candidate substrates for anion transporters, and interactions with OATP transport proteins have indeed been described for several members of the class.[173,178,179] Key structural changes in macitentan versus bosentan constitute the replacement of the sulfonamide by a sulfamide moiety leading to an increase in pK_a from 5.1 to 6.2,[31] and an increase in overall lipophilicity. The octanol/water partition coefficient log $D_{7.4}$ of macitentan is 2.9, while it is only 1.3 for bosentan. Reduced acidity and increased lipophilicity both facilitate membrane permeability and consequently shift the balance driving liver disposition from OATP transport to passive diffusion. Intrahepatic macitentan concentration is therefore determined by the free concentration in blood. As a result of this optimization, oral clearance of macitentan in human is 1.74 Lh^{-1}. Considering the estimated oral bioavailability of 74%,[180] this leads to a systemic clearance of 2.3 Lh^{-1}, ie, about 10 times lower than the corresponding value of 30 Lh^{-1} for bosentan.[172] Macitentan consequently qualified for a once-a-day dosing regimen at a marketed dose of 10 mg for the treatment of PAH.[170] The increased lipophilicity, however, was at the expense of solubility, and macitentan's low solubility in the gut is the likely reason for its slow oral absorption, as median T_{max} is reached after 8 h. Peak plasma concentrations and plasma exposure (AUC_t) at a single dose of 10 mg are 106 ng mL^{-1} and 1722 ng $(mL\,h)^{-1}$, respectively.[181] Drug levels decline with an apparent terminal elimination half-life of 16 h.[181] As a consequence of its long half-life, macitentan accumulates by about 1.74-fold after multiple dosing. The pharmacologically active metabolite M6 (also known as ACT-132577) is slowly formed in man and reaches peak plasma concentrations only about 9 h after macitentan administration. Plasma half-life of M6 is about 43 h, leading to an accumulation of 7.1-fold after multiple dosing. M6 exposure at steady-state exceeds that of parent macitentan by 2.9-fold.[181,182]

8.10.4.2 Metabolism

Metabolic disposition of macitentan in man was investigated in healthy subjects after a single 10 mg dose of ^{14}C-labeled macitentan.[182] Macitentan was extensively metabolized prior to excretion into urine and feces to an about equal extent. Macitentan metabolism in man is characterized by four distinct pathways (**Scheme 1**), ie, (1) oxidative depropylation of the sulfamide group to M6, mainly catalyzed by CYP3A4 and a minor contribution of the CYP2C family; (2) oxidative dearylation of the ethylene glycol to M4 catalyzed by CYP2C9. M4 then undergoes oxidation to the acid M5 followed by hydrolysis to M17; (3) hydroxylation of the propyl chain to form M7, catalyzed by CYP2C enzymes; and (4) hydrolysis of macitentan and M6 to form M3. M17 was the most prominent metabolite detected in human urine, followed by the glucose conjugate M1, the hydrolysis product M3 and the acid M5. Metabolites M3, M5, and M17 were also observed in human feces, accompanied by smaller amounts of M6 and M7. Metabolism studies in bile duct-cannulated rats and dogs showed that all four primary pathways present in humans were also evident in animals.[171]

8.10.4.3 Liver Safety

During clinical development of bosentan, elevated ALT levels were observed in 16% of chronic heart failure patients at 500 mg bosentan twice daily[183] and in 11% of PAH patients[28,30]at 125 mg bosentan twice daily, compared to 4% and 2% on placebo, respectively. Dose-dependent increases in plasma bile salts and alkaline phosphatase were observed alongside changes in liver transaminases. Mechanistically, inhibition of the bile salt export pump BSEP by bosentan and its metabolites has been identified as the likely reason for the observed changes in plasma transaminases.[39] BSEP is an ATP-dependent transport protein located at the canalicular domain of hepatocytes and mediates the rate-limiting step in bile salt secretion from blood into bile.[184,185] In canalicular rat liver membrane vesicles and in Sf9 vesicles overexpressing rat bsep, bosentan and its metabolites inhibited taurocholate transport in vitro. In rats, plasma bile salts increased in a dose-dependent manner after intravenous dosing of bosentan.[39] These rat findings were later substantiated with human BSEP.[186] Moreover, bosentan itself accumulates in liver cells as it is a substrate of OATP transport proteins.[173] Both elements together led to the hypothesis that bosentan treatment might initially disrupt bile salt homeostasis through blockade of BSEP-mediated bile salt excretion into bile. As the accumulating bile salts are cytotoxic at high concentrations, the observed liver transaminase elevations in man are likely the result of secondary bile salt toxicity in hepatocytes. This hypothesis is supported by observations in PAH patients receiving concomitant HIV protease inhibitors like Kaletra® (lopinavir/ritonavir), a potent inhibitor of both CYP3A4 and OATP. Bosentan trough plasma concentrations were increased by 48-fold in this subpopulation.[175]

The effects of macitentan and its active metabolite M6 on bile salt homeostasis were tested at a single-dose in the above-mentioned rat model developed by Fattinger et al.[39] Macitentan and M6 were individually tested at an intravenous dose of 25 mg kg^{-1}, and the change in plasma bile salts measured at 10, 45, and 120 min after dosing. Bosentan as well as a vehicle control were included into the design (**Table 7**). In agreement with literature data,[39] bosentan increased plasma bile salts by 18 ± 13 μM at 10 min post-dose, which then returned to pre-dose values within 45 min after dosing. Under the same conditions, plasma bile salt changes after 10 min were 3.7 ± 4.4 μM for macitentan and 2.5 ± 6.7 μM for M6, and thus not different from vehicle (0.4 ± 3.4 μM).

Bile salt changes upon chronic macitentan treatment were monitored in the toxicology program in the rat and dog.[187] Rats were treated for 4 weeks at doses up to 1500 mg kg^{-1}, and for 26 weeks at up to 250 mg kg^{-1}. No difference between dose groups was noted in any of the rat studies. Steady-state plasma exposures for macitentan and M6 in male rats at 250 and 1500 mg kg^{-1} were about 23- to 212-fold and 42- to 183-fold, respectively, above human exposure at the approved dose of 10 mg. Top doses in the 4- and 39-week studies in the dog were 250 and 100 mg kg^{-1}, respectively. There was no difference between dose groups treated with macitentan and vehicle in any of the three chronic toxicity studies in the dog. Plasma exposures of macitentan and M6 at 100 and 250 mg kg^{-1} were about 18- to 26-fold and 187- to 500-fold, respectively, above human exposure at 10 mg. Serum bile salt concentrations monitored in the multiple-ascending dose study in healthy male subjects at macitentan doses of 1–30 mg for 10 days were in a narrow range from 7.7 to 19 μM and showed no discernible trend toward increased levels at any dose (**Table 8**).[188]

From a more mechanistic perspective, inhibition of bile salt transport was investigated at the level of the transport proteins responsible for hepatic bile salt trafficking, ie, the sodium-dependent taurocholate cotransporting polypeptide (NTCP) and the bile salt export pump (BSEP). NTCP (SLC10A1) and BSEP (ABCG2) are the major transport proteins responsible for moving bile salts from blood into liver cells.[184,185,189] The results of these inhibition experiments are summarized in **Table 9**.

NTCP was equally inhibited by macitentan and M6 with IC_{50} values in the range of 14–18 μM, whereas BSEP was inhibited with IC_{50} ranging from 18 to 60 μM. These in vitro data are thus not different from those of bosentan with reported IC_{50} values on BSEP and NTCP of 25–77 μM and 24–30 μM, respectively. From a drug discovery perspective, it is a fair question whether an isolated view on BSEP inhibition would have been an appropriate approach to identify follow-up compounds devoid of cholestatic potential. It is important to conceptionalize that toxicity is not only a function of (off-)target affinity but also of drug concentrations at the target site. A complete assessment, therefore, also needs due consideration of local drug concentrations. As outlined in the section on macitentan PK, hepatic disposition differs significantly between bosentan and macitentan. Bosentan uptake into liver cells is largely dependent on OATP transport.[173] In contrast, the increased lipophilicity of macitentan allows it to enter liver cells by passive diffusion, while OATP transport only contributes about 20% to overall cellular uptake.[187,193] These mechanistic considerations were substantiated using a physiology-based pharmacokinetic (PBPK) model for macitentan and M6.[180] For a human 10 mg dose, this PBPK model projected total macitentan concentrations at steady-state in plasma, portal vein, and liver of 400 nM, 419 nM, and 72 nM, respectively, while the corresponding values for M6 were 1722 nM for plasma/portal vein and 159 nM for liver. Even without correction for plasma protein binding, these concentrations are significantly below those observed in the bile salt transport experiments described earlier. Based on this more physiological view, it is obvious why macitentan's liver safety profile is much superior to that of bosentan despite a similar inhibitory potency on BSEP and NTCP.

8.10.4.4 Drug–Drug Interactions

The drug–drug interaction potential of bosentan is mostly driven by its P450 induction potential. Biochemically, bosentan shows a classical P450 induction pattern as it activates the PXR nuclear receptor and induces CYP2C9 and CYP3A4 in human hepatocytes.[194] Clinically, concomitant bosentan at 125 mg b.i.d. reduces drug levels of a number of comedications dependent on these enzymes including cyclosporine A,[174] simvastatin,[195] and warfarin[196] by about 50%. Its dependency on OATP-mediated hepatic uptake leads to marked, up to 48-fold increases in bosentan plasma levels when given together with rifampicin, cyclosporine, or ritonavir/lopinavir.[175]

The inhibition potential of macitentan and its active metabolite M6 on a panel of P450 enzymes and drug transporters was characterized in vitro (**Table 10**).[180,197]

While macitentan and M6 showed no inhibition of CYP1A2, CYP2A6, CYP2B6, CYP2C19, CYP2D6, and CYP2E1 ($IC_{50} > 50$ μM), they showed weak to moderate inhibition of CYP2C8, CYP2C9, and CYP3A4. Macitentan and M6 are P450 inducers in vitro.[180] Both compounds increased CYP3A4 expression in human hepatocytes, while no relevant changes in CYP1A2 or CYP2C9 expression were observed.[180] Upregulation of CYP3A4 is likely mediated via PXR, as both compounds activated the nuclear receptor in a reporter-gene assay with EC_{50} values of 1.2 and 8.0 μM, respectively. Macitentan is a substrate of CYP3A4 and CYP2C enzymes.[180] Moreover, macitentan as well as M6 are weak substrates of OATP1B3 but not OATP1B1.[198]

The relevance of these in vitro studies was investigated in a series of clinical drug–drug interaction studies with macitentan at a dose of 10 mg. Sildenafil and warfarin were chosen as CYP3A4 and CYP2C9 substrates to assess the P450 inhibition potential clinically, as both are important comedications in the treatment of PAH. Concomitant macitentan caused a minor, not clinically relevant increase in exposure to sildenafil.[199] The anticoagulant warfarin is marketed as a racemic mixture of which the R-

enantiomer is a sensitive CYP2C9 substrate. No interaction was observed when warfarin was concomitantly administered with macitentan.[200] The lack of P450 induction was confirmed in a recent drug–drug interaction study with the oral contraceptive Trinovum® (ethinyl estradiol/norethisterone).[201] These studies indicate that macitentan at a dose of 10 mg is neither an inhibitor nor an inducer of P450 enzymes.

Interaction studies with ketoconazole, rifampicin, and cyclosporine A were conducted to quantify the dependence of macitentan clearance on CYP3A4 and OATP transporters. Macitentan exposure increased by about twofold in the presence of the strong CYP3A4 inhibitor ketoconazole, given at a once daily dose of 400 mg, while the exposure to metabolite M6 was reduced by 26%.[202] The CYP3A4 inducer rifampicin reduced exposure to macitentan by approximately 80% but had no effect on M6 concentrations in plasma.[198] Both studies confirm the important role of CYP3A4 in the clearance of macitentan as indicated by the in vitro studies. PBPK modeling suggested that CYP3A4 contributes about 60% to total clearance.[180] The sensitivity of macitentan PK to OATP inhibition was probed in a clinical interaction study with cyclosporine A.[198] Concomitant cyclosporine A had only a marginal effect on macitentan drug levels. This is a marked difference to the 30-fold increased trough levels observed in the corresponding interaction study with bosentan,[174] confirming the role of passive diffusion, a consequence of increased lipophilicity, in the hepatic disposition of macitentan.

8.10.4.5 Macitentan for the Treatment of PAH

The research efforts leading to the discovery and development of macitentan culminated in a landmark Phase III clinical trial, the Study with an Endothelin Receptor Antagonist in Pulmonary Arterial Hypertension to Improve Clinical Outcome (SERAPHIN). SERAPHIN was an ambitious study, and differed from previous clinical trials of PAH treatments in several important ways. Whereas in previous trials the primary endpoint was change in the 6-min walk distance, a measure of exercise tolerance, SERAPHIN, in an event-driven design, used a composite endpoint of time to first morbidity or mortality event as a direct measure of disease progression. Furthermore, previous trials were relatively small—enrolling less than 200 patients—and, with 12–24 weeks of treatment, of relatively short duration.[203,204] SERAPHIN enrolled 742 patients, who were treated for up to 3.6 years, with a median exposure time of about 2 years.[170]

Macitentan 10 mg significantly reduced the risk of morbidity and mortality by 45% as compared to placebo ($p < 0.001$), confirming the expectations raised by the preclinical efficacy profile not only in terms of hemodynamics but also with regard to reversal of vascular and cardiac remodeling.[170,205] The effect on the primary endpoint was driven mainly by a decrease in worsening of PAH and consistent across disease severity and patient populations receiving macitentan as monotherapy or in combination with other PAH-specific therapies. There was also a significant decrease in the risk for PAH-related death or hospitalization, a secondary endpoint.[170] Significant improvements were observed for several additional parameters including exercise capacity as measured with the 6-min walk test, World Health Organization functional class, and health-related quality of life. Macitentan was generally well tolerated in this long-term study, and, especially important, the incidence of elevated liver enzymes was not different in the macitentan-treated groups compared to the placebo group, validating our screening efforts to improve the liver safety profile.

In 2013, in part on the basis of SERAPHIN, the US FDA approved macitentan 10 mg once daily for the treatment of PAH to delay disease progression and to reduce PAH related hospitalizations.[206] It was the first time that an oral PAH medication was approved for this indication based on a morbidity/mortality endpoint. In contrast to bosentan, for which liver monitoring is required, for macitentan liver monitoring is recommended and should be performed as clinically indicated. A benefit of macitentan on top of concomitant-specific PAH treatments was recognized. By the end of 2014, macitentan had been launched in 18 countries worldwide. In the EU, macitentan was granted orphan drug status based on the data from SERAPHIN.[207]

8.10.5 Conclusions

The goal of our drug discovery efforts was to identify a novel dual ERA for the treatment of patients with PAH that is devoid of the shortcomings of bosentan, ie, is more potent and more efficacious, can be administered to patients once a day only, and, in

particular, has no liver liability. In view of the large number of known ERAs, we decided to start our own drug discovery efforts from the structure of published ERAs rather than to perform a high-throughput screening. A careful analysis of the structures of these ERAs suggested that they could be divided into five structural classes, and we selected one prototypical structure from each of these categories for further optimization. In the course of our medicinal chemistry program, close to 2000 final compounds were prepared based on a core pyrimidine, about 400 represented benzodiazepinone derivatives, and another 100 compounds consisted of analogs of peptidomimetic **5**, pyrazole **12**, and *N*-acetylsulfonamide **28**. Of the about 2500 compounds tested in ET-1 binding assays, around 400 showed IC_{50} values of <20 nM and <400 nM on ET_A and ET_B, respectively, and were therefore tested for their functional potency ex vivo in rat aorta and trachea constriction experiments. About 300 compounds passed the in vitro and ex vivo potency criteria and were directly tested in an in vivo efficacy model. Nearly 40 compounds were clearly superior to bosentan in reducing the MAP in hypertensive Dahl-S rats and were therefore shortlisted for the in vivo liver safety assessment. A handful of compounds showed no effect on plasma bile salt levels after i.v. administration to Wistar rats and macitentan was finally selected among those compounds that passed additional standard safety tests.

This approach offered several attractive features that had a clear impact on the speed and the way the discovery project progressed. The use of telemetered conscious hypertensive Dahl-S rats allowed relatively easy, fast, and reliable hemodynamic monitoring and under the experimental settings chosen, the compound consumption for in vivo characterization was so little (10 mg) that the first batch of a compound usually delivered sufficient material for in vivo testing. The relatively high throughput of the in vivo experiment enabled us to base our SAR analyses to a large extent on efficacy data. As a consequence, we did not follow a more "classical" stepwise approach by characterizing the compounds in in vitro and in vivo DMPK assays prior to in vivo efficacy testing.

Macitentan's outstanding in vivo efficacy is accompanied if not caused by a target receptor interaction mode distinct from other ERAs: its low acidity and very compact conformation in aqueous solution allow macitentan to bind to a small subpocket within its target receptor using hydrophobic rather than charge–charge interaction forces. This tight hydrophobic fit is the likely basis for the distinctly slow target dissociation kinetics and insurmountable antagonism of macitentan, which place it among the number of modern and efficacious antagonists that resist competition with the natural agonist by a kinetic mechanism. This property, together with a superior tissue distribution, allows for a more complete inhibition of ET_A and ET_B receptors. Indeed, macitentan showed superior in vivo pharmacological activity versus other ERAs; not only acutely on hemodynamics but also in chronic models of pulmonary hypertension. Its ability to reduce vascular and right ventricular hypertrophy translated into a significant improvement in survival in rats, demonstrating its potential for long-term benefit.

The obvious result of macitentan's pharmacokinetic optimization is its significantly lower daily human dose of 10 mg and its more convenient once-a-day dosing regimen, compared to the bosentan dose of 125 mg given twice daily. Macitentan's superior drug–drug interaction and liver safety profile is not obvious from basic pharmacokinetic data, as bioavailability of both compounds is in the range of 50–70%, and drug exposures at steady state only differ by about 2.5-fold. From a biochemical perspective, the liabilities of bosentan originate from its dependence on OATP transport, induction of P450 enzymes, and inhibition of BSEP. From a more physiological view, all three issues have a common denominator, ie, the high drug concentrations in the liver. The increased lipophilicity of macitentan leads to a significant change in hepatic disposition by shifting the driving force for tissue penetration from active OATP transport to passive diffusion. As a consequence, intrahepatic macitentan concentrations are determined by and limited to the unbound drug concentrations in plasma. Unbound drug concentrations in the liver are therefore expected to be in the nanomolar range and thus markedly below those concentrations associated with P450 induction or BSEP inhibition in vitro. It is unclear with hindsight whether macitentan would have been selected in a classical lead optimization approach based on preclinical safety readouts, as neither its BSEP inhibition nor its PXR activation profile in vitro offer obvious advantages over bosentan. This highlights the concept that lead optimization needs to consider physiological parameters as much as biochemical data early in the discovery process to identify the most promising drug candidates. The early use of PK/pharmacodynamics modeling should be considered to properly integrate physicochemical and biological data in a comprehensive manner. The outcome of this approach was validated in clinical trials in which the absence of P450 induction as well as the superior liver safety profile of macitentan was finally demonstrated. Clinical outcome favorably translated into the labels of Opsumit® (macitentan 10 mg).[206,208]

Bosentan, the first ERA to be approved and the first oral therapy for PAH, was unquestionably a major breakthrough in the treatment of PAH. Macitentan, discovered through the rational targeted approach described here, represents an optimized ERA. In the landmark SERAPHIN trial, macitentan significantly reduced the risk of morbidity and mortality (composite endpoint) and of PAH related hospitalizations, and was effective in combination with other PAH therapies. In addition to excellent efficacy, macitentan showed an improved safety profile and was not associated with excess peripheral edema or liver enzyme elevations. Taking all these aspects into consideration, macitentan represents a genuine advance in the care of patients with PAH.

8.11.1 Introduction

The discovery and development of anacetrapib provides insight into the intense feedback loop that drives biopharmaceutical research. The preclinical discovery program provided a compound with significant therapeutic potential. The clinical development program revealed features of the compound and the target that triggered additional preclinical research, which in turn influenced the clinical development plan. This ongoing process has been correctly characterized by Jordan elsewhere in this series as "a conversation between the laboratory and the clinic."[1] This case history illustrates the dynamic nature in which the discovery and development of anacetrapib has progressed in light of a continual flow of new information. Importantly, the account also demonstrates how the discovery team is called upon throughout the clinical program to address new developments as they arise.

8.11.1.1 The HDL Hypothesis and CETP

Heart disease is the leading cause of death in both low and high income countries, and over half of all deaths from heart disease in the United States are due to coronary artery disease.[2,3] The analysis of the Framingham Heart Study established that high levels of low-density lipoprotein cholesterol (LDL-C) and very low-density lipoprotein cholesterol (VLDL-C) were associated with higher mortality from coronary heart disease (CHD). This epidemiological study provided an even stronger inverse correlation associating high levels of high-density lipoprotein cholesterol (HDL-C) and lower CHD mortality.[4,5] Indeed, from this and other population-based studies, it is apparent that each 1 mg dL^{-1} decrease in plasma VLDL-C/LDL-C is associated with a 1% decrease in CHD risk, and that each 1 mg dL^{-1} increase in plasma HDL-C is associated with a 2–3% decrease in CHD risk.[6] This epidemiology correlation led to the cholesterol hypotheses of intervention that CHD mortality risk could be reduced by the pharmacologic lowering of VLDL-V/LDL-C and the pharmacologic elevation of HDL-C.

The intervention hypothesis for lowering of LDL-C has been thoroughly validated by clinical data, whereas the benefit of HDL-C elevation is not yet established. Since the publication of these epidemiology findings, a variety of LDL-C lowering agents have proven to be effective in reducing the risk of CHD mortality. The primary therapy for LDL-C reduction includes the HMG Co-A reductase inhibitors (statins) that inhibit the biosynthesis of cholesterol in the liver. Aggressive intervention therapy with statins can significantly reduce plasma LDL-C and reduce CHD event risk by 30–40%.[7] A further reduction in LDL-C has been achieved by the addition of the cholesterol absorption inhibitor ezetimibe, and this has provided a further risk reduction in patients with acute coronary syndrome (ACS).[8] Very recently, data have emerged from therapy with inhibitory antibodies to proprotein convertase subtilisin-kexin type 9 (PCSK9) that additionally indicate the mortality benefit of further reduction in LDL-C, although cardiovascular outcome studies are ongoing with this therapy.[9]

Despite the impressive 30–40% reduction in CHD mortality risk from lowering LDL-C, considerable residual risk remains. It is possible that additional pharmacologic intervention to concomitantly elevate HDL-C would provide a further CHD mortality risk reduction. Niacin and fibrates have been utilized for modest elevation of HDL-C (5–25%), but niacin therapy induces side effects such as flushing that makes high-dose use intolerable for many. In addition, a recent meta-analysis of clinical results for existing

HDL-C raising drugs did not demonstrate a reduction in cardiovascular mortality associated with the level of HDL-C elevation available from these therapies.[10]

A mechanism that more aggressively elevates HDL-C was needed to more conclusively test the HDL-C intervention hypothesis. In 1985, Koizumi, Mabuchi, and colleagues published a study of a Japanese population of healthy individuals with a genetic deficiency in cholesteryl ester transfer protein (CETP).[11] These individuals exhibited 300–600% increase in plasma HDL-C, and decreased incidence of CHD as compared to the general population. Subsequent studies of multiple CETP-deficient subject groups have generally validated the elevation of circulating HDL-C in this population. However, conflicting and even contradictory data have been reported on the influence of CETP deficiency for CHD risk for these individuals, possibly due to small sample sizes and varying methodology.[12]

CETP is a plasma glycoprotein that is physically associated with HDL particles in circulation.[13] The primary function of CETP involves the transfer of cholesterol esters (CE) and triglycerides (TG) between particles of VLDL/LDL and HDL to promote concentration equilibrium (Fig. 1). The mechanism for CETP transfer was originally proposed as a shuttle between lipoprotein fractions, where CETP carried a cargo of cholesterol ester (CE) and/or triglycerides (TG) in a central channel of the protein.[14] However, recent cryo-electron microscopy studies support the function of CETP as a conduit tunnel in a ternary complex with two lipoprotein particles for CE and TG exchange.[15] The conduit tunnel mechanism has been questioned, as CE transfer was demonstrated in vitro in the presence of selective antibodies that bind either end of the central channel of CETP.[16]

Pharmacologically, CETP is critically involved in the reverse cholesterol transport pathway for cholesterol excretion through the liver. As illustrated in Fig. 1, ApoA1 containing HDL particles are a primary vehicle for hepatic excretion of cholesterol. In this mechanism excess cholesterol ester is removed from macrophage foam cells in vascular tissue by nascent, preβ-HDL and HDL particles through the action of ATP-binding cassette transfer proteins such as ABCA1 and ABCG1. The HDL particle transports the cholesterol ester to the liver for uptake by the hepatic scavenger receptor B1 (SR-B1) for excretion to the bile. In this way, the extraction of cholesterol from vascular tissue by HDL leads to cholesterol-enriched HDL particles for excretion, providing an overall antiatherogenic effect. This process may be circumvented by CETP, which transfers CE from HDL to more CE-deficient ApoB containing LDL and VLDL particles, and conversely transfers triglycerides from VLDL/LDL to HDL. These LDL particles may similarly facilitate hepatic CE removal via uptake by the LDL receptor, as a parallel cholesterol disposal route. However, LDL particles may also be absorbed beyond the epithelium of vascular wall where they become oxidized, releasing CE into macrophages and contributing to atherosclerotic plaque formation.

Inhibition of CETP blocks the transfer of CE from HDL to VLDL/LDL, and blocks the transfer of TG from VLDL/LDL to HDL. This inhibition is anticipated to maintain the CE-rich HDL for liver-mediated cholesterol disposal and facilitate a net increase in reverse cholesterol transport and cholesterol efflux. The fundamental hypothesis of CETP inhibition therapy is that inhibiting the transfer of CE from HDL particles to LDL particles will result in net increased efflux of CE from the arterial wall to the bile, thus preventing progression of atherosclerotic occlusion.

8.11.1.2 Pharmacodynamic Validation with Early CETP Inhibitors

Preclinical studies published in the 1990s and early 2000s supported the proposal that CETP inhibition would have an antiatherogenic effect. Several species, including mice, rats, and dogs, express little or no plasma CETP. These species exhibit a significantly higher fraction of total cholesterol in HDL-C as compared to species that express CETP, such as cynomolgus monkeys, hamsters,

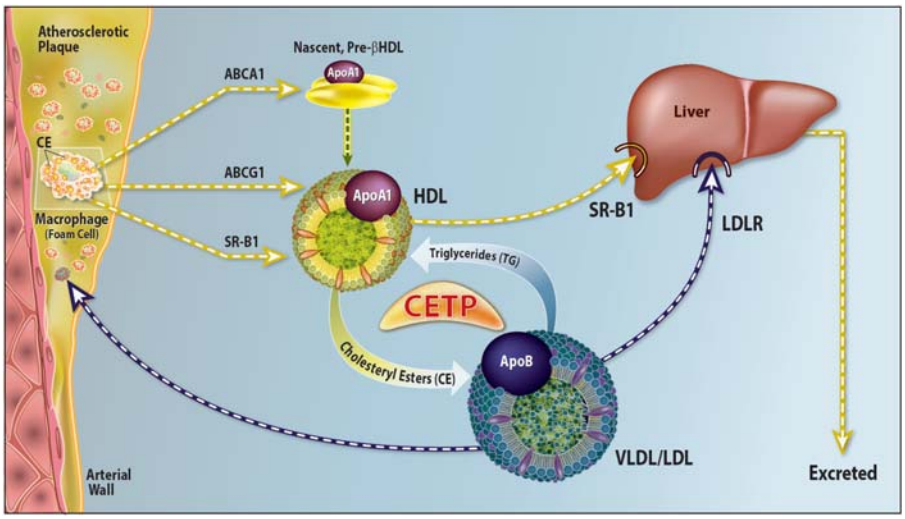

Fig. 1 The role of CETP in reverse cholesterol transport.

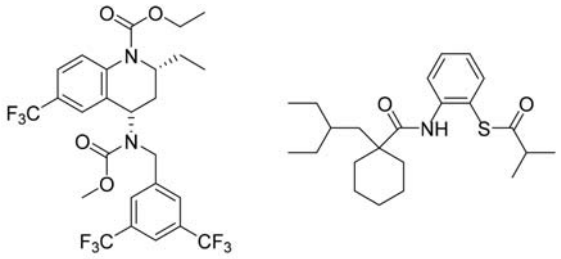

Fig. 2 Early clinical CETP inhibitors

and rabbits.[17] Researchers were further intrigued by the characterization of transgenic C57B6 mice that express cynomolgus[18] or human[19] CETP protein and display a more atherogenic lipoprotein profile, with significantly reduced HDL-C/LDL-C ratio, relative to their wild-type counterparts.

In conjunction with these preclinical genetic studies in the 1990s, several research groups reported the first small molecule CETP inhibitors.[20] The field accelerated considerably in the early 2000s with the publication of potent and reversible CETP inhibitors from Pfizer in the patent literature,[21] followed by their description of these CETP inhibitors, including CP-529,414 (torcetrapib **1**, Fig. 2) in scientific meetings.[22] During the same period, Japan Tobacco had reported less potent covalent thioester-containing CETP inhibitors including JTT-705 (dalcetrapib **2**, Fig. 2).[23] Importantly, Japan Tobacco had also reported the first administration of a CETP inhibitor in healthy volunteers and established that a 4-week treatment with 900 mg JTT-705 resulted in a 37% decrease in CETP activity and a 34% increase in total HDL-C.[24]

Based on preclinical studies and the early clinical data, it became apparent that CETP inhibition could elevate HDL-C levels by an unprecedented magnitude. In order to harness this powerful mechanism, a discovery research team was assembled at Merck that included a significant medicinal chemistry effort. The team initiated a drug discovery program for potent and selective CETP inhibitors in 2002 using a dual approach. They searched for lead compounds that would provide novel chemical matter for SAR investigations, and they examined CETP inhibitors that were being reported in the literature for insights into the pharmacophore properties of the compounds and in vitro pharmacology of the biological pathway.

8.11.2. Structure Activity Studies and the Discovery of Anacetrapib

The search for novel CETP inhibitors was enabled by the development and miniaturization of a fluorescence-based assay system utilizing a BODIPY fluorescence CE label that provided a significantly improved signal-to-noise ratio over prior CETP assays.[25] This optimization allowed the assay to be successfully miniaturized to 3456-well assay plate format, enabling the successful high-throughput screening campaign.

The screen of the entire Merck sample collection resulted in the identification of the 2-aryl benzoxazole **3** (Fig. 3). The compound represented a reasonable starting point for the program with CETP inhibitory potency IC_{50} of 1.1 μM, but it was highly lipophilic and contained undesirable structural characteristics such as an aniline moiety. Remarkably, the chemistry team learned during the course of lead optimization that this compound was not unique to Merck. Benzoxazole **3** had been similarly identified as a screening hit by scientists at Bristol Myers Squibb.[26] This compound was the focus of intense optimization efforts at Merck, which included varying substituents on the benzoxazole ring,[27] phenoxyl replacement,[28,29] the incorporation of structural constraints,[30] and the replacement of the embedded aniline substituent.[31] Each of these lines of investigation led to compounds of moderate intrinsic potency. Additionally, some of the compounds exhibited modest pharmacodynamic (PD) activity in the in vivo assay with the elevation of HDL-C in transgenic mice expressing cynomolgus CETP.[18] However, despite extensive efforts, the lead compounds in this series remained constrained by poor solubility, low oral exposure, and/or prohibitive off-target activity.

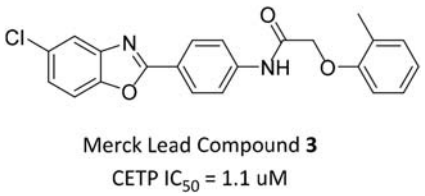

Fig. 3 Merck lead compound for CETP inhibition.

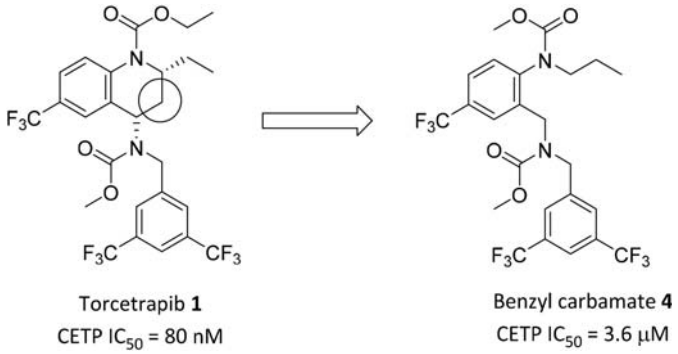

Fig. 4 Arylbenzoxazole and benzyl carbamate CETP leads.

In a parallel effort, attention was focused on other CETP inhibitors that had been reported in the literature, including Pfizer's CETP inhibitor torcetrapib **1** (Fig. 2). The goal was the design of novel, proprietary lead structures with unique properties and fresh directions for further optimization. The chemistry team approached this activity with the hypothesis that the substituents responsible for the potency and efficacy of known CETP inhibitors might be constrained using alternative scaffolds to impart novel and more favorable characteristics. Several lines of research were pursued, taking inspiration from substituents contained in several disclosed CETP inhibitors. The progress in some of these additional investigations has been published.[32] However, the most fruitful line of research would ultimately lead to the discovery of anacetrapib, and that account is presented here in detail.

The early investigations included novel compounds that open the ring of the central dihydroquinoline core of torcetrapib **1**, which yielded a proprietary acyclic scaffold as illustrated in Fig. 4. The resulting benzyl carbamate **4** was approximately 50-fold less potent than torcetrapib in the in vitro CETP inhibition assay, exhibiting an IC_{50} of 3.6 μM. Early SAR efforts were focused on elaboration of the phenyl carbamate and benzylic substituents, and cyclization of the phenyl carbamate. These efforts were largely unsuccessful. In the search for a nontraditional isostere for the phenylcarbamate substituent, the team reasoned that a biphenyl substituent might occupy the same pharmacophore space with readily accessible chemistry. A series of molecules relying on simple Suzuki coupling reactions was designed and executed to interrogate this idea. This work afforded a meaningful advance in the series with the synthesis of the prototype biphenyl CETP inhibitor **5**, which was twofold more potent than the lead carbamate **4** (Fig. 5).[33] Based on this encouraging result, a number of biphenyl analogs were prepared to probe their impact on potency in vitro

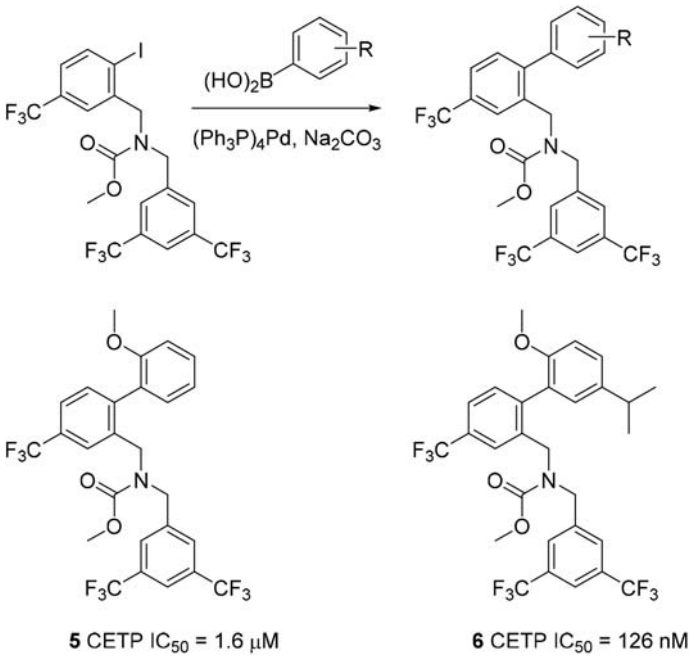

Fig. 5 Prototype biphenyl CETP inhibitors.

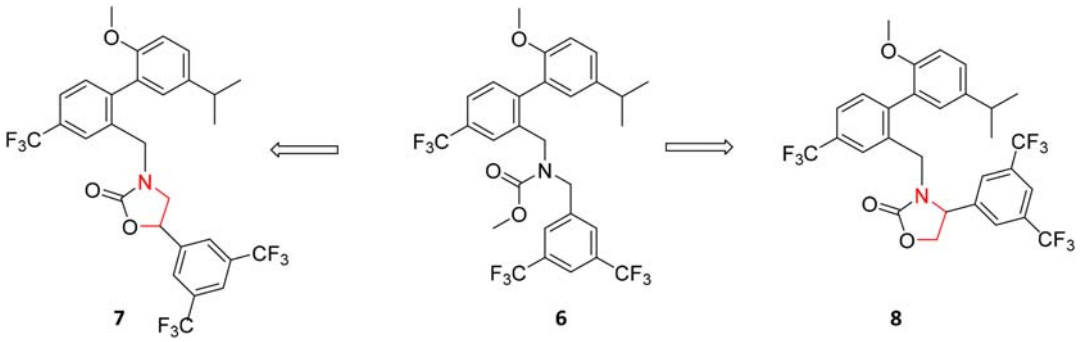

Fig. 6 Proposal of oxazolidinone constrained biphenyl CETP inhibitors.

and in vivo. It quickly became apparent that the optimal substitution pattern on the distal phenyl ring would be 2-methoxy, 5-isopropyl as in **6**, which exhibited another 15-fold improvement in intrinsic CETP inhibitory potency as compared to **5**. Indeed this substitution pattern on the biphenyl substituent would ultimately be retained in anacetrapib.

Compound **6** was an early benchmark compound for the program due to its potent inhibitory activity against CETP ($IC_{50}=126$ nM). It exhibited significant pharmacodynamic (PD) activity in an assay utilizing the CETP B6 transgenic mouse model.[34] The PD assay was optimized using compound **6** to provide maximal HDL-C elevation as a means to standardize in vivo testing of subsequent compounds. The ideal protocol involved use of a 24-h BID dosing regimen. A prebleed plasma sample was taken followed by dosing of the test compound at $t=0$ h, $t=7$ h and a terminal bleed at $t=24$ h to examine the change in HDL-C due to compound administration. The benchmark compound **6** administered at 10 mg kg^{-1} BID exhibited a moderate PD response affording elevation of 10 mg dL^{-1} in HDL-C (+54%). However, significant liabilities with **6** still needed to be addressed. The compound was rapidly metabolized when incubated in liver microsomes from rats or humans, and **6** exhibited low oral bioavailability in mouse pharmacokinetic (PK) studies of $<10\%$.

The chemistry team focused on improving the potency and efficacy of lead candidates, and a number of conformationally constrained analogs were prepared to probe their impact on in vitro and in vivo potency. Among these were the oxazolidinone regioisomers **7** and **8** (Fig. 6).[35] The chemistry team reasoned that a structural constraint around the remaining carbamate functionality might secure the carbamate and bis-trifluoromethyl phenyl substituent in an active conformation for CETP inhibition.

Regioisomer **7** was prepared by reaction of the epoxide **9** with benzylamine **10** to yield the corresponding amino alcohol **11**, which was then cyclized to the corresponding oxazolidinone using triphosgene (Scheme 1). Regioisomer **8** was prepared by alkylation of benzylamine **10** with bromide **12** affording intermediate **13**. This ester was then reduced to the desired amino alcohol **14** with $LiAlH_4$. Cyclization with triphosgene led to the racemic oxazolidinone **8**. Regioisomer **8** was disappointingly weak as an inhibitor of CETP ($IC_{50}=14$ μM). Gratifyingly, regioisomer **7** was a potent CETP inhibitor as the racemic mixture ($IC_{50}=133$ nM). Stereochemistry appeared to be important to potency, as chiral resolution of **7** provided the (4*S*)-oxazolidinone enantiomer ($IC_{50}=93$ nM) and the (4*R*)-oxazolidinone, which afforded significantly weaker inhibitory potency. Unfortunately, the incorporation of an oxazolidinone conformational constraint did not improve the PK of the series, as (*S*)-**7** exhibited low oral bioavailability in mice ($<5\%$) and no significant PD effect in the transgenic mouse assay.

It was possible that further improvements in PK and potency could be achieved from the oxazolidinone scaffold by building additional rotational constraints on the substituents. The chemistry team reasoned that the 5-methylene position on the oxazolidinone ring of **7** could be investigated using commercially available chiral oxazolidinones derived from norephedrine.[36] Indeed, the preparation of **15** and **16** (Table 1) demonstrated that introduction of a stereospecific methyl group on the oxazolidinone ring resulted in substantial boost of in vitro potency for **15** ($IC_{50}=39$ nM). This improvement was also accompanied by increased PD activity in the CETP transgenic mouse model. Interestingly, the majority of the biological activity was found to reside in the (+) *cis* enantiomers (**15** and **22**) rather than the (−) *cis* isomers (**16** and **19**) and *trans* isomers (**17**, **18**, and **21**), which were substantially less active (Table 1). Importantly, this work established that the (*S*)- and (*R*)-stereochemistries at the 4-and 5-positions, respectively, afforded significantly more potent CETP inhibition. Substitution of the oxazolidinone at the 4-position was further investigated by the synthesis of the ethyl derivatives **21** and **22**, the gem-dimethyl derivatives **25** and **26**, and spiro-cyclopropyl derivatives **27** and **28;** however, none of these structural modifications led to further improvements in in vivo activity.

The in vitro potency and PD efficacy of **15** inspired the incorporation of the 3,5-bis-trifluoromethyl substituents on the phenyl ring, as in **7** and **8**. This combination afforded **20**, which exhibited further improvement in intrinsic potency, and provided the highest PD activity that had been observed on the program. The compound had modest mouse PK, with oral bioavailability of 15%, and poor physical properties ($\log D=7.1$), but it also afforded reduced activity on ancillary ion channels (IK_r, $Na_v1.5$, $Ca_v1.2$) and metabolic enzymes. As such, the compound became an important benchmark for the program.

[b] The IV doses were formulated in DMSO:PEG400:water (10:55:35. v/v/v) and injected at 0.6 mg kg^{-1} to male C57BL/6 mice, and were formulated in PEG300:water (70:30, v/v) and injected at 0.4 mg kg^{-1} to male Sprague–Dawley rats and 0.1 mg kg^{-1} to male Beagle dogs and rhesus monkeys. The oral doses were formulated in DMSO:Cremophor:Saline (2:4:94, v/v/v) and given at 2 mg kg^{-1} to mice, and were formulated in Imwitor:Tween80 (1:1, w/w) and given at 1 mg kg^{-1} to rats, dogs, and monkeys.

In-depth characterization of the metabolism of **20** and related analogues revealed a metabolic liability due to glutathione addition to the biphenyl ring. In an interesting development, fluorine substitution of the biphenyl ring reduced glutathione conjugation relative to the des-fluoro analog. Despite the reluctance of the chemists to introduce the tenth fluorine substituent into the lead candidate, this modification was ultimately adopted owing to the decreased propensity of in vivo reactive metabolite formation and a safer projected overall toxicological profile.[37] The addition of the 4-fluoro substituent to **20** afforded the biphenyl oxazolidinone **23**, which was further characterized as a potential development candidate. Compound **23** consistently increased HDL-C levels in a dose-dependent manner at doses of 1, 3, and 10 mg kg^{-1} respectively in the B6-Tg(CETP) mouse model with an effect comparable to or better than torcetrapib (Fig. 7). The pharmacokinetic profile of **23** was characterized in multiple species (Table 2). Although **23** did not provide significantly greater exposure in mice than the des-fluoro analogue **20**, it was possible that the decreased likelihood of a reactive metabolite would improve the long-term safety profile of the compound. The compound exhibited a good pharmacokinetic profile across species with moderate oral bioavailabilities, low clearances, and long half-lives consistent with likely QD dosing in humans. Additional derivatives of the oxazolidinone lead class were thoroughly investigated,[38] but these modifications did not provide compounds superior to **23**.

Based on its favorable in vitro and in vivo properties, compound **23** was selected as a development candidate for the CETP inhibitor program. The compound was subjected to a standard battery of preclinical safety characterization tests, including Ames assays, cardiovascular studies in mice, dogs, and rhesus monkeys, and dose-limiting toxicity studies in mice and rhesus monkeys. The results validated the development potential for compound **23** as a novel agent for lipid therapy. The compound was redesignated as MK-0859 for development, and ultimately designated as anacetrapib.

8.11.3. Early Clinical Evaluation of Anacetrapib

On the basis of the positive preclinical safety and pharmacodynamic evidence developed above, anacetrapib was advanced to phase I clinical studies. The single rising dose studies established the effect of food, age, gender, and obesity on compound exposure and plasma CETP inhibition.[39] Anacetrapib was found to be safe and well tolerated at single doses from 2 to 1000 mg, with nonlinear dose-dependent increase in exposure that was similar among demographic groups. However, systemic exposure was significantly enhanced when anacetrapib was administered with a high-fat meal, affording a 3.7-fold increase in the oral $AUC_{0-\infty}$ of the

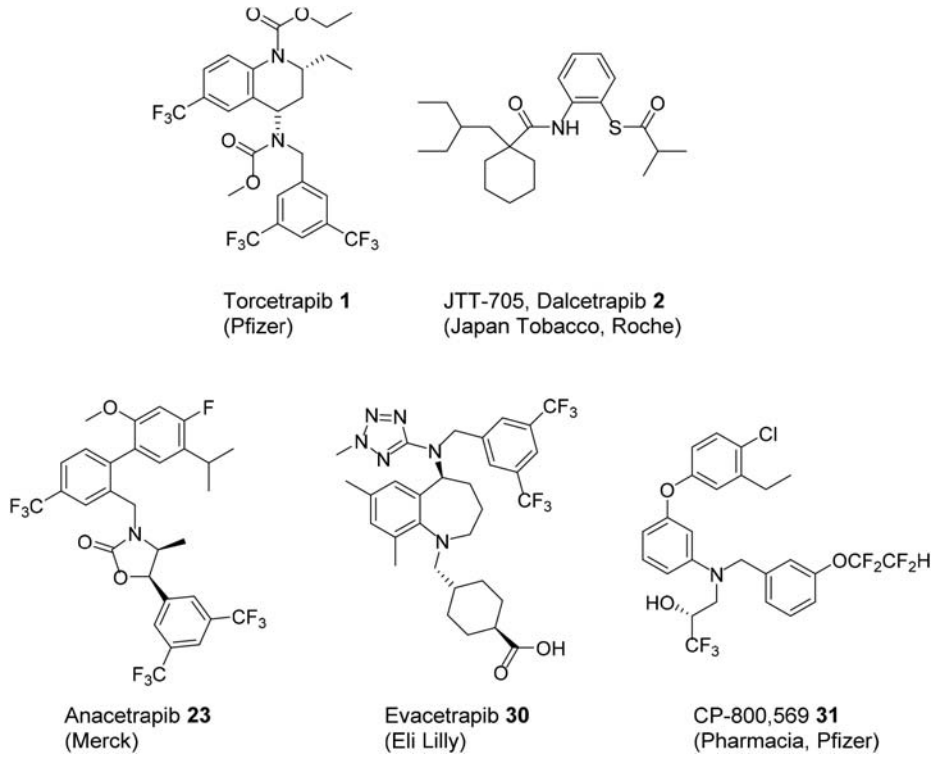

Fig. 8 Clinically investigated CETP inhibitors with disclosed structures.

compound following a 25-mg dose. Furthermore, anacetrapib was found to be primarily metabolized by the CYP3A4 enzyme, as coadministration with the CYP3A inhibitor ketoconazole led to a four- to sixfold increase in exposure.[40]

The multiple ascending dose studies provided further insight on the food effect, as well as the target engagement and pharmacodynamic effects of anacetrapib when administered alone.[41] Healthy volunteers were administered anacetrapib at once daily doses of 20–800 mg for 14 days, and the food effect was found to be more prevalent after steady-state exposure had been achieved (day 7). The oral AUC of a 200-mg dose of the compound increased from 1 to 2 $\mu M \cdot h\ L^{-1}$ following an overnight fast to 38 $\mu M \cdot h\ L^{-1}$ when administered with a high-fat meal. Plasma CETP activity was maximally inhibited to ~90% within 4 h of the first dose, and this inhibition was attenuated by day 14 to 80–85% inhibition at peak and 40–60% inhibition at trough (24 h post dose). The decreased inhibitory activity with anacetrapib over 2 weeks was accompanied by over twofold increase in circulating CETP protein. This study also provided evidence establishing the lipid-altering effects of anacetrapib. Maximal lipid effects were noted following a 200-mg dose after a high-fat meal, afforded a 123% increase in HDL-C and a 56% decrease in LDL-C. Higher doses did not further alter lipids, regardless of the higher exposure achieved. This observation was important to the further study of anacetrapib, in the conclusion that the compound had achieved the maximum possible pharmacodynamic effects available through this mechanism.

The Phase I studies also provided evidence of the biphasic pharmacokinetic elimination profile of anacetrapib. Although the compound exhibited an effective half-life of ~20 h, a longer terminal elimination phase of ~60–80 h was observed. This profile was best described by a two-compartment pharmacokinetic model with clearance occurring from a low-volume central compartment, accompanied by a slower clearance, high volume peripheral compartment.[39]

During the discovery and development program for anacetrapib, the team closely monitored the safety and efficacy profile that was being reported by Pfizer for torcetrapib. Eight-week phase II studies of torcetrapib in a small number of dyslipidemic subjects revealed elevations in both systolic and diastolic blood pressure when torcetrapib was dosed either alone[42] or in addition to atorvastatin.[43] The incidence of blood pressure elevation was low in each of these trials and was not dose-dependent or consistent over time. It was noted with interest, however, that Pfizer advanced to phase III trials testing a submaximal 60 mg fixed dose of torcetrapib with atorvastatin in imaging trials (ILLUSTRATE,[44] RADIANCE 1, and RADIANCE 2[45]) and an outcomes trial (ILLUUMINATE[46]). This dose was below the 90 mg dose that afforded the highest elevation in HDL-C and greatest decrease in LDL-C in their phase II studies, and the Merck team speculated that the lower development dose of torcetrapib may have been selected in an attempt to mitigate blood pressure effects.

Fig. 8 and **Table 3** provide the structures of CETP inhibitors and full names of clinical trials, respectively, mentioned by name in this case history.[47] The chemical structure for TA-8995 (Dezima, Amgen) (**Table 4**) has not yet been disclosed.

As a result of the reported observations with torcetrapib, a clinical trial was initiated in Jul., 2006 with anacetrapib to investigate the effect on 24-h ambulatory blood pressure in healthy individuals.[48] The results from this study established that anacetrapib had

Death or major CV event	27 (3.3)	43 (5.3)

no significant effect on ambulatory blood pressure as compared to placebo. This supported the development team's conclusion that the blood pressure effects observed with torcetrapib in human subjects and preclinical species were compound-specific to torcetrapib, and not mediated by CETP inhibition.

Concurrent with the ambulatory blood pressure study outlined above, Merck launched a phase II placebo-controlled dose ranging study of anacetrapib administered as monotherapy and coadministered with atorvastatin in 589 patients with primary hypercholesterolemia or mixed hyperlipidemia.[49] In this 8-week study, patients were randomized to receive either placebo or daily doses of anacetrapib at 10, 40, 150, or 300 mg, with or without 20 mg of atorvastatin. The study was designed to provide the critical pharmacodynamic data needed to perform a large cardiovascular outcomes trial that would be required to establish the benefit of CETP inhibitors in addition to statins for the management of cardiovascular risk. The final patient completed this study on Friday, Dec. 1, 2006, providing a complete and closed data set for analysis of primary and secondary endpoints. The timing and duration of this study would turn out to be a remarkable and fortuitous coincidence for Merck.

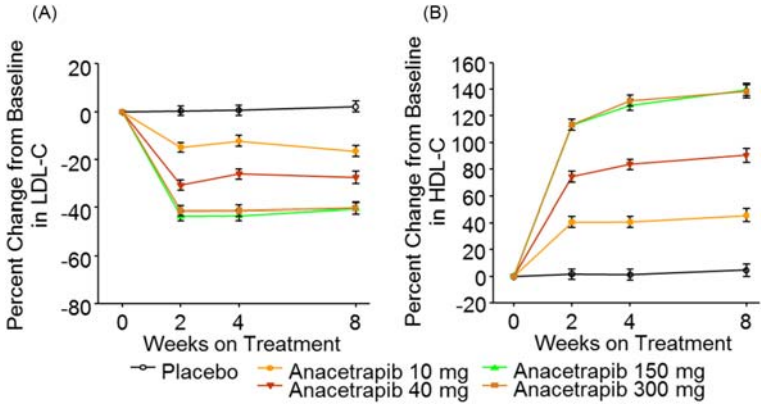

Fig. 9 Changes from baseline in LDL-C (A) or HDL-C (B) over time for anacetrapib administration at the indicated dose versus placebo.

8.11.4 Torcetrapib Termination and the Safety Analysis of CETP Inhibition

On Saturday, Dec. 2, 2006, Pfizer announced that the ILLUMINATE trial of torcetrapib was being halted prematurely for safety reasons by recommendation from the independent data and safety monitoring board (DSMB).[46] The ILLUMINATE trial had enrolled over 15,000 patients with a history of cardiovascular disease, with half receiving an optimized dose of atorvastatin (10–80 mg) and half receiving atorvastatin plus 60 mg of torcetrapib. The data monitoring board had noted a significant 25% increased risk of cardiovascular events and 58% increase in death from any cause in patients receiving torcetrapib as compared to placebo. The announced termination of the ILLUMINATE trial caused an immediate precautionary suspension of further developmental activities for anacetrapib until significant additional data could be gathered. The Merck team sought to fully examine the data from the ILLUMINATE trial, to analyze the internal anacetrapib clinical data for any similar safety signal, to examine both compounds extensively in preclinical safety models to differentiate their profile, and to develop additional safety steps in the development plan to proceed with anacetrapib clinical investigation.

In light of the torcetrapib termination, the efficacy and safety data from the anacetrapib phase II study outlined above were carefully analyzed. The results supported the further clinical development of the compound.[49] Following 8 weeks of drug administration as monotherapy, anacetrapib resulted in a dose-dependent increase in HDL-C of maximally 139% and a maximal reduction in LDL-C of 40% (Fig. 9). The results from coadministration with 20 mg of atorvastatin afforded a similar maximal elevation in HDL-C and an additive reduction in LDL-C to 70% reduction as compared to baseline. Additional dose-related effects included a reduction in apolipoprotein B ($\leq$30%), an increase in apolipoprotein A1 ($\leq$47%), an increase in apolipoprotein E ($\leq$40%), reduction in lipoprotein(a) ($\leq$50%), and no change in total cholesterol, total triglycerides, or c-reactive protein. These plasma biomarkers were further supportive of the potential for anacetrapib to provide an antiatherogenic effect. As is evident from Fig. 9, the efficacy was similar for the 150 mg and 300 mg doses, indicating that maximal efficacy could be achieved following $\leq$150 mg dose of the compound. The maximal changes in lipid profile were greater than those achieved with torcetrapib (HDL-C = +72%, LDL-C = −25% at 60 mg)[46] or dalcetrapib (JTT-705) (HDL-C = +30–40% at 600 mg)[24] indicating that greater CETP inhibition had been achieved with anacetrapib than in comparator clinical studies. Importantly, anacetrapib was safe and well tolerated at all doses. The data demonstrated that anacetrapib had no effect on blood pressure while achieving a CETP-mediated lipid response greater than torcetrapib.

8.11.5 Further Preclinical Safety Evaluation of CETP Inhibition

The clinical safety findings with torcetrapib inspired the research team to a deeper preclinical safety evaluation of CETP inhibition. The details from the ILLUMINATE trial of suggested several avenues to investigate the safety pharmacology of torcetrapib as compared to other CETP inhibitors. The ILLUMINATE researchers noted that after 12 months of treatment with torcetrapib, patients exhibited decreased plasma potassium, increased sodium, and increased bicarbonate as compared to the placebo group.[46] This cluster of biomarkers suggested to the clinical researchers that a potential mineralocorticoid excess was associated with the blood pressure elevation. A post hoc evaluation of patient plasma from the ILLUMINATE trial supported this hypothesis, showing increased aldosterone levels in the torcetrapib group following 3 months of dosing with torcetrapib. The findings of elevated plasma aldosterone and electrolyte changes were further supported by pooled analysis of plasma from the RADIANCE imaging trials of torcetrapib.[50]

Biopharmaceutical research teams from several organizations began intensive study of torcetrapib to identify the mechanism of ancillary pharmacology, and these studies have been reviewed.[51] A research team at Merck embarked on a significant preclinical safety evaluation of several CETP inhibitors to more fully derisk the mechanism of CETP inhibition before further clinical

progression of this target. The Merck team focused first on the significant increase in systolic blood pressure in the ILLUMINATE trial (~4 mmHg) among patients taking torcetrapib as compared to placebo.[46] In preclinical studies, torcetrapib infusion produced a significant elevation of mean arterial pressure in both B6-CETP transgenic mice and wild-type B6 mice that lack CETP.[52] Additionally, torcetrapib was found to increase mean arterial pressure in anesthetized rats, anesthetized dogs, and conscious rhesus monkeys. These experiments indicated that the blood pressure effects of torcetrapib were evident in the absence of circulating CETP (B6 mice and rats) or in the presence of CETP (B6-CETP mice, dogs, and rhesus monkeys), and therefore are not mediated by CETP inhibition. None of this ancillary pharmacology was exhibited by anacetrapib.

The possible mechanism of the blood pressure effect of torcetrapib was also investigated in these experiments.[52] Torcetrapib had no direct effect on isolated rat vascular smooth muscle, eliminating vascular contraction as a likely cause. The potential for a central nervous system mechanism was also eliminated, as torcetrapib produced an identical increase in blood pressure in both control and pithed rats. The involvement of the sympathetic nervous system was eliminated, as mean arterial pressure elevation by torcetrapib was not affected by coadministration with an angiotensin II blocker or a mixed endothelin A/B antagonist. The team did note, however, that an intravenous infusion of torcetrapib to conscious rats produced a significant elevation in the plasma of the adrenal stress hormones aldosterone and corticosterone. This effect was not observed with a similar infusion of anacetrapib. Notably, the blood pressure effect of torcetrapib was not evident in adrenalectomized rats, indicating an adrenal origin for the mean arterial pressure increase. However, blood pressure elevation by torcetrapib in rats remained during coadministration of an α_1-adrenoreceptor antagonist or a β_1-adrenoreceptor antagonist. Additionally, the torcetrapib-mediated aldosterone and corticosterone release was prevented by coadministration with a 3β-hydroxysteroid dehydrogenase inhibitor, but the mean arterial pressure increase was not affected. These results indicated that the blood pressure increase due to torcetrapib is related to the adrenal gland, but not in direct response to aldosterone or corticosterone release.

The unique preclinical toxicity profile of torcetrapib was further validated by elegant pharmacology experiments from several teams that included scientists from Pfizer, Roche, Eli Lilly, Abbott, Johnson and Johnson, and numerous academic institutions. Particularly noteworthy among these studies was careful ancillary SAR experiments of the torcetrapib lead class reported by scientists at Pfizer.[53,54] Their studies revealed that the reversal of a single (2*S*)-ethyl stereocenter in torcetrapib to the (2*R*)-stereochemistry eliminated the BP elevation in rats in the dihydroquinoline series.[55] The results of these collective investigations by several research groups have recently been reviewed.[51] The experiments conclusively established that the preclinical BP elevation and hormone release associated with torcetrapib were not associated with the mechanism of CETP inhibition, and were not shared by structurally differentiated CETP inhibitors such as anacetrapib.

8.11.6 Return to the Clinic: The *DEFINE* Study

The preclinical and clinical safety biomarkers discovered for torcetrapib were not evident in the analysis of clinical patient samples from other CETP inhibitors. The phase II study of anacetrapib showed no changes in electrolytes or aldosterone following 8 weeks of dosing up to 300 mg.[49] Similarly, the reported studies of dalcetrapib indicated no change in electrolytes or aldosterone following 48 weeks of dosing at up to 900 mg.[56]

Based on the analysis of the clinical biomarkers and safety data from the anacetrapib trials, along with extensive preclinical safety assessment investigations, Merck proceeded with the clinical development program of anacetrapib. The development team had achieved full confidence that anacetrapib lacked the blood pressure effects of torcetrapib, and that it did not induce the changes in plasma aldosterone and serum electrolytes that had been identified in post hoc analyses of plasma from torcetrapib clinical studies. In light of these positive comparator biomarker data, the development team designed a study to establish with predictive probability that treatment with anacetrapib is not associated with the rate of adverse cardiovascular effects reported with torcetrapib.

Since maximal lipid-altering effects were achieved at submaximal exposure of anacetrapib, it was important to determine the minimum dose required for maximal efficacy. The development team utilized a population pharmacokinetics model-based approach to determine the appropriate dose for phase III development studies.[57] There were multiple variables that had been identified in the phase I and phase II trials that were incorporated into the pharmacodynamic model of anacetrapib. These included nonlinear pharmacokinetics, accumulation to steady-state exposure, variable exposure due to fasting, low-fat or high-fat meal consumption, the potential for differential exposure in healthy volunteers versus dyslipidemic patients, and the different formulations utilized in the early clinical studies. Additionally, the complex two-compartment elimination profile was incorporated into the model to calculate the degree of plasma CETP activity at both peak and trough drug concentrations that would afford the maximal response in HDL-C and LDL-C. This complex model was then utilized in computational clinical trial simulations to select the final dose and formulation for phase III development and registration. The simulation analysis resulted in a prediction that a 100-mg dose formulated as a hot-melt extrusion would provide the minimum dose necessary to provide the maximum pharmacologic effect. These recommendations were utilized in the subsequent phase III studies.

The development team sought to determine the likelihood that the 25% increase in CV events observed in the ILLUMINATE trial of torcetrapib would not be observed in larger patient populations using anacetrapib therapy. The DEFINE trial (**Table 1**) was designed as an extensive phase III safety study, and was significantly overpowered to establish lipid effects.[58] This study randomized over 1600 patients who had a history or risk of coronary heart disease and who were receiving statin treatment to maintain their LDL-C levels between 50–100 mg dL^{-1} and with HDL-C levels <60 mg dL^{-1}. Study subjects were administered 100 mg of anacetrapib or placebo for 18 months, followed by a 3-month study follow-up. The primary endpoints included both LDL-C reduction

from baseline and prespecified clinical safety parameters, such as cardiovascular death, myocardial infarction, stroke, and hospitalization for unstable angina. Only a small number of cardiovascular events were anticipated from this sample size and study duration, but the DEFINE study was powered using a Bayesian probability approach to provide statistical confidence that a cardiovascular safety signal similar to that seen with the torcetrapib ILLUMINATE trial would not likely be observed in larger anacetrapib outcomes studies.

The DEFINE trial achieved its primary endpoints.[59] In the final analysis of 1623 patients, a 100 mg dose led to an increase of 138% in circulating HDL-C and a reduction of almost 40% in LDL-C beyond that achieved with statin therapy by 24 weeks. This is precisely the degree of lipid modification that was predicted by the computational modeling effort outlined previously.[57] These lipid effects were sustained throughout the 18-month treatment period. It must be noted that the LDL-C levels reported for the DEFINE study were derived using the Friedewald equation, which is commonly used in clinical practice and relies on an assumption of the ratio of TG to very low-density cholesterol (VDL-C).[60] This ratio is actually altered during the course of treatment with a CETP inhibitor, as transfer of TG from LDL fractions is inhibited. Indeed, a post hoc analysis of a subset of serum samples from DEFINE revealed that the actual magnitude of LDL-C reduction may have been closer to 25–35% when samples were reanalyzed using the more resource intensive β-quantification method.[61]

Importantly, the DEFINE study established the safety of anacetrapib therapy, and by inference the safety of aggressive CETP inhibition. In contrast to torcetrapib, anacetrapib had no effect on plasma electrolyte levels, circulating aldosterone levels, or blood pressure. The prespecified adjudicated clinical safety endpoints of death or major CV events are provided in **Table 4**. These endpoints were observed in 16 patients receiving anacetrapib and in 21 patients receiving placebo. Based on the Bayesian analysis prespecified for this trial, the results provided a 94% predictive probability of dismissing the likelihood of a 25% (torcetrapib-like) increase in CV events in larger outcomes studies with anacetrapib.

Further extension of the DEFINE trial provided additional information on the efficacy, safety, and pharmacokinetics of anacetrapib. A 2-year extension study was completed for 803 patients from the DEFINE study ($n=370$ on anacetrapib, $n=433$ on placebo).[62] This extension provided similar exposure and efficacy to the treatment period of the DEFINE trial, and further validated the safety of exposure to anacetrapib for up to 58 months. Additionally, a wash-out study was completed to determine the residual levels of anacetrapib in plasma, as well as residual effects on lipid parameters.[63] At 12 weeks following the last dose of anacetrapib, the mean plasma concentration was approximately 45% of the mean trough concentration while on treatment. There was continued evidence of anacetrapib pharmacodynamic effect on lipid parameters at the end of the wash-out period as well, with a mean 20% reduction from baseline LDL-C (Friedewald equation method) and 79% elevation in HDL-C. A further evaluation of patients from earlier phase II studies of anacetrapib found that residual drug levels of 7–8% of mean trough concentration could still be detected in plasma up to 4 years following the cessation of dosing of anacetrapib. Therefore, it is apparent that anacetrapib does have complex elimination kinetics, with a terminal half-life for anacetrapib that is significantly longer than was estimated from earlier phase I studies.

8.11.7 Adipose Distribution Studies with Anacetrapib

It was evident from the residual elimination data from the DEFINE trial that additional preclinical and clinical characterization of anacetrapib biodistribution would be helpful to further understand the half-life of anacetrapib, and so an effort was undertaken to fully characterize the disposition of the compound in vivo. Anacetrapib is a poly-fluorinated lipophilic compound ($\log D=7.1$), raising the possibility that the compound accumulates in adipose tissue during the treatment phase with slow release following the cessation of dosing. Additionally, CETP itself could function as a depot for bound anacetrapib, as CETP is expressed in multiple tissues including adipose.[64] To fully investigate this distribution, the preclinical research team performed a dose-accumulation and wash-out study in four groups of mice: wild type (WT) lean and WT with diet-induced obesity (DIO) mice that naturally lack CETP, and transgenic NFR-lean and NFR-DIO mice that express human CETP.[65] Anacetrapib exposure and distribution were analyzed during 6 weeks of dosing at 10 mg kg^{-1} in feed, to approximate the human exposure from the daily 100 mg dose, and during a 35-week washout period. The study confirmed the central role of white adipose tissue in the accumulation and retention of anacetrapib, as well as the contribution of this tissue to the long terminal elimination phase in DIO mice. CETP expression afforded higher blood concentration during the treatment phase of the study, but had a diminished impact on drug retention during the elimination phase. There was significantly lower accumulation of anacetrapib in brown adipose tissue, and the compound did not exhibit appreciable accumulation in the mouse brain.

The clinical team similarly examined adipose biopsy tissue from healthy human subjects who received 100 mg day^{-1} for up to 16 weeks, followed by a 52-week recovery phase.[66] During and after the dosing regimen, blood and adipose tissue were analyzed for concentrations of anacetrapib. The concentration of anacetrapib in plasma reached a plateau by ~4 weeks of dosing, but the concentration in adipose tissue continued to accumulate to levels ~64-fold higher than plasma by 16 weeks of dosing. During the recovery phase, concentrations of anacetrapib in adipose tissue remain stable for at least 1 year after cessation of dosing. These studies established that anacetrapib accumulates in adipose tissue, with the slow release from adipose hypothesized to contribute to the observed long terminal plasma half-life. Similar to all other clinical studies of anacetrapib, there were no safety findings of note in this investigation.

8.11.8 Preclinical Efficacy Support for Reverse Cholesterol Transport

The DEFINE trial had firmly established the safety of CETP inhibition by anacetrapib, and had affirmed the pharmacodynamic effect of CETP inhibition on HDL-C and LDL-C. However, the clinical team remained intrigued by the lack of meaningful benefit of torcetrapib in the ILLUMINATE trial despite achieving robust lipid effects. It was possible that the beneficial effect of torcetrapib therapy was overwhelmed by ancillary safety pharmacology. Post hoc analyses of phase III trials of torcetrapib provided some supporting evidence for this hypothesis. The imaging trials using intravascular ultrasonography did not meet the primary endpoints of reduced progression in the change of atheroma volume[67] (ILLUSTRATE trial) or reduced yearly rate of change of carotid intima-media thickness (RADIANCE 1 trial[68] or RADIANCE 2[69] trial). However, a post hoc analysis of the ILLUSTRATE trial results revealed a possible signal of efficacy. An inverse relationship was observed between the increase in HDL-C due to torcetrapib administration, and the progression of atherosclerosis. Patients in the highest quartile of HDL-C elevation achieved an actual regression of percent atheroma volume as compared to continued progression for other quartiles in the torcetrapib group and the entire placebo group.[70] While this observation was encouraging, it was not definitive.

An alternative hypothesis for the lack of clinical efficacy of torcetrapib continues to be investigated, which is that the subfraction of HDL that is enhanced by CETP inhibition is less effective as a vehicle for reverse cholesterol transport than the HDL produced by other means such as lifestyle changes (weight loss, increased exercise, dietary restrictions, and smoking cessation). As illustrated in Fig. 1, CETP mediates the transfer of CE and TG between HDL and VLDL/LDL particles (heterotypic transfer). However, it may also mediate the transfer of CE and TG among the various subfractions of HDL (homotypic transfer). These HDL subfractions include (in increasing size) preβ-HDL, HDL_3, HDL_2, and apoE-rich HDL, as illustrated in Fig. 10. By inhibiting homotypic transfer of CE and TG, CETP inhibition would alter the relative population of these HDL subclasses. In this way, it would be possible that CETP inhibitors promote the formation of HDL particles that are suboptimal for reverse cholesterol transport. Indeed, in an early phase II trial, the addition of torcetrapib (120 mg QD for 4 weeks) to atorvastatin therapy resulted in almost 10-fold higher increase in larger HDL_2-C than smaller HDL_3-C.[71] The distinctions among HDL subclasses are not trivial. Different subclasses have been proposed to have differing correlative benefit for protection against coronary heart disease, although conflicting results have been found for the relative importance of HDL_3-C and HDL_2-C from prospective studies.[72] As such, a hypothesis has developed that the magnitude of HDL-C elevation is not as important as the efficiency of the resultant HDL in promoting cholesterol efflux capacity through reverse cholesterol transport. The importance of cholesterol efflux capacity was recently supported in an analysis of the Dallas Heart Study.[73] In this prospective study of almost 3000 adults over 9 years, subjects in the highest quartile of cholesterol efflux capacity maintained a 67% reduction in cardiovascular risk over the lowest quartile, whereas overall HDL-C level was not associated with cardiovascular risk.

In light of this hypothesis, biopharmaceutical researchers including those at Merck and Roche embarked on a major effort to investigate the impact of CETP inhibitors on cholesterol efflux, and whether different inhibitors had unique attributes for reverse cholesterol transport. Among the CETP inhibitors investigated in the clinic, dalcetrapib from Roche has a unique biochemical mechanism of action. Dalcetrapib inhibits CETP by forming a labile covalent disulfide bond with Cys13 of the protein.[74] Dalcetrapib

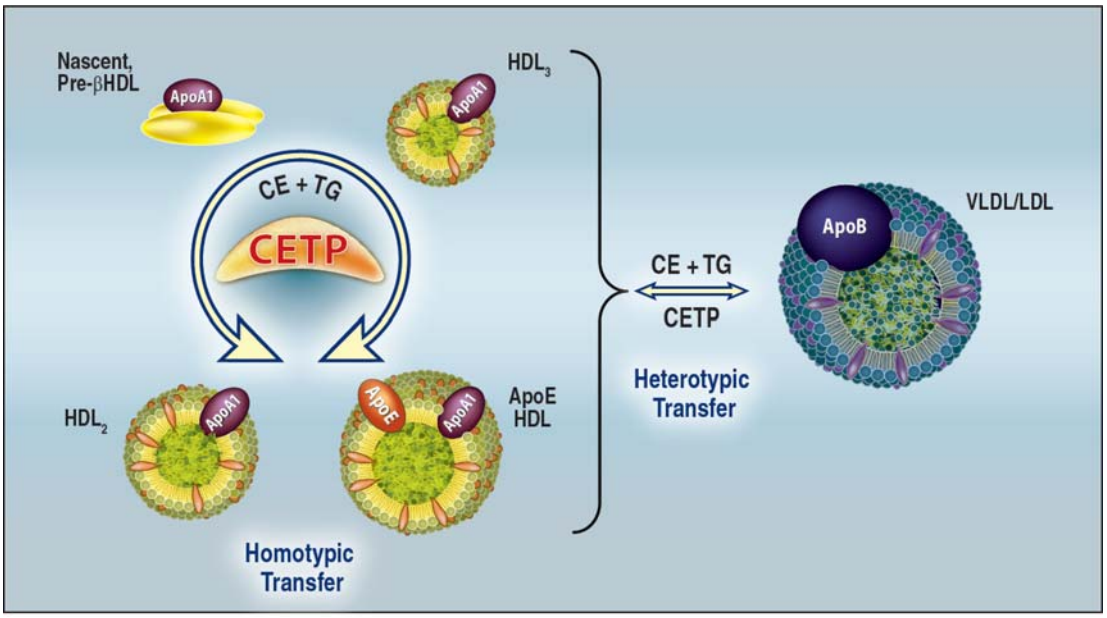

Fig. 10 Homotypic and heterotypic transfer of CE and TG by CETP.

inhibition is time dependent with the intrinsic potency (IC_{50}) increasing 26-fold following a 24-h incubation of dalcetrapib with CETP, while anacetrapib and torcetrapib are reversible and show no such time dependence.[75]

Scientists at both Roche and Merck intensively investigated whether the covalent modification of CETP by dalcetrapib conferred unique efficacy as compared to the reversible CETP inhibitors anacetrapib and torcetrapib. These studies lead to divergent and in some cases contradictory results. Functionally, the three compounds share several features of in vitro pharmacology.[75] All three of the compounds inhibited the transfer of both CE and TG between HDL and LDL particles, and all three compounds induced the formation of a stable CETP–HDL complex in vitro. All three compounds were found to displace radiolabeled anacetrapib or torcetrapib with binding potencies equivalent to their functional potencies, indicating a common active site for inhibition. Subsequently, the X-ray crystal structure of the CETP–torcetrapib complex was solved by scientists at Pfizer, confirming the binding of torcetrapib in the direct vicinity of the Cys13 residue of CETP required for dalcetrapib inhibition.[76] This observation provided evidence of a conserved binding site in CETP for dalcetrapib and torcetrapib, and by inference anacetrapib.

However, the nature of the functional inhibition may be different between dalcetrapib and anacetrapib. Scientists at Roche were the first to propose this distinction with in vitro studies measuring the transfer of [^{3}H]cholesteryl ester between HDL subfractions.[77] They found that anacetrapib and torcetrapib inhibited the transfer of CE from HDL_3-C to HDL_2-C, whereas dalcetrapib did not inhibit homotypic transfer of CE among HDL subfractions. This distinction was not observed by the Merck team, who found that all three compounds inhibited homotypic transfer from HDL_3-C to HDL_2-C in vitro.[78] The Roche team also found that incubation of human plasma with anacetrapib and torcetrapib actually decreased the level of preβ-HDL at concentrations of 1–10 μM, whereas incubation with dalcetrapib increased the level of preβ-HDL (at 10 μM only).[77] It is generally recognized that small preβ-HDL is critical as an early component of reverse cholesterol transport.[79] These distinctions led the Roche team to classify dalcetrapib as a CETP modulator, as opposed to the CETP inhibitors anacetrapib and torcetrapib.

The Merck team further investigated the inhibition of HDL_3-C to HDL_2-C homotypic transfer by anacetrapib both in vitro (human plasma) and in vivo in NFR-CETP transgenic mice.[78] Both anacetrapib and dalcetrapib were shown to moderately inhibit homotypic transfer of [^{3}H]cholesterol from HDL_3 to HDL_2 in vitro, with maximal inhibition of $\leq$50% despite further increases in inhibitor concentration. In vivo, transgenic mice were treated with anacetrapib at 100 mg kg^{-1} day^{-1} for 5 days, then injected with [$^2H_6$]-cholesterol labeled HDL_3. The radiolabeled cholesterol appeared almost immediately in HDL_2, similar to vehicle-treated mice during the first hour, and then accumulated more rapidly in HDL_2 than vehicle-treated mice over the next six hours, in direct contrast to the in vitro studies. The appearance of labeled cholesterol was significantly reduced in LDL or VLDL particles ($\leq$30% in anacetrapib-treated mice as compared to vehicle). The experiments provided a puzzling contrast between the in vitro inhibition of homotypic transfer and the in vivo appearance of CE homotypic transfer. It remains possible that CETP inhibition blocks homotypic transfer of CE among HDL subfractions in vivo, and that alternate mechanisms are available for HDL remodeling such as particle maturation from HDL_3 to HDL_2.

The researchers at Roche also studied the in vivo effects of the three inhibitors in normolipidemic (lean) golden Syrian hamsters, which naturally express CETP.[77] Following a 7-day treatment of dalcetrapib (100 mg kg^{-1} BID), torcetrapib (30 mg kg^{-1} QD) or anacetrapib (30 mg kg^{-1} QD), the hamsters were injected with [^{3}H]cholesterol-labeled macrophages. The fecal excretion of [^{3}H] total sterols was monitored for the next ten days to measure the efficiency of reverse cholesterol transport from macrophages to feces for the radiolabeled cholesterol. The Roche team found that dalcetrapib and torcetrapib significantly increased fecal excretion of [^{3}H]sterols, whereas anacetrapib afforded no significant effect despite affording the largest relative increase in HDL-C levels. The authors proposed that the clinical outcome of a CETP modulator such as dalcetrapib may be distinct from CETP inhibitors such as anacetrapib in the reduction of CVD risk, and that the relative magnitude of overall HDL-C elevation between the compounds may not be fully relevant for the prediction of clinical efficacy.

To the contrary, the Merck team subsequently demonstrated effective anacetrapib-mediated reverse cholesterol transport in golden Syrian hamsters that were made dyslipidemic by a high-fat diet.[80] Following treatment with anacetrapib for 14 days in feed (60 mg kg^{-1}), [^{3}H]cholesterol-loaded macrophages were injected into the hamsters and fecal excretion was monitored for 48 h. The team found significant increases in [^{3}H]cholesterol by 90% and [^{3}H]bile acids by 57% relative to vehicle. The difference between the Roche and Merck observations with anacetrapib could be ascribed to important methodological differences in the experiments, including the use of normolipidemic versus dyslipidemic hamsters, differences in dose and duration of anacetrapib treatment, and differences in collection period for feces. In fact, a subsequent study of anacetrapib and dalcetrapib in hamsters indicated that this was indeed the case. At doses that provide equal levels of CETP inhibition in vivo, only dalcetrapib stimulated HDL-derived cholesterol fecal excretion in normolipidemic hamsters, whereas only anacetrapib promoted macrophage-derived cholesterol fecal excretion in dyslipidemic hamsters.[81]

Similar to the Roche investigators, the Merck team found that anacetrapib inhibited the generation of preβ-HDL when incubated in human plasma in vitro, whereas dalcetrapib did not inhibit or increase preβ-HDL (up to 10 μM).[82] However, the effect was quite different in vivo. In dyslipidemic golden Syrian hamsters, treatment with anacetrapib for 14 days (60 mg kg^{-1} QD) showed a significant elevation of preβ-HDL, whereas treatment with dalcetrapib (200 mg kg^{-1} BID) produced no such elevation. The divergent results between the two compounds might be ascribed to differences in intrinsic potency, but the results indicate that CETP inhibition in vivo does not decrease levels of preβ-HDL, at least in dyslipidemic hamsters.

The multiple complex experiments outlined above illustrate the sophisticated preclinical tools that are used for the evaluation of CETP-mediated reverse cholesterol transport, as well as the difficulty in translating the results to human cardiovascular disease. In order to identify the optimal translational pharmacology system for lipid research, the Merck researchers coordinated an exhaustive lipidomics analysis of 24 experimental pharmacology models.[83] By examining five primate species (including humans), six mouse

strains, and six other nonprimate species, the team found that nonhuman primate models demonstrated the closest overall match to dyslipidemic humans. Based on these findings, anacetrapib was examined in lean rhesus macaques at a dose of 150 mg kg^{-1} for 10 days.[84] The compound afforded similar effects on plasma lipids as those found clinically in humans, with an elevation of HDL-C of 110% and reduction of LDL-C of 65–79%. The rhesus studies have also featured analysis of the inhibition of TG transfer as well as CE by anacetrapib.[85] This species may enable preclinical RCT experiments that are more fully translational to clinical observations.

A single clinical trial has examined the effect of CETP inhibition on cholesterol efflux. The dal-ACUTE study administered 600 mg of dalcetrapib or placebo to patients within 1 week of acute coronary syndrome (myocardial infarction or unstable angina) for 24 weeks of treatment.[86] The researchers found that dalcetrapib elevated HDL-C by 32% with no significant change in LDL-C. An ex vivo analysis of patient plasma revealed no change in preβ-HDL. Notably, serum from patients in the treatment group exhibited a significant 9.5% improvement in ex vivo capacity for cholesterol efflux capacity a macrophage-derived cell line assay.[87] Whether this improvement was sufficient to improve cardiac outcome would be independently determined in the dal-OUTCOMES study.

8.11.9 The Re-Emergent Importance of CETP Inhibitor-Induced Lowering of LDL-C

There remained an intriguing aspect of dalcetrapib, which was the only clinically investigated CETP inhibitor to afford elevation of HDL-C with no significant reduction of LDL-C. Before proceeding with a large-scale outcomes study for anacetrapib, the Merck team examined the clinical data supporting a hypothesis that HDL-C and LDL-C levels might be independently modified by different CETP inhibitors.[88] An analysis of all of the published phase II data for monotherapy with CETP inhibitors suggests that a common functional mechanism is operative for all CETP inhibitors. A graphical representation of the phase II studies for anacetrapib (Merck),[49] evacetrapib (Eli Lilly),[89] CP-800,569 (Pfizer),[90] Torcetrapib (Pfizer),[91] dalcetrapib (Roche),[92] and including the recently reported data from the TULIP trial for TA-8995 (Dezima/Amgen)[93] is provided in Fig. 11. It is apparent from this graphical examination of the clinical data that all CETP inhibitors have similar relative effects on the elevation of circulating HDL-C and reduction of circulating LDL-C. This linear relationship in pharmacodynamic effect supports a common pharmacologic mechanism among the CETP inhibitors, including anacetrapib and dalcetrapib, and indicates they do not afford unique profiles for HDL-C effects or LDL-C effects.

An emergent line of research into the effects of CETP inhibition regards the importance of inhibitor-mediated lowering of LDL-C, and the decreased number of LDL particles as an additional contributor to cardiovascular disease risk reduction. Treatment with anacetrapib changes the distribution balance of CE from LDL to HDL particles (Fig. 1), which is hypothesized to have an atheroprotective effect. However, anacetrapib has recently been shown to afford a significant decrease in the number of LDL particles in both healthy individuals and dyslipidemic patients, as measured by plasma ApoB protein concentration.[94,95] The clinical team further investigated the kinetics of ApoB clearance in dyslipidemic patients treated with anacetrapib either with or without atorvastatin for 4 weeks.[96] Anacetrapib was found to reduce the ApoB pool by significantly increasing the clearance rate of LDL-ApoB without affecting the production rate.

8.11.10 Clinical Outcomes Trials of CETP Inhibitors: The *REVEAL* Study

The clinical safety profile established by the DEFINE study for anacetrapib indicated that ancillary safety pharmacology would not hinder the analysis of clinical outcomes data. Furthermore, the preclinical efficacy experiments performed on anacetrapib and other CETP inhibitors supported the likelihood that CETP inhibition would facilitate reverse cholesterol transport, which may provide an overall antiatherogenic effect. However, it was clear following the experience with Pfizer's torcetrapib in the ILLUMINATE trial that

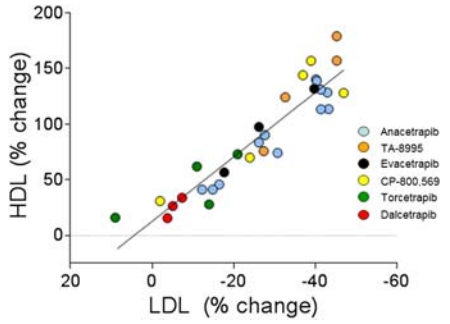

Fig. 11 Comparison of the relative low- and high-density lipoprotein cholesterol changes observed in phase II studies with CETP inhibitors at multiple dose levels for each compound. Adapted with permission from Johns, D. G.; Duffy, J. L.; Fisher, T.; Hubbard, B. K.; Forrest, M. J. On- and Off-Target Pharmacology of Torcetrapib: Current Understanding and Implications for the Structure Activity Relationships (SAR), Discovery and Development of Cholesteryl Ester Transfer Protein (CETP) Inhibitors. *Drugs* **2012**, *72*, 491–507.

a large outcomes study would be required to establish a significant reduction in cardiovascular disease risk for CETP inhibitors to provide value.

As the development team contemplated the design of the outcomes study for anacetrapib, they were aware that dalcetrapib was under broad investigation by Roche in several late-stage clinical trials listed in Table 3 and known collectively as the dal-HEART (DALcetrapib HDL Evaluation, Atherosclerosis and Reverse cholesterol Transport) program. The largest of these, the dal-OUTCOMES trial, initiated in April, 2008 and was designed to randomize $\geq$15,600 patients who had been hospitalized for acute coronary syndrome within 4–12 weeks prior to initiating treatment.[97] Patients received either placebo or 600 mg dalcetrapib for a minimum of 2 years, with the primary efficacy measurement as first occurrence to acute myocardial infarction, unstable angina requiring hospitalization, atherothrombotic stroke, or coronary heart disease mortality. The trial was to proceed until $\geq$1600 primary events had been registered, which was anticipated to conclude in 2013. The research program also included three surrogate endpoint trials. The dal-PLAQUE trial examined high-risk cardiovascular disease patients on dalcetrapib or placebo for 24 months for differences in progression of vascular wall thickness and plaque burden as assessed by MRI and PET/CT techniques.[98] The dal-PLAQUE 2 study examined coronary artery disease patients for the effect of dalcetrapib or placebo on carotid intima-media thickness by ultrasonography.[99] The dal-VESSAL study examined the effect of dalcetrapib versus placebo in coronary heart disease or coronary artery disease patients for brachial flow-mediated dilation by ultrasound techniques, as well as 24-h ambulatory blood pressure.[100]

While the dal-OUTCOMES study was underway, Merck initiated the REVEAL cardiovascular outcomes trial in June, 2011 (Table 4).[101] The study is ongoing and is anticipated to conclude in early 2017, once a median follow-up time of 4 years has been achieved for patients on treatment. As of the time of submission for this case history, REVEAL has completed enrollment with 30,450 patients randomized to receive 100 mg anacetrapib or placebo in addition to atorvastatin therapy. Rather than focus on recent acute coronary syndrome patients as had been examined in dal-OUTCOMES, the REVEAL trial enrolled patients with established coronary artery disease, with a history of myocardial infarction, cardiovascular disease, peripheral artery disease, or diabetes mellitus with other evidence of coronary heart disease. Patients in the study are evaluated for the primary endpoints of coronary mortality, myocardial infarction, or coronary revascularization procedure. A companion study of anacetrapib in patients with heterozygous familial hypercholesterolemia was also launched in February of 2012. The REALIZE study (Table 1) evaluated the efficacy of anacetrapib when added to other lipid modifying agents in this difficult to treat patient population.[102]

Important developments have occurred among studies of comparator CETP inhibitors while the REVEAL study has been underway. On May 7, 2012, after the initiation of the REVEAL trial, Roche announced the early termination of the dal-OUTCOMES trial due to a lack of clinically meaningful efficacy based on the second interim analysis by the independent data safety monitoring board.[103] All ongoing studies in the dal-HEART program were also terminated. In their analysis, over 70% of the primary end-point events had occurred with no significant difference between the dalcetrapib group and the placebo group on the composite or individual endpoints.[104] During the median dosing period of 31 months, HDL-C levels were elevated by 31 to 40% by the administration of dalcetrapib, with no significant effect on LDL-C. There was no dalcetrapib-mediated change in systolic blood pressure, plasma aldosterone, or circulating electrolytes. However, the interim analysis established that there was only 1.1% likelihood that a risk reduction of $\geq$10% would be observed among the entire study population if the trial was completed.

At the time of early termination for the dal-HEART program, two of the surrogate endpoint trials had fully completed. The dal-VESSEL trial showed no improvement or impairment in flow-mediated dilation over 3 months, and also showed no change in ambulatory blood pressure.[105] However, the dal-PLAQUE trial indicated that dalcetrapib may decrease inflammation and total vessel area over 6–24 months of treatment as measured by MRI and PET/CT.[106] A recent post hoc analysis of PET data from dal-PLAQUE indicated that dalcetrapib treatment had no effect on the progression of vascular calcification over 6 months of treatment.[107]

It must be noted that a preliminary post hoc pharmacogenomic analysis of dal-OUTCOMES data has provided some indication of efficacy for a subgroup of patients in the study. A team of researchers, including several involved in the dal-OUTCOMES trial, have identified a specific polymorphism in the *ADCY9* gene that is associated with a 39% risk reduction in primary endpoints for patients in the dalcetrapib treatment group, and this correlation was supported by further pharmacogenomic analysis of patients, the smaller dal-PLAQUE-2 study.[108] This polymorphism is present in 20% of the general population, which potentially identifies a sizable group of acute coronary syndrome patients that could receive benefit from dalcetrapib therapy. Based on these results, DalCor Pharmaceuticals was formed to continue development of dalcetrapib in patients with this polymorphism. They have announced a plan to return to the clinic to evaluate dalcetrapib in this subgroup in 2016.[109]

Following the termination of the dal-OUTCOMES trial, in October, 2012, Eli Lilly initiated an outcomes trial with evacetrapib called ACCELERATE (Table 3).[110] In this study, 12,092 patients were randomized to receive 130 mg of evacetrapib or placebo in addition to standard medical treatment for a minimum of 1.5 years. Similar to the dal-OUTCOMES enrollment, patients were enrolled in ACCELERATE if they had experienced acute coronary syndrome within the preceding 4–52 weeks. Patients were also enrolled if they had peripheral vascular disease, transient ischemic stroke, or diabetes with coronary artery disease. The primary efficacy endpoints were similar to dal-OUTCOMES (coronary mortality, myocardial infarction, or coronary revascularization). The trial was designed to proceed until $\geq$1670 patients reached the primary end point.

However, on Oct. 12, 2015, Eli Lilly announced the early termination of the ACCELERATE trial due to lack of clinically meaningful efficacy based on an interim analysis by the independent data safety monitoring board.[111] Eli Lilly noted that the study was not being stopped for safety reasons, but rather based on the low probability that the study would achieve its primary endpoints based on the interim results. As of the submission of this case history, the full results of the interim analysis of the ACCELERATE trial have not been reported.

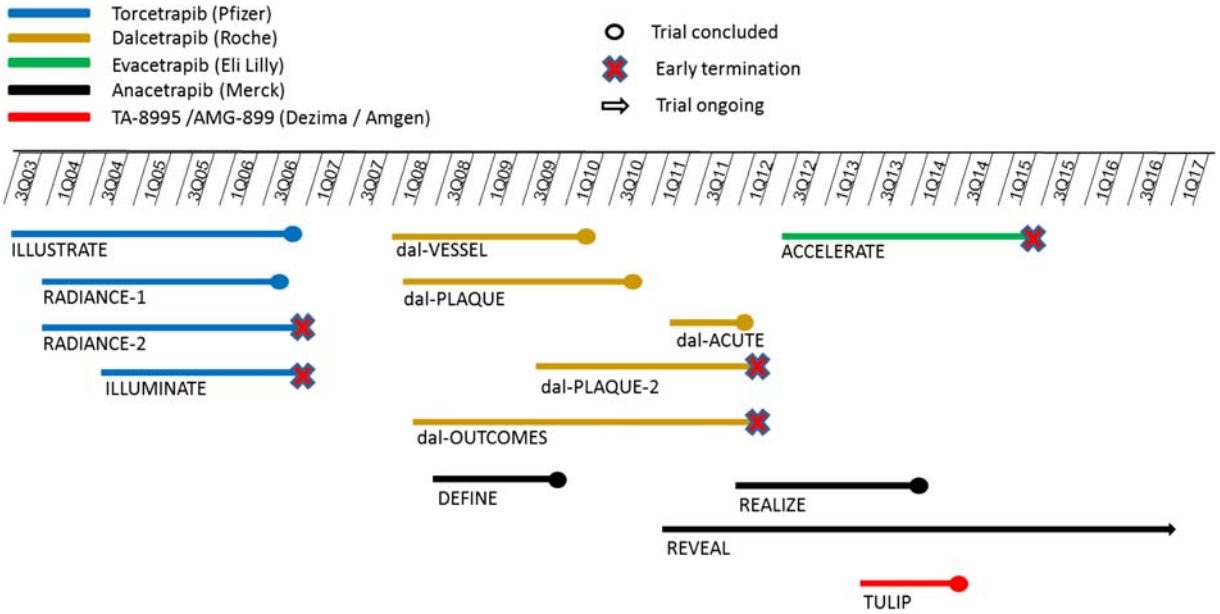

Fig. 12 Timeline of efficacy clinical trials for CETP inhibitors

The trial terminations described above leave only the REVEAL outcomes study for anacetrapib ongoing to completion. A prespecified interim analysis was performed in Nov., 2015 by the independent data monitoring committee, who recommended that the REVEAL trial continue to completion.[112] Their analysis included both a safety analysis and a futility analyses. The timelines associated with the CETP clinical trials above are illustrated in Fig. 12.[113] The details and summary results of each of these trials are summarized in Table 5.

8.11.11 Conclusion

The outcomes studies on three CETP inhibitors have been terminated during interim analysis by their respective monitoring committees for either safety (torcetrapib) or futility (dalcetrapib, evacetrapib). Anacetrapib has completed the final interim analysis by the independent data safety monitoring board, and it remains the sole CETP inhibitor under investigation in a clinical outcomes trial. The data from the completed REVEAL study are expected in 2017. Contrary to torcetrapib, anacetrapib has established a positively differentiated safety profile in both preclinical and clinical studies that will facilitate the completion of the outcomes trial. Contrary to dalcetrapib, anacetrapib has established significantly greater pharmacodynamic effect in the elevation of HDL-C and reduction of LDL-C that would indicate that anacetrapib would afford a more robust test of the CETP inhibition hypothesis. By comparison with evacetrapib, however, anacetrapib shares a similar efficacy pharmacodynamics and safety profile at the dose administered.

Differences between the design of the ACCELERATE trial of evacetrapib and the REVEAL trial of anacetrapib could provide insight into the possibility that different results will be observed with these two compounds. The ACCELERATE trial was terminated following a median follow-up time of ~2 years, which may not have provided enough time for evacetrapib to exert a beneficial effect. Prior studies of statins have demonstrated a lag in efficacy ranging from 6 months to 2 years. For example, a ~1-year lag in outcome efficacy was observed in the IMPROVE-IT trial of ezetimibe added to simvastatin, in which over 18,000 patients with acute coronary syndrome were treated for a median follow-up of 6 years to identify an additional 2% absolute reduction in cardiovascular disease risk.[114] By contrast, the REVEAL trial will maintain 4 years median follow-up. Additionally, the patient populations for ACCELERATE included subjects 1–12 months following acute coronary syndrome, who may be more prone to early cardiovascular events as opposed to a more chronic vascular disease population for REVEAL. Improved reverse cholesterol transport, achieved through CETP inhibition, may be more beneficial in the chronic cardiovascular disease population in REVEAL. Finally, the ACCELERATE trial enrolled over 12,000 patients as compared to over 30,000 patients in the REVEAL study. This larger sample size of REVEAL, coupled with the longer follow-up for the completed interim analysis (~3 years), may allow for the detection of a smaller effect size that passed interim futility analysis as compared to the interim analysis of ACCELERATE.

The utility of CETP inhibition to reduce cardiovascular risk is the subject of considerable debate in the scientific community. As such, the continued investigation of CETP inhibition has been alternately referred to in editorial analyses as either a "strategy to reduce cardiovascular risk"[115] or the "suspension of disbelief."[116] The debate will be significantly informed by the results of the REVEAL clinical investigation, which is anticipated in 2017.

Table 5 Summary of CETP inhibitor advanced safety and efficacy trials

Compound (dose)	*Trial*	*Patient population*	*Efficacy measure*	*↑HDL-C/ ↓LDL-C*	*Outcome*	*Ref.*
Torcetrapib (60 mg)	ILLUMINATE	15,067 High CV risk	CV death, MI, stroke, UA outcomes	70-80%/ 20–30%	Interim analysis early termination: ↑CV end point and all-cause mortality.	46
	RADIANCE 1	Familial hypercholesterolemia or atherogenic dyslipidemia	Progression of carotid intima-medial thickening via ultrasonography	54%/ 20%	Negative	68
	ILLUSTRATE	1188 CAD	Progression of coronary atherosclerosis via intravascular ultrasound	61%/ 20%	Negative	67
Dalcetrapib (600 mg)	dal-OUTCOMES	15,871 ACS (within 4–12 weeks of MI)	CV death, MI, stroke, UA outcomes	30–40%/ 0–7%	Interim analysis early termination in 2012: Clinical futility.	104
	dal-ACUTE	300 ACS (within 1 week of MI or UA)	% HDL-C change at 24 weeks	32%/0%	Increased total cholesterol efflux 9%, no change in preβ-HDL	86
	dal-PLAQUE	130 High CV risk	Progression of vascular wall thickness and plaque burden by MRI and PET/CT	31%/0%	Slight decrease in total vessel area and inflammation	106
	dal-VESSEL	476 High CV risk	Improvement in flow-mediated dilation by ultrasound	31%/0%	No improvement or impairment	105
	dal-PLAQUE 2	931 CAD	Progression of coronary atherosclerosis via intravascular ultrasound		Early termination, data not available	108
Evacetrapib (130 mg)	ACCELERATE	12,092 ACS (within 4–52 weeks of MI) or high CV risk	CV death, MI, stroke, UA, coronary revascularization outcomes	130%/ 40%	Interim analysis early termination in 2015: Clinical futility	111
Anacetrapib (100 mg)	DEFINE			130–140%/ 30–40%	Safe and well tolerated	59
	REALIZE	306 Heterozygous familial hypercholesterolemia	% LDL-C change at 52 weeks	102%/ 40%	Safe and well tolerated	102
	REVEAL	30,624 CAD	CV death, MI, stroke via outcomes		Interim analysis recommended continuation in 2015, anticipated conclusion in 2017	112
TA-8995/ AMG-899 ($\leq$10 mg)	TULIP	364 Mild dyslipidemia	% LDL-C and % HDL-C change at 12 weeks	$\leq$179%/ $\leq$45%	Safe and well tolerated	93

8.12.1 Introduction

Renal outer medullary potassium (ROMK) was the first identified member[1] of the inwardly rectifying family of potassium (K_{ir}) channels, which include seven subfamilies ($K_{ir}1$–7) that differ in tissue distribution, strength of rectification, and in their regulation.[2] K_{ir} channels are tetramers comprising four identical or related subunits, each containing two transmembrane helices, which form a central conduction pathway.[3] ROMK expression is highly restricted to the kidney, where it plays a critical role in the regulation of electrolyte and extracellular fluid-volume homeostasis.[4] Importantly, ROMK is expressed on the apical membrane of epithelial cells lining multiple segments of the nephron, including the thick ascending loop of Henle (TALH), the collecting tubule (CT), and the cortical collecting duct (CCD).[5–7] At the TALH, ROMK participates in potassium recycling across the apical membrane, providing the substrate K^+ ions necessary for NaCl reabsorption by the Na^+–K^+–$2Cl^-$ co-transporter, the rate-limiting step for sodium reabsorption in this part of the nephron and the target for loop diuretics such as furosemide (Fig. 1). Approximately 30% of the total filtered NaCl is reabsorbed in the TALH, with accompanying osmotic water reabsorption contributing to concentration of urine along the nephron. Since the potassium concentration in the tubular fluid is much less than that of sodium or chloride, ROMK secretion of potassium is critically required for NaCl reabsorption by the Na^+–K^+–$2Cl^-$ co-transporter. Thus, ROMK inhibitors should provide indirect inhibition of the

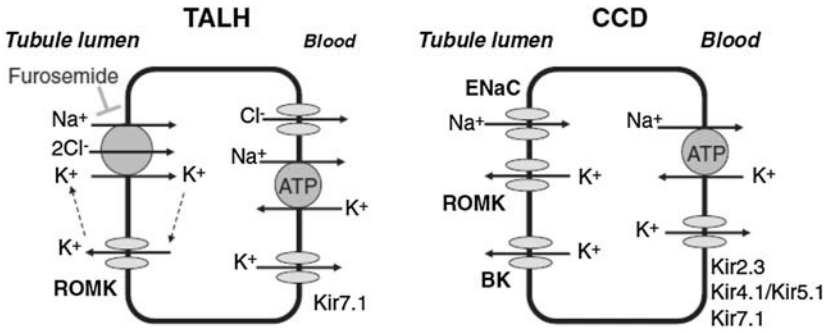

Fig. 1 Physiological role of ROMK in the thick ascending limb of Henle (TALH) and the cortical collecting duct (CCD) segments of the nephron. From Garcia, M. L.; Kaczorowski, G. J. *Curr. Opin. Pharmacol.* **2014**, *15*, 1–6.

Na^+–K^+–$2Cl^-$ co-transporter, evoking diuresis and natriuresis comparable to a loop diuretic. In the CT and CCD, ROMK represents a key potassium secretory pathway, critical for maintaining potassium homeostasis. In the CCD, potassium secretion by ROMK shifts the luminal membrane potential, thereby increasing the electrochemical driving force for sodium reabsorption via the amiloride-sensitive epithelial sodium channel, ENaC, the rate-limiting step for sodium reabsorption in the CCD (Fig. 1). Inhibition of ROMK in the CCD is therefore expected to counter the potassium loss and hypokalemia associated with loop and thiazide diuretics. In addition, the coupling of ROMK to ENaC in the CCD may provide additional natriuresis efficacy. Thus, selective inhibition of ROMK along multiple segments of the nephron may provide a greater cumulative efficacy with reduced potassium loss compared to loop and thiazide diuretics, which target transport pathways in only a single segment of the nephron.

The impetus for Merck's interest in developing ROMK inhibitors was twofold: First, available thiazide and loop diuretics remain key drug classes for treating hypertension and heart failure, respectively[8]; however, they are dose and efficacy limited,[9] in part due to safety issues such as hypokalemia, a decrease in plasma potassium levels which can trigger dangerous cardiac arrhythmias. In addition, they typically have short half-lives, leading to rebound sodium reabsorption, which blunts efficacy. In the case of loop diuretics such as furosemide, diuretic resistance[10] leads to loss of efficacy, particularly as heart failure or renal function worsens. Thus, there is a need for next-generation diuretics, which can provide improved efficacy without the liabilities of the current standards of care. Second, there is compelling human and rodent genetic validation for ROMK as a novel mechanism diuretic target. Notably, patients with Bartter syndrome type II have autosomal recessive loss-of-function mutations in the KCNJ1 gene, with a clinical presentation that includes renal salt wasting, polyuria, hypotension, mild hypokalemia, and metabolic alkalosis.[11] Moreover, Lifton and colleagues have reported that heterozygous carriers of loss-of-function KCNJ1 mutations, identified in the Framingham Heart Study, have lower blood pressure, a reduced risk of stroke, and are protected from developing hypertension by age 60; however, they otherwise do not present with the clinical features of Bartter syndrome.[12] ROMK knockout mice[13] recapitulate the Bartter syndrome type II phenotype. Finally, Zhou and colleagues at Merck have shown that Dahl salt-sensitive rats with heterozygous ROMK disruption display reduced blood pressure compared to wild-type rats when challenged with a 4% salt diet. Taken together, the genetic evidence, coupled with the expression and role of ROMK in the nephron, suggests that ROMK inhibitors will represent a new class of diuretics with the potential for improved efficacy and reduced risk of hyperkalemia compared to standard-of-care thiazide and loop diuretics.

The initial program goal was to identify a tractable lead series that could be optimized for selectivity over the cardiac voltage-gated potassium channel hERG and related K_{ir} channel family subtypes. In particular, a key requirement was for development of ROMK inhibitors with excellent selectivity over the related strong inward rectifier $K_{ir}2.1$ cardiac channel, which is associated with life-threatening long QTc syndrome.[14,15] In addition, we sought a lead series with suitable pharmacokinetic properties to enable proof of biology in pharmacodynamic models, and to permit eventual optimization for qd dosing in humans.

8.12.2 Hit Identification

In contrast to other ion channel families, the pharmacology of K_{ir} family channels is relatively unexplored.[16] Garcia and Kaczorowski noted that HTS campaigns directed toward K_{ir} family targets have yielded few interesting or chemically tractable hits, impeding discovery of selective inhibitors and potential drug development.[17] At the time that the ROMK program at Merck was initiated there were no known small molecule-selective ROMK inhibitors. Tertiapin (TPN), a bee venom peptide, was the only previously described ROMK inhibitor, demonstrating potent inhibition of the rat channel[18] but significantly weaker inhibition of the human isoform.[19] Later, Denton and coworkers at Vanderbilt University described the discovery of ROMK inhibitors **VU590** and **VU591** (Fig. 2). Inhibitor **VU590** was discovered directly through a high-throughput screening (HTS) campaign and was shown to inhibit both ROMK (IC_{50} 290 nM)[20] and $K_{ir}7.1$. Medicinal chemistry modification of another hit from the same screening campaign afforded inhibitor **VU591** (IC_{50} 240 nM), which demonstrated selectivity over the $K_{ir}7.1$ channel (no inhibition at 10 μM).[21] Unfortunately, **VU591** did not induce diuresis in rats,[22] possibly due to high plasma protein binding[21] or poor pharmacokinetic and physicochemical properties. In addition, efforts to replace the two nitro substituents were unsuccessful for these inhibitors.

An HTS campaign of Merck's internal sample collection of ~1.5 million compounds using a membrane potential-based fluorescent assay[23] identified very few attractive hits. The largest cluster of related hits originated from Merck's abandoned hERG channel

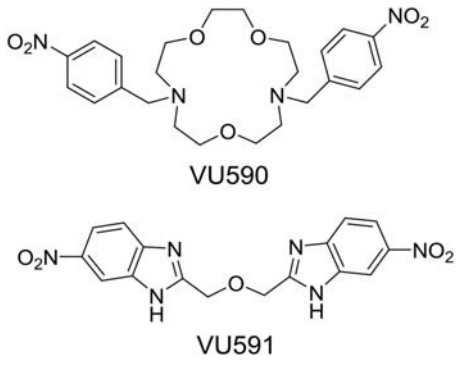

Fig. 2 ROMK inhibitors discovered by Vanderbilt University researchers.

blocker antiarrhythmic program from the late 1980s, and these hits displayed picomolar hERG inhibition and relatively weak ROMK inhibitory activity (>1 μM). Based on the low probability of success for converting these highly potent hERG blockers to selective ROMK inhibitors, we chose not to pursue these hits. On surveying our hit package we observed that there were several structurally unrelated weak hits bearing a nitrophenyl group. One of these was the simple and low molecular weight fragment hit, 1-(4-nitrophenethyl)piperazine **1**. Compound **1** displayed moderate inhibitory potency on ROMK, IC_{50} 5.2 μM, in a functional $^{86}Rb^{+}$ efflux assay from CHO cells stably expressing the human ROMK channel, but showed ~30-fold greater potency on the outward delayed rectifier potassium channel (Kv11.1, human ether-a-go-go-related gene, hERG). Importantly, compound **1** demonstrated excellent selectivity over the related cardiac $K_{ir}2.1$ channel. Surprisingly, when compound **1** was subjected to HPLC purification and resubmitted for assay, all of the ROMK inhibitory activity was lost (**Fig. 3**). A careful examination of the HPLC–MS data from the original sample showed good overall purity, but a minor peak, integrating to about 1% abundance, was visible and corresponded to a molecular weight of 384. We wondered whether this minor impurity could possibly account for all of the ROMK activity seen for the screening hit **1**. Based on the molecular weight, we hypothesized that a likely structure for the impurity could be the symmetrical 1,4-bis(4-nitrophenethyl)piperazine, **2**. We independently synthesized compound **2** and confirmed in our assays that, indeed, all of the activity of the original hit must be derived from this impurity.[24] Consistent with this, the inhibition of ROMK (IC_{50} 0.052 μM) and hERG (IC_{50} 0.005 μM) was approximately two orders of magnitude more potent; fortunately the potency on $K_{ir}2.1$ remained negligible (IC_{50} > 100 μM). It is noteworthy that two independent screening campaigns of unique sample collections (one by Vanderbilt University researchers and the other by Merck) each led to the discovery of symmetrical bis(nitrophenyl) containing lead scaffolds, suggesting the privileged role of the nitrophenyl pharmacophore for interactions with ROMK and provoking the speculation that these compounds may be binding in a symmetrical fashion or in a way such that each nitrophenyl forms a similar interaction with two of the identical or similar tetrameric subunits within the channel, which itself displays quasi-C4 symmetry. Based on mutagenesis studies and computational analysis of binding of **VU591** to a homology model of ROMK, Denton proposed a V-shaped or folded conformation with the nitrophenyl pharmacophores of **VU591** interacting near identical asparagine residues on adjacent tetramer subunits.[25]

Clearly there were concerns about compound **2** as a program starting point. The nitro groups were viewed as a potential toxicity liability[26] and would need to be replaced as a first order of business. Compound **2** had poor pharmacokinetic properties in rats with high clearance (261 mL/min/kg) and was 10-fold more potent on hERG than on ROMK. The selectivity would need to be inverted and significantly improved. Further, there was concern that the "privileged" piperazine scaffold could lead to promiscuous off-target activity.

8.12.3 Program Assays

The ROMK functional assays that drove SAR development in the Merck program have been previously described in detail by Felix and coworkers.[27] Early in the program the team employed a functional assay in CHO cells stably expressing human $K_{ir}1.1$, where efflux of the $^{86}Rb^{+}$ isotope was monitored as our primary assay. A key advantage of this assay was that measurements could be made in the absence and presence of increasing concentrations of human serum (up to 100%), helping to assess, in a high-throughput fashion, the impact of protein binding to the potency of ROMK inhibitors. Spot checking of plasma protein binding indicated a good correlation of serum shift with measured plasma protein binding. As a secondary medium-throughput assay, we employed

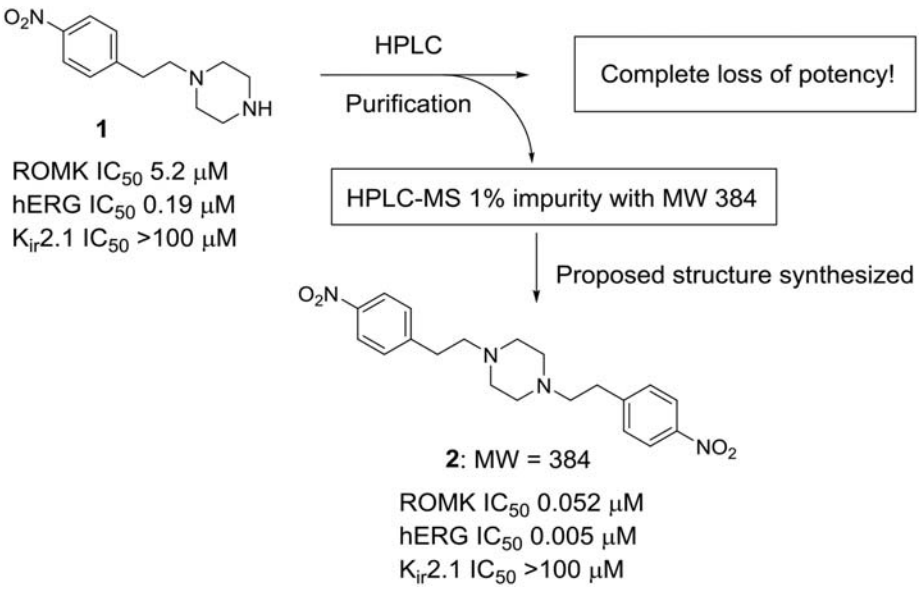

Fig. 3 Discovery of a viable ROMK hit from a 1% impurity detected in an otherwise inactive screening hit.

a functional electrophysiology (voltage clamp) assay in CHO cells stably expressing Kir1.1 channels using the IonWorks automated electrophysiology platform (molecular devices). As the program progressed the team developed an alternative primary screen, a high-throughput functional thallium flux fluorescence assay measuring the ability of thallium to permeate through $K_{ir}1.1$ channels, employing HEK293 cells stably transfected with $hK_{ir}1.1$ or $rK_{ir}1.1$, or MDCK cells stably transfected with $rK_{ir}1.1$.

hERG activity was assessed initially by measuring displacement of ^{35}S MK-499 from HEK-293 cells stably expressing hERG.[28] Functional hERG activity was measured by electrophysiology studies employing QPatch (Biolin Scientific) or PatchXpress (Molecular Devices) platforms. In general, correlation between hERG binding potency and functional activity was good, but there were exceptions where significant potency shifts were observed (~10% of the time); therefore, the hERG functional electrophysiology assay was used as a routine secondary assay for compounds prioritized for advancement down the program's research operating plan (ROP). Counterscreening versus $K_{ir}2.1$ was measured using a functional fluorescence assay that measures the ability of thallium to permeate through open $K_{ir}2.1$ channels stably expressed in HEK293 cells.

8.12.4 Hit to Lead

Tang and coworkers have described initial SAR efforts to define the optimal scaffold dimensions and identify bioisosteres for ROMK hit **2**.[24] Extension or contraction of one of the ethyl linkers between the piperazine core and a nitrophenyl pharmacophore (not shown) led to significant reductions in potency (IC_{50} 3.8 and >10 μM, respectively), establishing that the dimensions of hit **2** are optimal with the two carbon linker on each side of the piperazine core and a total atom count of 8 atoms between nitrophenyl pharmacophores. Nitro groups are capable of forming hydrogen bonding and other interactions,[29] and when present on aromatic rings, nitro groups polarize the aromatic π-system. Relatively few nitrophenyl group bioisosteres have been described, with examples including pyridyl, benzoate, and difluorophenyl.[30] As described in Table 1, both nitro groups present in compound **2** are absolutely necessary for maintaining ROMK potency; elimination of one nitro group by replacing with hydrogen (**3**) led to a complete loss of potency (>10 μM). Numerous potential nitrophenyl bioisosteres were surveyed systematically (Table 1). These included alternative substituted phenyl or fused bicyclic systems capable of acting as hydrogen bond acceptors, and/or alternative electron-withdrawing substituents. Previously described nitrophenyl bioisosteres, benzoate (**11**) and pyridyl (not shown, IC_{50} >30 μM) led to complete loss of potency. 4-Substitution of phenyl with ester (**10**), trifluoromethyl (**14**), halogen (**12**, **13**), methoxy (**15**), methyl sulfone (**16**)/sulfoxide, and heterocycles (**7**, **8**) all led to significant or complete loss of potency; however, 4-cyanophenyl (**4**), 5-benzo(2,1,3-oxadiazole) (**6**), and 4-phthalide (**9**) pharmacophores retained comparable activity to

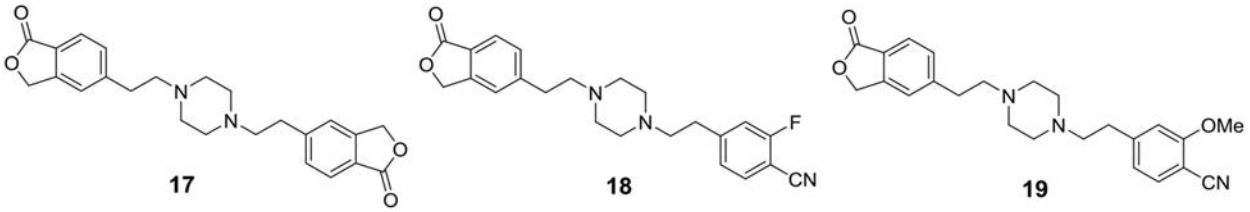

Fig. 4 Mixing and matching nitrophenyl bioisosteres provide ROMK leads without nitro groups.

nitrophenyl. Of particular interest was the 4-phthalide (**9**) pharmacophore, which in addition to retaining ROMK potency, also demonstrated slightly weaker hERG potency (30-fold weaker compared to compound **2**). It is also noteworthy that the 4-phthalide group displayed good ROMK activity while related acyclic 4-substituted esters were significantly less potent, possibly suggesting a tight binding fit without space for acyclic extended esters.

Having identified three nitrophenyl bioisosteres the next step was to mix and match these groups, eliminating all nitro groups in the series. Through this exercise and some follow-on SAR work, Tang and coworkers identified compounds **17**–**19** (Fig. 4), which displayed comparable potency to hit **2** in the $^{86}Rb^{+}$ efflux functional assay (Table 2). Compounds **17**–**19** also demonstrated similar high ROMK potency to hit **2** in a follow-up electrophysiology assay. When assessed in the ^{35}S MK-499 displacement binding assay, all three compounds provided reduced hERG potencies, leading to some of the first examples of ROMK inhibitors that were selective over hERG. In particular, compounds **17** and **19** demonstrated 73- and 37-fold selectivity windows for ROMK over hERG. Moreover, compounds **17** and **18** were assessed for off-target K_{ir} channel activity and were shown to display no significant inhibition of the $K_{ir}2.1$, $K_{ir}2.3$, $K_{ir}4.1$, and $K_{ir}7.1$ channels (all >100 μM).

ROMK inhibitor **17** was assessed for its pharmacokinetic properties in rats, where it demonstrated a significantly improved profile compared to hit **2** (Table 3), supporting the tractability of this lead series for identification of analogs with pharmacokinetic properties suitable for conduct of proof-of-biology studies in pharmacodynamic models.

8.12.5 Parallel Discovery of the 2-(4-(1*H*-Tetrazol-1-yl)phenyl)-1-(piperazin-1-yl)ethan-1-one Scaffold

During the search for nitrophenyl bioisosteres an intermediate **20** leading to the synthesis of analog **21** was submitted to the program assays and found to display better ROMK potency as the acylpiperazine **20** than as the reduced dibasic target analog **21** (Fig. 5).[31] In addition, the resulting ROMK inhibitor **20** had balanced ROMK/hERG potency, representing a 10-fold improvement in ROMK selectivity compared to the starting point **2**. Thus, the phenyl tetrazole pharmacophore added to our list of nitrophenyl bioisosteres. Encouraged, we prepared a series of analogs with a variety of small heterocycles to further expand our options; surprisingly, no other heteroaryl, even the closely related tetrazoles and triazoles, provided comparable ROMK potency (Fig. 6).

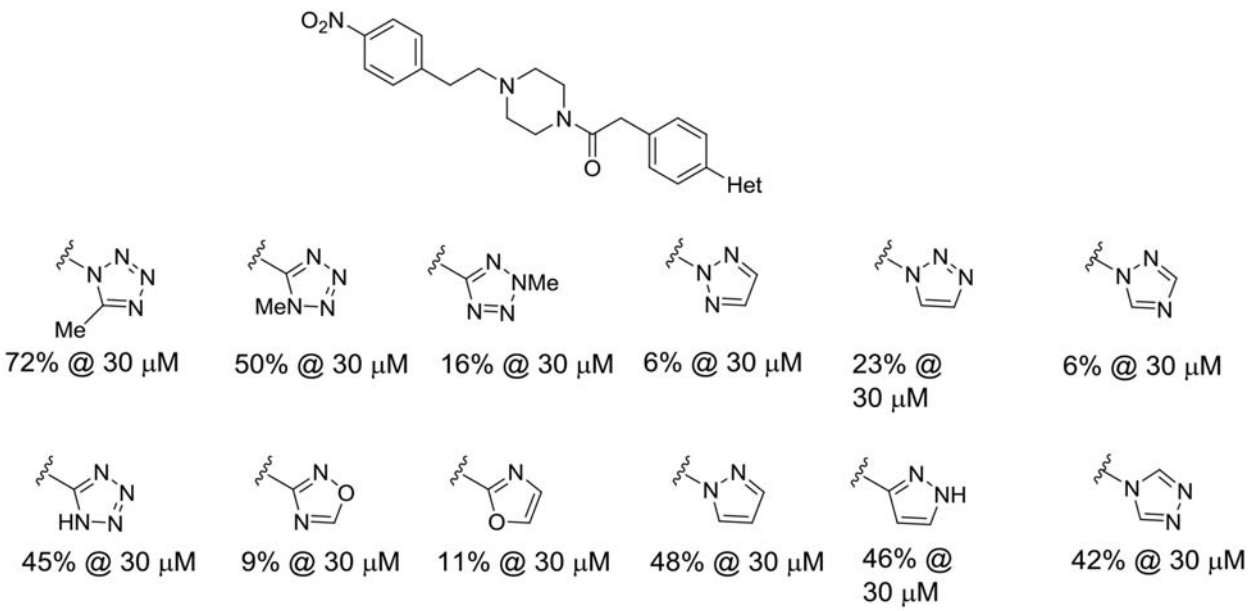

Fig. 6 Heterocycle replacements attempted for the phenyl tetrazole ($^{86}Rb^{+}$ efflux % inhibition at 30 μM).[31]

One interpretation of this observation is that the tetrazole may engage in multiple interactions with involvement of more than one nitrogen; substitution is not tolerated due to steric/space requirements and/or possible change in the angle between phenyl and tetrazole, which may prefer to be planar rather than twisted.

With the modified scaffold and a new nitrophenyl bioisostere in hand we again paired these features with the other available isosteres and further probed SAR, providing the compounds described in Table 4. The analog bearing the 4-phthalide pharmacophore (**25**) provided the best ROMK potency and an ~100-fold selectivity window for ROMK over hERG. The regioisomeric phthalide **26** displayed significantly weaker ROMK potency; however the ring expanded isochroman-1-one **30** gave comparable ROMK potency to **25** with excellent selectivity over the hERG channel (~200-fold). Notably, conversion of compound **25** to the corresponding benzolactam **27**, or removal of one of the lactone oxygen atoms to give **28** or **29**, led to complete or partial loss of ROMK potency. This suggests that, like the phenyl tetrazole, it may be that the lactone moiety is engaging in more than one hydrogen bonding acceptor interactions and that this may be a required feature for optimal interaction with ROMK.

Having established the phthalide pharmacophore in compound **25** as a preferred one, Tang and coworkers explored substitution around the phthalide ring system (Table 5). Small groups such as methyl (**31**) and fluoro (**34**) were tolerated at the 4-position, giving comparable potency to the unsubstituted parent **25**, and in the case of fluoro, a slightly improved selectivity over hERG (hERG/ROMK 282-fold). Unfortunately, 4-fluoro substitution generally led to higher clearance in rat PK studies (not shown), possibly by making the phthalide more susceptible to lactone ring opening. Increasing the 4-substituent size led to erosion of ROMK potency (**32**, **33**, **35**, and **36**). Substitution at the 6- and 7-positions of the phthalide system uniformly led to loss of potency.

Compounds **25**, **30**, and **31** were further assessed in ROMK and hERG electrophysiology assays as shown in Table 6. All three compounds provided good ROMK potency and selectivity for ROMK over hERG of 70-fold for compound **25**, 295-fold for compound **30**, and 181-fold for compound **31**. As a general observation, the isochroman-1-one and 4-methylphthalide pharmacophores present in **30** and **31** generally give improved selectivity over hERG by two- to threefold, and reduced clearance in pharmacokinetic studies compared to the parent unsubstituted phthalide pharmacophore.

Compound **25** was evaluated in functional assays for several related inward rectifier channels and demonstrated excellent selectivity for ROMK ($K_{ir}2.1$ and $K_{ir}2.3$ IC_{50}'s >50 μM, $K_{ir}4.1$ and $K_{ir}7.1$ IC_{50}'s >10 μM).[32] Compound **25** also gave excellent selectivity over the cardiac channels Nav1.5 (>30 μM) and Cav1.2 (>100 μM). Compound **25** was further assessed for off-target activity in a panel of 166 enzymes and radioligand binding assays run by MSD Pharma Services; when tested at 10 μM, **25** inhibited only the serotonin transporter with an IC_{50} of 9.1 μM. Compound **25** was shown to have comparable activity against the rat ROMK channel using the $^{86}Rb^{+}$ efflux assay (0.113 μM), making it amenable for in vivo studies in rats.

ROMK inhibitor **25** was assessed in pharmacokinetic studies in Sprague–Dawley (SD) rats and in dogs, where it demonstrated good oral bioavailabilities with moderate oral exposures and short half-lives (Table 7).[32] In a rat bile duct cannulated rat study using ^{3}H-**25**, the primary metabolites identified were the lactone ring opened acid (>parent, urine and bile), and to a lesser extent a metabolite resulting from oxidation of the phthalide system (urine).[33] The parent compound was also eliminated intact in urine and bile.

8.12.6 First Proof of Biology: Diuresis and Natriuresis Efficacy With a Neutral Potassium Excretion Profile

With a selective and orally bioavailable ROMK inhibitor now available in **25**, the next step was to assess pharmacodynamic activity in animal models. The acute diuretic, natriuretic, and kaliuretic activity of compound **25** was assessed in conscious, volume-loaded SD rats, with the clinically used thiazide diuretic hydrochlorothiazide (HCTZ) employed as a positive control (Fig. 7).[32] Oral administration of compound **25** at 1, 3, 10, and 50 mg/kg doses evoked dose-dependent increases in urine output and sodium excretion in the 4 h post saline load compared to the vehicle-treated group, while potassium excretion remained unchanged at all doses. A maximal diuretic and natriuretic effect was observed at the 10 mg/kg dose. As expected, HCTZ also provided dose-dependent

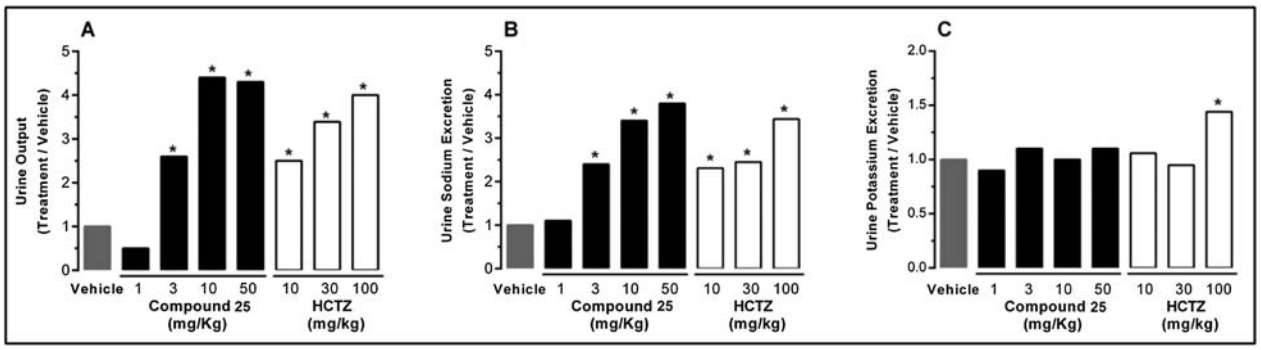

Fig. 7 Effect of compound **25** and HCTZ on urinary output and sodium and potassium excretion rates in SD rats. Adult male SD rats ($n=5$–6 per treatment) were dosed by oral gavage with indicated doses of either compound **25** or HCTZ. After 30 min, voiding was induced by giving each animal a saline load. Urine collection took place over the next 4 h and was analyzed for volume (A) and for sodium (B) and potassium (C) content. Data are presented as fold change relative to values obtained in the vehicle-treated animals. $^*p<.05$ vs. vehicle. This figure is taken with permission from Garcia, M. L.; Priest, B. T.; Alonso-Galicia, M.; Zhou, X.; Felix, J. P.; Brochu, R. M.; Bailey, T.; Thomas-Fowlkes, B.; Liu, J.; Swensen, A.; Pai, L.-Y.; Xiao, J.; Hernandez, M.; Hoagland, K.; Ownes, K.; Tang, H.; de Jesus, R. K.; Roy, S.; Kaczorowski, G. J.; Pasternak, A. *J. Pharmacol. Exp. Ther.* **2014**, *348*, 153–164.

elevations in urine output and sodium excretion at 10, 30, and 100 mg/kg doses, with its maximum effect observed at 100 mg/kg; however, in contrast to compound **25**, at the maximally efficacious dose HCTZ significantly elevated potassium excretion. Both compounds provided similar magnitudes of diuresis and natriuresis at their maximally efficacious doses. Similarly, diuresis and electrolyte excretion of **25** and HCTZ were assessed in conscious, euvolemic dogs, where compound **25** at 10 and 50 mg/kg produced dose-dependent natriuresis and diuresis reaching a similar magnitude to that of an approximately efficacious dose of HCTZ (data not shown).[32] Again, in dogs, compound **25** did not increase potassium excretion in urine, while HCTZ did at an equally natriuretic dose. Taken together, the pharmacodynamic data in rats and dogs provided a first proof of biology that ROMK inhibitors will be new mechanism diuretic agents with a reduced propensity for potassium loss in urine compared to standard-of-care diuretics.

8.12.7 Mechanism of ROMK Inhibition by Compound 25

With potent and selective ROMK inhibitors in hand we sought to better understand the mechanism of inhibition. To inform on the potential binding site of compound **25** several site-directed ROMK mutants were generated, with a focus on residues facing the ion conduction pore that differed between ROMK and $K_{ir}2.1$, which our compounds do not significantly inhibit.[32] These residues were selected using homology models generated based on the crystal structure of the chicken $K_{ir}2.2$ channel.[3] Amino acid residues in ROMK were mutated individually to the corresponding residues from $K_{ir}2.1$ and all mutants were transiently expressed in TsA-201 cells and examined by whole cell voltage clamp. Of the seven mutant constructs generated (M81L, L128F, S130A, Q152E, L166V, V168C, N171D), five generated measurable currents (all but S130A and L166V). Of these five constructs, four were potently inhibited by compound **25** ($IC_{50}<100$ nM); however, the mutant resulting from replacement of asparagine 171 (N171) in ROMK with aspartate (found in $K_{ir}2.1$) led to a reduced inhibition by compound **25** by two orders of magnitude (**Table 8**). Based on the significant reduction in inhibitor potency evoked by addition of a charged amino acid, we prepared a second mutant construct, N171Q, replacing the asparagine with a still neutral related glutamine. This also resulted in a shift to weaker inhibition potency by about one order of magnitude. These data suggest that N171, which faces the pore within the transmembrane region of the channel below the selectivity filter, may contribute to potent inhibition of ROMK by compound **25**. This is consistent with site-directed mutagenesis and patch clamp data generated by Denton and colleagues with ROMK inhibitor **VU591**, which also showed a dependence of channel block on pore residue N171.[25] We have explored potential docking poses of compound **25** and other ROMK inhibitors. Both horizontal and vertical poses within the pore, wherein the N171 residue can interact through hydrogen bonds with two or one of the terminal pharmacophores, respectively, seem possible. We favor the horizontal pose which would allow similar interactions between the terminal pharmacophores to adjacent or opposite transmembrane tetrameric subunits; this would nicely account for the favorable inhibition profiles of symmetrical ROMK inhibitors.

Table 8 Loss of inhibitor **25** potency in ROMK N171 mutants by whole cell voltage clamp[32]

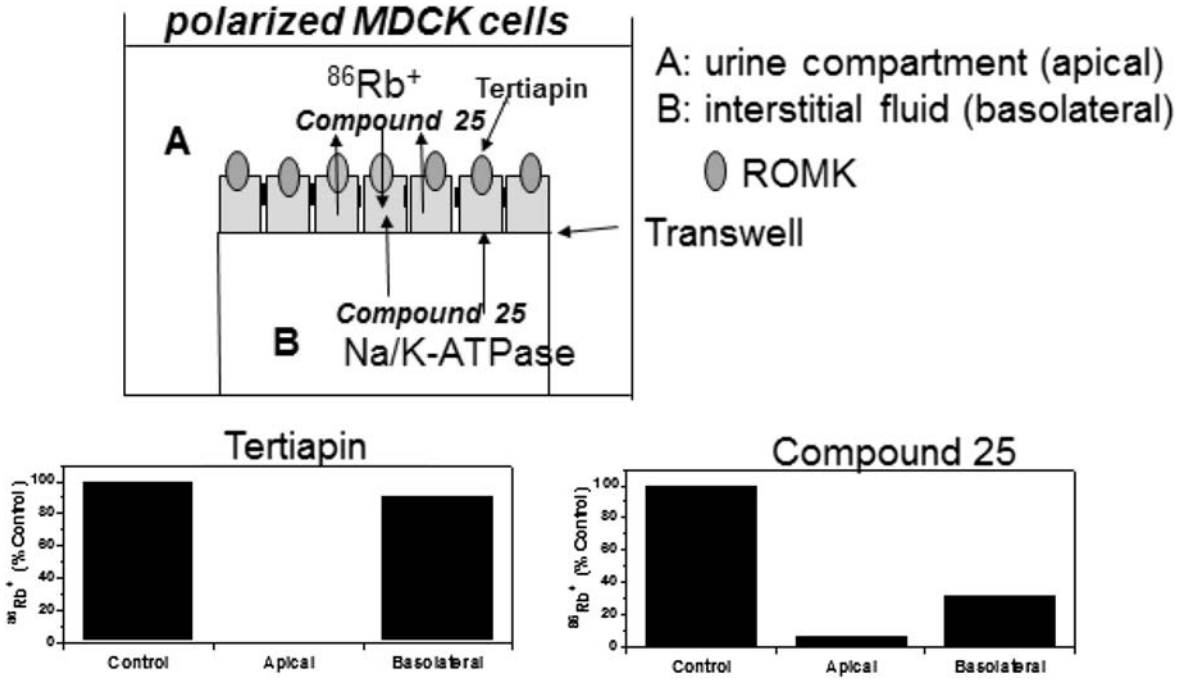

Fig. 8 Inhibition of ROMK stably expressed in polarized MDCK cells on permeable Transwell supports. Tertiapin inhibits ROMK only when applied to the apical side, while compound **25** inhibits when applied from either the apical or basolateral sides. Adapted from: Garcia, M. L.; Priest, B. T.; Alonso-Galicia, M.; Zhou, X.; Felix, J. P.; Brochu, R. M.; Bailey, T.; Thomas-Fowlkes, B.; Liu, J.; Swensen, A.; Pai, L.-Y.; Xiao, J.; Hernandez, M.; Hoagland, K.; Ownes, K.; Tang, H.; de Jesus, R. K.; Roy, S.; Kaczorowski, G. J.; Pasternak, A. *J. Pharmacol. Exp. Ther.* **2014**, *348*, 153–164.

Most diuretics, including thiazide and loop diuretics, access their targets from the apical (luminal) side of the epithelial cells lining the nephron.[34] In order to do this, loop and thiazide diuretics are actively transported into the tubular lumen by organic anion or cation transporters. Because of this, patients with renal insufficiency are susceptible to reduced efficacy of diuretic treatment, requiring dose escalation to maintain efficacy. Garcia and colleagues explored access of compound **25** to ROMK using MDCK-rK_{ir}1.1 cells grown as a monolayer on permeable Transwell supports. This model provides a polarized system with apical and basolateral membranes separated by an impermeable barrier due to the tight cell junctions (Fig. 8).[32] Inhibition of ROMK was determined by measuring inhibition of efflux of $^{86}Rb^+$ from the basolateral compartment to the apical side. Application of the impermeable peptide ROMK inhibitor tertiapin to both the apical and basolateral compartments led to ROMK inhibition only from the apical face, supporting that ROMK is exclusively expressed at the apical surface of the MDCK-rK_{ir}1.1 cells, that tertiapin only blocks the channel from the apical face, and that there is not leakage of tertiapin through the cell monolayer. In contrast, compound **25** inhibited efflux of $^{86}Rb^+$ whether applied to the apical or basolateral compartments, indicating that compound **25** accesses the channel from the cytoplasm which can be reached from either the apical (urine) or basolateral (blood) compartments, presumably due to the high cell permeability of compound **25** (Papp 23×10^{-6} cm/s in LLC-PK1 cells). This feature differentiates ROMK inhibitors from loop and thiazide diuretics, which generally have poor permeability, and only access their targets from the apical face.

Denton and colleagues at Vanderbilt University have used compound **25** in studies to elucidate the sites of action of ROMK inhibitors in the nephron.[35] In these studies compound **25** was administered to volume-loaded rats alone and in combination with diuretics acting in the TALH (bumetanide), the distal tubule (HCTZ), and in the CCD (amiloride and benzamil). Compound **25** was shown to produce diuresis and natriuresis without loss of potassium in urine when dosed alone. Additive effects on diuresis and natriuresis were observed when compound **25** was combined with HCTZ, amiloride, and benzamil, but not with bumetanide. Based on this, the Vanderbilt team concluded that, as expected, the major diuretic site of action of ROMK inhibitors is in the TALH and CCD. Since additive effects were seen when combining compound **25** with the ENaC inhibitors amiloride and benzamil, the authors concluded that blockade of ROMK in the CCD does not completely inhibit sodium reabsorption by ENaC. Finally the Vanderbilt team observed that compound **25** blocked the potassium loss in urine caused by the loop diuretic bumetanide, which they attributed to inhibition of potassium secretion by ROMK in the TALH and CCD.

8.12.8 Efforts to Enhance ROMK Selectivity Over the hERG Channel

Despite the ~100-fold selectivity of compound **25** for ROMK over the hERG channel, the team sought to further enhance the ROMK/hERG selectivity window. It is now well established that inhibition of hERG is associated with QT prolongation, which

can trigger torsade de pointes and possible degeneration into life-threatening ventricular fibrillation.[36] Walsh and Tang described a number of approaches that were explored to improve selectivity of **25** for ROMK over hERG.[37,38] Lipophilic amines are a common feature of many hERG channel blockers; consequently, a common strategy for dialing out hERG activity is to reduce amine basicity.[39] To probe the role of the basic amine in **25**, neutral compound **31** in which the basic amine is replaced by CH was targeted (Fig. 9). While elimination of the basic amine was tolerated (only a twofold loss of ROMK potency), this modification did not provide any enhancement in selectivity over hERG. In a related approach, addition of carboxylic acid groups in various positions (unpublished, not shown) to generate neutral zwitterionic analogs uniformly led to loss of ROMK activity in parallel with decreased hERG activity. Hydroxy and fluoro substituents were installed onto the phthalide benzylic linker position since these were expected to reduce basicity of the piperazine. Both modifications led to significant reductions in hERG potency and improvements in the hERG/ROMK selectivity ratio. Hydroxy analog **45**, while twofold more selective over hERG, lost potency on ROMK. The fluoro analog **46** retained ROMK potency and demonstrated a 1000-fold selectivity over hERG. Unfortunately, compound **46** provided a short half-life in rat pharmacokinetic studies (half-life 0.35 h). Interestingly, compound **44** with a benzylic methyl substituent also improved ROMK selectivity over hERG, and in this case, this effect cannot be attributed to reduced basicity of the piperazine, suggesting that conformational factors may also be playing a role.

Since small molecule inhibition of hERG is thought to be enhanced by π-stacking and hydrophobic interactions with aromatic residues in the hERG pore, common approaches to improve selectivity over hERG include reducing log *P* and modifying aromatic rings to be more electron deficient, for example by replacing with electron-deficient heterocycles like pyridyl.[39] Walsh and colleagues described testing this approach in the Merck ROMK inhibitor series by making a variety of analogs in which the phthalide and phenyl tetrazole pharmacophore phenyl groups were replaced with heterocycles such as pyridyl (Fig. 10).[37] Aza-phthalide analogs **47** and **48** both resulted in loss of ROMK potency; however, right-side pyridyl tetrazole analogs retained ROMK potency. Of the two regioisomers, compound **50** demonstrated better potency and selectivity over hERG (500-fold, by ROMK $^{86}Rb^{+}$ efflux and hERG ^{35}S MK-499 displacement binding assay). When compound **50** was assessed in ROMK and hERG electrophysiology assays it demonstrated excellent potency on ROMK (IC_{50} 20 nM) and very good selectivity over hERG (hERG EP IC_{50} 17 μM, 850-fold selectivity). Compound **50** was assessed in an anesthetized vagotomized cardiovascular dog model ($n=3$)[40] to confirm that the high selectivity for ROMK over hERG would ensure CV safety in vivo. Following a rising dose IV infusion of compound **50** at a cumulative 10 mg/kg dose (average peak unbound plasma concentration 21 μM), no changes were observed in the QT interval. In an acute diuresis model in Sprague–Dawley rats, compound **50** at 10 mg/kg provided robust diuresis and natriuresis (4-fold and 2.8-fold increase compared to vehicle-treated rats, respectively), exceeding that of 10 mg/kg of HCTZ (2.8-fold and 2.2-fold increase compared to vehicle-treated rats, respectively). Unfortunately, compound **50** had short half-lives across preclinical species presumably due to high clearance resulting from elimination by intact renal clearance and metabolism, similar to that observed with compound **25**. In addition, compound **50** had poor bioavailability in rhesus monkeys (Table 9).[37] Therefore, **50** was not selected for further advancement.

8.12.9 Scaffold Modification Toward Improving ROMK Inhibitor Pharmacokinetic Properties

Loop diuretics such as furosemide are viewed as less efficacious blood pressure lowering agents than thiazide diuretics; this has been attributed to their short durations of action followed by rebound sodium reabsorption, due in part to short half-lives and lack of sustained target engagement.[41,42] As part of the program's SAR efforts we explored many different conformationally constrained analogs in which a variety of saturated and unsaturated ring systems were incorporated by tethering from the ethyl linkers either to the terminal pharmacophores or to the central piperazine ring (Fig. 11). Many of these cyclized analogs retained good ROMK potency (e.g., all of the scaffolds shown in Fig. 11 provided active ROMK inhibitors), demonstrating the remarkable tolerance for core scaffold modification, which is in contrast to modifications of the terminal pharmacophores, where we found SAR to be very narrow and unforgiving. A more thorough description of the scope and profiles of some the scaffolds explored can be found in a ROMK patent review by Martelli and coauthors.[43]

While many of the resulting analogs demonstrated good ROMK potency and in some cases improved pharmacokinetic properties, these modifications frequently reduced selectivity over the hERG channel. An exception to this trend was recently reported by Zhu and coworkers who described the discovery of conformationally constrained ROMK inhibitor analogs in which the central piperazine ring is fused to morpholine, thiomorpholine, and piperazine rings.[44] The rationale was to (1) modulate basicity of the piperazine nitrogen to probe effects on hERG selectivity; (2) introduce rigidity which we hoped would help to make the

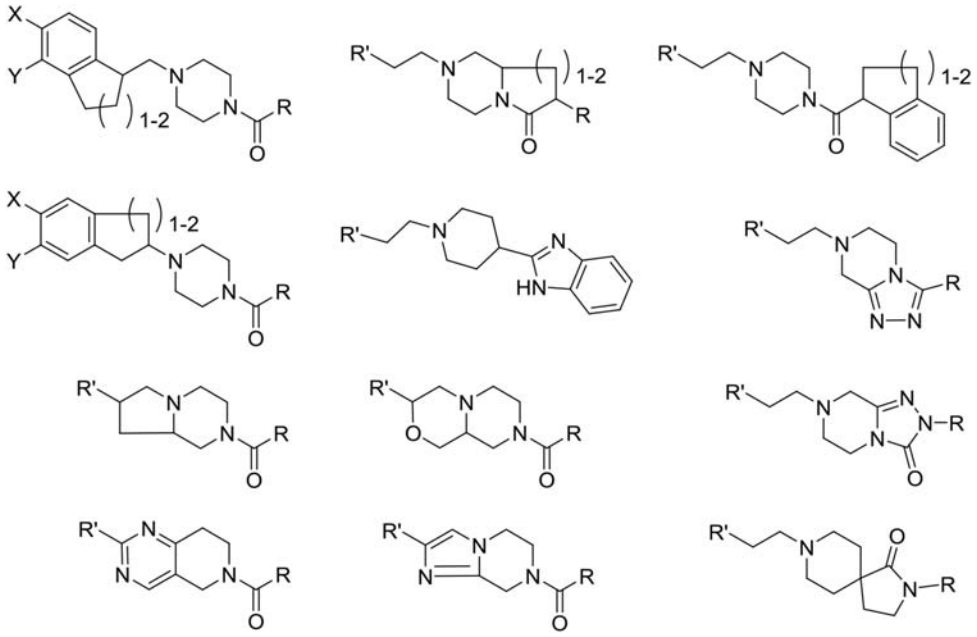

Fig. 11 ROMK scaffolds incorporating cyclic conformation constraints.

resulting analogs less susceptible to CYP enzyme-mediated oxidative metabolism; (3) incorporate substitution at the pharmacophore benzylic position which we had observed could modestly reduce clearance in pharmacokinetic studies (e.g., benzylic methyl substitution). While fused ring systems incorporating morpholine, thiomorpholine, and piperazine rings all led to active ROMK inhibitors, the morpholine-fused (octahydropyrazino[2,1-c][1,4]oxazine)-based analogs provided the best overall profiles. Key compounds highlighted by Zhu and coworkers are shown in Fig. 12. Direct cyclization from compound **50** led to four diastereomers, all retaining potency on ROMK, with the most potent isomer being compound **52**. The lack of a strong preference for a single diastereomer, or especially for *trans* or *cis* relative stereochemistry, was surprising. A general observation was that with analogs in which the terminal pharmacophore was more sterically encumbered (such as with ortho-methyl) there was not a strong preference

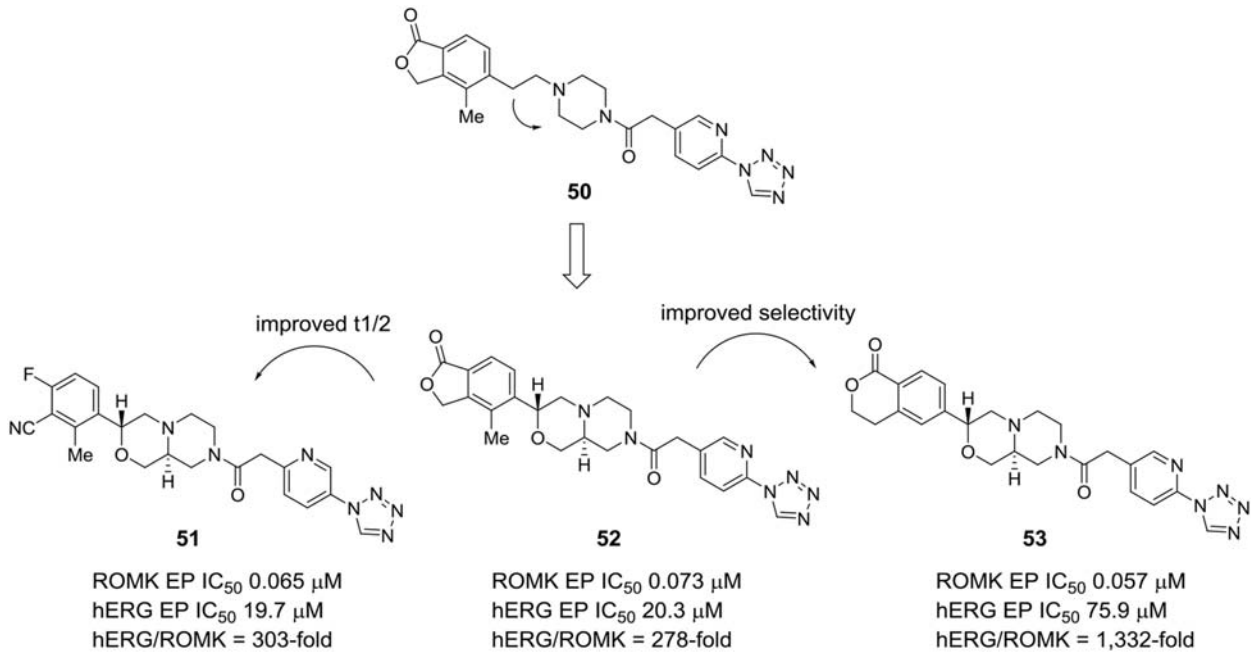

Fig. 12 Lead compounds from the conformationally constrained octahydropyrazino[2,1-c][1,4]oxazine scaffold. ROMK and hERG data are from electrophysiology studies (EP). Reduced clearance rate is associated with significantly diminished in vitro turnover in microsomes.

between *trans* versus *cis* relative stereochemistry, possibly because of more facile flipping between the morpholine boat and chair conformations (less energy difference between them with hindered pharmacophores). On the other hand, smaller terminal pharmacophores (such as that of **53**) led to a greater preference for the *trans* relative stereochemistry, which favors a more extended, rather than bent scaffold arrangement.

Following the discovery of compound **52**, further mix and match combinations of left- and right-side pharmacophores led to compounds **51** and **53**. Compound **53** demonstrated good functional ROMK potency and excellent (improved) selectivity over the hERG channel. Compound **53** was assessed in an anesthetized vagotomized cardiovascular dog model ($n=3$) where no changes were observed in the QT interval or other cardiovascular parameters up to the maximally achieved peak total plasma concentration 82 μM (dog plasma-free fraction, Fu = 22%). Incorporation of the 2-fluoro-6-methylbenzonitrile pharmacophore in compound **51** was associated with improved pharmacokinetic properties while maintaining ROMK potency and ~300-fold selectivity over the hERG channel. Compound **51** was assessed in an anesthetized cardiovascular guinea pig model ($n=3$) where no changes were observed in the QT interval up to the maximally achieved average peak unbound plasma concentration of 59 μM. Compounds **51** and **53** demonstrated excellent selectivity for ROMK. Both compounds were selective against the related inwardly rectifying cardiac $K_{ir}2.1$ channel ($IC_{50} > 100$ μM), as well as the Cav1.2, Nav1.5, and Iks cardiac channels (all $IC_{50} > 30$ μM). Compounds **51** and **53** were assessed in a panel of 115 and 164 assays, respectively, at MDS Pharma Services. Compound **51** had only one hit at < 10 μM (somatostatin subtype 2, IC_{50} 4.1 μM). Compound **53** had only one hit at < 10 μM (endothelin converting enzyme, IC_{50} 9.7 μM). Neither **51** nor **53** demonstrated significant inhibition against a panel of CYP enzymes (3A4, 2D6, and 2C9, all $IC_{50} > 50$ μM). Both compounds showed low plasma protein binding across species (e.g., %Fu for compound **51**: rat 48%, dog 52%, monkey 60%, human 58%). Both compounds had excellent cell permeability measured in LLC-PK1 cells: **51** Papp 28; **53** Papp 25.

A comparison of the rat pharmacokinetic properties of octahydropyrazino[2,1-c][1,4]oxazine analogs **51**, **52**, and **53** in comparison to the parent acyclic compounds **25** and **50** is shown in **Table 10**. The fused bicyclic analogs all demonstrated reduced clearance and improved half-lives compared to their acyclic precursor compounds. All three analogs showed good oral bioavailability. The reduced clearance seen for compounds **51–53** correlates with significantly lower turnover in microsome and hepatocyte incubation studies compared to the parent acyclic analogs.[45] As an example, when compound **51** was incubated with rat, dog, rhesus, and human hepatocytes for 90 min the % parent remaining was 61%, 96%, 91%, and 99%, respectively. A ^{14}C-**51** bile duct cannulated dog study confirmed that the compound is eliminated primarily as intact parent in urine and bile, and is by far the major component in plasma. **Table 11** shows the pharmacokinetic properties of compounds **51** and **53** in dogs and rhesus monkeys. Compound **53** had relatively short half-lives in dog and monkey; however compound **51** had long half-lives, significantly differentiating from earlier program compounds. Both compounds were considered as potential clinical candidate compounds (see later).

8.12.10 ROMK Inhibitors Reduce Blood Pressure in Spontaneously Hypertensive Rats

Compounds **51** and **53** were assessed for blood pressure lowering, diuresis, and natriuresis efficacy in conscious telemetered spontaneously hypertensive rats (SHR) housed in metabolism cages.[46] Compound **51**, when dosed by oral gavage, provided robust

blood pressure lowering at 3 and 10 mg/kg doses (Table 12), comparable or exceeding that of hydrochlorothiazide at a 25 mg/kg dose (approximately the maximally efficacious dose in this model based on a prior full dose–response study). This demonstrates that beyond inducing diuresis and natriuresis, ROMK inhibitors are able to reduce blood pressure in preclinical models, as expected based on the human and rodent genetics. Surprisingly, compound **53** provided minimal blood pressure lowering, which correlated to a reduced 24-h diuretic effect compared to compound **53**. Based on the comparable in vitro potency of the two compounds (Fig. 12) and the similar or higher exposure levels in plasma and urine for compound **53** compared to **51**, it is difficult to explain the discrepancy in the 24 h diuresis and blood pressure lowering effects. Considering the rat pharmacokinetic studies, the rat half-life of compound **51** is nearly twofold that of compound **53**, suggesting the possibility that compound **51** engages ROMK for a longer period of time; if trough exposures contribute to driving efficacy, then this might explain the superior efficacy of compound **51**. In any case, the team learned that the SHR model can provide key differentiation between compounds enabling prioritization of the compounds that will provide the greatest in vivo efficacy. Moreover, the SHR model could be used as a tool to gain a better understanding of the pharmacokinetic–pharmacodynamic relationships.

8.12.11 Parallel SAR Evolution of the Original Piperazine Series

As SAR in the acylpiperazine lead series was diverging from the original piperazine hit series, the Merck team continued in parallel to develop the SAR in the latter series. In some cases SAR between the two series corresponded well and was transferable, and in others SAR diverged, leading to greater structural differentiation between the two subseries. Similar to the acylpiperazine series, Walsh and coworkers demonstrated that installation of a phthalide 4-methyl substituent led to retained or improved ROMK potency and an incremental improvement in hERG selectivity (Fig. 13 and Table 13).[47]

As described earlier, installation of a benzylic hydroxyl group in the acylpiperazine lead series led to a significant reduction of hERG inhibitory potency; however this was accompanied by a corresponding drop in ROMK potency, so the net improvement in selectivity over hERG was only twofold (see compounds **31** and **45** in Fig. 9). When this same modification was explored in the original piperazine series the resulting SAR diverged from that in the acylpiperazine series (Fig. 14 and Table 14). For example,

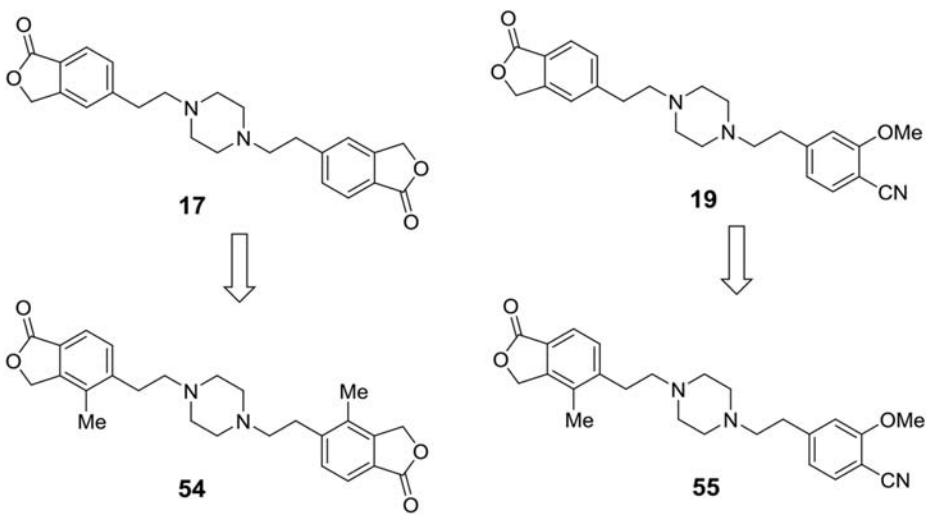

Fig. 13 Incorporation of phthalide 4-methyl provides incremental improvements in hERG selectivity.

installation of a single hydroxyl group into symmetrical analog **54**, provided **56**, which retained ROMK potency and still demonstrated a twofold improvement in selectivity over hERG (as a mixture of two enantiomers).[38] Encouraged, a second benzylic hydroxyl group was installed, leading to three single diastereomers analogs (*R,R*; *meso*; *S,S*; **57–59**, respectively). Amazingly, not only did these analogs retain excellent functional inhibition potency on ROMK, but selectivity over hERG also dramatically improved (1800- to >3300-fold, Table 14), affording some of the most potent and selective compounds identified in the program. The *meso* compound **58** had poor solubility and was challenging to isolate, while the *R,R* and *S,S*-isomers had much better solubility.

Compounds **57** and **59** had comparable PK profiles; however the *meso*-isomer **58** demonstrated somewhat higher clearance and a shorter half-life (Table 15). Based on its physicochemical properties, pharmacokinetic characteristics and inferior *in vivo* diuresis profile in volume-loaded SD rats, *vide infra*, the *meso*-isomer **58** was not advanced further.[38]

Compounds **57–59** were assessed in an acute volume-loaded SD rat diuresis model (described in reference 32).[38] Adult male SD rats were dosed by oral gavage with the indicated doses of compounds. After 30 min, voiding was induced by giving each animal a saline load. Urine collection took place over the next 4 h and was analyzed for volume and electrolyte content. Data are presented as fold change relative to values obtained in the vehicle-treated animals (Table 16). The *R,R*-isomer **57** provided the most robust diuretic and natriuretic effect, with the *S,S*-isomer **59** giving intermediate efficacy and the *meso*-isomer giving relatively modest efficacy. Even at the 0.3 mg/kg dose compound **57** provided greater efficacy than compounds **58** and **59** at 10-fold higher (3 mg/kg) doses. Although the exact reason for these differences in not clear, the shorter half-life of **58** may account for its weaker efficacy.

Other factors that could impact the relative efficacy of the diastereomers might be differential urinary exposure at the site of action in the tubular lumen and/or differing ROMK channel dissociation rates. On the basis of the in vivo data, compound **57** was selected for further profiling.

In an assay that measures the ability of thallium to permeate through open hROMK channels stably expressed in HEK293 cells, compound **57** blocks the thallium-induced fluorescence signal with an IC_{50} value of 6.6 ± 1.9 nM ($n=9$), in good correspondence with the potency observed by automated IonWorks electrophysiology (9 nM).[46] In MDCK cells stably expressing the rat ROMK channel, thallium flux is inhibited by compound **57** with an IC_{50} value of 6.3 ± 1.7 nM ($n=4$). In manual electrophysiological recordings of HEK-rKir1.1, HEK-dKir1.1, or rhesus Kir1.1 channels transiently transfected into TsA-201 cells, **57** provided estimated IC_{50} values of 4.9, 8.8, and 8.6 nM, for rat, rhesus or dog Kir1.1, respectively, indicating little species differences. To determine the off rate of compound **57** from rat ROMK channels, stable recordings of rat ROMK currents were established, compound was applied and equilibrated (100 nM), at which point compound was removed from the bath solution and recovery of the rat ROMK current was monitored. Compound **57** demonstrated a slow recovery of current [off rate (time constant, τ_{off}) >40 min.]. This distinguishes it from its diastereomers **58** and **59** which when tested in a similar fashion had estimated off rates of 22 and 4 min, respectively. It also distinguishes it from acylpiperazine analog **53** which had an estimated off rate of 19 min. The long off rate of compound **57** may play a role in its superior diuretic efficacy at matched doses compared to these other analogs by extending target engagement.

Compound **57** did not demonstrate significant inhibition of other K_{ir} family channels screened (IC_{50} $K_{ir}2.1$ and $K_{ir}2.3$, >100 μM; IC_{50} $K_{ir}4.1$ and $K_{ir}7.1$ >30 μM), nor did it significantly inhibit other cardiac channels such as Cav1.2 and Nav1.5 (both with IC_{50} >30 μM); in electrophysiology assays with I_{Ks}, I_{Na}, and L-type I_{Na} channels, no inhibition was observed (<5%) at the highest tested concentration of 30 μM. In a broad counterscreening panel of 166 enzymes and radioligand binding assays performed at MSD Pharma Services, compound **57** demonstrated good overall selectivity, showing inhibition of 50% or greater at 10 μM for only three assays: acetyl cholinesterase, ACES, $IC_{50}=9.94$ μM, human serotonin transporter, SERT, $IC_{50}=0.12$ μM, and somatostatin subtype 1, sst1, IC_{50} 2.63 μM. In a functional assay using HEK293 cells stably transfected with human SERT, compound **57** inhibited uptake of ^{3}H-serotonin with an IC50 value of 2.40 ± 0.32 μM ($n=5$). Somatostatin subtype 1 activity was assessed in an internal binding assay measuring displacement of ^{125}I-somatostatin-14 where it demonstrated an IC_{50} of 14.5 μM. In a functional assay using cAMP in agonist mode in CHO K1 cells stably expressing sst1 performed at Multispan compound **57** did not display significant agonist activity (EC_{50} >30 μM). Based on the ~300-fold selectivity for ROMK over SERT, the low plasma exposures required for efficacy in diuresis and blood pressure models, and the observation that compound **57** is a Pgp substrate (human Mdr1 B–A/A–B ratio = 12), we concluded that there should be sufficient margins against any adverse CNS effects related to SERT inhibition.[38] It should be noted that based on PET tracer studies using ^{11}C-DASB, the efficacy of SERT inhibitors is believed to require ≥80% SERT occupancy at trough in humans.[48]

Table 17 Pharmacokinetic properties of compound **57** in dogs and rhesus monkeys

Species	*Dog*	*Rhesus*
Cl (mL/min/kg)	56	29
Vdss (L/kg)	7.5	6.7
$AUCN_{po}$ (μM h kg/mg)	0.32	0.30
Half-life (h)	1.7	4.0
F%	51	25

Compound **57** was assessed in an anesthetized vagotomized cardiovascular dog model ($n=3$)[40] to confirm that the high selectivity for ROMK over hERG would ensure CV safety in vivo. Following a rising dose IV infusion of compound **57** at a cumulative 10 mg/kg dose (average peak plasma concentration 11.6 μM), no changes were observed in heart rate, mean arterial pressure, or in the QT interval and other electrocardiographic parameters.

ROMK inhibitor **57** was evaluated in pharmacokinetic studies in dogs and rhesus monkeys where it demonstrated moderate clearance rates (**Table 17**).[38] Compound **57** had a short half-life in dog and a moderate half-life in monkey. In a bile duct cannulated rat study with ^{3}H-**57**, the major clearance mechanisms were oxidative metabolism by CYP3A4 and urinary excretion of unchanged parent; minor metabolism pathways included glucuronidation and lactone hydrolysis.[49] The major circulating component was parent. ROMK inhibitor **57** was not a potent reversible inhibitor of human CYP3A4, CYP2C9, or CYP2D6 ($IC_{50}>50$ μM) and was not a time-dependent inhibitor of CYP3A4 at 10 and 50 μM. Inhibitor **57** was not a potent hPXR activator ($EC_{50}>30$ μM; 5% activation at 30 μM). Compound **57** had low plasma protein binding across species (%Fu rat 57%, dog 62%, rhesus monkey 67%, and human 29%), differentiating from standard-of-care loop and thiazide diuretics which typically have high plasma protein binding. The projected human half-life of compound **57** was estimated to be ~5 h based upon a combination of in vitro to in vivo correlation and allometric scaling from preclinical species. Inhibitor **57** had good permeability in LLC-PK1 cells (Papp: 20×10^{-6} cm/s) and demonstrated significant colonic absorption in dogs with an $AUC_{0-24\ h}$ ratio of colonic to oral exposure of 0.36.[49] This supported the possibility that compound **57** could be formulated for extended release if the human half-life should prove to be inconsistent with qd dosing.

Hampton and coworkers have described the acute renal excretory function of compound **57** in conscious female mongrel dogs.[46] In this model restrained mongrel dogs were fitted with catheters inserted into the urinary bladder to permit timed urine collections and maintained with a continuous intravenous saline-based infusion (1 mL/min) via venous catheter. Following a 60-min equilibration period, dogs were dosed orally with compound **57** and comparator diuretics and urine and blood samples were collected for 180 min. **Fig. 15** shows the natriuretic dose response for compound **57** in this model in comparison to an approximately maximally efficacious dose of HCTZ.

The acute diuretic and electrolyte excretion responses of **57** (0.1, 0.3, 1, or 3 mg/kg) is compared with HCTZ (10 mg/kg) and furosemide (1, 3, 10, or 25 mg/kg) in **Table 18**. Compound **57** evoked dose-dependent increases in diuresis and natriuresis. At the 0.3-mg/kg dose the magnitude of diuresis and natriuresis was greater than that obtained with HCTZ at its maximally efficacious dose in this model, and equivalent to that obtained at 3 mg/kg of furosemide. The maximal effect of **57** was achieved at 1 mg/kg; no further significant response was obtained at 3 mg/kg. Similarly, the maximal effect of furosemide was achieved at 10 mg/kg as no further increase in diuresis or natriuresis was observed at 25 mg/kg. Kaliuresis in compound **57**-treated animals was comparable to that of vehicle-treated animals whereas an approximately twofold increase was observed in animals that received HCTZ. Consequently, the U_K/U_{Na} excretion ratio was more favorable for ROMK inhibitor **57** than for HCTZ. Similarly, furosemide at 3 mg/kg also elicited increased kaliuresis relative to vehicle, again leading to a more favorable U_K/U_{Na} excretion ratio for ROMK inhibitor **57** at 0.3 mg/kg compared to furosemide at 3 mg/kg, doses at which both compounds gave similar natriuresis. This observation is consistent with expectations based on the expression of ROMK in the CCD, where it plays a critical role in potassium homeostasis

[a]Fold change is calculated relative to vehicle.

and suggests that ROMK inhibitors may have a reduced risk of inducing hypokalemia compared to thiazide and loop diuretics. Both compound **57** and furosemide increased calcium and magnesium excretion to a similar extent at equinatriuretic doses, while HCTZ did not. Loop diuretics such as furosemide are known to increase calcium and magnesium excretion since they attenuate the transepithelial potential which establishes the driving force for paracellular uptake of calcium and magnesium ions. Mechanistically, ROMK inhibitors would be expected to act in the same way as they also (indirectly) block sodium reabsorption through the Na^+–K^+–$2Cl^-$ co-transporter. Glomerular filtration rate (GFR) was not changed in animals that received **57** in this acute setting.

In addition to monitoring the response to acute treatment, both **57** (0.3 mg/kg/day) and HCTZ (10 mg/kg/day) were dosed po, for 7 days and urinary and plasma electrolytes, as well as compound levels, were monitored at 30 min intervals for 3 h post dosing on Days 1 and 7.[46] The dose of compound **57** was selected based on its equinatriuretic potency to the 10 mg/kg dose of HCTZ. The acute diuretic and natriuretic response to compound **57** was maintained upon 7-day dosing whereas both responses were diminished in dogs dosed with HCTZ for 7 days (data not shown). Plasma potassium levels were not significantly altered by compound **57** treatment at the 0.3 mg/kg dose, whereas a marked decrease was observed at day 7 in HCTZ-treated dogs (Fig. 16). Compared to vehicle-treated group, chronic dosing with **57** had no effect on plasma glucose, calcium, magnesium, sodium, chloride, uric acid, or blood urea nitrogen levels (data not shown). However, bicarbonate levels were found to be elevated after 6 days of dosing with MK-7145, consistent with metabolic alkalosis associated with loop diuretics. In the 3 h post dosing plasma and urine concentrations of **57** were very similar on days 1 and 7 with ~30- to 60-fold higher exposures in urine compared to plasma. As an example exposure on day 7 in plasma and urine for the 150–180-min time interval was 0.060 and 1.81 μM, respectively. Since ROMK is expressed on the apical face of epithelial cells lining the tubular lumen of the nephron, it is possible that urinary exposure may play a key role in driving efficacy.

The BP lowering and diuretic activity of compound **57** (0.3, 1, 3, 10, and 30 mg/kg/day, po) administered daily for 4 days was assessed in male SHR using radiotelemetry.[46] ROMK inhibitor **57** evoked dose-dependent decreases in systolic blood pressure (SBP) (Fig. 17, panel A) and diastolic blood pressure (DBP). Maximal lowering of SBP (~20 mmHg) was observed by day 2 at both the 10

and 30 mg/kg/day doses. At the 3 mg/kg dose of compound **57**, the magnitude of BP lowering (∼12 mmHg) was similar to that achieved with HCTZ (25 mg/kg/day) at its approximately maximally efficacious dose based on a prior dose range study. Importantly, in comparison to the blood pressure efficacy seen for earlier ROMK inhibitors **51** and **53** (Table 12, earlier) compound **57** produced a greater magnitude of blood pressure lowering at the same doses and produced efficacy at lower doses and at lower plasma exposures (Table 19). For example, compound **51** lowered systolic blood pressure by 16 mmHg at a 10 mg/kg dose, while compound **57** provided comparable blood pressure lowering at the 3 mg/kg dose. Despite the short half-life of compound **57** in rats, the extent of BP lowering was maintained throughout day 3 in all treatment groups (Fig. 17, panel B). Parallel pharmacokinetic studies established that at the maximally efficacious (10 mg/kg) dose of compound **57**, trough unbound plasma levels (∼0.003 μM) are below the compound's IC_{50} on the rat channel. However, late urine collection near trough (20–24 h) indicated that urine exposures are ∼100-fold higher than plasma exposures at trough,[49] suggesting the possibility that urine exposure helps to maintain target engagement throughout the full 24 h dosing interval.

Analysis of the correlation between blood pressure lowering efficacy and diuresis and natriuresis indicated that blood pressure efficacy is not correlated to acute peak effects (not shown), but instead to day 1 net 24 h diuresis and natriuresis (Fig. 18, panels A and B, respectively). Typically, ROMK inhibitor-mediated acute diuretic and natriuretic effects in rats are very robust and return to baseline after about 2 h post dose. In some cases, there is a rebound sodium and water retention which diminishes the overall net 24 h diuretic and natriuretic effect. Thus, the more potent ROMK inhibitors in lowering blood pressure or the doses at which blood pressure lowering is observed are those that are able to sustain a net 24 h diuretic and natriuretic response (Fig. 19); this ability may be linked to the ROMK inhibitor half-life, trough urine, and plasma exposure, in vitro potency, and possibly to the channel off rate. Note from Fig. 19 that diuresis efficacy is maintained through all days of the study and this is associated with increased water intake by the rats (not shown).

Urine samples were also analyzed to determine the magnitude of calcium excretion relative to vehicle. During the 4 h postdose, compound **57** at all doses led to an increased calcium excretion rate compared to vehicle (three- to sixfold, data not shown). During the subsequent 20 h (4- to 24-h interval) calcium excretion became less pronounced, with only the 10 and 30 mg/kg doses of **57** giving a 1.5- to 3-fold increase in calcium excretion rate. This calciuretic effect is consistent with observations in dogs, *vide supra*, and is also associated with the profile of clinically used loop diuretics such as furosemide.

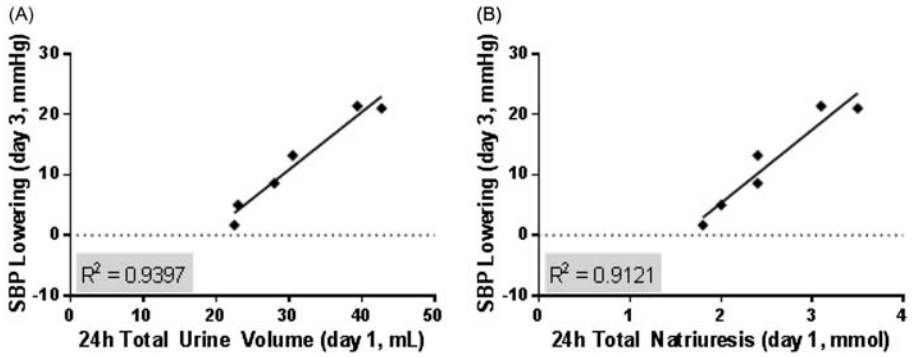

Fig. 18 Blood pressure lowering in SHR by compound **57**. Panel A: correlation of blood pressure lowering with 24 h urine volume; Panel B: correlation of blood pressure lowering with 24 h natriuresis. Adapted from: : Hampton, C.; Zhou, X.; Felix, J. P.; Priest, B. Fig. 19 Comparison of acute and 24 h diuretic effects for compound **57** in SHR rats.

In light of the short half-life of compound **57** in rats, 3 mg/kg and 10 mg/kg qd and 3 mg/kg bid po doses were compared in a 4-day study in SHR to probe the pharmacokinetic (PK)–pharmacodynamic (PD) correlation of **57**.[50] The bid doses were at 12 h intervals. The results (Fig. 20 and Table 20) illustrate that 3 mg/kg bid dosing confers superior systolic blood pressure lowering (−23 mmHg on Day 4) to either 3 or 10 mg/kg qd dosing (−12 and −17 mmHg, respectively). These results, together with exposure data from a parallel bid versus qd PK study, suggest that trough, but not peak exposure, correlates better with BP lowering efficacy of the compound in SHR. Despite the lower total dose, 3 mg/kg bid dosing provides a higher trough plasma exposure and an equivalent 12–24 h urine exposure compared to the 10 mpk qd dosing paradigm. This prolonged exposure correlates to a more prolonged diuretic effect (Table 21). In a parallel pharmacokinetic study, the 10 mg/kg qd and 3 mg/kg bid dose regimens give the same 24 h diuresis fold change versus vehicle when averaged over 3 days; however, the 3 mg/kg bid dose regimen gives greater diuresis than the 10 mg/kg dose from 12–24 h (1.9-fold compared to 1.5-fold change compared to vehicle, respectively). Because both qd and bid dosing conferred full 24-h systolic blood pressure reduction compared to vehicle, bid dosing improves the magnitude of blood pressure lowering, but is not required for maintaining the 24-h duration of efficacy. Taken together, these data suggest that ROMK inhibitors with longer half-lives and reduced peak-to-trough ratios will provide improved efficacy.

Finally, to test the durability of blood pressure lowering by ROMK inhibitors, a 14-day study in SHR evaluating compound **57** at 1 and 3 mg/kg doses was conducted. Blood pressure lowering was maintained throughout the course of the study, indicating that the pharmacodynamic effects are sustained and do not wane over time.[46]

8.12.12 Selection of Compound 57 as the Clinical Compound MK-7145

Starting from the program initial lead **2**, two quite distinct subclasses of potent and selective ROMK inhibitors were developed (Fig. 21). From these two subclasses, compounds **51**, **53**, and **57** were milestone compounds that were profiled as potential clinical

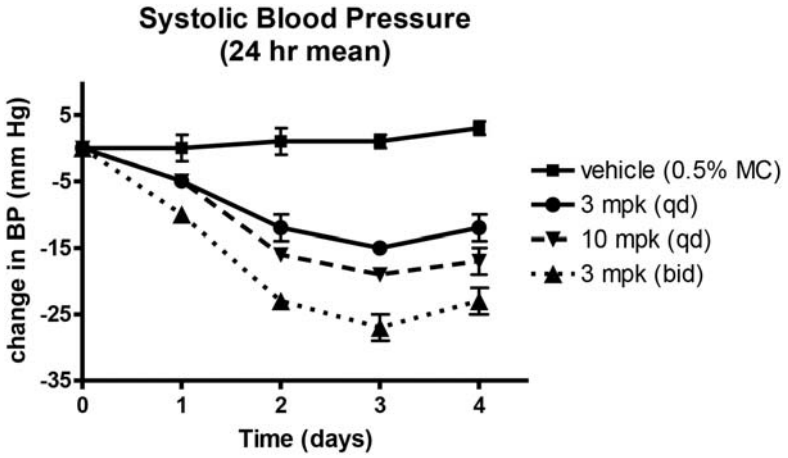

Fig. 20 Blood pressure lowering efficacy of 3 and 10 mg/kg qd vs. 3 mg/kg bid dosing of **57** in SHR (bid doses are at 12 h intervals).

development compounds (Table 22). All three compounds demonstrated good selectivity over the hERG channel and good margins in cardiovascular safety models. Based on allometric scaling of preclinical PK and in vitro–in vivo correlation studies, compound **51** had the longest projected human half-life (10 h), followed by compound **57** (5 h). However, compound **57** consistently demonstrated robust efficacy at lower doses in all pharmacodynamic models assessed compared to other available compounds. Therefore, compound **57** was selected as the clinical development compound and was designated MK-7145. The main perceived risk associated with MK-7145 was that its human half-life might not be compatible with qd dosing. As discussed previously, MK-7145 has good cell permeability and demonstrated acceptable colonic absorption in a dog model. Therefore, MK-7145 was deemed a candidate for development of an extended release formulation should the human half-life be determined to be insufficient. In addition, identification of backup clinical candidates would focus on identification of longer half-life compounds in addition to structural differentiation versus MK-7145. In this regard, compound **51** was viewed as a potential backup compound in that it provided good structural differentiation and improved preclinical half-lives compared to MK-7145. Ultimately, additional modifications to compound **51** would further improve preclinical half-lives and efficacy in spontaneously hypertensive rats and lead to a structurally differentiated backup molecule.

8.12.13 MK-7145 Displays Additive or Synergistic Blood Pressure Lowering Efficacy in Combination With Candesartan and HCTZ

Combination therapy with two or more antihypertensive drugs is required for most patients with hypertension in order to reach target blood pressure.[51] Combination therapy can provide improved blood pressure control and may offer improved tolerability compared to higher dose monotherapy. For example, Lacourciere and coworkers reported improved responder rates in patients with stage 2 and stage 3 systolic hypertension by combination of angiotensin receptor blocker valsartan with HCTZ compared to valsartan monotherapy; this was achieved without significant effect on tolerability.[52] Similarly, it is likely that ROMK inhibitors could be used clinically in combination with other antihypertensive agents with a potential to provide superior combination effects compared to standard-of-care thiazide and loop diuretics used in treatment of hypertension and heart failure, respectively.

To explore the combination therapy potential of ROMK inhibitors with angiotensin receptor blockers, the effect of combined treatment of MK-7145 with candesartan on blood pressure was evaluated in SHR.[46] MK-7145 (10 mg/kg/day, po), HCTZ (25 mg/kg/day, po), or vehicle was administered for 7 days to achieve a stable level of BP reduction. Subsequently, all animals received a submaximal dose of candesartan (0.1 mg/kg/day, po) for 2 days. In agreement with the dose–response study, MK-7145 (10 mg/kg) reduced systolic blood pressure (~20 mmHg) by day 2 which was sustained for the duration of the 7 day treatment. The magnitude of blood pressure lowering with HCTZ (25 mg/kg) was 10–15 mmHg. Addition of candesartan to the vehicle group (0.1 mg/kg) lowered blood pressure in by ~15 mmHg. In animals previously administered HCTZ, the addition of candesartan provided an additional 15–20 mmHg reduction in systolic blood pressure. However, candesartan when administered in combination with MK-7145 provided an additional 20–30 mmHg reduction in BP (Table 23), demonstrating a greater than additive effect on blood pressure and a greater overall magnitude of efficacy compared to the HCTZ/candesartan combination. Additional combination studies with submaximal and maximal doses of candesartan (0.1 and 1 mg/kg, respectively), using a range of doses of MK-7145 (1, 3, and 10 mg/kg), consistently provided greater than additive blood pressure lowering for all combinations tested (data not shown). Consequently, the combination of MK-7145 with angiotensin receptor blockers may provide an attractive option for treatment of hypertension.

To identify whether there is potential synergy between MK-7145 and HCTZ and to evaluate the ability of HCTZ to block the calciuretic response elicited by MK-7145, two combination studies were performed in SHR.[46] Minimally (study 1) and maximally (study 2) effective doses of HCTZ (10 and 25 mg/kg, respectively) were combined with doses of MK-7145 which produce a minimal (1 mg/kg) and maximal (10 mg/kg) calciuretic effect. MK-7145 and HCTZ were also dosed alone at these doses. The results demonstrate that the blood pressure lowering efficacy achieved is at least additive at each combination tested (Table 24), supporting that the two diuretics lower blood pressure by distinct additive mechanisms.

In the first of the two combination studies, the 10 mpk dose of HCTZ was able to block the small calciuretic effect seen with 1 mg/kg of MK-7145 and reduce the calciuretic effect of the 10 mpk dose of MK-7145 by ~50% (Table 25). In the second study (with 25 mg/kg HCTZ), the higher dose of HCTZ was able to reduce the calciuretic effect of MK-7145 by ~80% (data not shown). Taken together, the combination of ROMK inhibitors with hydrochlorothiazide provides additive blood pressure lowering while providing a more calcium neutral excretion profile.

8.12.14 Backup Efforts Focused on Longer Preclinical Half-Lives and Structural Diversity: The Dibasic Piperazine Series

Following the discovery of MK-7145, a similar SAR approach was explored on the unsymmetrical hybrid dibasic piperazine analogs. Consistent with the trend seen in Fig. 14, installation of two hydroxyl groups into analogs **60** and **55** led to potent analogs with improved selectivity over the hERG channel. Incorporation of cyanopyridyl in place of cyanophenyl further enhanced selectivity over hERG, leading to potent ROMK inhibitors, **61** and **63**, both with excellent selectivity over the hERG channel (Fig. 22 and Table 26).[47] Interestingly, in this case there were more profound differences between diastereomers in terms of ROMK potency. For example, of four possible diastereomers of **61**, the *R,S*-isomer (shown) provided the best ROMK potency (ROMK EP IC_{50} 0.018 μM), followed by the *R,R*-isomer (ROMK EP IC_{50} 0.090 μM) and the much weaker *S,S* and *R,R*-isomers (ROMK EP IC_{50} both >1 μM). As shown previously, installation of an ortho-methoxy group onto the cyanophenyl (and here also cyanopyridyl) pharmacophores provided better selectivity over hERG (**63** compared to **61**). Similar to **61**, the optimal absolute stereochemistry of **63** was *R,S*. Preparation of the three possible diastereomers of the symmetrical methoxypyridylnitrile pharmacophore type provided compound **64** as the most potent single diastereomer (undetermined absolute stereochemistry, but presumed to be *S,S* based on analogy to other analogs); however, this compound, while potent on ROMK, demonstrated significantly reduced selectivity over the hERG channel, indicating that at least one phthalide pharmacophore is required for optimal selectivity over hERG.[49] Interestingly, as a general observation, the cyanopyridyl pharmacophores provide improved pharmacokinetic profiles compared to the phthalide pharmacophores, but this comes at the price of hERG selectivity. By striking a balance, with one phthalide and one cyanopyridyl pharmacophore, we hoped to achieve improved pharmacokinetic properties, while retaining sufficient hERG

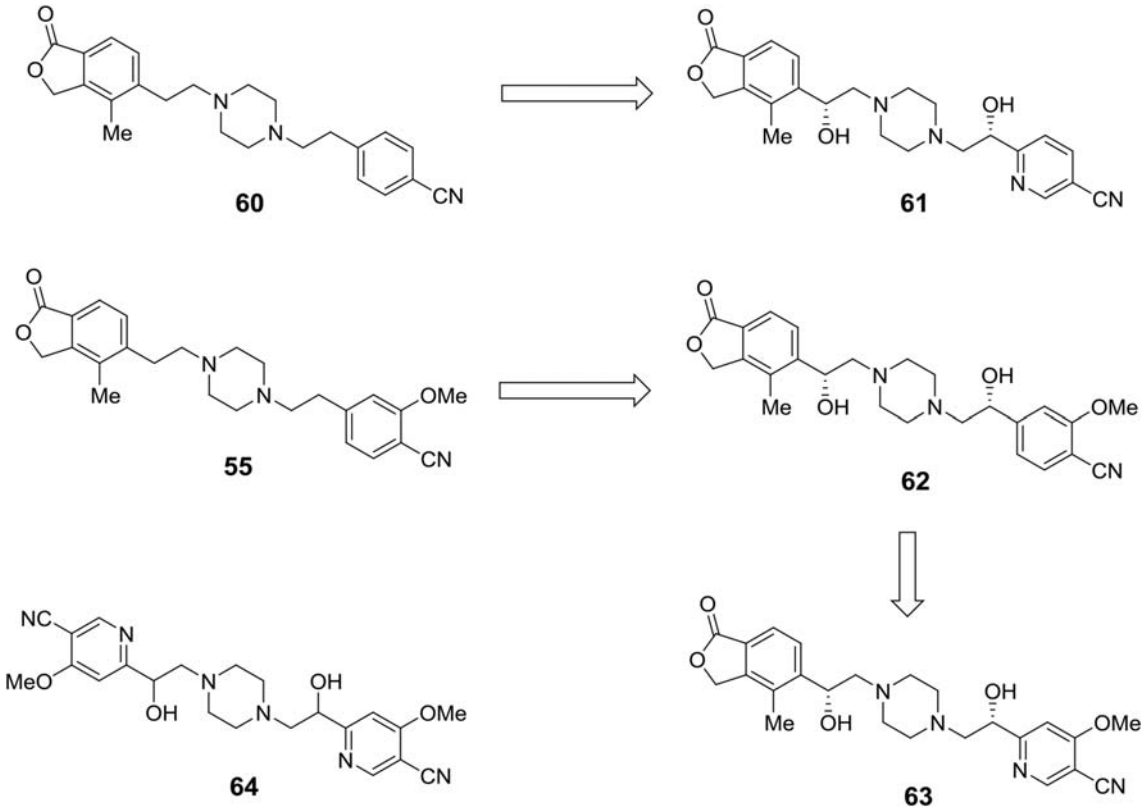

Fig. 22 Incorporation of benzylic hydroxyl groups and cyanopyridine in unsymmetrical dibasic piperazine lead series.

Table 26 ROMK and hERG potency of **60**, **61**, **55**, **62**, **63**, and **64** measured by electrophysiology

Compound	*ROMK EP IC_{50} (μM)*	*hERG EP IC_{50} (μM)*	*Ratio hERG EP/ROMK EP*
60	0.30[a]	0.43[b]	1.4[a,b]
61	0.018	12	667
55	0.087	86%@10 μM	–
62[c]	0.033	5.1[b]	155[b]
63	0.027	33	1222
64[d]	0.050	3.5[e]	70[e]

[a]ROMK potency for **60** was determined using the functional $^{86}Rb^{+}$ efflux assay.
[b]hERG activity for **60** and **62** was measured using the ^{35}S MK-499 displacement binding assay.
[c]Absolute stereochemistry at cyanophenyl benzylic position is not confirmed, but presumed as *R* since it is the more potent of the two single diastereomers.
[d]Single diastereomer with undetermined absolute stereochemistry; most potent of three stereoisomers. By analogy, stereochemistry presumed to be *S,S*.
[e]hERG activity for **64** was measured using a hERG thallium flux functional assay in HEK 293 cells.

selectivity. In fact, both compounds **61** and **63** had attractive pharmacokinetic properties in rats, with good oral bioavailability, reduced clearance rates, and longer half-lives compared to the symmetrical analogs such as **57** (Table 27).

Compound **63** was further assessed in dog and monkey pharmacokinetic studies, where it similarly demonstrated good oral bioavailability and good half-lives (Table 28). ROMK inhibitor **63** was not an inhibitor of CYP3A4, 2D6, 2C9 (IC_{50} all >50 μM), but showed weak inhibition of CYP2C8 (IC_{50} 8.2 μM). Compound **63** had low plasma protein binding across species (%Fu rat 43%, dog 83%, rhesus 63%, and human 58%) and had good permeability measured in LLC-PK1 cells (Papp 23×10^{-6} cm/s). The projected human half-life of compound **63** determined from allometric scaling of preclinical PK was estimated to be 10 h, significantly longer than commonly used loop diuretics such as furosemide and longer than the projected human half-life of MK-7145 (~5 h). Compound **63** demonstrated robust diuretic and natriuretic efficacy without loss of potassium in urine (kaliuresis) in both volume-loaded SD rats and in female mongrel dogs (data not shown).[47]

ROMK inhibitor **63** demonstrated comparable functional potency in thallium flux assays for rat and dog ROMK (0.014 and 0.042 μM, respectively). Like other members of this class of ROMK inhibitors, **63** had good selectivity over other members of

Table 27 Rat pharmacokinetic properties of compounds **61** and **63** (1 mg/kg iv, 2 mg/kg po)

the K_{ir} channel family ($K_{ir}2.3$, $K_{ir}2.1$, >100 μM; $K_{ir}4.1$ and $K_{ir}7.1>10$ μM) and over the cardiac channels screened (Nav1.2 and Cav2.1, both >30 μM). In a panel of 115 assays conducted by Ricerca Biosciences, compound **62** had no activities identified at ≤ 10 μM. Thus, inhibitor **63** has excellent selectivity for ROMK.

Compound **63** was assessed for blood pressure lowering, dieresis, and natriuresis efficacy using conscious spontaneously hypertensive rats[46] (SHR) equipped with telemetry devices and held in metabolism cages (Table 29). ROMK inhibitor **63** provided dose-dependent and robust blood pressure lowering by day 3, at least equivalent to that provided by MK-7145 (**57**). At a 1 mg/kg dose compound **63** reduced systolic blood pressure by 18 mmHg, comparable to an approximately maximally efficacious 25 mg/kg dose of hydrochlorothiazide which lowered systolic blood pressure by 15 mmHg. The magnitude of blood pressure lowering correlated well with both day 1 24 h natriuresis fold increase and the average 24 h diuresis fold increase from days 1–3.

Based on its overall profile, compound **63** was positioned as a structurally related potential backup clinical development compound with longer projected human half-life in the event that the lead compound **57** (MK-7145) should have an inadequate human half-life for qd dosing. Ultimately, MK-7145 demonstrated a longer human half-life than predicted in human clinical trials in healthy male subjects (~13 h), and the decision was made to focus on identifying a long half-life more structurally differentiated backup to mitigate risk of a potential tolerability issue occurring at some later time during development. Nonetheless, compounds **61** and **63** were used as tool compounds and surrogates to MK-7145 for numerous studies to further characterize ROMK inhibitors, explore mechanism of action, and determine points of differentiation from standard-of-care thiazide and loop diuretics.

8.12.15 Effects of ROMK Inhibitor 61 in Dahl Salt-Sensitive Rats

The Dahl salt-sensitive hypertensive rat (Dahl SS) is a well-established rodent model of salt-sensitive hypertension and progressive kidney injury. Dahl rats fed a high salt diet rapidly develop hypertension and reduced renal function with increased proteinuria, and exhibit other features common with hypertension in humans.[53] Zhou and coworkers recently described studies examining systemic hemodynamic, renal function and structure, vascular function, and cardiac structure in Dahl salt-sensitive rats on a high salt diet employing tool ROMK inhibitor **61** and comparing to HCTZ.[54] Zhou conducted two studies, one a therapeutic study in which Dahl rats had been maintained on a high salt (4% salt) diet for 5 weeks to establish a hypertensive state followed by treatment with **61** and HCTZ for 4 weeks, and a second prophylactic study where diuretic treatment was initiated after only 1 week on a high salt diet and

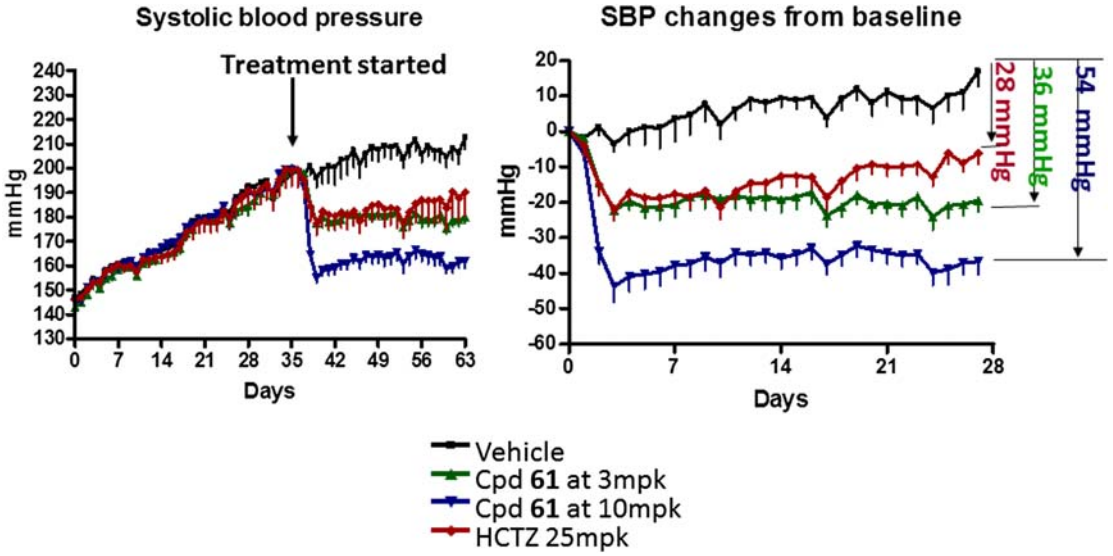

Fig. 23 Therapeutic treatment of Dahl salt-sensitive rats previously maintained on a 4% salt diet for 5 weeks with compound **61** (3 and 10 mg/kg) and HCTZ (25 mg/kg). From Zhou, X.; Forrest, M. J.; Sharif-Rodriguez, W.; Forrest, G.; Szeto, D.; Zhu, Y.; Cui, Y.; Pan, Y.; Urosevic-Price, O.; Wang, L.; Stevenson, A. S.; Zhou, Y.; Stribling, S.; Dajee, M.; Zhao, H.; Ormes, J. D.; Pasternak, A.; Walsh, S. P.; Roy, S.; Sullivan, K. A. *Hypertension* (submitted for publication).

prevention of development of hypertension compared to the vehicle group was monitored over the following 8 weeks. In the therapeutic study (Fig. 23), 4-week treatment of the resulting hypertensive rats with 3 and 10 mg/kg/day doses of **61** and a 25 mg/kg/day dose of HCTZ lead to decreased systolic blood pressure for all treated groups, with a continued rise in blood pressure observed in the vehicle group. By the end of the 4-week treatment period, compound **61** at both doses provided greater blood pressure lowering compared to HCTZ at 25 mg/kg/day. At the 10 mg/kg/day dose, compound **61** reduced blood pressure to nearly baseline levels prior to salt feeding. Moreover, blood pressure lowering efficacy was maintained throughout the 4 weeks of treatment.

In the prophylactic study (not shown), both doses of **61** lowered systolic blood pressure to approximately presalt feeding baseline levels and prevented development of hypertension for the full 8 weeks of treatment.[54] HCTZ also lowered blood pressure and maintained reduced blood pressure throughout the 8 weeks of treatment; however there was a gradual erosion of efficacy such that there was only a 44 mmHg decrease compared to the vehicle-treated animals at the study end, while there was a 62 and 70 mmHg reduction compared to vehicle for the 3 and 10 mg/kg/day dose groups of compound **61**.

In addition to superior blood pressure lowering efficacy compared to HCTZ, compound **61** reduced proteinuria, a marker of kidney injury, in both studies with a greater benefit for compound **61** at the 10 mg/kg/day dose compared to HCTZ at 25 mg/kg/day. Both compound **61** and HCTZ reduced biomarkers for kidney injury (LPN, KIM-1) compared to the vehicle-treated group. Compound **61** also preserved vascular function, decreased kidney and heart weight changes, and improved kidney and heart histopathological scoring compared to the vehicle-treated groups.

8.12.16 Backup Efforts Focused on Longer Preclinical Half-Lives and Structural Diversity, Efforts Involving Alternative Scaffolds

As indicated previously, analogs such as **51**, based on the octahydropyrazino[2,1-c][1,4]oxazine scaffold, represented a structurally distinct subclass of ROMK inhibitors showing improved preclinical pharmacokinetic profiles compared to MK-7145. Future publications will detail additional SAR studies following from compound **51**, and leading to analogs with even longer preclinical half-lives and culminating in the identification of the first backup ROMK clinical compound. Other scaffold modifications to the original dibasic piperazine core compounds also proved fruitful. Chobanian and coworkers recently reported on the discovery of potent ROMK inhibitors with good selectivity over hERG based upon a spirocyclic core scaffold (Fig. 24).[55] Very potent ROMK inhibitors could be generated from this scaffold. Importantly, from an SAR perspective, the spiropyrolidine could be used for C—N coupling reactions, allowing much more rapid pharmacophore SAR exploration, including by parallel synthesis techniques. This resulted in identification of several novel pharmacophores, providing structural differentiation from the limited selection of previously known left- or right-side pharmacophores. In some cases, the new pharmacophores were only useful when incorporated into these spirocyclic scaffolds. Compound **65** represents a milestone compound with good ROMK potency and selectivity over hERG, and favorable overall preclinical pharmacokinetic properties (half-lives in rat 2.1 h, dog 8.6 h, rhesus 1.8 h). Future communications will detail subsequent modification of compound **65**, providing improved compounds, including a second backup clinical development compound.

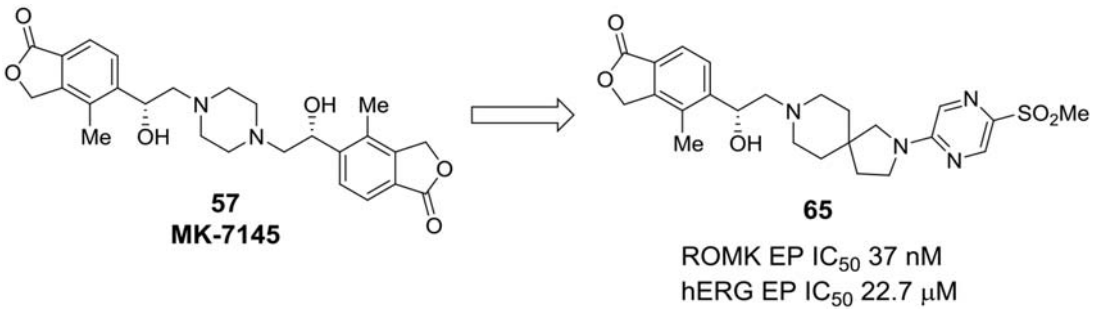

Fig. 24 Scaffold hopping leads to potent spirocyclic ROMK inhibitors.

8.12.17 MK-7145 Clinical Trials

At the time of writing this manuscript, data from clinical trials with MK-7145 have not been disclosed. A search of ClinicalTrials.gov lists two clinical trials conducted with MK-7145. One study is entitled "A Phase Ib, Randomized, Double-Blind, 4-Treatment, 2-Period Incomplete Block Study to Evaluate the Multiple Dose Effects of MK-7145 and Hydrochlorothiazide Compared to Placebo on Blood Pressure in Male Patients With Hypertension" (ClinicalTrials.gov Identifier: NCT01370655). The described purpose of this study was to evaluate the antihypertensive efficacy and tolerability of MK-7145 in comparison to HCTZ in participants with mild-to-moderate hypertension. The 28-day study's listed primary endpoints included, (1) time-weighted average over 24 h post dose decrease in systolic blood pressure with MK-7145 at 6 mg/day versus placebo; (2) time-weighted average over 24 h post dose decrease in systolic blood pressure with MK-7145 6 mg versus hydrochlorothiazide; and (3) urinary sodium excretion (UNaV) for MK-7145 at 6 mg/day versus placebo (24 h post dose on Day 1). This study enrolled 46 male patients with essential hypertension between the ages of 18 and 75. Daily doses of MK-7145 were 3 mg/kg/day and 6 mg/kg/day and doses of HCTZ were 25 mg/kg/day. This study was indicated to be completed in Jan. of 2012.

The second study listed at the ClinicalTrials.gov (described as terminated) is entitled, "A Two Part, Open-label, Phase I Study to Evaluate the Safety, Tolerability, Pharmacokinetics and Pharmacodynamics of MK-7145 in Patients With Renal Insufficiency (Part I) and Heart Failure With Renal Insufficiency (Part II)" (ClinicalTrials.gov Identifier: NCT01558674). Part I is described as a 3-period, active comparator-controlled, fixed sequence study to evaluate the safety, tolerability, pharmacokinetics, and pharmacodynamics of MK-7145 compared to furosemide in participants with moderate-to-severe renal insufficiency without heart failure. The primary hypothesis for Part I was that at least one well-tolerated dose of MK-7145 will produce a greater 24 h urinary excretion of sodium on the 1st day of MK-7145 dosing than 80 mg furosemide (on the 1st day of furosemide dosing) in participants with moderate-to-severe renal insufficiency. If MK-7145 was shown safe at natriuretic doses in renal insufficiency in Part I of this study, MK-7145 would then be investigated in participants with heart failure and renal insufficiency (Part II). Part II was planned as a 4-period, fixed sequence, active comparator-controlled (in Period 1), titration (in Periods 2, 3, and 4) study to evaluate the safety, tolerability, pharmacokinetics, and pharmacodynamics of a titration regimen of MK-7145 compared to an optimized stable maintenance regimen of furosemide or torsemide in participants with New York Heart Association (NYHA) Class II and III heart failure and moderate or severe renal insufficiency. The primary hypothesis for Part II was that at least one dose of MK-7145, titrated according to a fixed dose titration regimen, will be associated with a reduction in N-terminal pro-brain natriuretic peptide (NT-proBNP) compared to furosemide or torsemide (at 24 h postdose on the last dosing day of each period) in participants with NYHA class II/III HF with moderate or severe renal insufficiency. The doses of MK-7145 are listed as 2 and 8 mg/day and the dose of the comparator furosemide was 80 mg/day. The study's primary endpoints are indicated as, (1) change from baseline in first 24 h UNa (Part I) [Time Frame: Baseline (Day 3 predose) and 0–24 h postdose on Day 4 (first day of active treatment) of each treatment period (Treatments A, B, and C)]; and (2) NT-proBNP values at 24 h post last dose (Part II) [Time Frame: Day 14 for Periods 1–3 (Treatments D, E, and F); Day 28 of Period 4. Twelve patients were enrolled for this study. Inclusion criteria for part I included a requirement for estimated creatinine clearance of $\leq$45 mL/min. Inclusion criteria for part II included a requirement for estimated creatinine clearance of $\leq$45 mL/min and the designation of Class II or III heart failure as specified by the New York Heart Association (NYHA) functional classification for heart failure with NT-proBNP $\geq$1000 pg/mL on clinically optimized therapy with a stable dose (for at least 2 weeks) of furosemide or torsemide.

Considering that these two trials are listed for patients with hypertension and renal insufficiency, one may surmise that MK-7145 must have been safe and well tolerated and provided adequate exposures and overall pharmacokinetic properties in initial first-in-human single ascending and multiple ascending dose studies in healthy subjects. In addition, one would expect that initial indications of diuresis and natriuresis efficacy would have warranted further studies in patient populations. Moreover it is noteworthy that the doses in these two trials ranged from 2 to 8 mg/day, suggesting that efficacy was anticipated at low doses. The details of these and other clinical studies will be reported in due course.

8.12.18 Conclusions

Thiazide and loop diuretics remain important and widely used therapeutic agents in the management of hypertension and heart failure, respectively; however, no new diuretic agents have been introduced for decades, despite the opportunities for improvements over existing standard-of-care diuretics.

Hypertension is a primary risk factor for cardiovascular morbidity and mortality. It is a leading cause of end-stage renal disease, and is a risk factor for myocardial infarction, heart failure, stroke, and dementia. Hypertension affects an estimated 30% of the adult US population (>72 million people) and has a prevalence of >65% in people older than 60 years.[56] Despite the large number of medications available, blood pressure remains largely uncontrolled, with almost half of the hypertensive population remaining suboptimally controlled.[57] Clinicians frequently need to use combination therapies for achieving target blood pressure levels. Even then, ~14% of patients are categorized as having resistant hypertension, defined as inadequate blood pressure control even when adhering to a combination of at least three optimally dosed antihypertensive agents of different classes, with one ideally being a diuretic.[58] Moreover, certain hypertensive patient segments are underserved by available treatments, including patients with hypertension and diabetes, hypertension and chronic kidney disease, and heart failure with preserved ejection fraction.[56] Within the diuretic class, thiazides, such as HCTZ, are the most widely prescribed and are used as first line therapy to treat uncomplicated hypertension, or as a component of combination therapy. Hypokalemia (serum potassium concentration <3.5 mequiv./L) and elevations in fasting blood glucose are the major liabilities associated with thiazides and limit the doses used clinically to those that are suboptimal for natriuresis and blood pressure lowering. No new diuretics are known to be in development for hypertension, but an ideal novel diuretic should be potassium neutral, provide blood pressure efficacy ≥25 mg HCTZ, and be suitable for combination therapy. In addition, advantages in treating underserved patient segments such as patients with hypertension and diabetes or hypertension and chronic kidney disease would provide additional value.

Heart failure is a worldwide healthcare problem, with more than one million hospitalizations in the United States for acute heart failure per year. About one third of acute heart failure patients are rehospitalized with congestive symptoms within 6–12 months. By the year 2030 the prevalence of heart failure in the United States is projected to be 2.97%, with >8 million Americans living with heart failure.[59] Loop diuretics are the preferred agents used to treat the symptoms and signs of congestion; however, they appear to be suboptimal in preventing heart failure-related rehospitalization. In addition, loop diuretics typically have short half-lives, leading to rebound sodium reabsorption, which blunts overall efficacy. Loop diuretics such as furosemide are also subject to diuretic resistance,[10] leading to progressive loss of efficacy, particularly as heart failure or renal function worsens. Dose-dependent adverse events associated with loop diuretics include disruptions in plasma electrolyte levels, including hypokalemia, as well as deafness. An ideal new diuretic for heart failure would provide improved efficacy, a reduced incidence of hypokalemia, a smoother more sustained and tolerable diuresis profile, immunity to diuretic resistance, and improved efficacy when renal function is impaired.

In this article, the medicinal chemistry story leading to the development of ROMK inhibitors as new mechanism diuretics was reviewed, tying together work described in a series of publications over recent years. The story started with discovery of the program lead from a screening hit minor impurity, then continued with identification of nitrophenyl pharmacophore isosteres and the SAR steps leading to incremental, step-wise improvements in selectivity over hERG and improvements in pharmacokinetic properties. The review concluded with a detailed description of the Merck clinical compound MK-7145 along with its pharmacology in preclinical species. Overall, these efforts led to the discovery of several structurally differentiated subclasses of potent and ROMK inhibitors, all originating from the common initial hit. Proof of biology in rat and dog diuresis models and in SHR and Dahl salt-sensitive rat hypertension models was described, confirming expectations based on human and rodent genetics that ROMK inhibitors should be potent diuretics with a neutral potassium excretion profile. Importantly, MK-7145 and other ROMK inhibitors demonstrated superior blood pressure lowering compared to hydrochlorothiazide in preclinical hypertension models. These effects were additive or synergistic in combination with angiotensin receptor blockers and with thiazide diuretics. The combination of MK-7145 at 3 and 10 mg/kg/day doses with candesartan provided synergistic blood pressure lowering of a greater magnitude than that observed with the combination of 25 mg/kg/day of hydrochlorothiazide with candesartan. ROMK inhibitors further differentiate from thiazide and loop diuretics in that they can access their target from both the apical and basolateral faces of the epithelial cells lining the tubular lumen (standard-of-care loop diuretics and thiazides access their targets only from the apical face). This offers the potential that ROMK inhibitors could demonstrate improved efficacy in patients with renal insufficiency compared to loop diuretics like furosemide which has reduced delivery to the tubular lumen in the presence of renal dysfunction. The ROMK inhibitors described here project to, or have been shown to have significantly longer half-lives in humans compared to loop diuretics such as furosemide and torsemide, which may improve the time course of diuresis and limit rebound sodium reabsorption effects. Taken together, ROMK inhibitors such as MK-7145 represent the first new mechanism diuretics to be discovered in decades, and offer the possibility of providing improved outcomes in the treatment of hypertension or heart failure.

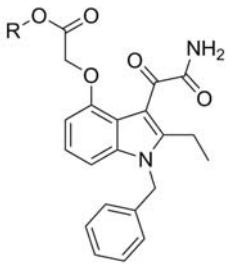
8.13.1 Introduction

Phospholipase A_2 (PLA_2) is a diverse family of lipolytic enzymes that hydrolyze the acyl ester bond at the *sn*-2 position of glycerophospholipids to yield free fatty acids and lysophospholipids.[1] Among the various classes of PLA_2s insofar described, secreted PLA_2s ($sPLA_2$s) are characterized by low molecular mass (13–18 kDa), a histidine–aspartic acid catalytic dyad, and are dependent on Ca^{2+} for their catalytic function.[2] As their hydrolytic activity is directed to substrates with micellar and surfactant properties, $sPLA_2$'s biological function is a complex result of subtle interfacial kinetics of enzyme–substrate recognition, partitioning, and subsequent catalysis.[3] A total of 11 different $sPLA_2$ isoforms (group Ib, IIa, IIc, IId, IIe, IIf, III, V, X, XIIa, and XIIb) have been reported in mammals.[4,5] The different $sPLA_2$ isoforms display unique tissue and cellular distributions, and enzymatic properties, suggesting diverse, tissue-specific contributions in various pathophysiological phenomena. For instance, four $sPLA_2$ isoforms (IIA, III, V, and X) have been detected in human atherosclerotic lesions.[6] Among these, group IIA, V, and X $sPLA_2$s have been independently associated with disease progression, due to their direct implication in several proatherogenic actions in the arterial wall.[7–9] The enzymatic action of $sPLA_2$s rapidly degrades lipoproteins' phospholipids. As such, $sPLA_2$s induce the accumulation of bioactive lipids in the vessel wall and promote significant lipoprotein modifications, which in turn alter their function. The products of $sPLA_2$s' catalysis significantly activate macrophages and directly contribute to foam cell formation.[5,7,9,10] Additionally, as arachidonic acid is one of the most frequent fatty acids esterified at the *sn*-2 position of phospholipids, $sPLA_2$s are de facto affecting the rate-limiting step in eicosanoid production.[11] Overall, $sPLA_2$s' action triggers the release and accumulation of several pro-inflammatory stimuli and mediators in atherosclerotic lesions.[5,7,9,10] Furthermore, epidemiological analyses have indicated that increased levels of $sPLA_2$ mass and activity are significantly related to increased occurrence of cardiovascular events, prevalence, and progression of atherosclerosis and may constitute independent risk factors.[12]

Due to the crucial importance of $sPLA_2$s in modulating the function of lipids and lipoproteins, as well as controlling several mechanisms directly related to inflammation, $sPLA_2$s seem well poised to influence atherogenesis. Accordingly, $sPLA_2$ inhibitors could be useful for the treatment of atherosclerosis. Interestingly, the historical $sPLA_2$ inhibitor varespladib methyl (Fig. 1), developed by scientists at Eli-Lilly as an early example of structure-based optimization,[13,14] has been evaluated in short duration (12–16 weeks) clinical trials for the treatment of rheumatoid arthritis and acute coronary syndrome (ACS) with negative results.[15,16] The clinical failure in ACS has been ascribed to the limited duration of treatment in a severely impaired patient population, where the postulated beneficial lipid-altering effects of $sPLA_2$ inhibition could not be realized fully. These results prompted for a different clinical strategy addressing an alternative patient segment.



R = H, **varespladib**; $clogD_{7.4}$: -0.6
R = Me, **varespladib methyl**; $clogD_{7.4}$: 2.9

Fig. 1 Archetypal $sPLA_2$ inhibitors: varespladib and its methyl ester prodrug, varespladib methyl. Relevant log *D* values at pH 7.4 have been calculated with ChemAxon.

Atherogenesis is a dynamic process resulting from lengthy and complex physiological modifications along multiple axes (e.g., lipid metabolism, inflammation, and cardiac function). Specifically, we were interested to more thoroughly investigate the lipoprotein modifying effects[17–19] of $sPLA_2$ inhibition on cardiovascular disease alongside its anti inflammatory properties. As part of AstraZeneca' cardiovascular and metabolic disorders portfolio, we therefore started a research program directed to the identification of a novel $sPLA_2$ inhibitor to be evaluated in long-term clinical studies in a coronary artery disease patient population.

8.13.2 Medicinal Chemistry Strategy

The competitive situation in which we operated prompted for a very pragmatic approach. Varespladib methyl provided a useful benchmark for evaluating our progress and defining the sought target product profile. Varespladib is a potent $sPLA_2$ inhibitor whose marked polar character is optimized by the use of a prodrug (varespladib methyl) to enable sufficient intestinal absorption during oral administration. Importantly, the glyoxamide and carboxylate functionalities of varespladib that are responsible for its low lipophilicity are essential pharmacophoric features for chelating the catalytic Ca^{2+} ion in the $sPLA_2$ binding site.[13,14] As dosing to a large patient population over a long therapeutic regimen was required in a coronary artery disease setting, the use of a prodrug was judged to be inappropriate for our intended clinical candidate due to the potential interpatient variability at a pharmacokinetic (PK) level and pharmacodynamics (PDs) implications. Anticipating a common pharmacophore to varespladib, the polar character of the series should have been compatible with once daily oral administration, as a further requirement in a patient population which is already exposed to multiple concomitant therapies as standard of care. Lipophilicity was therefore understood as a critical optimization parameter as it influences cellular membrane permeability.[20] While in this case high lipophilicity would be advantageous for intestinal absorption and partitioning into phospholipids and lipoproteins with a view to access the $sPLA_2$ binding site, it could also be counterproductive when critical development parameters such as aqueous solubility, metabolic stability, and toxicology are concerned.[20] For these reasons, we envisioned a structure-based fragment approach with strong monitoring of ligand efficiency parameters in order to maximize the odds of combining chemical matter novelty, lipophilicity control, and developability.[21]

Cheminformatics analysis of $sPLA_2$-centered biological data in combination with available structural data as from apo and ligand-bound $sPLA_2$ crystal structures[13,14] highlighted the effectiveness of primary carboxamides in interacting with the $sPLA_2$ catalytic pocket. Specifically, their carbonyl atom is coordinating the Ca^{2+} ion as well as establishing a hydrogen bond with the protein, while the amide nitrogen atom is hydrogen bonded to two additional sites on $sPLA_2$. We therefore compiled a selection of primary aromatic amide-containing fragments (heavy atom count ≥ 10 and ≤ 18) by triaging our corporate database for (a) fit to the $sPLA_2$ binding site using molecular docking, (b) biochemical inhibition of $sPLA_2$-IIa, as the most widely expressed $sPLA_2$ isoform in humans,[22] and (c) functional inhibition of $sPLA_2$ activity in human plasma, as assessed using an established protocol.[23] The last step was of critical importance in ensuring translatability to a clinical setting as plasma $sPLA_2$ activity inhibition represented the mode-of-action biomarker to be used in future clinical trials. While $sPLA_2$-IIa is the most widely expressed $sPLA_2$ isoform, additional $sPLA_2$ isoforms will likely contribute to total plasma $sPLA_2$ activity. For these reasons, and considering their role in lipoprotein modulation,[17–19] inhibition of $sPLA_2$-V and $sPLA_2$-X was also monitored as part of the screening cascade. Lastly, the lipophilic profile of the compounds was projected against passive permeability, metabolic stability, and solubility as in vitro signposts before a more thorough assessment of their PK and PD profiles in vivo. Here, multispecies PK analyses were used to preliminary gauge dosing estimates for preclinical toxicological studies and clinical development. Nonhuman primates were instead utilized to minimize translational differences in $sPLA_2$-related biology and lipoprotein profiles, thereby providing a measure of the PD effect.

8.13.3 Results

The results of the initial hit identification process previously described are summarized in Table 1. Three fragment hits were singled out from the triaging workflow as potential starting points for future chemical exploration. These include benzamide, anthranilic amide, and imidazopyridine carboxamide derivatives **1**–**3** (Table 1). While all three fragments displayed significant $sPLA_2$-IIa inhibition (IC_{50}: 2.1–24 μM) and adequate ligand efficiency parameters (LE: 0.35–0.39), the reduction of human plasma $sPLA_2$ activity represented a major discriminant among them. Here, only compound **1** was able to potently inhibit plasma $sPLA_2$ activity in a concentration-dependent fashion with an unbound IC_{50} value of 0.9 μM, probably because of its enhanced solubility compared to **2** and **3**. In an effort to evaluate whether plasma $sPLA_2$ inhibition of **2** and **3** could be brought on par with the more efficient fragment **1**, nearest neighbor analysis and screening was employed to explore the structure–activity relationships of **2** and **3** (data not shown). Unfortunately, this exercise did not highlight any immediate potency gain opportunities. Instead, it revealed a consistent low aqueous solubility profile for fragment hit **3** and analogs. As this liability also prevented successful cocrystallization of $sPLA_2$ and **3**, we turned our attention to the most potent fragment hit **1** insofar identified.

Resolving the molecular complex between **1** and $sPLA_2$-X using X-ray crystallography highlighted the high-quality interactions established by the carboxamide function of **1**, as shown in Fig. 2. Here, the amide group engaged $sPLA_2$-X with three hydrogen bonds to G28, H46, and D47 (corresponding to $sPLA_2$-IIa G29, H47, and D48) and one additional coordination bond to the catalytic Ca^{2+} ion in the binding pocket. Furthermore, the 4-benzyl side chain was accommodated in a lipophilic cleft consisting of residues I2, L5, A6, V9, P17, I18, and M21 (corresponding to L2, F5, H6, I9, A17, A18, and G22 in $sPLA_2$-IIa, Fig. 2). It is noteworthy to mention

Table 1 Hit identification results

Entry	*Structure*	*sPLA$_2$-IIa (− X) IC$_{50}$ (μM)*	*Plasma IC$_{u,50}$ (μM)*[a]	F$_u$ *(%)*	*LE/LLE* [b]

[b]Ligand efficiency, LE (kcal/mol/HAC), calculated as − RTln(sPLA$_2$-IIa IC$_{50}$)/heavy atom count. Ligand lipophilicity efficiency (LLE) calculated as pIC$_{50}$ (sPLA$_2$-IIa)–log *D*.
Salient properties for the top 3 fragment hits are listed.

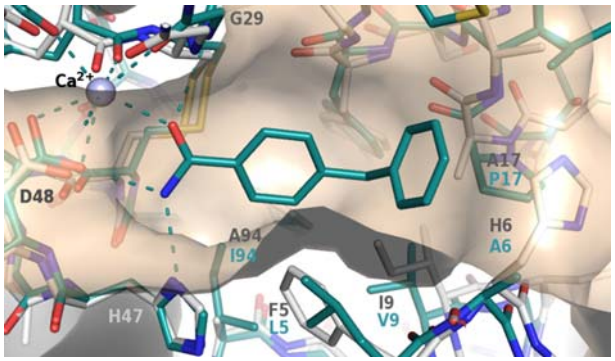

Fig. 2 Superposition of the crystal structure of **1** bound to sPLA$_2$-X (*cyan*) and a crystal structure of sPLA$_2$-IIa (*gray*). Residues that differ between the two proteins are labeled in *cyan* and *gray*, respectively. The calcium ion is depicted as a *purple sphere* and hydrogen bonds are displayed as *dashed lines*. The surface is generated from the sPLA$_2$-IIa crystal structure.

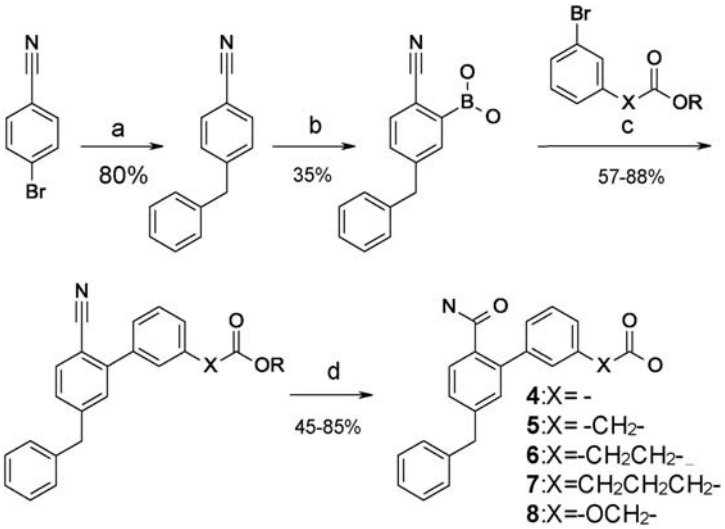
that the catalytic sites of sPLA$_2$-IIa and sPLA$_2$-X are identical in the amide coordinating amino acids and display similar lipophilic character in the side lipophilic pocket. Overlay of the available sPLA$_2$-IIa and sPLA$_2$-X crystal structures indicated that the 4-benzyl group of **1** could establish an adequate, although not optimal, steric fit to the slightly less voluminous sPLA$_2$-IIa pocket, as suggested by the lower affinity for such isoform (cf. 2.2 and 24 μM, **Table 1**). Based on the biochemical and structural data generated, **1** represented an ideal starting point for a structure-based, medicinal chemistry exploration. The limited size of the fragment hit coupled with its significant human plasma sPLA$_2$ inhibition and the presence of several exit vectors on its structure for further chemical manipulation offered adequate potential for its optimization. Moreover, the benzamide moiety also appeared favorable from an intellectual property perspective, as prior art analysis indicated no chemical precedents in the sPLA$_2$ field, which has been historically dominated by indole-containing chemotypes.[13,14] Based on the binding mode of **1**, we then hypothesized an optimization strategy aimed at establishing a second coordination bond between the inhibitor and the catalytic Ca^{2+} ion in the sPLA$_2$ binding site. This was driven by (a) a potential affinity and functional inhibition increase as a result of a bidentate Ca^{2+} chelate and additional van der Waals contact with the sPLA$_2$ enzymes, and (b) to afford an overall less lipophilic inhibitor considering that the additional Ca^{2+} interacting element would have required the introduction of a carboxylic acid functionality in its structure. Due to structure-based constraints, the ortho position of the benzamide ring was identified as an adequate growth vector for extending toward the Ca^{2+} ion. Using iterative molecular modeling and pragmatic forecasting of affinity increments using ligand efficiencies isovalues, we synthesized an initial set of compounds, **4**–**8**, to test the validity of our strategy. As described in **Scheme 1**, bromo benzonitrile was benzylated using a Neghishi coupling protocol with benzylzinc bromide in 80% yield. The directing capacity of the cyano group was then used to *ortho* lithiate the obtained 4-benzyl-benzonitrile using the bulky lithium 2,2,6,6-tetramethylpiperidide (LTMP).[24] Quenching of the obtained lithium



Scheme 1 Synthetic approach to compounds **4–8**. Reagents and conditions: (A) benzylzinc bromide, $Pd(Ph_3)_4$, THF, 60°C. (B) 1. nBuLi, tetramethylpiperidine 2. $B(OiPr)_3$, THF −78°C. (C) 3-Bromophenyl carboxylic acid **A**, $Pd(dppf)Cl_2$, Cs_2CO_3, DMF, 90°C. (D) *n*-Propanol:H_2O (10:1), KOH (10 equiv.), 80–100°C.

anion by triisopropylborate ($B(OiPr)_3$) generated the key boronic acid intermediate. Suzuki–Miyaura coupling of the corresponding ester-containing bromides was performed under anhydrous conditions in order to avoid ester hydrolysis. This gave the corresponding benzonitrile esters in generally moderate-to-high yields (57–88%). Compounds **4–8** were then obtained by simultaneous hydrolysis of the nitrile and ester functionalities to the corresponding carboxamide and carboxylic acid, respectively, with yields typically in the range of 45–85%. Here, in order to minimize hydrolysis of the formed primary amide, we use excess KOH in *n*-propanol and water at elevated temperatures ($\sim 80-100°C$) over 0.5–3 h. The use of lower aliphatic alcohols (e.g., methanol) resulted in faster hydrolysis of the nitriles but also increased formation of the corresponding di-carboxylic acid byproducts and was not deemed suitable.

The potential for further derivatization of the chosen ortho position on the benzamide scaffold was confirmed by derivatives **4–8,** which displayed improved $sPLA_2$-IIa inhibition compared to the unsubstituted parent compound (Table 2). Here, introduction of a 3-benzoic acid moiety (**4**) was the least favored with an IC_{50} of 0.91 μM for the $sPLA_2$-IIa isoform. By progressively increasing the distance between the carboxylic acid group and the phenyl ring via the insertion of methylene units (**5–7**), a parabolic effect on potency was observed. Specifically, the best compromise was afforded by the phenylpropionic acid side chain (**6**) over the phenylacetic acid (**5**) and phenylbutanoic acid (**7**) counterparts. When the benzylic methylene was replaced by an oxygen atom, a greater than 10-fold decrease in $sPLA_2$-II inhibition was observed (cf. **6** and **8**, Table 2). This result indicated a precise conformational requirement for the carboxylic acid-containing side chain (see in the following section). Derivative **6** offered submicromolar IC_{50} values against all the $sPLA_2$ isoforms tested, being most potent on $sPLA_2$-IIa (IC_{50}: 0.012 μM). The measured potencies were consistent with favorable efficiency parameters, both in terms of size (ligand efficiency, LE: 0.4) as well as lipophilicity (ligand lipophilicity efficiency, LLE: 6.4). Gratifyingly, the measured inhibition at the recombinant protein level translated to significant inhibition of human plasma $sPLA_2$ activity, with compound **7** displaying comparable inhibition to varespladib ($IC_{u,50}$: 0.007 and 0.008 μM, respectively). We succeeded in obtaining the cocrystal structure of **6** bound to $sPLA_2$-IIa and were able to evaluate the validity of our structure-based hypotheses. The bound conformation of **6** confirmed the sought ligand-mediated calcium chelation, as shown in Fig. 3. In an analogous manner to that observed for the original fragment hit **1**, the carbonyl oxygen atom of the amide group of **4** established the first coordination bond to the Ca^{2+} ion and three additional hydrogen bonds to G29, H47, and D48. Furthermore, the carboxylate moiety of **6** established the second coordination bond to the catalytic Ca^{2+} ion (interatomic distance: 2.8 Å) and an additional hydrogen bond to the backbone amide group of G31, as shown in Fig. 3. The 4-benzylbenzamide part of **6** was observed bound in a similar orientation, rotameric state, and interactions pattern as in **1**, while the additional phenyl ring substituting the carboxamide scaffold in its ortho position engaged significant van der Waals contacts with the aliphatic side chains of L2 and V30 and the backbone methylene of G29.

Compound **6** demonstrated a broad $sPLA_2$ potency profile coupled with significant plasma $sPLA_2$ inhibition ability and favorable size and lipophilicity efficiency. This prompted a widespread characterization campaign in order to verify any potential limitations for further development. The main concern was the combination of lipophilicity and unsubstituted phenyl rings. Despite the carboxamide and carboxylate functionalities, **6** demonstrated a relatively high experimental log *D* (1.5) and its lipophilicity had to be related to typical in vitro parameters as PK and safety surrogates. Furthermore, several positions on three phenyl rings would have been available for oxidative metabolism, adding to potential phase II metabolism targeting the carboxylic acid group. Table 3 summarizes the findings from such an investigation.

Table 2 Profile for the initial exploration set comprising compounds **2**–**6**

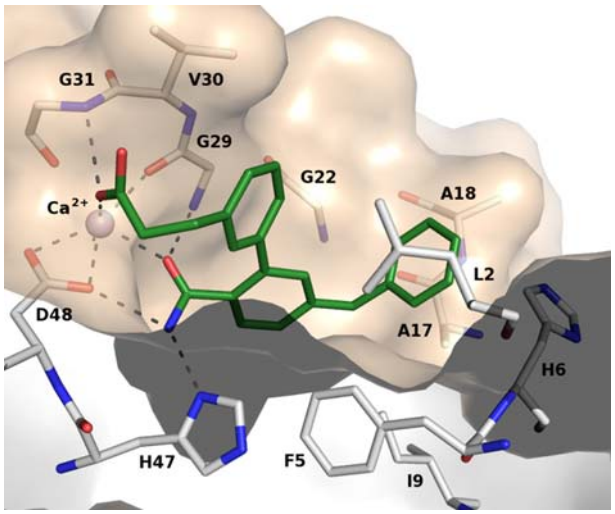

Fig. 3 Cocrystal structure of **6** bound to sPLA$_2$-IIa. The calcium ion is depicted as a *purple sphere*, and relevant hydrogen bonds are displayed as *dashed lines*.

Compound **6** was found to be soluble in the Hank's Balanced Salt Solution (HBSS), endowed with high passive diffusion in Caco-2 cells without any significant efflux, and metabolically stable when incubated in human cryopreserved hepatocytes. These positive attributes were further confirmed by in vivo PK analysis using two different species, rat and dog. Here, high bioavailabilities, low systemic clearances, and distribution volumes were observed. At the highest tested concentration, compound **6** did not inhibit any of the major human cytochrome P450 enzymes or ion channels which are of special relevance to cardiac function. Nevertheless, **6** inhibited the uptake of pitavastatin in HEK293 cells transfected with the human organic anionic transporter polypeptide 1B1

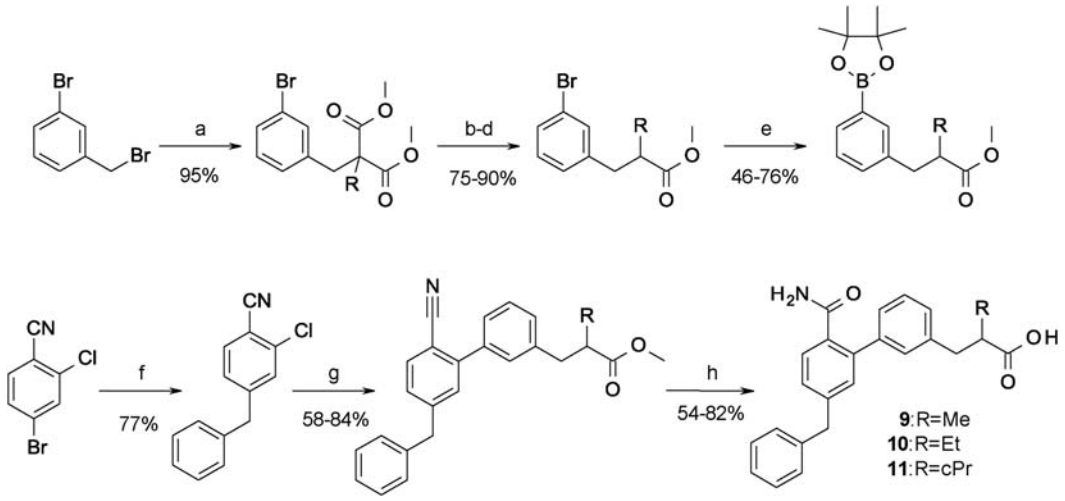
(OATP1B1) with an estimated IC_{50} of 2.2 μM. This finding was of specific relevance since the OATP1B1 transporter is mechanistically required for statin's hypocholesterolemic action. In fact OATP1B1 mediates the access of statins to the liver compartment where they can then inhibit the function of their target enzyme 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase.[25–27] Considering that an eventual $sPLA_2$ inhibitor for the treatment of coronary artery disease will have to be co-administered with statin and additional medications, as established standard of care, it was important to try and minimize the risk for such clinically relevant drug–drug interaction. OATP1B1 has a preference for anionic compounds such as statins. Given that the anionic nature of our compound was also part of the established $sPLA_2$ pharmacophore due to the second coordination bond to the Ca^{2+}, complete removal of the carboxylate group was initially not deemed feasible. Instead, we resorted to the notion that modification of the molecular environment around the carboxylic acid of **6** might have been sufficient to perturb its interaction with OATP1B1 while being compatible with the $sPLA_2$ binding pocket environments. More specifically, substitution of the carbon atom in alpha to the carboxylic acid was of special appeal. This was postulated to (a) provide a steric impediment to the interaction with OATP1B1 and (b) enhance $sPLA_2$ potency through a conformational "freezing" of the carboxylic acid side chain due to gauche-like effects. Based on structure-based constraints in the $sPLA_2$ pocket and atomic economy considerations with a view to minimize the impact on compound lipophilicity, we opted to install mono and diatomic substituents on compound **6**. Accordingly, we synthesized compounds **7**–**9**, following **Scheme 2**. Here, the appropriately 2-substituted-dimethyl malonate was alkylated using 3-bromo benzylbromide, followed by a three-step telescoped sequence to the propionic methyl ester derivative. This consisted of (1) hydrolysis of the malonate derivative using NaOH, (2) decarboxylation in an oil bath at 140°C using acetic acid as medium, and (3) re-esterification to afford the relevant methyl ester derivative (75–90%). The subsequent boronylation step was accomplished using $(Bpin)_2$, Pd-106 in the presence of potassium acetate as base to yield, after column chromatography, the corresponding boronic pincacol esters (46–76%). These could then be used directly without further purification in the successive Suzuki–Miyaura coupling step with 4-benzyl-2-chlorobenzonitrile, which was prepared via Negishi coupling analogously to the route depicted in **Scheme 1**. Finally, racemic **9**–**11** were obtained by hydrolysis using KOH in *n*-propanol, as previously described in **Scheme 1**. Separation of enantiomers for racemic mixture **9** using chiral stationary HPLC-phases afforded (*R*)-**9** in 34% overall yield over nine operational steps. This general synthetic route has proven very practical in a discovery setting and was scaled to yield up to >10 g of title compound (*R*)-**9**. Nevertheless, a more robust, scalable, and enantioselective synthetic approach was developed in our laboratories to support early development activities for (*R*)-**9**. The route hinged on an elegant asymmetric hydrogenation step and has been recently described in detail.[28]

As shown in **Table 4**, the introduction of a methyl group in alpha to the carboxylate (**9**) demonstrated an isoform-specific effect on potency: it was neutral at $sPLA_2$-IIa, while it significantly increased inhibition of $sPLA_2$-V and reduced that of $sPLA_2$-X. As a result, the plasma $sPLA_2$ inhibition profile of **9** was superior to that of **4** ($IC_{u,50}$: 0.001 and 0.007 μM, respectively). Remarkably, the structural modification of the carboxylic acid surroundings by an alpha-methyl group yielded the sought-after effect at the statin transporter level, and **9** did not show any significant inhibition of OATP1B1 at the maximum tested concentration (25 μM). Interestingly, ethyl and cyclopropyl substitutions (**10**, **11**) were not as effective when considering the added size and lipophilicity, possibly highlighting suboptimal van der Waals contacts with the $sPLA_2$. More importantly, they showed a deteriorating effect on metabolic stability in human hepatocytes (cf. **10**, **11**, and **9**, **Table 4**), which was not regarded to be compatible with further progression.



Scheme 2 Synthetic approach to compounds **9**–**11**. Reagents and conditions: (A) dimethylmalonate, Cs_2CO_3, DMF, 70°C, 2 h. (B) NaOH (4 equiv.), H_2O:MeOH 3:1 80°C 2 h. (C) HOAc (3 M), reflux. (D) HCl, MeOH 60°C, 2.5 h. (E) $(Bpin)_2$ (1.3 equiv.), KOAc (2.5 equiv.), $Pd(dppf)Cl_2$ (6.5 mol%), dioxane, 90°C. (F) BnZnBr (1.5 equiv., 0.5 M in THF), $Pd(PPh_3)_4$ (5 mol%), THF, 60°C, 2 h. (G) **B**, $Pd(dbpf)Cl_2$ (5 mol%), Cs_2CO_3, DMF, 90°C, 1.5 h. (H) *n*-propanol, H_2O (10:1), KOH (10 equiv.), 80–100°C.

The racemic mixture 9 displayed a substantial improvement in key optimization properties in the current compound series. We therefore proceeded to separate and characterize the two enantiomers to verify individual compound's contributions to the properties of interest. In line with expectations informed by the structural biology framework in which we operated, $sPLA_2$ inhibition was profoundly affected by stereochemistry. Here, the *R* enantiomer proved to be the most active, half-maximally inhibiting $sPLA_2$-IIa, -V and -X at 10, 40, and 400 nM, respectively (Table 4). As a result, (*R*)-9 was the most potent human plasma $sPLA_2$ inhibitor in this study ($IC_{u,50}$: 0.1 nM) and maintained no OATP1B1 inhibitory activity at the highest tested concentration. Despite a higher metabolic turnover in human hepatocytes compared to previous analogs in the series (cf. (*R*)-9 and **4**, Table 4), the combination of excellent potency and minimized risk for drug–drug interactions with statins triggered additional profiling of its PDs and PK properties.

$sPLA_2$ activity in human plasma has shown relevant correlations to the risk of developing cardiovascular events and associated mortality.[12] Nevertheless, we were also interested to assess inhibition of $sPLA_2$ activity beyond the plasma compartment. As atherosclerotic lesions are complex matrix environments with a marked cellular context, we first evaluated cellular $sPLA_2$ activity inhibition using a HepG2 cell line as a cellular model system. Here, (*R*)-9 effectively inhibited $sPLA_2$ activity with an IC_{50} of less than 14 nM. It is noteworthy that, in the same experiment, (*R*)-9 also suppressed the production of $sPLA_2$-IIa (IC_{50}: 176 ± 28 nM) via a mechanism

[a]Pharmacokinetic parameters calculated from noncompartmental analysis concentrations in fasted animals.

not yet elucidated, probably involving paracrine feedback loops.[8] We then proceeded to verify the $sPLA_2$ inhibitory ability of (*R*)-**9** in a more pathological setting. To this end, we homogenated atherosclerotic plaques obtained from carotid endarterectomy of coronary artery disease patients ($N=7$).[29] When (*R*)-**9** was incubated in this disease-relevant milieu, it inhibited $sPLA_2$ activity with an IC_{50} of 56 ± 10 nM, thus confirming a broad spectrum $sPLA_2$ inhibitory profile, which is independent of the biological compartment considered.

In vivo PK analysis of (*R*)-**9** generally reflected the in vitro characteristics previously highlighted, as summarized in **Table 5**. Across multiple species absorption was rapid and T_{max} was reached in less than 2 h resulting in consistently high bioavailabilities (76.3–91%). Despite the moderate intrinsic clearance recorded in hepatocytes across different animal species, in vivo systemic clearance was overall low and enabled significant, sustained compound exposure over time ($AUC_{0\text{-}inf}$: 69.7–284.1 μM × h).

Building on the observed PK parameters, and the in vitro $sPLA_2$ inhibition measured in cynomolgus monkey plasma ($IC_{u,50}$: 1 nM), we resolved to evaluate the in vivo $sPLA_2$ inhibitory effect of (*R*)-**9** in an effort to delineate PK–PD relationships and assist further allometry-based dose predictions. PK–PD modeling indicated that a 30 mg dose of (*R*)-**9** would have been enough to maintain half maximal $sPLA_2$ inhibition over a 24 h period (data not shown). (*R*)-**9** was thus orally administered to cynomolgus monkeys ($N=2$) and sampling of plasma at different time points was used to simultaneously analyze the compound concentration and $sPLA_2$ activity. An appropriate vehicle correction using a 30 mg bolus of aqueous suspending vehicle (the formulation used for dosing (*R*)-**9**) was applied to quantify $sPLA_2$ activity inhibition, as summarized in **Fig. 4**. A concentration-dependent inhibition of $sPLA_2$ activity in plasma ($IC_{u,80}$: 13 ± 3 nM) was observed and this reflected very well the time course of (*R*)-**9**'s exposure profile

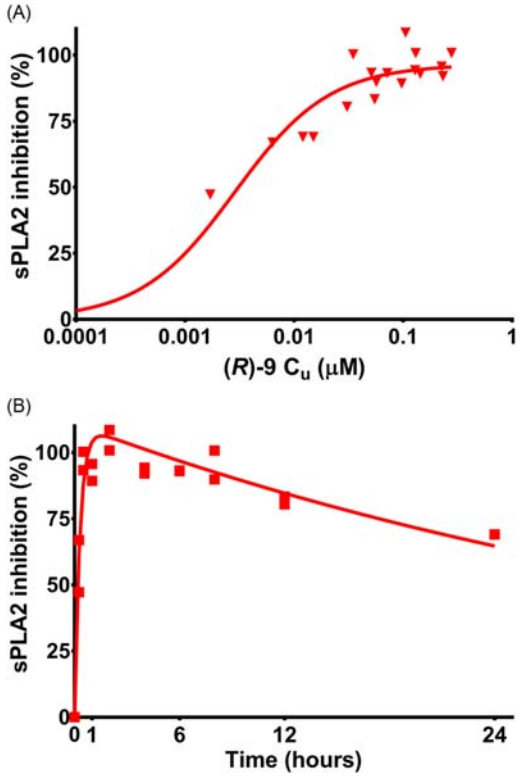

Fig. 4 Vehicle-corrected plasma $sPLA_2$ activity inhibition, corresponding PK–PD relationship (A) and time course (B) following oral administration of 30 mg (*R*)-**9** to cynomolgus monkeys ($N=2$).

(Fig. 4). These results further corroborated the sPLA$_2$ inhibitory potential of (*R*)-**9**. The compounds also displayed a favorable toxicological profile, as from standard 1 week to 1 month maximum tolerated dose protocols, in three different preclinical species (i.e., Wistar rat, beagle dog, and cynomolgus monkey). Overall, the experimental evidence accumulated indicated sufficient potential for further clinical development of (*R*)-**9**.

The aim of the project was to deliver inhibitors of sufficient quality to be used in long-term clinical studies focusing on carotid artery disease patients, where the combination of antiinflammatory and lipoprotein modifying effects deriving from sPLA$_2$ inhibition was postulated to deliver maximum therapeutic benefits. Due to the high stringency requirements in terms of efficacy, PK, and safety of the target patient population, we wanted to access the best possible chemical starting points with the greatest potential for successful optimization. We therefore initiated a fragment-based project to bias our chemical matter selection process on small and highly efficient compounds. We therefore used a triaging process focused on sPLA$_2$ inhibition and X-ray crystallography. Of special importance was the integration of a clinically relevant functional endpoint as part of the fragment selection process, in order to minimize translational uncertainties. This resulted in the identification of 4-benzylbenzamide (**1**) as an initial fragment hit fulfilling our requirements. Two design cycles based on structural information, ligand efficiency reasoning, physicochemical property control, and medicinal chemistry tactics rapidly optimized key developmental properties such as potency, PK, and risk for drug–drug interactions. In this context, the importance of readily available, relevant experimental data cannot be overemphasized enough. These activities culminated in the design of (*R*)-**9** (**AZD2716**), a novel, potent sPLA$_2$ inhibitor with excellent PK properties, sustained in vivo target engagement and minimized risk for drug–drug interactions. Based on the available results, **AZD2716** was selected as a clinical candidate for the treatment of coronary artery disease. One sentence on current status?

8.14.1 Introduction

Humans have acquired many physiological systems through evolution to maintain blood glucose homeostasis. Blood glucose levels are under the control of several hormones, such as glucagon, adrenaline, and cortisol, and are additionally controlled via absorption by sodium glucose co-transporters (SGLTs). However, dietary changes, satiation, and sedentary lifestyle in recent years have increased the number of patients with type 2 diabetes (T2DM).[1]

In 1990, Rossetti put forward a hypothesis of glucose toxicity,[2] stating that continuous hyperglycemia induces insulin resistance and impaired insulin secretion. Further, glucose reacts as an aldehyde with the amine portion of proteins to produce denatured proteins, called advanced glycation end products (AGEs). AGE deposition induces microangiopathy and causes diabetic complications. Therefore, despite being the essential energy source, glucose ironically acts as a toxic substance when in chronic excess.

Most of the currently available diabetes treatments are aimed at improving either insulin secretion or insulin sensitivity via targeting insulin-dependent mechanisms.[3,4] However, treatment with such agents is often accompanied by secondary failure in efficacy and adverse events, including hypoglycemia or weight gain. Furthermore, in a diabetes outcome progression trial (ADOPT) study, which evaluated the long-term therapeutic effects of oral agents, those operating via insulin-dependent mechanisms, including

rosiglitazone, metformin, and glyburide, increased hemoglobin A1c (HbA1c) levels several years later.[5] This suggests that pancreatic β-cell dysfunction progresses with long-term treatment of drugs with an insulin-dependent mechanism of action.

8.14.2 Concept for Novel Antidiabetic Agents

In 1996, we, for the first time, asked whether it is possible to discharge excessive glucose from the body through medication. An agent capable of mediating such effects could normalize energy balance, and the induced decrease in blood glucose levels would cancel glucose toxicity to alleviate impaired insulin secretion, insulin resistance, and diabetic complications. We began to research into this concept with an aim to identify prototypic compounds that could enhance urinary glucose excretion (UGE).[6]

Glucose homeostasis is mainly regulated by hormones, such as insulin and glucagon, and by the autonomic nervous system. Plasma glucose levels fluctuate in response to the absorption of glucose in the intestines and utilization and production in peripheral tissues, including the liver and skeletal muscles.[7] In the kidney, glucose is filtered through the glomerulus, with glucose concentration in the filtrate at the glomerulus being the same as that in plasma. Filtered glucose is reabsorbed in the proximal tubules from the lumen to prevent the loss of calories.

Glucose reabsorption in renal epithelial cells is predominantly mediated by SGLT2, a low-affinity, high-capacity SGLT located in the early S1 segment of the proximal tubules. Glucose reabsorption is also, to a lesser extent, mediated by SGLT1, a high-affinity, low-capacity SGLT distributed in the more distal S3 segment of the proximal tubules (Fig. 1).[8–10] Reabsorbed glucose is then transferred to the basolateral extracellular space by the function of facilitating glucose transporters (GLUTs). In normoglycemic states, glucose levels in the filtrate are below the maximum transport capacity of tubular SGLTs. All glucose is, therefore, transported from the tubular lumen to the blood, and no UGE is detected. In contrast, when the glucose levels in the filtrate exceed the tubular SGLT's maximum transport capacity, the reabsorption process is saturated, and nonreabsorbed glucose is excreted in the urine. Under such hyperglycemic conditions, UGE increases in proportion to the blood glucose concentration above the threshold level.[11]

Although SGLT2 is located solely in the kidney, SGLT1 is distributed in the intestine and heart besides the kidney. In the small intestine, luminal glucose is absorbed through SGLT1 located on the luminal surface of epithelial cells. Therefore, SGLT2 mainly mediates renal glucose reabsorption, and SGLT1 mediates both intestinal glucose absorption and renal glucose reabsorption. SGLT2 expression is increased in patients with T2DM compared with that in nondiabetic subjects, and renal glucose uptake is enhanced in T2DM patients.[12] It is, therefore, likely that enhanced glucose reabsorption may contribute to the maintenance of hyperglycemia. Whereas mutations of SGLT1 are associated with intestinal glucose/galactose malabsorption, individuals with gene mutations in SGLT2 have persistent renal glycosuria in normoglycemia without any serious symptoms.[13–15] Thus, although the elimination of excess plasma glucose in the urine is a physiologically reasonable strategy to reduce plasma glucose levels and body calories, SGLT2 had never been considered as a drug target before the discovery of the oral SGLT2 inhibitor, T-1095.[16]

8.14.3 The First Oral SGLT2 Inhibitor

8.14.3.1 Discovery of T-1095

It has been reported that parenteral administration of phlorizin (**1**, Fig. 2), a natural glucoside derived from the bark of apple and pear trees, prevents renal glucose reabsorption through SGLT inhibition and promotes renal glycosuria.[17–21] Isolated by French chemists in 1835, phlorizin is well known for a long time to induce glycosuria. After the cloning of SGLT1 and SGLT2 in the

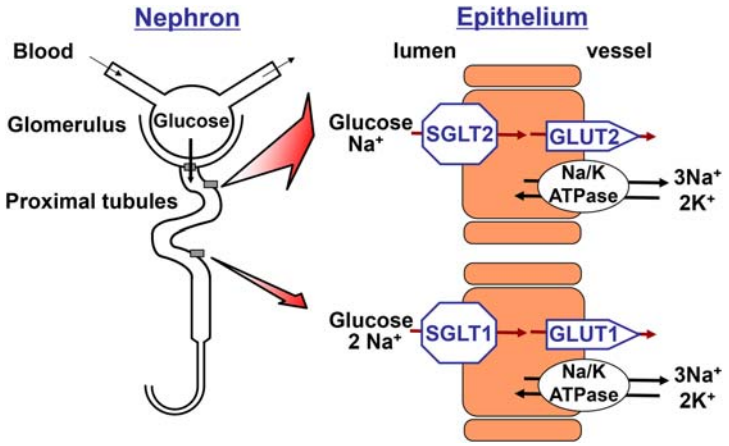

Fig. 1 Renal glucose reabsorption by sodium glucose cotransporters (SGLTs). Modified from Nomura, S. Renal Sodium-Dependent Glucose Cotransporter 2 (SGLT2) Inhibitors for New Anti-Diabetic Agent. *Curr. Top. Med. Chem.* **2010**, *10* (4), 411–418.

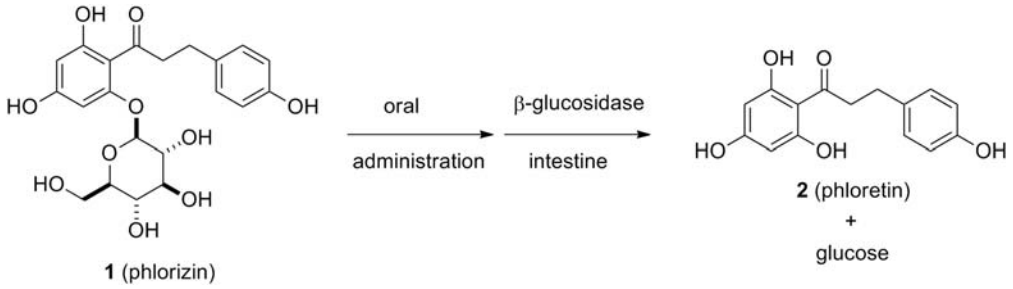

Fig. 2 Hydrolysis of **1** (phlorizin) by β-glucosidase in the intestine. Modified from Nomura, S. Renal Sodium-Dependent Glucose Cotransporter 2 (SGLT2) Inhibitors for New Anti-Diabetic Agent. *Curr. Top. Med. Chem.* **2010**, *10* (4), 411–418.

1990s, it became clear that phlorizin specifically and competitively inhibits both SGLT1 and SGLT2. Based on this knowledge, we pioneered the revolutionary idea of treating T2DM with an agent that enhances the excretion of glucose in the urine. The effect of phlorizin is, however, markedly reduced when administered orally because intestinal β-glucosidase hydrolyzes this compound into phloretin (**2**) and glucose (Fig. 2). Phlorizin had also been reported to induce renal impairment.[21] Hence, there had been no attempt to use phlorizin as an antidiabetic agent.

We explored the structure–activity relationship (SAR) of phlorizin derivatives to inhibit rat kidney SGLT activity and to increase UGE by oral administration in Sprague Dawley (SD) rats (Fig. 3). Removal of the 4′-hydroxyl group on the B ring of phlorizin provided resistance to β-glucosidase on oral treatment,[6] and the use of bicyclic benzofuran as the A ring showed superior UGE activity.[23] Finally, introduction of a methyl group on the B ring resulted in a selective human SGLT2 (hSGLT2) inhibitor, **3** (T-1095A). Further exploration of prodrugs to improve in vivo activity led to the discovery of the methoxycarbonyl prodrug **4** (T-1095) with enhanced resistance to β-glucosidase.[16,24] T-1095 induced UGE, following oral administration, and lowered blood glucose levels in diabetic animal models independent of insulin action. T-1095 is the first orally active SGLT2 inhibitor. Proof of concept for SGLT2 inhibitors, using T-1095, was published in 1999.[25]

8.14.3.2 Efficacy and Pharmacokinetic Issues of T-1095

Orally administered prodrug T-1095 is absorbed in the small intestine and converted to its active form, T-1095A, by the liver esterase. T-1095A then inhibits SGLT2 located in the proximal tubules (Fig. 4). Single oral administration of T-1095 dose-dependently

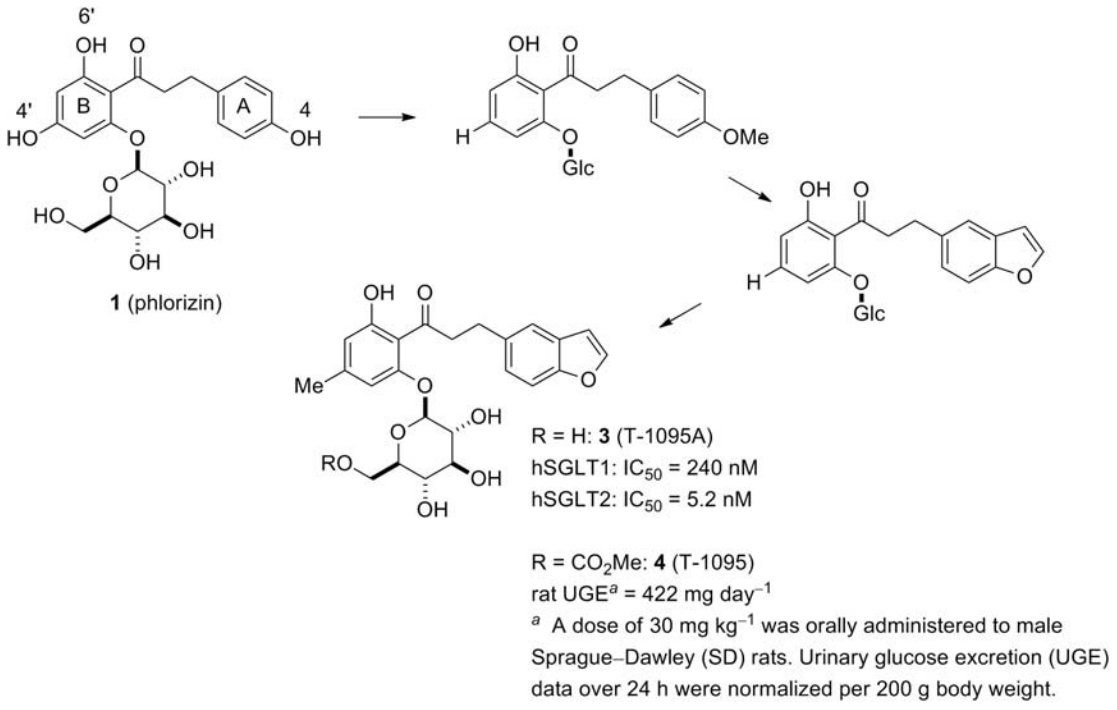

Fig. 3 Discovery of **4** (T-1095), the first orally active SGLT2 inhibitor. Data from Nomura et al.[22]

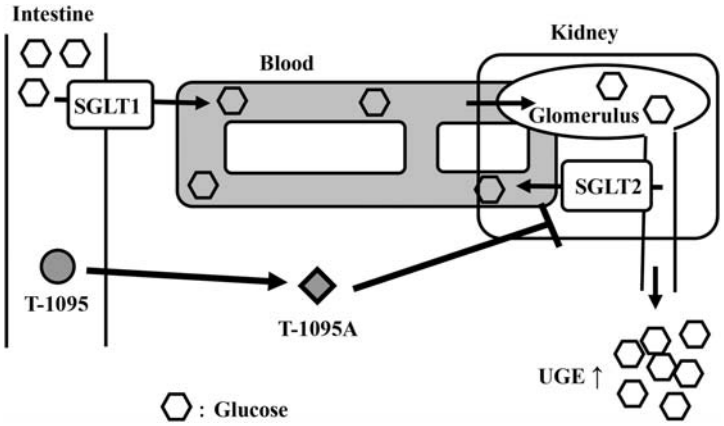

Fig. 4 Action of T-1095. Modified from Nomura, S. Renal Sodium-Dependent Glucose Cotransporter 2 (SGLT2) Inhibitors for New Anti-Diabetic Agent. *Curr. Top. Med. Chem.* **2010**, *10* (4), 411–418.

increased UGE in neonatally streptozotocin (STZ)-treated (n-STZ) rats, a nonobese rat model of T2DM. A concomitant significant reduction in blood glucose levels was also seen in this model. In contrast, T-1095 only slightly increased UGE, and blood glucose levels were only slightly affected in normoglycemic rats even at 100 mg kg^{-1} (Figs. 5 and 6).[26] This showed that the inhibition of renal SGLT2 does not significantly reduce blood glucose levels in normoglycemic ranges, suggesting the risk of hypoglycemia induction is low in contrast to insulin secretagogues, such as sulfonylureas and glinides.

Since increase in UGE by SGLT2 inhibition is dependent on the glomerular filtration of glucose, SGLT2 inhibition was expected to reduce blood glucose levels in any model of hyperglycemia. Single oral administration of T-1095 reduced blood glucose levels dose-dependently in a type 1 diabetic rat model produced by treatment with STZ at 6 or 7 weeks of age. Since these rats lack β-cell function, the results demonstrate that T-1095 exerts antihyperglycemic effects in an insulin-independent fashion (Fig. 7).[27] The antihyperglycemic effect of T-1095 was demonstrated in various T2DM rodent models, including Goto–Kakizaki rats,[28] Zucker diabetic fatty (ZDF) rats,[29,30] KKAy mice,[25] and db/db mice.[31] Taken together, the findings from these models have demonstrated that SGLT inhibition reduces hyperglycemia but hardly causes hypoglycemia below the normoglycemic range.

In addition to the acute reduction of hyperglycemia, long-term treatment with T-1095 controlled glucose levels and reduced fasting glucose and HbA1c levels in various animal models of hyperglycemia. After 4-week treatment with T-1095 in n-STZ rats, an oral glucose tolerance test (OGTT) revealed that an elevated glucose excursion in hyperglycemic animals was reduced and concomitant insulin release was restored. A hyperinsulinemic glucose clamp study in ZDF rats revealed that 4-week treatment with T-1095 reduced insulin resistance in peripheral tissues, including the liver and skeletal muscles.[29,30] In db/db mice, the progression of hyperglycemia and hyperinsulinemia was suppressed, and the exhaustion of pancreatic β-cells was prevented.[31] As hyperglycemia was controlled over a 4-week period in db/db mice, the improvement of insulin secretion and insulin sensitivity in hyperglycemic

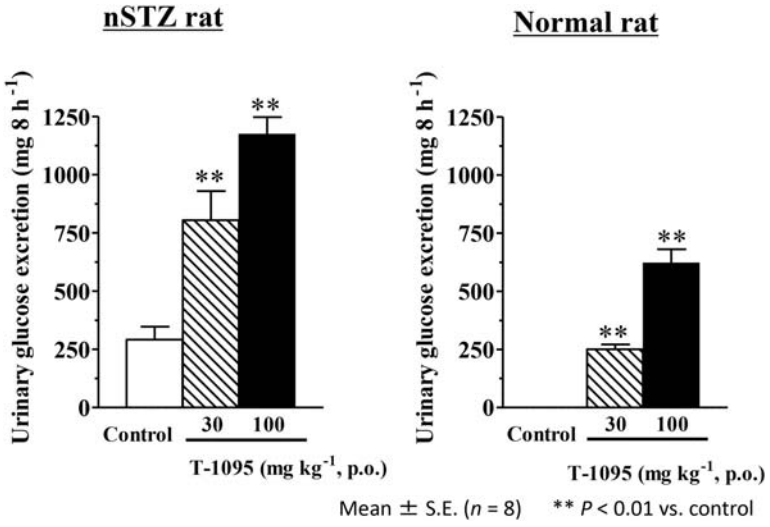

Fig. 5 T-1095 enhances urinary glucose excretion (UGE) more markedly in hyperglycemic than that in normoglycemic states. Data from Oku et al.[26]

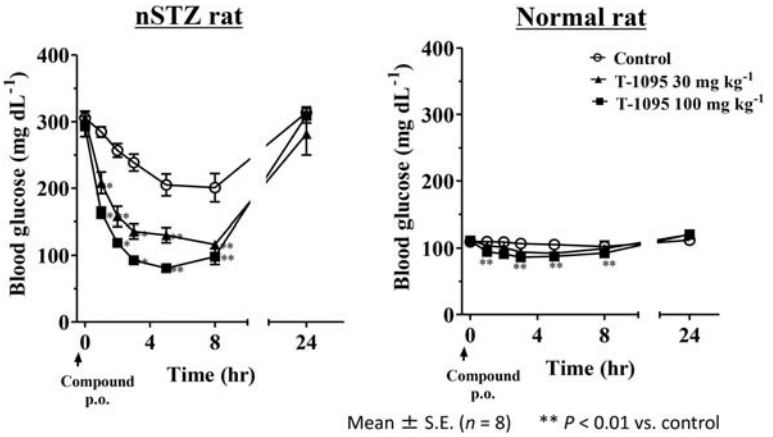

Fig. 6 T-1095 lowers blood glucose more markedly in hyperglycemic than that in normoglycemic states. Data from Oku et al.[26]

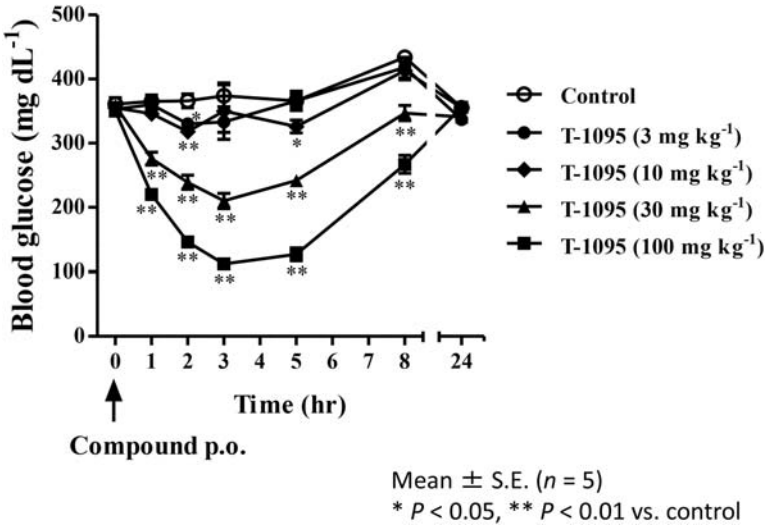

Fig. 7 T-1095 lowers blood glucose in streptozotocin-induced diabetic rats (STZ rats), a type 1 diabetes model. Data from Oku et al.[27]

animals was believed to be due to the alleviation of glucose toxicity. Furthermore, renal impairment in hyperglycemic animals was mitigated by long-term treatment with T-1095. These results indicated that a long-term inhibition of SGLT2 controls hyperglycemia and restores insulin secretion and insulin sensitivity through the alleviation of glucose toxicity, thus having the potential to relieve diabetic complications.

The aforementioned results provided a proof of principle for SGLT2 inhibition as a novel antidiabetic strategy with potential to control hyperglycemia, glucose toxicity, and complications. However, it was found that the *O*-glucoside portion of T-1095 is to some extent hydrolyzed to its aglycon in vivo in preclinical studies (Fig. 8). We, therefore, explored novel backup compounds that are more metabolically stable than T-1095.

8.14.4 Discovery of Canagliflozin

8.14.4.1 Exploration of *C*- and *N*-glucosides Bearing a Heteroaromatic Ring

After the reporting of T-1095-related compounds, several pharmaceutical companies began investigation into SGLT inhibitors (Fig. 9). Oral administration of nonglucoside pyrazole derivative **5** (WAY-123783) was reported to increase glycosuria in mice.[32] Later, WAY-123783 was speculated to be converted to an active metabolite pyrazole-*O*-glucoside, such as **6**, which inhibits SGLT activity and induces UGE in rats, following intravenous administration.[33] However, the compound **6** had already been patented by Kissei Pharmaceutical Co. (Kissei) in 2001.[34] Simplified benzylbenzene *O*-glucoside **7** was disclosed by Kissei[35] and Bristol-Myers Squibb (BMS)[36] in 2001. In addition, Kotobuki Seiyaku Co.[37] and BMS[38] unveiled the *C*-glucosides dihydrochalcone **8**

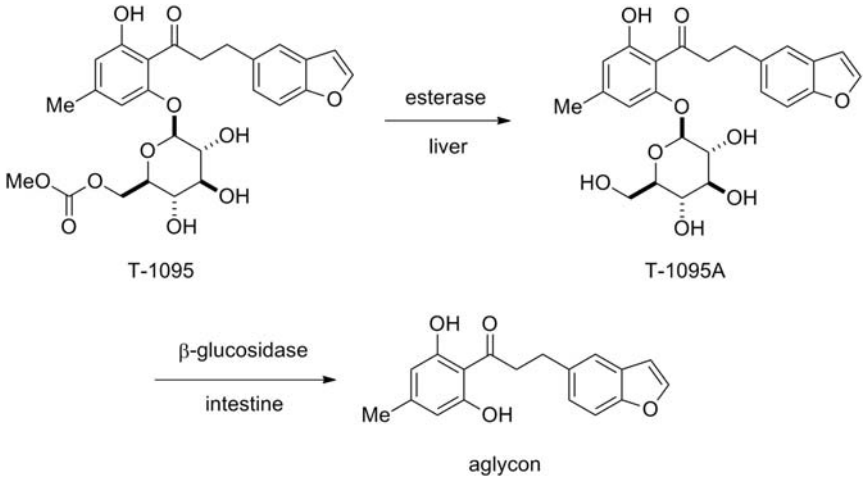

Fig. 8 Pharmacokinetic issues of T-1095.

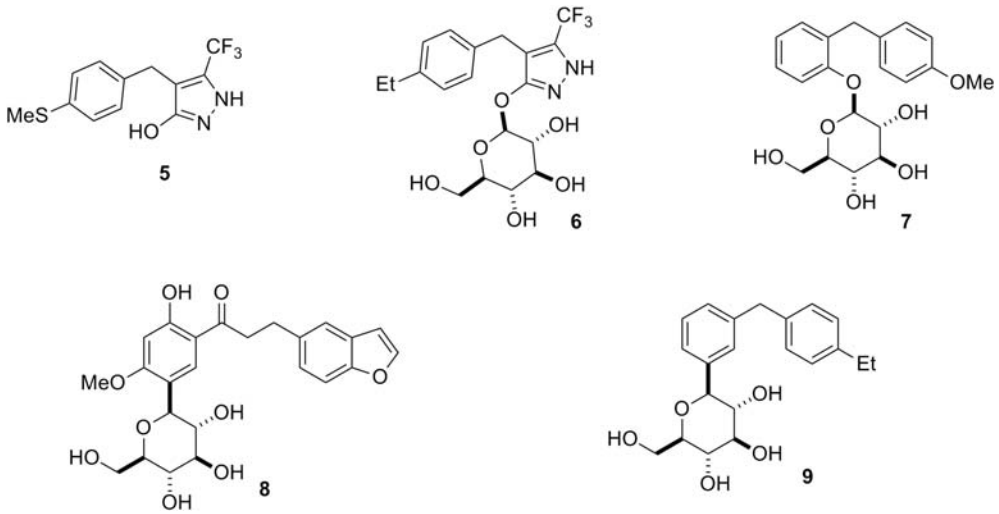

Fig. 9 Synthetic approach based on T-1095.

and benzylbenzene **9**, respectively, in the same year. We focused on the modification of *C*-glucosides because they are metabolically more stable than *O*-glucosides.

We explored *C*-glucosides and *N*-glucosides from scratch, with an aim to deliver compounds superior to previously published ones (Fig. 10). Benzylbenzyl *C*-glucoside **10** showed a weak inhibitory activity. In contrast, benzylaniline *N*-glucoside **11** possessed a strong inhibitory activity in vitro, although this aniline *N*-glucoside was metabolically unstable.[39,40] We, therefore, synthesized and evaluated a series of aromatic *C*-glucosides and aza-aromatic *N*-glucosides **12** bearing a heteroaromatic ring as the A or B ring. Exploration of aromatic *C*-glucosides **12** bearing a heteroaromatic ring as the A or B ring resulted in a series of *C*-glucosides **13** with a heteroaromatic B ring, which were more potent in vitro and in vivo than those with a heteroaromatic A ring (Fig. 11).[22] Optimization of these *C*-glucosides **13** led to the discovery of canagliflozin that has a substituted thiophene ring. The SAR of the representative compounds is shown in section "SAR of the Typical C-glucosides With a Heteroaromatic Ring." In addition, novel indole *N*-glucosides **14** were found among aza-aromatic *N*-glucosides **12** (Fig. 11).[39,41]

8.14.4.2 Syntheses of *C*-glucosides Bearing a Heteroaromatic Ring

The synthetic route for *C*-glucosides is outlined in Scheme 1.[22] As an aglycon part, arylbromides **15** were treated with *n*-butyllithium or *tert*-butyllithium to generate the corresponding aryllithium, followed by coupling with trimethylsilylated gluconolactone **16**. The resulting lactols directly led to desilylated methyl ethers **17** by the addition of methanesulfonic acid and methanol. Finally, *C*-glucoside derivatives **13** were obtained by the stereoselective reduction of **17** with a combination of triethylsilane and boron trifluoride etherate. The stereochemistry of *C*-glucosides **13** was determined as β-configuration based on the coupling constant of ~9.5 Hz between

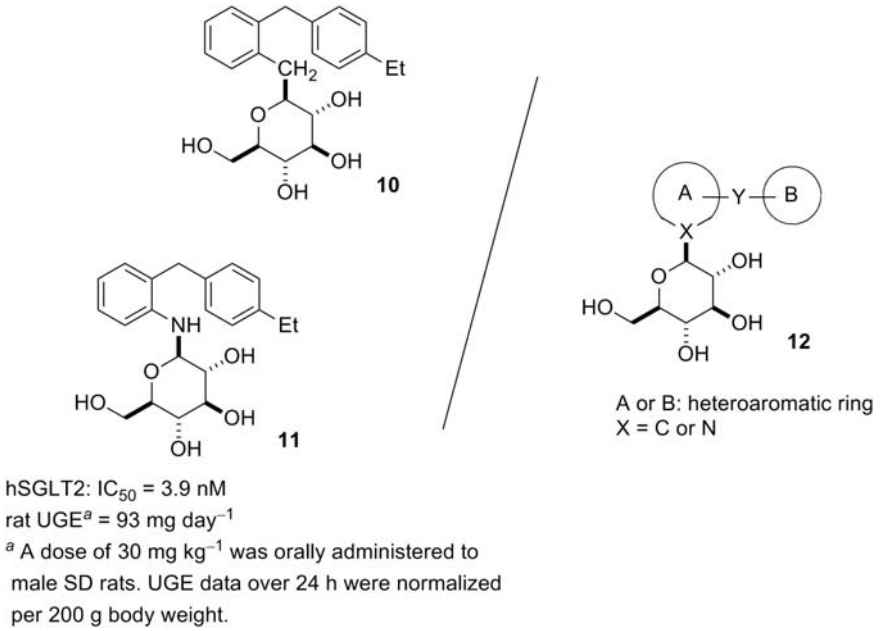

Fig. 10 Exploration of *C*- and *N*-glucosides. Data from Yamamoto et al.[39]

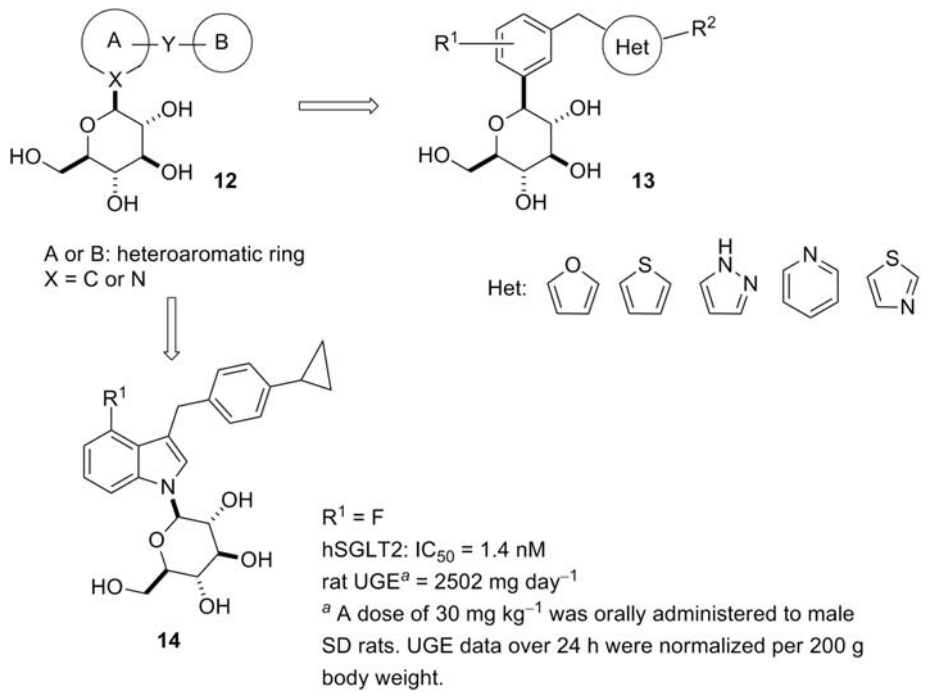

Fig. 11 Exploration of *C*- and *N*-glucosides bearing a heteroaromatic ring. Data from Nomura et al.[41]

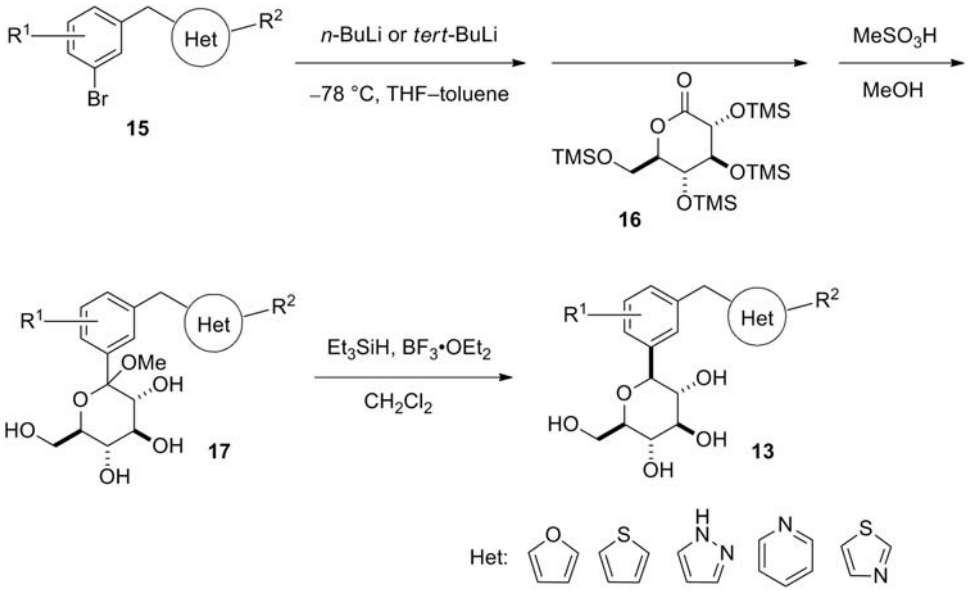
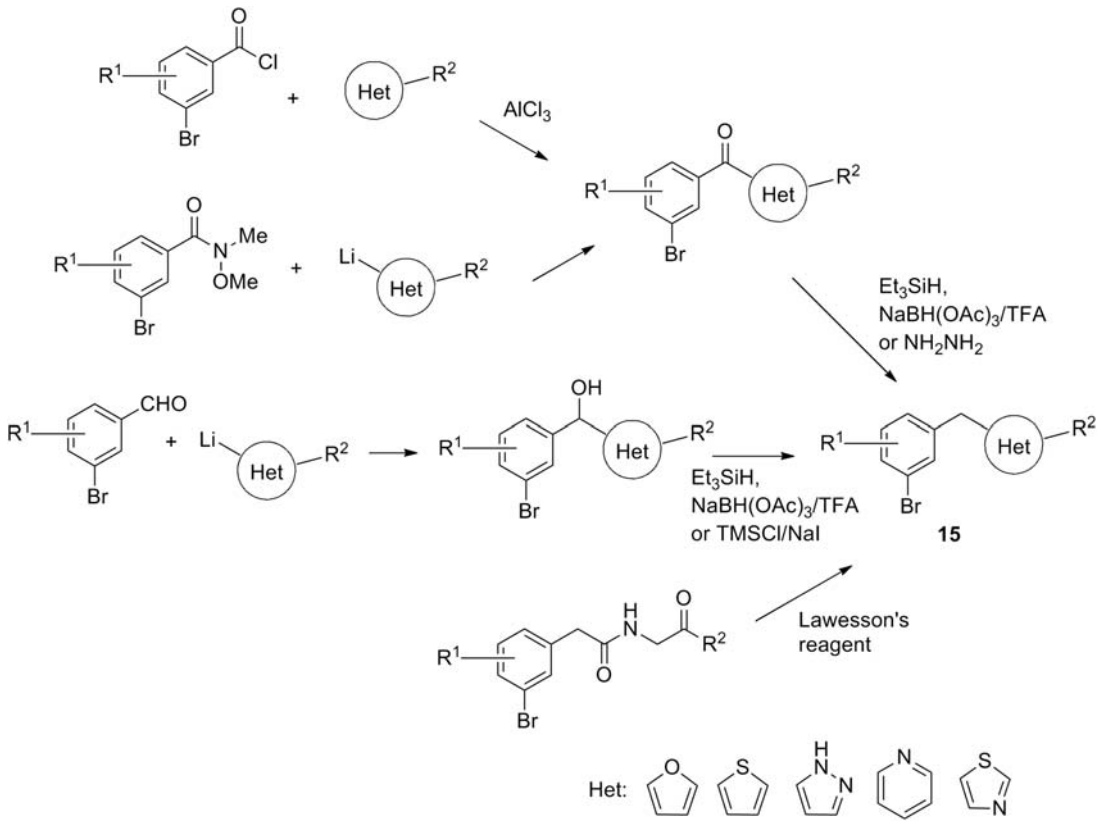
anomeric proton and adjacent proton in the proton NMR spectrum. Aglycons represented by **15** were prepared via Friedel–Crafts acylation or by coupling reaction with heteroaryllithium followed by the reduction of ketone or carbinol. To provide thiazole derivatives, the corresponding ketoamides were cyclized using Lawesson's reagent (Scheme 2).[22]

8.14.4.3 SAR of the Typical *C*-glucosides With a Heteroaromatic Ring

The SAR of the typical *C*-glucoside compounds is shown in Table 1.[22] Effects of furan, thiophene, pyrazole, pyridine, and thiazole derivatives **13** were evaluated for hSGLT2 activity and for UGE in male SD rats per 200 g of body weight over 24 h. Ethylthiophene derivative **19** showed higher hSGLT2 inhibitory potency compared with ethylfuran **18** or ethylpyridine **23** derivatives.



Scheme 1 Syntheses of **13**. Modified from Nomura, S.; Sakamaki, S.; Hongu, M.; Kawanishi, E.; Koga, Y.; Sakamoto, T.; Yamamoto, Y.; Ueta, K.; Kimata, H.; Nakayama, K.; Tsuda-Tsukimoto, M., Discovery of Canagliflozin, A Novel C-Glucoside with Thiophene Ring, as Sodium-Dependent Glucose Cotransporter 2 Inhibitor for the Treatment of Type 2 Diabetes Mellitus. *J. Med. Chem.* **2010**, *53* (17), 6355–6360.



Scheme 2 Syntheses of aglycons **15**. Modified from Nomura, S.; Sakamaki, S.; Hongu, M.; Kawanishi, E.; Koga, Y.; Sakamoto, T.; Yamamoto, Y.; Ueta, K.; Kimata, H.; Nakayama, K.; Tsuda-Tsukimoto, M., Discovery of Canagliflozin, A Novel C-Glucoside with Thiophene Ring, as Sodium-Dependent Glucose Cotransporter 2 Inhibitor for the Treatment of Type 2 Diabetes Mellitus. *J. Med. Chem.* **2010**, *53* (17), 6355–6360.

Table 1 Structure–activity relationship (SAR) of the typical *C*-glucosides with a heteroaromatic ring

	Compound	R^1	Het-R^2	hSGLT2 IC_{50}(nM)	UGE[a] (mg day^{-1})
 13	**18**	H		920	ND[b]
	19	H		17	373
	20	Cl		2.4	2495
	21	Me		2.2	3696
	22	Cl		32	ND[b]
	23	Cl		28	ND[b]
	24	Me		8.1	1277

[a]Each compound was orally administered at a dose of 30 mg kg^{-1} to male SD rats. UGE data over 24 h were normalized per 200 g body weight.
[b]*ND*, not determined.
Data from Nomura et al.[22]

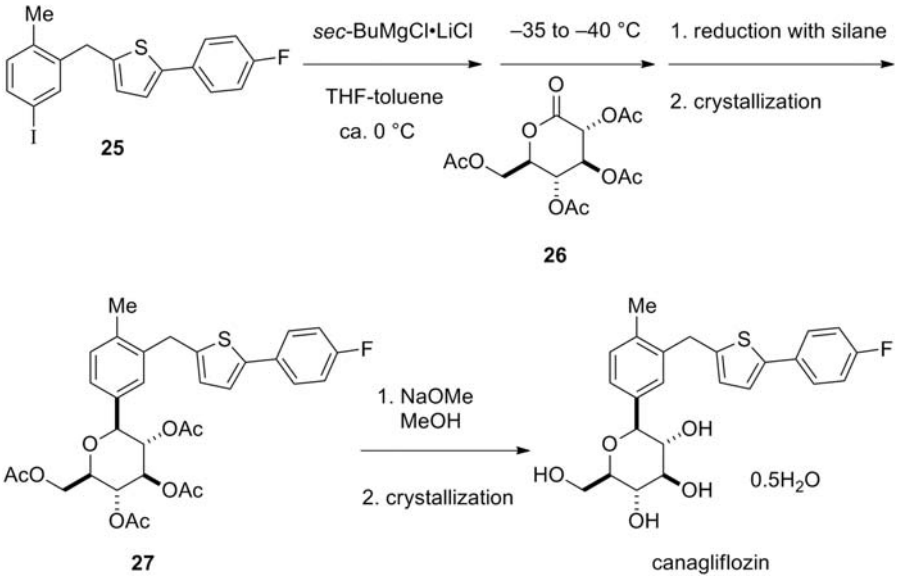
Phenylthiophene derivative **21** also exhibited higher hSGLT2 inhibitory activity and higher UGE than phenylpyrazole **22** or phenylthiazole **24** derivatives. Thiophene derivatives showed the highest potency among these *C*-glucosides. For R^1 substituents, the halogeno (chloro of **20**) or lower alkyl (methyl of **21**) group provided higher in vitro potency than proton (**19**). Regarding in vivo potency and chemical stability, a substituted aryl (4-fluorophenyl of **21**) group was more preferable to alkyl (ethyl of **19**) or halogeno (chloro of **20**) groups in the R^2 substituent position. From these thiophene derivatives, **21** (canagliflozin, TA-7284/JNJ-28431754) was selected as a clinical candidate.

8.14.4.4 The Synthesis of Canagliflozin

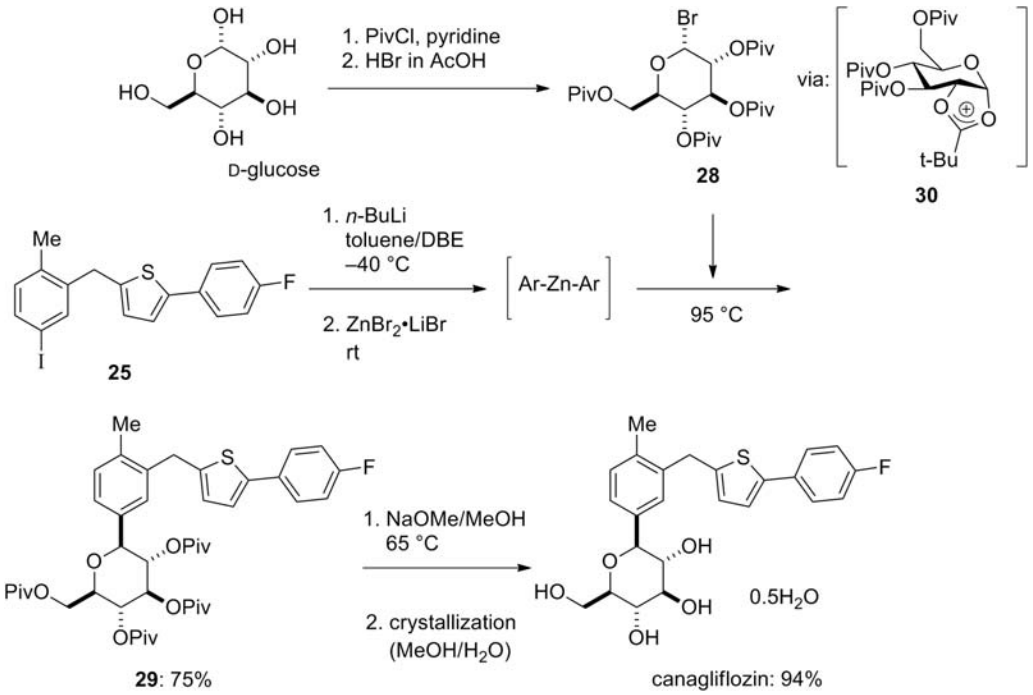
An alternative synthetic route was evaluated (Scheme 3).[42] Aryl iodide **25** was treated with 2-butylmagnesium chloride–lithium chloride complex to generate arylmagnesium salt, followed by coupling with acetylated gluconolactone **26** at −35°C to −40°C. The resulting lactol was directly converted to **27** by reduction with silane. Finally, canagliflozin was obtained by the hydrolysis of **27**. Lemaire et al. reported a short and efficient stereoselective synthesis of canagliflozin (Scheme 4).[43] Aryl iodide **25** was treated with *n*-butyllithium to generate aryllithium, followed by the addition of zinc bromide–lithium bromide complex. The resulting transmetallated Ar–Zn–Ar was coupled with glucosyl bromide **28** at 90–100°C to produce the β-arylated glucoside **29** in 75% yield. The highly stereoselective cross coupling reaction was achieved via anomeric oxonium ion **30** due to the neighboring effect of a pivaloyl group. Finally, canagliflozin was obtained by the hydrolysis of **29**.

8.14.4.5 Canagliflozin: A Selective SGLT2 Inhibitor

The IC_{50} values of T-1095A and canagliflozin were 240 and 910 nM, respectively, for hSGLT1 and 5.2 and 2.2 nM, respectively, for SGLT2 in assays using Chinese hamster ovary-K (CHOK) cells stably expressing either hSGLT1 or hSGLT2. GLUT1 conducts the uptake of glucose in almost all tissues. Neither compound inhibited GLUT1 activity in L6 myoblast cells up to 10 μM (Table 2).[22] In addition, canagliflozin showed only weak inhibition of other SGLTs and GLUTs (Table 3).[44,45] Based on this data, canagliflozin is a highly potent and selective inhibitor of hSGLT2. Single oral administration of either T-1095 or canagliflozin at 30 mg kg^{-1} to male SD rats induced UGE over a 24 h period of 422 and 3696 mg, respectively, per 200 g body weight (Table 2).[22]



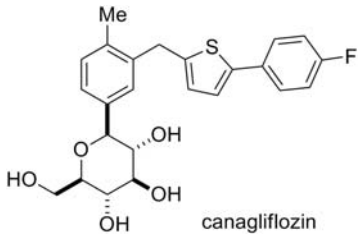
Scheme 3 Additional synthetic route for canagliflozin.



Scheme 4 Stereoselective synthesis of canagliflozin. Modified from Lemaire, S.; Houpis, I. N.; Xiao, T.; Li, J.; Digard, E.; Gozlan, C.; Liu, R.; Gavryushin, A.; Diène, C.; Wang, Y.; Farina, V.; Knochel, P., Stereoselective C-Glycosylation Reactions with Arylzinc Reagents. *Org. Lett.* **2012**, *14* (6), 1480–1483.

Pharmacokinetic (PK) studies revealed a much higher exposure of canagliflozin compared with T-1095 following oral administration at 10 mg kg^{-1} in male SD rats (Table 4) with $AUC_{0-inf,po}$ 35,980 ng h mL^{-1}, $t_{1/2,po}$ 5.2 h, and oral bioavailability of 85%.[22] At 24 h after oral administration of 3 mg kg^{-1} canagliflozin, unbound plasma concentration was similar to the IC_{50} value for SGLT2.[44] These studies demonstrate that the plasma level of canagliflozin is sufficient to inhibit SGLT2 in the renal tubules after oral dosing. The notable UGE most likely reflects superior PK properties of canagliflozin and highly potent SGLT2 inhibition in vivo.

Table 2 Effects of T-1095A, T-1095, and canagliflozin on hSGLT1, hSGLT2, facilitating glucose transporter 1 (GLUT1), and UGE



canagliflozin

IC_{50} (nM)				
Compound	*hSGLT1*	*hSGLT2*	*GLUT1*	*UGE*[a] *(mg day^{-1})*

8.14.4.6 Efficacy of Canagliflozin

Single oral administration of canagliflozin smoothly and continuously reduced blood glucose levels in ZDF rats over 24 h. Conversely, canagliflozin hardly affected blood glucose levels in normoglycemic rats (Fig. 12).[44] Whereas at 24 h after oral administration of 3 mg kg^{-1} canagliflozin, unbound plasma concentration was similar to the IC_{50} value for SGLT2, and the C_{max} value was much lower than the IC_{50} value for SGLT1 even after treatment with 30 mg kg^{-1} canagliflozin. Although UGE is increased after treatment with canagliflozin, 24 h accumulated UGE was not significantly different between canagliflozin- and vehicle-treated ZDF rats. This is because the plasma glucose levels of ZDF rats are higher than the renal threshold for glucose (RT_G), and UGE is detected in nontreated ZDF rats. After treatment with canagliflozin, glucose reabsorption is temporarily inhibited due to SGLT2 inhibition, and reduction in plasma glucose levels and renal glucose filtration is observed. Due to reduced glucose levels in the glomerular filtrate, UGE is reduced compared with that in nontreated hyperglycemic ZDF rats. As glucose excretion is reduced along with reduction of hyperglycemia, it is likely that the control of hyperglycemia with canagliflozin would be accompanied with a low risk of hypoglycemia.

Table 5 shows the result of 4-week treatment of canagliflozin in ZDF rats. ZDF rats develop hyperglycemia and hyperinsulinemia from 5 to 12 weeks of age, and plasma insulin levels decrease thereafter, while hyperglycemia persists. Fed plasma glucose and HbA1c levels decreased markedly following canagliflozin treatment. Chronic canagliflozin treatment also alleviated reduction in plasma insulin levels after 12 weeks of age via continuous control of hyperglycemia. In addition, canagliflozin treatment reduced blood glucose excursion and improved impaired insulin secretion following glucose challenge in an OGTT.[46] Histochemical analysis also revealed the preservation of pancreatic β-cells. Thus, it was demonstrated that canagliflozin improves pancreatic β-cell function through canceling glucose toxicity.

Effects of treatment with a combination of canagliflozin and dipeptidyl peptidase IV (DPP4) inhibitors were evaluated in ZDF rats.[47,48] A single oral treatment of canagliflozin and teneligliptin suppressed plasma glucose elevation in an OGTT in

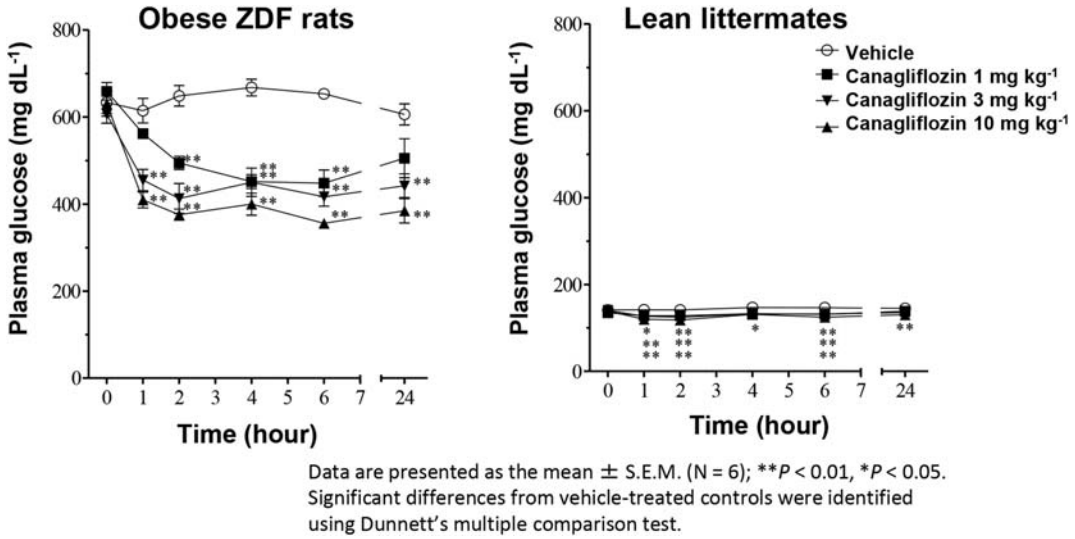

Fig. 12 Blood glucose-lowering effects in Zucker diabetic fatty (ZDF) rats. Data from Kuriyama et al.[44]

Table 5 Effects of a 4-week treatment of canagliflozin on blood glucose and insulin levels in ZDF rats

	Vehicle	*3 mg kg^{-1}*	*10 mg kg^{-1}*	*30 mg kg^{-1}*

13-week-old ZDF rats. The combined treatment further improved glucose intolerance and elevated plasma active glucagon-like peptide-1 (GLP-1) in a synergistic manner compared with single treatment of canagliflozin or teneligliptin (Fig. 13).[47] Because there were no PK interaction of the drugs and no further inhibition of plasma DPP4 activity compared with that in the teneligliptin-treated animals, it was suggested that canagliflozin promoted the meal-induced secretion of GLP-1 in intestinal cells.

SGLT1 mediates glucose absorption in intestinal epithelial cells. Although canagliflozin is an SGLT2 inhibitor, it also inhibits SGLT1 at a concentration 150 times higher than that for SGLT2 inhibition.[44] When canagliflozin is administered by oral gavage, intraluminal concentration in the upper small intestine is believed to be sufficient for SGLT1 inhibition. It was suggested that glucose absorption is partly suppressed and that intraluminal glucose concentration is temporarily increased through intestinal SGLT1 inhibition. Increase in intraluminal glucose stimulates secretion of GLP-1 in the distal part of small intestine. Detailed analysis of the combined use of canagliflozin and the DPP4 inhibitor sitagliptin showed close correlations between SGLT1 inhibition and elevation of plasma GLP-1 levels. It was, therefore, concluded that canagliflozin inhibits SGLT1 and suppresses glucose excursion in an OGTT through the suppression of glucose absorption in the upper small intestine and an increased glucose stimulates secretion of GLP-1 in the lower small intestine (Fig. 14).[48]

Hypertension and T2DM are often comorbid with obesity, and patients with comorbidity of these diseases have high risk of cardiovascular and cerebrovascular incidents. Spontaneously hypertensive corpulent congenic rats (SHR-cp) develops hypertension, obesity, hyperglycemia, and hyperlipidemia. A preliminary study indicated that canagliflozin reduces the development of hyperglycemia, hypertension, and hyperlipidemia in these animals. It was suggested that these effects were mediated by diuresis and calorie loss due to enhanced UGE and subsequent body weight reduction.[49]

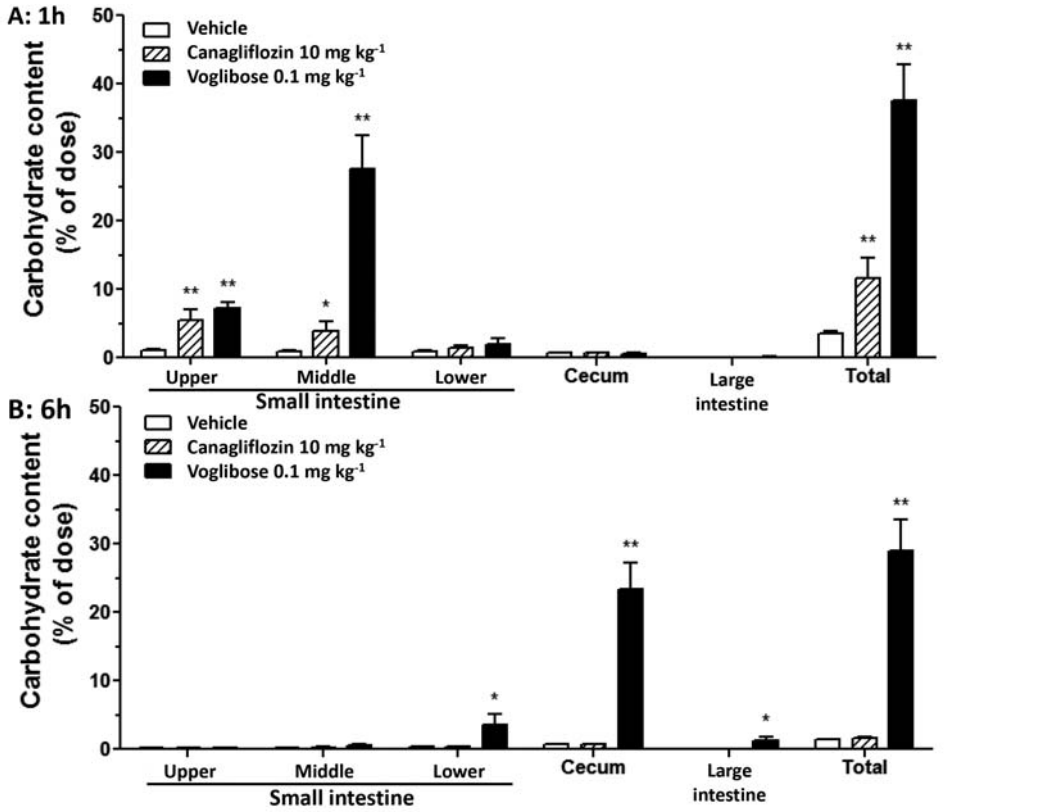
8.14.5 Clinical Outcomes

8.14.5.1 Mechanism of Action of SGLT2 Inhibitors

The term "RT_G" defines the plasma glucose concentration at which tubular reabsorption of glucose reaches saturation; therefore, when glucose concentrations are above this threshold, UGE increases linearly. RT_G in healthy subjects is ~180 mg dL^{-1}, while RT_G in patients with T2DM rises to ~240 mg dL^{-1}. This higher value appears to be due to increased SGLT2 expression in patients as previously mentioned.[12] Canagliflozin lowers RT_G to 70–90 mg dL^{-1} in patients with T2DM. This value is safely above the plasma glucose levels causing symptomatic hypoglycemia. Therefore, a low risk of hypoglycemia is expected during treatment with canagliflozin. The inhibition of renal glucose reabsorption by canagliflozin decreases RT_G, enhances UGE, and consequently reduces blood glucose levels in patients with T2DM (Fig. 15).[50,51]

8.14.5.2 24-Week Phase 3 Study in Japanese Patients

Efficacy and safety of canagliflozin monotherapy were determined in patients with T2DM, with decreases in HbA1c and fasting plasma glucose (FPG) levels as the primary endpoints. In a phase 3 study, T2DM patients, who were inadequately controlled by diet and exercise, received 100 mg or 200 mg canagliflozin or placebo orally once per day for 24 weeks. The change in HbA1c at the end of the treatment period was −1.03% in the 100 mg canagliflozin group, this being a statistically significant reduction compared with that in the placebo group. The decrease in HbA1c in the canagliflozin group was evident by week 4 and reached



Carbohydrate content in upper SI, middle SI, lower SI, cecum, LI, and total segment of intestine 1-h (A) or 6-h (B) after sucrose-loading. Canagliflozin (10 mg kg^{-1}) or voglibose (0.1 mg kg^{-1}) and sucrose solution (2.5 g kg^{-1}) were simultaneously administered to SD rats by oral gavage. Intestinal contents were collected from GI tract divided into five parts. Data are presented as the mean ± S.E.M. (N = 6); *P < 0.05, **P < 0.01, Significant differences from vehicle treated groups were identified using Student's t-test.

Fig. 14 Effects of canagliflozin on carbohydrate absorption in the gastrointestinal (GI) tract in sucrose-loaded SD rats. Data from Oguma et al.[48]

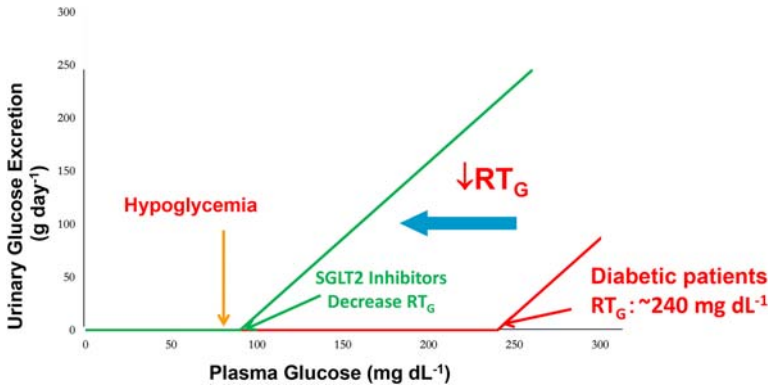


Fig. 15 SGLT inhibition lowers the renal threshold for glucose reabsorption (RT_G).

a plateau at around 12 weeks. Along with this change in HbA1c, FPG decreased over time in the canagliflozin group. In addition, plasma glucose excursion decreased significantly in the canagliflozin group in an OGTT conducted at week 24. The proinsulin/C-peptide ratio decreased, and HOMA-β increased significantly in the canagliflozin group. This result demonstrates that the 24-week treatment with canagliflozin improves pancreatic β-cell function and controls plasma glucose levels in a long-term period. Canagliflozin was generally well tolerated with a low incidence of hypoglycemia.[52]

In addition to the favorable improvement in the glycemic control, canagliflozin at 100 mg decreased body weight over time, with a change of −3.00% at 24 weeks. It is believed that continuous calorie loss due to glucose excretion in the urine induces weight reduction. Furthermore, systolic blood pressure was reduced significantly in the 100 mg canagliflozin group compared with that in

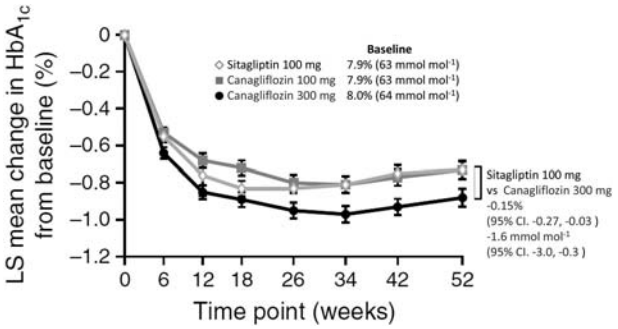

Fig. 17 CANTATA-D trial: reduction in HbA1c. Data from Lavalle-González et al.[54]

the placebo group, by 5.16 mmHg at the end of the treatment period. The reduction in systolic blood pressure may have been due to weight loss and osmotic diuresis.[52]

8.14.5.3 Phase 3 CANTATA Trials

The efficacy for lowering of HbA1c was similar between canagliflozin (100 mg) and sulfonylurea glimepiride (5.6 mg) in patients with T2DM at 52 weeks in the phase 3 CANTATA-SU trial. Canagliflozin significantly reduced body weight at week 52, whereas a slight increase was shown with glimepiride (Fig. 16). In the canagliflozin group, roughly two-thirds of the reduction in body weight was due to the loss of fat mass, and reduction in visceral fat was slightly greater than that in subcutaneous adipose tissues.[53] The efficacy for lowering HbA1c of 100 mg canagliflozin was noninferior to sitagliptin, and that of 300 mg canagliflozin was superior to sitagliptin (100 mg) in the phase 3 CANTATA-D trial in subjects with T2DM at 52 weeks of treatment (Fig. 17).[54]

8.14.5.4 Improvement of β-Cell Function

Phase 3 trials have also shown that in mixed-meal tolerance tests (MMTTs), postprandial plasma glucose excursion is reduced, and glucose-induced insulin secretion is enhanced in canagliflozin-treated T2DM patients.[55] In addition, postprandial GLP-1 and peptide YY (PYY) levels were elevated.[56] These results suggested that canagliflozin delays glucose absorption immediately after oral treatment and improves pancreatic β-cell function over long-term treatment.

8.14.6 Conclusion

Researchers at the Mitsubishi Tanabe Pharma Corporation discovered and developed SGLT2 inhibitors T-1095 and canagliflozin based on the revolutionary idea for treating T2DM with drugs that induce the excretion of excess glucose in the urine. The inhibition of renal glucose reabsorption enhances UGE and improves hyperglycemia. A long-term control of hyperglycemia reduces glucose

toxicity and preserves pancreatic β-cell function. Moreover, calorie loss due to enforced glucose disposal is associated with weight loss and reduction in blood pressure.[57] With its highly effective antidiabetic properties and strong safety profile, we expect canagliflozin to provide an innovative new approach to diabetic therapy.

8.15.1 Introduction

In this article, we describe the medicinal chemistry program that led to the identification and clinical development of the potent and selective PI3Kδ inhibitor *seletalisib*, currently in a Phase 2 trial for Sjögren's syndrome.[1,2] The therapeutic rationale for selective PI3K inhibition in inflammatory diseases will be discussed followed by a detailed description of the medicinal chemistry campaign. Highlights include the use of a virtual library of heterocycles[3] coupled with electrostatic modeling to identify novel chemical starting points, the optimization of physicochemical parameters to achieve drug-like properties, the use of in vitro genotoxicity screening in drug discovery, and the successful application of a pyridine *N*-oxide as a bioisostere of a amide. It is hoped that the story of our research will enlighten and inform current and future generations of medicinal chemists as we discuss the highs and lows of our program and the many lessons learnt upon the ultimately successful journey to *seletalisib*.

8.15.1.1 The Rationale for Selectively Targeting PI3Kδ to Treat Inflammatory Disease

The Class 1 phosphoinositide 3-kinase enzymes are a well characterized family of lipid kinases that catalyze the phosphorylation of phosphatidylinositol 4,5 bisphosphate (PIP_2) to the key signaling molecule phosphatidylinositol 3,4,5 trisphosphate (PIP_3) which in turn triggers a wide range of downstream biological events impacting diverse functions including cell growth, proliferation, chemotaxis, differentiation, and survival.[4,5] The Class I subset of PI3K comprises four isoforms of the catalytic p110 subunit, the Class 1A isoforms p110α, β, and δ, and the Class 1B isoform, p110γ (**Fig. 1**). The fundamental role of the Class 1 PI3Ks in a wide range of critical cellular events has made them attractive targets for therapeutic intervention.[6–8] The PI3Kα and PI3Kβ isoforms are ubiquitously expressed, whereas PI3Kγ and PI3Kδ are expressed more highly in leukocytes than in other cell types, implying a more specific and important role in leukocyte development and function.[4,9,10] PI3Kδ is also expressed in endothelial cells, synoviocytes, osteoclasts, and stromal cells.[11,12]

Although PI3Kγ and PI3Kδ have a similar cellular distribution, they are differentially coupled in specific cells. PI3Kγ is generally coupled to G protein-coupled receptors, including leukotriene and chemokine receptors, and plays a particularly important role in chemokine-mediated cell recruitment and the activation of innate immune cells at sites of inflammation.[4,11] In contrast, PI3Kδ is required for signaling downstream of several tyrosine kinase immune receptors, including the T-cell receptor (TCR), the B-cell receptor (BCR), and the Fc epsilon receptor 1 (FcεR1), thereby playing a key role in the acquired immune response.[13,14]

The selective expression and function of PI3Kδ in leukocytes provides a rationale for exploring this isoform as a therapeutic target for diseases featuring pathological activation of the PI3K pathway in hematopoietic cells, including B-cell malignancies and immune disorders.[15,16] Indeed in genetically modified mice that either lack p110δ or express the kinase inactive mutant, $p110\delta^{D910A/D910A}$, phenotypes, including lymphocyte developmental defects, attenuated signaling by antigen receptors, B-cell functional defects, and decreased T-cell-dependent responses, are observed while the mice remain viable and fertile.[17–19]

The ubiquitous expression of the PI3Kα and PI3Kβ isoforms has consequently limited their therapeutic utility to the field of oncology, however in contrast the enriched expression of the PI3Kδ and PI3Kγ isoforms to leukocytes and the revelation of their functional effects have led to the hypothesis that selective inhibition of these two isoforms will provide an opportunity to target inflammatory and autoimmune disease.[7]

The crucial role of the PI3K kinases in multiple physiological functions has ensured that they have long been a favored target of the medicinal chemistry community.[20,21] To date that research has culminated in the successful delivery of multiple classes of potent and selective PI3K inhibitors into clinical development (**Fig. 2**).[7,8] Isoform-selective PI3K inhibitors include those that selectively target p110α (BYL-719, INK-1117), p110β (AZD6482), p110δ (e.g., AMG 319, GSK2269557,[22] idelalisib [CAL-101]), p110α/p110δ (e.g., copanlisib, pictilisib, AZD8835), p110β/p110δ (e.g., acalisib, AZD8186), and p110δ/p110γ (e.g., duvelisib [IPI-145, INK1197], Tenalisib [RP-6530], RV-1729).[6,7]

The most clinically advanced PI3Kδ inhibitor *idelalisib* (Zydelig) has been approved by the FDA in combination with rituximab for the treatment of adult patients with chronic lymphocytic leukemia.[23,24] The current limitation of *idelalisib* to hematological malignancies is presumed to be due to the tolerability of the molecule and side effect profile. Interestingly although *idelalisib* is described as a PI3Kδ selective inhibitor, the fold-selectivity against the gamma isoform compared to the delta isoform in biochemical kinase assays is relatively modest (α 328-fold, β 226-fold, and γ 35-fold).[25] Additionally the PI3Kδ/γ dual selective inhibitor *duvelisib* (α 640-fold, β 34-fold, and γ 11-fold) has recently failed to meet the primary endpoint in a Phase 2 trial of rheumatoid arthritis when dosed at 0.5, 1, and 5 mg twice a day. Clinical trials with *duvelisib* are still ongoing in hematological cancers at higher doses (25 mg twice a day) potentially indicating a tolerability issue limiting dose in the arthritis clinical trial and thereby impacting

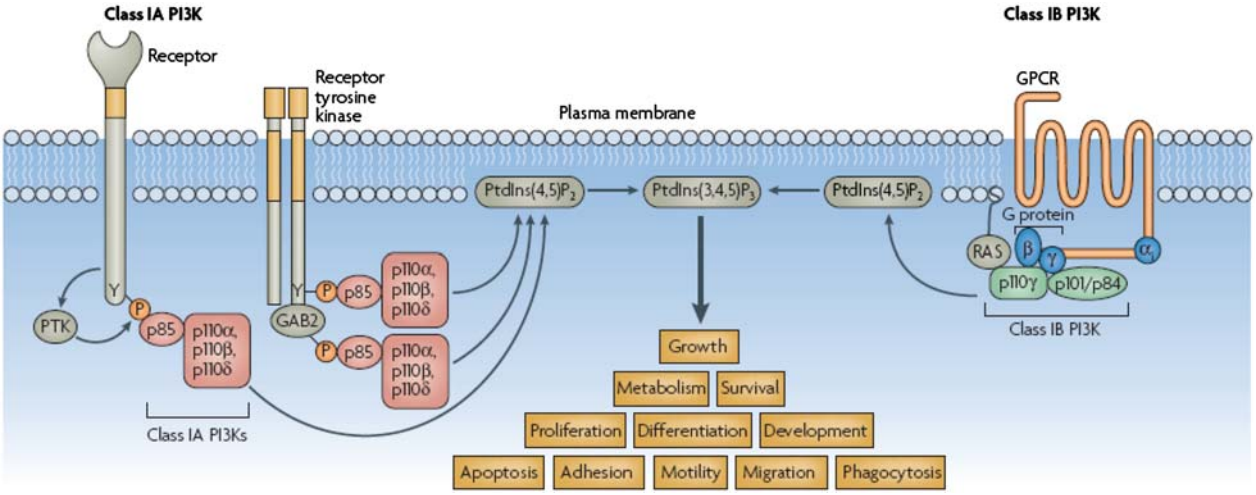

Fig. 1 The Class 1 PI3 kinases. Reproduced from Rommel, C.; Camps, M.; Ji, H. PI3K Delta and PI3K Gamma: Partners in Crime in Inflammation in Rheumatoid Arthritis and Beyond? *Nat. Rev. Immunol.* **2007**, *7* (3), 191–201.

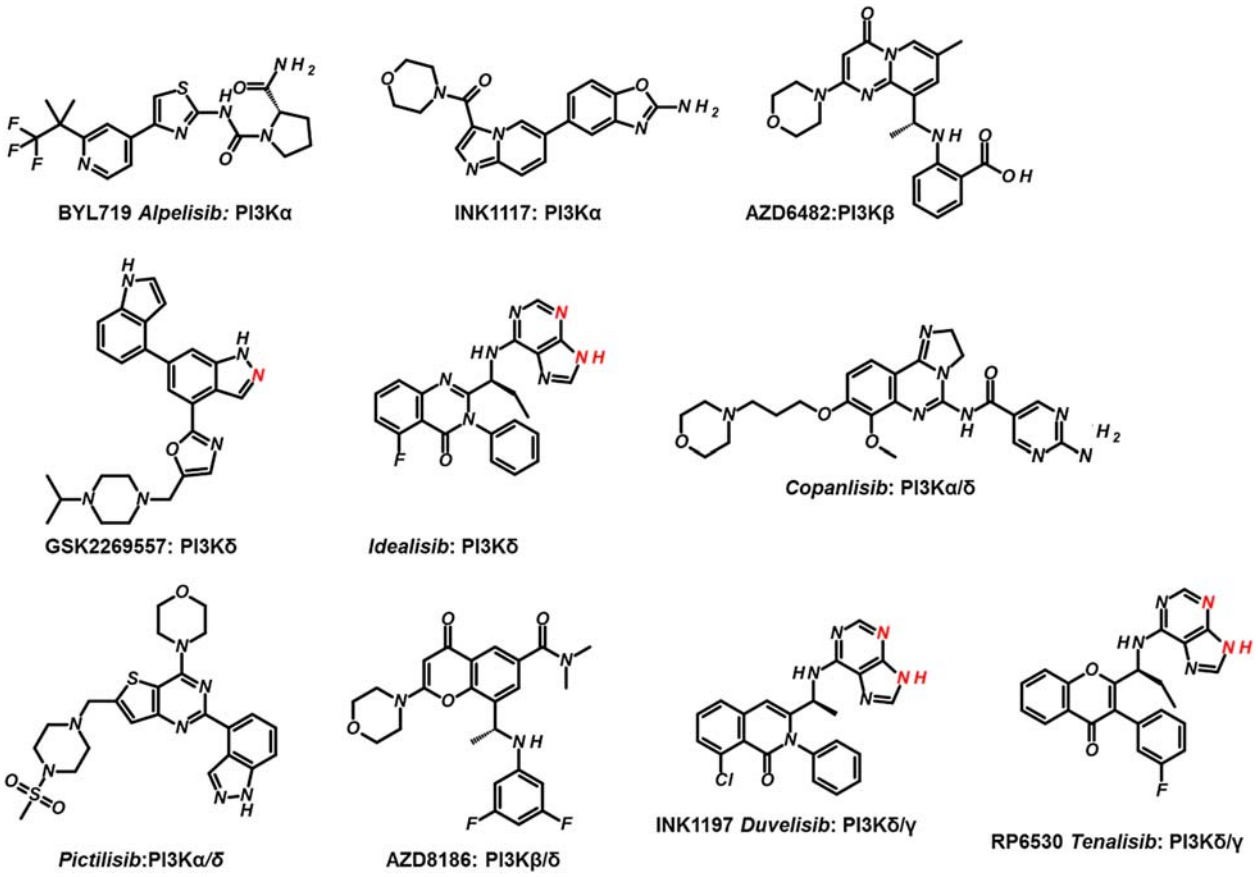

Fig. 2 Structures of representative ATP competitive and isoform-selective PI3K inhibitors currently in clinical development. Compounds are grouped by their isoform selectivity profiles. The key hydrogen bond interactions with the hinge region of the PI3K kinase are shown in *red* where known.

efficacy. While both the delta and gamma isoforms have been implicated in the proinflammatory pathways involved in rheumatoid arthritis, it is not clear that inhibition of both isoforms is necessary for clinical benefit.[11] It can be postulated that exquisitely selective PI3Kδ inhibitors *without* gamma isoform activity could provide additional tolerability benefit and hence open up the potential for clinical efficacy in inflammatory and immunological diseases.

In summary, there is evidence to conclude that the therapeutic utility of Class 1 PI3K inhibitors in inflammatory disease would be best accomplished by an isoform-selective inhibitor targeting PI3Kδ for those diseases with a significant B- and T-cell involvement. Certainly selectivity against the PI3K alpha and beta isoforms would be an absolute requirement for any PI3K inhibitor targeting inflammatory disease with selectivity against the gamma isoform also potentially providing additional tolerability benefit.

With this information in mind, we established our medicinal chemistry program to discover selective PI3Kδ inhibitors.

8.15.1.2 Implementation of a Screening Cascade and Description of Key Assays

One of the most fundamental aspects of any medicinal chemistry program is the establishment of a robust screening cascade. The first objective is to establish the potency and efficacy of the molecules in a range of pharmacological models, from primary enzyme activity and selectivity, through cellular assays to confirm target engagement and functional effect, and ultimately into animal models of disease. Concurrently, a range of drug-like properties are assessed, to ensure that the molecules possess the desired physicochemical and ADMET properties. The screening cascade established for our program is presented in Fig. 3.

In a screening paradigm typical of many small molecule drug discovery projects, the screening cascade is arranged in a series of tiers whereby compounds progress from initial assessment of in vitro potency in *Tier 1* through progressively more complex and resource intensive assays designed to establish the PI3Kδ potency, efficacy, and specificity in cellular assays (*Tier 2*) and finally in vivo pharmacology (*Tier 4*). In parallel, the ADMET and PK characteristics of the compounds are also assessed to establish the suitability of the compounds both for preclinical testing and their likely predicted human PK profile (*Tiers 2 and 3*). Given the large number of small molecules synthesized in a typical small molecule drug discovery program (in our case ~3000), a key requirement of the cascade is to filter out compounds which do not meet preset criteria in the high-throughput assays to ensure that only compounds with the desired profile progress to the later assays.

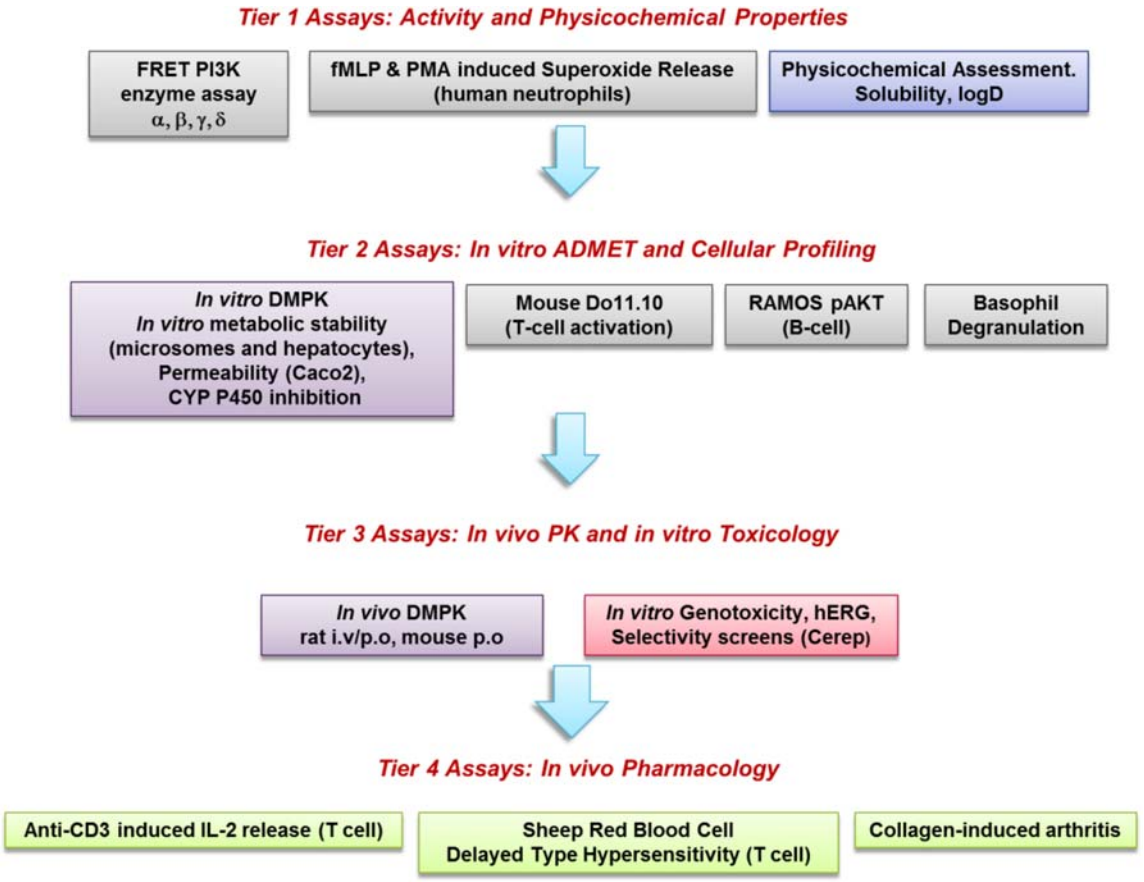

Fig. 3 The screening cascade established for our PI3Kδ program. In vitro potency assays are shown in *gray* boxes, physicochemical property assays shown in *blue* boxes, ADMET and PK assays shown in *purple* boxes, safety assays shown in *red* boxes, and in vivo pharmacology assays shown in *green* boxes.

These criteria are typically defined by a target product profile (TPP) which outlines the desired biological profile of a molecule. In our case, the critical aspects of the TTP were >500-fold-selectivity against the α, β, and γ isoforms, <100 nM cellular potency, efficacy in PI3Kδ driven pharmacology models, and a predicted human PK profile consistent with a once-daily oral dosing regimen. Clearly the critical assays for our program were therefore PI3K isoform enzymatic selectivity, potency in a functional PI3K specific cellular assay (fMLP-stimulated superoxide release), and finally proof of efficacy and potency in the in vivo disease model (murine CIA).

8.15.1.2.1 Description of in vitro potency assays

Initially newly synthesized molecules were assessed for activity and isoform selectivity in a enzymatic inhibition assay using a homogeneous time resolved fluorescence[26] PI3 kinase enzymatic assay (Millipore) with either p110 α, β, and δ (Millipore), or p110γ (produced in-house). Compounds with sufficient activity against PI3Kδ and isoform selectivity were then assessed for cellular activity in a range of secondary assays. Fig. 3 describes four critical cellular assays: the fMLP and PMA induced superoxide release assay in primary human neutrophils, the phospho-AKT assay in the RAMOS B-cell line, the D0.11.10 T-cell proliferation assay and the human whole blood basophil degranulation assay. Each assay and their function in the screening cascade are briefly described here.

8.15.1.2.1.1 The fMLP/PMA superoxide release assay in neutrophils

The fMLP-stimulated superoxide release neutrophil assay was established as the primary functional assay to demonstrate the cellular activity and selectivity of the compounds. Superoxide release by human neutrophils in response to fMLP stimulation has a time-dependent requirement for PI3Kδ signaling.[27] Critically the use of differential stimuli (fMLP vs. PMA) allowed the selectivity of the biological response to be established. Superoxide release via fMLP stimulation is regulated by the PI3K pathway, while in contrast PMA-stimulated superoxide release is regulated via PKC and is therefore not PI3K dependent. By establishing the selectivity of the cellular response through the PMA *counterscreen*, we could rapidly establish that the cellular activity generated was due to inhibition of the PI3K pathway and not potential off-target activities. Due to the ability to deploy the fMLP- and

PMA-stimulated cellular assay in a high-throughput plate format, we were able to establish this assay as our frontline cellular assay and screen >50 compounds a week.

8.15.1.2.1.2 The D0.11.10 proliferation assay

The key in vivo mechanistic and disease pharmacology studies were performed in murine models and consequently we needed to confirm functional activity against mouse PI3Kδ. To characterize the functional activity of our PI3Kδ inhibitors in a mouse system, and as TCR signaling is PI3Kδ-dependent,[13] a murine TCR-dependent cellular assay was established. T-cells from the D011.10 mouse express a transgenic TCR which recognizes a peptide from ovalbumin.[28] In response to OVA peptide stimulation, the T-cells from D011.10 mice are activated and subsequently proliferate. Selective inhibition of murine PI3Kδ can therefore be expected to inhibit the proliferation of these cells and formed the basis of the assay. The D011.10 proliferation assay served to confirm the activity of our compounds against mouse PI3Kδ ahead of screening in the pharmacology cascade.

8.15.1.2.1.3 The pAKT assay in RAMOS cells

While the high-throughput superoxide release assay provided confirmation of a PI3K-dependent functional effect in human cells, we also wished to establish a cellular readout of mechanistic target engagement. The development of a robust target engagement assay requires the identification of a downstream biological event that is (a) selectively driven by, and is proximal to, PI3Kδ and (b) can be effectively measured in a readily accessible and robust way. The phosphorylation of AKT following activation of the BCR is a selective event mediated by PI3Kδ[4] (Fig. 4).

Activation of the BCR in Ramos cells was achieved by cross-linking with anti-IgM. Cellular phosphorylated AKT ($pSer^{473}$) was detected using the Meso Scale Discovery pAKT assay protocol. Selective PI3Kδ inhibitors can therefore be expected to inhibit the production of pAKT and thus provide evidence of target engagement in cells.

8.15.1.2.1.4 The basophil degranulation assay

In addition to the high-throughput cellular assays established for screening of new molecules and the target engagement assay, the project also required a functional cellular assay which would provide a potential ex vivo biomarker for PI3Kδ inhibition in clinical studies. Such an assay would require the following properties: (a) a functional readout dependant on PI3Kδ inhibition, (b) an assay compatible with testing human whole blood, and (c) suitable sensitivity and robustness to enable use in a clinical setting.

Basophils are circulating granulocytes that play a key role in allergic hypersensitivity reactions. FcεRI-induced degranulation of basophils has been shown to be PI3Kδ-dependent and therefore provides a mechanistic readout for activity of PI3Kδ inhibition.[29] Upon degranulation, CD63 is expressed on the cell surface when granule membranes containing CD63 fuse with the plasma membrane and this marker was used to determine the activity of compounds in human whole blood by flow cytometry. Establishment of a robust basophil degranulation assay provided a measure of target engagement and PI3Kδ-mediated functional inhibition that was successfully deployed as a clinical biomarker in the Phase 1 clinical studies with *seletalisib*.

8.15.1.2.2 The in vivo pharmacology screening cascade

Compounds with suitable potency and selectivity in the in vitro assays and appropriate exposure in mouse following oral dosing were subsequently assessed in a range of in vivo pharmacology models briefly described here:

8.15.1.2.2.1 Anti-CD3-induced IL2 release model

The first pharmacology model assessed the inhibition of IL2 release following intravenous administration of anti-CD3 antibody to male Balb/c mice. The anti-CD3 antibody activates the TCR via cross-linking and IL-2, a key T-cell growth factor, is the first cytokine produced. PI3Kδ plays a pivotal role in the signaling cascade downstream of the TCR (Fig. 4) and thus PI3Kδ inhibitors can be

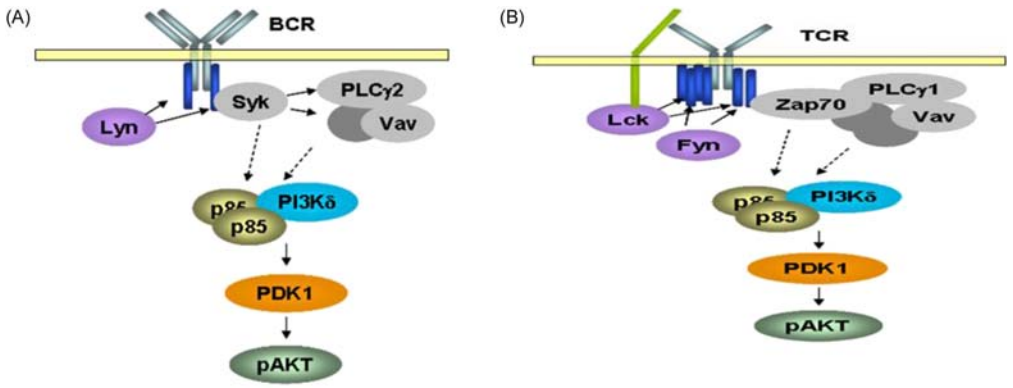

Fig. 4 PI3Kδ mediated signaling downstream of the (A) B-cell receptor and (B) T-cell receptor showing the location of PI3Kδ and AKT in the signaling cascade.

expected to inhibit this model. The anti-CD3-induced IL2 release model provides our first in vivo assessment of PI3Kδ inhibition on T-cells and requires only short-term (2 h) exposure in mouse.

8.15.1.2.2.2 Sheep red blood cell delayed type hypersensitivity model

The sheep red blood cell delayed type hypersensitivity (SRBC DTH) model is a classical Type IV hypersensitivity reaction. Male Balb/c mice are sensitized by intravenous administration of SRBCs and subsequently challenged with additional SRBC to the footpad 4 days later. This results in an antigen-specific footpad swelling that is dependent upon CD4+ T (compared to a group of mice which are nonsensitized but received the footpad challenge with SRBCs, thus providing a baseline level of nonantigen specific footpad swelling). PI3Kδ inhibitors are administered orally throughout the study duration with the first dose prior to sensitization. Data are shown as the change in footpad swelling compared to prechallenge levels and plotted as the mean.

8.15.1.2.2.3 Murine collagen-induced arthritis model

In order to establish the functional efficacy of our PI3Kδ inhibitors in a model of human inflammatory disease, we deployed the murine collagen-induced arthritis model (CIA).[30,31] Male DBA/1 mice are immunized by intradermal injection of type II Collagen (CII) in Complete Freund's adjuvant on day 0 and then in Incomplete Freund's adjuvant on day 14. Body weights and clinical scores are recorded daily using the following scoring system for each individual paw; 0 = normal, 1 = ankle/wrist swollen, 2 = ankle/wrist and pad swollen, and 3 = ankle/wrist and pad and digits swollen. The maximum score per paw is three with each mouse scoring a maximum of 12. Total scores per animal are used to calculate the group mean score per day and data is shown as mean ± SE. Compounds are administered orally and dosing is either initiated prior to immunization (prophylactically) or on the day of disease onset (therapeutically).

8.15.2 The Medicinal Chemistry Program

8.15.2.1 Initial Approaches to PI3Kδ Selective Inhibitors

Our initial approach to PI3Kδ selective inhibitors derived from an earlier internal program dedicated to the discovery of pan selective PI3K inhibitors for oncology indications[32] (Fig. 5). From a series of substituted thiazolylmorpholines, we noticed that 3-substituted thiophenes displayed emerging selectivity for the delta isoform, further development of this series led to the compound **UCB1412727** which displayed excellent PI3Kδ selectivity and importantly efficacy in the murine CIA model when dosed prophylactically. Unfortunately development of **UCB1412727** proved problematic due to its poor physicochemical properties and solubility. In preclinical toxicology **UCB1412727** demonstrated an unacceptable safety profile and further development was therefore halted.

Encouraged by the pharmacological proof of principal demonstrated by **UCB1412727** that selective PI3Kδ inhibitors could inhibit the mouse CIA model, but keen to identify a different chemotype devoid of the toxicity issues, we turned our attention to a structurally differentiated back-up series that we had been developing in parallel.

8.15.2.1.1 Looking for a new approach—Identification of a novel scaffold

During our development of **UCB1412727** several Class 1 PI3K inhibitors were reported with promising isoform selectivity profiles: PIK-39 (**1**) and IC87114[33,34] (**2**). The cocrystal structure of PIK-39 in PI3Kδ was reported[35] revealing the structural basis of selectivity for this novel molecular class (Fig. 6). The structure revealed that the compounds were able to selectively inhibit PI3Kδ due to the formation of a ligand induced allosteric "specificity pocket," not present in the apo-structure, caused by the movement of the Met^{752} and Trp^{760} residues. The 3*H* quinazolin-4-one core of **1** and **2** occupy this hydrophobic "specificity pocket" sandwiched between Trp^{760} and Ile^{777} on one side and Met^{752} and Pro^{758} on the other. In PI3Kδ these residues are inherently more flexible

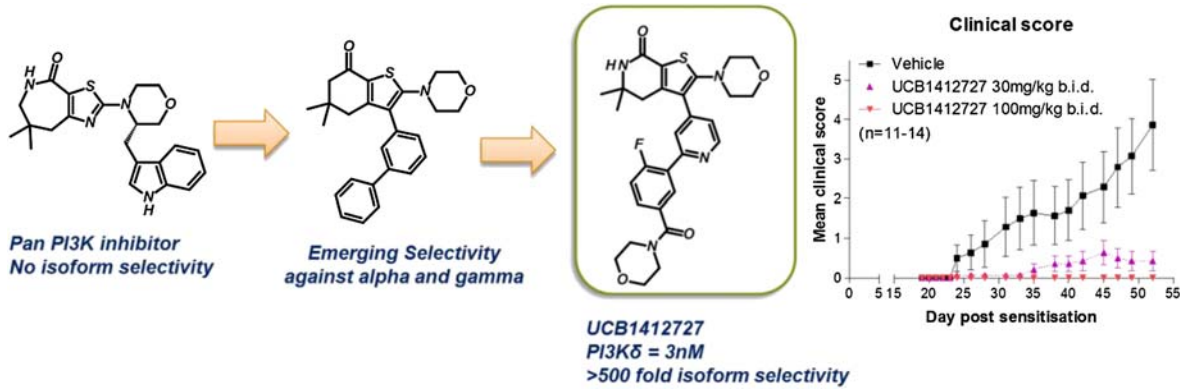

Fig. 5 The development of **UCB1412727** and efficacy in the murine cAIA model of arthritis.

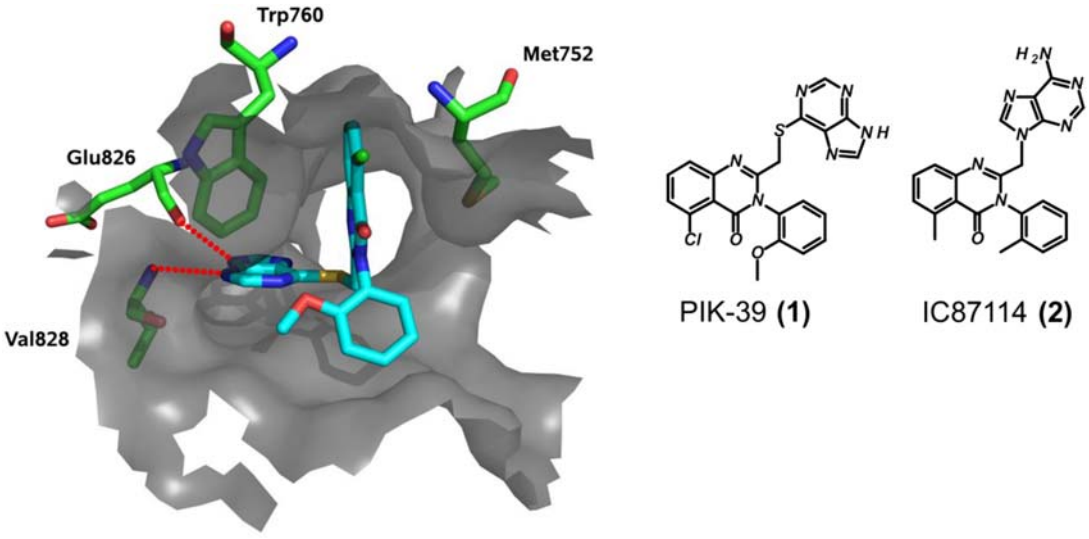

Fig. 6 Cocrystal structure of PIK-39 (**1**) in PI3Kδ (PDB code 2wxf). The *ligand induced selectivity pocket* is formed by the movement of Met752 and Trp760 residues to accommodate the 3*H*-quinazolin-4-one core. The purine hinge-binding group forms a bidentate hydrogen bond interaction (shown in *red*) to the backbone residues Val^{828} (NH) and Glu^{826} (C=O) in the hinge region of the kinase. The *ortho* methoxy group points toward the mouth of the pocket over a hydrophobic region.

than in the other isoforms and thus the formation of the selectivity pocket is tolerated and the key 3*H* quinazolin-4-one core accommodated. The *ligand induced selectivity pocket* present in PI3Kδ is thought to be the primary basis of the PI3Kδ isoform selectivity of this class of compounds. The other key-binding features were revealed to be a bidentate hydrogen bonding interaction between a hydrogen bond acceptor on the purine and the amide NH of the backbone Val^{828} and a complementary hydrogen bond donor (NH) of the purine to the carbonyl group of the Glu^{826} residue. These residues are located in the hinge region of the kinase and thus the motifs which interact with these residues are commonly known as *hinge-binding groups*. The *ortho*-substituted phenyl rings of **1** and **2** sit in a hydrophobic region pointing toward the mouth of the pocket and ultimately to solvent, thus providing a potential area of the molecule to introduce polar functionality and modify physicochemical properties.

With both PIK-39 and IC87114 reliant on a substituted 3*H* quinazolin-4-one core, we wished to develop novel series of inhibitors taking advantage of the induced Met^{752}/Trp^{760} selectivity pocket but based on alternative heterocyclic core structures. Initially we examined conservative structural variations and moved a nitrogen in the 3*H* quinazolin-4-one to give the regioisomeric pyrido [1,2-*a*]pyrimidin-4-one (**3**). We were surprised to find that (**3**) possessed no quantifiable activity against any PI3K isoform (**Table 1**). Clearly a simplistic attempt to mimic the core by synthesis of topologically close analogs was unlikely to prove successful and we realized that other properties, in particular the electronics of the ring systems, would need to be evaluated.

Concurrently we had developed a propriety virtual database containing a complete set of all feasible heterocyclic ring systems Virtual Exploratory Heterocyclic Library (VEHICLe).[3] A potential application of this database was scaffold-hopping by facilitating the in silico comparison of heterocyclic ring systems based on a range of calculated parameters, including electrostatic potential (ESP). We reasoned that this approach would be ideally suited to identifying potential replacements of the 3*H*-quinazolin-4-one core of (**1**). Analysis of the ESP of the core of **1** (Core A) compared to the inactive regioisomer **3** (Core B) allowed us to rationalize this loss of potency in terms of the comparably low electronegativity (electron richness) of the pyridyl ring in Core B (**Fig. 7**) compared to the benzo ring in Core A. This part of the ligand sits within the induced *selectivity pocket* and may indicate a preference for electron-rich aromatic rings in the pocket. After calculating the ESP of a large number of heterobicyclic systems in VEHICLe, the quinoxaline (Core C) was selected on the basis of its ESP similarity to 3*H*-quinazolin-4-one (Core A) and synthetic tractability.

We were delighted to observe that synthesis of the quinoxaline and then the quinolone derivatives provided potent PI3Kδ inhibitors with promising selectivity profiles (compounds **4** and **5**, **Table 1**). The inactivity of compound **3** compared to the quinoline matched pair **6** highlights the criticality of electrostatic analysis in successfully identifying novel scaffolds for this inhibitor class. Our use of VEHICLe allowed rapid identification of novel core scaffolds and the establishment of a series of selective PI3Kδ inhibitors. This technique can conceivably find productive application in any small molecule medicinal chemistry program.

8.15.2.2 Development of the Structure Activity Relationship

With novel quinoxaline and quinoline scaffolds in hand we embarked on a campaign to rapidly define the structure activity relationship (SAR). Guided by the crystal structure of PIK-39, we envisaged that potency would be determined by substitution of the core and the nature of the hinge-binding group. The aryl substituent in the C2-position meanwhile could serve as a handle to

modify the physicochemical properties of the molecule without impacting potency due to its orientation out of the enzyme pocket and toward solvent.

8.15.2.2.1 Early SAR development

8.15.2.2.1.1 Quinoline core substitutions and C2 aryl SAR

Following the identification of the quinoxaline and quinoline inhibitors **4** and **5** we focused our efforts on the quinoline **5** due to the synthetic tractability of the scaffold and initially established the SAR on the quinoline core (Table 2) and C2 aryl group (Table 3).

Notably a methyl scan of the quinoline core confirmed that substitution in the 6- and 7-positions eroded potency but substitution in the 8-position (**9**) modestly increased potency by approximately threefold. In the C2-position, substitution of the phenyl ring produced a detrimental effect on potency in the *meta* or *para* positions (**11** and **12**) but was tolerated in the *ortho* position (**10**).

Table 2 Quinoline core SAR: Substitution in the 8-position increases potency

18	–		0.3			

Both electron withdrawing (**13**) and electron donating groups (**14**) were accommodated in the *ortho* position. Importantly replacement of the phenyl ring by a range of 5- or 6-membered heterocycles was also possible; the 3-pyridyl group in particular would play a pivotal role in the eventual identification of *seletalisib*.

8.15.2.2.1.2 SAR of the linker between the quinoline and hinge-binding group

Our initial inhibitors were based on a thioether linkage between the quinoline core and the hinge-binding group. Benzylic thioethers are well-known metabolic liabilities due to the oxidation of the sulfur atom and the adjacent methylene group (Fig. 8). In our case, oxidation of the benzylic methylene led to a hydrolytically unstable thioacetal (**A**) and subsequent loss of the purine hinge-binding group, while oxidation of the sulfur to a sulfoxide or sulfone leaving group (**B**) resulted in the formation of an electrophilic center and a potentially reactive metabolite.[36]

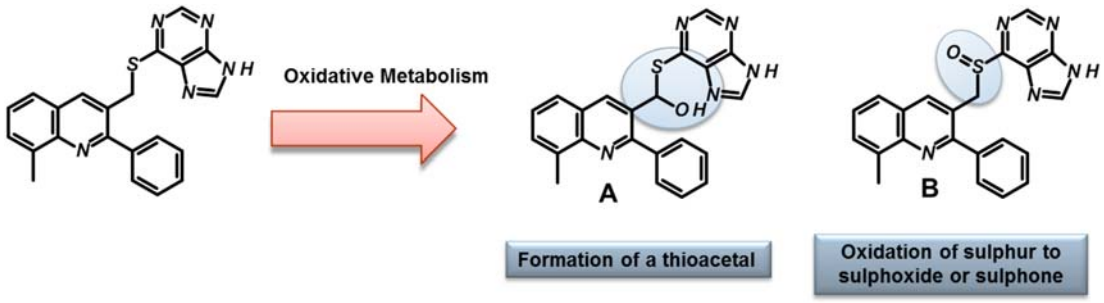

Fig. 8 Putative metabolic pathways and formation of potential reactive metabolites associated with the benzylic thioether.

Given the limitations of the thioether, we first investigated alternative linking atoms and also substitution on the methylene carbon (Fig. 9). Two key modifications produced exceptional increases in potency, namely the incorporation of a methyl group onto the benzylic methylene of **9** which resulted in a 10-fold increase in potency against PI3Kδ (compound **19**) and the replacement of the sulfur atom in **9** with an NH group providing an additional 20-fold increase in potency (compound **20**).

Critically combination of these two productive modifications led to compound **22** which delivered our first single digit nanomolar PI3Kδ inhibitor with an IC_{50} of 7 nM and a 53-fold increase in potency compared to the original thioether **9**. Promising isoform selectivity was observed against PI3Kα (~500-fold) and PI3Kβ (~200-fold), but optimization of the selectivity over PI3Kγ (20-fold) was clearly necessary.

The stereochemistry of the methyl group was critical with the *S* enantiomer demonstrating a eudismic ratio of ~40-fold over the *R* enantiomer (**23**). The preference for the *S* enantiomer was demonstrated in a number of matched pairs and is a consistent feature of the SAR. A tentative explanation for the stereochemical preference is suggested in Fig. 10. Docking of compounds **22** and **23** into the PI3Kδ crystal structure confirms that both molecules, as expected, make the crucial bidentate hydrogen bond interactions with the hinge residues with the 8-methyl quinoline occupying the induced selectivity pocket. The chiral methyl group occupies different environments depending on the stereochemistry. For the more active *S* enantiomer (**22**), the methyl group is directed toward the

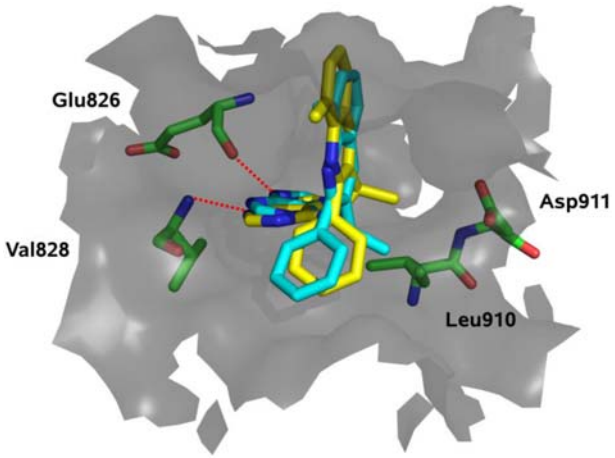

Fig. 10 Docking of compound **22** *S* enantiomer *(cyan)* and compound **23** *R* enantiomer *(yellow)* into the PI3Kδ crystal structure 2WXF (PIK-39). The docking pose indicates that **22** directs its methyl group toward Leu^{910} forming a more favorable hydrophobic contact while **23** potentially directs its methyl group toward Asp^{911} forming a less favorable hydrophobic/polar clash with the carboxylic acid side chain.

side chain of Leu^{910} making a favorable hydrophobic interaction. In contrast when the methyl group is in the *R* configuration, it is directed toward the side chain of Asp^{91}, a highly polar carboxylate residue potentially resulting in unfavorable interactions.

Crystal structures would be necessary to unequivocally prove the hypothesis, but SAR developed in the series consistently showed that lipophilic groups were preferred on the benzylic position with a strong preference for the *S* enantiomer, consistent with our hypothesis.

Replacement of the amine with an oxygen atom (**24**) while maintaining excellent potency against PI3Kδ ($IC_{50} = 11$ nM) possessed inferior selectivity against the gamma isoform (PI3Kγ $IC_{50} = 18$ nM). Crucially these O-linked compounds proved to be hydrolytically unstable which precluded their further utility. Methylation of the benzylic amine (compound **21**) was not tolerated resulting in a 100-fold reduction in activity compared to **20**.

8.15.2.2.1.3 SAR of the hinge-binding group

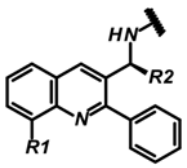
With a highly optimized and potent α methyl-benzylamine linker in hand, our attention next turned to the nature of the heterocyclic hinge-binding group. In our first generation of inhibitors, the purine motif provided a bidentate interaction with Val^{828} and Glu^{826}. Purines, however, are ubiquitous scaffolds in a wide variety of pharmacologically active compounds and we were wary of the potential off-target activities and associated toxicology that this structural motif could bring. We therefore assessed a number of alternative hinge-binding groups (>50 examples) with a selection of these described in **Table 4**.

The regioisomeric pyrazolo[1,5-*a*]pyrimidine where the NH hydrogen bond donor (HBD) is eliminated (**25**) established that the bidentate hydrogen bond was not necessary for activity. The critical requirement for effective binding was a hydrogen bond acceptor *para* to the linking nitrogen, (the HBA highlighted in red in **Table 4**). Compounds lacking this feature such as **32** had greatly diminished activity compared to the molecular matched pair (MMP) **31**. A wide range of heterocycles provided effective hinge-binding groups including 6,6, 6,5, and 5,6 bicyclic ring systems and also monocyclic groups with the triazine **33** proving the most efficient monocycle. Interestingly, incorporation of an exocyclic amino group into the purine compound **20** to provide **27** retained activity against PI3Kδ but also introduced significant activity against the PI3Kγ isoform ($IC_{50} = 65$ nM). Similar incorporation of the exocyclic amine into the pyrazolo[1,5-*a*]pyrimidine **25** did not result in a compound with dual δ/γ activity (compound **26**), suggesting that the gamma activity relied on the potential tridentate hydrogen bond donor/acceptor/donor motif in the 2-aminopurinyl hinge-binding group. Somewhat surprisingly the profile of **26** was consistent with dual PI3K δ/α inhibitors (PI3Kα $IC_{50} = 15$ nM).

The importance of the 2-amino exocyclic amine as a HBD for activity is supported by the observation that replacing the amine in **26** with a methyl to give **28** resulted in a significant reduction in potency across the Class IA isoforms especially PI3Kα although interestingly the potency of the Class 1B isoform PI3Kγ was not significantly affected. These observations highlight the dramatic effects on isoform selectivity that small structural changes of the hinge-binding group can induce. The SAR illustrates the potential of this molecular class to access alternative PI3K isoform selectivity profiles.

Although dual PI3Kδ/γ selective compounds were not the focus of our project, we were keen to determine if the initial observation that 2-aminopurinyl groups increase PI3Kγ activity (and concomitantly reduce δ/γ selectivity) was consistent across a range of molecules. To explore these phenomena we analyzed a set of MMPs. MMP analysis is a powerful method of interpreting and analyzing SAR[37,38] by comparing data between pairs of molecules that differ by a single and consistent structural change. We compared eight identical pairs of molecules (**Fig. 11**) where the pairs differed only in the nature of the 2-purinyl substituent ($R = H$ vs. $R = NH_2$).

Table 4 Development of the hinge-binding group



Compounds	*Hinge binder*	*R1*	*R2*	*PI3Kδ IC_{50}*	*PI3Kα IC_{50}*	*PI3Kβ IC_{50}*	*PI3Kγ IC_{50}*
25		CH_3	CH_3	3 nM	2452 nM	1510 nM	120 nM
26		CH_3	CH_3	11 nM	15 nM	805 nM	1240 nM
27		CH_3	H	9 nM	>10 μM	5600 nM	65 nM
28		CH_3	CH_3	200 nM	>10 μM	6200 nM	580 nM
29		CH_3	CH_3	0.2 nM	630 nM	350 nM	19 nM
30		Cl	CH_3	0.16 nM	330 nM	245 nM	5 nM
31		CH_3	H	500 nM	>30 μM	>10 μM	>10 μM
32		CH_3	H	>10 μM	>30 μM	>10 μM	>30 μM
33		CH_3	CH_3	16 nM	6170 nM	2344 nM	64 nM

Comparison of these matched pairs demonstrated that the 2-amino group consistently delivered compounds with improved PI3Kγ activity by 5- to 50-fold. Furthermore the analysis clearly demonstrated that the 2-amino compounds possessed reduced selectivity against gamma (compared to the delta activity).

For our program PI3Kγ activity was not desired, however the observation demonstrates how, through the SAR fieldwork demanded by medicinal chemistry, new selectivity opportunities can be developed and furthermore illustrates the power of MMP analysis in confirming empirical observations made initially with single compounds.

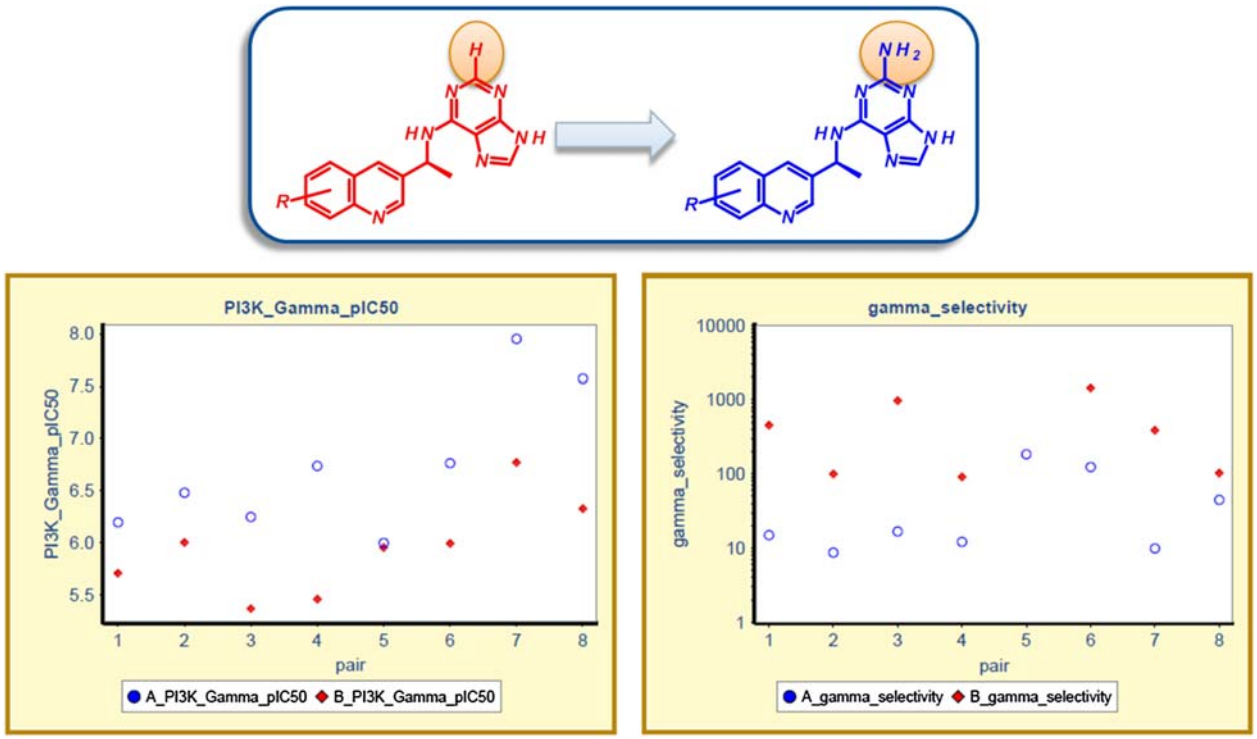


Fig. 11 Molecular matched pair analysis of 2-amino purine (in *blue*) versus purine (in *red*) containing PI3K inhibitors demonstrating consistent increased PI3Kγ activity and reduced selectivity against PI3Kδ.

8.15.2.3 *First Generation* PI3Kδ Inhibitors: Scope and Limitations

Our initial SAR drive allowed us to replace the metabolically compromised thioether with a highly potent and stable alpha methyl benzylamine. A wide range heterocycles were able to act as effective hydrogen bond acceptors for the crucial hinge-binding interaction replacing the initial purine group. Combining these SAR insights led to a number of highly potent PI3Kδ inhibitors with good selectivity against the alpha and beta isoforms, a representative selection of which are described in Table 5.

Exquisite potency against PI3Kδ could be achieved with primary enzyme potency <1 nM for compounds **30** and **29** translating into good activity in the primary cellular fMLP-stimulated superoxide release assay ($IC_{50}<20$ nM). Importantly the compounds were inactive in the PMA counter screen confirming that the cellular activity was driven solely through the PI3K pathway. While the selectivity against the Class 1A PI3K isoforms (α and β) was excellent, typically >1000-fold, selectivity against PI3Kγ was modest ranging from only 4- to 30-fold despite the significant changes to the hinge-binding group. We hypothesized that the poor selectivity against the Class 1B PI3Kγ isoform was linked to the presence of the C2 aryl group as it had been a common feature of the molecules synthesized at that time.

The physicochemical properties of the molecules were poor with high lipophilicity ($\log D$ generally >3) translating into poor aqueous solubility and high metabolic clearance as measured in both the human liver microsome and rat hepatocyte in vitro incubations. These characteristics unsurprisingly led to poor in vivo PK properties. Compound **22**, a representative example of the *First Generation* compounds, possessed high clearance equivalent to liver blood flow (i.v. $CL_b = 88$ mL min^{-1} kg^{-1}) and consequently poor bioavailability in rat consistent with high in vitro metabolic instability.

In particular, compound **29** characterized the challenge with these molecules. Despite exquisite enzyme and cellular potency, the high lipophilicity ($\log D$ 3.8) led to unacceptably high in vitro metabolic instability in both human and rat systems. Gratifyingly replacement of the pyrazolo[1,5-*a*]pyrimidine in **29** with the methyl amino1,3,5-triazine to give **33** led to the expected reduction in lipophilicity ($\log D$ 2.1), providing a significant increase in both in vitro metabolic stability (in human liver microsomes) and aqueous solubility. Unfortunately **33** lost ~10-fold in cellular potency compared to **29** and still possessed an unacceptably poor PI3Kγ selectivity profile. However it had been clearly demonstrated that reduction in global lipophilicity could provide the desired improvement in the in vitro metabolic stability and solubility. The challenge presented was to achieve this without compromising the nanomolar PI3Kδ activity and at the same time improving the selectivity profile against PI3Kγ.

While we had established a highly potent molecular platform for selective PI3Kδ inhibition, a number of significant challenges remained. Optimization of the drug-like properties[39] of the molecules was necessary to establish in vivo exposure and pharmacological activity. In addition, to achieve our ideal candidate profile, the selectivity against PI3Kγ required drastic improvement.

8.15.2.4 Driving Improvement of ADMET Parameters Through Physicochemical Modification

The insights gleaned from the X-ray structure suggested that the C2-position of the quinoline would be ideally placed as a handle to modify the physicochemical properties of the molecules due to its proximity to solvent and lack of obvious interactions with the protein. Furthermore, the highly lipophilic substituted phenyl moieties that had been utilized to date were obvious targets for replacement due to the poor PI3Kγ selectivity and physicochemical properties of the *First Generation Molecules* and therefore this is where our attention turned.

8.15.2.4.1 Replacement of the C2 phenyl with acyclic amines

If, as we supposed, the C2 group was not making any significant interactions with the protein, we envisaged that replacement of the phenyl ring with smaller and more polar groups should be accommodated. Initially we replaced the C2 phenyl moiety with a simple *N*-methyl amine (Table 6) and discovered that compound **35** maintained reasonable PI3Kδ potency of 43 nM representing only an approximately fivefold drop in potency from the analogous C2 phenyl-substituted compound. Furthermore compound **35** presented a unique selectivity profile compared to the *First Generation* C2 aryl compounds in that the selectivity over the Class 1B PI3Kγ isoform was greater (100-fold) than the selectivity against the Class 1A isoforms (α 80-fold and β 12-fold). Intrigued by this surprising selectivity profile, we synthesized a range of acyclic amine analogs a selection of which are presented in Table 6.

As expected a wide range of polar functionality was tolerated with alcohols (**37**), amides (**38–40**), ethers (**36**), and bases (**41** and **42**), all providing potent molecules. The differentiated selectivity profile suggested by **35** was maintained with typically the selectivity against PI3Kγ exceeding the selectivity against the alpha and beta isoforms. Up to 1000-fold-selectivity against gamma could be achieved for the imidazole substituted compound **41** with good (>300-fold) selectivity against alpha and beta. The initial SAR conducted on the purine hinge-binding group was transferable to the other potent hinge-binding groups previously identified illustrated by the exceptional potency of **42**.

Replacing the phenyl ring by polar acyclic amines led to a reduction in lipophilicity by at least 1 log unit. Gratifyingly this brought the expected benefits to the drug-like properties of these molecules with improved solubility (all compounds in Table 6 >350 μM in the kinetic aqueous solubility assay) and improved stability in in vitro microsomal incubations. Notably the potency against PI3Kδ matched or exceeded the C2 phenyl analogs with compound **41** <1 nM in the enzyme assay and 5 nM in the fMLP cell-based assay. The compounds were also inactive in the PMA counter screen, confirming that the exceptional cellular potency was driven through the PI3K pathway. The increasing potency in parallel with reduced lipophilicity resulted in markedly improved lipophilic ligand efficiency[40] with values for these molecules typically >5.

Improvement in in vitro drug-like properties is only valuable if that improvement translates to robust in vivo PK properties, and, in particular, oral exposure in appropriate preclinical species. We took compound **39** into in vivo rat PK studies, and the PK parameters are summarized in Table 7.

Disappointingly **39** suffered from high clearance, equivalent to liver blood flow and no oral bioavailability. The high in vivo clearance was not predicted from the in vitro hepatocyte data, indicating that **39** was a substrate for active transporter-mediated

clearance. The Caco-2 data revealed that **39** was indeed a strong efflux substrate (ER = 500). In order to determine the mechanisms of clearance more precisely, we conducted a rat bile duct cannulated (BDC) study with **39**. Anesthetized rats were dosed i.p. with compound and plasma, bile and urine sampled over 2 h. We discovered that 40% of the dose was excreted as parent in the bile, confirming that active transport of parent was the major clearance pathway in vivo. Typically high HBD count is strongly correlated with propensity for efflux and active transport.[41] We sought to reduce the HBD count by methylation of the C2 amine to give **40** (Table 6). This resulted in a potent compound with improved Caco-2 profile, however the methyl group proved to be a metabolic weakness and the in vitro metabolic instability precluded in vivo assessment.

High metabolic clearance driven by dealkylation continued to plague compounds such as **41**, where we had removed one HBD. Furthermore, the imidazole function despite providing exceptional potency proved to be a liability, displaying potent cytochrome P450 inhibition.

8.15.2.4.2 Replacement of the C2 phenyl with cyclic amines

Based on the emerging data, it was clear that tertiary amines at C2 provided a basis to balance the improved physicochemical properties, solubility, and metabolic stability of the secondary amines with reduced efflux potential by reducing the HBD count. Cyclic

tertiary amines were an obvious strategy to avoid the ubiquitous metabolic dealkylation pathways plaguing the acyclic analogs and it was here we next focused our attention. An illustrative selection of the SAR is described in Table 8.

The initial cyclic amine is exemplified by the morpholine **43** which displayed moderate potency against PI3Kδ (IC_{50} = 37 nM) but significantly eroded selectivity against the gamma isoform. Substitution at the 3-position (**44**) led to a reduction of potency. We next synthesized a number of 4-substituted piperidine and piperazine analogs in order to place polar substituents toward the solvent exposed "neck" of the binding pocket in accordance with the previously described structural data. Similar to the SAR described for the acyclic amines, a wide range of polar substituents encompassing both HBD and acceptor groups could be tolerated.

In particular, the *N*-acetyl piperazine **45** produced a significant potency boost and combined with the potent pyrido[3,2-*d*]pyrimidine hinge-binding group (**48**) provided unprecedented PI3Kδ potency of 60pM and good isoform selectivity (>500-fold). Pleasingly the exceptional potency in the enzymatic assay also translated into high potency in the fMLP cellular assay (2 nM). The key carbonyl functionality could also be extended further out into the pocket as exemplified by the dimethyl amide **47** which provided a potent molecule but suffered from high metabolic clearance due to dealkylation of the piperazine and the terminal amide group. Interestingly the carboxylic acid **46** maintained enzymatic potency (PI3Kδ IC_{50} 65 nM), however in contrast to the neutral compounds the acid lacked cellular activity probably due to poor cellular permeability of the carboxylic acid. The isoform selectivity of **46** showed an unexpected profile with significant PI3Kβ activity. Importantly this was not due to a broad loss of isoform selectivity, the molecule retained good selectivity against the alpha and gamma isoforms but a specific increase in PI3Kβ potency. A similar profile was apparent in compound **49** with a hydroxylethyl piperazine C2 substituent. We hypothesized empirically that the increased beta activity was due to the presence of a HBD in the C2-position. While activity against the beta isoform was intolerable for our program, we were alert to the potential opportunities in oncology for differentially *dual* selective PI3K inhibitors such as these. These empirical observations similar to the dual δ/γ selectivity described for the aminopurines earlier again highlight the additional selectivity opportunities provided by an extensive interrogation of the SAR.

We realized that although the *N*-acetyl piperazine substituted quinolines such as **48** provided exceptional potency, the rapid metabolism by deacetylation prevented their further development. Wishing to explore the topological requirements of the carbonyl hydrogen bond acceptor and to incorporate it into the molecule in a metabolically robust fashion, we synthesized the piperazinone analogs **50** and **53**. We were delighted to find that the piperazinones retained the exceptional potency displayed by the *N*-acetyl piperazines but with reduced lipophilicity and improved metabolic stability. Synthesis of the *N*-methyl analog **51** resulted in an ~10-fold reduction of potency demonstrating the importance of the amide NH and suggesting additional interactions with the protein. Ring expansion to the homopiperazinone **52** also led to a reduction of potency.

Our successful campaign to replace the metabolically vulnerable phenyl ring with amines resulted in compounds where the exceptional enzymatic and cellular potency achieved in the *First Generation* inhibitors was maintained but importantly, the global reduction in lipophilicity drove a significant improvement in solubility and metabolic stability.

Serendipitously we found that the C2 amino compounds also improved the selectivity over PI3Kγ and we were able to maintain this selectivity as we developed the SAR. Cyclic tertiary amines allowed us to address issues with active transport and poor permeability and we identified that a strategically positioned amide function within the piperazinone ring could combine the desired potency with metabolic stability as exemplified by compounds **50** and **53**. Having alighted on the piperazinone as an optimal

C2 substituent in combination with the triazinyl or pyrido[3,2-*d*]pyrimidine hinge binder, our attention next turned to establishing the in vivo exposure and subsequent pharmacological activity of these molecules.

8.15.2.5 Development and Pharmacological Characterization of Triazinyl-Piperazinones

8.15.2.5.1 Potency and ADMET characterization of triazinyl-piperazinones

We combined the piperazinone with triazinyl and pyrido[3,2-*d*]pyrimidine hinge-binding groups to provide a panel of compounds which were subjected to a broader panel of in vitro potency (Table 9) and ADEMT assays (Table 10) in order to identify compounds suitable for in vivo assessment.

The pyrimidopyridine compound **53** exhibited the most potent activity in cell assays but was compromised by the high in vitro metabolic clearance in rat hepatocytes and human microsomes, while also exhibiting potent CYP inhibition activity especially against the 2C9 isoform. Pleasingly, replacement of the pyrimidopyrimidine with triazinyl hinge-binding groups (compounds **50** and **54–56**) provided compounds with good stability in human hepatocytes and an improved CYP inhibition profile. In terms of potency, the 8-Cl substituted compounds **50** and **54** maintained better cellular potency in the fMLP and D0.11.10 assays than the 8-CH_3 substituted quinolines. In particular **54** exhibited excellent potency in the target engagement pAKT RAMOS assay (IC_{50} 8 nM). The presence of the 5-methyl triazine in **50** reduced selectivity against the PI3Kβ isoform 10-fold compared to the 5H triazine **54** although improved the CYP inhibition profile especially against the 2C9 isoform (13 μM vs. 0.7 μM). The thermodynamic aqueous solubility at neutral pH of these compounds was promising and compound **54** showed good permeability and low efflux in the Caco-2 assay. Based on these encouraging in vitro data, we assessed these compounds in rat PK studies with the data presented in Table 11.

The compounds displayed low to moderate in vivo clearance and good oral bioavailability. In contrast to earlier compounds such as **39**, the in vivo clearance values were well predicted from the in vitro clearance data, indicating that the nonmetabolic active transport mediated clearance which prevented the progression of earlier compounds had been overcome.

8.15.2.5.2 Metabolite ID studies with compound 54

With compound **54** displaying an encouraging profile, we sought to identify the major metabolites from in vitro hepatocyte and microsomal incubations and the in vivo PK studies. A summary of the main metabolic pathways identified are summarized in Fig. 12, with the metabolites identified from human hepatocyte incubations described in Table 12.

In human hepatocytes the major metabolite identified was oxidation of the triazine hinge-binding group. Lower levels of piperazinone metabolism were seen, either hydrolysis or low levels of direct glucuronidation thought to occur on the secondary amide.

In human in vitro systems no metabolism of the quinoline core was observed, however in rodent systems, both in vitro and in vivo, metabolism of the quinoline core is observed albeit with the triazine and piperazinone metabolic pathways still predominating.

8.15.2.5.3 Pharmacological assessment of compound 54

To support pharmacological evaluation of **54**, we conducted an oral PK study in Balb–c mice at 10 mg kg^{-1} (Fig. 13). Excellent exposure was achieved with a C_{max} of 11.2 μM and AUC_{last} of 41.2 μM h. The free concentration (total concentration corrected for plasma protein binding) of **54** at 1 and 7 h was 170 and 33 nM, respectively. These free concentrations exceeded the cellular IC_{50} activities in the fMLP and D0.11.10 assays at 1 h and both the enzymatic PI3Kδ and RAMOS pAKT activity over the measured 7 h period demonstrating that **54** was suitable for assessment of the dose and exposure relationship in in vivo models.

Overall **54** exhibited an excellent in vitro and in vivo profile and the best balance of properties in the triazinyl-piperazinone class. The in vivo efficacy of this molecule was assessed in a range of immune mechanistic models.

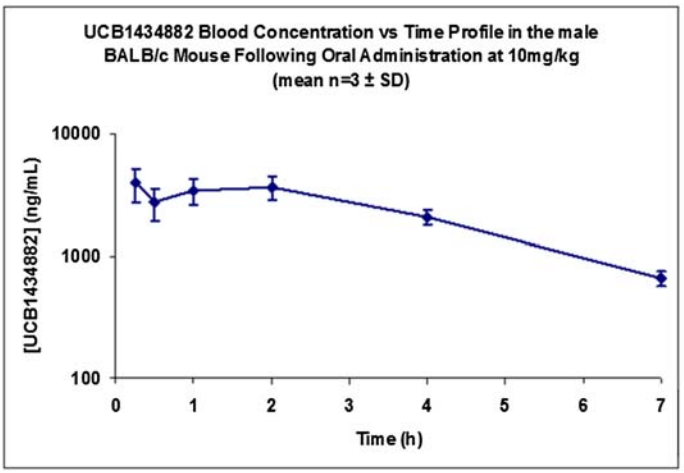
*8.15.2.5.3.1 Assessment of **54** in the anti-CD3 IL-2 release assay*

In order to demonstrate mechanistic inhibition of PI3Kδ in vivo, we first determined the activity of **54** in a short-term model, the inhibition of IL-2 release following anti-CD3 antibody administration in Balb/c mice (Fig. 14). Pretreatment with **54** (0.1–30 mg kg^{-1} p.o.) 30 min before anti-CD3 antibody administration produced a dose-dependent inhibition of IL-2 levels (Fig. 11). The relationship between the total compound concentration in blood and effect (% inhibition of IL-2 release) was analyzed using an I_{MAX} model. The relationship was described by an IC_{50} value of 201 nM (95% CL of 152–266 nM) and an I_{MAX} value of 92 ± 3%. Taking into account the protein binding of the compound, this equates to an unbound IC_{50} value of 4 nM which was in good agreement with both the PI3Kδ enzymatic activity (IC_{50} 7 nM) and the inhibition of pAKT in RAMOS cells (IC_{50} 8 nM), providing confidence that the observed pharmacological effect was driven by PI3Kδ inhibition.

While the activity in the mechanistic anti-CD3 IL-2 release assay provided evidence of target engagement in vivo, we wished to demonstrate a functional effect in a more complex model. To this end we took **54** into the SRBC DTH model.

*8.15.2.5.3.2 Assessment of compound **54** in the SRBC DTH model*

Sensitization and challenge with SRBC resulted in an antigen-specific footpad swelling. **54** was administered orally once daily from prior to sensitization at 3, 10, and 30 mg kg^{-1}. All dose levels significantly inhibited footpad swelling such that the magnitude of residual footpad swelling was comparable to the negative control group (Fig. 15). The total compound concentration in blood was determined 1 h postdose on the final day of dosing, for the 3 mg kg^{-1} dose a free concentration of 32 ± 8 nM was obtained which correlated with the enzyme potency activity of **54**.



Parameter	
C_{max}	11.2μM
AUC_{last}	41.2 μM.hr
Free conc @ 1 hour	170nM
Free conc @ 7 hours	33nM

Fig. 13 PK profile of compound **54** in Balb–c mice at 10 mg kg^{-1} following oral administration.

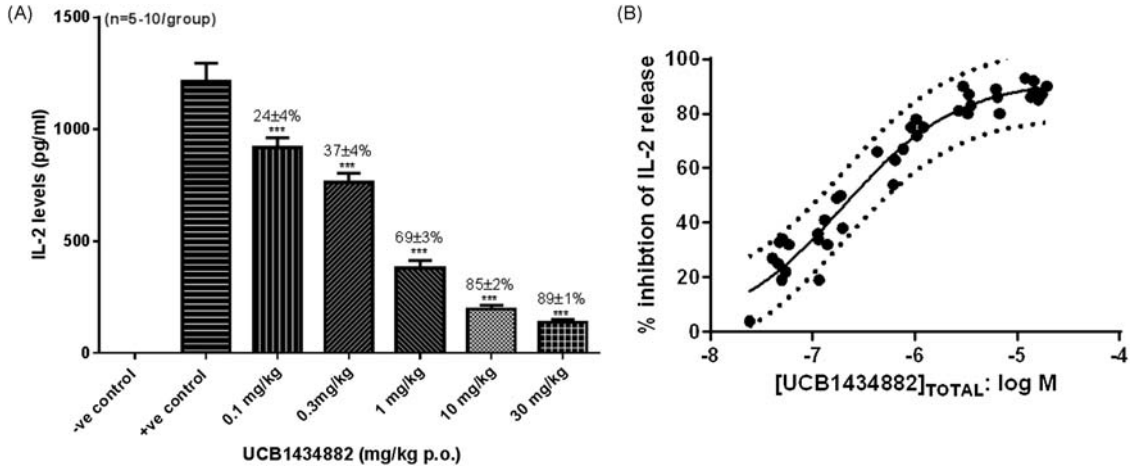


Fig. 14 Inhibition of anti-CD3 antibody-induced IL-2 release in vivo. Vehicle and **54** in 1% methylcellulose (400 cps) was administered 30 min prior to anti-CD3 antibody (0.01 mg kg^{-1} i.v.), which activated T-cells. Mice were sacrificed 90 min later. Dose (A) and concentration (B) response relationships are shown. Statistical significance is denoted as follows, $***p < 0.001$ compared to positive control group (Dunnets multiple comparison test).

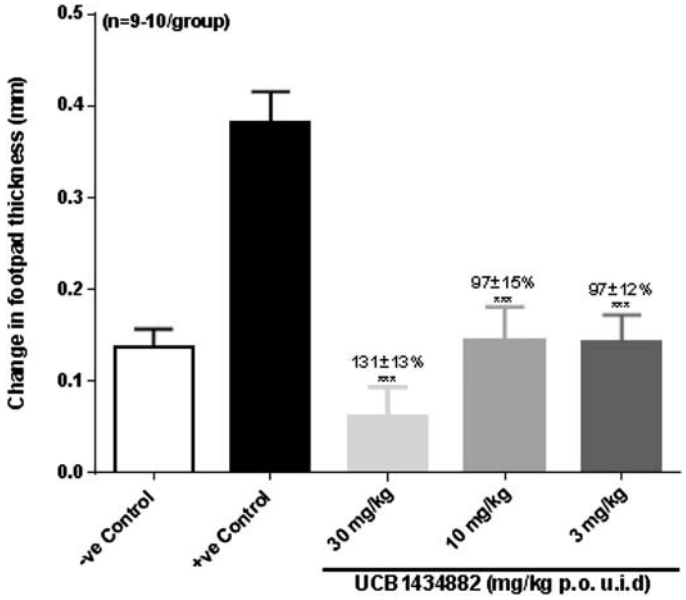

Fig. 15 Inhibition of the SRBC DTH model in vivo. Vehicle and compound **54** in 1% methylcellulose (400 cps) was administered orally once daily throughout the study. Animals were sensitized (i.v.) and challenged (i.pl.) with SRBC to elicit an antigen-specific footpad swelling. Mice were sacrificed 60 min after the last compound dose and 24 h post footpad challenge. Dose-dependent inhibition of footpad swelling was obtained. Statistical significance is denoted as follows, $***p < 0.001$ compared to positive control group (Dunnets multiple comparison test).

The efficacy and potency of compound **54** in both the anti-CD3 and SRBC DTH assays provided validation of our in vivo cascade and importantly, validation of the quinoline chemotype in PI3Kδ driven models. Furthermore, the good correlation of the in vivo activity with the in vitro PI3Kδ potency provided additional confidence that the effects observed were driven by on target activity.

8.15.2.5.4 Off-target and ancillary profiling of compound 54

Following the promising pharmacological activity demonstrated by **54**, we next profiled the compound in a range of in vitro toxicology screens in order to evaluate suitability for further preclinical development. The screening included initial in vitro genotoxicity assessment, activity against the hERG channel, and an off-target screen against a variety of biological targets (performed at Cerep and Invitrogen). The significant off-target activities are shown in Table 13.

Compound **54** proved remarkably clean in a panel of approximately 200 kinases, enzyme, and receptor targets, the only significant activities ($IC_{50} < 10$ μM) were observed against Aurora A (0.48 μM) and FGR kinase (2.1 μM). To assess the potential cardiovascular safety, we screened compound **54** against the hERG ion channel as activity against this ion channel is commonly associated

Table 13 Selected ancillary profile of compound **54**

Invitrogen kinase selectivity		*In vitro genotoxicity*		*In vitro cardiac toxicity*
Aurora A IC_{50}	FGR IC_{50}	AMES test	HGS	hERG IC_{50}
0.48 μM	2.1 μM	−ve	+ve	17.5 μM

with the risk of QTc prolongation in the clinic.[42,43] Gratifyingly, we saw only modest activity against the hERG channel. The critical issue with compound **54** was the positive activity in the genotoxicity assays, in particular the Human Greenscreen (HGS), an assay measuring induction of the DNA repair enzymes.[44,45] Close analogs of compound **54** also induced micronucleus formation in in vitro assays.[46] The potential for genotoxicity highlighted by these in vitro screens coupled with the micromolar inhibition of the cytochrome P450 enzymes described previously led us to conclude that compound **54** was not suitable for further development. Furthermore, the genotoxicity issues seen with **54** turned out to be a class wide liability with the triazinyl-piperazinones and therefore a fundamental redesign of our leading chemical matter was necessary.

In the following section, the genotoxicty screening process we used at the time of the program and the extent of the issue we faced will be outlined before describing how we reengineered the lead series to overcome the genotoxicity issues, leading ultimately, to the identification of *seletalisib*.

8.15.2.6 In Vitro Genotoxicity Screening

The genotoxicity screening cascade, we used consisted of firstly, the HGS assay[44,45] to assess the potential for DNA damage, followed by confirmation in an in vitro micronucleus test[46] measuring the formation of micronuclei in Chinese hamster ovary cells. In parallel, an AMES mpf[47] test for mutagenesis potential was also conducted.

We quickly identified that compound **54** and other representative leading triazine molecules were positive in the HGS assay. Crucially we found that molecules positive in the HGS assay were also positive in the in vitro micronucleus assay, confirming that the propensity for DNA damage translated into undesired functional effect (formation of micronuclei in vitro). Broadly the compounds tended to be inactive in the AMES mutagenicity tests. A representative selection of the SAR observed in the HGS assay is provided in **Table 14**.

Crucially we observed positives in the HGS assay both in the presence and absence of the rat microsomal fraction S9, indicating that we were dealing with two potential genotoxic mechanisms; intrinsic ability to interact with and damage DNA (−S9) and also via the production of genotoxic metabolites (+S9) possibly involving reactive intermediates. With these mechanisms in mind, analysis of the emerging SAR led to some key empirical observations. Firstly we observed that the amino triazinyl (compounds **58**, **61**, and **62**) and amino purinyl (data not shown) hinge-binding groups tended to have a high hit rate in the HGS in the absence of S9, indicating a propensity for intrinsic genotoxicity. Additionally a similar profile, suggesting an increased potential for intrinsic genotoxicity, was apparent for piperazinones and *N*-acyl piperazines C2 substituents (compounds **53**, **58**, **48**, and **60**). Although certain combinations with the C2 piperazinone could provide a clean in vitro profile such as **63**, this particular molecule suffered from high metabolic clearance and it was clear that the potentially genotoxic functionality (piperazinone and triazine) limited the scope of the SAR to address other drug-like properties.

For compounds that were HGS positive in the presence of S9 (+S9), it appeared that electron-rich quinolines had a greater propensity for genotoxicity as illustrated by the positives for compounds with the 8-CH_3 substituents (**57** and **58**) compared to the 8-Cl substituted quinolines where no HGS hits in the presence of S9 were observed. We had shown through metabolite ID studies (see section "**General metabolic profile of the quinoline C2 pyridyl *N*-oxides**") that the quinoline ring could be oxidatively activated to an aryl epoxide (a well-known metabolic pathway for quinolines[48,49]) and furthermore we had demonstrated glutathione conjugation through the quinoline epoxidation pathway from the in vitro metabolic studies. The potential for this reactive metabolite pathway to lead to DNA damage, or other adverse drug reactions was evident. Clearly addressing this problematic metabolic pathway in future molecules would be desirable.

The broad conclusions from the genotoxicity screening are summarized in **Fig. 16**.

These empirical observations led us to conclude that in order to address the genotoxicity issues with confidence, we would need to accomplish three key goals:

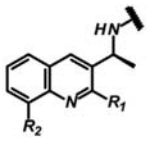
(1) Replace the triazinyl hinge-binding group
(2) Design a replacement for the C2 piperazinone which maintained the advantageous potency and physicochemical properties but was devoid of genotoxic liabilities
(3) Focus on electron deficient quinolines to reduce or eliminate the potential for metabolism via the epoxidation pathway

8.15.2.7 *Second Generation Inhibitors*: Development of the 3-Pyridyl *N*-Oxides

8.15.2.7.1 Identification of 3-pyridyl N*-oxide as an effective bioisostere of a carbonyl group*

Armed with these new objectives, we initially turned our attention to replacement of the C2 piperazinone group, as we had already established a large number of potent hinge-binding group alternatives to the aminotriazine (see **Table 4**).

Table 14 Representative genotoxicity data generated on lead molecules in the HGS and AMES mpf assays



Compounds	Hinge binder	R1	R2	PI3Kδ IC_{50} (nM)	Human Greenscreen +S9	Human Greenscreen −S9	AMES mpf assay
57			8-CH_3	0.7			
53			8-Cl	<1

61			8-Cl	10			
62			8-Cl	32			
63			8-Cl	0.3			

Red indicates a positive result in the assay (genotoxicity flag) while *green* represents a negative result (no genotoxicity flag).

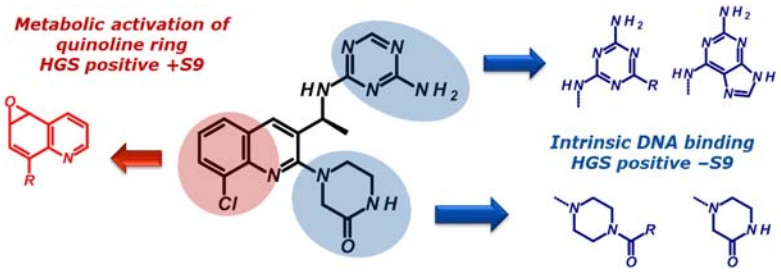

Fig. 16 Summary of the two genotoxic mechanisms identified. (i) Metabolic activation of the quinoline ring and (ii) intrinsic ability to induce DNA damage.

Having established that the presence of a hydrogen bond acceptor in C2 was critical to high potency, we reasoned that a 3-pyridyl or pyridone could prove potent alternatives to the piperzinone carbonyl (Table 15).

The 3-pyridyl group (**66**) proved to be a potent replacement but suffered from high metabolic clearance and unacceptable inhibition of cytochrome P450 enzymes. We reasoned that the 3-pyridone could overcome these limitations and were delighted to find that **64** provided a potent compound without the CYP inhibition liabilities. However **64** suffered from unacceptably high metabolic clearance in human hepatocyte incubations. We reasoned that the high metabolic clearance in human hepatocytes was primarily driven by glucuronidation of the pyridone functionality based on metabolite identification studies on close analogs. Attempts to eliminate the potential for glucuronidation by methylation to give **65** unfortunately eroded PI3Kδ potency 100-fold. Encouraged by the potency of **64**, we further reasoned that replacement of the pyridone with a 3-pyridyl-*N*-oxide would maintain the desired hydrogen bond acceptor functionality but remove the potential for glucuronidation and improve metabolic stability.

We were pleased to find that, as expected, the pyridine *N*-oxide **67** resulted in a potent compound with promising selectivity against the alpha and beta isoforms. Importantly the CYP liabilities associated with the analogous pyridyl compound were eliminated and metabolic stability in hepatocyte incubations improved. Most importantly compound **67**, in contrast to the triazinyl-piperazinones, was clean in the in vitro HGS assay. Further genotoxicity screening in the in vitro micronucleus and AMES testing confirmed that compound **67** was not genotoxic. Combination of the 3-pyridyl-*N*-oxide with the aminotriazinyl hinge-binding group to give **68** provided a compound free of the genotoxicity flags associated with previous triazine analogs but the reduced PI3Kδ and cellular activity discouraged further investigation.

Interestingly moving the position of the *N*-oxide from the 3- to the 4-position to provide compound **69** resulted in a dramatic and substantial loss of potency and selectivity especially against the PI3Kα isoform. It is unclear from the known binding mode of these compounds why such a modest change would induce a profound loss of selectivity. The pyridyl *N*-oxide sits toward solvent and a small change in the regiosiomer should leave the key interaction with the induced selectivity pocket intact. One potential explanation is that the molecules undergo a fundamental change in binding mode such that the classic "selectivity pocket" formed by the movement of Met^{752} and Trp^{760} is not induced. Unfortunately crystallographic data to substantiate this tentative hypothesis was unobtainable, however the example serves to illustrate once again how seemingly small structural changes in molecules can change selectivity profiles in unexpected ways and open up potential for other therapeutic opportunities.

The discovery of the 3-pyridyl-*N*-oxide group as an effective replacement of the piperazinone was a vital strategic breakthrough in the medicinal chemistry program. The *N*-oxide provided a solution to the genotoxicity flags associated with the piperazinone and in combination with the pyrido[3,2-*d*]pyrimidine hinge-binding group provided highly potent inhibitors exemplified by compound **67**. Furthermore incorporation of the polar pyridine *N*-oxide provided compounds with good solubility, metabolic stability in human and rat hepatocyte incubations and that were devoid of cytochrome P450 inhibition.

8.15.2.7.2 Characterization of compound 67

8.15.2.7.2.1 Comparison of UCB1434882 and UCB1442243

As compound **67** solved the genotoxicity issues associated with our previous lead molecule **54**, we next fully characterized **67**, Table 16 describes the comparative data between **67** and our previous lead triazinyl-piperazinone **54**.

The comparative data presented in Table 16 highlights how the key structural changes, namely the replacement of the C2 piperazinone with the 3-pyridyl-*N*-oxide and replacement of the triazinyl hinge-binding group with the pyrido[3,2-*d*]pyrimidine, resolved the ancillary issues that prevented the development of the triazinyl-piperazinones. Notably compound **67** was devoid of the genotoxicity, kinase activity, and cytochrome P450 inhibition that blighted **54**. Excellent enzymatic and cellular potency was maintained, although typically for C2 aryl groups we observed suboptimal selectivity against the PI3Kγ and β isoforms.

Comparing the ADMET properties of these molecules, the in vitro metabolic stability in human hepatocytes was encouraging and greatly improved from the earlier highly lipophilic C2 phenyl analogs. Compound **67** displayed a reasonable oral rat PK profile; despite a relatively high in vivo clearance (equivalent to approximately 2/3 of liver blood flow) oral bioavailability of 29% was achieved due to the excellent permeability and aqueous solubility (426 μM @ pH 7.4) of compound **67**. Although the rat PK of **67** was suitable for preclinical development and would support achieving the exposures required for the rat toxicology program,

we felt that there was room to further improve the in vivo PK profile of **67** in addition to the improvement necessary in the selectivity against PI3Kγ and β isoforms.

8.15.2.7.2.2 X-ray structure of UCB1442243 in PI3Kγ

We obtained a cocrystal structure of compound **67** with PI3Kγ (Fig. 17) which confirmed that the compound adopted the classical binding mode with the pyrido[3,2-*d*]pyrimidine hinge-binding group making a key hydrogen bond with the NH of Val^{882} and the 8-Cl quinoline positioned in the induced selectivity pocket.

*8.15.2.7.2.3 In vivo efficacy assessment of compound **67***

We assessed the pharmacological activity of **67** in a similar manner to triazinyl-piperazinone **54**. The data from the anti-CD3-induced IL2 release assay is presented in Fig. 18 and the SRBC DTH model in Fig. 19.

8.15.2.7.2.3.1 Anti-CD3-induced IL2 release model

Pretreatment with **67** (0.3–30 mg kg^{-1} p.o.) produced a dose-dependent inhibition of IL-2 levels (Fig. 18). As previously mentioned, the relationship between the total compound concentration in blood and effect was analyzed using an I_{MAX} model.

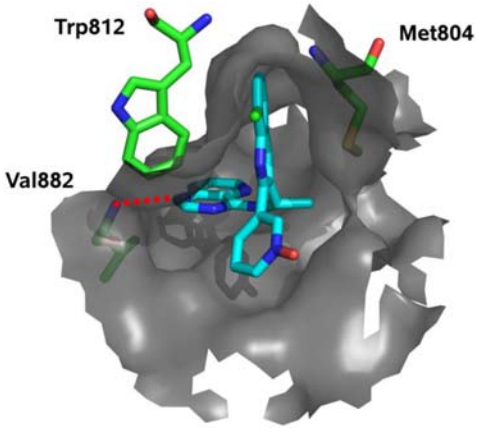

Fig. 17 Cocrystal structure of compound **67** with PI3Kγ. The pyrido[3,2-*d*]pyrimidine hinge-binding group forms a monodentate hydrogen bond with Val^{882} backbone NH (shown in *red*) while the 8-Cl quinoline core sits in the *induced selectivity pocket* formed by movement of Met^{804} and Trp^{812}. The 3-pyridyl-*N*-oxide is orientated toward solvent and makes no obvious interactions with the protein.

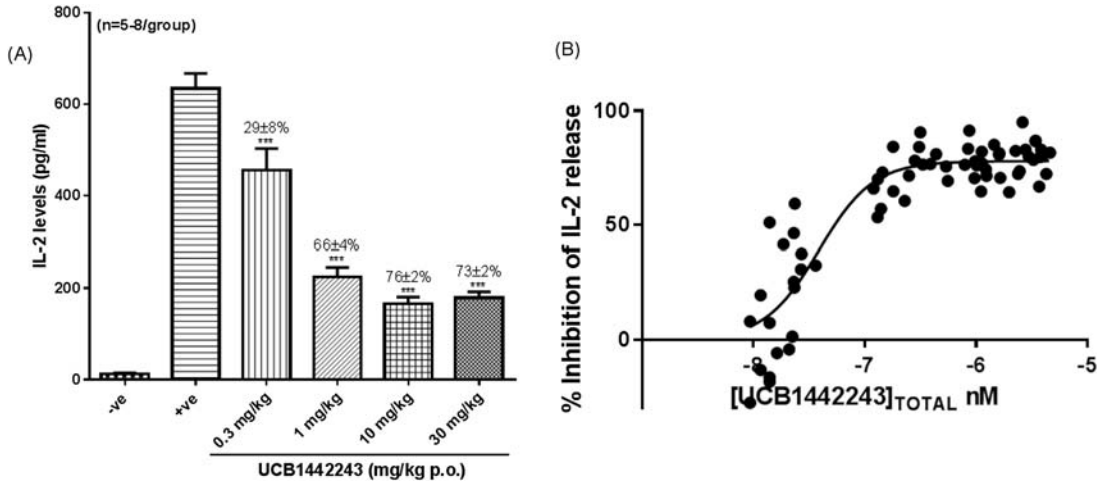

Fig. 18 Inhibition of anti-CD3-induced IL-2 release in vivo. Vehicle and compound **67** in 1% methylcellulose (400 cps) was administered 30 min prior to anti-CD3 (0.01 mg kg^{-1} i.v.), mice were sacrificed 90 min later. Dose (A) and concentration (B) response relationships are shown. Statistical significance is denoted as follows, $***p < 0.001$ compared to positive control group (Dunnets multiple comparison test).

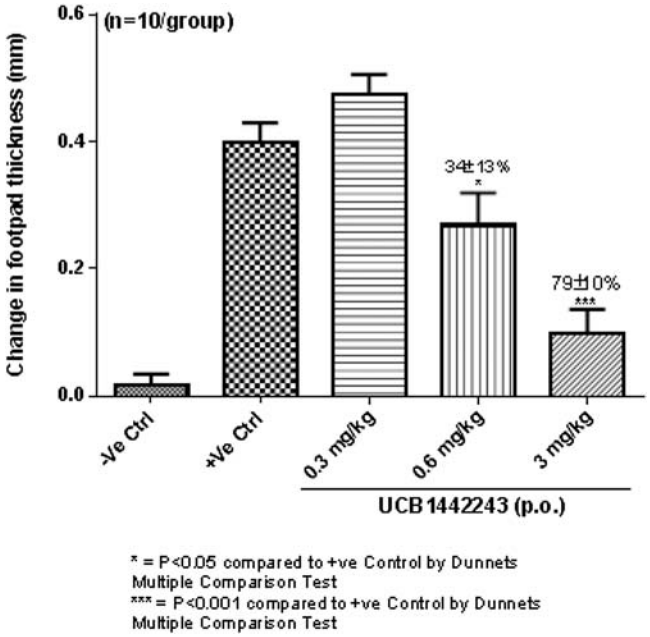

Fig. 19 Inhibition of the SRBC DTH model in vivo. Vehicle and compound **67** in 1% methylcellulose (400 cps) was administered orally once daily throughout the study. Animals were sensitized (i.v.) and challenged (i.pl.) with SRBC to elicit an antigen-specific footpad swelling. Mice were sacrificed 60 min after the last compound dose and 24 h post footpad challenge. Dose-dependent inhibition of footpad swelling was obtained. Statistical significance is denoted as follows, $*p < 0.05$ and $***p < 0.001$ compared to the positive control group (Dunnets multiple comparison test).

The relationship was described by an IC_{50} value of 39 nM (95% CL of 27–55 nM). Taking into account the plasma protein binding of the compound, this equated to an unbound IC_{50} value of 10 nM which was consistent with the in vitro enzyme potency of **67**.

8.15.2.7.2.3.2 Sheep red blood cell delayed type hypersensitivity

Sensitization and challenge with SRBC resulted in an antigen-specific footpad swelling. Compound **67** was administered orally once daily from prior to sensitization over the dose range 0.3–3 mg kg^{-1}. Dose-dependent inhibition of footpad swelling was obtained at 0.6 and 3 mg kg^{-1} (Fig. 19).

Overall compound **67** demonstrated a very similar pharmacological profile to the lead triazinyl-piperazinone **54**, confirming that the reengineering of the lead molecules to avoid the genotoxicity issues had not compromised the in vivo potency and efficacy of our initial series of compounds.

8.15.2.7.3 General metabolic profile of the quinoline C2 pyridyl N-oxides

While the C2 pyridyl *N*-oxide class of quinolines exemplified by **67** had resolved a number of issues with the triazinyl-piperazinone class of inhibitors, we wished to optimize the PK profile of these compounds by further reducing metabolism. In order to construct rational medicinal chemistry strategies, a detailed knowledge of the metabolic pathways across species coupled with identification of the metabolic weak spots was required. In the following section, we will describe the global metabolic understanding we developed on the quinoline C2 pyridyl *N*-oxides illustrated by specific metabolite identification. Finally we will show how we applied this knowledge to the optimization of compound **67**.

8.15.2.7.3.1 Metabolism of the quinoline core

The major metabolic pathways identified on the quinoline core fell into two broad subclasses:

(1) Oxidative Phase 1 metabolism of the quinoline ring to a reactive, electrophilic aryl epoxide intermediate followed by a number of different fates, including glucuronidation or glutathione trapping dependant on the nature of the rest of the molecule
(2) Oxidation of metabolically labile quinoline substituents, most notably the 8-methyl group

8.15.2.7.3.1.1 Phase 1 and Phase 2 metabolism of the quinoline core via an aryl epoxide

The susceptibility of quinolines to suffer metabolic oxidation through the formation of aryl epoxide intermediates is well known.[49] These aryl epoxides are reactive electrophiles which are not isolated but are opened by nucleophilic addition of either water (Pathway A) or glutathione (GSH) (Pathway B) (Fig. 20). The hydroxylated products (phenols), in certain cases, became a handle for further Phase 2 glucuronidation.

In our case the general 2,3 substitution pattern of the quinolines meant that epoxidation can be expected to occur on the benzo ring in the 5,6; 6,7; or 7,8-positions. Metabolite screening across a wide range of quinolines identified two major metabolic pathways from this reactive epoxide intermediate (Fig. 20):

(i) *Pathway A* oxidation followed by subsequent hydrolysis of the epoxide intermediate to a diol, elimination to a phenol, and finally (in most cases) Phase 2 glucuronidation (+OGlu)
(ii) *Pathway B* oxidation followed by nucleophilic addition of glutathione to the common reactive intermediate epoxide (+GSH and H_2O)

High levels of glutathione trapping can potentially be an issue in drug development as it indicates a propensity for the formation of reactive metabolites, and thus increased potential for toxicity.[50,51] Therefore, in addition to the metabolite identification studies, we also screened key compounds in reactive metabolite screens, microsomal (S9) incubations with added glutathione or KCN to examine reactive metabolite potential.

As part of our SAR development and to reduce the susceptibility of the quinoline ring to oxidative metabolism, we had prepared a number of halogenated analogs with fluorine or chlorine substituents on the aromatic ring. Incorporation of these leaving groups led to changes in metabolic fate that allowed us to define more precisely the regiochemistry of oxidation and also led to the observation of a unique metabolic pathway in dog.

Specifically fluorinated analogs presented metabolites with a mass gain of +303 consistent with addition of glutathione, oxygen, and loss of fluorine. The proposed pathway for this metabolism is described in Fig. 21. Formation of the aryl epoxide intermediate

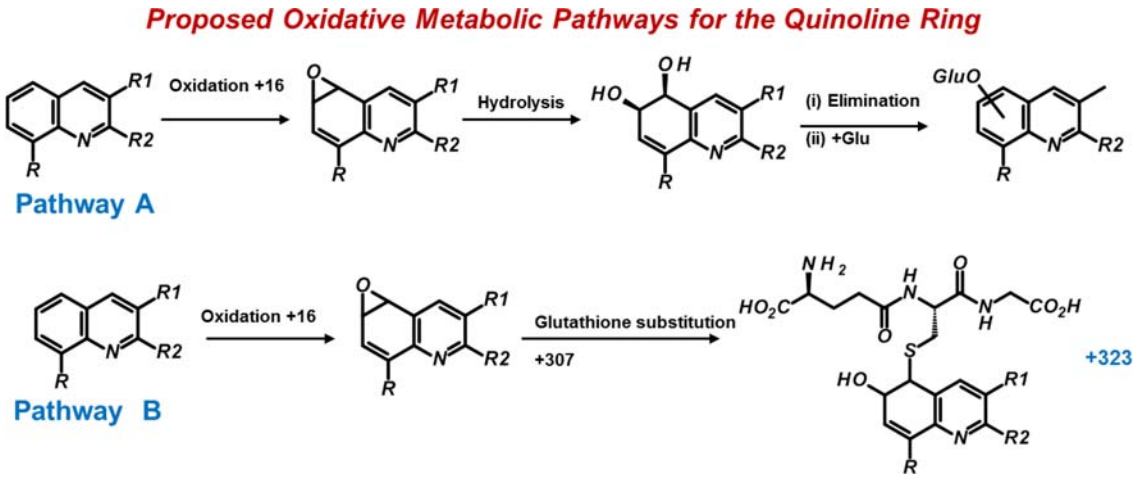

Fig. 20 General scheme for the oxidative activation of the quinoline core through an aryl epoxide intermediate and subsequent trapping by water or glutathione nucleophiles.

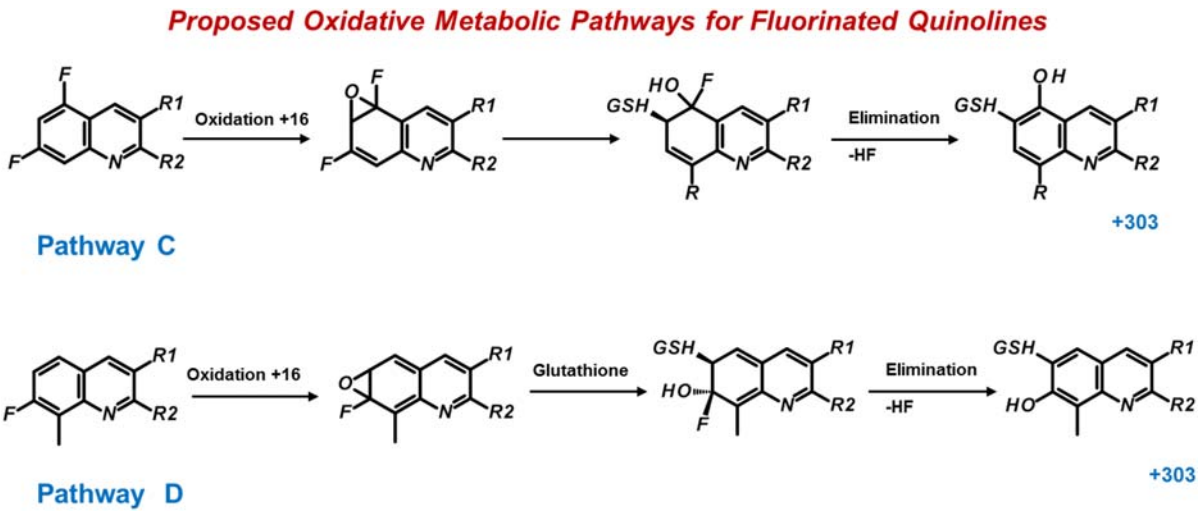

Fig. 21 Addition elimination metabolic pathway for 5, 7, and 7 fluorinated quinolines.

next to the aromatic fluoride provides an alternative metabolic fate after the addition of glutathione, namely elimination of hydrogen fluoride with concomitant aromatization of the quinoline ring.

The addition/elimination pathway was initially observed for the 5,7 difluro substituted quinolines (*Pathway C*), in this case the precise regiochemistry of the formed metabolite cannot be certain (elimination of either the 5F or 7F can be envisaged). However in the case of the 7F,8Me core (*Pathway D*), confirmation of the +OGSH, −F metabolite (+303) allows a more certain postulation of the likely regiochemistry. Elimination of the 7F must occur, with likely epoxidation occurring at the least sterically hindered 6,7-position with subsequent glutathione addition postulated to occur at the least sterically encumbered 6-position on the quinoline. Unequivocal assignment of the metabolite structure would require isolation of the metabolite or independent synthesis and subsequent NMR analysis, a significant effort beyond the scope of these molecules. However, the example serves to illustrate how metabolite identification through mass spectrometry coupled with mechanistic reasoning can allow structural assignment of metabolites with a reasonable degree of confidence.

A strategically important quinoline substitution pattern was the 8-Cl, as it was well represented in leading molecules including **54** and **67**. Metabolism of quinolines containing the 8-Cl substituent is illustrated in Fig. 22.

Interestingly compound **70** demonstrated a different metabolic pathway in human and rat systems compared to dog. In rat and human hepatocytes, *Pathway E* provided a +OGSH –Cl metabolite consistent with epoxidation at the 7,8-position followed by opening of the aryl epoxide intermediate by glutathione and elimination of HCl (in analogy to the pathways described for fluorinated quinolines). In contrast, dog microsomal incubations produced a major +O metabolite (*Pathway F*). The postulated

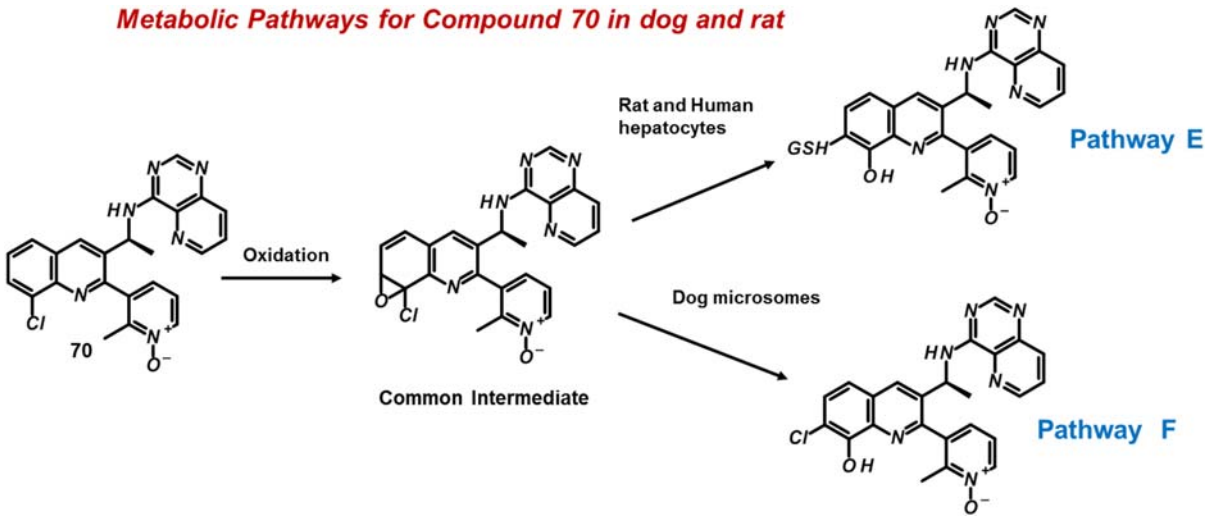

Fig. 22 Metabolic pathways observed for compound **70** a representative 8-Cl quinoline. Of note is the dog-specific chlorine migration pathway the "NIH" shift.

metabolic pathway involves formation of the same common aryl epoxide intermediate but, in this case, rather than reaction with glutathione the epoxide opening is accompanied by migration of the chlorine atom to the 7-position. This migratory pathway was seen in other closely related analogs where the regiochemistry was unambiguously confirmed by independent chemical synthesis of the metabolite. The hydroxylation induced migration of a halogen, commonly known as the "NIH" shift after the *National Institute of Health* was first reported in 1967[52] and furthermore similar dog-specific "NIH" shift metabolism has been previously reported.[53] The involvement of the chlorine atom in both metabolic pathways provided evidence that epoxidation occurs in the 7,8-position as shown.

8.15.2.7.3.1.2 Oxidation of quinoline substituents

While the predominant metabolic fate of the quinoline core was arene oxidation, where metabolically vulnerable groups such as methyl were present specific hydroxylation could occur on the substituents as opposed to the quinoline core itself. In the following section, the metabolic profile of compound **68** will be discussed. The elucidation of the metabolic profile of **68** also illustrates the utility of ^{1}H NMR in the unequivocal identification of metabolites and the occasional discrepancy between in vitro and in vivo metabolic clearance values.

Compound **68** (Table 15) possessed low in vitro clearance in both rat (hepatocyte $Cl_{int} = 8$) and human (microsome $Cl_{int} = 3$) systems with low levels of a single minor +O metabolite, *Metabolite A*. However when dosed in rat **68** demonstrated surprisingly high CL_b (77 mL min^{-1} kg^{-1}) and low oral exposure ($AUC_{inf} = 273$ ng h mL^{-1}). To understand the high clearance, which was not predicted from the in vitro hepatocyte data, a BDC rat study was performed. Based on the relatively high efflux ratio seen in Caco-2 cells (ER 26), we expected to see high levels of parent excreted in the bile consistent with a nonmetabolic clearance pathway. To our surprise, only a relatively small amount of parent was seen in the bile with ~90% of the dose present as one major +O metabolite. Fig. 23 shows the LC-UV trace for the bile from the rat BDC study. The metabolite profile was consistent with *Metabolite A*; however, the levels seen from the in vivo study greatly exceeded those seen from the in vitro incubation explaining the unexpectedly high in vivo clearance. The disconnect between the in vitro and in vivo clearance data highlights the importance of obtaining confirmatory in vivo data and not relying exclusively on in vitro measurements.

In order to unequivocally identify the major metabolite, rat bile was harvested from the study and the metabolite isolated by preparative reverse phase HPLC. Sufficient quantity was isolated to obtain ^{1}H NMR spectra of the major metabolite (Fig. 24). By comparison to the spectra of the parent molecule, which had been fully structurally assigned, it can be clearly seen by the downfield shift of the protons of carbon 8 (from 2.7 to 5.3 ppm) and the appearance of the OH (signal 9) at ~5 ppm, that the major metabolite was the oxidation of the quinoline 8-CH_3 group to the corresponding benzylic alcohol.

The benefit of ^{1}H NMR is that it allows unequivocal structural assignment to be made. However unless in vitro or in vivo studies are designed specifically to generate enough metabolite for ^{1}H NMR studies, there is often insufficient concentration of metabolite to provide meaningful ^{1}H spectra. The relatively low sensitivity and the ubiquitous presence of hydrogen in endogenous molecules necessitate the concentration and purification of samples from biological matrices. The use of ^{19}F NMR, however, can provide highly selective spectra, with very good signal to noise sensitivity from unpurified samples due to the very low natural abundance of fluorine in biological matrices. While ^{19}F NMR does not facilitate structural assignment as comprehensively as ^{1}H NMR, it is a powerful technique for monitoring levels of metabolite from biological samples.[54] As **68** contained a fluorine atom we wished to evaluate the utility of ^{19}F NMR in monitoring the metabolite levels directly from rat bile. Fig. 25 shows the ^{19}F NMR spectra of a sample of unprocessed rat bile showing a clear single peak for the benzylic alcohol metabolite. Clearly ^{19}F NMR would be an excellent tool for monitoring the metabolic turnover of compounds such as **68** especially as the peaks for parent and metabolite are clearly distinguished and are directly proportional to each other in quantitative terms.

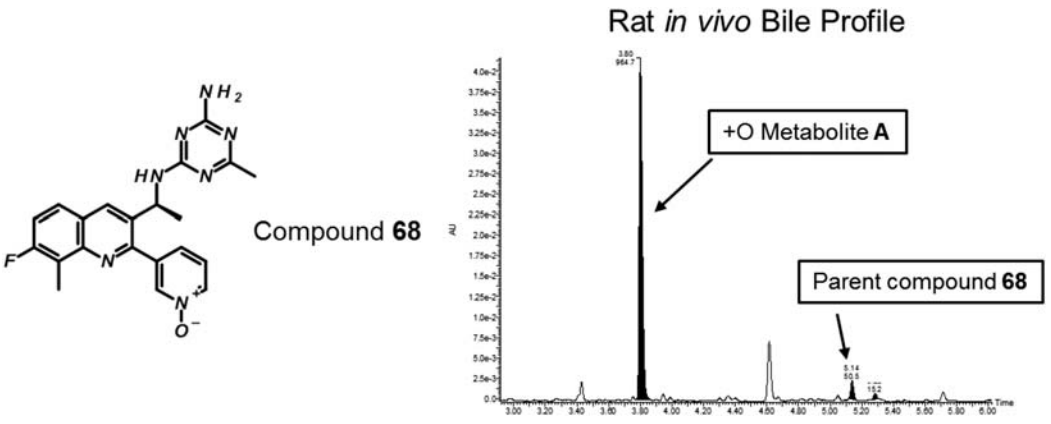

Fig. 23 LC-UV trace of **68** and metabolite A in rat bile.

8.15.2.7.3.2 Metabolism of the pyrido[3,2-d]pyrimidine hinge-binding group

The pyrido[3,2-*d*]pyrimidine hinge-binding group was subject to a variety of phase 1 oxidative metabolism resulting in either *N*-oxidation or oxidation on the carbon between the two nitrogen atoms on the pyrimidine ring (Fig. 26). Typically in human in vitro systems, metabolism of the hinge-binding group was a significant metabolic pathway compared to the oxidation of the quinoline core, whereas conversely in rat quinoline core oxidation predominated. The species difference in relative metabolic pathways is not atypical and, in our case, it reiterated the need to address both potential sites of metabolism in order to improve the PK profile in rat (to support preclinical toxicology), and ultimately reduce human metabolism to achieve the desired once-daily dosing drug profile.

8.15.2.7.3.3 Metabolism of the pyridyl-N-oxide

The C2 pyridyl-*N*-oxide predominantly suffered from reduction to the parent pyridine with little or no observable direct oxidation of the heterocyclic ring itself. Metabolite ID studies of parent pyridines typically revealed the potential for oxidation of the pyridine to the *N*-oxide so the potential for a reduction/oxidation recycling of 3-pyridyl-*N*-oxide compounds could be envisaged. In our case the production of the pyridine as a significant metabolite necessitated full profiling of the parent pyridines both in terms of their intrinsic PI3Kδ potency (potential formation of active metabolites), inhibitory potential with the CYP 450 cytochromes, and other ancillary profiles.

8.15.2.7.4 Metabolite identification studies with compound 67

Specific metabolite identification studies with **67** from both in vitro incubations and in vivo studies revealed the main metabolic pathways for this molecule summarized in Fig. 27.

The main metabolite identified from human hepatocyte incubations was reduction of the pyridine *N*-oxide to the pyridine **66** with additional minor oxidation products both on the pyrido[3,2-*d*]pyrimidine hinge-binding group and the quinoline core (via the epoxidation mechanisms described in the previous section). In rat in vivo studies, a glutathione adduct was also observed suggesting that quinoline core oxidation was the major metabolic pathway in rat. Although human in vitro data provided no direct evidence of glutathione conjugation (Table 17), the levels of glutathione adducts produced in in vitro systems were generally low and as such could well be below the limits of detection of the LCMS system. Certainly the possibility of glutathione metabolites being generated in vivo could not be entirely discounted based on the in vitro data.

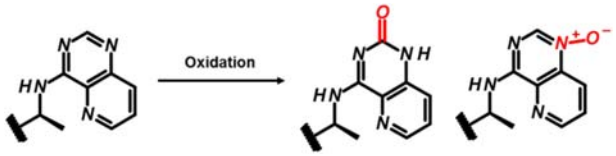

Fig. 26 Proposed primary oxidative metabolites of the pyrido[3,2-*d*]pyrimidine hinge-binding group shown in *red*.

8.15.2.7.5 Optimizing the PK profile of compound 67

8.15.2.7.5.1 SAR and impact on metabolism of quinoline substitution

The metabolite ID studies with **67** and broader metabolite ID studies with related quinolines highlighted oxidation of the quinoline ring and pyrido[3,2-*d*]pyrimidine hinge-binding group as significant metabolic pathways with potential for formation of reactive metabolites. From a medicinal chemistry point of view, the introduction of electron withdrawing groups into strategic positions on the molecule was an attractive tactic to reduce the metabolic clearance of compound **67**. We wished to further explore the possibilities of other electron withdrawing groups on the quinoline ring and set about exploring the SAR.

The effect of introducing electron withdrawing groups into the quinoline ring on PI3Kδ activity and metabolic stability is summarized in **Table 18**. The electron-rich 8-CH_3 quinoline **71** suffers from very high metabolic clearance in rat hepatocytes and a positive genotoxicity flag. Introducing a simple electron withdrawing substituent such as a fluorine into the 7-position, (compound **72**), results in a substantial increase in metabolic stability in rat hepatocytes, despite an increase in lipophilicity. The observation highlighted the sensitivity of metabolic clearance to the electronic nature of the quinoline ring. The PI3Kδ activity of **72** was maintained in the key cellular assays. Replacement of the metabolically vulnerable 8 methyl group with chlorine to give **67** also resulted in a substantial increase in metabolic stability especially in human hepatocytes.

In order to reduce the metabolic clearance of **67**, we sought to incorporate strongly electron withdrawing groups into the 8-position. Incorporation of a CF_3 group (**75**) resulted in an increase in rat hepatocyte stability, but no significant effect on human hepatocyte stability; perhaps consistent with the observation that quinoline oxidation is the major metabolic pathway in rat. The modest effect on metabolic stability could be attributed to the fact that while electron density on the quinoline ring was reduced compared to **67**, the lipophilicity was increased (log *D* 1.8 to log *D* 2.5) potentially producing opposing influences on metabolic stability. Synthesis of the tri-fluoro substituted analog **78** provided an electron deficient quinoline but with a log *D* similar to **67**. Pleasingly the metabolic stability in human hepatocytes was greatly enhanced, demonstrating the ability of the multifluorinated aromatic ring to eliminate oxidative metabolism. Unfortunately, the compound was ~100-fold less potent than **67** thought to be due to the sensitivity of substitution on the 6-position as compounds **73** and **74** demonstrated that 5-position substitution was well tolerated. Synthesis of the 8-CN (**76**) and 8-SO_2Me (**77**) analogs provided compounds that were both potent against PI3Kδ in the enzymatic assay and metabolically stable in both human and rat hepatocytes. The increased metabolic stability was

Table 18 Quinoline SAR and the effect of electron withdrawing groups on metabolic stability and PI3Kδ IC_{50} activity

driven by both the reduced electron density on the quinoline core and the greatly reduced lipohilicity. However the low log *D* values resulted in poor cellular activity for both compounds, approximately 10-fold less potent than **67** in both the fMLP and D0.11.10 proliferation assays. We hypothesized that the loss of cellular potency was due to poor cellular permeability, and it appeared that a log *D* value of between 1.5 and 2.0 would result in the ideal balance of cellular potency and metabolic stability.

An alternative approach to reducing electron density in the quinoline ring could be envisaged by introducing a nitrogen to provide the corresponding napthyridine ring systems (Fig. 28). If the quinoline ring could be replaced by a napthyridine, we could anticipate that the epoxidation and glutathione conjugation metabolic pathways could be eliminated.

We synthesized a selection of napthyridine analogs, however the PI3Kδ activity was severely impaired. While the 1,5-napthyridine proved the most promising in terms of activity (PI3Kδ $IC_{50} = 120$ nM) and further improvements in activity could be anticipated by introduction of an 8 substituent and resolution of the enantiomers, the lack of potency compared to our lead molecules led us to abandon this particular approach.

Overall, despite extensive modifications to the quinoline core, the 8-Cl substituent and hence compound **67** remained the leading molecule based on in vitro data. We therefore turned our attention to other chemical modifications which could result in the desired reduction of electron density and oxidative metabolism.

8.15.2.7.5.2 Methyl to trifluoromethyl switch: Effects on PK and selectivity profile

Although our attempts to improve the profile of **67** by modification of the quinoline core had not proved successful, two key lessons could be taken from the process. Firstly that reducing electron density could improve metabolic stability but secondly reduction of log *D* below 1.5 led to significant and unacceptable loss of cellular activity. With these lessons in mind, we reasoned that apart from the quinoline C8-position, the only two other positions on the quinoline core amenable to modification were the C2- and C3-positions. As previously discussed, although the C2-position is tolerant of a wide range of substitution we had already alighted on a well-balanced and highly optimized substituent in the 3-pyridyl-*N*-oxide and felt that further modification here would prove unproductive. In contrast, the C3-position provided an opportunity to introduce a strongly electron withdrawing group if we replaced the chiral methyl group in **67** with a trifluoromethyl group (Fig. 29).

The introduction of fluorine into lead molecules is a commonly employed tactic in medicinal chemistry.[55,56] In this case, the strongly electron withdrawing effect of the trifluoromethyl could be expected not only to reduce the electron density on the quinoline core but also to have a significant impact on the ESP of the pyrido[3,2-*d*]pyrimidine hinge-binding group. We would expect that the basicity of the amino heterocycle would be reduced and the lipophilicity of the molecule increased (calculated log *P* increase of 0.6). We therefore reasoned that incorporation of the trifluoromethyl group in such a strategically sensitive point would have a beneficial impact in terms of reducing electron density across the whole molecule compared to the C8 substituents previously explored where the impact would be restricted primarily to the quinoline ring. Furthermore, as the CF_3 group is more lipophilic than a methyl group we could avoid compromising the global physicochemical properties of the molecule and retain cellular potency.

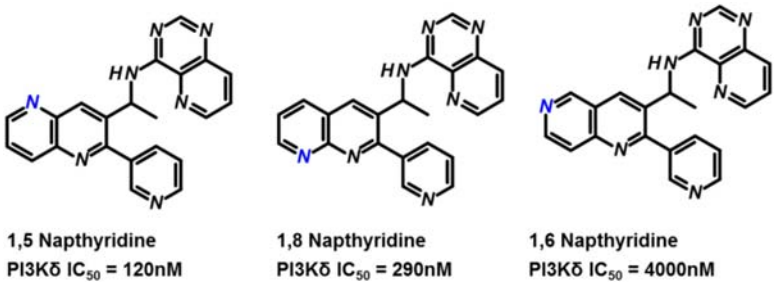

Fig. 28 Napthyridine replacements of the quinoline ring result in reduced PI3K activity.

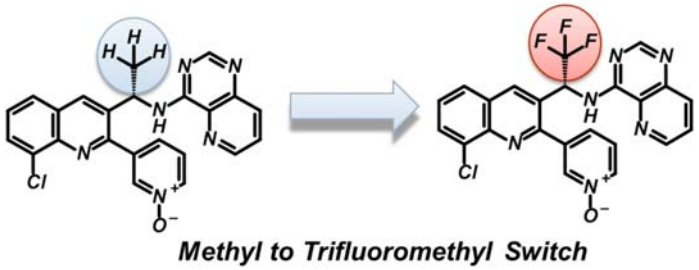

Fig. 29 Replacement of the chiral benzylic methyl group with trifluoromethyl.

We synthesized a number of MMPs where we replaced the chiral methyl group with a trifluoromethyl substituent (Table 19). We also conducted a methyl scan of the 3-pyridyl-*N*-oxide group with the intention of introducing steric bulk in the flanking positions *ortho* to the *N*-oxide. We reasoned that steric bulk in these positions could reduce the rate of pyridine *N*-oxide metabolism and also reduce the CYP inhibition potential of any resultant pyridine metabolites.

Replacement of the chiral methyl with a trifluoromethyl group pleasingly did not erode PI3Kδ potency and across the matched pairs a small improvement in in vitro human hepatocyte stability was observed despite the expected increase in lipohilicity (~0.5 log *D* increase for the $CH_3 \rightarrow CF_3$ switch). Interestingly comparing compound **79** to the trifluoromethyl analog **81** suggested that the trifluoromethyl group significantly improved selectivity against PI3Kγ; the >1000-fold-selectivity with **81** was the highest we had observed for a C2 aryl.

Substitution of the pyridine ring with a methyl groups in the 6-position reduced potency ~10-fold (**80** compared to **67**), but a methyl group in the 2-position was well tolerated (compounds **70** and **82**). The rationale for incorporating the 2-methyl substituent was to reduce the rate of pyridyl-*N*-oxide metabolic reduction and also reduce the CYP inhibition profile of the analogous pyridines. Metabolite ID studies in rat and human hepatocytes and metabolite analysis of rat bile confirmed that no pyridine *N*-oxide reduction was observed for compounds **70** and **82**, confirming that a methyl substituent in the 2-position of the pyridyl *N*-oxide was a suitable strategy for preventing *N*-oxide reduction.

Encouraged by the apparent improvement in the in vitro metabolic stability, we sought to establish if the increased stability translated into improved in vivo PK properties. Fig. 30 compares the in vitro and in vivo profile of compounds **84** and **85**. The trifluoromethyl analog **85** possessed an improved metabolic stability profile in rat hepatocytes that translated into lower in vivo clearance in rat and a markedly improved oral PK profile, with significantly increased exposure and oral bioavailability.

In summary, through our attempts to improve the metabolic stability of the first C2 pyridine-*N*-oxide **67**, we discovered that replacement of the chiral methyl group with a trifluoromethyl conferred greatly improved oral PK properties in rat, partly attributable to the improved in vitro metabolic stability. Furthermore in some analogs, the selectivity against the gamma isoform was markedly improved, a profile that was not easily accomplished in the C2 aryl subseries. We had also established that the 8-Cl quinoline substituent was optimal and that substitution of the pyridyl ring provided only limited benefit. With these observations in mind, the trifluoromethyl analog of **67** was clearly a key molecule demanding synthesis. As will be described in the following section, the profile of this molecule met our target criteria and ultimately led to the development of the compound as our clinical candidate *seletalisib*.

8.15.2.8 Identification and Characterization of *Seletalisib*

8.15.2.8.1 Impact of the CF_3 Group 1: In vitro biology comparison between compounds 67 and 86

The in vitro potency and selectivity profile of compounds **67** and **86** are presented in Table 20.

Notably the trifluoromethyl group conferred markedly improved selectivity against both the beta and gamma isoforms (approximately 10-fold). While the precise reasons behind the improved selectivity profile are unclear, it is significant as the selectivity profile for compound **86** (*seletalisib*) is highly competitive compared to the reported selectivity for the clinical PI3Kδ inhibitors *idelalisib*[25] and *duvelisib*[57] (Table 21). To the best of our knowledge, seletalisib represents the most selective PI3Kδ inhibitor reported to date.

Table 21 *idelalisib*[25] and *duvelisib*[57] data are taken from the biomedical literature and presented for comparison with *seletalisib*

PI3K isoform	Seletalisib *IC_{50} nM (fold-selectivity for PI3Kδ)*	Idelalisib *IC_{50} nM (fold-selectivity for PI3Kδ)*	Duvelisib *IC_{50} nM (fold-selectivity for PI3Kδ)*
PI3Kδ	1.1 (–)	2.5 (–)	2.5 (–)
PI3Kγ	900 (818×)	89 (35×)	27 (11×)
PI3Kβ	2563 (2330×)	565 (226×)	85 (34×)
PI3Kα	4356 (3960×)	820 (328×)	1602 (640×)

Specifically *seletalisib* displays at least a 10-fold-selectivity improvement against all the PI3K isoforms compared to the current clinical candidates. Against PI3Kγ and PI3Kβ, the selectivity is markedly improved and it will be intriguing to see if this improved isoform selectivity profile translates into improved tolerability in a clinical setting.

Compound **86** as expected displayed excellent cellular potency in a range of B-cell and T-cell driven assays [Ref. UCB JPET Biol Paper]. The selective inhibition of PI3Kδ is demonstrated by the potent inhibition of the fMLP driven superoxide release assay in neutrophils (IC_{50} 16 nM) and inactivity in the same assay when stimulated by the non-PI3K-dependant ligand PMA. Potent inhibition of downstream signaling from the BCR was demonstrated in the pAKT assay in RAMOS cells with an IC_{50} of 15 nM. In order to be able to measure directly the inhibition of PI3Kδ in a clinical setting, we had developed a whole blood basophil degranulation assay (described in Section "**The basophil degranulation assay**"). Compound **86** potently inhibited this assay with an IC_{50} of 35 nM.

The wider selectivity of **86** was also assessed in in vitro receptor binding and enzyme assays across a broad range of target classes, demonstrating that **86** is highly selective for PI3Kδ. Specifically when screened against a panel of 239 kinases, **89** showed no inhibitory activity against any targets >50% @ 10 μM. Wider screening against nonkinase enzymes, ion channels, and receptors revealed no significant activity. As expected, **86** maintained the clean profile in the early in vitro genotoxicity screens and hERG assays established by the methyl analog **67**.

In summary, replacement of the methyl in **67** with trifluoromethyl resulted in **86** which retained the excellent e*nzymatic and cellular* potency of **67** but with markedly improved selectivity against the gamma and beta isoforms. Importantly compound **86** is the most selective PI3Kδ inhibitor reported to date with a differentiated selectivity profile compared to the current PI3Kδ inhibitors in clinical development *idealisib* and *duvelisib*.

8.15.2.8.2 Impact of the CF_3 Group 2: Comparison of PK parameters between compounds 67 and 86

Given the promising biochemical and cellular profile of **86**, we investigated the PK parameters of this molecule. **Tables 22** and **23** disclose the comparative in vitro ADMET and in vivo PK data for compounds **67** and **86**.

The in vivo clearance data for rat and dog clearly illustrate that the trifluoromethyl analog **86** has approximately twofold lower in vivo clearance that the methyl compound **67**. The in vitro hepatocyte data in dog, rat, and human also suggest greater metabolic stability for the trifluoromethyl analog **86** compared to the methyl analog **67**. In the case of rat, the oral bioavailability is markedly improved from 29% to 98%. The Caco-2 data suggests an improved efflux ratio and intrinsic permeability for **86** which, together with the greater metabolic stability may explain the improved oral PK parameters for both trifluoromethyl analogs **86** and **85** compared to their methyl counterparts. Although the precise reasons for the improved in vivo intrinsic clearance and bioavailability for the trifluoromethyl compounds are not entirely clear, the consistent and significant positive impact of the chiral trifluoromethyl modification on the PK parameters is not in doubt.

Table 22 In vivo PK parameters of compounds **67** and **86** in rat, dog, cynomolgus monkey, and mouse

	TDI	>10 μM all isoforms	>10 μM all isoforms
CYP induction			Minor

Pleasingly compound **86** did not display any CYP P450 induction or inhibition liabilities, suggesting a low potential for drug/drug interactions in the clinic.

The in vivo PK profile of compound **86** in a range of preclinical species (rat, dog, and cyno), characterized by low to moderate intrinsic clearance and good bioavailability, supported progression to the necessary preclinical toxicology studies.

8.15.2.8.3 Metabolic profile of compound 86

The metabolic profile of **86** was determined in in vitro human, rat, dog, cynomolgus monkey hepatocytes, and microsomes, with the major human metabolites identified presented in Fig. 31. As expected, the metabolic profile was very similar to the methyl analog **67** with the major metabolic pathway in human and cynomolgus monkey hepatocytes being reduction to the pyridine (*Metabolite **A***) with further oxidation of the pyrido[3,2-*d*]pyrimidine hinge-binding group to *Metabolite **B***. In human microsomes, direct oxidation of the hinge-binding group was also seen (*Metabolite **C***). Importantly the metabolite profile in cynomolgus monkey hepatocytes and microsomes closely mirrored the human profile both in the metabolites produced and their relative levels.

Identification of the major metabolites across species is critical to the selection of the preclinical toxicology species to ensure that the metabolites produced in human systems are reproduced in the preclinical toxicology studies. In our case, the fact that cynomolgus monkey produced a metabolite profile that closely resembled the human results made it a promising candidate for the non-rodent toxicology species.

In summary, the metabolite profiling of **86** across species in vitro confirmed that, similar to the profile of compound **67**, the major metabolic pathway in human was reduction of the pyridyl *N*-oxide. Secondary pathways involved oxidation of the pyrido[3,2-*d*]pyrimidine hinge-binding group with the metabolic profile very similar in cynomolgus monkey.

8.15.2.8.4 Pharmacological evaluation of compound 86

Compound **86** was evaluated in our pharmacology cascade, as expected the compound demonstrated good efficacy and potency in the anti-CD3-induced IL2 assay and SRBC DTH assay similar to the data presented with compound **67**. We wished to determine the

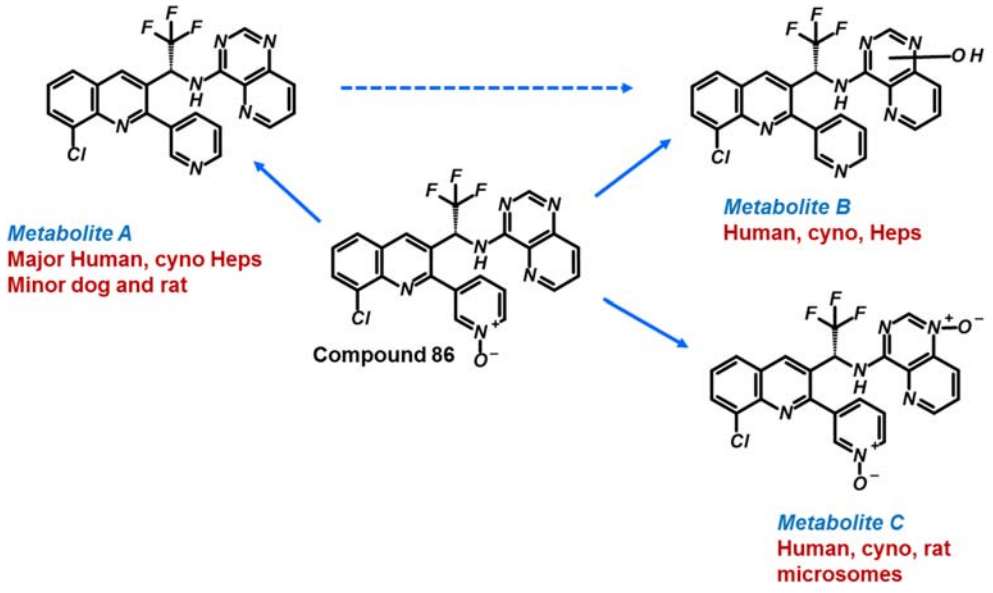

Fig. 31 Major metabolites of compound **86** identified from human in vitro hepatocyte and microsomal incubations.

efficacy of **86** in models of inflammatory disease and evaluated the compound in the mouse CIA (Fig. 32). Compound **86** was dosed at 10 mg kg^{-1} u.i.d. therapeutically (from disease onset) and significantly reduced clinical score over time with statistically significant difference from day 14. A reduction of AUC of the clinical score of $64 \pm 12\%$ compared to the vehicle control group was achieved.

The profound inhibition of the CIA model combined with the optimized potency, class leading PI3K isoform selectivity, and good in vivo PK profile led us to nominate compound **86** as a candidate for preclinical toxicology studies. The outline of these studies and the ultimate progression of compound **86** into the clinic as *seletalisib* are described in the next sections.

8.15.3 Preclinical Development

Preliminary repeat dose toxicity studies with *seletalisib* were performed in rats (5 days and 2 weeks) and monkeys (2 weeks). In light of the results of these studies, a GLP package was conducted to support clinical use and included a standard genotoxicity battery, 4-week repeat dose toxicity studies in rats and monkeys, and safety pharmacology studies assessing the respiratory, cardiovascular, and CNS functions. A brief summary of this GLP package is provided here.

Seletalisib was negative in in vitro (Ames test and Mouse lymphoma mutation assay) and in vivo (micronucleus induction assay in rat bone marrow erythrocytes) genotoxicity tests.

No adverse effects were observed on respiratory function or on general behavior.

In the hERG assay, *seletalisib* displayed an IC_{50} value of 52 μM, indicating a potential liability for blockade of the human-encoded IKr potassium channel only at high concentrations compared to the pharmacological activity. Indeed, 52 μM represents around 56,000-fold the free concentration inhibiting by 90% (IC_{90}) the PI3K delta enzymatic activity in vitro. In the pivotal GLP telemetry study conducted in conscious monkeys, *seletalisib* did not induce relevant QTc prolongation when administered at oral doses as high as 100 mg kg^{-1}, corresponding to c. 2585-fold the in vitro IC_{90} from the PI3K delta enzymatic activity assay. These data allowed us to conclude that *seletalisib* presented a low risk of proarrhythmia potential.

When administered orally once a day for 4 weeks to monkeys and rats, *seletalisib* induced similar histopathological findings in both species, mainly characterized by lymphoid tissue atrophy and inflammatory changes in the large intestine. In both monkeys and rats, these lymphoid tissue and intestinal findings showed reversibility after a 4-week treatment-free period and provided sufficient safety margin and confidence that *seletalisib* could be safely tested in humans.

8.15.4 Clinical Data and Status

Seletalisib entered first in man studies in Aug. 2013 successfully completing two combined single ascending dose/multiple ascending dose studies in healthy volunteers and mild-to-moderate psoriatic subjects (PS0001/NCT02303509: UP0021/NCT02207595) to evaluate its safety, tolerability, pharmacokinetic, and pharmacodynamic profile.

Seletalisib was well tolerated at doses ≤15 mg (PS0001) and ≤45 mg QD (UP0021) for 14 days. No safety concerns or dose-limiting toxicities were identified (PS0001). Incidence of gastrointestinal-related adverse events (AEs) was not dose related but higher incidences of skin rash AEs were associated with higher-dose *seletalisib* (UP0021).

Mean *seletalisib* plasma concentration-time profiles increased with increasing doses after single and multiple dosing, with no major deviations from dose proportionality and apparent $T_{1/2}$ values were supportive of once-daily dosing. Pharmacodynamic findings demonstrated ex vivo inhibition of basophil degranulation and identified improvements in histological assessment of skin biopsies and other markers of psoriatic biology with evidence of target engagement in psoriatic skin tissue.

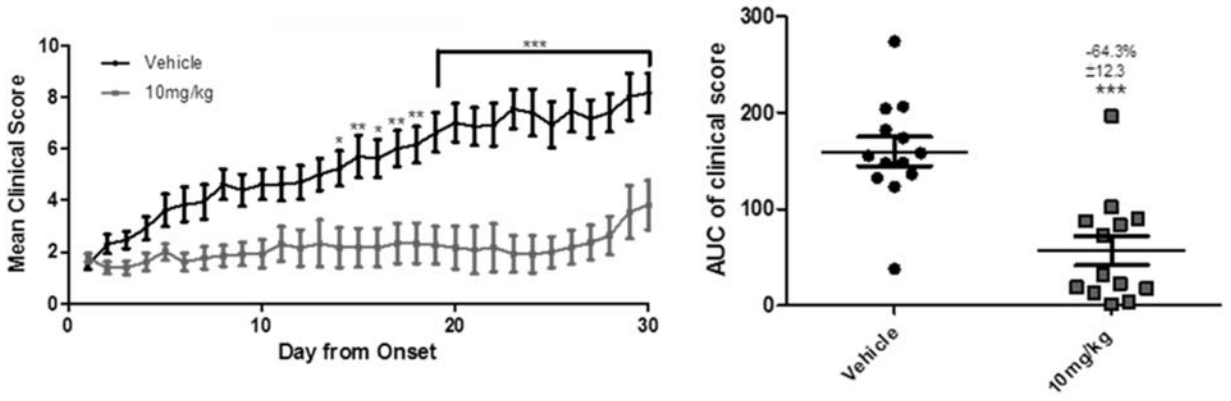

Fig. 32 Inhibition of collagen-induced arthritis in vivo. Vehicle and compound **86** in 1% methylcellulose (400cps) was administered orally once daily from day of disease onset. Animals were immunized with CII in CFA (i.d.) on day 0 and boosted with CII in IFA (i.d.) on day 14. Clinical score was assessed daily and mice were sacrificed 30 days after disease onset. Statistical significance is denoted as follows, $*p<0.05$, $**p<0.01$, and $***p<0.0001$ compared to positive control group (ANOVA with Bonferroni's post test).

The results of both PS0001 and UP0021 demonstrated a manageable safety and tolerability profile of *seletalisib*, provided PK results supportive of once-daily dosing, showed evidence of biological effect, and provided data supportive of exploration of efficacy in proof-of-concept studies.

On these bases, *seletalisib* has been progressed into a proof of concept (PoC) study in primary Sjögren's Syndrome (NCT02610543).

8.15.5 Conclusion

In this article, we have described the medicinal chemistry program leading to the discovery and development of *seletalisib*, which is, to our knowledge, the most selective PI3Kδ inhibitor yet reported. We began our journey with the hypothesis that inhibition of only the delta isoform of PI3 kinase would bring an optimal balance of clinical efficacy and tolerability for chronic use in inflammatory and autoimmune diseases. Through the efforts described in this article, we have successfully delivered *seletalisib* to the clinic in order to test that proposal.

As with any medicinal chemistry program, the experience has provided many valuable lessons which we hope the reader will find as instructive as we have. Of note has been the successful use of a virtual database of heterocyclic rings (VEHICLe[3]) and in silico electrostatic modeling to generate new scaffolds, an approach that can be applied to any medicinal chemistry program. Our exploration of the SAR led to the emergence of several unexpected selectivity profiles which could not be easily explained from our structural understanding. These empirical selectivity observations proved critical to the ultimate development of compounds with high selectivity against PI3Kγ and highlight the importance of thorough and comprehensive SAR "fieldwork" fully exploring the chemical diversity of the scaffold. The crucial gamma selectivity breakthroughs, both the C2 amines and the benzylic trifluoromethyl group, came indirectly from attempts to optimize physicochemical properties and PK. Crucial to the identification of this serendipitous gamma isoform selectivity was our early PI3K isoform selectivity screens and confirms that in medicinal chemistry "fortune favors the prepared screening cascade."

Our medicinal chemistry strategy focused on rapidly developing highly potent inhibitors and then subsequently optimizing the physicochemical and DMPK properties. We have shown how metabolite identification and developing a good mechanistic understanding of the major routes of metabolism can inform and guide a successful medicinal chemistry program in optimizing PK profiles.

The realization of the genotoxic potential of the triazinyl-piperazinones was a significant setback for the program and necessitated a major, but ultimately successful, redesign of the molecules. Access to a number of parallel in vitro genotoxicity assays to eliminate the possibility of false positives and negatives was crucial to be able to rapidly identify chemical space devoid of the genotoxicity risk. Our successful redesign of the molecules was based on the deployment of a 3-pyridyl-*N*-oxide as a bioisostere of a carbonyl group. In our case, the pyridyl-*N*-oxide also brought greatly improved metabolic stability and solubility to our molecules and, as shown in this article, is a valuable functional group in the medicinal chemist's armory.

The replacement of the benzylic methyl group with trifluoromethyl proved to be final piece in the *seletalisib* puzzle. It is one example of many in the medicinal chemistry literature[55] where judicious incorporation of fluorine results in improved PK properties. In our case, the in vitro ADMET data suggested marginal improvement and it was only when the compounds were taken into in vivo PK studies that the full benefit of the *trifluoromethyl switch* became apparent, highlighting the importance of in vivo experimentation to fully understand and interpret in vitro ADMET data.

Seletalisib completed preclinical toxicology and has successfully progressed into clinical studies. *Seletalisib* is currently undergoing a PoC study in primary Sjögren's syndrome where it will been seen if selective PI3Kδ inhibition can provide relief to patients suffering from chronic inflammatory and autoimmune diseases.

Acknowledgments

The author would like to acknowledge the many colleagues and functions that are a crucial part of any successful drug discovery program. In particular, thanks to the medicinal chemistry, DMPK, pharmacology, primary pharmacology, and nonclinical development teams at UCB.
The medicinal chemistry program was conducted in close collaboration with BioFocus DPI who provided medicinal chemistry support and expertise to the UCB project team. The author would like to thank the members of the BioFocus medicinal chemistry team who played a crucial role in the successful identification of *seletalisib* through a highly productive and enjoyable collaboration. Finally the comments, opinions, and statements in this article are entirely the authors own and do not represent those of UCB or any other party.

8.16.1 Inflammatory Diseases

Inflammation and immunity form the bases of many physiological and pathological processes. While of benefit during infection, excessive inflammation can contribute substantially to the pathogenesis of many chronic diseases, in which the immune system erroneously targets the body's own cells, tissues, and organs.[1,2]

Rheumatoid arthritis, inflammatory bowel disease, psoriasis, lupus, and multiple sclerosis are all autoimmune diseases, conditions in which the immune system loses its ability to differentiate the self from the foreign and directs an attack against healthy cells and tissues.[3] In rheumatoid arthritis (RA), the immune system attacks the synovium (tissue lining the joint capsule) causing local inflammation. It affects the lining of the joints, causing pain, swelling, and reduced mobility for the patient. This inflammatory response ultimately results in the destruction of ligaments, tendons, and muscles that support the joint.[4,5] Patients with severe joint damage are subject to surgical options. Systemic inflammation is also involved in the pathogenesis of chronic obstructive pulmonary disease (COPD).[6–8] Reduced lung function is associated with increased levels of systemic inflammatory markers, which may have important pathophysiological and therapeutic implications for subjects with stable COPD.

8.16.1.1 Synthetic DMARDS

As clinicians strive to achieve and maintain remission of symptoms and preserve joint function in patients, disease-modifying antirheumatic drugs (DMARDs) are introduced in early treatment of RA to limit joint damage from the outset. Methotrexate (MTX) is the most frequently used first-line DMARD due to its efficacy and low cost.[9–11] As an antifolate, it has multiple mechanisms of action in RA. However, it is often associated with serious side effects. Hepatotoxicity, fibrosis, and cirrhosis after prolonged use and liver enzyme elevations are frequently seen. Patients who take methotrexate need to be monitored regularly for liver and kidney function. It is also associated with potentially fatal opportunistic infections, especially *Pneumocystis* pneumonia. The adverse effects of methotrexate have prompted the search for safer and more efficacious new treatments.

8.16.1.2 Biological DMARDs

Several preeminent biologics have been approved for treatment of RA by the Food and Drug Administration (FDA). Treatment with infliximab (Remicade), adalimumab (Humira), etanercept (Enbrel), abatacept (Orencia), and rituximab (Rituxan) reduces joint pain and swelling and retards progression of bone loss in patients whose disease is unsatisfactorily controlled by conventional DMARDs.[12–15] A large number of the biological agents act as inhibitors of tumor necrosis factor (TNF), a monocyte-derived cytokine that has a wide variety of functions. The leading anti-TNF products (infliximab, adalimumab, and etanercept) have been shown to be effective in slowing down the signs and symptoms of rheumatoid arthritis, inhibiting the progression of structural damage, and improving physical function in patients with moderately to severely active rheumatoid arthritis.[16,17] The TNF inhibitors are intended chiefly to antagonize TNF-α, an inflammatory cytokine produced by activated monocytes, macrophages, and T cells in the synovium. Of the currently available anti-TNF therapies, etanercept is the only biologic that also blocks TNF-β, or lymphotoxin, as both infliximab and adalimumab block only TNF-α.

The main limitation with anti-TNF treatment is that large populations of patients do not respond to the drugs.[18,19] Clinical data show that between 59% and 75% of patients achieved an American College of Rheumatology 20 (ACR20) level of improvement, the minimum improvement expected and a common clinical trial primary endpoint. That leaves between 25% and 41% of patients who stop taking the anti-TNF drugs due to inadequate responses.

Rituximab (Rituxan) is a chimeric monoclonal antibody against CD20 that is primarily expressed on the cell surface of the mature B cells.[20] It is approved to treat diseases that are characterized by excessive numbers of B cells, overactive B cells, or dysfunctional B cells. By depleting the CD20 B cells, rituximab has been approved to treat autoimmune diseases including rheumatoid arthritis. In combination with methotrexate, rituximab has been shown to reduce signs and symptoms in adult patients with moderately to severely active RA who have had an inadequate response to one or more anti-TNF therapies.

Orencia (abatacept) is a T cell costimulation modulator that was approved for the RA treatment by the FDA in 2005 and by the European Commission in 2007.[21,22] The drug is a fully humanized soluble fusion protein that consists of the extracellular domain of cytotoxic T lymphocyte antigen-4 (CTLA4) linked to the Fc portion of human IgG1. It allays inflammation by interfering with the interaction between CD80/86 on antigen-presenting cells and CD28 on T cells, thus preventing T cell activation. It is labeled for reducing the signs and symptoms of RA, slowing the progression of structural damage, and improving physical function in adults who have had an inadequate response to one or more DMARDs.

In addition, other biological agents have been explored to complement the existing inhibitors. Among them, the IL-1 receptor antagonist anakinra (Kineret), the IL-6 antagonist tocilizumab (Actemra), the IL-15 antagonist AMG-714, and the adhesion molecule blockers (e.g., anti-CD20 antibody ocrelizumab) have emerged.[21–23]

The more targeted biologic therapies have not entirely reduced the side effects of traditional DMARDs and are sometimes associated with additional common effects, usually due to the disruption of the immune response and injection site reactions.[24] Despite the fact that these side effects are usually less harsh than traditional DMARDs, it is an area for improvement in new treatments. However, since the majority of biological DMARDs are used in practice in combination with methotrexate, their side effects are in addition to those mentioned earlier.

In general, the biological agents are limited due to requirement for parenteral administration, difficulty in dose titration, poor reversibility, induction of host neutralizing antibody response, high production costs, and a significant population of patients who are refractory to the treatment. Therefore, given the great successes of anti-TNF agents and advances made in understanding the molecular basis of their efficacy surrounding the role of TNF in the innate immune system, small-molecule targeted therapies remain a major goal of pharmaceutical research.

8.16.2 The p38 MAPK Pathway

Excessive production of TNF-α and other proinflammatory cytokines is involved in the pathogenesis of rheumatoid arthritis, Crohn's disease, inflammatory bowel disease, psoriasis, and COPD.[25,26] In an innate immune response, mitogen-activated protein kinase (MAPK) and nuclear factor-kB (NF-kB) are activated by pattern recognition receptors (PRRs) upon binding of the pathogen-associated molecular patterns (PAMPs). The 14 MAPKs discovered in mammalian cells are crucial to generating immune responses. Among them, extracellular signal-regulated kinase (ERK), p38, and Jun N-terminal kinase (JNK) have been extensively studied in the context of innate immunity.[27–30] Altogether, they play pivotal roles in the MAPK signal transduction pathway that cells use to adapt to inflammatory and stressful conditions. At the center of regulating a broad spectrum of inflammatory activities, the p38 kinase controls the biosynthesis of key proinflammatory cytokines at both the transcriptional and translational levels. As depicted in Fig. 1, pathogens or inflammatory stimuli initiate a phosphorylation cascade mediated by p38 kinase that leads to the transcription and translation of inflammatory response-associated genes that encode proteins such as TNF-α, IL-1β, IL-6, and IL-8.[28,31] TNF-α, IL-1β, and IL-6 are macrophage- and fibroblast-derived proteins that induce expression of inflammatory mediators such as COX-2, inducible nitric oxide synthase, adhesion molecules, and metalloproteinases, resulting in synovial inflammation and associated cartilage and bone destruction. In addition, the expression of cytokines and chemokines during an innate immune response could lead to subsequent induction of the adaptive immune response, further intensifying the amplitude and duration of an inflammatory reaction. The increased gene expressions of immune signaling molecules are vital to the magnitude and perpetuation of inflammatory mediators, causing chronic autoimmune disorders.

Inhibition of p38 MAPK has the potential of blocking the production of these cytokines and the subsequent amplification of the inflammatory cascade. Modulation of p38 by ATP-competitive small molecules has led to the generation of a variety of novel p38 inhibitors as potential therapeutics for the treatment of inflammatory conditions including Crohn's disease, COPD, psoriasis, and RA.[31–35]

The p38 MAP kinase family belongs to serine/threonine protein kinases and consists of four isoforms: α, β, γ, and δ. These kinases show a high degree of sequence homology, with 60–75% overall sequence identity and > 90% within the kinase domain.[36] The p38β kinase is the closest structural homologue to p38α, sharing 75% overall sequence identity, and close to 90% in the ATP-binding site. In general, p38 α and β kinase inhibition values parallel each other, and both isoforms are ubiquitously expressed. The α-isoform, however, is better characterized in terms of its role in inflammation.

Activation of the p38 MAPK signaling pathway also leads to the production of anti-inflammatory cytokines such as IL-10, activation of negative feedback loops initiated by the phosphorylation of transforming growth factor β-activated kinase-1-binding protein, and upregulation of MAP kinase phosphatases that dephosphorylate and inactivate p38 kinase, ERK, and JNK.[37–39] These multiple positive and negative pathway components highlight the complex feedback mechanisms that could limit MAPK activation to prevent excessive inflammation.[30]

8.16.2.1 Small-Molecule p38 Clinical Candidates for Inflammatory Indications

In the past two decades, the pharmaceutical industry has invested tremendous resources into research and development for p38 MAPK inhibitors resulted in the discovery of a variety of inhibitor classes with diverse molecular architecture.[32,34,40] A wide variety

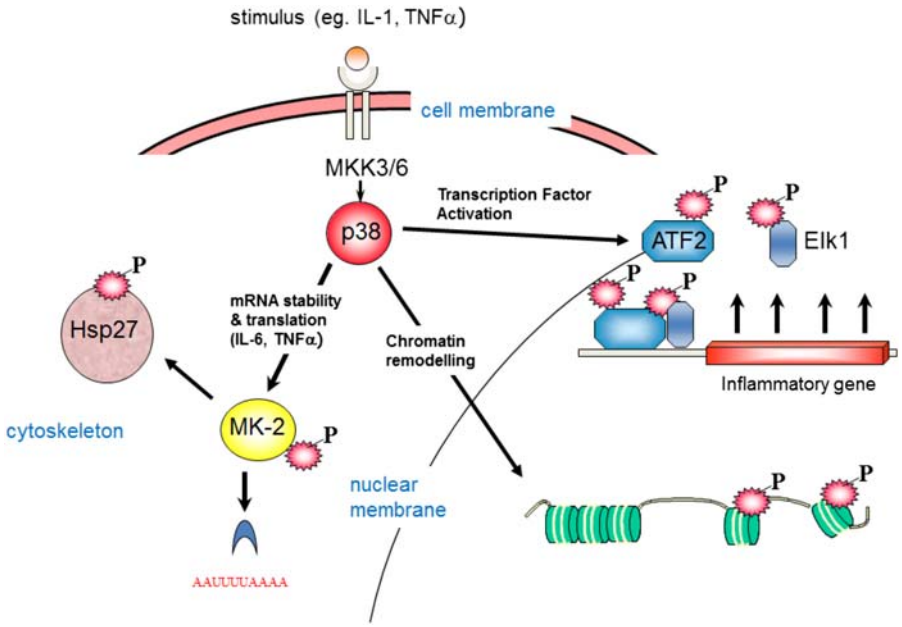

Fig. 1 The p38 MAPK as a central locus in inflammatory pathways.

of autoimmune disease treatments were attempted in clinical setting including rheumatoid arthritis, inflammatory bowel disease, psoriasis, systemic lupus erythematosus (SLE), and other indications like chronic obstructive pulmonary disease (COPD) that are characterized by chronic inflammation. Herein, we review the major advancement into human clinical studies in the field of p38 inhibition (Fig. 2) alongside the discovery of the most recent clinical p38 inhibitors within Pfizer.

The pyrimido-pyridazinone (VX-745) and pyridinyl-urea (VX-702)-based compounds were discovered by Vertex Pharmaceuticals.[41,42] In human whole blood, a cellular system that mimics the physiological *in vivo* milieu, LPS-stimulated TNF-α and IL-1β

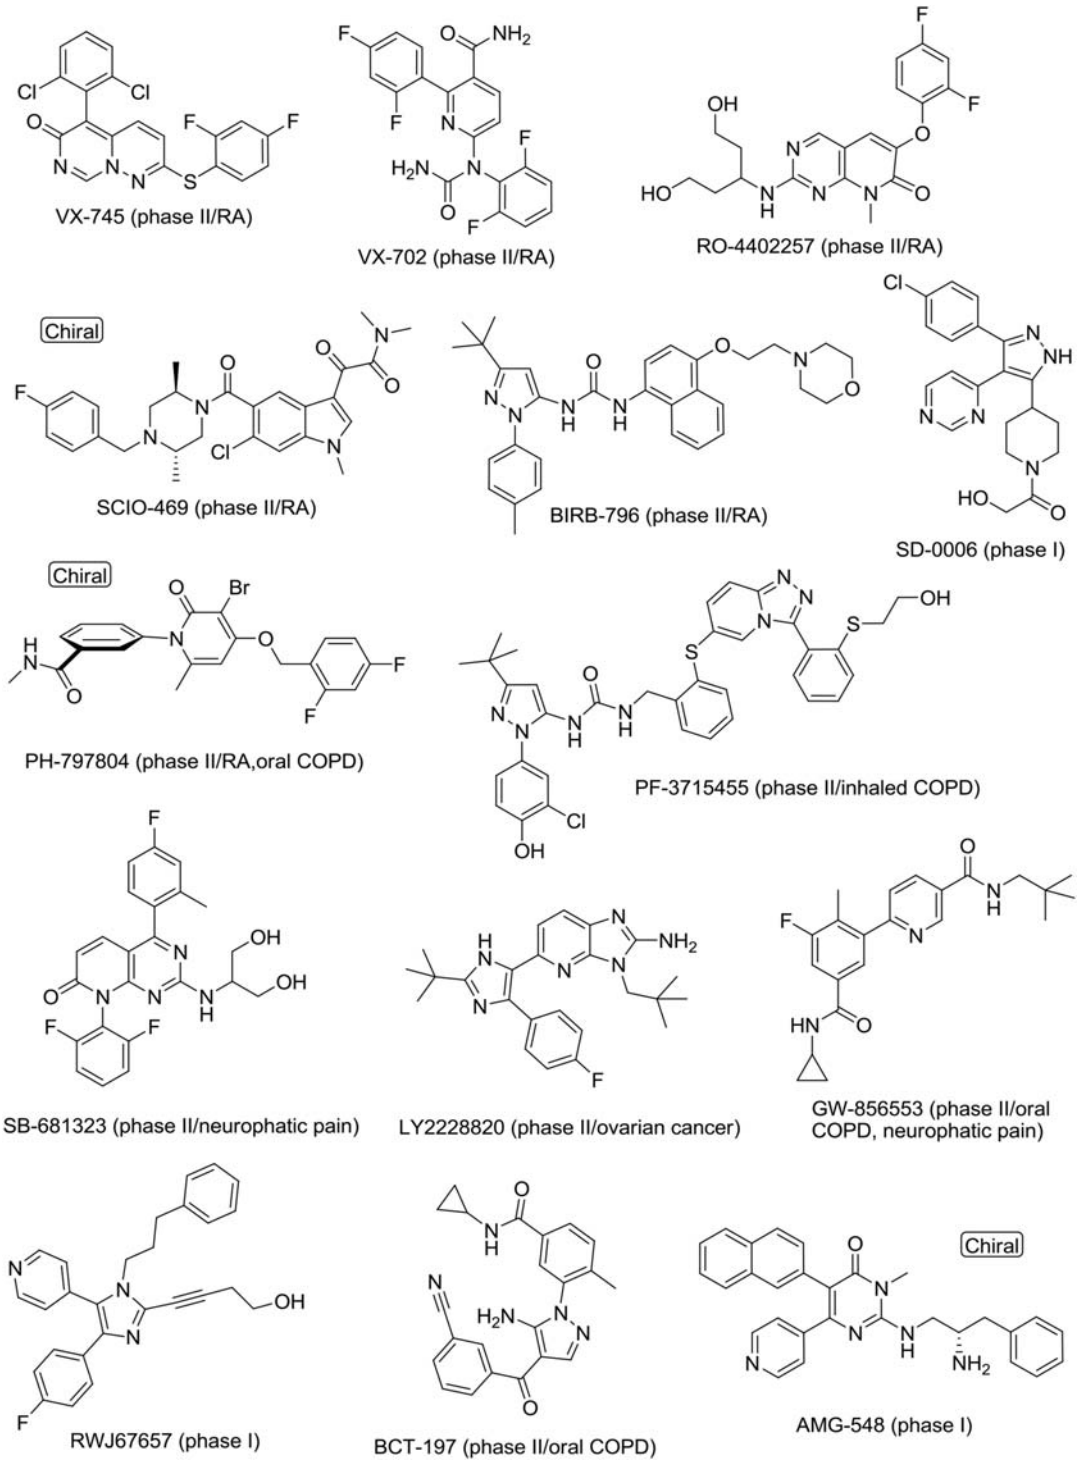

Fig. 2 Clinical candidates of p38 MAPK inhibitors along with their intended indications.

production were measured. VX-745 inhibits p38α and LPS-TNF-α in human whole blood (hWB) at IC_{50}'s of 5.0 nM and 700 nM, respectively. In RA patients, VX-745 was well tolerated and produced significantly higher ACR20 response rate than placebo (43% vs. 8%). However, further trials were suspended after neurological effects were observed in dogs. With much lower penetration of the blood–brain barrier, VX-702 was chosen as a backup to VX-745.[43] Two clinical trials were completed in the third quarter of 2007, one with VX-702 as a single agent in RA patients and the other phase II study as a once daily (QD) medicine in combination with methotrexate for three months.[44] In both studies, the ACR20 response rates among patients did not reach statistical significance. Reductions in the levels of C-reactive protein were observed as early as week 1, but the levels rapidly returned to baseline values by week 4.

SCIO-469 (talmapimod) was advanced to phase II human clinical trials for the treatment of rheumatoid arthritis, myelodysplastic syndrome (MDS), and acute dental pain.[45–49] It is a selective p38α inhibitor with >1000-fold selectivity versus ERK2, JNK1, and LCK. It potently inhibits p38α at enzyme level (IC_{50}: 9 nM) and moderately inhibits LPS-induced TNF-α production in human whole blood (IC_{50}: 300 nM).[50,51] Oral SCIO-469 administered at doses ranging from 90 to 360 mg daily was tolerated with common adverse events in MDS patients. Bone marrow and cytogenetic responses were rare, suggesting low likelihood of SCIO-469 at the tested dose levels having any disease-altering activity. In RA patients dosed at 30, 60, and 100 mg daily, no significant differences in ACR20 responses were found between SCIO-469 and placebo. Declines in C-reactive protein (CRP) and erythrocyte sedimentation rate during early treatment did not persist. Pharmacokinetic analysis demonstrated no statistically significant correlation in SCIO-469 average plasma trough concentrations with change in CRP values.

While most inhibitors of p38α bind only in the purine site, with p38α remaining in a "DFG-in" conformation, BIRB-796 binds at a site that extends into a "selectivity pocket," that is not used by ATP, displacing the Asp168-Phe169-Gly170 (DFG) motif at the start of the activation loop and promoting a "DFG-out" conformation.[52]

An inhibition in solution assay (ISA) measured K_D of BIRB-796 for nonactivated p38α to be <0.8 nM.[53] DFG-out compounds associate with p38α over 30-fold more slowly than purine site compounds (k_{on}: $0.85 \times 10^5\ s^{-1}\ M^{-1}$, k_{off}: $8.3 \times 10^{-6}\ s^{-1}$), apparently due to low abundance of the DFG-out conformation. At concentrations that inhibit cellular production of an inflammatory cytokine, TNF-α, selectivity pocket compounds decrease levels of phosphorylated p38α and β. In the *in vitro* and *in vivo* experiments, BIRB-796 inhibits all p38 MAPK isoforms.[54] By binding to a different conformation of the enzyme, compounds that prevent activation were believed to offer an alternative approach to modulation of p38α.

Out of a series of diaryl pyrazole-based inhibitors, SD-0006 was identified as a potent and selective compound for p38α and b MAP kinases over 50 other kinases screened including p38γ and p38δ.[55,56] In the mouse collagen-induced arthritis (mCIA) model, equivalent efficacy was shown to anti-TNF antibody treatment.[57] SD-0006 demonstrated good oral anti-inflammatory efficacy and cross species correlation between the rat, cynomolgus monkey, and human. Its development has been discontinued after phase I study in human healthy volunteers.

RO-4402257 (pamapimod) is a selective inhibitor of the α-isoform of p38. It inhibited p38α and p38β enzymatic activity, with IC_{50} values of 14 and 0.48nM, respectively, but showed no activity against p38δ or p38γ isoforms.[58] In murine collagen-induced arthritis, RO-4402257 reduced clinical signs of inflammation and bone loss at 50 mg/kg or greater. In a clinical study in patients with active RA, RO-4402257 was administrated as monotherapy in comparison with methotrexate (MTX).[59] After 12 weeks of daily therapy at one of the three doses (50, 150, or 300 mg), no clear evidence of efficacy was demonstrated. Intriguingly, the level of C-reactive protein (CRP) initially declined in the 300-mg patient group but rapidly returned to baseline at the second week and remained over the rest of the study period. Typical adverse findings are liver enzyme elevation and/or skin rash.[59,60]

In a randomized, placebo-controlled study in chronic obstructive pulmonary disease (COPD) patients, SB-681323 (dilmapimod) was given orally at single doses of 7.5 and 25 mg and shown to inhibit the p38 MAPK pathway via biomarker pHSP27 measurement and the TNF-α production.[61] In a separate trial, to evaluate the effect of dilmapimod on neuropathic pain symptoms and signs following nerve injury, 43 patients received twice daily doses at 15 mg/day for two weeks. Dilmapimod was well tolerated, with no clinically relevant safety findings. The average daily pain score was reduced with statistical significance during the second week of treatment among patients compared to placebo.[62]

GW-856553 (losmapimod) is a potent p38 MAPK inhibitor of both α (Ki: 8.1 nM)- and β (Ki: 7.6 nM)-isoforms.[63] A post hoc analysis based on a 6-month clinical study demonstrated reduction of exacerbations with the 15 mg twice daily dose in the subgroup of COPD patients with blood eosinophils 2% at baseline.[64] To fully support further clinical development, the findings need to be explored in a prospectively designed study in a COPD population. Identification of a subgroup of patients more likely to respond to treatment is a step toward personalized medicine by offering effective therapy to specific populations of high unmet need. GW-856553 was also evaluated in patients with chronic neuropathic pain, but the analgesic efficacy was not clinically meaningful.[65] Additionally, GW-856553 suppressed inflammation in patients with cardiovascular disease and improved vascular function.[66–68]

BCT-197 (acumapimod) is being developed by Novartis as an oral agent for COPD. From patent application, the compound inhibits p38α with an IC_{50} value of less than 1 μM.[69,70] In COPD patients, BCT-197 was evaluated at single dose of 20 and 75 mg with and/or without prednisone. The ongoing development is expected for regulatory filings in 2018. No further clinical trials in COPD patients have yet been disclosed. A phase II study was also performed in acute renal patients undergoing cardiac surgery, but development for that indication appears to have been terminated.

Using p38α immunoprecipitated from LPS-activated human monocytes, the IC_{50} of RWJ67657 was measured at 30 nM.[71] The compound inhibited the production of TNF-α and IL-1β by LPS-stimulated human PBMCs, with IC_{50} values of 3 and 11 nM, respectively. In the single-dose first-in-human (FIH) study, the terminal half-life of RWJ67657 was determined to be in the range of 5.1 to 7.7 hours.[72] The apparent clearance was proportional and decreased with increasing doses. The inhibition of

TNF-α, IL-6, and IL-8 was reported in a dose-dependent manner.[73] At the maximum dose of 1400 mg, reduction in peak serum levels of the proinflammatory cytokines exceeded 90%. Furthermore, RWJ67657 demonstrated potential in treating endocrine-resistant breast cancer.[74] Utilizing well-established xenograft tumor models, RWJ67657 exhibited potent antitumor properties, markedly decreasing tamoxifen-resistant tumor growth.

Following on to SD-0006, the lead generation and optimization efforts led to the identification of a novel pharmacophore **PH-797804** as a clinical candidate for RA and COPD.[75–79] First identified by molecular modeling and subsequently confirmed by chiral chromatography, **PH-797804** is the more potent atropisomer (aS) of a racemic pair.[75] In biochemical assays and other assays, **PH-797804** demonstrated high potency ($K_i = 5.8$ nM) and superior selectivity across broad human kinase genome.

In addition to treating autoimmune and the related disorders, LY2228820 dimesylate (Ralimetinib) is being investigated in a clinical trial in patients with ovarian cancer. The compound potently inhibited p38 α- and β-isoforms *in vitro* (IC_{50}: 5.3 and 3.2 nM, respectively) and produced significant tumor growth delay in multiple animal cancer models.[80]

Several additional compounds were evaluated clinically for the treatment of chronic inflammatory disorders. These included BMS-582949, ARRY-797, and AMG-548.[81–83] Either their structures were not disclosed or there were very little clinical data reported.

8.16.3 Approaches to the Discovery of p38 MAPK Inhibitors

8.16.3.1 Structure-Based Drug Design

Structural information of p38α kinase is rich with more than a hundred published structures generated by x-ray crystallography over the past two decades. Besides a small number of unphosphorylated, apo structures, most of the three-dimensional structures are binary complexes of p38α kinase and small-molecule inhibitors that compete for binding with cellular ATP.[55,84–92] The kinase hinge recognition elements predominantly involve a hydrogen bond with the Met109 backbone NH group. Some inhibitors engage an additional hydrogen bond with the upstream residue His107 via its backbone carbonyl, strictly mimicking the donor–acceptor pattern of the nucleoside interaction of ATP.[93]

The ATP-binding pocket is situated at the folding cleft of the N- and C-lobes of the kinase, which are connected by the hinge region. Interactions are formed with the hinge backbone through potentially two hydrogen bonds: The adenine N1 of ATP is an acceptor pairing with the backbone NH of Met109, and the 6-amino group is a donor to the backbone Leu108 downstream of the gatekeeper residue Thr106. Effective interaction in the ATP-binding pocket that complements the topological and the electrostatic characteristics of the kinase hinge is essential for potent inhibition of protein kinases.[94,95] Such canonical p38α kinase conformation is represented by the apo p38α crystal structure in Fig. 3A.

In addition to the catalytically active conformations, the DFG-out arrangement constitutes one of the frequently encountered inactive kinase conformations.[96,97] When the specific classes of inhibitor molecules bind, the conserved Asp168-Phe169-Gly170 (DFG) motif at the beginning of the activation loop rotates out of the ATP-binding site, creating a new pocket that is inaccessible in the active kinase conformation. By exploiting the induced pocket, submicromolar p38α kinase inhibitors were achieved, sparing the conventional hinge interaction entirely.[93] BIRB-796 exploits this catalytically incompetent conformation of the p38 kinase, which was envisioned to afford its high degree of selectivity against other protein kinases.[52] The urea moiety of BIRB-796 forms bidentate hydrogen bonds with the catalytic Glu71, and the naphthalene group occupies the p38α hydrophobic pocket (Fig. 3B). Both interactions facilitate the DFG-out conformation.

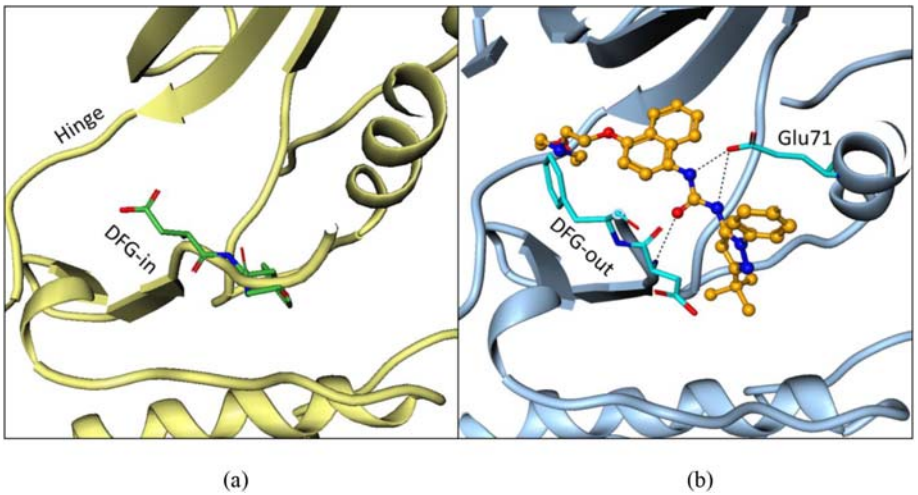

Fig. 3 The p38α kinase crystal structures. (A) Apo p38α showing DFG-in (Asp168-Phe169-Gly170) (PDB code: 1p38); (B) BIRB-796 binds to the DFG-out conformation of p38α kinase (PDB code: 1KV2).

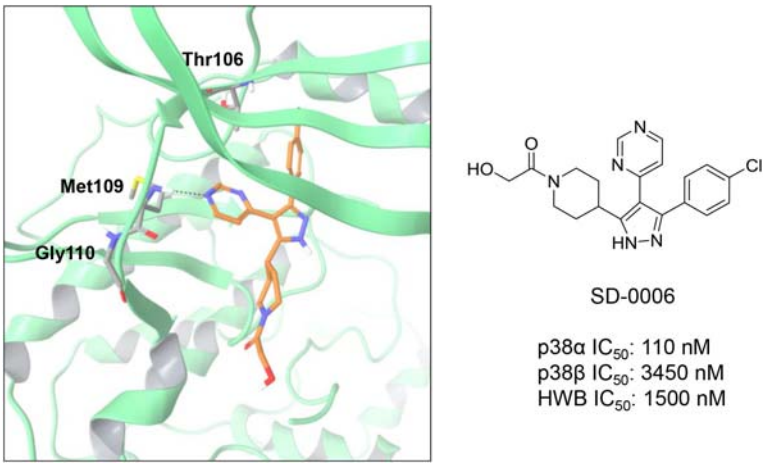

Fig. 4 Crystal structure of SD-0006 in p38α MAP kinase (PDB code: 3HL7).

8.16.3.2 First-Generation Pyrazole-Based Inhibitors

From high-throughput screening (HTS), a novel series of C(5)-substituted diarylpyrazoles were identified.[55] Following on, lead optimization identified pyrimidine to switch out the original pyridine at the C(4) position. The structure–activity relationships of the series were extensively explored with a focus on the various substituents at the C(5) position.[55,56] As this vector points to the opening cleft of ATP-binding site, it provided a handle to modulate the physicochemical properties of the compounds. SD-0006 was discovered out of the efforts. The pharmacokinetic experiments in both dog and rat indicated desirable properties in terms of half-life (rat and dog $t_{1/2} = 5–6$ hours) and bioavailability (>80% in both species).

The pyrazole group of SD-0006 serves as a central framework that helps to optimally position the two aromatic groups in the ATP-binding site of p38α kinase (Fig. 4). Crystal structure represented by SD-0006 has revealed a number of binding elements. One edge of the pyrazole moiety is stabilized by interactions with the flexible glycine flap that contains the consensus GXGXXG motif. One of the nitrogen atoms of the pyrazole ring directly interacts with the carboxylate side chain of Asp168. The 4-pyrimidine overlaps with adenine of ATP binding and forms conserved hydrogen bond with the hinge of p38α via Met109. The 4-chlorophenyl group binds in the lipophilic pocket of p38α. Overall, the binding of SD-0006 did not in any significant way perturb the native conformation of the apo p38α structure.[84,85]

8.16.3.3 Second-Generation Pyridinone-Based Inhibitors

The N-benzylpyridinone template was identified as a key feature for novelty and selectivity from the high-throughput screening hit SC-25028.[76] While its activity against p38α kinase was modest ($IC_{50} \sim 0.7$ μM), an early evaluation of selectivity against a panel of 48 kinases revealed that SC-25028 was very selective for p38, with less than 30% inhibition at 10 μM against the entire panel.

The crystal structure of SC-25028 bound to p38α kinase highlighted the key structural features associated with its binding mode.[76] In comparison with the earlier biaryl pyrazole-based structure, SC-25028 not only retained the conserved elements of binding to p38α kinase in the conventional kinase inhibition mode but also demonstrated unique structural features (Fig. 5).

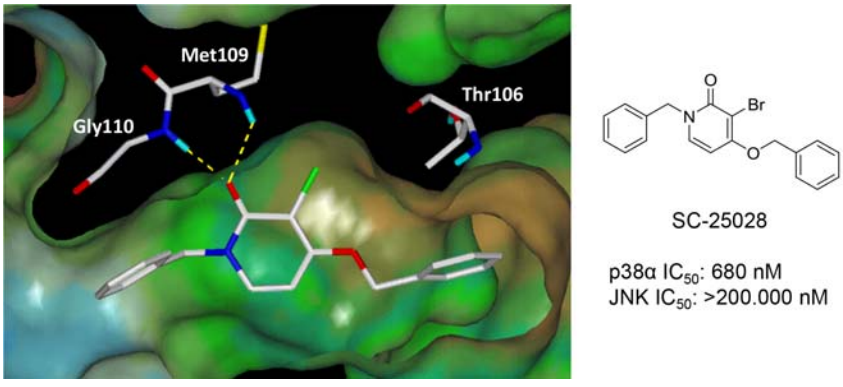

Fig. 5 Crystal structure of SC-25028 in complex with p38α kinase (PDB code: 3HP2).

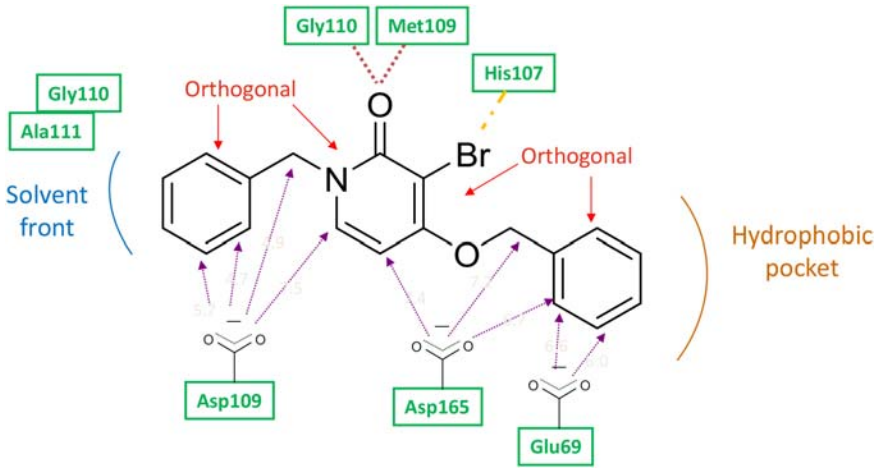

Fig. 6 Ligand–protein interaction map of SC-25028 chemical series.

A dual hydrogen bond to the backbones of Met109 and Gly110 was observed, which requires a peptide bond flip of Gly110. Devoid of a side chain, Gly110 uniquely furnishes the required flexibility for the conformational switch. The bromine atom uniquely forms a favorable halogen bond interaction (3.1 Å) with the backbone carbonyl of His107. The benzyloxyl group occupied the lipophilic pocket, and the N-benzyl group was directed toward the opening of the folding cleft. The two-dimensional schematic of the protein–ligand interaction pharmacophores of the chemical series represented by SC-25028 is delineated in Fig. 6.

8.16.3.4 Structural Hypothesis of Human Kinome Selectivity

Despite modest p38α activity of the initial hit, we postulated that the pyridinone class of compounds exhibits superior selectivity for p38 MAP kinase over other kinases, thanks to the TXXXG sequence motif on the kinase hinge. This was derived from the two characteristics of the binding interactions: (i) The hydrophobic encapsulation in a pocket that is distinct from phosphate binding of ATP, gated by Thr106, (ii) and the bidentate hydrogen bonds with Met109 and Gly110 requiring a peptide bond flip into the conformation that is only available for a glycine residue. The backbone flip occurs in p38α due to the presence of the glycine in the hinge region, which has no side chain and consequently affords necessary structural flexibility to be induced for a conformational flip. The flipped backbone conformation is prohibited by any residues other than a glycine due to their side chain presence.

Thr106 sits at the gatekeeping position that circumscribes access to the p38α aryl pocket. Its important role was substantiated by a number of site-directed mutagenesis studies.[98–100] Residues bearing side chains larger than threonine would temper the access to the aryl pocket. We mined the TXXXG motif in the human genome consisting of 518 protein kinase complements. The sequence profiles at the equivalent positions of Thr106 and Gly110 of p38α were plotted in Fig. 7. The analysis reveals

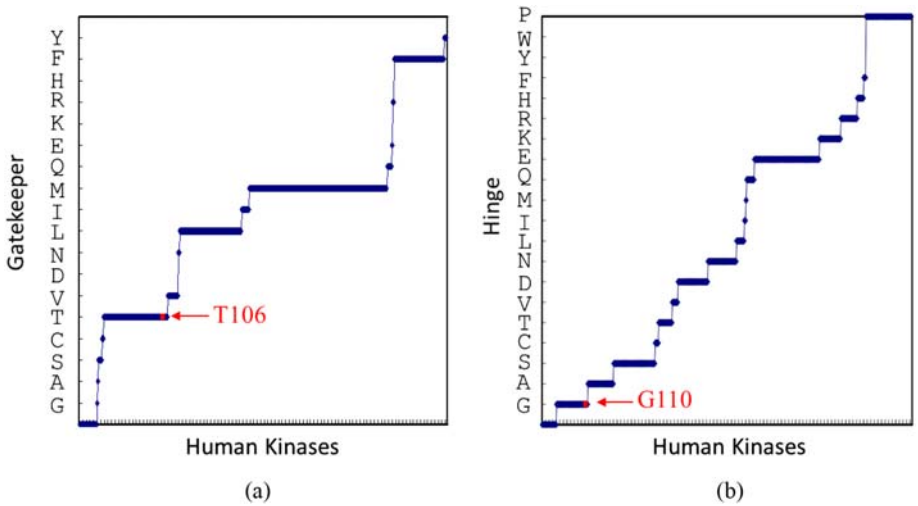

Fig. 7 Amino acid frequencies of the human kinome at positions corresponding to p38α kinase Thr106 (a) and Gly110 (b).

that 99 kinases or 20% of the kinome have threonine or an equivalent residue (cysteine, serine, alanine, and glycine) of similar or smaller side chain in place of Thr106. Likewise, 44 kinases share a glycine residue at the position corresponding to Gly110, which constitute 9% of the human kinase genome. The combined TXXXG motif is sparingly conserved in three kinases, p38α, p38β, and Myt-1 specifically. We thus derive a structural rationale for the observed high level of selectivity. Myt-1 is a mixed serine/threonine and tyrosine kinase upstream of CDKs. Its kinase domain is merely 23% identical to p38α in primary structure. Cross-reactivity is not anticipated for the pyridinone class of compounds due to the remote evolutionary relationship between Myt-1 and p38α kinase. Understanding the implication of such structural features to the desirable potency and specificity that can be achieved by a drug-like small molecule has paramount importance for targeting p38α kinase as a therapy for many chronic autoimmune disorders.

8.16.3.5 Structure-Guided Lead Optimization

Metabolic stability of SC-25028 was recognized as a primary liability as revealed by the human liver microsomal assay,[98–100] with only 52% of the parent compound being detected after incubation of 45 minutes. We believed that the two unsubstituted aromatic rings were most likely to be the site of oxidative metabolism. Efforts to increase metabolic stability were focused on halogen substitution to reduce the electron density in the rings, which also provides a steric block at certain positions. This strategy produced 10-fold potency improvement, largely owing to the augmented hydrophobic interaction via the 2,4-difluorobenzyloxy group in the deep selectivity pocket of p38α (compound 1, Fig. 8). Based on the SAR of halo substituted benzyloxy groups, it was concluded that the 2,4-difluorobenzyloxy group was optimal for potency.[76] In addition, N-debenzylation could be a potential contributor to the observed high clearance. In order to block oxidative cleavage of the C-N bond of N-benzyl moiety, the N-phenyl group was attempted. A series of N-phenyl pyridinone derivatives were prepared and evaluated for their activity, selectivity, *in vitro* stability, and pharmacokinetic profiles. The investigation led to the generation of 2 (Fig. 8), a potent and selective p38 kinase inhibitor that is stable in both the human and rat liver microsomal assays. Its ligand efficiency (LE) is comparable to SC-25028. JNK2 activities were measured as a tool to evaluate the potential for kinase selectivity. Consistent with the selectivity hypothesis, the compounds of the series remained inactive against JNK2.

Molecular modeling comparing the binding conformations using the overlaid models revealed that the N-benzyl and N-phenyl moieties superimposed closely in three-dimensional space (Fig. 9). Both aryl systems aligned in a parallel orientation to the peptide bond connecting residues Gly110 and Ala111. In such organization, the aryl rings are oriented in an orthogonal conformation with respect to the pyridinone to favor the ligand–protein interaction. Based on this observation, it was anticipated that rigidifying N-phenylpyridinone in its unbound state would reduce the entropic loss and yield a net gain in binding free energy. This was accomplished by installing orthosubstituents on both the phenyl and the pyridinone rings.[78] Further optimization produced the highly selective and potent clinical candidate **PH-797804**.

8.16.3.6 PH-797804 is the More Potent Atropisomer

Guided by the strategy of introducing orthogonality into the N-phenylpyridinone template, two methyl groups were installed onto the orthopositions. Due to steric constraints imposed by the pyridinone carbonyl and the 6,6′-methyl substituents, the rotation

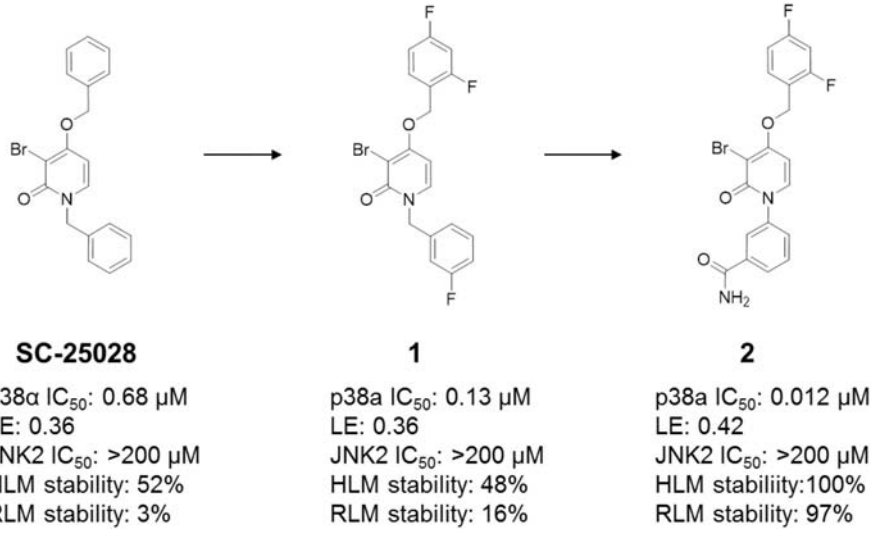

Fig. 8 Progression of lead optimization upon initial HTS hit.

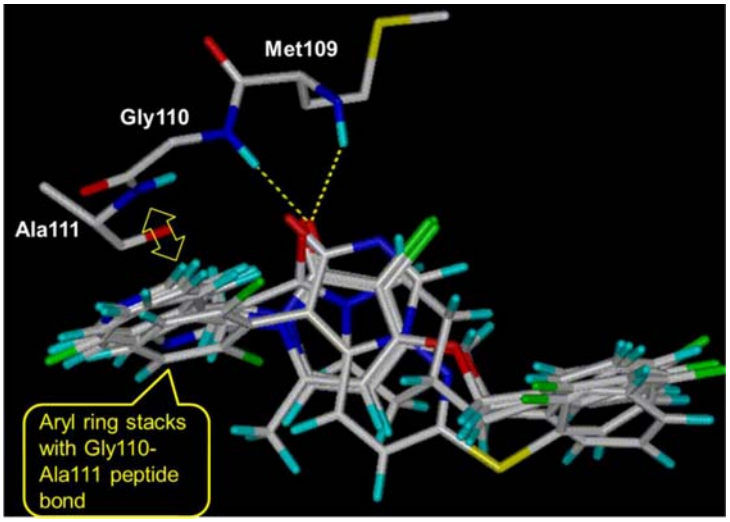

Fig. 9 An overlay model of p38 compounds showing consistent stacking interaction between the aryl ring of ligands of different chemotypes and the amide moiety of Gly110-Ala111.

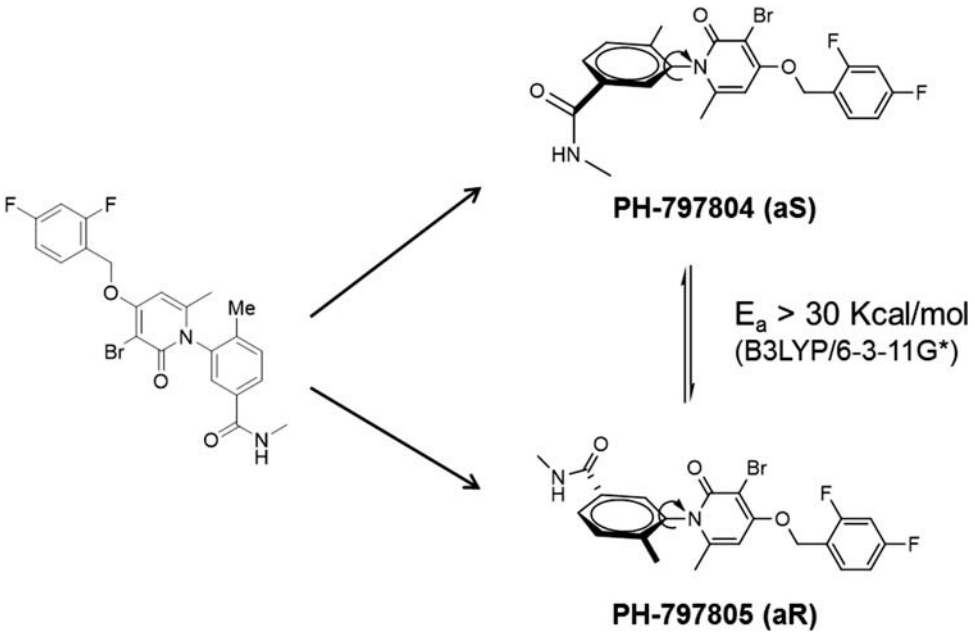

Fig. 10 **PH-797804** and **PH-797805** are the atropisomers of a racemic pair.

around the connecting bond of the pyridinone and the N-phenyl ring is restricted. This gives rise to discrete conformational spaces of N-phenyl pyridinone group, and as a result, two atropisomers do not interconvert under ambient conditions (Fig. 10). Molecular modeling predicted that the two isomers should differ in their binding affinity to p38α kinase. Whereas the atropic S isomer (aS) binds favorably, the opposite aR isomer incurs significant steric interferences with the p38α kinase.[79] Subsequently, chiral chromatography identified and separated the two isomers. Upon chiral separation and small-molecule x-ray diffraction experiment, it was confirmed that the more potent atropisomer (**PH-797804**) is the aS isomer of the racemic pair. The IC_{50} values from the p38α enzyme assay confirmed that **PH-797804** is 26 nM, whereas the off-isomer PH-797805 is more than 100-fold less potent (IC_{50}: 1800 nM). MAP kinase-modulated cytokine production (LPS-stimulated TNF-α and IL-1β) in whole blood was inhibited with comparable 26-fold differences in IC_{50} values by **PH-797804** (85 nM) and PH-797805 (4600 nM). Taking into account the inhibitor protein binding in the whole blood, the cellular potency of **PH-797804** correlates well with its inhibition of recombinant enzyme activity.[79] Extensive pharmacological characterization corroborates that **PH-797804** carries most activity *in vitro* and *in vivo* and possess high level of specificity across the broad human kinase genome.

8.16.4 Characterizations of PH-797804

8.16.4.1 *In Vitro* Activity

The average enzymatic competitive inhibition constant (K_i) of **PH-797804** for p38α kinase is 5.8 nM. Determined by ligand exchange reaction, the on-rate (K_{on}) and off-rate (K_{off}) values for **PH-797804** are 1.53x107 $M^{-1} \cdot s^{-1}$ and 0.058 s^{-1}, respectively, demonstrating reversibility along with rapid association and dissociation kinetics. The corresponding $t_{1/2}$ value for dissociation was 12.6 s.[101]

In monocytes, LPS-stimulated production of both TNF-α and IL-1β was inhibited by **PH-797804** in a concentration-dependent manner, with an IC_{50} value 3.4 nM for each cytokine. In human monocytic U937 cell line, LPS-stimulated TNF-α production was inhibited with an IC_{50} value of 5.9 nM. The p38 kinase activity was inhibited with an IC_{50} of 1.1 nM as measured by immune complex kinase assay of the downstream kinase MK-2. In contrast, no inhibitory effect was observed on either the JNK pathway (c-Jun phosphorylation) or ERK pathway (ERK phosphorylation) in U937 cells at concentrations up to 1 M.[75]

In addition to modulating inflammatory cytokine production, **PH-797804** also regulates COX-2 induction and PGE2 production. After treating with **PH-797804,** complete concentration-dependent inhibition of PGE2 production with RASF stimulation was observed (IC_{50}: 1.5 nM).[101]

8.16.4.2 Kinase Selectivity Screening

PH-797804 was extensively tested against several kinase screening panels for its off-target activities.[75] Over a hundred kinases have been screened, and **PH-797804** was found completely selective with no off-target signal.

The selectivity windows are greater than 500-fold compared with the primary target p38α kinase. In cellular assays, **PH-797804** demonstrated superior potency and selectivity consistent with biochemical measurements.[75] In addition, from our kinome mining, Myt-1 was identified as one of the three kinases that conserve the TXXXG motif. Myt-1 is a mixed serine/threonine and tyrosine kinase upstream of CDKs. Despite its low sequence identity to p38α, **PH-797804** was measured in an enzymatic assay developed at Pfizer. A marginal inhibition of 14% at 10 μM concentration confirmed the exceptional selectivity of **PH-797804**.

8.16.4.3 Crystal Structure of PH-797804 Bound in p38α Kinase

Fig. 11 illustrates binding interactions of **PH-797804** that are consistent with the other analogs of the pyridinone series.[75] The pyridinone carbonyl oxygen of **PH-797804** forms two hydrogen bonds, one with the amide nitrogen of Met109 and the other with the backbone NH group of Gly110. The 2,4-difluorophenyl group of **PH-797804** is encapsulated in a lipophilic pocket of p38α kinase, completely shielded from the solvent. The contour of the pocket appears to be thoroughly complementary to the halogenated phenyl ring of the inhibitor, from which a major portion of the binding free energy is derived as suggested by modeling studies. This hydrophobic pocket, unoccupied by ATP, appears to be the anchor point for the positioning and orientation of p38α kinase inhibitors of diverse chemical scaffolds. The gatekeeper residue Thr106, sitting at the entrance, thus controlling the access to the pocket, therefore is of essential importance to the binding affinity of p38α inhibitors.

In **PH-797804**, the 6,6′-methyl substituents and the pyridinone carbonyl together render the N-phenyl ring orthogonal to the pyridinone core. The density functional theory (DFT) calculation yielded a torsion angle of 76.2 upon full optimization (B3LYP/3-21G*), which suggests that in the minimum-energy state, the 6′-methyl derived from the N-phenyl ring is tilted slightly toward the pyridinone carbonyl. Upon binding to p38α kinase, **PH-797804** demonstrates a dihedral angle of 103.2, with the 6′-methyl tilting toward the 6-methyl off the pyridinone. The orthogonality of the N-phenyl pyridinone appears to be instrumental

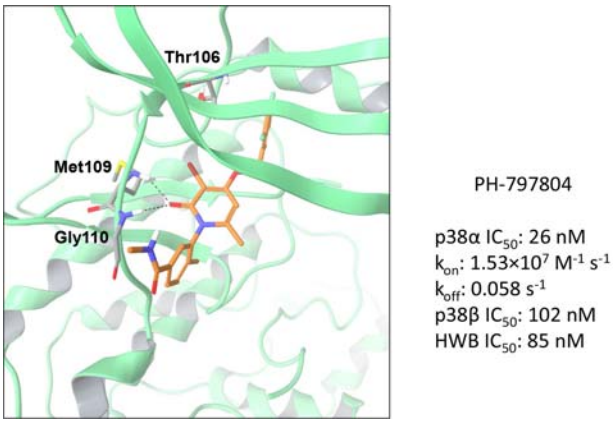

Fig. 11 Crystal structure of **PH-797804** bound in p38α kinase (PDB code: 3HLL).

to the inhibitory activity against p38α kinase, which strengthened the hydrogen bond acceptor of pyridinone oxygen and the stacking interaction with the p38α kinase hinge.

8.16.4.4 Rotational Barrier, Chemical Stability, and Pharmaceutical Properties

The interconversion rate of the atropisomers is an important consideration for the pharmaceutical development of a single enantiomer as a clinical candidate. Quantum mechanics theory was applied early on to determine the rotational energy barrier between the atropisomers. In the torsional scan experiments, the rotation around the bond connecting the pyridinone group and the N-phenyl ring was driven in both forward and backward directions to reveal possible hysteresis. The complete torsional profile was obtained by B3LYP/LACV3P level of theory, exhibiting two lowest energy conformers corresponding to **PH-797804** and PH-797805 (Fig. 12). Strain energies increase as the bond torsion deviates from the lowest energy states. The activation energy of isomeric interconversion is predicted to be greater than 31 kcal/mol, predicting a half-life of more than 100 years at ambient conditions for **PH-797804**.

At elevated temperatures, the relative amounts of each isomer were measured by HPLC in aqueous media and various solvents including dimethylfuran and toluene. Very little interconversion, typically $<1\%$, was observed over a period of two to four days. The highest interconversion was detected at 110 °C in toluene: $\sim 6\%$ after two days. Additional stability measurements were conducted in aqueous media for comparison of temperature effects. Two samples were taken from the single fraction collection in the preparation of PH-797805, characterized with a purity of $>99\%$. One sample was heated at 79 °C with a 90 °C bath. After 55 hours, it showed 97.1% enantiomeric excess, corresponding to $<1\%$ conversion into **PH-797804**. The other sample was maintained at 37 °C, and no change was detected after the same period of time. It is therefore concluded that racemization does not occur under the conditions tested.

The separate atropisomers are stable at ambient conditions during storage. The compounds were stored either in the solid state or as solutions in ethanol or acetonitrile. No loss in optical purity was observed at room temperature for at least three weeks. Furthermore, in preclinical pharmacokinetic studies and in *in vivo* efficacy models using various animal species, no isomeric conversion of **PH-797804** has been observed.

Consistent with the theoretical prediction, extensive pharmaceutical characterization has established the chemical stability of the conformationally restricted p38α inhibitor **PH-797804**. As a result, a chiral process was developed to support the preclinical and clinical development of **PH-797804**.

8.16.4.5 Pharmacokinetic Properties of PH-797804

The solubility of **PH-797804** was measured at <5 μg/ml in pH 7.0 phosphate buffer at room temperature. The intrinsic solubility remained the same given that no ionization in the physiological pH range was detected. The permeability of **PH-797804** was measured in Caco-2 studies from the apical to basolateral phase, ranging from 10×10^{-6} cm/s at 1 μM to 25×10^{-6} cm/s at 100 μM. **PH-797804** was determined to be a weak substrate of P-gp at projected clinical doses (efflux ratios <2.5).

Nonclinical pharmacokinetic studies of **PH-797804** were conducted in male Sprague–Dawley rat, male beagle dog, and male cynomolgus monkey, and all studies were conducted using crystalline compound. Based on these studies, **PH-797804**

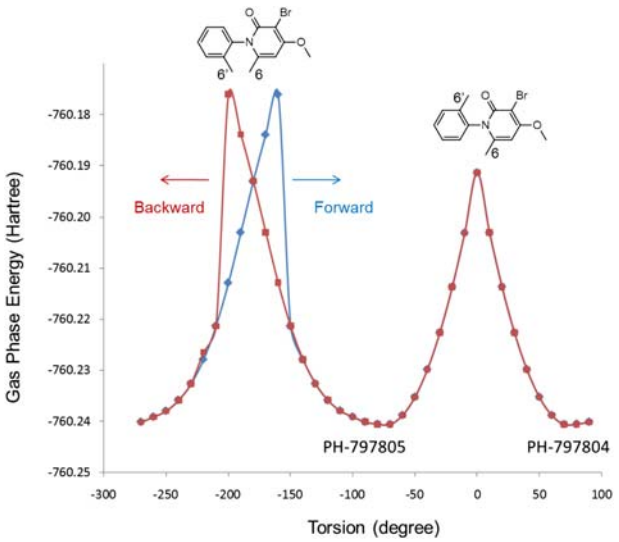

Fig. 12 Rotational profile of the model system by DFT B3LYP/LACV3P theory. Separate drives in forward and backward directions revealed hysteresis in transition along the 6,6'-Me phase.

has low plasma clearance and low to moderate volume of distribution resulting in half-lives of 2.60–3.86 h in rat and 11.4 and 3.93 h in dog and monkey, respectively. Moderate oral bioavailability was observed in monkey (23.2%) and rat (35.7–40.5%) when **PH-797804** was dosed orally as a milled suspension. Bioavailability in monkey increased to 36.2% after an oral solution dose, and the bioavailability of an oral solution dose in dog was 59.6%. Bioavailability in rat increased to 80.4% and >100% when **PH-797804** was dosed at 15 and 2 mg/kg, respectively, as oral solutions, which was consistent with dissolution limited absorption.

8.16.4.6 *In Vivo* Efficacy of PH-797804

The dose–response analysis demonstrated disparate efficacies for the two atropisomers in the acute *in vivo* model. LPS-induced TNF-α production in rats allowed evaluation of oral efficacy for inhibition of an acute inflammatory response.[101] Treatment of rats with **PH-797804** resulted in dose-dependent inhibition of LPS-induced TNF-α production, yielding an ED_{80} value of 0.3 mg/kg. In comparison, the ED_{80} for PH-797805 is greater than 10 mg/kg. **PH-797804** and PH-797805 have essentially the same pharmacokinetic properties (95% remaining in the rat metabolic stability assay); hence, the difference observed *in vivo* can be primarily attributed to translation from their *in vitro* activities.

The ability to suppress chronic inflammation was evaluated in an inflammatory arthritis model in rats induced by streptococcal cell wall (SCW) extract. The SCW model is characterized by an acute phase of inflammation from day 1 to day 5, followed by a more severe and chronic phase of bone destruction that occurs from day 10 to day 21. A role for TNF-α and IL-1β in the chronic phase has been demonstrated with neutralizing TNF-α and IL-1 antibodies. **PH-797804** was highly effective in attenuating SCW-induced inflammation. Untreated control rats exhibited profound joint inflammation from day 10 to day 21. **PH-797804** treatment resulted in dose-dependent inhibition of paw swelling when administered daily with an $ED_{50}$of 0.186 mg/kg. In comparison, PH-797805 required a daily dose of about 40 mg/kg to produce the half maximal efficacy. The potency and efficacy demonstrated by **PH-797804** provided sufficient rationale to advance it as a viable human drug candidate.

8.16.5 Designing Inhaled Inhibitors of p38α

In contrast to the requirements for successful oral drugs, highlighted in the discovery of **PH-797804**, delivery by inhalation requires a compound to demonstrate features that should deliver high local efficacy, allied to high systemic clearance and low oral bioavailability.[102–104]

These include (i) high potency to drive a low inhaled total dose, as current delivery options limit practical delivery of doses to approximately 1 mg of active pharmaceutical ingredient, (ii) low oral absorption and high clearance of any swallowed component to minimize systemic exposure, (iii) multiple routes of clearance to mitigate the risk of significantly increased exposure due to drug–drug interactions (DDIs), and (iv) physical characteristics suitable for a dry powder formulation, which includes crystallinity, melting point greater than 125 °C to allow for successful milling, and compatibility with lactose as the most commonly used inhaled excipient.

In addition to minimizing systemic exposure, features that facilitate an extended pharmacodynamic duration of action (DoA) in the lung, such as slow pharmacological dissociation (k_{off}) from the target, may be beneficial to drive local efficacy for inhaled drugs (Fig. 13).

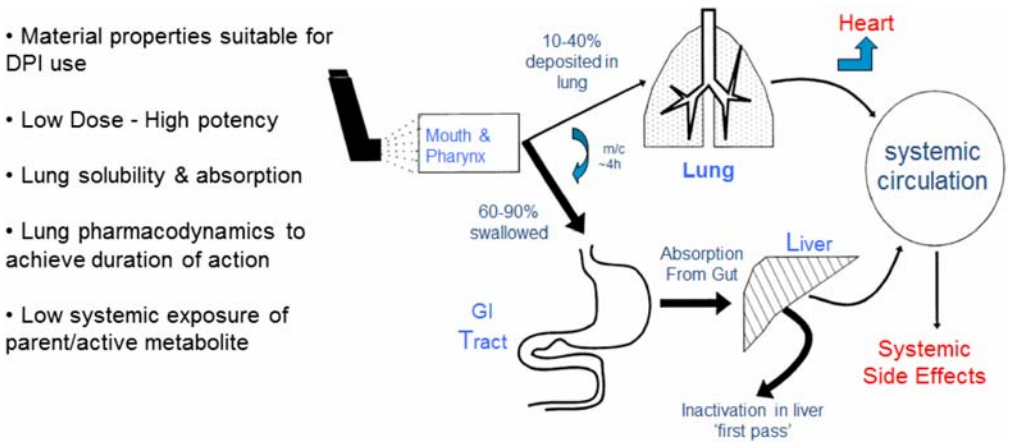

Fig. 13 Features associated with 'inhalation by design'.

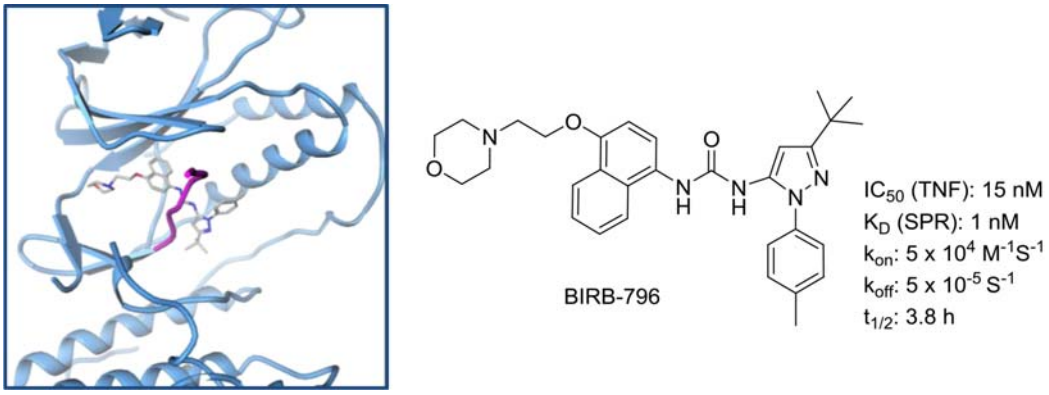

Fig. 14 BIRB-796 bound to p38α and kinetic binding parameters determined by SPR.

8.16.5.1 DFG-Out Conformation of p38

The reports of the oral p38 inhibitor **BIRB-796**[105] and, most importantly, its (then) novel mode of binding to p38 in a DFG-out conformation (Fig. 14), resulting in a slow onset/slow offset binding profile, suggested that leveraging this feature could deliver novel p38α inhibitors with excellent properties for inhalation through structure-based drug design.

The slow k_{on} and slow k_{off} rates observed with **BIRB-796** could be rationalized on the basis of the x-ray crystallography structure. For **BIRB-796** to bind to p38α, the activation loop (highlighted) containing the residues Asp168 (**D**)-Phe169 (**F**)-Gly170 (**G**) must undergo a movement of ~10 Å. The kinetics of this loop movement, allied to the affinity for the binding site thus created, dictate the rates of association and dissociation between the enzyme and inhibitor in this DFG-out binding mode.

Once the DFG-out conformation is obtained, a large lipophilic pocket is created, which can accommodate the arylpyrazole moiety of **BIRB-796**, driving a high affinity lipophilic interaction. The slow k_{off} then requires the DFG loop to move again and dissociation of the high affinity ligand.

8.16.5.2 Design to Target the DFG-Out Conformation of p38

Targeting the DFG-out conformation, therefore, appeared to be a very attractive strategy for the design of potent, lipophilic, long-acting p38α inhibitors for inhalation.[104]

Intriguingly, analogs containing an ATP-binding moiety allied to a urea substituent, exemplified by compound **CE-159167** (Fig. 15), had been identified from one of our oral p38α inhibitor programs and have been cocrystallized in p38α in the DFG-in conformation. In keeping with this binding mode, these compounds had been shown to display fast k_{on} and k_{off} rates, as determined by surface plasmon resonance (SPR).[104]

The overlay of a DFG-in structure of **CE-159167** with the DFG-out structure of **BIRB-796** in p38α (Fig. 15) highlighted several intriguing features including the following: (i) The urea groups of **CE-159167** and BIRB-796 are aligned perfectly, (ii) the N-2 and N-3 of the triazolopyridine group in **CE-159167** stabilize the unusual Gly110 flip in the hinge region of the ATP hinge site, and (iii)

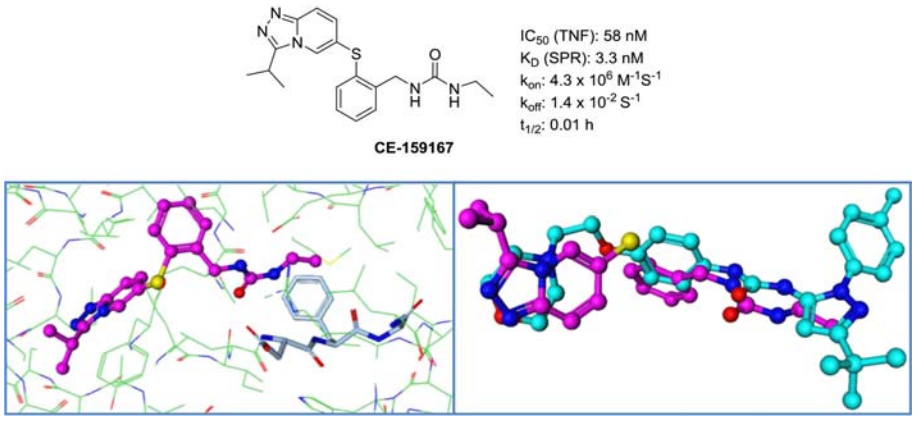

Fig. 15 Hybridization potential of a Pfizer DFG-in lead **CE-159167** (magenta) with BIRB-796 (cyan) in its DFG-out conformation.

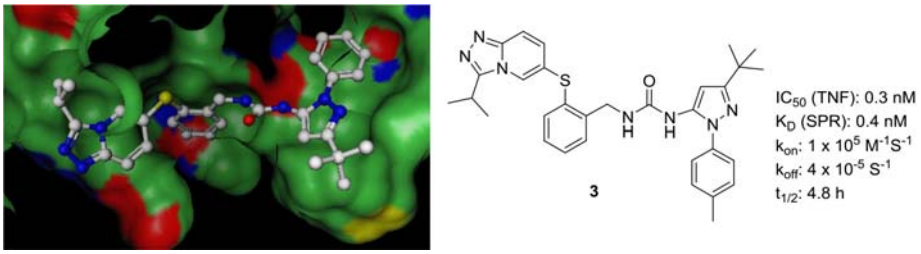

Fig. 16 Structure, binding kinetics, and crystal structure of lead 3 in p38α kinase.

the phenyl ring of **CE-159167** interacts with the gatekeeper residue (Thr106) and overlays with the naphthalene ring system of **BIRB-796**.

This overlay suggested that a hybrid between compounds **CE-159167** and **BIRB-796** could deliver a novel DFG-out binding inhibitor of p38α that would simultaneously engage the hinge, gatekeeper, and DFG-out pockets, displaying a similar slow k_{on}/slow k_{off} enzyme binding profile to that of BIRB-796. The hybrid compound **3** (Fig. 16) did, indeed, prove to be a very potent p38α inhibitor with slow k_{on}/k_{off} binding kinetics akin to those of BIRB-796.[104]

To obviate any issues from the slow k_{on} and k_{off} rates in our primary screening data, we used a cell-based assay, with a preincubation period, to profile target compounds for their ability to inhibit TNF-α production from LPS-stimulated human isolated peripheral blood mononuclear cells (PBMCs).

8.16.5.3 Lead Optimization of DFG-out Binders

With a promising lead (**3**) in hand, we sought to optimize the pharmacokinetic and pharmaceutical properties for inhalation while maintaining the high levels of potency and selectivity achieved.

Targeting high hepatic clearance, by multiple clearance pathways, was important for minimizing systemic exposure following absorption through the lung and absorption from the gut for any swallowed component of the dose. Ensuring that any metabolites produced lacked significant activity versus p38α was also a major design consideration.

While oxidative phase I metabolism was a clear design focus, we also sought to mitigate any potential for increased systemic exposures driven by CyP450-mediated drug–drug interaction (DDI) potential, by introducing handles for phase II, conjugation-based metabolism. Glucuronidation is a well-characterized phase II metabolic pathway that has high capacity and provides rapid drug inactivation via the polar glucuronide metabolites produced.[106]

The cocrystal structure of compound **3** in p38α (Fig. 17) highlighted several opportunities to incorporate suitable functionality to facilitate both phase I and phase II metabolism in order to achieve our desired clearance profile.

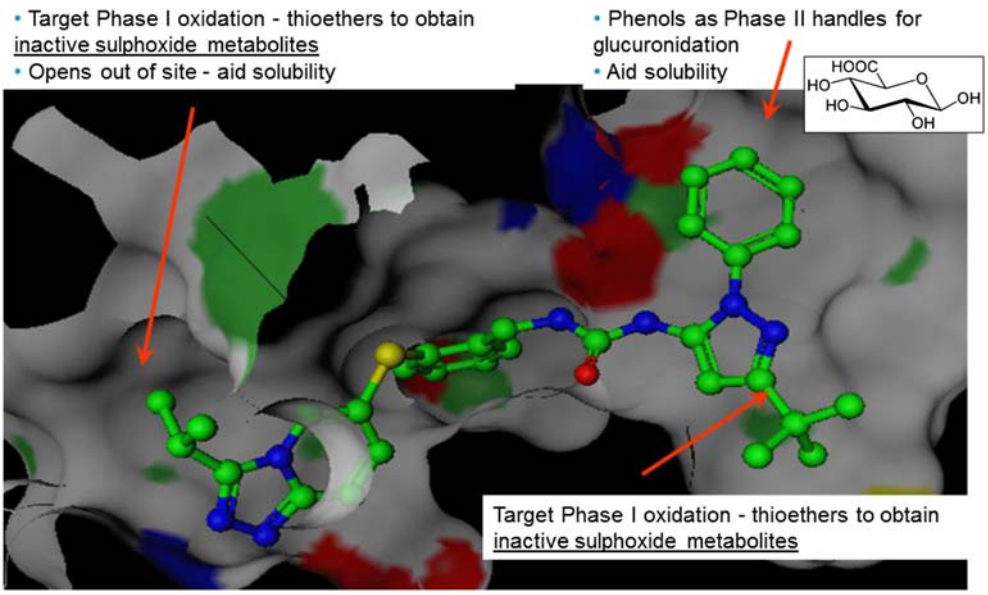

Fig. 17 Specific targeting of sites for metabolic soft spot design.

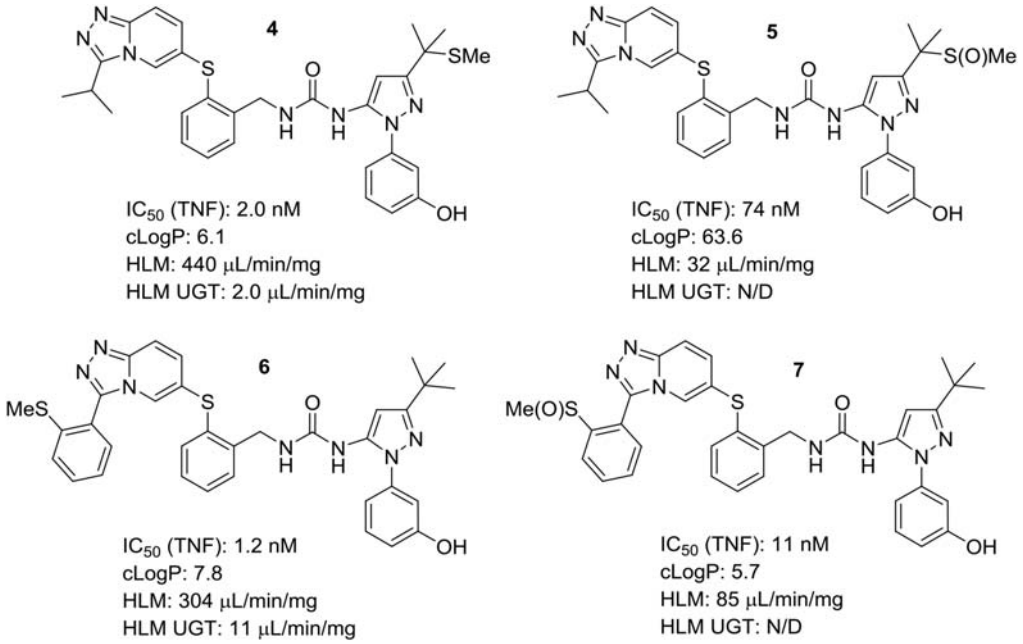

Fig. 18 Thioether-derived inhibitors of p38α targeting phase I metabolism.

8.16.5.4 Design Phase I Metabolism

Both the tert-butyl pyrazole and triazolopyridine isopropyl substituents in **3** occupy very lipophilic portions of the binding pocket. Introduction of a substituent vulnerable to phase I oxidative metabolism within these regions should direct metabolism toward the production of a more polar metabolite at these sites, with significantly reduced affinity for p38α.

The central thioether linkage already present in **3** could have also served this purpose effectively, as the likely polar sulfoxide and sulfone derivatives in the position were completely inactive versus p38α. The highly hindered nature of the linkage, however, completely obviated metabolism at this position in any of our *in vitro* hepatic systems.

As depicted in Fig. 18, introduction of a thiomethyl group into the tert-butyl pyrazole motif led to compound **4**, which demonstrated good potency and further increases in phase I metabolic liability. Moreover, the sulfoxide primary metabolite (**5**) displayed a significant (>30-fold) reduction in activity versus p38α.

Similarly, introducing a thiomethyl group into the triazolopyridine isopropyl substituent led to compound **6**. Again, compound **6** demonstrated good potency and high levels of phase I metabolic liability. The sulfoxide primary metabolite (**7**) also displayed > 10-fold reduction in activity versus p38α.

8.16.5.5 Design Phase II Metabolism

Weakly acidic phenols are well documented to undergo rapid glucuronidation.[106] The N-phenyl ring of the arylpyrazole moiety in **3** binds into an open and hydrated area of the DGF pocket and, therefore, seemed a suitable place to introduce phenolic substituents, with confidence that binding potency could be maintained.

Indeed, the introduction of phenol substituents in both the para- and metapositions of the N-aryl group, in **8** and **9**, respectively, retained potency, relative to **3**, and high levels of phase I metabolism were demonstrated in HLM systems by both compounds (Fig. 19).

When we assessed the phase II glucuronidation profile of both **8** and **9**, however, in HLM (by including the cofactor UDPGA and excluding the cytochrome P450-dependent cofactor NADPH), we did not observe appreciable levels of turnover, suggesting that both compounds were only substrates for phase I metabolic pathways. The acidity of the phenol groups was increased by approximately two units by flanking with an orthochlorine atom, leading to compounds **10** and **11** with pK_a values of 7.6 and 7.5, respectively. In both cases, potency versus p38α was enhanced slightly, relative to the analogous phenols. Moreover, high levels of metabolism were demonstrated both in *in vitro* HLM and HLM-UGT systems, indicating good potential for high clearance by phase I and phase II pathways from these orthochlorophenol derivatives.

In addition to exploring the structure-based incorporation of metabolic handles, we also used the cocrystal structure of **3** as the basis to explore whether we could incorporate flexible groups at the triazolopyridine isopropyl substituent in order to break up crystalline packing and improve solubility. Toward this end, compounds like **12** were prepared and demonstrated equivalent

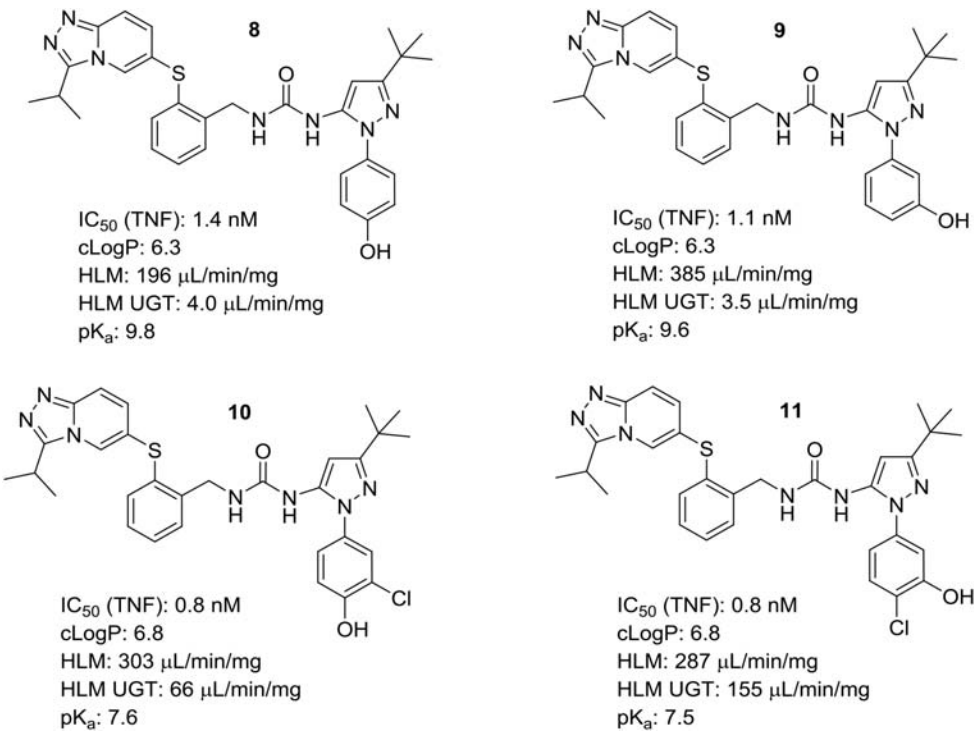

Fig. 19 Phenol-derived inhibitors of p38α targeting phase I metabolism.

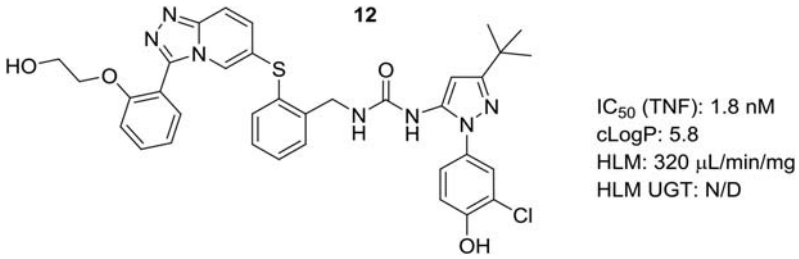
potency and metabolic profiles while also increasing solubility in simulated lung fluid (SLF), relative to direct analog compound **6**, into the range of 1.0 μg/mL (which was comparable to that of our benchmark, the inhaled corticosteroid fluticasone).



8.16.5.6 Identification of PF-3715455

Combining these features for potency, phase I and II metabolism and the enhanced SLF solubility increased solubility led to the discovery of our inhaled p38 inhibitor clinical agent **PF-3715455 (13)** (Fig. 20). Protein cocrystallization confirmed that compound **13** bound in the DFG-out mode in p38α as expected (Fig. 21).

Compound **13** is a very potent and selective inhibitor for the p38α enzyme, which translates into potent inhibition of proinflammatory cytokine release in whole cells relevant to COPD. Activity of **13** in the PBMC TNF assay (preincubation time of 1 h) was 1.7 nM, with the primary phase I sulfoxide metabolite (**14**) losing approximate 50-fold potency (no attempt was made to separate/identify sulfoxide stereochemistry in **14**).

The binding kinetics of **13** were determined versus the inactive/nonphosphorylated form of human p38α using SPR. The k_{on} and k_{off} kinetic parameters were observed, which suggested a K_D of approximately 1 pM and a half-life of approximately 80 h for binding to the inactive form of p38α. The mismatch between K_D generated for **13** from SPR binding kinetics and the biochemical IC_{50} from our PBMC assays likely reflects the fact that the cellular assay has not achieved equilibrium at the maximum 1 h time point that we used. These data suggest that **13** should provide optimal binding kinetics to overcome competition with high cellular levels of ATP and drive an extended cellular pharmacodynamics response following delivery to the lung.

Broad kinome profiling confirmed that **13** displays high selectivity, with IC_{50} at enzyme K_m for ATP of <1 μM for only 15 enzymes of the 205 recombinant kinases screened.[104]

Whole cell assays demonstrated that no whole cell activity was observed for three of these kinases, leaving p38β (SPR K_D: 23nM). This level of selectivity over p38β was not seen as a concern regarding potential for efficacy or to represent a safety liability.

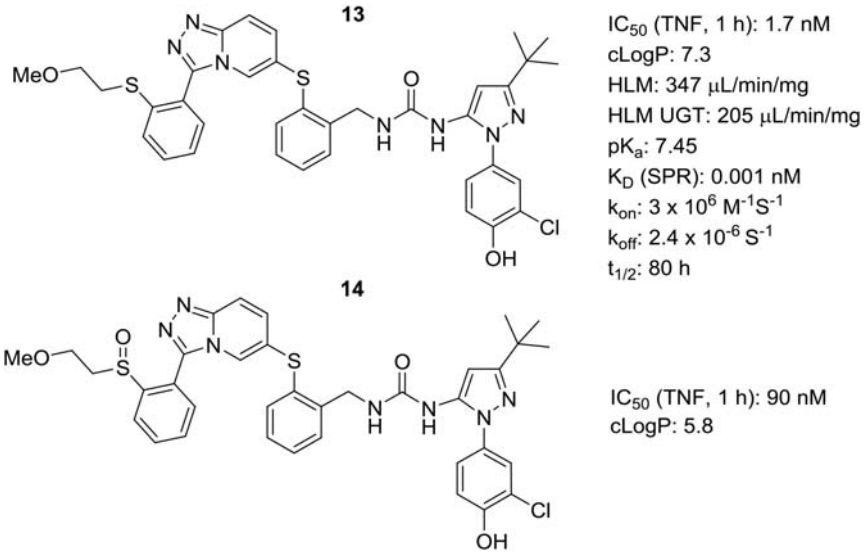


Fig. 20 **PF-3715455** (**13**) and its primary oxidative metabolite (**14**).

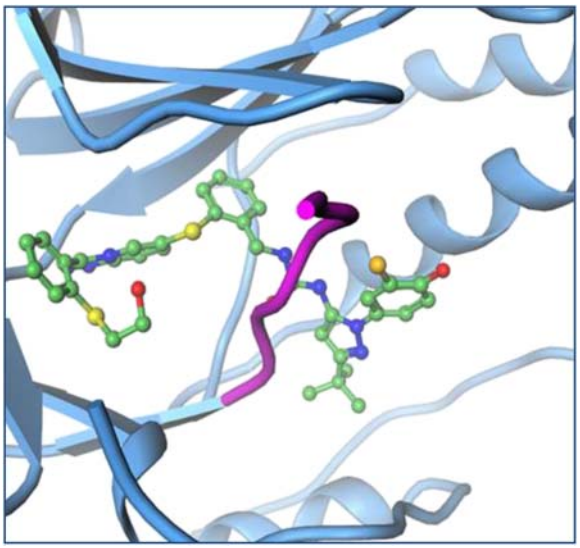

Fig. 21 Crystal structure of **PF-3715455** bound to p38α kinase.

In spite of their high molecular weight and very lipophilic nature, the crystallinity of compounds in this series had been confirmed by PXRD on a regular basis throughout optimization, and the pharmaceutical properties for **13** (clogP = 7.3, log D > 4.1) including crystallinity and stability on lactose were all assessed and considered suitable for dry powder inhalation.

Notably, solubility in simulated lung fluid (3.0 μg/mL) had been enhanced from previous members of the series through the inclusion of (i) the weakly acidic orthochloro phenol group and (ii) the flexible methoxy thioether substituent.

Key elements from the *in vitro* and *in vivo* pharmacokinetic analysis for **13** included (i) metabolite profiling from human hepatocytes to suggest that the glucuronide resulting from transfer to the chlorophenol is the major metabolite; (ii) coadministration of 2 μM ketoconazole (CYP3A4 inhibitor) in human hepatocytes, which did not lead to any significant reduction in intrinsic clearance, over the control incubations, suggesting that 13 should not be a victim of a DDI; and (iii) extremely high unbound clearance values of 33 and 15 mL/min/kg, following IV administration in rat and dog, respectively.

These data support our projections of low oral bioavailability in humans following any swallowed dose, coupled with very high intrinsic clearance for compound **13**. As such, any drug that reaches the systemic compartment would be expected to be cleared rapidly through conversion to inactive metabolites by both oxidative (phase I) and conjugation (phase II) pathways.

Finally, the preclinical safety profile of compound **13** suggests it would be tolerated in humans at clinically relevant inhaled doses.[104]

8.16.6 Highlights of Clinical Data for PH-797804 and PF-3715455

Historically, orally administered p38 MAPK inhibitors have been poorly tolerated in the clinic, eliciting side effects such as liver toxicity.[47] This is thought to be due, at least in part, to off-target polypharmacology driven by inhibitory effects on other closely related kinases.

The advent of highly selective oral p38α MAPK inhibitors, such as **PH-797804** and losmapimod, along with selective inhaled agents such as **PF-3715455**, which do not access the systemic compartment, is providing greater insight on the toleration and efficacy of p38 inhibitors in the clinic.

Lipopolysaccharide (LPS) inhalation in healthy subjects causes p38 activation in bronchial epithelial cells,[107] leading to the release of chemokines such as CXCL8 that promote neutrophil chemotaxis[108] and an influx of inflammatory cells into the airways of healthy subjects. The subsequent increase in the proportion of neutrophils observed in induced sputum should, therefore, be attenuated by drugs that inhibit p38 activation.

In three recent clinical trials, single doses of **PH-797804** (oral) and **PF-3715455** (inhalation) were administered to healthy subjects to explore the effect on neutrophilic lung inflammation in response to an inhaled LPS challenge. These studies aimed to provide mechanistic insights into the effectiveness of oral and inhaled p38 inhibitors in a human model of neutrophilic lung inflammation that is poorly responsive to current COPD medications such as corticosteroids. The effects of a single dose of an ICS (fluticasone propionate) in this model were also explored.[109]

Each study was a randomized, double-blind, placebo-controlled, single-dose crossover design. Study 1 used a 30 mg oral dose of **PH-797804**. Study 2 used a 30 mg oral dose of **PH-797804** with a 20 mg inhaled dose of **PF-3715455**. Study 3 used a 500 μg inhaled dose of fluticasone propionate. In each study, a baseline sputum sample was obtained within 14 days of the first dosing period when subjects were administered a single dose of randomized treatment. LPS challenge was administered 24 h after dosing with **PH-797804**/placebo in study 1. In study 2, inhaled LPS was administered either 24 h after dosing with **PH-797804** or 30 min after **PF-3715455**. In study 3, inhaled LPS was administered 30 min after dosing with fluticasone/placebo.

In studies 1 and 2, sputum supernatants were analyzed for interleukin 6 (IL-6), myeloperoxidase (MPO), monocyte chemotactic protein-1 (MCP-1), and macrophage inflammatory protein-1β (MIP-1 β). In study 3, sputum supernatants were analyzed for IL-6, MCP-1, and MIP-1β.

There was a statistically significant inhibition of the sputum neutrophil percentage post-LPS challenge caused by **PH-797804** compared to placebo in studies 1 and 2 ($p = 0.0096$ and 0.0001, respectively), with 15.1 and 15.3% reduction in mean sputum neutrophil percentage representing approximately 50% attenuation of the modeled LPS response. Study 2 also showed significant inhibition of sputum neutrophil percentage post-LPS challenge after administration of **PF-3715455** of 8.0%, which was approximately 25% attenuation of the modeled LPS response ($p = 0.031$). Sputum neutrophil percentage post-LPS challenge was not changed significantly by fluticasone propionate ($p = 0.55$).

Sputum supernatant cytokine levels were generally increased by LPS challenge in the placebo treatment period in all three studies. In study 1, **PH-797804** did not significantly inhibit cytokine levels compared with placebo, but there was evidence of trends toward significance for MCP-1 and MPO. In study 2, **PH-797804** significantly reduced IL-6, MPO, MCP-1, and MIP-1β levels compared with placebo. **PF-3715455** and fluticasone propionate had no effects on sputum cytokine measurements.

Efficacy has been achieved by **PH-797804** in moderate-to-severe COPD patients in proof-of-concept studies. The first phase II study of **PH-797804** demonstrated a clinically significant improvement in pulmonary function and dyspnea in 230 moderate-to-severe COPD patients.[110] In the double-blinded, parallel-group, multicenter trial, patients were randomized to orally receive placebo, 0.5, 3, 6, or 10 mg **PH-797804** once daily and treated for 6 weeks following a 2-week run-in. Compared with placebo, **PH-797804** showed statistically significant improvement in trough forced expiratory volume in 1 second (FEV_1) at 3 and 6 mg dosing regimens at week 6. **PH-797804** 3 mg and 6 mg also demonstrated improvement in the baseline dyspnea index/transition dyspnea index total focal score. An extended study evaluated **PH-797804** on top of salmeterol/fluticasone background.[111] Patients on stable does of ICS/LABA combination were randomized to receive either 6 mg of oral **PH-797804** or placebo once daily for 12 weeks. At 12 week, **PH-797804** demonstrated statistically significant improvement in trough FEV1 and the transitional dyspnea index. The hs-CRP level was consistently reduced throughout the dosing period.

In subjects with rheumatoid arthritis who are also taking methotrexate at stable dosage of 12.5-25 mg, **PH-797804** was evaluated for its safety, pharmacokinetic profile, and efficacy. The randomized, placebo-controlled study used 1 mg and 5 mg **PH-797804** orally administered once daily for 4 weeks.[112] Efficacy was demonstrated initially but was not sustained after two weeks. The decline of C-reactive protein (CRP) levels was also transient during the initial weeks of oral administration.

The difference in sustained efficacy that appears to be observed between the RA and COPD indications may reflect the different nature of the inflammatory response in the two diseases and continues to suggest that oral p38 inhibitors may yet deliver a medicine to treat COPD.

A number of competitive p38 kinase inhibitors have been reported to show anti-inflammatory efficacy in phase IIa studies of rheumatoid arthritis over the years, but their development has been terminated by the dose-limiting side effects of liver enzyme elevation and/or skin rash. **PH-797804** and **PF-3715455** are differentiated from the other p38 MAPK inhibitors by being generally safe and well tolerated in healthy volunteers, supported by their high level of potency, selectivity, biochemical efficiency, and/or extended lung retention. More importantly, in patients **PH-797804** was safe with a relatively low incidence of liver enzyme elevations (< 0.5%) and skin rash (< 10%). These observations are on the basis of five phase I studies and three proof-of-concept studies in rheumatoid arthritis, post-herpetic neuralgia, and/or COPD.

8.16.7 Conclusions

For the treatment of chronic diseases, small-molecule kinase inhibitors have to be highly specific in order to avoid unwanted effects caused by off-target inhibition. This is a high hurdle considering that the human kinome contains over 500 protein kinases sharing varying degrees of sequence homology. Structural insights into the unique p38 binding mechanism have guided discovery of several highly selective inhibitors. They advantageously engage the selectivity prerequisite encoded by the TXXXG sequence motif of p38α kinase. For **PH-797804**, its superior kinome selectivity is predicted by structural bioinformatics analysis and corroborated by large panels of screening assays.

The oral agent **PH-797804** was designed to be potent and selective for p38α, with an emphasis on (i) excellent selectivity, (ii) good pharmacokinetic parameters, and (iii) very low peak-to-trough exposure ratios, in order to deliver efficacy with a minimum potential for mechanism-driven side effects. The inhaled agent **PF-3715455** was designed to be potent and selective for p38α, with an emphasis on (i) slow enzyme association/dissociation kinetics to deliver prolonged lung inhibition of p38α allied to (ii) pharmacokinetic properties tuned to deliver very low oral bioavailability and (iii) pharmaceutical properties such as solid-form stability and crystallinity to ensure compatibility with a dry powder formulation for inhalation.

Both **PH-797804** and **PF-3715455** reduced neutrophilic airway inflammation after LPS challenge in healthy subjects. In contrast, inhaled fluticasone propionate at a dose of 500 μg had no effect. While inhaled delivery is often favored for respiratory drugs, as it increases lung compared with systemic exposure with the aim of increasing therapeutic pulmonary effects relative to systemic side effects, it appears that the increased systemic exposure of orally administered **PH-797804** provided superior pulmonary anti-inflammatory effects in these studies.[109]

Several compounds of different scaffolds blocking the p38 MAPK pathway have entered phase II clinical trials for RA patients.[46,59] They failed to demonstrate significant efficacy, showing early suppression of C-reactive protein (CRP) that was not sustained and often reversed by 2–4 weeks into the study. This suggests that other inflammatory pathways may have been upregulated in response to p38 blockade in RA.

The modest clinical efficacy and the transient suppression of biomarkers of inflammation observed in multiple studies suggest that p38 MAPK inhibition may not provide meaningful, sustained suppression of the chronic inflammation seen in RA. Inflammation acts along complex and overlapping pathways. Although p38α was originally proposed to carry predominantly proinflammatory functions, increasing evidence suggested that it also has crucial roles in tuning down inflammatory responses in specific cell types. It remains unknown whether compensatory upregulation of redundant or parallel pathways or autoactivation of the p38 signaling system may attenuate potential benefit of the investigational anti-inflammatory therapeutics.[113] Most of the clinical p38 programs have been terminated due to the lack of prolonged efficacy during the trial period of several months. They showed early suppression of C-reactive protein (CRP) that was not sustained and often reversed by 2–4 weeks into the study, hence failing to demonstrate statistically significant efficacy. The results suggest that other inflammatory pathways may have been upregulated in response to prolonged p38 blockade. The modest clinical efficacy and the transient suppression of biomarkers of inflammation observed in multiple studies suggest that p38 MAPK inhibition may not provide meaningful, sustained suppression of the chronic inflammation. It remains debatable whether it is preferable to combine inhibition of p38 with other targets in parallel inflammatory signaling pathways to achieve the desired efficacy in chronic inflammatory diseases. A mechanistic understanding of the clinical phenomenon would help direct efforts toward next generation of potentially promising therapies.

Acknowledgment

We acknowledge the work of colleagues on the p38 program teams over many years on the discovery and development of Pfizer p38 inhibitor clinical candidates. Compound **PH-797804** is commercially available via Sigma-Aldrich (catalog no. PZ0259).

8.17.1 Introduction

Rheumatoid arthritis (RA) is an inflammatory and degenerative autoimmune disease which affects approximately 1% of the adult population. All conventional concepts of therapy provided until now can influence the inflammation processes only in an inadequate manner and are linked to adverse side effects.

Biological agents (i.e., Infliximab (IFX), Adalimumab, Golimumab, Certolizumab, and Etanercept) that recognize and neutralize the inflammatory mediator tumor necrosis factor alpha (TNFα), also referred to as TNFα blockers, are also regarded as promising drugs for the treatment of other inflammatory diseases such as Crohn's disease, plaque psoriasis, psoriatic arthritis, and ankylosing spondylitis. However, these therapeutic strategies do not work successfully in some patients and moreover, these drugs are not administrable orally.

For other chronic inflammatory diseases such as asthma and chronic obstructive pulmonary disease (COPD), anticytokine treatment with, for example, IFX, has remained unsuccessful at doses that correspond to those applied for treatment of RA. The significantly higher costs are a significant disadvantage for the healthcare system when compared to the conventional concepts of therapy.

Based on both the safety issues and the extremely high costs of anti-TNFα therapy, we considered the significant advantages related to the development of orally active, small molecule drugs that target the specific signaling and synthesis pathways for TNFα by, for example, inhibition of p38α mitogen-activated protein kinase (MAPK) or phosphodiesterase 4 (PDE-4).

Available evidence suggests that additional benefits may be gained by combining the overlapping and complementary effects of p38α MAPK and PDE-4 inhibition in a single molecule, thereby offering the opportunity of a remarkably broad spectrum of multitargeted antiinflammatory activities.

8.17.1.1 Selective p38α MAPK Inhibition May Be Not Sufficient for Therapy of Inflammatory Disorders

Identified in the 1990s as a key enzyme for the regulation and expression of proinflammatory cytokines, such as TNFα, the protein kinase p38α MAPK has emerged as a treatment of inflammatory joint diseases as well as for other indications such as inflammatory bowel disease.

The family of p38 MAPKs, also known as stress-activated protein kinases, consists of four isoforms (α, β, γ, and δ), which are serine/threonine kinases with a molecular weight of 38 kDa being expressed in a tissue-specific manner. In general, there are three major signal transduction pathways involving MAPKs: the so-called extracellular signal-regulated kinase (ERK), the c-Jun N-terminal kinase (JNK), and the p38 MAPK pathway.

The p38 MAPK pathway regulates the synthesis of TNFα and IL-1β at both the transcriptional and the translational levels. In addition to the prevention of TNFα and IL-1β synthesis, inhibitors of p38α MAPK have been demonstrated to inhibit the production of nitric oxide as well as the expression of cyclooxygenase-2 and IL-6.

Furthermore, p38α MAPK has also been implicated in the regulation of IL-12 and interferon-γ, IL-4, and IL-10 gene transcription.[1]

Consequently, several drug candidates demonstrating potent inhibition of p38α MAPK in vitro also achieved significant antiinflammatory effects in various animal models. However, more than a dozen candidates failed in human phase II studies, for example, due to lack (or successive loss) of efficacy.

8.17.1.1.1 The p38 MAPK cascade

Under the effect of extracellular stimuli (e.g., mechanical stress, UV-radiation, oxidative stress, osmotic shock, hypoxia, proinflammatory cytokines such as IL-1/TNFα and lipopolysaccharide (LPS)), a concerted kinase cascade is set off, consisting of four hierarchically arranged levels (Fig. 1). The stimulus is relayed to an intracellular activator which, in turn, activates the MAP-kinasekinasekinases (MAP3Ks), such as ASK1, DLK1, TAK1, TAO, TPL2, MLK3, MEKK3/4, and ZAK. The MAP3Ks then activate the MAP-kinasekinases (MAP2Ks), such as MKK 3, 4, 6, and 7.

The p38 MAPKs are activated by the MAP2Ks via dual phosphorylation of the activation loop sequence Thr-Gly-Tyr. While both the MAP2Ks MKK3 and MKK6 are responsible for the activation of all four p38 MAPK isoforms, MKK4 specifically activates the isoforms 1 and 2 of the family of JNKs. Once being activated, the p38 MAPKs allow a swift and amplified response by activating a plethora of transcription factors and, in turn, activate downstream protein kinases and transcription factors that finally result in an increase of cytokine production, induction of apoptosis, leukocyte migration inflammatory responses, oxidative bursts, and degranulation. This complex signaling pathway allows redundancy and the development of escape mechanisms following chronic p38 MAPK inhibition.[1]

8.17.1.1.1.1 First generation antiinflammatory drugs

The p38α MAPK substrates MK2 and MK3 are particularly important in this inflammation pathway. This idea was demonstrated with knock-out mice which were insensitive to collagen-induced arthritis and much less sensitive to oxazolone-induced skin inflammation.

Encouraged by the idea of a possible decrease in the occurrence of adverse effects with simultaneously improved clinical safety, several companies initiated discovery programs for inhibitors with targets downstream of p38α MAPK. However, a recent review of publicly available data revealed no MK2 inhibitors involved in advanced stages of clinical development.[2]

In both in vitro models as well as in experimental in vivo arthritis models, p38α MAPK inhibitors effectively reduced or even completely suppressed the inflammatory events. Based on this knowledge, extensive research was undertaken for evaluation of new lead structures, identification of new target molecules, and for exploration of new synthetic strategies. Researchers at SmithKline Beecham (SKB) identified the mechanism of action of antiinflammatory pyridinylimidazoles as cytokine-suppressive

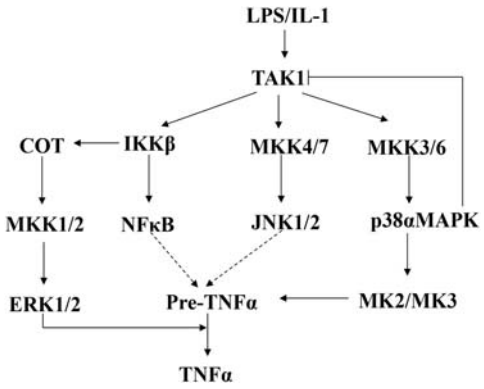

Fig. 1 Three major pathways lead to the activation of TNFα.[1]

antiinflammatory drugs and the resulting first prototype selective p38α MAPK inhibitor, SB203580 facilitated the experimental elucidation of various biological functions. However, clinical studies of this first generation p38α inhibitor revealed a dose limiting hepatotoxicity that may be due to interactions with the cytochrome P450 system.

8.17.1.1.1.2 Second generation antiiinflammatory drugs: Large variations in effectiveness against RA

The rationale for selecting p38α MAPK as a target for pharmacological intervention was based on the elucidation of its key role in the regulation of proinflammatory cytokine expression, the observations that p38α MAPK is highly activated in inflamed tissue from patients suffering from RA, inflammatory bowel disease, or COPD and on the demonstrated antiinflammatory efficacy of p38α MAPK inhibitors in experimental disease models which were associated with cytokine suppression.

Unfortunately, all p38α MAPK inhibitors that were advanced to clinical trials showed no effects that were superior to that of the placebo. Although the exact molecular mechanism behind this unexpected outcome has not yet been elucidated, p38α MAPK is generally no longer considered as a valid target for treatment of chronic inflammatory diseases.[2]

Highly potent and selective p38α MAPK inhibition could not provide efficacy and the treatment of chronic inflammatory diseases using p38α MAPK inhibitors remained unsuccessful. Despite excellent scientific rationale, it was shown that selective p38α MAPK inhibition was not sufficient for substantial long term TNFα inhibition due to the presence of various shunt or escape mechanisms.[1,3,4]

The failure of 22 p38α MAPK inhibitors in phase II/III RA studies demonstrated impressively the unforeseen lack of efficacy despite promising preclinical results.[5]

As described by Genovese: " … Finally, perhaps the most interesting science yet to be done will be that which yields a better understanding of why inhibition of this enzyme results in only a transient reduction in inflammation. Elucidating the cause of this phenomenon may yet help us understand how new classes of intracellular enzyme inhibitors may perform when they are evaluated in studies of inflammatory diseases."[6]

New approaches for the applicability of p38α MAPK inhibitors aim at indications that differ from RA, as well as distinct routes of administration, for example, treatment of COPD with an inhalative p38α MAPK inhibitor in contrast to the initial oral administration for RA treatment. Furthermore, in a shift of focus, the targets of p38α MAPK inhibitors have moved away from treatment of inflammation and toward the field of cancer. Recent research shows impressive results for the combination of Sorafenib with a selective p38α MAPK inhibitor in order to bypass the Sorafenib resistance of hepatocellular carcinoma which may be caused by an escape mechanism of the tumor via the p38α MAPK cascade.[7]

Additional approaches to overcome the aforementioned shunt or escape mechanisms that have developed out of p38α MAPK inhibition have been proposed. The cross-talk between the p38 MAPKs and the JNK or ERK-1/-2 pathway (**Fig. 1**) may offer a potential pathway of investigation. Both the JNKs and p38 MAPKs lead to the production of proinflammatory cytokines and thus enhance the inflammatory processes. One shunt and escape mechanism with reasonable impact on the failure of p38α MAPK inhibitors in clinical development is based on the overactivation of TAK1 which causes an overactivation of JNK pathways.[1–4]

Blockage of the p38 MAPK pathways leads to a positive feedback mechanism for JNK pathways. The intention to inhibit these bypasses gave rise to the idea that multitarget drugs inhibiting both key drivers of inflammatory processes may exhibit additive or even synergistic effects in vivo. Consequently, dual inhibitors of p38α MAPK and JNKs were developed and investigated. Deactivation of JNK3 and p38α MAPK provided neuroprotective effects as it resulted in complete rescue of primary striatal neurons from polyglutamine-expanded htt toxicity. Therefore, the design of dual JNK3/p38α MAPK inhibitors may be a promising strategy for treatment of, for example, Huntington's disease.[8]

In general, there has been a certain trend toward polypharmacology, even beyond the field of kinase inhibitors. In the words of Frantz, "Forget drugs carefully designed to hit one target, … a better way of treating complex diseases … may be to aim for several targets at once."[9]

8.17.1.1.2 Phosphodiesterase 4 (PDE-4)

The family of PDE-4 is cyclic adenosine phosphate (cAMP) hydrolyzing enzymes consisting of at least four subtypes (PDE-4 A, PDE-4 B, PDE-4 C, and PDE-4 D) which are primarily expressed in immune cells. They are involved in the regulation of a variety of cellular processes. The PDE pathway represents one of the most prominent mechanisms of degradation of cAMP, an important cellular second messenger. High intracellular concentration of the second messenger cAMP causes antiinflammatory signaling and thus, PDE-4 inhibition results in elevated intracellular cAMP levels which provide the antiinflammatory properties of PDE-4 inhibitors.

PDE-4 A and PDE-4 B are the predominant subtypes involved in inflammation. The role of PDE-4 C, with its very low expression levels, is unclear. The correlation of PDE-4 D inhibition with emesis is consistent with its expression in the brain and with knockout mouse studies that showed reduced or no emetic potential. Unfortunately, subtype selectivity for clinical PDE-4 inhibitors has not been reported by independent groups, thereby leaving a high level of uncertainty for the validity of this target.

Inhibitors of both p38α MAPK and PDE-4 have originally been considered as promising drugs for treatment of inflammatory disorders. In animal models PDE-4 inhibitors provided both bronchodilator and antiinflammatory effects. However, only a few PDE-4 inhibitors have reached approval with the most prominent examples being Roflumilast (Daxas EU, Daliresp US) in the treatment of a special subgroup of COPD affected patients and Apremilast (Otezla EU, US) in the treatment of psoriatic arthritis and severe plaque psoriasis.

Promising results from in vitro studies and experimental murine arthritis models suggested that Apremilast may also be effective for treatment of RA.[10]

In a phase II study, however, when Apremilast was administered at dose levels, which were efficacious in patients with psoriasis and psoriatic arthritis (20 mg b.i.d. and 30 mg b.i.d.) on top of a stable methotrexate treatment to patients with RA, no superior effect compared with placebo was achieved.[11]

As mentioned earlier, achievement of subtype selectivity of PDE-4 inhibitors has been a difficult task and thus, application of PDE-4 inhibitors is associated with nausea and emesis as major side effects. So far, for most of the developed PDE-4 inhibitors, the therapeutic window has not been large enough to achieve a significant clinical benefit at tolerated doses.[2]

In patients with asthma and COPD, TNFα, IL-1β, and IL-6 are found in increased amounts in the sputum and Bronchoalveolar lavage (BAL) fluid. Directly increasing the contractile response, TNFα acts directly on human airway smooth muscle. Furthermore, these cytokines amplify inflammation, in part through the activation of NF-κB, which leads to the increased expression of a number of inflammatory genes. However, treatment with biological TNFα blockers, such as IFX, produced relief in asthma patients, while COPD patients, in contrast, did not benefit from treatment with IFX when administrated at the doses that are effective in individuals with RA. An innovative and alternative strategy for treatment of airway inflammation is the application of small molecules with specific anticytokine action which interfere in cell signaling and thereby modulate the release of several cytokines.

In experimental models on airway inflammation, p38α MAPK inhibitors showed a significant effect whereas the results of in vitro experiments, which addressed the direct effect of the p38α MAPK inhibitors on the release of different cytokines were ambiguous. However, stimulation of macrophages from lung tissue and isolated monocytes from peripheral blood with LPS, p38α MAPK inhibitors significantly reduced expression and release of TNFα.[2]

Due to their lack of efficacy in RA and their emetogenic potential respectively, neither p38α MAPK inhibitors nor PDE-4 inhibitors met the high expectations as therapeutic targets for treatment of inflammatory disorders, when administered as monotherapy. However, the combination of PDE-4 inhibition with the antiinflammatory properties of p38α MAPK inhibition may be a successful approach. The conclusion that inhibition of p38α MAPK is not a valid strategy in chronic inflammation such as RA is based on the results of clinical phase II studies, in which the p38α MAPK inhibitor was administered either alone or in combination with Methotrexate (MTX). Surprisingly, except for a very few in vitro studies, the potential of p38α MAPK inhibition, when combined with a second mode of action, has never been systematically investigated.

This article reports the discovery of CBS-3595, a dual p38α MAPK/PDE4 inhibitor as well as the results of its evaluation in preclinical and phase I studies to elucidate this potentially synergistic antiinflammatory effect of dual inhibition of these two enzymes.

8.17.2 Chemistry: 1,2,4,5-Tetra-Substituted 2-Thioimidazoles: Preferred Templates to Target the ATP-Site of Protein Kinases

Starting from SKF-86002, initially reported as early as 1988, the reference compound SB203580 was developed as the prototypic p38α MAPK inhibitor with major off-target activity in the JNKs. This series of compounds were extremely valuable as tools and chemical probes, but suffered from CYP-450 interactions.[5] Fig. 2 shows the development of SB203580 and the tetrasubstituted 2-thioimidazoles from the early dihydrothiazoline-derived lead compound SKF-86002.

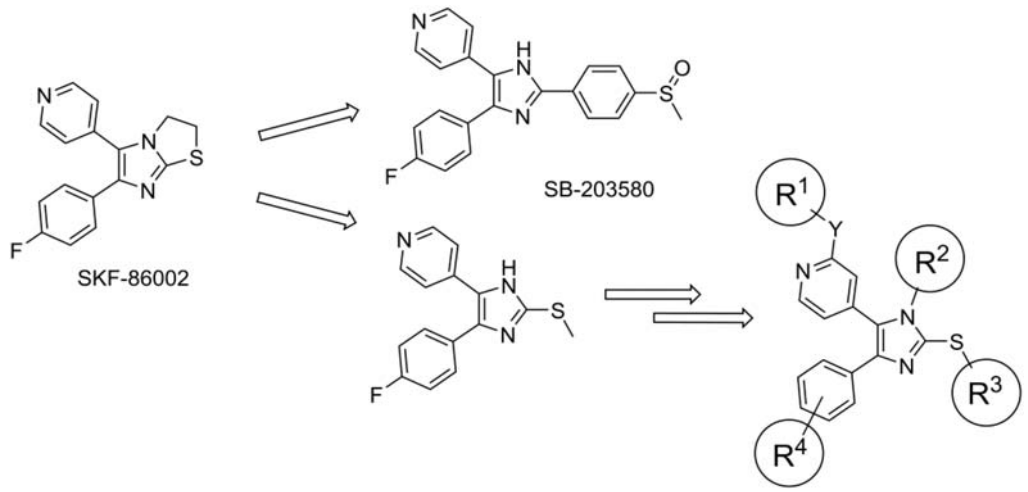

Fig. 2 Template development of tetrasubstituted 2-thioimidazoles from the Laufer Group.

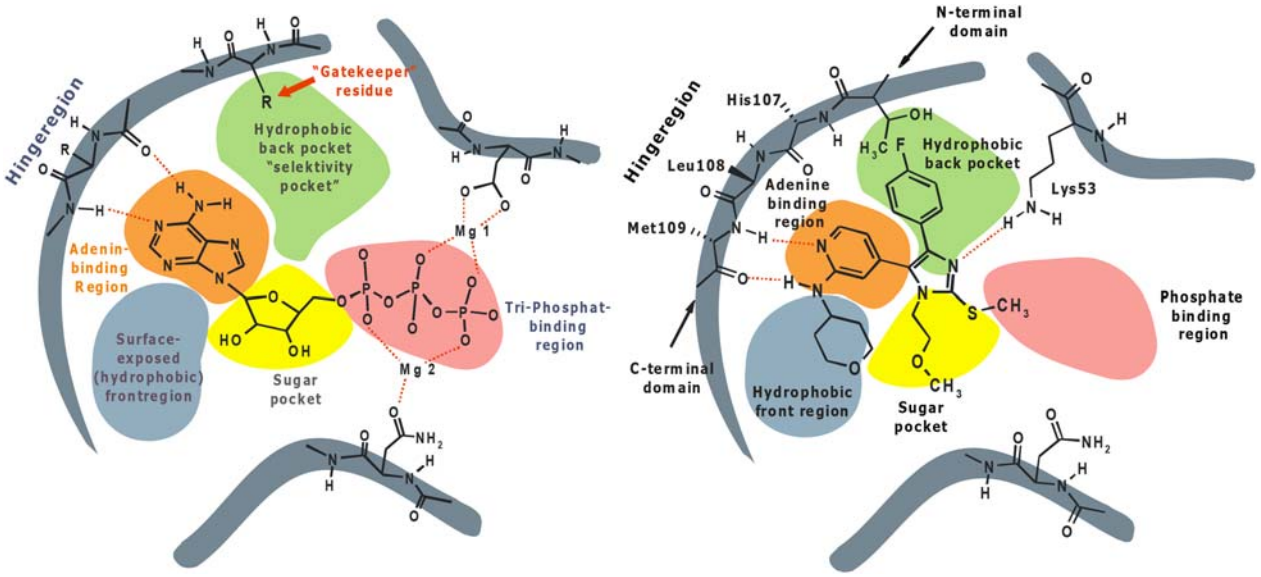

Fig. 3 Schematic binding modes of ATP (according to the Traxler model) and a tetrasubstituted 2-thioimidazole inhibitor to the ATP binding pocket according to Ref. 13.

Still maintaining the SKF-86002-derived pyridinyl-imidazole scaffold as the core structure, we cleaved the thiazole-ring of SKF-862002 in a manner that kept the sulfur atom at position 2 of the imidazole ring. Depending on the substitution pattern of these 2-thioimidazoles, the CYP-450 interactions could be reduced substantially.[12]

Tetrasubstituted 2-thioimidazoles are a perfect template to address the ATP binding site of protein kinases as shown in Fig. 3. In various research programs targeting, for example, p38 MAPKs, JNKs, Creatine kinase (CK), and Epidermal growth factor receptor (EGFR) we have synthesized more than 2500 compounds over the years. The synthetic strategies are extremely flexible and allow regioselective synthesis of a wide range of tri- and tetrasubstituted derivatives. For a general sketch, see Fig. 4. The outcome of this work is described in patents (WO 2002066458, WO 2004018458, WO 2006089798, and WO 2008023066) and numerous publications.

This compound collection (CBS library) with distinct substitution patterns (R^1–R^4) covers a broad range of specific interactions at the ATP binding site. Fig. 5 gives an overview.

1. Hydrophobic substituents at the pyrimidine ring (R^1)
2. Substitution of the imidazole ring (R^2)
3. Substitution of the sulfur atom in position C-2 for different substituents (R^3)
4. Substitution of the phenyl moiety (R^4)

Modification of the substituents at these four locations allows the regulation of selectivity and potency toward p38α MAPK, JNKs, CKs, EGFRs, and others.

Fig. 3 illustrates the binding interactions between the amino acids of the ATP-binding pocket of p38α MAPK and ATP as well as for one of our inhibitor molecules. The main interactions, as, for example, hydrogen bonds which are essential for the inhibitor's affinity, are shown.

Analyzing the Structure–activity relationships (SARs) within the CBS library comprising 2500 compounds, we could postulate for, for example, p38α MAPK: optimal interactions with the enzyme requires the tetra-substituted2-thioimidazoles to possess a 4-pyridinyl moiety, a 4-fluorophenyl group, and an unsubstituted N-atom in the imidazole ring adjacent to the 4-fluorophenyl group.

The nitrogen atom of 4-pyridinyl moiety interacts with the backbone amide-NH of Met109 located in the hinge region via a hydrogen bond. The 4-fluorophenyl ring is buried in the hydrophobic region I (selectivity pocket), which is limited by the so-called gatekeeper amino acid Thr106. The imidazole N-3 accepts a hydrogen bond from the ε-amino group of the Lys53 side chain.[8]

For the JNKs and CKs, some SARs could be derived as well; for other hits, for example, for EGFRs, were more random.

8.17.2.1 In Vitro and In Vivo Pharmacodynamics

In in vitro assays employing the isolated enzymes, the tetrasubstituted 2-thioimidazoles showed potent inhibition on p38α and JNK3 with IC_{50} values within the low nanomolar range and good kinome selectivity (for details, see synthesis references 8,12,13,15,17–29 and patents).

Furthermore, these compounds effectively prevented the release of TNFα and IL-1β from human Peripheral blood mononuclear cells (PBMCs) and human whole blood in vitro. Unfortunately, there was only a poor correlation between the enzyme data and data

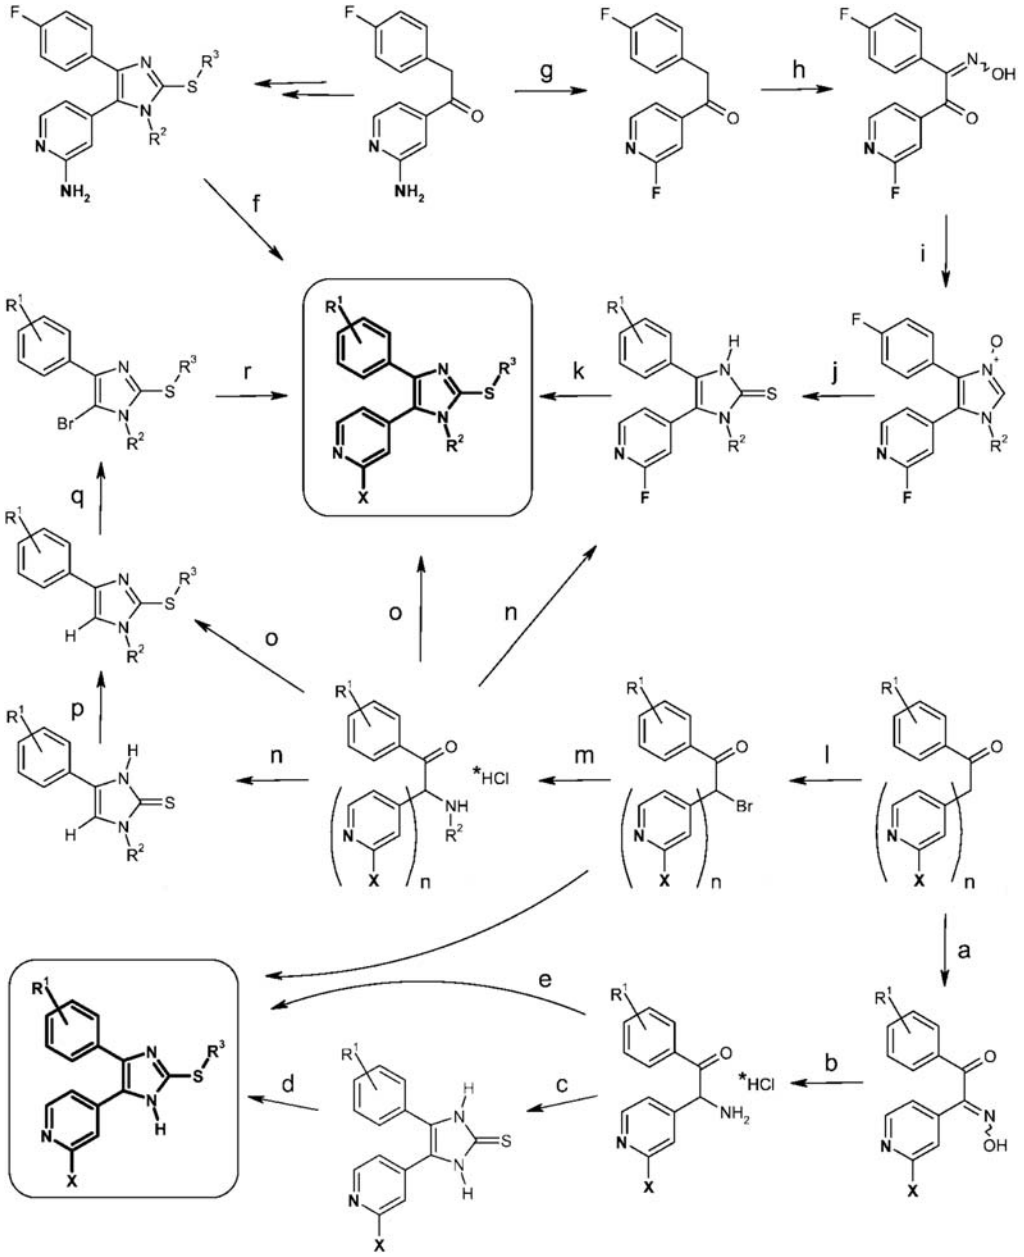

Fig. 4 Synthetic strategy to address all four substitution positions regioselectively; about 2500 compounds have been synthesized (CBS library). This overview was modified from Refs. 13–15. Reagents and conditions: (A) $NaNO_2$, AcOH, room temperature; (B) H_2, Pd/C, 1 atm, HCl in iPrOH, room temperature; (C) N,N-Dimethylformamide (DMF), Potassium thiocyanate (KSCN), reflux; (D) MeI, EtOH/THF, reflux, see also Ref. 12; (E) DMF, methyl-/ethyl-/benzylthiocyanate, reflux; see also Ref. 16; (F) 50% HBF_4 (aq), $NaNO_2$, 0-45°C; (G) $NaNO_2$, 70% HF in pyridine (Olah's reagent), −15 to −10°C to room temperature; (H) $NaNO_2$, AcOH, room temperature; (I) $(H_2CNR^2)_3$, EtOH, reflux; (J) 2,2,4,4-tetramethylcyclobutane-1,3-dithione, Dichloromethane (DCM), room temperature; (K) Hal-R^3, K_2CO_3, MeOH, room temperature; (L) Br_2, AcOH, room temperature; (M) excess H_2N-R^2, DCM, −5 to 0°C, then HCl in EtOH, Et_2O/acetone; (N) KSCN, DMF, reflux; (O) R^3-SCN, DMF = N,N-Dimethylformamide, reflux; (P) Hal-R^3, K_2CO_3, MeOH, room temperature; (Q) 1-Bromo-2,5-pyrrolidinedione (NBS), CCl_4, 0°C to room temperature; (R) $Pd(PPh_3)_4$ or $Pd(PPh_3)_2Cl_2$/PPh_3, Na_2CO_3 or K-OAc, toluene or DMF, 80-120°C. Parentheses: n=1: 4-pyridinyl- or n=0: hydrogen.

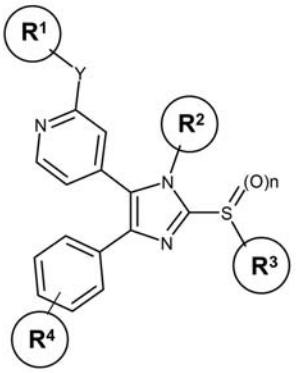
from pharmacologically more complex models as, for example, whole blood data. Thus, neither p38α MAPK inhibition, nor JNK3 inhibition, nor a combination of both correlated sufficiently with TNFα release from human whole blood, a complex but very predictive test system for in vivo models.

To evaluate their in vivo efficacy, inhibition of TNFα release was determined in an LPS/Galactosamine (D-Gal) mouse model after p.o. administration of a p38α MAPK selective compound (CBS-3408) and a dual p38α MAPK/JNK3 inhibitor (CBS-3435), both derived from the CBS library (Fig. 5).



CBS #	R^1	R^2	R^3	R^4	n
3403	$NHCHCH_3Ph$	H	CH_3	4-F	0
3408	NHAc	CH_3	CH_3	4-F	0
3435	NHPh	H	CH_3	4-F	0
3595	NHAc	CH_3	CH_3	4-F	1
3728	NH_2	CH_3	CH_3	4-F	1

Fig. 5 Examples of pyridinyl-imidazole core structure substitution generating compounds of the CBS library.

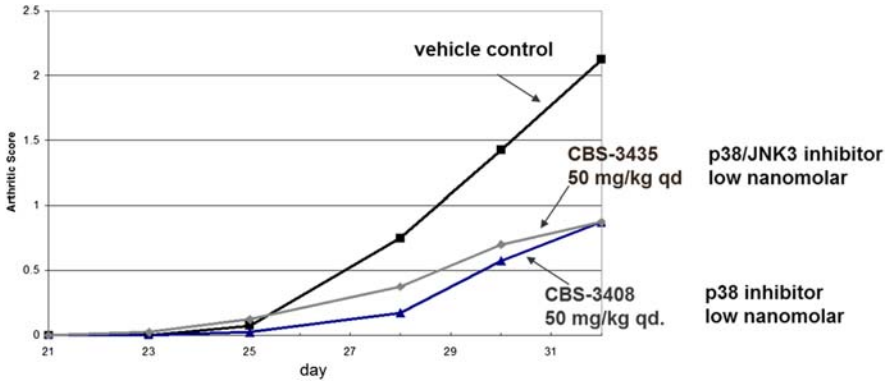


Fig. 6 Effect of CBS-3408 and CBS-3435 on collagen-induced arthritis in DBA/1 mice.

In the well-established collagen-induced arthritis in DBA/1 mice, a superior activity of the dual inhibitor was assumed, but even if the dual inhibitor CBS-3435 showed a slightly earlier onset. Surprisingly, both compounds reached the same arthritic score after 32 days. Also other compounds with inhibitory activities shifted to either one or the other enzyme and did not allow a correlation between in vivo activity and p38/JNK3 balance (Fig. 6).

8.17.3 Discovery of Dual p38α MAPK and PDE4 Inhibitors: Promising Compounds for Treatment of Inflammatory Disorders

The p38 MAPK inhibitors of the chemical class of pyridinylimidazoles have been intensely investigated and since the discovery of SB203580, many derivatives have shown substantially improved kinase selectivity and reduced liver toxicity potential (Fig. 7).

CBS-3408 is a low nanomolar p38α MAPK selective inhibitor. When applying CBS-3408 in an animal toxicology study, the compound was very well tolerated by rodents and gave clean in vitro toxicology outcomes. However, administration of CBS-3408 showed in the *Cynomolgus* monkey gender specific pharmacokinetics. Parallel metabolic studies discovered sulfoxidation as one pathway of metabolism (Fig. 8).[29]

Stimulated by these findings, a series of sulfoxides and sulfones were synthesized, finally leading to CBS-3595. This compound, having only moderate activity on both p38α MAPK and PDE-4 (around 200 nM), showed excellent in vitro and in vivo activities in various models of TNFα-driven inflammation.

At first glance, this sulfoxidation was considered as unfavorable, as its kinetics differed significantly between male and female animals in pharmacokinetic studies. Providing pro-chiral features, oxidation of the sulfur atom of the imidazole-S-alkyl-group may lead to two distinct enantiomers. Nevertheless, the dual inhibitory properties of CBS-3595 toward p38α MAPK and PDE-4 were verified in a variety of screening approaches. These approaches included in vitro characterization of the inhibitory potency on the isolated enzymes and kinome selectivity. Ex vivo experiments were performed to evaluate the compound's ability to reduce TNFα release from LPS-stimulated whole blood from human, rat, and monkey.

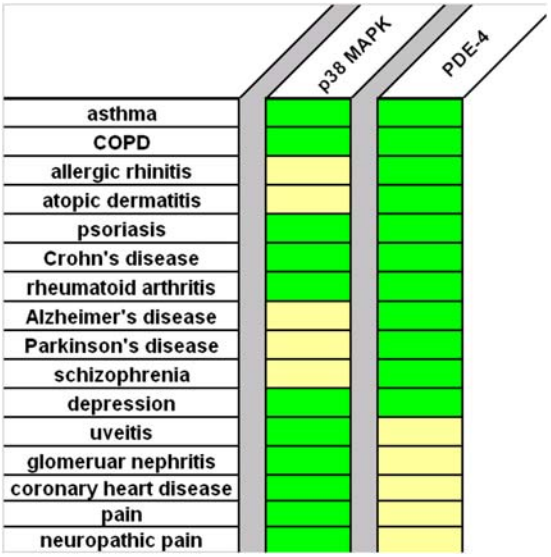

Fig. 7 Potential indications of p38α MAPK and PDE-4 inhibitors based on nonclinical experimental models and clinical studies according to Ref. 2. There is a substantial overlap with a chance of synergism by dual inhibition.

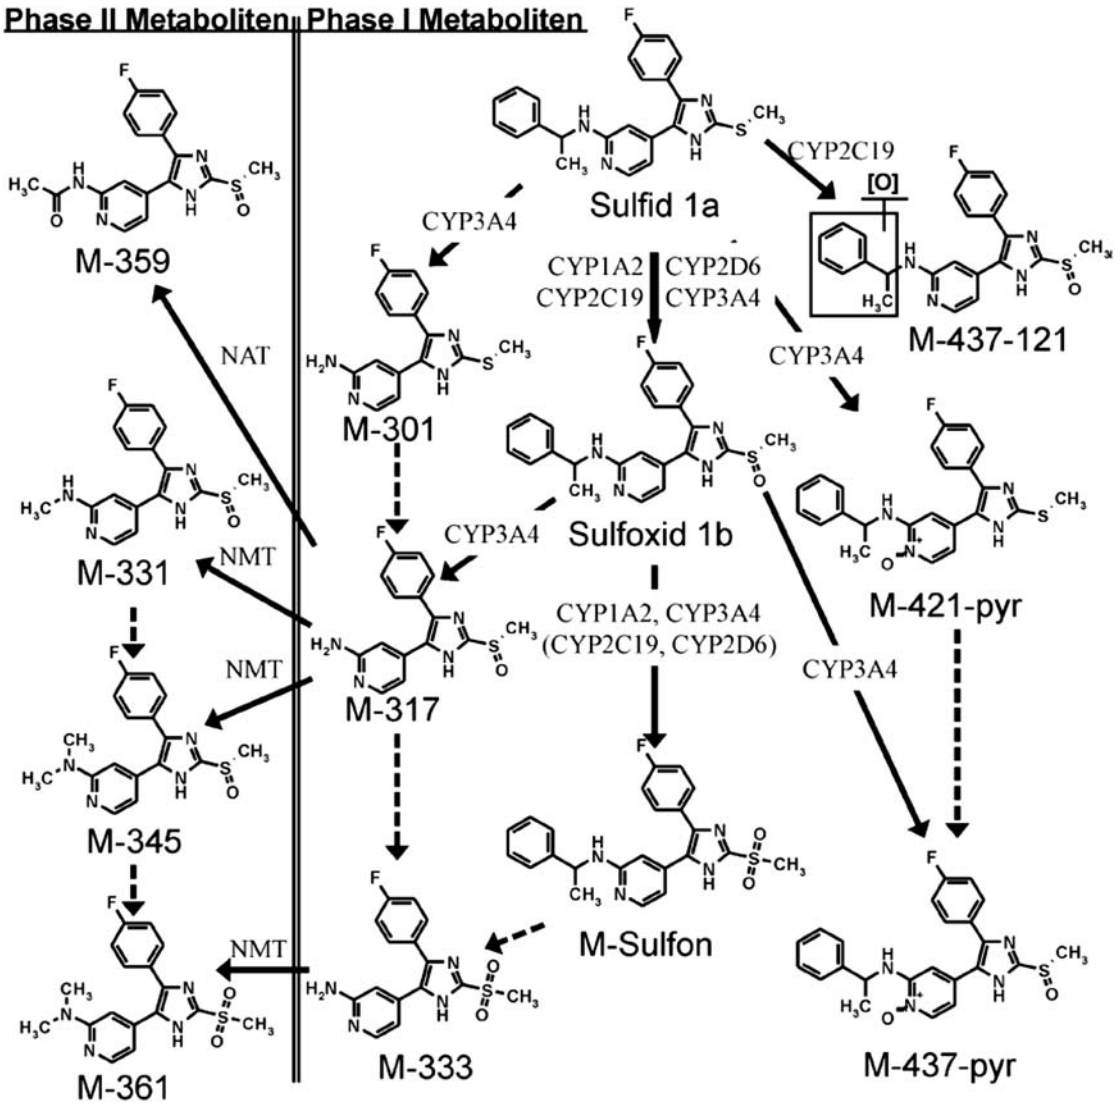

Fig. 8 Metabolic pathways of 2-thioimidazoles according to Ref. 29.

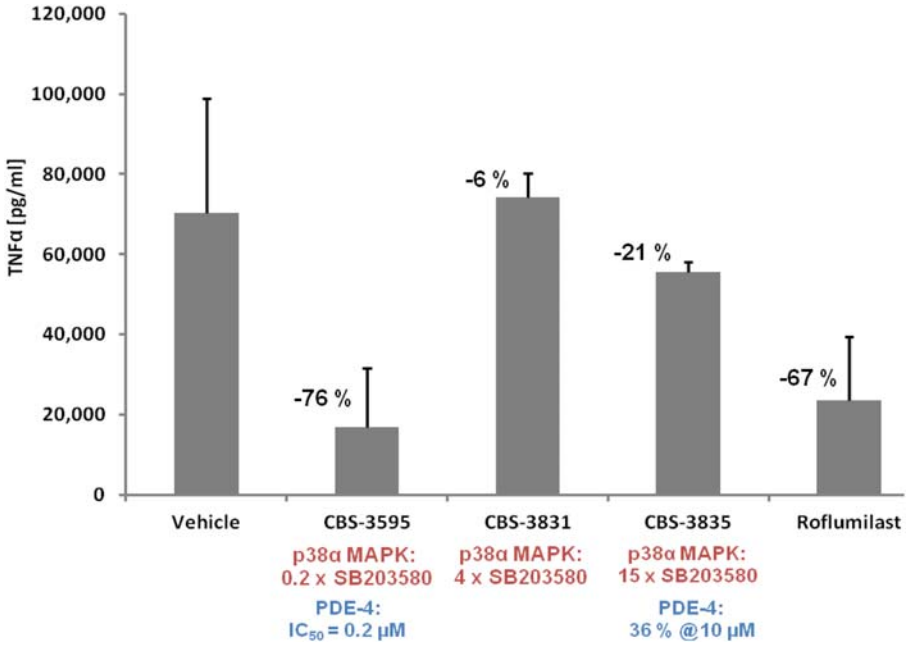

Fig. 9 Comparison of dual p38α MAPK/PDE-4 inhibitors bearing the tetrasubstituted imidazoles core with distinct inhibitory potencies with regard to their inhibition of TNFα release. Inhibition of TNFα release in Wistar rats following LPS-challenge.

Pharmacokinetic evaluations for determination of achieved plasma levels and relationship between dose and plasma concentrations were carried out in rats, dogs, and primates and also the metabolism of CBS-3595 was characterized.

CBS-3595, a dual p38α MAPK/PDE-4 inhibitor, was discovered by coincidence during preclinical experiments with CBS-3408, which is a selective and highly potent p38α MAPK inhibitor. In contrast, CBS-3595 shows only moderate, but well-balanced IC_{50} values of 100-500 nM and 200 nM for p38α MAPK and PDE-4, respectively. Sulfoxidation during metabolism of CBS-3408 yielded CBS-3595, which featured increased affinity toward the PDE-4 enzyme. Like p38α MAPK, PDE-4 represents an attractive target for treatment of chronic inflammatory diseases. Consequently, this specific class of dual inhibitors could result in the establishment of a new class of antiinflammatory drugs.

The inhibition of both p38α MAPK and PDE-4 seems to be synergistic. Neither p38α MAPK alone nor PDE-4 shows a similar effect on, for example, TNFα release in vivo. Even very potent p38α MAPK inhibitors such as CBS-3835 (15 times more potent than reference compound SB 203580) or Roflumilast, a registered PDE-4 inhibitor with an IC_{50} of 200 nM, feature similar performance as CBS-3595 (Fig. 9).

8.17.3.1 Chemistry of CBS-3595

The common synthetic route of CBS-3595 yielded the compound as racemic mixture. Single enantiomers are accessible via an enantioselective sulfoxidation in a good yield of 77% and an excellent optical purity of 98% ee, as described in Ref. 18 in more detail (Fig. 10).

8.17.3.1.1 Profiling of CBS-3595

R-CBS-3595 is one metabolite (sulfoxide) of CBS-3408 and due to its PDE-4 inhibition, is considered to account for the emetic side effects in monkeys when given in very high doses. This p38α MAPK/PDE4 inhibitor (100-500 nM/200 nM) is somewhat balanced in the middle nanomolar range.

Only the *R*-enantiomer is formed in vivo. This enantiomer is 10 times more active against PDE-4. In contrast, *S*/*R* enantiomers are equally active against p38α MAPK.

8.17.4 From in vitro Experiments Into Phase-I Clinical Trial: CBS-3595, a Dual Inhibitor of p38α MAPK/PDE-4

In a series of in vitro, ex vivo, and in vivo experiments, the potency of CBS-3595, its systemically available and pharmacologically active metabolite CBS-3728 and the reference compound SB203580 to suppress the production of the proinflammatory cytokine TNFα was demonstrated. These data indicated that CBS-3595 is a promising clinical candidate for treatment of human immune diseases which relate to the overproduction of TNFα.

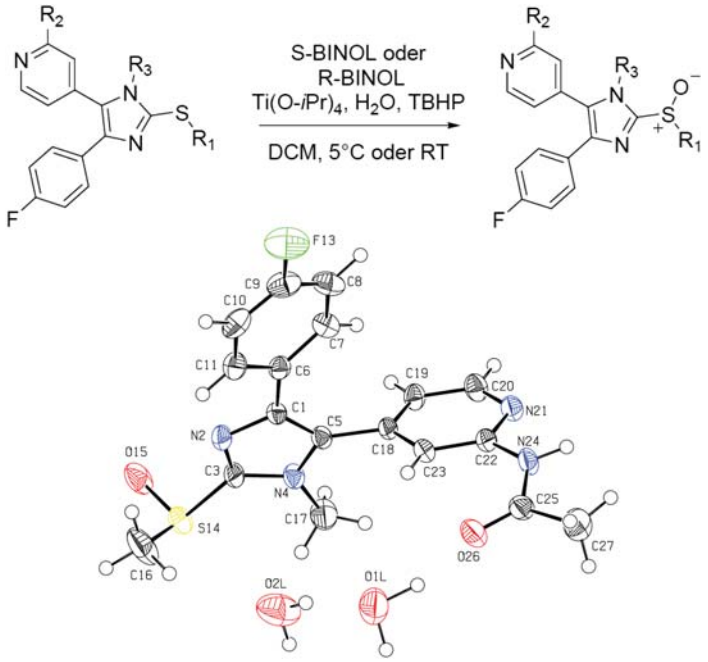

Fig. 10 Enantioselective synthesis of CBS-3595 and crystallographic confirmation of the R-conformer according to Ref. 18. Stereochemistry confirmed by x-ray single crystal analysis. CBS-3595 substitution: $R_1 = CH_3$; $R_2 = NHAc$; $R_3 = CH_3$.

Experiments for evaluation of the safety profile of CBS-3595 included acute toxicity and dose-finding studies as well as a 4 week toxicity study in the rat including a 2 week recovery phase. Moreover, the maximum tolerated dose was studied in Cynomolgus monkeys and also a 4 week toxicity study in Cynomolgus monkeys including a 2 week recovery phase was performed.

Above that, the mutagenic and carcinogenic potency was evaluated with an AMES test and also cytogenetic assay in human lymphocytes and an in vivo micronucleus test in mice.

The in vivo efficacy of CBS-3595 was first investigated in a polyarthritis rat model and a transgenic mouse model before the first clinical human use study was carried out in 44 volunteers for investigation of safety, tolerability, and pharmacokinetics and ex vivo pharmacodynamics of CBS-3595.

8.17.4.1 Nonclinical Evaluation of CBS-3595 and Its Metabolite CBS-3728

8.17.4.1.1 IC_{50} determination in in vitro kinase activity assays

Surface plasmon resonance studies with CBS-3595 and SB203580, an ATP-competitive, 4-(4-fluorphenyl)-5-pyridyl-imidazole p38α MAPK inhibitor, suggested that CBS-3595 was also an ATP-competitive p38α MAPK inhibitor.

The activity of recombinant p38α MAPK was inhibited with an IC_{50} of 4.19 ± 1.08 μM (mean ± SEM; $n = 8$) by CBS-3595 and 4.12 ± 1.45 μM (mean ± SEM; $n = 3$) for CBS-3728. The IC_{50} value for the reference compound SB203580 determined in this experiment was 0.45 ± 0.15 μM (mean ± SEM; $n = 12$). The activity in various p38α MAPK phosphorylation assays ranged between 200 and 500 nM.

PDE-4 expressed in U937 cells was inhibited by CBS-3595 and CBS-3728 with IC_{50} values of 0.2-0.4 μM and 1.98 μM, respectively.

8.17.4.1.2 Investigation of kinome selectivity and other potential off-targets

For evaluation of its kinome selectivity, a concentration of 10 μM of CBS-3595, corresponding to a concentration which was achieved in vivo during toxicological studies, was tested against a panel of 134 kinases (radiometric screening technology KinaseProfiler, Upstate, United Kingdom). Other p38 MAPK isoforms were inhibited by 18% (p38β), 0% (p38γ), and 35% (p38δ). JNK2α2 and JNK3 were inhibited by 51% and 76%, respectively.

Relevant off-target hits were JNK2α2, JNK3, and CK1δ (51%, 76%, and 94% of inhibition at 10 μM). Furthermore, the adenosine A_1 receptor was influenced to a lesser extent by CBS-3595 and CBS-3728 (50% and 40% of inhibition at 10 μM, respectively).

Apart from the above results, a set of 39 other G-protein coupled receptors remained unaffected after incubation with 10 μM of CBS-3595 and CBS-3728, as evaluated by a radioligand binding assay (MDS Pharma Services, Profiling Assays, Taiwan).

Additionally, the PDE isoforms PDE-3 and PDE-5 remained unaffected at a concentration of 10 μM of both CBS-3595 and CBS-3728.

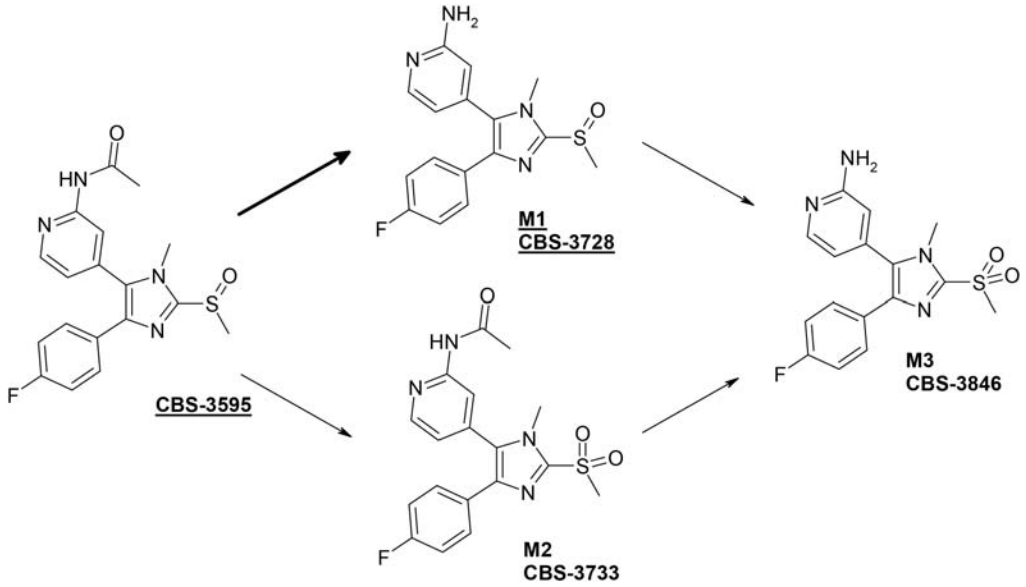

Fig. 11 Metabolic pathways of CBS-3595. http://emboj.embopress.org/content/22/21/5793.

8.17.4.1.3 Metabolism studies

In vitro absorption studies with Caco-2 cells indicated good membrane permeability and that CBS-3595 was not a substrate of P-glycoprotein. In vivo efficacy studies show excellent plasma levels after oral administration.

In vitro metabolism studies performed with liver microsomes from humans, rats, and monkeys as well as with human hepatocytes, demonstrated moderate to high metabolic stability of CBS-3595.

Two metabolites were identified: cleavage of the *N*-acetyl bond leading to the pharmacologically active metabolite M1 (CBS-3728) and oxidation to the sulfone leading to M2 (CBS-3733) as shown in Fig. 11.

However, it is unknown if the two enantiomers of CBS-3595 differ in metabolism and rates.

CBS-3595 had a low affinity toward plasma proteins. The unbound fraction varied between 78.1% and 90.0% in human, 63.1-86.3% in rat, and 58.3-66.7% in monkey plasma.

In vivo pharmacokinetic data were generated from the rat, dog, and Cynomolgus monkey. Despite the lack of pharmacokinetic data following intravenous drug administration, the extent of drug absorption of CBS-3595 appears to be similar in all species. After C_{max} was reached, a monophasic decline of plasma concentrations was observed in dogs, rats, and monkeys. Elimination half-lives of approximately 4 h in mongrel dogs, 8 h in beagle dogs, 1.8-2.2 h in rats, and 4-6 h in monkeys were determined. Therefore, the systemic elimination appears to be more rapid in rats when compared to dogs and monkeys. In all species, systemic exposure increased with the administered dose. In monkeys, no gender-specific pharmacokinetics was observed. Systemic exposure to CBS-3728 was much lower in monkeys compared to rats and dogs.

The metabolites of CBS-3408 were further characterized and it was found that mainly the *R*-enantiomer (*R*-CBS-3595) is formed in vivo. As mentioned earlier, the stereochemistry was confirmed by x-ray single crystal analysis. However, for synthesis of larger amounts of *R*-CBS-3595, methods allowing an enantioselective oxidation had to be developed, as the conventional chemical oxidation resulted in a racemic mixture of both enantiomers.

With regard to inhibitory activity against PDE-4, *R*-CBS-3595 showed a 10-fold higher potency, while both the *S*-enantiomer and the *R*-enantiomer of CBS-3595 were equally active toward p38α MAPK.

8.17.4.1.4 Effect of CBS-3595 on leukotriene B_4 (LTB_4) release in LPS/fMLP-stimulated human whole blood

In this assay, the reduction of the fMLP/LPS-triggered release of the eicosanoid lipid mediator LTB_4 from human whole blood was evaluated for CBS-3595 and Roflumilast was determined. Both compounds were able to reduce the levels of LTB_4 in a concentration-dependent manner. However, Roflumilast was more potent when compared to CBS-3595 which correlates with stronger inhibition of PDE-4. The p38 MAPK reference inhibitor SB203580 served as the negative control and, as expected, had no effect in this assay.

8.17.4.1.5 Effect of CBS-3595 on TNFα release in the rat following LPS-challenge

The in vivo efficacy of CBS-3595 was investigated in the rat model of LPS-induced TNFα release. In the first study using Sprague Dawley rats, a clear dose-response relationship was observed and ED_{50} and ED_{80}-values of 1 and 3 mg kg^{-1} p.o., respectively were calculated. These values correlated well with the determined serum concentrations of CBS-3595. These findings were later confirmed in additional studies with Lewis rats and Balb/c mice.

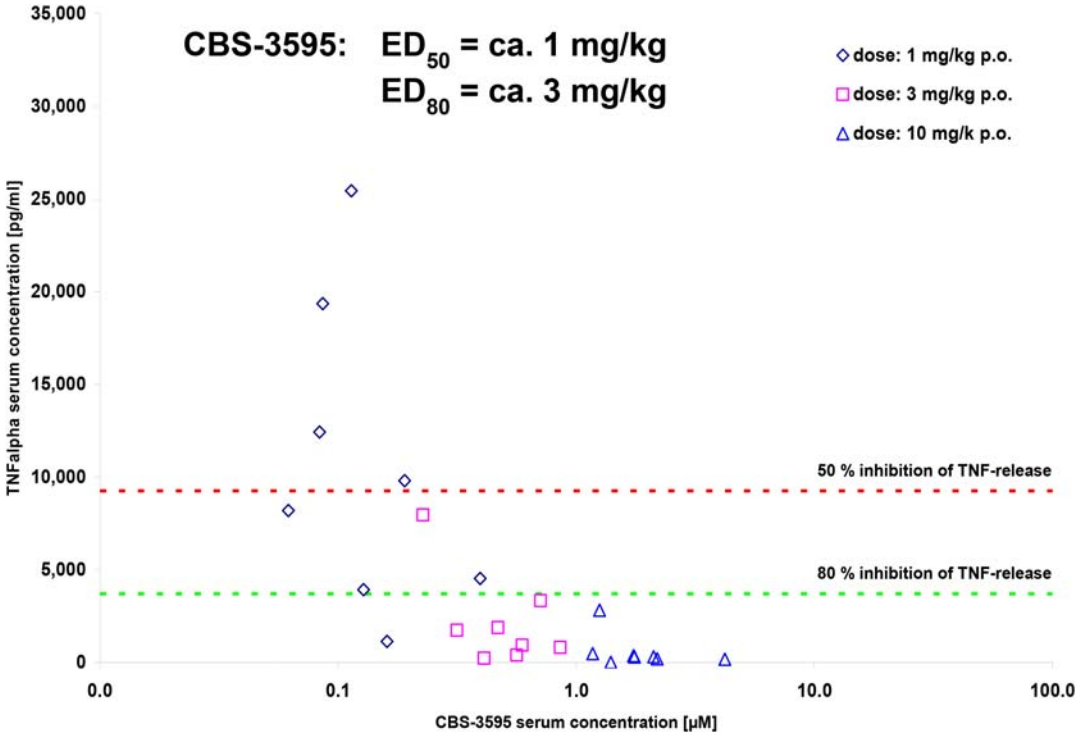

Fig. 12 Relationship between individual CBS-3595 serum concentrations, determined 2 h post LPS-challenge (3 h postdose) and TNFα release.

In detail, administration of 1, 3, and 10 mg kg^{-1} CBS-3595 led to a more effective inhibition of TNFα release of 43%, 88%, and 96%, respectively, while 3 mg kg^{-1} of SB203580 only led to a mean inhibition of TNFα release of 37%. This compares to a no-adverse-effect-level of 15 mg kg^{-1} day^{-1} p.o. as determined in the 4 weeks toxicity study in Sprague Dawley rats.

Thus, CBS-3595 is more potent in reduction of TNFα release when compared to the reference compound SB203580 and at least as effective as Roflumilast in these experiments. In TNF-transgenic mice, which develop a chronic inflammatory and destructive polyarthritis, CBS-3595 demonstrated beneficial effects on paw swelling, synovitis, erosion, and cartilage damage during 4 weeks of treatment.

The relationship between drug concentrations, determined 2 h post LPS-challenge (i.e., 3 h postdose) and TNFα release is illustrated in Fig. 12.

In seven out of eight animals dosed with 3 mg kg^{-1}, the TNFα concentrations were below the value which corresponds to an 80% inhibition. After administration of 10 mg kg^{-1}, the TNFα concentrations in all animals were below this 80% limit.

A second study clearly demonstrated that the extent of TNFα release depends on the time point of dosing. The closer the time of dosing to LPS-challenge, the higher the plasma concentrations at 1.5 h postdose, and the higher the inhibition of TNFα release. The comparison of data obtained with male and female animals indicated the absence of gender-specific differences in pharmacokinetics or efficacy. As already demonstrated in the first study, CBS-3595 was more effective than the reference compound SB203580 in blocking TNFα release (see Fig. 13).

When compared to Roflumilast in a head-to-head setting, both CBS-3595 and Roflumilast exhibited comparable effects toward the inhibition of TNFα release, with mean inhibition values of 8% and 67%, respectively.

8.17.4.1.6 Effect of orally administered CBS-3595 on TNFα release in ex vivo-stimulated whole blood in Cynomolgus monkeys

As part of the 4 week toxicity study in *Cynomolgus* monkeys, toxicokinetic blood sampling was also used to investigate the effect of orally administered CBS-3595 on TNFα release in ex vivo stimulated whole blood. In this study, a dose- and time-dependent inhibition of TNFα release was demonstrated. Following the first dose, a clear dose-dependent effect was observed. At the end of the 4 week treatment period, the highest efficacy was observed at the intermediate (males) and low dose levels (females).

Animals were treated with vehicle (five males, five females), 6 mg kg^{-1} day^{-1} (three males, three females), 12 mg kg^{-1} (three males, three females), and 20 mg kg^{-1} (five males, five females).

After 2 weeks of treatment, the high dose was increased to 25 mg kg^{-1}. On day 1 and day 27, blood samples were taken 1, 4, and 8 h postdose (on day 27 also 24 h postdose), for ex vivo stimulation with LPS. After 4 h of incubation at 37°C, plasma was harvested and TNFα concentrations were determined by ELISA.

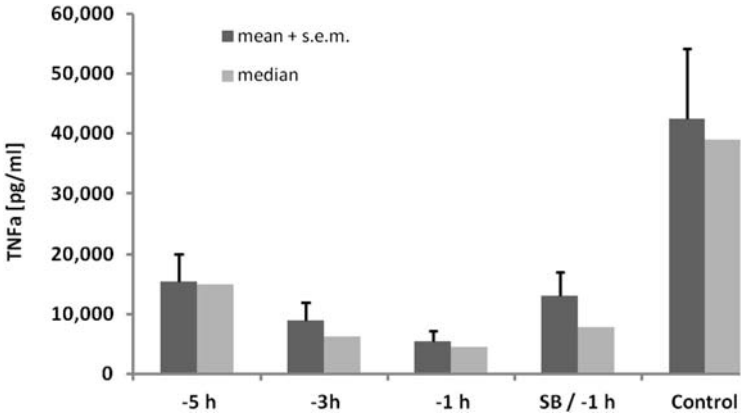

Fig. 13 Influence of time point of dosing with CBS-3595 on the inhibition of TNFα release in rats after LPS challenge and correlation with plasma concentrations.

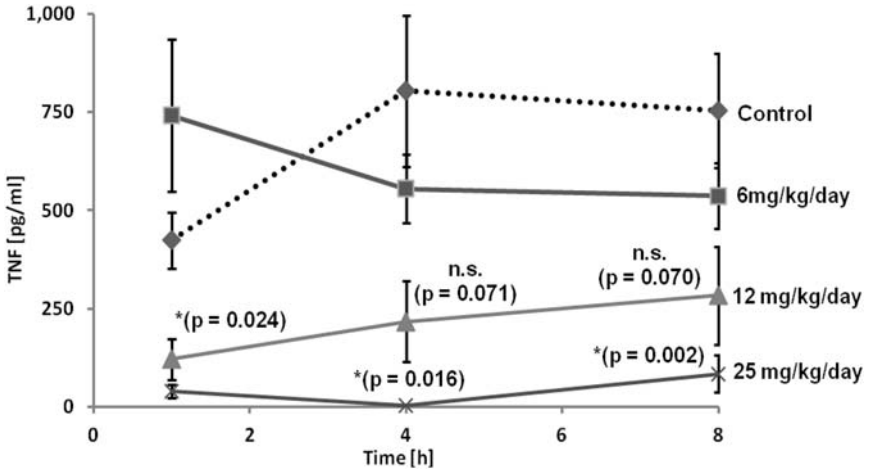

Fig. 14 Effect of orally administered CBS-3595 on TNFα synthesis in ex vivo LPS-stimulated whole blood from Cynomolgus monkeys.

In control animals, TNFα concentrations determined at 1 h postdose were substantially lower compared to the values determined at later time points. This result suggests that stress associated with repeated toxicokinetic blood sampling may have induced an endogenous TNFα production or may have increased the susceptibility to ex vivo added LPS.

Furthermore, it could be demonstrated that oral administration of CBS-3595 led to a substantial reduction of TNFα levels following ex vivo stimulation. The effect of orally administered CBS-3595 on TNFα release in ex vivo-stimulated whole blood was investigated in *Cynomolgus* monkeys.

In Fig. 14, TNFα levels determined in male and female animals on day 1 are illustrated demonstrating inhibition of TNFα after administration of CBS-3595 compared to vehicle.

8.17.4.1.7 Efficacy in hTNF-transgenic mice

A very challenging model for RA is human TNF (hTNF)-transgenic mice as only few highly active compounds show activity.[30] Even very potent p38α MAPK inhibitors from the structural class of pyridinyl imidazole from Roche and Aventis, Ro-4399249 and AVE-8677, gave moderate results even at a high dose of 100 mg kg^{-1} qd.[30]

In contrast, CBS-3595, at a dose of 20 mg kg^{-1} yielded similar activity to IFX, the current gold standard in RA after 10 days of treatment, showing again superior activity of dual p38α MAPK/PDE-4 inhibition (Fig. 15).

8.17.4.1.8 CBS-3595 in a complete Freund's adjuvant (CFA) arthritis model using male Wistar rats

A study comparing the efficacy of p38α MAPK inhibition of CBS-3595 versus ML3403, a known potent p38α MAPK inhibitor was conducted, the desired outcome being the decrease in TNFα plasma levels in a CFA arthritis model using male Wistar rats.

The reduction of TNFα levels after 21 days in the CBS-3595 group was significantly lower than in the ML3403 group (see Fig. 16). These results indicated that the decrease of TNFα levels could not be accounted for solely by p38α MAPK inhibition.[31]

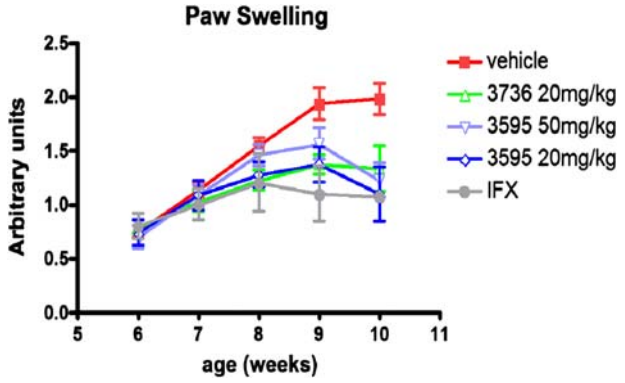

Fig. 15 Efficacy of CBS-3595 in hTNF-transgenic mice in comparison to Infliximab (IFX).

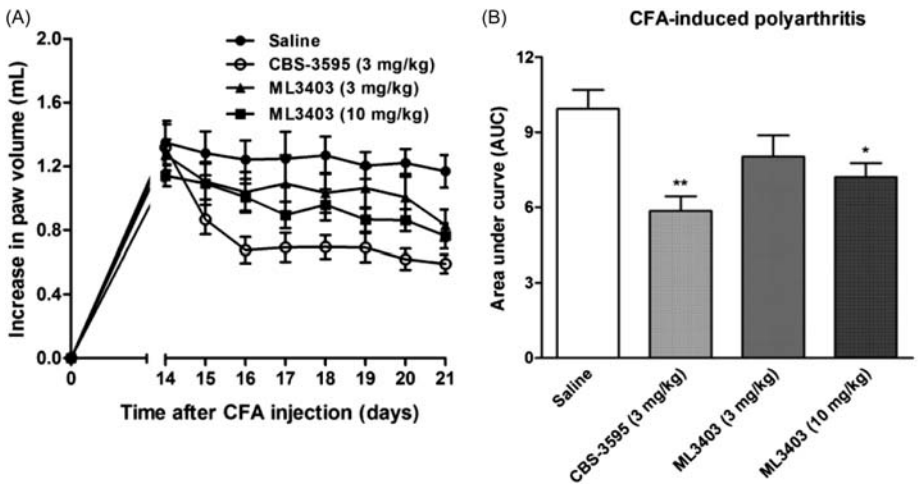

Fig. 16 Rheumatoid arthritis model and results for CBS-3595.

Similar results were claimed but not fully published for CGH2466 (Fig. 17), which proved to be a dual inhibitor of p38α MAPK and PDE-4 as well.

8.17.4.1.9 Safety pharmacology studies

The effects of CBS-3595 on vital functions, that is, CNS, respiratory tract, and cardiovascular system were investigated in vivo. In addition, the effect of the compound on the hERG channel was tested in an electrophysiological in vitro assay. However, based on expected maximum plasma concentrations in the range below 10 μM, the observed inhibition (IC_{50} = 213 μM) is without any safety relevance.

The effect of CBS-3595 on CNS activity was investigated after a single oral administration to conscious rats. Besides the observation of excessive defecation and soft feces after treatment with the test item at the dose levels of 30 and 300 mg kg^{-1}, loud breathing and excessive salivation were also noted on some occasions after treatment with CBS-3595 at the dose level of 300 mg kg^{-1}. No modifications in the reactivity to manipulation and stimuli associated with administration of CBS-3595 were reported at any of the dose levels tested. Thus, it was concluded that CBS-3595 had no major effects on the central nervous system at any of the tested dose levels.

The effects of CBS-3595 on cardiovascular function and cardiac electrophysiology were investigated after a single oral administration of 6, 12, and 20 mg kg^{-1} to conscious *Cynomolgus* monkeys with implanted telemetric devices. As the only clinical sign of this study, traces of whitish vomiting were reported for some animals at all dose levels of CBS-3595.

When compared to the control group, CBS-3595 induced tachycardia from 30 min after dosing until the end of the recording period at all the dose levels tested in the study. No modifications of systolic, diastolic, or mean blood pressure were reported after dosing with CBS-3595 at any dose level.

Decreases in the PQ and QT interval durations were reported after dosing with CBS-3595 at all dose levels, from 15 min after dosing until the end of the recording period and until 180 min after treatment. This was probably related to the concomitant increase in heart rate. When compared to the vehicle group, no significant modifications of corrected QT duration (QTf

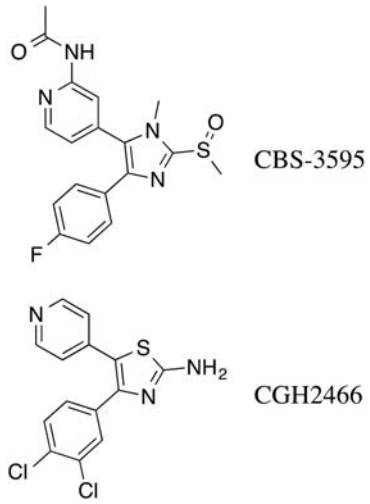

Fig. 17 Structures of CBS-3595 and CGH2466.

and QTv) were reported after dosing with CBS-3595 at any dose level. No modifications of QRS interval duration were observed after dosing with CBS-3595 at any of the dose levels tested in this study. In addition, periods of sinusal brady-arrhythmias were reported. These observations were dose-related and can possibly be a consequence of deep inspiration or nausea (this is consistent with the vomiting observed in the study). However, such periods of brady-arrhythmia were also reported before dosing on the third day of treatment. Premature ventricular complexes were also observed in two animals treated with CBS-3595.

To evaluate the potential modifications in respiratory function caused by CBS-3595, respiratory parameters were measured by whole body plethysmography following single doses of 0 (vehicle), 30, 100, and 300 mg kg^{-1} CBS-3595. Respiratory rate, peak flow times, enhanced pause, minute and tidal volume, were measured until 6 h postdosing. An increase in the minute volume, consecutive to an increase in the peak inspiratory flow, was observed after dosing with CBS-3595 at the dose-level of 300 mg kg^{-1}.

8.17.4.1.10 Toxicological studies

To investigate the acute toxicity of CBS-3595, five male and five female Sprague Dawley rats received a single oral (gavage) dose of 2000 mg kg^{-1} and the effects were observed for a period of 14 days. No mortalities were observed. As clinical signs, piloerection, hypoactivity, and dyspnea were noted on days 1 and 2. No clinical signs were noted from day 3.

In the sub-acute dose range finding study in the rat doses of 0 (vehicle), 50, 150, or 450 mg kg^{-1} day^{-1} were administered for a period of 7 days. There were no premature deaths during the study. Based on treatment-related and dose-dependent clinical signs such as hunched posture, piloerection, and ptyalism as well as effects on blood cells, a dosing schedule for the 4 week toxicity study was concluded.

The 4 week toxicity study was performed at dose levels of 0 (vehicle), 15, 50, and 150 mg kg^{-1}. After termination of the 28-day treatment period, animals of the control and high dose group were observed for a further 2 week treatment-free period. For toxicokinetic analysis, satellite animals were included. This study was conducted in compliance with Good laboratory practice (GLP) regulations.

There were no unscheduled deaths during this study. No treatment-related clinical signs were noted in the group receiving 15 mg kg^{-1}. In the intermediate and high dose groups, mild adverse effects were observed and a No-observed-effect level (NOEL) of 15 mg kg^{-1} day^{-1} was concluded.

In the 4 week toxicity study, the effect of CBS-3595 was investigated at doses of 0 (vehicle), 6, 12, and 20 mg kg^{-1}. After 2 weeks of treatment, the high dose was increased to 25 mg kg^{-1}. After termination of the 28-day treatment period, two male and female animals of the control and high dose group each were observed for a further 2 week treatment-free period. This study was conducted in compliance with GLP-regulations. There were no unscheduled deaths during this study. Except for occasional liquid feces, observed in a male animal of each treatment group, no treatment-related findings were observed. There was no significant difference in body weight between treatment groups and controls.

Under the conditions of this study, a NOEL could not be established for males or females, and is considered to be lower than 6 mg kg^{-1} day^{-1}. However, as none of the observed changes were considered to be adverse or of toxicological importance, the No Observable Adverse Effect Level is considered to be greater than 25 mg kg^{-1} day^{-1}.

To investigate the genotoxicity of CBS-3595, the following studies were performed: Ames test, in vivo micronucleus test in the mouse and a cytogenetic test in human lymphocytes. In the Ames test, CBS-3595 gave a negative, that is, nonmutagenic response in all *S. typhimurium* and *E. coli* strains investigated, in both the presence and absence of S9-mix.

The mouse bone marrow micronucleus test demonstrated that CBS-3595 was not clastogenic. In the cytogenetic assay with cultured human lymphocytes, CBS-3595 was not clastogenic in vitro in either the presence or absence of S9-mix.

8.17.4.2 Phase I: First-Use-in-Human Study of CBS-3595

As described, CBS-3595 shows a clearly superior pharmacodynamic profile compared with selective p38α MAPK inhibitors and has been widely investigated:

- PK data available from studies in rats, dogs, and primates, rapid absorption after oral administration of CBS-3595;
- low variability;
- very low plasma protein binding ($\ll$50%);
- in rats (LPS-model), very good correlation of plasma concentration with the observed inhibition of TNFα release;
- one pharmacologically less active major metabolite;
- no inhibition of Cytochrome P450s (CYPs) (1A2, 2C9, 2C19, 2D6, and 3A4) at 10 μM;
- dose-proportional pharmacokinetics;
- no critical findings in nonclinical studies to investigate the genotoxicity and the effect on the central nervous, respiratory, and cardiovascular system;
- dose-dependent safety profile in general toxicity studies in rodents and Cynomolgus monkeys.

A clinical study to investigate the safety, tolerability, pharmacokinetics, and ex vivo pharmacodynamics of CBS-3595 was therefore conducted.

The study was designed as a placebo-controlled, single-blind, randomized, consecutive dosing study. Based on nonclinical findings, a starting dose of 10 mg was selected and in case of absence of adverse events, 50 mg was chosen as next dose level. The dose of 10 mg was tolerated well but after administration of 50 mg CBS-3595, all four subjects reported nausea and malaise and some vomiting events were recorded. In a subsequent setting, doses of 20 and 30 mg were applied, which confirmed a clear relationship between dose and adverse events which were characteristic for PDE4-inhibitors.

To investigate the pharmacokinetics of CBS-3595 and its major metabolite CBS-3728, blood samples were analyzed by a validated Liquid chromatography–mass spectrometry (LC MS)/MS method. Noncompartmental analysis of concentration versus time profiles was applied to determine main pharmacokinetic parameters (C_{max}, T_{max}, $t_{½}$, AUC_{0-t}, and $AUC_{0-\infty}$) and urine samples were analyzed to determine the cumulative excretion of parent compound and metabolites. Additional blood samples were taken and treated with bacterial LPS, which induced the formation of the proinflammatory cytokine TNFα. To determine the ex vivo pharmacodynamics of CBS-3595, TNFα concentrations versus time profiles were generated.

8.17.4.2.1 Pharmacodynamic results

In placebo-treated subjects, the TNFα release did not remain constant during the observation period. Compared to the predose activity, which was set to 100% by definition, a trend toward increasing TNFα production was observed. Compared to placebo data, in subjects treated with CBS-3595, a clear inhibition of TNFα release was achieved.

8.17.4.2.2 Pharmacokinetic results

Determination of plasma concentrations of the parent drug CBS-3595 and the metabolite CBS-3728 suggests that CBS-3595 is readily absorbed from the gastro-intestinal tract. The absorption profile of CBS-3728 indicates an efficient presystemic metabolism of CBS-3595.

Mean peak plasma concentrations of CBS-3595 were in the range of 2-3 h postdosing. Afterwards, the parent drug is eliminated from systemic circulation with a half-life of approximately 3 h. In contrast, for the metabolite CBS-3728 an elimination half-life of 9-11 h was determined. Mean pharmacokinetic parameters of CBS-3595 (parent drug) and CBS-3728 (metabolite) are summarized in the table below:

CBS-3595 *CBS-3595 dose*	*Period* n	T_{max} *(h)*	C_{max} *(ng mL^{-1})*	AUC_{0-t} *(ng h mL^{-1})*	$T_{½}$ *(h)*	$AUC_{0-\infty}$ *(ng h mL^{-1})*

Periods: I = prematurely interrupted part of study; II = cross-over part of study; III = 20 mg, 30 mg s.d. part of study.

In summary, 44 volunteers completed the study. After single oral dosing of a tolerated dose (10, 20 mg s.d.), inhibition of TNFα release in ex vivo stimulated blood samples reached approximately 50-80%.

A representative profile of the determined pharmacokinetics, pharmacodynamics, and time course of TNFα levels are shown in Figs. 18 and 19.

8.17.5 Conclusion and Lessons Learned in Retrospect

It was demonstrated that in both in vitro and animal models that combined dual p38α MAPK/PDE-4 inhibition is clearly superior for inhibition of biosynthesis and release of TNFα with regard to sheer TNFα release as well as for treatment of RA.

Pharmacokinetic criteria are often more important than pure activity. Even moderate inhibition of p38α MAPK and PDE-4 in the higher nanomolar range was observed, but with excellent kinetic properties and low plasma protein binding results with excellent efficacy in humans. A single 10-20 mg oral dose yielded 50-80% TNFα suppression ex vivo.

An unanswered question remains: why did vomiting occur in humans at much lower doses that provoked the same response in monkeys? One explanation could be differences in metabolism which are difficult to predict. In humans, the major metabolite CBS-3728 occurred in much higher doses than predicted by in vitro studies, even with human enzymes and microsomes as well as with animal in vivo studies, including monkeys.

A retrospective analysis of PDE-4 subtype inhibition showed that the metabolite CBS-3728 inhibited the isoform PDE-4 D3 much more strongly than the parent drug CBS-3595 (Fig. 20). Meanwhile, this isoform PDE-4 D3 is considered to be mainly responsible for the vomiting and nausea side effects of PDE-4 inhibitors.

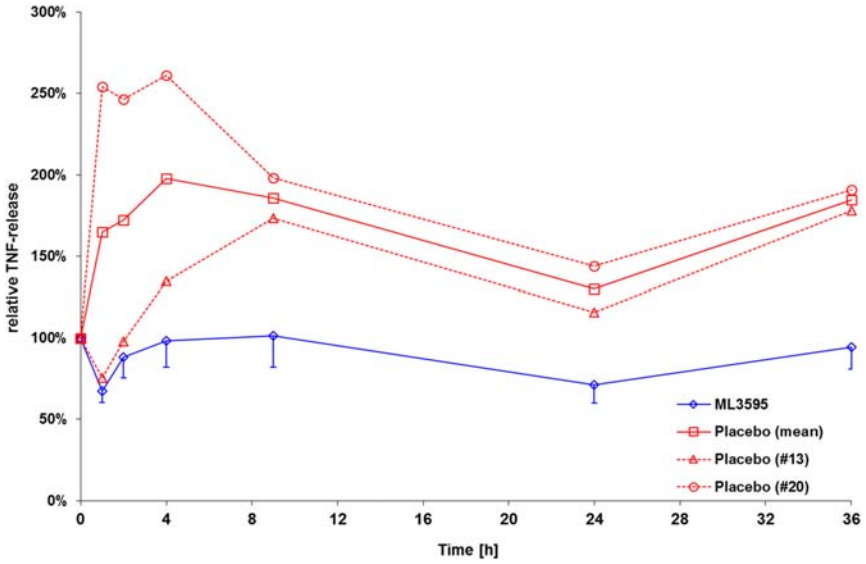

Fig. 19 Impact of CBS-3595 on TNFα release (ex vivo stimulation) in comparison with placebo.

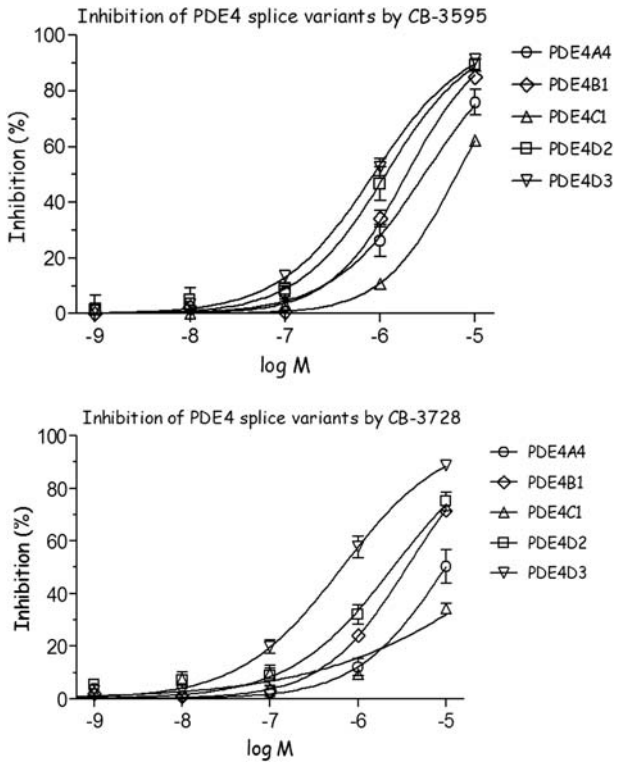

Fig. 20 PDE-4 isoform inhibition by CBS-3595 and its major human metabolite CBS-3728.

8.17.6 Perspective and Outlook

As of today, predicting isoform selectivity as applicable to rational design of inhibitors is still not possible. Even the contribution of the various isoforms to both activity and side effects is still unclear and has prevented many candidates from being further developed. Changing the route of application and systemic exposure seems to be a possible avenue to pursue. Besides RA, COPD and psoriasis are other indications for dual p38α MAPK/PDE-4 inhibitors. Both COPD and psoriasis allow topical/local application and therefore, allow low systemic exposure.

Follow up candidates of CBS-3595 for oral dosing may be selected by their isoform selectivity and metabolic stability. For topical/local application, one might vary the p38α MAPK/PDE-4 ratio and the metabolic stability.

To evaluate the effectiveness of CBS-3595 for treatment of COPD after inhalative application, ADME and physicochemical properties might be reconsidered. As CBS-3595 was selected for oral application, probably other candidates of the CBS library might be more suitable for topical or inhalative application.

8.18.1 Introduction

8.18.1.1 Inhaled Glucocorticoids for the Treatment of Respiratory Diseases

Glucocorticoids represent the most potent antiinflammatory drugs available today and allow successful treatment of cancer, several chronic inflammatory, and autoimmune diseases.[1] This also includes the treatment of respiratory diseases, such as asthma and chronic obstructive pulmonary disease (COPD), where inhaled glucocorticoids (IGCs) used alone or in combination with bronchodilators are the mainstay of clinical therapy.[2]

There are a number of IGCs approved for the treatment of respiratory diseases, either alone or in combination with a long-acting inhaled β2-agonist (LABA). The most well-known IGCs are budesonide, fluticasone propionate, fluticasone furoate, beclometasone dipropionate, ciclesonide, mometasone furoate, and flunisolide (**Fig. 1**).

Asthma is a chronic disease that affects 235 million sufferers worldwide with ~250,000 annual deaths attributed to the disease. Prevalence is in the range of 4–11% across countries and is increasing due to western lifestyle and urbanization. An additional 100 million patients are estimated worldwide by 2025 (http://www.who.int/respiratory/asthma/en/). Asthma is characterized by

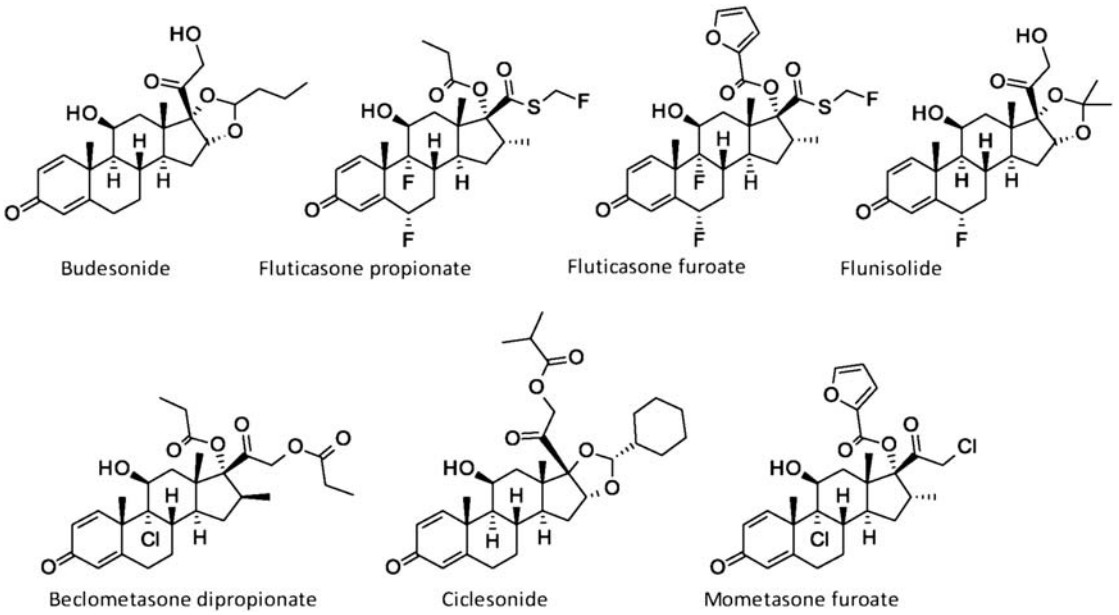

Fig. 1 Inhaled glucocorticoids used in the treatment of respiratory diseases.

varying, reversible airflow limitation, the airway narrowing causes symptoms such as wheezing, shortness of breath, chest tightness, and coughing. During periods of asthma exacerbations massive variability in lung function is seen, and this causes disruption in patients' lives and can even be life threatening. Today IGCs form the base of prophylactic asthma therapy in the Western world. Early intervention with IGCs has been shown to improve asthma control, normalizes lung function, and may also prevent irreversible airway damage. The combination of IGCs and LABAs represents a further improvement in the therapy of asthma, efficient in the treatment of the mild-to-moderate disease segment.[3]

Globally, COPD is a major cause of morbidity and disability, according to the latest estimates from the WHO 64 million people are suffering from COPD leading to 3 million annual deaths, COPD is by 2030 estimated to be the third leading cause of death in the world (http://www.who.int/respiratory/copd/en/). The cost to society caused by COPD in 2010 has been estimated to be $32BN in the United States alone and is expected to rise to $49BN by 2020.[4] Numbers aside, the devastating effect of the disease to the quality of life for the patients suffering from COPD must be remembered.[5] Smoking is shown to be the dominating risk factor in the industrialized world leading to the development of COPD, and it is estimated that 5–10% of the population is affected in most countries. The disease is progressive, leading to an irreversible airflow limitation, with a subsequent decrease in lung function that is characterized by recurrent episodes of cough, sputum production, and breathlessness. Most patients with COPD suffer from exacerbations, which may vary in severity and duration. Frequent exacerbations result in an accelerated lung function decline, decreased quality of life, and drives mortality. Current drug therapy is largely based on bronchodilators and GCs.[6] In spite of the impressive clinical efficacy of IGCs and IGC/LABA combinations observed in asthma, these effects do not fully translate to COPD. IGCs and IGC/LABA combinations have proven clinical efficacy on several patient outcomes in moderate to severe COPD, especially on preventing and treating exacerbations. Clinical efficacy has also been shown by IGS in reducing the overall mortality, as well as slowing down the rate of decline in quality of life of patients.[7] The IGC/LABA combination salbutamol–fluticasone furoate did show a significant reduction CD8 positive T cells, whilst it did not significantly change neutrophils and eosinophils numbers compared to placebo.[8] Emerging data on combining tiotropium with IGC/LABA fixed dose combinations suggest an even further improved potential for reducing COPD exacerbations, improving lung function, and quality of life.[9]

Despite the clinical efficacy of IGCs, it is clear that there is still a significant unmet medical need in the treatment of both diseases, particularly in COPD and severe asthma disease segments.

In patients whose disease is well controlled, IGCs are associated with a low frequency of systemic glucocorticoid-related side effects. However, target-related adverse effects have been reported in the literature, and the long-term use of high-dose IGCs therapy has the potential to cause systemic side effects associated with glucocorticoid-driven pharmacology. Side effects reported include: growth velocity decrease in children,[10] osteoporosis resulting from altered bone metabolism,[11] effects on the hypothalamic–pituitary–adrenal (HPA) axis,[12] and altered diabetic control (glucose mobilization, lipid metabolism).[13] Local side effects in the respiratory tract are also commonly associated with IGCs, including oropharyngeal candidiasis, dysphonia, reflex cough, bronchospasm, and pharyngitis.[14]

For the above reasons, highly selective glucocorticoid receptor (GR) modulators with an improved safety profile and improved therapeutic index (TI) are highly desirable and besides leading to overall improved safety profile. Such a compound also has a potential for further dose escalation leading to generate greater efficacy without compromising safety, ultimately leading to improved disease control in patients.

It is well known that adherence to asthma and COPD medication often is poor and is a significant contributor to poor treatment outcome.[15] Once daily inhaled dosing is envisioned as a strategy to improve compliance and ultimately health outcome. For this reason, developing new inhaled GR modulators, it is highly desirable to achieve duration of action that allows for a once daily dosing regimen for the use in all levels of asthma severity. Long-acting, inhaled GCs combined with once daily bronchodilators in a fixed-dose combination is envisioned to provide the basis for future improved inhaled treatments of asthma and COPD.[16]

8.18.1.2 The Glucocorticoid Receptor

Glucocorticoids exert their function through binding to the intracellular GR.[17] GR is a ligand-activated transcription factor that belongs to the nuclear hormone receptor (NHR) superfamily. Together with the mineralocorticoid receptor (MR), the progesterone receptor (PR), the androgen receptor (AR), and the estrogen receptors (ERα and ERβ) GR forms the steroid receptor subfamily. Phylogenetic analysis shows that GR, MR, PR, and AR are further distinct from the estrogen receptors and are referred to as the 3-ketosteroid receptors.[18]

GR is present in nearly all mammalian cells and is involved in a broad range of fundamental physiological functions spanning from metabolism and the immune response to skeletal growth and cognition. GR is activated by the glucocorticoid hormones cortisol in humans and corticosterone in rodents. These hormones are derived from cholesterol and are synthesized in an endocrine fashion.

Upon stimulus, the hypothalamus releases corticotrophin-releasing hormone, which triggers the anterior pituitary gland to produce adrenocorticotropic hormone (ACTH). ACTH, in turn, stimulates the adrenal cortex to synthesize and release cortisol. The cortisol levels are under circadian control, but the hormone can also be released in response to stress. To ensure that the magnitude of the functional response is appropriate, plasma concentration of cortisol is further adjusted by a negative feedback mechanism governed by GR occupancy in hypothalamus and the pituitary gland.[19]

GR is a modular protein comprising three domains: the N-terminal domain (NTD), the DNA-binding domain (DBD), and the C-terminal ligand-binding domain (LBD). In the resting state, GR predominantly resides in the cytoplasm in complex with several chaperone (hsp70, hsp90, and p23) and co-chaperone (FKBP51, FKBP52, Hop, and Tpr2) proteins. This assembly maintains both receptor stability and ensures hormone sensitivity.[20] Hormone binding to the LBD leads to a partial release of the chaperone complex and to nuclear translocation.[21] In the nucleus, GR binds to both DNA response elements and various coregulator proteins in a highly dynamic fashion.[22] These complexes can directly modify chromatin structure and will ultimately impact on the activity of the gene transcription apparatus. While the DBD governs the interactions to the DNA, the interactions between GR and the coregulators are primarily mediated by the activation functions on the NTD (AF-1) and the LBD (AF-2).[23] GR is an extremely versatile receptor, and several genomic modes of action have been described. The commonly accepted mechanism is transactivation (TA) where a GR dimer binds to the consensus glucocorticoid response element (GRE) leading to an upregulation of the gene transcript.[24] However, GR can also interfere with other transcription factors such as AP-1 or NF-κB in a process called transrepression (TR). In this instance, GR either tethers directly onto the other transcription factor or binds on an adjacent DNA element to repress the corresponding gene product.[25] In addition, a negative glucocorticoid response element (nGRE) where GR mediates direct repression of the target genes has been described.[26] Structural studies reveal that GR binding to the nGRE prevents DNA-mediated dimerization and illustrates how DNA sequences can directly influence the receptor arrangement and the polarity of the transcriptional response.[27]

The functional response to any specific glucocorticoid will depend both on the availability of the DNA response elements and the relative expression levels of the coregulator proteins. In addition, alternative splicing of the GR transcripts and different translation initiation sites gives rise to multiple GR isoforms, and several studies reveal that they exhibit distinct functional profiles.[28] The activity of each receptor isoform can be further modulated by a range of posttranslational modifications.[29] Ultimately, these factors will be integrated on the cellular, tissue, organ, and organism level delivering a pharmacological response.

8.18.1.3 Nonsteroidal Glucocorticoid Modulators

Modulation of GR receptor activity with nonsteroidal ligands, through differential coregulator recruitment, is envisioned as a route to develop GR ligands with improved efficacy and safety margins compared to conventional steroids-based GR ligands.[30] This idea is supported by related work in the field of nonsteroidal ligands acting on the estrogen and ARs.[31] During the last decade nonsteroidal GR ligands have been identified by several groups, a number of reviews are available that describe these efforts.[30,32] The aim for the majority of these programs has been to develop differentiated GR modulators aimed at oral administration (**Fig. 2**). Early examples of nonsteroidal selective GR modulators (SGRMs) include AL-438 (**1**) by Abbott/Ligand,[33] ZK 216348 (**2**) by Bayer Pharma AG,[34] and the *N*-arylpyrazolo derivative (**3**) by Merck.[35] More recent examples are BI 653048 (**4**) by Boehringer Ingelheim,[36] the trifluorocarbinol derivative **5** by GSK,[37] and the benzoxepine (**6**) by Lilly.[38] Two examples of compounds that are reported to have entered clinical trials are mapracorat (**7**) studied for topical treatment of inflammatory skin and ocular disorders[39] and fosdagrocorat (**8**) undergoing studies for the treatment of rheumatoid arthritis.[40] It should be noted that several of these nonsteroidal GR ligands contain the trifluoromethylcarbinol moiety (**2**, **4**, **5**, and **7**). A similar motif was studied in the discovery of the androgen antagonist bicalutamide (**Fig. 7**), and this will be discussed further in this account.[41]

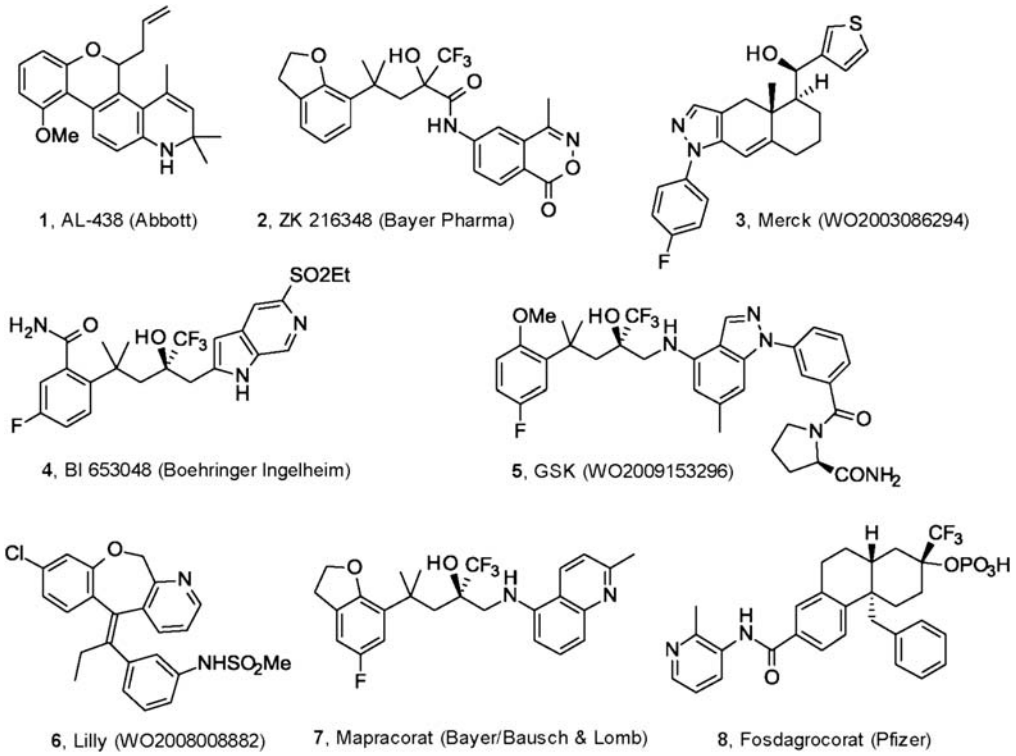

Fig. 2 Examples of nonsteroidal GR modulators reported in the literature.

8.18.1.4 Structure of the Glucocorticoid Receptor

It was realized at an early stage within the project, that access to high-quality experimental GR structure data would be a key success factor for the progression of the project allowing for an in-depth understanding of the structure–activity relationships (SARs) for the individual series. Furthermore it was envisioned that the structural data would form the basis for any computationally guided design efforts able to formulate and address complex hypotheses linking changes of the receptor structure to ligand-dependent changes in the pharmacological responses.

The first in-house X-ray structure obtained of the GR LBD confirmed the canonical nuclear receptor three-layered alpha helical sandwich fold previously reported (Fig. 3A).[42] Furthermore the structure showed how dexamethasone binds in the fully enclosed ligand-binding pocket in the receptor domain (Fig. 3B).

The interaction between the ligand and the receptor provides the basis for ligand potency and allosteric modulation of auxiliary surfaces, primarily AF-2 and the dimerization surface, directing functional response. As the ligand is completely surrounded by the receptor protein, nearly all atoms of dexamethasone are in contact with the surface of the ligand-binding pocket. While the bulk of the interactions is hydrophobic in nature, dexamethasone also forms the typical key hydrogen bond interactions with helices 3, 5, and 11. Specifically, the A-ring ketone moiety (Fig. 3C) makes direct interactions to the gatekeeper residues Gln570 and Arg611 from helices 3 and 5, respectively. The conformation of the gatekeeper residues is further stabilized by several conserved water molecules. A number of studies have highlighted that the helix 3–helix 5 interface is crucial for receptor activation, and all steroid hormones contain an A-ring functionality to exploit this agonist trigger.[43] At the opposite end of the ligand-binding pocket, Asn564 in helix 3 makes direct interactions to both the C11 and C21 hydroxy groups of dexamethasone. Asn564 is an important anchoring point for the ligands, this residue is fully conserved among the oxosteroid receptors, and the corresponding residue in the estrogen receptor is threonine. Looking at the second shell interactions, the asparagine residue is part of an extended hydrogen-bonding network that extends to the backbone carbonyl of a glutamate residue in the loop in between helices 11 and 12.[44] In close proximity to Asn564, Thr739 in helix 11 makes a direct interaction to the dexamethasone C20 ketone oxygen. However, in a number of subsequent complex structures of GR and different steroid-based ligands the threonine residue adopts different rotamer conformations, slightly changing the interaction pattern of this region and highlighting the versatility of ligand binding.[45] Nevertheless, the threonine residue is fully conserved among all steroid receptors where the endogenous hormone has a C20 ketone group (GR, MR, and PR). Taken together, the direct interactions to Asn564 and Thr739 have important roles in both ligand recognition and receptor activation through stabilization of the active helix 12 conformation. Finally, looking beneath the plane of the steroid ligand, the dexamethasone C17α hydroxyl makes a direct interaction to Gln642 in helix 7. This residue is a distinct feature of the GR-binding pocket. While AR also has a glutamine residue at the corresponding amino acid position in the protein sequence, a structural comparison reveals that it is further removed from the ligand.[44b]

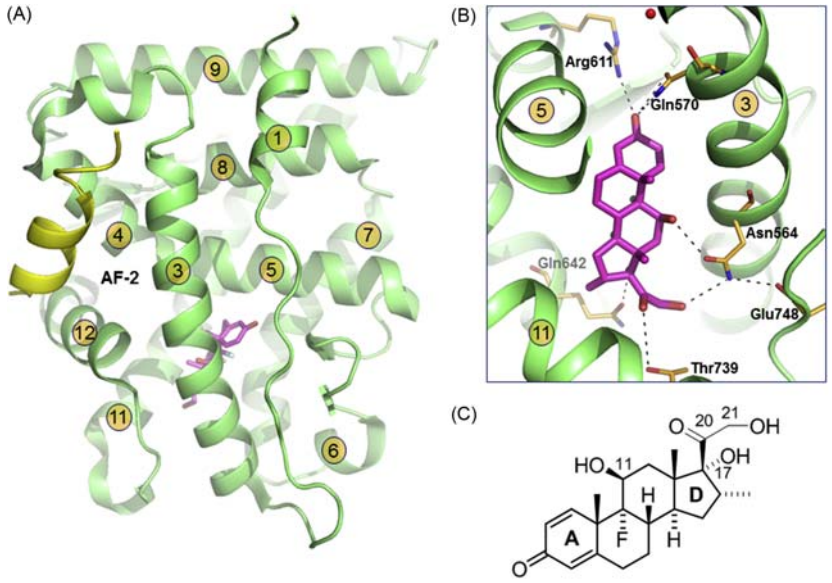

Fig. 3 (A) The GR LBD (*green*) with a TIF-2 peptide (*yellow*) and dexamethasone (*magenta*) binding at the receptor core. The structure comprises three helix layers; helices, 6, 7, and 10/11 at the back; 4, 5, 8, and 9 at the center; and 1, 3 at the front. The ligand-binding pocket is fully enclosed in the receptor delineated by helices 3, 5, 7, 11, and 12. (B) Details of the interaction in between dexamethasone and key residues of the ligand-binding pocket. Putative hydrogen bond interactions are shown as dashed lines. (C) The chemical structure and annotation of dexamethasone.

While the structure of GR in complex with dexamethasone provides a static view of the interactions in between the ligand and the receptor, a large numbers of complex structures with a range of different steroidal and nonsteroidal ligands have been published since.[37,45,46] Together, the ensemble of structures builds a more comprehensive appreciation of plasticity of the GR receptor and provides an emerging understanding of the underlying molecular drivers for different pharmacological responses.

8.18.2 Project Objective, Screening Cascade, and Compound Target Profile

In 2003, AstraZeneca launched a project with the aim to develop novel-inhaled SGRMs with improved efficacy and safety margin compared to existing IGCs aiming for once-daily treatment of Asthma and COPD. In 2005, AstraZeneca entered into a joint, 4 year, research collaboration with Bayer Pharma AG. The program included a joint discovery programs for discovery and development of inhaled, oral, and topically administrated GR modulators aiming at addressing a broad range of disease indications. However, the key focus for AstraZeneca was to progress inhaled GR modulators for the treatment of respiratory diseases which will be the focus for this article.

To progress the discovery program a set of biochemical and cellular assays was established. This included GR-binding assays using two different formats to measure receptor affinity, either in a competitive receptor-binding scintillation proximity assay using full-length human GR and radiolabeled dexamethasone. The second assay was a fluorescence polarization-binding assay (FP) using full-length GR measuring the displacement of a fluorescence labeled GR ligand.[47] NHR receptor selectivity for the PR, MR, AR, ERα, and ERβ receptors was determined using FP-based competitive receptor-binding assays. Receptor selectivity was determined as the ratio between receptor potencies in the different FP assays.

The functional GR activity was determined using an array of different cell assays. To determine the functional pharmacological effect, a reporter gene assay system was established allowing for both gene TR and TA to be measured. The TR activity was determined in Chago K1 cells stably transfected with a construct containing several TRE sites (AP-1 pathway) in front of a LacZ reporter gene. The TA activity was determined in Chago K1 cells, stably transfected with a plasmid construct where the MMTV promoter containing several GREs was inserted up-stream of the LacZ reporter gene. The antiinflammatory effects in primary cells were measured in peripheral blood mononuclear cells (PBMCs), measuring the inhibition of the release of tumor necrosis factor-α (TNF-α) in response to lipopolysaccharide (LPS) stimulation. The PBMC assay was established for both human and rat to allow for species cross-over estimates in a primary functional assay. Finally, an assay measuring the inhibition of TNF-α release from LPS-stimulated whole blood was established for both human and rat (Fig. 4).

Although various cellular models were used to describe the pharmacological effects of different compounds, the final differentiation versus IGCs ultimately relied on a direct comparison in in vivo models. To evaluate potency, duration, functional responses, mechanistic side effects, and the effects in "disease-like" scenarios in vivo, a range of animal models was used. In the studies described later, compounds were administered to the animals either using the intratracheal instillation or through inhalation.

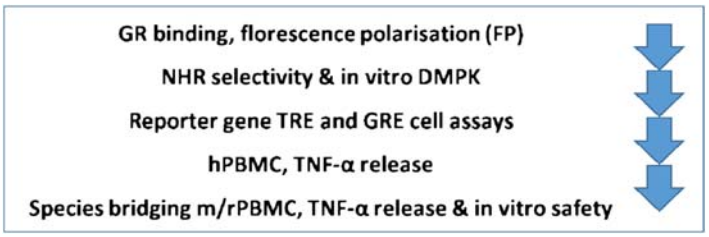

Fig. 4 Inhaled SGRM screening cascade, key in vitro assays used for compound progression.

Compound potency and mechanistic side effects were measured in the rat Sephadex model.[48] Male Sprague–Dawley rats were challenged via intratracheal instillation of Sephadex beads, and due to the inborn hypersensitivity of the rats toward dextran, an eosinophilic-driven inflammation develops over time in the lungs. The inflammatory response can be monitored by following the increase in lung weight (edema), which peaks at 24–48 h and is maintained for more than 7 days after provocation. GR-dependent effects on thymus weight were used to provide an estimate of the TI compared to IGCs.[49]

Effects on neutrophils and cytokine release were studied using the rat or mouse LPS models. As the exposure to significant levels of LPS is reported to be associated with the development and/or progression of many types of lung disease. In addition, human LPS studies have been used in several programs as the proof of principle model to progress compounds for further studies in COPD patients. The effects of following LPS simulation may be characterized by inflammatory processes in the lung, including neutrophilic inflammation and the increase in levels of cytokines.

Antiinflammatory responses were also studied in the acute cigarette smoke mouse model. In this model, female Balb/C mice were exposed to cigarette smoke twice daily for 4 days to induce a local inflammatory response in the lung, reflected by an increase in the number of neutrophils. Cigarette smoke is the main risk factor for developing COPD in humans.

Criteria for the project were defined including the following key criteria (candidate drug target profile):

- Potency in human peripheral blood mononuclear cells (hPBMCs), $IC_{50} < 1$ nM
- High clearance; >70% liver blood flow
- Nonhygroscopic, stable crystalline polymorph

In vivo differentiation assed in the rat Sephadex model showing improved therapeutic ratio versus ref IGCs.

8.18.3 Inhaled Drug Design and Challenges

Inhalation is the preferred route of administration for glucocorticoids for several reasons, but most importantly in order to reduce systemic GR-related side effects. This became evident though the successful introduction of beclomethasone dipropionate in 1972, the first IGC with a targeted delivery into the lung to achieve pulmonary effects with reduced systemic side effects compared to oral administration of the GR ligands.[50] Inhalation of drugs is based on a nonequilibrium concept where improvements in dose potency and safety of the administered drug are related to the ability to achieve high local concentrations while maintaining a low systemic exposure. Key properties targeted for compounds in the project were high pulmonary deposition and rapid systemic clearance. High pulmonary deposition may be achieved either via dissolution-dependent retention of the drug to the lung, such as seen for existing IGCs, or by basic compounds having a high degree of tissues distribution, reflected in large terminal volume of distribution (Vz) such as seen in LABAs. At the initiation of the project it was assumed that lung retention would be achieved using a slow dissolution rate approach, since GR is known to prefer binding to neutral ligands, while no examples were found of acidic or basic ligands showing any significant affinity to the receptor.

Compounds were tested in animal models either through dry powder inhalation or alternatively administered directly into the trachea of intubated animals, intratracheal (i.t.) instillation. There are pros and cons with each of the two methods: Generally, administration via inhalation to animals is regarded to be more relevant for the human clinical situation, since conscious animals are used and more uniform distribution in the lung is achieved. For this reason inhalation was used to obtain more precise measurements of compound pharmacology and also used for dose to man predictions. A significant disadvantage using this method is that crystalline compound is required to conduct the studies. The experimental procedure available also requires rather large amounts, ~2 g, of compound to prepare the tablet used to generate the powder flowing into the inhalation towers (Fig. 5).

A constraint of the inhaled dry powder administration is the limited dose that can be delivered to the patients' lung. The limitations of the dosage leads to that the predicted daily human dose (delivered to the lung) needs to be well below 100 $\mu g\,kg^{-1}$ or 3500 μg total daily dose assuming twice daily dosing (BID). Compared to oral dosing this limit may seem quite restrictive but reviewing inhaled compounds currently in clinical use, and most are efficacious at doses below 500 μg (~14 $\mu g\,kg^{-1}\,day^{-1}$). To achieve this level of potency provided a significant challenge to the SGRM project. While, for example, the endogenous hormone adrenaline meets this potency criterion binding to the β2-receptor, cortisol the natural hormone of the GR does not. IGCs such as budesonide and fluticasone propionate are several orders of magnitude more potent than cortisol. The following rule of thumb was

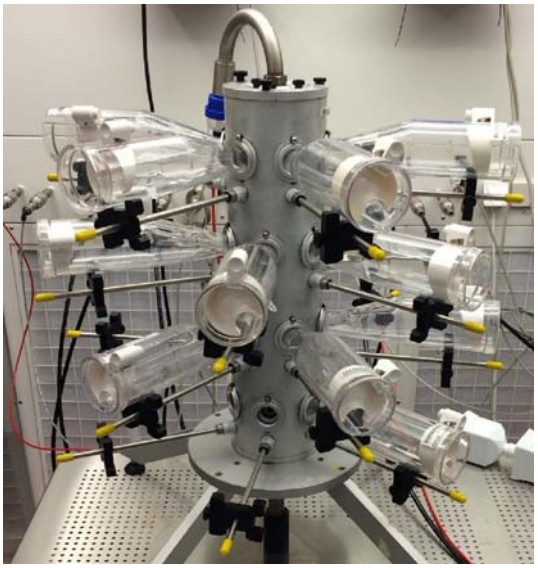

Fig. 5 Inhalation tower used in the dry powder inhalation (DPI) in vivo studies.

used in the project: to progress a compound into the primary in vivo studies, the potency in the PBMC assay needed to be equal or higher than that of budesonide, meaning that an IC_{50} of <1 nM was used as progression criteria.

In order to minimize systemic GR-dependent side effects, rapid metabolic deactivation was desired. There are a number of potential strategies to achieve this, such as esterase-mediated cleavage or via hepatic oxidative deactivation. Hepatic deactivation has many advantages and was preferred by the project. Preclinical in vitro models using microsomes and hepatocytes generally predict in vivo clearance well and are available for many species, e.g., human, rodent, dog. Furthermore, deactivation of existing IGCs relies on hepatic oxidative clearance, proving the viability of this principle also in the clinical setting. As systemic deactivation of ligands is of high importance to minimize systemic GR-dependent side effects, metabolite identification, synthesis of metabolites, and pharmacological evaluation of these became an integral part of the discovery project make-test cycle.

8.18.4 Lead Identification

A broad spectrum of lead generation methods was considered at the initiation of the project; however the early success of high-throughput screening (HTS) delivering workable chemical starting points prompted the project to fully focus the efforts to progress these screening hits.

The AstraZeneca, 660 k HTS compound collection was screened using a competitive GR fluorescence polarization assay leading to 5575 retest actives with $>50\%$ inhibition at 10 μM. A selection of retest actives (2409 DMSO solutions) was submitted for LC/MS purity and identity confirmation. Remaining compounds were clustered based on their chemical structure, and 435 cluster members were retested using freshly prepared DMSO solutions. This resulted in that 14 structurally diverse series and a number of structural singletons were selected for in-depth characterization including in vitro DMPK, physicochemical properties, selectivity over related steroid hormone receptors (PR, MR, ERα/β), and cell cytotoxicity providing the basis for prioritization (Fig. 6). Two hit series, exemplified by structures **9**–**12**, were selected as starting points for the Hit-to-Lead chemistry program. An additional set of compounds based on the three series exemplified by compounds **13**–**15** were retained within the program considered as back-up series. These series were all viewed as novel and potent GR binders, displaying binding potencies in the nM range. The most potent compound **11** had a GR-binding potency of IC_{50} 14 nM. In addition, most compounds showed high degree of selectivity toward other steroid hormone receptors tested.

The functional cellular activity was determined for all series using a reporter gene assay system run in agonistic mode, determining gene TR activity. The results revealed that all compounds tested showed low or no functional activity and were therefore considered to be antagonists. This was confirmed by screening compounds in the TR cellular assay in antagonistic mode using dexamethasone (10 nM) as agonistic substrate. Under these test conditions, at 10 μM concentration, compounds **9** and **11** showed 85% and 50% downregulation of the reporter gene signal, respectively. Thus, an initial key objective for the project was to introduce functional agonism in the series. It has previously been shown that limited structural changes to the structure of nonsteroidal ligands binding to steroid hormone receptors may change functional activity from antagonism to agonism and vice versa.[41] In the original report by Tucker et al., describing the discovery of the androgen antagonist bicalutamide, it was noted that matched pair, methyl congeners **16**, **18**, and **20** displayed no agonistic activity, while the trifluoromethyl analogues **17**, **19**, and **21** all exhibited high level of functional agonism. Though it was assumed that the increased acidity of the hydroxyl proton induced by the electron-withdrawing

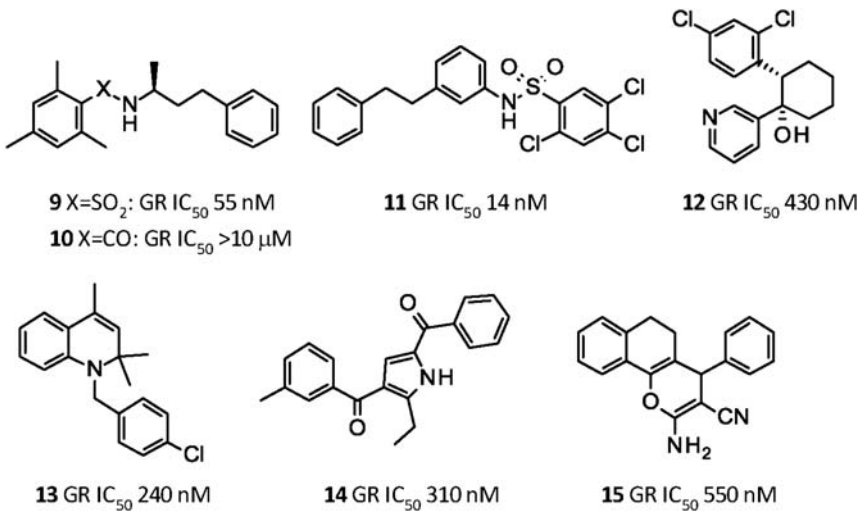

Fig. 6 HTS hits selected based on follow-up screening of primary actives. Compounds **9**–**12** were chosen for progression into the Hit-to-Lead chemistry program.

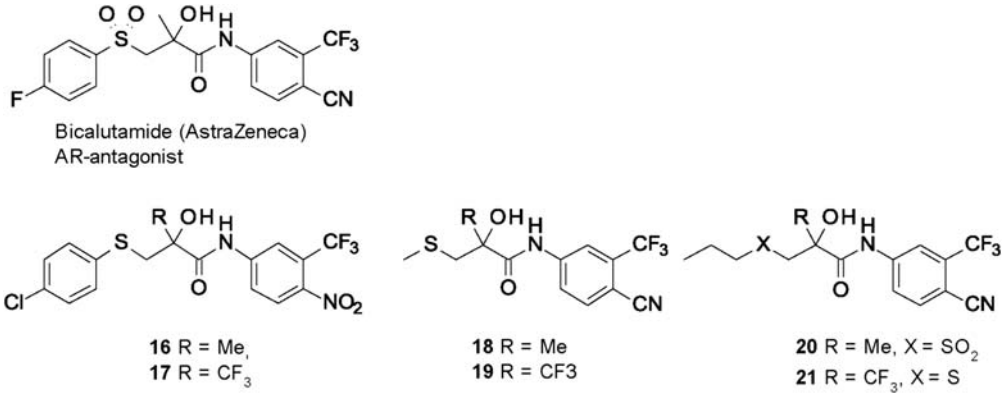

Fig. 7 Bicalutamide and bicalutamide analogues showing different antagonist–agonist receptor pharmacology. Compounds **16**, **18**, and **20** show no agonistic activity, while **17**, **19**, and **21** all displayed functional agonism.

trifluoromethyl group was driving agonism, lack of structural understanding of ligand–receptor interaction prevented a structure-based mechanistic understanding (Fig. 7). The publication of the first X-ray crystal structure of the W741L mutant AR LBD bound to *R*-bicalutamide in 2005 showed the interaction of the bicalutamide hydroxyl group with Asn705 in helix 3 and thus pointed to the importance of this interaction and stabilization of helix 3 as key structural drivers for functional agonism.[51]

The cyclohexanol-based series originated from the HTS singleton **12** showed nanomolar potency in the GR-binding assay, excellent NHR selectivity, but as previously mentioned displayed antagonism in the cellular TR reporter gene assay. A series of analogues to **12** was prepared aimed to improve the overall property profile and to explore the introduction of agonist triggers. However, the efforts to improve properties by reducing lipophilicity resulted in reduced biochemical GR potency, and as a result this series was parked.

The most promising hit series, the sulphonamides, included several compounds that displayed nanomolar potency in the GR-binding assay as well as a high degree of NHR selectivity as exemplified by compound **9**. This easily accessible compound was particular attractive based on the synthetic scope as it could be synthesized in one-step from commercially available starting materials. However, as previously mentioned all members of this series displayed functional antagonism. An initial key objective was therefore to introduce functional agonism in this series. The metabolic and physical–chemical properties also needed to improve during the initial phase of the project.

Early expansion of the sulphonamide HTS hit **9** included the synthesis of corresponding carboxamide **10**; however this resulted in complete loss of binding affinity to the GR receptor. The introduction of a heteroatom (N, O) in the benzylic position of compound **22** improved the synthetic scope now allowing parallel chemistry to be used in the initial exploitation of the series. A study of the activity of various aryl ethers and anilines was then initiated, using a synthetic route that enabled preparation of ethers (entry **23**) and amines (entries **26**–**29**) as single enantiomers starting from (*S*)-2-Amino-1-propanol.

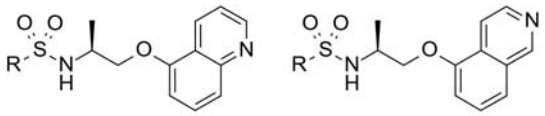
[b]% of dexamethasone at 10^{-6} M.

For several of the analogues the affinity to the receptor was retained or improved compared to compound **9** (Table 1). Interestingly, the attachment point to the heterocycle demonstrated a steep SAR. For example, the quinoline (**25**) linked through the 5-position has an affinity to the GR of 75 nM, whereas affinity is completely abolished for the 6-linked quinoline derivatives (**28–29**). This observation is supported by modeling studies in which the elongated ligand-binding pocket in the receptor strictly dictates size and shape of substituents allowed. From Table 1 it is also clear that the positioning of aromatic heteroatoms plays an important role for the functional activity. While the 5-isoquinoline (**24**) is more potent than the 5-quinoline (**25**) in the binding assay, only the 5-quinoline (**25**) is an agonist in the cellular TR assay. Modeling studies provide an explanation that positions the heterocyclic ring in the same region of the ligand-binding pocket as the A and B rings of conventional steroids. For optimal interactions to the receptor, the heteroatom of the heterocyclic ring should mimic the 3-keto oxygen of the steroid to pick up the key Arg611, Glu570 interactions, and a conserved water molecule.[7] These interactions between GR helices 3 and 5 have been shown to be critical drivers for functional agonism.[43a]

To determine the impact of the sulphonamide substituent a range of sulphonamides of different size and shape were investigated **30–34** (Table 2). All substituted phenyl sulphonamides, entries **30–33**, showed inferior GR binding compared to the mesityl

Table 2 GR binding and activity in TR reporter gene assay for selected compounds



30, 31 **32-34**

sulphonamides. Modeling indicates that the sulphonamide substituent binds in the same region as the steroid D-ring 17α position, and the data confirm the critical role of this pocket for binding affinity. The fact that the potent 1,2-diazole (**34**) is much larger than the original mesityl group also illustrates the flexibility in this region of the receptor, as previously reported.[46a] Since the 1,2-diazole used in compound **34** contributes favorably to decrease the lipophilicity, this motif was selected for further investigations together with the more potent mesityl congeners.

In an effort to mimic the phenyl-pyrazole A-ring substituents in steroid derivatives, e.g., cortivazole (**Fig. 8**), a series of 1-aryl indazoles were investigated (**Table 3**).[46c]

Many compounds from this series showed excellent potency in the binding and TR assays. The activity of compounds in primary cells was studied in hPBMCs, where the release of TNF-α in response to LPS stimulation was used to test the antiinflammatory effects. As can be seen from data in **Table 3**, several of the compounds were confirmed to be potent agonists in this assay.

Functional agonism is driven by a well-defined structural state of the receptor, where coactivators are recruited to the binding surface outlined by helix 3, 4, and 12 (**Fig. 3A**).[42,46e]

While the position of helix 12 is instrumental for achieving receptor activation,[46g] helix 3 also plays an important role spanning the full length of the receptor and provides interaction surfaces that are key for the structural integrity of the receptor. It also has several direct interactions with both ligand and coactivator peptide. As such, helix 3 could be considered the spine of the LBD; both provides a framework that enables productive positioning of helices 5 and 12 and has sensory neurons that read the ligand information and helps transmit this information to the AF-2 surface. Ultimately, the ligand-induced structural state of the LBD drives the intermolecular (in between LBD, DBD, and NTD) and intramolecular (in between GR, coregulators, and DNA) interactions providing the functional response.

To better understand the molecular details of the conformations induced by the sulphonamides, the X-ray structure of the LBD in complex with compound **36** was determined.[46c]

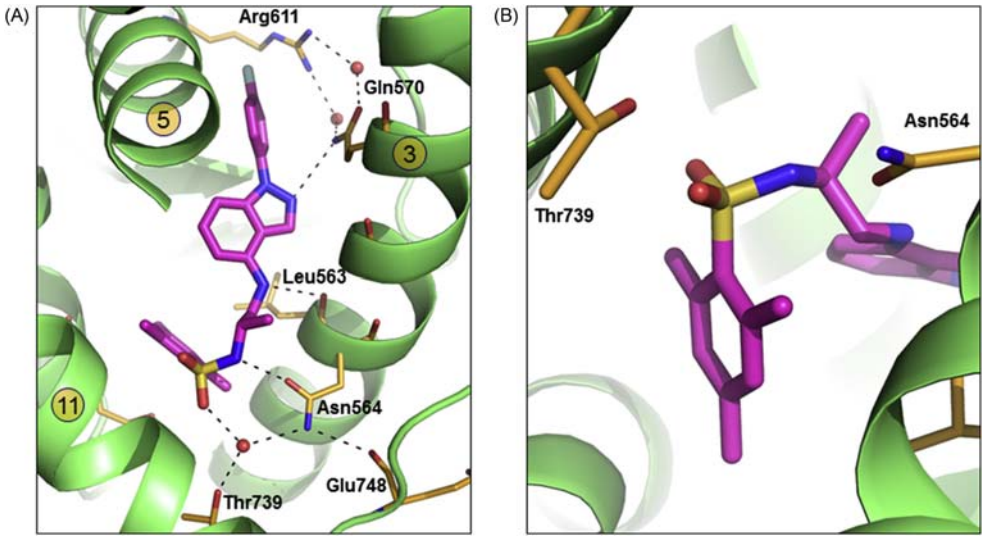

Fig. 9 (A) Refined 2mFo-DFc electron density of GR LBD in complex with the sulphonamide **36**. The dotted lines represent putative hydrogen bonds. The structure shows that **36** make extensive interactions with residues on helix 3. (B) Detailed view of the mesitylene tail.

The compound **36** complex structure confirms the formation of multiple interactions between the ligand and helix 3, stabilizing an agonistic conformation (Fig. 9A). Specifically the nitrogen of the sulphonamide linker makes a direct interaction to the O_δ atom of Asn564 corresponding to Asn705 in AR. In addition, one of the sulphone oxygens is located within hydrogen-bonding distance to a putative water molecule, optimally positioned to make interactions with both Thr739 and the N_δ atom of Asn564. As mentioned previously, interactions to Asn564 are of particular importance as the N_δ atom makes a hydrogen bond to the backbone carbonyl group of Glu748, in the loop between helices 11 and 12, thus stabilizing this region.[44]

Adjacent to Asn564, the backbone carbonyl of Leu563 is within hydrogen-bonding distance of the amino group in the indazole 4-position (Fig. 9). The importance of this interaction highlighted by the ether congener **35**, which lacks a donor at this position and shows no activity in the hPBMC assay (compared to 14 nM for **36**). Interestingly, compound **37** illustrates that the hPBMC activity is restored if a trifluoromethyl group is introduced adjacent to the sulphonamide nitrogen. It is reasonable to argue that the introduction of the electron-withdrawing group strengthens the ability of the sulphonamide nitrogen to donate its hydrogen to Asn564.

Beyond the sulphonamide, the mesitylene group enters the hydrophobic volume created at the intersection of helices 3, 7, and 11 (Fig. 9B). This volume overlaps with the 17α substituent that found in most high potency steroid-based ligands. Compounds like **38**, having a large 17α substituent, highlight the significant flexibility of this region. It is interesting to note that none of the endogenous steroid receptors ligands extends into this volume. In a series of unbiased ligand-binding simulations, it was shown that the plasticity of this region is likely coupled to the ligand entry and exits trajectories into and out of the ligand-binding pocket.[45]

The indazole fragment of **36** makes an interaction to the N_ε atom of Gln570 (Fig. 9A). The gatekeeper residues, Gln570 and Arg611, arranged in the open conformation to accommodate the *p*-fluorophenyl substituent.[46i] The *p*-fluorophenyl acts as a hydrophobic link between helices 3 and 5 at the core of the receptor and contributes significantly to the functional agonism observed for compounds with this and similar moieties.[43b] Mutation studies confirm that the interaction strength in between these helices is a powerful agonist trigger across the steroid receptor family.[22b,43a]

The structural analysis of compound **36** shows that the sulphonamide template exhibits a differentiated binding mode relative to steroid-based ligands. Taken together with the fact that steroids are based upon a more rigid scaffold, we hypothesized the sulphonamides induces a distinct structural state leading to a unique protein–protein interaction pattern. To test this hypothesis, we measured the binding of the GR LBD to various coregulator peptides in the presence of compounds **36** and **38** using surface plasma resonance measurements.[46c] In essence, this is a biophysical measurement of how the structural state of the AF-2 interface varies dependent on the ligand structure (Fig. 10). The result indicates that the sulphonamides **36** and **38** have a different cofactor recruitment profile relative to the glucocorticosteroids dexamethasone and fluticasone propionate; the full pharmacological impact of this observation is yet to be understood.

Both compounds **36** and **38** displayed excellent receptor selectivity against a panel of steroid hormone receptors, in comparison the receptor selectivity for key reference-inhaled steroidal glucocorticoids is less pronounced (Table 4).[52] The antiinflammatory effect measuring TNF-α from LPS-stimulated rat PBMCs (rPBMCs) was used to determine the rat–human crossover preceding the in vivo studies. The physicochemical and in vitro PK properties (Table 4) indicate that both compounds as suitable for inhaled delivery and with property profiles similar to reference IGCs. This includes high hepatic clearance to minimize systemic exposure.

The in vitro metabolite profiles were determined in human liver microsomes and human hepatocytes. For both compounds, oxidative *N*-dealkylation was identified as the major metabolic pathway leading to the release of 4-aminoindazoles. Generally, compounds in this series showed little CYP P450 inhibition.

The lung and blood concentrations after i.t. instillation were determined for compounds **36** and **38** (Fig. 11). A key driver for lung retention of neutral compounds is the rate of dissolution, often linked to solubility. Compound **36** is less soluble than compound **38**, the lower solubility of compound **36** leading to higher degree of lung tissue retention, with ~50% of the dose remaining in the lung 24 h after dosing compared to only minor amounts remaining in the lung 4 h after dosing for the more polar compound **38**. In a separate study, the blood concentration-time curves after i.t. instillation were determined. The data are in line with the results from the study of lung tissue levels, showing more rapid systemic absorption for compound **38** resulting in higher C_{max} as compared to compound **36**.

The in vivo efficacy of compound **36** was studied in the rat LPS model of acute inflammation.[53] In this model compound **36** was instilled intratracheally 2 h prior to LPS challenge. The total number of leukocytes in the broncho-alveolar lavage (BAL) fluids and increase in lung weight (edema) determined 4 h after challenge. Compound **36** significantly inhibited cell influx at doses of 30 and 100 μg kg^{-1} by 90% and 85%, respectively. The compound also inhibited lung edema, as measured by total lung weight, in a dose-dependent manner. Fluticasone propionate dosed at same doses as compound **36** was used as reference (Figs. 12 and 14).

Cigarette smoke is the main risk factor for developing COPD in humans. Using a mouse model of inflammation, female Balb/C mice were exposed to cigarette smoke for 50 min twice daily for 4 days to induce a local, smoke-induced, inflammatory response in the lung reflected by an increase in the number of neutrophils in BAL fluid.[22] Animals were pretreated with compound **36**, 30 min prior to the first cigarette smoke exposure on each day (4 days treatment in total). Twenty-four hours after last exposure mice were terminated, and the number of neutrophils in the BAL fluids is determined.

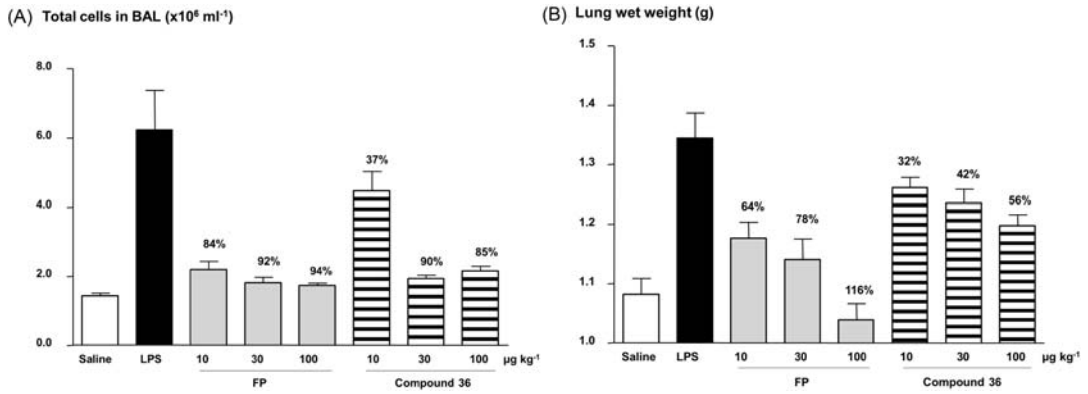

Fig. 12 (A) Inhibition of leukocyte influx. (B) Inhibition of lung edema following *i.t.* administration of compound **36** and fluticasone propionate in the acute LPS model.

In this model **36** significantly inhibited neutrophil influx into BAL fluid of mice exposed to cigarette smoke for 4 days at a dose of 30 μg kg^{-1} (Fig. 13). Fluticasone propionate and budesonide were used as references in this study.

With the identification of potent sulphonamides such as **36** and **38** a series of highly potent and selective nonsteroidal GR modulators had been identified that were suitable for progression into lead optimization.

8.18.5 Lead Optimization Leading to AZD5423, Inhaled SGRM CD1

The initial data generated for compounds belonging to the sulphonamides had shown that this series could provide the project with potent and selective ligands. Selected compounds were shown active in pharmacodynamic models including the acute tobacco smoke model. Structure studies of the receptor–ligand binding provided insight into functional drivers of agonism and cofactor affinity profiles that revealed a differentiated binding mode compared to reference steroidal glucocorticoids. The ligands showed PK properties such as high clearance and a solubility range suitable for further optimization as inhaled GR modulators. *N*-dealkylation via oxidation of the α-methylene position was identified as the major metabolic pathway for this series, leading to compound cleavage and formation of several fragments, including 4-aminoindazoles. However, while the cleavage of the ligand into two discrete parts ensured effective deactivation of GR activity, the formation of 4-aminoindazoles posed an issue due to the potential genotoxicity risk. The lead compound **36**, together with its aniline fragment 4-amino-1-phenylindazol, was subjected to a full Ames test also including metabolizing enzymes. Parent compound **36** came out as inactive from the Ames testing and showed no activity in mutagenic strains of *Salmonella typhimurium* LT2 TA98 and TA100. However, the aniline fragment 4-amino-1-phenylindazol showed a positive response in the Ames test in the presence of lung S9 fraction. Considering that metabolite profiling of **36** had shown that this fragment was formed, it clearly pointed to a genotoxicity risk within the series that needed to be addressed.

Therefore, the primary objective at the initiation of the lead optimization program was to identify GR ligands that were Ames-negative, not forming Ames positive metabolites that retained the overall favorable properties of the lead compound.

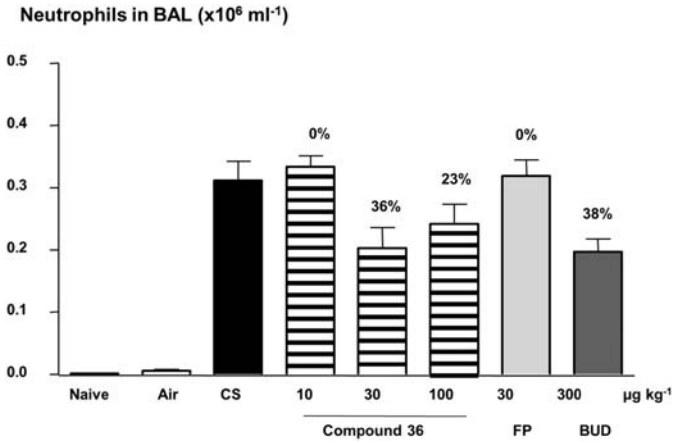

Fig. 13 Inhibition of neutrophil influx in bronchio alveolar lavage (BAL) following *i.t.* administration of compound **36**, fluticasone propionate and budesonide (BUD) in the acute cigarette smoke mice model.

Multiple approaches to resolve the potential Ames issue were investigated in parallel. A particular concern was the fact that crystallography studies of the GR–ligand complexes revealed the formation of a hydrogen bond interaction of the 4-aminoindazole with the backbone carbonyl of Leu563 in helix 3 (Fig. 9A). The importance of this interaction was emphasized by a set of congeners lacking the proton donating capability at this position as exemplified by compound **35**. This compound displayed no activity in cellular functional assays, while the corresponding 4-aminoinazole congener **36** showed excellent functional activity in the cell assays. Interestingly, compound **36** illustrates that the hPBMC activity may be partly recovered if a trifluoromethyl is introduced adjacent to the sulphonamide nitrogen. It is believed that the introduction of the electron-withdrawing group strengthens the ability of the sulphonamide nitrogen to donate its hydrogen to Asn564. However, it is clear that the hydrogen bond formed by the aromatic amine is an integral part of the agonistic pharmacophore by stabilizing GR LBD helix 3 and initially believed to be very difficult to replace.

The first attempt to prevent the metabolic cleavage leading to the formation of aromatic amines focused on the synthesis of compounds **39**–**43** where the secondary amine was made metabolically stable to oxidative cleavage, either by incorporation aromatic amine as a part of a pyrrolidine or a piperidine unit. A second, alternative approach was to block oxidation of the α-position by introduction of a α-methyl or gem-dimethyl substitution next to the aromatic amine. However, both approaches resulted in reduced binding and cellular potency compared to lead compound **36** (Table 5). In the case of the pyrrolidine and piperidine congeners, the loss of functional activity can partly be understood considering that these ligands lack the ability to form a hydrogen bond with Leu563. Compound **43** illustrates an attempt to improve the potency of ether congeners, by moving the ether oxygen away from a potential clash with the Leu563 carbonyl by shifting the ether connection point from 4- to 5-position of the indazole, but again cellular potency was compromised.

Another strategy tried was to identify aromatic amines that were free of genotoxicity, while retaining GR affinity and functional activity in cellular assays for the nonmetabolized sulphonamide ligand. Although aromatic amines have an increased risk, it is far from automatically linked to genotoxicity as has been concluded in several recent articles and reviews.[54] Close aniline congeners such as 5-aminoindazoles or 5-chloro-4-aminoindazoles remained Ames positive. However, the electron-deficient bicyclic aromatic amine, pyrazolopyridin-4-amine showed no activity in the Ames assay, and the corresponding sulphonamide **44** incorporating this amine showed an encouraging PBMC IC_{50} of 15 nM. However, this track to remove the genotoxicity liability was downprioritized in favor of the indazole ether series that was explored in parallel and making significant progress.

As part of the collaboration with Bayer Pharma AG, several series was worked upon in parallel. One compound (**45**) belonging to a series of tetrahydronaphtalenes that showed cellular activity in the TRE assay and in the PBMCs was cocrystallized with the GR-LBD (Fig. 14A).[55] The X-ray structure revealed a binding mode different to the sulphonamide **36**. From the structure it was noted that the aromatic amine in **45** is located 4.5 Å away from the Leu563 carbonyl and, as such, did not appear to make a direct interaction with the helix 3 backbone. Thus, the geometry of the core of **45** offered an option to connect the aromatic amine through an ether linkage instead of an amino group while retaining functional cellular agonistic activity. Furthermore, the structure of compound **45** in complex with GR LBD allowed compounds belonging to a third series part of the collaboration, exemplified by compound **46**, to be confidently modeled into the ligand-binding pocket (Fig. 14B).[56] All key interactions are maintained, but as the tetrahydronaphtalene ring has been opened up resulting in a perpendicular rotation of the phenyl substituent in the minimized conformation. The orientation of the phenyl now allows for the ligand to better exploit the shape and plasticity of the 17α-pocket, which is reflected in a significant improvement of the cellular potency for **46** over **45**.

The GR-LBD ligand complex structure of **46** inspired the design and synthesis of a new series of indazole ether-based GR ligands. Key motifs of the sulphonamide lead **36** were preserved, indazole moiety and the sulphonamide linker, but the connectivity was rearranged (Fig. 15). The secondary amino group was replaced by an ether linkage, and the connection point was moved from 4- to 5-position on the indazole moiety. The terminal aryl group (mesityl in compound **36**) was attached as a branch from the linker unit

and directed into the 17α-pocket. The sulphonamide group is now pointing toward a pocket between helices 7 and 11 to enable a new interaction with the binding pocket, not utilized by lead **36**. Furthermore an additional lipophilic moiety was attached to the sulphone group to compensate for the loss of an H-bonding interaction to helix 3 as a consequence replacing the aromatic amine with an ether linker. Thus the cyclopropyl substituent enables an additional interaction with helix 11, a protein region to which **36** made no interactions, compare **Fig. 9**.

The first compound to be synthesized in this series was compound **47** formed by reacting norephedrine with 1-(4-fluorophenyl)-5-iodoindazole (**I1**) using Ullmann conditions as the key synthetic step (**Scheme 1**). The compound **47** showed excellent cellular potency and did, importantly, not show any Ames activity as the compound lacks the possibility to form Ames positive metabolites. Thus meeting the primary objective for the initial phase of the Lead optimization phase. Compound **47** was selected for further characterization in vitro and in vivo. The compound retained the steroid hormone receptor selectivity previously observed for

the lead compound **36**. Inhibition of TNF-α release from LPS-stimulated rPBMCs was used to establish antiinflammatory effects of compounds in rat and to ensure species cross over to in vivo pharmacodynamic models. Analysis of physicochemical and in vitro PK properties (Table 6) indicated that the compound could be regarded as suitable for inhalation and with properties similar to reference IGCs.

Although **47** displayed an excellent profile several properties had to be improved in order to generate a clinical drug candidate. The cellular potency was still too low to meet the dose limitations for a dry powder inhaler for once daily administration. Another property that needed to be improved was metabolic deactivation as measured by its stability in human hepatocytes. A set of analogues was synthesized and profiled (Table 7). Of the arylindazoles synthesized, *p*-fluorophenylindazole was found to be the most potent, and only compounds containing this group will be further discussed. Small alkyl sulphonamides were clearly preferred, as the introduction of larger substituents such as pentyl (**51**) and benzyl (**53**) lost most of the functional cellular activity. This may be rationalized from the X-ray structures indicating that the introduction of a large group would lead to a steric clash with helix 11. The cyclopropyl substituent, as seen in compound **47**, appeared to be the optimal size allowing for a productive interaction with helix 11 when bound to the receptor. It was also observed that the core motif appeared to be inert to oxidative hepatic metabolism, and the metabolism observed was confined to the sulphonyl substituent. Groups such as methyl (**48**) and trifluoromethyl (**49**) were found to be metabolically stable, while compounds containing groups such as benzyl (**55**) and isobutyl (**50**) showed attenuated metabolic stability. A first attempt to introduce metabolic lability was made through the synthesis of the compound **52** demonstrating that metabolic lability could be built in to the norephedrine aryl moiety. However, the postulated oxidation products, **53** and **54**, displayed limited, or no deactivation as compared to compound **52**.

[b]% of dexamethasone at 10^{-6} M.

During the work with the initial sulphonamide hit **9**, it was noted that replacing the sulphonamide with carboxamide congeners, such as **10**, led to complete loss of GR-binding affinity. This was explained by X-ray structure data and modeling indicating that the sulphonamide aryl group enters the hydrophobic volume formed at the intersection of helices 3, 7, and 11 (Fig. 3A). As predicted, this volume of the receptor overlaps with the volume occupied by the steroid 17α substituent, a key structural feature of highly potent steroid GR ligands. Modeling studies indicate that the geometry of corresponding aryl carboxamide is prevented from reaching 17α-binding pocket, as seen for the matched pair **9** and **10**. For the indazole ether series, corresponding alkyl or aryl group no longer serves to occupy the 17α-pocket (Fig. 16). Thus, it was possible to exchange the sulphonamide by a carboxamide group to generate the indazole ether carboxamides **56–63** (Table 8). As the geometry of sulphonamide and carboxamide groups differs significantly in their bonding angles, a diverging SAR for the residue R^1 (Tables 7 and 8) could be expected for the two subclasses. For the most potent sulphonamide residue cyclopropyl, similar cellular potency was found for the corresponding carboxamide, as

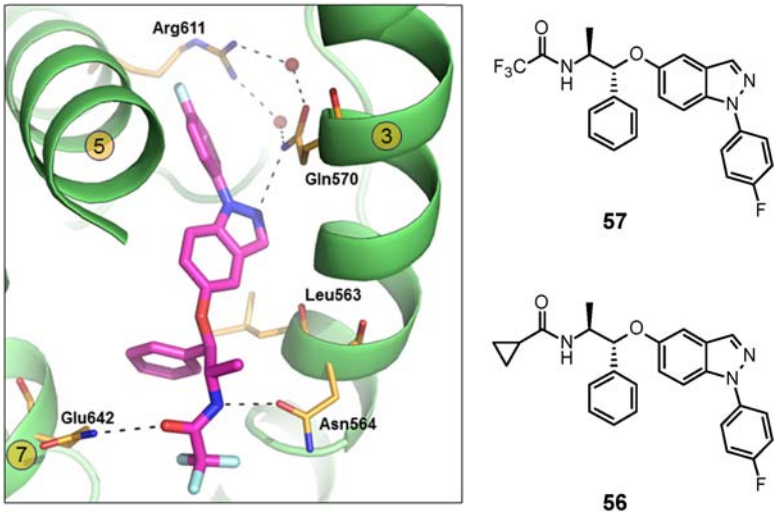

Fig. 16 The X-ray structure of GR-LBD in complex with hybrid **57**.

demonstrated by the matched pair **47** and **56**. However, while the trifluoromethyl sulphonamide showed poor cellular potency (**49**), the corresponding trifluoromethyl carboxamide **57** showed excellent, picomolar cellular potency. Similar level of cellular potency was also obtained for 5-membered ring heterocyclic amide residues, exemplified by compounds **61** and **62**. A loss of potency was observed when alkyl substituents (**58**, **59**) or larger lipophilic phenyl or benzyl substituents (**60**, **64**) were introduced. The compact *tert*-butyl substituent (**63**) was tolerated and showed a similar potency as cyclopropyl. The corresponding amide of lactic acid displayed reasonable potency and provided an opportunity to introduce polar groups. Finally, introduction of an oxalic acid moiety led to pharmacologically inactive compound (**66**). This was expected from SAR of steroids, where formation of acids is known deactivate GR ligands, for example, as seen for fluticasone propionate.

In summary, by the introduction of small electron-withdrawing carboxamides, indazole ethers with excellent cellular potency in range of the project CD target profile had been identified. The compounds tested were lipophilic, with a calculated log *P* ranging from 4 and upwards. Since the objective of the project was to provide compounds for inhaled delivery, issues normally associated with high lipophilicity were not regarded as significant as it would have been for an oral project. However, although several compounds displayed excellent potency in the primary cell assays, they were not suited for further studies in vivo for two reasons. First, the metabolic stability in the in vitro hepatocyte assay of the indazole ether core motif, exemplified by compound **57**. Highlighting the need for introduction of a metabolic soft spot able to generate inactive metabolites to be designed into new compounds. This was in contrast to lead compound **36**, where the core motif had an in-built cleavage point at the aromatic amine α-methylene position and by that, providing means for deactivation of GR activity. The second hurdle to overcome was the need to use crystalline material for appropriate in vivo evaluation on new compounds and ultimately to be used in a dry powder inhaler for clinical use. Most carboxamide analogues synthesized so far in the series were amorphous, probably due to the low number of H-donors and acceptors. Of the 11 compounds **56–66** only **57** was crystalline with a melting point of 123°C. The assumption was that this amide was among the strongest electron withdrawing in the set and with increased electron accepting and donating properties of the amide bond. The chemistry program was therefore guided by two overarching goals: the expansion of the SAR toward crystalline motives and identification of substituents that provided potency, crystalline compounds, and metabolic deactivation via hepatic clearance.

To address these issues a set of compounds were designed and synthesized, key examples are highlighted in **Table 9**. Several of the examples demonstrate that substitution in the 3- and 4-positions of the norephedrine aryl group significantly improved the cellular potency into the low digit picomolar range. Methoxy substitution was accepted and led to rapid oxidative metabolism, as exemplified by entries **67**, **68**, and **72**. The high potency of compounds **70**, **73**, and **75** illustrates the plasticity of the receptor in the 17α-pocket also being able to accommodate larger substituents. The set also generated compounds such as the ether **73** that combined potency with fast clearance in human microsomes. Still morphology was a problem in series. As previously noted crystallinity was sporadically observed for compounds belonging to the trifluoroacetamides sub series, such as **72**, but most compounds remained amorphous even after significant efforts made to crystallize. In order to increase the probability to introduce crystallinity more polar amides, such as oxamides, as well as other electron-withdrawing groups such as 2,2-difluoropropionamides were examined. The oxamides, such as **75**, provided compounds with significant lower lipophilicity but did not yield crystalline compounds. Most often, potency was compromised and metabolic clearance was reduced when lowering log *D*. The examples shown in **Table 9** demonstrate that demethylation of the anisole moiety, which constituted the soft spot in **68**, was reduced and prevented progression as seen for matched pair **68** and **74**. However, 2,2-difluoropropionamides, exemplified by **77** and **78**, provided crystalline and highly potent ligands. Finally, the importance of the stereochemistry of the two chiral centers is highlighted for compound **69**. The depicted compound with absolute stereo configuration (1S,2R) had a GR-binding affinity of IC_{50} 3.6 nM, as expected its enantiomer (1R,2S) had significant weaker-inding IC_{50} of 25 nM. The corresponding diasteromers (1R,2S) and (1R,2R) had GR-binding affinities of IC_{50} 49 and 79 nM, as could be expected from modeling that indicated a less optimal fit.

The structure–activity for variations in other positions was also studied but did not lead to any improvements of properties and is only discussed briefly (**Table 10**). It was previously noted that the *S*-stereochemistry the methyl was clearly preferred over *R*-configuration. Removal of this methyl led to significant loss of activity (**79**). Substitution of the methyl by substituents lager than ethyl (**84**) led to loss of activity (**85**). This may be rationalized from the structural data, where larger substituents collide with helix 11 of the receptor. Variation of the *p*-fluorophenyl moiety by halogen and heteroatom replacements was also investigated, with some compounds showing excellent potency as exemplified by **82**, **87**, and **88**. Introduction of small alkyl ether and amines in the *meta* and *para* positions led to significant loss of potency. As expected, introduction of a carboxylic group (**86**) led to complete loss of activity, similar to what was seen with compound **66**. Use of small saturated alkyl rings led to loss of activity (**80**), and the use pyridyl groups **87** and **88** showed some loss of activity. Finally, substitution of 6-H for Cl or methyl on the indazole was tolerated (matched pairs **81–57** and **83–72**).

From the set of compounds evaluated, compounds **72**, **77**, and **78** were selected for in-depth profiling in vitro and in vivo. This led to the selection of compound **72**, with the development code AZD5423, as the first inhaled SGRM Candidate Drug for progression into clinical studies. Properties will be further described below. Both compounds **77** and **78** showed excellent potency at 18 hours pretreatment in the rat Sephadex model. But neither of the two compounds was considered to provide an improvement over **72** and was therefore parked.

8.18.6 Lead Optimization Leading to AZD7594, Inhaled SGRM CD2

With compound **72** being progressed into clinical studies a follow-up program was initiated. Several properties of AZD5423 needed to be retained, such as the picomolar potency in PBMCs as well as blood flow controlled human hepatic metabolic clearance. While

[d]Crystalline.

clearance of AZD5423 showed the desired profile in human and dog, the clearance profile in rat had two weaknesses: first, the hepatic clearance rate was low, leading to a significant systemic exposure in vivo. Second, metabolism in rat also leads to a significant systemic exposure levels of the GR active metabolite (**71**, rPBMC IC_{50} 0.5 nM), in hPBMCs activity was significantly lower (hPBMC IC_{50} 4.6 nM). However since this metabolite is only present in low concentration in human, **71** was not considered to contribute to any GR-related systemic side effects. Since all PD studies were performed in rodents, this led to a more complex situation estimating the TI for this compound versus reference GR ligands, such as budesonide or fluticasone propionate. Thus a hepatic clearance profile, liver blood flow controlled and without formation of any GR active metabolites was targeted in the back-up program. Furthermore, the deactivation of AZD5423 is dependent on both phase 1 and phase 2 metabolic processes. It was envisioned that the direct deactivation dependent merely on phase 1 metabolism alone would lead to a more efficient reduction of the GR activity. Other properties that could be envisioned to improve the overall properties of a back-up compound were improved solid-state properties, reduced oral absorption to <5%, and a lower volume of distribution.

The initial efforts focused on compounds having a two atom spacer connecting the amino alcohol core chain and the aryl substituent as shown for **90**, introducing a new metabolic soft spot into the core scaffold that would enable complete deactivation by metabolic fragmentation of the molecule (Table 11). The compound **90** showed a rapid clearance in hepatocytes. Furthermore, development led to the identification of **91**, fulfilling the CDTP with regard to cellular potency; this compound was crystalline with a melting point of 160°C associated with rapid metabolism in human hepatocytes. Since the lipophilicity was significantly lower compared to CD1, the volume of distribution was also expected to be reduced. Metabolite ID studies suggested that the main metabolism route was cleavage of the phenol moiety, thus eliminating GR agonism activity.

[c]All compounds showed efficacy in range of 30–72% of dexamethasone at 10^{-6} M.

Compound **91** was investigated in a range of assays as a potential back-up CD, and the compound generally behaved well, including initial safety studies such as being clean in 5-strain Ames. Also, the compound showed excellent efficacy in the tobacco smoke model as well as increased duration of action when compared with fluticasone propionate. However compound repeatedly showed relatively poor potency in the 4-day inhalation Sephadex model with an ED_{50} of 10 μg kg^{-1}. This should be compared to AZD5423 having an ED_{50} of 1 μg kg^{-1} in the same model. Considering that PBMC potency of AZD5423 was approximately twice that of **91** meaning that an unexpected fivefold loss of potency was observed. It should be noted that a similar pattern was also observed in the corresponding studies made using intratracheal administration in the Sephadex model. This unexpected loss of potency eroded the margins with regard to several of the targeted CDTP properties, and the compound was consequently parked.

A breakthrough in the development of a back-up compound came by an integrated crystallography and computational chemistry approach that prompted the exploration of a relatively large and polar cavity adjacent to the position binding to the *p*-fluorophenyl moiety, named by the project as the "water pocket" (Fig. 17). Exploration of this pocket by elongation of the ligands from the *meta*-position of the phenyl group on the phenylindazole moiety provided high clearance compounds with optimized morphological properties preserving both the potency and selectivity profiles. The water pocket is not accessed by current steroid-based ligands. Since this cavity is relatively polar with lattice-bound water molecules in crystal structure this elongation provided decreased lipophilicity as compared to the AZD5423-based series. One property that was significantly influenced was crystallinity. Compounds with an additional amide group were often crystalline and with melting points in the 200°C range.

The first set of compounds represented by compounds **93–95** (Table 12), all showing significantly lower logD compared to AZD5423, still with retained potency as compared to the carboxylic acid matched pair compound **86**. A general issue is that the unsubstituted norephedrine core in this series shows slow hepatic clearance, and it became clear that further optimization was needed to introduce substituents that would be rapidly metabolized into molecules with low affinity to the GR receptor. This was a similar situation as with the original indazole ether lead **57**. Two norephedrine derivatives showing rapid metabolism was identified exemplified by compounds **96–98** and **99** (Table 12). Compound **96–98** and **99** were all crystalline and fulfilled expectation with regard to potency in hPBMCs, hepatic clearance, and improved morphology to be investigated further by profiling in vivo. The compounds were also less lipophilic than AZD5423 with the potential to have lower volume of distribution. Finally, since melting point was higher, solubility was lower than AZD5423 and likely leading to longer lung retention as well as reduced oral bioavailability.

The compounds were profiled in a set of in vitro and in vivo models. Inhaled administration of the compounds in the 4-day Sephadex model was used as primary model in vivo to evaluate potency and mechanistic side effects in the rat. This model was shown to be a good predictor of human efficacy of inhaled steroids in the clinical use, Table 13.

The pyridyl-based ligands **98** and **99** both showed inferior potency compared to compounds **96** and **97** in the Sephadex model, and this was one reason why they were deselected for further progression in clinical studies. Finally compound **97** was prioritized over **96**; one important reason for selecting this compound was that this compound was considered to have a better balanced lung retention profile with a rat lung half-life of 15 h while **96** showed significantly longer retention to the lung (Table 14). Properties such as solubility and optimization of lung retention will be further discussed below. Compound **97** was finally selected as candidate drug for the inhaled treatment of respiratory diseases such as Asthma and COPD, was given AstraZeneca development code AZD7594, and is currently undergoing clinical studies.

8.18.6.1 Synthesis of AZD5423 and AZD7594

The discovery route for the synthesis of both AZD5423 and AZD7494 followed the same overall scheme. The key synthetic step in the synthesis of both compounds was an Ullmann coupling generating the aryl ether linkage. AZD5423 was synthesized in five

linear steps leading to a pure enantiomer with an overall yield of 28% as depicted in **Scheme 2**. The key step was the coupling reaction between the linker alcohol and the 5-iodoindazole fragment. The norephedrine moiety was synthesized applying a variant of a Weinreb–Nahm α-aminoketone synthesis, and bromo-(3-methoxyphenyl)magnesium was added to the deprotonated Weinreb amide to yield the arylketone **I2**.[57] The subsequent Meerwein–Ponndorf–Verley reduction proceeded with a high degree of diastereoselectivity to afford the protected *anti*-amino alcohol **I3** (de >99%) which was deprotected to yield the norephedrine analogue **I4** (ee >99%).[58] 1-(4-fluorophenyl)-5-iodoindazol (**I1**) is readily accessible from a condensation reaction of the *ortho*-fluorinated

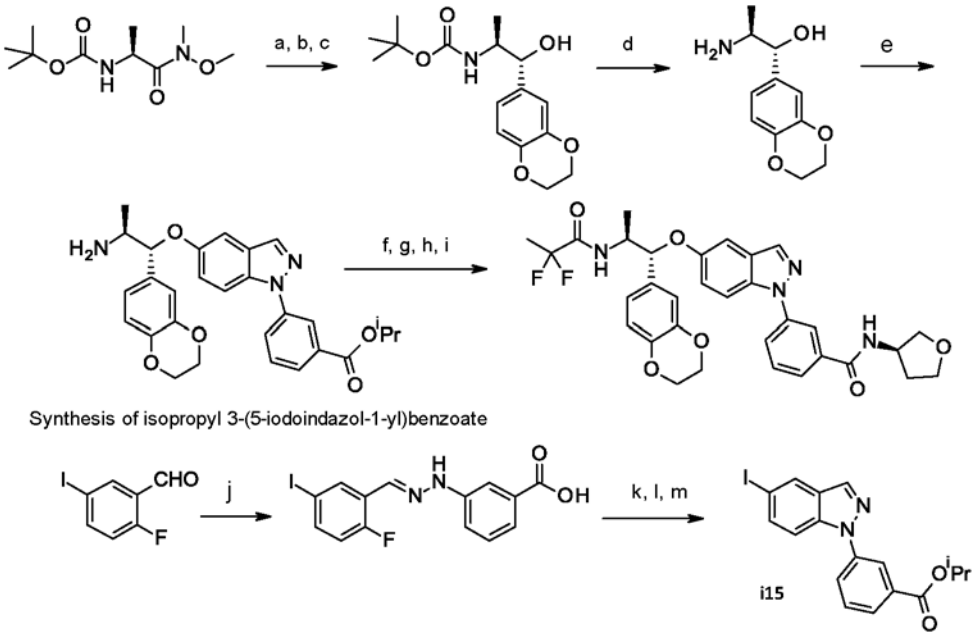
benzaldehyde with *p*-fluorophenylhydrazine under basic conditions at elevated temperatures. The primary amine of indazole ether scaffold was synthesized in a Ullmann coupling reaction with the iodoindazole **I1**, along with *N*-coupled byproducts limiting the yields in this step.[59]

The synthesis depicted in Scheme 2 leads to a polymorph (form A), with a melting point of 82°C. However in the continued process optimization efforts the synthesis was modified at several steps, leading to the discovery of a new polymorph (form B) with a melting point of 109°C. The different melting points lead to different solubility and as a result different pharmacokinetic properties, both in the lung and in the blood will be discussed in below.

AZD7594 was synthesized in seven linear steps with an overall yield of 13–26%. The 5-iodoindazole intermediate, **I5** was obtained quantitatively in four synthetic steps (Scheme 3).

8.18.6.2 Physical Chemical Properties of Drug Candidates

The physical chemical properties for AZD5423 and AZD7594 are shown in Table 14 as well as properties for fluticasone propionate, budesonide, and compounds **96** and **99**. These properties are important to understand the lung and systemic pharmacokinetic properties. They also illustrate some of the principles of dissolution rate-driven lung pharmacokinetics used to control the duration of effect.



Scheme 3 Discovery route for the synthesis of AZD7594 (**97**), reagents and conditions: (a) ^{i}PrMgBr, THF, −15°C to 0°C; (b) ^{i}PrMgCl, (2,3-dihydrobenz[b](1,4)dioxin-6-yl)magnesium bromide, THF, −15°C to r.t.; (c) Al(O^{i}Pr)$_3$ (0.2 equiv.), ^{i}PrOH (11 equiv.), toluene, 50°C (d) 6 M aq. HCl, EtOAc 40°C; (e) (**i2**), CuI, Cs_2CO_3, dimethylglycine, PrCN, 110°C; (f) 2,2-difluoropropionic acid, HBTU, DIPEA, DCM, r.t.; (g) 0.25 M NaOH, THF/MeCN (5/2); (h) HBTU, DIPEA, DMF, r.t.; (i) (3R)-Tetrahydro-3-furanamine, MeCN; (j) 3-hydrazinylbenzoic acid, Cs_2CO_3, DMF, r.t.; (k) KOtBu/^{i}PrOH, toluene, 50°C,; (l) $NaCO_3$, NMP, 40°C; (m) ^{i}PrBr.

The set of inhaled GR ligands in Table 14 display a range of lipophilicities and melting points. AZD5423 is the more lipophilic, but the low melting point makes it the most soluble compound in the set. It should be noted that solubility in human biological fluids such as human intestinal fluid (HIF) or epithelial lining fluid is more relevant measure to understand properties in the pharmacological setting. Solubility is significantly higher in these fluids and provides a better prediction of in vivo properties. Since epithelial lining fluid is difficult to obtain, HIF was used as surrogate for screening purpose in the project. As predicted from comparator data the lung retention of AZD5423 is expected to be between that of budesonide and fluticasone propionate, while AZD7594 is predicted to have lung retention similar to fluticasone propionate.

8.18.6.3 Metabolism, Major Deactivation Pathways

Rat and dog liver clearances were studied in microsomes and hepatocytes followed by determination of in vivo clearance. As predicted, AZD5423 had high turnover when incubated with hepatocytes and liver microsomes from dog and man. Rat hepatocyte clearance was somewhat lower, the hepatocyte hepatic extraction for male rats was 0.50, compared to 0.77 and 0.68 in dog and human hepatocytes respectively, this difference was even more pronounced using hepatocytes from female rats. AZD5423 was found to be stable when incubated with the S9 sub cellular fraction isolated from human and rat lung, indicating stability in lung tissue. High permeability in combination with the relatively high solubility in HIF indicates full absorption following oral administration. Bioavailability after oral administration was 35% in rat and dog, which is in line with the observed in vivo clearance of 70% and 60% of liver blood flow in rat and dog, respectively.

The in vivo pharmacokinetics for AZD7594 was studied in rat (p.o. and i.v) and dog (i.v.) with data summarized in Table 15. In general, AZD7594 in rats has a high clearance (CL) and low volume of distribution (Vss) and a relatively long half-life. In dog, CL and Vss were lower, and the corresponding half-life was 16 h. The intrinsic clearance (CL_{int}) in rat liver microsomes and hepatocytes predicts in vivo CL relatively well while dog hepatocytes over predict the in vivo CL. The oral bioavailability in rat was low at doses tested.

The pharmacokinetic kinetic profiles of AZD5423, AZD7594, and fluticasone propionate in rats after dry powder inhalation are shown in Table 16. As expected from the solubility differences, AZD5423 has a shorter retention to the lung compared to AZD7594 and fluticasone propionate. However the lung retention is considerably longer than for budesonide (data not shown) as predicted by its lower solubility (Table 14). For AZD7594 lung retention is longer than for fluticasone propionate. Blood PK mirrors the lung PK properties. For AZD5423 higher solubility leads to a higher peak blood C_{max}, it is especially interesting to note the difference between the two polymorphs of AZD5423. Form B with higher melting point has lower solubility and as a consequence longer lung retention and lower blood C_{max}. AZD7594 and fluticasone propionate have similar blood area under curve (AUC); this is what can be expected since both compounds have blood flow controlled hepatic clearance and very limited oral bioavailability.

Table 15 Intravenous and oral pharmacokinetics of AZD5423, AZD7594 and fluticasone propionate in male rats (male Wistar, $n=3$) and dogs (female Beagle, $n=3$). Comparison to scaled CL from liver microsomes and hepatocytes

Compound	*Species*	*Scaled CL (liver mics) (mL min^{-1} kg^{-1})*	*Scaled CL (heps) (mL min^{-1} kg^{-1})*	*CL (mL min^{-1} kg^{-1})*	*Vss (L kg^{-1})*	*F (%)*
AZD5423	Rat	>60	49	31–64	8.6–9.3	35[a]
	Dog	–	30	22	24	35[a]
AZD7594	Rat	>60	49	43–97	0.34–0.58	<1
	Dog	–	30	7.5	0.43	–
Fluticasone propionate	Rat	>60	45	149	4.0	–
	Dog	–	29	40	8.9	–

[a]AZD5423 crystal form A used.

Table 16 Kinetic profile in female Wistar rat after dry powder inhalation (DPI) in nose-only exposure inhalation chamber at 0.1 nmol kg^{-1} (lung dose). Lung levels and corresponding systemic exposure (area under curve, AUC)

Compound	*Lung half-life (h)*	*Lung level at 24 h (% of lung dose)*	*Lung AUC$_{0-24}$ (nM × h)*	*Blood AUC$_{0-24}$ (nM × h)*	*Blood free AUC$_{0-24}$ (nM × h)*	*C$_{max}$ (nM)*
AZD5423 (form A)	<1	<1	9100	288	0.02	83
AZD5423 (form B)	1	<1	21,300	246	0.017	55
AZD7594	15	45	500,000	28	0.13	2.3
Fluticasone propionate	4	3	66,000	29	0.4	ND

Thus, similar dose should lead to similar blood exposure. For AZD5423, due to the low hepatic clearance observed in rat, the blood AUC is significantly higher in rat compared to AZD7594. In dog and human similarly high AUC levels are not expected due to the high hepatic clearance.

Furthermore, inhalation experiments have low lung deposition of ~10%, compared to 35% in human delivered to the lung via inhalation. It can be estimated that ~50% of systemic exposure in the rat experiment will originate from the intestine. In the human about 20% will be originate from the fraction swallowed. Considering these factors, the project expected that systemic exposure at similar doses for AZD5423 and AZD7594 should be similar in the human setting.

8.18.6.3.1 AZD5423 metabolic profile

Identification of the metabolites formed in rat, dog, and human hepatocytes was performed using radiolabeled compounds (Figs. 18 and 20). For AZD5423, the dominating metabolic pathway and deactivation route are O-demethylation providing the phenolic alcohol (**71**) found in rat (44%), human (1.2%), and dog (5.2%) hepatocytes. This metabolite is subjected to phase II

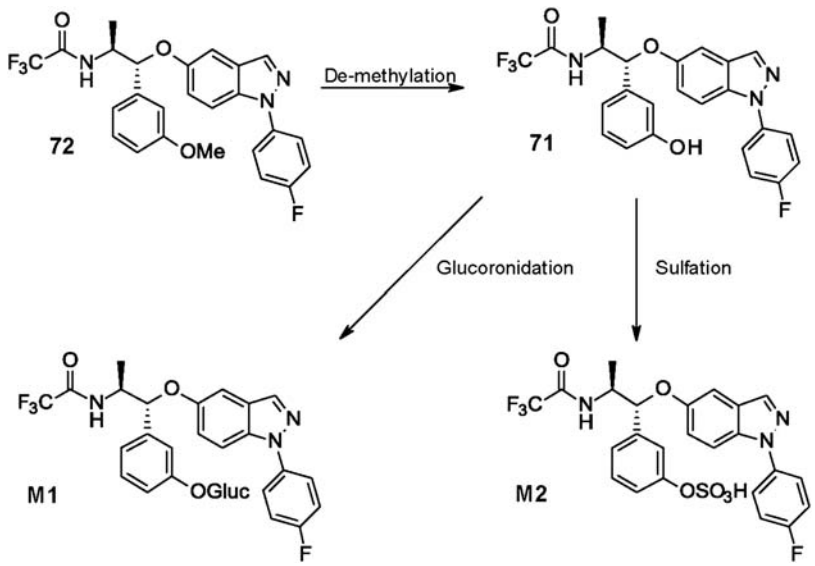


Fig. 18 Major pathways identified leading to metabolic deactivation of AZD5423 (**72**).

Table 17 Amount of metabolites formed following incubation in hepatocytes using ^{14}C-labeled AZD5423 (**72**), expressed as amount of total radioactivity

	71	*M1*	*M2*
Human heps (%)	1	1	97
Dog heps (%)	5	10	65
Rat heps (%)	44	22	19

conjugation, and in human hepatocytes the sulfate was found to be the main metabolite (97%). The sulfate metabolite was also formed, but to a somewhat lesser extent in dog hepatocytes (64%) and in rat hepatocytes (19%). Glucuronide adducts were also identified, including a metabolite with a glucuronic acid in conjugation with the O-demethylated metabolite. In rat hepatocytes these glucuronides represent 22% of the identified metabolites and in human hepatocytes 1.2% (Table 17). The major sulfate metabolite **M2** in man was also detected in vivo in the tox species rat and dog; thus no human specific metabolites was identified. The main metabolites **71** and **M2** were synthesized and tested for PBMC activity. While the polar compound **M2** was inactive in PBMCs, as expected, the phenolic ligand **71** showed significant activity in rPBMCs (Table 18).

The in vivo PK studies in rat and dog with AZD5423 confirmed the presence of the demethylated metabolite **71**. Following oral administration, the blood levels (AUC) of **71** were 85% and 7% of parent in rats and dogs, respectively. In summary, the profiling showed that effective deactivation of GR activity should be expected in man as well as in dogs. Minor contribution of metabolite **71** to systemic GR activity should be expected in rat. Still this contribution is small, compared to the relatively high systemic exposure in rat of AZD5423 due to not full blood flow controlled clearance and absorption from intestine.

8.18.6.3.2 AZD7594 metabolic profile

AZD7594 was metabolized in a similar way in man, dog, and rat hepatocytes (Table 19). The major metabolic pathway was oxidation in the 1,4-dioxane ring giving the hemiacetals **M10** and **M11**. These metabolites were further oxidized to the catechol **M8** that underwent glucuronidation, forming glucuronides **M5** and **M6**. The formation of the 5-hydroxyindazole **M4** as an oxidative cleavage product and its sulfate conjugate **M3** was detected in all three species and represents another pathway of metabolism. Metabolism was also found to occur in the 3-aminotetrahydrofurane ring leading to the carboxylic acid **M9** (Fig. 19).

The project was confident in a significant loss of GR activity for most of the metabolites identified, as they were only fragments, **M3** and **M4**, or highly polar structures such as **M5**, **M6**, **M7**, and **M8**. **M10** and **M11** could potentially have some GR activity. However, as part of evaluating compounds **96**, **97**, **98**, and **99**, the corresponding **M10** and **M11** metabolites for AZD7594 congener **96** were synthesized, and both compounds were found to lose one order of magnitude or more in potency in both hPBMCs and rPBMCs. This in combination with the fact that **M10** and **M11** represent only about 10% of metabolites formed makes it highly unlikely that they would lead to any measurable systemic GR levels of activity. Finally since metabolite **M9** contains a carboxylic acid group located in the very polar part of the GR receptor, it could not be ruled out that some residual activity remained. As expected, activity was largely lost, and the compound showed no activity in rPBMCs and 29 nM in hPBMCs. This should be compared to parent AZD7594 activity in rPBMCs and hPBMCs of 0.30 and 0.42 nM, respectively. This result in combination with the fact that this metabolite was formed in $<10\%$ led to the conclusion that this metabolite should not contribute to any measurable systemic levels of GR activity.

Table 18 Potency of AZD5423 (**72**) primary metabolites in peripheral blood mononuclear cells

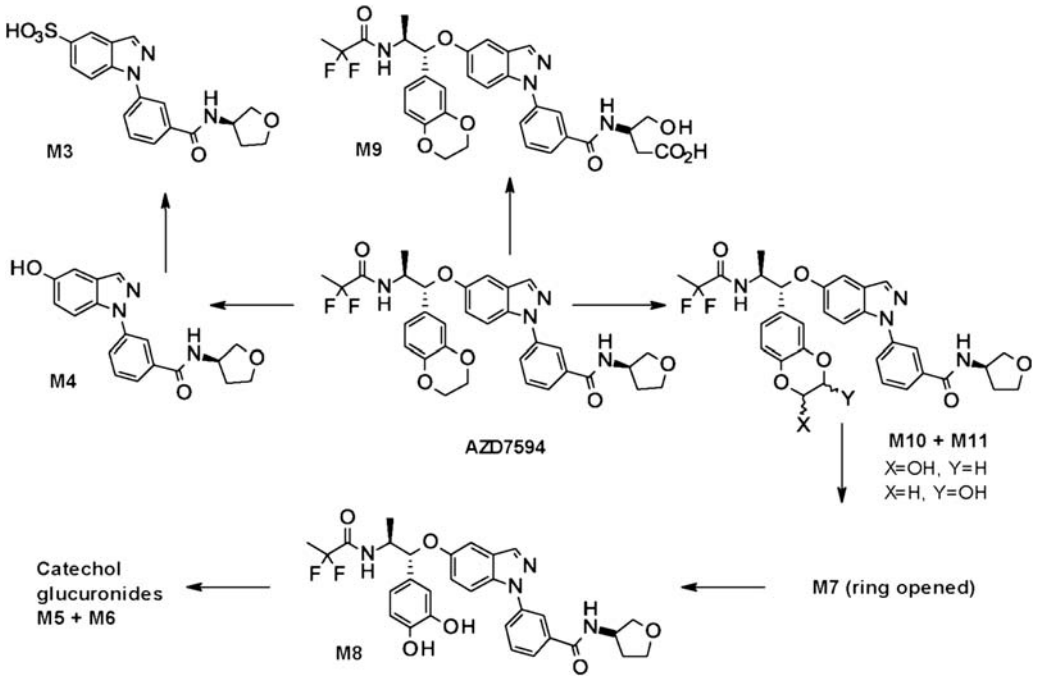

Fig. 19 AZD7594 (**97**) metabolites identified in rat, dog, human, hepatocytes, and in rat bile. All structure identifications are based on MS/MS data.

In bile-cannulated rats, only minor amounts of parent AZD7594 were detected in bile and urine. The metabolites formed in rat hepatocytes were also detected in vivo. It was concluded that the major route of clearance for AZD7594 in rat is by metabolism. The metabolites formed were predominately excreted in bile.

8.18.6.3.3 Assessment of PK based drug–drug interaction potential

The potential of AZD5423 and AZD7594 to inhibit cytochrome P450 was assessed using fluorescent-based in vitro assays and prototypic fluorogenic P450 substrates for CYP 1A2, 2C9, 2C19, 3A4, and 2D6. IC_{50} was >1 μM for all isoforms except 2C9 and where the IC_{50} was determined to 0.9 and 0.45 μM, respectively (Table 20). For both compounds having low predicted doses, low predicted systemic exposure and high plasma protein binding ($<1\%$ fu) ensure that the margins to free C_{max} concentrations are high (100,000-fold).

8.18.6.3.4 Prediction of human pharmacokinetics

The predicted dose to man (PDtM) is based on the efficacious lung-deposited dose levels in the rat Sephadex 4-days model. The PDtM (lung-deposited dose) for AZD5423 and AZD7594 is 1.2 and 0.8 μg kg^{-1}, respectively. This also takes into account the full cross-over potency in rat and human in vitro PBMC models.

The predicted pharmacokinetic profile of AZD5423 in man was based on in vitro to in vivo scaling from liver microsomes and hepatocytes and on allometric scaling of CL and Vss from rat and dog. Furthermore the predicted human absorption profile was based on absorption profile in rats after dry powder inhalation (Table 21).

For AZD7594, the human AUC at PDtM is based on the predicted CL range and assuming that 100% of the lung-deposited dose will be systemically available, according to the formula AUC = Lung Dose/CL (Table 21). Systemic exposure (Free AUC) in man at the therapeutic dose is predicted to be 120 times less than budesonide and at least 9 times less than and fluticasone propionate.

Taking into account in vitro potency the GR-mediated systemic side effects are predicted to be significantly less (>10 times) than for budesonide and fluticasone propionate.

8.18.6.4 In Vitro Pharmacology Assessment

8.18.6.4.1 Receptor binding and steroid NHR selectivity

In vitro potencies of AZD5423 and AZD7594 were measured in a competitive receptor-binding FP assay using the full-length human GR and radiolabeled dexamethasone. As it is common that GR ligands show crossover to other steroid hormone receptors the binding potency was assessed against the PR, MR, AR, and estrogen receptor α and β (ER α/ER β) in competitive receptor-binding assays using FP-based assay technology. Selectivity was determined as the ratio between receptor potencies.

Both AZD5423 and AZD7594 bound potently to GR, with mean IC_{50} values of 0.9 nM and also demonstrate excellent selectivity over other steroid NHRs (>1000-fold) for all the steroid NHRs. It can be concluded that both compounds showed an excellent level of potency and a better selectivity profile compared to the reference IGCs tested (Table 22).

8.18.6.4.1.1 Cell-based assays

The potency of AZD5423 and AZD7594 was determined in several cell assays. Both compounds demonstrated excellent level of potency in the reporter gene assay measuring gene transrepression(TRE) assay with mean EC_{50} values of 49 and 55 pM, respectively. In hPBMCs, the release of TNF-α in response to LPS stimulation was used to determine the antiinflammatory effects in human primary cells. AZD5423 and AZD7594 were highly potent inhibitors of LPS-induced TNF-α release, with mean IC_{50} values of 161 and 420 pM, respectively. In rPBMCs, the potency was in a comparable range demonstrating good species cross-over to rodents. To test the compound in a physiologically relevant environment mimicking the systemic exposure of free drug, human whole blood was stimulated with LPS and following determination of TNF-α release. In this assay AZD5423 and AZD7594 displayed mean IC_{50} values of 8.0 and 12 nM, respectively. Finally, cross over to rat was confirmed also in the rat whole blood assay (Table 23).

Overall both inhaled SGRM compounds show excellent level of cell potency with good cross over to rat. It has been claimed in the literature that high protein binding leads to a relative lower whole blood activity due to a potency drop off that is beneficial for systemic side effects.[60] This has been claimed, for example, for ciclesonide and fluticasone furoate; however in our hands fluticasone furoate does not have a better in vivo profile compared to fluticasone propionate.

8.18.6.5 In Vivo Pharmacology Assessment

To evaluate compound potency, duration, functional parameters, mechanistic side effects, and the effects in respiratory animal models in vivo, a variety of animal models was utilized. In the studies described below, AZD5423 and AZD7594 have been delivered to the lung via the intratracheal (it) or inhaled route, and all doses stated refer to the lung-deposited dose.

8.18.6.5.1 Potency and mechanistic side effects in the rat Sephadex model

Male Sprague–Dawley rats were challenged via *it* instillation of Sephadex beads, and due to the inborn hypersensitivity of the rats towards dextran, an eosinophilic-driven inflammation develops in the lungs over time. The inflammatory response can be monitored as an increase in the lung weight (edema), which peaks at 24–48 h and is maintained for more than 7 days after provocation. AZD5423 and AZD7594 were administered to rats as a nose-only inhaled dry powder, where the first administration was given 2 h prior to challenge with Sephadex and was followed by 4 once daily treatments prior to termination.

AZD5423 and AZD7594 demonstrated a potent dose-dependent inhibition of lung edema, with ED_{50} of 1.2 μg kg^{-1} day^{-1} and 0.8 μg kg^{-1} day^{-1}, respectively. Fluticasone propionate dosed within the range 0.4–73.5 μg kg^{-1} day^{-1} resulted in a dose-dependent inhibition of lung edema with a combined ED_{50} of 6.0 μg kg^{-1} day^{-1} (Fig. 20).

8.18.6.6 Predicted Therapeutic Dose

The human dose (DtM) estimates for AZD5423 and AZD7594 were based on the mean efficacious lung-deposited dose levels (ED_{50}) in the rat Sephadex 4-day model (Table 24). The predicted human lung-deposited doses are 1.2 and 0.8 μg kg^{-1}, which is equivalent to predicted daily total doses of 200 and 120 μg for AZD5423 and AZD7594, respectively. When comparing the lung ED_{50} values obtained from the Sephadex model with the clinical effective nominal doses reported in the Swedish PDR (FASS) for a range of registered IGCs, the preclinical in vivo model was shown to be predictive. This evidence from well-known comparators further supports the predicted effective nominal dose to man.

8.18.6.7 Mechanistic Side Effects

To determine mechanistic systemic side effects of ligand models thymic involution was measured in parallel in the 4-day Sephadex model. Thymus involution was chosen as readout due to the high sensitivity of this organ to glucocorticoids (thymus weight decrease compared to vehicle-treated animals), expressed as ED_{25}. This value was then used to determine the therapeutic ratio for the compounds (the ratio between mechanistic side effects [ED_{25} thymus involution] and potency [ED_{50} lung edema]).

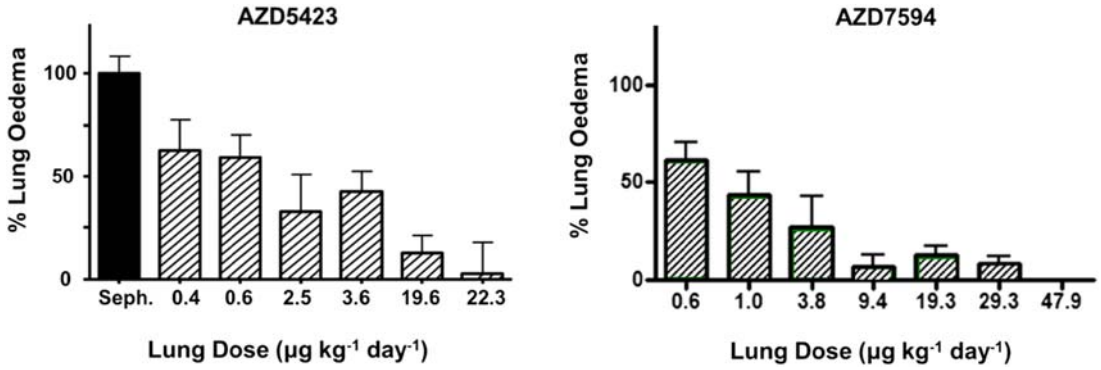

Fig. 20 Effects of repeated dry powder inhalation of AZD5423 and AZD7594 on lung edema reduction in the 4-day Sephadex model.

Table 24 Comparison of lung ED_{50} values from Sephadex model with reported clinical effective nominal doses for IGCs

Compound	*Efficacy in Sephadex model (Lung ED_{50} μg kg^{-1} day^{-1})*	*Clinically effective nominal dose PDR (μg)*
AZD5423	1.25	200[a]
AZD7594	0.8	120[a]
Fluticasone propionate	6.0	500 (50–500)
Budesonide	9.6	800 (200–800)

[a]Predicted.

AZD5423 showed a dose-dependent effect on thymus involution, with an ED_{25} of 4.6 μg kg^{-1} day^{-1} and an estimated therapeutic ratio of 3.7. However, as earlier pointed out, this compound has a significantly higher relative systemic exposure in rat, relative to what's expected in man. For this reason there was reason to believe that the therapeutic ratio would be better in man. AZD7594 demonstrated a weak effect on thymus involution, resulting in ED_{25} of 40 μg kg^{-1} day^{-1}, and estimated therapeutic ratios of 50. Fluticasone propionate had a thymus ED_{25} of 3.9 μg kg^{-1} day^{-1} and an estimated therapeutic ratio of 0.7 (Fig. 21 and Table 25).

8.18.6.8 Duration of Effect

Both AZD5423 and AZD7594 were studied in in vivo models for their potential to be used as a once daily treatment (i.e., 24-h duration of effect). The studies were set up somewhat differently between the two compounds. AZD5423 was administered 6 h prior to Sephadex challenge at time zero, animals were terminated 18 h later, and reduction of lung edema was determined. Administration of AZD5423 at lung doses of 28 and 30 μg kg^{-1} via inhalation resulted in a significant inhibition (69% and 87%, respectively) of lung edema after 24 h. Administration of AZD7594 at lung doses of 39 and 23 μg kg^{-1}, 9 and 24 h prior to Sephadex challenge via inhalation resulted in significant inhibition (107% and 76%, respectively) of lung edema. These data, supported by PK lung retention data, suggest that once daily treatment is feasible with both compounds. Fluticasone propionate was used as reference in the AZD7594 duration study (Fig. 22).

8.18.6.9 Functional Measurements in the Rat Sephadex Model

To investigate the effect of AZD5423 on Sephadex-induced changes in lung function, male Sprague–Dawley rats were treated with AZD5423 (100 μg kg^{-1}) via *it* instillation 30 min prior to challenge with Sephadex. Eighteen hours after Sephadex challenge animals were anesthetized and connected to a ventilator (FlexiVent system) for lung function measurements.

AZD5423 dosed at *it* 100 μg kg^{-1} reduced the Sephadex-induced increase in dynamic lung resistance (lung constriction) (dyn R) and reversed the decline in dynamic lung compliance (lung stiffness) (dyn C) similar to what is observed for budesonide dosed at 1000 μg kg^{-1} (Fig. 23).

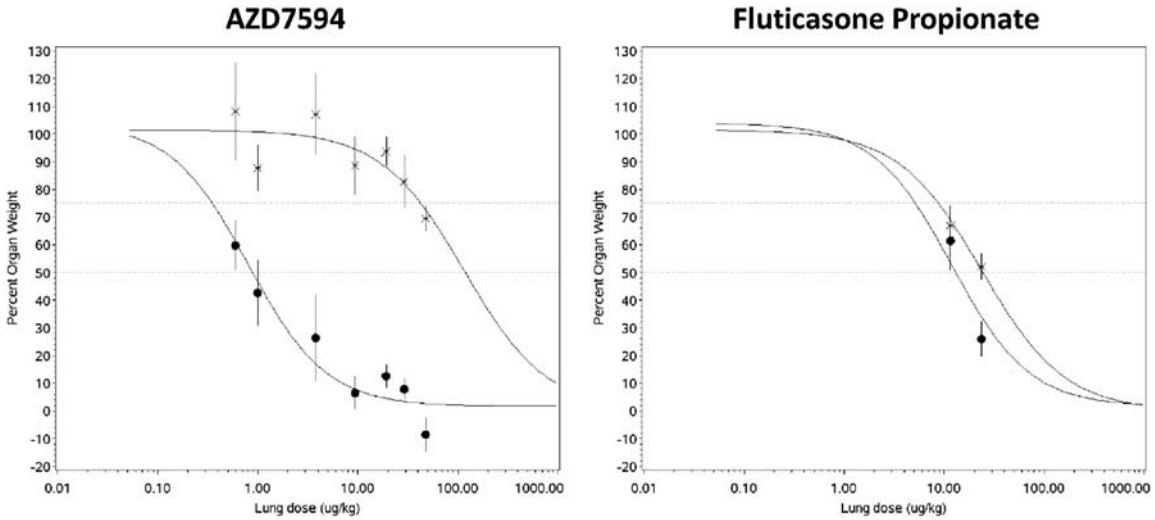

Fig. 21 Effects of repeated dry powder inhalation of AZD7594 and fluticasone propionate on lung edema (●) and thymus weight observed (**X**) reduction in the 4-day rat Sephadex model.

Table 25 Potency, thymus involution and calculation of therapeutic ratio in 4 day rat Sephadex model

Read-out	*AZD5423*	*AZD7594*	*Fluticasone propionate*
ED_{50} inhibition of lung oedema (μg kg^{-1})	1.2	0.8	6.0
ED_{25} for thymus involution (μg kg^{-1})	4.6	40	3.9
Therapeutic ratio, rat (ED_{25}/ED_{50})	3.7	50	0.7
Therapeutic ratio, rat (vs. *fluticasone propionate*)	~5	>10	–

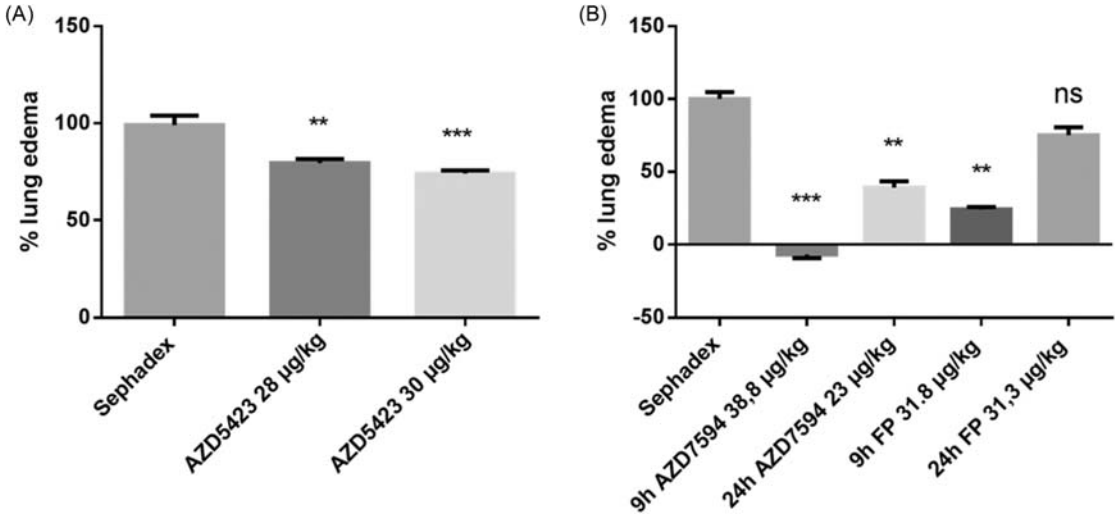

Fig. 22 Duration of effect for (A) AZD5423, (6 h pretreatment, two doses 28 and 30 μg kg^{-1} lung dose) and (B) AZD7594 (9 and 24 h pretreatment, 39 and 23 μg kg^{-1} lung dose respectively) after inhaled administration in the Sephadex rat model.

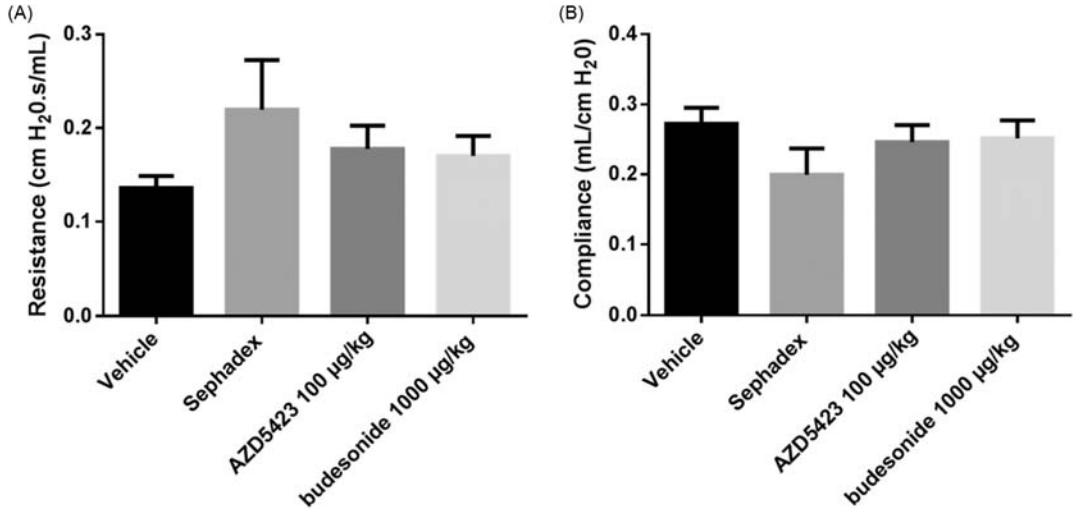

Fig. 23 AZD5423 reduces lung resistance (A) and improves compliance (B) in the rat Sephadex model.

8.18.6.10 Efficacy in a "Disease-Like" Setting (Ovalbumin Model)

AZD5423 and fluticasone propionate were dosed at 100 μg kg^{-1} intratracheally (i.t.) to ovalbumin (OVA) challenged rats (2 week rat model for "asthma") 24 and 1 h prior to, and 24 h after challenge. This resulted in a significant reduction in total cells, eosinophils and neutrophils in lung lavage fluids for AZD5423 and to a lesser degree fluticasone propionate (Table 26).

8.18.6.11 Acute Mouse LPS Model

Exposure to significant levels of LPS is reported to be associated with the development and/or progression of many types of lung disease. In addition, human LPS studies have been used in several programs as the proof of principle model to progress compounds for further studies in COPD patients. The acute effects of LPS can be characterized by inflammatory processes in the lung, including neutrophilic infiltration and the increase in levels of cytokines.

Mice were treated *it* with AZD5423 and AZD7594, one hour before challenge with nebulized LPS (1 mg mL^{-1}) of *Pseudomonas aeruginosa* LPS. Twenty-four hours after the LPS challenged animals were terminated and inflammatory cell numbers in BAL were counted. At a dose of 0.3 mg kg^{-1} AZD5423 significantly inhibited by 78%, the influx of neutrophils recovered from lavage fluids. AZD7594 inhibited the LPS-induced influx in the number of neutrophils in BAL by 66% at a dose of 1 mg kg^{-1}. In the latter study

Table 26 Inhibition of the numbers of total cells, eosinophils and neutrophils in the lung lavage fluids of AZD5423 and fluticasone propionate on OVA-induced eosinophilia in Brown Norway rats

	AZD5423 100 μg kg^{-1}	*Fluticasone propionate 100 μg kg^{-1}*
Total cells (%)	77	55
Eosinophils (%)	80	58
Neutrophils (%)	100	84

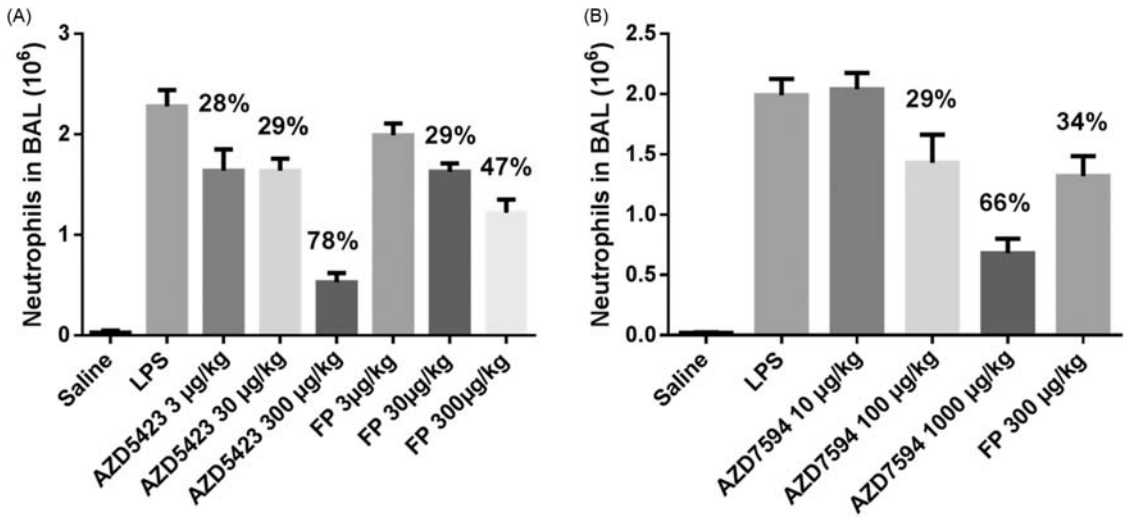

Fig. 24 Effects of (A) AZD5423 and (B) AZD7594 on neutrophil influx in the LPS model compared to fluticasone propionate.

fluticasone propionate was used as reference to benchmark compound efficacy. Fluticasone propionate inhibited the number of neutrophils accumulating in BAL by 47% and 31%, respectively, dosed at 0.3 mg kg^{-1} (Fig. 24).

8.18.6.12 Acute LPS Model—Lung Function Changes and MRI Imaging

LPS-induced effects on lung function change can be investigated using magnetic resonance imaging (MRI) and measuring cell influx in lung. Female Balb/c mice were treated with AZD5423 (0.3 mg kg^{-1}) via *it* instillation 1 h prior to, and 24 and 47 h after challenge with inhaled LPS. Budesonide-dosed 0.3 mg kg^{-1} twice daily was used as reference.

AZD5423 (0.3 mg kg^{-1}) inhibited the inflammatory response to LPS, assessed by the reduction in total number of cells (84% inhibition), neutrophils (85% inhibition), and macrophages (86% inhibition) when compared to vehicle and LPS challenged mice. Budesonide reduced the inflammatory response by the reduction in total number of cells (49% inhibition) and neutrophils (55% inhibition) without effect on macrophages.

Hyperpolarized ^{3}He-MRI which detects ventilation defects and ^{1}H-MRI which primarily detects fluid in the lungs (edema) were used to study the effects of AZD5423 and budesonide in mice. After 24 h both AZD5423 and budesonide showed efficacy by improving ventilation and reducing edema in this model. The two compounds inhibited the number of LPS-induced lung lesions determined by 100% and 86%, and the LPS-induced increase in unventilated lung volume by 100% and 96%, assessed by ^{1}H-MRI and ^{3}He-MRI, respectively (Fig. 25).

8.18.6.13 Acute Cigarette Smoke Model

Cigarette smoke is the main risk factor for developing COPD in humans. By using a mouse model of inflammation, female Balb/C mice the effect of twice daily cigarette smoke exposure for 4 days were studied. The effects on local inflammatory response in the lung are reflected by an increase in the number of neutrophils.

AZD5423 dosed *it* at 0.3 mg kg^{-1} day^{-1} inhibited the cigarette smoke-induced influx of neutrophils into BAL by 29%. Fluticasone propionate dosed at 0.03 and 0.3 mg kg^{-1} day^{-1} had no effect on the number of neutrophils in BAL. In a separate study, AZD7594 at a dose of 0.3 mg kg^{-1} day^{-1} significantly inhibited influx of neutrophils into BAL by 58%. Kineret, a biological that inhibits the IL-1β pathway, was used as a positive control in his study and was administered at 48 mg kg^{-1} day^{-1} via an

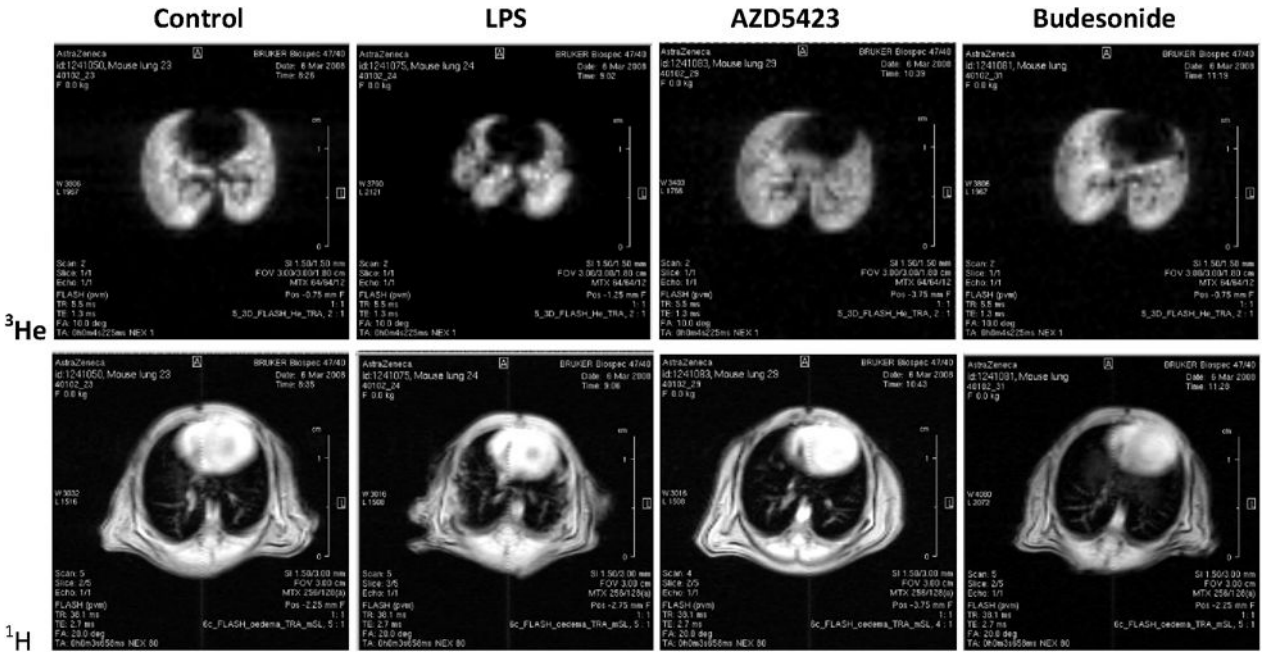

Fig. 25 Effects of AZD5423 (0.3 g kg^{-1}, o.d.) and budesonide (0.3 μg kg^{-1}, bid) improving ventilation and reducing edema in mice 24 h after first administration. The first row images show the free airspace using hyperpolarized ^{3}He-MRI, and the second row images show fluid in the lung using ^{1}H-MRI.

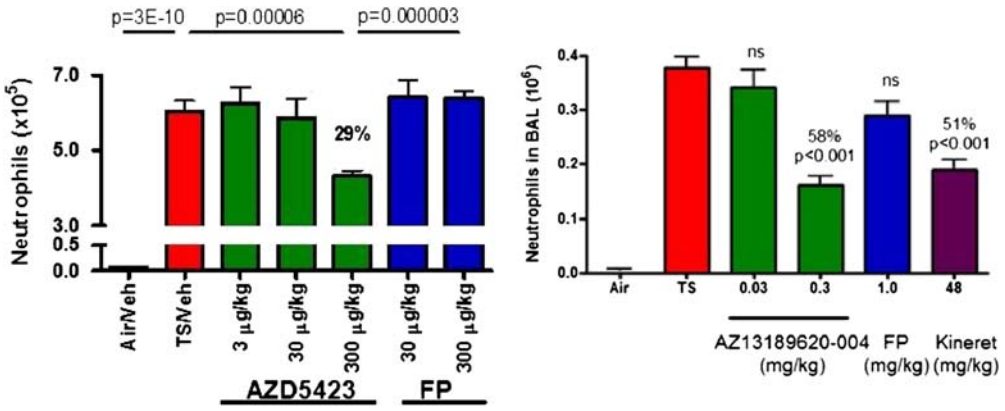

Fig. 26 Effects of AZD5423 and AZD7594 on neutrophil influx in the cigarette smoke model.

osmotic mini-pump placed under the skin of the animal inhibited neutrophil influx into BAL by 51%. In contrast, fluticasone propionate dosed at 1.0 mg kg^{-1} day^{-1} had no significant effect on the number of neutrophils in BAL in both studies (Fig. 26).

8.18.7 Progression of AZD5423 and AZD7594 Into Development

The progression of AZD5423 and AZD7594 into development will only be described briefly, and further details may be found in reference here or will be disclosed in future reports.

8.18.7.1 Progression of AZD5423

AZD5423 was nominated as CD in Dec. 2007. After safety pharmacology studies were completed the compound was approved for human clinical studies. Safety pharmacology data will not be described here, but it is interesting to note that predicted PK profile was confirmed in the larger set of studies that followed in the assessment of the compound. AZD5423 was rapidly absorbed in rat and dog after inhalation. Plasma AZD5423 profile after absorption phase showed rapid distribution kinetics with multiphasic plasma decay.

Data from repeated dose studies in both the rat and dog showed approximate dose linear plasma exposure of AZD5423, and no significant accumulation was observed. In contrast to the dog, a sex difference was indicated for the rat with females having an about twofold higher plasma exposure. A significant plasma exposure of a metabolite **71** was observed in the rat but not in the dog.

An early clinical program was undertaken across several studies to define the safety profile and characterize the pharmacokinetics and pharmacodynamics of AZD5423 following single and multiple ascending doses in healthy subjects, prior to testing in patients with asthma and COPD.[61] AZD5423 was submitted to single and repeat dose-escalating studies in healthy male subjects, including one cohort of male Japanese subjects, up to 1248 μg single doses and 499 μg as once daily lung delivered doses for 14 days. Inhaled, nebulized AZD5423 was safe and well tolerated up to and including the highest doses tested for up to 2 weeks of once daily treatment. Plasma exposure suggested dose-proportional pharmacokinetics and dose-related effects on 24-h plasma and urine cortisol.

Effects on HPA function appeared to increase with dose of inhaled AZD5423: Maximal suppression of 24-h plasma cortisol was 49% attained after the single 1248 μg dose and 40% after the 499 μg daily dose for 14 days. There were no or marginal effects on other biomarkers tested (Osteocalcin, TRAP5b, DHEA-S, and 4βOH-cholesterol). No clinically relevant differences in safety or PK could be distinguished between the two study populations although HPA effects appeared to be marginally greater in the Japanese versus the Caucasian dominant study population. It was concluded that AZD5423, inhaled via nebulization, could be safely used in healthy subjects at doses of at least 300 μg for 2 weeks.

AZD5423 was then evaluated for the effect on allergen-induced responses patients with mild allergic asthma. A study design including 7 days of treatment with nebulized AZD5423 (75 or 300 μg) once daily, budesonide 200 μg twice daily via Turbuhaler, or placebo in a double-blind, four-period, crossover design study.[62] AZD5423 significantly attenuated the drop in FEV1 during the late asthmatic response (both doses led to an 8.7% drop) versus placebo (14% drop) with no effect of budesonide (12.5% drop) versus placebo. There was no effect on the drop in FEV1 during early asthmatic response. AZD5423, 300 and 75 μg significantly attenuated allergen-induced sputum eosinophilia by 63% and 61% at 7 h, respectively, and by 46% and 34% at 24 h after allergen challenge, versus placebo. Budesonide did not reduce allergen-induced sputum eosinophilia versus placebo. AZD5423 at 300 μg significantly attenuated allergen-induced airway hyper responsiveness at 24 h after allergen challenge versus placebo. The efficacy data, taken together with HPA-axis data from phase I studies, indicate that the benefit-risk ratio may be improved relative to conventional inhaled steroids, since effects on markers of adrenal capacity and HPA-axis function were qualitatively similar for AZD5423 as to what has been previously shown for inhaled steroidal GR agonists like budesonide, fluticasone propionate, and fluticasone furoate.[63]

Clinical program for AZD5423 continued with a study to evaluate the efficacy and tolerability of inhaled AZD5423 compared with placebo or budesonide in patients with COPD receiving the LABA formoterol. Patients were randomly assigned (in a ratio of 1:1:1) to a 12-week double-blind treatment to receive one of the following: AZD5423 via Turbuhaler (75 μg lung-deposited dose once daily for 4 weeks followed by 300 μg lung-deposited dose once daily for 8 weeks) or budesonide via Turbuhaler (320 μg delivered dose, 2 doses twice daily), or placebo via Turbuhaler (2 doses twice daily).[61a]

8.18.7.2 Progression of AZD7594

AZD7594 was nominated as CD in Dec. 2009. After safety pharmacology studies were completed the compound was approved for human clinical studies.[64] Safety pharmacology data will not be described here, but it is interesting to note that in a similar way as for AZD5423 the predicted PK profile for AZD7594 was confirmed in the larger set of studies that followed in the safety assessment. AZD7594 was absorbed into systemic circulation in rat and dog after inhalation with C_{max} in plasma generally observed within 30 min after inhalation. There were no significant differences in AZD7594 exposure between genders. Data from the repeated dose studies showed, taken together, a dose-proportional increase in exposure. In general limited accumulation was observed (about two- to threefold or less). An apparent terminal half-life was calculated after single dosing in rat and ranged between 9 and 13 h.

An early clinical program was undertaken to define the safety profile and characterize the pharmacokinetics and pharmacodynamics of AZD7594 following single and multiple ascending doses in healthy subjects, prior to testing in patients with asthma. AZD5423 was submitted to single and repeat dose-escalating studies in healthy male subjects, up to 1872 μg single doses on day 1 and multiple doses days 5–16. The systemic exposure of AZD7594 increased in proportion to dose, and the relatively long half-life of 27.2 and 31.4 h supports that it is potentially suitable for once-daily dosing. At doses up of 7–1248 mg, the plasma cortisol suppression was comparable to placebo. Suppression of the HPA-axis based on plasma cortisol was observed at the highest dose of 1872 mg.[65]

AZD7594 was then studied in a 14-day randomized, double-blind, multiple dosing, placebo-controlled, asthma study to assess efficacy and safety of three dose levels of AZD7594 (58, 250, and 800 μg) given once daily using a commercially available dry powder inhaler, in patients with mild-to-moderate asthma.[66]

8.18.8 Summary

IGCs used either alone or in combination with bronchodilators provide the basis for current treatments of respiratory diseases such as asthma and COPD affecting the life of millions of patients. There is currently a need to develop novel GR modulator-based treatments offering improved therapeutic margins and the possibility for once daily treatment regimens to further improve disease control. AZD5423 and AZD7594 are two novel-inhaled selective, nonsteroidal, GR modulators optimized for the inhaled route of delivery now progressed into clinical development for the treatment of asthma. Data from preclinical in vivo models indicate that these compounds may offer a significant advantages compared to current steroid-based GR modulators.

The identification of the chemical starting point leading up to the candidate compounds AZD5423 and AZD7594 was based on the output from a HTS campaign that identified a series of sulfonamide-based compounds suitable for further optimization. The hit series, represented by compound **9**, showed functional antagonism when tested in the GR TR assay. By applying structural understanding of key GR agonist triggers the desired functional agonistic profile where obtained through the design and synthesis of a series of heterocycle containing analogues. These efforts lead to the identification of the lead series represented by compound **36**.

Compound **36**, and its structural analogues, comprised several of the key features viewed as necessary for successful progression towards an inhaled clinical candidate, including promising level of GR potency, in vitro DMPK profile, and significant level in vivo efficacy when tested in the rat Sephadex model following local administration to the lung. However the continued profiling of the series identified the formation of potentially genotoxic metabolites linked to core pharmacophore motifs requiring a significant redesign of the lead series to allow further progression.

Throughout the duration of the project the design of new SGRM ligands and understanding of their functional behavior benefited significantly from the access to high-quality X-ray structures. In particular this became evident during the redesign of the lead series to remove the potential genotox liabilities associated with compound **36** metabolites. By integration of structural information from multiple GR–ligand complexes a novel series of norephedrine-based GR modulators were discovered. Key motifs of the sulphonamide lead **36** were preserved in the new series, e.g., the indazole moiety and the sulphonamide linker, but their connectivity was rearranged.

The new series, represented by compounds **47** and **56**, offered a significant scope for further optimization of the GR potency as well as other key properties e.g., metabolic soft spots, morphology that ultimately lead to identification of the two clinical candidates AZD5423 and AZD7594.

Key for the final prioritization was the in-depth in vivo evaluation of the short-listed compounds in a panel of pharmacokinetic and pharmacodynamic inhalation in vivo models to fully understand the potential of each individual compound compared to the leading inhaled glucocorticosteroids. So far the clinical data obtained at this point in time confirms the pharmacokinetic and efficacy predictions made from the animal models.

8.19.1 Introduction

Obesity is a chronic, relapsing health risk defined by excess body fat. A large volume of research suggests the pathogenesis of obesity involves the complex interaction of genetic, environmental, and behavioral factors. Excess body fat increases significantly the risk of death and the occurrence of major comorbidities such as type 2 diabetes, hypertension, dyslipidemia, cardiovascular disease, osteoarthritis of the knee, sleep apnea, and some cancers.[1] Unfortunately, obesity has reached the global epidemics level, as it is

observed in most developed and developing countries in both adult and pediatric populations. Therefore, obesity prevention and management is a public health priority, and intervention strategies have focused primarily on healthy eating and physical activity in children and adults.[2] Naturally, the challenge to discover drug treatments for obesity has been at the center of major research efforts across the whole life science ecosystem.

Several novel drugs and drug combinations to treat obesity have recently been approved by the FDA. There are now five approved treatments, including orlistat (trade name Xenical), lorcaserin (trade name Belviq), liraglutide (trade name Saxenda), phentermine/topiramate extended release (trade name Qsymia), and naltrexone/bupropion (trade name Contrave).[3,4] There are significant differences in the limited efficacy of these approved treatments, as well as with responder rates and differing side effect profiles. No single drug or drug combination has emerged as a first-line treatment for obesity, and comparative drug trials between any of these agents have not been performed. The results from several ongoing cardiovascular outcome trials will be important in assessing the future market potential of these treatments. Therefore, the current state of obesity drugs and novel drug candidates to treat obesity is in its infancy.

The melanin-concentrating hormone (MCH) system has long been known to be involved in the control of feeding behavior and weight control in mammals.[5,6] The discretely localized lateral hypothalamic area (LHA) neurons synthesize the nonadecapeptide MCH and the neuronal projections synapse in cortical, hippocampal, nucleus accumbens, and intra-hypothalamic nervous system regions. Thus, the MCH system appears to integrate appetite with reward, memory, sleep, and emotion centers in the central nervous system (CNS). In rodent species, there exists one MCH receptor type, melanin-concentrating hormone receptor 1 (MCHR1), a G-protein coupled receptor. In dogs, humans, and other higher mammalian species, there exists a second highly homologous MCH receptor type, termed melanin-concentrating hormone receptor 2 (MCHR2). MCH, when administered intracerebroventricularly, induces food and water intake and body weight gain in several animal species. Multiple genetic rodent models have been generated, and a metaanalysis of MCH and MCHR1 deficiency models has been carried out.[7] This analysis has shown that deletion of MCH signaling suppressed body weight, fat mass, and plasma leptin, while MCH signaling deficiency increased body temperature, oxygen consumption, heart rate, and mean arterial pressure. Additional behavioral studies have shown that deletion of MCH signaling enhanced wakefulness, locomotor activity, aggression, and male sexual behavior, and that MCH signaling deficiency suppressed non-REM sleep, anxiety, responses to novelty, startle responses, and conditioned place preferences.[2] More recently, substantial data has been generated, suggesting a role of the MCH system in REM sleep and in depression-like symptoms in experimental animals.[8] Despite the varied potential pharmacologies that could be explored in man, the rationale and degree of robustness for MCH in food intake and obesity control appear to have the best validation in animal systems. Thus, in spite of the lack of clinical target validation and good-quality tool compounds, we embarked on a program aiming to discover and develop a novel MCHR1 antagonist for the treatment of obesity using reliable preclinical molecular and whole animal pharmacology models.

Our strategy was to discover and qualify a good small-molecule tool to enable the testing of the obesity-related target validity of MCHR1 in an MCHR1-only expressing rodent species first, followed by a canine species expressing both MCH receptor types, to explore both the efficacy and potential compensatory effects taking place when MCHR1 is antagonized. Should these efforts meet with success, we then would engage in the discovery of an antiobesity drug for human.

When our efforts began, no high-quality MCHR1 antagonists tool compounds had been reported that could be used in our planned in vivo studies. Over the years, a number of such compounds were disclosed that reached clinical studies. These include compounds **1**,[9] **2**,[10] **3**,[11] **4**,[12] and **6**.[13] We now, for the first time, disclose the discovery, chemical structure, and early development work on NGD-4715 (**7**).

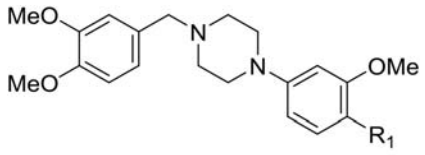
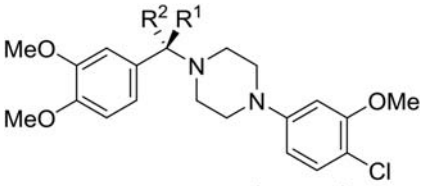
8.19.2 Hit-Finding: The Serendipitous Discovery That Led to NDT 9522320, a Tool Compound for in vivo Target Validation

A high-throughput screening campaign was conducted on the Neurogen proprietary compound library, using a calcium mobilization assay on stably transfected Chinese hamster ovary (CHO) cells overexpressing monkey MCHR1.[14] Among a number of hits considered for confirmatory studies, a compound registered as the arylpiperazine HBr salt (**8**) was shown to have converted under regular vial manipulation and storage conditions (DMSO solution, occasional exposure to air) to bromide **9**. The structure of **9** was confirmed by comparison of spectroscopic (H-1 and C-13 NMR) and chromatographic (high-pressure liquid chromatography–mass spectrometry, HPLC-MS) properties with an authentic specimen synthesized from commercially available starting materials. Compound **9** was an excellent starting point for a CNS drug discovery project, based on its physicochemical attributes ($c\log P = 3.8$; MW = 421.3 amu; polar surface area (PSA) = 34 Å^2, five hydrogen bond acceptors and zero donors, and no violations of the rule of 5, Ro5 = 0), as well as the ease of structure–activity relationship (SAR) development. While compound **9** was a potent inhibitor of MCHR1 in vitro (monkey MCH $K_i = 12$ nM), was stable in microsomal incubations, and showed favorable in vivo pharmacokinetics (PK) in rat, it had significant cross-reactivity with the human ether-a-go-go related gene (hERG) channel (81% inhibition at 3 μM), the α1 adrenergic receptor ($K_i = 400$ nM), and serotonin transporter ($IC_{50} = 460$ nM). Improvements, therefore, were required to generate a suitable tool compound.



8: R^1=H
9: R^1=Br



10: NDT 9522320 (R^1=Me; R^2=H)
11: NDT 9522321 (R^1=H; R^2=Me)

The initial objective of the medicinal chemistry program was to discover a tool compound with appropriate attributes to conduct target validation studies in vivo and interrogate the biological hypothesis that central antagonism of MCHR1 leads to observable feeding effects. Some aspects of the SAR of arylpiperazines as MCHR1 antagonists are broadly summarized in Fig. 1. We were encouraged by the highly tractable nature of this SAR. Among a number of productive strategies followed to improve lead compound **9**, the bromine substituent was replaced by chlorine, which reduced lipophilicity and molecular weight, and a methyl group was introduced at the benzylic position. Indeed, the "magic methyl" strategy is well known in medicinal chemistry, and, often times, it results in a favorable trade-off between enhancements to the compound under study (e.g., improvements of in vivo stability, in vitro potency and selectivity, and solubility) and a manageable small increase in molecular weight and lipophilicity.[15] This led to the pair of enantiomers **10** and **11**. As we shall see later on, this SAR tractability was key in the design strategy that led to a novel core and eventually to the clinical compound NGD-4715.

8.19.3 Characterization of NDT 9522320 (10): Absolute Configuration, Physicochemical Attributes, and Large-Scale Synthesis

The two homochiral analogs **10** and **11** were made as exemplified for the former compound in Fig. 2. (1*R*)-1-(3,4-Dimethoxyphenyl)ethan-1-amine (**12**) was obtained by resolution of the racemate using (*R*) mandelic acid. Alkylation with

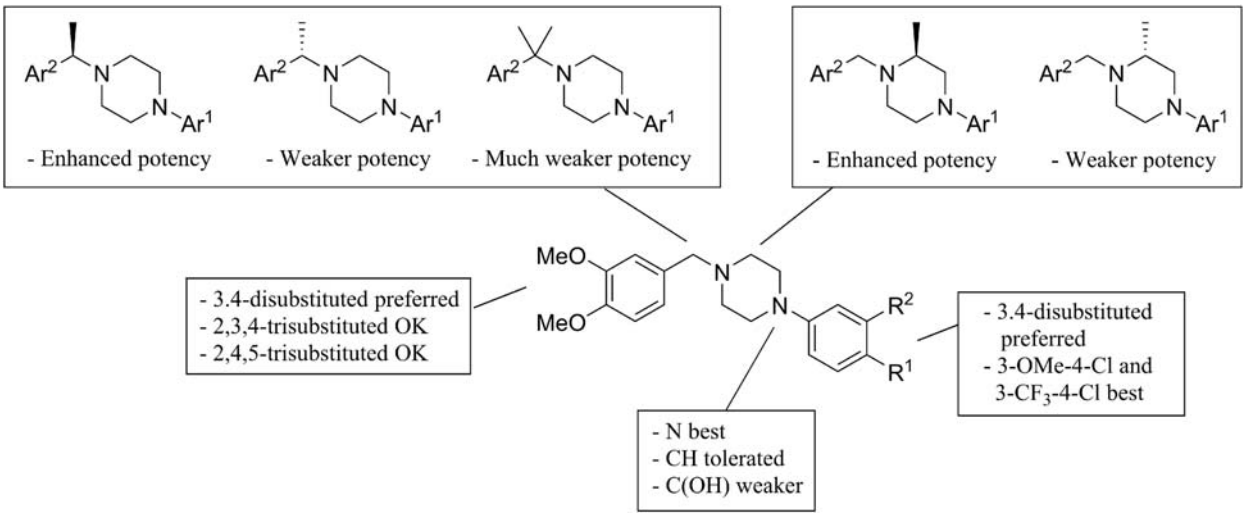


Fig. 1 Some broad aspects of the SAR for in vitro functional activity of arylpiperazines as MCHR1 antagonists.

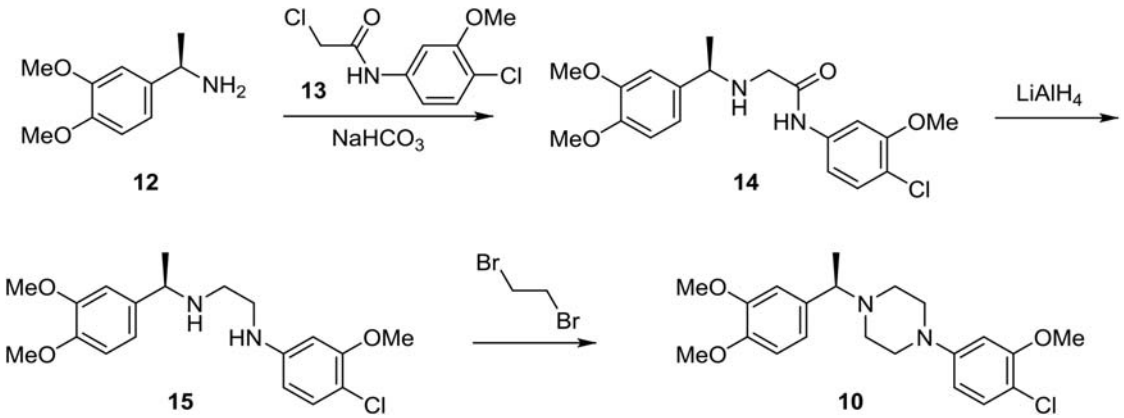

Fig. 2 Reaction sequence used for the enantiospecific preparation and characterization of absolute configuration determination of NDT9522320 (**10**).

chloroacetanilide **13**, followed by amide reduction with $LiAlH_4$, afforded diamine **15**. Alkylation with 1,2-dibromoethane produced compound **10**, also known as NDT 9522320, in 100% enantiomeric excess. The same process, but using (*S*)-mandelic acid, delivered the less-active enantiomer **11**. Since the absolute configuration of the starting material **12** was known, and it remained intact during the synthetic sequence, this scheme enabled the assignment of the absolute configuration of **10**, in spite of a relatively low total yield.

A larger scale synthesis was developed as shown in Fig. 3. Using this protocol enabled the preparation of up to 500 g of compound **10** in a total yield of 14% and enantiomeric excess ee > 99%, as determined by HPLC analysis, which enabled the execution of subchronic studies in rat and dog. 3,4-Dimethoxyacetophenone (**16**) was reacted with piperazine **17** under reductive amination reaction conditions using excess $Ti(OiPr)_4/NaBH_4$, yielding racemic benzylamine **18**. Hydrolysis under strongly basic conditions afforded piperazine **19**, which was resolved with L-tartaric acid (three crystallizations) to produce chiral **20**. Palladium-catalyzed coupling of **20** with 4-bromo-1-chloro-2-methoxybenzene under Buchwald reaction conditions ($Pd_2(dba)_3$, BINAP, KO*t*Bu) delivered after chromatographic purification, compound **10**, which was converted to its bis-HCl salt by treatment with excess HCl in dioxane.

Compound **10** showed high affinity for the MCHR1 receptor, inhibiting the binding of the peptidic agonist [^{125}I]-S36057 in a rat brain membrane assay with $K_i = 15$ nM,[16] and was also a potent inhibitor of the functional effects of MCHR1 in vitro (MCH-stimulated monkey MCHR1 Ca flux $K_i = 4$ nM and GTPγ^{35}S $K_i = 17$ nM). In a monkey MCHR-CHO cell membrane GTPγ^{35}S assay,[17] compound **10** acted as a competitive inhibitor with a $K_d = 12$ nM based on Schild analysis (slope factor 1.14). Compound **10** showed excellent selectivity versus human MCHR2 (no detectable activity at 10 μM) and encouraging improvements in cross-reactivity with hERG (58% inhibition at 3 μM, $IC_{50} = 2.5$ μM), the α1 adrenergic receptor ($K_i = 1933$ nM), and the serotonin transporter ($IC_{50} = 6.5$ μM). A broad panel (40 relevant GPCRs) indicated < 50% inhibition of radioligand binding at 1 μM, with the exception of the histamine H2 receptor, with an $IC_{50} = 470$ nM.

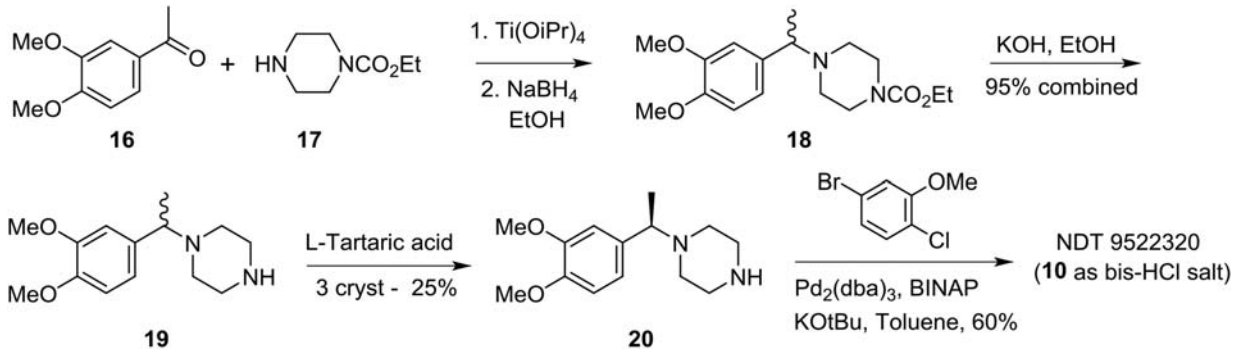

Fig. 3 Reaction sequence used for the scale up of up to 500 g of NDT 9522320 (**10**).

Furthermore, the 100-fold weaker functional in vitro activity at the target of the distomer **11** (mMCH $K_i = 379$ nM) provided a tool compound that could be used as negative control during in vivo efficacy studies, and mechanistically support a link to pharmacodynamic effects of compound **10**.

In terms of physicochemical attributes, **10** has a molecular weight MW = 390.9 amu, calculated $c \log P = 4.2$ and PSA = 34 Å^2, rotatable bonds (RB) = 6, hydrogen bond acceptors and donor are HBA = 5 and HBD = 0, respectively, thus affording no violations of the Lipinski Rule of 5 (Ro5 = 0). It is weakly basic (experimental p$K_a = 7.3$). Aqueous kinetic solubility was moderate (17 μg mL^{-1} or 44 μM at pH 7.4 or 250 μg mL^{-1} or 641 μM at pH 5.4).

Stability in rat, dog, monkey, or human liver microsomes preparations generally was moderate, with predicted hepatic clearance values of CL_H of 60 mL min^{-1} kg^{-1}, 22 mL min^{-1} kg^{-1}, 18 mL min^{-1} kg^{-1}, and 10 mL min^{-1} kg^{-1}, respectively. In vivo rat PK parameters were consistent with expectations set from in vitro values. Compound **10** was dosed as a solution in methylcellulose/triacetin (0.5%/0.1%; 10 mg kg^{-1}, PO or 1.5 mg kg^{-1}, IV). The compound was highly bioavailable ($F = 88\%$), with short $T_{max} = 0.75$ h, high volume of distribution (15 L kg^{-1}), $C_{max} = 268$ ng mL^{-1}, $T_{1/2} = 7.2$ h, and CL = 35 mL min^{-1} kg^{-1}. Compound **10** is highly brain penetrant in rat, showing total brain-to-plasma ratios B/P = 8–10. In a rat brain ex vivo receptor occupancy assay, compound **10** had an $RO_{50} = 4$ mg kg^{-1}. The cerebrospinal fluid levels of **10** were determined at 5 and 20 mg kg^{-1}; dose-proportional concentrations seen were 7 ng mL^{-1} (18 nM) and 31 ng mL^{-1} (80 nM), respectively, commensurate with functional IC_{50} values and in good agreement with the ex vivo RO_{50}.

In dog PK studies, compound **10** was dosed as the bis-HCl salt (IV: 1.5 mg kg^{-1} in 50% PEG; PO: 2 mg kg^{-1} in 2% D-α-tocopheryl polyethyleneglycol succinate). Oral bioavailability was moderate ($F = 54\%$), with short $T_{max} = 0.8$ h, high volume of distribution (9.5 L kg^{-1}), $C_{max} = 393$ ng mL^{-1}, and $T_{1/2} = 19$ h. No differences in drug exposure in fed versus fasted dogs were observed in dog (PO dosing; 10 mg kg^{-1}, capsules; $F = 92\%$ vs. 94%; $C_{max} = 1477$ ng mL^{-1} vs. 1239 ng mL^{-1} for fed and fasted, respectively).

In terms of safety, conjugation with glutathione in vitro was observed (75% vs. 20% for acetaminophen).[18] No reversible or time-dependent inhibition of CYP450 could be determined in vitro.[19] We explored further the potential for cardiovascular liabilities since there was moderate hERG activity, and were pleased to find that **10** had < 10% change in action potential duration at 90% repolarization at 3 μM in rabbit heart Purkinje fiber studies, bolstering its cardiovascular safety profile.[20] Based on these results, we considered that compound **10** was a suitable tool compound to test the biological hypothesis in vivo in both rat (MCHR1-only species) and dog (dual MCHR1/2 species).

8.19.4 Preclinical Proof-of-Concept in Rat

Mechanistic support for the effects of tool compound **10**, being driven by blocking the MCHR1 receptor, came from studies where feeding is elicited by intracerebroventricular (ICV) administration of MCH, and then blocking these effects in the presence of the MCHR1 antagonist. Fig. 4 shows an example of the effects of **10** (dosed at 2 mg kg^{-1}) on MCH-elicited feeding behavior. Similar effects were observed at 5, 10, and 20 mg kg^{-1} doses of compound **10**. On the other hand, the feeding effects elicited by galanin, another orexigenic peptide, were not antagonized by **10**, showing a level of selectivity in its antifeeding effect. These results are consistent with the orexigenic effects of the MCH peptide agonist, and the biological response interrogated with compound **10**.

The diet-induced obesity (DIO) model in rat was chosen to study the effects of MCHR1 antagonism by **10** on the rate of body weight and food intake in drug-treated animals (10 mg kg^{-1}) compared to vehicle-treated control animals on a high-fat diet.[21] In this model, rats are treated with a high-fat diet. Some of them will become obese, some will not. These animals were separated into two groups: obesity-prone and obesity-resistant. Fig. 5 shows that compound **10** had no effect on obesity-resistant animals, while it caused a reduction in the rate of weight gain and food intake in obesity-prone animals.[22] Note that in the experience of Neurogen, the drugs fenfluramine, sibutamine, and rimonabant were active in this DIO model.

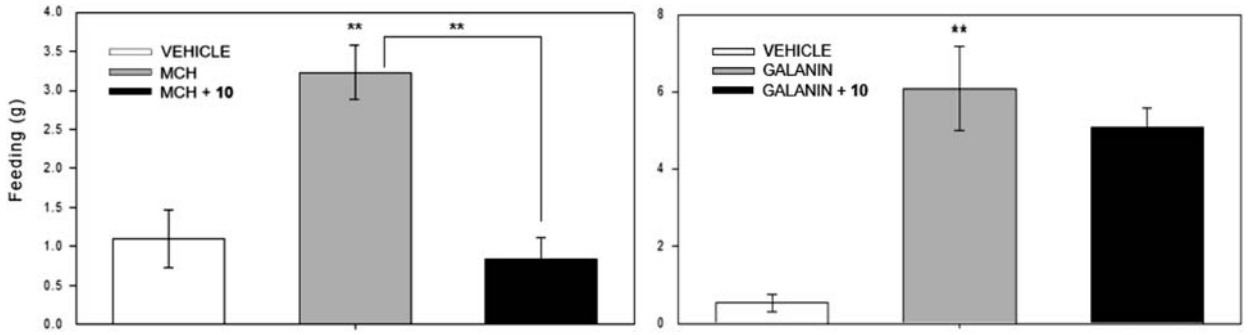

Fig. 4 Effect of **10** (2 mg kg^{-1}, PO) on rat feeding behavior elicited by MCH (*left panel*, 5 μg MCH, ICV) or galanin (*right panel*, 10 μg galanin); 2-h test, $n=7$. Comparisons made against vehicle group. $^{**}p<0.01$.

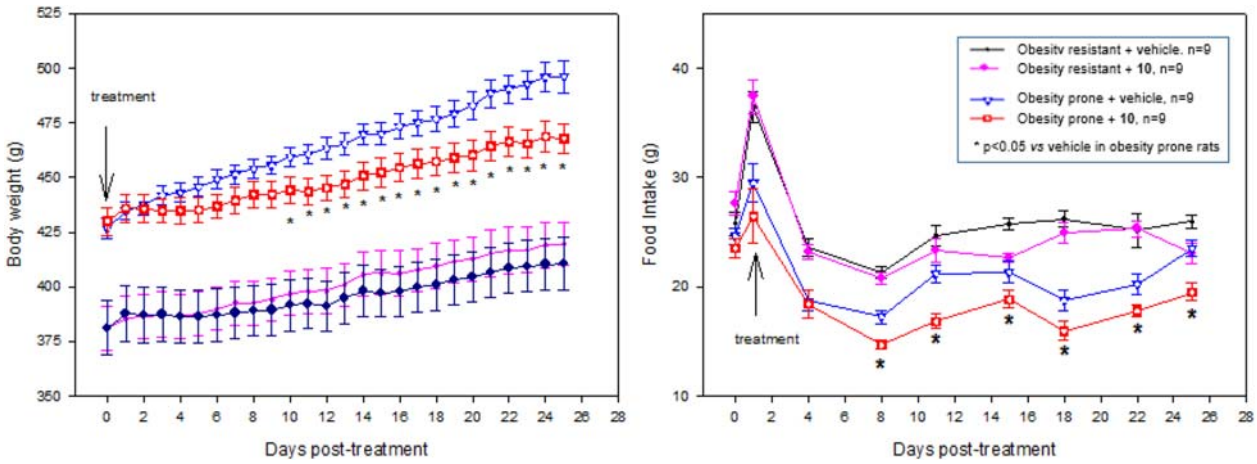

Fig. 5 Effect of **10** (10 mg kg^{-1}, PO) on body weight and feeding behavior in obesity-prone rats. No statistically significant effects of **10** are seen in rats that are not obesity-prone, either on body weight *(left panel)* or food intake *(right panel)*. On the other hand, compound **10** significantly reduces the rate of weight gain and the food intake in obesity-prone rats (*red* vs. *blue squares*).

To rule out the possibility that the feeding behaviors seen were driven by a drug-mediated toxic effect, we evaluated potential changes in a number of behavioral domains. General potential effects of **10** on motor behaviors were explored through their spontaneous locomotor activity, where no evidence of hypo- or hyperactivity was seen. Drug-induced gastrointestinal (GI) malaise may lead to a reduction in food intake, and it is difficult to detect as rats lack the emetic response. However, persistent consumption of nonnutritive substances like kaolin has been considered similar to vomiting in other species. These GI effects were ruled out, as no increase in kaolin consumption was observed versus controls (10 mg kg^{-1} of **10**).[23] Potential anxiogenic effects were investigated in the elevated plus maze, and also were ruled out (2, 5, or 10 mg kg^{-1}). Thus, no effects were seen in any of these tests, suggesting no malaise was caused by **10**, and increasing confidence that the feeding effects could be attributed to central MCHR1 antagonism.

These results support the role of the MCHR1 in weight control in a species only expressing the MCH1 receptor. Would this reduced feeding phenotype be maintained in higher species containing both MCHR1 and MCHR2 receptors? To address this question, we conducted investigations in dog.

8.19.5 Proof of Concept in Dog, a MCHR1/2 Species

As previously discussed, MCH is an orexigenic peptide involved in energy homeostasis expressed in the LHA of the brain. Two MCH receptors are known: MCHR1 and MCHR2, the latter being expressed only in higher species such as dog, monkey, and human.

To explore the effects of MCHR1 antagonism on body weight and food intake in a species expressing both receptors, female spayed beagle dogs were used as subjects and fed 400 g of a high-fat diet daily throughout the study. Three weight-matched groups ($N=6$; vehicle, 3 and 10 mg kg^{-1} bid; capsules) were dosed for 29 days. NGD 9522320 (**10**) significantly prevented body weight gain in the 3 and 10 mg kg^{-1} groups compared with a control group (Fig. 6). The cumulative food intake for the 10 mg kg^{-1} group was reduced significantly from control. Umbilical girth increase was significantly smaller for the 10 mg kg^{-1} group versus control. A Purina body condition score (PBCS) was determined for each dog by veterinary exam.[24] All three treatment groups were scored as

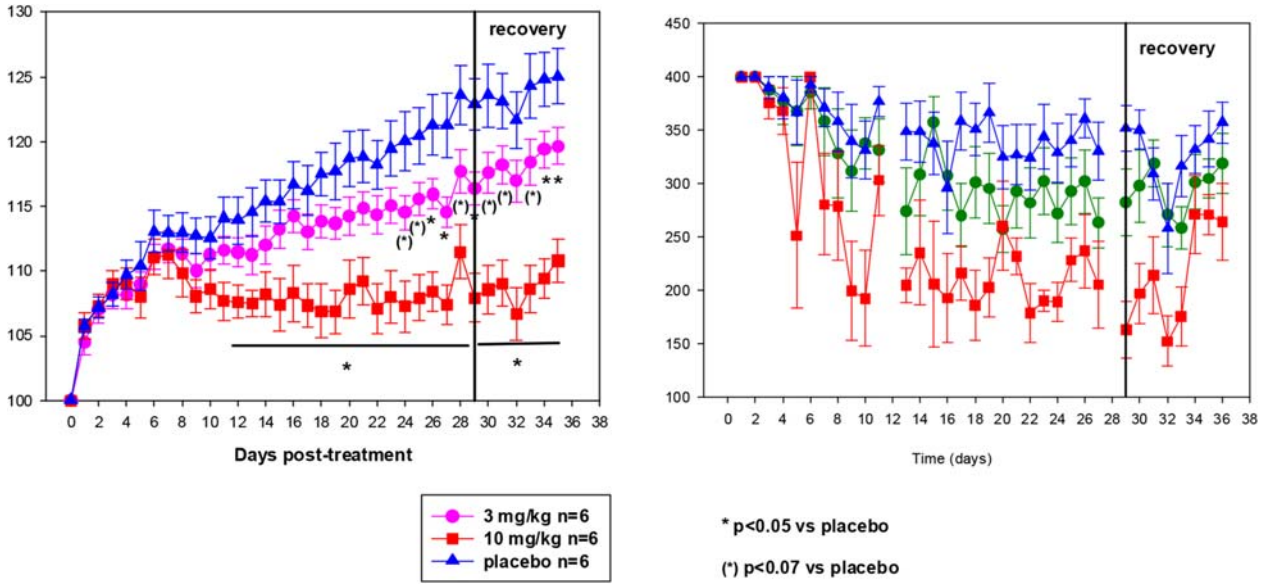

Fig. 6 Effect of NDT 9522320 (**10**, 3 or 10 mg kg^{-1} PO, capsule) on body weight change (left) or food intake (right) in beagle female spayed dogs. Treatment was discontinued after 28 days of dosing.

Table 1 Plasma concentrations for compound **10** at different time points in the dog subchronic study

Dose	*Time (ng mL^{-1})*	*Day 1*	*Day 15*	*Day 29*	*Day 36 (Recovery)*
3 mg kg^{-1}	Peak	410 ± 317	893 ± 323	1101 ± 231	–
	Trough	26 ± 19	199 ± 65	309 ± 129	41 ± 25 ($T_{1/2}$ = 48 h)
10 mg kg^{-1}	Peak	1625 ± 764	2410 ± 962	4412 ± 1051	–
	Trough	196 ± 157	1707 ± 611	2185 ± 912	1009 ± 682 ($T_{1/2}$ = 122 h)

heavy at the start of the study (PBCS = 6.4). By the end of the treatment, the 10 mg kg^{-1} group showed no significant increase in the score (6.7), signifying no increase in adiposity. PBCS for the control group increased to 8.0 (obese). Hormonal measurements revealed that treatment with **10** (3 and 10 mg kg^{-1}) prevented the diet-induced abnormal insulin secretion after the meal as observed in the control group. Neither dose group showed significant alterations in clinical and blood chemistry or any signs of malaise (Kaolin assay). Plasma levels for compound **10** at different time points during the study, including recovery, are shown in Table 1. In agreement with the slow decay in compound **10** plasma concentrations upon ending dosing, both the rate of weight gain and food intake tend to increase toward those for the control group, suggesting a PK–pharmacodynamic relationship.[25]

In summary, this study demonstrated that compound **10**, a selective, brain penetrant, orally active MCHR1 antagonist, was efficacious in an R1/R2 species as evidenced by a dose-related reduction in rate of body weight gain and food intake, reduction in visceral adiposity as measured by girth at the umbilicus, and the PBCS remaining unchanged on Day 29 compared to Day 1 for the 10 mg kg^{-1} group. Treatment with **10** was effective in controlling the hyperinsulinemia associated with the ingestion of a high-fat diet at 3 and 10 mg kg^{-1} (data not shown). Support for MCHR1 antagonism for the treatment of obesity has been obtained in a species that expresses both MCHR1 and MCHR2.

Overall, these data strongly support the efficacy of MCHR1 antagonists in preclinical feeding models of obesity and suggest that MCHR1 antagonists may be useful in the control of multiple complications associated with obesity, diabetes, and metabolic syndrome.

Having gained confidence in the biological hypothesis of MCHR1 antagonism using NDT9522320, we realized that some safety aspects (glutathione conjugation, hERG channel inhibition) of this compound fell short of the very high expectations for an anti-obesity drug.[26] Therefore, our team embarked on a search for a clinical drug candidate with higher safety and efficacy attributes.

8.19.6 A Novel Bicyclic System: NGD 9522330 (31)

Although we could not advance our tool compound, NDT 9522320 (**10**), any further through early development, we nonetheless were encouraged to continue our investigations, this time through the development of additional heterocyclic cores that might provide compounds with superior properties that would further enlarge our patent estate and probability of clinical success. A

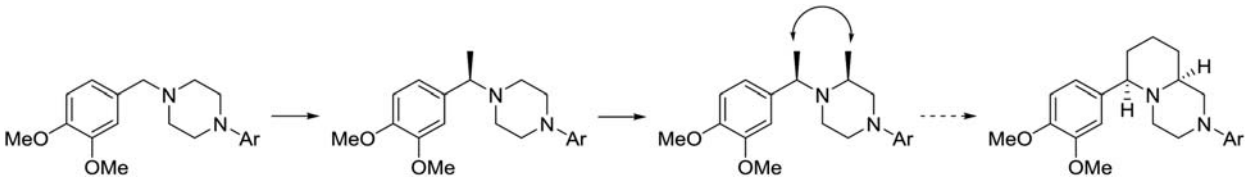

Fig. 7 Proposed pyrido[1,2-*a*]piperazine core.

classic medicinal chemistry strategy is to cyclize portions of a molecule to restrict bond rotation and conformational mobility (Fig. 7). Exploration of this strategy mandated the synthesis of a completely novel bicyclic ring system. It required no small amount of experimentation to devise a successful synthesis of the pyrido[1,2-*a*]piperazine ring system. The preparation methodology finally discovered is presented in the following figures.

Having established the required absolute chirality through our studies on NDT 9522320 (**10**), we turned to the chiral pool for the necessary synthons. Thus, treating L-2-amino-pent-4-enoic acid (**21**) with solid di-*tert*-butyl dicarbonate in 1 N NaOH and dioxane gave L-2-*tert*-butoxycarbonylamino-pent-4-enoic acid (**22**) in quantitative yield. A solution of **22** and 4-chloro-3-methoxyaniline in pyridine was treated with 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDCI) to give (*S*)-[1-(4-chloro-3-methoxy-phenylcarbamoyl)-but-3-enyl]-carbamic acid *tert*-butyl ester (**23**) in 72% yield. Alane-*N*,*N*-dimethylethylamine complex was added to a solution of **23** in toluene. After 25 h, the reaction was quenched and worked up, and the crude product was resubjected to the reduction conditions just described, which provided (*S*)-{1-[(4-chloro-3-methoxy-phenyl-amino)-methyl]-but-3-enyl}-carbamic acid *tert*-butyl ester (**24**) in quantitative yield. A solution of chloroacetylchloride was added to a biphasic mixture of ethyl acetate and saturated sodium bicarbonate to provide (*S*)-1-{[(2-chloro-acetyl)-(4-chloro-3-methoxy-phenyl)-amino]-methyl}-but-3-enyl-carbamic acid *tert*-butyl ester (**25**) in 89% yield. The benzyloxycarbonyl (BOC) group was removed, giving (*S*)-5-allyl-1-(4-chloro-3-methoxy-phenyl)-piperazin-2-one (**26**) in 78% yield. These reactions are summarized in Fig. 8.

To continue the reaction sequence, **26** was subjected to alane-*N*,*N*-dimethylethylamine complex reduction, giving (*S*)-3-allyl-l-(4-chloro-3-methoxy-phenyl)-piperazine (**27**) in quantitative yield. Compound **27** was mixed with di-*tert*-butyldicarbonate in THF to provide (*S*)-2-allyl-4-(4-chloro-3-methoxy-phenyl)-piperazine-1-carboxylic acid *tert*-butyl ester (**28**) in quantitative yield. Wacker oxidation of intermediate **28** gave (*S*)-4-(4-chloro-3-methoxy-phenyl)-2-(2-oxo-propyl)-piperazine-1-carboxylic acid *tert*-butyl ester (**29**) in 63% yield. The BOC group was removed, and the product was treated with 3,4-dimethoxybenzaldehyde and 6 N NaOH in MeOH leading to (6*R*,10*S*)2-(4-chloro-3-methoxy-phenyl)-6-(3,4-dimethoxy-phenyl)-octahydro-pyrido[1,2-*a*]pyrazin-8-one (**30**) in 29% yield. Formation of the tosyl hydrazine followed by reduction with sodium borohydride gave (6*R*,10*S*)2-(4-chloro-3-methoxy-phenyl)-6-(3,4-dimethoxy-phenyl)-octahydro-pyrido[l,2-*a*]pyrazine (NDT9522330, **31**) in 67% yield. These final reactions are presented in Fig. 9.

NDT 9522330 (**31**) exhibited the following physical properties: MW = 416.95 amu, calculated mLogP = 3.1; PSA = 43 Å^2; RB = 6; HBD = 0; and HBA = 6. Thus, only one Lipinski rule was violated, and that only slightly (Ro5 = 1). Compound **21** is weakly basic (calculated pK_a = 7.16). This compound was the first analog made in the pyrido[1,2-*a*]piperazine aniline series. It was a highly potent MCH antagonist in vitro with an IC_{50} = 0.26 nM in a mouse calcium flux assay and K_i = 2.5 nM inhibiting the binding of the peptidic MCHR1 agonist [^{125}I]-S36057 in a rat brain homogenate assay. The half-life in human and rat liver microsomes was

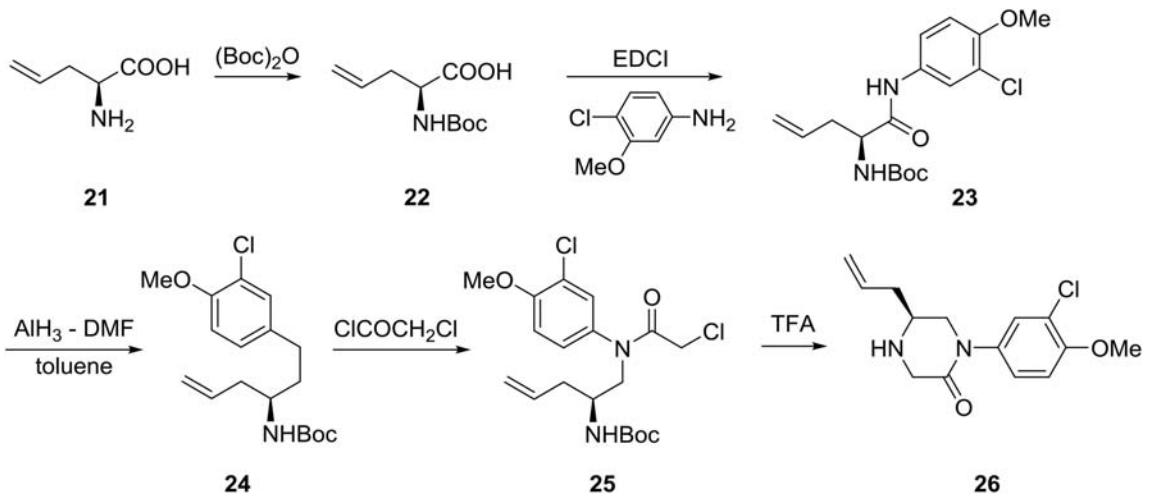

Fig. 8 Preparation of (*S*)-5-allyl-1-(4-chloro-3-methoxy-phenyl)-piperazin-2-one (**26**).

Fig. 10 Medicinal chemistry strategy seeking MCHR1 antagonists with the right balance of safety and efficacy attributes to become human drugs.

25 min and 43 min, respectively, thereby predicting acceptable metabolic stability. A rigorous analysis of the SAR of this series is beyond the scope of this work, but, despite the compound's excellent in vitro properties, it was found to be a hERG inhibitor with 50% inhibition at a 3 μM concentration in a patch-clamp assay. Indeed, hERG inhibition was a recurring issue with this series and prompted us to continue our exploration.

During the course of our studies in the aryl piperazine series, we discovered that the replacement of the 3,4-dimethoxyphenyl group with a 2,3-dimethyl-4-methoxypheny group resulted in compounds with superior MCH antagonist activity, presumably by restricting rotation about the bond between the phenyl ring and the heterocycle. Furthermore, it is known that reducing the basicity of a compound often reduces the degree of hERG inhibition.[27] Therefore, we thought to accomplish this by replacing the aniline with a carboxamide as shown in Fig. 10.

In order to generate analogs rapidly, we needed a synthesis that would allow facile modification of the western aryl group and modification of the carboxamide. The route utilized by medicinal chemists was designed to allow the exploration of the effects of variable functionality at the head and tail of the bicyclic octahydro-1*H*-pyrido[1,2-*a*]piperazine core. To this end, the sequence of reactions shown in Figs. 10–12 was employed. Benzyl protected L-aspartic acid was coupled to *N*-benzyl glycine ethyl ester using DCC and hydroxybenzotriazole. The resulting dipeptide cyclized spontaneously upon removal of the BOC group with trifluoroacetic acid to give **32**. Reduction with lithium aluminum hydride gave **33**, which was followed by reintroduction of the BOC group,

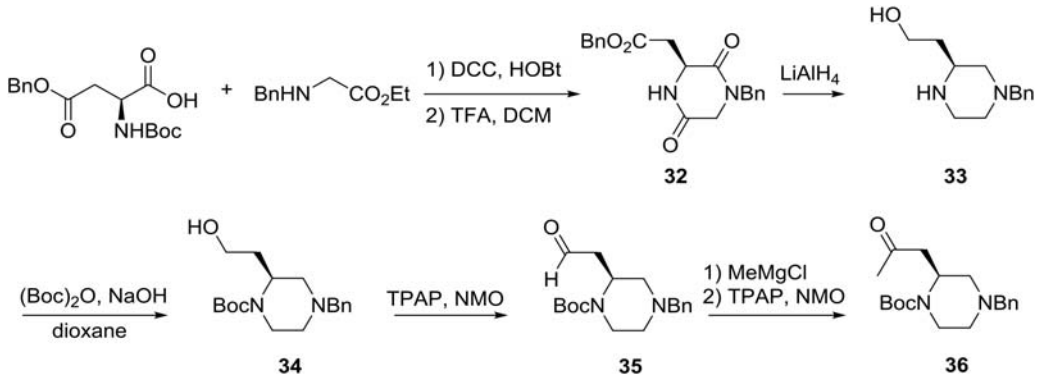

Fig. 11 Preparation of 1-[2*S*-4-benzylpiperazine-2-yl]propan-2-one (**36**).

gave the orthogonally protected piperazine ethyl alcohol **34** in 41% yield for the four steps after column chromatography. This was oxidized to the aldehyde **35** with tetrapropylammonium perruthenate (TPAP) and *N*-methyl morpholine oxide (NMO) in 79% yield after chromatography. After treatment with methyl magnesium chloride, the crude secondary alcohol oxidized using TPAP and NMO to provide the methyl ketone **36** in 73% yield for two steps after chromatography (Fig. 11).

With compound **36** in hand, aldol condensation with 2,3-dimethylanisole (**37**), mediated by DBU and lithium chloride in THF, followed by the removal of the BOC group, gave the enone **38** as a mixture of *cis*/*trans* isomers. The isomeric ratio was not determined, and the mixture was carried on to the next step without additional purification. The bicyclic intermediate **39** was obtained in 50% yield for three steps after chromatography by an intramolecular Michael addition mediated by ammonium acetate. Deoxygenation was accomplished by reduction of the intermediate tosyl hydrazone with sodium cyanoborohydride to give compound **40** in 62% yield for two steps after chromatography. The benzyl group was removed by catalytic transfer hydrogenation using ammonium formate as the hydrogen source in 96% yield, and the deprotected amine then was acylated with a commercially available aroyl chloride, or the acid chloride was prepared using the corresponding aroyl acid using thionyl chloride under standard conditions to give the intermediate (**41**) in good to excellent yields after chromatography. The methyl ether was cleaved with boron tribromide in ~80% yield to give the phenol (**42**), which was used as an intermediate to prepare analogs modified at the 4-position of the (6*R*,9a*S*)-6-(2,3-dimethylphenyl)-octahydro-1*H*-pyrido[1,2-*a*]piperazine ring system (generic structure **43**, Fig. 12).

Selected examples of analogs made are shown in Table 2. As can be seen, the 4-trifluoromethyl group confers optimal activity in this series, although the benzamide **44** still has an unacceptably high level of hERG inhibition. Compound **47**, the 4-trifluoromethyl nicotinamide, exhibits the best in vitro potency with an acceptable level of hERG inhibition—greater than 500-fold its IC_{50} in MCHR1 functional assays. Compound **47** was, therefore, chosen for further optimization.

Compound **47** was demethylated using boron tribromide in good yield, and the resulting phenol (**51**) was alkylated with a variety of agents in poor to good yields depending on the chemistry (Fig. 13). Scores of compounds were prepared and assayed. Table 3 provides a sampling of the data obtained.

The ether analog **53** displayed superior in vitro activity with an acceptable level of hERG inhibition—greater than 1800-fold its IC_{50} in MCHR1 functional assays, and was, therefore, selected for advanced testing. Compound **53** had the following rat PK properties: $T_{1/2}=3.1$ h; CL = 24.8 mL min^{-1} kg^{-1}; $V_{ss}=38.9$ L kg^{-1}; $T_{max}=0.5$ h, $C_{max}=86$ ng mL^{-1}, $F=20\%$; and an $AUC_{0-\infty}=427$ ng h mL^{-1} (10 mg kg^{-1} PO, 1 mg kg^{-1} IV, in 0.5% methyl cellulose/0.1% triacetin as vehicle, as in all studies unless otherwise noted). Brain penetration was good, with a partition B/P = 1.6.

Ether **53** was very active in vivo in our rat DIO model, producing a 3.1% reduction in body weight in male Wistar rats dosed at 5 mg kg^{-1} BID (Fig. 14). Although encouraged as we were by these results, our hopes soon were dashed. We discovered that this compound was retained extensively in adipose tissue in chronically dosed obese rats. We found that invasion into adipose tissue was high, elimination from the adipose was moderate to slow, and the adipose-to-plasma ratio was high (400–500). Since the expected patient population was to be chronically dosed obese humans, this posed an unacceptable potential risk. In retrospect, this high degree of adipose retention might have been indicated by a very large volume of distribution ($V_{ss}=38.9$ L kg^{-1}).

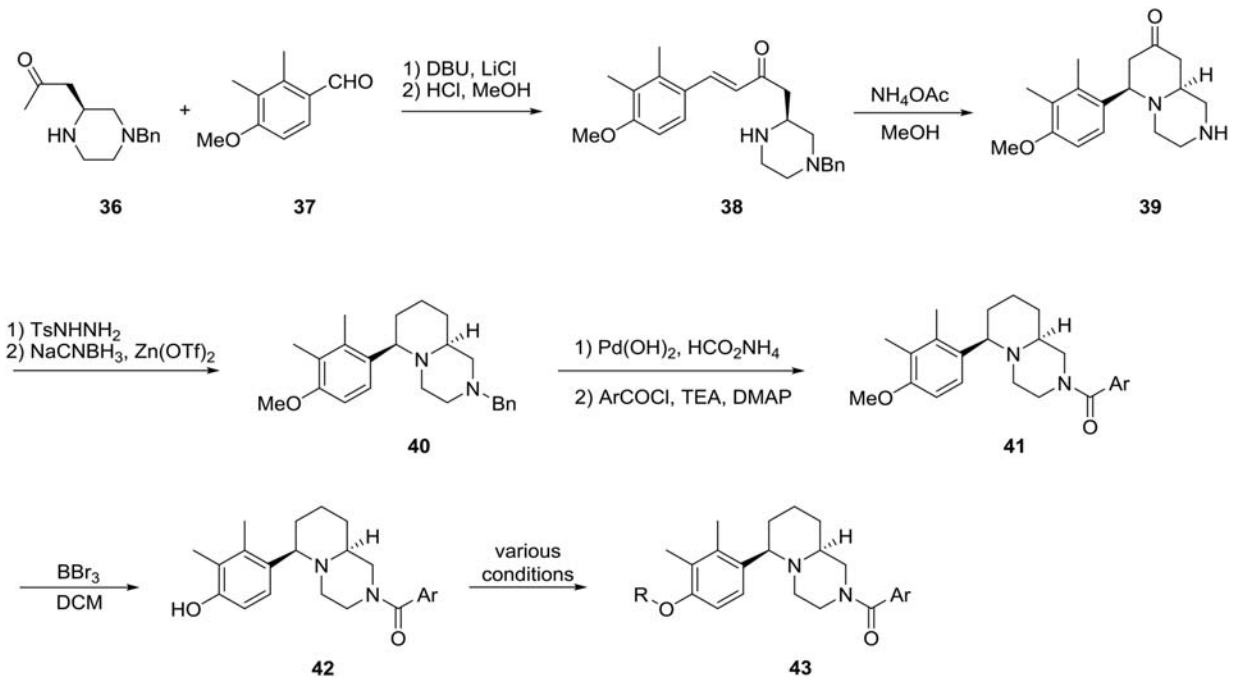

Fig. 12 Synthesis of 5-[(6*R*,9a*S*)-6-(4-methoxy-2,3-dimethylphenyl)-octahydro-1*H*-pyrido[1,2-*a*]piperazine-2-carboxamides (**43**).

51 NGD-4715 (**7**)

Fig. 15 Final steps to NGD-4715 (**7**) in the medicinal chemistry synthetic route.

In an effort to reduce the lipophilicity and improve the solubility of the series, we undertook the synthesis of several hydroxylated analogs using the sequence shown in Fig. 15; among these was the hydroxyethyl derivative **7**, which would be designated as NGD-4715. Thus, phenol **51** was treated with (2-bromoethoxy)-*tert*-butyldimethylsilane and powder potassium to provide **7**. In summary, the medicinal chemistry synthetic route to NGD-4715 required linear 17 steps, including nine column chromatography purifications with an overall yield of ~9%.

As an interesting footnote, a metabolite identification study of the ether **53** indicated that NGD-4715 was a major circulating metabolite in vivo, suggesting that the efficacy observed in the DIO study with **53** was, at least in part, due to the presence of the primary alcohol **7** (Fig. 16).

NGD-4715 possesses the following physical properties: MW = 477.5 amu; $Qsol_{7.4}$ = 36 μg mL^{-1}; log $D_{7.4}$ = 3.4–3.8; log P = 2.9; RB = 6; PSA = 68 $Å^2$; Rule of Five violations Ro5 = 0. It possesses the following in vitro activity: Ca K_i = 10.6 nM; GTP K_i = 5.9 nM; and rat striatum K_i = 9 nM. The IC_{50} for hERG inhibition was 38.4 μM, which is 6857-fold its IC_{50} in MCHR1 functional assays. In

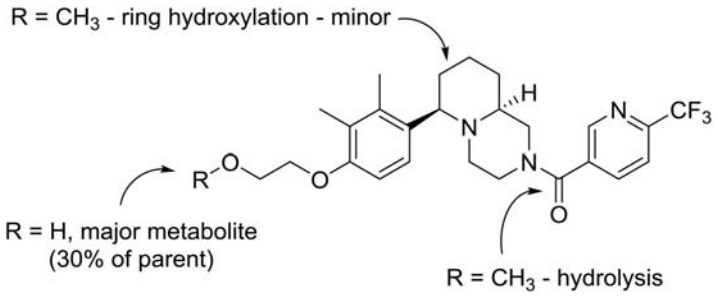

Fig. 16 Metabolites of compound **53** (R = Me).

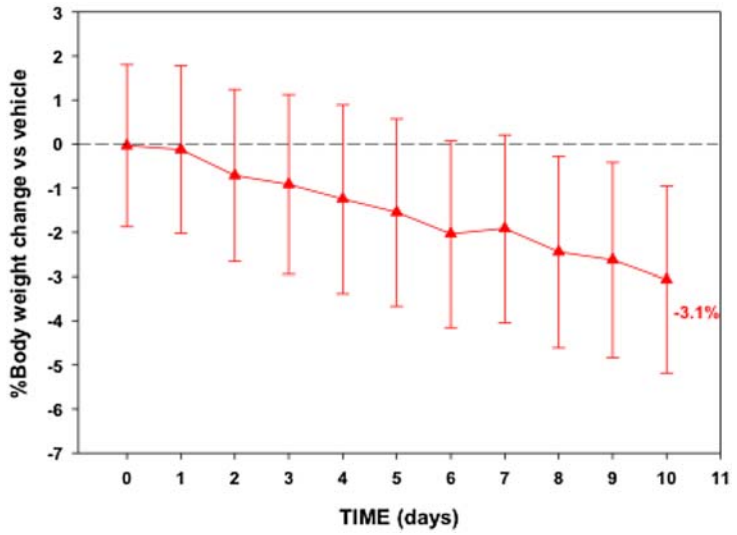

Fig. 17 Effect of NGD-4715 (**7**) on body weight of obesity-prone male Wistar rats dosed orally at 5 mg kg^{-1} BID; % body weight change versus vehicle.

rats, NGD-4715 exhibited the following PK properties: $T_{1/2}=2.1$ h; CL = 27.7 mL min^{-1} kg^{-1}; $V_{ss}=2.8$ L kg^{-1}; $T_{max}=0.5$ h, $C_{max}=212$ ng mL^{-1}, $F=40.0\%$; and $AUC_{0\rightarrow\infty}=765$ ng h mL^{-1} (10 mg kg^{-1} oral in MC/TA). With respect to in vivo activity, the DIO model produced a 3.1% reduction in body weight over 10 days (dosed orally BID at 5 mg kg^{-1}, Fig. 17). NDG-4715 (**7**) had a profound effect on food intake over a 24-h time period in male Wistar DIO rats dosed orally at 5 mg kg^{-1} BID. The animals consumed nearly 12% less food than animals dosed with vehicle (Fig. 18).

In a 26-day study, DIO rats in the control group showed a progressive weight gain during the study. The 5 mg kg^{-1} NGD-4715 treatment group showed less weight gain over the same period, and the 15 mg kg^{-1} group lost body weight compared to the pre-dosing weight. The 15 mg kg^{-1} dose group lost similar body weight compared to a pair-feeding group. A pair-feeding group is one in which food availability is matched to the food intake of a specific drug treatment group. The data obtained from the pair-feeding group allows one to conclude whether the weight loss effect can be attributed to a reduction in food intake alone, or is combined with other effects on metabolic parameters. The pair-feeding data suggest that the weight reduction following NGD 4715 treatment is due to food intake suppression with no apparent contribution from a metabolic effect. Daily food intake also was dose-dependently reduced by NGD-4715. In data not shown, NGD-4715 also lowered blood glucose levels and improved glucose tolerance. Drug treatment also reduced the hyperinsulinemia and hyperleptinemia associated with the ingestion of this high-fat diet. Hyperphagia was not seen in drug-treated groups following discontinuation of drug treatment, and body weight gain in the drug treatment groups paralleled that of the vehicle group during the recovery phase (Fig. 19). It is important to note there

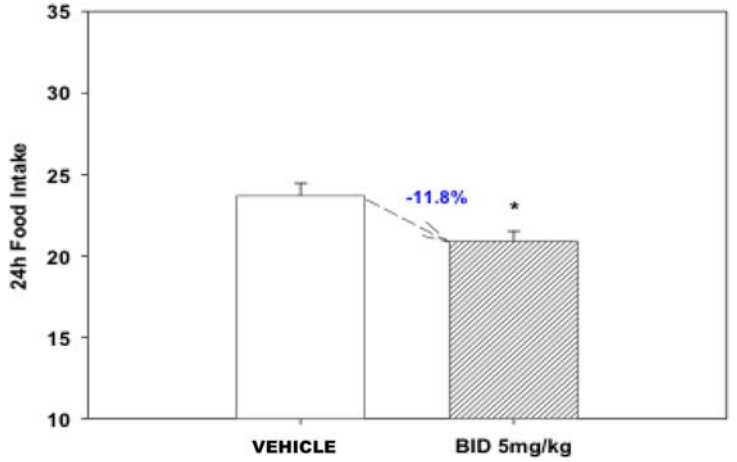

Fig. 18 Effect of NGD-4715 (**7**) on 24-h food consumption of obesity-prone male Wistar rats dosed orally at 5 mg kg^{-1} BID versus rats dosed vehicle (0.5% methyl cellulose/0.1% triacetin) only.

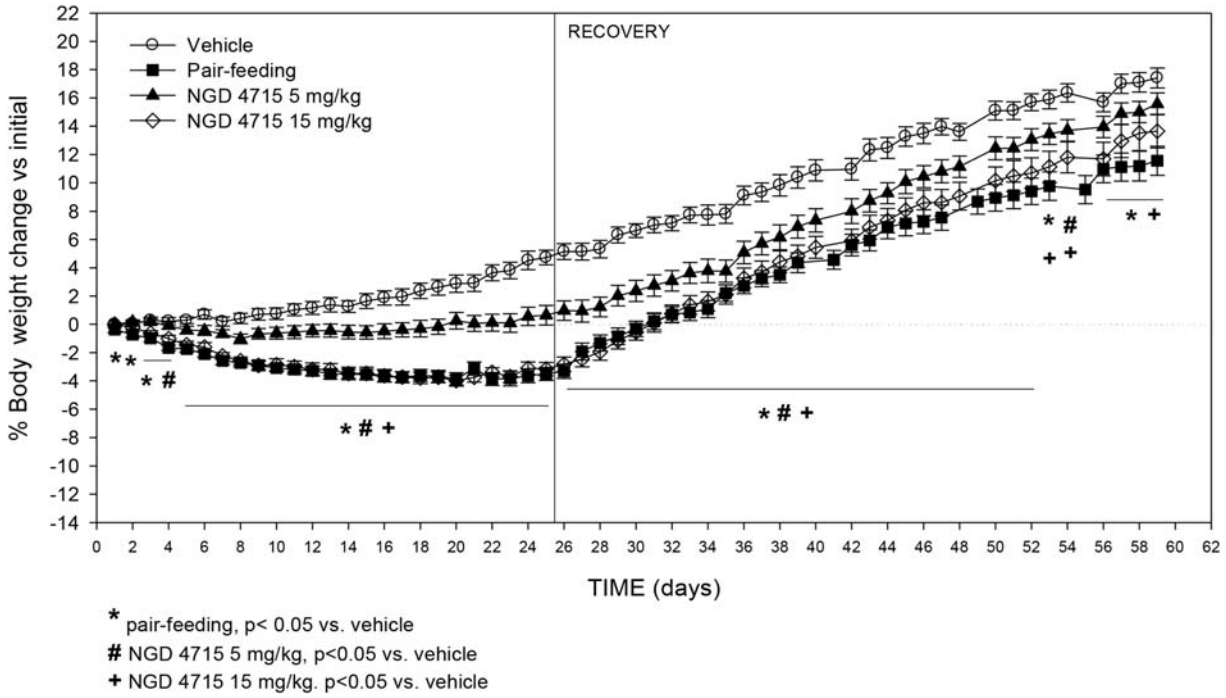

Fig. 19 Effects of orally administered NGD-4715 besylate on body weight gain in a 26-day diet-induced obesity study in rats. Values represent the mean percent body weight change and SEM for each day. All weights were taken before dosing in the afternoon and at the same time during recovery phase. The *n* for each group was 8–9. Rats received vehicle or NGD 4715 besylate 1 h prior to the lights off in the afternoon and 2.5 h after the lights on in the morning. All treatment groups were provided ad libitum access to food without any treatment during the recovery phase. Symbols placed below individual data points denote significant differences from the vehicle group ($p < 0.05$ Fisher's least significant difference test). Vehicle used was methylcellulose (0.5%)/triacetin (0.1%).

was no apparent malaise detected in the kaolin assay, no hypo- or hyperactivity in the locomotion assay, and no apparent anxiogenic effect in elevated plus maze experiment.

8.19.7 Process Development and cGMP Delivery

While useful for the synthesis of compounds to elucidate the SAR of MCH-1 receptor antagonists, the medicinal chemistry route suffered from a number of deficiencies:

1. linear as opposed to convergent;
2. lack of crystalline intermediates, resulting in multiple chromatographic purifications;
3. included a number of "problematic" reagents ($LiAlH_4$, BBr_3, $NaCNBH_3$, $TsNHNH_2$, DCC, TPAP); and
4. too many steps.

One obvious way to make the route more convergent would be to start with a more elaborated 2,3-dimethylanisole. To this end, commercially available and inexpensive 2,3-dimethylphenol (**60**) was alkylated in 83% yield using ethylene carbonate and potassium carbonate in hot DMF to give **61**. Friedel–Crafts acylation of **61**, using two equivalents of acetyl chloride, gave the acetophenone **62** in 97% isolated yield. The *para* isomer was the only product obtained.[30] The terminal acetate group was removed with a catalytic amount of sodium methoxide in methanol in 85% yield after distillation, and the resulting alcohol was protected as the tetrahydropyranyl ether[31] in 87% yield after crystallization to provide **63** (Fig. 20).

An important breakthrough came from the discovery, by Lubell's lab, that enantiopure pipecolate esters could be prepared via catalytic hydrogenation of a suitably protected amino enone (Fig. 21).[32]

Since NGD-4715 could be envisioned as a bicyclic pipecolate derivative, we wondered whether a similar strategy could be used in its preparation (Fig. 22).

Having a suitable route to the acetophenone component (**63**), we turned our attention to preparing an appropriately protected piperazine acetaldehyde, **66**. Our first attempt is outlined in Fig. 22. The reduction of compound **32** was effected with sodium bis(2-methoxyethoxy)aluminum hydride (Red-Al) instead of lithium aluminum hydride. Red-Al is safer (i.e., less pyrophoric), less expensive, and also allows for a simpler work-up when compared to lithium aluminum hydride. The crude product, **33**, then was isolated as the acetate salt, which could be purified from benzyl alcohol and other by-products by simple slurrying with methyl ethyl ketone.

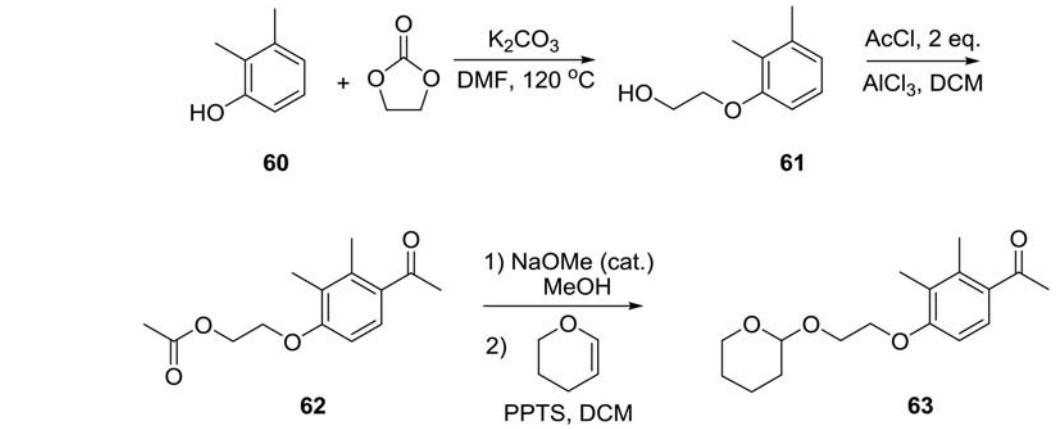

Fig. 20 Preparation of 1-{2,3-dimethyl-4-[2-(oxan-2-yloxy)ethoxy]-phenyl}ethan-1-one (**63**).

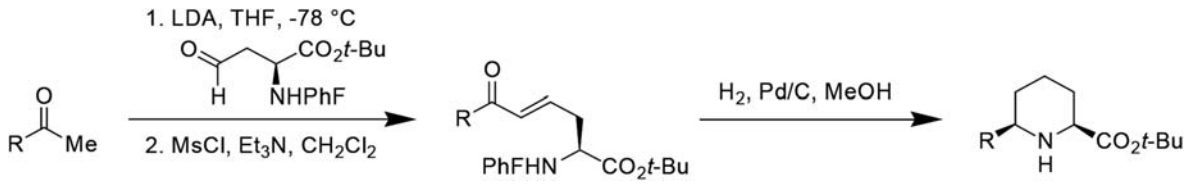

Fig. 21 Lubell's route to enantiopure pipecolic esters (PhF = 9-phenyl fluorene).

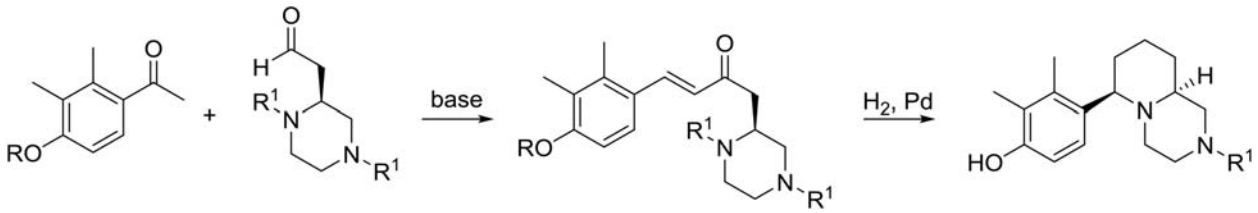

Fig. 22 Catalytic hydrogenation strategy for the synthesis of a key octahydro-1*H*-pyrido[1,2-*a*]piperazine intermediate.

The free base of purified **33** then could be isolated as a solid upon treatment with aqueous sodium hydroxide solution. Removal of the benzyl group by catalytic hydrogenation gave 2-*S*-hydroxethyl piperazine (**2-HEP**, **64**). The carboxybenzyl group (Cbz) was chosen as a protecting group, because it is robust enough to survive various aldol conditions, and because it can be removed by catalytic hydrogenation to facilitate the proposed cyclization.[33] It was installed using classical techniques, and the benzyl alcohol by-product was removed by azeotropic distillation with water (boiling point: 100°C)[34] giving **65**. Finally, oxidation under modified Anelli–Montanari conditions[35], using trichloroisocyanuric acid as the stoichiometric oxidant and a catalytic amount of 1-oxyl-2,2,6,6-tetramethylpiperidine, gave the desired aldehyde (**66**) in 91% yield as a syrup, which was used without further purification (Fig. 23).

With both parts of the target molecule in hand, we now were ready to attempt our new cyclization strategy. Aldol condensation of acetophenone **63** and aldehyde **66** was accomplished using lithium diisopropyl amide in THF at −78°C to give the β-hydroxyketone **67** after quenching the reaction with acetic acid at −78°C (Fig. 24).

Keeping the reaction temperature below −50°C was critical because higher temperatures resulted in the loss of a Cbz group to give the mono-protected enone **68**. At first glance, this would seem to be inconsequential or perhaps advantageous, but attempts to perform the cyclization on compound **68** resulted in a partially racemized product. This was related to a similar result previously observed when an attempt to cyclize the aldol product derived from a bis-benyzl protected aldehyde. We suspect the basicity of the unprotected or benzyl protected nitrogen promoted a retro-Michael reaction that resulted in racemization of the stereocenter. The postulated mechanisms for the Cbz loss and retro-Michael reaction are presented in Fig. 25.

Returning to the reaction sequence, we were delighted to find that the proposed reductive cyclization could be performed directly on β-hydroxyketone **67**. Under the conditions highlighted in Fig. 22, a one-pot sequential hydrogenolysis of both Cbz groups, dehydration, saturation, and reductive amination using hydrogen gas at 50 psi, and Pearlman's catalyst in methanol, with three equivalents of acetic acid in a Parr shaker, resulted in the diastereoselective formation of **68** as a syrup in 90% yield. The crude

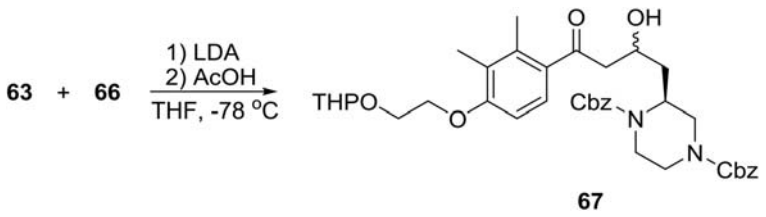

Fig. 24 Aldol reaction yielding 1,4-dibenzyl (2*S*)-2-(4-{2,3-dimethyl-4-[2-(oxan-2-yloxy)ethoxy]phenyl}-2-hydroxy-4-oxobutyl)piperazine-1,4-dicarboxylate **67**.

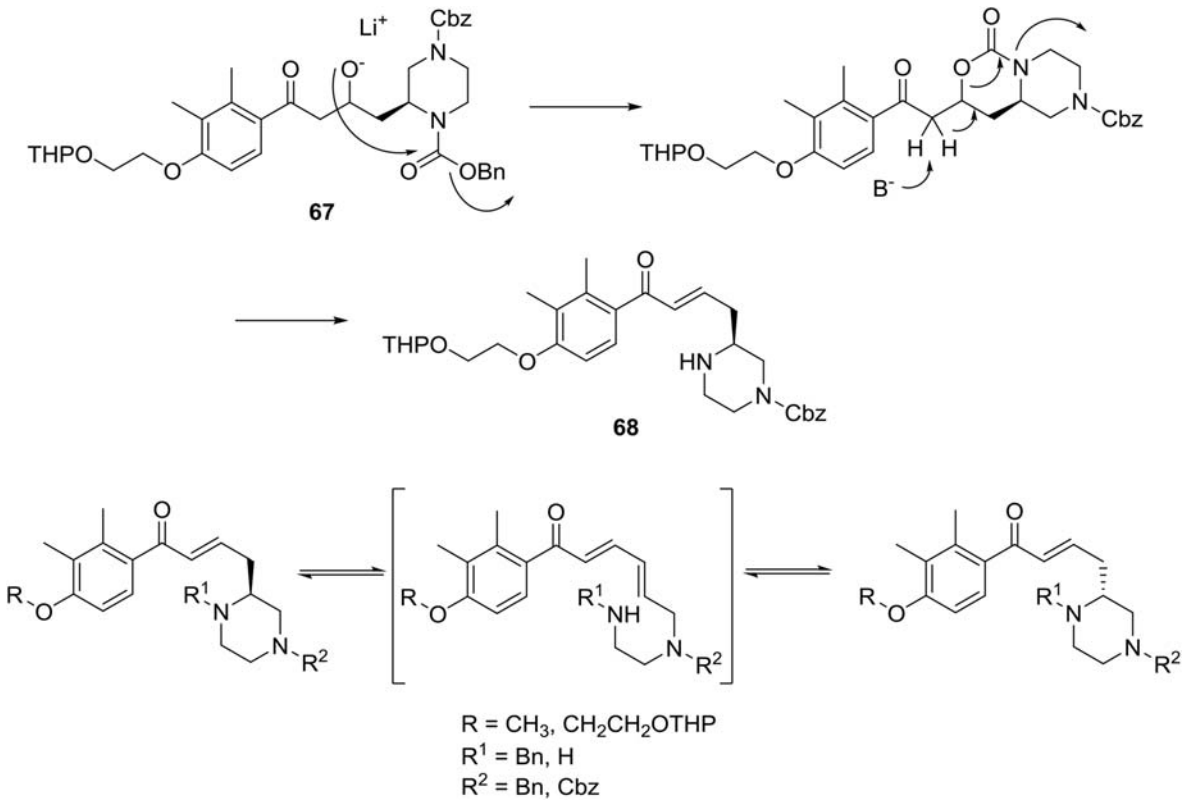

Fig. 25 Proposed mechanisms for Cbz loss above −50°C and retro-Michael reaction.

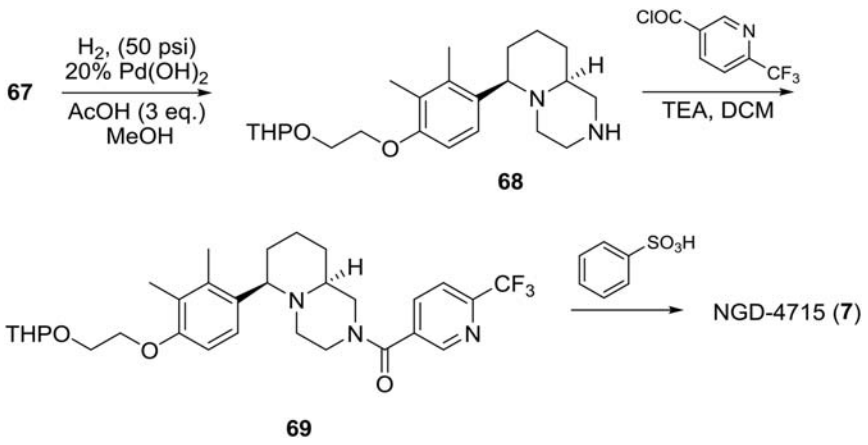

Fig. 26 Reductive cyclization, acylation, and deprotection to form NGD-4715 besylate (**7**).

material could be acylated as before, to give penultimate intermediate **69**, but the presence of diastereoisomers from the THP group made crystallization impossible, and a chromatography was required for purification. Treatment of **69** with benzene sulfonic acid removed the THP group and allowed isolation and crystallization of the desired product as the besylate salt (**7**, Fig. 26).[36]

Clearly, the requirement for a chromatography to purify the penultimate intermediate **69** was disappointing and unsatisfactory. While optimizing the reductive cyclization, we discovered a work-up that allowed us to remove the THP group and isolate the deprotected material (**70**) as a foam in 80% purity. This material then could be converted to the L-tartrate salt and crystallized to a white solid in >95% purity. The L-tartrate salt (**71**) could be used directly in the acylation step, this time using classical Schotten–Bauman conditions, to give **7**. The *iso*-propyl acetate extract then could be used directly to form the besylate salt (Fig. 27).

To summarize, this new route allowed us to prepare in-house 267 g of drug in support of a preclinical toxicology study and was transferred to a contract manufacturer to prepare 6.2 kg of cGMP quality material. NGD-4715 was obtained in 6.6% overall yield in 98.5% chemical purity and >99:1 er. The new route consisted of nine linear steps (13 total) and required no chromatography.

While this route was a significant improvement over the medicinal chemistry route, it still suffered from some deficiencies. The aldol reaction never resulted in the complete consumption of all the acetophenone **63**, and the use of cryogenic reaction conditions was less than ideal. The need for the alcohol to be protected throughout the reaction sequence also was less than desirable. We wondered if a Horner–Wadsworth–Emmons olefination might be employed to give us the reductive cyclization precursor without the requirement of a protecting group.

We were pleased to discover a facile method to prepare a phosphonate from the previously prepared 2,3-dimethyl-hydroxyethoxybenzene (**61**) by treating it with 2-(dimethoxy-phosphoryl)acetic acid in the presence of TFAA and concentrated phosphoric acid to provide ketophosphonate **72** in 66% yield for two steps with >99:1 *para*:*ortho* selectivity (Fig. 28).[37,38] Compound **72** obviated the need for a protecting group, was a crystalline solid, and was soluble in water.

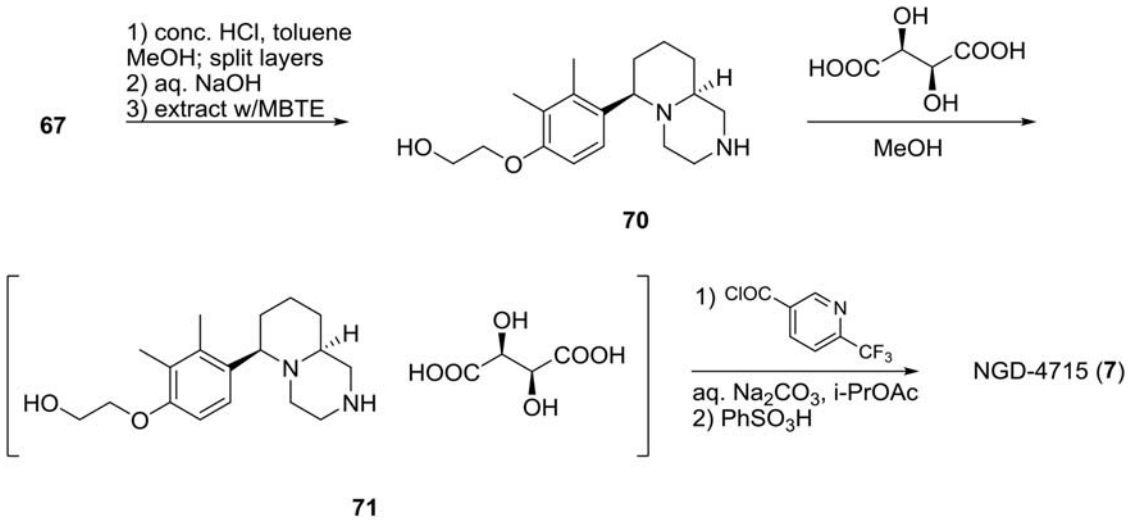

Fig. 27 Formation of crystalline penultimate tartrate **71** and preparation of NGD-4715 (**7**).

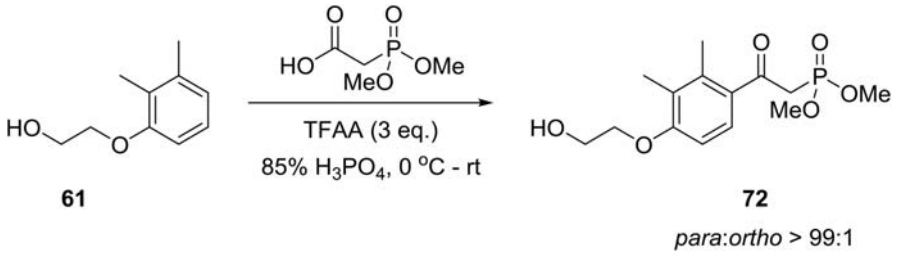

Fig. 28 Preparation of dimethyl {2-[4-(2-hydroxyethoxy)-2,3-dimethylphenyl]-2-oxoethyl}phosphonate (**72**).

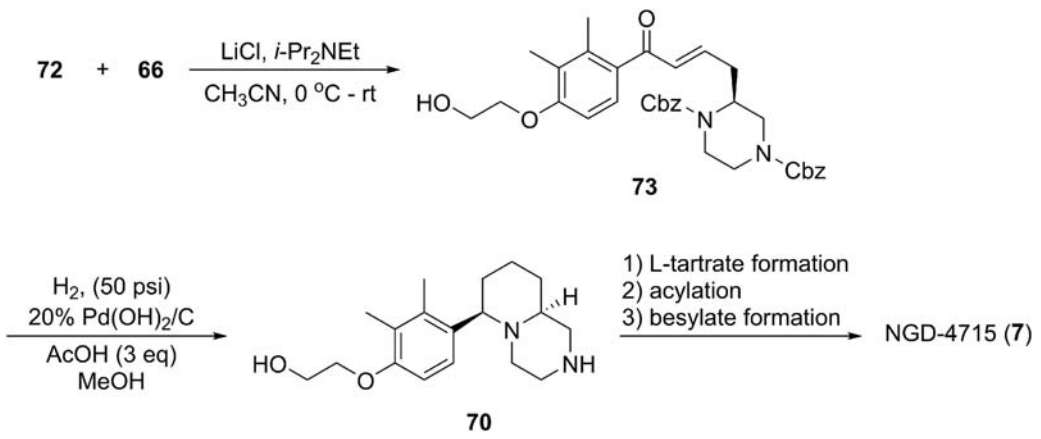

Fig. 29 Ketophosphonate route to NGD-4715 (**7**).

Reaction of ketophosphonate **72** with aldehyde **66** in the presence of lithium chloride and Hunig's base in acetonitrile provided the desired enone (**73**, Fig. 29), which could be reductively cyclized under our standard conditions to give octahydro-1*H*-pyrido [1,2-*a*]piperazine **67** in 80% yield for two steps. Purification of **67** by conversion to the L-tartrate salt proceeded as previously discussed, and this intermediate then was acylated and purified as the besylate salt to give NGD-4715 (**7**, Fig. 29).

Thus, the ketophosphonate route provided NGD-4715 after nine linear steps (11 total) with no chromatographic purifications in 17.9% overall yield. This route was used to prepare a second cGMP batch.

All batches of NGD-4715 besylate that were prepared for nonclinical and clinical use exhibited a single crystalline form, designated as "Form 1." Polymorph screening of NGD-4715 besylate was conducted in 50 solvent systems, including slurries, slow cooling, fast cooling, fast evaporation, sudden cooling, and vapor diffusion. Grinding caused the besylate to revert to an amorphous state. An X-ray crystallographic study on the crystalline besylate salt of NGD-4715 served as the ultimate structural confirmation (Fig. 30).

One last adjustment was required. LC/MS/MS analysis of a batch of NGD-4715 besylate revealed two unexpected impurities (**74** and **75**), shown in Fig. 31. Sulfate impurity **74** probably forms from reaction with sulfuric acid either contaminating the benzene sulfonic acid, or that which arises from sulfuric acid generated during the process of salt formation. Impurity **74** arises from the elimination of the sulfate to give the vinyl ether (Fig. 30). Regardless of the chemistry leading to the formation of these impurities, we thought it necessary to change the NGD-4715 salt to eliminate these impurities from the final drug product.

All batches of NGD 4715 fumarate that were prepared for nonclinical and clinical use exhibited a single crystalline form, designated as "Form 1." Polymorph screening of NGD-4715 fumarate was conducted in 55 solvent systems, including slurries, slow cooling, fast cooling, fast evaporation, sudden cooling, and vapor diffusion. The fumarate was soluble in methanol (42 mg mL^{-1}), sparingly soluble in absolute ethanol (17 mg mL^{-1}), and slightly soluble in *iso*-propanol and acetonitrile (10 mg mL^{-1} and 3 mg mL^{-1}, respectively).

The fumarate salt was formed by reaction of NGD-4715 free base with fumaric acid in *iso*-propyl alcohol followed by recrystallization from acetone and water, as shown in Fig. 32.

In conclusion, to support late-stage development and to supply drug for clinical trials, we were able to substantially improve the medicinal chemistry route to NGD-4715 by reducing the number of steps from 17 linear steps, requiring nine column chromatography purifications with an overall yield of ~9%, to a process requiring nine linear steps (11 total) with no chromatography and a 17.9% overall yield. We were able to eliminate all of the problematic reagents, develop a novel reductive cyclization protocol, and, through the development of a Horner–Wadsworth–Emmons reaction, we were able to eliminate the use of cryogens from the process. We were, thus, successful at conceiving and executing a process for preparing NGD-4715 on a multikilogram scale.

8.19.8 Seeking a Superior Backup Compound

Following the nomination of NGD-4715, the project team identified a number of properties to improve upon in a back-up compound. The properties included improved potency and elimination of CYP3A4 induction, while maintaining the other excellent properties of NGD-4715.

Previously, we demonstrated that the 6-(trifluoromethyl)pyridine-3-carboxyl amide group was a key element to controlling the hERG inhibition that plagued earlier series and competitors' compounds. Replacement of the pyridine in NGD-4715 gave the pyrimidine **76**, which was more potent and had very low hERG inhibition. Unfortunately, **76** demonstrated a similar level of CYP3A4 induction risk as NGD-4715, as measured in the pregnane X receptor (PXR) assay, and was not advanced (Fig. 33). The pyrimidine fragment of **76** was retained in the next series of analogs, as new substituents were introduced to the hydroxyethyl side-chain. This modification was of interest to block oxidation of the primary alcohol, which potentially could form a reactive aldehyde, and as a strategy to lower the clearance and increase half-life observed with NGD-4715. Small alkyl groups (e.g., Me, Et, etc.)

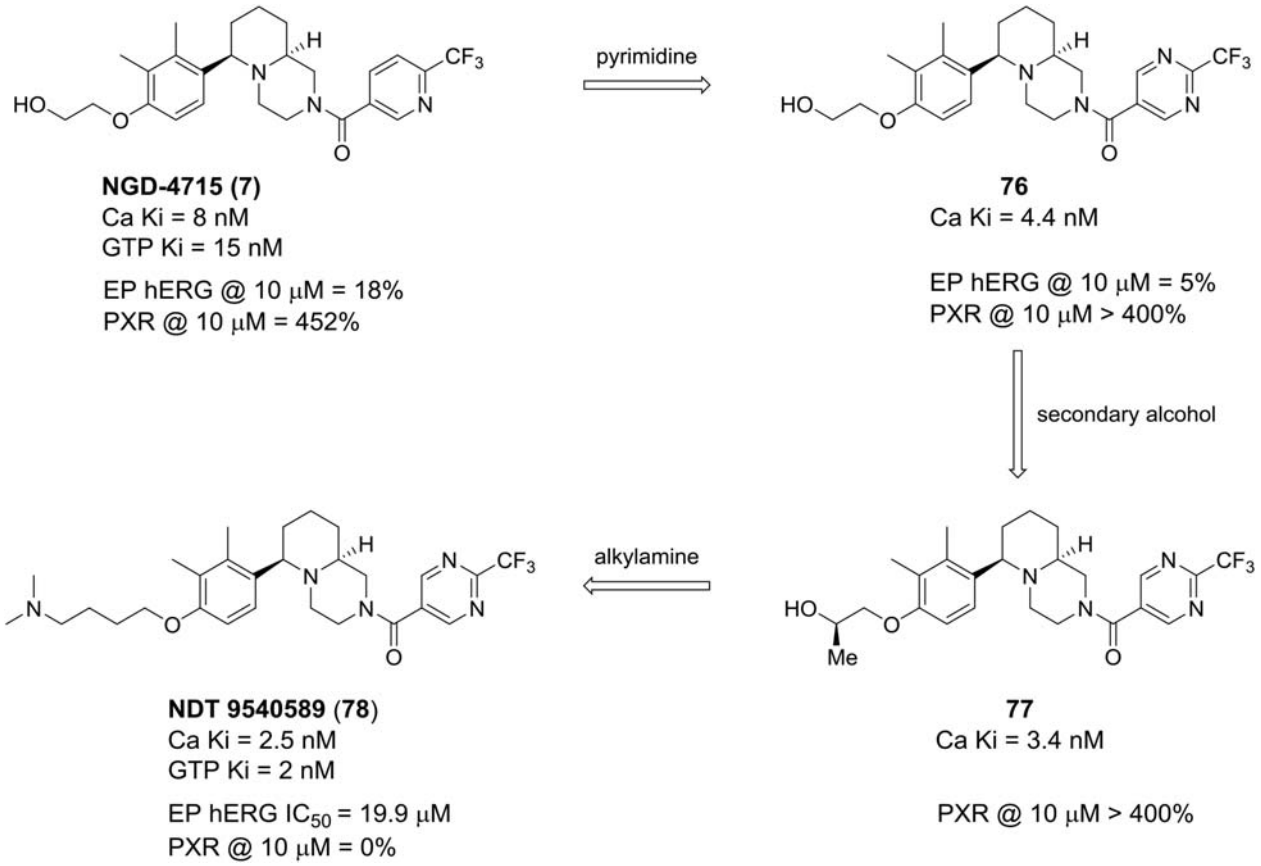

Fig. 33 Discovery of NDT 9540589 (**78**).

were tolerated on the side-chain; for example, the homo-chiral secondary alcohol **77** was of similar activity as **76**, although PXR induction was still high. The strategy that ultimately proved successful in the mitigation of CYP3A4 induction was the incorporation of a basic amine tail. The hydroxyethyl side-chain was replaced by a series of amine and amide groups. It was discovered that a basic amine tail, for example, NDT 9540589 (**78**), gave a modest boost in in vitro potency, but, most significantly, there was no induction in the PXR assay @ 10 μM, and hERG liability was moderate (EP hERG $IC_{50} = 19.9$ μM). NDT 9540589 was advanced as a strong potential back-up to NGD-4715, and it was profiled extensively both in vitro and in vivo.

Physical characteristics: NDT 9540589 (**78**) has many physical chemical characteristics that are consistent with good CNS drugs. The parent molecule has a log $D_{7.4}$ of 2.64 and good solubility (pH 7.4 > 3.0 mg mL^{-1}; pH 5.4 > 500 mg mL^{-1}). This solubility is facilitated by two basic centers with pK_a values of 9.6 and 6.3. The compound has moderate protein binding (82–85%) across species at a concentration of 3 μM. And the molecule conforms to the Rule of Five, except for a molecular weight above 500 (533).

Pharmacology: NDT 9540589 is a potent MCHR1 neutral antagonist in vitro with $IC_{50} = 4$–6 nM in calcium mobilization FLIPR-, GTPγS-, and MCHR1-binding (rat striatum) assays.[39] In an ex vivo receptor occupancy time-course assay, NDT 9540589 (10 mpk) achieved 75% of maximal receptor occupancy over a 6-h test period. An ex vivo ED_{50} was determined to be 0.7 mg kg^{-1} in a dose–response study run with a 3-h compound pretreatment. Single oral doses of compound, ranging from 2.5 to 10 mg kg^{-1}, effectively blocked the orexigenic effect of ICV-administered MCH in the rat, supporting MCH receptor antagonism as the mechanism of action. Additionally, a dose range of 1–10 mg kg^{-1} PO resulted in reduction in overnight food intake from 6% to 18% in DIO rats. Subchronic animal studies in DIO rats (10 days) demonstrated a dose-dependent reduction of food intake and body weight gain versus controls. A persistent, dose-dependent reduction of cumulative food consumption, ranging from 3.6% at 0.75 mg kg^{-1} QD to 21.1% at 10 mg kg^{-1} QD, resulted in a reduction of body weight gain ranging from 1.2% to 5.5%, respectively.

Chronic animal studies in DIO rats (26 days) demonstrated a dose-dependent reduction of food intake and body weight gain versus controls. At 5 mg kg^{-1}, there was a 22.5% reduction in cumulative food intake and a reduction in body weight gain of 9.5% (Fig. 34). Treatment also resulted in decreased blood glucose, basal plasma insulin, and leptin levels, and improvement in glucose tolerance. The reduction in food intake is believed to be mechanism-related, and not due to compound-related general malaise or sedation, since doses up to 20 mg kg^{-1} (20 times the MED) did not increase kaolin consumption or cause changes in locomotor activity.

ADME: NDT 9540589 was well absorbed across species, consistent with its excellent solubility and permeability properties. In addition, high dose PK and 10-day toxicology studies in rats suggest achieving high multiples of therapeutically efficacious plasma

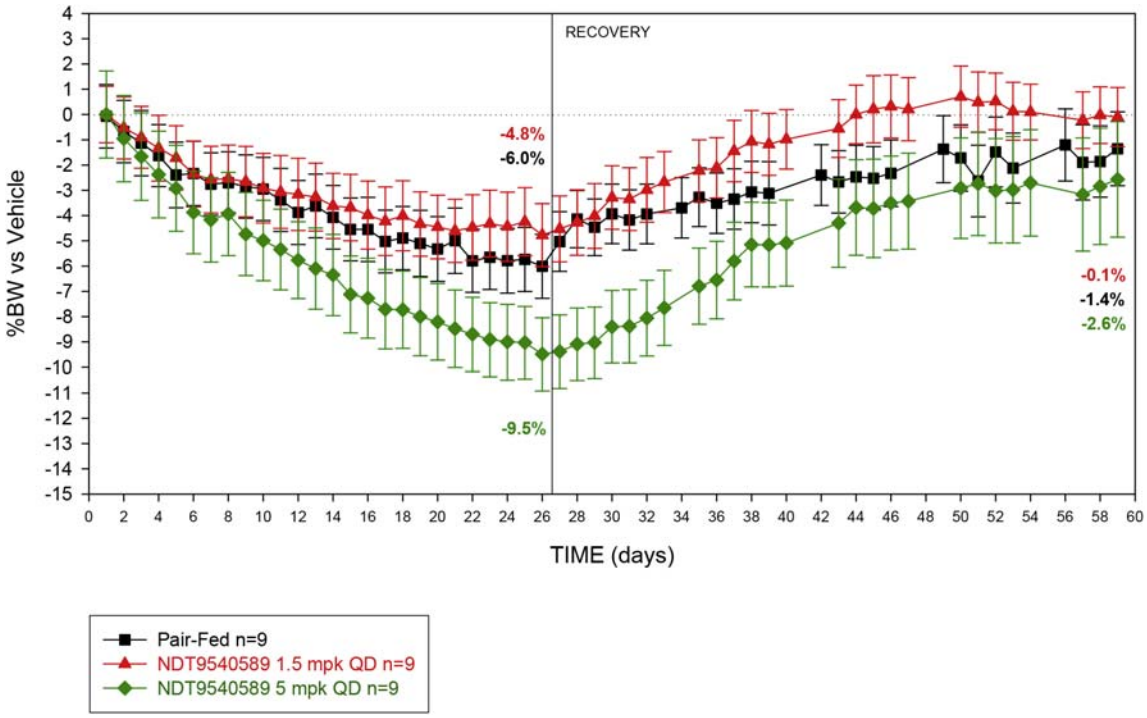

Fig. 34 Obesity-prone rat 26-day DIO study with NDT 9540589 (**78**) with recovery: percent weight loss versus vehicle. Pair-fed group was matched to the 5 mg kg^{-1} day^{-1} dose group.

[a]Consistent with enterohepatic recirculation.

concentrations. Plasma protein binding appears to be moderate across species, and the compound achieved good brain penetration (B/P 1.6) in rats. NDT 9540589 appeared to have a lower potential to cause induction of CYP450 enzymes compared to NGD-4715. This was evidenced by little to no interaction with PXR, a nuclear receptor responsible for CYP induction, and CYP450 induction in a human hepatocyte assay. These results, along with weak or no CYP inhibition by the compound, suggest a low propensity for drug–drug interactions. NDT 9540589 had moderate to long half-lives, likely driven by its high volumes of distribution across species (Table 4). The predicted human half-life of NDT 9540589, based on allometric scaling, is in excess of 90 h.

NDT 9540589 has properties that favorably differentiate it from NGD-4715 in three distinct areas:

1. the compound has greater in vitro and in vivo potency in decreasing food intake and promoting weight loss compared to NGD-4715;
2. there appears to be a weight loss effect that is greater than that due to decreased food intake alone; and
3. NDT 9540589 appears to have a lower risk of causing CYP450 induction at concentrations substantially higher than the projected efficacy range.

On the basis of these improvements, it was advanced into additional preclinical safety studies.

Safety: NDT 9540589 was assessed in a hERG channel EP assay, where it had an $IC_{50} = 19.9$ μM. This is >1000-fold the IC_{50} in MCHR1 functional assays and >800 times its free efficacious plasma concentration. No changes were observed in QTc interval in a dog CV study at doses as high as 15 mg kg^{-1} IV. A transient decrease in heart rate was observed at 5 and 15 mg kg^{-1}.

In a broad panel of receptors, enzymes, hormones, and ion channels (Neuroscreen and CEREP) no significant interactions (e.g., >50% inhibition of ligand binding) were observed at 10 μM.

A key finding from the exploratory 10-day rat toxicity study was vacuoles and/or foamy macrophages in the liver, lung, and thymus at doses as low as 50 mg kg^{-1} (8–9 times plasma levels), and in the spleen at 150 mg kg^{-1} (16–18 times plasma levels). Electron microscopy study of the spleen revealed the presence of macrophages with lamellar bodies consistent with a finding of phospholipidosis (PL) (**Fig. 35**).

Phospholipidosis: has been associated with "chronic" administration of some small molecule pharmaceuticals, known as cationic amphiphilic drugs (CADs).[40] PL is described as an excessive intracellular accumulation of phospholipids in lysosomes. The accumulation is characterized by formation of lamellar membranous intralysosomal inclusion bodies (LLB) giving a "foamy appearance" in the affected tissues. PL is the result of systemic drug exposure, and can be manifest in many different cell types/tissues (e.g., hepatocytes, kidney, lung, lymphoid cells, and muscle). Some of the postulated mechanisms for induction of PL are the result of inhibition of phospholipid metabolism, inhibition of lysosomal enzyme transport, and/or increased phospholipid or cholesterol biosynthesis. Unfortunately, the pattern of cell type or tissues affected by phospholipigenic agents is not entirely predictable on the basis of structural activity relationships, and may vary according to the species, strain, and age of drug recipient. The toxicological significance of PL is not easy to interpret, as it may (or may not) interfere with cellular function in the affected tissues. It is not known whether drugs that produce PL preclinically also produce PL in humans.[41] Thus, the diagnosis of PL during compounds development raises concerns because of the difficulty in interpreting the outcome of this histopathologic finding.

On the basis of the findings with NDT 9540589, we decided our strategy moving forward would include compound design to *minimize structural elements similar to those in known PL drugs*.

CADs known to cause PL have a combination of both lipophilic and basic functional groups. Prediction of the capacity of drugs to induce PL can be performed by calculation or measurement of their cationic amphiphilic properties. Sophisticated analysis and calculation of the physicochemical interaction of amphiphilic drugs with phospholipids have been reported. Nevertheless, the easily calculated physicochemical parameters pK_a and $c\log P$ proved to be especially helpful in predicating whether a compound may have the potential to induce PL, according to Eq. (1).[42] The "rule of thumb" is that a cationic amphiphilic compound can be suspected to induce PL.

$$\text{PL risk if} (c\log P)^2 + (cpK_a)^2 > 90 \tag{1}$$

For NDT 9540589 ($c\log P = 4.0$ and $cpK_a = 9.6$) the PL risk value >108 indicates a high risk. While compounds that fall into the danger category do not necessarily cause PL, from our experience, there appears to be good correlation between this analysis, the in vitro Nile Red assay using U937 cells, and in vivo observations.

Even though the induction issue could be controlled by a basic amine tail (e.g., NDT 9540589), the basic amine also led to a large volume of distribution, long half-life, and potential for PL. We chose to eliminate any alkylamine ($pK_a > 8$) tails from molecules, and began to consider other SAR on the A-ring (**Fig. 36**). Removal of the hydroxyethyl side-chain itself gave some reduction in PXR activity (e.g., **79**), PXR = 204% @ 10 μM). On analysis of the SAR of the A-ring, it was apparent that 2,3-dimethyl-4-alkoxy substituted A-rings were predominant; indeed, >99% of all analogs in the bicyclic series contained these substituents.

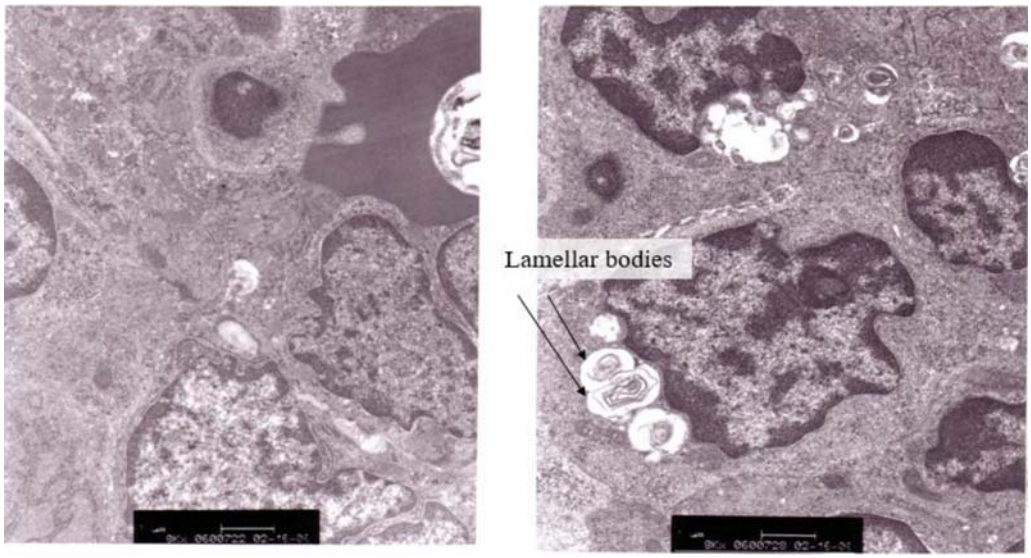

Fig. 35 Rat spleen electron microscopy studies on NDT 9540589 (**78**) confirming a phospholipidosis diagnosis. Left is control (22,400×); right is the spleen from rat following 150 mg kg^{-1} day^{-1} treatment for 10 days.

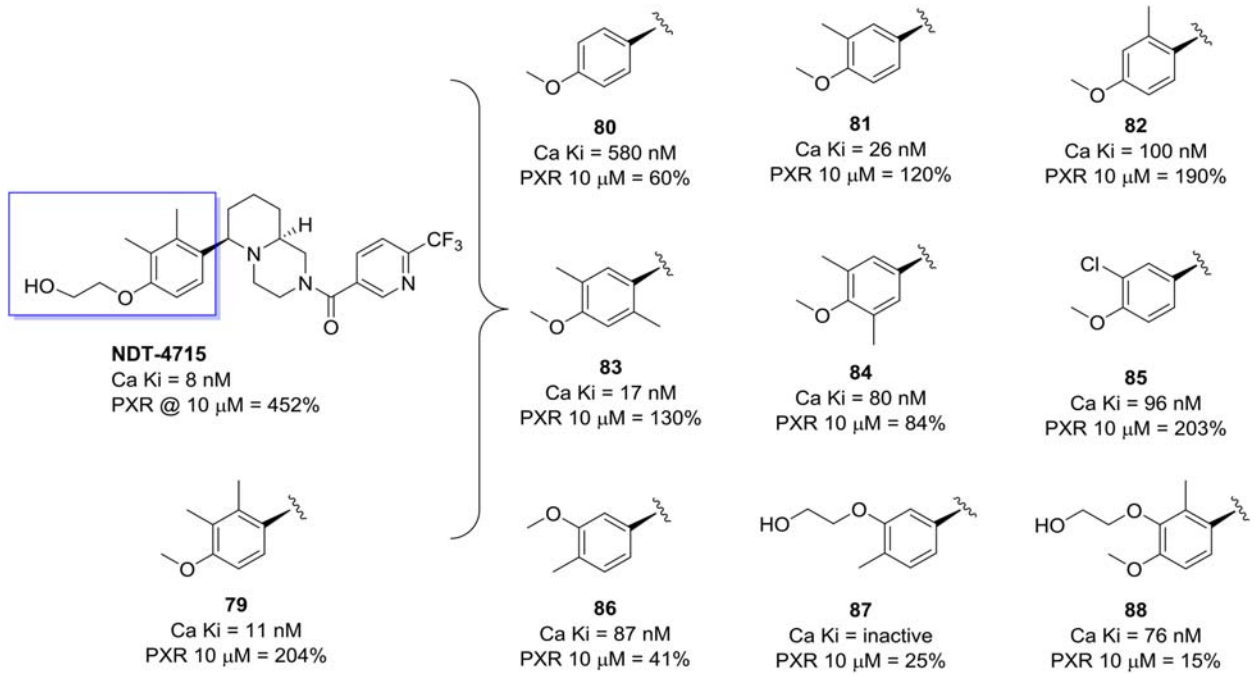

Fig. 36 MCH and PXR activity of non 2,3-dimethyl-4-alkoxy A-rings.

We then reevaluated the nine analogs without the 2,3-dimethyl-4-alkoxy A-ring. We discovered that, although MCHR1 potency generally was reduced, there were compounds with significantly lower induction potential. Deletion of both the 2- and 3-methyl groups gave a significant drop in both MCHR1 and PXR activity (e.g., **80**). Reintroduction of the 3-methyl group (e.g., **81**) restored MCHR1 potency, and there was significant lower PXR activity compared to **83**. The 2-methyl analog (e.g., **79**), however, was less active and had a similar PXR activity as **83**. The three analogs with an alkoxy substituent at the 3-position **84–86** each exhibited significantly lower PXR activity, although MCHR1 inhibition also was reduced. In general, A-rings lacking an *ortho*-substituent had lower levels of PXR induction, as did analogs incorporating a 3-alkoxy substituent.

We considered **81** and **86** to have a promising balance between MCHR1 activity and PXR induction, and that they should be viewed as starting points for the design of new analogs. We chose to incorporate the 3,4-substituents into a heterocyclic ring, and a number of indole, benzimidazole, and indazole isomers were investigated (Fig. 37).

For example, the *N*-methyl indazole (**89**) had very encouraging MCHR1 inhibition (e.g., MCHR1 Ca $K_i = 15$ nM); but of greatest significance was the ablation of PXR induction (PXR = 2% @ 10 μM) along with maintenance of low hERG inhibition (electrophysiology hERG = 6% inhibition @ 10 μM). To increase the MCHR1 inhibition, we introduced a methyl group at each of the three vacant ring positions—aware that this may bring back PXR induction. Indeed, the two *ortho*-methyl analogs (4-methyl indazole (**90**) and 6-methyl indazole (**91**)) both displayed unacceptable levels of PXR induction. However, the 7-methyl indazole (**92**) had excellent MCHR1 inhibition, and there was no induction in the PXR assay @ 10 μM. Next, **92** was evaluated further for CYP3A4 induction potential in cryopreserved cultured human hepatocytes and, gratifyingly, gave only a 0.2-fold induction over control @10 μM. Compound **92** was assessed, in a hERG channel electrophysiology assay, where it had minimal activity at 10 μM. Preliminary oral PK in rat were very encouraging (Fig. 38), and a single 10 mg kg^{-1} PO dose resulted in reduction in overnight food intake of 17% in DIO rats.

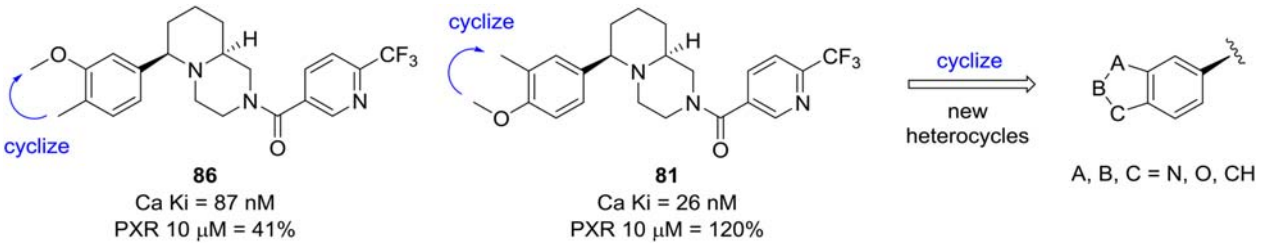

Fig. 37 Design of hetero-bicyclic A-rings.

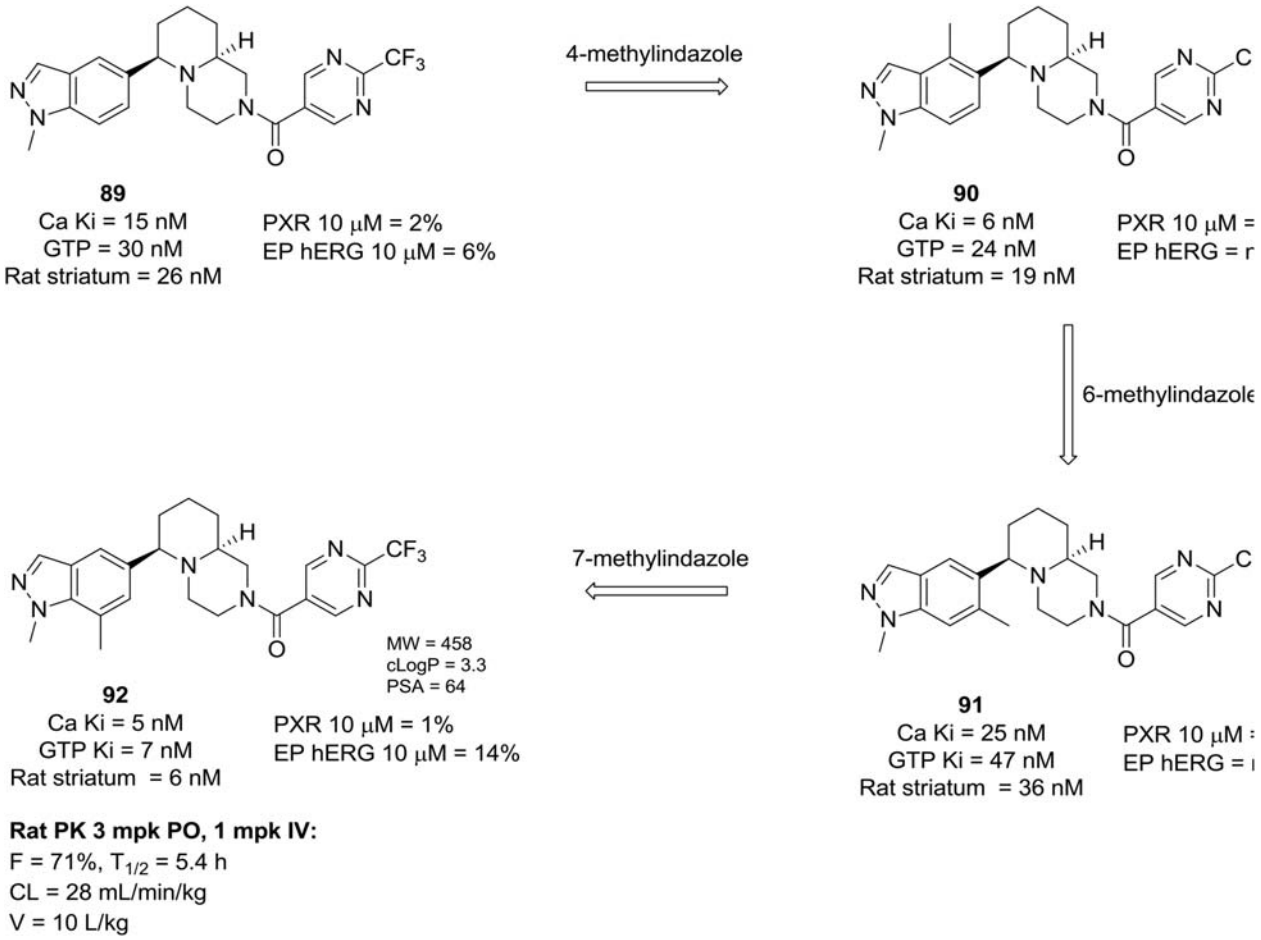

Fig. 38 Indazole A-rings and the effect of the methyl group on PXR induction.

In summary, a back-up program ran in parallel with the advanced preclinical development of NGD-4715 identified NDT 6287241 (**92**) as a development candidate with reduced risk of hepatic CYP450 induction. Compound **92** was efficient in preclinical models of obesity.

8.19.9 NDT-4715 Clinical Studies

NGD-4715, a potent and selective MCHR1 antagonist, was Neurogen's lead drug candidate for the treatment of obesity. While exploration of safety and exposure are the primary goals of phase I clinical studies, we hoped to demonstrate some evidence that blockade of MCHR1 would provide some benefit in the obese population. To achieve these ambitious goals, our approach was to first demonstrate the safety of single ascending doses (SAD) of NGD-4715. We then would progress to multiple ascending doses (MAD) in healthy obese volunteers. In addition, since NGD-4715 was thought to be a moderate inducer of CYP3A4, we included a drug–drug interaction assessment into the MAD portion of the phase I program. Thus, the goals of our phase I clinical study were:

- to evaluate the safety, tolerability, and PK of SAD of NGD-4715 administered to normal healthy volunteers (double blind, placebo controlled);
- to evaluate safety and markers of clinical pharmacology of multiple, escalating oral doses of NGD-4715 in healthy obese (BMI of 30–40 kg m^{-2}) subjects in a 2-week phase I study (double blind, placebo controlled); and
- to characterize the potential for NGD-4715 to induce CYP3A4 activity (midazolam as probe substrate).

During the SAD portion of our clinical program, we evaluated single doses of NGD-4715 from 10 to 900 mg. The compound, generally, was well-tolerated. Exposures (both as C_{max} and AUC) increased with dose, as shown in Fig. 39 and Table 5. With this encouraging data, we progressed into the MAD portion of phase I.

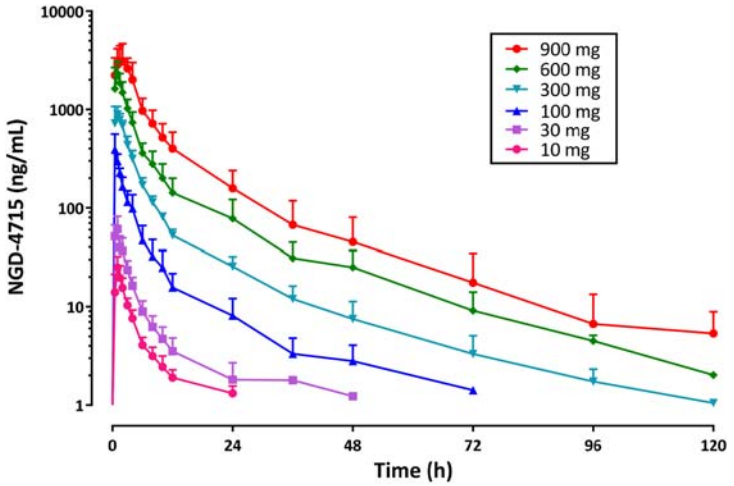

Fig. 39 Exposure-time profile of NGD-4715 in healthy human subjects.

[a]Median and range provided for T_{max}.

The MAD study was a randomized, double blind, placebo controlled investigation of NGD-4715 conducted in four cohorts ($n = 12$ per cohort, 8 drug, 4 placebo) dosed BID on a q8h schedule for 14 days. The sequential dose groups were 30, 100, 200, and 400 mg (total dose per day). Subjects were in the phase I unit for 3 weeks. Unlimited access to food was allowed during the study. Standardized body weights were collected daily prior to morning dosing. Subjects received 5 mg oral midazolam on days 1 and 16. On days 2–15 subjects received their assigned treatment q8h. The projected minimum efficacious plasma concentration was 146 ng mL^{-1}, as determined in the rat model DIO dose–response study.

Steady-state C_{max}, AUC, and C_{min} increased with dose in a less than dose-proportional manner. C_{min} achieved the target efficacious concentration (146 ng mL^{-1}) at 200 mg q8h. Mean steady-state C_{ave} at 100 mg q8h was 123 ng mL^{-1} (Fig. 40).

In terms of efficacy, all treatment groups gained weight. Overall, there was no consistent decrease in body weight gain compared to the placebo group in any of the cohorts tested. This was not surprising, given the low *n* in this study, the short study duration, and the resulting variability. However, there were several hints of efficacy based on an analysis of hormonal and metabolic and metabolic parameters. Nearly all drug treatment groups had lower concentrations of both fasting glucose and insulin compared to placebo on Day 16. NGD-4715 also showed a dose-dependent decrease in total plasma cholesterol levels and low-density lipoprotein (LDL) -cholesterol, and all drug-treated groups showed decreased triglyceride levels relative to placebo. This constellation of biochemical changes in the absence of weight loss represents a highly desirable profile that merits further study. Future experimental design of MCHR1 antagonist clinical trials should consider a standardized reduced caloric diet and exercise paradigm along with behavioral counseling, encompassing a minimum 4-week study duration and 1-week placebo run-in period.

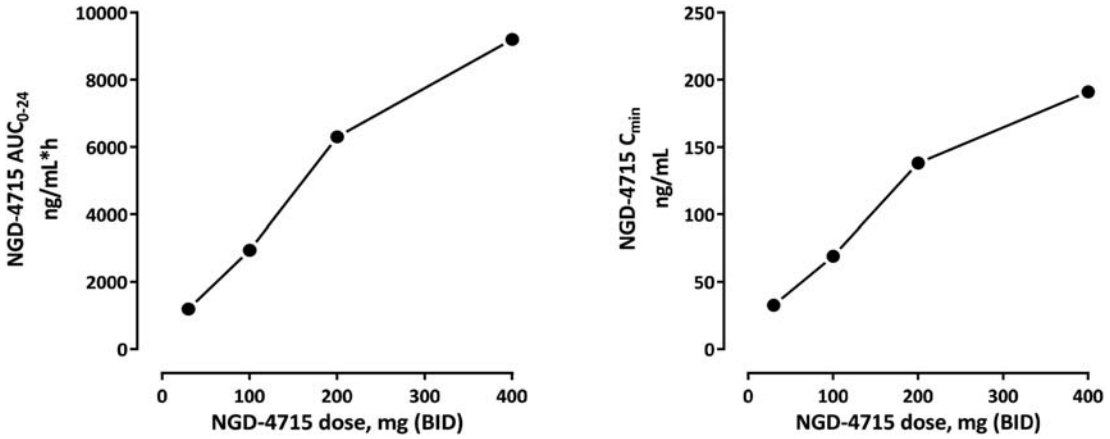

Fig. 40 Multiple ascending dose study with NGD-4715 showing target exposures were achieved at the 200 and 400 mg BID doses, and that increases were less-than-dose-proportional.

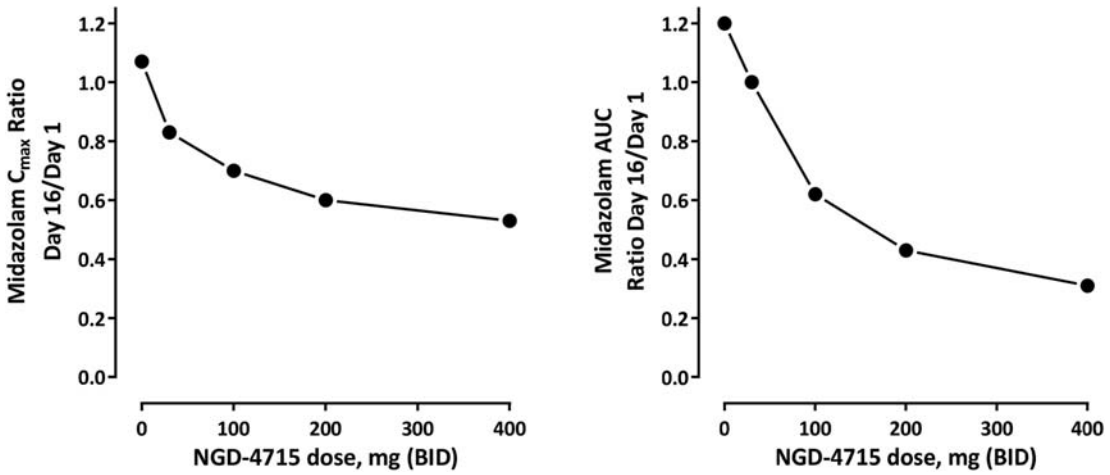

Fig. 41 Multiple ascending dose study with ND-4715 exploring the degree of CYP3A4 induction using midazolam as a substrate.

In terms of safety, unfortunately, NGD-4715 dose-dependently decreased midazolam C_{max} and AUC. The reduction in midazolam exposure was consistent with induction of CYP3A4 (Fig. 41). Thus, NGD-4715 had the potential to cause drug–drug interactions, including with drugs commonly prescribed to the obese population (statins, for example).

Otherwise, NGD-4715, generally, was safe and well-tolerated across the dose range tested. Reported adverse effects include: fatigue from midazolam dosing; GI disturbances (diarrhea, constipation, flatus, nausea); headache; and anorexia. Interestingly, in cohort 3 (200 mg q8h), four subjects reported nightmares and/or vivid dreams and feelings of anxiety, which resolved after study drug discontinuation. In cohort 4 (400 mg q8h), two subjects reported vivid dreams and/or nightmares that resolved within a day of drug discontinuation. All of the above subjects were on NGD-4715.

8.19.10 Conclusions

In summary, we describe, for the first time, the highlights of our efforts at Neurogen Corporation to investigate the potential use of MCHR1 antagonists for the treatment of metabolic diseases including obesity. We discovered an excellent tool compound (NDT 9522320) with which we conducted in vivo proof-of-concept studies both in rat (MCHR1-only species) and dog (MCHR1- and MCHR2-containing species). Encouraged by these positive results, we discovered NDT-4715 and advanced it to clinical testing. Superior compounds were delivered by a back-up program.

Acknowledgments

The authors are grateful to every one of our highly talented former colleagues for their outstanding contributions to the MCH program at Neurogen Corporation.

We thank Dr. Lin Zhi (Ligand Pharmaceuticals) for his help securing approval to publish this work.

8.20.1 Introduction

8.20.1.1 Background on Human African Trypanosomiasis

Human African trypanosomiasis (HAT), also known as African sleeping sickness, is a disease of sub-Saharan Africa caused by kinetoplastid protozoan parasites of the species *Trypanosoma brucei* and transmitted by the bite of a blood-sucking tsetse fly (*Glossina* spp.). All cases of HAT disproportionally affect the very poor, living in rural areas, and although numbers of new cases have significantly dropped in the last 5 years,[1] unreported cases in rural areas make it difficult to accurately evaluate eradication efforts.

Two main subspecies of *T. brucei* are responsible for human disease, each with distinct geographic areas of habitation and distinct pathologies. *T. b. gambiense*, which is endemic in West and Central Africa, causes a chronic disease and is responsible for 98% of the cases of HAT reported in the last decade.[2] *T. b. rhodesiense*, endemic in eastern and southern Africa, is a zoonotic disease, with animals (livestock and wildlife) as the primary reservoir, thus interruption of transmission is not likely to be feasible.[2a] It is less well adapted to humans and causes an acute and rapidly progressive disease, usually fatal within 6 months.

There are two stages of sleeping sickness, which are commonly referred to as Stage 1 and 2. The initial and acute Stage 1 involves proliferation of the parasites in the bloodstream and lymphatic system (hemolymphatic stage). Clinical symptoms are relatively nonspecific and include fever, pruritus and dermatological problems, arthralgia, enlarged lymph nodes, spleen and liver, fatigue, and headaches. In Stage 2, the meningoencephalitic stage, the parasites have migrated across the blood–brain barrier into the central nervous system (CNS) of the patient, and residence there leads to a multitude of neurological symptoms including sleep disorders, hallucinations, and coma. HAT is a fatal disease with patients progressing from neurological issues to coma, severe organ failure, and death if left untreated.[3]

In sub-Saharan Africa, 97% of all reported cases of HAT occur in only seven countries, with the Democratic Republic of the Congo (DRC) accounting for two-thirds of reported cases.[4] Numbers of cases have dropped dramatically in the last 10 years, but HAT remains a significant problem with over 3000 cases reported in 2014 in DRC.[1] Treatment options for HAT, particularly Stage 2, continue to be complex, with older treatments limited by lack of efficacy, toxicity, and resistance. The current standard of care, nifurtimox–eflornithine combination therapy (NECT) is highly efficacious and nontoxic, but is complex to administer in disease-endemic areas.

For the treatment of Stage 1 HAT where parasites are limited to the blood and lymphatic system, two very old drugs are routinely used. Pentamidine and Suramin (**Fig. 1**), both of which were developed in the early 20th century, are used to treat early stage of *T. b. gambiense* and *T. b. rhodesiense* infections, respectively, and are generally able to cure the patient. For Stage 2 HAT, until 5 years ago the only efficacious drugs are melarsoprol (**Fig. 1**), an arsenic-based derivative that has been used for over 50 years, or eflornithine (α-difluoromethylornithine, DFMO), which was initially developed in the 1970s as an anticancer drug at Merrell Dow Research Institute.[5] In the 1970s, Dr. Cyrus Bacchi at Pace University showed that DFMO cured mice infected with a virulent strain of *T. b. brucei* without any apparent toxic side effects. DFMO was shown to have activity against *T. b. gambiense*, but not *T. b. rhodiesense*, since the target of DFMO, ornithine decarboxylase has a very rapid turnover in *T. b. rhodiesense* ($t_{1/2} = 4.3$ compared to 18–19 h in *T. b. gambiense*).[6] In 1990, DFMO was approved for the treatment of *T. b. gambiense* HAT although it requires lengthy intravenous administration (four infusions per day for 14 days), which is difficult to administer in rural areas. Due to the inactivity of DFMO against *T. rhodesiense*, melarsoprol continues to be the only treatment option for Stage 2 patients

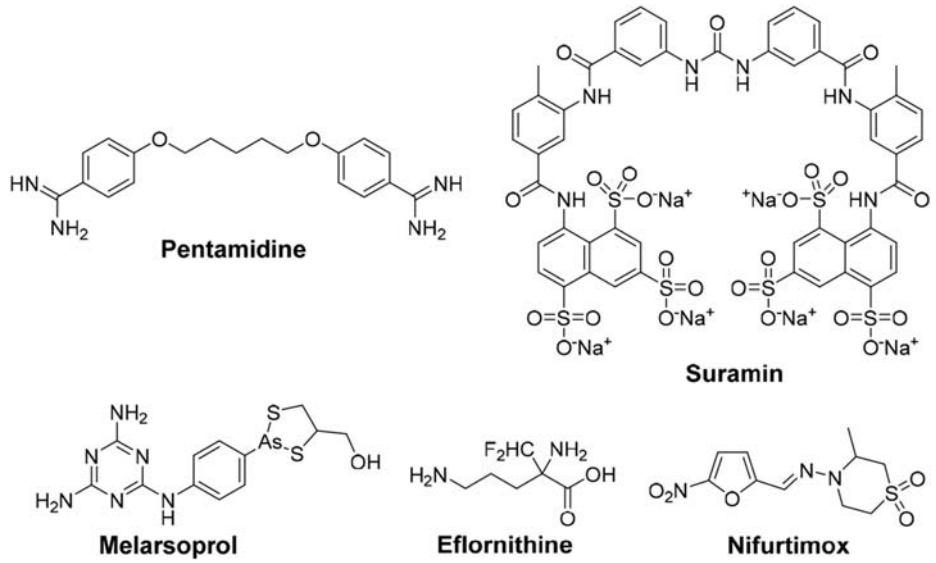

Fig. 1 Drugs approved to treat HAT.

infected with this parasite. While generally effective, melarsoprol treatment is associated with a wide range of adverse effects, the most feared being an encephalopathic syndrome which kills 3–6% of patients.[3b] In addition, treatment failures of up to 25% have been reported for melarsoprol in recent years, due to a combination of resistance to the drug and dosing limitations related to toxicity.[7]

Nifurtimox is an orally active 5-nitrofuran derivative that is used in the treatment of Chagas' disease, caused by the kinetoplastid *Trypanosoma cruzi*, a parasite that is phylogenetically close to the *T. brucei* parasites which cause HAT. In the early 2000s, a combination of eflornithine and nifurtimox (NECT) was explored by the Drugs for Neglected Diseases *initiative* (DND*i*) as an improved treatment option for Stage 2 HAT.[8] NECT was included on the World Health Organization's "Essential Medicines List" in May 2009 and has quickly become the standard of care for the treatment of Stage 2 disease caused by *T. gambiense*.[1,9] This treatment is as effective as melarsoprol, has an improved safety profile, and is easier to administer than eflornithine alone. The NECT protocol consists of an abbreviated course of intravenous eflornithine (two infusions per day for 7 days) accompanied by 10 days of oral nifurtimox (three times daily). The decrease in infusion frequency and duration significantly decreases the burden on health-care providers, reduces the risk of infections for patients in resource-poor settings, and reduces the cost of treatment by 50%.[1,9] This cost reduction is an important factor, as all NECT therapy used for the treatment of HAT is donated by the manufacturers, Sanofi–Aventis and Bayer Schering Pharma AG. Although the NECT therapy is a great improvement, it remains challenging to implement in disease-endemic areas and is not efficacious against *T. b. rhodesiense* HAT.[9] Consequently, there is still an urgent need to discover and develop novel and safe orally active drugs to treat patients with HAT.

8.20.1.2 Progression of Anacor Boron Chemistry Establishing the Benzoxaborole Scaffold for AN5568 (SCYX-7158)

Anacor Pharmaceuticals, Inc. was established in 2002 as a biopharmaceutical company focused on discovering, developing, and commercializing novel small-molecule therapeutics derived from its boron chemistry platform. The primary therapeutic areas that Anacor has focused efforts on include, but are not limited to, inflammatory diseases of the skin such as atopic dermatitis and psoriasis, and infectious diseases caused by bacteria, fungi, viruses, and parasites. In the early days of the company when there were about 15 full-time employees, with tangible excitement and energy surrounding the research projects; there was a weekly, company-wide research meeting chaired by David Perry, then CEO of the company. With tight timelines and a limited research budget, the entire group met to discuss research results, review chemistry strategy, plan next studies, and prioritize resources. The meeting itself was a setting where researchers were challenged with excellent, difficult questions about both the scientific and business aspects of the proposed studies and strategies. The chemistry group was small, and all of the chemists in the group were actively working in the laboratory, synthesizing new boron-containing molecules. In addition to identifying antibacterial and antifungal compounds, it was important that these molecules exhibited attractive chemical stability and pharmacokinetic properties. In 2004, chemists were working on compounds belonging to a B-aryl cyclic borinic ester scaffold, that is depicted in **Fig. 2**.[10] While most substitution patterns on the B-aryl substituent, including 2,6-dialkyl-substituted analogs (**2**) were synthesized without any difficulty, Yong-Kang Zhang observed that during attempted preparation of the 2,6-dimethoxy analog **3** the chromatographic behavior of the product of this reaction was very different from other analogs. Specifically, the new product was much more polar than anticipated. Curious about the apparent failure of the reaction to prepare **3**, he isolated the more polar compound, and characterized it by ^{1}H NMR and LC-MS. These analytical data were consistent with the benzoxaborole structure **4**, which is much more

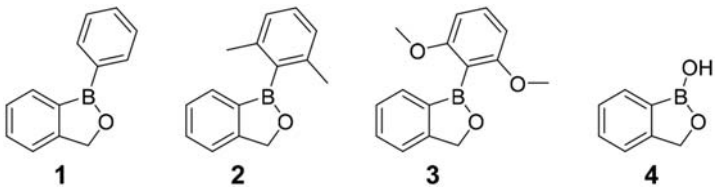

Fig. 2 Structures of three cyclic borinic esters (**1**, **2**, and **3**) and a benzoxaborole (**4**).

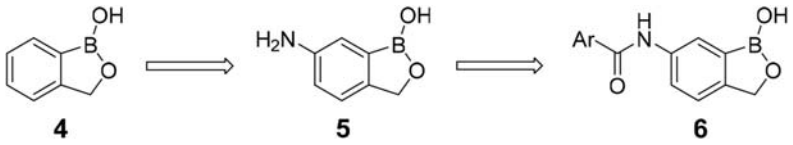

Fig. 3 Structures of small-molecule benzoxaboroles.

polar than the expected product, as TLC analysis had indicated. Considering compound **4** was structurally very different from compounds **1** and **2**, it was submitted to the Anacor library for immediate antifungal testing. As this molecule demonstrated good antifungal activity,[10,11] the chemistry team's focus was expanded to include analogs of this new scaffold.

As part of this effort, the 6-amino analog (**5**) was synthesized by Vincent Hernandez in 2006 (Fig. 3). He demonstrated that the 6-amino group could be further elaborated using traditional methods to make amides, sulfonamides, and ureas. The team recognized the opportunity afforded to generate structurally diverse benzoxaboroles based on these chemistries. With the close involvement of other chemistry team members including Jacob Plattner, Steven Baker, and Tsutomu Akama, Yong-Kang Zhang designed a focused library of 6-carboxamides (**6**) and managed the execution of chemical syntheses in a contract research organization. This focused compound library was later used for screening against a variety of parasites and provided a chemistry foundation for the subsequent discovery of AN5568 (SCYX-7158).[12]

8.20.2 Early Phenotypic Screening of Benzoxaborole Library Against *T. brucei* Parasites

In the early years of Anacor's development, we were interested in exploring all potential activities of the Anacor boron-containing small-molecule library. Some preliminary work to explore the effects of early scaffolds on several parasitic species was initiated with Dr. Reto Brun at the Swiss Tropical Institute (STI) in Basel (now Swiss TPH). Although ~100 compounds were screened in vitro against various parasites, and a few were taken into in vivo efficacy models. These compounds were from early scaffolds such as quinolones, picolinates, and cyclic borinic esters which were deprioritized once the oxaborole scaffold became the primary focus of the chemistry effort. In late 2004, in order to explore the antiparasitic potential of the oxaborole and cyclic borinic esters in the library, Yvonne Freund contacted Drs. Phillip Rosenthal and James McKerrow at the University of California, San Francisco (UCSF) (Fig. 4).

Both had screening capacity and agreed to screen samples from the Anacor library free of charge. Oxaboroles were screened in phenotypic screens against *Plasmodium falciparum* in the Rosenthal laboratory and against *T. cruzi* (Chagas' disease) and *T. brucei* (HAT) in the McKerrow laboratory. Compounds which had been screened at STI and had interest were rescreened at UCSF. Initial screening against *T. brucei* consisted of measuring percent inhibition of parasite growth in triplicate at 1 μM concentrations. From these phenotypic screens, a group of 6-position-linked thioethers (**7**), sulfoxides (**8**), and sulfones (**9**) (Fig. 5) emerged that inhibited *T. b. brucei* growth between 95% and 99% at 1 μM.

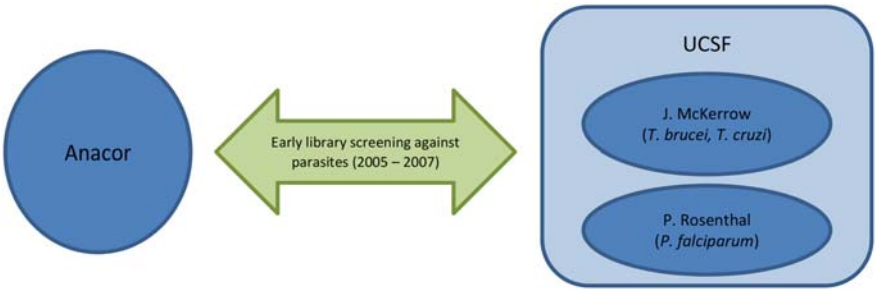

Fig. 4 Initial screening of the Anacor Library at UCSF.

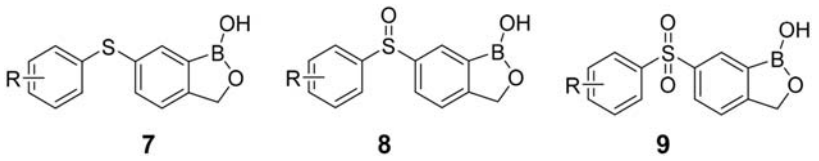

Fig. 5 Screening hits.

Follow-up screening of these analogs, including generation of dose–response data, identified the 4-chlorophenyl sulfoxide benzoxaborole AN2920 as the first lead for inhibition of *T. brucei* growth ($IC_{50} = 1.2$ μg mL^{-1}, 410 nM).[13] Early data for AN2920 suggested it to have acceptable safety, as demonstrated in a 5-day CD-1 mouse study when dosed orally, once daily at 50 and 150 mg kg^{-1}. No gross clinical observations, hematological or clinical chemistry abnormalities were noted with these treatment regimens. When dosed orally once daily at 500 mg $kg^{-1} \times 5$ days, some toxicity was noted, as only 66% survival was observed. Pharmacokinetic parameters were measured in male Sprague-Dawley rats using an IV dose of 25 mg kg^{-1} and oral dose of 100 mg kg^{-1}. Oral bioavailability of 31%, a low volume of distribution (416 mL kg^{-1}) and a $t_{1/2}$ of 1.2 h supported progression to a murine in vivo efficacy model. AN2920 was tested in a murine model of acute *T. b. brucei* infection at 100 mg $kg^{-1} \times 5$ days by intraperitoneal (ip) injection at UCSF and later at 50 mg kg^{-1} BID, ip × 5 days at Pace University.[13,14] In these early days the ip route was used, based on the assumption that this would provide a greater exposure than the oral route, although these experiments were later repeated using oral dosing. Plasma exposure was not measured; however, treatment with 50 mg kg^{-1} resulted in 100% survival and no parasitemia 40 days postinfection. In 2007, with AN2920 and related compounds showing interesting in vitro and in vivo potency, Jake Plattner approached the DND*i* about a potential collaboration to further explore oxaboroles for the treatment of HAT. In December of this year a contract was established between Anacor and DND*i* for this purpose, that provided Anacor with access to the contract research organization Scynexis (Research Triangle Park, North Carolina) for medicinal chemistry, biological screening, and pharmacokinetics (PK) services (Fig. 6).

The first meeting of the DND*i*–Anacor–Scynexis consortium took place on Mar. 14, 2008. Robert Don and Denis Martin attended from DND*i*; Jacob Plattner, Yvonne Freund, Huchen Zhou, and Tsutomu Akama from Anacor; and Robert Jacobs, Bakela Nare, Matthew Orr, Joe Perales, Daitao Chen, and Steven Wring from Scynexis. At this meeting, it was agreed that a set of ~50 compounds would be provided to the Scynexis team for evaluation in the biological and PK assays run in Research Triangle Park, North Carolina. In addition, it was agreed at this meeting that a small number of compounds that exhibited good activity and PK would be evaluated for in vivo efficacy in an acute, blood stage *T. brucei* model that was run at Pace University under the direction of Drs. Cyrus Bacchi and Nigel Yarlett. At Scynexis, Robert Jacobs was the HAT program and medicinal chemistry team leader. Steve Wring was in charge of the PK efforts and Bakela Nare led the activity for the in vitro screening and biology for the project. The final component of the multinational consortium incorporated the expertise of Reto Brun, Marcel Kaiser, and colleagues at the Swiss Tropical and Public Health Institute, and provided the team with access to a broad array of *T. brucei* strains, including *T. b. rhodiense* and *T. b. gambiense* isolates which could be used to test compounds in both in vitro and in vivo assays.

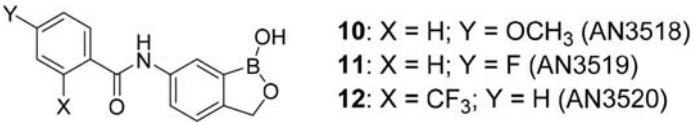

Fig. 7 Structures of benzoxaborole-6-carboxamides which exhibited in vivo activity.

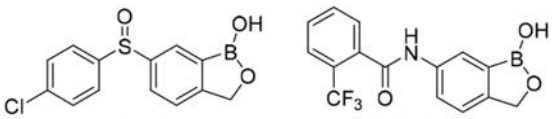
Table 1 Comparison of in vivo efficacies of early leads **AN2920** and **AN3520** in an acute HAT mouse model



Compound	*Parasites used to infect mice*	*Treatment and dose*	*Result*
AN2920[a]	600 *T. b. brucei*, EATRO 221 strain	50 mg kg^{-1}, b.i.d., ×5 days, *i.p.*	100% cured, 40 days
	10^4 *T. b. rhodesiense*, strain IL1852	Same as above	100% cured, 60 days
	T. b. brucei, EATRO 110 strain	20 mg kg^{-1}, *i.p.*; or 20 mg kg^{-1}, *p.o.*	Effective (*i.p.*); not effective (*p.o.*)
AN3520[b]	2×10^5 *T. b. brucei*, EATRO 110 strain	50 mg kg^{-1}, single dose, 24 h or 48 h postinfection, *i.p.*	Both 100% cured
	2×10^5 *T. b. brucei*, EATRO 110 strain	5 mg kg^{-1}, b.i.d., ×4 days, *p.o.*	100% cured, >30 days
	2×10^5 *T. b. brucei*, EATRO 110 strain	10 mg kg^{-1}, b.i.d., ×4 days, *p.o.*	67% cured (2/3)[c]

[a]Compound **AN2920** efficacy data from Ref. 13.
[b]Compound **AN3520** efficacy data from Ref. 14.
[c]No evidence of compound-related toxicity was found.

The lead 4-chlorophenylsulfoxide benzoxaborole, AN2920, which originated from the McKerrow screening was tested in the mouse model of blood stage *T. brucei* infection at Pace University, as mentioned above. As AN2920 has been tested at UCSF at 100 mg kg^{-1}, b.i.d. ×5 days, the initial assay at Pace was conducted at 50 mg kg^{-1}, b.i.d, for 5 days using the *T. b. brucei* EATRO221 strain. This assay confirmed the previous work, as this dosing paradigm resulted in 100% survival with no detectable parasitemia 40 days after infection, but 20 mg kg^{-1}, b.i.d. for 5 days was not effective, with only 33% survival (at 40 days) observed following ip administration. Treatment of *T. b. rhodesiense* (strain IL18152, 104 parasites)-infected mice at the same dose and route also cleared parasites 60 days after infection.[13] AN2920 was also tested in the *T. b. brucei* EATRO221 assay at Pace at 20 mg kg^{-1}, b.i.d. for 5 days by the oral route, where it was found not to be effective. In these early in vivo efficacy studies at Pace University, a number of other substituted benzoxaboroles, including several 6-carboxamides (**10–12**, Fig. 7), were also evaluated.[13,14]

These studies demonstrated that the 6-carboxamides, and in particular the 2-trifluoromethylbenzamide AN3520, were efficacious following oral administration at doses as low at 5 mg kg^{-1}, b.i.d. for 4 days. The in vivo activities of AN2920 and AN3520 are summarized in Table 1.

8.20.3 Lead Optimization Project and Identification of AN5568 (SCYX-7158) as a Preclinical Candidate

8.20.3.1 HAT Screening Cascade for the Discovery of AN5568 (SCYX-7158)

With these initial results and organizational structure established, the project team initiated a lead optimization program focused on improvement of the benzoxaborole 6-carboxamides with the following specific objectives: (1) improve or maintain the in vitro potency of compounds, (2) improve or maintain the low cytotoxicity of compounds, (3) improve the pharmacokinetic behavior of compounds following oral dosing, (4) demonstrate that compounds in this class could achieve penetration into the CNS, and (5) demonstrate efficacy in models of both Stage 1 and 2 HAT. In order to achieve these goals, a screening cascade was established and is shown in Fig. 8. Compounds from existing libraries or newly synthesized by HAT program chemists were screened in a *T. b. brucei* whole cell assay. Concurrently, in vitro cytotoxicity was evaluated in L929 mouse fibroblasts.[14] Compounds which exhibited good antiparasitic activity ($IC_{50} \leq 1$ μg mL^{-1}) and low cytotoxicity were progressed to a range of in vitro absorption, distribution, metabolism and excretion (ADME) and physicochemical property assays designed to be predictive of potential for good oral pharmacokinetic behavior. Compounds meeting the criteria established for these assays were then progressed to in vivo PK experiments and the Stage 1 HAT mouse model. As experience was gained in the series, evaluation of brain exposure in mice was included as part of the initial PK experiments. Compounds which exhibited good plasma and brain exposure, and were active at doses <10 mg kg^{-1} in the Stage 1 HAT mouse model were progressed to the long duration (180 day)

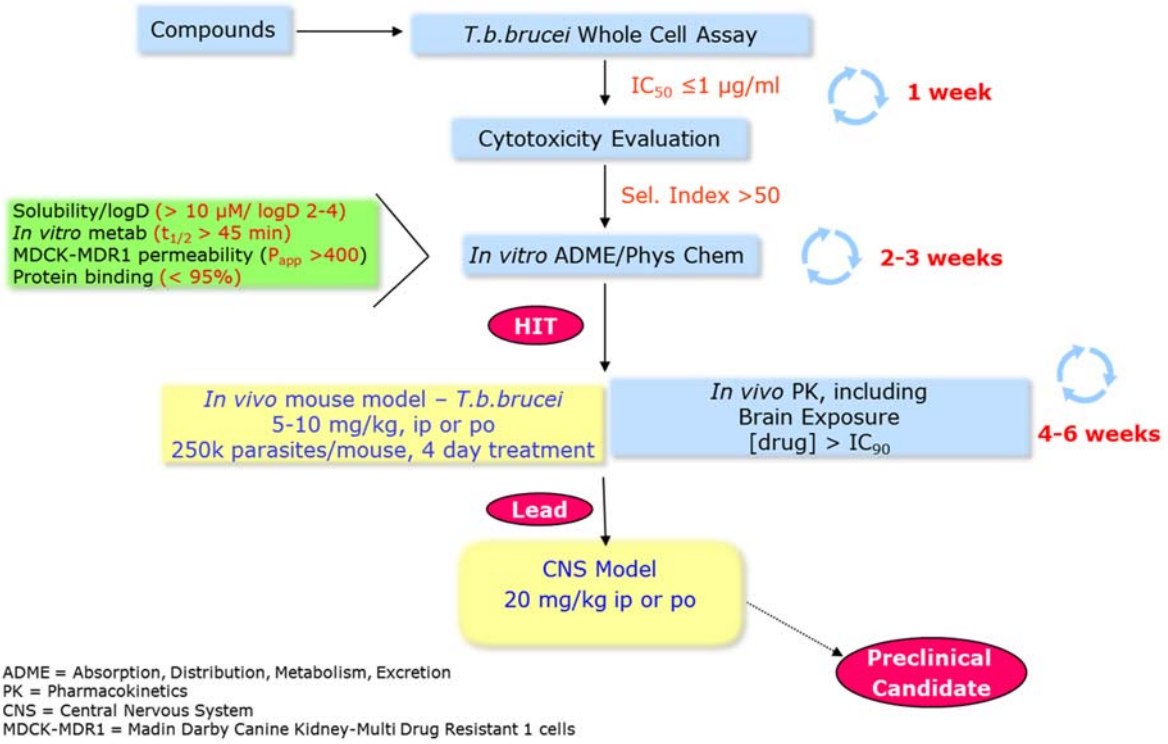


Fig. 8 Screening cascade of the HAT program related to AN5568 (SCYX-7158) discovery.

Stage 2 HAT mouse model. Throughout the program, compounds which represented significant advances in structure-activity relationship (SAR) understanding were also evaluated for a spectrum of activity in other *T. brucei* strains available at both Pace University and STPH.

8.20.3.2 Early Lead Optimization: Exploration of Linker Groups

Given the attractive in vitro profiles (Table 2) of the three carboxamides as shown in Fig. 7, one initial focus of the team was to examine alternative linkers between the benzoxaborole core and the pendant aryl ring including linkers with one, two, or three atoms as summarized in Fig. 9 and Table 3.[13,15]

In addition to the sulfide (**7**), sulfoxide (**8**), sulfone (**9**), and amide (**18**) linkers that were already identified, the ketone (**15**), sulfonamide (**19**), and urea (**24**) groups were found to have good in vitro potency. Synthetic tractability rendered the ketone series less attractive, and in vitro ADME profiling of the sulfonamides and ureas suggested these series would be challenged by permeability, particularly into the CNS. Consequently, the project further refined the chemistry focus to the benzoxaborole 6-carboxamides.

8.20.3.3 Lead Optimization of the Benzoxaborole-6-Carboxamides

The lead optimization chemistry strategy for the benzoxaborole 6-carboxamides was to systematically modify substituents in the amide region and on the benzoxaborole core to improve PK and in vivo efficacy in HAT Stage 2 mouse model (CNS model)[14]

Table 2 Profiles of benzoxaborole 6-carboxamides **10–12**[a]

Compound	T. b. brucei *IC50 (nM)*	*L929 cytotox IC50 (μM)*	*Clint mouse microsomes (μL min^{-1} mg^{-1})*	*Solubility (pH 7.4 PBS, μM)*	*logD*	*Papp (nm s^{-1})*	*Papp + 918 (nm s^{-1})*
10	70	>35	18	>200	2.21	643	647
11	260	>35	17	>200	2.27	625	647
12	120	11.7	2	>200	2.25	471	464

[a]For descriptions of assays summarized in this table, see Ref. 14.

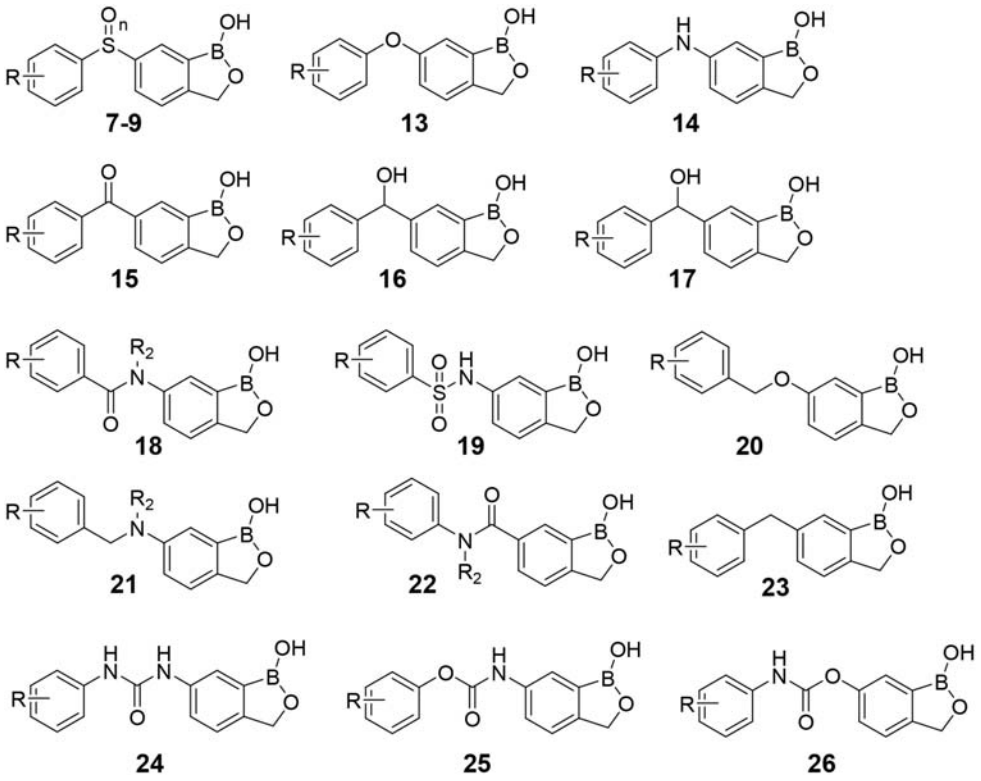

Fig. 9 Linkers explored related to the benzoxaborole-6-carboxamides.

following oral dosing. More specifically, we examined a multitude of substituents on the benzamide ring, substituents at C(3), C(5), and C(7) of the benzoxaborole core.[16] While SAR of the benzamide ring substituents was relatively flat in terms of in vitro potency, we quickly found that addition of a fluorine substituent to C(4′) (Fig. 10) provided a significant improvement in metabolic stability that was reflected in improved plasma and brain exposure following oral dosing. This compound, designated AN4169 (SCYX-6759) exhibited PK and efficacy in the Stage 1 mouse model that viewed as sufficient to warrant evaluation of this compound in the Stage 2 mouse model. In these initial experiments AN3520 was included as well, and it was found to cure 7/9 infected mice when administered intraperitoneally (*ip*) at a dose of 50 mg kg^{-1} twice daily for 14 days (Table 4). AN4169 was able to cure 10/10 infected animals with *ip* administration, and cured 5/6 mice when dosed orally at 50 mg kg^{-1}, BID for 7 days. Lower doses (25, 12.5, or 6 mg kg^{-1}, BID × 7 days) of AN4169 were not effective in the Stage 2 mouse model.[14]

The most significant improvement in the development of the benzoxaborole 6-carboxamide series was when substituents were introduced at the C(3) position of the benzoxaborole ring. Introduction of a single methyl group at C(3) on the 4-fluoro-2-trifluoromethyl benzamide of AN4169 provided (as a racemic mixture) a compound (AN5344) that was essentially equipotent with AN4169, but was significantly more cytotoxic to mouse L929 cells. Interestingly, when the individual enantiomers were prepared, both activities (antitrypanosomal and cytotoxicity) were found to be expressed in the (R) enantiomer, but the (S) enantiomer retained only the antitrypanosomal activity, albeit at a slightly reduced potency. Introduction of larger C(3) substituents (e.g., isobutyl and cyclopentyl) resulted in loss of potency.[16]

This SAR prompted us to prepare several 3,3-disubstituted analogs, and in particular the 3,3-dimethyl analogs. We were pleased to find that the 3,3-dimethyl analogs were only of slightly reduced potency, but this loss of in vitro potency was compensated for by a substantial improvement in PK properties. Of greatest interest was the observation that exposures in the brains of mice increased substantially both in terms of C_{max} and duration of exposure. Of several compounds profiled in the 3,3-dimethyl series, the direct analog of AN4169, AN5568 (SCYX-7158, Fig. 11) stood out as having the best balance of in vitro potency, lack of cytotoxicity, in vitro ADME, and in vivo PK. We initially hypothesized that the improvements in in vivo PK were due to decreased affinity of AN5568 to one or more transporters in the blood–brain barrier as a result of the increased steric bulk around the benzoxaborole core. Data obtained later in the program suggested that a more likely explanation for this behavior was due to different protein binding properties for AN5568 between plasma and brain proteins.[18] We were quite happy to find, therefore, that these properties translated into significantly improved efficacy in both the Stage 1 and 2 mouse models of HAT, with AN5568 exhibiting 100% cure in the Stage 2 model after oral dosing at 25 mg kg^{-1}, qd for 7 days and 80% cure at a dose of 12.5 mg kg^{-1}, qd for 7 days (Table 5). Other 3,3-dimethyl analogs showed similar efficacy, but none surpassed AN5568.

8.20.4 Preclinical Development of AN5568

With AN5568 having emerged as a potential preclinical candidate for the treatment of HAT, we next initiated a comprehensive characterization of this compound. We confirmed that AN5568 was potent ($IC_{50} < 0.5$ μg mL^{-1}) against a wide range of *T. brucei* strains, including *T. b. rhodesiense* and *T. b. gambiense* isolates that were resistant to melarsoprol.[17] AN5568 was also fully profiled in a standard battery of non-GLP safety pharmacology and toxicology studies, including AMES, in vitro micronucleus, human Ether-a-go-go Related Gene (hERG), and cytochrome P450 enzyme inhibition studies, where it was found to have properties consistent with those needed for progression.[17] One of the most interesting observations made during the preclinical phase concerned the in vivo PK of AN5568, particularly in dog. In mice, rats, and cynomolgus monkeys, AN5568 exhibited very good and well-behaved PK; plasma concentrations were maintained well above the in vitro minimum inhibitory concentration (MIC) of the compound for at least 24 h, clearance was low across these species, and oral exposure and bioavailability were high. In these species, the plasma half-lives ($T_{1/2}$) of AN5568 following oral administration was 7.7 (m), 15.3 (r), and 20.3 (c) h. When AN5568 was administered to dogs by either the intravenous or oral routes, we were surprised to find that plasma exposures were maintained for several days at concentrations well in excess of the in vitro MIC; a plasma half-life of >63 h was calculated for a 10 mg kg^{-1} oral dose. Furthermore, the shape of the concentration vs. time curve in dogs was suggestive of enterohepatic recirculation, likely a consequence of the

very high metabolic stability of AN5568. This long half-life was of consequence to our clinical development of AN5568, as in the first human dosing cohort (20 mg), we observed a very long half-life (~400 h, vide infra)—behavior similar to the dog and dissimilar to the rodent and cynomolgus monkey. This observation prompted us to examine whether we could reduce the concentration of the compound in plasma by the administration of activated charcoal.[19] In a series of in vitro experiments, we demonstrated that AN5568 could be removed from phosphate-buffered saline, simulated intestinal fluid (SIF), or SIF containing taurocholic acid by the addition of activated charcoal. In an in vivo experiment, dogs were given a single dose of AN5568, and 24 h later, were administered oral doses (either b.i.d. or t.i.d. for 24 h) of Actidose-Aqua. The results of this experiment demonstrated that the concentration of AN5568 in plasma was reduced more rapidly following the administration of charcoal, and the elimination half-life following charcoal treatment was reduced to 27–29 h, consistent with that predicted by allometric scaling from the mouse, rat, and cynomolgus monkey data.

Concurrent with these experiments to more fully understand the pharmacokinetic behavior of AN5568 in dogs, our colleagues at DND*i* completed all the preclinical toxicology and safety pharmacology studies required to support preparation of an Investigational Medicinal Product Dossier for submission to the European Medicines Agency (EMA) in advance of a first-in-human Phase 1 study.

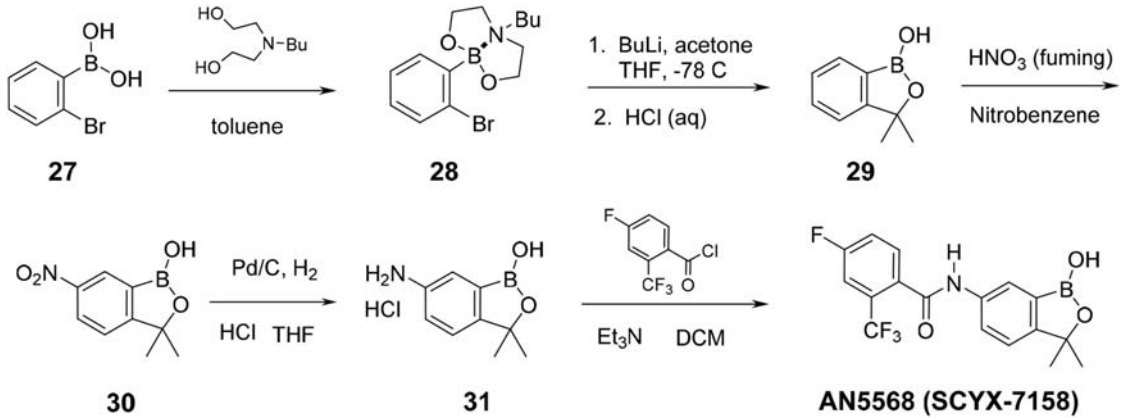

Fig. 12 A synthetic route used for the preparation of AN5568 (SCYX-7158).

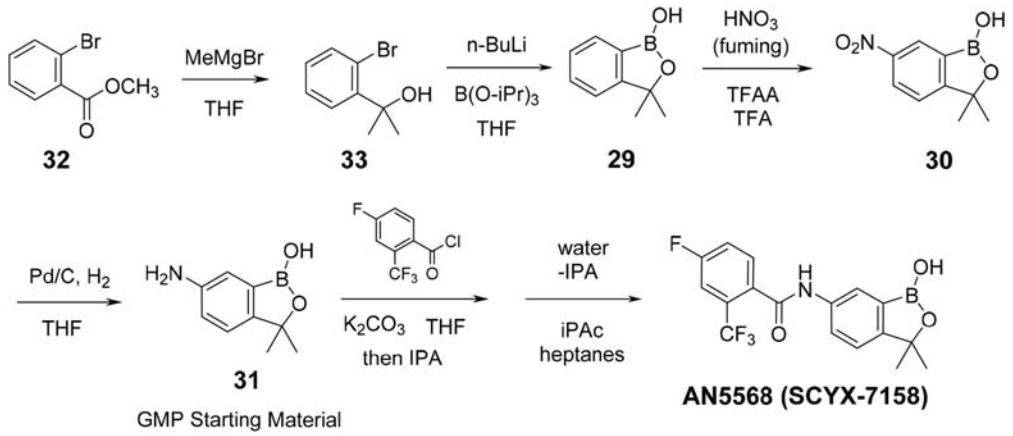

Fig. 13 Process chemistry method used for the preparation of AN5568 (SCYX-7158).

8.20.5 Chemical Synthesis

Two synthetic routes have been used for the preparation of AN5568.[16,20] The method in Fig. 12 was used during the discovery stage of the HAT program and the key common intermediate (**28**) was shared to synthesize the benzoxaboroles with substituent variation at the 3-position. The overall yield was 43% with four isolable solids in the route and no chromatography used. The raw materials are readily available. This route was also used for the first 1 kg synthesis of AN5568 in Mar. 2010.

Following the nomination of AN5568 as a preclinical candidate, development of a more cost effective and efficient process to synthesize the compound was initiated at Scynexis under the supervision of Mark Jensen. The route developed, which has been operated on multikilogram scale including a cGMP manufacture is shown in Fig. 13. Starting from readily available methyl 2-bromobenzoate (**32**), treatment with methyl magnesium bromide provides the 2-bromocumyl alcohol (**33**) in excellent yield. Lithium–halogen exchange followed by boronylation of the incipient aryllithium and benzoxaborole ring closure induced by acid workup afforded the 3,3-dimethylbenzoxaborole (**29**) in modest yield, with cumyl alcohol as a by-product from protonation of the aryllithium reagent. Pure benzoxaborole was isolated following acid–base extraction. Nitration of 3,3-dimethylbenzoxaborole was safely and efficiently accomplished using fuming nitric acid (1.0 eq) in a mixture of trifluoroacetic acid and trifluoroacetic anhydride.[21] Reduction of the nitro group using catalytic hydrogenation gave the 6-amino-3,3-dimethylbenzoxaborole (**31**) a high yield. The final two steps of the synthetic route were operated in a telescoped fashion. Acylation of the 6-amino-3,3-dimethylbenzoxaborole provided crude AN5568, which was converted in situ to the corresponding *O*-isopropyl boronate by azeotropic removal of water. This was then crystallized and isolated to remove colored impurities from the nitration/hydrogenation steps. Resuspension of the boronate in isopropyl acetate, tetrahydrofuran (THF), and water was followed by azeotropic removal of isopropanol affording pure AN5568 upon cooling. No chromatography was required throughout this process, as the isolated intermediates and final active pharmaceutical ingredient (API) were well-behaved crystalline materials. This six-step method has progressed to completion of synthesis of more than 3 kg of AN5568 (SCYX-7158) under chemical good manufacturing process (cGMP) with high purity (>99.5%).

8.20.6 First-in-Human Clinical Trial of AN5568

AN5568 was selected as a preclinical candidate for HAT in late 2009. A reproductive toxicity package was completed in 2014 showing that the drug did not induce any abnormalities. A tablet formulation demonstrated comparable PK to capsules used in a Phase 1 study and was, therefore, suitable for further clinical studies.[22]

The Phase 1 study assessing the safety, tolerability, PK, and pharmacodynamics of AN5568 after single oral ascending doses was a double-blind randomized study which included 128 healthy human volunteers of sub-Saharan origin. This study was completed in France in 2015. In the first volunteer cohort (20 mg), it was determined that the half-life of AN5568 in humans was very long (~400 h per 17 days). This observation, which was suggested by the long half-life observed in dogs, resulted in a protracted withdrawal period for the volunteers, which slowed the rate of dose escalation. In addition, studies were conducted in volunteers to confirm that the reduction of half-life observed following charcoal treatment in dogs could be reproduced in humans. These additional cohorts successfully demonstrated the ability to reduce plasma levels of AN5568 in human volunteers following a 20 mg dose by the activated charcoal method if necessary. Reduction of plasma concentrations of drug was less substantial at higher doses due to limitations in the amount of charcoal that could be administered. A potentially beneficial consequence of this very long half-life in humans is the possibility for AN5568 to be a single-dose cure of Stage 2 disease. Based on the PK–PD relationships established in pre-clinical studies, we hypothesize that maintenance of plasma and brain concentrations in excess of the MIC for trypanocidal activity can be achieved by a single dose of appropriate size.

With this background, and the objective to develop an understanding of the dose required to maintain brain concentrations above the MIC in humans, the Phase 1 study continued until a maximum dose of 1200 mg was reached. During this phase, several cohorts included sampling of CSF, which confirmed that AN5568 crossed the blood–brain barrier and provided CSF concentrations predicted to be sufficient to kill parasites in the brain of infected patients. Based on the PK observed in the Phase 1 trial, it was determined that a single oral dose of 960 mg would be predicted to provide 95% confidence of efficacy in Stage 2 patients.[23] This dosing approach is currently being evaluated for the Phase 2/3 clinical trial design, with implementation of these trials in patients in the DRC anticipated to begin in late 2016.

8.20.7 Successful Partnership Model Among DND*i* and Its Research Partners

As described in this review, the multinational and multipartner consortium, funded by DND*i* and accessing expertise at DND*i*, Anacor, SCYNEXIS, Pace University, Swiss TPH, and many contract research organizations was key to successful completion of this program. The research program delivered AN5568 as a preclinical candidate within 18 months of program initiation, an effort that included hit-to-lead and lead optimization. A reflection about the reasons behind such an excellent achievement may be useful to the tropical diseases research community. It is the view of the authors that each of the following components is necessary for successful delivery of drug candidates for neglected tropical diseases such as HAT in a cost-effective and efficient manner. The components are

(1) *A strong, dedicated, and committed research team*: At Scynexis under the program leadership of Robert Jacobs, the team members included, Bakela Nare, Stephen Wring, Daitao Chen, Eric Gaukel, Matt Orr, Jennifer Owens, Beth Beaudet, Tana Bowling, Matthew Jenks, Luke Mercer, Andy Noe, Robin Parham, Ryan Randolph, Cindy Rewerts, and Jessica Sligar. At Pace University, the team members included Cy Bacchi, Elena Mejia, Ali Hussain, Donna Rattendi, and Nigel Yarlett. At Swiss TPH, the team members included Reto Brun, Marcel Kaiser, Tanja Wenzler, and Monica Cal. At Anacor, the team members included Jacob Plattner, Yvonne Freund, Yong-Kang Zhang, Tsutomu Akama, and Eric Easom. At DND*i*, the team members included Simon Croft, Shing Chang, Graeme Bilbe, Denis Martin, Robert Don, Ivan Scandale, Delphine Launay, and Stephanie Braillard. Many unnamed people in these institutions may have contributed to the success of this research program in various ways. With the tight timeline established for this project, the dedication and commitment of these individuals was critical to success. In addition, it was also critical to have the support of the CEOs of the companies involved in this work (David Perry at Anacor and Yves Ribeill at Scynexis) to permit the teams to be dedicated to developing these drugs, which would have no commercial value to the companies.

(2) *Strong support and leadership from DNDi*: As the sponsor of the HAT research program, DND*i* allocated needed financial resources to ensure the research progressing well. For example, since this program was targeting Stage 2 HAT disease, the active compounds were required to have sufficient CNS exposure. The key to the successful medicinal chemistry strategy was to integrate in vivo pharmacokinetic characterization of lead molecules concurrent with in vivo efficacy studies. These studies were very labor intense and required substantial resources.

(3) *Well-established in vitro assays and in vivo HAT models*: Access to reproducible biological assays and models for HAT research takes special expertise, experience, and time. Therefore, contributions from the biology and pharmacology scientists at Pace University, Scynexis, and Swiss TPH were very critical to the success of the HAT research program. While some of these models were established and had been operated in support of other research programs, the capacity and throughput required to execute an integrated lead optimization project demanded considerable flexibility and adaptation of these models throughout the program.

(4) *Effective communication across different institutions*: Scientists from five organizations participated in the HAT research program. To progress the hit-to-lead (HtL) and lead optimization (LO) projects, as rapidly as, we did required close communication among all of the scientists involved in the research. Fruitful communication and frequent interaction stimulated creative ideas, saved time, and made the program progress well. For example, during the early stage of the research program, chemistry experimental procedures for hit compounds that already existed in the Anacor library were always provided to Scynexis chemists within 24 h of when requested. Biological screening results from both in vitro and in vivo experiments were made available within similar time frames through a web-based data service.[24]

(5) *Privileged benzoxaborole chemistry platform*: Since the discovery of the first benzoxaborole at Anacor in 2004, this class of molecules has been an outstanding source for novel therapeutic product candidates. Twelve new small molecules from the benzoxaborole class have progressed to preclinical evaluation, and six have been tested in humans for antifungal, antibacterial, anti-inflammatory, or antiprotozoal applications. These include Anacor's first drug, KERYDIN (tavaborole) topical solution, 5%, an antifungal LeuRS editing-domain inhibitor that was approved by the US Food and Drug Administration in Jul. 2014 for the topical treatment of onychomycosis of the toenails due to *Trichophyton rubrum* or *Trichophyton mentagrophytes*. Crisaborole topical ointment, 2%, a novel nonsteroidal topical anti-inflammatory PDE-4 inhibitor in development for the potential treatment of mild-to-moderate atopic dermatitis is currently being reviewed by the FDA. In the neglected disease area, several development candidates in addition to AN5568 have been identified, and are currently progressing through preclinical development activities, with the potential to be used as novel antitubercular and antiparasitic agents.[25]

8.20.8 Summary and Perspective

In 1995, a WHO Expert Committee estimated that 60 million people were at risk of being infected with the *T. brucei* parasites that cause HAT, with an estimated 300,000 new cases per year in Africa and fewer than 30,000 cases diagnosed and treated. In 2009, the number of new cases reported dropped below 10,000 (9878) for the first time in 50 years and the actual number of cases at that time was estimated to be ~30,000.[1] This trend has been maintained in 2010, with 7139 new cases reported. HAT caused by *T. b. gambiense* is the most common form of the disease and levels of Gambiense HAT have reached the lowest levels since the disease was targeted for elimination in the WHO's 2012 roadmap on neglected tropical diseases. In Mar. 2016, it was noted that fewer than 3000 new cases were recorded in 2015, the lowest level since the start of systematic global data collection 75 years ago. With the extremely long half-life, potential for a single-dose cure and preliminary safety record of AN5568, this compound has the potential to play a significant role in the elimination of HAT if demonstrated as safe and effective in future clinical trials.

Based on the promising results of preclinical, reproductive toxicity, and Phase 1 studies, AN5568 (SCYX-7158) has been targeted for progression to pivotal Phase 2b/3 clinical trials.[26]

8.21.1 Introduction

Malaria caused by *Plasmodium* spp. is a parasitic disease transmitted to humans through the bite of an *Anopheles* mosquito. The earliest descriptions of the periodic fevers associated with malaria can be found in Chinese medical texts dating back to 2700 BCE (http://www.cdc.gov/malaria/about/history/), and by some estimates, the disease is claimed to have killed over half of all the people who have ever lived.[1] Although malaria remains a curable disease, in 2015 there were 214 million reported cases and approximately 438,000 deaths worldwide. Over the past 15 years, incidences of new malaria cases have declined 37% which corresponds to a 60% drop in the overall mortality rate (http://www.who.int/malaria/publications/world-malaria-report-2015/report/en/). Despite the progress in recent years, emerging resistance to current drug therapies threatens to reverse this trend. A disproportionately high number of the global malaria burden is found in Sub-Saharan Africa and was home to 89% of malaria cases and 91% of malaria deaths in 2015. New global health policies which include the widespread deployment of insecticide-treated bed nets have contributed to reducing the prevalence of the disease, however the most significant contribution to reduce the malaria burden over the last two decades has arguably been the development of artemisinin-based combination therapies (ACTs). Among the current list of clinically approved treatments, artemisinin and its derivatives represent the latest (and last) line of approved antimalarial drugs. Their overall success can be traced to the development of this class of drug as a fixed-dose combination, as compared to a single agent therapy, which has resulted in the successful treatment of millions of patients.[2] However as the malaria parasite has shown time and time again, resistance to ACTs, threatens to reverse any progress gained as more cases of artemisinin-resistant malaria are discovered in Southeast Asia.[3–5] Continued efforts are needed to discover and develop classes of antimalarials that work not only though new mechanisms of killing but also have the ability to target more than one developmental stage of the parasite within the human host or mosquito vector.

Among the latest generation of antimalarial drugs currently in clinical development are the spiroindolones, exemplified by KAE609 (cipargamin). KAE609 represents the first antimalarial discovered which works through a previously unknown mechanism of action to enter clinical trials since the artemisinins. The compound was discovered and optimized through a collaborative effort between the Novartis Institute for Tropical Diseases, the Genomics Institute of the Novartis Research Foundation, the Swiss Tropical and Public Health Institute, and the Biomedical Primate Research Center. The work was funded through a public–private partnership between Novartis, the Wellcome Trust, the Medicines of Malaria Venture (MMV), and the Economic Development Board of Singapore. Cipargamin is currently in Phase II development for uncomplicated *Plasmodium falciparum* and *P. vivax* malaria.

This article describes the discovery and optimization of the spiroindolone class of antimalarials. The process from the discovery of the lead to proof of concept in man took little under four and a half years; a remarkably short time span compared to a typical drug discovery program. Along the way some critical findings which in retrospect were rather serendipitous played a large role in continuing to drive the project though lead optimization and development. Although cipargamin has more challenges to overcome before reaching approved drug status, the process of its discovery, chemical, optimization, and impact on the current antimalarial pipeline has changed the way many researchers approach drug discovery for malaria. As much of this work has been previously disclosed I have tried to bridge the various publications to chronologically convey the discovery of this new class of antimalarials.

8.21.2 Important Aspects of Current Antimalarial Drug Discovery

History has shown the malaria parasite to be extremely resilient to chemotherapy with examples of the parasite rapidly developing drug resistance to a new drug, and in some cases within 1 year of the introduction (Table 1).[6] Any new antimalarial drug should have a profile which complements and bolsters the current antimalarial drug arsenal and must include activity against all existing resistant parasite strains and preferably work through a unique, fast acting mechanism of killing.[7] It should have a long half-life to support a single or 3 day dosing regimen for low pill burden and increased patient compliance.

Fixed-dosed combination therapies released over the past decade have proven effective in delaying drug resistance compared to monotherapies and will be a requirement for any next generation drug. These treatments must be formulated for a long shelf life in endemic regions and be orally administrated both for the ease of treatment and keep manufacturing costs low (around $1 per treatment). Finally, the safety profile of the drug needs to be compatible with a target population primarily made up of women of child bearing age and children less than 5 years old but must also be safe for individuals with other indications such as tuberculosis or human immunodeficiency virus (HIV).

In the past, research on malaria drug discovery has largely focused on targeting the asexual blood stage parasites as they are responsible for the symptoms of the disease but also because they are more amenable to manipulate in the laboratory. However, the need for next generation drugs which work through new pathways and targets has lead researchers to broaden their strategy by targeting other life stages of the parasite.[8] For example targeting the parasite liver-stages can result in a drug for prophylactic use while targeting the sexual stages (gametocytes) can result in a drug with transmission blocking properties. Until relatively recent times, few biological tools and assays existed which allowed compound screening outside of asexual blood-stages, however new assays, some of which are amenable to high throughput screening (HTS), can now be leveraged to identify compounds active on blood, liver, and transmission stages of the parasite.[9]

8.21.3 Restarting Antimalarial Research and the Search for Next Generation Antimalarial Drugs

Over the past decade there has been a resurgence in efforts to discover new drugs for neglected diseases facilitated through partnerships between pharmaceutical companies, academic research groups, and funding agencies. This has also coincided with breakthroughs in the pharmaceutical industry in HTS and assay development applied to hit discovery. These advancements have led to the development and implementation of HTS campaigns on *P. falciparum* to identity new chemical starting points for drug discovery.[10–12]

As part of effort to discover new antimalarials we carried out an HTS campaign on *P. falciparum* and against the Novartis natural product (NP) library. At the time this library contained over 12,000 pure natural and NP-like (synthetic) compounds. The screen employed a fluorescence-based assay in 384-well format and active hits were identified as those compounds displaying $>50\%$ inhibition at a single 1.25 μM concentration. The assay monitors parasite proliferation through the fluorescence enhancement of a dye (SYBR green I) upon interacting with *Plasmodium* DNA. As erythrocytes lack both RNA and DNA, changes in the fluorescence intensity directly relates to and monitors parasite growth.[13,14]

Of the 12,000 compounds screened, we identified 275 primary hits that were reconfirmed in a secondary *P. falciparum* in vitro assay of which 49 compounds remained active at <1 μM. The hit list was further refined by testing for toxicity against a mammalian cell-line and for cross resistance on a chloroquine (CQ) resistant (K1) *P. falciparum* strain; leaving 32 compounds remaining out the 275 original hits.

8.21.3.1 Identification and Triaging Potential Leads From Screening

Among the 32 hit compounds selected, several known NPs with antimalarial activity were also identified (Fig. 1). Three different chemotypes were followed up as part of triaging efforts but we were unable to overcome various issues associated with these

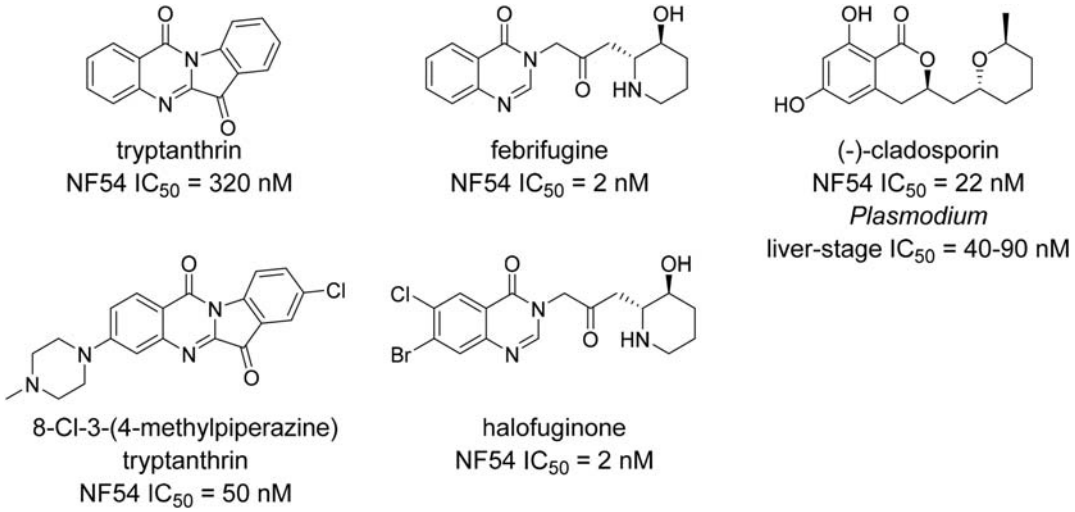

Fig. 1 Examples of known natural product antimalarials and their analogs identified from high throughput screening.

antimalarial scaffolds. Most of the problems encountered centered primarily on improving the drug-like properties and safety profile of the scaffold.

Tryptanthrin is an alkaloid isolated from the medicinal plant, *Strobilanthes cusia* and has been previously described for its potent antimicrobial and antiprotozoal activity.[15] Tryptanthrin and its derivatives display low nanomolar activity on both CQ-sensitive and -resistant malaria and although optimal in terms of their molecular size and synthetic feasibility, their poor drug-like properties (low solubility) has prohibited their development as an oral drug. A number of analogs were prepared and exemplified by the 8-Cl-3-(4-methylpiperazine) derivative of tryptanthrin. Although better potency could be achieved we were unable to improve the solubility of the compound through the introduction of ionizable, polar groups. We attributed the low solubility to the high planarity (sp2 character) of the scaffold and all efforts to reduce the planarity resulted in a loss of potency.[16]

Halofuginone is a halogenated derivative of febrifugine, the active component of a medicinal herb (*Dichroa febrifuga*) long used as a treatment for malaria in traditional Chinese medicine.[17] It displays remarkable in vitro activity against the parasite and is believed to target prolyl-tRNA synthetase (proRS).[18] Although its biological activity also extends to cancer and autoimmune diseases it is believed to operate through an alternative mechanism of action.[19] Similar to tryptanthrin, halofuginone is a chemically tractable scaffold and a potent antimalarial lead; however its polypharmacology and poor tolerability in patients makes it unsuitable for development as a safe antimalarial treatment.[20]

Cladosporin is a fungal secondary metabolite that displays a wide range of biological properties including antibacterial[21] and antifungal[22] activity through an unknown mechanism of action. In addition to its antimalarial activity on *Plasmodium* blood-stages, cladosporin inhibits the development of *P. yoelii* liver-stage parasites as well.[23,24] As opposed to tryptanthrin and halofuginone, cladosporin was not deemed chemically accessible due to its relatively complex structure although there have since been recent reports of the total synthesis of cladosporin and analogs.[25,26] In addition, cladosporin was found to display poor metabolic stability in both mouse plasma and liver S9 fractions which we attributed to Phase II metabolism (glucuronidation of phenol) or hydrolysis of the isocoumarin ring system.

Although unable to explore the structure–activity relationships (SAR) of cladosporin, the liver-stage activity associated with this compound led to an extensive target identification effort. Target identification was carried out using a collection of yeast deletion strains in a haploinsufficiency profiling (HIP) assay.[27] The HIP target discovery assay uses a genome-wide collection of heterozygous knockout yeast strains, each of which contains a marked gene deletion.[28,29] Heterozygous diploid strains bearing a deletion in one copy of a small molecule's target gene will display an increased sensitivity to that small molecule relative to those strains that have two copies of the gene; which is the result of decreased expression of the target in the heterozygous diploid strain.

Using this approach, cladosporin was found to specifically inhibit protein synthesis by directly targeting *P. falciparum* cytosolic lysyl-tRNA synthetase.[23] Furthermore, cladosporin is more than 100-fold potent against *Pf*lysyl-tRNA synthetase relative to the human enzyme, and remarkably conferred by the difference of only two amino acids within the enzyme active site. More recent data supports *Pf*lysyl-tRNA synthetase is an attractive, druggable, antimalarial target that can be selectively inhibited.[30]

Compounds with promising activity from phenotypic cell-based screens, like cladosporin, may not necessarily be good drug leads, however they are still useful in determining their mechanism of action through the identification of specific targets.[31] The successful validation of a target from this approach provides a proof of concept for small molecule inhibition and can support drug discovery based on rational design of the hit compound.

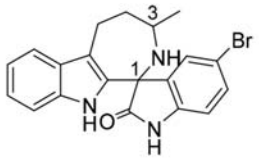
8.21.4 Identification of the Lead

As one of the key profiles for an antimalarial drug is oral route dosing, we prioritized the remaining hit compounds based on their bioavailability in rodents as opposed to in vitro potency alone. Seventeen compounds were selected but only one, a racemic spiroazepineindole **1**, displayed a favorable oral pharmacokinetic (PK) profile in mice (C_{max} = 3.6 μM, bioavailability (F) = 59%) (Fig. 2). Interestingly in our background search it was revealed that compound **1** was not a NP but a synthetic compound previously reported and tested for anticonvulsant activity.[32] The compound was included in our library for its *NP-like* structural properties (i.e., chirality and indole carboline moiety) and purchased as part of the NP library expansion activities. No antimalarial activity had been previously reported for the compound in the original publication.

Spiroindolone **1** displayed moderate activity against both wild type (NF54) and CQ resistant (K1) strains of the parasite when tested in the *P. berghei*-infected mouse model.[33] A single 100 mg kg^{-1} oral dose of the compound resulted in a 96% reduction in parasitemia (activity); although animals survived only up to day 7 post dosing. Nonetheless this was a surprising result for a compound with moderate in vitro activity (~100 nM) and we attributed this to a good oral PK profile. Encouraged by these preliminary results, we surmised that a chemical optimization effort to increase potency and further improve the in vivo PK profile of **1** could deliver a drug candidate.[34]

8.21.5 The Active Enantiomer of the Lead Compound

Resynthesis of **1** was carried out to reconfirm the antimalarial activity. We expected the reported synthetic route to yield a mixture of all four possible stereoisomers based on the reaction conditions (Scheme 1A), however the reaction of the indoleamine and



(*rac*)-spiroindolone (**1**)
NF54 IC_{50} = 90 nM
K1IC_{50} = 80 nM

Oral PK parameters (25 mg/kg)

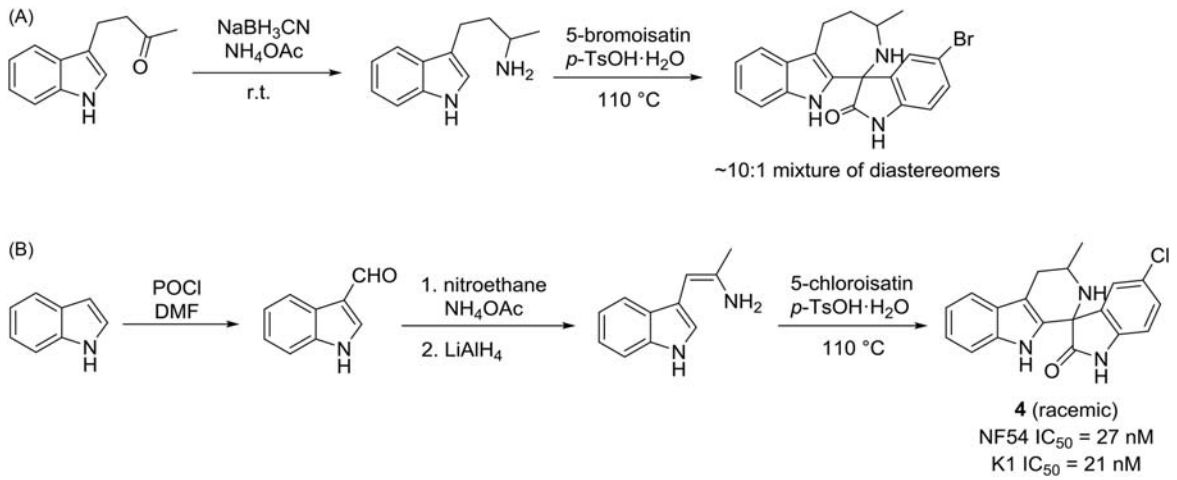
3.6	0.25	16.51	3.73	59

Fig. 2 The structure and oral PK properties of the spiroindolone hit.



Scheme 1 (A) and (B) Diastereoselectivity in the Pictet–Spengler reaction.

5-bromoisatin provided a 9:1 diastereomeric excess favoring one pair of enantiomers. Diastereoselectivity in the Pictet–Spengler reaction has been widely reported,[35,36] however there have been few examples of reactions involving α-methyl tryptamines and isatin to form the corresponding spirocenter.[37] We extensively investigated the key cyclization step of the spiroindolones to deliver the more favored *trans* product under the thermodynamic conditions of the reaction (Fig. 3).[38] Under reaction conditions, the cyclization step goes through a bis-spiro intermediate independent of the initial imine geometry resulting in **A** and **B**.[39] The formation of the bis-spiro intermediates is fast and reversible but does not influence the stereochemistry of the spirocenter. Instead, bond migration to form the central six-membered ring in intermediates **C** and **D**, is rate determining.[39] The two diastereomeric cations (**C** and **D**) differ only in the configuration of the spirocenter, which places the lactam or the chlorophenyl portion of the isatin in the pseudo-axial position. Of these two possibilities, **C** is favored due to its lower $A^{1,3}$ strain from the *trans* diaxial positioning of the indole and the chlorophenyl of the isatin resulting with the *trans* configuration as the major product formed.

Chiral separation of the mixture of the major product followed by X-ray crystallography provided spiroindoleazepines **2** and **3** and unambiguously identified the active enantiomer as having the 1*R*,3*S* configuration (Fig. 4). Interestingly, its enantiomer (1*S*,3*R*) was completely inactive which possibly implied the presence of a discrete molecular target. This trend was also observed in the spiro-β-carboline series exemplified by **4** (Scheme 1B). In this case all four diastereoisomers were isolated and showed that the major product consisted of the 1*R*,3*S* and 1*S*,3*R* enantiomeric pair (*trans* product) while the 1*R*,3*R* and 1*S*,3*S* enantiomers (*cis* product) made up the minor product (Fig. 5). Ranking the potency of isomers **5**–**8** was useful in rationalizing the SAR between diastereoisomers. The 1*R*-configuration of the spirocenter (C1) is essential as over 100-fold potency is lost with the 1*S*-configuration (**5** and **8** vs. **6** and **7**). The stereochemistry at C3 favors the *S*-configuration as a 50-fold loss in potency is observed for the *R*-configuration (**5** vs. **8**). This trend could also be extended to other spiroindolones analogs where all four diastereoisomers were isolated and profiled. It was completely fortuitous that the active 1*R*,3*S* diastereoisomer was a component of the major *trans* products; had it been a component of the minor products, it would have severely hampered overall progression of the series and likely ended the project if the low yields could not be overcome.

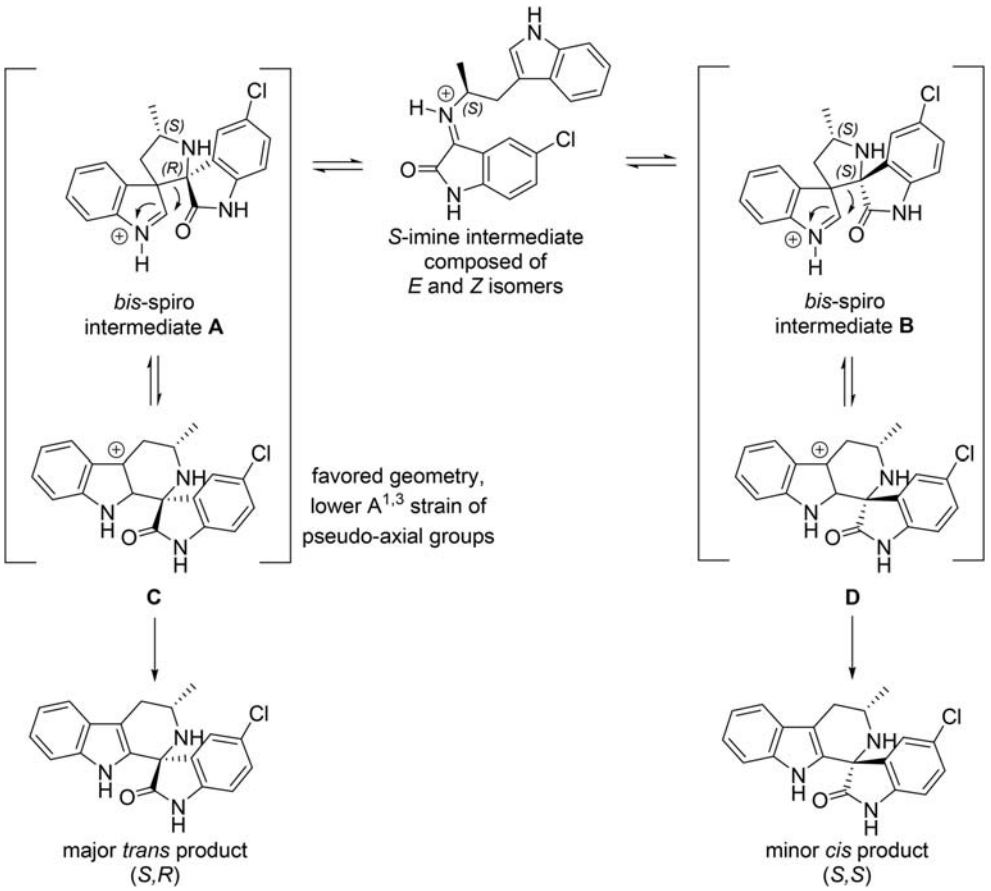


Fig. 3 A proposed mechanism for the cyclization of the *S*-imine under thermodynamic conditions favoring the *trans* product.

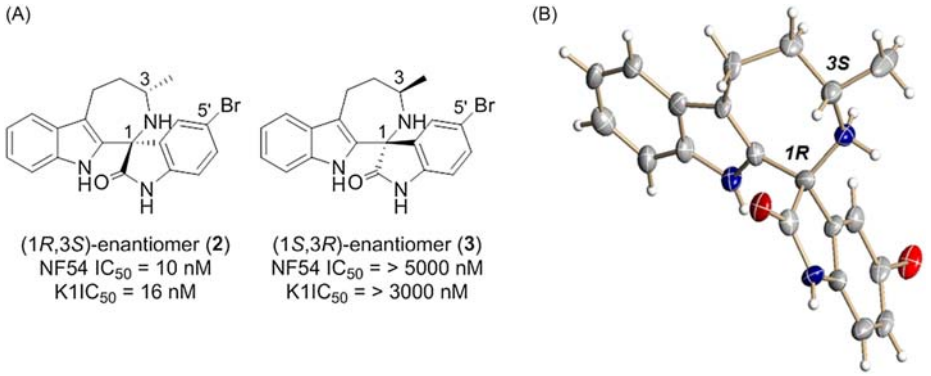

Fig. 4 (A) The activity of the purified enantiomers of the hit. (B) The X-ray crystal structure of the active enantiomer (**2**).

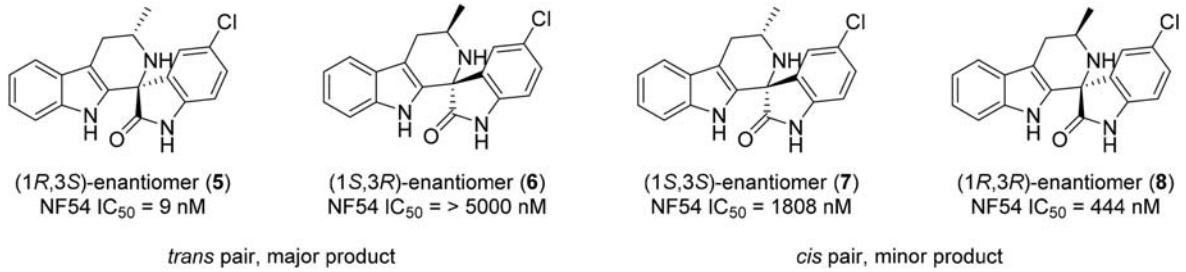

Fig. 5 The four stereoisomers of the spiroindolone products.

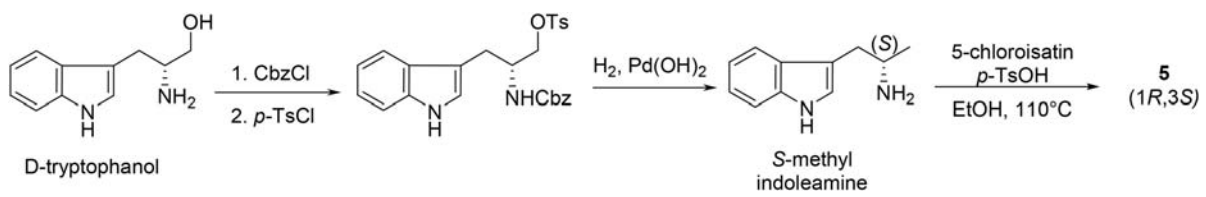
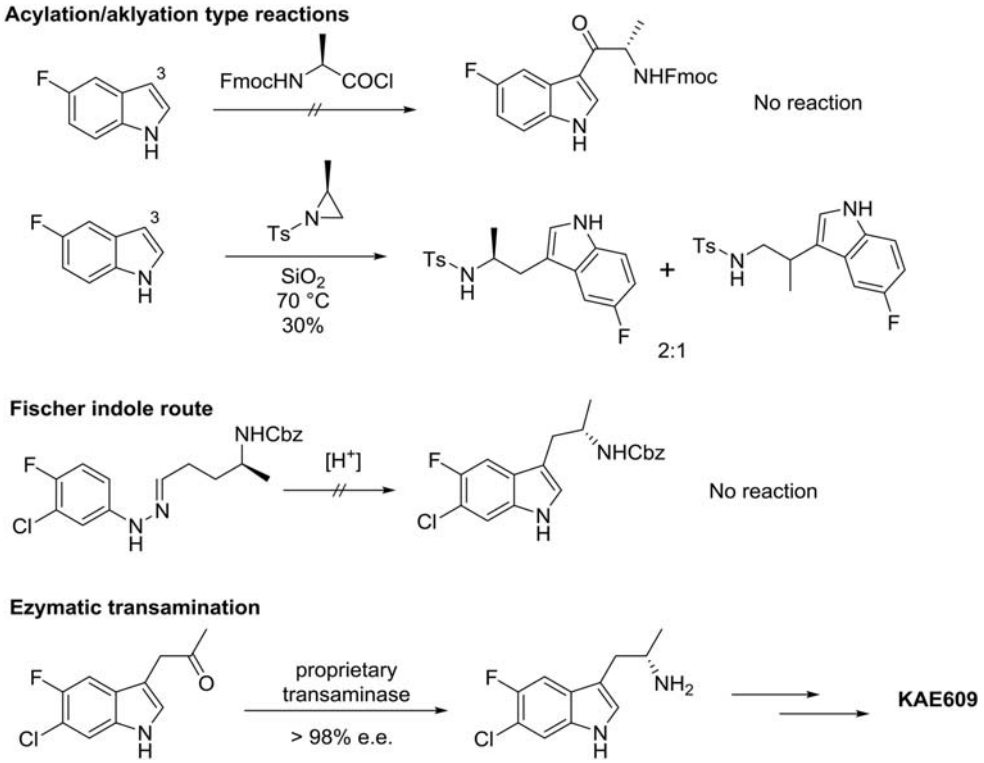
8.21.6 Asymmetric Synthesis of the Active Enantiomer

The high diastereoselectivity of the Pictet–Spengler reaction observed in the synthesis of **1** could be exploited to access the active 1*R*,3*S* enantiomers by starting with enantiomerically pure *S*-α-methyl indoleamines (Scheme 2). Starting from D-tryptophanol and following the complete reduction of the hydroxymethyl group to the corresponding methyl, cyclization with 5-chloroisatin in the presence of catalytic acid provided **5** and **6** (Fig. 5) as a 9:1 mixture. Unfortunately, we were unable to capitalize on this route due to the high cost and scarcity of substituted D-tryptophan derivatives. This led us to a significant synthetic effort towards identifying a robust and practical route to substituted *S*-α-methyl indoleamines. Unfortunately, many of the reported or established routes to chiral indoleamine derivatives were not amenable for the substituted or the halogenated indoles we required (Scheme 3). For example, while the acylation reactions generally work well for unsubstituted indoles, the corresponding reaction with 5-fluoroindole and the acid chloride of Fmoc-alanine does not provide the product under any reaction conditions attempted. If the substituted aziridine is used as the alkylating agent, the desired product can be isolated in low yields and poor regioselectivity. Other S_N2-type reactions attempted also resulted in no reaction or poor yields which we were unable to extend to wider array of indole derivatives. One of our final attempts using Fischer indole synthesis not only required a lengthy route to the chiral phenylhydrazone intermediate but also not cyclize under various reaction conditions. We concluded that many of the electron deficient indoleamines we would require for SAR studies could not be easily accessed through an asymmetric route and we ended up reverting to the shorter and more robust racemic synthesis (Scheme 1B). This change in route allowed us to quickly establish the early SAR on racemic mixtures from which the active enantiomer could be obtained through chiral purification.

The two stereogenic centers required for activity for the spiroindolones was deemed a potential liability for the compound as a complex synthetic route would likely result in a high development cost. Simplifying the structure by removing one or both of



Scheme 2 An asymmetric route to the active enantiomer from D-tryptophanol.



Scheme 3 Attempts to prepare substituted *S*-indoleamine derivatives and the enzymatic route used in the development of KAE609.

the centers resulted in a loss of activity and in the case of the spirocenter, leads to the loss of the pharmacophore as well. Indeed, both centers are required not only for activity but the *S*-configuration methyl group of the indoleamine is needed to set the *R*-configuration of the spirocenter.[38] The racemic route used for lead optimization could not be used as a route for development. Since the active 1*R*,3*S*-enantiomer could be readily obtained from enantiomerically pure *S*-indoleamines, it was necessary to revisit an asymmetric route to the chiral intermediate. The breakthrough came from our colleagues in Novartis Pharma working with a biocatalysis company to identify an efficient enzymatic route to the *S*-indoleamines from achiral starting materials. A proprietary transaminase was developed specifically for the 5-fluoro-6-chloro-indole ketone intermediate that could provide exclusively the *S*-amine with high enantiopurity (Scheme 3).[40] The successful implementation of this process has been critical in overcoming the risk of high development costs associated with an antimalarial drug for widespread distribution.

8.21.7 SAR of the Spiroindolones

A large part of our optimization strategy of **1** was to maintain overall structure of the hit.[34] We believed that the *R*-configuration of the quaternary center was not only important for activity but that the three-dimensionality of the molecule was the source of its favorable physicochemical properties (i.e., high solubility and permeability and low cytotoxicity); and very different from the flat heterocyclic compounds which make up a large part of chemical libraries. The relative compactness and rigidity of the scaffold implied that all the elements representing the complete pharmacophore were present in the molecule. Introducing minute changes to the hit (**1**) such as removing the methyl or bromine substituents markedly impacted the activity. Because of this, much of the optimization focused on the β-carboline ring system as the oxindole moiety was needed to easily access the spirocenter though a Pictet–Spengler cyclization with the corresponding isatin. Halide substituents on the oxindole were needed to maintain activity and the 5′-chloro was found to be equipotent to the 5′-bromo; however, fluorine or hydrogen (**10** and **11**) were not tolerated. Other functional groups and substitution patterns on the oxindole were explored but the 5′-chloro substituent which was identified early, proved to be the optimal balance between potency, synthetic feasibility, and cost (Table 2).

Modifications to the spirocyclic core were directed at optimizing potency by varying the ring size as well as the C3 substituent. The 8-membered ring was inactive (**15**) and deemed too large however 7-membered (azepine) or 6-membered (piperidine) maintained activity around the 100 nM range. The C3 methyl in the azepine series (**9** vs. **16**) had less of an impact on potency than in the piperidine series (**4** vs. **18**) moreover the gem-dimethyl reinforced the importance of the proper stereochemistry at C3; both with respect to potency and diastereoselectivity of the spirocenter at C1. In general, increasing the steric bulk at C3 gave deleterious results as larger groups such as hydroxymethyl, trifluoromethyl, methyl esters, or carboxamide lost activity. Due to the synthetic route

Table 2 The SAR summary of the spiroindolones

(Pictet–Spengler cyclization), we were restricted to tryptamines with limited structural diversity at position C3. The tryptamine $-NH_2$ was optimized for the cyclization step however it was possible to replace it with hydroxyl; albeit with significantly diminished potency and reaction yields. We also briefly explored electron rich phenethylamine derivatives, however these intermediates did not undergo the spiro-cyclization step under various reaction conditions attempted. We concluded that tryptamine derivatives were most amenable to the Pictet–Spengler reaction in terms of yields and diastereoselectivity but it brought an additional chemically-unrelated issue we had up to this point overlooked. During the early days of the project it became apparent that the synthesis of α-methyltryptamine derivatives as spiroindolone intermediates could have led to a potentially serious situation for our chemists given the strict antidrug laws in Singapore. In retrospect many of the substituted α-methyltryptamine derivatives we prepared as racemates or single enantiomers were likely to be highly pharmacologically active (psychedelic and entactogenic properties). As a protective measure we contacted the Central Narcotic Bureau of Singapore to seek approval and establish some guidelines for the synthesis of spiroindolone intermediates that would not result in the incarceration of our medicinal chemists. This was eventually resolved by not preparing any methyltryptamine derivatives on controlled substance list, limiting the quantity of intermediates prepared, and immediately using the intermediates in the cyclization reaction; thereby neutralizing the pharmacological properties of the compound. To date, we are unaware if the pharmacological properties of the 6-Cl-5-F-methyltryptamine intermediate of KAE609 have ever been fully characterized.

To further expand the SAR of the spiroindolones, substitutions to the indole were found to have the largest impact on improving the activity against *P. falciparum* in vitro (Table 3). Chloro-substitutions at C5 (**22**) and C8 (**25**) did not alter the activity compared with the unsubstituted analog (**4**) however low nanomolar potency was reached when the substitution was at C6 or C7 (**23** and **24**, respectively). Combining both C6 and C7 substituents proved to have an additive effect and when incorporated into the active 1*R*,3*S* enantiomer, compounds **28** and **29** achieved subnanomolar inhibitory activity against the parasite.

The enantiomers comprising the racemic mixture of **4** showed markedly different in vitro profiles with respect to metabolic stability and CYP450 inhibition and on the surface seemed like a significant challenge to overcome (Table 4). The moderate stability of the racemate **4** proved to mask the high clearance of eutomer (**5**) versus the low clearance distomer **6**. Both enantiomers proved to represent this trend for all of the pairs of spiroindolone enantiomers. More specifically the distomers exhibited the desired profile that being low clearance in mouse and human liver microsomes and a low propensity for drug–drug interactions (CYP450 inhibition); while in contrast the biologically active 1*R*,3*S* enantiomers displayed high clearance with low microsomal stability and were found to inhibit CYP450 isoforms, 2C9 and 3A4 preferentially. In retrospect this result would not be completely unpredicted based on the marked structural differences between enantiomers of spirocyclic compounds. One might expect significant differences both in the way the individual enantiomers bind within the CYP450 active site and are metabolized. As a result, the optimization

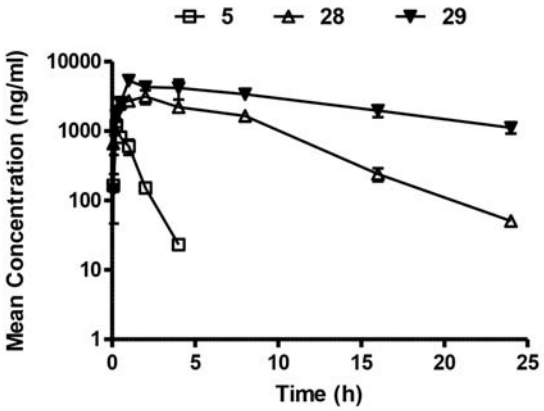
shifted from addressing potency to incorporating the long lasting and stable profile of the distomer to that of the active (1*R*,3*S*) enantiomer.

We identified the unsubstituted indole moiety on the β-carboline as potentially susceptible to oxidation and high clearance in vivo; and later proven in a follow up metabolite identification study using primary hepatocytes. Electron rich heterocycles like indole are prone to oxidation by CYP450 enzymes and we sought to install electron withdrawing groups (Cl and F) to deactivate the ring.[41] Starting from the active (1*R*,3*S*)-enantiomers, C6-F (**26**), and C7-F (**27**) spiroindolone derivatives exemplified the types of derivatives that were prepared and evaluated in vitro. Both analogs showed marked improvements in potency as predicted by the SAR and although **26** displayed a slightly better in vitro profile to that of compound **5**, the improvements were marginal at best (Table 4). In contrast introducing the C7-F proved to have the desired effect and compound **27** displayed low microsomal clearance and a much improved CYP450 profile across isoforms. Combining both C6 and C7 modifications further improved potency and stability in a profile similar to that of the inactive enantiomers (**28** and **29**). More often than not during the lead phase, chemical optimization of one parameter such as metabolic stability comes at a cost of another—usually potency. This additive effect, where optimizing one parameter on the spiroindolones had a positive influence on another, help to facilitate the lead optimization and resulted in the identification of metabolically stable and highly potent inhibitors of *P. falciparum*. The parallel optimization of two key parameters significantly shortened the lead phase and represented the second occasion where serendipity played a role in delivering a potential drug candidate.

The low in vitro microsomal clearance indicated in vitro was well correlated and highly predictive of the in vivo clearance for compounds **5**, **28**, and **29** (Table 4). Indeed, when evaluated head to head in a mouse PK study there was a marked difference between unsubstituted and substituted spiroindolones with respect to their overall PK parameters (Fig. 6).[42] Following intravenous administration, **5** displayed moderate hepatic clearance on par with what was predicted in vitro and the relatively low oral exposure (3.9 μM h) of the compound resulted in modest bioavailability (13%). In contrast both **28** and **29** displayed significant improvements in C_{max}, area under the curve (AUC), half-life, and bioavailability coupled with a low hepatic clearance rate. Oral exposure was improved 18- and 50-fold for **28** and **29** respectively and when combined with their low nanomolar in vitro potency, the collective data suggested that di-substituted spiroindolones were amenable to a single or low dose treatment regimen for malaria.

The in vitro PK profile of spiroindolones **5**, **28**, and **29** correlated well with their respective in vivo parameters (Table 4 and Fig. 6) which we attributed to the physicochemical properties of the scaffold; namely high solubility and cell permeability. We believed the underlying drivers for this were the presence of sp3 centers and the overall three-dimensionality of the molecule. Unlike other lead optimization programs where compounds possess a high degree of sp2 character, we carried out no efforts to improve the solubility or permeability of the spiroindolones greatly simplifying (and shortening) the overall optimization process.[43]



compound	Oral PK parameters					I.V. PK parameters		
	C_{max} (μM)	T_{max} (h)	AUC_{∞} (μM·h)	$t_{1/2}$ (h)	F (%)	Vss (L/kg)	CL (mL/min/kg)	$t_{1/2}$ (h)
5	3.58	0.25	3.88	0.66	13	0.91	49.66	0.42
28	8.32	2.00	71.44	3.18	53	1.60	8.53	2.94
29	13.73	1.0	207.97	10	132	1.42	6.67	3.47

C_{max}, maximum concentration of drug; T_{max}, time to maximum concentration of drug; AUC, area under the curve; V_{ss}, volume of distribution at steady state; CL, clearance; $t_{1/2}$, half-life; F, oral bioavailability.

Fig. 6 The oral PK profile of three spiroindolones depicting their relative exposures following an oral dose of 25 mg kg^{-1} and an i.v. dose at 5 mg kg^{-1} in mouse (see Ref. [42]).

8.21.8 Surrogate Models of Human Malaria for Drug Discovery

In the early days of malaria drug discovery, widespread in vivo screening of the first antimalarial compounds was carried out with *P. gallinaceum* (avian malaria) in chickens because it could easily be maintained and transmitted by mosquitoes.[44] Not until the discovery of the first rodent malaria, *P. berghei*, and the development of a laboratory-adapted *Anopheles* species, *A. stephensi* did the rodent model become the mainstay of malaria research.[45] Since then other rodent species, *P. yoelli*, *P. chabaudi*, and *P. vinckei* have also been used extensively in malaria research and chemotherapeutics to different degrees. The study of the malaria parasite in rodent models has contributed most to our understanding of the life cycle and transmission of human malaria. This is because the *Plasmodium* species that causes disease in humans are unable to infect nonprimate animal models; although an immunocompromised mouse model of *P. falciparum*-infected human erythrocytes has recently been developed for compound screening.[46]

The *P. berghei*-infected mouse remains one of the most widely used efficacy models for antimalarial drug discovery. Compound efficacy is measured by the suppression of parasitemia by a drug as compared to untreated animals.[47] Blood parasitemia levels are monitored postinfection (p.i.) after dosing which provides important preliminary data on the relative potency of a test compound. For the spiroindolones, we employed a 3-day suppressive test in which the effectiveness of three daily oral doses of the compound was measured. In addition to oral dosing, the model also supports alternate routes of administration including intraperitoneal, intravenous, and subcutaneous; generally used for compounds with limited absorption or solubility.

The model can also provide ED_{50} and ED_{90} values for dose ranging as well as useful information on the oral bioavailability of a compound. In parallel to the 3 day test we employed an onset of disease or recrudescence test, where mice were administered a single dose on day 3 p.i. and monitored daily for parasitemia. The results of these tests can be expressed as the rate decrease (or increase) in parasites, the time to the onset of recrudescence, and mouse survival in number of days.[33]

8.21.9 In Vivo Efficacy of Spiroindolones in the *P. berghei* Mouse Model

Average mouse survival results were evaluated at different dose regimens with compound **5**, **28**, and **29** and are shown alongside CQ and artesunate (AS) for comparison (Table 5). Like the standard of care (AS and CQ), the spiroindolones show an excellent initial activity of 99% or greater after a single dose. However, this is not sufficient to completely cure the mice as $<1\%$ parasites remaining can quickly recrudesce in a matter of days. The spiroindolones begin to distinguish themselves in this model only after a multiple dosing regimen (30 mg kg^{-1} q.d. for 3 days). Under these conditions even a high clearance spiroindolone (**5**) with low bioavailability (13%) gives a 60% cure rate. Multiple doses with **28** and **29** have improved the absorption (C_{max}) and exposure (AUC) leading to 29.4 (80% cure) and 29.1 (90% cure) days average mouse survival, respectively, while a single dose of **29** (KAE609) at 100 mg kg^{-1} completely cured infected mice beyond 30 days (end of the study). Optimizing the metabolic stability and improving potency resulted in increased oral absorption, exposure, and efficacy in mice resulting in an in vivo efficacy profile of KAE609 that is consistent with the pharmacokinetic properties required for a single or low dose antimalarial drug.

8.21.10 The Target and Mechanism of Action of the Spiroindolones

The spiroindolones were identified from a phenotypic screen on *P. falciparum* and one of the drawbacks of this approach is that the mechanism of action or molecular target of the compound of interest is usually unknown. However recent advances in parasite biology and biological tools coupled with forward genetic techniques has been successfully leveraged to identify several new antimalarial targets including that of the spiroindolones.

Table 5 In vivo efficacy in the *P. berghei* rodent malaria model of the spiroindolones compared to standard antimalarials

Compound	*Oral dose (mg kg^{-1})*	*% Parasitemia reduction*	*Avg. survival (days)/cure rate (%)*
Artesunate[a]	1×30	99.5	5.8/0
	3×30	99.0	12.2/0
Chloroquine[a]	1×30	99.6	12.5/0

Plasmodium often acquires mutations in the gene (target) affected by a particular agent as a way of combating drug-induced toxicity. This characteristic of the parasite has been shown to make the in vitro selection of resistance a powerful method for target identification.[31] Changes in the DNA sequence of resistant clones can manifest as small insertions or deletions, copy number variations, and single nucleotide polymorphisms (SNPs) during resistance evolution.[48] The significant genomic changes related to the drug target can then be verified by the reintroduction of the mutant allele into a *P. falciparum* background to validate the conference of resistance.

In order to identify the target of the spiroindolones, drug resistant *Plasmodium* strains were evolved in vitro under sublethal drug pressure in triplicate to yield parasites which displayed a 7–24 fold greater IC_{50} shift compared to wild type strains. The resulting clones were analyzed by whole genome sequencing then compared against the parent strain. Nonsynonymous SNPs, which indicate a change in amino acid sequence, identified mutations in a gene representing a P-type ATPase cation transporter (*Pf*ATP4). These mutations were localized to the putative transmembrane domain of the enzyme and were found to confer low levels of resistance to the spiroindolones.[49]

Upon invasion of *Plasmodium* into the host erythrocyte, merozoites move from a high $[Na^+]$/low $[K^+]$ environment of blood plasma to a low $[Na^+]$/high $[K^+]$ conditions of the host cell cytosol.[50] After establishing an infection, merozoites develop into the ring stage of the parasite which increases the permeability of the erythrocyte to ions such as Na^+ and K^+ among other solutes as part of nutrient uptake within the infected cell. These permeability pathways give rise to an influx of Na^+ effectively raising the $[Na^+]$ in the erythrocyte cytosol close to blood plasma levels.[51] However because the intraerythrocytic parasite requires a low $[Na^+]$ environment it must continuously extrude the influx of sodium ions by continuous efflux through the function *Pf*ATP4.

Plants, fungi, and some protozoa extrude Na^+ through an ENA (*exitus natrus*) P-type Na^+-ATPase which is closely related to sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPases and plasma membrane Ca^{2+}-ATPases.[52] Although we initially postulated the target of the spiroindolones as a Ca^{2+}-ATPase based on sequence homology, experiments carried out by our collaborators at the Australian National University provided strong evidence that *Pf*ATP4 is in fact a Na^+-ATPase.[53] Live cell assays that monitor the $[Na^+]$ within the parasite have shown that in the presence of spiroindolones, *Pf*ATP4 function is inhibited leading to a rapid increase in the internal $[Na^+]$ resulting in parasite death.

This represents a highly parasite-specific inhibitory mechanism and completely different from the Na^+ transport system used by animals (Na^+/K^+-ATPases). Furthermore it seems unlikely that this unique mechanism of killing would have been discovered by a reverse genetic approach. In other words, in the absence of a tool compound from phenotypic screening, *Pf*ATP4 and is mechanism of action would have likely been overlooked as a potential drug target based on its perceived drugability profile alone (i.e., a membrane-bound transporter and a poorly predicted selectivity index over the host target). Since our disclosure of *Pf*ATP4, at least two other chemotypes have been discovered to work through this mechanism of action and are currently in clinical development for the treatment of malaria.[54,55]

8.21.11 Proof of Concept—Rapid Parasite Clearance in Patients

A Phase II, open-label study was conducted in Thailand to assess the antimalarial efficacy, safety, and adverse event profile of KAE609. A dose of 30 mg day^{-1} for 3 days was chosen for adults with either uncomplicated *P. vivax* malaria (10 patients) or *P. falciparum* malaria (11 patients) with parasite clearance time being the primary endpoint. After treatment, the median parasite clearance time was 12 h in each patient group and the median half-lives for parasite clearance were 0.95 h in the patients with *P. vivax* malaria and 0.90 h in those with *P. falciparum* malaria. Artemisinin and its derivatives are the fastest acting antimalarial agents identified to date; however, the preliminary data from this study suggests that KAE609 may affect an even faster parasite clearance rate. Moreover, some of the patients treated with KAE609 in the study were found to have been infected with artemisinin-resistant *P. falciparum* strains. In general, less than 1% of patients with *P. falciparum* malaria treated with oral AS in Southeast Asia had a parasite clearance half-life of less than 1 h which suggests that the spiroindolones may be highly effective against artemisinin-resistant malaria.[56]

Some adverse events were reported, with nausea being the most common but were generally mild and did not lead to discontinuation of the drug. However more extensive safety studies will be needed to fully assess the adverse event profile of KAE609.

The preliminary clinical findings above support some in vitro and in vivo observations made during the preclinical profiling of KAE609. First, the good pharmacokinetic profile observed in mouse efficacy studies is also present in patients where the mean terminal half-life of elimination of 20.8 h supports a once a day dosing regimen. Secondly, KAE609 displays potent activity on asexual blood-stages but additionally kills ring stage parasites similar to the artemisinin which is believed to translate to the rapidity of symptom resolution. KAE609 also has gametocytocidal activity against *P. falciparum* in vitro and thus may have transmission blocking properties however this will require additional studies to determine its clinical impact.[57]

The remarkable parasite clearance rate in patients dosed with KAE609 has been linked to a particular phenotype that is the result of and specific to *Pf*ATP4 inhibition. In a normal infected red blood cell, parasite development has little effect on the flow of infected blood throughout the body, and in particular the spleen. In the spleen blood is mechanically filtered through splenic sinusoids which are approximately 2 μm in diameter. In the presence of KAE609, infected red blood cells were shown to become more spherical and rigid and thus unable to traverse splenic sinusoids thereby becoming trapped and destroyed by phagocytes. It is believed that the inhibition of *Pf*ATP4 disrupts osmotic regulation in parasite-infected cells leading to parasite death and eryptosis (red blood

cell suicide). By comparison, artemisinins do not have any effect on the rheology of infected red blood cells and lack this dual mechanism of killing which is unique to the spiroindolones and other *Pf*ATP4 inhibitors.[58]

8.21.12 Summary and Final Thoughts

The spiroindolone hit was obtained as part of an effort to expand our chemical libraries and had been through numerous internal HTS campaigns before being identified as a malaria hit. Perhaps the most interesting aspect of the hit compound was that it possessed the essential structural elements required for the desired activity, all of which remain in drug candidate (i.e., the spirocenter, C3-methyl, and oxindole substituents), as well as representing the complete pharmacophore. This simplified and focused our optimization efforts on potency and stability which turned out to have an additive effect; a rarely encountered event in lead optimization. Moreover, the favorable physicochemical properties imparted by the spirocyclic core (three-dimensionality) did not require addressing low solubility or permeability and translated to good oral bioavailability in vivo. Because of these combined factors we were able to identify several potential preclinical candidates after synthesizing around 100 spiroindolone analogs in just over a year.

The discovery of the KAE609 and its path to Phase II clinical trials has also had an impact on the process by which we now approach malaria drug discovery. The HTS approach of large chemical libraries on *Plasmodium* blood-stages has successfully identified other new malaria-specific chemical scaffolds that have been placed in the public domain (www.ebi.ac.uk/chembl). Although the mechanism by which most of these hit compounds inhibit the parasite remains unknown, they in principle represent all potential *Plasmodium* drug targets. By combining forward genetic techniques for target identification through the evolution of drug resistant mutant strains, it is now possible to identify these new targets associated with the active compounds as exemplified by the discovery of *Pf*ATP4. This combined drug discovery approach can lead to new drugs and new drug targets, both of which will be essential to achieve the ultimate goal of malaria eradication.

8.22.1 Malaria Disease and Burden

Malaria is both a prevalent and a persistent infectious disease with wide global impact. Currently 3.2 billion people in over 97 countries live in malaria endemic regions, and in 2015 there were an estimated 214 million new cases.[1] The disease has its highest impact in Sub-Saharan Africa where 90% of the estimated 438,000 deaths in 2015 occurred mostly in children under the age of 5.[1] The female Anopheles mosquitoes carry the malaria parasite and infect the human host during a blood meal.[2,3] Sporozoites, transmitted through the saliva of the mosquito, travel first to the liver where they invade hepatocytes and propagate into merozoites which are then released to invade red blood cells. This is followed by the erythrocytic stage where parasites undergo repeated rounds of replication, release, and reinfection and it is this cycle that leads to the clinical symptoms of fever, chills, headache, nausea, and eventually death. During the blood stage, a small proportion of the asexual parasites develop into sexual stage male and female gametocytes that are transmitted back to the mosquito during a subsequent blood meal, where they develop into the infective stage ready for transmission to a new host. While five *Plasmodium species* cause malaria, *Plasmodium falciparum* is responsible for almost all mortality and has also been the species for which drug resistance has most impacted treatment options. *P. vivax* is also a significant player as it has a large global distribution and has a dormant form that remains in the liver for years after the primary infection, being released periodically to initiate a relapse infection through mechanisms that are still poorly understood. Disease presentation can vary from uncomplicated malaria to severe infection, with mortality increasing as the percentage of infected erythrocytes rises above about 2%. In severe *P. falciparum* malaria, adherence of infected erythrocytes to blood vessel walls leads to sequestration into key organs including the brain, which can lead to cerebral malaria.[2] Adults living in areas of continual transmission develop temporary protective immunity, which reduces parasite burden and lessens disease severity.[4] As a consequence, young children, pregnant woman, and naive hosts, all of whom lack this immunity are most likely to develop severe disease.

Treatment and prevention of malaria currently relies on a combination of drug therapies and insect control programs.[2] The possibility of developing a vaccine for the prevention of malaria has been pursued vigorously; however, the best candidate vaccine (RTS,S/AS01) developed by GSK has been reported to provide only limited protection (<30% in infants, which are the target

population) and the effects were of short duration.[5,6] Lack of a fully effective vaccine means that malaria control programs will continue to rely on drug therapy for the foreseeable future. A number of safe and effective drugs for the treatment of malaria have been approved for clinical use including the historically important drugs, quinine, chloroquine, and pyrimethamine/sulfadoxine, which provided effective antimalarial therapy for many years.[2] Unfortunately, by the late 1970s both chloroquine and pyrimethamine had become ineffective in many endemic regions due to drug resistance.[7–9] Current treatment therapies are centered on semisynthetic derivatives of the natural product artemisinin, which form the basis of artemisinin combination therapies (ACTs). Wide-spread use of ACTs combined with insecticide-treated bed nets has been largely credited with the significant decline in malaria deaths over the past decade.[2] However, ring stage resistance to the artemisinin derivatives has now been documented in Southeast Asia and threatens to erase the progress that has been made in malaria control and elimination. Kelch13 propeller protein mutations have been linked to delayed parasite clearance times for patients being treated with ACTs, providing a genetic marker to help track the spread of resistance.[10–13] In addition, resistance to the artemisinin combination partners such as dihydroartemisinin and piperaquine (Cuo-cortexin, Euartesim) has been reported in South East Asia.[14,15]

8.22.2 Target Candidate Profiles for New Antimalarial Drugs

The call for malaria eradication by the Bill and Melinda Gates Foundation in 2007 sparked a series of focused reviews that have greatly impacted subsequent drug discovery efforts. The first was an extensive 2 year consultative review involving more than 250 scientists worldwide that defined the scientific knowledge base, strategies and tools required within an eradication agenda.[16] This initiative, called the Malaria Eradication Research Agenda (malERA), identified ideal Target Product Profiles for new drugs being designed for both treatment and chemoprotection.[17] In response to this initiative, the Medicines for Malaria Venture defined a set of target candidate profiles (TCPs, briefly outlined in **Fig. 1**), which describe the key attributes required of candidate molecules to fulfill four different treatment scenarios, in addition to the obvious requirements for safety, low cost of goods, and ease of administration.[8] While a single molecule may well have more than one attribute, new drug products will be developed as fixed dose combinations to reduce the likelihood of developing resistance to a single agent.[18] The concept of Single Exposure Radical Cure and Prophylaxis (SERCaP), a product that would be effective following a single administration against all forms of parasite in a patient as well as providing posttreatment prophylaxis, places enormous demands on any new drug product both in terms of its activity profile and its pharmacokinetic characteristics. Combination products would ideally contain molecules with similar pharmacological durations of cover such that no single agent is left exposed to parasites on its own.[8]

Given the propensity for the malaria parasite to develop drug resistance, a large global effort is underway to deliver new combination therapies that can augment the use of ACTs.[5,7–9] The first novel chemical entities that have advanced to human testing for the treatment of malaria are now in Phase II clinical trials and include a long half-life synthetic peroxide,[19,20] a spiroindolone that targets the P-type cation-transporter ATPase4,[21] an imidazolopiperazine[22,23] and the triazolopyrimidine-based dihydroorotate

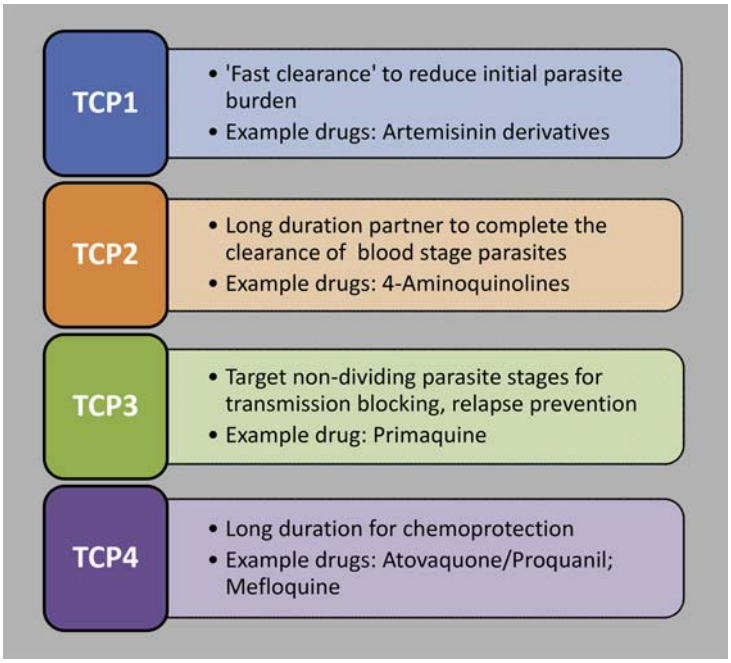

Fig. 1 Target candidate profiles (TCPs) that currently guide antimalarial drug discovery. The reader is referred to the manuscript by Burrows et al. for full details of target profiles.[8]

dehydrogenase (DHODH) inhibitor *DSM265*, which was developed by our group[24] and is the topic of this review. New agents are being developed as combination therapies to combat drug resistance, increasing the number of compounds needed to fill the portfolio. Candidate molecules with activity against all members of the *Plasmodium* genus are desired to simplify treatment in the clinical setting. A broad portfolio of activities covering blood stages for treatment, liver stages for prophylaxis, and sexual stages for transmission-blocking activity are also being pursued, while therapies that are effective with a single dose administration are being prioritized to improve patient compliance.[22,25]

8.22.3 Pyrimidine Biosynthesis and DHODH as a Drug Target in Malaria

Pyrimidine nucleotides are essential for the synthesis of DNA, RNA, and sugar nucleotides, required for glycosylation of proteins and lipids.[26] Pyrimidine nucleosides and bases can be either synthesized de novo from glutamine, aspartic acid, ATP, and bicarbonate, or they can be salvaged from the environment (Fig. 2). Once in the cell they are phosphorylated to yield the final nucleotides. Because of the importance of pyrimidine biosynthesis to cell survival, most cells, including human cells, encode the enzymes necessary for both pathways. However, *Plasmodium* species are atypical and are only able to obtain pyrimidines via the de novo route and thus they are highly vulnerable to inhibition of this pathway.[27] In *Plasmodium*, de novo pyrimidine biosynthesis is accomplished through the action of five enzymes, with the first two steps catalyzed by the same bifunctional enzyme. DHODH catalyzes the fourth step in the pathway, which is the flavin mononucleotide (FMN) dependent conversion of dihydroorotate to orotic acid (Fig. 2). Depending on the species, DHODH can be localized to the mitochondria or the cytoplasm; the distribution of the different enzyme types is spread across evolutionarily diverse organisms.[27] For example, both human and *Plasmodium* species use the mitochondrial-type II enzyme, whereas yeast and Trypanosomatids encode cytoplasmic enzymes. Mitochondrial enzymes (type II) require Coenzyme Q (CoQ) to reoxidize the FMN cofactor, whereas the cytoplasmic enzymes use either fumarate (type 1a) or NAD^+ (type 1b). The mitochondrial enzymes are anchored in the inner mitochondrial membrane and face the inner membrane space. Substrates and products (dihyroorotate and orotate) must diffuse across the outer mitochondrial membrane from and to the cytoplasm.

Prior to our work to develop DHODH as a target for malaria, the usefulness of the pyrimidine biosynthetic pathway as a source for drug targets to treat malaria was already well documented.[27–29] Pyrimethamine, which was a key drug in the antimalarial arsenal until the development of resistance, targets dihydrofolate reductase (DHFR) and prevents formation of thymidine nucleotides. To overcome resistance, recent work has identified a novel *P. falciparum* DHFR inhibitor (P218, currently in preclinical development) that has activity against drug-resistant strains harboring up to four point mutations in the enzyme.[30] In addition to DHFR inhibitors, atovaquone, which targets the cytochrome *bc*1 complex in mitochondria, has also been shown to kill parasites by inhibiting pyrimidine biosynthesis.[28] In elegant work by Vaidya and coworkers,[31] it was shown that blood-stage *P. falciparum* only require mitochondrial electron transport to drive the synthesis of pyrimidines because bc1 is required to reoxidize the CoQ substrate of DHODH (Fig. 2). The authors demonstrated that *P. falciparum* parasites genetically engineered to express yeast DHODH were resistant to atovaquone. This study also served to genetically validate DHODH as an essential target in *P. falciparum*. In subsequent works,

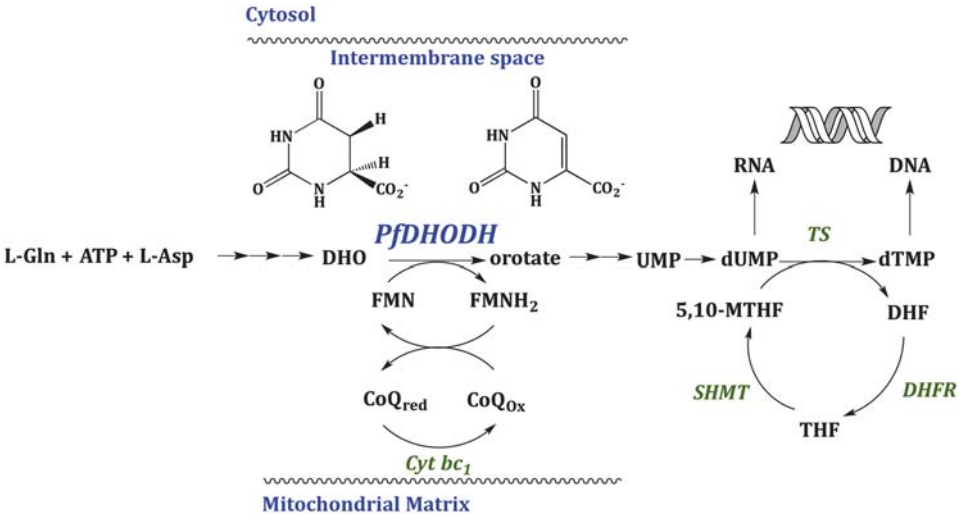

Fig. 2 Pyrimidine biosynthetic pathway in *Plasmodium* species. *Plasmidial* DHODH is a mitochondrial enzyme found anchored in the inner membrane of the mitochondria oriented with the catalytic domain in the intermembrane space.[28] All other enzymes in the pathway are cytoplasmic. *DHODH*, dihydroorotate dehydrogenase; *TS*, thymidylate synthase; *DHFR*, dihydrofolate reductase; *SHMT*, serine hydroxymethyltransferase; *cyt* bc_1, cytochrome bc_1.

this cell line has been used to validate the mechanism of action of DHODH inhibitors, and the yeast DHODH plasmid has been used as a selectable marker for genetic manipulation of *P. falciparum* with DSM1 serving as the selection antibiotic.[32,33]

While the essentiality of the de novo pyrimidine biosynthetic pathway in *Plasmodium* was clear, we sought to first determine if additional enzymes in the pathway would be both druggable and provide the needed species selectivity versus the human enzyme to achieve the necessary safety margin for the treatment of malaria. Our efforts quickly focused on DHODH as the strongest candidate in the pathway. Firstly, there was strong precedence that the mitochondrial-type II DHODH was a druggable target and that small molecule inhibitors that were disease modifying and had "drug-like" properties could be identified. The human DHODH inhibitor leflunomide (Arava) was already marketed for the treatment of rheumatoid arthritis with clear evidence that the mechanism of action occurred via DHODH inhibition by the active metabolite A77 1726 (teriflunomide).[34–37] Teriflunomide has subsequently also been approved for the treatment of multiple sclerosis.[38] While human cells are able to acquire pyrimidines by both de novo synthesis and salvage, proliferation of B and T cells during an immune response requires more nucleotide precursors than can be obtained by the salvage pathway alone and thus inhibition of the de novo pathway dampens the immune response and has proven to be an effective method for managing autoimmune diseases. Additionally, a second class of human DHODH inhibitors, brequinar and its derivatives, had also been described that were potent inhibitors of the enzyme and they were tested as potential anticancer agents and for prevention of graft rejection, eventually failing in Phase II clinical trials.[39–41] A detailed account of reported DHODH inhibitors from a range of eukaryotic and bacterial species can be found in a recent review by Munier-Lehmann et al.[42]

Turning to the question of species selectivity, several cocrystal structures of human DHODH bound to either A77 1726 or brequinar[43] had been reported and our analysis indicated that the inhibitor binding site showed significant species variability at the amino acid sequence level between the human and *Plasmodium* enzymes.[27] This analysis strongly suggested that species selective inhibitors of *Plasmodium* DHODH could be identified that would allow DHODH to be safely targeted for the treatment of malaria. We obtained additional proof for this hypothesis by testing a series of human DHODH inhibitors against recombinant *P. falciparum* DHODH (*Pf*DHODH) and demonstrating that these compounds were poor inhibitors of the *P. falciparum* enzyme.[44] Thus, the available data supported the hypothesis that *Plasmodium* DHODH was essential, druggable, and could be selectively targeted making it a strong candidate for a drug discovery program to identify new compounds for the treatment of malaria.

8.22.4 Discovery of DSM265

8.22.4.1 High-Throughput Screen

To initiate the program to identify *Plasmodium* selective DHODH inhibitors, we performed a high-throughput screen (HTS) of a medium size compound library (220,000 compounds) available from the UT Southwestern HTS core.[45] Recombinant *Pf*DHODH truncated to remove the N-terminal membrane-spanning domain and expressed as a His_6-tag fusion in *E. coli* was used for the screen. A simple end-point colorimetric assay using 2,5-dichloroindophenol as the final oxidant was used to detect enzyme activity. We identified a number of potent ($IC_{50} < 600$ nM) and selective *Pf*DHODH inhibitors in the screen including a series of halogenated phenyl benzamide/naphthamides and urea-based compounds,[45] a singleton called DSM1 that contained a triazolopyrimidine core,[46] and a number of other structural classes which have not yet been disclosed. The triazolopyrimidine series was chosen as the top lead compound series based on superior drug-like properties and the finding that DSM1 inhibited growth of *P. falciparum* in whole cell assays at a similar concentration as observed for inhibition of *Pf*DHODH, while showing no detectable activity against either human DHODH or mammalian cell lines (**Fig. 3**). Genetic rescue studies with the yeast DHODH *P. falciparum*

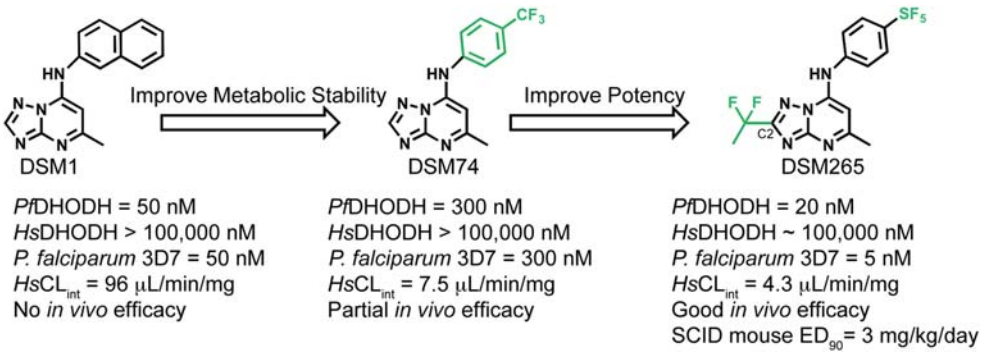

Fig. 3 Key compounds during the lead optimization program that informed the discovery of DSM265. Key compounds along the discovery pathway with relevant activity and ADME properties. *PfDHODH*, *P. falciparum* dihydroorotate dehydrogenase; *HsDHODH*, human dihydroorotate dehydrogenase; *P. falciparum 3D7*, blood-stage *P. falciparum* in vitro growth assay; $HsCL_{int}$, human in vitro intrinsic clearance (μL/min/mg protein) measured using human liver microsomes. Potency data are given in nM to allow comparison between compounds, whereas data in other figures and **Tables 2** and **3** are shown in μg/mL to allow direct comparison to the in vivo pharmacokinetic data.

cell line (described earlier) demonstrated conclusively that DSM1 killed *P. falciparum* parasites by inhibiting *Pf*DHODH.[32] In contrast, the phenyl benzamide series compounds were much less active against the parasite than against the enzyme and thus were not considered as good lead molecules for further medicinal chemistry.

X-ray structure analysis of the most potent benzamide (DSM59)[47] and of DSM1[48] indicated that both compounds bind to a similar conformation of *Pf*DHODH. The observed binding conformation for DSM1 differs to that reported for A77 1726[49] and for the thiophene carboxamide Genz-667348[50] due to the conformational flexibility of F188 which is rotated 180 angles in the pocket between its two conformational states.[48] This conformational flexibility likely accounts for the diversity of chemical scaffolds that can bind potently to *Pf*DHODH and increases the druggability of the target. DSM1 and DSM59 were shown to be specific inhibitors of *Pf*DHODH, and a series of enzymatic studies including pre-steady-state kinetics and mutagenesis analysis showed that they blocked only the second half of the reaction, the reoxidation of the FMN cofactor, and that they were competitive inhibitors of the second substrate CoQ.[46,51]

8.22.4.2 Early Structure–Activity Relationships and Pharmacokinetic Issues

Metabolic and pharmacokinetic studies were performed on DSM1 to profile any liabilities that would need to be addressed in the medicinal chemistry program to advance the series towards lead status. DSM1 was found to have poor metabolic stability based on in vitro studies in liver microsomes and there was a significant reduction in exposure upon repeat dosing to mice over a 4-day period indicative of likely enzyme induction.[52] We suspected that the naphthyl moiety attached to the triazolopyrimidine ring via a bridging nitrogen was associated with these unfavorable metabolism properties and it was replaced by a series of substituted anilines.[52] A total of 39 compounds were synthesized and tested in both enzyme assays and on the parasite in whole cell assays. The most potent compounds contained large bulky substituents at the para position; ortho substituents were not tolerated but fluorine at the meta position could improve the potency of the best para substituents. Metabolism and pharmacokinetic studies showed that compounds that contained fluorinated hydrocarbons in the para position had the best combination of potency and metabolic stability, and from this analysis DSM74 (**Table 1** and **Fig. 3**) was identified. DSM74 had lower potency against *Pf*DHODH and *P. falciparum* 3D7 parasites than DSM1 but it showed good oral bioavailability and prolonged plasma exposure when dosed in mice. Based on these properties, DSM74 was dosed in a *P. berghei* mouse model of malaria infection where doses of 50 mg/kg twice daily for 4 days were shown to suppress parasitemia during the dosing period, but DSM74 was not curative in this model.[52] Importantly, these studies served as a proof of concept that DHODH inhibitors could be disease modifying for the treatment of malaria in vivo and the project progressed to lead optimization status.

While having found a solution to the poor metabolic stability we had reduced the potency of the series necessitating additional lead optimization to improve potency while retaining metabolic stability. One avenue of research led us to explore substitution and heteroatom rearrangement within the triazolopyrimidine ring.[53] We identified imidazole [1,2-*a*]pyrimidine as a core that also gave good binding affinity to *Pf*DHODH, but metabolic stability and pharmacokinetic properties were not as good as with the triazolopyrimidines so this scaffold was not pursued further. Concurrently, additional efforts were also made to further optimize the aniline group in the context of the triazolopyrimidine core leading to the identification of DSM161 (*para*-SF_5 aniline in place of the CF_3 aniline of DSM74) and DSM190 (*meta*-difluoro, *para*-CF_3 aniline) (**Table 1**), both of which had slightly improved potency and improved pharmacokinetic properties when compared to DSM74.[54] These studies led to the identification of the SF_5-aniline as a naphthyl replacement; however, these compounds still lacked the needed potency for a preclinical candidate and so additional lead optimization was required.

8.22.4.3 X-Ray Structure Determination Informed the Final Step of Lead Optimization

In order to improve the potency of the series it was important to gain structural insight into the binding mode of key triazolopyrimidines bound to *Pf*DHODH. To that end, we solved the X-ray structures of *Pf*DHODH bound to both DSM1 and DSM74.[48] These structures showed that most of the molecule formed a good fit into the inhibitor binding site but importantly, allowed us to see that

Table 1 Comparative properties of key compounds in the series contributing to the identification of DSM265

Compound	Pf*DHODH (nM)*	Hs*DHODH (nM)*	Pf*3D7 (nM)*	HsCl_{int} *(μL/min/mg)*	*Kinetic solubility pH 6.5 (μM)*
DSM1	50	>100,000	80	96	50*
DSM74	300	>100,000	300	8	20
DSM161	100	>100,000	200	<5	70
DSM190	200	>30,000	200	<5	9
DSM330	40	20,000	4	<5*	30*
DSM331	20	2000	10	<5*	30*
DSM338	20	2000	2	7*	30*
DSM267	40	>100,000	6	<5	70
DSM265	20	~100,000	5	4	30

Data were taken from Refs. 46, 52, and 54–56, with the exception of the in vitro metabolism and solubility data for * that have not been previously published.

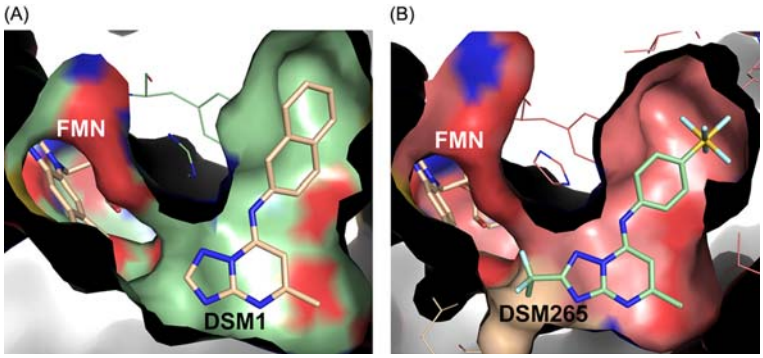

Fig. 4 Comparison of the van der Waals surface between the inhibitor binding site of *Pf*DHODH bound to (A) DSM1 (3I65) and (B) DSM265 (4RX0). The figure shows the van der Waals surface of the triazolopyrimidine binding site to illustrate the channel between the C2 of the inhibitor and FMN. (A) DHODH is shown in *green* and FMN and DSM1 are shown in *tan*. (B) The protein is shown in *salmon* and FMN and DSM265 are shown in *green*. Carbons are colored as indicated, nitrogens are *blue*, oxygens are *red*, fluorine is *light blue* and sulfur is *yellow*. Structures were displayed in PyMol.

there was room to extend into a narrow channel that led from the C2 carbon of the triazolopyrimidine ring towards the FMN cofactor (Fig. 4A). These structural studies provided the insight necessary to improve the potency of the series. Based on this information, we next synthesized a small library of 83 triazolopyrimidine analogs that combined modifications at C2 with several different anilines known to give good binding affinity, including the *para*-CF_3 and *para*-SF_5 anilines found in DSM74 and DSM161, respectively.[55] This work demonstrated that small, halogenated hydrocarbons at C2 (e.g., CF_3, CF_2CH_3, $CF_2CH_2CH_3$) provided the best boast in potency while retaining good metabolic stability. From this effort DSM265, which contains a *para*-SF_5 aniline and a CF_2CH_3 at the C2 position, was discovered (Fig. 3). The X-ray structure of DSM265 bound to *Pf*DHODH was solved demonstrating that it formed good interactions in the channel leading from C2 towards the FMN cofactor as predicted by our design strategy (Fig. 4B).[24] Throughout development of the series we observed very good correlation of activity for *Pf*DHODH versus *P. falciparum* 3D7 in whole cell assays, providing additional evidence that DHODH inhibition was responsible for parasite killing. Several other potent inhibitors with good in vivo properties were also discovered during this final round of lead optimization. These included various combinations of *para*-CF_3-anilines with and without additional *meta*-fluorines and either CF_3 or CF_2CH_3 at the C2 position (Table 1). DSM267 (*para*-CF_3 aniline and CF_2CH_3 at C2) had good properties but was less potent in the SCID mouse in vivo efficacy model than DSM265.[55] Compounds with *meta*-fluorines showed better in vivo potency (e.g., DSM338 (*para*-CF_3, *meta*-difluoro aniline and CF_3 at C2)); however, addition of *meta*-fluorines to the *para*-CF_3 aniline ring led to loss of species selectivity due to inhibition of mammalian DHODHs.[56] Two *meta*-fluorines (DSM331 (CF_2CH_3 at C2) and DSM338 (CF_3 at C2)) led to greater loss of selectivity than one *meta*-fluorine (DSM330 (CF_2CH_3 at C2)), and the rodent DHODHs (mouse and rat) were most vulnerable to inhibition by these compounds. For compounds with two *meta*- fluorines (e.g., DSM338), significant inhibition of the human enzyme was also observed (Table 1). Our X-ray structural and biophysical data for DSM338 suggested that the loss of selectivity was driven by the increasing hydrophobicity of these compounds. Importantly, DSM265 retained selectivity versus human DHODH, although it does inhibit the rodent DHODHs to an extent and these data will be discussed later in the biological activity section. Thus, based on its overall superiority to other potential candidates from the series at the time, DSM265 was nominated as a preclinical development candidate and it has since progressed to clinical development. Subsequently we found that substitution of the SF_5-aniline with halogenated tetrahydro-2-naphthyls led to the identification of compounds that were potent inhibitors of *Pf*DHODH and which showed no activity on human or animal DHODHs.[57] Several compounds from the tetrahydro-2-naphthyl series (most notably DSM426) have the potential to be developed as antimalarial drugs but are less metabolically stable than DSM265 and thus are unlikely to show a long-enough human half-life to support a single dose cure. These analogs have therefore not been progressed as backups to DSM265 but remain as options if needed.

8.22.4.4 DSM265 Synthesis

DSM265 (2-(1,1-difluoroethyl)-5-methyl-[*N*-[4-(pentafluorosulfanyl)phenyl]1,2,4]triazolo[1,5-*a*]pyrimidin-7-amine) is synthesized in four straight-forward steps (Fig. 5). The synthetic method has been well described, including its optimization to generate kilogram quantities of GMP grade material.[24,55] Briefly, the synthetic method starts from aminoguanidine hydrochloride (**1**) and ethyl 3-oxobutanoate (**2**) to generate 2,3-diamino-6-methylpyrimidine-4(3*H*)-one (**3**). Combining **3** with ethyl 2,2-difluoropropionate leads to generation of the triazolopyrimidine ring **4** (2-(1,1-difluoroethyl)-5-methyl-[1,2,4]triazolo[1,5-*a*]pyrimidin-7-ol). Chlorination of **4** followed by addition of 4-(pentafluorosulfanyl)aniline produces the final DSM265 product. All four reactions proceed in good yield. A minor impurity in the final product is DSM430, which contains an additional *meta*-fluorine on the aniline ring and which arises from impurities in the 4-(pentafluorosulfanyl)aniline starting material. The level of this impurity is strictly controlled to remain below 1% in the final product.

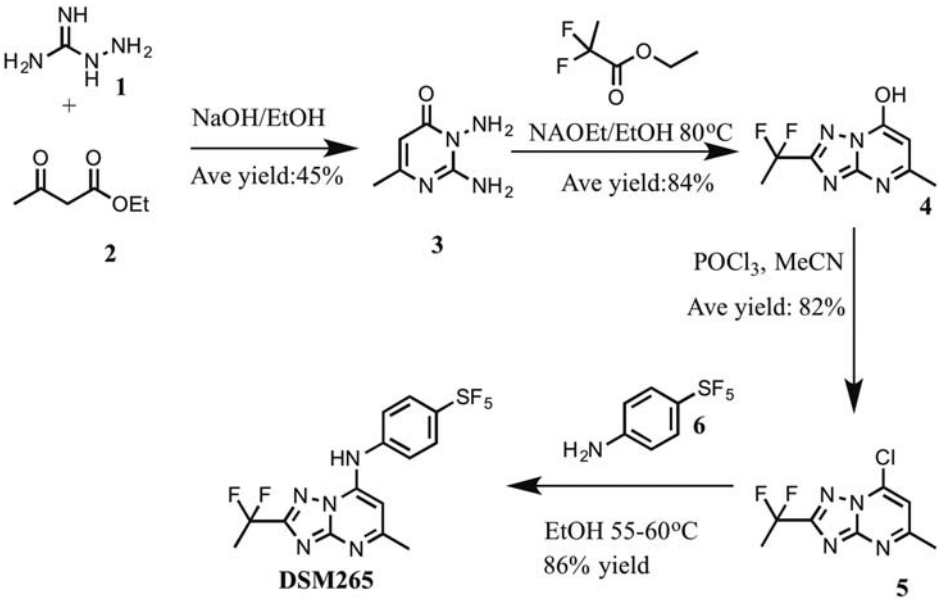

Fig. 5 DSM265 synthetic scheme. The DSM265 synthetic route is displayed with yield values shown for the 12 kg GMP batch.[24]

8.22.5 DSM265 Biological Activity

8.22.5.1 Enzyme Activity Including Mammalian DHODH Selectivity

Recombinant DHODHs, truncated to remove the mitochondrial membrane-spanning domain and any additional sequence to the N-terminus of that region, were expressed as His_6-tagged fusion proteins as described.[24,45,48,54,55] DSM265 was found to be a potent inhibitor of *Pf*DHODH ($IC_{50} = 0.010$ μg/mL).[24,55] The IC_{50} is approximately twofold higher for the *P. vivax* enzyme (Table 2), which may translate to reduced activity on *P. vivax* in the field. Importantly, DSM265 does not show significant inhibition of human DHODH, strongly suggesting that on-target toxicity will not be a concern for clinical use (Table 2). DSM265 was also tested on the enzyme from a range of species potentially important for toxicological studies to support human clinical trials.[24] It showed a range of activities on the rodent and dog enzymes, but like the human enzyme, the rabbit and pig DHODH are not sensitive to DSM265 inhibition (Table 2). It remains much less potent on even the most sensitive mammalian enzyme than on the *Plasmodium* enzymes, but the observation of activity on the rodent and dog enzymes did require careful consideration when selecting species for toxicity studies as described later.

8.22.5.2 X-Ray Structure of DSM265 Bound to *Pf*DHODH

The X-ray structure of DSM265 bound to *Pf*DHODH was solved providing insight into key interactions that drove good binding towards *Pf*DHODH and selectivity against human DHODH.[24] The structure was solved for the N-terminally truncated protein that removes the mitochondrial membrane-spanning domain. DHODH folds into a β/α-barrel with an N-terminal extension that includes two highly hydrophobic α-helices, which presumably pack against the mitochondrial membrane, and which form part of the inhibitor binding site (Fig. 6A). DSM265 sits between these helices and the FMN cofactor, which is bound in the center of the β/α-barrel. Substrate L-orotate is bound on the opposite face of the FMN cofactor compared to DSM265. The DSM265 binding site is likely to overlap the CoQ binding site based on data collected for DSM1 (described earlier). The triazolopyrimidine ring of DSM265 is bound between the only residues in the pocket (R265 and H185) that have side chains that can form hydrogen-bonding interactions. These residues are conserved across all type II DHODH enzymes. DSM265 forms hydrogen bonds with both of these residues (H185 to the bridging nitrogen and R265 to a pyrimidine nitrogen) and these interactions are thought to provide significant binding energy to the interaction of DSM265 with *Pf*DHODH (Fig. 6B). Indeed, in related studies we found by X-ray structure analysis that the inability of human and rat DHODH to form a direct hydrogen

Table 2 DSM265 inhibition data for recombinant *Plasmodium* and mammalian DHODHs

Species	*P. falciparum*	*P. vivax*	*Human*	*Mouse*	*Rat*	*Dog*	*Rabbit*	*Pig*

(A) Cartoon diagram showing the overall structure. α-Helices are shown in *salmon*, β-sheets are shown in *tan*, orotate (Oro) (*salmon*), FMN (*tan*), and DSM265 (*green*) are shown as spheres. (B) Inhibitor binding site of DSM265 showing key interactions within the 4 Å shell. Hydrogen bonds are shown by *dashed lines* with indicated distances. *Pf*DHODH is *salmon*, FMN is *tan*, and DSM265 is *green*. (C) Comparison of the DSM265 *Pf*DHODH inhibitor binding site with the human DHODH A77 1726 (1D3H) binding site. Limited residues in the 4 Å shell of DSM265 are shown. Structures were aligned in PyMol using the align command. *Pf*DHODH is in *salmon*, human DHODH is in *blue*, *Pf*DHODH FMN and orotate are shown in *tan*, DSM265 is shown as *green sticks* with transparent spheres. A77 1726 from the human DHODH structure is shown in *blue* and the FMN and orotate from the human structures are shown as *blue lines*. Non-carbon atoms are colored as described in **Fig. 3**.

bond between H56 (H185 equivalent) and analogs from the series contributes to weaker binding to the mammalian enzymes.[47] The remaining DSM265 binding pocket is entirely hydrophobic and the aniline ring of DSM265 forms edge-to-face stacking interactions with F227 and F188, as well as making a number of additional van der Waals contacts with other hydrophobic residues in the binding pocket (primarily leucine and methionine residues) (**Fig. 6B,C**). The CF_2CH_3 group on the C2 carbon of the triazolopyrimidine ring makes close contacts with I263 and I272. These interactions are likely to contribute significant binding energy to the interaction. The structural basis for the species selectivity, which leads to >5000-fold better binding to *Pf*DHODH versus the human enzyme, is also apparent from the structure. A number of amino acid differences are found between the *P. falciparum* and human enzymes within the 4 Å van der Waals radius of DSM265 that change the shape and nature of the binding site (**Fig. 6C**).

8.22.5.3 In Vitro Activity Against Parasites

DSM265 has potent activity against *P. falciparum* blood-stage parasites in phenotypic assays, with similar efficacy observed against both drug-sensitive and drug-resistant strains (EC_{50} in a 72 h assay in albumax media ranged from 0.00066 to 0.0041 μg/mL) with an average of 0.0018 μg/mL.[24] Considering the data from reference strain *P. falciparum* 3D7 (**Table 3**) and assuming that the EC_{99} can be approximated as $9\times$ EC_{50}, these assays show that an unbound concentration of approximately 0.0028 μg/mL is sufficient to completely kill parasites in this test system. In order to assess if the parasite-based activity was cytocidal or cytostatic, washout and regrowth studies were performed after incubation of parasites with DSM265 for 24–120 h. These studies showed that after a 24–48 h lag phase, DSM265 had a kill rate that was similar to that for atovaquone and pyrimethamine, and the time required for >99.9% parasite clearance was ~80 h of drug exposure.[24] Thus, DSM265 does not kill as quickly as the artemisinin derivatives (which provide complete kill in <24 h[58]), but once past the lag phase it demonstrates a medium rate of kill similar to other clinically used antimalarial drugs. The mechanism of cell

Table 3 Activity of DSM265 on *P. falciparum* in blood and liver stages

Assay	*Total conc. (μg/mL)*	*Unbound conc. (μg/mL)*[a]
In vitro blood-stage assays		
P. falciparum 3D7 72 h assay—EC_{50} (EC_{99})	0.0018 (0.016)	0.00031 (0.0028)
P. falciparum 3D7 in vitro washout/regrowth assay—MPC	0.014	0.0020
In vitro liver-stage assays		
P. falciparum schizont 48 h assay—EC_{50}	0.0057	0.0012
In vivo SCID mouse efficacy		
P. falciparum—MPC plasma	1.1	0.0011

[a]Data were corrected for protein binding in the assay media or in plasma.
Data were taken from Ref. 24. *EC_{50}*, concentration required to inhibit 50% of parasite growth. The EC_{99} was estimated as $9\times$ EC_{50}.
MPC, minimum concentration required to achieve the maximum rate of kill.

killing was investigated and as expected, the transgenic *P. falciparum* line expressing yeast DHODH was resistant to DSM265, confirming that its mechanism of parasite killing is DHODH inhibition.[55] Drug synergy studies showed that DSM265 activity was additive with a number of clinically used antimalarial agents and no synergy nor antagonism was observed in these studies.[24]

8.22.5.4 Efficacy in the *P. falciparum* SCID Mouse Model

The gold standard in vivo assay for testing antimalarial drug candidates is currently a SCID (severe combined immune deficiency) mouse model which can be engrafted with human erythrocytes to support infection with *P. falciparum*.[59] When given orally twice daily for 4 days with parasitemia measurements 24 h after the last dose, DSM265 showed potent in vivo activity with an ED_{90} of 3.0 mg/kg/day. The minimum dose that gave the maximum rate of parasite killing was 13 mg/kg/day. The minimum total blood concentration at this dose was 0.53 μg/mL (plasma concentration of 1.1 μg/mL), which corresponds to a minimum unbound plasma concentration of 0.0011 μg/mL (**Table 3**).[24] This concentration represents the minimum concentration that results in the near maximal rate of parasite death and is frequently referred to as the minimum parasiticidal concentration (MPC). The unbound MPC estimated from the in vivo SCID mouse study (0.0011 μg/mL) is very similar to the unbound EC_{99} (0.0028 μg/mL) obtained in the standard in vitro assay as well as the in vitro estimated unbound MPC (0.002 μg/mL) from the washout/regrowth assay, providing confidence in the predictive value of these studies to support human dose predictions (see the following text).

8.22.5.5 Other Plasmodium Stages

From the standpoint of malaria elimination and eradication, assessing the activity of drug candidates on life cycle stages other than the blood stage has become an important priority in an attempt to identify new drugs that not only treat the infection, but that can also be used for prevention and for reducing transmission. DSM265 was tested against *P. falciparum* liver stages where it was found to have potent activity in a cultured hepatocyte model, with similar efficacy to that seen against the blood stage (**Table 3**).[24] These data suggest that DSM265 will be useful not only for treatment of malaria but also for prevention. While DSM265 had activity against liver-stage schizonts, it was not effective against in vitro liver forms most closely related to the dormant hypnozoites present with *P. vivax* infection. DSM265 also did not show activity against the *P. falciparum* sexual stage gametocytes, which is consistent with its mechanism of action. Both blood and liver stages (apart from the dormant stages) undergo many rounds of replication, and DSM265 has been shown to block progression of the life cycle in the early trophozoite immediately before RNA and DNA replication required for cell growth.[24] In contrast, the gametocyte stages in the mammalian host are nonreplicative, and late stage gametocytes are essentially metabolically inactive.[60] Consistently, DSM265 does show activity against the mosquito stage V oocyst, which is also a replicative form, suggesting that DSM265 taken up in the mosquito blood meal could potentially exert some transmission-blocking activity.[24]

8.22.5.6 Mechanism and Frequency of Resistance

The mechanism and frequency of resistance has been evaluated in vitro for both DSM1 and DSM265.[24,61] Resistant parasites were selected in a single step using multidrug-resistant strains (Dd2 and K1) that have a greater propensity to develop resistance. Resistant parasites could be selected using a drug concentration of $3\times$ EC_{50}, but at DSM265 concentrations of $8\times$ EC_{50} and above, resistant parasites were not obtained. Both gene amplification and point mutations in the DHODH gene were observed in these studies, providing additional validation of the target. The frequency of resistance at $3\times$ EC_{50} ranged from 10^5 to 10^7, which is similar to what has been observed for atovaquone. Given the potential for resistant parasites to emerge in vitro, careful monitoring for resistance is an important consideration in the early clinical studies that are underway. These studies also highlight the importance of marketing DSM265 as a combination partner with another antimalarial agent that has similar pharmacokinetic properties to help prevent the development of resistance in the field.

8.22.6 DSM265 Pharmacokinetic Properties to Meet the Goal of Single Dose Cure

8.22.6.1 Physicochemical Properties and In Vitro ADME Characteristics

With the exception of its high log *D* (4.0), DSM265 generally meets accepted "drug-like" criteria in terms of its molecular weight (415 Da), polar surface area (55 Å^2), number of hydrogen bond donors and acceptors (1 and 4, respectively), and freely rotatable bonds (4).[62,63] DSM265 displays high permeability across Caco-2 cell monolayers (P_{app} 50–60 $\times$ 10^{-6} cm/s) with no evidence for efflux. The primary physicochemical liability of DSM265 is its poor aqueous solubility ($\sim$5 μg/mL in simulated fasted state intestinal fluid), leading to it being classified as a BCS Class II molecule (high permeability, low solubility).[24] DSM265 is chemically stable in the solid state but is unstable when solutions are exposed to simulated sunlight.

Consistent with its high log *D*, DSM265 is highly bound to plasma proteins (>99% in human mouse and dog plasma and $\sim$98% in rat plasma).[24] Throughout the program, binding properties were also assessed in various protein-containing media used for in vitro activity testing to enable conversion of total concentrations to unbound concentrations to facilitate comparisons across assays and with the in vivo data. The high binding to plasma proteins resulted in a low blood to plasma partitioning ratio, ranging from 0.7 to 0.8 across species, except in the SCID mouse where the value is 0.5 due to the high hematocrit. When assessed for metabolic stability in vitro using hepatic microsomes or cryopreserved hepatocytes, DSM265 exhibited minimal degradation with an intrinsic clearance of <5 μL/min/mg microsomal protein and <1 μL/min/10^6 hepatocytes for each of the species tested.[24] The major metabolite identified from pooled in vivo plasma samples was DSM450 formed by oxidation of the methyl side chain.[24] This metabolite is approximately 40-fold less active than DSM265 against parasites and so would not be expected to contribute to the efficacy profile.

8.22.6.2 In Vivo Pharmacokinetic Studies in Preclinical Species

Pharmacokinetic studies were conducted in a number of preclinical species to inform the design of preclinical efficacy and toxicology studies, to understand the impact of poor solubility on oral absorption and bioavailability, and to provide a basis for human pharmacokinetic and dose predictions. Across all species tested, clearance following intravenous (IV) administration was low at less than 10% of hepatic blood flow[24] which is qualitatively consistent with the low rate of degradation detected in vitro following incubation with hepatic microsomes and hepatocytes. As would be expected given its log *D*, there was no evidence of renal elimination so hepatic metabolism is likely the main route of elimination. The half-life after IV administration increased from about 3 h in mice, to around 12 h in rats, but could not be determined in dogs due to evidence for enterohepatic recirculation. In monkeys, the half-life was approximately 45 h, providing confidence that there would likely be a further increase in half-life in humans.[24]

As shown in **Fig. 7**, the half-life following oral dosing increased from approximately 3 h in mice to 15 h in rats and more than 20 h in dogs. DSM265 exhibited moderate oral bioavailability following administration of a simple suspension formulation generally ranging from 20% to 50% across species.[24] There was evidence of a food effect in dogs, with area under the curve increasing approximately twofold in the fed state compared to that in fasted dogs (**Fig. 7B**). These initial pharmacokinetic results provided evidence that oral bioavailability was incomplete, most likely due to the poor aqueous solubility of DSM265. Several different formulation approaches were considered to address the low solubility including salt formation, particle size reduction, and an amorphous spray dried dispersion (SDD), with the latter demonstrating the greatest benefit for improving bioavailability.[24] As shown in **Fig. 7C**, exposure in fasted dogs increased approximately eightfold following oral dosing of the SDD formulation compared to a simple suspension formulation. In vitro, the SDD formulation improved the solubility of DSM265 in simulated fasted state intestinal fluids by approximately 20-fold and maintained this level for a period of at least 90 min. Given the high permeability of DSM265, even a short-term increase in solubility would likely be sufficient to improve absorption. These results provided confidence that the solubility-limited absorption could be overcome by disruption of the crystal lattice thereby improving both dissolution and solubility over the timeframe necessary for oral absorption.

8.22.6.3 Human Pharmacokinetic and Dose Predictions

Estimation of the human dose and dosing frequency required an estimate of the target concentration required for efficacy and an estimation of human pharmacokinetic parameters (primarily clearance). In vitro and in vivo activity models all pointed to an unbound concentration of 1–2 ng/mL being needed to achieve the maximum rate of parasite death (**Table 3**). Correcting this unbound concentration to a total plasma concentration, the target efficacious plasma concentration in humans is therefore 1–2 μg/mL. Since DSM265 exhibits a moderate rate of parasite kill, it was estimated that this target concentration would need to be maintained for a minimum period of about four parasite life cycles or 8 days.[64]

To estimate human clearance, we first considered the microsomal and hepatocyte stability data following scaling and application of the well-stirred model of hepatic clearance taking into account binding to both plasma proteins and proteins present in the in vitro incubation media and the blood to plasma ratio.[65] As has been reported previously for drugs that undergo minimal degradation in in vitro test systems,[66] this approach led to an underestimation ($\sim$20-fold) of the measured in vivo clearance in mice, rats, and dogs and we therefore considered this to be an unacceptable approach for predicting human clearance. We instead used allometry of the unbound IV clearance across the available species to estimate a human clearance of 0.25 L/h. To obtain an estimation of the in vivo absorption and distribution properties, measured physiochemical properties (log *D*, solubility of the SDD formulation in simulated intestinal fluids), permeability, plasma protein binding, and blood to plasma partitioning along with the predicted

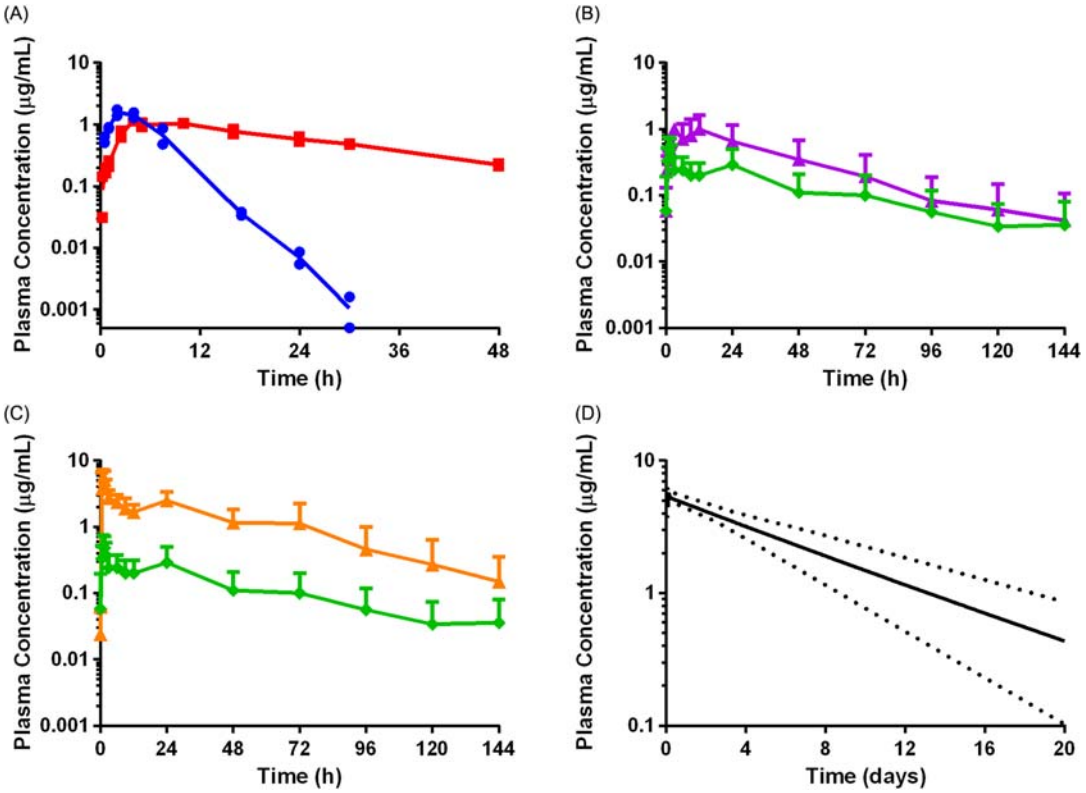

Fig. 7 Pharmacokinetic profiles in preclinical species and predicted human profile. Plasma pharmacokinetic profiles following a 10 mg/kg oral dose of DSM265 as a suspension formulation. (A) Male Swiss outbred mice (*blue*) or male Sprague Dawley rats (*red*); (B) fasted (*green*) or fed (*purple*) male beagle dogs. (C) Administration of a free base suspension (*green*) or spray dried dispersion (*orange*) to fasted male beagle dogs. (D) Predicted human profile following an oral dose of 250 mg along with the predicted 5th and 95th percentiles (*dotted lines*) for the simulated profile (Gastroplus). Data for mice ($n=2$ mice per time point) and rats ($n=2$) are shown as individual data points and data for dogs represent the mean ± SD ($n=6$). Graphs were generated from data reported in our published work.[24]

human clearance were input into a physiologically based pharmacokinetic (PBPK) model (GastroPlus, version 9.0). This software package uses the ACAT model[67] for predicting absorption, and the human physiological fasting condition was selected. A human PBPK model was used with clearance assumed to occur exclusively in the liver. Tissue disposition was simulated using the perfusion rate limited model by Rodgers and Rowland.[68,69] The model provided an estimate of the volume of distribution at steady state (46 L) and the half-life (126 h). We also used the PBPK model to simulate human plasma profiles along with the 5th/95th percentiles for a cohort of 25 males and females aged between 20 and 40 using the population variability data within the software (Fig. 7D). These simulations suggested that a single dose in excess of approximately 250 mg would likely maintain plasma concentrations above the target 1–2 μg/mL for a period of at least 8 days. The Phase I human clinical study has subsequently been completed at single doses (25–1200 mg range) and is currently reporting. Preliminary results for cohorts dosed from 25 to 400 mg confirm that the human half-life is ~104 h (range 60.4–141) and that a dose of 250–400 mg is likely to provide a single dose cure.[70] Thus, the long half-life and acceptable dose estimation, combined with both blood- and liver-stage activity, suggested that DSM265 was a good candidate for both treatment and chemoprotection. For use within a treatment scenario, DSM265 would ideally be combined with a fast-acting compound having a similar pharmacological duration of cover.

8.22.7 Safety Studies and the Importance of Knowing the Target

The safety of DSM265 was evaluated using in vitro safety pharmacology studies and exploratory multi-dose studies in mice and dogs.[24] There were no significant safety pharmacology signals. An initial positive response in the hERG patch clamp study (IC_{50} ranged from 0.7 to 3 μg/mL) was mitigated by completion of both a rabbit wedge study and a dog cardiovascular study, both of which showed that there was no propensity for cardiac risk under the conditions tested. Additionally, because of the high plasma protein binding of DSM265 in humans, the unbound drug concentration at the efficacious dose is expected to be 70–320-fold lower than the IC_{50} in the patch clamp study, suggesting a very low risk. DSM265 was well tolerated in mice and dogs in exploratory 7 and 10 day studies, respectively.[24,61] These studies in addition to subsequent 14-day GLP studies in these same species supported the

advancement of DSM265 into Phase I and II clinical studies. Of note during preliminary exploratory toxicity studies in rats, we found that rats tolerated DSM265 less well than mice and dogs. This result was traced back to the findings that rats suffer from both a low IC_{50} on rat DHODH and higher unbound concentrations compared to other species. As neither of these properties are reflective of the situation in humans, it was determined that rats were an inappropriate species for evaluating the toxicity of DSM265 and mice and dogs were used for the GLP studies to enable the first in man dosing. However importantly, these studies illustrate the value of knowing the protein target of a drug candidate. Knowledge of the target not only assisted the lead optimization, but it was also key to our ability to understand the toxicity that was observed in rats and to mitigate this risk through an understanding of the underlying factors.

8.22.8 Conclusion and Perspectives

DSM265 is a new entity for the treatment of malaria from the triazolopyrimidine structural class that was identified through a target-based screen followed by structure-guided lead optimization. It is the first inhibitor targeting DHODH to be developed for the treatment of malaria. The novel mechanism of action allows it to be active against *Plasmodium* species in the field that are resistant to currently used antimalarial agents. DSM265 has potent blood- and liver-stage activity and thus is expected to be useful for either treatment or chemoprevention of malaria. Its long predicted half-life in humans ($\sim$100 h) has now been confirmed and this supports its use as either a single dose cure or for once weekly prophylaxis. Due to the ability of the malaria parasite to develop resistance to drug therapies, all new drugs will be introduced into the clinic as combinations. Thus, the product development plan for DSM265 is to identify a suitable partner compound for its use in either treatment or prevention of malaria. DSM265 is currently in Phase II clinical development to assess both human safety and efficacy against *P. falciparum* and *P. vivax* malaria (http://www.mmv.org).

8.23.1 Introduction

The hepatitis C virus (HCV) is a heptatrophic virus that chronically infects approximately 150 million individuals worldwide. Chronic HCV infection is known to cause liver cirrhosis and hepatocellular carcinoma (HCC) and is a leading cause of liver transplants worldwide. Approximately 700,000 individuals globally die from HCV-related liver disease.[1]

The HCV, originally known as non-A non-B hepatitis, was identified and its genome was elucidated in 1989.[2,3] This work led to screening of the human blood supply that has prevented transmission of HCV by blood transfusion. However, HCV continued to be spread through the sharing of needles by injection drug users, unprotected sex, and accidental needle sticks.

The HCV is a single-stranded positive-sense RNA virus of the *Flaviviridae* family of viruses in the genus *Hepacivirus*. There are six major HCV genotypes (GT1–6), the distribution of which varies globally with GT1, 2, and 3 viruses being predominant in North America and Europe. In Africa, HCV infections are almost exclusively genotypes 4 and 5 virus, and genotype 6 virus is most prevalent in Asia and other parts of the world.[4] No protective vaccine exists for HCV.

Until 2011 the standard of care for treating HCV infection was the use of injectable interferon (IFN) and oral ribavirin (RBV).[5,6] This therapeutic regimen provided only a modest 40% cure rate after 48 weeks of therapy and an undesirable side effect profile that included flu-like symptoms, severe anemia, and neurological problems. The side effects were so intolerable that the patient discontinuation rate was exceptionally high. In addition the IFN-containing therapies were shown to have limited effectiveness in difficult to treat patient populations that included African-American patients and patients that harbor a TT or TC allele 3 kb upstream of the IL28B gene in a region that encodes the type III interferon, IFN-λ3.[7,8]

The HCV genome encodes three structural and seven nonstructural proteins (**Fig. 1**). The seven nonstructural proteins play a wide variety of roles in enabling the viral life cycle. These include the processing of the genome-derived polypeptide into the individual viral nonstructural proteins (NS2 protease, NS3 protease, and NS4 cofactor) and formation of the viral replication complex associated with the endoplasmic reticulum (NS4B, NS5A, and NS5B). The NS3 protease also plays a role in how the virus controls the host innate immune response.[9] HCV has a very high error-prone rate of replication which does not incorporate a proof-reading function. Therefore, HCV exhibits a high mutation rate.[10,11]

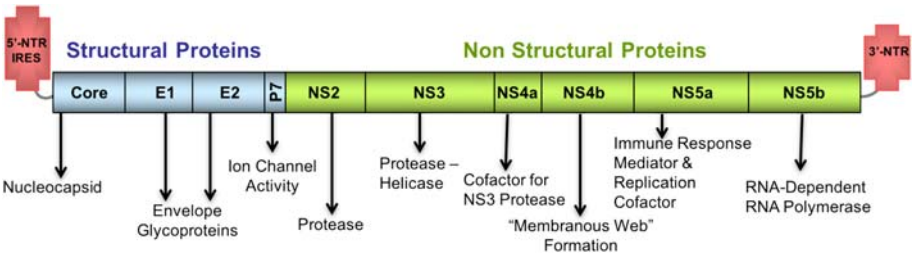

Fig. 1 HCV genome, structural proteins, and nonstructural proteins.

By 1999 with the development of the HCV whole cell replicon assay, the search for direct acting antivirals against HCV became more feasible. However, the search for curative therapies posed many questions which included whether IFN could be eliminated from therapy and whether the duration of therapy could be shortened from 48 weeks. Furthermore, it was not obvious which HCV drug targets were the most relevant for delivering an improved cure rate or what would be the best combination of direct acting antivirals for achieving cures. Other concerns included whether a therapeutic regimen could be identified that covered all viral genotypes and if drug resistance to new therapies would become a major issue. These questions were ultimately answered with the approval of NS5B polymerase inhibitor sofosbuvir (Sovaldi®) **1** plus ribavirin **2** for the treatment of HCV patients infected with genotypes 2 and 3 virus and subsequently with the introduction of Harvoni®, the fixed-dose combination of sofosbuvir **1** and the NS5A inhibitor, ledipasvir **3**, for the treatment of genotype 1 patients.

This article will discuss the discovery and development of sofosbuvir (Sovaldi®) and ledipasvir and the development of the fixed-dose combination agent Harvoni® as a curative therapy for HCV patients.

8.23.2 The Discovery of Sofosbuvir

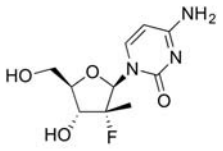
8.23.2.1 Target Rationale: HCV NS5B RNA-Dependent RNA Polymerase

The HCV NS5B RNA-dependent RNA polymerase (RdRp) is one of seven HCV nonstructural proteins and is a viral specific enzyme that is essential for HCV replication (Fig. 1).[12] The NS5B RdRp is a 66 kDa protein that exhibits the typical palm–finger–thumb structural motif found in many viral polymerases. The Gly317–Asp318–Asp319 (GDD) catalytic motif found in the palm domain of the HCV NS5B RdRp is an invariant element in RNA viral polymerases and is highly conserved across all HCV genotypes.[13] Therefore the HCV RdRp provided an ideal target against which to develop a pan-genotypic, direct-acting-antiviral (DAA) with a high barrier to resistance.

8.23.2.2 A 2′-F, 2′-*C*-Methylnucleoside Inhibitor of HCV Replication

The path forward for the development of a pan-genotypic and high barrier to resistant inhibitor of the HCV NS5B polymerase began with the idea of using a nucleoside analog that resembled the viral polymerase's natural substrate. However, pursuing a nucleoside

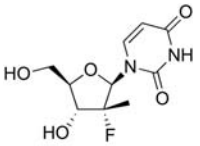
drug discovery strategy posed a number of obstacles, one being the complexity of nucleoside metabolism necessary to effect its mechanism of action and the other being selectivity for the viral polymerase over host polymerases. The activity of a nucleoside analog is dependent on the generation of the nucleoside triphosphate in the cell because it is this triphosphate that acts as the alternate substrate for the viral polymerase, and consequently, inhibits viral replication. Early work identified the unique 2′-α-F-2′-β-C-methyl substitution as having anti-HCV activity, leading to the novel nucleoside PSI-6130 **4**, a 2′-F-2′-C-methylcytidine nucleoside.[14] Extensive structure–activity relationship (SAR) work showed that any modification to the ribose or base portion of this nucleoside did not lead to nucleosides with improved potency.[15]



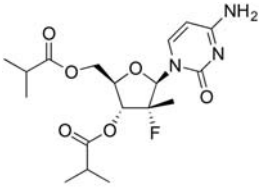
PSI-6130
4

PSI-6130 was shown to be a highly selective inhibitor of HCV replication and functioned as a nonobligate chain terminator.[16] It was also shown to be highly selective for inhibiting HCV over other viruses including human polymerases. The S282T NS5B mutation was identified as the only significant resistant mutation after extended passaging.[17,18] In combination studies with other anti-HCV agents, PSI-6130 showed additive or synergistic activity. The preclinical safety profile supported progression into human clinical studies; however, PSI-6130's pharmacokinetic profile demonstrated modest bioavailability and extensive metabolism into an inactive uridine derivative **5**.[15]

After clinical confirmation of an unfavorable pharmacokinetic profile for PSI-6130, an attempt to overcome this drug's limitations led to the development of a prodrug. This prodrug, RG7128 (mericitabine) **6**, which masked the 3′- and 5′-hydroxyl groups of the nucleoside as their isobutyrate esters did improve oral bioavailability, but formation of significant amounts of the inactive uridine metabolite still persisted.[19,20] However, this prodrug did demonstrate proof of concept for the 2′-F, 2′-methyl nucleosides as inhibitors of HCV replication in humans.[15,21,22] It also showed for the first time that a DAA was effective not only against genotype 1 virus but also against genotypes 2 and 3 virus. Furthermore, within these clinical studies it was observed that no resistant virus emerged when patients were treated with RG7128 and the drug was well tolerated.

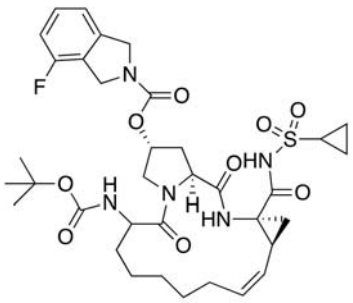


PSI-6206
5



RG7128
(Mericitabine)
6

A seminal study evaluating the all DAA combinations of mericitabine with an HCV protease inhibitor, danoprevir **7**, showed that an IFN-free DAA combination could produce viral load declines (-4.9 to $-5.1\ \log_{10}\ \mathrm{IU\ mL^{-1}}$) on par with regimens containing PEG-IFN/RBV + protease inhibitors.[23] This observation laid the groundwork for future PEG-IFN free all DAA regimens. Unfortunately, because of its modest potency, PK profile, and short intrahepatic triphosphate half-life that required administration of a significant amount of drug, mericitabine lacked the ideal profile for a successful HCV therapy.



Danoprevir
7

8.23.2.3 Rationale and Design of a Liver-Targeted Nucleotide Prodrug

To overcome the deficiencies with mericitabine, it was determined that a next generation agent would need to demonstrate better intrinsic potency, a PK profile that supported once-daily dosing, a longer intrahepatitic triphosphate half-life, and if possible enable liver targeting while maintaining the clean safety profile, high selectivity for HCV, and a high barrier to resistance exhibited by the 2′-F-2′-*C*-methyl nucleoside substitution. These objectives led to a complete redesign of the nucleoside inhibitor with attention drawn to an unlikely compound, the inactive uridine metabolite of PSI-6130 **4**, PSI-6206 **5**. It had been determined that although the uridine nucleoside PSI-6206 was inactive in the replicon assay, its triphosphate derivative was active as an inhibitor of the HCV polymerase in a biochemical assay (Fig. 2).[19,20] In addition the half-life of the uridine triphosphate in primary hepatocytes was determined to be significantly longer than the triphosphate of the cytidine derivative indicating the potential for increased potency and less frequent dosing in vivo. Ultimately, the inactivity of the uridine nucleoside was attributed to it not being enzymatically

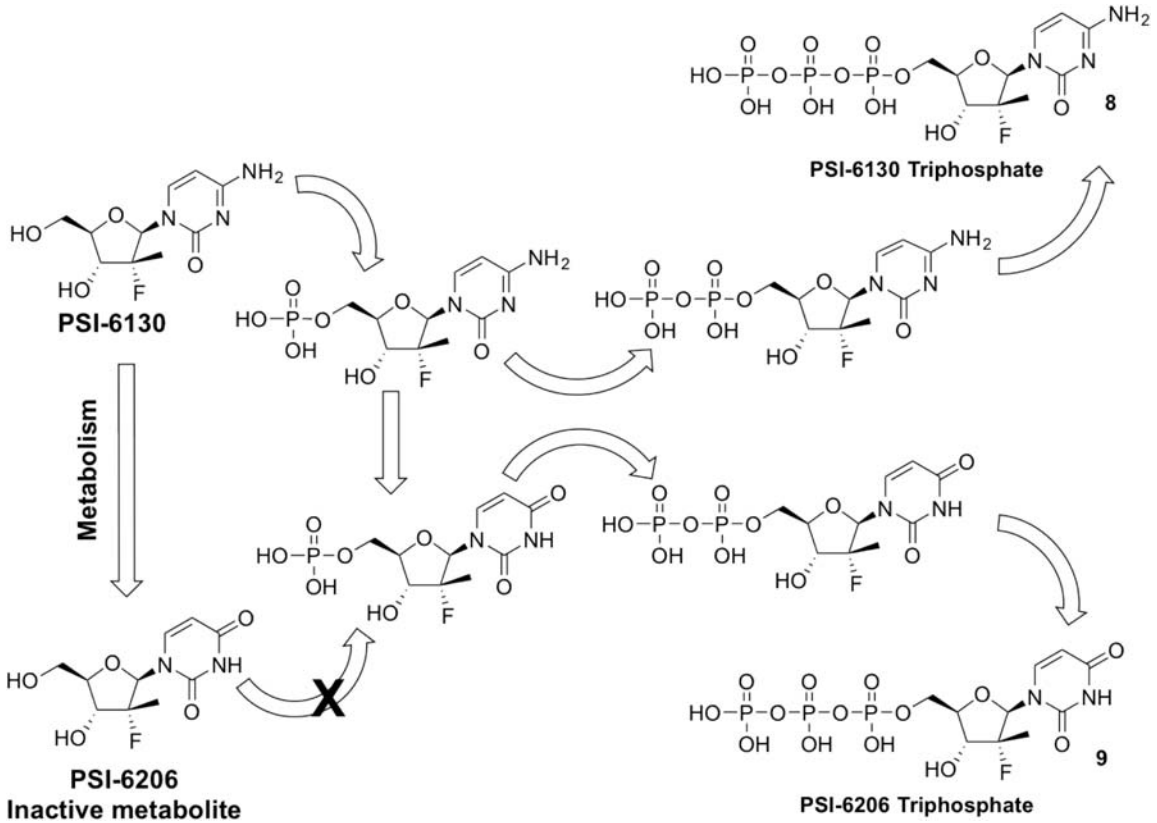


Fig. 2 Metabolism of PSI-6130. Formation of the HCV inactive metabolite PSI-6206 and the formation of the active metabolite triphosphates.

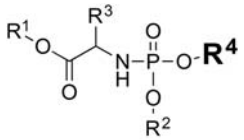
converted to the monophosphate precursor of the triphosphate. The solution to accessing the uridine triphosphate in cells was to find a way of bypassing the blocked phosphorylation step and deliver the monophosphate into hepatocytes (Fig. 2). However, the delivery of a highly charged and chemically and enzymatically unstable molecule was not going to be a simple task.

A possible solution to the delivery of a nucleoside monophosphate into liver cells was to mask the phosphate group such that the molecule is able to traverse biological membranes and is stabilized to chemical and enzymatic degradation. With the eventual loss of the mask in hepatocytes, the nucleoside monophosphate could then be further metabolized to give the active triphosphate. To achieve this objective an appropriate prodrug strategy would need to be implemented.

In considering prodrug options not only did we want to consider the need to mask a phosphate group to impart membrane compatibility and stability but we also introduced the requirement that the prodrug should enable liver targeting (Fig. 3). The concept of designing liver targeting character into a molecule was an aspirational objective and one that had yet to be realized in HCV drug discovery, notwithstanding the fact that a nucleoside phosphate had never been successfully delivered and shown to be effective in a human clinical setting. In contemplating the concept of live targeting, it became apparent that this might be achievable by leveraging liver first pass metabolism. However, the issue became how to build all these requirements into a single molecule.

When considering all of the numerous phosphate prodrug options, the phosphoramidate prodrug construct **10** was thought to potentially provide the best possibility of meeting the requirments.[24] Conceptually, first pass liver metabolism of the terminal ester of the phosphoramidate moiety would initiate a cascade of chemical and enzymatic events that would ultimately result in 2′-F-2′-*C*-methyluridine 5′-monophosphate being trapped within hepatocytes (Fig. 3). However, there still existed the significant hurdle of developing a prodrug that would be stable in the gastrointestinal tract, get sufficiently absorbed through the gut, reach the liver intact, and have an acceptable safety profile (Fig. 3). To predict a priori that the phosphoramidate could deliver on all of these requirements was not possible. There was no literature precedent to support delivery in a human, liver targeting or human safety. Consequently, an extensive structure activity exploration and preclinical assessment was undertaken to determine if we could find the right molecule that could achieve the outcome we desired.[24]



10

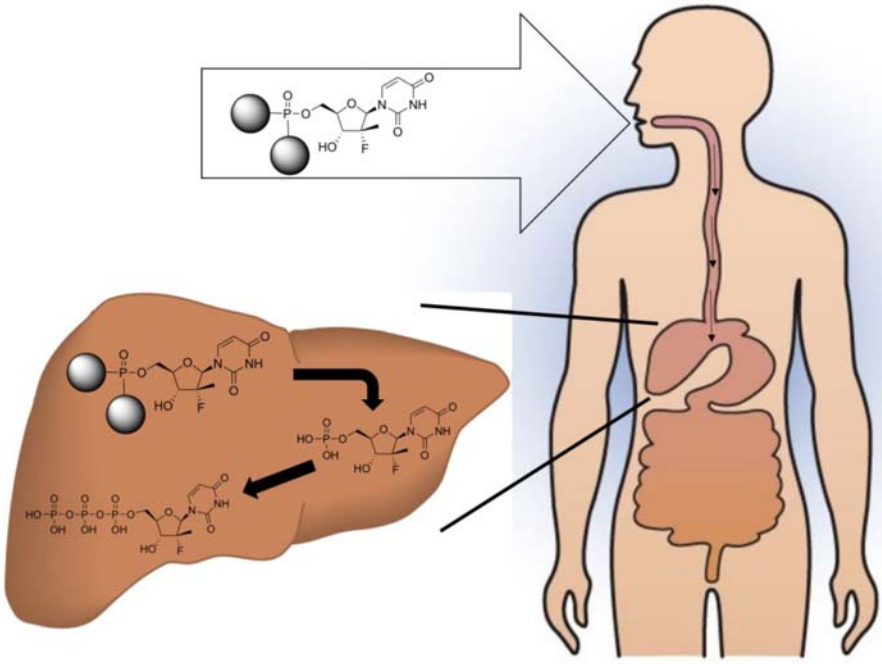


Fig. 3 The concept of a phosphate prodrug and liver first pass metabolism.

8.23.2.4 Prodrug Optimization and Preclinical Evaluation

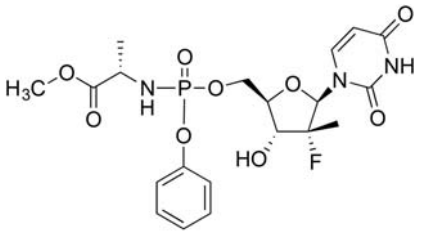
We concluded that to develop the ideal drug candidate, a preclinical assessment scheme would be needed to consider not only whole cell HCV replicon activity but also cellular toxicity, stability in gastric fluids, and plasma and liver enzyme stability. Other key in vitro studies included assessment of the desired triphosphate levels in primary hepatocytes. Our view was that the ideal drug candidate would demonstrate submicromolar inhibition of HCV replication in the whole cell replicon assay, no cellular toxicity, stability in gastric fluid and plasma, low stability against liver enzymes, and the production of high intracellular triphosphate levels.

Because of historic concerns around nucleoside-based drugs, safety profiling became an important consideration as the preclinical evaluation progressed. This led us to undertake extensive evaluation of cytotoxicity across many different cell lines, and mitochondrial and bone marrow toxicity assessments to address the potential for off-target effects typically seen with nucleosides.

In vivo assessment relied on the development of a surrogate animal model. Chimpanzees were the only HCV animal model available at the time but access to this model was limited. Consequently, we developed an in vivo model that relied on quantitation of nucleoside triphosphate levels in the liver of animals when the drug candidates were administered orally.[24] This animal model was based on the assumption that high liver triphosphate levels correlated with improved efficacy. This model allowed us to assess many compounds and compare pharmacokinetics and efficacy across different species.

With our compound evaluation scheme in place, a structure–activity study of the phosphoramidate moiety was undertaken.[24] The strategy was to evaluate the three variable regions of the phosphoramidate moiety where each compound was first prepared as a diastereomeric mixture at phosphorus. With no available synthetic methods for accessing diastereomerically pure phosphoramidates, the program would have had to develop such methods and slow down progression to proof of concept in humans. Thus this strategy allowed us to more rapidly execute the SAR study and quickly reach a proof of concept for this prodrug approach. It was realized that if the proof of concept was achieved, then we would eventually have to face the task of developing a single isomer approach to this class of molecules.

We were encouraged by the whole cell replicon activity of the first 2′-F-2′-*C*-methyluridine 5′-monophospate phosphoramidate prodrug, PSI-7672 **11**, but to assess whether this prodrug approach would meet all the criteria necessary for a clinical candidate, further development had to be done.[25] As we progressed with the SAR study, there was a constant awareness and concern of potential toxicities that could result from prodrug release products in the liver. This led to a careful selection of prodrug substituents based on known toxicities. The SAR exploration led to the following observations.



PSI-7672

11

The α-amino acid position of the phosphoramidate only tolerated monosubstitution, and the L-configuration was required (Fig. 4).[24] The preferred substituents at the α-position of the phosphoramidate amino acid moiety were small unsubstituted alkyl groups (Fig. 4). Large alkyl ester groups on the amino acid, such as *n*-butyl, 2-butyl, and *n*-pentyl esters, resulted in molecules with undesired cytotoxicity (Fig. 5). The phosphate ester SAR revealed that aromatic groups were preferred over alkyl esters and that the most potent aryl esters such as 1-naphthyl and halogenated phenyl groups, although superior with respect to potency, generally suffered from unwanted cytotoxicity (Fig. 5).[24]

Further assessment of replicon active compounds looked at gastric fluid stability, plasma stability, and liver enzyme stability and led to the selection of seven key compounds (Fig. 6).[24] This key compound selection set was also chosen because it represented a structurally diverse group since it was not clear to us what structural characteristics were going to control pharmacokinetics and efficacy in vivo.

The seven key compounds were studied first in an in vivo rat model. Each candidate was analyzed for plasma and liver levels of the intact prodrug, the mono-, di-, and triphosphates, and the intermediate prodrug metabolites. This study produced three advanced candidates that were subsequently progressed into in vivo activity and PK evaluation in dogs and cynomolgus monkeys.[24]

In parallel each of the advanced leads, **11**, **12**, and **17**, were incubated with human, rat, dog, and monkey primary hepatocytes to evaluated PSI-6206 triphosphate levels produced.[24] These data would provide a cross species comparison with human hepatocytes and correlation with the in vivo animal studies.

Following in vitro mitochondrial and bone marrow toxicity studies and in vivo whole animal non-GLP 7-day toxicity studies, PSI-7851 **12** was selected as the lead clinical development candidate.[24] PSI-7851 demonstrated submicromolar whole cell replicon activity with no cytotoxicity against a range of primary cell lines and no mitochondrial or bone marrow toxicity. It was metabolically

stable in plasma and gastric and intestinal fluids. High liver levels of the uridine nucleoside triphosphate were observed in multiple species that were translated into a high liver to plasma ratio. PSI-7851 **12** demonstrated the pan-genotypic activity, and the high barrier to resistance that had been sought in a second generation nucleos(t)ide agent. It was shown that PSI-7851 **12** was sensitive to the S282T amino acid change in the HCV RdRp which had been identified as the resistant variant for 2′-methyl nucleoside HCV inhibitors such as PSI-6130. However, as was observed for the 2′-F, 2′-*C*-methylcytidine nucleoside PSI-6130, the viral phenotype containing the mutated RdRp was shown to have reduced viral replication capacity making the mutant virus very unfit for survival.[26]

A detailed analysis of the metabolism of PSI-7851 that included both in vitro and in vivo radiolabeled whole cell studies and in vivo metabolite profiling provided a complete picture of the prodrug release mechanism and metabolism to the active triphosphate (Fig. 7). These studies showed that carboxylesterase 1 or cathepsin A were responsible for cleavage of the terminal amino acid ester and histidine triad nucleotide binding protein 1 (HINT-1) cleaved the bond between the amino acid and the phosphate group. Isolation and characterization of the putative prodrug cleavage intermediate di-acid, PSI-352707, solidified the prodrug degradation mechanism.[27,28]

8.23.2.5 Clinical Proof of Concept of a Liver-Targeted Nucleotide Prodrug

PSI-7851 was taken into a Phase 1 clinical study to evaluate safety, human pharmacokinetics, and efficacy. The proof of concept for the delivery of a nucleotide prodrug specifically to the liver and its utility as an anti-HCV agent was finally demonstrated when HCV GT1 patients were treated orally with PSI-7851 at doses ranging from 50 to 400 mg once daily over 3 days.[15] HCV RNA declined in these patients in a dose-dependent manner with mean changes from baseline of -0.49 to -1.95 $\log_{10}$ IU mL^{-1}.[29] Analysis of the PK profile showed a systemic profile consistent with rapid uptake by the liver with low plasma exposure of the prodrug PSI-7851 and the 5′-monophosphate prodrug release product, therefore, supporting a liver targeting mechanism. Consistent with earlier work using 2′-F, 2′-methyl nucleosides, patients treated with PSI-7851 exhibited no preexisting nor treatment emergent S282T mutations detected nor evidence of viral resistance following the 3 days of therapy. The proof of concept was achieved.

8.23.2.6 The Single Diastereomer: Sofosbuvir

With the proof of concept that delivery of a nucleotide directly targeted to the liver can reduce HCV levels in patients now in hand, our objective was to access the more potent of the two isomers found in PSI-7851 and complete the clinical development. This was done by first carefully separating the two isomers chromatographically and determining their relative potencies.[24] Following the development of a selective crystallization method to separate the two isomers and then determining by X-ray crystallography the configuration of the preferred isomer a homochiral synthesis of the more potent isomer was designed.[30]

PSI-7977 **1** was determined to be the more potent of the two diastereoisomers found in the mixture PSI-7851 **12** and its configuration at phosphorus was assigned to be Sp (Fig. 8).[24] PSI-7977 **1** was shown to be a potent inhibitor of the HCV RdRp with and

$EC_{90} = 0.42$ μM in the HCV GT1b replicon assay. It demonstrated pan-genotypic activity and showed additive to synergistic effects when combined with IFN and a wide variety of HCV DAAs including NS5A inhibitors, NS3/4 protease inhibitors, non-nucleoside NS5B inhibitors, and other nucleos(t)ide inhibitors.[31,32] This ability to combine with other DAAs was going to become important in the future development of HCV-cure drug combinations. In vitro, PSI-7977 **1** exhibited no cytotoxicity, mitochondrial toxicity, or bone marrow toxicity.[24] PSI-7977 **1** was shown not to be a substrate for human DNA polymerases, RNA polymerases, or mitochondrial polymerases.[33] Animal toxicology studies and preclinical animal pharmacology studies showed no significant drug-related findings. In addition PSI-7977 **1** was not genotoxic when studied in a battery of in vitro and in vivo tests nor did it show effects on embryo–fetal viability or on fertility when studied in rats.[34] Ultimately, PSI-7977 became known as sofosbuvir (SOF).

A commercially attractive diastereoselective synthesis of sofosbuvir was eventually developed based on new methodology unprecedented in the literature.[30,35]

The synthesis utilized a stable phosphoramidating reagent that incorporated a phenolate leaving group (Fig. 9). When the stable crystalline and isomerically pure phosphoramidating reagent was reacted with the unprotected uridine nucleoside, sofosbuvir was produced in high yield and with high diastereoselectivity (>99.7de).

8.23.2.7 Sofosbuvir Clinical Studies and the Backbone of Drug Combinations

Phase 2 clinical studies with sofosbuvir demonstrated that in combination with IFN at doses of 100, 200, and 400 mg qd over 28 days in GT1 patients, a rapid virological response (RVR) was observed in 88–94% of the patients and viral load declines of 5.1–5.3 $\log_{10}$IU mL^{-1} were observed. Studies also showed that sofosbuvir was significantly more effective at reducing viral load in HCV patients than the single isomer PSI-7851.[36,37]

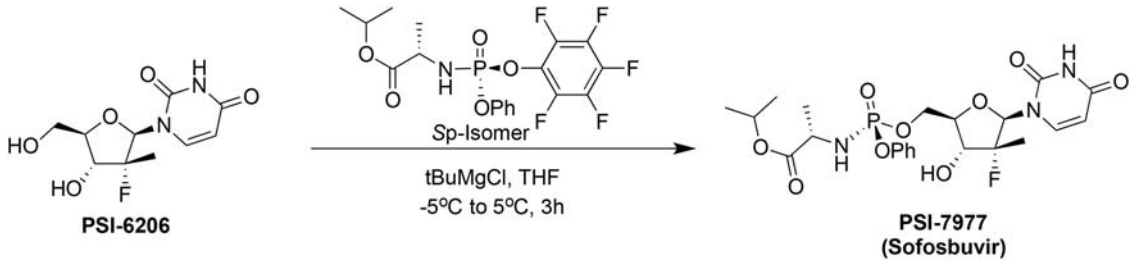

Fig. 9 Diastereoselective synthesis of the phosphoramidate portion of PSI-7977 (sofosbuvir).

A small 50-patient 5-arm Phase 2 clinical study evaluated sofosbuvir as monotherapy, in combination with RBV, or in combination with IFN/RBV for 12 weeks in GT2,3 patients and assessed SVR (sustained viralogic response, or cure—measured as no detectable virus post the last drug dose) rates 12 and 24 weeks after cessation of therapy.[38] The results showed that patients on the IFN-free combination achieved a 100% SVR 12 and 24, identical to patients taking the sofosbuvir + IFN/RBV triple combination.

Subsequently, initial registration studies focused on sofosbuvir in combination with RBV for GT2 and 3 patients and sofosbuvir in combination with Peg-IFN/RBV for GT1 and 4 patients. In a broad GT2 HCV patient population, sofosbuvir + RBV led to high cure rates (SVR12) between 92% and 94% following only 12 or 16 weeks of therapy. This study also showed that GT2 patient status (i.e., treatment naïve, cirrhotics, or treatment experienced) had no impact on cure rates.[39,40]

For GT3 patient the sofosbuvir-based IFN-free regimen containing only RBV was not quite as efficacious as had been seen for GT2 patients. For GT3 patients the best treatment regimens required sofosbuvir + RBV for 24 weeks and achieved an SVR of 86%. GT3 patient status did appear to play some role in outcome where treatment-experienced patients responded less well than treatment-naïve patients, and treatment-experienced cirrhotic patients (SVR12 60%) responded less well than patients without cirrhosis (SVR12 85%).[39,40]

In GT1 or 4 patient populations, sofosbuvir + RBV alone was not sufficient to deliver high cure rates (Fig. 9). In this patient population a sofosbuvir + PEG-IFN/RBV combination therapy for 12 weeks was required to deliver a high overall response rate (SVR12) of 91% (GT1 89%, GT4 96%).[39,40]

Throughout its clinical study history, sofosbuvir resistance never became a concern. Preemergent or on-treatment-emergent resistant variants had never been observed for sofosbuvir-based combination therapies. The HCV polymerase S282T amino acid change, which was identified in the laboratory as the primary sofosbuvir resistance mutation, was shown to be unfit and was not identified as a preemergent variant in the clinic; nor were viral breakthroughs observed on treatment.[26,32,39,41] The less frequent novel double mutation (L159F/L320F) which conferred low level resistance to sofosbuvir was also identified in the laboratory but these single and double mutations were also shown to have a low replication capacity.[41]

On Dec. 6, 2013 sofosbuvir was approved by the US FDA for the treatment of HCV GT1–4 patient populations with regulatory approval for the first IFN-free combination of sofosbuvir + RBV being approved for GT2 and 3 patient populations. However, with all the demonstrated success of sofosbuvir regimens, there still existed the need for an IFN-free regimen for GT1 patients.

From all critical preclinical and clinical data that had been amassed on sofosbuvir, it became clear that sofosbuvir was the ideal backbone therapy for HCV-cure drug combinations. Sofosbuvir demonstrated a high barrier to resistance; it showed pan-genotypic character and exhibited a stellar safety profile.[42,43] Preclinical studies showed that it could be combined with all other DAAs, and drug–drug interaction assessments showed sofosbuvir and its major metabolite, the uridine nucleoside, were not substrates or inducers of CYP450 enzymes, although sofosbuvir was observed to be a substrate for P-glycoprotein and breast cancer resistance protein.[34] Furthermore, in clinical studies no food effects were observed and no accumulation of sofosbuvir or its major metabolite was noted. Finally, clinical drug–drug interaction studies did not identify any limiting combinations that would restrict sofosbuvir's use in a broad patient population.[42,44,45] The question became what other mechanism of action DAA would become the preferred partner with sofosbuvir that would lead to the development of an IFN-free DAA combination to treat HCV GT1 patients?

8.23.3 Ledipasvir

Ledipasvir (LDV, GS-5885) is a highly potent, orally available inhibitor of the HCV nonstructural protein 5A (NS5A) and has a long pharmacokinetic (PK) half-life making it suitable for once-daily dosing (Fig. 10).[46,47] In genotype (GT) 1 HCV-infected patients, monotherapy with LDV results in a rapid ~3 $\log_{10}$ viral load reduction (VLR) for doses from 3 to 90 mg within 24 h from administration of the first dose.[48] The potency, pharmacokinetics, and low efficacious dose make LDV amenable to formulation as a component in a single-tablet regimen (STR).[49] Ledipasvir was selected for development because it met the targeted NS5A program goals: discovery of a once-daily oral molecule that could be coformulated in a complete regimen of drugs efficacious in the

treatment and cure of HCV infection. Ledipasvir's picomolar replicon potency, excellent preclinical and clinical safety profile, long PK half-life, favorable drug interaction profile, and rapid and potent antiviral effect in patients are some of the attributes that make LDV an excellent partner for combination with sofosbuvir as Harvoni®. Harvoni® is the first STR approved for treating HCV infection and provides a safe, simple, and efficacious cure.

8.23.3.1 Mechanism of Action and Structural Information

The 56–58 kDa NS5A phosphoprotein is required for replication of the HCV.[50] Although there has been a significant study of this viral protein, a detailed mechanistic understanding of its role in HCV replication remains unclear. NS5A has no known enzymatic activity and has no known homologs in prokaryotes or eukaryotes. NS5A has binding affinity for a number of host cellular proteins, the HCV NS5B RNA-dependent RNA polymerase, and viral RNA, and from the crystal structure of a truncated NS5A dimer, it has been hypothesized to have a viral RNA binding groove.[51–53]

The role of NS5A in HCV replication remains enigmatic, and it is therefore not surprising that the mechanistic basis for the antiviral activity of LDV has not been fully elucidated. A longstanding method of defining the molecular target of antiviral inhibitors has been to treat replicating virus (or replicons) with inhibitor under conditions of incomplete inhibition allowing resistance mutations to develop.[54] Studies of resistance-associated variants (RAVs) provide a connection between LDV and the viral target NS5A. Treatment of the HCV genotype 1a or 1b replicon with LDV results in mutations in the NS5A protein as shown in **Table 1**.[55] In GT1a, Q30E and Y93H are observed along with Y93H in GT1b. These mutations lead to potency shifts for LDV, and are observed in patient isolates (vide infra). The simplest explanation for the association of LDV with mutations in the NS5A protein would be a direct binding of LDV to NS5A. In cases where small molecule inhibitors derive mutations in the active site of a viral enzyme, direct inhibitor/enzyme binding is a reasonable conclusion. Mutational data alone are only suggestive of the direct binding of LDV to NS5A; it is possible that NS5A could act through an independent host protein or proteins to exert its effect on NS5A. Since the molecular details of the role of NS5A in viral replication are unknown, a conclusion on direct binding of LDV based on mutation patterns in NS5A is less clear than for enzyme active-site inhibitors.

Experimental evidence supports direct binding of LDV to NS5A as the basis for LDV's antiviral activity. To help understand the mode of inhibition for LDV, studies of LDV with full-length recombinant GT1b NS5A have been undertaken and demonstrate specific, saturable, and high avidity binding between LDV and NS5A ($K_d = 58.9 \pm 6.6$ nM).[56] Additionally, consistent with its antiviral profile in the GT1b replicon, LDV binding to the Y93H mutant of the full-length recombinant NS5A protein is not measureable up to the solubility limit of LDV in the assay (10 μM). Interestingly, there is a disparity between the nanomolar K_d of LDV for the recombinant wild-type protein and the picomolar EC_{50} of LDV in the GT1b replicon. The shift in K_d has been attributed to a number of possibilities, including the absence of cellular structures (the helices of NS5A are hypothesized to bind to the cellular membrane), or cellular components such as host proteins or RNA that may bind to NS5A during replication. The influence of cellular structures could contribute to the NS5A binding conformation or conformations relevant for NS5A/LDV binding in an infected cell. Further, since the molecular mechanism of NS5A is unknown, the quantitative connection between K_d of binding and inhibition of viral replication is unclear. Indeed, studies have suggested that a stoichiometry of one molecule of an NS5A inhibitor per 10,000 NS5A proteins in the replicon is needed to achieve 50% inhibition of viral replication.[57]

X-ray crystal structures of NS5A where the N-terminal helix domain is removed have been reported. In two GT1b[58,59] and two GT1a[60] structures, truncated NS5A constructs form dimers in the unit cell, although the protein contacts and symmetry in the dimeric forms in the two GT1b reported structures are strikingly different from each other, and the researchers crystallizing the truncated GT1a construct found two additional, distinct dimeric forms. The dimeric forms of the truncated protein, along with the dimer-like structures of inhibitors such as LDV, have prompted some researchers to hypothesize binding modes of NS5A inhibitors to dimeric structures based on modeling studies using reported crystal structures as starting points.

Dynamic imaging during productive infection of Huh-7.5 cells has demonstrated that NS5A undergoes varying multimeric states, where NS5A foci of differing sizes are formed and traffic during the HCV viral life cycle.[61] Further, it has been shown that NS5A can bind to multiple host proteins, and it has been hypothesized that NS5A can bind to viral RNA. With the unknown mode of action of the NS5A protein, multiple states of oligomerization during the HCV viral life cycle, multiple phosphorylated states, and the identification of viral and host binding partners including RNA, it brings into question the biological relevance of static dimeric crystal structures of truncated forms of the NS5A protein, and ultimately their utility in structure-based drug design. Indeed, the existence of multiple dimeric forms of the GT1a and GT1b truncated proteins when crystallized confounds attempts to

identify relevant binding modes. The multiple dimeric forms found in apo NS5A crystal structures, and hypothetical binding modes of NS5A inhibitors, present a complex landscape in which to attempt to understand the multiple mechanistic roles of the NS5A protein in HCV replication and the molecular mechanism in which NS5A inhibitors block replication.

8.23.3.2 Discovery of Ledipasvir

The discovery of LDV involved SAR studies where potency and PK enhancing elements were discovered, and their combinations were studied to define optimal properties.[46] Genotype 1a replicon cellular potency (measured as a concentration effective to inhibit by 50%, or EC_{50}) was studied in a range of symmetric *bis*-benzimidazole inhibitors with various aromatic and alkyne-based groups interconnecting the benzimidazoles.[62] Single aromatic groups, such as phenyl in **19**, or naphthyl in **20**, interconnecting the benzimidazoles (Fig. 11) result in potent inhibitors, while biphenyl inhibitor **21** is 7–33-fold less potent. Overall, fused-ring containing core groups were found to be the most potent as exemplified by naphthyl inhibitor **20**, GT1a replicon $EC_{50} = 110$ pM.

Studies with unsymmetric imidazole-X-benzimidazole cores were undertaken and the SAR data is shown in Table 2. The phenyl-based core **22** did not show GT1a activity within the range of the assay (>44,000 pM). It is notable that the phenyl-based core in the unsymmetric series resulted in dramatically lower potency than the phenyl-based core in the symmetric *bis*-benzimidazole series (compound **19**, Fig. 11, 500 pM). The phenyl-alkyne cores **23** and **24** in Table 2 show significant differences in GT1a activity depending on the directionality of their connectivity, where the alkyne connection to the benzimidazole enhances activity by ~sixfold. This potency differential underscores a fundamental property of these unsymmetric-core molecules. The phenyl-alkyne directionality is degenerate in a symmetric *bis*-benzimidazole core, but in the unsymmetric imidazole/benzimidazole core in Table 2, directionality results in strikingly disparate SAR. The theme of directionality relative to an unsymmetric core is important in the discovery of LDV, and is a theme that will be revisited when discussing the SAR of differential modifications to the ends of an unsymmetric series. Biaryl aromatics in **25** and **26** produced potent inhibitors, with the biphenyl inhibitor **26** showing higher potency at 170 pM. In this series, naphthyl inhibitor **27** displays the most potent activity with a GT1a EC_{50} of 71 pM. It is interesting to note that replacement of phenyl in **19** by naphthyl in **20** results in ~fivefold increase in potency, while the phenyl to naphthyl change in compounds **22** and **27** results in a potency difference of >600-fold. The properties of the symmetric and unsymmetric series are clearly different. Nonetheless, in both the earlier *bis*-benzimidazole inhibitors, and in the imidazole/benzimidazole inhibitors, fused-ring core systems produce the most potent compounds within each series, with the naphthyl providing the highest potency overall in the imidazole/benzimidazole series. In the imidazole/benzimidazole system the biphenyl inhibitor **26** is the most potent of the biaryl ring inhibitors. The high potency of biaryl inhibitor **26**, and the finding that ring fusions produce high potency, together led to the design of a series of tricyclic fused-ring inhibitors.

The SAR of tricyclic fused-ring systems (Table 3) were initially studied in a symmetric system to allow rapid synthetic accessibility. The fluorene **28**, although potent, is unstable even to air oxidation, and the oxidation product ketone **29** has decreased

potency, as does the blocked dimethyl fluorene **30**. To avoid the apparent detrimental properties of polarity in **29** and out-of-plane bulk in **30**, the exo-dimethylmethylene compound **31** was synthesized but was the least tolerated of all ring systems with a potency of 7000 pM (unpublished results). From this SAR it was postulated that a small hydrophobic blocking group could be optimal, and difluoro substitution of the fluorene ring system was targeted. Since introduction of fluorine to the fluorene ring system posed synthetic challenges, it was deemed worthwhile to synthesize this important analog directly in the unsymmetric imidazole/benzimidazoles series (inhibitor **32**, Fig. 12). The difluorofluorene indeed introduced stability, and resulted in a highly potent inhibitor with a GT1a potency of 40 pM and PK half-lives of 1.8 and 2.6 h in rat and dog, respectively.

Replacements and modifications of the pyrrolidine ring system were undertaken. It was found that employment of a [2.2.1] azabicyclic ring system imparted a beneficial enhancement in the PK half-life in dog in a biphenyl bisimidazole series,[46] and we sought to further exploit this property. The theme of differential substitution of the unsymmetric benzimidazole/imidazole scaffold was revisited and an intriguing and important SAR emerged. This [2.2.1] azabicyclic pyrrolidine ring system was employed in the unsymmetric scaffold in compounds **33** and **34** (Fig. 13). Compound **34**, with the [2.2.1] azabicyclic ring on the benzimidazole side of the inhibitor is significantly more potent (160 pM) than the corresponding compound **33** with the bicyclic ring system on the imidazole side (660 pM). Attaining such high potency (160 pM) with incorporation of the azabicyclic ring system was important based on the aforementioned PK half-life improvements that this ring system had afforded in the biphenyl bisimidazole series. Importantly, this PK enhancement was successfully translated in the unsymmetric series, where the half-lives for the potent [2.2.1] azabicyclic inhibitor **34** are (1.5 h) in rat and (5.3 h) in dog. The half-life in dog is significantly improved over the corresponding pyrrolidine inhibitor **26** which has a half-life in dog of 2.3 h. Further potency and PK enhancements of **34** were sought.

Fig. 13 Bridged azabicyclic ring system more potent on benzimidazole side, and improves PK half-lives versus pyrrolidine **26**.

Replacement of the biaryl in **34** with the optimized fused tricyclic difluoroflourene afforded **35** (Fig. 14) with a potency enhancement from 160 to 56 pM EC_{50} in the GT1a replicon. Based on a dialysis method to measure plasma protein binding,[63] compound **35** has a protein-adjusted (PA) GT1a EC_{50} of 784 pM, corresponding to a 14-fold protein-binding shift.

In the final stage of optimization, modifications of the remaining pyrrolidine of **35** were investigated. Modification incorporating a spirocyclopropyl pyrrolidine produced ledipasvir (Fig. 10), the most potent compound in the series (GT1a $EC_{50}=31$ pM, GT1b$=4$ pM), which, coupled with its low protein shift of 6.7-fold, results in PA EC_{50} values of 208 pM for GT1a and 27 pM for GT1b. The PK properties of LDV are highly optimized. LDV is stable to oxidative metabolism and no disappearance of LDV is observed in 60 min microsomal incubations resulting in low hepatic extraction values: rat <9.2, dog, <9.5, cyno monkey <12.7, human <12.7% hepatic extraction. Hepatic clearance (CL) predicted from analysis of product formation in human hepatocytes using tritiated LDV is 0.012 L h^{-1} kg^{-1}. The long PK half-lives in rat (4.7 h), dog (7.4 h), and monkey (10.3 h) are apparent in Fig. 15. Bioavailabilities ranging from 32% to 53% and low clearance in all species with volumes of distribution significantly higher than total body water are hallmarks of the favorable PK profile of LDV (Table 4).

Ledipasvir has a free fraction of <1% in rat, dog, cyno, and human based on plasma protein binding. It is interesting that such a highly protein-bound compound can exhibit volumes of distribution in preclinical species significantly higher than the volume of the plasma compartment (V_{ss} from 1.2 to 2.7 L kg^{-1}), since highly protein-bound compounds typically have low volumes of distribution.[64] It is further notable that LDV is highly protein-bound even in the cell-culture medium of the replicon assay at only 1.1% free drug (the replicon cell-culture medium contains 10% bovine serum albumin). Accounting for the low free drug concentration

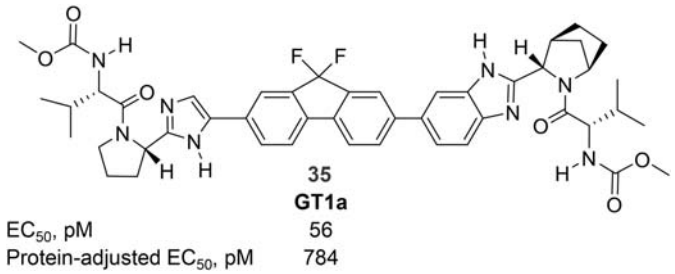

Fig. 14 Difluorofluorene core improves potency in combination with azabicyclic pyrrolidine.

in the replicon assay, the intrinsic EC_{50} of LDV is 310 femtomolar (fM) for GT1a and 40 fM for GT1b. Ledipasvir's exceptionally high intrinsic potency at the intended viral target, combined with its high level of protein binding, results in a very low free drug concentration in vivo.

8.23.3.3 The Genotype 1 Resistance Profile of Ledipasvir

HCV has a replication rate that is estimated to produce 10^{12} viral particles per day. This high replication rate coupled with the highly error-prone NS5B polymerase leads to production of heterogeneous viral species with a high number of variants, many of which can be detected in circulating virus prior to antiviral treatment.[65] A number of clinically relevant RAVs have been identified in the NS5A region of HCV. The activity of LDV against these RAVs is shown in Fig. 16.[55]

8.23.3.4 Broad Genotype Activity of Ledipasvir

The activity of LDV in genotype 1–6 replicons is shown in Table 5.[55] Ledipasvir has potent activity against genotypes 1a, 1b, 4a, 5a, and 6a replicons with potency ranging from 4 pM to 1.1 nM. Ledipasvir has potent GT1,4,5, and 6 activity and accordingly Harvoni® has been approved for the treatment of patients infected with genotype 1, 4, 5, or 6 HCV. Ledipasvir has weaker antiviral activity against GT2 and 3. Replicon data for NS5A inhibitors are often reported using the JFH-1sequence in the replicon for genotype 2 activity.[66] The JFH-1 sequence includes leucine at position 31 (L31). Baseline sequence differences between genotypes in the NS5A region are the basis for the differing potency of LDV across genotypes. Sequence differences in GT2 are an example: GT2 patients vary significantly at position 31 with the GT2 patients relatively evenly split between leucine and methionine at position 31 (L31 and M31).[67] Thus reporting JFH-1 data for GT2 activity only represents the major viral species for about half of the GT2 infected patients. Table 5 shows that LDV is 12–33-fold less potent in GT2a and GT2b replicons with M31 compared to the L31 replicons. Decreases in antiviral potency when M31 is the dominant amino acid in GT2 have been seen for other NS5A inhibitors both in replicon assays and in suboptimal VLR in the clinic.[68] Despite the weaker potency of LDV in vitro against GT2 and GT3 replicons, clinical efficacy has been observed in several Phase 2 clinical trials with LDV/SOF ± RBV.[69,70]

8.23.3.5 Translation to the Clinic: Ledipasvir Phase 1 Human Pharmacokinetics, Monotherapy Antiviral Activity, and Studies on RAVs

In pharmacokinetic studies, 3, 10, 30, 60, and 100 mg of LDV were dosed in healthy volunteers.[46] The half-life ranged from 37 to 45 h, consistent with the potential for LDV to be used in once-daily dosing (Fig. 17, Table 6). GT1a patients received 1, 3, 10, 30, or 90 mg once daily for 3 days, and 10 mg was dosed to GT1b patients daily for 3 days (Fig. 18, Table 7) in a Phase 1b study. After the third and final dose at 90 mg (LDV dose used in Harvoni®) the half-life of LDV was 49.7 h.[48] An approximately twofold accumulation factor is expected with this long PK half-life. In both healthy volunteers and patients, the AUC increased linearly over the dosing range. In section "Discovery of Ledipasvir" detailing the discovery of LDV, the intensive optimization of PK half-life was discussed. A goal of the preclinical PK optimization was to achieve a long half-life in patients to facilitate efficacy through high drug concentrations over wild-type and resistant virus in real-world settings—that is, to provide consistently high drug exposure outside of the controlled environment of clinical trial settings. The approximate 50-h half-life in patients demonstrates achievement of this goal.

Ledipasvir's protein-adjusted GT1a EC_{50} is 208 pM (dotted red line, Fig. 17), and the GT1b protein-adjusted EC_{50} is 27 pM. The LDV 24 h trough concentration (C24) is 12- and 470-fold over the protein-adjusted GT1a EC_{50} at the 3 and 100 mg doses, respectively (Fig. 17). These C24-fold over PA EC_{50} values would further increase upon reaching steady-state concentrations. The 3 and 100 mg C24 trough concentration are 90- and 3660-fold over the GT1b protein-adjusted EC_{50} after a single dose of LDV.[46] Similar exposures were observed in HCV-infected patients (Fig. 18, Table 7). In patients, the trough concentration (C_{tau}) at 24 h post the third and last LDV dose is 610-fold over the GT1a protein-adjusted EC_{50} at the 90 mg dose used in Harvoni®. The LDV concentration remains multifold above the protein-adjusted EC_{50} at 4 days post the last dose (96 h timepoint in Fig. 18).

Plasma viral RNA measurements in patients treated with 3–90 mg LDV reveal rapid, ≥ 3 $\log_{10}$ median maximal VLRs with three daily doses of 10, 30, or 90 mg of LDV. Approximately 3 $\log_{10}$ VLRs were achieved within 24 h from the first oral dose (Fig. 19).[48] All dose levels were administered in GT1a patients, and a GT1b cohort received the 10 mg dose. This high rate of VLR is a unique feature of NS5A inhibitors. NS5A inhibitors produce the most rapid VLRs among all clinically tested HCV direct-acting antiviral classes including NS3 protease inhibitors, NS5B non-nucleotides, and NS5B nucleosides. The rapid VLR of NS5A inhibitors has been attributed to their interruption of putative roles of the NS5A protein not only in viral RNA replication but also in viral assembly and secretion. Based on viral dynamic modeling, inhibition of several steps in the viral replication cycle is projected to lead to a greater rate of VLR than for inhibitor classes acting by a single mechanism.[46,71]

Table 7 Mean LDV PK parameters post third dose in HCV GT1-infected patients

	LDV dose (mg)				
	1	*3*	*10*	*30*	*90*
$t_{1/2}$ (h)	13.0 (7.7, 17.8)	22.8 (13.1, 36.8)	39.9 (28.5, 47.2)	41.7 (25.8, 53.4)	49.7 (37.8, 54.3)
C_{max} (ng mL^{-1})	2.2 (39.7)	6.1 (56.6)	25.3 (40.0)	103.3 (57.5)	247.7 (45.4)
C_{tau} (ng mL^{-1})	0.3 (161.0)	2.4 (73.6)	9.7 (41.5)	46.5 (62.7)	115.9 (42.6)
AUC_{tau} (ng h mL^{-1})	34.0 (29.8)	89.7 (54.6)	368.8 (39.0)	1592.4 (59.5)	3815.5 (42.1)

Tau values are at 24 h postdose.
10 mg cohort ($n=19$) includes GT1a,b patients, others are GT1a ($n=10$).

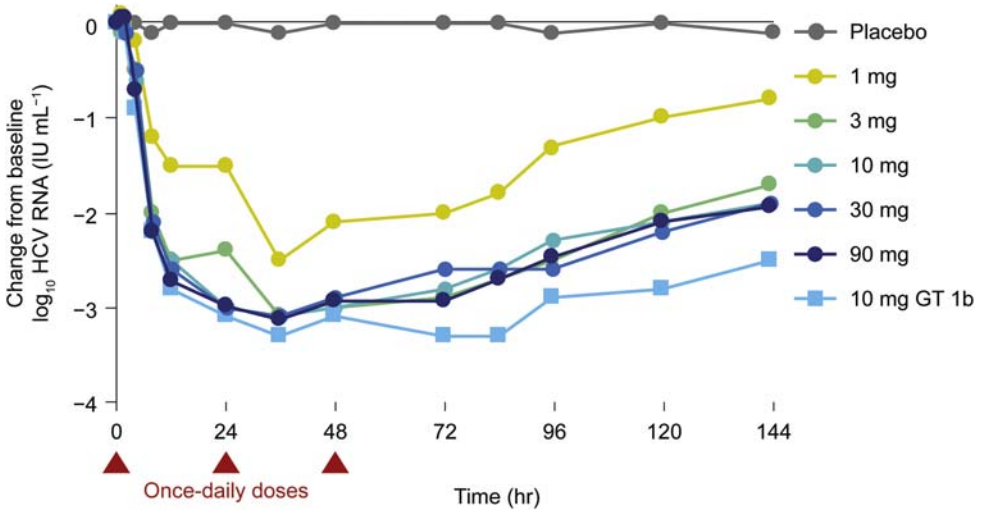

Fig. 19 Viral load reduction, 3-day LDV dosing in monotherapy, GT1a/b patients.

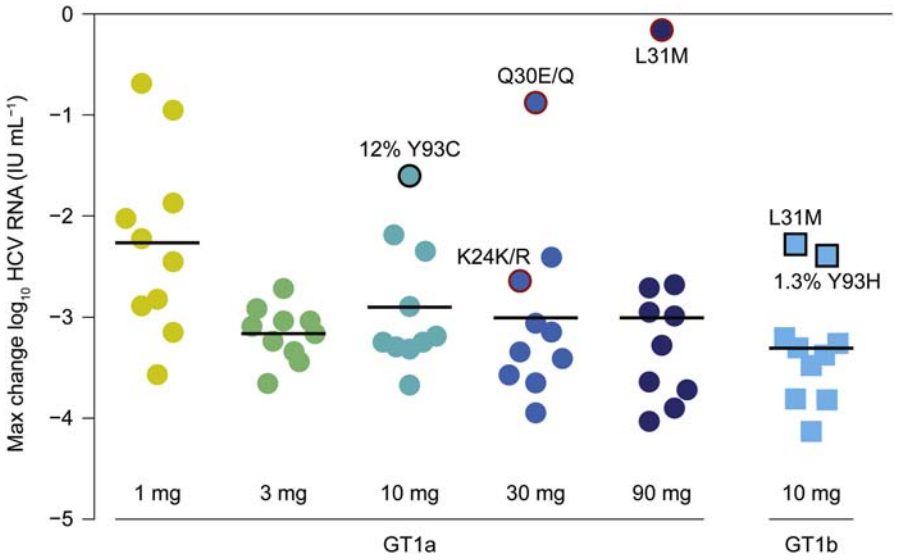

Fig. 20 LDV clinical viral load reduction by patient. Clinical resistance-associated variants (RAVs) found at baseline are noted. RAVs by population sequencing (detectable as >25% of total viral population) are labeled and outlined in *red*. RAVs by deep sequencing (limit of detection ~1% of total population) are labeled and outlined in *black* with the percentage of the resistant population noted. Horizontal lines represent the median viral load reduction.

Fig. 20 depicts the mean maximal VLR for individual patients in the Phase 1 monotherapy dosing of LDV, and also annotates those individual patients who had preexisting RAVs.[72] Of 49 patients that received LDV, six patients had NS5A RAVs prior to dose administration (i.e., at "baseline") either by population sequencing (limit of detection 25% of total viral population, enclosed by square) or by deep sequencing (limit of detection ~1% of total viral population, enclosed by circle). These six baseline RAVs were Y93C (12%, GT1a 10 mg dose), Q30E/Q and K24K/R (GT1a, 30 mg dose), L31M (GT1a, 90 mg dose, and GT1b 10 mg dose), and Y93H (GT1b, 1.3%, 10 mg dose). Only the patient harboring the GT1a L31M RAV at baseline achieved a <0.5 $\log_{10}$ VLR (0.16 $\log_{10}$ from baseline). The other five patients with preexisting RAVs achieved 0.88–2.64 $\log_{10}$ VLRs from baseline. For LDV in combination with sofosbuvir, baseline RAVs have not been associated with statistically significant differences in SVR, and baseline RAV testing is not indicated prior to initiation of LDV/SOF therapy. The Phase 3 clinical section includes a detailed discussion of baseline RAVs in LDV/SOF therapy.

Ledipasvir was well tolerated at all doses and no serious adverse events were reported and no patients discontinued therapy due to adverse events in these early studies.

8.23.3.6 Phase 2 Studies With Ledipasvir and Agents Other Than Sofosbuvir

Prior to its use in combination with sofosbuvir, LDV was studied in interferon-containing and interferon-free regimens in six Phase 2 studies with over 1000 patients in the LDV treatment arms. LDV was studied with GS-9451 (an HCV protease inhibitor) ± ribavirin (RBV) and ± tegobuvir (an HCV NS5B non-nucleoside polymerase inhibitor) in 469 patients.[73] Ledipasvir was also studied with pegylated interferon and RBV ± GS-9451 in 622 patients. These studies demonstrated that LDV was safe and well tolerated in a large number of patients. No patients experienced the same serious adverse event, and no patients had overlapping adverse events that led to discontinuation. Hemoglobin declines were observed but attributed to the presence of ribavirin, and neutrophil declines were associated with the presence of pegylated interferon. Similarly, as discussed in the section "Sofosbuvir Clinical Studies and the Backbone of Drug Combinations," SOF had been studied in a number of Phase 2 clinical trials with a large database supporting its safety in humans. The data from these separate Phase 2 studies formed the extensive safety database supporting the use of LDV in combination with SOF in the ION-1/2/3 registrational Phase 3 studies.

8.23.4 Phase 3 Registrational Clinical Studies With Ledipasvir and Sofosbuvir

Genotype 1 treatment-naïve and treatment-experienced patient populations were the focus of the ION-1, -2, and -3 trials and these results are summarized in Fig. 21.[74–76] In these trials, a STR of LDV (90 mg) and SOF (400 mg) was administered once daily for 8, 12, or 24 weeks with or without RBV (RBV was administered twice daily with its dose adjusted to body weight, 1000 mg daily for patients 75 kg). In ION-1 and -3, treatment durations of 12 and 24 weeks of LDV/SOF with or without RBV in treatment-naïve patients (16% with cirrhosis) were explored. The 12 week arms had SVR rates of 99% without ribavirin and 97% SVR with ribavirin.

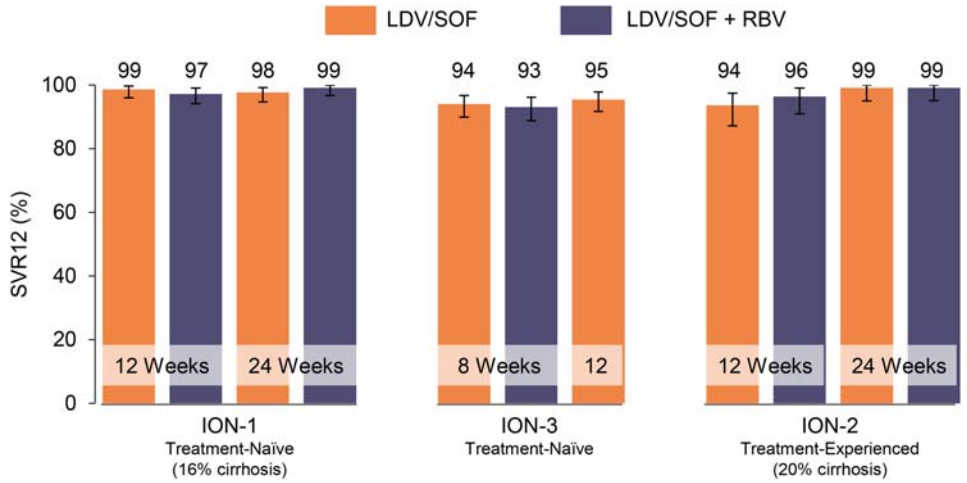

Fig. 21 SVR results from the Phase 3 ION trials of LDV/SOF ± RBV in treatment-naïve and treatment-experienced patients.

The 24-week arm treatment without ribavirin afforded a 98% SVR and 99% with RBV. SVR rates were uniformly high, and differences in SVR in these arms were not statistically significant, demonstrating that addition of RBV or increased treatment duration did not affect outcomes. Shorter treatment was assessed in naïve noncirrhotic patients in ION-3, where 8 weeks of LDV/SOF ± RBV were compared against 12 weeks of SOF/LDV. An SVR rate of 94% in the 8-week arm of LDV/SOF without RBV was comparable to the 8-week arm including RBV (93%) and to the 12-week arm of SOF/LDV alone (95%). These small SVR differences were not statistically significant, demonstrating that 8-week treatment leads to high SVR rates. In ION-2, patients who had previously failed treatment (20% with cirrhosis) with either PEG/RBV alone or the combination of PEG/RBV with a protease inhibitor were treated with LDV/SOF regimens ± RBV. The SVR results in the 12-week arms were 94% (− RBV) and 96% (+ RBV), and in the 24-week arms the SVR was 99% with or without RBV.

In the combined ION-1, -2, and -3 trials the overall SVR rate was 97%. Virologic failure during treatment ("breakthrough" as opposed to virologic failure after treatment, i.e., "relapse") is exceptionally rare during LDV/SOF treatment. Of the 1952 patients treated in ION 1–3, there were only two patients to experience breakthrough, and it was determined that one of these two patients did not adhere to therapy (drug levels were measured at or below the limit of detection at weeks 2, 4, and 6 of treatment). Of the 66 out of 1952 patients who did not achieve SVR, 28 patients were lost to follow-up (patients lost to follow-up are considered treatment failures in the intent-to-treat analysis), and 36 patients relapsed. Therefore, documented virologic failure occurred in 1.9% of the patients in the ION studies.

Analyses of RAVs were completed for the ION studies. In ION-1, deep sequencing showed that 16% of patients (140/861) had NS5A RAVs prior to treatment (baseline RAVs). Approximately 96% of these patients with baseline RAVs achieved SVR. Only three patients had virologic failure; two of the patients with virologic failure had NS5A RAVs at baseline while none had RAVs to SOF. In ION-2 62/439 (14%) had NS5A RAVs at baseline by deep sequencing and 89% of these patients achieved SVR. RAVs associated with NS3/4A protease inhibitors were present in 163/228 patients (71%) in this ION-2 treatment-experienced cohort, and 98% of these patients achieved SVR. No patient had the NS5B polymerase RAV S282T at baseline, during, or after treatment. In ION-3 116/647 patients (18%) had NS5A baseline RAVs by deep sequencing, and 104 (90%) of the patients with RAVs achieved SVR. Baseline RAV testing is not indicated prior to the treatment with LDV/SOF in the United States or European Union (**Fig. 22**).[77,78] In these studies the most common adverse events (AEs) were fatigue, nausea, and headache and were generally mild. In patient arms where ribavirin was added there were higher rates of RBV-associated AEs (headache, fatigue, nausea, insomnia, pruritus, irritability, rash, cough, and anemia). No patient in 12-week arms of ION-1, no patient in ION-2, and no patient in the 8-week LDV/SOF arm of ION-3 discontinued LDV/SOF treatment due to an adverse event.

8.23.4.1 Harvoni® Approval

LDV (90 mg) and SOF (400 mg) are combined in a single tablet that is taken once daily and is branded as Harvoni®. Harvoni® was approved by the Federal Drug Administration (FDA) on Oct. 10, 2014 for the treatment of GT1 infection, and the European Medicines Agency (EMA) on Nov. 18 for GT1 and 4 infection that same year. The US prescribing information (**Fig. 22**) indicates Harvoni once daily for 12 weeks in GT1 treatment-naïve or treatment-experience patients without cirrhosis, and treatment-naïve patients with compensated cirrhosis.[77] Treatment is recommended for 24 weeks in treatment-experienced patients with compensated cirrhosis. Harvoni is the only HCV treatment presently approved for an 8-week duration (considered for treatment-naïve patients without cirrhosis who have HCV RNA < 6 million IU mL^{-1}). Harvoni® is the first STR approved for the treatment and cure of HCV infection and provides a highly effective and a simple treatment option for a broad patient population.

	Patient Population	Treatment Regimen and Duration
Genotype 1	Treatment-naïve without cirrhosis or with compensated cirrhosis (Child-Pugh A)	HARVONI 12 weeks*
	Treatment-experienced** without cirrhosis	HARVONI 12 weeks
	Treatment-experienced** with compensated cirrhosis (Child-Pugh A)	HARVONI 24 weeks*
	Treatment-naïve and treatment-experienced** with decompensated cirrhosis (Child-Pugh B or C)	HARVONI + ribavirin† 12 weeks
Genotype 1 or 4	Treatment-naïve and treatment-experienced** liver transplant recipients without cirrhosis, or with compensated cirrhosis (Child-Pugh A)	HARVONI + ribavirin† 12 weeks
Genotype 4, 5, or 6	Treatment-naïve and treatment-experienced**, without cirrhosis or with compensated cirrhosis (Child-Pugh A)	HARVONI 12 weeks

*HARVONI for 8 weeks can be considered in treatment-naïve genotype 1 patients without cirrhosis who have pre-treatment HCV RNA less than 6 million IU mL^{-1} [see Clinical Studies (14.2)].
**Treatment-experienced patients include those who have failed a peginterferon-alfa + ribavirin based regimen with or without an HCV protease inhibitor.
HARVONI+ribavirin for 12 weeks can be considered in treatment-experienced genotype 1 patients with cirrhosis who are eligible for ribavirin [see Clinical Studies (14.2)]. See footnote for ribavirin dosage recommendations.
In patients with decompensated cirrhosis, the starting dosage of ribavirin is 600 mg and can be titrated up to 1000 mg for patients <75 kg and 1200 mg for those ≥75 kg in two divided doses with food. If the starting dosage of ribavirin is not well tolerated, the dosage should be reduced as clinically indicated based on hemoglobin levels.
†The daily dosage of ribavirin is weight-based (1000 mg for patients >75 kg and 1200 mg for those ≥75 kg) administered orally in two divided doses with food.

Fig. 22 US HARVONI® prescribing information for patients with genotype 1, 4, 5, or 6 HCV (updated 11/13/15).

8.23.4.2 Harvoni® Postapproval Studies, Label Expansion and Study in Japan

FDA approval for the treatment of HIV/HCV coinfected patients is based on the Phase 3 ION-4 trial including 335 patients, where 96% SVR was achieved for GT1 patients, and 100% of GT4 patients achieved SVR (eight patients with GT4 infection were enrolled).[79] Two more studies of LDV–SOF showed high SVR rates in genotypes outside of GT1 in 12-week therapies. These are Study 1119 (GT4, 94% SVR, 65 patients and GT5, 95% SVR, 41 patients)[80,81] and Electron 2 (GT6, 96% SVR, 26 patients) (Fig. 23).[70] 12-week treatment is indicated in the US Harvoni label, Fig. 22 (updated Nov. 13, 2015), for patients with genotype 4, 5, or 6 infection without cirrhosis or with compensated cirrhosis who are treatment naïve or treatment experienced.

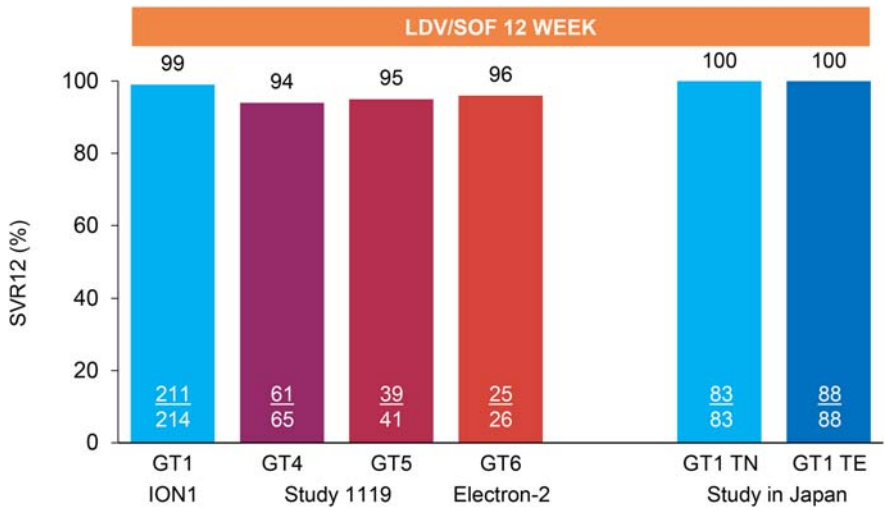

Fig. 23 GT4–6 postapproval studies supporting US label expansion, and study in Japan.

Subsequent to the approval of Harvoni for GT4,5, or 6 HCV-infected patients and for patients with HIV/HCV coinfection, Harvoni was approved for use in combination with RBV for 12 weeks in treatment-naïve and treatment-experienced patients with decompensated cirrhosis. This approval was based on the treatment of patients with decompensated cirrhosis either pre- or postliver transplantation in the SOLAR-1 trial. This 12-week regimen is the first approved HCV therapy for patients with advanced liver disease and represents a major clinical breakthrough with respect to the high efficacy observed in the clinical trials and clinical improvements observed in some patients who achieved SVR.[82]

Treatment of HCV patients in Japan, where GT1b HCV infection is dominant, resulted in 100% SVR in the 170-patient 12-week LDV/SOF arm (Fig. 23). The high SVR rate is notable because this population has increased numbers of patients with characteristics associated with poor outcomes—this population tends to be older, with more advanced liver disease, and many are treatment experienced.[83]

8.23.4.3 Harvoni® Real World Results

It has been long understood that the efficacy or safety results obtained in controlled clinical trials may not translate in "real-world" settings. "Efficacy" (risk benefit in a clinical trial setting) has been contrasted with "effectiveness" (risk benefit in real-world healthcare practice) and differences in outcomes have been described as an "efficacy-effectiveness gap."[84] A number of biological and behavioral factors may contribute to an efficacy-effectiveness gap: contraindications to therapy, drug tolerability, patient compliance, patient demographics, severity of disease, comorbidities, drug interactions, and quality of healthcare. For a disease such as HCV infection where a large population resides in resource-limited settings these factors can be exacerbated.[85] A regimen with high efficacy, safety, and simplicity is of paramount importance for addressing the worldwide HCV burden.

In clinical trial settings, interferon/RBV regimens have achieved approximate SVR rates of 40–50% for GT1, ~80% for GT2, and ~70% for GT3 patients.[86] These relatively high efficacy rates are not recapitulated in studies of effectiveness. A real-world study by the US veteran's administration (VA) underscores the severe shortcomings of interferon-based therapies for the treatment of HCV infection (Fig. 24).[87] For 99,156 veterans with HCV (GT1-4 and "Unknown" HCV GT) assessed in this study, only 36% had no contraindications to treatment. Of the total, 11.6% initiated treatment; low initiation rates for interferon-based therapy are often attributed to patient's unwillingness to undergo this poorly tolerable therapy. Roughly half of those initiating therapy went on to complete therapy, again attributable to poor tolerability. Of the total, the percentage of patients achieving SVR was 3.5%. Since GT1 patients have historically responded with lower SVR rates than GT2 and 3 patients in clinical trials, it might be considered that these real-world results covering combined GT1–4 patients represent an upper limit of response for GT1 patients in the VA.

Recently, the VA also reported a real-world study of the effectiveness of LDV/SOF in GT1 treatment-naïve patients under their care.[88] Fig. 24 shows that the real-world effectiveness of LDV/SOF therapy ($n=4365$) contrasts sharply with the effectiveness of IFN/RBV in the VA patient populations. In the LDV/SOF study, 90% of patients were eligible for treatment, with 92% achieving SVR in 8-week treatment and 94% achieving SVR in 12-week treatment. The authors proposed that the small numerical decrement in effectiveness in their "real world" cohort compared to clinical trial results was based upon patient population differences; the VA study included older male patients, patients with generally higher body mass index, a greater proportion of African Americans, and patients with a greater prevalence of advanced liver disease (fibrosis and cirrhosis including decompensated cirrhosis). These baseline characteristics have historically resulted in lower SVR rates in HCV clinical trials. The advance in therapy represented by the improved real-world effectiveness of LDV/SOF therapy over the prior interferon-based standard of care is striking.

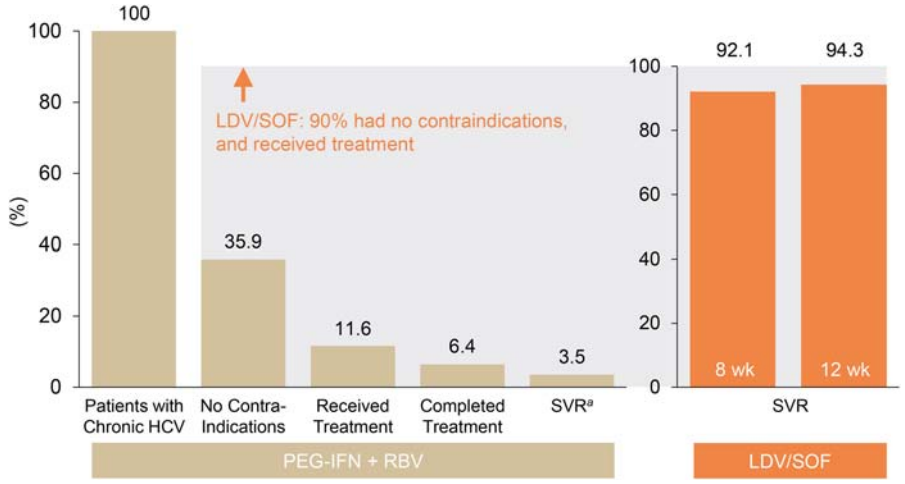

Fig. 24 Real-world SVR rates in the VA: IFN-based effectiveness contrasted with LDV/SOF. Tolerability and simplicity of LDV/SOF therapy present a striking real-world effectiveness advantage. [a]VA calculated IFN-based SVR by including attrition from contraindications, and those who did not receive treatment.

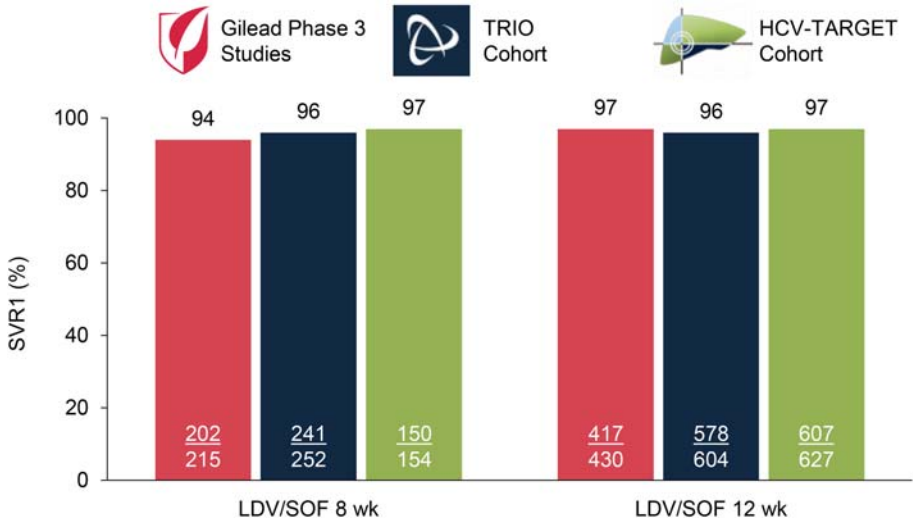

Fig. 25 Comparison of overall SVR rates in Gilead Phase 3 Clinical Studies, to "Real World" SVR reporting from the Trio and HCV-Target Studies (treatment-naïve patients).

Two further real-world studies are compared to ION-1 and ION-3 results in Fig. 25. The Hepatitis C Therapeutic Registry and Research Network (HCV-TARGET) is a multicenter observational study including academic and community medical centers in North America and Europe. Trio Health Innervation Platform (TRIO) is a cloud-based disease-management platform collecting data from specialty pharmacies.[89] In 8-week treatment, TRIO and TARGET reported 96% and 97% SVR rates compared to the 94% reported in ION-3. TRIO and TARGET SVR rates were also 96% and 97% for 12-week therapy, compared to an overall 97% for combined ION-1 and ION-3 12-week arms. The authors noted that unlike prior HCV regimens, the TRIO and TARGET studies suggest that LDV/SOF results in real-world studies provide high rates of SVR similar to those achieved in controlled clinical trials.

8.23.5 Conclusion

Harvoni® is the first STR for HCV treatment, and was approved 25 years after the discovery of the HCV. The 25 years between HCV discovery and the first STR have witnessed therapy that has been interferon-based, with cure rates starting at 10–20% SVR for treatment-naïve noncirrhotic GT1 patients, improving to ~40% for optimized IFN therapy including RBV, and then to ~70% with addition of a protease inhibitor in clinical trials. Severe side effects have been a common in these 24–48-week IFN treatments with examples of "real-world" cure rates at 30%, and most patients unwilling or unable to undergo these difficult treatment regimens.[87] With high SVR rates in real-world settings (Figs. 24 and 25), Harvoni® is a safe, simple, and effective treatment with significant potential to improve human health worldwide. HCV now represents the first prevalent, chronic, life-threatening disease that can be readily cured with simple, finite drug therapy.

8.24.1 Introduction

The last 30 years have witnessed an explosive growth in the understanding and treatment of HCV infections. The introduction of direct acting antivirals has caused a paradigm shift in hepatitis C treatment. Prior to this the only treatment option for about 180 million infected with HCV was a regimen of PEG-interferon and ribavirin which had low sustained virologic response (cure) and severe treatment-related side effects.[1,2] Patients infected with HCV were treated for 48 weeks with interferon which resulted in flu-like symptoms and suicidal tendencies for many patients. Patients also suffered from anemia primarily caused by PEG-interferon and ribavirin. Lower sustained virologic response rates particularly in genotype 1-infected patients demanded better treatment options to abate the progression of the disease to liver fibrosis and hepatocellular carcinoma. In fact, the primary cause for liver transplantation in USA is liver failure as a result of chronic hepatitis C infections.[3]

The discovery of the hepatitis C virus as the primary etiological agent for non-A non-B hepatitis resulted in the understanding of the life cycle of the virus.[4,5] The unraveling of HCV genome identified various potential therapeutic targets for drug intervention.[6] Hepatitis C is a positive-strand RNA virus which primarily infects the hepatocytes. Upon entry into the hepatocytes the virus codes for a single polypeptide of approximately 3000 amino acids with the help of host machinery utilizing the IRES site. This polypeptide contains all the structural and nonstructural proteins required for replication, and assembly of new viral particles. HCV virus broadly falls into six genotypes (gt 1–6) and has significant genetic variability resulting in many quasi species. They are widely distributed in the world with gt 1a and 1b prevalent in North America and Western Europe. Until the discovery of direct acting antivirals, the most unmet need in hepatitis patients was the treatment of gt 1 infections. Standard of care was treatment with pegylated interferon which achieved SVR in less than 40% of patients infected with gt-1. The response was much improved in gt-2 and gt-3 patients; however, tolerability and discontinuations to PEG-interferon were high due to severe side effects.

Advances in characterization of HCV biology identified many targets for drug intervention. The single polypeptide encoded by the HCV virus is posttranslationally modified to a number of structural and functional proteins whose functions are well defined.[7] The polypeptide undergoes a *cis* cleavage at the NS2–NS3 junction to release NS3 protease which along with the NS4A cofactor catalyzes the cleavage of the NS3–NS4A, NS4A–NS5A, and NS5A–NS5B junction to form active proteins for viral replication. It was immediately clear from the central role of NS3 protease that inhibition of this enzyme could result in the development of direct acting novel HCV drugs. The success in the development of HIV drugs by inhibition of key viral proteins also increased the confidence in developing HCV therapies adopting similar strategies (Fig. 1).

The X-ray crystal structure of HCV NS3 protease was solved by various groups.[8–10] HCV NS3, a serine protease structurally belonging to the trypsin/chymotrypsin superfamily, shares significant structural similarities to these enzymes.[11] Analysis of the X-ray crystal structure revealed a catalytic site that is shallow, highly solvent, exposed, and located on the surface of the protein. It was immediately clear that any inhibitor that interacts with the enzyme would need to derive a large portion of its binding by only partially interacting with the enzyme. The protease recognizes the natural substrate via an array of hydrogen bond spanning

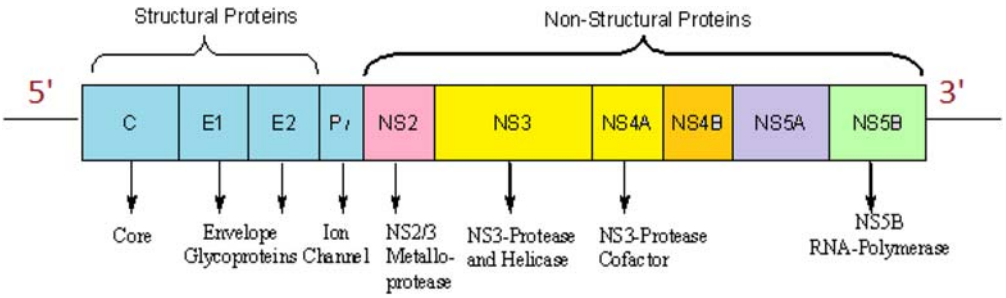

Fig. 1 HCV genome and key structural and nonstructural proteins involved in viral replication.

from P6 to P5′ making these interaction specific. A zinc atom located ~20 Å from the catalytic site is held by four cysteines which impart stability to the tertiary structure. The catalytic triad consisting of His57, Ser139, and Asp81 are located in two subdomains of the enzyme. Binding of NS4A, a 54 amino acid cofactor enhances the catalytic efficiency of the protease. The binding of the NS4A organizes the catalytic triad in a preferred conformation and facilitates His57 to deprotonate Ser139 and hydrogen bond to Asp81. Cysteine is conserved at the P1 position in all *trans* cleavage events, whereas it is replaced with a threonine in the *cis* cleavage process. The P1′, P2, and P3 residues contain hydrophobic amino acids, whereas the P5 and P6 residues contain acidic amino acids such as aspartic or glutamic acid.[12–14]

Advances in biochemical and cell culture assays further augmented the discovery of novel direct acting antiviral to treat HCV. The development of a continuous enzyme binding assay[15] and the replicon-based cell assay[16] by transfection and replication of HCV replicons in hepatocytes allowed rapid triage of chemical compounds to search for potential lead compounds to initiate a drug discovery and optimization program. Screening of libraries containing many diverse compounds did not result in the identification of a lead that inhibited the enzyme even at micromolar levels. Having failed to identify a viable lead to develop structure–activity relationship we resorted to a structure-based design using the natural substrate as the starting point.

Incorporation of a ketoamide at the scissile bond and small modifications of key residues of the NS3 substrate allowed identification of **1** (Fig. 2) which bound to the enzyme with a K_i* [17] of 1.9 nM. Analysis of binding kinetics and X-ray structure of **1** bound to the enzyme revealed a two-step binding mechanism with fast on rates and slow off rates.[17] The hydroxyl group from serine-139 formed a reversible covalent bond at the ketoamide site forming a tetrahedral intermediate. A composite binding efficiency K_i* was measured which allowed rank ordering of compounds for SAR analysis. Compounds were also evaluated for the inhibition of human neutrophil elastase (HNE) as a measure of selectivity for binding to HCV. HNE was chosen because of it close homology to HCV NS3/4A protease.

X-ray crystal structure of **1** bound to the HCV NS3 protease clearly indicated binding to the active site with the nucleophilic serine making a covalent interaction with the enzyme. The ketoamide unlike the natural substrate was attacked from the Re face which placed the oxygen of the amide into the oxyanion hole. This is different from the binding of the natural substrate leading to proteolysis where the serine attacks the substrate from a Si face and the oxygen of the tetrahedral intermediate formed is stabilized by hydrogen bond in the oxyanion hole (Fig. 3).

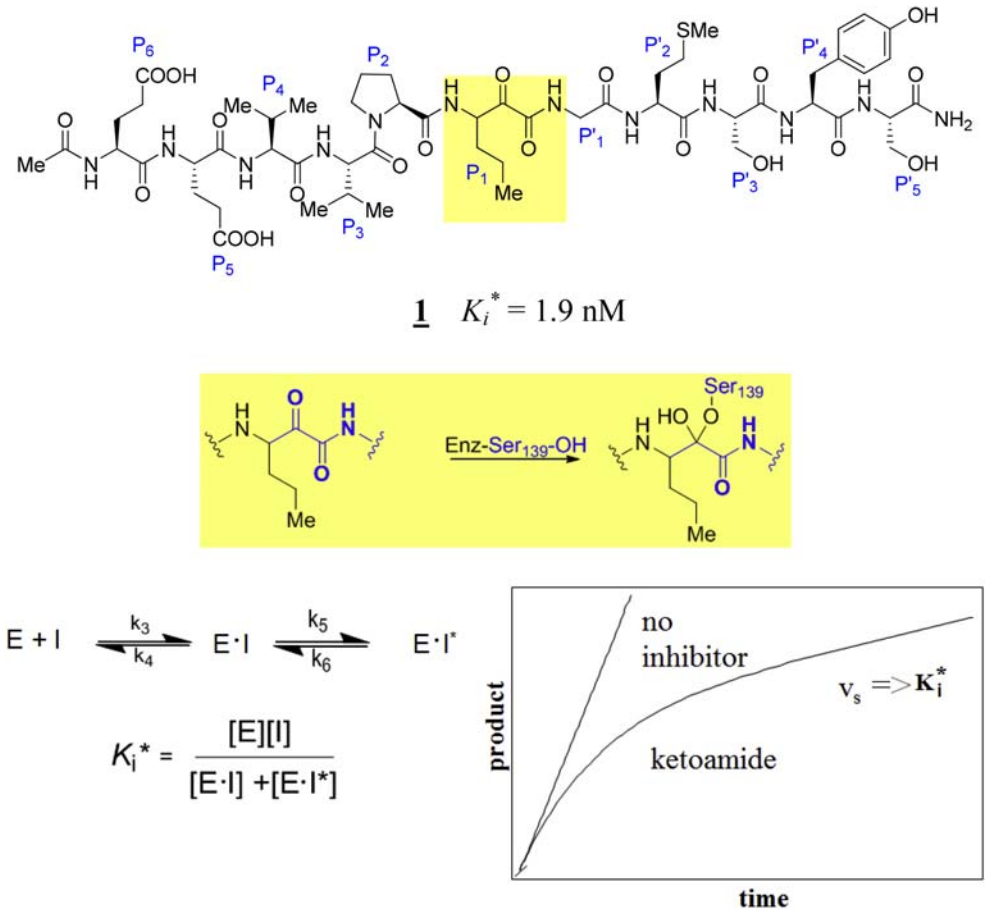

Fig. 2 Kinetics of undecapeptide **1** bound to HCV NS3 protease.

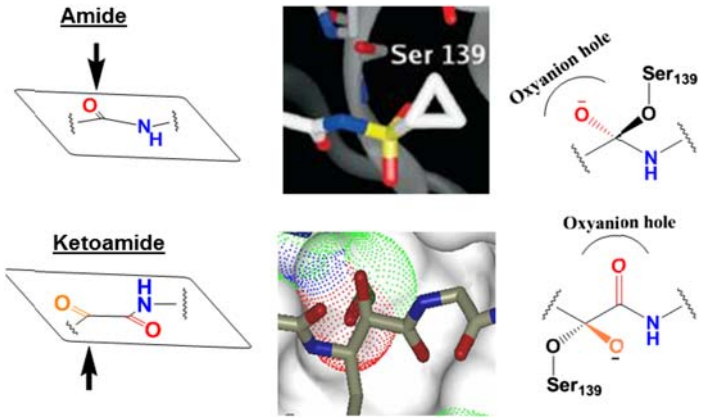

Fig. 3 Mode of attack of serine in ketoamide derived inhibitors.

From the X-ray crystal structure of ketoamide **1** bound to the enzyme it was clear that the inhibitor made several key interactions with the protein. The norvaline at P1 occupied the S1 pocket and the S2 pocket was occupied by the P2 proline moiety. P3 and P4 valines made lipophilic interactions at the shallow S3 and S4 pockets. The acidic groups at P5 and P6 made key interactions with arginines in the backbone. Looking at the structure of **1** with a molecular weight of 1265, it was clear that it could not be developed into an orally bioavailable drug. It was also clear that the peptidic nature of **1** containing all natural amino acids would likely render it unstable in plasma. We therefore decided a strategy to reduce the molecular weight of the inhibitor and replace natural amino acids with nonproteinogenic ones which could render enhanced plasma stability. It was decided to initially truncate the group at P1′ thus eliminating all substitutions from P2′ to P5′. This strategy was taken to understand the extent of loss in potency that would result from the truncation at P1′ position. Table 1 summarizes some of our efforts toward this.

Table 1 Truncation of **1** at P1′ position

6		0.760

Replacement of the P1′–P5′ segment in **1** with glycine allyl ester resulted in a loss of 25-fold with analog **3** showing a $K_i^* = 0.057$ μM. Also, modification with glycine amide resulted in compound **4** ($K_i^* = 0.043$ μM) with similar potency. These two analogs indicated that though truncation at the right-hand side resulted in analogs with diminished activity they still retained significant inhibitory activity. However, truncation at the P1 site was less tolerated with analogs **5** ($K_i^* = 0.270$ μM) and **6** ($K_i^* = 0.760$ μM) losing potency by more than 100-fold. From these studies it was clear that the right-hand piece was not required to maintain acceptable potency. The loss in activity may be offset by substituting with a smaller group (at P′) or improving ligand efficiency of P site residues. It was therefore decided that all future SARs would be done with the truncated analogs.

Even though the truncation of **1** at P1′ with glycine and allyl moieties yielded compounds with significantly lower molecular weighs it was clear that the newer analogs **3–6** were still larger with acidic groups at P5 and P6. The team was concerned that the acidic groups could present hurdles to absorption and cellular activity. After significant exploration the team decided to limit the inhibitor at P3 position and eliminate the polar glutamic acid residues at P5 and P6 positions. Analogs were truncated at P3 with a capping group such as isobutyl or *tert*-butyl carbamate where the alkyl group occupied the S4 pocket. Simultaneous SAR studies for replacing different residues with nonproteinogenic amino acids resulted in the discovery of cyclohexyl glycine and *tert*-butyl glycine as suitable replacements at the P3 position that were well tolerated and improved potency. At the same time the SAR at P2 identified a leucine as a potential replacement that was well tolerated and improved potency. Analogs of leucine such as cyclopropyl alanine and cyclobutyl alanine were also well tolerated.

The introduction of P2′ phenyl glycine amide as a replacement for allyl amide had a profound improvement on the potency of P2 leucine-derived analogs of type **7** ($K_i^* = 0.006$ μM). X-ray crystal structure of inhibitor bound to the enzyme revealed P1′–P2′ glycine–phenyl glycine segment wraps around Lys136 forming a "C-shaped clamp" resulting in hydrophobic interaction with the alkyl side chain of the lysine (Fig. 4). Further analogs in this series were synthesized by keeping the P2′ phenyl glycine and modifying the P2 residue with small cyclic alanine-derived amino acids. Table 2 summarizes the inhibitory potencies of these analogs.

Replacement of P2 leucine with homoleucine and pentyl glycine resulted in analogs **9** ($K_i^* = 0.31$ μM) and **10** ($K_i^* = 0.3$ μM) with loss in potency. However, replacement of P2 groups with cyclic amines resulted in marked improvement in potency of resultant analogs. Modification of P2 isoleucine with cyclobutyl alanine resulted in analog **11** with $K_i^* = 0.4$ μM, whereas the replacement with cyclopropyl alanine resulted in a sixfold improvement with $K_i^* = 0.05$ μM. Analysis of X-ray structure of **12** bound to the protease showed the cyclopropyl group making nonbonding interactions with the Arg155 contributing to improved potency (Fig. 5). Having identified a potent inhibitor in the low nM region, we further profiled **12** in the replicon-based cellular assay to determine the cellular potency.

Analog **12** although potent in the enzyme assay was significantly less active in the cellular assay with an $EC_{90} > 5$ μM probably due to the low cell penetration of the compound (Fig. 6). We initially ascribed the poor cellular penetration to the amide moieties. Since analog **12** had 6 hydrogen bond donors and 9 hydrogen bond acceptors, we decided to block some by methylating the nitrogen atoms. It was also recognized that the carboxylic acid would be ionized at physiological pH and would be contributing to low cellular permeability. Previous SAR had shown that the replacement of the P2′ acid with dimethyl amide had retained most of the inhibitory activity. We also decided to explore this strategy to reduce the hydrogen bond donor and avoid acid groups. With this in mind, we initially made the N-methylated analog of P2 cyclopropyl alanine resulting in compound **13**. Methylation of P2 group was well tolerated with analog **13** demonstrating potent enzyme inhibition ($K_i^* = 0.12$ μM); however, the cellular potency was still > 5 μM. We further decided to synthesize the dimethyl amide derivative resulting in compound **14** ($K_i^* = 0.060$ μM). Analysis of this analog in the cellular assay resulted in the first analog to show modest cellular activity with $EC_{90} = 0.95$ μM. We also synthesized dimethyl amide derivative **15** which lacked the P2 methyl group. Even though this analog retained most of the enzyme activity it was not active as analog **14** in the cellular assay. This clearly showed that reducing the number of hydrogen bond donors from six in **12** to four in **14** was required and possibly blocking the P2 amide group was paramount for cellular potency. Having

discovered that methylation of P2 resulted in analogs with improved cellular potency we envisioned new analogs with cyclic P2 amino acids derived from proline (Table 3).

Introduction of proline at P2 with P1 norvaline resulted in analog **16** with modest inhibitory activity of $K_i^* = 0.36$ μM. This analog was not evaluated in the cellular assay. X-ray structure of proline derivative revealed that the S2 pocket was large and proline did not occupy this pocket efficiently. We therefore decided to investigate substitutions on the proline moiety. Incorporation of

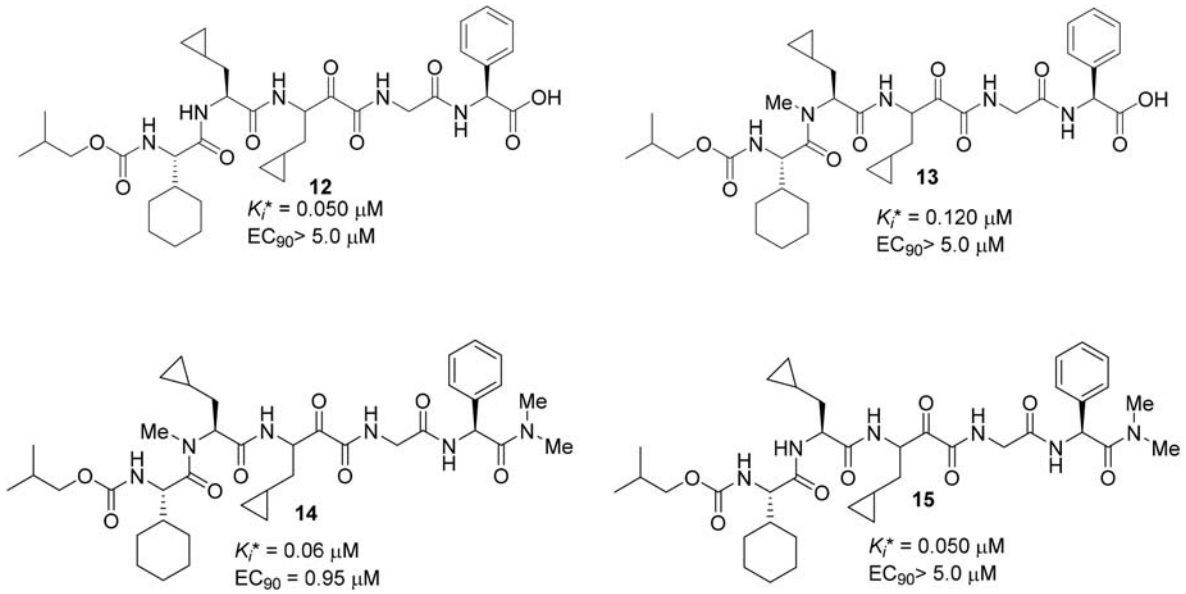

Fig. 6 Effect of P2 N-methylation on potency and cellular activity.

methyl substitution at the 4 position resulted in compound **17** with $K_i^* = 0.14$ μM. It was very encouraging to see the introduction of methyl group having a modest improvement in potency compared to the proline supporting our hypothesis of substituting on the prolines to achieve improvement in potency. We further investigated the introduction of P3 thioacetal modified proline which yielded analog **18** with much improved inhibitory potency of $K_i^* = 0.026$ μM. Concomitant to our efforts of exploring substitutions in the four position of proline we also investigated three, four bicyclic proline analogs. These analogs had a profound influence on potency and cellular activity. Introduction of the bicyclic ether-derived proline (3aR,4S,6aR)-2,2-dimethylhexahydro-2H-furo[2,3-c] pyrrole-4-carboxylic acid resulted in analog **19** ($K_i^* = 0.010$ μM) and a cellular potency of $EC_{90} = 1.9$ μM. Synthesis of the carbon analog **20** ($K_i^* = 0.015$ μM; $EC_{90} = 0.9$ μM) that lacked the oxygen in the proline ring did not change the profile significantly compared to **19**. As we were investigating bicyclic proline derivatives, we became aware of reports from Professor Madalengoitia who had published a novel cyclopropyl proline as a mimic of leucine. Madalengoitia had shown (1R,2S,5S)-6,6-dimethyl-3-azabicyclo[3.1.0]hexane-2-carboxylic acid mimicked leucines in peptide sequences.[18] Since leucine was a P2 moiety that imparted desirable potency in our analogs, we decided to evaluate this moiety. Introduction of (1R,2S,5S)-6,6-dimethyl-3-azabicyclo[3.1.0] hexane-2-carboxylic acid had a profound effect on the activity of the resultant analog **21**. Analog **21** demonstrated improved binding activity of $K_i^* = 0.010$ μM and cellular activity of $EC_{90} = 0.2$ μM. This was a 30-fold improvement compared to unsubstituted proline derivative **16** and a fivefold improvement in cellular activity compared to analog **14**. The strategy of incorporating secondary amino acids was successful in designing derivatives with potent binding and cellular activity. SAR studies around P1 led to the identification of SCH 6 (**22**).[19]

SCH6 (**22**) had an enzyme inhibitory activity of $K_i^* = 0.0038$ μM and a cellular activity of $EC_{90} = 0.10$ μM, our first analog to display potent binding and cellular activity (Fig. 7). We also evaluated the selectivity of this analog against HNE and it had an excellent selectivity of HNE/HCV = 1000. Having accomplished desired potency requirement we next evaluated pharmacokinetics of analog **22**. Administration of SCH6 orally to rats at 10 mg kg^{-1} resulted in poor plasma levels and bioavailability ($AUC_{0-24h} = 0.35$ μM h and $\%\underline{F} = 4$). The same compound when administered subcutaneously resulted in excellent plasma levels ($AUC_{0-24h} = 19.5$ μM h). The same was true for pharmacokinetics in monkeys with subcutaneous administration demonstrating excellent plasma concentration whereas poor blood levels were observed when administered orally.

The poor oral pharmacokinetics of compounds of type **22** was a serious concern and created an additional barrier for further progression of compounds. It was clear from the PK studies that the compound was stable in plasma and the poor oral exposure was primarily due to low drug absorption. We reasoned that the high molecular weights and peptidic nature of these inhibitors made it difficult to be absorbed and significant modifications would be required to achieve absorption. The team devised a strategy to further reduce the molecular weight by increasing ligand efficiency and/or reduce the number of hydrogen bonds by depeptidizing amide bonds. The team explored various strategies to depeptidize analogs such as incorporating peptide isosteres and macrocyclizing these compounds. Fig. 8 outlines some of our efforts in macrocyclization.

Analysis of the X-ray structure of analog **22** bound to the enzyme showed close proximity of P1 and P2 moieties to P3 and P4 groups. We therefore envisioned cyclizing the P2–P4 groups and the P1–P3 groups to form 14- to 17-membered macrocycles (Fig. 8).

Synthesis of P2–P4 biphenyl ether analog **23** resulted in compound with modest inhibitory activity $K_i^* = 0.11$ μM.[20] Replacement of P2 phenyl alanine with proline resulted in analog **24** with much improved potency ($K_i^* = 0.006$ μM and

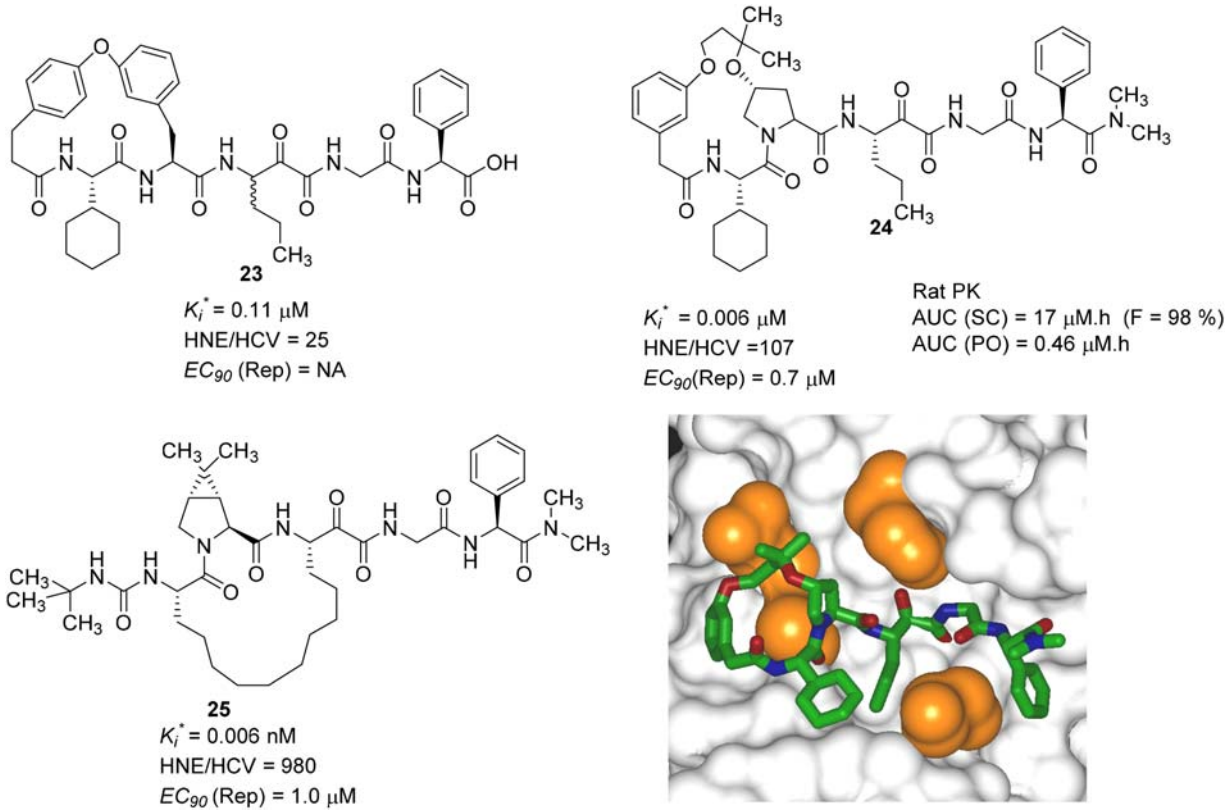

Fig. 8 P2–P4 and P1–P3 macrocyclic analogs.

$EC_{90} = 0.7$ μM).[21,22] With high expectations, analog **24** was evaluated for oral bioavailability in rats. Similar to analog **22**, analog **24** had an excellent exposure when administered subcutaneously with an $AUC_{0-24h} = 17$ μM h. However it was poorly absorbed orally and demonstrated an exposure of 0.46 μM h at 10 mg kg^{-1}. This was no different from the exposure achieved by SCH6. Cyclization to form a P1–P3 macrocycle was tolerated resulting in analog **25** ($K_i^* = 0.006$ μM and $EC_{90} = 1.0$ μM); however, its cellular potency was modest.[23] The X-ray structure of **24** bound to the HCV NS3 protease revealed a doughnut-like structure that encircled Ala156 where majority of the binding efficiency was derived by lipophilic interaction of P2 proline with methyl group of the alanine residue. Since the efforts of macrocyclization did not result in improvement of oral exposures it became necessary to devise other strategies to achieve improved potency and PK.

The lack of oral absorption was once again attributed to the higher molecular weight of the compound and the peptidic nature. It was clear that a reduction in the number of amide bond would overall improve the PK profile of these analogs. We therefore decided to truncate these molecules further and see the effect on potency. We initially explored truncation at P1 glycine position. With the optimized P2 groups we wanted to see the effect of replacement of the (P2′) phenyl glycine amide with smaller alkyl groups (Fig. 9). Replacement of (P2′) glycine–phenylglycine–dimethylamide segment with glycine propyl amide resulted in analog **26** with $K_i^* = 1.0$ μM, a significant loss in potency compared to **22**. However introduction of a cyclopropyl group analog **27** ($K_i^* = 0.090$ μM) and a benzyl amide **28** ($K_i^* = 0.056$ μM) retained significant activity. Analysis of the PK of these analogs in rat at 10 mg kg^{-1} showed improved oral absorption with compound **28** showing an oral $AUC_{0-6h} = 1.27$ μM h. Analog **29**, P3 *tert*-butyl glycine derivative of **28** ($K_i^* = 0.040$ μM and $EC_{90} = 0.8$ μM) was equipotent to the cyclohexyl glycine analog and significantly improved oral exposure ($AUC_{0-6h} = 4.2$ μM h). It was very gratifying to see that the strategy of truncation/depeptidization was on the right track and analogs had potency, cellular activity, and rat PK in desirable range. To further explore this strategy we decided to investigate analogs that were truncated at P1′.

Truncation of P1′–P2′ glycine–phenyl glycine dimethyl amide segment with allyl amide resulted in analog **30** with $K_i^* = 0.48$ μM (Table 4). This was a significant loss in activity compared to analogs of type **22**. However the compound had excellent oral exposure in rats when dosed at 10 mg kg^{-1} ($AUC_{0-24h} = 13.7$ μM h; $\%F = 34$). Replacement of allyl amide with methyl amide also resulted in analog with improved oral exposure. However the potency of both analogs **30** and **31** was suboptimal and needed significant improvement. Replacement of the P1 methyl amide with dimethyl amide resulted in analog **32** ($K_i^* > 13$ μM) with complete loss in potency. This suggested that the NH groups may be involved in hydrogen bonding with the protein backbone. We therefore investigated the synthesis of the primary ketoamide resulting in analog **33**. Introduction of a primary amide was well tolerated with eightfold improvement in potency compared to the methyl amide **31**. The primary amide

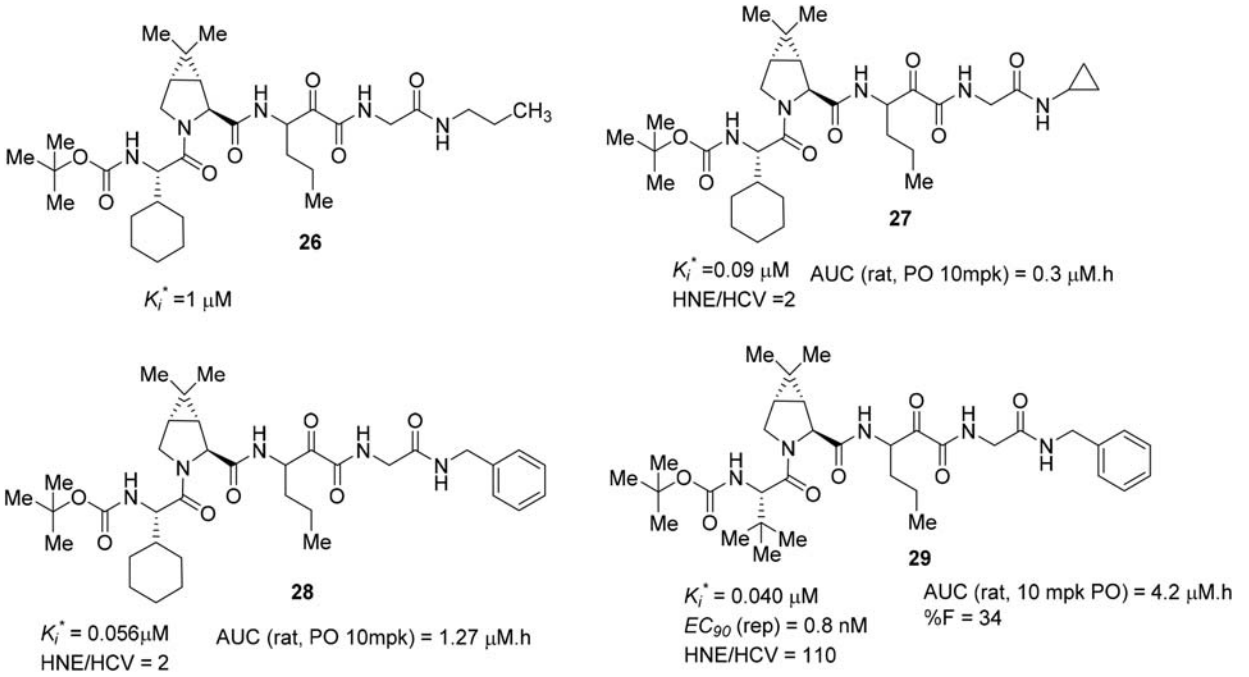

Fig. 9 P2′ truncated analogs

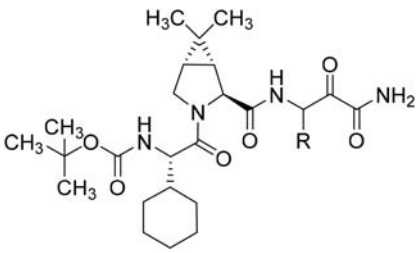
32	NMe_2	>13	–
33	NH_2	0.22	12.8

analog **33** was evaluated for PK in rats dosed at 10 mg kg^{-1}. The compound was well absorbed with an excellent oral exposure of AUC_{0-6h} = 12.8 μM h. Having identified the introduction of primary amide resulted in analogs with acceptable inhibitory activity we next focused our efforts to optimize these analogs by modification of P1 and P3 groups.

X-ray structure of primary ketoamide **33** bound to the enzyme showed that the amide hydrogens making key hydrogen bond interactions with the backbone of the enzyme. This could be an important contributing factor for the improved binding of **33** compared to **31**. With the identification of a primary ketoamide **33** as a key small molecule lead, we next focused our attention in optimizing the potency and cellular activity of this analog. We initially focused our effort toward SAR of the P1 moiety to identify P1 ligands with higher ligand efficiency. Analysis of the X-ray crystal structure of analogs of type **33** showed that the S1 pocket was not completely occupied by the propyl chain of P1 norvaline. We therefore decided to investigate amino acids with small cyclic groups in an effort to fill the S1 pocket. Table 5 summarizes some of the results of our investigation.

Replacement of P3 *tert*-butyl glycine in **32** with P3 cyclohexyl glycine resulted in analog **33** with inhibitory activity of K_i^* = 0.1 μM similar to the *tert*-butyl glycine analog **32**. We therefore investigated P1 SAR with P3 cyclohexyl glycine. Replacement of P1 norvaline with a branching group resulted in leucine analog **34** (K_i^* = 0.40 μM), with significant loss in inhibitory activity. We next evaluated the effect of incorporating small carbocyclic-derived alanines at P1. Introduction of cyclopropyl alanine resulted in

Table 5 Modification at P1 in primary ketoamide series

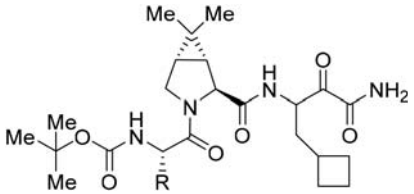


Cpd.	*R*	K_i* (μM)	EC_{90} (μM)	*HNE/HCV*	*Rat AUC (μM h)*
33		0.10	–	3	–
34		0.40	–	9	–
35		0.025	0.40	23	1.3 (F=3%)
36		0.008	0.40	100	1.5 (F=28%)
37		0.15	–	370	–
38		>12.0	–	–	–

analog **35** with K_i* = 0.025 μM and a cellular potency of 0.4 μM. Administration of **35** in rats at 10 mg kg^{-1} resulted in an oral AUC_{0-24h} = 1.3 μM h and a poor bioavailability of F = 3%. It was reassuring to see that introduction of cyclopropyl alanine resulted in improved potency with acceptable cellular activity and oral exposure. Further SAR investigation at P1 identified cyclobutyl alanine as an excellent P1 group that resulted in analog **36** with excellent in vitro activity of K_i* = 0.008 μM and EC_{90} of 0.4 μM. The selectivity of the cyclobutyl analog was much improved compared to the cyclopropyl analog. The cyclobutyl analog was also well absorbed and demonstrated improved oral bioavailability compared to cyclopropyl derivative. Further expansion of the P1 ring to cyclopentyl alanine was less tolerated resulting in **37** with a 15-fold loss in potency compared to **36** but a significantly improved HNE/HCV selectivity. Further expansion of the ring resulted in analogs with K_i* > 12 μM. The introduction of the cyclobutyl P1 resulted in analogs with desirable potency, cellular activity, and PK. We therefore investigated further SAR retaining this moiety. We next decided to investigate the P3 position and P1 group in the primary ketoamide series. Table 6 summarizes the SAR of the P3.

As previously discussed introduction of the cyclobutyl alanine at P1 had a profound effect on the inhibitory activity with analog **36** having a K_i* = 0.008 μM and EC_{90} of 0.4 μM. Replacement of P3 cyclohexyl glycine with *tert*-butyl glycine resulted in analog **39** (K_i* = 0.076 μM and EC_{90} = 0.8 μM) with a 10-fold loss in activity compared to **36** and similar cellular activity. Even though there was a loss in binding efficacy analog **39** had an improved HNE/HCV selectivity. Constraining P3 *tert*-butyl glycine into a ring to form methyl cyclopropylated glycine resulted in loss in the activity with analog **40** having a K_i* = 0.12 μM. We ascribed the loss in potency of **40** to inefficient interaction of the P3 side chain in the S3 pocket. Keeping this in mind we designed methylcyclohexyl glycine to impart characteristics of cyclohexyl glycine for potency and *tert*-butyl glycine for selectivity. The resultant analog **41** had a good binding activity and cellular potency of K_i* = 0.008 μM and EC_{90} of 0.4 μM; however, the HNE/HCV selectivity was suboptimal. Lastly replacement of P3 group with dimethyl-substituted serine to introduce polarity at P3 was not well tolerated. Analog **42** had a significant loss in activity. Structure–activity relationship at the P3 site identified *tert*-butyl glycine **39** as an excellent substitution which retained the cellular activity and improved HNE/HCV selectivity even though it had loss in binding activity. We

Table 6 SAR of P3 modification in primary ketoamide series



Cpd.	*R*	K_i* (μM)	EC_{90} (μM)	*HNE/HCV*

41		0.08	0.40	100
42		0.22	–	55

therefore decided to retain this along with P3 cyclohexyl glycine as the preferred P3 group and investigate SAR at the P4 region. We also investigated the SAR at P4 region retaining P1 cyclopropyl alanine group and decided to translate key finding to the cyclobutyl glycine series later (Table 7).

Replacement of P4 carbamate in **35** with isopropyl carbamate resulted in analog **43** with K_i* = 0.060 μM whereas the corresponding P3 *tert*-butyl glycine derivative had a K_i* = 0.15 μM. Constraining the isopropyl carbamate into a cyclopropyl ring resulted in twofold loss in potency (P3 Cyg K_i* = 0.12 μM; and P3 *tert*-butyl glycine K_i* = 0.30 μM). Replacement of the P4 group to cyclic cyclohexyl urea yielded analogs with potency of K_i* = 0.054 μM (P_3 cyclohexyl glycine) and K_i* = 0.020 μM (P_3 *tert*-butyl glycine). This replacement of P4 carbamate with urea resulted in improved potency in the case of P3 *tert*-butyl glycine. We next replaced the Boc group with *tert*-butyl urea resulting in analog **46** with K_i* = 0.050 μM and K_i* = 0.013 μM. We next evaluated the synthesis of secondary ureas with the synthesis of isopropyl N-methyl urea P4 cap. This resulted in fivefold loss compared to the *tert*-butyl urea analog. It was clear from these studies that P3 cyclohexyl accommodated a P4 carbamate whereas ureas were preferred when P3 group was a *tert*-butyl glycine. We next evaluated the effect of the potent P4 caps with P1 cyclobutyl alanine groups. This SAR also had a profound effect on the cellular activity and NHE/HCV selectivity of the resultant analogs (Fig. 10).

As previously discussed the introduction of Boc group at P4 with P3 cyclohexyl glycine and P1 cyclobutyl alanine resulted in analog **36** with K_i* = 0.008 μM and EC_{90} of 0.7 μM. The HNE/HCV selectivity of this analog was 140. The corresponding P3 *tert*-butyl glycine analog (**39**) had an enzyme activity of K_i* = 0.076 μM with similar cellular activity of **36** but improved HNE/HCV selectivity. Replacement of P4 Boc in P3 cyclohexyl glycine series with P4 *tert*-butyl urea yielded analog **48** (K_i* = 0.050 μM; EC_{90} = 0.5 μM, HNE/HCV = 90) with a 10-fold loss in binding activity. However, the introduction of *tert*-butyl urea into at P3 *tert*-butyl glycine series analog **49** (K_i* = 0.014 μM; EC_{90} = 0.35 μM, HNE/HCV = 2000) improved enzyme potency cellular activity and selectivity compared to **39** (K_i* = 0.076 μM; EC_{90} = 0.8 μM, HNE/HCV = 580). Since, analog **49** had acceptable binding, cellular activity, and desired selectivity we decided to further profile it for PK (Table 8).[24]

Administration of **49** to rats at 10 mg kg^{-1} resulted in AUC_{0-24h} = 1.52 μM h with an oral bioavailability of 26%. The compound was well absorbed with a mean residence time of 2.1 h. Administration to dogs at 3 mg kg^{-1} resulted in an AUC_{0-24h} = 3.2 μM h with oral bioavailability of F = 30% and a mean residence time of 1.2 h. The compound was poorly absorbed in monkeys with an oral exposure AUC_{0-24h} = 0.12 μM h and bioavailability of 4%. Based on the acceptable oral exposures of the compound in rats and dogs we evaluated the tissue distribution of the drug in rats. Following a 10 mg kg^{-1} administration in rats the concentration of the compound in the liver and plasma was followed (Fig. 11). A significant amount of the compound was distributed into the liver at first pass with a liver/plasma ratio of 30 which was 14 X EC_{90}. This preferential distribution of the compound in the target organ of the disease made it attractive in profiling further.

Analog **49** was evaluated in other studies for progression as a clinical candidate.[25,26] The compound was clean in inhibition of CYP panel with $EC_{90} > 8$ μM against CYP's 3A4, 2D6, 2C9. It was clean in hERG with an $IC_{50} > 30$ μM and clean in Ames test for mutagenicity studies. When dosed in animals the compound showed a linear increase in exposure with rising dose. Based on these characteristics the compound was developed into a clinical candidate for further evaluation in humans.

The X-ray structure of analog **49** bound to HCV NS3 protease was solved and key interaction of the inhibitor was identified (Fig. 12).[27]

The ketoamide moiety at P1 was attacked by serine-139 from the backbone to make a reversible covalent bond. The planar sp2 center of the ketone was transformed into a tetrahedral center with the oxygen of the ketone making a hydrogen bond with His57. The oxygen of the amide moiety was projected toward the oxyanion hole. The primary ketoamide made a key hydrogen bond to the backbone with Gly41 and the oxygen accepted hydrogen bond from the backbone from Ser139 and Gly137. The P1 amide nitrogen was involved in key hydrogen bonding with Arg155 and P3 and P4 groups made key hydrogen bond with Ala 156 and Ala157. This array of hydrogen bond donors and acceptors made the interaction of **49** specific, and P2 proline and the methyl group on the cyclopropyl ring made lipophilic interactions with the methyl group of Ala-156. The P1 cyclobutyl group was deeply buried in the S1 pocket and the P3-*tert*-butylglycine made Van der Waals interactions with the enzyme in the shallow S3 pocket. In combination with the hydrogen bonds the lipophilic interactions contributed to binding and selectivity of **49** to the protease.

A computational analysis revealed the contributions of the various fragment to the overall binding of the inhibitor to the enzyme. As shown in Table 9, the covalent bond with the ketoamide and the P1 cyclobutyl alanine each contributed about two orders of magnitude to affinity. The P2 proline contributed an increase in 16-fold whereas the P3 and the P3 cap contributed to about eightfold in binding. These were in line with the percentage of the surface area that made contact with the protein. It was clear that the P1 ketoamide made significant contribution and the removal of it resulted in significant loss in activity. In addition to binding, the ketoamide group provided additional beneficial effects such as slow off rates from the enzyme.

The ketoamide in **49** is readily hydrated in aqueous medium existing in equilibrium of the keto and hydroxylated form (Fig. 13). The P1 group also readily epimerizes to a ratio of ~1.6:1 and both the P1 *S* and *R* isomers are hydrated. This ready hydration of the ketoamide imparted properties such as improved solubility, potentially contributing to higher free fraction of the compound.

Analog **49** was evaluated in a panel of HCV genotypes and ability to develop resistance. The pan-genotype activity of **49** is shown in Table 10. The compound was active in various genotypes in the enzyme assay with a fourfold loss in activity against genotype 4. It was also tested in replicon-based cellular assay and was found to be potent in most genotypes.

Resistance to **49** was selected against genotype 1b and mutation was mapped by sequencing. In the replicon system, primary resistance was observed at the arginine 155 which was replaced by lysine. Mutation at Ala156 to serine or threonine was also developed that conferred significant loss in potency. Also the mutation of asp168 to glutamic acid resulted in significant loss in potency. Mutations developed in vitro in the replicon system translated well into the clinic with both arg155 mutation and asp168 mutation seen in patients on treatment with **49**.[28–31]

With many desirable properties **49** was evaluated in clinical trials for the treatment of gt1 infections in combination with Peg-interferon and Ribavirin.[32–34] It was well tolerated in SPRINT 2 phase 3 clinical trials. Patients treated with **49** over standard of care demonstrated improved cure rates (SVR) compared to patients on then standard of care (**Fig. 14**). Based on the outcome of these studies **49** (Boceprevir) was approved as first direct acting protease inhibitor for the treatment of HCV for gt1 infections.

In summary, **Fig. 15** describes the transition of undecapeptide **1–49** which resulted in substantial lowering of molecular weights and introduction of all the desired properties for a drug candidate. The molecular weight was reduced from the initial lead of 1265 to 519 retaining most of the inhibitory activity. In this process the selectivity of the analog was improved significantly from HNE/HCV of 7 to 2000 making **49** selective to HCV. Compounds were designed to incorporate cellular activity and desirable pharmacokinetics.

Having identified Boceprevir (**49**) as the first generation compound we decided to initiate a backup program to improve issues faced with its development. A close analysis of PK of **49** revealed it was suboptimal and had to be dosed at 800 mg TID in humans. As a team we decided to address this in the back-up compound with the goal of administering a BID or QD compound at significantly reduced doses. Boceprevir was also administered in an amorphous form as a mixture of isomers at P1 and had significant developmental issues for synthesis, purification, and formulation. We early on decided to develop a back-up compound as a single isomer at P1 which could be also readily purified and administered in a crystalline form. Moreover the oral exposure of the compound in cynomolgus monkeys was poor with a bioavailability of 4–11%. We decided to identify a compound which had acceptable exposures in monkeys for back-up compounds. With these requirements we decided to further improve the PK and potency of **49**.

A review of the metabolism of Boceprevir showed it was primarily metabolized by aldo-keto reductase (AKR) which reduced the ketoamide to the significantly less active hydroxy ketoamide (**Fig. 16**). Our initial efforts were to suppress this reduction by coadministration with AKR inhibitors which did not improve oral exposures significantly. A detailed investigation of various analogs in the ketoamide series revealed that although many primary ketoamides were substrates for AKR reduction, secondary amides were not and the compounds were mostly metabolized by CYPs. This information was vital in devising a strategy for the design of the back-up analogs.

We formulated a back-up strategy for Boceprevir with a target replicon cellular potency of $EC_{90} \leq 0.1$ μM and an improved PK across all preclinical species that could potentially support a BID or a QD dosing in humans. The compound would be a single isomer at P1 and crystalline for development. While investigating the SAR of Boceprevir, we investigated allyl amides at P1′

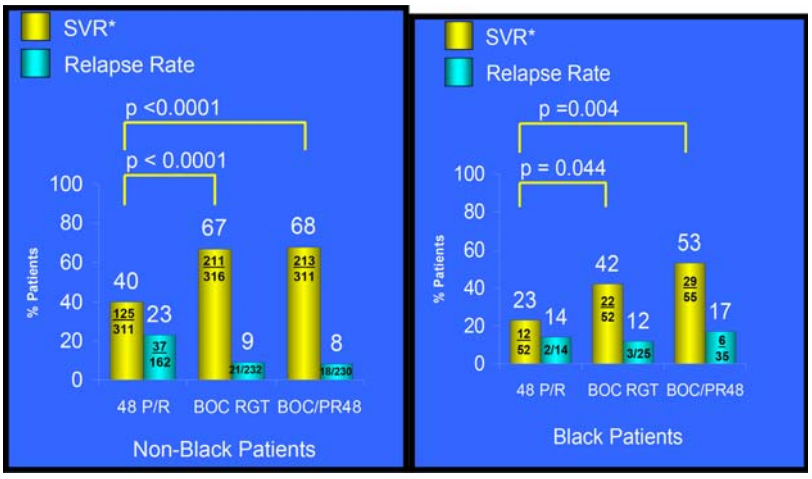

Fig. 14 Response of gt 1 HCV-infected patients treated with **49** in a Phase 3 SPRINT 2 trial.

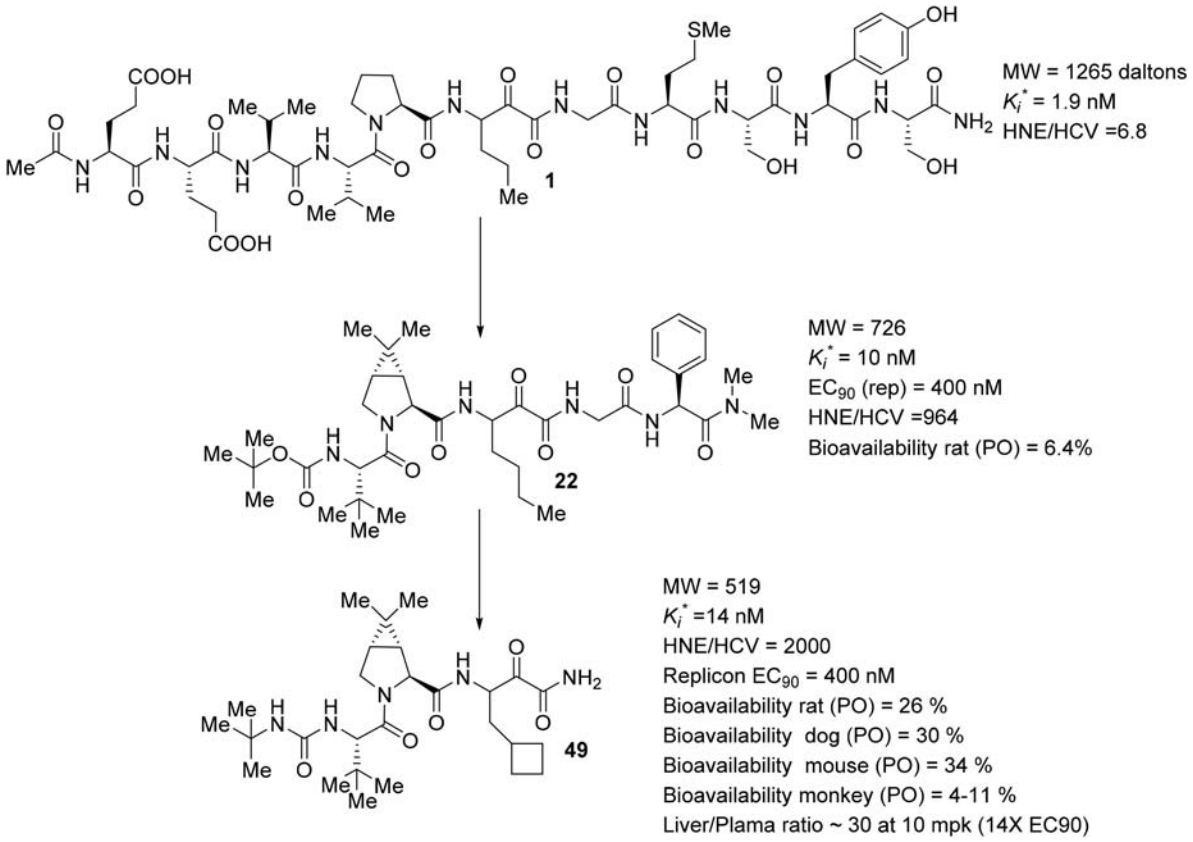

Fig. 15 Summary of optimization of initial lead **1** to Boceprevir (**49**).

Fig. 16 Metabolism of Boceprevir by aldo-keto reductase.

such as compound **30**. Even though the potency of these analogs was suboptimal they were readily absorbed and displayed excellent oral exposure. We thought this could be an excellent starting point. We therefore decided to retain the P1′ allyl group and investigate P4 groups simultaneously modifying P1 and P3 groups. A series of novel P4 substitutions were identified which imparted significantly improved cellular potencies and retained HNE/HCV selectivity. Fig. 17 summarizes some of the classes we identified.

Introduction of P4 urea derived from *tert*-butyl glycinol and capping it with ethyl carbonate resulted in analog **55** with a $K_i^* = 0.009$ μM and a replicon cellular activity of $EC_{90} = 0.150$ μM.[35] It was readily absorbed in rat with an excellent oral $AUC_{0-24h} = 26$ μM h when dosed at 10 mg kg^{-1} and bioavailability of 43%. However it had a modest exposure of AUC = 0.25 μM h in monkeys when dosed at 3 mg kg^{-1}. Similarly capping P4 *tert*-butyl glycine with N-methylated reverse sulfonamide yielded analog **56** with twofold improved cellular activity compared to carbamate analog **55** and much improved HNE/HCV selectivity.[36] However it had a much inferior PK profile compared to **55** with both the rat and rhesus having a significantly poor exposure. We next modified the P4 position by introduction of a lactam and an imide group resulting in analogs **57** and **58** which had excellent inhibitory activity in the replicon system with $EC_{90} = 0.06$ and 0.03 μM and acceptable exposures in rats and dog.[37] Unfortunately oral exposure of the compound **58** was greatly diminished when rats were dosed with crystalline material resulting in reduced interest in this class.

Previously in the process of discovery of Boceprevir **49**, we had designed targets that were functionalized at P4 position with a spirocyclohexyl group. These analogs had significantly improved cellular activity; however, they lacked desirable oral PK in rats. We decided to further investigate this class of analogs and anticipated to engineer desirable PK properties (Fig. 18).

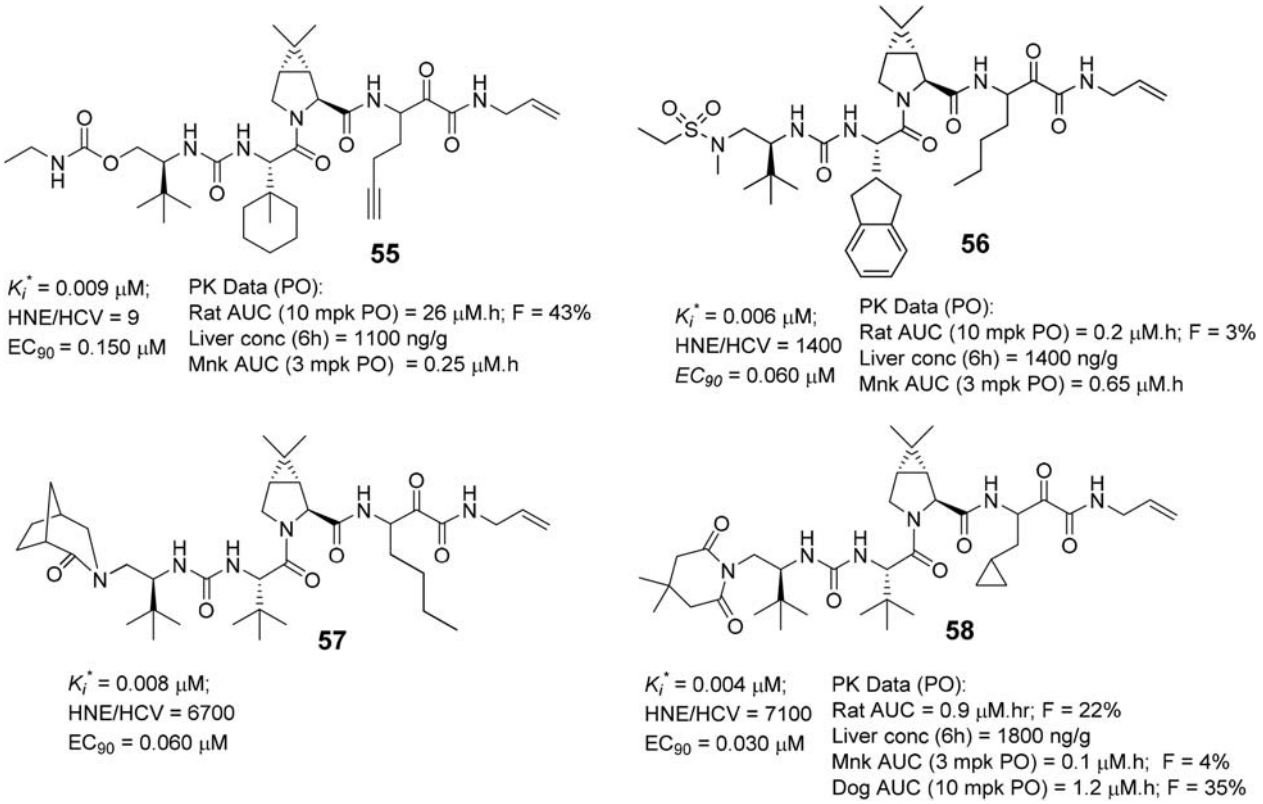

Fig. 17 P1′ allyl amide derivatives with modified P4 groups that imparted improved potency.

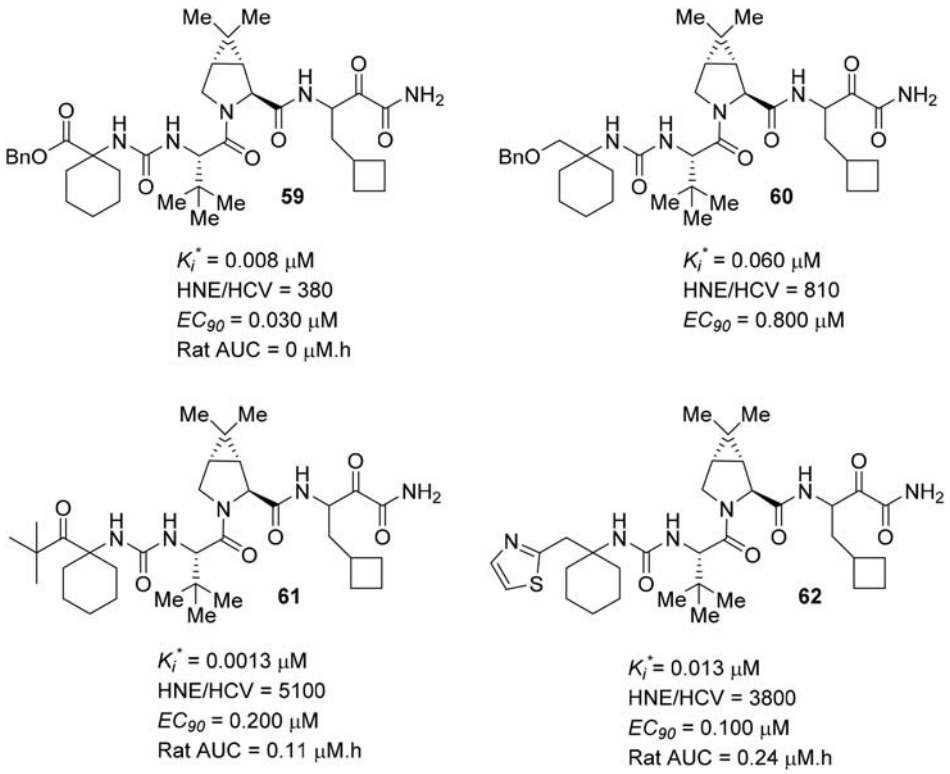

Fig. 18 P4 spirocyclohexyl glycine analogs of Boceprevir.

Introduction of urea derived from benzyl 1-aminocyclohexane-1-carboxylate at P4 resulted in analog **59** with $K_i^* = 0.008$ μM and potent cellular activity of $EC_{90} = 0.030$. However the PK of this analog was poor and no oral exposure was found in rats when orally administered at 10 mg kg^{-1}. Even though the PK of the compound was poor, we learnt that the introduction of a P4 group derived from spirocyclohexane had a potential to yield compounds with much improved cellular activity. The poor oral PK of **59** was probably due to the P4 benzyl ester which was readily hydrolyzed in the gut, resulting in poor absorption and metabolism. We therefore reduced the ester to form P4 benzyl ether exemplified by compound **60** which was significantly less active with $K_i^* = 0.060$ μM and a cellular replicon activity of $EC_{90} = 0.8$ μM. Further SAR analysis also identified analogs **61** and **62** with improved cellular activity. However all these analogs had poor PK and in rats.

In the process of these titrations a series of analogs containing P4 sulfone moiety were synthesized. Many of these analogs were potent in the replicon cellular assay. As shown in **Table 11**, a systematic modification of the alkyl group on the sulfone imparted improved potency. Analogs **64** and **65** containing an ethyl sulfone and *tert*-butyl sulfone are noteworthy.[38] Introduction of these P4 caps yielded analogs with $EC_{90} = 0.100$ μM in the replicon cellular assays and acceptable HNE/HCV selectivities. Further evaluation of these analogs in PK also showed *tert*-butyl analogs to have improved PK in monkeys (**Fig. 19**). This improved monkey PK feature attracted our attention to this series.

Analog **65** derived from P1 cyclobutyl group and analog **69** with P1 cyclopropyl group exhibited poor PK in rats; however, they were very well absorbed in monkeys and dosing these analogs in monkeys showed acceptable oral exposures of 3–4 μM h at 3 mg kg^{-1}. Based on this observation the team decided to focus on this class. Our previous experience had shown the replacement of a primary ketoamide with allyl amide improved rat oral exposure. We therefore wanted to evaluate the effect of incorporating allyl amides in analogs **65** and **66**. The results of this investigation are shown in **Table 12**.

As expected, the introduction of allyl group at P1 in **65** and **69** had a positive effect on rat PK. Allyl amide derivative of analog **65** resulted in analog **70** which had a binding activity of $K_i^* = 0.020$ μM and a cellular activity of $EC_{90} = 0.25$ μM. This modification resulted in a twofold loss in cellular activity; however, it had an oral AUC = 2.8 μM h in rats when dosed at 10 mg kg^{-1}. This was a significant improvement compared to compound **65**. Similarly **71**, ally amide of the P1 cyclopropyl derivative **69**, had an enzyme inhibition activity of $K_i^* = 0.022$ μM and a cellular activity of $EC_{90} = 0.14$ μM. This compound also showed acceptable oral

Rats were dosed at 10 mg kg^{-1} and monkeys at 3 mg kg^{-1} orally in 0.4% methylcellulose.

exposure in animals with an AUC of 1.7 μM h in rats and 7.1 μM h in monkeys when dosed at 10 and 3 mg kg^{-1}, respectively. With this encouraging finding we next evaluated additional P1 groups to see the effect on potency and PK. Introduction of a butynyl-derived amino acid at P1 resulted in analog **72** which was much potent compared to the cyclobutyl and cyclopropyl analogs. However the selectivity of this analog was modest with HNE/HCV = 60 and the monkey PK was poor. Saturating the triple bond in **72** resulted in norleucine analog **74** with K_i* = 0.011 μM and EC_{90} = 0.180 μM. The compound was well absorbed and had an oral AUC of 5 μM h in both rats and monkeys. It had a good bioavailability in rats (%F = 52%) and good HNE/HCV selectivity of 1350. Even though this compound did not meet the cellular potency cut off of $EC_{90} \leq 0.1$, we felt it was acceptable and we profiled it further. As previously mentioned one of the criteria for identification of a back-up compound to Boceprevir was the development of a crystalline material with single diastereomer at P1. We therefore decided to evaluate future analogs as pure P1 isomers. Secondly the presence of a double bond with allyl group was metabolically concerning. The formation of reactive intermediates had the potential to functionalize proteins and cause liver injury. We therefore decided to investigate new P1′ derivatives of analog **74** that lacked double bond and made new analogs as a single diastereomer at P1 (**Table 13**).

Separation of the P1 isomers of compound **74** resulted in analogs **75** (*S* isomer) and **76** (*R* isomer) at P1. The *S*-isomer was very potent with a K_i* = 0.008 μM and the *R*-diastereomer had a potency of 0.21 μM. Saturation of the double bond of the allyl group at P1′ resulted in loss in potency with analog **77** having a K_i* = 0.014 μM and cellular activity of EC_{90} = 0.100 μM. Replacement of P1′ with ethyl group resulted in analog **78** with similar potency to the propyl group. Further truncation to methyl group resulted in analog **79** with improved potency (K_i* = 0.004 μM and EC_{90} = 0.055 μM). Modifications by replacing P1′ with cyclopropyl methyl or methoxyethyl resulted in significant loss in potency resulting in analogs **80** (K_i* = 0.021 μM) and **81** (K_i* = 0.018 μM). We next investigated introduction of small cyclic moieties at P1′. Introduction of cyclopropyl resulted in analog **82** with K_i* = 0.006 μM and cellular activity of EC_{90} = 0.040 μM. The compound was potent in both the enzyme and cellular assays. It was also selective against HNE with an HNE/HCV selectivity of 600. Further expansion of the ring to cyclobutyl or cyclopentyl amine resulted in loss in activity with K_i* = 0.026 and 0.045 μM. Branching also had a detrimental effect at P1′ with methyl cyclopropyl analog **85** losing a substantial portion of the binding resulting in analog with K_i* = 0.30 μM. The separation of P1 resulted in a marked improvement in activity with the *S*-isomer being more active than the *R*-isomer. Replacements at P1′ were generally well tolerated. The cyclopropyl analog **82** retained most of the enzyme and cellular activity and cyclopropyl group was a good replacement for the allyl group which had a lower potential for formation of reactive intermediate. Having optimized the P1′ we decided to quickly scan the P3 group and P1 group on the optimized core with cyclopropyl group at P1′ and evaluate the pure (*S*)-diastereomer to make sure no difference in SAR was observed (**Fig. 20**).

Replacement of P3 *tert*-butyl glycine with cyclohexyl glycine was well tolerated resulting in analog **87** with K_i* = 0.006 μM and EC_{90} = 0.055 μM. However the HNE/HCV selectivity of the analog was modest with HNE/HCV selectivity of 120. Our previous SAR had indicated that *tert* butyl groups at P3 in general had improved HNE/HCV selectivity. We therefore synthesized analog **88** that contained a P3 methylcyclohexyl glycine group. Though this improved the HNE/HCV to 235 this was still lower than analog **82**. In an effort to improve solubility we next introduced tetrahydropyran-derived glycine analog, which resulted in analog **89** with significant loss in activity. From this scan at P3 it was clear that the *tert*-butyl glycine was still preferred and analog **87** was the optimized analog. We next focused to evaluate the P1 SAR. Analogs with selected P1 group were synthesized and the SAR at P1 was similar to the P1 racemic group.

Table 13 Effect of P1′ residues in P1 chiral norleucine derivative

86		0.006	0.090	250

SAR at P1 still identified the norleucine group as still the most desirable group for overall potency and PK (Table 14). The replacement of P1 norleucine with norvaline resulted in compound **90** which had similar potency and PK profile to analog **82**. However the HNE/HCV selectivity of the norvaline analog was significantly inferior with norvaline analog **90** having HNE/HCV selectivity 8 as compared to 600 for norleucine analog. Introduction of trifluoro norvaline (**91**) and cyclopropyl alanine (**92**) was well tolerated yielding compounds potent in the binding and cellular assays. However these compounds had poor PK in rats and monkeys compared to the norleucine analog **82**. The introduction of a homo cyclopropyl alanine at P1 although well tolerated yielding compound comparable in potency to norleucine derivative had inferior PK in rats and monkeys making the norleucine compound most attractive.[39,40]

From the SAR of the back-up analogs it was clear that the norleucine was still the most preferred and compound **82** had all the desirable properties required in a back-up compound. It satisfied all the key goals that we set out to accomplish in a back-up compound. The compound had a potency of $EC_{90} < 100$ nM in replicon-based cellular assay, a single diastereomer at P1, and good exposure in rats and monkeys with acceptable selectivity. The X-ray structure of the compound **82** was also solved identifying key interactions with the protease (Fig. 21). In addition to the key interactions observed with Boceprevir additional interaction to the backbone contributed to the improved potency. The cyclopropyl amide occupied the lipophilic S1′ pocket and the spirocyclohexyl group occupied the S4 pocket. The oxygen of the sulfone made a hydrogen bond to cysteine 159 on the backbone of the protease.

Sulfone analog **82** was evaluated for oral PK in different species and the parameters were summarized in Table 15. The compound was well absorbed across all species with 43% in rats and 67% in cynomolgus monkeys and good overall oral AUCs. The AUC in rats when dosed at 10 mg kg^{-1} was 0.65 μM h mg^{-1} and 0.3 and 0.45 μM h mg^{-1} in dogs and monkeys. The

Monkey	10/3	4.5	67	39	6.8	21

bioavailability was acceptable, ranging from 30% to 50% and in vivo total clearances were modest in low double digits. Based on the overall exposure, the team decided to further progress this compound. The concentration of the compound in the liver was assessed and the compound had a favorable partition in the rat liver with concentration over the EC_{90} being greater than 400-fold. It was clean in the counterscreens and had no issues of P_{450} inhibition and/or potential for enzyme induction. It was clean in Ames mutagenicity test. Based on these characteristics it was chosen as a potential candidate for toxicology and progression into clinical studies.

Sulfone **82** was evaluated for inhibition of various genotypes and activity against mutant (Fig. 22). The potency of the compound across genotypes is shown. It is interesting to note that the compound is equipotent among all the genotypes and is about 10-fold more potent in genotype 1a compared to 1b. Resistant mutants were developed in replicon cells and the fold loss in potency compared to WT was measured (Table 16). As previously seen with Boceprevir the primary mutations leading to loss in potency were A156S (70-fold) and A158T (>1000-fold). Also Arg155 mutation to lysine conferred a 15-fold loss in activity compared to the wild type. The combination of interferon suppressed the emergence of mutations.

Analog **82** (Narlaprevir) was evaluated in toxicity studies and based on acceptable toxicity profile it was further progressed to phase 1 clinical studies in healthy volunteers and HCV-infected patients. In a clinical study NEXT-1, patients treated with 200 mg QD of Narlaprevir in combination with PEG-interferon, ribavirin, and ritonavir achieved undetectable viral titers in 85% of patients compared to 17% of patients on standard of care (Fig. 23).[41] Based on the positive SVR rates the compound was further progressed to phase 2 studies.

8.24.2 Summary

The identification and characterization of structural and functional proteins that are vital for the replication of hepatitis C virus paved the way for efforts to develop direct acting antivirals for the treatment of HCV. NS3/4A, a central protein required for post-translational modification and replication of the virus, was identified as an excellent target for drug discovery. The lack of starting

points as initial leads for rapid SAR development led to a structure-based approach. An undecapeptide **1** containing a ketoamide electrophilic trap with MW = 1265 was discovered to bind in the active site with a K_i* = 1.9 nM. The catalytic serine made a reversible covalent bond with the inhibitor which attacked the enzyme from the *Re* face. It was clear from the onset that the lead was suboptimal and lacked desirable properties of a potential lead. The initial lead was peptidic with a high molecular weight and was mainly composed of natural amino acids. It was evident that the peptide would not be orally absorbed and would lack the desired pharmacokinetic profiles.

The team initially adopted a strategy to identify a minimum pharmacophore and remove proteinogenic amino acids from the lead. A conscious decision to limit the size of the inhibitor and remove the acidic group at P5 and P6 resulted in truncating analogs at P4. On the P1′ site the team systematically scanned nonnatural amino acids and investigated the effects of truncation on enzyme potency and cellular activity. The identification of P2′ phenyl glycine group and P2 leucine resulted in a series of analogs that were very potent in biochemical assays exemplified by analog **7**. However these analogs did not exhibit the desired cellular potency. To engineer the cellular activity the team went to the drawing board and redesigned the inhibitors by systematically changing the P2′ acid and methylating the amide nitrogens. It was found that methylating the P2 nitrogen had a profound effect on the cellular activity of the inhibitors with analog **15** demonstrating both enzyme potency and cellular activity. This resulted in new analogs derived from modified prolines which led to the identification of the potent inhibitor SCH6 which had both the desirable enzyme activity and cellular potency. Further evaluation of SCH6 and analogs demonstrated that these compounds were poorly absorbed and did not show oral exposure.

The team decided to further reduce the molecular weight and number of amide bonds. Truncation at P1 with a primary ketoamide resulted in analogs such as **35** that retained most of the activity and also was orally absorbed. Modifications at P1, P3, and P4 groups identified cyclobutyl alanine at P1, *tert*-butyl glycine at P3, and a *tert*-butyl urea at P4 as the desirable group that imparted optimal potency, PK, and selectivity. The combination of P3 and P4 capping group had a profound effect on human neutrophil elastase with P1 cyclobutyl alanine in combination with P3 *tert*-butyl glycine imparting high HNE/HCV selectivities. These SAR studies led to the discovery of Boceprevir which was potent with acceptable safety and PK properties and was subsequently progressed to clinical trials. Adding Boceprevir to the then standard of care improved SVR in patients infected with HCV. It was the first direct acting HCV antiviral to be approved for the treatment chronic gt-1 HCV infections.

The team next focused in solving some of the issues faced in the development of Boceprevir in the identification of a back-up compound. The team focused on key issues of improving potency, identifying a single isomer to facilitate development, and improving PK in monkeys. The introduction of a P1′ allyl amide changed the elimination pathway which was now primarily metabolized oxidatively by cytochrome $P_{450's}$. A spirocyclic sulfone-derived P4 moiety, which made a hydrogen bonding with cys-159, was identified that enabled improvement of binding and cellular potencies. Replacement of P1′ from allyl to cyclopropyl group further retained potencies yielding compound with much improved PK in monkey. The separated *S*-isomer at P1 resulted in analog

82 (Narlaprevir) which satisfied all the key requirements of a potential back-up candidate. Adding Narlaprevir to standard of care with ritonavir resulted in a >80% of treatment naive patients achieving undetectable viral titers within 12 weeks of treatments.

From the initial introduction of first-generation direct-acting antivirals Boceprevir and Telaprevir[42,43] targeting the viral protein NS3, many new second-generation drugs have been designed and introduced that vastly improve cure rates in gt1b patients and also exhibit pan genotypic activity. More importantly, other proteins in the life cycle of HCV have been successfully targeted and efficacious drugs have been developed inhibiting HCV NS5B polymerase and HCV NS5A enzymes. From the initial proof of concept demonstrated by BILN-2061[44] various macrocyclic NS3 drugs such as Simeprevir,[45] Vaniprevir,[46] Grazoprevir,[47,48] and Paritaprevir[49] have been approved for the treatment of HCV. The design and development of these compounds is a major accomplishment in medicinal chemistry. Each of these drugs is a testament to ingenious designs and problem solving skills when faced with lack of leads for SAR optimization. Starting from a peptide substrate teams have worked tirelessly to incorporate all the desired properties required for successful drugs. In the processes of introducing novel HCV drugs teams have broken barriers in medicinal chemistry. For example, they have explored novel macrocyclic scaffolds in an undesirable chemical space with molecular weights in ranges >700, depeptidizing them and engineering desirable properties in them and developing excellent synthetic routes for manufacturing and commercialization.

In addition to HCV NS3 protease inhibitors, novel inhibitors to inhibit HCV NS5B have been developed. The identification of nucleoside inhibitors such as Sofosbuvir[50] had a profound impact in the treatment of HCV. It dramatically shortened the treatment times and introduced higher barrier to resistance becoming a backbone for the combination drugs. In addition to NS5B protein the inhibition of NS5A enzyme was a fertile ground which yielded many potent inhibitors. From the initial development of Daclatasvir[51] many imaginative modification to this structures have resulted in the identification of new compounds such as Ombitasvir,[52] Ledipasvir,[53] and Elbasvir[54] with improved potency and activity against key mutants.

The identification of compounds targeting a wide range of mechanisms opened avenues to develop novel combination therapies. Combination therapies allowed not only achievement of very high cure rates >99% but also suppression of resistance and development of regimens to successfully treat different genotypes, null responders, and HIV/HCV coinfected patients. A major positive development of combination therapies is the development of all oral therapies and elimination of PEG intron which was plagued with serious side effects, and significant shortening of treatment durations from initial 48 weeks to around twelve weeks or less with much less side effects.

From the dawn of the century the landscape for HCV treatment has significantly changed with the prognosis for HCV-infected patients being bright. For the first time the vast majority of patients infected with chronic HCV need not progress to liver transplantation or hepatocellular carcinoma. Treatment of patients with a combination of direct acting antiviral will result in complete cure. In combination with blood screening and new drugs for treatments, HCV infections can be hopefully eliminated as a public burden in foreseeable future.

INDEX

Notes

Cross-reference terms in *italics* are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to each article for additional cross-references — not all of these cross-references have been included in the index cross-references.

The index is arranged in set-out style with a maximum of three levels of subheading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by t, f, and b refer to Tables, Figures, and Boxes respectively. *vs.* indicates a comparison.

The index entries are presented in word-by-word alphabetical sequence in which a group of letters followed by a space is filed before the same group of letters followed by a letter. For example, entries beginning 'air density' are alphabetized before 'aircraft.' Prefixes and terms in parentheses are excluded from the initial alphabetization.

Where index subentries and sub-subentries pertaining to a subject have the same page number, they have been listed to indicate the comprehensiveness of the text.
